We relied on the official scripts for fine-tuning and inference.[9] During inference KG-BART utilizes a beam search with beam size of 5, along with an n-gram-based repetition constraint.

GDC controls the text generation of a pre-trained CLM by fine-tuning towards point-wise and distributional constraints with policy gradient. Additionally, GDC incorporates a KL-Divergence loss, to keep the fine-tuned model similar to the initial CLM. However, this fine-tuning process is extraordinarily expensive requiring roughly 72 hours to tune a GPT-2 Small model towards a single word. Furthermore, it lacks a setting for general word inclusion and is thus excluded from our experiments.

POINTER solves the word inclusion task in a non-autoregressive manner, iteratively injecting words around the target words. The target words are thus all included prior to the generation process. POINTER can therefore only fail on the coverage task if it combines a target word with another word. It is designed to generate single sentences, and cannot handle contexts without significant modifications. We used the standard decoding script provided on the official GitHub page[10] but changed the separator to ", ".

D.3 GPT Prompting

The currently most popular approach to steering CLM's is via what is called prompting. In this approach the desired instruction is formulated as a textual context, from which the CLM continues. Following the popular paradigm of few-shot prompting, each prompt starts with a number of examples of the word inclusion task. We found that careful tinkering of the prompt layout and the included examples had significant impact on the performance. The final prompt used for the various experiments are available in Appendix H. A beam size of 4 was used during inference for all experiments.

E Evaluation Metrics

E.1 String Matching as Evaluation Metrics

The current default way of evaluating CommonGen results is to compare the generated sentence with a few label sentences, using standardized string matching metrics such as BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), CIDER (Vedantam et al., 2015), and SPICE (Anderson et al., 2016). While we see the value of such metrics in tasks like machine translation, where there is a constrained number of acceptable text formulations, we intuitively disagree of the usage of these metrics for CommonGen. Controllable text generation with word inclusion allows for vast amounts of creativity, something we believe is easily lost when one is tasked to stay similar to a few label sentences. It is easy to imagine how this evaluation system could unjustifiably penalize creative texts, although they adhere to commonsense. For this reason, we did not evaluate on string matching, and did not collect any label sentences for C^{2}GEN.

E.2 Automatic Metrics

Word Inclusion Coverage is calculated using pattern matching of lemmatized versions of the generated texts (Lin et al., 2020). To avoide the obvious flaw of comparing lemmatized output with non-lemmatized input, we also lemmatize the input words. To further increase the coverage fairness we include all word lemmas using the python packages lemminflect (Jascob, 2019) and Spacy. The correlation between coverage and sequence length varies between models, but longer sequences often provide more space to include the target words.

Perplexity is calculated for the generated token sequence $X = (x_c, x_{c+1}, ..., x_{c+n-1})$, where c depicts the context length. This means, that for the C^{2}GEN dataset the perplexity is conditioned on the context, while $c = 0$ for the original CommonGen. Perplexity is strongly correlated with sentence length, meaning that both longer context and longer generated texts decreases perplexity. All our perplexity calculations utlize GPT-2XL, and follows the formula below.

$$\exp\left\{-\frac{1}{n}\sum_{i=c}^{c+n-1}\log p_\theta\left(x_i \mid x_{<i}\right)\right\}$$

Self-BLEU-5 (Zhu et al., 2018) evaluates the syntactic diversity of a given set of texts. It is defined as the average BLEU-5 (Papineni et al., 2002) between all text pairs in the given set. Due to BLEU measuring the ratio of overlap, longer sequences tend to yield lower Self-BLEU scores, as it is less likely that two long texts completely overlap.

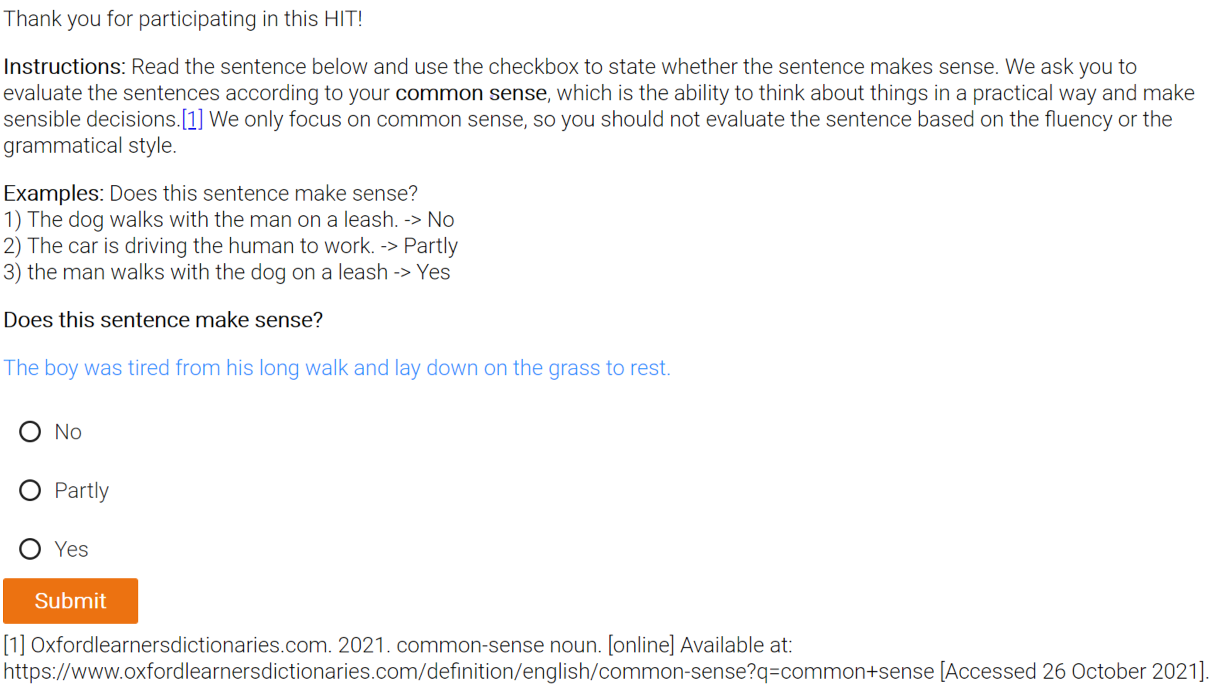
E.3 Human Evaluation Metrics

For each experimental setting, 100 generated texts are sampled from each algorithm. These samples are evaluated by humans on *common sense*, and in the case of C^{2}GEN, also *contextual relevance* (see definitions below). Using Amazons Mechanical Turk, each sample received 5 unique native English judges for both common sense and contextual relevance. Meaning that samples in C^{2}GEN were evaluated first by 5 judges on common sense, then independently judged by 5 potentially other judges on contextual relevance.

For both metrics, the annotators were tasked to answer either *"Yes"*, *"Partly"*, or *"No"*, as demonstrated in Figure 9. These responses were then mapped to the scalar values '*1*', '*0.5*' or '*0*', which resulted in an inter-annotator agreement of 0.51, and a Fleiss' κ of 0.115 (Celikyilmaz et al., 2020). A detailed depiction of the annotations for CommonGen is available in Table 9.

Common Sense is calculated as the overall average of all human annotators for the selected 100 samples. The final reported scores in Table 2 and Table 3 are hence each the average of 500 annotations. To ensure that common sense is separated from contextual relevancy, only the generated text is displayed to the human annotators. Meaning that for C^{2}GEN, the common sense annotators cannot consider the context in which the text has been generated.

Contextual Relevance (CTX) is calculated as an average identically to the common sense score. The only difference is that the annotators are tasked to consider how well the generated texts adheres to the given context, without considering if it makes sense or not.



Thank you for participating in this HIT!

Instructions: Read the sentence below and use the checkbox to state whether the sentence makes sense. We ask you to evaluate the sentences according to your **common sense**, which is the ability to think about things in a practical way and make sensible decisions.[1] We only focus on common sense, so you should not evaluate the sentence based on the fluency or the grammatical style.

Examples: Does this sentence make sense?
1) The dog walks with the man on a leash. -> No
2) The car is driving the human to work. -> Partly
3) the man walks with the dog on a leash -> Yes

Does this sentence make sense?

The boy was tired from his long walk and lay down on the grass to rest.

○ No

○ Partly

○ Yes

Table 10: The results on the C^{2}GEN dataset with the GPT-2 Large model prompted with the context only, i.e. no prompted instruction on the target words. This provides a simple baseline on how likely the target words are to appear naturally, when the model only focuses on generating a natural continuation of the context.

F Dataset C^{2}GEN

The C^{2}GEN dataset is mainly constructed in accordance with the data in the CommonGen test set. However, minor modifications were made to the distribution of the number of word targets per sample. The CommonGen test set only consists of samples with 4 or 5 target words, while the training and validation data includes samples with only 3 target words. After careful reading we found no argument for this, and speculate that it is purposefully intended to make the task more difficult. Artificially increasing task difficulty by skewing the test set away from the intended training data is however not something which we intuitively agree with.

To remedy this discrepancy, certain words were removed from samples in the CommonGen test set, resulting in all set sizes being equally represented. This results in a more similar and fair distribution between C^{2}GEN, and the CommonGen train and dev split. The filtering of words from the CommonGen test set did however result in a small number of samples being identical. These samples were deduplicated, which resulted in C^{2}GEN being slightly smaller than the CommonGen test set. However, as can be seen in Table 11, this discrepancy is insignificant.

To ensure the quality of the data generation, only native English speakers with a recorded high acceptance were allowed to participate. Finally, all contexts were manually verified, and fixed in terms of typos or poor quality.

The context lengths of the collected dataset are visualized in Figure 10. The perplexity and the Self-Blue metrics of the texts are available in Table 11. To evaluate the probability of the target words appearing naturally in a textual continuation, we use GPT-2 to generate text without the given target words and report on the coverage in Table 10.

```
1. Include the words [eat, hay, horse]: The horse was hungry and went down to the other animal in the barn
to eat hay. There they stood, as every evening at this time, eating hay. It was warm and cozy in there, so
she joined them and felt very welcomed. After a while, when she was done, she went out for a run with the
other horses.

2. Include the words [computer, scientist, office]: In the office at this time of day, one could see a large
group of enthusiastic scientists sitting by their computers. They looked calm and at peace, knowing that
they were contributing to something great.

3. Include the words [lawn, mow, noon, day]: David had to mow the lawn by noon, he had worked all day
and start
ed to get really exhausted. He had one last yard before he could go home and finally sleep. There was no
doubt that this was much needed after so many hours of work.

4. Include the words [soccer, sit, sofa, chance]: The whole group got the chance to sit down on the sofa
before the soccer game. Tommy entered the room, holding a plate full of beers for everyone. They all
shouted in joy for the beverages they were going to drink, one of them even fell off the couch.

5. Include the words [dog, cat, dirt, floor, window]: The floor was full of dirt after the dog had chased the cat
out of the window. Even the rug had been torn to pieces after the rough chase of the cat. He was surprised
when he came home and opened the door, despite the mess he smiled lovingly.

6. Include the words [<words>]:
```

Figure 12: Prompt template used with GPT2-Large for 32 Token CommonGen text generation.

```
1. The horse was hungry and went down to the other animal in the barn. There they stood, as every
evening at this time, eating hay. It was warm and cozy in there, so she joined them and felt very welcomed.
Include the words [run, rain, horse]: After a while, when she was done, she went out for a run with the other
horses in the rain.

2. In the office at this time of day, one could see a large group of enthusiastic scientists sitting by their
computers. They looked calm and at peace, knowing that they were contributing to something great.
Suddenly, the CEO walked in.
Include the words [employee, furious, room]: He was furious with one particular employee and asked him to
follow him to the conference room.

3. David had to mow the lawn by noon, he had worked all day and started to get really exhausted. He had
one last yard before he could go home and finally sleep. There was no doubt that this was much needed
after so many hours of work.
Include the words [dream, game, play, night]: He was dreaming about his younger days when he could play
games with his friends every night.

4. The whole group got the chance to sit down on the sofa before the soccer game. Tommy entered the
room, holding a plate full of beers for everyone. They all shouted in joy for the beverages they were going to
drink, one of them even fell off the couch.
Include the words [point, laugh, stand]: His friends laughed and pointed at him before they decided to help
him stand up.

5. The floor was full of dirt after the dog had chased the cat out of the window. Even the rug had been torn
to pieces after the rough chase of the cat. Stacy was surprised as she came home and opened the door,
despite the mess she smiled lovingly.
Include the words [treehouse, shoulder, look, jump, pet]: She looked outside by the treehouse to make sure
everything was alright when suddenly her pet jumped down and landed on her shoulder.

6. She had been hugged by a complete stranger. She also thought she had been called a thief, whatever
the reason for this was. She was confused.
Include the words [sprint, imagine, imagination, bicycle]: She sprinted to her bicycle and set off for home,
hoping she was imagining it all, which she had never dared to think before, because she did not like the
thought of imagination.

Language-Agnostic Meta-Learning for Low-Resource Text-to-Speech with Articulatory Features

Florian Lux and **Ngoc Thang Vu**
Institute for Natural Language Processing
University of Stuttgart
florian.lux@ims.uni-stuttgart.de

Abstract

While neural text-to-speech systems perform remarkably well in high-resource scenarios, they cannot be applied to the majority of the over 6,000 spoken languages in the world due to a lack of appropriate training data. In this work, we use embeddings derived from articulatory vectors rather than embeddings derived from phoneme identities to learn phoneme representations that hold across languages. In conjunction with language agnostic meta learning, this enables us to fine-tune a high-quality text-to-speech model on just 30 minutes of data in a previously unseen language spoken by a previously unseen speaker.

1 Introduction

The advance of deep learning (Vaswani et al., 2017; Goodfellow et al., 2014) has enabled great improvements in the field of Text-to-Speech (TTS). (Towards-)end-to-end models, such as Tacotron 2 (Wang et al., 2017; Shen et al., 2018), TransformerTTS (Li et al., 2019b), FastSpeech 2 (Ren et al., 2019, 2020), FastPitch (Łańcucki, 2021) and many more famous instances (e.g. Arık et al. (2017) and Prenger et al. (2019)) allow for speech synthesis with unprecedented quality and controllability. The models mentioned here rely on vocoders, such as WaveNet (van den Oord et al., 2016), MelGAN (Kumar et al., 2019), Parallel WaveGAN (Yamamoto et al., 2020) or HiFi-GAN (Kong et al., 2020) to turn the parametric representations that they produce into waveforms. Recently proposed models even include some with the ability to go directly to the waveform from a grapheme or phoneme input sequence, such as EATS (Donahue et al., 2020) or VITS (Kim et al., 2021).

While these methods all perform remarkably well if given enough data, cross-lingual use of data remains a key challenge in TTS. Most modern methods are limited to languages and domains that are rich in resources, which over 6,000 languages are not. Attempts at reducing the required resources in a target language by making use of transfer learning from multilingual data have been made by Azizah et al. (2020); Xu et al. (2020); Chen et al. (2019). The mismatch of input spaces however requires complex architectural changes, which limits their ability to be used in conjunction with other modern TTS architectures. Attempts at fixing the issue of having to transfer knowledge from a source to a target by just jointly training on a mixed set of more and less resource rich languages have been made by He et al. (2021); de Korte et al. (2020); Yang and He (2020), which requires complex training procedures. In this work, we will also attempt to transfer knowledge from a set of high resource languages to a low resource language. We fix previous shortcomings by 1) using a linguistically motivated representation of the inputs to such a system (articulatory and phonological features of phonemes) that enables cross-lingual knowledge sharing and 2) applying the model agnostic meta learning (MAML) framework (Finn et al., 2017) to the field of low-resource TTS for the first time.

Using articulatory features as inputs for neural TTS has been attempted recently by Staib et al. (2020) and Wells et al. (2021), following the classical approach of Jakobson et al. (1961). Both achieved good results when applying this idea to the codeswitching problem, since unseen phonemes in the input space no longer map to nonsensical positions, as it would be the case for the standard embedding-lookup. It has to be noted however, that this only works across languages with similar types of phonemes. Also Gutkin (2017) have applied phonological features to low-resource TTS with fair success. They did however rely on supplementary features, such as dependency parsers and morphological analyzers. Furthermore all of their data and models are proprietary and can therefore not be used to compare results to. In this work, we extend the use of articulatory inputs with

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 6858 - 6868

the MAML framework to enable very simple yet well working low-resource TTS that can be applied to almost all modern TTS architectures.

We encounter severe instabilities when using MAML on TTS, which make the standard formulation of MAML infeasible to use. Thus we also propose a modification to MAML, which reduces the procedure's complexity. This allows us to create a set of parameters of a model that can be used to fine-tune to a well working single-language single-speaker TTS model with as little as 30 minutes of paired training data available and even enables zero-shot adaptation to unseen languages. We evaluate the success of our approach with both automatic measures and human evaluation.

Our contributions are as follows: 1) We show that it is beneficial to train a TTS model on articulatory features rather than on phoneme-identities, even in the standard single-language high-resource case; 2) We introduce a training procedure that is closely related to MAML which allows training a set of parameters for a TTS model that can be fine-tuned in a low resource scenario; 3) We provide insights on how much data and training time are required to fine-tune a model across different languages and speakers simultaneously using said meta-parameters; 4) We show that the meta-parameters can generalize to unseen phonemes and rapidly improve their ability to properly pronounce them when fine-tuning. [1]

2 Background and Related Work

2.1 Input Representations

Character Embeddings The simplest approach to representing text as input to a TTS is using indexes of graphemes to look up embeddings. This is however prone to mistakes. Taylor and Richmond (2020) bring up the example of *coathanger*. If the TTS is not aware of the morpheme boundary between the *coat* and the *hang*, it will be inclined to produce something like [kʌθəɪnʤə] rather than the correct [koʊthæŋə]. Such a representation of the input will be highly language dependent, since special pronunciation rules rarely hold for more than a single language.

The textual input can be augmented by adding information, such as morpheme boundaries, intonation phrase boundaries derived from e.g. syntactic parsing as is done in many TTS frontends (Schröder and Trouvain, 2003; Clark et al., 2007; Ebden and Sproat, 2015), or even the semantic identity of the word a character belongs to, using e.g. BERT embeddings (Hayashi et al., 2019).

Phoneme Embeddings Rather than looking up embeddings for graphemes, it is often beneficial to use embeddings of phonemes. Phonemizers (Bisani and Ney, 2008; Taylor, 2005; Rao et al., 2015) produce a sequence of phonetic units, which correlate with the segments in the audio much more than raw text. One such standard of phonetic representation which we make use of is the International Phonetic Alphabet (IPA). Using this set of phonetic units alleviates the problems of TTS fine-tuning and transfer-learning to low-resource domains, because the phonetic units should be mostly language independent. Deri and Knight (2016) provide a data driven approach for the grapheme to phoneme conversion task, which performs well on over 500 languages and can be adapted fairly easily to any new low-resource language. There remains however one major challenge: The use of different phoneme sets for each language, leading to completely unseen units in inference or fine-tuning data.

Latent Representations Li et al. (2019a) claim that multilinguality in speech recognition and TTS can be achieved by changing the input to a latent representation that is trained across languages. While their results seem very promising, their technique needs training data in all languages it should be applied to, which rules out zero-shot settings.

Articulatory Features We fix the shortcoming of not being able to handle unseen phonemes by specifying phonemes in terms of articulatory features such as position (e.g. frontness of the tongue) and category (e.g. voicedness). We show that systems trained on this input can produce a phoneme given nothing but an articulatory description and thus generalize to unseen phonemes. This makes the transfer of knowledge across languages much simpler. A similar approach for the purpose of handling codeswitching has been done in Staib et al. (2020). Our work builds on top of theirs by extending the idea to transfer learning an entire TTS in a new language with minimal data, making use of meta learning on top of articulatory features.

---

[1] All of our code, as well as the checkpoints for a low-resource fine-tuning capable Tacotron 2 and FastSpeech 2 model are publicly available at `https://github.com/DigitalPhonetics/IMS-Toucan`.

2.2 Model Agnostic Meta Learning (MAML)

The goal of MAML (Finn et al., 2017) is to find a set of parameters, that work well as initialization point for multiple tasks, including unseen ones. The procedure consists of an outer loop and an inner loop. The outer loop starts with a set of parameters, which we will call the Meta Model. The inner loop trains task specific copies of the Meta Model for a low amount of steps. Once the inner loop is complete, the loss for each of the models is calculated, summed, and backpropagated to the original Meta Model by unrolling the inner loop. This includes the very costly calculation of second order derivatives. The Meta Model is then updated and the inner loop starts again.

This procedure moves the initialization point closer to the optimal configuration for each of the trained tasks, which generalizes to even unseen tasks. Multiple variants of MAML have been suggested that try to fix the high computational cost of the second order derivatives. The simplest one is called first-order MAML and simply applies the gradient of the task specific model at the end of the inner loop directly to the Meta Model. Other variants are described in Antoniou et al. (2019); Rajeswaran et al. (2019).

3 Approach

3.1 System Description

For the implementation of our method, we use the open source IMS Toucan speech synthesis toolkit, first introduced in (Lux et al., 2021), which is in turn based on the ESPnet end-to-end speech processing toolkit (Watanabe et al., 2018; Hayashi et al., 2020, 2021). Neekhara et al. (2021) show, that it is beneficial to fine-tune a single-speaker model to a new speaker rather than to train a multi-speaker model. Inspired by this, we decided to also use a model that is not conditioned on speakers or on languages rather than a conditioned multi-speaker multi-lingual model and fine-tune it on the data from a new speaker in a new language. In preliminary experimentation we got similar results to them within one language, but found their method to not work across languages. In comparison to the fine-tuning of a simple single speaker model, we found training and fine-tuning a model conditioned on language embeddings and speaker embeddings much more sensitive to the choice of hyperparameters. Figure 1 shows an overview of our system, underlining how it is not specific to a certain architecture, but could instead be used in conjunction with almost all modern TTS methods.

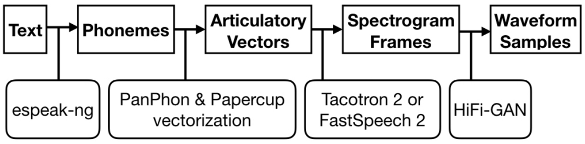

Figure 1: Overview of the TTS pipeline we use. The top row shows the modality in which the data is at this point in the pipeline. The lower row shows the methods that handle the transitions. Each of the blocks in the lower row can be exchanged easily with other methods that have the same interfaces.

Tacotron 2 For our implementation of Tacotron 2 (Shen et al., 2018), we make use of the forward attention with transition agent introduced in Zhang et al. (2018), which uses a CTC-like forward variable (Graves et al., 2006) to promote the quick learning of monotonic alignment between text and speech. To further help with this, we make use of the guided attention loss introduced in Tachibana et al. (2018).

FastSpeech 2 To train the parallel FastSpeech 2 model (Ren et al., 2020), annotations of durations for each phoneme are needed. These also have to be generated for the low-resource fine-tuning data. To that end, we generate alignments using the encoder-decoder attention map of a Tacotron 2 model. Following Kim et al. (2020); Shih et al. (2021); Badlani et al. (2021), we apply the Viterbi algorithm to find the most probable monotonic path through the attention map, which significantly improves the quality of the alignments.

This is especially important, because we train our FastSpeech 2 model with pitch and energy labels that are averaged over the duration of each individual phoneme to allow for great controllability during inference, as is introduced by Łańcucki (2021). Incorrect alignments would lead to follow-up errors such as an unnaturally flat prosody.

Furthermore, we make use of the conformer block (Gulati et al., 2020) as the encoder and decoder, rather than the standard transformer (Vaswani et al., 2017).

3.2 Articulatory Vectors

PanPhon The PanPhon resource (Mortensen et al., 2016) can be used to get linguistic specifications of phonemes. It comes with an open-source tool[2] which we use to convert phonemes into numeric vectors. Each vector encodes one feature per dimension and takes the value of either -1, 0 or 1, putting the features on a scale wherever meaningful. This featureset also includes phonological features which go beyond simple phonetics, such as whether a phoneme is syllabic.

Papercup Additionally we make use of the purely articulatory description system of phonemes introduced in Staib et al. (2020), which we will call Papercup features in the following. For the encoding we use one-hot vectors, similar to their implementation. Some of the features, like openness or frontness, should be on a scale rather than one-hot encoded. However since the articulatory vector is fed into a fully connected layer, we leave the reconstruction of this dependency between features for the network to learn.

3.3 Language Agnostic Meta Learning

We find that the standard implementation of MAML does not work well for the TTS task. The inner loop needs hundreds of updates in order to make a significant change to the performance of the task specific model. This is probably due to the TTS task being a one-to-many mapping task, where the loss function of measuring the distance to a spectrogram is not an accurate objective for the TTS. For every text, there are infinitely many spectrograms, which could be considered gold data. Those spectrograms could differ in e.g. the speaker who reads the text and how they read the text. Since there are no conditioning signals, the TTS has to update its parameters towards a certain speaker's characteristics in general. However because in our case each task is a different language and a different speaker, the training becomes highly unstable. So ideally we would either need to run MAML's inner loop until convergence, which is generally infeasible, or stabilize the procedure by not allowing the model to adapt further to one task than to the others.

To fix this issue, we calculate the Meta Model's loss on one batch per language. We then sum up the losses, backpropagate and update the Meta Model directly using Adam (Kingma and Ba, 2015). This stabilizes the learning procedure, but still allows the model to update its parameters towards a more universal configuration. Since we have to make this simplification to MAML in order to deal with the different languages as tasks, we call this procedure language agnostic meta learning (LAML). Ultimately, the model should not care about the language it is fine-tuned in, since it should be close to a universal representation of an acoustic model. To give an exact notion of our modifications: We simplified equation 1 to equation 2, where *opt* is a gradient descent update, B_i is a batch sampled from task i, $\mathcal{L}$ is an objective function, Θ is the set of parameters from the Meta Model and θ_i is the set of parameters specific to task i. To the best of our knowledge, we are the first to successfully apply MAML to TTS with languages being the tasks.

for t steps do:

$$\Theta_t = \mathit{opt}\left(\Theta_{t-1}, \nabla \sum_i \mathcal{L}\left(\theta_{i,d}, B_i\right)\right) \tag{1}$$

where $\theta_{i,d=0} = \Theta_{t-1}$ and for d steps do:

$$\theta_{i,d} = \mathit{opt}\left(\theta_{i,d-1}, \nabla \mathcal{L}\left(\theta_{i,d-1}, B_i\right)\right)$$

for t steps do:

$$\Theta_t = \mathit{opt}\left(\Theta_{t-1}, \nabla \sum_i \mathcal{L}\left(\Theta_{t-1}, B_i\right)\right) \tag{2}$$

4 Experiments

In this section we will go over the experiments we conducted. First we will evaluate the articulatory features on their own in a single language setting using automatic measures. Then we will evaluate the combination of LAML and articulatory features in a cross-lingual setting using both automatic measures and human evaluation.

In our experiments we make use of the following datasets: The English Nancy Krebs dataset (16h) from the Blizzard challenge 2011 (Wilhelms-Tricarico et al., 2011; King and Karaiskos, 2011); The German dataset of the speaker Karlsson (29h) from the HUI-Audio-Corpus-German (Puchtler et al., 2021); The Greek (4h), Spanish (24h), Finnish (11h), Russian (21h), Hungarian (10h), Dutch (14h) and French (19h) subsets of the CSS10 dataset (Park and Mulc, 2019).

4.1 Mono-Lingual Experiments

4.1.1 Embedding Function Design

To explore our first hypothesis, we investigate the capabilities of the articulatory phoneme representations to be used in a single-speaker and single-language TTS system. To compare different ways

---

[2] `https://github.com/dmort27/panphon`

of embedding the features, we train only the embedding function. As gold data we use the embeddings from a well trained lookup-table based Tacotron 2 model. In table 1 we show the average distances of all articulatory vectors as projected by the embedding function to their identity based embedding counterpart. The distance d between two embedding vectors A and B is defined in equation 3.

$$d = \left(\sum_i |A_i - B_i|\right) - \frac{\sum_i A_i \cdot B_i}{\sqrt{\sum_i A_i^2} \cdot \sqrt{\sum_i B_i^2}} \tag{3}$$

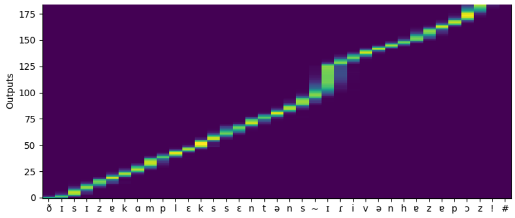
This distance function is also used as the objective function. The embedding functions are each trained for 3000 epochs using Adam (Kingma and Ba, 2015) with a batchsize of 32. The first column shows the results of the articulatory features being fed into a linear layer that projects them into a 512 dimensional space. The second column shows the results of the articulatory features being fed into a linear layer that projects them into a 100 dimensional space, applies the tanh activation function and then further projects them into a 512 dimensional space. As can be seen from the results, it is beneficial to both concatenate the PanPhon features with the Papercup features despite their overlap and to add a nonlinearity into the embedding function to match the embeddingspace of a well trained Tacotron 2 model. Hence we use this setup in all following experiments.

d	Linear	Non-Linear
PanPhon	0.47	0.1
Papercup	0.44	0.05
Combined	0.4	**0.001**

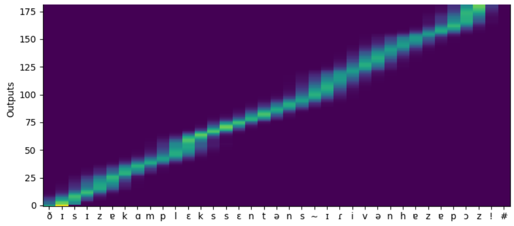
Table 1: Average distance of all embedded articulatory vectors to their position in an embedding space learned in a lookup-table based model.

4.1.2 Convergence Time

To investigate the impact that the articulatory features have on their own, we train a Tacotron 2 with and without them on the Nancy dataset and compare their training time and final quality. While the model trained on embedding tables shows a clear diagonal alignment of text and spectrogram frames on an unseen test sentence after 2,000 steps, the one trained on articulatory features does so already at 500 steps. This is visualized in figure 2. The decoder of the Tacotron 2 model can only start to learn to decode after the alignment of inputs to outputs is learned. So learning the alignment earlier gives the articulatory model a clear benefit. After training for 80,000 steps however, our own subjective assessment finds no difference in quality between the two. The earlier convergence of the alignment however shows a possible advantage of using the articulatory features on low-resource tasks, as quicker training progress means that training can be stopped earlier, before overfitting on little data becomes too problematic.



(a) Proposed Tacotron 2 with articulatory features at 500 steps with a batchsize of 32.



(b) Baseline Tacotron 2 with embedding-lookup at 2000 steps with a batchsize of 32.

Figure 2: The first instance of diagonal encoder-decoder attention on an unseen test sentence.

4.2 Cross-Lingual Experiments

In order to investigate the effectiveness of our proposed LAML procedure, we train a Tacotron 2 model and a FastSpeech 2 model on the full Karlsson dataset as a strong baseline. We also train another Tacotron 2 model and another FastSpeech 2 model on speech in 8 languages with one speaker per language (Nancy dataset and CSS10 dataset) and fine-tune those models on a randomly chosen 30 minute subset from the Karlsson dataset. To our surprise, we did not only match, but even outperform the model trained on 29 hours with the model fine-tuned on just 30 minutes in multiple metrics.

As a second baseline we tried to train another meta-checkpoint using the embedding lookup-table approach to also further investigate the effectiveness of the articulatory features. We did however not manage to get such a model to converge to a usable state. This already shows the superiority of the articulatory feature representations for such a multilingual use-case.

Furthermore we tried to fine-tune the well trained English single speaker models from the first experiment on the 30 minutes of German to have another baseline that can be used to measure the impact of the LAML procedure. This setup however also did not yield any usable results. During the fine-tuning process, the model was capable of speaking German with a strong English accent, yet it did not properly learn to speak in the voice of the target speaker. By the time the model learned to speak in the new speaker's voice, it had overfitted the 30 minutes of training data and collapsed, producing no more intelligible speech. We conclude that the method proposed in this paper not only improves on the ability to use cross-lingual data easily, but actually enables it in the first place. Both the articulatory features, as well as the LAML pretraining seem necessary to achieve cross-lingual fine-tuning on low-resource data.

The texts we use for the following experiments are disjunct from any training data used. Human speech as gold standard is not used, since we are interested in the difference in performance between the systems, not their absolute performance. The close to state-of-the-art performance of the baselines is considered as given, considering their ideal training conditions and use of proven methods. Furthermore, we chose to use German as our benchmark language over an actual low-resource language, since it is much easier to acquire reliable ratings on intelligibility and naturalness for German, than it would be for an actual low-resource language.

4.2.1 Intelligibility

To compare intelligibility between our baseline models and our low-resource models, we use the word error rate (WER) of an automatic speech recognition system (ASR) as a proxy. We synthesize 100 sentences of German radio news texts taken from the DIRNDL corpus (Eckart et al., 2012) with each of our baselines and corresponding low-resource systems. Table 2 shows WERs that the German IMS-Speech ASR (Denisov and Vu, 2019) achieves on the synthesized data. For both Tacotron 2 and the FastSpeech 2 based system, the WER of the low-resource model is slightly lower than that of the baseline, thus the low-resource models performed slightly better.

WER	Baseline	Low-Resource
Tacotron 2	13.1%	12.7%
FastSpeech 2	9.9%	9.7%

Table 2: WER of the synthesis systems on 100 radio news texts measured using the IMS-Speech ASR.

Looking into the cases where the low-resource system outperformed the baseline, we find code-switched segments, where the texts contain names of Russian cities. Since the pretraining data of the low-resource model includes Russian speech, it seems to have not forgotten entirely about what it has seen in the pretraining phase, which in our interpretation confirms the effectiveness of the LAML against the catastrophic-forgetting problem (French, 1999) of regular pretraining.

4.2.2 Naturalness

In order to assess the naturalness of the fine-tuned models, we conduct a preference study with 34 native speakers of German. Each participant is shown 12 phonetically balanced samples produced by the Tacotron 2 and FastSpeech 2 models. For every sentence, there is one sample produced by the baseline and one by the low-resource model. The participants are then asked to indicate their subjective overall preference between the two samples. The results for Tacotron 2 are shown in figure 3 (a). The low-resource system was the preferred system in more than half of the cases, with an equal rating taking up more than another third, showing a clear preference for the low-resource model over the baseline. The results for FastSpeech 2, as seen in figure 3 (b), are a lot more balanced. While the baseline is preferred more often than the low-resource variant, it is not the case in the majority of the ratings. In 56% of the cases, the model fine-tuned on 30 minutes of data was perceived to be as good or better than the model trained on 29 hours.

Computational Resources All models were trained on a single NVIDIA A6000 GPU. Training the Tacotron Baseline took 2 days. Training time of the FastSpeech Baseline was 1 day. Training time of the meta-checkpoint was 4 days, finetuning to a new model from the meta-checkpoint however only takes 2 hours. The HiFi-GAN vocoder used to generate all samples took 4 days to train and was not fine-tuned on the unseen data. We did not perform hyperparameter searches and used the suggested default settings for all methods, which worked sufficiently well, but could surely be improved.

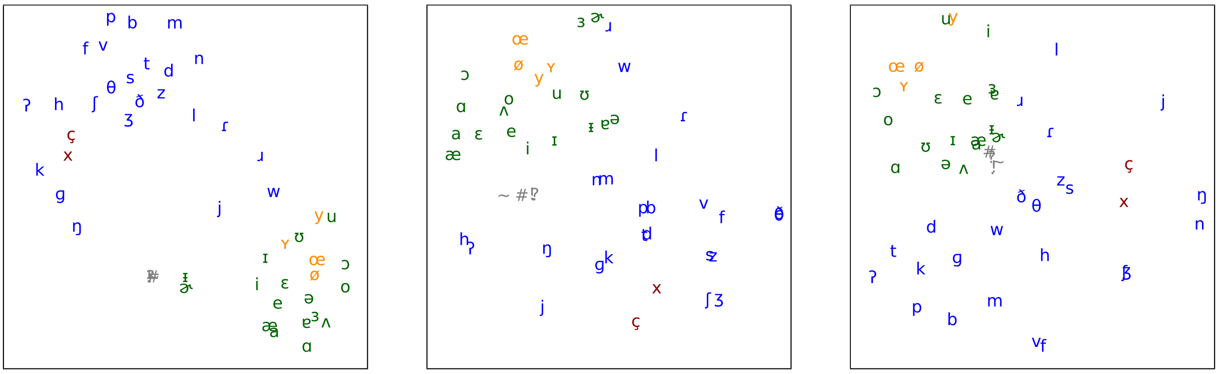
5 Further Analysis and Future Work

What is the ideal amount of training steps for fine-tuning? To investigate the amount of update steps needed to fully adapt to the new speaker with the added difficulty of learning a new language, we show the cosine similarity of a speaker embedding of the fine-tuned model to that of the ground truth throughout the fine-tuning process in figure 4. The speaker embedding is built according to the ECAPA-TDNN architecture (Desplanques et al., 2020) and provided open source by SpeechBrain (Ravanelli et al., 2021). It is trained on VoxCeleb 1 and 2 (Nagrani et al., 2017, 2019; Chung et al., 2018) which to the best of our knowledge does not overlap with any of the other training and evaluation data we used. We tried to decrease adaptation time further by incorporating said speaker embedding similarity as an additional objective function, similar to Nachmani et al. (2018), we did however see only marginal improvements in the amount of steps needed at the expense of greatly increased training time.

Can this setup handle zero-shot phonemes? We show the model's zero shot capabilities in figure 5. We removed Dutch and Finnish from the training data of the meta-checkpoint and trained another version of it, to be able to see how it handles all of the now completely unseen phonemes specific to German. While their correct position in plot (a) can be considered given, since it shows the articulatory featurespace, their meaningful positions in plot (b) and (c) show that the meta-checkpoint does not just collapse the vector of the unseen phoneme to the one it is most similar to, but actually generalizes. While their pronunciation when produced does not match the correct pronunciation perfectly, it can be understood in the context of a longer sequence. This is congruent with the results of Staib et al. (2020). During the adaptation phase, the pronunciation of the unseen phonemes rapidly matches the correct pronunciation after less than 100 steps.

Does this setup learn the difference between language and speaker? When analyzing the fine-tuned meta-checkpoint, we observed that it seems to link the language of the input to the voice of the speaker. For example when synthesizing an unseen Hungarian text using Tacotron 2, the voice of the synthesis resembles that of the Hungarian female speaker, even though the model has been fine-tuned on the male German speaker and there are no additional conditioning signals. We hypothesize that the LAML procedure induces certain subsets of parameters in the model to be speaker dependent and the encoder of the model priming those parameters purely based on the phoneme sequence. This leads us to believe, that the fine-tuning of all parameters in the model may neither be necessary, nor even the best way of adapting to new data. This also fits the observations of the speaker embedding over time, since the Tacotron model adapts to the new speaker very rapidly. Further investigations into



(a) 66 dimensional Featurespace (24 PanPhon and 42 Papercup features)

(b) 512 dimensional embeddingspace learned during Tacotron 2 training

(c) 384 dimensional embeddingspace learned during FastSpeech 2 training

Figure 5: t-SNE visualizations of phoneme representations, illustrating zero-shot capabilities. Special characters are grey, consonants are blue, vowels are green, unseen consonants are red and unseen vowels are orange.

the interactions between parameter groups could allow cutting down the amount of parameters that need to be trained significantly, further reducing the need for training data.

How can we bring down FastSpeech 2's data need further? A similar observation regarding language and speaker can be made with FastSpeech 2, however as could be seen from the experiment on naturalness and the training time, the FastSpeech 2 model can benefit more from additional data and training time. This may come down to its nearly twice as high parameter count. So a more effective fine-tuning strategy, that considers some parameters as constants, could benefit the fine-tuning capabilities of the FastSpeech 2 model greatly.

Does this work across language families? One limitation to our findings is that we investigated only the transfer of languages that share similar phoneme inventories. It is possible that fine-tuning to a language that uses e.g. the lexical tone rather than pitch accents or word accents would require pretraining in more closely related high-resource languages, such as Chinese. However, as Vu and Schultz (2013) find in their analysis of multilingual ASR, the fast adaptation of an acoustic model trained on multiple languages to unseen languages works well, even across different language families. We thus believe that the technique and analysis presented in this paper also holds across language families and types.

6 Conclusion

In this paper, we show an approach for training a model in a language for which only 30 minutes of data are available by making use of articulatory features and language agnostic meta learning. The main takeaways from our work are as follows:

Articulatory Features for TTS Using articulatory features as the input representation to a TTS system enables the use of multilingual data without the need for increased architectural complexity, such as language specific projection spaces. It is furthermore beneficial to use even in single-language scenarios, since the knowledge sharing between phonemes makes the TTS system converge much earlier to an usable state during training.

MAML on TTS Applying MAML to TTS does not work well. If we however remove the inner loop, we are able to pretrain a low-resource capable checkpoint for TTS. This modification not only makes it work, it also simplifies the formulation.

Zero-shot capabilities The use of articulatory features enables zero-shot inference on unseen phonemes. This is further enhanced by the LAML training procedure. The implications of this are particularly interesting for codeswitching, as Staib et al. (2020); Wells et al. (2021) have pointed out previously. Using these two techniques in conjunction could be used to reduce the problem of codeswitching to a problem of token-wise language identification.

Abstract

Modern Irish is a minority language lacking sufficient computational resources for the task of accurate automatic syntactic parsing of user-generated content such as tweets. Although language technology for the Irish language has been developing in recent years, these tools tend to perform poorly on user-generated content. As with other languages, the linguistic style observed in Irish tweets differs, in terms of orthography, lexicon, and syntax, from that of standard texts more commonly used for the development of language models and parsers. We release the first Universal Dependencies treebank of Irish tweets, facilitating natural language processing of user-generated content in Irish. In this paper, we explore the differences between Irish tweets and standard Irish text, and the challenges associated with dependency parsing of Irish tweets. We describe our bootstrapping method of treebank development and report on preliminary parsing experiments.

1 Introduction

Irish is a minority language spoken mostly in small communities in Ireland called 'Gaeltachtaí' (CSO, 2016) but social media sites, such as Twitter, provide a platform for Irish speakers to communicate electronically from any location. Users may reach a wide audience quickly, unconstrained by the conventions of standard language upheld by editors in publications, revealing the orthographic, lexical, and syntactic variation abundant in informal Irish. Analysis of up-to-date, real-world language data can provide an insight into how Irish is used in everyday communication and how such informal texts compare to prescriptive norms of standardised language to which published texts tend to adhere.

User-generated content (UGC), such as tweets, is a valuable, highly available resource for training syntactic parsers that can accurately process social media text. UGC is a genre with features different from those of both spoken language and standardised written language more traditionally found in natural language processing (NLP) corpora. Plank (2016) notes the advantages of utilising *fortuitous data* in order to create more adaptive, robust language technology.

Given that the accuracy of syntactic parsing tools has been shown to decline when evaluated on noisy UGC data (Foster et al., 2011; Seddah et al., 2012) and that domain[1] adaptation has been shown to improve parser performance for dependency annotation of English tweets (Kong et al., 2014) and POS-tagging in Irish tweets (Lynn et al., 2015), the need for genre-specific resources is clear in order to reliably process this variety of data. The prerequisite, therefore, for research in this area is a data set of Irish UGC. This research attempts to fill this gap through the development of TwittIrish, a treebank of Irish tweets, within Universal Dependencies (UD) (Nivre et al., 2020), a cross-lingually consistent framework for dependency-based syntactic parsing. TwittIrish provides linguistic information for Irish in a digitally accessible format valuable for linguistic research and the development of NLP tools.

Open-source projects such as UD facilitate collaboration and rapid evolution of ideas among linguists internationally. In order to maintain optimum consistency with other UD treebanks, the annotation methodology employed in this research closely follows the general UD guidelines and the language-specific guidelines for Irish while aiming to incorporate the most up-to-date recommendations (Sanguinetti et al., 2022) for UGC in this evolving area of NLP. UGC, especially social media text, has recently become a popular focus within UD and NLP research more broadly (Silveira et al., 2014; Luotolahti et al., 2015; Albogamy and Ram-

---

[1] The terms genre and domain are used interchangeably throughout this paper to refer to the category of text such as standard published text or Twitter text.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 6869 - 6884
May 22-27, 2022

say, 2017; Wang et al., 2017; Zeldes, 2017; Bhat et al., 2018; Blodgett et al., 2018; Van Der Goot and van Noord, 2018; Cignarella et al., 2019; Seddah et al., 2020) and has encouraged active conversation around how best to represent it within this framework among the UD community.

We carry out preliminary parsing experiments with TwittIrish, investigating the following two questions: How effective is a parser trained on the Irish UD Treebank (Lynn and Foster, 2016), which contains only edited text and no UGC, when applied to tweets? And what difference do pre-trained contextualised word embeddings make? We observe a difference of approximately 23 LAS points between TwittIrish and the IUDT test set and find that the use of monolingual BERT embeddings (Barry et al., 2021) improves performance by over 10 LAS points.

The paper is structured as follows: Section 2 details the existing Irish NLP resources we use for our research, Section 3 outlines the development of the treebank, Section 4 describes the characteristics of UGC evident in Irish tweets, and Section 5 presents parsing experiments and error analysis.

2 Irish NLP Resources

We use the following resources:

Indigenous Tweets (IT)[2] This project compiles statistics on social media data of 185 minority and indigenous languages including Irish. All tweets in the TwittIrish treebank were sourced via IT.

Lynn Twitter Corpus (LTC)[3] **(Lynn et al., 2015)** A corpus of 1,493 lemmatised and POS-tagged Irish language tweets randomly sampled from 950k tweets by 8k users posted between 2006 and 2014, identified by IT. The LTC data also contains code-switching information (Lynn and Scannell, 2019).

Irish Universal Dependencies Treebank (IUDT)[4] **(Lynn and Foster, 2016)** A UD treebank consisting of 4,910 sentences sampled from a balanced mixed-domain corpus for Irish.

gaBERT (Barry et al., 2021) A monolingual Irish BERT model, trained on approximately 7.9 million sentences, which outperforms Multilingual BERT (mBERT) (Devlin et al., 2019) and WikiBERT (Pyysalo et al., 2021) at the task of dependency parsing for Irish.

3 TwittIrish Development

We combined 700 POS-tagged tweets from the LTC with 166 tweets more recently crawled by IT in order to leverage previous linguistic annotations while also including newer tweets. This involved converting the LTC annotation scheme to that of the UD framework and then POS-tagging the new raw tweets. We provide further detail in Appendix A.

LTC conversion With regard to tokenisation, multiword expressions were automatically split into separate tokens following UD conventions. Only minor manual adjustments were required for lemmatisation to ensure alignment with the IUDT (to enable bootstrapping – see Section 3). Finally, the POS tagset used in the LTC was automatically converted to the UD tagset. Appendix A.2 describes this process.

Preprocessing of newly-crawled tweets Due to the lack of a tokeniser designed to deal specifically with UGC in Irish, we compared two tools for this task: UDPipe (Straka et al., 2016),[5] a language-agnostic trainable pipeline for tokenisation, tagging, lemmatisation and dependency parsing, and Tweettokenizer[6] from NLTK (Bird et al., 2009), a rule-based tokeniser designed for noisy UGC. The latter proved to be more effective for tokenising UGC phenomena such as emoticons, URLs, and meta language tags. Manual corrections were then applied in order to adhere to the Irish-specific tokenisation scheme within current UD guidelines. In order to establish the best system to use for automatic lemmatising and POS-tagging, two tools, Morfette (Chrupala et al., 2008) and UDPipe (Straka et al., 2016), were analysed with Morfette achieving higher scores on both tasks.

Syntactic annotation As a method shown to reduce manual annotation efforts in syntactic annotation (Judge et al., 2006; Seraji et al., 2012), we carry out a bootstrapping approach to dependency parsing as recommended by UD. [7]

The bootstrapping process is illustrated in Figure 1. After converting the LTC and new tweets

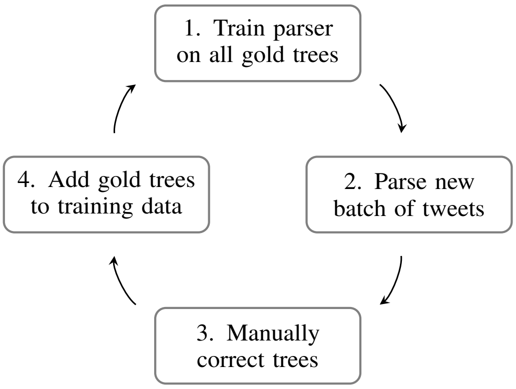

Figure 1: Bootstrapping approach to semi-automated syntax annotation.

to the CoNLL-U format, we manually annotated a small set of 166 tweets and began the bootstrapping cycle.[8] (Step 1) A parsing model[9] was trained on the IUDT in combination with the newly annotated tweets. (Step 2) The parsing model was used to automatically annotate the next batch of 100 tweets. (Step 3) These tweets were manually corrected. (Step 4) The corrected tweets were added to the training data. Steps 1 to 4 were repeated until all 866 tweets were fully parsed. This dataset represents the TwittIrish test set in the UD version 2.8 release.[10]

4 Annotating Irish UGC

This section describes the linguistic features that can create challenges when parsing Irish social media text. We provide Irish examples and discussion around the factors that influence these phenomena.

4.1 Orthographic Variation

Orthographic variation refers to deviation from the conventional spelling system of the language and is observed at the token level. Therefore, it can affect the lemmatisation of a token in an NLP pipeline, potentially affecting other downstream areas of annotation. In the TwittIrish dataset, 2.5% of tokens contained some orthographic variation. Table 1 exemplifies some frequently-occurring phenomena in Irish tweets that deviate from standard orthography.

Diacritic variation Diacritic marks are often omitted or incorrectly added to tweets. The acute accent or *síneadh fada* is used in Irish to indicate a long vowel and is necessary to disambiguate between certain words. Example 1 shows the most probable intended word *léacht* 'lecture' rendered as *leacht* 'liquid'.

(1) ***Leacht*** *faoi stair Príosún Dún Dealgain*
'Lecture about the history of Dundalk Prison'

Abbreviation Predictable shorthand forms can occur in standard Irish texts e.g. *lch* as an abbreviated form of *leathanach* 'page'. While more unconventional, and thus less predictable, abbreviations are observed in Irish tweets, as per Example 2 in which the word *seachtain* 'week' is shortened to *seacht* 'seven'. Abbreviations are more common in tweets than standard text as the character limit and real-time, up-to-date nature of the platform encourages the user to be efficient with time and space.

(2) *Bím de ghnáth ach sa bhaile an* ***tseacht*** *seo*
'I usually am but home this week'

Lengthening This refers to the elongation of a token by repeating one or more characters. This can be thought of as an encoding of sociophonetic information (Tatman, 2015) and is strongly linked to sentiment. Despite incentives to save time and space while tweeting, users often elongate certain words for expressive purposes (Brody and Diakopoulos, 2011). Example 3 demonstrates the lengthening of the word *buí* 'yellow'.

(3) *tá siad go léir* ***buuuuuuí***
'They are all yellooooow'

Case variation Nonstandard use of upper- and lowercase text is another method of encoding sociophonetic information by focusing attention or emotion on a particular word or phrase. Heath (2021) discusses the association between the use of all-caps and perceived shouting as in Example 4.

(4) *Níl todhchaí na Gaeilge sa Ghaeltacht, ach in aon áit* ***AR DOMHAIN***
'The future of Irish is not in the Gaeltacht but anywhere ON EARTH'

---

[8] Due to the limited funding available, all manual annotation and correction was performed by one linguist annotator.

[9] Biaffine Parser (Dozat and Manning, 2017) with mBERT (Devlin et al., 2019) embeddings.

[10] The TwittIrish Treebank is available here: `https://github.com/UniversalDependencies/UD_Irish-TwittIrish/tree/master`

Phenomenon	**Example**	**Standard form**	**Gloss**
Diacritic variation	***nior*** *fhoghlaim* ***tu***	*níor fhoghlaim tú*	‘you did not learn’
Abbreviation	***fhoir*** *rugbaí na* ***hÉir***	*fhoireann rugbaí na hÉireann*	‘Irish rugby team’
Lengthening	***obairrrr***	*obair*	‘work’
Case variation	*ceolchoirm* ***DEN SCOTH***	*ceolchoirm den scoth*	‘excellent concert’
Punctuation Variation	**folúntas**	*folúntas*	‘vacancy’
Transliteration	*go* ***wil***	*go bhfuil*	‘that is’
Other spelling variation	*O ’Bama*	*Obama*	‘Obama’

Table 1: Examples of orthographic variation in Irish tweets.

Transliteration The practice of transliteration, in which a word in one language is written using the writing system of another, is common within the language pair of Irish and English. In the TwittIrish treebank, the English language phrase ‘fair play’ occurs twice while variations ‘fair plé’, as shown in Example 5 and ‘féar plé’ occur once each.

(5) ***Fair plé*** *daoibh* 💗’
‘Fair play to you 💗’

Punctuation variation Punctuation is used creatively in UGC to format or emphasise strings of text. However, due to the lack of standardisation, occurrences of unconventional punctuation can make text difficult to parse for both human and machine, as in Example 6 which shows a phrase from an Irish tweet appended by two punctuation characters ‘-)’. It is unclear whether this should be interpreted as some form of punctuation, creative formatting, or a smiley e.g. ‘:-)’.

(6) *sin a dhóthain****-)***
‘That‘s enough-)’

Other spelling variation These are mostly slight variations very close to the intended word and may occur due to typographical error. Typos are very common in UGC due to lack of editing or proofreading and may occur via insertion, deletion, substitution, or transposition of characters. Example 7 shows *sraith* (season) rendered as **staith*. Due to their phonetic dissimilarity and the fact that ‘t’ and ‘r’ are adjacent on the QWERTY keyboard layout, it is reasonable to infer that the substitution was unintentional. Less commonly, disguise or censorship of words or phrases may occur to encrypt profanity or taboo language.

(7) tus **staith** 6 de Imeall
‘start of season 6 of Imeall’

4.2 Lexical Variation

Just 38.32% of the set of unique lemmata that make up the vocabulary of the TwittIrish treebank occur in the IUDT training data. Table 2 shows examples of lexical variation in Irish tweets.

Dialectal vocabulary Irish has three major dialects; Connaught, Munster, and Ulster. Distinctive features of these dialects in the form of lexical variation are evident in spoken language and informal text such as tweets. Example 8 shows the use of *domh*, the Ulster variant of *dom* ‘to me’.

(8) *Ba chóir* ***domh*** *rá!*
‘I should say!’

Initialism Multiword phrases are frequently represented by the initial letter of each of their constituent tokens. Example 9 shows *GRMA* ‘Thank you’ used to represent its expanded form *Go raibh maith agat*.

(9) *Scaip an scéal!* ***GRMA!***
‘Spread the word! Thank you!’

Pictogram Emojis, emoticons, etc. can be added to text to emulate gesture (Gawne and McCulloch, 2019) or they may play a syntactic role in a phrase, replacing a word as in Example 10, in which the symbol, 🖤, acts as the object of a verb. Pictograms tend not to have a one-to-one correspondence with natural language words.

(10) *Conas a deireann tú* 🖤*?*
‘How do you say 🖤’

Truncation Due to the current limit of 280 characters per tweet, the end of a tweet may be unnaturally attenuated, sometimes mid-sentence as in Example 11 or even mid-word.

(11) *Súil agam go bheas sé mar sin don…*
‘I hope it will be like that for the…’

Code-switching vs. borrowing 66.74% of tokens in the TwittIrish treebank are in Irish, 4.85% of tokens are in English and the remainder (consisting of punctuation, meta language tags, etc.)

Phenomenon	**Example**	**Standard form**	**Gloss**
Dialectal vocabulary	**fé**	*faoi*	‘about’
Initialism	**BÁC**	*Baile Átha Cliath*	‘Dublin’
Pictogram	**<3** *mór*	*Grá mór*	‘Lots of love’
Truncation	*thart fa’ 53* **nó. . .**	*thart fa’ 53 nóiméad*	‘over 53 mi. . . (minutes)’
Code-switching vs. borrowing	*sa* **town** *amárach*	*sa bhaile amárach*	‘in town tomorrow’
Other nonstandard lexical forms	**TochaltÓr**	*Tochaltóir óir*	‘Gold-digger’

Table 2: Examples of lexical variation in Irish tweets.

are classified as neither, or indeed both in the case of intraword code-switching or nonce borrowing in which the morphologies of two languages are combined in a single word. In Example 12 the English verb root ‘happen’ is used instead of the Irish equivalent *tarlaigh*. Insertional code-switching (Muysken et al., 2000) and borrowing are common in informal Irish. 74.71% of the tweets in the TwittIrish treebank were considered to be entirely in Irish, the remaining 25.29% of tweets being considered bi- or multilingual. Example 13 shows a section of an Irish tweet utilising the English word ‘Dubs’, a nickname for ‘Dubliners’, and Example 14 shows the use of an eclipse and an acute accent applied to the foreign proper noun ‘Barcelona’.

(12) *Eachtra i ndiaidh* ***Happenáil***
‘An event (is) after happening’

(13) *Roimh na* ***Dubs***
‘Before the Dubs’

(14) *Tá sin i* ***mBarcelóna***
‘That is in Barcelona’

Other nonstandard lexical forms Other unfamiliar terms may occur in the form of hypercorrection and neologisms. Hypercorrection occurs when an autocorrection system is either not activated or available in a user’s language of choice. As a result, their attempts to type a word are corrected to a word with a similar spelling in another language. Example 15 shows the Irish word *coicíse* rendered as ‘concise’ probably due to automatic English spelling correction software. It is often difficult to distinguish between hypercorrection, neologisms, typos, or other spelling variations. Example 16 shows *agus* (and) rendered as *agua* which may have occurred due to automatic hypercorrection as ‘agua’ (water) is a frequent token in other languages such as Portuguese and Spanish. However, it could also be a simple typo.

(15) *Mhúscail mé i mo leaba féin ar maidin i ndiaidh* ***concise***
‘I woke up in my own bed after a fortnight’

(16) *tá an teanga ag fáil bháis* ***agua***
‘the language is dying and’

4.3 Syntactic Variation

Grammatical phenomena observed in Irish tweets are described in this section. As these idiosyncrasies occur at the phrasal rather than token level, they may directly affect the structure of the parse tree. Some phenomena, such as contraction and over-splitting, cause difficulty during the tokenisation stage, potentially having a negative downstream effect on parsing. Table 3 exemplifies syntactic variation in Irish tweets.

Contraction Much like abbreviation at the token level, contraction is defined here as the fusion of several tokens for the purpose of brevity, sometimes mimicking spoken pronunciation. Figure 2 shows the phrase *go bhfuil siad* ‘that they are’ reduced to *gowil siad* tokenised incorrectly. Figure 3 shows the same contraction tokenised correctly.

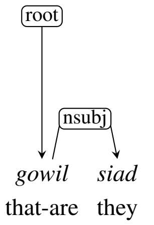

Figure 2: Incorrectly tokenised contraction ‘that they are’.

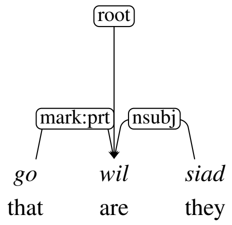

Figure 3: Correctly tokenised contraction ‘that they are’.

Over-splitting The inclusion of extra white space within tokens is often observed in Irish tweets e.g. *Níl mé ró chinnte*. The prefix *ró-* (‘too’) is conventionally fused with the adjective it precedes in standardised text and so such tokens are annotated with the `goeswith` label as shown in Figure 4.

Phenomenon	Example	Standard form	Gloss
Contraction	*go **dtí'n***	*go dtí an*	'until the'
Over-splitting	***ana shuimiúil***	*an-suimiúil*	'very interesting'
Syntax-level code-switching	*Tá an **tweet machine** ró-tapa*	*Tá inneall na tvuíte ró-tapa*	'The tweet machine is too fast'
Dialectal grammar	*Ní **fhacthas***	*ní fhaca mé*	'I did not see'
Ellipsis	***jab iontach déanta aige***	*tá jab iontach déanta aige*	'he has done a wonderful job'
Meta language tags	***#sonas***	*sonas*	'happiness'
Non-sentential segmentation	***haha:) tá súil agam go raibh sé ann***	*ha ha! Tá súil agam go raibh sé ann.*	'haha:) I hope he was there.'
Other grammatical variation	***ce ata an athair?***	*cé hé an t-athair?*	'who is the father?'

Table 3: Examples of syntactic variation in Irish tweets.

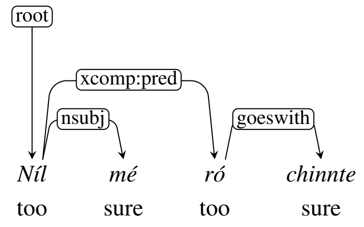

Figure 4: Over-splitting 'I am not too sure'.

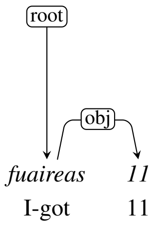

Figure 6: Synthetic verb form 'I got 11'.

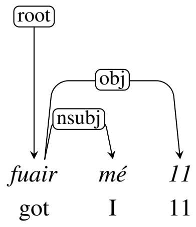

Figure 7: Analytic verb form 'I got 11'.

Syntax-level code-switching Alternational code-switching or congruent lexicalisation (Muysken et al., 2000) are likely to cause a change in the structure of the syntax tree, due to differing word orders of the languages involved, thus complicating the task of dependency parsing. In Irish, the adjectival modifier usually *follows* the noun it modifies whereas the inverse is true for English. Figure 5 exemplifies a case of congruent lexicalisation in which English adjective 'hippy-dippy' is positioned *before* an Irish noun rather than after as would be expected in 'classic' code-switching.

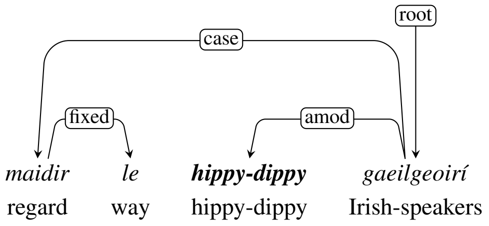

Figure 5: Congruent lexicalisation 'as for hippy-dippy Irish speakers'.

Dialectal grammar Figures 6 and 7 show semantically equivalent statements rendered using the synthetic, more common to the Munster dialect of Irish, and analytic verb forms respectively.

Ellipsis Example 17 shows a sentence fragment lacking a main verb. The probable inferred full phrase is *tá báisteach anseo* 'rain is here'.

(17) *báisteach anseo*
'rain here'

Meta language tags Hashtags are used in tweets to render a topic searchable and at-mentions are used to address or refer to another user. Either can play a syntactic role as exemplified in Figure 8.

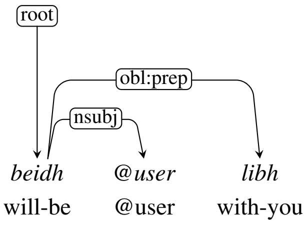

Figure 8: Syntactic meta language tag '@user will be with you'.

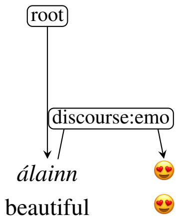

Figure 9: Non-sentential tweet using emoji in place of punctuation 'beautiful 😍'.

Non-sentential structure In tweets, the sentence is not an appropriate unit of segmentation as frequently non-standard punctuation, or none at all, is used. Figure 9 exemplifies a tweet utilising an emoji instead of punctuation.

Other grammatical variation Grammatical variation can also occur via unintentional deviation from conventional spelling or grammar by an L2 Irish speaker. Example 18 shows a grammatically incorrect phrase roughly translating to 'I have to *going'. In such cases, though the annotator may be able to infer the intended phrase *Caithfidh mé dul* 'I have to go', no corrections are made by the annotator to the surface form, however this information can be represented in the annotation via the label `CorrectForm` as described by Sanguinetti et al. (2022). Additionally, Irish tweets contain extremely unconventional constructions. This can occur in the form of unnatural phrases that have been machine-translated or generated by bots. Example 19 shows an ungrammatical construction that appears to have been translated automatically word by word. A more natural construction might be *conas tonna morgáiste a fháil* 'How to get a tonne of mortgage'. Some examples of this variety are easy to identify from surrounding context such as links to websites with similar content however, tweets may consist of text alone making it difficult to infer whether the author is human or machine.

(18) *Caithfidh mé* ***ag*** *dul*
'I have to *going'

(19) *Conas a Faigh tonna de Morgáiste*
'*How to get a tonne of mortgage'

5 Parsing Experiments

We compare the performance of two widely used neural dependency parsers on the TwittIrish test set, and examine the effect of using pre-trained contextualised word embeddings from a monolingual Irish BERT model (gaBERT). We report parsing performance broken down by sentence/tweet length, UPOS tags, and dependency labels and carry out a manual error analysis. Further information is detailed in Appendix B.

5.1 Parser Comparison

We experiment with two neural dependency parsing architectures: UDPipe (Straka et al., 2016), an NLP pipeline that includes a transition-based non-projective parser, and AllenNLP (Gardner et al., 2018), a biaffine dependency parser with a BiLSTM encoder (Dozat and Manning, 2017). Both systems are trained on IUDT version 2.8[11] and tested on the IUDT and TwittIrish test sets for comparison. Gold standard tokenisation is provided to the models which then predict UPOS tags and dependency relations. As the TwittIrish test set is the only gold annotated treebank of Irish UGC, no UGC is used as training or development data in these experiments. We opt to preserve it as a test set so that our results and results of future research in this area will be comparable.

System	LAS IUDT	LAS TwittIrish
UDPipe v1	70.58	47.33
AllenNLP	71.56	48.73
AllenNLP + gaBERT	**84.25**	**59.34**

Table 4: Comparison of parsing systems UDPipe v1, AllenNLP: Biaffine dependency parser (Dozat and Manning, 2017) with BiLSTM encoder, and AllenNLP + gaBERT: Biaffine dependency parser where BiLSTM is replaced with pretrained Irish BERT model (Barry et al., 2021). All were trained on IUDT version 2.8 and tested on the IUDT and TwittIrish test sets.

To leverage the substantial advances in accuracy achieved in dependency parsing by the use of pretrained contexualised word representations (Che et al., 2018; Kondratyuk and Straka, 2019; Kulmizev et al., 2019), we use AllenNLP with token representations obtained from the last hidden layer of the gaBERT model (Barry et al., 2021) which are then passed to the biaffine parsing component.

Table 4 shows that, when tested on the IUDT version 2.8 test set, UDPipe achieves 70.58 labelled attachment score (LAS). In comparison, UDPipe achieves a much lower LAS of 47.33 on the TwittIrish test set. Similarly to UDPipe, AllenNLP achieves 71.56 LAS on the IUDT test set with a similar decrease of 22.83 points on the TwittIrish test set. The highest accuracy of 84.25 LAS is achieved by gaBERT with a difference of 24.91 points when tested on the TwittIrish test set. The lower accuracy obtained by parsers on the TwittIrish test set is unsurprising given the linguistic differences between the training and test sets. The 10+ LAS improvement provided by the gaBERT embeddings is seen in both test sets.

5.2 Analysis

Analysis was carried out on the AllenNLP parser with gaBERT embeddings using Dependable (Choi et al., 2015).

LAS by Number of Tokens per Sentence/Tweet The mean sentence length of the IUDT is 23.5 tokens, whereas the mean tweet length in TwittIrish is 17.8. Figure 10 shows that, when tested on the IUDT, parsing accuracy decreases as the length of the sentence increases. The highest accuracy of 87.92 LAS is associated with sentences of 10

---

[11] Models were trained with and without XPOS and feature annotation. The results shown here are without XPOS and features. The addition of XPOS and features constituted a difference of approximately +/-1 LAS.

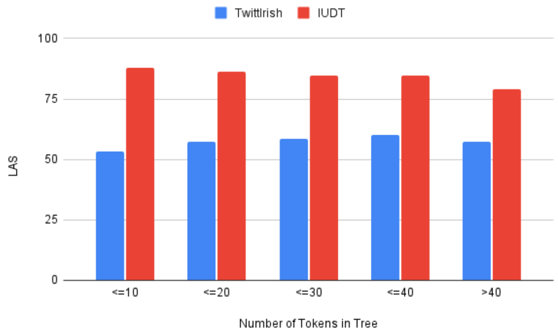

Figure 10: LAS broken down by number of tokens per tree achieved by AllenNLP Parser with gaBERT embeddings on the IUDT and TwittIrish test sets.

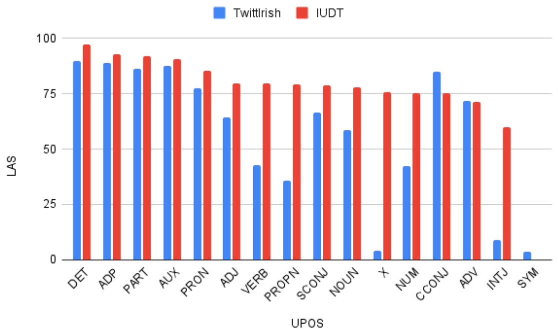

Figure 11: LAS broken down by UPOS tag achieved by AllenNLP Parser with gaBERT embeddings on the IUDT and TwittIrish test sets.

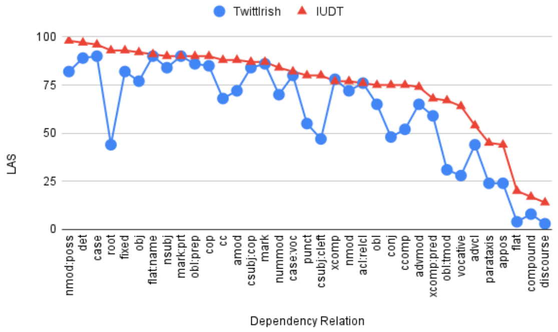

Figure 12: LAS broken down by dependency relation achieved by AllenNLP Parser with gaBERT embeddings on the IUDT and TwittIrish test sets.

tokens or fewer, and the lowest accuracy is observed in sentences of 40 tokens or more. This is an unsurprising trend as a higher number of tokens increases the probability of longer dependency distances and more complex constructions within a sentence. While the range of scores is smaller and trend less pronounced, the opposite effect is observed when the same parser is tested on TwittIrish, whereby LAS tends to increase as the length of the tweet increases. The highest LAS of 59.97 is associated with tweets of 31 to 40 tokens in length and the lowest accuracy of 53.47 LAS is associated with tweets of 10 tokens or less. This trend is also observed when gaBERT representations are not used, suggesting that, in this case, deep contextualised word embeddings do not cause this effect as observed in (Kulmizev et al., 2019). From manual inspection of the data, we observe that the genre-specific phenomena which challenge the parser such as ellipsis, meta language tags, and URLs, occur in higher proportions in shorter tweets, which would explain this trend.

LAS by UPOS and dependency relation We observe a larger proportion of `PROPN`, `SYM`, and `PUNCT` tags in Irish tweets in comparison to standardised Irish text, which contains a higher proportion of `NOUN`, `DET`, and `ADP` tags. This reflects the observations of Rehbein et al. (2019), who compare the distribution of POS tags in four German treebanks. Additionally, we compare the POS tag distribution in treebanks of English (Liu et al., 2018) and Italian (Sanguinetti et al., 2018) tweets to treebanks of standard text in those languages. We similarly observe that symbols, punctuation, and pronouns are more frequent in tweets and that nouns, determiners, and prepositions are more frequent in standard text for both languages.

Figure 11 shows LAS associated with each UPOS tag when tested on the IUDT and TwittIrish. LAS is higher when tested on the IUDT for all UPOS tags except `CCONJ`, `ADV`, and `SYM` and in these cases the difference is small (<10 LAS). The most notable differences are `X` (71.6 LAS), `INTJ` (51.3 LAS), `PROPN` (43.5 LAS). These differences are due to 1) the divergent genres of the treebanks e.g. in the TwittIrish treebank the UPOS tag `X` is used for all non-syntactic hashtags, and `PROPN` is used for all at-mentions, neither of which occur in the IUDT and 2) differing annotation conventions e.g. in the IUDT, the tag `X` is used mostly for foreign-language tokens, whereas, in TwittIrish, due to the high proportion of English language tokens, non-Irish words are annotated with their true UPOS tag where the language is known to the annotator. The tag `INTJ` occurs very rarely in IUDT. However, due to the conversational nature of tweets, phatic expressions and emotional signifiers (not normally present in standard text) are frequent.

Our analysis of the dependency relation distribution of standard English, German, and Italian text compared to that of tweets in those languages reveals that the `parataxis`, `vocative`, and `advmod` relations are more frequent in tweets and that the `case`, `det`, and `nmod` relations are more frequent in standard text. We observe that this same effect is present in Irish tweets.

Figure 12 shows LAS broken down by dependency relation. The parser obtains higher scores on the IUDT for all dependency relations except `xcomp` for which it is just one point higher when tested on TwittIrish. The largest differences between the parsing performance on the two test sets are associated with the labels `root`, `vocative`, `obl:tmod`, `csubj:cleft`, `conj`, and `punct`. As regards `root` and `punct`, the difference in accuracy could be attributed to the non-sentential nature of tweets. In the IUDT each tree consists of a single sentence, whereas tweets may consist of sentence fragments or indeed several sentences, making root identification and establishing punctuation attachment more complex. `csubj:cleft` tends to be mislabelled in the absence of the copula which is often elided in standard text. This copula drop occurs even more frequently in tweets, negatively impacting on parsing accuracy. With regard to `conj`, both nonstandard forms of coordinating conjunctions (e.g. 'and', '+', misspellings etc.) and differing annotation styles between IUDT and TwittIrish lead to attachment errors. As regards `obl:tmod` and `vocative`, the respective differences in accuracy are due to the infrequent occurrences in the IUDT of a speaker or author directly addressing someone in the text and references to time (e.g. 5pm), both of which are common occurrences in tweets.

Error Analysis In order to assess the effect of the UGC phenomena present in Irish tweets, we analyse the most and least accurate parses as shown in Table 5. Seven tweets (76 tokens) were parsed with LAS between 0 and 5. On investigation, we observed fifteen occurrences of emojis that were most commonly incorrectly labelled `punct`. The ten English tokens were most commonly attached incorrectly via `flat:foreign`. The nine (two syntactic) usernames were most commonly mislabelled as `root`. There were five occurrences of ellipsis in the form of verb omission obfuscating the task of root selection. The three hashtags were most commonly mislabelled as `nmod` as were the three URLs. One occurrence of spelling variation in the form of diacritic omission caused the parser to misinterpret the token *ár* 'our' as *ar* 'on' meaning it was mislabelled as `case` instead of `nmod:poss` . Seven tweets (89 tokens) were parsed with an accuracy between 95 and 100 LAS. All of these were grammatical, well-formed sentences. There were three usernames and one hashtag all of which were syntactically integrated and so they were parsed correctly. There was one of insertional single-word code-switch which was accurately parsed. There were two occurrences of spelling variation, both in the form of diacritic omission but, as these do not resemble any other words, they were parsed correctly.

Phenomenon	Easiest Tweets	Hardest Tweets
Emoji	0	15
English Token	1	9
Username	3	10
Ellipsis	2	5
Hashtag	1	3
RT	0	3
URL	0	3
Spelling variation	2	2

Table 5: Number of occurrences of UGC phenomena where 'Easiest Tweets' refers to the 7 tweets that were parsed well with LAS between 95 and 100 and 'Hardest Tweets' refers to the 7 tweets (76 tokens) that were badly parsed with LAS between 0 and 5.

6 Conclusion

Presented in this paper is the novel resource, TwittIrish, the first Universal Dependencies treebank for Irish UGC. Analysis of this linguistic genre and anonymised examples of Irish tweets are presented. This research facilitates the development of NLP tools such as dependency parsers for Irish by providing a test set on which future Irish language technology can be tested. Future work will involve both further annotation and exploration of semi-supervised techniques.

Acknowledgements

We warmly thank the anonymous reviewers, as well as Steven Bird and Kevin Scannell for their valuable feedback. This work was funded by the Irish Government Department of Tourism, Culture, Arts, Gaeltacht, Sport and Media under the GaelTech Project, and also supported by Science Foundation Ireland in the ADAPT Centre (Grant No. 13/RC/2106) at Dublin City University.

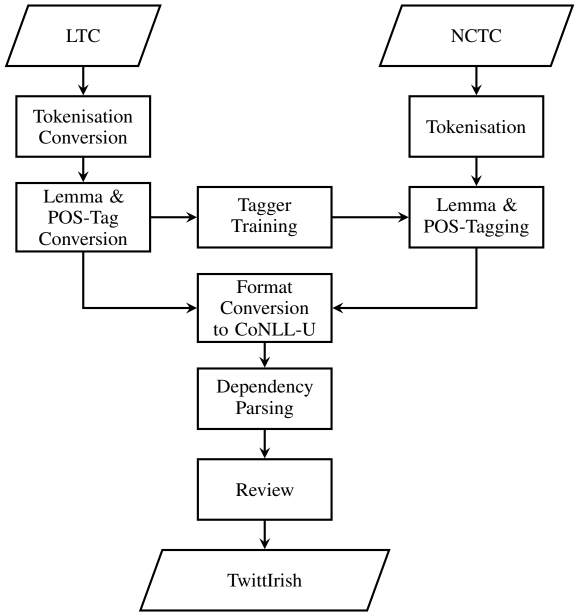

Figure 13: Diagram of the TwittIrish development process where LTC and NCTC refer to corpora of tweets.

A TwittIrish Development

Figure 13 outlines the stages of the TwittIrish treebank development.

A.1 LTC Tokenisation Conversion

The most notable difference in the tokenisation approach of LTC as compared to that of UD, was in the treatment of multi-word expressions (MWEs). In LTC, the individual tokens of MWEs are fused with an underscore whereas words with spaces are not allowed in UD. [12] Several minor differences were also observed between the two tokenisation schemes such as whether or not certain symbols, abbreviations, or punctuation marks should be attached to the token they follow or considered as a separate token. e.g. 5%, ama..., 1-0, 10pm. UD tends to favour the approach of separating such combinations[13] therefore we resolved to manually separate such occurrences in the TwittIrish tokenisation scheme.

A.2 LTC POS-tag Conversion

Table 6 shows the mapping of LTC POS to UPOS. LTC POS tags were automatically converted to the corresponding UPOS tag where a one-to-one or many-to-one mapping existed. In the case of one-to-many relationships, automatic identification and manual correction was performed. [14]

LTC POS	UPOS
N, VN	NOUN *
^, @	PROPN *
O	PRON
V	VERB, AUX †
A	ADJ
R	ADV
D	DET
P	ADP
T	PART
,	PUNCT
&	CCONJ, SCONJ †
$	NUM
!	INTJ
U, ~, E	SYM *
#, #MWE	X *
EN	any †
G	any †

Table 6: POS tag Mapping
* Many-to-one relation
† One-to-many relation

Surface	LTC POS	UPOS
@user	@	PROPN
#cutie	#	X
ca	R	ADV
bhfuil	V	VERB
an	D	DET
ghra	N	NOUN
you	EN	PRON
ask	EN	VERB

@user #cutie ca bhfuil an ghra you ask [15]
'@user #cutie where is the love you ask'

Table 7: Example Irish tweet with LTC and corresponding universal POS tags.

Table 7 demonstrates the mapping of a sample tweet from one scheme to the other. As all English language tokens were annotated with a single tag 'EN' in the LTC POS scheme, these tags were converted to the appropriate UPOS tag in the TwittIrish treebank.

Table 8 shows that, using the LTC POS tagset, all verbs are tagged `V`. According to UD, the Irish copula (e.g. *is*, *ní*) is tagged as `AUX` distinguishing it from other verbs (e.g. *tá*, *níl*) which are tagged `VERB`.

A.3 Preprocessing of newly-crawled tweets

Table 9 shows that hashtags and emoticons were not correctly handled by the UDPipe tokenizer trained

---

[12] https://universaldependencies.org/v2/mwe.html

[13] Not all treebanks apply this consistently.

[14] Both the Gimpel et al. (2011) and UD tagsets derived from the Google Universal POS tagset (Petrov et al., 2012)

Surface	LTC POS	UPOS
Ní	V	AUX
duine	N	NOUN
cáilúil	A	ADJ
é	O	PRON
ach	&	CCONJ
táim	V	VERB
bródúil	A	ADJ
#Grá	#	X

Ní duine cáiliúil é ach táim bródúil #Grá
‘He is not a celebrity but I’m proud #Love ’

Table 8: Example Irish tweet with LTC and corresponding universal POS tags.

Dé	Dé
Céadaoin	Céadaoin
# Midweek	#Midweek
# Beagnachann	#Beagnachann
:)	:)
:)	:)

Dé Céadaoin #Midweek #Beagnachann :) :)
‘Wednesday #Midweek #Almostthere :) :)’

Table 9: Example Irish tweet with UDPipe and NLTK tokenization

on the IUDT. Despite being trained on Irish data, Twitter-specific features such as meta language tags are not present in its training data.

A.4 Conversion to CoNLL-U format

Table 10 shows that the Morfette format is a subset of the CoNLL-U format used by UDPipe. The LTC and NCTC (newly-crawled tweets) were thus converted automatically from the 3-column Morfette format, consisting of the token, lemma, and POS-tag to the 10-column CoNLL-U format. CoNLL-U enables additional token-level annotation i.e. a token id, language-specific part-of-speech tags (XPOS), morphological features, the head of the current word, the dependency relation, an enhanced dependency graph in the form of a list of head-deprel pairs, and any other miscellaneous annotation.[16] CoNLL-U also requires a sentence ID and the original raw text to be included preceding the annotation. Further, in the miscellaneous column, the label ‘SpaceAfter=No’ encodes information about which tokens have a space after them in the original text for detokenisation purposes enabling automatic conversion from raw text to tree and vice versa.

A.5 Review

In order to assess the accuracy of the dependency annotation, a subset of the annotated data, consisting of 46 trees (773 tokens), was reviewed for errors by another Irish speaker trained in linguistic annotation. The task of the reviewer was to flag possible errors in the form of a token with an incorrect head and/or label. 46 possible errors were identified by the reviewer. The possible errors were then discussed by a team of two expert annotators to confirm whether the possible errors were true errors. 32 possible errors were confirmed as true errors. The overall accuracy of the treebank annotation can be estimated as 95.86% by dividing the number of correctly annotated tokens by the total number of tokens in the review. 16 tokens (2.07% of all tokens in the review) had an incorrect label and correct head. 12 tokens (1.55% of all tokens in the review) had an incorrect head and correct label. The most common error (5 instances) was incorrect punctuation attachment. Only 4 tokens (0.52%) were identified as having both an incorrect head and label. Figure 14 shows the phrase *maith sibh* (‘good on you’) incorrectly annotated with *sibh* as the `root` and *maith* as its `adjectival modifier`. It was identified in the review that *maith* should be considered the adjective predicate of an elided copula (Stenson, 2019). The full phrase is thought to be *is maith sibh* and the corrected annotation is shown in Figure 15.

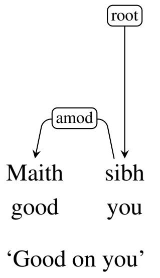

Figure 14: Example of tweet with incorrect head and label.

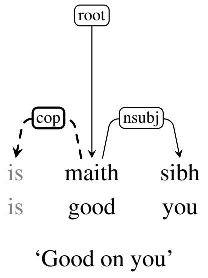

Figure 15: Reviewed tweet with corrected head and label.

---

[16] In order to make optimum use of the time spent by the annotator, language-specific part-of-speech tags, morphological features, and enhanced dependency annotation were not included in this version of the TwittIrish dataset. These elements can be automatically added in later versions of the treebank.

CoNLL-U	Morfette			CoNLL-U					
ID	FORM	LEMMA	UPOS	XPOS	FEATS	HEAD	DEPREL	DEPS	MISC
1	Cuirfidh	cuir	VERB	_	_	0	root	_	_

B Parsing Experiments

B.1 Parser Hyperparameters

Biaffine Parser Details	
AllenNLP	
Word embedding	100
Character embedding	32
Char-BiLSTM layers	3
Char-BiLSTM size	64
BiLSTM layers	2
BiLSTM size	200
AllenNLP + gaBERT	
BERT word-piece embedding size	768
BERT word-piece type	average
Parser	
Arc MLP size	500
Label MLP size	100
Dropout LSTMs	0.33
Dropout MLP	0.33
Dropout embeddings	0.33
Nonlinear act. (MLP)	ELU
Optimiser and Training Details	
Optimizer	AdamW
Learning rate	3e-4
beta1	0.9
beta2	0.999
Num. epochs	50
Patience	10
Batch size	16

Table 11: Chosen hyperparameters for the AllenNLP and the AllenNLP + gaBERT parsers. In the AllenNLP parser, a character- and word-level BiLSTM is used. In the gaBERT variation, these components are replaced by the Transformer model. The parsing module and training setup is the same for both parsers.

LAS	TwittIrish High	TwittIrish Low
IUDT High	`DET`, `ADP`, `PART`, `AUX`, `PRON`, `SCONJ`	`VERB`, `PROPN`, `PUNCT`, `X`, `INTJ`
IUDT Low	`ADJ`, `CCONJ`, `ADV`	`NOUN`, `NUM`, `SYM`

Table 12: Confusion matrix of LAS by UPOS tag achieved by AllenNLP Parser with gaBERT embeddings on the IUDT and TwittIrish test sets

B.2 LAS by UPOS

Table 12 shows which UPOS tags are associated with higher or lower than average LAS in both test sets. High accuracy is correlated with tokens which occur frequently and have low variation.[17]

UPOS tags `DET`, `ADP`, `PART`, `AUX`, `PRON`, and `SCONJ` are associated with higher than average LAS in both the TwittIrish and IUDT test sets. In the IUDT, a high proportion, 8.87%, of tokens have the UPOS tag `DET`. As is common with function words, `DET` comprises of a closed set of lemmata and thus has the low variation of 0.21%.

The tags `ADJ`, `CCONJ`, and `ADV` are associated with higher than average LAS in the TwittIrish test set but lower than average LAS in the IUDT. This might be because these tags are more likely to be involved in more complex, ambiguous, or long-distance attachments.

The tags `VERB`, `PROPN`, `PUNCT`, `X`, and `INTJ` are associated with higher than average LAS in the IUDT test set but lower than average LAS in TwittIrish. In the case of `VERB` and `PUNCT`, this can be attributed to the non-sentential nature of tweets.

UPOS tags `NOUN`, `NUM`, and `SYM` are associated with lower than average LAS in both the TwittIrish and IUDT test sets. In the IUDT, a low proportion, 0.02%, of tokens have the UPOS tag `SYM`. The variation is high (83.33%).

---

[17] Variation is calculated by dividing the number of occurrences by then number of unique lemmata

B.3 LAS by Dependency Relation

LAS	TwittIrish High	TwittIrish Low
IUDT High	`nmod:poss`, `det`, `case`, `fixed`, `obj`, `flat:name`, `nsubj`, `mark:prt`, `obl:prep`, `cop`, `cc`, `amod`, `csubj:cop`, `mark`, `nummod`, `case:voc`	`root`, `csubj:cleft`, `punct`
IUDT Low	`xcomp:pred`, `advmod`, `obl`, `acl:relcl`, `nmod`, `xcomp`	`discourse`, `compound`, `flat`, `appos`, `parataxis`, `advcl`, `vocative`, `obl:tmod`, `ccomp`, `conj`

Table 13: Confusion matrix of LAS by dependency label achieved by AllenNLP Parser with gaBERT embeddings on the IUDT and TwittIrish test sets

Table 13 shows that high accuracy is associated with dependency relations `nmod:poss`, `det`, `case`, `fixed`, `obj`, `flat:name`, `nsubj`, `mark:prt`, `obl:prep`, `cop`, `cc`, `amod`, `csubj:cop`, `mark`, `nummod`, `case:voc` in both the IUDT and TwittIrish. `root`, `csubj:cleft` and, `punct` are associated with higher than average LAS in the IUDT test set but lower than average in the TwittIrish set. `xcomp:pred`, `advmod`, `obl`, `acl:relcl`, `nmod`, and `xcomp` are associated with higher than average LAS in the TwittIrish test set but lower than average LAS in the IUDT. `discourse`, `compound`, `flat`, `appos`, `parataxis`, `advcl`, `vocative`, `obl:tmod`, `ccomp`, and `conj` are associated with lower than average LAS in both the TwittIrish and IUDT test sets.

Length Control in Abstractive Summarization by Pretraining Information Selection

Abstract

Previous length-controllable summarization models mostly control lengths at the decoding stage, whereas the encoding or the selection of information from the source document is not sensitive to the designed length. They also tend to generate summaries as long as those in the training data. In this paper, we propose a length-aware attention mechanism (LAAM) to adapt the encoding of the source based on the desired length. Our approach works by training LAAM on a summary length balanced dataset built from the original training data, and then fine-tuning as usual. Results show that this approach is effective in generating high-quality summaries with desired lengths and even those short lengths never seen in the original training set.

1 Introduction

Abstractive summarization (Nallapati et al., 2016; See et al., 2017; Çelikyilmaz et al., 2018; Dong et al., 2019; Lewis et al., 2020; Liu et al., 2021; Dou et al., 2021) aims at reproducing the semantics and topics of the original text in a concise and fluent summary by paraphrasing. In order to display the summary on different mobile devices or websites with space limitations, we have to produce summaries in different lengths. Length-controllable summarization is a multi-objective optimization problem, including generating complete summaries within desired lengths and selecting proper information to summarize based on desired lengths. The existing length-controllable summarization based on encoder-decoder models can be divided into two categories: (1) *early-stop during decoding* and (2) *information selection before encoding*.

Source Document
... iranians erupted in celebration as young people waved flags from their sunroofs , blasted music from stereos and chatted online with the hashtag #irantalks . the excitement came after a breakthrough nuclear deal with the united states and other world powers ...

Length	**Reference Summary**
10	iranians celebrate the deal online and in the streets .
30	after a breakthrough nuclear agreement deal with the united states and other world powers , celebration broke out in iranians . young people waved flages and chatted online .

Table 1: The reference summaries of one source document with lengths as 10 and 30.

Early-stop during decoding methods (Kikuchi et al., 2016; Liu et al., 2018; Makino et al., 2019; Yu et al., 2021) focus on when to output *eos* (end of sequence), indicating the end of the summary. An ad-hoc method (Rush et al., 2015) generates the *eos* by assigning a score of $-\infty$ to all candidate words at the position of the desired length during test. Ad-hoc can be applied to any seq2seq model. Others learn the relationship between length and the decoder state at training time. However, these methods simply add length requirements to the decoder and ignore the fact that encoding the content, or the information selection, from the source document must also adapt to different length requirements. Table 1 gives an example. The content of the reference summary with 10 tokens is the celebration of iranians. The reference summary with 30 tokens contains the reason for the celebration. Some generated summaries with short desired lengths are likely to be incomplete, similar to the truncated version of summaries generated by models without length constraints. The summaries of ad-hoc and LenAtten in Table 2 are not complete and lose the information about "deal".

Generated Summaries (Desired Length=10)
BART (Lewis et al., 2020) + Ad-hoc (Rush et al., 2015) (10 tokens)
iranians erupted in celebration as young people waved flags from
LenAtten (Yu et al., 2021) (12 tokens)
the agreement on the final day of persian new year festivities ,
LPAS (Saito et al., 2020) (22 tokens)
iranians erupted in celebration . the excitement came after a breakthrough nuclear deal with the united states and other world powers .

stage methods (See et al., 2017; Sarkhel et al., 2020; Saito et al., 2020). One prominent example is LPAS (Saito et al., 2020), which in the first stage, extracts top l most important tokens from the source document as a prototype summary where l is the desired length, and in the second stage encodes the original source document and prototype summary by a dual-encoder. On the one hand, such two-stage approaches suffer from noises introduced in the intermediate results. On the other hand, the second stage of these methods does not have first-hand length information, which weakens the length control. Table 2 shows that LPAS contains redundant information about "deal" and its length is much longer than the reference summary.

In this paper, we propose a **length-aware attention mechanism** (LAAM) which extends a transformer seq2seq model with the ability to select information in the context according to the length constraint. LAAM re-normalizes the attention between encoder and decoder to boost the tokens with higher attention scores based on the desired length, helping with selecting length-aware information from source document. The number of boosted tokens decreases step by step until eos gets the highest attention score, which is helpful in stopping the decoding process at desired length. LAAM can be thought of as a hybrid approach between the two types of previous approaches.

We observe that there is a big difference in the number of summaries within different length ranges in the original training set in any summarization dataset. The shorter reference summaries are especially rare. As shown in Table 1, given a short desired length, the summaries of the previous methods and LAAM still select redundant information. To balance the distribution of summaries in different length ranges, we propose a heuristics to create a length-balanced dataset (LBD) by prepredefining the length ranges and constructing extractive summaries within different length ranges, which helps model to select different information from source document via desired lengths.

In our approach, we can create an LBD from original summarization dataset. We first train LAAM on such LBD to enhance the ability of LAAM on information selection with length constraints. Then we fine-tune the pretrained LAAM on original dataset to learn to paraphrase the selected information as abstractive summaries in different lengths. The task of generating short summaries by the models fine-tuned on datasets without short reference summaries can be seen as a *zero-shot* problem. Benefiting from the pretraining with LBD, our approach can solve the zero-shot length control problem.

Our contributions are as follows:

1. We propose a new length-aware attention mechanism (LAAM) to generate high-quality summaries with desired length. LAAM outperforms the state-of-the-art length-controllable methods on CNN/Daily Mail and XSUM in terms of ROUGE scores, length variance and human evaluation (Table 5).

2. We design a heuristics to create a length-balanced dataset (LBD) from original dataset. After pretraining LAAM on LBD, the pretrained LAAM performs better than LAAM and can effectively solve the zero-shot length control problem (Table 10).

2 Approach

In this section, we first introduce the length-controllable summarization (LCS) problem, then introduce the length-aware attention mechanism (LAAM), which attends the existing transformer seq2seq models, and finally explain how to create a length-balanced dataset (LBD) for pretraining.

2.1 Preliminaries

In LCS, the model takes the source document $\mathbf{x} = (x_0, x_1, ..., x_m)$ and the desired length l as input and the summary $\mathbf{y} = (y_0, y_1, ..., y_n)$ as output. x_i is the i^{th} token of document and y_t is the t^{th} token of summary. x_m and y_n are eos tokens. The goal is to estimate the conditional probability $p(\mathbf{y}|\mathbf{x})$:

$$p(\mathbf{y}|\mathbf{x}, l) = \prod_{t}^{n} p(y_t|y_1, y_2, ..., y_{t-1}, \mathbf{x}, l) \quad (1)$$

We take the transformer seq2seq model (Vaswani et al., 2017) as our basis. Suppose that the encoder output is $\mathbf{h} = \{h_0, h_1, ..., h_m\}$, $\mathbf{h} \in \mathbb{R}^{m\times d}$, and the output of the decoder's masked self-attention sub-layer is $\mathbf{z} = \{z_0, z_1, ..., z_n\}$, $\mathbf{z} \in \mathbb{R}^{n\times d}$. The normal cross attention is calculated as:

$$\mathbf{A} = \text{softmax}(\mathbf{z} \cdot \mathbf{h}^T) \quad (2)$$

where $\mathbf{A} \in R^{n\times m}$ is an attention matrix. $A_t = \{a_{t,0}, a_{t,1}, ..., a_{t,m}\}$ shows the attention scores of y_t. $a_{t,i}$ is the attention score between y_t and x_i.

2.2 Length-aware Attention Mechanism

In the transformer seq2seq model, the cross attention of an output token y_t is likely to *summarize* those tokens with high attention scores in the input (source document). By formulating the cross attention as a function of the desired length l, we can manipulate the input information selection according to l. This is the intuition behind LAAM, which is illustrated in Figure 1.

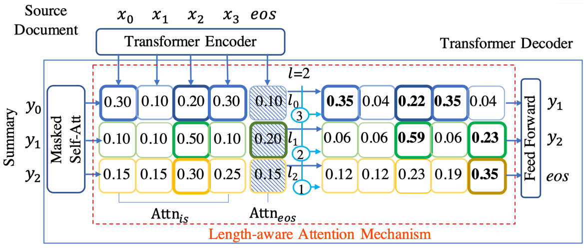

Figure 1: Overview of LAAM on Transformer Seq2seq. The bold values are boosted attention scores. The shadow boxes denote the attention scores of *eos*.

LAAM is made up of two parts: *attention for input selection* ($Attn_{is}$) and *attention for eos token* ($Attn_{eos}$), each optimized for *information selection* and *length control*, the two objectives in LCS.

***$Attn_{is}$*.** At decoding, given the initial desired length l, $l+1$ is the number of tokens in the output with eos, the remaining length budget (l_t) decreases as more tokens are generated. Specifically, at step t,

$$l_t = \begin{cases} l+1-t, & 0 \le t \le l \\ 1, & \text{otherwise} \end{cases} \tag{3}$$

Intuitively, at each decoding step, the decoder should plan its output y_t given the remaining number l_t of tokens it will generate. Our key idea is to increase the attention scores of the top l_t tokens with the highest attention scores in A_t, which gives a boost to the chance of these tokens to be selected and summarized. The interesting effect of this is that i) the longer l, the more source information will be selected for summarization; and ii) as the decoder generates more tokens,the number of tokens to be mainly attended in input decreases. We use one-hot vector $\mathbf{p} = \{p_0, p_1, ..., p_m\}$ to label the indices of the top l_t tokens with the highest attention scores in A_t as 1 and others as 0, and then the length-aware attention score is computed as:

$$a'_{t,i} = w_{t,i} \times a_{t,i} \tag{4}$$

$$w_{t,i} = \begin{cases} 1, & p_i = 0 \\ l_t, & p_i = 1 \end{cases} \tag{5}$$

where $w_{t,i}$ is the *weight for boosting the attention* between x_i and y_t. According to Eq. (5), the weight for cross attention decreases as the remaining length decreases, resulting in a decrease in the gap between the enhanced tokens and other tokens. This makes the model evenly attend to tokens related to the enhanced tokens and output general words to end the decoding. The model can learn to select information to be summarized by desired length.

***$Attn_{eos}$*.** At each decoding step t, to enhance the ability of model to generate eos at the desired length, we modify the attention score between y_t and eos in source document x_m as follows:

$$a'_{t,m} = (l+1-l_t) \times a_{t,m} \tag{6}$$

The length-aware attention of eos increases step by step, which demonstrates the probability of stopping decoding will increase as the length of the output close to the desired length.

Finally, we re-normalize the modified attention scores $A'_t = \{a'_{t,0}, a'_{t,1}, ..., a'_{t,m}\}$ to get the context vector $\mathbf{c_t}$ and compute the probability distribution of predicted tokens via:

$$p(y_t | y_{<t}, \mathbf{x}, l) = \text{softmax}(W\mathbf{c}_{t-1} + b) \tag{7}$$

$$\mathbf{c_t} = \sum_{0}^{m} \tilde{a}_{t,i} h_i \tag{8}$$

$$\tilde{a}_{t,i} = \frac{a'_{t,i}}{\sum_{i=0}^{m} a'_{t,i}} \tag{9}$$

where W and b are trainable parameters.

2.3 LBD Creation for Pretraining LAAM

Since the summary lengths of a training dataset may be highly concentrated in a small range (see Table 4), neural-based abstractive summarization models tend to select source information according to the summary lengths they have seen in training data and generate summaries with similar lengths. In order to make the model learn to select proper information according to different desired lengths, we propose a heuristics to create a length-balanced dataset (LBD) by extracting summaries with various lengths from each document in original dataset and makeing lengths of these extractive summaries evenly distributed in different ranges.

Given an abstractive summarization dataset D, which consists of a training set T and a validation set V, we create the training set T' and validation set V' of LBD. To create T', we set the discrete bins $B = \{b_1, b_2, ..., b_k\}$ to represent the ranges of summary length of T'. k is the number of the bins. For example, $B = \{(0, 10], (10, 20], ...\}$ and $b_0 = (0, 10]$. For each document src and its reference summary ref in T, we produce length-controllable pairs (LCPs) consisting of src and its extractive summaries in various length ranges. Let e be the extractive summary of length $b \in B$. We apply a greedy approach, where we add one sentence at a time incrementally to the e, until the length of e is within the proper range of b and has the highest ROUGE-1 (R-1) recall with respect to ref. Generally, the more training data, the greater the impact on the model. To make T' effective, the number of samples in T' should be close to $|T|$. $S(b)$ is the subset of T', including LCPs with extracted summaries with length in b. We add top $\lceil |T|/k \rceil$ extractive summaries (length $\in b$) with the highest R-1 recall and their source documents to $S(b)$, which makes the summaries equally distributed in the bins or length ranges. The details are in Algorithm 1.

Algorithm 1 Creating Training Set of LBD

```
Input: the training set $T$
Output: the training set $T'$

$rec()$ computes the R-1 recall score between two texts.
$len()$ computes the length of token sequence.
for each training pair $(src, ref) \in T$ do
    $src = \{s_0, s_1, ...\}$, where $s_t$ is the $t^{th}$ sentence in $src$.
    for $i = 0 \rightarrow k$ do
        $min$ and $max$ denote minimum and maximum length of length range $b_i$, respectively.
        $e_i \leftarrow \emptyset$
        while $S = \{s | s \in src \cap len(e_i \cup s) \leq max\}$ do
            Select the $s_{sel}$ with best $rec(e_i \cup s_{sel}, ref)$ from $S$.
            if $rec(e_i \cup s_{sel}, ref) > rec(e_i, ref)$ then
                $e_i \leftarrow s_{sel}$; $src \leftarrow src - s_{sel}$
            else
                break
        if $len(e_i) > min$ then
            Add $(src, e_i, rec(e_i, ref))$ to $S(b_i)$.
$S(b_i) \leftarrow$ top $\lceil |T|/k \rceil$ samples from $S(b_i)$ sorted by $rec(e_i, ref)$
$T' \leftarrow S(b_1) \cup S(b_2) \cup \cdots \cup S(b_k)$
return $T'$
```

For V', we create an extractive reference summary by selecting one sentence at a time until we get a subset of sentences from src that maximizes the R-1 F1 with respect to ref. Given an original source document and reference summary pair, R-1 recall computes the similarity between extracted sentences and reference without considering the length of extracted sentences. This meets our requirements for creating T', that is, we can extract multiple summaries within different length ranges for one document. To evaluate the model at training, each document in V' only needs one extractive summary. R-1 F1 considers the difference between the lengths of compared summaries, which can select an extractive summary most similar to the reference in length and content.

In this paper, we first pretrain LAAM on LBD for the ability to select information from source document to be summarized according to length constraint. Then we fine-tune the pretrained LAAM (**PtLAAM**) on original dataset. At this stage, armed with the ability to select information from source document, the model further learns to paraphrase the selected information into abstractive summaries with desired length.

3 Evaluation

We first introduce the datasets and the experimental setup. We design two experiments, **general length control** and **zero-shot length control**, to compare our approach with baselines. [1] General length control experiment trains and tests the models on the entire original dataset. Zero-shot length control experiment tests the model on a subset of the test set whose summary lengths fall within a certain range, and trains the model on training data with summary lengths outside this range. In each of the two experiments, we evaluate methods' ability to do **length control** and **information selection**.

3.1 Datasets

We use two popular summarization datasets. **CNN/Daily Mail** (CNNDM) (Hermann et al., 2015) consists of pairs of a single source document and a multi-sentence summary. The dataset includes 286,817 training pairs, 13,368 validation pairs and 11,487 test pairs. **XSUM** (Narayan et al., 2018) is composed of article and single-sentence summary pairs. The number of samples in training/validation/test sets are 204,045/11,332/11,334.

3.2 Baselines

The existing length-controllable models with good performance are listed in Table 3.

In the experiments, LAAM and PtLAAM are im-

Abbrev.	Description
Exact	Ignore eos before generated summary within the desired length and insert eos at the desired length.
LenEmb	Input remaining length. (Kikuchi et al., 2016)
LC	Take desired length as input. (Liu et al., 2018)
GOLC	Apply length-aware loss. (Makino et al., 2019)
LenAtten	Add length attention unit. (Yu et al., 2021)
LPAS	Extract prototype summary. (Saito et al., 2020)
BLPAS	Apply Prot on top of BART

Table 3: The abbreviation and description of methods.

plemented on top of BART[2], because BART (Lewis et al., 2020) is one of the SOTA models in summarization, and it uses less memory and training time than its peers (Shleifer and Rush, 2020). Exact is not a summarization model but is used here to achieve hard length control on any seq2seq models to produce summaries of exact lengths.

3.3 Experimental Setup

We follow Liu et al. (2018) and Saito et al. (2020) to segment datasets by different length ranges and set the discrete bins B of summary length ranges in Sec. 2.3. The B of CNNDM is $B_c = \{(0, 10], (10, 30], ..., (90, +\infty)\}$ and that of XSUM is $B_x = \{(0, 10], (10, 30], (30, +\infty)\}$. [3] B_x has only 3 ranges as the summaries in XSUM are shorter. In zero-shot length control experiments, test length ranges for CNNDM and XSUM is $(0, 30]$ and $(0, 10]$, containing 488 and 176 samples respectively. The length distribution of the datasets is in Table 4. During training, we set the lengths of gold summaries as desired lengths and take them as input. During test, there are two different setups. The **gold length test** (Saito et al., 2020) asks the models to generate summaries with desired lengths equal to the reference summaries. The **arbitrary length test** asks the models to generate summaries with arbitrary lengths, regardless of the reference summary lengths. The output lengths are set at 10, 30, 50, 70 and 90 for CNNDM and at 10, 30 and 50 for XSUM due to the latter's shorter summaries.

In each experiment, to evaluate the ability to control length, we do **soft length control** tests, which sets $minlen$ and $maxlen$ to 0 and 200 respectively during decoding, covering a very large range. It is up to individual models to generate summaries as close as possible to the target length. To evaluate the ability to select information, we utilize **hard length control** at test, which applies Exact in Table 3 to all competing models at decoding.

Data	Length	Train	Val	Test
CNNDM	$(0, 10]$	421	1	1
	$(10, 30]$	20,429	573	487
	$(30, 50]$	114,521	4,255	4,144
	$(50, 70]$	101,461	4,746	4,380
	$(70, 90]$	31,470	2,321	1,509
	$(90, +\infty)$	18,925	1,472	969
	Total	287,228	13,369	11,491
XSUM	$(0, 10]$	3,049	167	176
	$(10, 30]$	193,237	10,732	10,729
	$(30, +\infty)$	77,60	433	429
	Total	204,046	11,332	11,334

Table 4: Length distributions of two datasets.

Following Lewis et al. (2020), we train our model based on *bart.large* with $lr = 3e\text{-}05$ and warmup $= 500$. We set the dropout as 0.1 and momentum as 0.99, and terminate the training when the $lr < 1.0e\text{-}5$. At test time, the batch size is 32. We set beam size as 4 for CNNDM and 6 for XSUM. All experiments are done on an RTX 2080Ti GPU with 11G RAM.

3.4 Evaluation metrics

ROUGE scores: ROUGE-1 (R-1), ROUGE-2 (R-2) and ROUGE-L (R-L) (Lin, 2004) by F1.

Variance (Var): Variance of the summary lengths against the desired length l:

$$var = 0.001 * \frac{1}{n} \sum_{i=0}^{n} |l_i - l|^2, \qquad (10)$$

where n is the number test cases, and l_i is the length of generated summary for case i.

Human Evaluation: We randomly select 50 samples from CNNDM and 50 samples from XSUM. We ask three human annotators who are native or proficient English speakers to score the generated summaries under 3 aspects: Grammatically correct (Gram.): How grammatical the sentences of a summary are?; Informativeness (Info.): How much important information about the source document is included in summary?; Overall: How good is the overall quality of the summary on you criterion? The score of each aspect will be judged as: Poor (1.0), Barely Acceptable (3.0) and Good (5.0).

3.5 Experiment 1: General Length Control

Length control. We use soft length control here. As shown in Table 5 and Figure 2, LAAM and PtLAAM achieve higher ROUGE scores and lower variance than all other approaches, which means our approaches can generate good quality summaries with tighter length control. LAAM and

---

[2] In rest of this paper, LAAM refers to BART using LAAM as cross-attention, for simplicity.

[3] Because historically, to test length control abilities, the test sets of the datasets are split into some predefined ranges, in this work, we adopt the same ranges in creating the bins.

PtLAAM outperform BART, indicating that by controlling lengths effectively, summary quality can be improved, too. LPAS performs better than LenAtten on ROUGE scores but worse on Var, because LPAS focuses more on information selection under the length constraint and overlooks where to stop decoding. BLPAS is better than LPAS as using the pretrained BART as the basic model. BART and BLPAS are considered the previous SOTA methods for length-agnostic summarization and length-controllable summarization respectively. Therefore, we compare our approaches with BART and BLPAS in the remaining experiments.

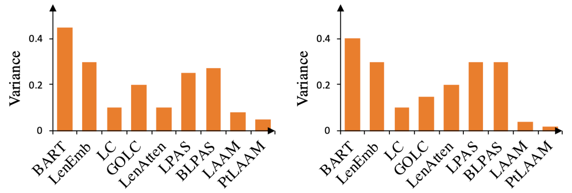
Table 6 also confirms that compared with BART and BLPAS, our best approach PtLAAM gives the best quality summaries by human judges. The summaries generated by PtLAAM achieve better scores in grammatically correct, informativeness and overall. The human evaluation scores of XSUM are lower than those of CNNDM because the summaries in XSUM are much shorter. It is more difficult for a shorter summary to ensure that it is grammatically correct and contains enough information.

	CNNDM			XSUM		
	R-1	R-2	R-L	R-1	R-2	R-L
BART [4]	43.13	20.05	39.32	44.61	21.19	36.00
LenEmb	32.74	13.78	24.50	28.45	8.92	23.13
LC	35.45	14.50	26.02	31.87	11.23	25.94
GOLC	38.27	16.22	34.99	32.94	14.38	26.11
LenAtten	39.82	17.31	36.20	37.20	16.05	31.24
LPAS	42.55	20.09	39.36	43.64	19.81	35.22
BLPAS	42.95	20.29	39.76	44.94	20.31	35.98
LAAM	43.55	20.44	40.63	45.30	21.77	36.64
PtLAAM	**44.17**	**20.63**	**40.97**	**45.48**	**21.80**	**36.84**

Table 5: Gold length test with soft length control. The LAAM and PtLAAM are statistically significantly better than BLPAS with $p<0.05$ according to t-test.

Data	Model	Gram.	Info.	Overall
CNNDM	Gold	4.6	4.3	4.1
	BART	3.8	2.7	2.2
	BLPAS	3.3	2.9	2.8
	PtLAAM	4.0	3.4	3.3
XSUM	Gold	4.8	3.7	4.5
	BART	3.0	2.9	2.0
	BLPAS	2.1	2.3	2.3
	PtLAAM	3.4	3.0	2.9

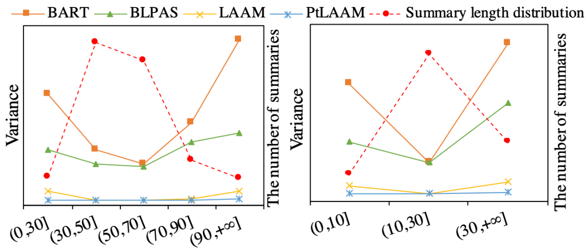
Table 6: Human evaluation. Average Cohen's Kappa is 0.62 among judges, indicating good agreement.



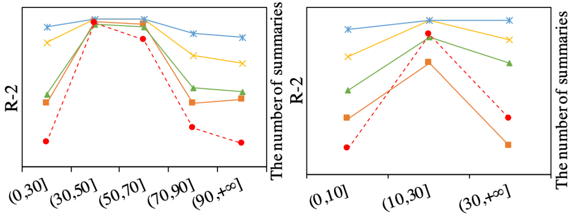
(a) CNNDM (b) XSUM

Figure 2: Variance of generated summary lengths in gold length test with soft length control.

To further test the models' length control ability in different target length ranges, we divide the test data into different sets according to length range in Table 4, and test the models on these sets separately. Figure 3 shows that LAAM and PtLAAM still achieve the lowest Var. For the same length range in Figure 3 and Table 4, the more training data in this range, the lower Var of the generated summaries with respect to the reference summaries within this length range. This denotes that the imbalance length distribution in training data interferes with controlling length. In Figure 3, LAAM and PtLAAM have better and more stable ROUGE scores in all length ranges, illustrating that our approaches are not affected by the summary length distribution in training set and can generate better summaries with desired lengths.



(a) Var of CNNDM (b) Var of XSUM



(c) R-2 of CNNDM (d) R-2 of XSUM

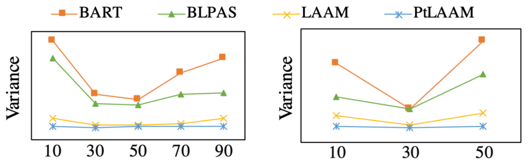
Figure 3: Var and R-2(F1) scores of gold length test with soft length control on divided test sets.

The results of arbitrary length test are listed in Figure 4, the lower Var of LAAM and PtLAAM illustrate our approach can control summary length better. As R-2 is the most popular metric in summarization, we report the R-2 related scores of generated summaries. We compute R-2 Precision

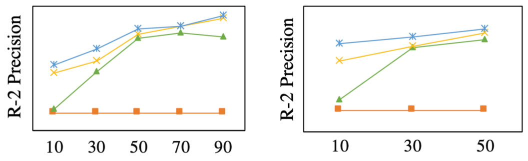
---

[4] We fine-tune the *bart.large* on CNNDM and XSUM via released code in `https://github.com/pytorch/fairseq/`. Due to incompleteness of the data preprocessing code and possible variance in computing resources and parameters, the results of BART in Table 5 are slightly lower than published version but similar to the numbers reported by others, such as `https://github.com/pytorch/fairseq/issues/2541.`

(**Pre**) of generated summaries instead of F1, because when the desired length of generated summaries is shorter than reference summary lengths, precision can reflect the accuracy of information selection within that limited budget. In Figure 4, LAAM and PtLAAM get better R-2 (Pre) on both datasets, which means our approaches can select more accurate information. As the desired length increases, the length-controllable models are more likely to select accurate information, causing the gap between our approach and BLPAS to gradually decrease. Bart is not designed to control length, resulting in unchanged R-2 (Pre). Although the arbitrary length test provides a unique perspective in the evaluation of the models, its automatic metric, i.e., R-2 (Pre) is only partial. Therefore, in the rest of the section, we will not do arbitrary length test unless the result is evaluated by human.



(a) Var of CNNDM (b) Var of XSUM



(c) R-2(Pre) of CNNDM (d) R-2(Pre) of XSUM

Figure 4: Var and R-2 (Pre) of arbitrary length test with soft length control on complete test sets.

Information selection. Next, we apply hard length control on all models to strictly enforce the exact desired length which is equal to the gold length. The better performance of our proposed approaches in Table 7 indicates that our approaches can cover more important information while producing exactly the same length of the reference summary. Compared to Table 5, our approaches also demonstrate more consistency.

Approach	CNNDM			XSUM		
	R-1	R-2	R-L	R-1	R-2	R-L
BART	43.43	20.11	39.52	44.82	21.34	36.23
BLPAS	43.15	20.52	40.01	45.03	20.57	36.02
LAAM	43.63	20.76	40.63	45.38	21.77	36.64
PtLAAM	**44.21**	**20.77**	**40.97**	**45.53**	**21.82**	**36.85**

Table 7: The ROUGE scores of models in gold length test with hard length control.

As shown in Table 8, the summaries are generated by the SOTA length-controllable approach BLPAS and our best approach PtLAAM with desired length as 10 tokens and 30 tokens. For BLPAS, the summary with desired length as 10 is just the truncated version of the summary with desired length as 30. Different from BLPAS, the content of summaries generated by PtLAAM are changed according to different desired lengths, which denotes that PtLAAM is more effective in selecting information to be summarized by length constraint.

Len	BLPAS Summaries	PtLAAM Summaries
10	iranians erupted in celebration , as young people waved flages	iranians celebrate online and in the streets after deal .
30	iranians erupted in celebration as young people waved flages , blasted music from stereos and chatted online . the agreement on the final day of persian new year festivities .	the excitement came after a breakthrough nuclear deal with the united states and other world powers . iranians erupted in celebration as young people waved flags and chatted online .

Table 8: Generated summaries of two different lengths from the source document in Table 1.

Ablation Studies. We evaluate the effectiveness of the pretraining LAAM on LBD and length-aware attention mechanism.

Pretraining on LBD. Compared with LAAM only training on original datasets, PtLAAM performs better on R-2 and Var in Figure 4 and Figure 3. The better R-2 scores indicates that the PtLAAM can select more important information with pretrained LAAM on our created dataset LBD. As one source document of LBD may have different extracted summaries within different length ranges, the model trained on LBD can learn to select different information from source document according to the length constraints. Besides, in LBD, the number of summaries with lengths in different ranges is balanced. PtLAAM gets lower Var, which denotes it can control length better. The Var scores in different length ranges are stable, which weakens the negative impact caused by the imbalanced length distribution of training data.

Length-aware attention mechanism, The length-aware attention consists of $Attn_{is}$ and $Attn_{eos}$. Table 9 shows the results of LAAM test on gold length test with soft length control. Compared with LAAM, the LAAM without $Attn_{is}$ has a big drop in ROUGE scores and a small drop in Var score, demonstrating that $Attn_{is}$ mainly focuses on select information with length constraint. The LAAM without $Attn_{eos}$ gets the much lower Var scores but not much difference in ROUGE scores than LAAM, which means that $Attn_{eos}$ is useful in limiting the output length. LAAM outperforms its variant because of the effectiveness of length-aware attention mechanism. Thus, in our experiments, we use PtLAAM model, which trains LAAM with both $Attn_{is}$ and $Attn_{eos}$ on LBD first and then fine-tunes the original datasets, as our best approach.

Data	Model	R-1	R-2	R-L	Var(%)
CNNDM	LAAM	**43.63**	**20.76**	**40.63**	**0.05**
	w/o $Attn_{is}$	42.77	19.32	39.13	0.06
	w/o $Attn_{eos}$	43.10	20.17	37.45	0.13
XSUM	LAAM	**45.38**	**21.77**	**36.64**	**0.03**
	w/o $Attn_{is}$	43.45	20.64	34.79	0.03
	w/o $Attn_{eos}$	44.62	21.32	35.03	0.08

Table 9: Usefulness of two kinds of attentions.

3.6 Experiment 2: Zero-shot Length Control

In this experiment, we use the modified dataset for zero-shot length control (Sec. 3.3). Zero-shot task can test a model's ability to generalize to summary lengths that it has never seen in the original training data before.

Dataset	Length	Approach	R-1	R-2	R-L	Var(%)
Soft length control						
CNNDM	$(0, 30]$	BLPAS	33.04	14.83	29.42	0.14
		LAAM	33.52	15.20	30.54	0.05
		PtLAAM	**33.65**	**15.77**	**31.26**	**0.03**
XSUM	$(0, 10]$	BLPAS	34.37	19.54	31.66	0.10
		LAAM	34.49	20.07	32.10	0.03
		PtLAAM	**35.16**	**20.55**	**32.47**	**0.02**
Hard length control						
CNNDM	$(0, 30]$	BLPAS	30.25	12.51	26.98	-
		LAAM	33.64	15.23	30.76	-
		PtLAAM	**33.78**	**15.89**	**31.30**	**-**
XSUM	$(0, 10]$	BLPAS	32.55	17.16	29.52	-
		LAAM	34.83	20.15	32.10	-
		PtLAAM	**35.16**	**20.58**	**32.49**	-

Table 10: Results of zero-shot length control.

Table 10 shows the performance of PtLAAM on ROUGE scores and Var on different datatsets are the best. For soft length control experiment, the ROUGE scores of different models are similar, because the lengths of summaries generated by BLPAS are longer than reference summary lengths (BLPAS has higher Var scores), which causes the generated summaries to match more tokens in the reference. Because ROUGE (F1) scores usually penalize summaries with longer lengths, PtLAAM, which controls the length better, is still better than other approaches. The lowest Var of our approaches means that our approach can better control summary length. In the hard length control experiment, the ROUGE scores of BLPAS drop a lot since the hard control shortens the length of summaries generated by BLPAS. The best performance of PtLAAM on ROUGE indicate PtLAAM learns to select information based on desired lengths. The ROUGE scores of our approaches are similar to those in soft length control experiment, which indicates our approaches are stable in controlling length. The LAAM performs worse than PtLAAM on ROUGE and Var denotes that the ability of LAAM to control length is impacted by length distribution of the training data. The pretraining on LBD is useful in generating high-quality summaries under desired summary length since the summaries are balanced in different length ranges of LBD.

3.7 Case Study

In this section, we analyze the performance of different models in controlling length.

Input Document
a gym teacher in new hampshire has been accused of posing as a young girl on a social media site and persuading an elementary school student to share inappropriate images of herself ... police charged 34-year-old paul johnson-yarosevich of acton , maine , on monday with prohibited use of computer after they say they discovered he 'd been fooling a pre-teen girl into sending him inappropriate photos of herself by posing as a young girl on social media . authorities soon learned that the girl was sending the photos to a grown man ...

Table 11: The generated summaries of Table 1 of various desired length **Len**. The *italicized* tokens repeat significant parts the shorter summaries. The red is the tokens longer than desired length.Here Exact refers to the BART using Exact at test, to be fair.

We use the example in Table 11 to analyze different length-controllable methods since the summaries of this example generated by different models are obviously different in *length control* and *information selection*.

As shown in Table 11, BART itself cannot control the length of generated summaries. So, the length of the summary generated by BART is always much longer for covering more information from source document. After adding Exact at test time, BART can generate summary with length exactly the same as desired length. But, as a *early-stop during decoding methods*, Exact always produce incomplete summaries. The summary with 30 tokens of Exact repeats its summary with 10 tokens during generation. Because such methods ignore that the summaries with different lengths of one document should represent different information of source document. BLPAS tends to select more information with length constraints, which may generate summaries with length longer than desired length (the red part in Table 11). The lengths of summaries generated by LAAM and PtLAAM in Table 11 are the same as the desired lengths.

Compared with PtLAAM, given the desired length as 10, LAAM loses the important information about the reason why Paul was charged as there are few training pairs with summary lengths as 10. PtLAAM pretrained on LBD can select information according to various desired lengths as the summary lengths in LBD are evenly distributed in different length ranges. The summaries with desired length as 30 of LAAM and PtLAAM are more similar than their summaries with desired length as 10. This is because there are many more summaries with length about 30 than those with length about 10 in original dataset. Thus, PtLAAM is more effective in generating summaries of lengths that do not appear in the original datasets.

4 Related Work

Previously, most length-controllable approaches in abstractive summarization focused on stoping decoding at a particular time. Ad-hoc (Rush et al., 2015) generated the *eos* token by assigning a score of -∞ to the tokens in vocabulary and generated a fixed number of words. LenEmb and LenInit (Kikuchi et al., 2016) input length embeddings to decoder respectively. Bian et al. (2019) took LenEmb and LenInit as an agent and adjusted the reward incorporating with the desired length. LC (Liu et al., 2018) added the desired length into the first layer of CNN encoder. GOLC (Makino et al., 2019) optimized LenEmb and LC by formalizing loss with an overlength penalty. Fan et al. (2018) predefined some special markers to denote different length ranges and prepended the input with such markers during training and testing. Takase and Okazaki (2019) extended the sinusoidal positional encoding (Vaswani et al., 2017) to take account of stepwise remaining length. LenAtten (Yu et al., 2021) added a length attention unit to exploit proper length information based on the stepwise remaining length.

Other length-controllable approaches decided the content to be summarized by length-aware intermediate summaries. LPAS (Saito et al., 2020) extracted a word sequence with the desired length from source document and generated summary by a non-length-controllable model with document and extracted summary as input. MLS (Sarkhel et al., 2020) generated a general summary and then input it to a length-controllable model.

Compared with previous methods, our approach can effectively control the length of generated summaries by pretraining the length-controllable information selection model on length-balanced dataset. Meanwhile, it can generate summaries with length approximate to the desired length in zero-shot controlling length problem.

Recently, the approaches fine-tune the pretrained transformer seq2seq models (Lewis et al., 2020; Zhang et al., 2020; Dou et al., 2021; Liu and Liu, 2021) on summarization datasets. They achieve outstanding performances on summarization tasks. Our approach is applied to transformer seq2seq model, which is orthogonal to above pretrained transformer models and can be added to them.

5 Conclusion

We present a novel approach to produce summaries in desired length that are fluent and coherent. This approach pretrains a transformer seq2seq model whose cross attention between input and output are re-normalized accordingly to the length requirement. The pretraining is done over synthetic summarization data extracted from the original training set but with summary lengths evenly distributed. Our results show that the framework achieves a good balance between information selection from input documents and length control when producing summaries.

Abstract

Multi-hop question generation focuses on generating complex questions that require reasoning over multiple pieces of information of the input passage. Current models with state-of-the-art performance have been able to generate the correct questions corresponding to the answers. However, most models can not ensure the complexity of generated questions, so they may generate shallow questions that can be answered without multi-hop reasoning. To address this challenge, we propose the CQG, which is a simple and effective controlled framework. CQG employs a simple method to generate the multi-hop questions that contain key entities in multi-hop reasoning chains, which ensure the complexity and quality of the questions. In addition, we introduce a novel controlled Transformer-based decoder to guarantee that key entities appear in the questions. Experiment results show that our model greatly improves performance, which also outperforms the state-of-the-art model about **25%** by **5** BLEU points on HotpotQA [1].

1 Introduction

Question generation (QG) aims to endow machines with the ability to ask relevant and to-the-point questions about a document. QG plays a vital role in question answering (QA), dialogue systems, and automated tutoring applications: – by enriching the training QA corpora (Tang et al., 2017; Yuan et al., 2017), helping chatbots start conversations with intriguing questions (Mostafazadeh et al., 2016), and automatically generating assessment questions (Heilman and Smith, 2010), respectively.

Most prior research on QG has focused on shallow *factoid-based* questions where answering the question simply by extracting the span of the text from a single input document (Zhou et al., 2018; Zhao et al., 2018; Kim et al., 2019; Fei et al., 2021). Recently, motivated by building the NLP systems that are capable of understanding and reasoning (Kaushik and Lipton, 2018; Sinha et al., 2019), there is an increasing interest in developing systems that are capable of more complex multi-hop question generation, where answering the questions requires reasoning over multiple documents (Pan et al., 2020; Sachan et al., 2020; Xie et al., 2020; Yu et al., 2020; Su et al., 2020).

Paragraph A: Celtic nations
The Celtic nations are territories in Western Europe where Celtic languages or cultural traits have survived. The term nation is used in its original sense to mean a people who share a common identity and culture and are identified with a traditional territory.

Paragraph B: Pan Celtic Festival
The Pan Celtic Festival is a Celtic-language music festival held annually in the week following Easter, since its inauguration in 1971. Its aim is to promote the modern Celtic languages and cultures and artists from all six Celtic nations: Brittany, Cornwall, Ireland, Isle of Man, Scotland and Wales.

Answer: Brittany, Cornwall, Ireland, Isle of Man, Scotland and Wales.

Shallow Question: Which six Celtic nations are modern Celtic languages from?

Deep Question: In which six Western European territories have Celtic languages or cultural traits survived?

Figure 1: An example that the uncontrolled question generation model may generate the correct but shallow questions. In this example, the model ignores the important entity Western European in paragraph A and then generate a shallow question without multi-hop reasoning chains.

Compared with shallow QG, there are two

challenges for multi-hop QG (MQG). At first, generating multi-hop questions requires the model to understand the relationship between disjointed pieces of information in multiple context documents (Sachan et al., 2020). Secondly, multi-hop questions must have complex chains of connecting the mentioned entities, which ensure the complexity of multi-hop questions, as such, multi-hop questions are also called deep questions (Pan et al., 2020).

To address the first challenge, existing research on MQG relies on the Graph-to-Sequence (G2S) architecture (Pan et al., 2020; Su et al., 2020; Yu et al., 2020). These methods construct a semantic-level graph or entity-graph to capture the information among multiple context documents that employ a graph neural network(GNN) and then feed it to the decoder. However, these models can not handle the second challenge because they can not ensure the complexity of generated questions; thus, they may generate shallow questions that can be answered without multi-hop reasoning chains. We show an example in Figure 1, where the uncontrolled model generates a shallow question that can be answered by a single sentence but ignores the other sentences and entities.

To solve this issue, we propose the CQG, a simple and effective controlled framework. (De Cao et al., 2018; Qiu et al., 2019) claim that the reasoning chains can be captured by propagating information along the edges in an entity graph using a GNN. Motivated by this, we construct the entity graph from the input documents first and then employ the Graph Attention Network (GAT) to extract the key entities that appear in multi-hop reasoning chains. Intuitively, all these key entities should appear in the generated questions to ensure the generated questions have complex and complete reasoning chains. We introduce the flag tag (Wang et al., 2021), a lexical constraint for generation at each decoding step, which will assist the controlled generation. In detail, in decoding progressing, each input token is provided a flag tag that indicates whether the constraint of this token has been satisfied. Three possible types of flag tags exist for each token, *is not a constrain*, *does not appear in question* and *appear in question*. As shown in Figure 2, the flag tag of *six* updates to *appear in question* at the fourth step because six is generated at this step. We represent the three flag tags by training the embedding and injecting them into the Transformer generator. The flag tag can explicitly inform the generator to satisfy as many as possible constraints. In the training stage, when the generation is stopped, the flag tags for each token are either not a constrain or satisfied. It is a strong signal for the model to try to satisfy all constrains.

We conduct experiments on HotpotQA (Yang et al., 2018): a challenging dataset in which the questions are generated by reasoning over text from separate Wikipedia pages. Results show that our model greatly improves performance; it outperforms the state-of-the-art about **25%** by **5** BLEU (Papineni et al., 2002) points.

Our main contributions are summarized as follows:

- We propose a simple and effective controlled generation framework for MQG; we are also the first one to provide a method to ensure the complexity of generated questions and the first one to introduce the controlled generation methods to MQG.
- Experiment results show that our model greatly improves the performance; it also outperforms the state-of-the-art about **25%** by **5** BLEU points.

2 Related Work

2.1 Question Generation

Early works on QG (Mostow and Chen, 2009; Heilman and Smith, 2010) focus on the rule-based approaches that rely on heuristic rules or handcrafted templates, with low generalizability and scalability. Recent works adopt the attention-based sequence-to-sequence neural model for QG tasks, taking sentences with the answer as input and outputting the question (Du et al., 2017), which proved to work better than the rule-based methods. (Zhou et al., 2018) proposes the feature-enriched encoder to encode the input sentence. To generate a question for a given answer, (Sun et al., 2018; Kim et al., 2019; Song et al., 2018) apply various techniques to encode answer location information into an annotation vector corresponding to the word positions, thus allowing for better quality answer focused questions. (Chen et al., 2020) presents a syntactic feature-based method to represent words in a document and to decide what words to focus on while generating the question. Furthermore, recent

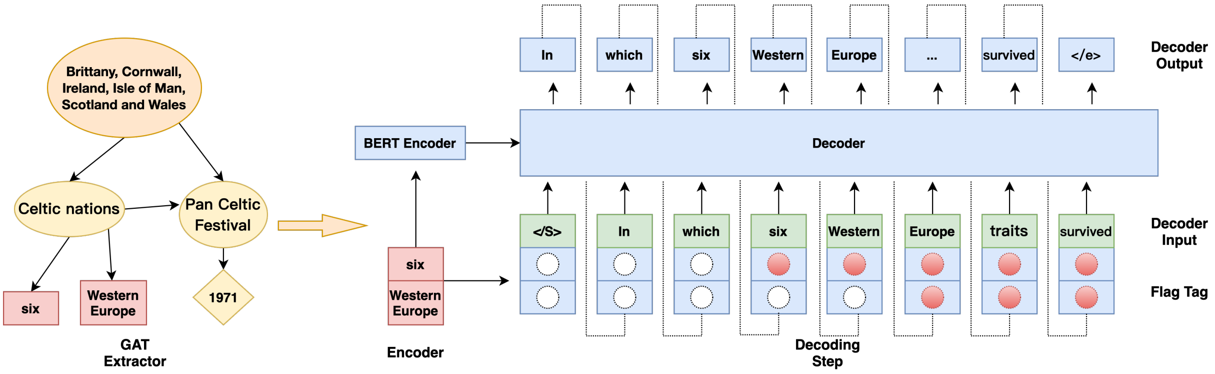

Figure 2: Overview architecture of the CQG model.

concurrent works apply the large-scale language model pre-training strategy for QG to achieve a new state-of-the-art performance (Chan and Fan, 2020).

Most prior research on QG has focused on shallow factoid-based questions, where answering the question simply by extracting the span of the text from a single input document.

Recently, there has been an increasing interest in MQG, to capture the complex information among different input documents, (Pan et al., 2020; Su et al., 2020) employ the GNN-based encoder in semantic graph and entity graph respectively, and (Sachan et al., 2020) use the strong transformer-based graph model. However, all these methods can not to ensure the complexity of generated questions where the generated questions may degenerate into shallow questions.

2.2 Controlled Generation

Two different types of control can be applied over generation models: soft control and hard control. Soft control aims at directing the option or the general topic of the generated text. In contrast, hard control aims at ensuring that some explicit constraints are met, e.g., specific words are contained in the text. The soft control can also be achieved via hard control, i.e., text that contains a set of words related to a certain topic should arguably revolve around that topic. Some recent works employ soft control on unconstrained language generation by training or fine-tuning language models (Ziegler et al., 2019; Keskar et al., 2019).

While hard control of constrained generation, such as machine translation, can be attained with grid beam search methods (Hu et al., 2019; Post and Vilar, 2018), which is impractical to use the same approach for hard control of unconstrained generation. Methods such as grid beam search rely on the assumption that there exists a core set of plausible candidates fulfilling the desired criteria, this is not often the case for open-ended generation tasks. Recent work on stochastic search (Sha, 2020) has approached this problem by performing bidirectional search during generation and editing the text until the constraints are fulfilled. Although stochastic search is suitable for bidirectional RNN models, it is not yet clear if it can be applied to forward generation models, e.g., transformer-based models.

3 Methodology

In this section, we formalize the multi-hop question generation (MQG) task and introduce our CQG. In particular, we first describe our Graph Attention Network (GAT) based key entities extractor. Following this, we describe the flag tag and finally we introduce our novel controlled Transformer-based generator with flag tag.

3.1 Problem Formulation

The input to the MQG task is a set of context documents $C = \{d_1, .., d_k\}$ where the k is the number of documents and an answer $A = [a_1, ..., a_m]$ where the m is the length of answer. These documents can be long containing multiple sentences, $d_i = [s_1, ..., s_n]$, where each $s_j = [w_1^j, ..., w_t^j]$ is composed of a sequence of tokens and the n and t are the number of sentences and the length of sentences respectively. The desired goal of MQG is to generate a question $y = [y_1, ..., y_t]$ conditioned on the context and the answer, where answering this question requires reasoning about the content in more than one of the context documents.

3.2 GAT-based Key Entities Extractor

According to existing research in multi-hop QA (De Cao et al., 2018), the reasoning chains can be captured by propagating local contextual information along edges in entity graph using a GNN. Motivated by this, we construct the entity graph from the input documents first and then employ the Graph Attention Network (GAT) (Veličković et al., 2017).

We follow the (Qiu et al., 2019) to construct the entity graph and we use the Stanford corenlp toolkit (Manning et al., 2014) to recognize named entities from the context C. The entity graph is constructed with the entities as nodes and edges built as follows. The edges are added 1. for every pair of entities that appear in the same sentence in C (sentence-level links); 2. for every pair of entities with the same mentioned text in C (context-level links); 3. between a central entity node and other entities within the same paragraph (paragraph-level links). The central entities are extracted from the title sentence for each paragraph. We do not apply co-reference resolution for pronouns because it introduces both additional useful and erroneous links.

We concatenate the answer A with the context C and pass the resulting sequence to a pre-trained BERT model to obtain representations $H = [h_1, h_2, ..., h_M]$ where M is the length of the context and answer. For each entity $e_i = [w_l, w_{l+1}, ..., w_j]$, we obtain its representation by a MaxPool and use it as the node embedding E_i in entity graph:

$$e_i = [w_l, w_{l+1}, ..., w_j] \quad (1)$$

$$E_i^0 = MaxPooling(h_l, h_{l+1}, ..., h_r) \quad (2)$$

The next step is to aggregate the information in the entity graph; here, we used a GAT to compute the multi-head attention score between two entity nodes by:

$$\alpha_{ij} = \frac{exp(\sigma(\mathbf{W}[h_i, h_j]))}{\sum_{k \in N_i} exp(\sigma(\mathbf{W}[h_i, h_k])} \quad (3)$$

$$\sigma(x) = LeakyReLU(x) \quad (4)$$

where $\mathbf{W}$ is the trainable matrix and N_i is the neighbors of entity i.

We aggregate the information by multi-head attention at each step:

$$h_i^{t+1} = \|_{k=1}^{K} \sigma(\sum_{j \in N_i} \alpha_{ij}^k \mathbf{W}^k h_j) \quad (5)$$

where $\|$ is the concatenate operation, $\mathbf{W}^k$ is the trainable weighting matrix for the kth head and all nodes share the same parameters of $\mathbf{W}^k$. Then we obtain the updated node embedding $E^{t+1} = [h_1^{t+1}, h_2^{t+1}, ..., h_n^{t+1}]$.

To generate a multi-hop question, we need to select the key entities in complex multi-hop reasoning chains. We formulate this as a node classification task, i.e., deciding whether each node should be involved in the process of asking, i.e., appearing in the reasoning chain for raising a multi-hop question, as exemplified by Figure 2.

To this end, we add one feed-forward layer on top of the final layer of the graph encoder, taking the output node representations E^T for classification. We deem a node as a positive ground-truth to train the key entities extract task if its contents appear in the ground-truth question and optimize it by cross-entropy loss.

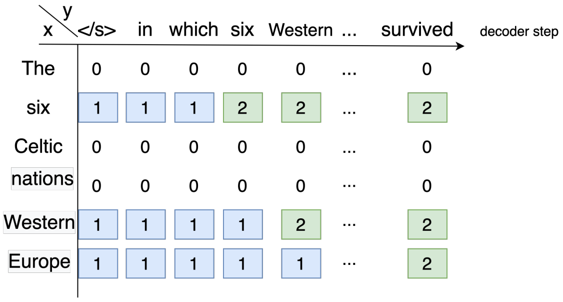
3.3 Controlled Generator with Flag Tag

In order to ensure the complexity of the generated question, the generated question must contain the key entities extracted from the entity graph. To this end, we need a controlled generator $G(Y|X, Y)$ where X is the input passage tokens and some x_i correspond to lexical constraints that must be satisfied in the generated outputs.

We describe the flag tag firstly, at decoding step t, the flag tag indicates whether each lexical constraint has been satisfied up until this step. Notably, the flag tag for each token at step t is that:

$$flag_i^t = \begin{cases} 0 & x_i \ is \ not \ a \ constrain \\ 1 & x_i \ does \ not \ appear \ in \ y_{1:t} \\ 2 & x_i \ appear \ in \ y_{1:t} \end{cases}$$

where $flag_i^t$ is the flag tag for ith input token at decoding step t, and $y_{1:t}$ is the generated tokens thus far. The tokens with the values 1 or 2 of the flag is a lexical constraint and the token with 0 is not constrained to appear in the question. Obviously, the flag tag for any token can only remain unchanged or updated to value 2. As shown in Figure 3, the input tokens X is that X = [The, six, Celtic, nations, Western, Europe] and the flag tag at the beginning is that $flag^0$ = [0,1,0,0,1,1] because the tokens are not constrained except *six*, *Western* and *Europe*. At step 4, the flags update to [0,2,0,0,0,1,1] because the token *six* has been generated but *Western* and *Europe* have not.



y x	</s>	in	which	six	Western	...	survived
The	0	0	0	0	0	...	0
six	1	1	1	2	2	...	2
Celtic	0	0	0	0	0	...	0
nations	0	0	0	0	0	...	0
Western	1	1	1	1	2	...	2
Europe	1	1	1	1	1	...	2

Figure 3: An example for flag tag update.

During the training of models, all the constraints have been satisfied before stopping the generation. This is a strong signal for the model to satisfy all the constraints. In addition, the flag tag is simple enough, which only adds the embedding with three tokens.

To utilize the rich information in flag tag, we employ a Transformer-based decoder as a generator to incorporate it and construct a simple controlled generation framework. We inject the flag tag into the embedding vector and use this embedding as the relative position embedding to bridge the decoder and the encoder.

In particular, at decoding step t, we incorporate the flag tag embedding by cross-attention in decoder. The conventional cross-attention module is computed by:

$$Cross(Q, K, V) = softmax(\frac{Q^\top K}{\sqrt{d_k}})V \quad (6)$$

where Q is the decoder states, K and V are encoder states and d_k is the dimensions of K vectors.

We introduce the flag tag at step t $F^t \in \mathbb{R}^{3*lenP}$ where $lenP$ is the length of the input passage, to transformer decoder as relative position embedding to compute the cross attention at step t as follows:

$$\alpha^t_{cross} = softmax(E^t) \quad (7)$$

$$E^t = \frac{Q^t(K + R^t)^\top}{\sqrt{d}} \quad (8)$$

$$R^t = Embedding(F^t) \quad (9)$$

where Q^t is the states of decoder at step t and the K is the outputs of encoder. And then the outputs of cross module is:

$$Cross(Q^t, K, V, F^t) = \alpha^t_{cross}V \quad (10)$$

where V is the outputs of encoder.

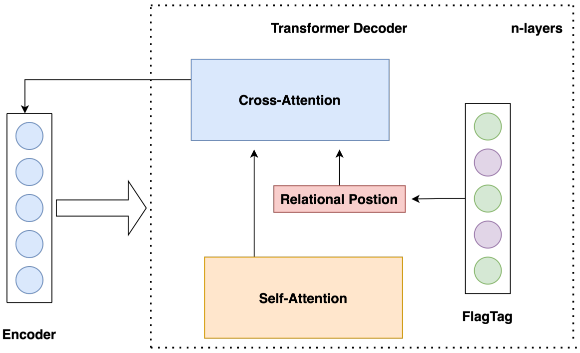


Figure 4: The controlled Transformer-based decoder where incorporate the flag tag as relational position embedding.

We train our model by the negative log likelihood for the target sequence y:

$$L = \frac{1}{T}\sum_{t=1}^{T} logP(\tilde{y}_t = y_t) \quad (11)$$

4 Experiments

4.1 Data and Metrics

To evaluate the model's ability to generate multi-hop questions, we conduct experiments on HotpotQA (Yang et al., 2018), which contains about 100,000 crowd-sourced questions that require reasoning over separate Wikipedia articles. Each question has two supporting documents that contain the necessary evidence to infer the answer. In this paper, we take the fact supporting sentences with the answer as inputs to generate the multi-hop questions. We follow the split of the original dataset including 90,447 and 7405 examples for training and developing respectively. Because the test set is not available publicly, so we set the original developing set as the test set and extract 500 samples from the training set as the developing set. Overall, we use the 89,947/500/7405 samples as training set, developing set and testing set, respectively.

Following the previous work, we employ BLEU (Papineni et al., 2002), ROUGE-L (Lin, 2004) and METEOR (Lavie and Agarwal, 2007) as automated evaluation metrics. BLEU measures the average n-gram overlap on a set of reference sentences. Both METEOR and ROUGE-L specialize BLEU's n-gram overlap idea for machine translation and text summarization evaluation, respectively.

Model	BLEU-1	BLEU-2	BLEU-3	BLEU-4	METEOR	ROUGE-L
Seq2Seq + attn (Bahdanau et al., 2014)	32.97	21.11	15.41	11.81	18.19	33.48

Table 1: Automatic evaluation results on HotpotQA. Our CQG achieves the best performance and have significant improvement in all metrics.

4.2 Baselines

We compare our proposed model against several strong baselines on question generation.

Seq2Seq + attn: (Bahdanau et al., 2014) the basic sequence-to-sequence (Seq2Seq) model with attention, which takes the document as input to decode the question.

NQG++ (Zhou et al., 2018): a Seq2Seq model with feature-enrich encoder.

s2sa-at-mp-gsa (Zhao et al., 2018): employs a gated attention encoder and a maxout pointer decoder to deal with long text inputs.

ASs2s (Kim et al., 2019): proposes an answer separated Seq2Seq model by replacing the answer in the input sequence with some specific words.

Semantic Graph (Pan et al., 2020): a graph-to-seq model for MQG, which constructs a semantic graph to capture the global information.

MuLQG (Su et al., 2020): a graph-to-seq model employs an encoder reasoning gate to capture the entity graph information.

IGND (Fei et al., 2021): a graph-to-seq model that introduces the copy tag and iterative graph-based decoder, it is the state-of-the-art model for shallow QG. We construct the graph following (Pan et al., 2020) to match the HotpotQA dataset.

BART (Lewis et al., 2020): The strong pre-training generation model that obtains the state-of-the-art performance on shallow question.

UniLM (Dong et al., 2019): Another strong pre-training generation model.

Strong Transformers (Sachan et al., 2020): the state-of-the-art model for MQG, which propose a series of strong Transformer models for MQG.

4.3 Implementation Details

We use the BERT base model loaded from transformers in huggingface library [2]. The embedding size and head hidden size of the flag tag are 64. The number of heads in BERT, transformer-based decoder and GAT attention is 8. The number hop of GAT in the entity graph is 3. As for entity extracting, if the number of key entities is more than 5, we use the top-5 entities with the highest probability. We use the AdamW (Loshchilov and Hutter, 2017) as the optimizer and the learning rate is set to 2e-5. We stop the training if the validation BLEU-4 score stops improving for 10 epochs. We clip the gradient at length 10. The batch size is 128 and the beam search width 5. All hyperparameters are tuned on the development set. We implement all models in MindSpore.

4.4 Main Results

Table 1 shows the experimental results of the HotpotQA dataset. In terms of BLEU-4 regarded as the main evaluation metric for text generation, our model greatly improves performance; it outperforms the strong Transformers about 25% by 5 BLEU points. We achieve state-of-the art results on HotpotQA. Not only in BLEU-4, our CQG achieves the best performance and shows significant improvement in all metrics.

4.5 Human Evaluation

Metrics for automatic evaluation based on n-grams may not truly reflect the quality of generated questions. Hence, we further randomly sample 300 examples in the test set for human evaluation. Following by (Pan et al., 2020), we conduct human

CQG w/o key entities + controlled decoder	19.89

Table 3: The ablation study for CQG.

evaluations on 300 random test samples consisting of 100 short (<50 tokens), 100 medium (50-200 tokens), and 100 long (>200 tokens) documents. We ask three workers to rate the 300 generated questions as well as the ground-truth questions between 1 (poor) and 5 (good) on three criteria: (1) fluency, which indicates whether the question follows the grammar and accords with the correct logic; (2) relevance, which indicates whether the question is answerable and relevant to the passage; (3) complexity, which indicates whether the question involves reasoning over multiple sentences from the document. We average the scores from raters on each question and report the performance of UniLM, MuLQG Semantic Graph, BART and our CQG. Workers were unaware of the identity of the models in advance. We show the results in Table 2.

We can see that the performance of pre-training generation models is much better than MulQG and Semantic Graph. Our CQG model shows the best performance for all three criteria and all lengths of context. Furthermore, CQG is outstanding in complexity where other models are weak in it, and this result proves that our model is effective in solving the complexity control issue of MQG task.

4.6 Ablation Study

To further evaluate and investigate the performance of different components and strategies in our model, we perform the ablation study in the HotpotQA test set and show the results in Table 3.

CQG w/o entity graph The model removes the entity graph and employs the context embedding passed BERT to extract the entity, which does not change the setting of the controlled generator.

CQG w/o controlled decoder The model removes the controlled decoder and employs the standard transformer model, where the BERT encoder encodes both input passage and key entities and feeds then into the decoder.

CQG w/o inference dynamical flag tag The model does not update flag tag in **inference stage**, which means all the values of flag tag at the last step are the same as those at the first step.

CQG w/o key entities + controlled decoder The model removes the key entities extractor and controlled generator; we can see it as a baseline model consisting of a BERT encoder and a Transformer decoder.

First of all, there is a huge gap between CQG and CQG w/o key entities + controlled decoder, which demonstrates that our controlled generation framework plays an important role. Comparing between CQG and CQG w/o controlled decoder, we find that the controlled generator with the flag tag is the critical module in CQG.

Secondly, CQG is higher than CQG w/o entity graph 0.97 of BLEU points. We can see that the entity graph constructed from the input passage contains rich structure information among entities and captures the information by GAT, which can improve the performance for CQG.

Thirdly, although the CQG w/o dynamical inference flag tag is worse than CQG, it is much higher than CQG w/o controlled decoder. This phenomenon shows that the flag tag is a strong signal that prompts the model to satisfy as many constraints as possible in the training stage. Although CQG w/o dynamical inference flag tag does not update the flag tag in the inference stage, the model also tries to generate the key entities to improve the performance.

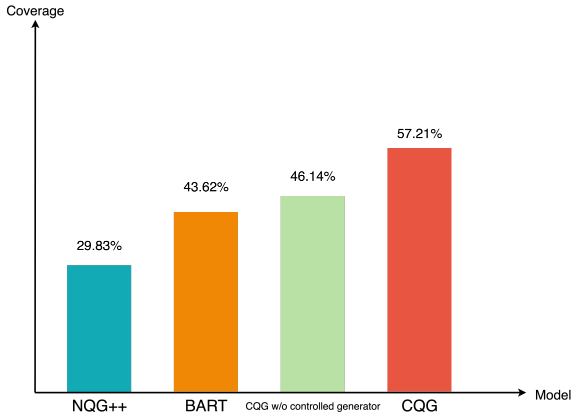

Figure 5: The coverage percentage of key entity

CQG w/o controlled decoder removes the hard controlled generator and employs the soft controlled method, which encodes the key tokens and feeds them to the decoder. CQG w/o controlled decoder is 0.98 higher than CQG w/o key entities + controlled decoder, which shows the soft controlled method is effective but is far from the hard method in CQG.

4.7 Analysis for controlled generator

We conduct some experiments to analyze the controlled generator in this section. At first, we compare the key entity coverage percentage for different models. In particular, we compute the coverage percentage of the appeared key entity in question generated by different models, where we think all the entities that appear in the gold question are key entities. This metric reflects the complexity of generated questions because the multi-hop reasoning chains are composed of these key entities. As shown in Figure 5, we can find that the coverage of CQG is much higher than in the other models, and this improvement is from the controlled generator according to the comparison between CQG and CQG w/o controlled generator. This result shows that our CQG improves the control of the model generation process.

4.8 Case Study

We present a case study to show the control ability of our model and compare the strong baseline BART model, CQG and the gold. The cases are presented in Table 4.

It is clearly shown the BART model generates the question only involved paragraph A, which is not the multi-hop question. As for CQG, we provide three examples with the different key entity and the questions generated by CQG contain the given key entity. The given key entity can control the semantic of the generated question, and we can see that the question in the first example, where the given key entities are the same entity as gold, have the same semantic as the gold question. The examples demonstrate that our CQG can be controlled to generate the high-quality multi-hop question with the given key entity.

Paragraph A: Letters to Cleo
Letters to Cleo are an alternative rock band from Boston, Massachusetts, best known for the 1994 single, "Here & Now, from their full-length debut album, "Aurora Gory Alice". The band's members are Kay Hanley, Greg McKenna, Michael Eisenstein, Stacy Jones, Scott Riebling, and later, Tom Polce.
Paragraph B: Screaming Trees
Screaming Trees was an American rock band formed in Ellensburg, Washington in 1985 by vocalist Mark Lanegan, guitarist Gary Lee Conner, bass player Van Conner and drummer Mark Pickerel. Pickerel had been replaced by Barrett Martin by the time the band reached its most successful period.
Answer: Letters to Cleo
Gold Question: Which band, Letters to Cleo or Screaming Trees, had more members?

BART: Which band's members are Kay Hanley, Greg Mckenna, Michael Eisenstein, Stacy Jones, Scott Riebling, and Tom Polce ?
Key Entity: Letters to Cleo, Screaming Trees
CQG: Which band has more members, Letters to Cleo or Screaming Trees?
Key Entity: Letters to Cleo, Kay Hanley
CQG: Is Kay Hanley the member of Letters to Cleo's member ?
Key Entity: Boston
CQG: Which rock band are from Boston ?

Table 4: Case study of one example from HotpotQA test set. We indicate the key entity by different color.

5 Conclusion

The MQG task is more challenging and worthy of exploration compared with conventional shallow QG. To address the complexity control problem of MQG, we propose a simple control framework CQG, which consists of a GAT-based key entity extractor and a controlled generated. CQG greatly improves the performance and we hope our model will help researchers to study the MQG task.

Word Order Does Matter
(And Shuffled Language Models Know It)

Abstract

Recent studies have shown that language models pretrained and/or fine-tuned on randomly permuted sentences exhibit competitive performance on GLUE, putting into question the importance of word order information. Somewhat counter-intuitively, some of these studies also report that position embeddings appear to be crucial for models' good performance with shuffled text. We probe these language models for word order information and investigate what position embeddings learned from shuffled text encode, showing that these models retain information pertaining to the original, naturalistic word order. We show this is in part due to a subtlety in how shuffling is implemented in previous work – *before* rather than *after* subword segmentation. Surprisingly, we find even Language models trained on text shuffled *after* subword segmentation retain some semblance of information about word order because of the statistical dependencies between sentence length and unigram probabilities. Finally, we show that beyond GLUE, a variety of language understanding tasks do require word order information, often to an extent that cannot be learned through fine-tuning.

1 Introduction

Transformers (Vaswani et al., 2017), when used in the context of masked language modelling (Devlin et al., 2018), consume their inputs concurrently. There is no notion of inherent order, unlike in autoregressive setups, where the input is consumed token by token. To compensate for this absence of linear order, the transformer architecture originally proposed in Vaswani et al. (2017) includes a fixed, sinusoidal position embedding added to each token embedding; each token carries a different position embedding, corresponding to its position in the sentence. The transformer-based BERT (Devlin et al., 2018) replaces these fixed sinusoidal embeddings with unique, learned embeddings per position; RoBERTa (Liu et al., 2019), the model investigated in this work, does the same.

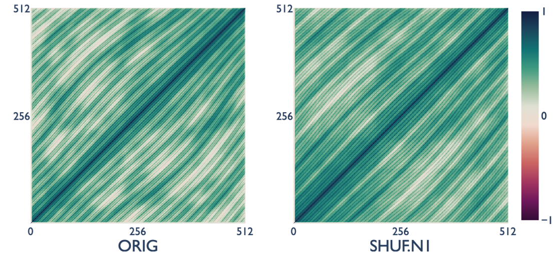

Figure 1: Pearson correlations between position embeddings for full-scale models; the patterns are similar to fully learnable absolute embeddings (Wang et al., 2021) and can be said to have learned something about position. We later demonstrate that this is not the case with post-BPE scrambling.

Position embeddings are the only source of order information in these models; in their absence, contextual representations generated for tokens are independent of the actual position of the tokens in a sentence, and the models thus resemble heavily overparameterised bags-of-words. Sinha et al. (2021) pre-trained RoBERTa models on shuffled corpora to demonstrate that the performance gap between these 'shuffled' language models and models trained on unshuffled corpora is minor (when fine-tuned and evaluated downstream on the GLUE (Wang et al., 2018) benchmark). They further show that this gap is considerably wider when a model is pre-trained without position embeddings. In this paper, we attempt to shed some light on why these models behave the way they do, and in doing so, seek to answer a set of pertinent questions:

- Do shuffled language models still have traces of word order information?
- Why is there a gap in performance between models *without* position embeddings and models trained on shuffled tokens, with the latter

---

*Equal contribution. Order was decided by a coin toss.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 6907 - 6919

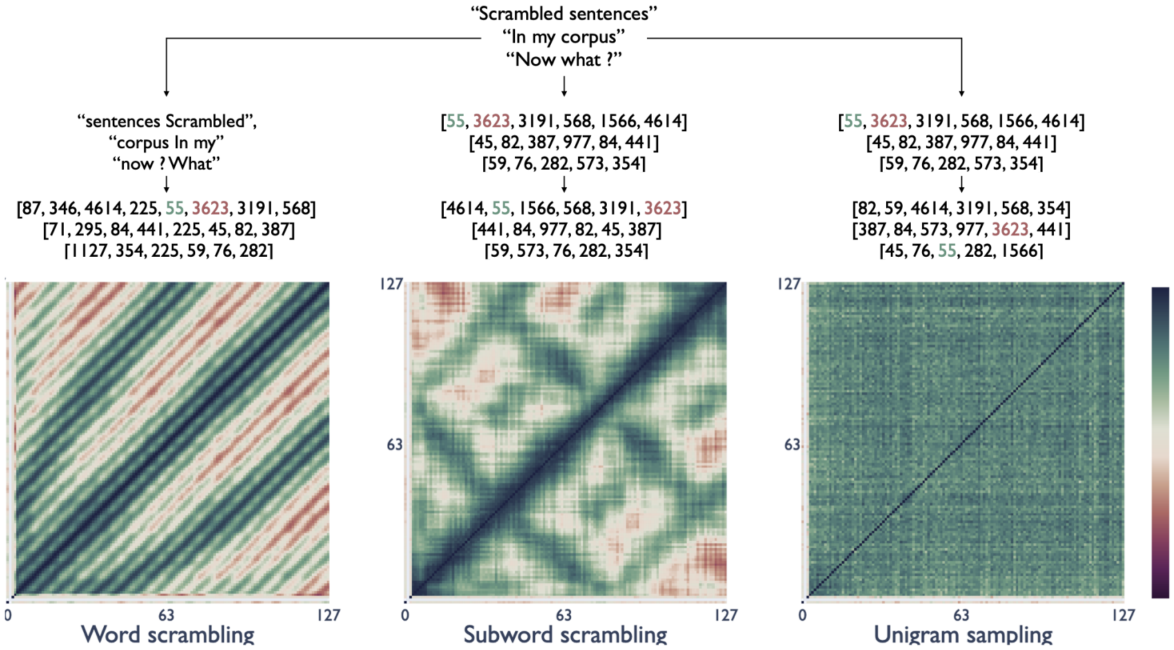

Figure 2: Correlations between position embeddings when shuffling training data *before* segmentation (left), i.e, at the word level, and *after* segmentation (middle), i.e., at the subword level, as well as when replacing all subwords with random subwords based on their corpus-level frequencies (right). The latter removes any dependency between subword probability and sentence length. The plots show that shuffling before segmentation retains more order information than shuffling after, and that even when shuffling after segmentation, position embeddings are meaningful because of the dependence between subword probability and sentence length.

performing better?

- Are there NLU benchmarks, other than GLUE, on which shuffled language models perform poorly?

Contributions We first demonstrate, in Section 3, that shuffled language models *do* contain word order information, and are quite responsive to simple tests for word order information, particularly when compared to models trained without position representations. In Section 4, we demonstrate that pre-training is sufficient to learn this: position embeddings provide the appropriate inductive bias, and performing BPE segmentation after shuffling results in sensible n-grams appearing in the pre-training corpus; this gives models the capacity to learn word order within smaller local windows. Other minor cues - like correlations between sentence lengths and token distributions - also play a role. We further corroborate our analysis by examining attention patterns across models in Sec. 5. In Section 6, we show that, while shuffled models might be almost as good as their unshuffled counterparts on GLUE tasks, there exist NLU benchmarks that do require word order information to an extent that cannot be learned through fine-tuning alone. Finally, in Section 7, we describe miscellaneous experiments addressing the utility of positional embeddings when added just prior to fine-tuning.

2 Models

Sinha et al. (2021) train several full-scale RoBERTa language models on the Toronto Book Corpus (Zhu et al., 2015) and English Wikipedia.[1] Four of their models are trained on shuffled text, i.e., sentences in which n-grams are reordered at random.[2] We dub the original, unperturbed model ORIG, and the scrambled models SHUF.N1, SHUF.N2, SHUF.N3 and SHUF.N4 depending on the size of the shuffled n-grams: SHUF.N1 reorders the unigrams in a sentence, SHUF.N2 reorders its bigrams, etc. For comparison, Sinha et al. (2021) also train a RoBERTa language model entirely *without* position embeddings (NOPOS), as well as a RoBERTa language model trained on a corpus drawn solely from unigram distributions of the original Book Corpus, i.e., a reshuffling of the entire corpus (SHUF.CORPUS).

---

[1] Training reportedly takes 72 hours on 64 GPUs.

[2] The shuffling procedure does not reorder tokens *completely* at random, but moves a token in position i to a *new* position selected at random among positions $j \neq i$.

We experiment with their models, as well as with smaller models that we can train with a smaller carbon footprint. To this end, we downscale the RoBERTa architecture used in Sinha et al. (2021). Concretely, we train single-headed RoBERTa models, dividing the embedding and feed-forward dimensionality by 12, for 24 hours on a single GPU, on 100k sentences sampled from the Toronto Book Corpus. To this end, we train a custom vocabulary of size 5,000, which we use for indexing in all our subsequent experiments. While these smaller models are in no way meant to be fine-tuned and used downstream, they are useful proofs-of-concept that we later analyse.

3 Probing for word order

We begin by attempting to ascertain the extent to which shuffled language models are actually capable of encoding information pertaining to the naturalistic word order of sentences. We perform two simple tests on the full-scale models, in line with Wang and Chen (2020): the first of these is a classification task where a logistic regressor is trained to predict whether a randomly sampled token precedes another in an unshuffled sentence, and the second involves predicting the position of a word in an unshuffled sentence. The fact that we *do not* fine-tune any of the model parameters is noteworthy: the linear models can only learn word order information if it reflects in the representations the models generate somehow.

Pairwise Classification For this experiment, we train a logistic regression classification model on word representations extracted from the final layer of the Transformer encoder, mean pooling over sub-tokens when required. For each word pair x and y, the classifier is given a concatenation of our model m's induced representations $m(x) \oplus m(y)$ and trained to predict a label indicating whether x precedes y or not. Holding out two randomly sampled positions, we use a training sets sized 2k, 5k, and 10k, from the Universal Dependencies English-GUM corpus (Zeldes, 2017) (excluding sentences with more than 30 tokens to increase learnability) and a test set of size $2,000$. We report the mean accuracy from three runs.

Regression Using the same data, we also train a ridge-regularised linear regression model to predict the position of a word $p(x)$ in an unshuffled sentence, given that word's model-induced representation $m(x)$. R^2 score is reported per model. To prevent the regressors from memorising word to position mappings, we perform 6-fold cross-validation, where the heldout part of the data contains no vocabulary overlap with the corresponding train set.

Model	Classification (acc.)			Regression (R^2)
	2k	5k	10k	-
ORIG	81.50	81.74	80.40	0.68
SHUF.N1	65.96	64.98	71.82	0.60
NOPOS	50.41	53.35	50.22	0.03

Table 1: Pairwise classification and regression results.

Results For both tasks (see Table 1), our results indicate that position encodings are particularly important for encoding word order: Classifiers and regressors trained on representations from ORIG and SHUF.N1 achieve high accuracies and R^2 scores, while those for NOPOS are close to random. Both ORIG and SHUF.N1 appear to be better than random given only 2k examples. These results imply that, given positional encodings and a modest training set of 2k or more examples, a simple linear model is capable of extracting word order information, enabling almost perfect extrapolation to unseen positions. Whether the position encodings come from a model trained on natural or shuffled text does not appear to matter, emphasizing that shuffled language models do indeed contain substantial information about the original word order.

4 Hidden word-order signals

In Section 3, we observed that Sinha et al. (2021)'s shuffled language models surprisingly exhibit information about naturalistic word order. That these models contain positional information can also be seen by visualizing position embedding similarity. Figure 1 displays Pearson correlations[3] for position embeddings with themselves, across positions. Here, we see that the shuffled models satisfy the idealised criteria for position embeddings described by Wang et al. (2021): namely, they appear to be a) monotonous within smaller context windows, and b) invariant to translation. If position embedding correlations are consistent across offsets over the entire space of embeddings, the model can be said to have 'learned' distances between tokens. Since transformers process all positions in parallel,

---

[3] We see similar patterns with dot products for all our plots; we use Pearson correlations to constrain our range to $[-1, 1]$.

and since language models without position embeddings do not exhibit such information, position embeddings have to be the source of this information. In what follows, we discuss this apparent paradox.

Subword vs. word shuffling An important detail when running experiments on shuffled text, is *when* the shuffling operation takes place. When tokens are shuffled *before* BPE segmentation, this leads to word-level shuffling, in which sequences of subwords that form words remain contiguous. Such sequences become a consistent, meaningful signal for language modelling, allowing models to efficiently utilise the inductive bias provided by position embeddings. Thus, even though our pre-trained models have, in theory, not seen consecutive tokens in their pre-training data, they have learned to utilise positional embeddings to pay attention to adjacent tokens. The influence of this is somewhat visible in Figure 2: while models trained on text shuffled before and after segmentation both exhibit shifts in the *polarity* of their position correlations, only the former show bands of varying *magnitude*, similar to the full-scale models. Ravishankar and Søgaard (2021) discuss the implications of these patterns in a multilingual context; we hypothesise that in our context, the periodicity in magnitude is a visible artefact of the model's ability to leverage position embeddings to enable offset attention. In Section 5, we analyse the effect of shuffling the pre-training data on the models' attention mechanisms.

Accidental overlap In addition to the n-gram information which results from shuffling before segmentation, we also note that short sentences tend to include original bigrams with high probability, leading to stronger associations for words that are adjacent in the original texts. This effect is obviously much stronger when shuffling before segmentation than after segmentation. Figure 3 shows how frequent overlapping bigrams (of any sort) are, comparing word and subword shuffling over 50k sentences.

Sentence length Finally, we observe some preserved information about the original word order even when shuffling is performed *after* segmentation. We hypothesize that this is a side-effect of the non-random relationship between sentence length and unigram probabilities. That unigram probabilities correlate with sentence length follows from the fact that different genres exhibit different sentence length distributions (Sigurd et al., 2004; Jin and Liu, 2017). Also, some words occur very frequently in formulaic contexts, e.g., *thank* in *thank you*. This potentially means that there is an approximately learnable relationship between the distribution of words and sentence boundary symbols.

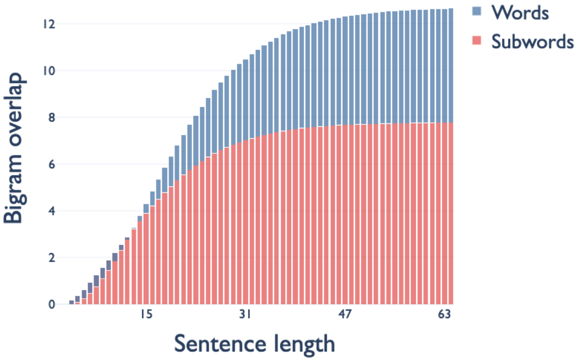

Figure 3: (Cumulative) plot showing subword bigram overlap after shuffling either words or subwords, as a percentage of the total number of seen bigrams. We see the overlap is significant, especially when performing shuffling before segmentation.

To test for this, we train two smaller language models on unigram-sampled corpora: for the first, we use the first 100k BookCorpus sentences as our corpus, shuffling tokens at a corpus level (yet keeping the original sentence lengths). The stark difference in position embedding correlations between that and shuffling is seen in Figure 2. For the second, we sample from two different unigram distributions: one for short sentences and one for longer sentences (details in Appendix B). While the first model induces no correlations at all, the second does, as shown in Figure 4, implying that sentence length and unigram occurrences is enough to learn *some* order information.

5 Attention analysis

Transformer-based language models commonly have attention heads that attend to neighboring positions (Voita et al., 2019; Ravishankar et al., 2021). Such attention heads are positional and can only be learned in the presence of order information. We attempt to visualise the attention mechanism for pre-trained models by calculating, for each head and layer, the offset between a token and the token

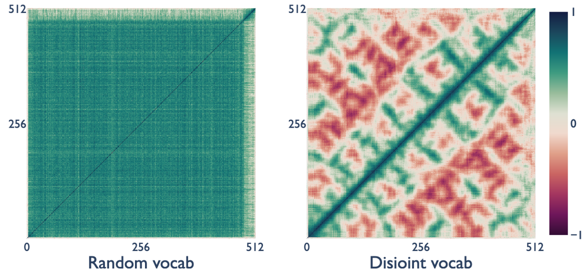

Figure 4: Similarity matrix between models with sentences sampled based on unigram corpus statistics; disjoint vocab implies a correlation between token choice and sentence length.

that it pays maximum attention to[4]. We then plot how frequent each offset is, as a percentage, over 100 Book Corpus sentences, in Figure 5, where we present results for two full-scale models, and two smaller models (see §2). When compared to NOPOS, SHUF.N1 has a less uniform pattern to its attention mechanism: it is likely, even at layer 0, to prefer to pay attention to adjacent tokens, somewhat mimicking a convolutional window (Cordonnier et al., 2020). We see very similar differences in distribution between our smaller models: Shuffling after segmentation, i.e., at the subword level, influences early attention patterns.

6 Evaluation beyond GLUE

SuperGLUE and WinoGrande Sinha et al. (2021)'s investigation is conducted on GLUE and on the Paraphrase Adversaries from Word shuffling (PAWS) dataset (Zhang et al., 2019). For these datasets, they find that models pretrained on shuffled text perform only marginally worse than those pretrained on normal text. This result, they argue can be explained in two ways: either a) these tasks do not need word order information to be solved, or b) the required word order information can be acquired during finetuning. While GLUE has been a useful benchmark, several of the tasks which constitute it have been shown to be solvable using various spurious artefacts and heuristics (Gururangan et al., 2018; Poliak et al., 2018). If, for instance, through finetuning, models are learning to rely on such heuristics as lexical overlap for MNLI (McCoy et al., 2019), then it is unsurprising that their performance is not greatly impacted by the lack of word order information.

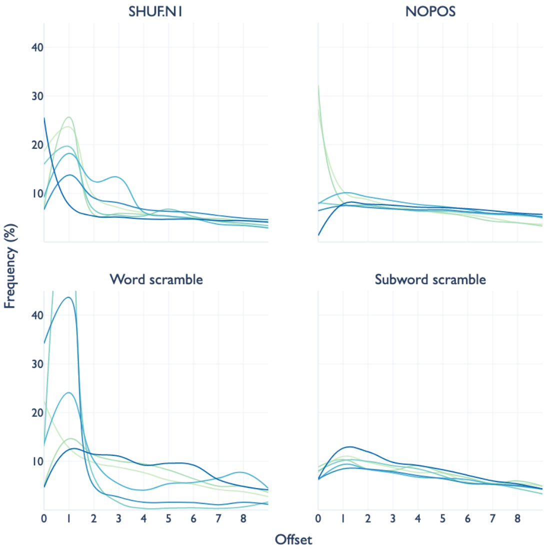

Figure 5: Relative frequency of offsets between token pairs in an attention relation; the y-axis denotes the percentage of total attention relations that occur at the offset indicated on the x-axis. We plot layers $l \in \{1, 2, 7, 8, 11, 12\}$ with increasing line darkness.

Evaluating on the more rigorous set of SuperGLUE tasks[5] (Wang et al., 2019) and on the adversarially-filtered Winograd Schema examples (Levesque et al., 2012) of the WinoGrande dataset (Sakaguchi et al., 2020) produces results which paint a more nuanced picture compared to those of Sinha et al. (2021). The results, presented in Table 2, show accuracy or F1 scores for all models. For two of the tasks (MultiRC (Khashabi et al., 2018), COPA (Roemmele et al., 2011)), we observe a pattern in line with that seen in Sinha et al. (2021)'s GLUE and PAWS results: the drop in performance from ORIG to SHUF.N1 is minimal (mean: 1.75 points; mean across GLUE tasks: 3.3 points)[6], while that to NOPOS is more substantial (mean: 10.5 points; mean across GLUE tasks: 18.6 points).

This pattern alters for the BoolQ Yes/No question answering dataset (Clark et al., 2019), the CommitmentBank (De Marneffe et al., 2019), the ReCoRD reading comprehension dataset (Zhang et al., 2018), both the Winograd Schema tasks,

---

[4] This method of visualisation is somewhat limited, in that it examines only the *maximum* attention paid by each token. We provide more detailed plots over attention *distributions* in the Appendix.

[5] Results are reported for an average of 3 runs per task. The RTE task is excluded from our results as it is also part of GLUE; RTE results can be found in Sinha et al. (2021).

[6] CoLA results are excluded from the GLUE calculations due to the very high variance across random seeds reported by Sinha et al. (2021).

and to some extent the Words in Context dataset (Pilehvar and Camacho-Collados, 2018). For these tasks we observe a larger gap between ORIG and SHUF.N1 (mean: 8.1 points), and an even larger one between ORIG and NOPOS (mean: 19.78 points). We note that this latter set of tasks requires inferences which are more context-sensitive, in comparison to the two other tasks or to the GLUE tasks.

Consider the Winograd schema tasks, for example. Each instance takes the form of a binary test with a statement comprising of two possible referents (blue) and a pronoun (red) such as: `Sid explained his theory to Mark but he couldn't convince him`. The correct referent of the pronoun must be inferred based on a special discriminatory segment (underlined). In the above example, this depends on a) the identification of "Sid" as the subject of "explained" and b) inferring that the pronoun serving as the subject of "convinced" should refer to the same entity. Since the Winograd schema examples are designed so that the referents are equally associated with their context[7], word order is crucial[8] for establishing the roles of "Sid" and "Mark" as subject and object of "explained" and "he" and "him" as those of "convinced". If these roles cannot be established, making the correct inference becomes impossible.

A similar reasoning can be applied to the Words in Context dataset and the CommitmentBank. The former task tests the ability of a model to distinguish the senses of a polysemous word based on context. While this might often be feasible via a notion of contextual association that higher-order distributional statistics are sufficient for, some instances will require awareness of the word's role as an argument in the sentence. The latter task investigates the projectivity of finite clausal complements under entailment cancelling operators. This is dependent on both the scope of the entailment operator and the identity of the subject of the matrix predicate (De Marneffe et al., 2019), both of which are sensitive to word order information.

A final consideration to take into account is dataset filtering. Two of the tasks where we observe the largest difference between ORIG, SHUF.N1, and NOPOS — WinoGrande and ReCoRD — apply filtering algorithms to remove cues or biases which would enable models to heuristically solve the tasks. This indicates that by filtering out examples containing cues that make them solvable via higher order statistics, such filtering strategies do succeed at compelling models to (at least partially) rely on word order information.

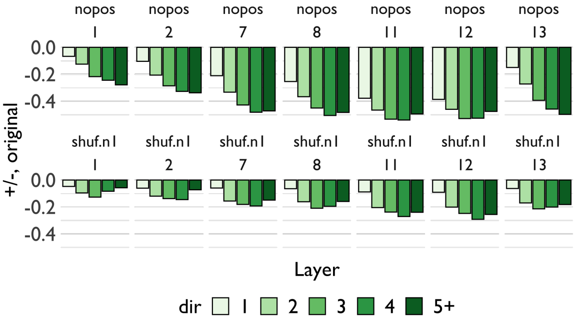

Figure 6: Δ, dependency arcs probing accuracy across lengths 1-5+, w.r.t. ORIG.

Dependency Tree Probing Besides GLUE and PAWS, Sinha et al. (2021)'s analysis also includes several probing experiments, wherein they attempt to decode dependency tree structure from model representations. They show, interestingly, that the SHUF.N4, SHUF.N3 and SHUF.N2 models perform only marginally worse than ORIG, with SHUF.N1 producing the lowest scores (lower, in fact, than SHUF.CORPUS). Given the findings of Section 3, we are interested in taking a closer look at this phenomenon. Here, we surmise that *dependency length* plays a crucial role in the probing setup, where permuted models may succeed on par with ORIG in capturing local, adjacent dependencies, but increasingly struggle to decode longer ones. To evaluate the extent to which this is true, we train a bilinear probe (used in Hewitt and Liang (2019)) on top of all model representations and evaluate its accuracy across dependencies binned by length, where length between words w_i and w_j is defined as $|i - j|$. We opt for using the bilinear probe over the Pareto probing framework (Pimentel et al., 2020), as the former learns a transformation directly over model representations, while the latter adds the parent and child MLP units from Dozat et al. (2017) – acting more like a parser. We train probes on the English Web Treebank (Silveira et al., 2014) and evaluate using UAS, the standard parsing

---

[7] e.g. Sid and Mark are both equally likely subjects/objects here. Not all Winograd schema examples are perfect in this regard, however, which could explain why scrambled models still perform above random. See Trichelair et al. (2018) for a discussion of the latter point.

[8] Particularly in a language with limited morphological role marking such as English.

Model	BoolQ	CB	COPA	MultiRC	ReCoRD	WiC	WSC	WinoGrande
ORIG	77.6	88.2 / 87.4	61.6	67.8 / 21.9	73.5 / 72.8	67.4	73.5	62.9
SHUF.N1	72.4	79.7 / 82.5	59.7	66.2 / 15.0	61.1 / 60.4	63.0	62.9	55.7
SHUF.N2	73.1	86.6 / 85.5	60.3	64.8 / 16.1	63.1 / 62.4	63.0	65.3	57.6
SHUF.N4	73.5	87.9 / 87.1	60.8	66.2 / 18.2	64.6 / 63.9	62.4	65.3	59.53
NOPOS	66.0	63.5 / 75.0	55.6	52.8 / 3.8	23.8 / 23.5	55.4	63.09	52.73
SHUF.CORPUS	66.7	65.6 / 73.8	56.1	52.6 / 6.4	31.0 / 30.3	57.3	65.14	51.68

Table 2: SuperGLUE and WinoGrande results for all models. Scores displayed are: Avg. F1 / Accuracy for CB; F1a / Exact Match for MultiRC; F1 / Accuracy for ReCoRD ; accuracy for the remaining tasks.

metric.

Figure 6 shows Δ probing accuracy across various dependency lengths for NOPOS and SHUF.N1, with respect to ORIG[9]; we include detailed Δs for all models in Appendix C. For NOPOS, parsing difficulty increases almost linearly with distance, often mimicking the actual frequency distribution of dependencies at these distances in the original treebank (Appendix C); for SHUF.N1, the picture is a lot more nuanced, with dependencies at a distance of 1 consistently being closer in terms of parseability to ORIG, which, we hypothesise, is due to its adjacency bias.

7 Other Findings

Random position embeddings are difficult to add post-training We tried to quantify the degree to which the inductive bias imparted by positional embeddings can be utilised, solely via fine-tuning. To do so, for a subset of GLUE tasks (MNLI, QNLI, RTE, SST-2, CoLA), we evaluate NOPOS, and a variant where we randomly initialised learnable position embeddings and add them to the model, with the rest of the model equivalent to NOPOS. We see no improvement in results, except for MNLI, that we hypothesise stems from position embeddings acting as some sort of regularisation parameter. To test this, we repeat the above set of experiments, this time injecting Gaussian noise instead; this has been empirically shown to have a regularising effect on the network (Bishop, 1995; Camuto et al., 2021). Adding Gaussian noise led to a slight increase in score for just MNLI, backing up our regularisation hypothesis.

Models learn to expect specific embeddings Replacing the positional embeddings in ORIG with fixed, sinusoidal embeddings before fine-tuning significantly hurts scores on the same subset of GLUE tasks, implying that the models expect embeddings that resemble the inductive bias imparted by random embeddings, and that fine-tuning tasks do not have sufficient data to overcome this. The addition of fixed, *sinusoidal* to NOPOS also does not improve model performance on a similar subset of tasks; this implies, given that sinusoidal embeddings are already meaningful, that model weights also need to learn to fit the embeddings they are given, and that they need a substantial amount of data to do so.

8 On Word Order

In Humans It is generally accepted that a majority of languages have “canonical” or “base’ word orderings (Comrie, 1989) (e.g. Subject-Verb-Object in English, and Subject-Object-Verb in Hindi). Linguists consider word order to be a *coding property* — mechanisms by which abstract, syntactic structure is encoded in the surface form of utterances. Beyond word order, other coding properties include, e.g. subject-verb agreement, morphological case marking, or function words such as adpositions. In English, word order is among the most prominent coding properties, playing a crucial role in the expression of the main verb’s core arguments: subject and object. For more morphologically complex languages, on the other hand, (e.g. Finnish and Turkish), word order is primarily used to convey pragmatic information such as topicalisation or focus. In such cases, argument structure is often signalled via case-marking, where numerous orderings become possible (shift in topic or focus nonwithstanding). We refer the reader to Kulmizev and Nivre (2021) for a broader discussion of these topics and their implications when studying syntax through language models.

More generally, evidence for the saliency of word order in linguistic processing and comprehension comes from a variety of studies using acceptability judgements, eye-tracking data, and neu-

[9] Note that Layer 13 refers to a linear mix of all model layers, as is done for ELMo (Peters et al., 2018).

ral response measurements (Bever, 1970; Danks and Glucksberg, 1971; Just and Carpenter, 1980; Friederici et al., 2000, 2001; Bahlmann et al., 2007; Lerner et al., 2011; Pallier et al., 2011; Fedorenko et al., 2016; Ding et al., 2016). Psycholinguistic research has, however, also highlighted the robustness of sentence processing mechanisms to a variety of perturbations, including those which violate word order restrictions (Ferreira et al., 2002; Gibson et al., 2013; Traxler, 2014). In recent work, Mollica et al. (2020) tested the hypothesis that composition is the core function of the brain's language-selective network and that it can take place even when grammatical word order constrains are violated. Their findings confirmed this, showing that stimuli with shuffled word order where local dependencies were preserved — as is, roughly speaking, the case for many dependencies in the sentences SHUF.N4 is trained on — elicited a neural response in the language network that is comparable to that elicited by normal sentences. When interword dependencies were disrupted so combinable words were so far apart that composition among nearby words was highly unlikely — as in SHUF.N1, neural response fell to a level compared to unconnected word lists.

In Machines Recently, many NLP researchers have attempted to investigate the role of word order information in language models. For example, Lin et al. (2019) employ diagnostic classifiers and attention analyses to demonstrate that lower (but not higher) layers of BERT encode word order information. Papadimitriou et al. (2021) find that Multilingual BERT is sensitive to morphosyntactic alignment, where numerous languages (out of 24 total) rely on word order to mark subjecthood (English among them). Alleman et al. (2021) implement an input perturbation framework (n-gram shuffling, phrase swaps, etc.), and employ it towards testing the sensitivity of BERT's representations to various types of structure in sentences. They report a sensitivity to larger constituent units of sentences in higher layers, which they deduce to be influenced by hierarchical phrase structure. O'Connor and Andreas (2021) examine the contribution of various contextual features to the ability of GPT-2 (Radford et al., 2019) to predict upcoming tokens. Their findings show that several destructive manipulations, including in-sentence word shuffling, applied to mid- and long range contexts lead only to a modest increase in *usable information* as defined according to the V-information framework of Xu et al. (2020).

Similarly, word order information has been found not to be essential for various NLU tasks and datasets. Early work showed that Natural Language Inference tasks are largely insensitive to permutations of word order (Parikh et al., 2016; Sinha et al., 2020). Pham et al. (2020) and Gupta et al. (2021) discuss this in greater detail, demonstrating that test-time word order perturbations applied to GLUE benchmark tasks have little impact on LM performance. Following up on this, Sinha et al. (2021), which our work builds on, found that *pretraining* on scrambled text appears to only marginally affect model performance. Most related to this study, Clouatre et al. (2021) introduce two metrics for gauging the local and global ordering of tokens in scrambled texts, observing that only the latter is altered by the perturbation functions found in prior literature. In experiments with GLUE, they find that local (sub-word) perturbations show a substantially stronger performance decay compared to global ones.

In this work, we present an in-depth analysis of these results, showing that LMs trained on scrambled text can actually retain word information and that – as for humans – their sensitivity to word order is dependent on a variety of factors such as the nature of the task and the locality of perturbation. While performance on some "understanding" evaluation tasks is not strongly affected by word order scrambling, the effect on others such as the Winograd Schema is far more evident.

9 Conclusion

Much discussion has resulted from recent work showing that scrambling text at different stages of testing or training does not drastically alter the performance of language models on NLU tasks. In this work, we presented analyses painting a more nuanced picture of such findings. Primarily, we demonstrate that, as far as altered pre-training is concerned, models still do retain a semblance of word order knowledge — largely at the local level. We show that this knowledge stems from cues in the altered data, such as adjacent BPE symbols and correlations between sentence length and content. The order in which shuffling is performed — before or after BPE tokenization — is influential in models' acquisition of word order, which calls for caution in interpreting previous results. Finally, we show that there exist NLU tasks that are far more sensitive to sentence structure as expressed by word order.

A Subword vs. word scrambling

B On biased sampling

We first split our vocab of size 5,000 into two halves, both of size 2500, such that the sum total of unigram frequencies of tokens in each half is roughly equivalent. Next, iterating over 100k BookCorpus sentences, we determine the sentence length l, for which there are an equivalent number of tokens in sentences with length $< l$ and sentences with length $>= l$. We then sample tokens from the first vocab half for sentences $< l$, and from the second vocab half for sentences with length $>= l$, 80% of the time; for the other 20%, we sample from the opposite half to introduce some overlap.

C Full UD results

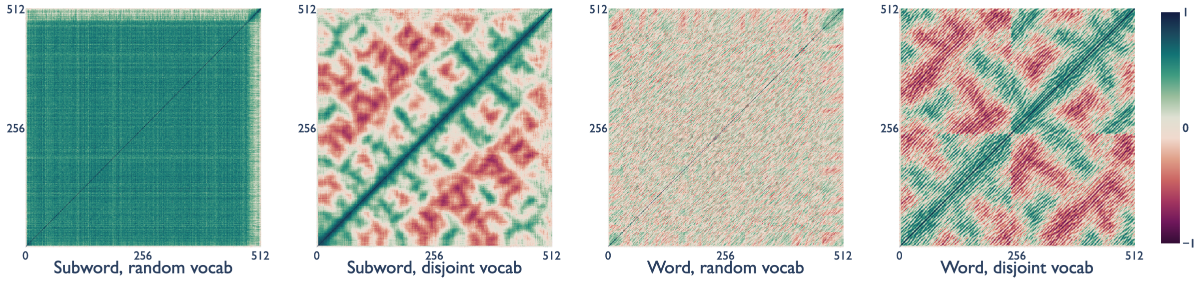

Figure 7: Pearson correlations, when scrambling by subword/word, with/without disjoint vocabularies. Disjoint vocabularies appear to induce patterns in position-position correlations, while scrambling at a word level induces ‘stripes’ of oscillating magnitude; this is likely due to position embeddings learning connections to adjacent tokens.

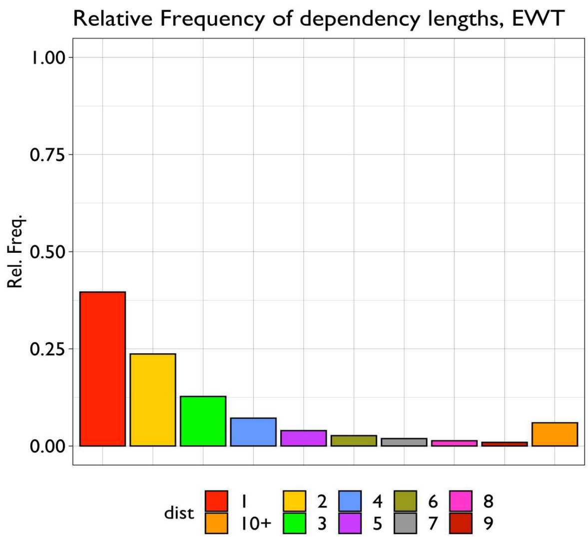

Figure 8: Relative frequencies of dependency relations in $UD_{English-EWT}$, at a dependency lengths indicated by the x-axis

An Empirical Study on Explanations in Out-of-Domain Settings

George Chrysostomou **Nikolaos Aletras**

Abstract

Recent work in Natural Language Processing has focused on developing approaches that extract faithful explanations, either via identifying the most important tokens in the input (i.e. post-hoc explanations) or by designing inherently faithful models that first select the most important tokens and then use them to predict the correct label (i.e. select-then-predict models). Currently, these approaches are largely evaluated on in-domain settings. Yet, little is known about how post-hoc explanations and inherently faithful models perform in out-of-domain settings. In this paper, we conduct an extensive empirical study that examines: (1) the out-of-domain faithfulness of post-hoc explanations, generated by five feature attribution methods; and (2) the out-of-domain performance of two inherently faithful models over six datasets. Contrary to our expectations, results show that in many cases out-of-domain post-hoc explanation faithfulness measured by sufficiency and comprehensiveness is higher compared to in-domain. We find this misleading and suggest using a random baseline as a yardstick for evaluating post-hoc explanation faithfulness. Our findings also show that select-then predict models demonstrate comparable predictive performance in out-of-domain settings to full-text trained models.[1]

1 Introduction

An explanation or rationale[2], typically consists of a subset of the input that contributes more to the prediction. Extracting faithful explanations is important for studying model behavior (Adebayo et al., 2020) and assisting in tasks requiring human decision making, such as clinical text classification (Chakrabarty et al., 2019), misinformation detection (Popat et al., 2018; Mu and Aletras, 2020) and legal text classification (Chalkidis et al., 2019, 2021). A faithful explanation is one which accurately represents the reasoning behind a model's prediction (Jacovi and Goldberg, 2020)

Two popular methods for extracting explanations are through feature attribution approaches (i.e. *post-hoc* explanation methods) or via inherently faithful classifiers (i.e. *select-then-predict* models). The first computes the contribution of different parts of the input with respect to a model's prediction (Sundararajan et al., 2017; Ribeiro et al., 2016; Shrikumar et al., 2017). The latter consists of using a rationale extractor to identify the most important parts of the input and a rationale classifier, a model trained using as input only the extractor's rationales (Bastings et al., 2019; Jain et al., 2020; Guerreiro and Martins, 2021).[3] Figure 1 illustrates the two approaches with an example.

Currently, these explanation methods have been mostly evaluated on in-domain settings (i.e. the train and test data come from the same distribution). However, when deploying models in real-world applications, inference might be performed on data from a different distribution, i.e. out-of-domain (Desai and Durrett, 2020; Ovadia et al., 2019). This can create implications when extracted explanations (either using post-hoc methods or through select-then-predict models) are used for assisting human decision making. Whilst we are aware of the limitations of current state-of-the-art models in out-of-domain predictive performance (Hendrycks et al., 2020), to the best of our knowledge, how faithful out-of-domain post-hoc explanations are has yet to be explored. Similarly, we are not aware how inherently faithful select-then-predict models generalize in out-of-domain settings.

Inspired by this, we conduct an extensive empirical study to examine the faithfulness of five

(a) Post-hoc explanation (b) Select-then-predict model

Figure 1: An example of rationale extraction using: (a) a feature attribution approach to identify the most important subset of the input (post-hoc explanation); and (b) using inherently faithful, select-then-predict models.

feature attribution approaches and the generalizability of two select-then-predict models in out-of-domain settings across six dataset pairs. We hypothesize that similar to model predictive performance, post-hoc explanation faithfulness reduces in out-of-domain settings and that select-then-predict performance degrades. Our contributions are as follows:

- To the best of our knowledge, we are the first to assess the faithfulness of post-hoc explanations and performance of select-then-predict models in out-of-domain settings.
- We show that post-hoc explanation sufficiency and comprehensiveness show misleading increases in out-of-domain settings. We argue that they should be evaluated alongside a random baseline as yardstick out-of-domain.
- We demonstrate that select-then-predict classifiers can be used in out-of-domain settings. They lead to comparable predictive performance to models trained on full-text, whilst offering inherent faithfulness.

2 Related Work

2.1 Rationale Extraction

Given a model $\mathcal{M}$, we are interested in explaining why $\mathcal{M}$ predicted $\hat{y}$ for a particular instance $\mathbf{x} \in \mathbf{X}$. An extracted rationale $\mathcal{R}$, should therefore represent as accurately as possible the most important subset of the input ($\mathcal{R} \in \mathbf{x}$) which contributed mostly towards the model's prediction $\hat{y}$.

Currently, there are two popular approaches for extracting rationales. The first consists of using feature attribution methods that attribute to the input tokens an importance score (i.e. how important an input token is to a model's $\mathcal{M}$ prediction $\hat{y}$). We can then form a rationale $\mathcal{R}$, by selecting the K most important tokens (independent or contiguous) as indicated by the feature attribution method. The second select-then-predict approach focuses on training inherently faithful classifiers by jointly training two modules, a *rationale extractor* and a *rationale classifier*, trained only on rationales produced by the extractor (Lei et al., 2016; Bastings et al., 2019; Treviso and Martins, 2020; Jain et al., 2020; Guerreiro and Martins, 2021). Recent studies have used feature attribution approaches as part of the rationale extractor (Jain et al., 2020; Treviso and Martins, 2020), showing improved classifier predictive performance.

2.2 Evaluating Rationale Faithfulness

Having extracted $\mathcal{R}$, we need to evaluate the quality of the explanation (i.e. how faithful that explanation is for a model's prediction). Typically, post-hoc explanations from feature attribution approaches are evaluated using input erasure (Serrano and Smith, 2019; Atanasova et al., 2020; Madsen et al., 2021). This approach masks segments of the input to observe if the model's prediction changed. DeYoung et al. (2020) proposed measuring the comprehensiveness and sufficiency of rationales as faithfulness metrics. A comprehensive rationale is one which is influential to a model's prediction, while a sufficient rationale that which is adequate for a model's prediction (DeYoung et al., 2020). The term *fidelity* is also used for jointly referring to comprehensiveness and sufficiency (Carton et al., 2020). Carton et al. (2020) suggested normalizing these metrics using the predictions of the model with a baseline input (i.e. an all zero embedding vector), to account for baseline model behavior. Select-then-predict models are inherently faithful, as their classification component is trained only on extracted rationales (Jain et al., 2020). A good measure for measuring rationale quality is by evaluating the predictive performance of the classifier trained only on the rationales (Jain et al., 2020; Treviso and Martins, 2020). A higher score entails that the extracted rationales are better when compared to those of a classifier with lower predictive performance.

2.3 Explainability in Out-of-Domain Settings

Given model $\mathcal{M}$ trained on an end-task, we typically evaluate its out-of-domain predictive performance on a test-set that does not belong to the same distribution as the data it was trained on (Hendrycks et al., 2020). Similarly, the model can also extract explanations $\mathcal{R}$ for its out-of-domain predictions.

Camburu et al. (2018) studied whether generating explanations for language inference match human annotations (i.e. plausible explanations). They showed that this is challenging in-domain and becomes more challenging in out-of-domain settings. In a similar direction, Rajani et al. (2019) and Kumar and Talukdar (2020) examined model generated explanations in out-of-domain settings and find that explanation plausibility degrades compared to in-domain. Kennedy et al. (2020) proposed a method for detecting model bias towards group identity terms using a post-hoc feature attribution approach. Then, they use them for regularizing models to improve out-of-domain predictive performance. Adebayo et al. (2020) have studied feature attribution approaches for identifying out-of-distribution images. They find that importance allocation in out-of-domain settings is similar to that of an in-domain model and thus cannot be used to detect such images. Feder et al. (2021) finally argued that explanations can lead to errors in out-of-distribution settings, as they may latch onto spurious features from the training distribution.

These studies indicate that there is an increasing need for evaluating post-hoc explanation faithfulness and select-then-predict performance in out-of-domain settings. To the best of our knowledge, we are the first to examine these.

3 Extracting Rationales

3.1 Post-hoc Explanations

We employ a pre-trained `BERT`-base and fine-tune it on in-domain training data. We then extract post-hoc rationales for both the in-domain test-set and two out-of-domain test-sets. We compute input importance using five feature scoring methods and a random baseline:

- **Random (RAND):** Random allocation of token importance.
- **Attention (α):** Token importance corresponding to normalized attention scores (Jain et al., 2020).
- **Scaled Attention ($\alpha\nabla\alpha$):** Attention scores α_i scaled by their corresponding gradients $\nabla\alpha_i = \frac{\partial\hat{y}}{\partial\alpha_i}$ (Serrano and Smith, 2019).
- **InputXGrad ($\mathbf{x}\nabla\mathbf{x}$):** Attributes input importance by multiplying the input with its gradient computed with respect to the predicted class, where $\nabla x_i = \frac{\partial\hat{y}}{\partial x_i}$ (Kindermans et al., 2016; Atanasova et al., 2020).
- **Integrated Gradients (IG):** Ranking words by computing the integral of the gradients taken along a straight path from a baseline input (zero embedding vector) to the original input (Sundararajan et al., 2017).
- **DeepLift:** Ranking words according to the difference between the activation of each neuron and a reference activation (zero embedding vector) (Shrikumar et al., 2017).

3.2 Select-then-Predict Models

We use two select-then-predict models:

- **HardKuma:** An end-to-end trained model, where the rationale extractor uses Hard Kumaraswamy variables to produce a rationale mask $\mathbf{z}$, which the classifier uses to mask the input (Bastings et al., 2019). Model training takes advantage of reparameterized gradients compared to `REINFORCE` style training employed by Lei et al. (2016) and has shown improved performance (Guerreiro and Martins, 2021).
- **FRESH:** We compute the predictive performance of a classifier trained on rationales extracted with feature attribution metrics (see

§3.1) using FRESH, following a similar approach to Jain et al. (2020). We extract rationales from an extractor by (1) selecting the top-k most important tokens (TOPK) and (2) selecting the span of length k with the highest overall importance (CONTIGUOUS).

We use `BERT`-base for the extraction and classification components of FRESH similar to Jain et al. (2020). However, for HardKuma we opt using a bi-`LSTM` (Hochreiter and Schmidhuber, 1997) as it provides comparable or improved performance over `BERT` variants (Guerreiro and Martins, 2021), even after hyperparameter tuning.[4]

4 Experimental Setup

4.1 Datasets

For evaluating out-of-domain model explanation, we consider the following datasets (see Table 1 and Appendix A for details):

SST: Stanford Sentiment Treebank (SST) consists of sentences tagged with sentiment on a 5-point-scale from negative to positive (Socher et al., 2013). We remove sentences with neutral sentiment and label the remaining sentences as negative or positive if they have a score lower or higher than 3 respectively (Jain and Wallace, 2019).

IMDB: The Large Movie Reviews Corpus consists of movie reviews labeled either as positive or negative (Maas et al., 2011; Jain and Wallace, 2019).

Yelp: Yelp polarity review texts. Similar to Zhang et al. (2015) we construct a binary classification task to predict a polarity label by considering one and two stars as negative, and three and four stars as positive.

Amazon Reviews: We form 3-way classification tasks by predicting the sentiment (negative, neutral, positive) of Amazon product reviews across 3 item categories: (1) Digital Music (**AmazDigiMu**); (2) Pantry (**AmazPantry**); and (3) Musical Instruments (**AmazInstr**) (Ni et al., 2019).

4.2 Evaluating Out-of-Domain Explanations

Post-hoc Explanations: We evaluate post-hoc explanations using:

Dataset	C	Splits
SST	2	6,920 / 872 / 1,821
IMDB	2	20,000 / 2,500 / 2,500
Yelp	2	476,000 / 84,000 / 38,000
AmazDigiMu	3	122,552 / 21,627 / 25,444
AmazPantry	3	99,423/ 17,546 / 20,642
AmazInstr	3	167,145 / 29,497 / 34,702

Table 1: Dataset statistics with number of classes (**C**) and train/development/test **splits**. For more details see Appendix A.

- **Normalized Sufficiency (NormSuff)** measures the degree to which the extracted rationales are adequate for a model to make a prediction (DeYoung et al., 2020). Following Carton et al. (2020), we bind sufficiency between 0 and 1 and use the reverse difference so that higher is better:

$$\text{Suff}(\mathbf{x}, \hat{y}, \mathcal{R}) = 1 - max(0, p(\hat{y}|\mathbf{x}) - p(\hat{y}|\mathcal{R}))$$
$$\text{NormSuff}(\mathbf{x}, \hat{y}, \mathcal{R}) = \frac{\text{Suff}(\mathbf{x}, \hat{y}, \mathcal{R}) - \text{Suff}(\mathbf{x}, \hat{y}, 0)}{1 - \text{Suff}(\mathbf{x}, \hat{y}, 0)} \quad (1)$$

  where $\text{Suff}(\mathbf{x}, \hat{y}, 0)$ is the sufficiency of a baseline input (zeroed out sequence) and $\hat{y}$ the model predicted class using the full text $\mathbf{x}$ as input.

- **Normalized Comprehensiveness (NormComp)** measures the influence of a rationale to a prediction (DeYoung et al., 2020). For an explanation to be highly comprehensive, the model's prediction after masking the rationale should have a large difference compared to the model's prediction using the full text. Similarly to Carton et al. (2020), we bind this metric between 0 and 1 and normalize it:

$$\text{Comp}(\mathbf{x}, \hat{y}, \mathcal{R}) = max(0, p(\hat{y}|\mathbf{x}) - p(\hat{y}|\mathbf{x}_{\backslash\mathcal{R}}))$$
$$\text{NormComp}(\mathbf{x}, \hat{y}, \mathcal{R}) = \frac{\text{Comp}(\mathbf{x}, \hat{y}, \mathcal{R})}{1 - \text{Suff}(\mathbf{x}, \hat{y}, 0)} \quad (2)$$

To measure sufficiency and comprehensiveness across different explanation lengths we compute the "Area Over the Perturbation Curve" (AOPC) following DeYoung et al. (2020). We therefore compute and report the average normalized sufficiency and comprehensiveness scores when keeping (for sufficiency) or masking (for comprehensiveness) the top 2%, 10%, 20% and 50% of tokens extracted by an importance attribution function.[5]

---

[4] See model details and hyper-parameters in Appendix B

[5] We also present results for each of these rationale lengths in Appendix F.

Table 2: AOPC Normalized Sufficiency and Comprehensiveness (higher is better) in-domain and out-of-domain for five feature attribution approaches and a random attribution baseline.

We omit from our evaluation the Remove-and-Retrain method (Madsen et al., 2021) as it requires model retraining. Whilst this could be applicable for in-domain experiments where retraining is important, in this work we evaluate explanation faithfulness in zero-shot out-of-domain settings.

Select-then-Predict Models: We first train select-then-predict models in-domain and then measure their predictive performance on the in-domain test-set and on two out-of-domain test-sets (Jain et al., 2020; Guerreiro and Martins, 2021). Our out-of-domain evaluation is performed without retraining (zero-shot). Similar to full-text trained models, we expect that predictive performance deteriorates out-of-domain. However, we assume that explanations from a select-then-predict model should generalize better in out-of-domain settings when the predictive performance approaches that of the full-text trained model.

We do not conduct human experiments to evaluate explanation faithfulness, since that is only relevant to explanation plausibility (i.e. how intuitive to humans a rationale is (Jacovi and Goldberg, 2020)) and in practice faithfulness and plausibility do not correlate (Atanasova et al., 2020).

5 Results

5.1 Post-hoc Explanation Faithfulness

Table 2 presents the normalized comprehensiveness and sufficiency scores for post-hoc explanations on in-domain and out-of-domain test-sets, using five feature attribution methods and a random baseline. For reference, we include the averaged F1 performance across 5 random seeds, of a `BERT`-base model finetuned on the full text and evaluated in- and out-of-domain (Full-text F1).[6]

In-domain results show that feature attribution performance varies largely across datasets. This is in line with the findings of Atanasova et al. (2020) and Madsen et al. (2021) when masking rationales (i.e. comprehensiveness). We find the only exception to be $\alpha\nabla\alpha$, which consistently achieves the highest comprehensiveness and sufficiency scores across all in-domain datasets. For example $\alpha\nabla\alpha$ evaluated on in-domain AmazDigiMu, results in sufficiency of 0.56 compared to the second best of 0.39 with IG.

Contrary to our expectations, results show that post-hoc explanation sufficiency and comprehensiveness are in many cases higher in out-of-domain test-sets compared to in-domain. For example using DeepLift, comprehensiveness for the in-domain test-set in Yelp (0.16) is lower compared to the out-of-domain test-sets (0.21 for SST and 0.23 for IMDB). This is also observed when measuring sufficiency with $\alpha\nabla\alpha$, scoring 0.32 when tested in-domain on Yelp and 0.45 for the out-of-domain SST test-set.

Apart from increased sufficiency and comprehen-

---

[6] We report predictive performance for all models and standard deviations in the Appendix.

siveness scores in out-of-domain post-hoc explanations, we also observe increased scores obtained by our random baseline. In fact, the random baseline outperforms several feature attribution approaches in certain cases in out-of-domain settings . As an example, consider the case where the model has been trained on AmazInstr and tested on AmazPantry. Our random baseline achieves a comprehensiveness score of 0.27 while α, DeepLift, $x\nabla x$ perform similarly or lower (0.22, 0.25 and 0.27 respectively). Similarly, using a model trained on Yelp and tested on SST, the random baseline produces equally sufficient rationales to $x\nabla x$ and IG, with all of them achieving 0.41 normalized sufficiency. A glaring exception to this pattern is $\alpha\nabla\alpha$, which consistently outperforms both the random baseline and all other feature attribution approaches in in- and out-of-domain settings, suggesting that it produces the more faithful explanations. For example with out-of-domain AmazPantry test data, using a model trained on AmazInstr results in sufficiency scores of 0.39 with $\alpha\nabla\alpha$. This is a 0.15 point increase compared to the second best ($x\nabla x$ with 0.24).

We recommend considering *a feature attribution for producing faithful explanations out-of-domain, if it only scores above a baseline random attribution. We suggest that the higher the deviation from the random baseline, the more faithful an explanation is.*

5.2 Select-then-predict Model Performance

HardKuma: Table 3 presents the F1-macro performance of HardKuma models (Bastings et al., 2019) and the average rationale lengths (the ratio of the selected tokens compared to the length of the entire sequence) selected by the model. For reference, we also include the predictive performance of a full-text trained bi-`LSTM`. Results are averaged across 5 runs including standard deviations in brackets.

As expected, predictive performance of HardKuma models degrades when evaluated on out-of-domain data. Surprisingly, though, we find that their performance is not significantly different (t-test; p-value > 0.05) to that of the full-text `LSTM` in 9 out of the 12 out-of-domain dataset pairs. For example, by evaluating the out-of-domain performance of a HardKuma model trained on AmazDigiMu on the AmazPantry test-set, we record on average a score of 54.3 F1 compared to 55.3 with an `LSTM` classifier trained on full text. We also observe that HardKuma models trained on SST and IMDB generalize comparably to models trained on full-text when evaluated on Yelp, however the opposite does not apply. Our assumption is that HardKuma models trained on Yelp, learn more domain-specific information due to the large training corpus (when compared to training on IMDB and SST) so they fail to generalize well out-of-domain.

Train	**Test**	**Full-text F1**	**HardKuma F1**	**L (%)**
SST	SST	81.7	77.6	56.8
	IMDB	71.9	**65.7**	39.5
	Yelp	68.7	**67.7**	32.7
IMDB	IMDB	87.4	82.0	1.9
	SST	77.5	73.6	16.8
	Yelp	41.0	**47.2**	3.1
Yelp	Yelp	96.0	92.4	7.4
	SST	80.4	72.4	14.1
	IMDB	84.5	73.3	4.7
AmazDigiMu	AmazDigiMu	67.6	66.8	18.4
	AmazInstr	54.2	**53.3**	25.8
	AmazPantry	55.3	**54.7**	27.8
AmazPantry	AmazPantry	67.9	66.6	18.9
	AmazDigiMu	50.9	**51.0**	11.2
	AmazInstr	55.9	**57.4**	18.2
AmazInstr	AmazInstr	67.2	**66.7**	19.2
	AmazDigiMu	54.3	**53.7**	13.9
	AmazPantry	61.1	**59.5**	24.4

Table 3: F1 macro performance (five runs) for HardKuma models and the selected rationale length (L). **Bold** denotes no significant difference between HardKuma and Full-text (t-test; $p > 0.05$). For clarity, we include F1 scores with standard deviations in Appendix C.

Results also show, that *the length of rationales selected by HardKuma models depend on the source domain, i.e. training HardKuma on a dataset which favors shorter rationales, leads to also selecting shorter rationales out-of-domain.* For example, in-domain test-set explanation lengths are on average 56.8% of the full-text input length for SST. In comparison, training a model on Yelp and evaluating on SST results in rationale lengths of 14.1%. We observe that *in certain cases, HardKuma models maintain the number of words, not the ratio to the sequence* in out-of-domain settings. For example, in-domain Yelp test-set rationales are about 11 tokens long that is the similar to the length selected when evaluating on IMDB using a model trained on Yelp. This is also observed where in-domain AmazInstr test-set rationales are on average 5 tokens long, which

Table 4: Average F1 macro performance of FRESH models (five runs) with the a priori defined rationale length in the brackets. **Bold** denotes no significant difference between FRESH and Full-text (t-test; p > 0.05). For clarity, we present F1 scores with standard deviations in Appendix D.

is the same rationale length when evaluating on AmazDigiMu using a model trained on AmazInstr.

In general, our findings show that in the majority of cases, using HardKuma in out-of-domain data results to comparable performance with their full-text model counterparts. This suggests that *HardKuma models can be used in out-of-domain settings, without significant sacrifices in predictive performance whilst also offering faithful rationales.*

FRESH: Table 4 shows the averaged F1-macro performance across 5 random seeds for FRESH classifiers on in- and out-of-domain using TopK rationales.[7] We also include the a priori defined rationale length in parentheses and the predictive performance of the Full-Text model for reference.[8]

We first observe that in-domain predictive performance varies across feature attribution approaches with attention-based metrics ($\alpha\nabla\alpha$, α) outperforming the gradient-based ones ($x\nabla x$, IG), largely agreeing with Jain et al. (2020). We also find that $\alpha\nabla\alpha$ and DeepLift are the feature attribution approaches that lead to the highest predictive performance across all datasets.

As we initially hypothesized, performance of FRESH generally degrades when testing on out-of-domain data similarly to the behavior of models trained using the full text. The only exceptions are when using $x\nabla x$ and IG in IMDB. We argue that this is due to these feature attribution methods not being able to identify the appropriate tokens relevant to the task using a rationale length 2% of the original input. Increasing the rationale length to 20% (SST) and 10% (Yelp) also increases the performance. Results also suggest that $\alpha\nabla\alpha$ and DeepLift outperform the rest of the feature attributions, with $\alpha\nabla\alpha$ being the best performing one in the majority of cases. In fact when using $\alpha\nabla\alpha$ or DeepLift, the out-of-domain performance of FRESH is not significantly different to that of models trained on full text (t-test; p-value > 0.05) in 5 cases. For example, a FRESH model trained on AmazPantry and evaluated on AmazInstr records 63.6 F1 macro (using DeepLift) compared to 64.5 obtained by a full-text model. However, this does not apply to the other feature attribution methods (α; $x\nabla x$; IG).

To better understand this behavior, we conduct a correlation analysis between the importance rankings using any single feature attribution from (1) a model trained on the same domain with the evaluation data; and (2) a model trained on a different domain (out-of-domain trained model). High correlations suggest that if a feature attribution from an out-of-domain trained model produces similar importance distributions with that of an in-domain model, it will also lead to high predictive performance out-of-domain. Contrary to our initial

---

[7] For clarity we include standard deviations and Contiguous results in Appendix D

[8] When evaluating out-of-domain, we use the average rationale length of the dataset we evaluate on. This makes FRESH experiments comparable with those of HardKuma.

assumption we found that the lower the correlation, the higher the predictive performance with FRESH. Results show low correlations when using $\alpha\nabla\alpha$ and DeepLift (highest FRESH performance). Surprisingly, IG and $x\nabla x$ (lowest FRESH performance) showed consistently strong correlations across all dataset pairs. Thus, we conclude that lower correlation scores indicate lower attachment to spurious correlations learned during training. We expand our discussion and show results for the correlation analysis in Appendix E.

Our findings therefore suggest that *using FRESH in out-of-domain settings, can result to comparable performance with a model trained on full-text. However this highly depends on the choice of the feature attribution method.*

HardKuma vs. FRESH: We observe that HardKuma models are not significantly different compared to models trained on the full text in out-of-domain settings in more cases, when compared to FRESH (9 out of 12 and 5 out of 12 respectively). However, *FRESH with $\alpha\nabla\alpha$ or DeepLift records higher predictive performance compared to HardKuma models (both in- and out-of-domain) in all cases*. We attribute this to the underlying model architectures, as FRESH uses `BERT` and HardKuma a bi-`LSTM`. As we discussed in §3.2, we attempted using `BERT` for HardKuma models in the extractor and classifier similar to Jain et al. (2020). However, the performance of HardKuma with `BERT` is at most comparable to when using a bi-`LSTM` similar to findings of Guerreiro and Martins (2021).

5.3 Correlation between Post-hoc Explanation Faithfulness and FRESH Performance

We hypothesize that a feature attribution with high scores for sufficiency and comprehensiveness, should extract rationales that result in high FRESH predictive performance. We expect that if our hypothesis is valid, faithfulness scores can serve as early indicators of FRESH performance, both on in-domain and out-of-domain settings.

Table 5 shows the Spearman's ranking correlation (ρ) between FRESH F1 performance (see Table 4) and comprehensiveness and sufficiency (see Table 2). Correlation is computed using all feature scoring methods for each dataset pair. Results show that only 4 cases achieve statistically significant correlations (p-value < 0.05) with only 3 out-of-domain and mostly between sufficiency and FRESH performance. We do not observe high correlations with comprehensiveness which is expected, as comprehensiveness evaluated the rationale's influence towards a model's prediction. Our findings refute our initial hypothesis and suggest that *there is no clear correlation across all cases, between post-hoc explanation faithfulness and FRESH predictive performance. Therefore, sufficiency and comprehensiveness scores cannot be used as early indicators of FRESH predictive performance.*

Train	**Test**	ρ	
	FRESH	**Sufficiency**	**Comprehen.**
SST	SST	**0.97**	0.15
	IMDB	0.36	0.21
	Yelp	**0.90**	0.56

Table 5: Spearman's ranking correlation (ρ) between FRESH performance and comprehensiveness, sufficiency across all feature attribution approaches. **Bold** denotes statistically significant (p-value ≤ 0.05) correlations.

6 Qualitative Analysis

Table 6 presents examples from a qualitative analysis we performed, aimed at better understanding out-of-domain post-hoc explanations. Rows with highlighted text in blue are from a model trained in the same domain as the presented example (ID), whilst those with highlighted text in red are from models trained on a different domain. Importance scores are computed using scaled attention ($\nabla\alpha\nabla$).

In Example (1), we observe that models trained on two closely related tasks (AmazInstr and AmazDigiMu) place more importance to the phrase "sound good". On the contrary, the model trained on AmazPantry which has not encountered such phrases during training, mostly focuses on "Work great". This is expected as the term "sound" is not typical of pantry reviews. Similarly, in Example

	$\mathcal{M}$ **Trained On**	**Example**
(1)	AmazInstr (ID)	Work great and sound good
	AmazDigiMu	Work great and sound good
	AmazPantry	Work great and sound good
(2)	AmazPantry (ID)	Delicious and at a good price . would recommend .
	AmazDigiMu	Delicious and at a good price . would recommend .
	AmazInstr	Delicious and at a good price . would recommend .
(3)	SST (ID)	A painfully funny ode to bad behavior
	IMDB	A painfully funny ode to bad behavior
	Yelp	A painfully funny ode to bad behavior
(4)	Yelp (ID)	The kouign - amann is so amazing ... must taste to appreciate .
	SST	The kouign - amann is so amazing ... must taste to appreciate .
	IMDB	The kouign - amann is so amazing ... must taste to appreciate .

Table 6: True examples of highlights with $\alpha\nabla\alpha$ using a model trained on data from the same distribution as the example (ID; with blue highlights) and two models trained on a different dataset (with red highlights).

(2) from the AmazPantry dataset, the in-domain model focuses on a domain-specific word "delicious". On the contrary, the two models trained on music-related tasks focus on more generic terms such as "good" and "would recommend". In Example (3) the model trained on Yelp focuses mostly on the word "behavior", a term we consider more relevant to restaurant reviews rather than movie reviews. In comparison, the other models which are both trained on movie reviews focus both on the term "funny". In Example (4), again the two movie-review models focus on more generic terms (i.e. "amazing") compared to "must taste" that the model trained in-domain (i.e. Yelp) identifies as important.

Overall, results show that rationales from models applied to a different domain (other than that they were trained for), comprise of terms that are mostly present within the domain they were trained for. This can partly explain the performance of out-of-domain FRESH classifiers. Our assumption, similar to (Adebayo et al., 2020), is that a model's inability to generalize to other domains, is based on the model latching on to specific features from the training dataset.

7 Conclusion

We conducted an extensive empirical study to assess the faithfulness of post-hoc explanations (i.e. using feature attribution approaches) and performance of select-then-predict (i.e. inherently faithful) models in out-of-domain settings. Our findings highlight, that using sufficiency and comprehensiveness to evaluate post-hoc explanation faithfulness out-of-domain can be misleading. To address this issue, we suggest comparing faithfulness of post-hoc explanations to a random attribution baseline for a more robust evaluation. We also show that select-then-predict models, which are inherently faithful, perform surprisingly well in out-of-domain settings. Despite performance degradation, in many cases their performance is comparable to those of full-text trained models. In future work, we aim to explore methods for improving the evaluation of faithfulness for out-of-domain post-hoc explanations.

A Dataset Characteristics

Table 7 presents extended data characteristics for all datasets. We present information across the three data splits, including: (1) The average sequence length; (2) The number of documents in each split and (3) the number of documents under each label.

Our dataset selection was highly motivated for also examining the differences when we have gradual shifts in-domain. For example for the triplet SST - IMDB - YELP, two datasets are closely associated (SST, IMDB) as they are movie reviews, whilst Yelp is a task for classifying restaurant reviews. Similarly, AmazDigiMu and AmazInstr share similar characteristics, as they are reviews about items related to music. On the contrary, AmazPantry consists of reviews about pantry items. This is also the primary reason why we focused on text classification tasks, as it is easier to control for the output and other parameters, whilst allowing for control over the task it-self.

Dataset		Train	Dev	Test
SST	Avg. Seq. Length	17	17	17
	No. of documents	6,920	872	1,821
	Docs in label-0	3,310	428	912
	Docs in label-1	3,610	444	909
IMDB	Avg. Seq. Length	241	248	247
	No. of documents	20,000	2,500	2,500
	Docs in label-0	9,952	1,275	1,273
	Docs in label-1	10,048	1,225	1,227
Yelp	Avg. Seq. Length	154	154	153
	No. of documents	476,000	84,000	38,000
	Docs in label-0	238,000	42,000	19,000
	Docs in label-1	238,000	42,000	19,000
AmazDigiMu	Avg. Seq. Length	38	39	38
	No. of documents	122,552	21,627	25,444
	Docs in label-0	2,893	510	601
	Docs in label-1	4,907	866	1,019

	Docs in label-2	144,913	25,574	30,087

Table 7: Extended dataset characteristics

B Models and Hyper-parameters

For feature attributions: We use `BERT`-base with pre-trained weights from the Huggingface library (Wolf et al., 2020). We use the AdamW optimizer (Loshchilov and Hutter, 2017) with an initial learning rate of $1e-5$ for fine-tuning `BERT` and $1e-4$ for the fully-connected classification layer. We train our models for 3 epochs using a linear scheduler with 10% of the data in the first epoch as warm-up. We also use a grad-norm of 1 and select the model with the lowest loss on the development set. All models are trained across 5 random seeds and we report the average and standard deviation. We present their test-set performance in Table 8 and their development set performance in Table 9.

For FRESH: For the rationale extractor, we use the same model for extracting rationales from feature attributions. For the classifier (trained only on the extracted rationales), we also use `BERT`-base with the same optimizer configuration and scheduler warm-up steps. We also use a grad-norm of 1 and select the model with the lowest loss on the development set. We train across 5 random seeds for 5 epochs.

In Table 8 we present full-text `BERT`-base F1-macro scores averaged across 5 random seeds with standard deviations included in the brackets. Additionally, we present the mean Expected Calibration Error (ECE) scores. Finally, in Table 9 we present the in-domain F1-macro performance and loss on the development set.

For HardKuma: We use the 300-dimensional pre-trained GloVe embeddings from the 840B release (Pennington et al., 2014) as word representations and keep them frozen during training. The rationale extractor (which generates the rationale mask z) is a 200-d bi-directional `LSTM` layer (bi-`LSTM`) (Hochreiter and Schmidhuber, 1997) similar to (Bastings et al., 2019; Guerreiro and Martins, 2021). We use the Adam optimizer (Kingma and Ba, 2014) for all models with a learning rate between $1e-5$ and $1e-4$ and a weight decay of $1e-5$. We also enforce a grad-norm of 5 and train for 20 epochs across 5 random seeds. Similar to Guerreiro and Martins (2021) we select the model with the highest F1-macro score on the development set and find that tuning the Lagrangian relaxation algorithm parameters beneficial to model predictive performance. We also attempted training HardKuma models with `BERT`-base, similar to Jain et al. (2020), however we found performance to be at best comparable with our `LSTM` variant, as in Guerreiro and Martins (2021), even after hyperparameter tuning.

Trained On	Tested On	F1	ECE

Table 10: F1 macro performance and Expected Calibration Error (ECE) of a full-text `LSTM` classifier trained on an in-domain dataset and tested on their in-domain test-set and two other out-of-domain datasets.

Kuma performance with standard deviations, and expected calibration error (ECE), across five runs.

D FRESH - Extended

Tables 12 and 13 presents FRESH F1 macro performance and Expected Calibration Error (ECE) for classifiers trained on TopK and Contiguous rationales respectively, with standard deviation in brackets. We include the a priori defined rationale length in the brackets (.%) and for reference, the ID performance of the Full-Text model (as also seen in Table 8).

Comparing with FRESH performance with Contiguous rationales rather than TopK (see Table 12), we first observe that performance degrades for most feature attribution methods. These findings are largely in agreement with those of Jain et al. (2020). However, $x\nabla x$ and IG, which perform poorly with TopK, record surprisingly better scores with Contiguous type rationales. For example, in-domain performance with IG becomes comparable with $\alpha\nabla\alpha$ in in-domain IMDB (83.2 with $\alpha\nabla\alpha$ and 82.5 with IG). This is in sharp contrast with TopK, where IG recorded an F1 score of only 59.7, compared to 87.9 of $\alpha\nabla\alpha$.

These findings also hold in out-of-domain settings, where $\alpha\nabla\alpha$, α and DeepLift result in poorer FRESH performance with Contiguous type rationales, compared to TopK. However, IG and in many cases $x\nabla x$ improves. For example with TopK rationales, evaluating on Yelp using IG from a model trained on IMDB, results on an F1-score of 69.1. On the contrary, with Contiguous rationales and the same set-up, IG results in FRESH performance of 87.0.

Our findings lead us to assume that, *the rationale type has a large impact on FRESH performance, both in-domain and on out-of-domain settings. Certain feature attribution methods benefit from one type of rationales (e.g. DeepLift with TopK), whilst others from another (e.g. IG with Contiguous).*

E Extended Analysis

E.1 Correlation of Rankings

We examine why $x\nabla x$ and IG, do not perform as well as DeepLift and $\alpha\nabla\alpha$ when using FRESH. We therefore conduct a study to gain better understand this. We first fix the domain of the data we evaluate on and then compute the correlation between importance rankings using any single feature attribution from: (1) a model trained on the same domain with the evaluation data and (2) a model from trained on a different distribution (out-of-domain trained model). High correlations suggest that a feature attribution from an out-of-domain trained model, produce similar importance distributions with that of an in-domain model (i.e. both attend to similar tokens to make a prediction). Therefore, we assume that this will lead to high predictive performance out-of-domain. In Figure 2 we show Spearman's ranking correlation across dataset pairs, between a model trained on the same distribution as the evaluation data (ID) and an out-of-domain trained model (OOD), such that (ID <-> OOD).

As expected, the random baseline produced almost no correlation between models. An interesting observation is that two of the gradient-based methods ($x\nabla x$ and IG) produce strongly correlated rankings. This suggests that these two metrics produce generalizable rankings irrespective of the domain shift, when comparing to the remainder of the feature attribution approaches. Surprisingly, Deeplift importance rankings exhibit almost low to no correlation betweenen them, despite being also gradient-based. We hypothesize that this happens because DeepLift considers a baseline input to compute its importance distribution, which highly depends on the model and as such is de-facto nor-

malized and perhaps generalizes better.

α for out-of-domain detection?: An interesting case is that of α, where we observe moderate to strong correlations across all test-cases. What is more evident, is that in the OOD tuples we considered, it appears that stronger correlations appear where the OOD task and the ID task are closer together. For example in the case of SST and IMDB (both sentiment analysis tasks for movie reviews), α produces a strong correlation (0.68). This contrasts the moderate correlation of 0.58 between SST and Yelp, which is for restaurant reviews. This is also evident in the case of AmazDigiMu and AmazInstr, where both tasks are for review classification, but for musical related purchases. They both score strong correlations between them and moderate correlations with reviews for pantry purchases (AmazPantry). This observation might suggest, that *using these correlation metrics with α might be an indicator of the degree of task-domain-shift*. Our observation is also supported by the

Table 15: Agreement in tokens at 10% rationale length between a feature attribution from an ID model tested on ID and the same feature attribution trained on an OOD dataset and tested on ID.

findings of Adebayo et al. (2020), who show that feature attributions are good indicators of detecting spurious correlation signals in computer vision tasks.Considering $\alpha\nabla\alpha$ we observe a wide range of correlations, ranging from low in the AmazInstr-AmazDigiMu pair to strong in the AmazPantry-AmazInstr pair, which we cannot interpret as something meaningful.

Correlation values and FRESH: We first observe that the lowest correlated feature attributions $\alpha\nabla\alpha$ and DeepLift perform the better on FRESH, followed by α which displays moderate correlations and at the end of the spectrum the two gradient-based methods which display high correlations. Contrary to our initial assumption, this suggests that the attributions which generalize better (i.e. return rationales that result in higher FRESH performance) are those which exhibit low to no correlations.

Agreement at different rationale lengths: As the correlation analysis considers the entire length of the sequence, we now examine a scenario where we have a priori defined rationale lengths. Similarly to the correlation analysis, we now compute the agreement in tokens between ID feature attribution rankings to those of an OOD trained model. In Tables 14, 15 and 16 we therefore show the token agreement between in-domain and out-of-domain post-hoc explanations (on the same data) for 2%, 10% and 20% rationale lengths.

Our findings show that across all rationale lengths, results largely agree with the correlation analysis. The two gradient-based methods exhibit higher agreement than the remainder, with $\alpha\nabla\alpha$ and DeepLift recording the lowest agreements. Surprisingly, the poorest performers on out-of-domain FRESH record the highest agreement in tokens with in-domain models. Whilst this suggests that they generalize better, we believe that the inhibiting factor to their performance is their limited in-domain capabilities (i.e. they record the lowest in-domain FRESH performance with TopK).

F Post-hoc Explanation Faithfulness - Extended

In Tables 17, 18 and 19, we present post-hoc explanation sufficiency and comprehensiveness scores at 2%, 10% and 20% rationale lengths.

Abstract

Open Information Extraction (OpenIE) is the task of extracting *(subject, predicate, object)* triples from natural language sentences. Current OpenIE systems extract all triple slots independently. In contrast, we explore the hypothesis that it may be beneficial to extract triple slots iteratively: first extract easy slots, followed by the difficult ones by conditioning on the easy slots, and therefore achieve a better overall extraction.

Based on this hypothesis, we propose a neural OpenIE system, MILIE, that operates in an iterative fashion. Due to the iterative nature, the system is also modular—it is possible to seamlessly integrate rule based extraction systems with a neural end-to-end system, thereby allowing rule based systems to supply extraction slots which MILIE can leverage for extracting the remaining slots. We confirm our hypothesis empirically: MILIE outperforms SOTA systems on multiple languages ranging from Chinese to Arabic. Additionally, we are the first to provide an OpenIE test dataset for Arabic and Galician.

1 Introduction

Open Information Extraction (OpenIE) aims to extract structured facts in the form of *(subject, relation, object)*-triples from natural language sentences (Etzioni et al., 2008). For example, given a sentence, *"Barrack Obama became the US President in the year 2008"*, an OpenIE system is expected to extract the following triples: (*Barrack Obama*; *became*; *US President*) and (*Barrack Obama*; *became US President in*; *2008*). We refer to subject, predicate and the object of the triple as slots of a triple. OpenIE extractions are schema-free, human understandable intermediate representations of facts in source texts (Mausam, 2016). They are useful in a variety of information extraction end tasks such as summarization (Xu and Lapata, 2021), question answering (Khot et al., 2017; Yan et al., 2018) and automated schema extraction (Nimishakavi et al., 2016).

The various slots of a triple are dependent on each other and hence an error in one slot renders the entire extraction unusable. We hypothesize that triple extraction errors largely stem from the difficulty of extracting certain slots of a triple and said difficulty may depend on the sentence construction and the language. For example, *"Barrack Obama became the US President in the year 2008"* contains two triples *(Barrack Obama; became; US President)* and *(Barrack Obama; became US President in; 2008)*. Extracting the predicate, *"became US President in"*, for the second triple is tricky, because the object of the first triple (US President) overlaps with the predicate of the second triple. But if the extraction system was provided with the object, *(2008)*, and then asked to extract a triple conditioned on this object, the predicate extraction would be easier.

This is precisely the hypothesis we wish to investigate —is it easier to extract certain slots of a triple, say subjects, compared to other slots, such as objects, and is it possible to improve performance by leveraging specific slot extraction orders?

Given the hypothesis, we propose MILIE, a Modular & Iterative multiLingual open Information Extraction system, which iteratively extracts the different slots of a triple. The iterative nature allows for (1) studying the effects of a slot extractions on the remaining extractions, (2) extracting easier triple slots followed by harder ones, (3) aggregating different slot extraction orders as a mixture of experts, and (4) integrating slots supplied by an external rule-based system, resulting in a hybrid system. The latter offers a system that combines the best of neural and rule based systems, e.g. by using a rule-based system to extract high precision slots on which the neural system is conditioned.

We empirically confirm our hypothesis: the iterative nature of MILIE outperforms several SOTA

systems. It proves especially useful for zero-shot multilingual extraction, which we evaluated on five different low resource languages. Additionally we show how MILIE can leverage rule-based slot extraction by conditioning on them to predict the remaining parts of the triple. Therefore MILIE is a boon for existing applications wishing to transition from a rule based information extraction system to a neural one, because MILIE would allow using the rule-based system to compensate for the lack of exhaustive training data. Finally, we perform linguistic analyses that uncovers useful insights on how different languages either make it easy or difficult for OpenIE systems to extract individual elements of the triple.

Our contributions are summarized as follows:

1. We propose MILIE, a multilingual OpenIE system that iteratively extracts the different slots of a triple.

2. We carry out extensive experiments on a variety of languages (English, Chinese, German, Arabic, Galician, Spanish and Portuguese) and demonstrate that MILIE outperforms recent SOTA systems by a wide margin, especially on languages other than English.

3. We perform an extensive analysis based on ablation studies and uncover interesting insights about the nature of OpenIE task in different languages.

2 MILIE

The backbone of our system is the iterative procedure (Section 2.1), which allows us to investigate our hypothesis. The iterative procedure allows us to extract triple slots in various pathway orders, which results in a series of possible aggregation schemes (Section 2.2). To create a strong iterative system, the training paradigm (Section 2.3 needs to consider two aspects: (1) it needs to prepare incomplete triple extractions which represent incomplete triple extractions the system is expected to predict; (2) it creates negative samples that allow for teaching the system when to not continue with an extraction due to a prior error. With the iterative nature we also integrate rule-based systems (Section 2.4) as well as elegantly handle the specific case of n-ary extractions, where more than 3 slots need to be extracted (Section 2.5).

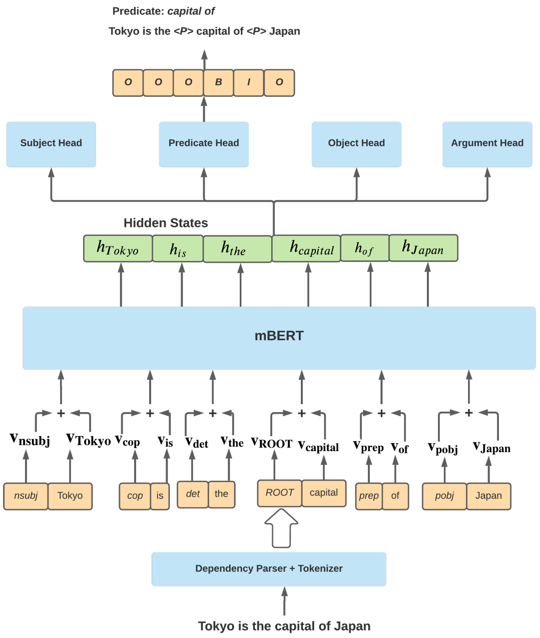

Figure 1: MILIE system architecture. An input sequence is is tokenized and, optionally, dependency parsed. This is given to a BERT-based transformer, which outputs a hidden state for each token. The hidden states are given to each of the extraction heads, here to the predicate head. This head marks the location of the predicate in the sequence. The system then proceeds to extract the other slots, see Figure 2.

2.1 Iterative Prediction

To implement the iterative nature of our system, we use a BERT-based transformer (Devlin et al., 2019) as the base building block. On top of this block, we add a total of four neural networks blocks in parallel, which we refer to as heads and which are each in charge of extracting a particular triple slot. Concretely, we have the heads f_s, f_o, f_p, f_a, which are in charge of predicting $s$ubject, $o$bject, $p$redicate and $a$rgument, respectively. The argument head is an extra feature, which is needed for n-ary extractions that occur in some datasets, where in addition to the triple there might be an argument that modifies the triple, e.g., a temporal phrase.

Given an input sequence of words of length N, $S = w_1, \cdots, w_N$, the task for each extraction head is framed as a BIO tagging problem. For this, each output head outputs a label l_i for token w_i, where $l_i \in \{B, I, O\}$, $i = 1 \cdots N$ (see Figure 1 for the architecture). The output heads use the final transformer hidden state and predict labels denoted by L_s, L_o, L_p, L_a where $L_{(\cdot)} = l_1, l_2, \cdots l_N$.

By having different extraction heads, we identify extraction slots iteratively. During prediction

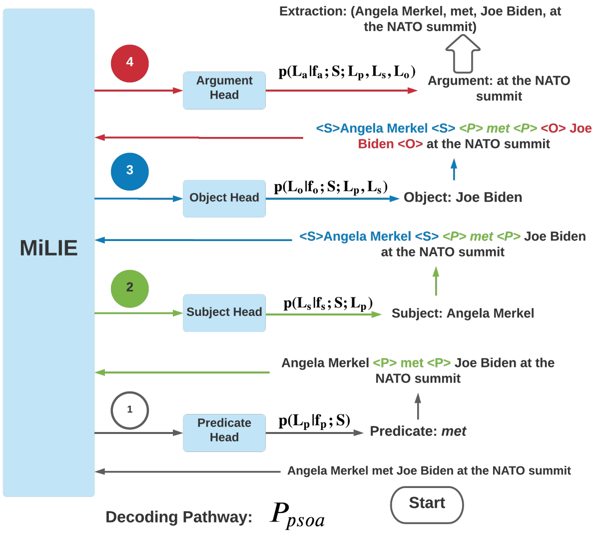

Figure 2: Iterative extraction dynamics for decoding pathway P_{psoa}. The numbers indicate the iteration number. Iterations are color coded, black is the predicate extraction, green subject extraction, blue object extraction and red argument extraction.

time, along with the input sentence, the model also expects extractions predicted by the previous iterations. To provide this information we add special symbols to the sentence that explicitly mark the previous extractions in the sentence. For example, we surround the predicate with the symbol <*P*>, subject with <*S*> and object with <*O*>. For example, for predicting the object given the predicate extracted from previous iteration, the extracted predicate is marked in the sentence using the <*P*> symbol and the sentence is consequently passed through the transformer for predicting the object using the object head. We always extract the arguments at the last iteration, therefore we do not mark the arguments in the sentence.[1]

Finally, we add the option to attach a dependency tag t_i to each word w_i in the sequence. This additional information may allow the system to more effectively learn how to extract triples. We use a language specific dependency tagger for obtaining the tags. We target languages, which are low resource for OpenIE, but could be high resource for other tasks, such as PoS tagging or dependency parsing. For a graphical overview of the MILIE architecture, see Figure 1.

2.2 Aggregating Decoding Pathways

The order in which the different triple parts are extracted can be varied. This allows us to investigate the challenge of extracting triple elements in specific order on different languages. Additionally different pathways aid different kinds of extractions and combining them results in a richer set of extractions. Choosing a particular order defines a decoding pathway P_{uvxy} as a sequence of output heads where $u, v, x, y \in \{s, p, o, a\}$. For example, the decoding pathway P_{spoa} denotes a sequence of output functions (f_s, f_p, f_o, f_a).

Fixing the n-ary argument extraction in the final iteration we obtain the following six decoding pathways- $P_{spoa}, P_{sopa}, P_{psoa}, P_{posa}, P_{ospa}, P_{opsa}$. Let's assume the decoding pathway P_{psoa}: predicates are extracted first, then for each predicate, subjects are extracted, then for each (predicate, subject) pair objects are extracted and finally for every extracted (predicate, subject, object) tuple all the n-ary arguments are extracted. This extraction procedure preserves the relationships between the extracted elements resulting in correctly extracting multiple triples. Figure 2 illustrates this procedure.

We hypothesize that some triples are easier to predict if, e.g., the predicate is extracted first while for others subject first would work well. This could differ from triple to triple, but also with different languages. Consequently, some decoding pathways might be more error prone than others. This leads to two questions: (1) Which pathways are best? (2) Can we improve recall by aggregating triples using different decoding pathways?

We propose a simple algorithm we term as *Water Filling* (WF) for aggregating the extractions. This is inspired by the power allocation problem in the communication engineering literature (Kumar et al., 2008). Imagine a thirsty person with access to different pots of water with varying levels of purity and with the caveat that the amount of water is inversely proportional to the purity. The natural solution is to first drink the high purity water and move on to the pots in decreasing level of purity until the thirst is quenched. We use the same idea. Treating each decoding pathways as an expert, we assume that the triples extracted by all 6 pathways are more accurate compared to those extracted by only 5 pathways, 4 pathways and so on. This can be thought of as triples obtaining votes from experts. Starting with an empty set, for each sentence we start adding triples to the set in the

---

[1] Preliminary experiments suggested that predicted the argument last leads to better overall results. This makes sense intuitively, as the argument can modify the entire triple.

order of decreasing number of received votes. The normalized votes a triple receives is used as the confidence value of the triple. Although the procedure is explained in a sequential manner it can be parallelized by running all 6 pathways in parallel.

2.3 Training

Triple preparation. For effectively extracting different triple slots conditioned on other slots, the model needs to see such combinations during training. However, enumerating all possible combinations exhaustively is prohibitively expensive. We propose a sampling technique that ensures that the model sees varied combinations of different targets and prior extractions. This is done by creating a training set that simulates a prior extraction and forces the model to predict the next extraction. To ensure that the training dataset size does not explode, we randomly sample one pathway order for each training instance.

Based on the sampled pathway, we randomly sample at which step in the decoding process we are at and then mark the slots prior to this step in the sentence and use the remaining steps as target labels. We allow for multiple instances of the target labels, however there is only one instance of the marked element. For example, given one subject the target could be multiple predicates. This procedure trains the model to predict an appropriate label conditioned on a variety of previous predictions. At each time step we update the parameters of the currently used head and the underlying model.

Given that triples are at different steps in their decoding process, we minimize different log-likelihood functions. We describe the log likelihood functions along with a few example of the training instances in Table 1. We list additional details in Appendix A.

Negative Sampling. Iterative prediction is prone to error amplification, i.e. if an error is made during the first iteration then the error propagates and affects subsequent extractions. Anticipating this, we train MILIE to recognize extraction errors made in the previous iteration. We purposely augment the training data with corrupted data points containing incorrectly marked extractions. For each of the incorrect extractions the model is trained to predict a blank extraction, i.e., predicting the outside label for all tokens. We use a similar sampling procedure as described previously. For every training data point from a fixed number of training data points, we create one negative sample using one of the three techniques and then choose k negative samples, where k is a hyperparameter.

We corrupt triples using three techniques: (1) corrupting the predicates by replacing them with randomly chosen tokens from the sentence, (2) corrupting the subject and object by exchanging them, and (3) by mismatching the subject object pairs from different triples. We detail the entire procedure in Appendix A.

2.4 Integrating Linguistic Rule based systems

Crucially, each output head is conditioned on the input and the output labels extracted by the previous function. This feature allows MILIE to seamlessly integrate rule based systems with neural systems since the conditioning can be also done on extractions obtained from rule based systems. This is advantageous in situations where a linguistic rule based system works well, for say, extracting objects. Then MILIE can complete the missing parts of the triple conditioned on the objects.

We treat the output of the rule based system as potential objects paired with subjects and extract the predicate connecting them. If the rule based extraction is incorrect, then MILIE can detect the error and extract nothing. This results in more accurate extractions compared to simply post-processing the extracted tokens using linguistic rules.

2.5 Binarizing n-ary Extractions

We evaluate MILIE on both n-ary as well as binary triple extraction datasets. One simple way to convert the n-ary extractions to binary extraction is to ignore the n-ary arguments. However, this will lead to a decrease in recall because the n-ary arguments may not be part of other extracted triples due to the initial n-ary extraction. Another method is to treat the extracted n-ary arguments as objects to the same subject, predicate pair. This would ensure that the extracted arguments are not dropped, however this may result in drop of precision since the n-ary argument may not attach to the same predicate. For example, consider the extraction (*Barrack Obama; became; US President; in the year 2008*). Treating n-ary arguments as objects results in (*Barrack Obama; became; US President*) and (*Barrack Obama; became; in the year 2008*) resulting in an incorrect extraction.

In contrast to the above subpar solutions, the iterative nature of MILIE allows us to elegantly address the problem of converting n-ary extractions into a

Likelihood function	Input Sentence	Head	Target

binary format: we treat the extracted n-ary arguments as hypothesized objects. We then provide the extracted subject, hypothesized object pair to the model, which then extracts a new predicate conditioned on the previously extracted subject and the hypothesized object, i.e., $p(L_p \mid f_p(\theta); S; L_s = \text{"Barrack Obama"}; L_o = \text{"year 2008"})$. This creates a possibility of extracting the correct predicate, something that is not possible with existing n-ary OpenIE systems.

3 Experiments

3.1 Setup

Baselines & Training. We compare MILIE with both unsupervised and supervised baselines. Specifically we compare MILIE with ClausIE, MinIE, Stanford-OIE, RNN-OIE, OIE6 (Del Corro and Gemulla, 2013; Gashteovski et al., 2017; Stanovsky et al., 2018; Angeli et al., 2015; Kolluru et al., 2020a) and Multi2OIE (Ro et al., 2020) on English. Multi2OIE is the only neural system capable of extracting triples from multiple languages and therefore it is the only available baseline for the non-English evaluations.

We use the English RE-OIE2016 (Zhan and Zhao, 2020) training dataset used in (Ro et al., 2020). This training dataset contains n-ary extractions allowing MILIE to be evaluated on both n-ary as well as binary extraction benchmarks. Evaluation on languages other than English is always zero-shot, i.e., the model is trained using only the English Re-OIE2016 dataset and tested on test set of the other languages.

CaRB benchmark. We use the CARB benchmark introduced in (Bhardwaj et al., 2019) for evaluating English OpenIE n-ary extraction. However, the CARB benchmark also suffers from serious shortcomings due to its evaluation method based on token overlaps. For example, (Gashteovski et al., 2021) discovered that a simple OpenIE system that breaks the sentence into a triple at the verb boundary achieves 0.70 recall and 0.19 precision. This is problematic since it indicates that simply adding extraneous words to the extraction results in improved recall.

BenchIE benchmark. Due to the issues identified for CaRB, we also evaluate using BenchIE, which is an exhaustive fact based multilingual OpenIE benchmark proposed by (Gashteovski et al., 2021). BenchIE evaluates explicit binary extractions in English, Chinese, and German. BenchIE is accompanied by an annotation tool, AnnIE (Friedrich et al., 2021), for extending the benchmark to additional languages. For Arabic, we translated 100 sentences from BenchIE-English to Arabic with the help of a native Arabic speaker and then extracted triples using AnnIE. Similarly for Galician we translated all 300 sentences to Galician

	Chinese			German			Arabic			Galician		
	F1	**P**	**R**	**F1**	**P**	**R**	**F1**	**P**	**R**	**F1**	**P**	**R**
M2OIE	17.1	25.7	12.8	4.0	8.9	2.6	4.9	16.3	2.9	8.7	14.7	6.2
milIE	**20.5**	**25.2**	17.3	8.5	13.4	6.3	—	—	—	**18.3**	**23.7**	**14.8**

- NS	59.1	**75.7**	48.5	62.4	**74.0**	54.0	**59.5**	**66.2**	**53.9**

Table 4: MILLIE performance comparison on CARB lexical match (LM) benchmark. - DEP represents MILIE trained and evaluated without dependency tags, -NS represents absence of negative sampling. MILIE always outperforms M2OIE, except for the recall on the erroneous automatic translation of Spanish and Portuguese.

with the help of a native Galician speaker who also annotated the dataset using AnnIE.

Multilingual CaRB. Additionally we also evaluate MILIE on the Spanish and Portuguese multilingual CaRB datasets introduced in Ro et al. (2020). The lexical match evaluation used in this dataset has numerous shortcomings (Bhardwaj et al., 2019), however we include it for a fair comparison to Ro et al. (2020)'s Multi2OIE system. The CARB test set was translated to Spanish and Portuguese using the Google Translate API. To investigate the quality of these automatic translations, we randomly sampled 100 sentences from the test sets and had them evaluated by native Spanish and Portuguese speakers. To our surprise we discovered that around 70 percent of the sentence or extraction translations were inaccurate. Table 2 shows a few examples of the incorrect translations. For an accurate and clean comparison with Multi2OIE we also cleaned up part of the Spanish test set by re-translating 149 sentences and their extractions in Spanish. These translations were done by native Spanish speakers.

On the CARB English benchmark we use results for baselines reported in (Ro et al., 2020) and (Kolluru et al., 2020a). For evaluating on BenchIE, we run all the baselines on the BenchIE English evaluation benchmark. For multilingual BenchIE we train Multi2OIE using the code and hyperparameters supplied in the paper. For hyperparameter tuning we use the CARB English validation set and use the F1 scores obtained using the CARB evaluation procedure for comparing models with different hyperparameters. The MILIE model is trained using negative sampling and includes the dependency tag information and binarization. We use the spaCy dependency parser for obtaining dependency tags. We were unable to find a dependency parsing tool with universal dependencies for Arabic and therefore we did not use dependency tags for Arabic. For BenchIE, MILIE uses the binarization function described in Section 2.5, but not for CARB and lexical match because they evaluate n-ary extractions.

3.2 Results

3.2.1 English

In Table 5, we compare MILIE with several unsupervised and supervised baselines in English on CARB and BenchIE. MILIE performs much better compared to other neural baselines on BenchIE. This is not the case for the CARB dataset since CARB penalizes compact extractions and rewards longer extractions (Gashteovski et al., 2021). Although rule based systems like ClausIE and MinIE outperform neural systems, they cannot be used for languages other than English.

English	CaRB-nary			BenchIE-binary		
	F1	Prec.	Rec.	F1	Prec.	Rec.
ClausIE	44.9	—	—	33.9	50.3	25.6
MinIE	41.9	—	—	33.7	42.9	27.8
Stanford	23.0	—	—	13.0	11.1	15.7
R-OIE	46.7	55.6	40.2	13.0	37.3	7.8
S-OIE	49.4	60.9	41.6	—	—	—
OIE6	**52.7**	—	—	25.4	31.1	21.4
M2OIE	52.3	**60.9**	**45.8**	22.8	39.2	16.1
milIE	45.0	48.6	41.8	**27.9**	**36.6**	**22.4**
-DEP	41.2	44.1	38.6	26.7	31.1	23.4
-NS	44.7	47.6	42.2	25.8	29.6	22.9
-Bin	—	—	—	27.7	34.6	23.1

Table 5: MILIE performance comparison on CARB and BenchIE English benchmarks. MILIE performs best out of all models on BenchIE. It performs worse compared to some model on CaRB, which is due to the CaRB evaluation scheme where overly long extractions are rewarded.

3.2.2 Multilingual

In Table 3, we compare MILIE with Multi2OIE (M2OIE) on the multilingual BenchIE benchmark. MILIE performs significantly better compared to Multi2OIE for all the languages. For German and Arabic both Multi2OIE and MILIE perform significantly worse compared to the other languages. The presence of separable prefixes in German verbs which cannot be extracted using BIO tags results in low performance. The BIO tagging scheme assumes continuity of phrases which is absent for most German verbs present in predicates, resulting in extremely low recall. For Arabic, the low scores are due to the Verb-Subject-Object nature of the Arabic language along with the fact that subjects or objects can be expressed as part of the verb. This calls for additional research on framing OpenIE tasks for languages such as German and Arabic. MILIE significantly outperforms Multi2OIE for Galician language which is closely related to Portuguese. Ablation results in Table 3 also indicate the usefulness of adding the dependency tags, negative sampling, and the binarization mechanism.

In Table 4, we compare MILIE with Multi2OIE on the CARB lexical match benchmark. MILIE, without negative sampling works best for Spanish clean data. This is not due to the language, but due to the lexical match evaluation which rewards overly long extractions even if incorrect. Not using negative sampling sometimes improves recall which may improve F1 score. This is observed for the German benchmark.

English	F1	Prec.	Rec.	Δ F1
MILIE	27.88	36.65	22.37	—
MILIE + CO	**29.71**	32.35	**27.48**	**+ 1.83 %**

Table 6: Performance comparison of Hybrid MILIE on English BenchIE. Here '+ CO' denotes system fused with extracted ClausIE Objects.

F1-Score	EN	DE	ZH	AR	GL	ES
SPOA	26.3	8.7	20.3	5.3	17.5	55.2
SOPA	24.9	8.2	18.2	5.8	17.5	53.1
PSOA	27.7	**8.8**	19.5	5.0	17.5	51.4
POSA	27.4	8.1	19.4	5.4	17.1	51.7
OSPA	22.4	8.0	17.1	5.7	15.3	45.5
OPSA	22.2	7.9	17.5	6.4	15.2	47.9
DYN	26.9	**9.0**	19.5	4.9	17.5	51.0
WF	**27.9**	8.5	**20.5**	**7.3**	**18.3**	**55.7**

Table 7: Comparison between different decoding schemes. WF represents water filling and DYN the dynamic setting.

3.2.3 Hybrid OpenIE

MILIE can easily integrate any rule based system that extracts even a part of the triple. To evaluate this, we first simulate a system that only extracts the object and use MILIE to extract other parts of the triple. We do this by employing ClausIE for extracting triples for the BenchIE English data and only use the object, discarding the rest of the triple.

The reason behind the choice of selecting object extraction from ClausIE is the fact that neural systems are not good at extracting objects (Kolluru et al., 2020a). This is also seen from additional experiments detailed in Section 4. Table 6 indeed confirms that combining rule based object extraction with MILIE improves performance by over 6% in F1 score. This showcases that MILIE's ability to integrate other systems can be a great advantage.

4 Analysis

We would like to analyze that the ability of MILIE to extract triples using different extraction patterns results in improved performance on multilingual data. For this, we compare MILIE with the water filling aggregation against MILIE with different extraction pathways.We also compared with a dynamic decoding scheme where MILIE chooses a decoding pathways based on the sentence. To do this we split a part of the English training set and for each sentence in the split we record the extraction pathway that provides the best F1 score MILIE

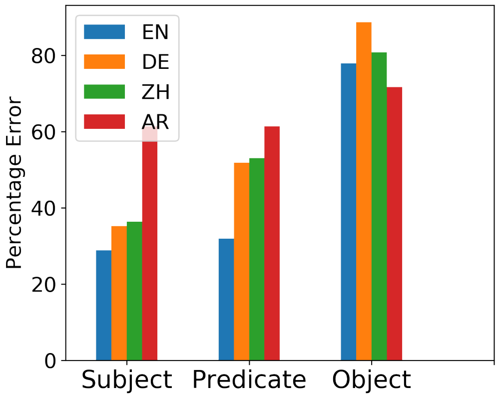

Figure 3: Percentage error contribution due to incorrect subject, predicate or object for EN, DE, ZH and AR. Most errors occur in the object.

	Subject		Predicate		Object	
	DEP	**POS**	**DEP**	**POS**	**DEP**	**POS**
EN	1.719	1.588	2.443	1.831	2.286	1.861
ZH	2.464	1.827	2.497	1.476	2.602	1.943
DE	1.587	1.567	1.811	1.457	2.115	2.095

Table 8: Entropy of dependency and part of speech tags for subject, predicate and objects in BenchIE test data. Objects exhibit the highest entropy which indicates their higher complexity.

as per CARB evaluation. We then use this as training data for training another mBERT model which classifies each sentence in one of the six classes where each class represents an extraction pathway.

Table 7 details the performance for different extraction schemes. All the extraction schemes except WF, use only one pathway. DYN provides mixed results across the different languages - for German it is the best approach, whereas for Arabic it is the worst. In contrast, the combination of multiple pathways allows to performing much better than the other approaches on all languages, except German. This demonstrates that combining triple extraction from multiple pathways is better than any single pathway, which in turn confirms that extracting triples repeatedly from the same sentence using multiple extraction pathways is more profitable than using a single extraction pathway.

Additionally, Table 7 provides an interesting insight: predicate first seems to be the best, followed by subject first and then object first for languages other than Arabic. This also shows how the difficulty of extracting triple slots using transfer learning from English varies with the target language.

Table 7 suggests that predicates are easier to extract leading to lesser number of errors propagated in the prediction chain. We suspect that this could result from differences in linguistic variability. To test our hypothesis we measured the entropy of the distribution of dependency and part-of-speech tags in the predicate, subject and object slots in the BenchIE English and the multilingual test sets. Results shown in Table 8 suggest that linguistic complexity of objects is higher than those of predicates and subjects.

This is also confirmed in Figure 3, where we plot the extraction errors in either subject, predicate or objects among incorrectly extracted triples. Most errors result from extracting incorrect objects compared to predicates and subjects. The percentage sum does not add to hundred because an incorrect triple can contain errors in more than one slot.

5 Related Work

OpenIE systems largely come in two flavors, (1) unsupervised OpenIE systems that use fine grained rules based on dependency parse trees (Del Corro and Gemulla, 2013; Gashteovski et al., 2017; Lauscher et al., 2019), and (2) supervised neural OpenIE systems, trained end-to-end with large training datasets (Stanovsky et al., 2018; Ro et al., 2020; Kolluru et al., 2020a). Neural OpenIE systems characterize OpenIE as either a sequence tagging task (Stanovsky and Dagan, 2016; Ro et al., 2020), span prediction task or a sequence generation task (Kolluru et al., 2020b). However all these prior approaches extract a triple in a single step, which does not allow us to study the effect of extracting a specific slot and its effect on extracting the rest of the triple.

Neural generative approaches to OpenIE use sequence-to-sequence models with a copy mechanism for generating triples (Sun et al., 2018; Kolluru et al., 2020b). The copy mechanism needs to be learned and is often a source of errors. A series of alternative approaches cast OpenIE as a sequence tagging task where each token is tagged as subject, predicate or object using a BIO like tagging scheme (Stanovsky et al., 2018; Ro et al., 2020; Kolluru et al., 2020a). In these systems, all triple slots are extracted simultaneously and it is therefore not possible to condition on easier slots.

More closely related to our work is SpanOIE (Zhan and Zhao, 2020) and Multi2OIE (Ro et al., 2020), which first extracts the predicate and then all additional arguments. Like us, Multi2OIE (Ro et al., 2020) addresses multilinguality by leveraging a pretrained BERT model (Devlin et al., 2019) for transfer learning. In contrast, through our iterative nature, it is possible to enrich the extractions in other languages if rule based models or other models (e.g. NER recognizers) exist to provide input for a triple slot. IMOJIE (Kolluru et al., 2020b) iteratively extracts entire triples from a sentence: first a triple is extracted, which is added to the input to extract the next triple. In contrast, our work iteratively extracts the slots of a single triple, which allows us to condition on the easier slots and therefore obtain higher quality triples. (Kolluru et al., 2020a) propose OpenIE6, a BERT based system, with iterative grid labelling and linguistic constraint based training. Such lingusitic constraints with soft penalties cannot be readily ported to other languages since such constraints use head verb based heuristics. Consequently OIE 6 is evaluated only on English.

6 Conclusion

We introduced MILIE, a modular & iterative multilingual OpenIE system. We confirmed our hypothesis that it is beneficial to extract triple slots iteratively which allows us to extract easier slots first. Our experiments on English as well as five low resource languages uncovered that, with the exception of Arabic, triples are easier to extract if the predicate is extracted first followed by the subject and object. More importantly we discovered that extracting triples using multiple extraction pathways is superior than the standard single extractions especially in the multilingual setting. We also demonstrated how MILIE can be combined seamlessly with rule based systems for improving performance. Although our experiments were focused on the OpenIE task, we believe that the insights gained can be translated to other information extraction tasks with coupled extractions. We plan to explore such connections in the future.

A Appendix

A.1 Training Details

MILIE is expected to predict slots iteratively conditioned on prior extracted slots of a triple, therefore it needs to be trained with similar examples. Exhaustively listing all possible combinations of prior extracted slots and slots to be extracted is prohibitively expensive. Therefore we use a sampling procedure that ensures the model sees a variety of combinations during training.

For every example in the Re-2016 training dataset we do the following

1. Sample an slot as target (for extraction) with the following probabilities (subject: 1/3, predicate: 5/12, object: 5/12)
2. Sample two slots, one that is assumed to be extracted and other the target that needs to be extracted conditioned on the first.
3. Sample three slots, first two assumed to be extracted and the third is the target conditioned on first two.
4. If the example contains n-ary arguments, the subject, predicate and object are assumed to be extracted and the n-ary arguments are treated as targets.

When a slot is sampled for target extraction, all instances of the slot are expected to be extracted. For example, if the target is the subject and if the example consists of multiple subjects then the targets are multiple subjects. However the sampled slots assumed to be extracted must be single instances, and if there are multiple instances, then each instance is considered for conditioning one after the other. Table 9 details the sampling probabilities for two and three slots. The sampling probabilities were not tuned, but rather chosen based on heuristics. Post sampling, we obtain training dataset with about 5 and a half million examples.

Negative Sampling

Extracted Slots	Target Slot	Probability
subject	object	3/12
subject	predicate	1/12
object	subject	2/12
object	predicate	1/12
predicate	subject	2/12
predicate	object	3/12
(subject, object)	predicate	2/12
(subject, predicate)	object	6/12
(object, predicate)	subject	4/12

Table 9: Sampling Probabilities for training data.

Extracted Slots	Target	Corruption	Prob.
subject	object	Invert	1/12
object	predicate	Invert	3/12
predicate	subject	Randomize	2/12
(subject, object)	predicate	Switch	1/12
(subject, predicate)	object	Switch	3/12
(predicate, object)	subject	Switch	2/12

Table 10: Negative Sampling Probabilities.

We provide MILIE with negative samples during training for reducing error amplification arising out of iterative prediction. In this case the target is always blank, i.e., all the tokens are marked as 'outside'. Thus the sampling revolves around creating incorrectly extracted slots. We sample negatives for every example in the training data and then select k negative samples uniformly at random. k is treated as a hyperparameter.

Table 10 provides the sampling probabilities for different slot arrangements. We use three corruption procedure for generating incorrectly marked slots, namely, invert, randomize and switch. The invert method consist of swapping the extracted slot with the target slot. For example, if the extracted slot is subject and target slot is object, then the object is marked as subject. The randomize method consists of choosing a random span of tokens near the actual slot. Finally the switch method involves switching one of the extracted slot with a slot from another triple associated with the sentence. For example, in the case of (subject, object), the object of this triple is switched with an object of another triple associated with the same sentence. It is possible that the same subject maybe associated with the new object as well. We check if this is true, and if true we filter out such positives.

Num. NS (k)	Learning Rate	F1
0	1×10^{-5}	39.88
0	3×10^{-5}	44.70
0	9×10^{-5}	40.76
10K	1×10^{-5}	43.45
10K	3×10^{-5}	47.03
10K	9×10^{-5}	47.19
100K	1×10^{-5}	48.03
100K	3×10^{-5}	47.30
100K	9×10^{-5}	45.87
1M	1×10^{-5}	46.01
1M	3×10^{-5}	46.16
1M	9×10^{-5}	45.26

Table 11: Hyperparameter Tuning

A.2 Hyperparameter Tuning

We train and evaluate MILIE on an NVIDIA Titan RTX with 24 GB GPU RAM. The training is done for a maximum of two epochs and each epoch takes about 9-10 hours. The maximum sentence length using the English train and validation dataset is found to be about 100. Due to the addition of extracted triple element markers we allow a slack of 20 tokens, thus fixing the maximum sentence length to 120. We use a maximum possible batch size that fits inside the GPU, which results in batch size of 192. We use ADAM (Kingma and Ba, 2015) as the optimizer with linear warmup and tune the learning rate. The linear warmup fraction is fixed at 0.1. We also treat the number of negative samples, k, as a hyperparameter and tune it. We choose the best hyperparameters based on the F1 score. Table 11 provides details on the recall scores for every hyperparameter arrangement.

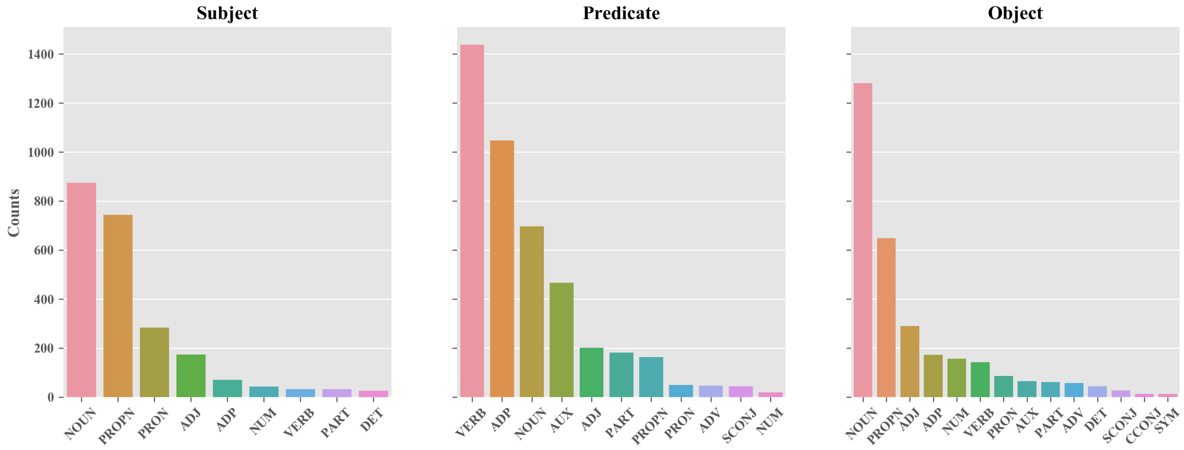

Figure 4: Distribution of the Part of Speech tags in subject, predicates and object tokens of triples in BenchIE English test data.

What Makes Reading Comprehension Questions Difficult?

Abstract

For a natural language understanding benchmark to be useful in research, it has to consist of examples that are diverse and difficult enough to discriminate among current and near-future state-of-the-art systems. However, we do not yet know how best to select text sources to collect a variety of challenging examples. In this study, we crowdsource multiple-choice reading comprehension questions for passages taken from seven qualitatively distinct sources, analyzing what attributes of passages contribute to the difficulty and question types of the collected examples. To our surprise, we find that passage source, length, and readability measures do not significantly affect question difficulty. Through our manual annotation of seven reasoning types, we observe several trends between passage sources and reasoning types, e.g., logical reasoning is more often required in questions written for technical passages. These results suggest that when creating a new benchmark dataset, selecting a diverse set of passages can help ensure a diverse range of question types, but that passage difficulty need not be a priority.

1 Introduction

State-of-the-art systems have shown performance comparable with humans on many recent natural language understanding (NLU) datasets (Devlin et al., 2019; Sun et al., 2021), suggesting that these benchmarks will no longer be able to measure future progress. To move beyond this, we will need to find better ways of building difficult datasets, ideally without sacrificing diversity or coverage (Bowman and Dahl, 2021). To obtain such human-written examples at scale, there are active lines of crowdsourcing research on protocols of worker handling and feedback (Nangia et al., 2021) and the design of the collection task (Ning et al., 2020; Rogers et al., 2020). However, we do not have clear information on what aspects of *text sources* affect the difficulty and diversity of examples.

MCTest: Tony walked home from school on his birthday. He was surprised to see a lot of cars in front of his house. When he opened the door and entered the house, he heard a lot of people yell, "Surprise!" It was a surprise party for his birthday. His parents called all his friends' parents and invited them to come to a party for Tony. [...]
Q: *Who were invited to the party and by who?*
☐ *Tony's parents invited only his friends*
☐ *Tony invited his friends and their parents*
☐ *Tony's parents invited his friends' parents*
☑ *Tony's parents invited his friends and their parents*

ReClor: Humanitarian considerations aside, sheer economics dictates that country X should institute, as country Y has done, a nationwide system of air and ground transportation for conveying seriously injured persons to specialized trauma centers. Timely access to the kind of medical care that only specialized centers can provide could save the lives of many people. [...]
Q: *What is the economic argument supporting the idea of a transportation system across the nation of Country X?*
☐ *Building the transportation system creates a substantial increase of jobs for the locals*
☑ *Increasing access to specialized medical centers can lower the chance of the workforce population dying*
☐ *Transportation ticket prices directly contribute to the government's revenue*
☐ *Country Y was successful with their attempts to potentially save lives so Country X should try it as well*

Figure 1: Example questions for passages from simple narratives (MCTest) and technical arguments (ReClor).

Crowdsourced datasets in reading comprehension use passages taken from a variety of sources, such as news articles, exams, and blogs, about which questions are written (Lai et al., 2017; Trischler et al., 2017; Rogers et al., 2020). The first example in Figure 1 is from MCTest (Richardson et al., 2013), the passages of which are written in grade-school-level English. The second example is from ReClor (Yu et al., 2020), which consists of passages and questions written for graduate and law school admission examinations. We hypothesize that difficult passages, such as those in the second example, are more suitable for crowdsourcing challenging questions. Passages that are linguistically

complex and have dense information could help facilitate the writing of questions that require understanding a wide range of linguistic and world knowledge, following intricate events, and comprehending logical arguments. In contrast, easy passages, as in children's stories, likely talk about common situations and simple facts, which might prevent workers from writing difficult questions.

In this work, we crowdsource multiple-choice reading comprehension questions to analyze how question difficulty and type are affected by the choice of source passage. Using passages extracted from seven different sources, we ask crowdworkers to write questions about the given passages. We compute the difference between human and machine accuracy, using it as a measure of the question difficulty, to investigate whether there is a correlation between the question difficulty and linguistic aspects of the passage, such as their source, length, and readability.

In addition to a standard setting where we directly accept crowdworkers' submissions, we use an adversarial setting in which they have to write questions that fool a strong reading comprehension model (Bartolo et al., 2020; Kiela et al., 2021). Previous work finds that questions that require numerical reasoning frequently appear in the adversarial data collection of the extractive QA task on Wikipedia articles (Kaushik et al., 2021), but our aim is to see whether we observe a similar trend in multiple-choice questions written for different passage sources or if the adversarial setting is useful for collecting especially diverse questions.

To our surprise, we find that the difficulty of collected questions does not depend on the differences of passages in linguistic aspects such as passage source, passage length, Flesch–Kincaid grade level (Kincaid et al., 1975), syntactic and lexical surprisal, elapsed time for answering, and the average word frequency in a passage. Our main positive finding comes through our manual annotation of the types of reasoning that each question targets, where we observe that questions that require numerical reasoning and logical reasoning are relatively difficult. In addition, we find several trends between the passage sources and reasoning types. For example, logical reasoning is more often required in questions written for technical passages, whereas understanding of a given passage's gestalt and the author's attitude toward it are more frequently required for argumentative and subjective passages than expository passages.

These results suggest that when creating a new benchmark dataset or choosing one for evaluating NLU systems, selecting a diverse set of passages can help ensure a diverse range of question types, but that passage *difficulty* need not be a priority. Our collected datasets could be useful for training reading comprehension models and for further analysis of requisite knowledge and comprehension types in answering challenging multiple-choice questions.[1]

2 Related Work

Crowdsourcing NLU Datasets Crowdsourcing has been widely used to collect human-written examples at scale (Rajpurkar et al., 2016; Trischler et al., 2017). Crowdworkers are usually asked to write questions about a given text, sometimes with constraints imposed to obtain questions that require specific reasoning skills such as multi-hop reasoning (Yang et al., 2018) or understanding of temporal order, coreference, or causality (Rogers et al., 2020). In this study, to analyze naturally written examples, we do not consider specific constraints on questions or answer options.

Current benchmark datasets constructed by crowdsourcing may not be of sufficient quality to precisely evaluate human-level NLU. For example, Ribeiro et al. (2020) reveal that state-of-the-art models in traditional NLP benchmarks fail simple behavioral tests of linguistic capabilities (*checklists*). Chen and Durrett (2019) and Min et al. (2019) show that questions in multi-hop reasoning datasets such as HotpotQA by Yang et al. (2018) do not necessarily require multi-hop reasoning across multiple paragraphs.

To investigate how to collect high-quality, challenging questions through crowdsourcing, Nangia et al. (2021) compare different sourcing protocols and find that training workers and providing feedback about their submissions improve the difficulty and quality of their reading comprehension questions. To encourage workers to write difficult examples, Bartolo et al. (2020) propose to collect questions using a model-in-the-loop setting. Although this adversarial approach enables us to collect challenging questions efficiently, Gardner et al. (2020) point out that the collected examples might be bi-

---

[1] Our datasets, annotation instructions and results, and crowdsourcing scripts are available at `https://github.com/nii-cl/qa-text-source-comparison`.

ased towards the quirks of the adversary models. Bowman and Dahl (2021) extend this argument, and point out that adversarial methods can systematically eliminate coverage of some phenomena. This is also supported by Kaushik et al. (2021), but their findings are limited to extractive QA for Wikipedia articles. Our motivation is to see if this argument is applicable to the multiple-choice format with a wide range of passage sources for which we expect crowdworkers to write linguistically diverse questions and answer options.

Sources of NLU Datasets Reading comprehension datasets are often constructed with a limited number of passage sources. Rajpurkar et al. (2016) sample about five hundred articles from the top 10,000 articles in PageRank of Wikipedia. Similarly, Dua et al. (2019) curate passages from Wikipedia articles containing numeric values to collect questions for mathematical and symbolic reasoning. Khashabi et al. (2018) construct a dataset in which questions are written for various passage sources such as news articles, science textbooks, and narratives. However, we cannot use their questions for our analysis of the variation of naturally written questions because they are designed to require local multi-sentence reasoning (such as coreference resolution and paraphrasing) by filtering out questions answerable only with a single sentence.

Similarly to our work, Sugawara et al. (2017) find that readability metrics and question difficulty do not correlate in reading comprehension datasets. Our study differs in the following two points, which could cause different findings: First, their observational study of existing datasets has fundamental confounding factors because the questions they examine are constructed using different sourcing methods (e.g., automatic generation, expert writing, and crowdsourcing), which could have an impact on the question difficulty. We aim to investigate uniformly crowdsourced examples across seven different sources to obtain insights for future data construction research using crowdsourcing. Second, they define question difficulty using human annotations alone, but this does not necessarily reflect the difficulty for current state-of-the-art models. In this study, we define the question difficulty as the human–machine performance gap using eight recent strong models, which enables a more fine-grained analysis of the collected questions for a better benchmark of current models.

Fisch et al. (2019) propose a shared task consisting of different in-domain and out-domain datasets. However, they combine datasets in different task formats and sourcing methods, which prevents us from comparing questions across passage sources alone. In contrast, our focus is to compare questions collected by crowdsourcing for the same task format to analyze the question difficulty for current state-of-the-art models. We adopt the multiple-choice format because, as discussed by Huang et al. (2019), it allows us to evaluate both human and machine performance easily.

3 Crowdsourcing Tasks

This study aims to analyze what kinds of passages make crowdsourced reading comprehension questions difficult. We use Amazon Mechanical Turk. To collect difficult and high-quality examples, we require crowdworkers to take a qualification test before accepting our question writing and validation tasks.

3.1 Worker Qualification

The qualification test has two parts, which we run in separate tasks: question answering and writing. To take the qualification test, workers have to meet the following minimum qualifications: based in the United States, Canada, or United Kingdom, have an approval rate of at least 98%, and have at least 1,000 approved tasks.

The question answering task is used to identify workers who answer reading comprehension questions carefully. A single question answering task has five questions that are randomly sampled from the validation set of ReClor in which most questions are taken from actual exams. Those who correctly answer at least four out of the five questions proceed to the next qualification phase.

The question writing task is used to familiarize workers with the writing of multiple-choice reading comprehension questions and select those who can carefully write examples. We ask workers to write two questions given two different passages randomly sampled from the validation set of RACE (Lai et al., 2017). This dataset consists of self-contained passages written for middle- and high-school exams in various subjects, which we expect the workers to be able to write questions for easily. Following Nangia et al. (2021), we then review the workers' submissions and grade them using a rubric with four criteria: the question (1) is answerable without ambiguity (*yes* or *no*); (2) requires reading the whole passage (five-point scale); (3) is creative and non-obvious (five-point scale); and (4) has distractor answers that could look correct to someone who has not read the passage carefully (*more than one*, *one*, or *no*). We rank workers using this rubric and allow approximately the top 50% of workers to proceed to the main writing task. We make sure that these workers write two unambiguous and answerable questions.

3.2 Writing Task

In the main writing task, a worker is shown a single passage and asked to write a question about it along with four answer options. We provide instructions where we describe that questions have to be challenging but still answerable and unambiguous for humans, and we include good and bad examples to illustrate what kinds of questions we aim to collect. For example, good examples require reading the whole passage and ask about characters' motivations or consequences of described events, while bad examples only ask about a simple fact or are answerable without reading the passage (Appendix P).

Each worker who passes the qualification round is randomly assigned to either standard or adversarial data collection. In the standard collection, we accept workers' submissions without any filtering. In the adversarial collection, a written question is sent to a reading comprehension model immediately. If the model cannot answer that question correctly, we accept it. We allow workers to submit questions (i.e., get paid) after three attempts even if they keep failing to fool the model. We use UnifiedQA 3B v2 (Khashabi et al., 2020) for the adversary model, which is trained on a wide variety of question answering datasets such as MCTest, RACE, NarrativeQA (Kočiský et al., 2018), and SQuAD. While the source of training data that we use in our models will inevitably influence our findings, focusing on a model with very diverse pretraining and fine-tuning will minimize this effect.

Passage Sources We use passages from the following seven sources: (1) MCTest children's narratives, (2) Project Gutenberg narratives, (3) Slate online magazine articles from the 1990s sourced from the Open American National Corpus (Ide and Suderman, 2006), (4) middle- and high-school exams from RACE, (5) graduate-level exams from ReClor, and (6) science and (7) arts articles from Wikipedia. We use the passages from the training sets of MCTest, RACE, and ReClor. For Gutenberg, Slate, and Wikipedia, we split available books and articles into passages. Details are in Appendix A. In the writing task, a passage is randomly taken from a passage pool in which there are the same number of passages extracted from each source.

3.3 Validation Task

We collect the votes of five workers for each of the collected questions. Those workers who passed the question answering task of the qualification round can accept the validation tasks. To incentivize workers, we use preexisting gold-labeled examples (from Nangia et al., 2021) as catch trials, representing about 10% of the tasks, and pay a bonus of $0.50 USD if a worker can answer those questions correctly at least 80% of the time. If a worker fails to answer them at least 60% of the time, we disqualify the worker from future rounds of data collection.

Worker Pay and Logistics For the writing tasks, the base pay is $2.00 per question, which we estimate to be approximately $15.00 per hour based on measurements from our pilot runs. If a worker succeeds in fooling the model in adversarial data collection, they receive an additional bonus of $1.00. For validation, a single task consisting of five questions pays $2.00, which we estimate to be approximately $15.00 per hour as well.

4 Crowdsourcing Results

4.1 Dataset Construction

We collect a total of 4,340 questions, with 620 in each of the seven sources, further divided into 310 each for the standard and adversarial methods. Each passage is paired with only one question. We randomly sample two out of five validation votes to validate the collected examples and use the remaining three votes for measuring human performance. In the validation, we regard a question as valid if at least one of the two votes is the same as the writer's gold answer. If both votes are the same as the gold answer, the question is regarded as a high-agreement example. We find that 90.3% of the collected questions are valid (92.0% for standard collection and 88.7% for adversarial collection). In addition, 65.7% of the collected questions are classified as high-agreement (68.7% and 62.7% for standard and adversarial collection, respectively). We present the dataset and worker statistics in Appendices B and C.

Table 1: Accuracy of humans and models and the difference (Δ) between human accuracy and the average zero-shot performance of eight different models (*M-avg.*) for all valid questions and the high-agreement portion of them. The highest and lowest gaps are highlighted in bold and underlined. The questions are crowdsourced with (*Adv.*) and without (*Dir.*) adversarial feedback. *UniQA* is the zero-shot performance by the UnifiedQA 3B model used in the adversarial data collection. *DeBERTa* is the performance by the xlarge model fine-tuned on RACE.

4.2 Human Performance

Table 1 displays human and model performance. We use the questions that are validated using two out of five human votes in the validation step above and take the majority vote of the remaining three votes to measure human performance on them. We observe 3.3% and 2.0% gaps between the standard and adversarial collection in the valid and high-agreement questions, respectively.

4.3 Machine Performance

To establish the model performance that is not biased towards a single model, we compute the average accuracy (*M-avg.*) of eight different models from the following two classes: RoBERTa large (four models with different random seeds; Liu et al., 2019) and DeBERTa large and xlarge (v2; He et al., 2021) either fine-tuned on MNLI (Williams et al., 2018) first or not.

The RoBERTa and DeBERTa models are all fine-tuned on RACE. Among these models, DeBERTa xlarge (MNLI-fine-tuned) performs best on RACE, achieving 86.8% accuracy. Because UnifiedQA 3B (72.3% on RACE) is used in the adversarial data collection, it shows lower accuracy on the adversarial questions (not included in the average). The performance of these two models is shown for comparison in Table 1. Except where noted, we do not train the models on any collected questions.

Supervised Performance For each dataset, we evaluate the performance of DeBERTa large trained on the datasets other than the target dataset in a leave-one-out manner. Our motivation is to see whether the accuracy values significantly improve by training (i.e., the human–model gaps decrease). If there is a large gain, it would imply that the datasets have simple patterns among examples that the models can exploit. The results show no significant gains in the adversarial datasets, but the standard datasets show some small gains (Appendix D).

Partial-Input Performance As Kaushik and Lipton (2018) point out, reading comprehension datasets might have annotation artifacts that enable

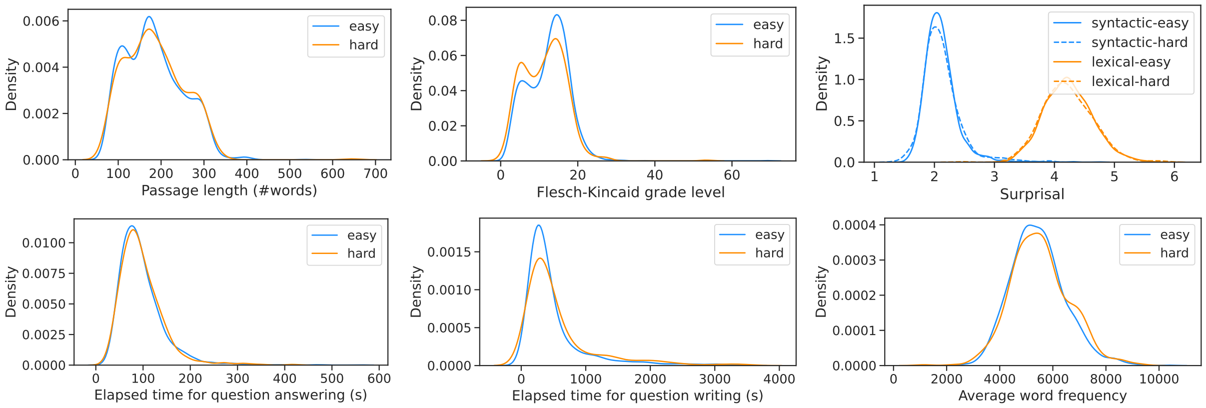

Figure 2: Passage length, Flesch–Kincaid grade level, syntactic and lexical surprisal, elapsed time for question answering and writing, and average word frequency of passages in the easy and hard examples.

models to answer questions without passages or question sentences. To investigate such artifacts in our collected examples, we evaluate the performance of two DeBERTa models (xlarge and large fine-tuned on MNLI), which are stronger than the others, with the ablation of questions (P+A), passages (Q+A), and both questions and passages (*A only*). We see large drops in the zero-shot performance of DeBERTa xlarge. In addition, we do not observe a significant performance improvement in the supervised performance by DeBERTa large (MNLI-fine-tuned). These results demonstrate that the collected questions and answer options do not have severe annotation artifacts for any passage source (Appendix E).

4.4 Human–Model Performance Gap

Following Nangia et al. (2021), we compute the human–model performance gap (Δ) between the human and the average model accuracies to estimate the difficulty of questions for models. We observe a small variation in the gap for different passage sources in the high-agreement questions ($\Delta = 14.9 \pm 3.6$). We find the highest human performance for MCTest questions in the high-agreement portion and the lowest for Gutenberg, whereas the model's highest performance is for Slate and the lowest for MCTest. Surprisingly, the questions sourced from MCTest, which consists of simple narrative passages, show the largest gap out of all sources for the high-agreement questions. Although ReClor consists of passages for graduate-level exams, it produces smaller gaps than RACE, which consists of passages for middle- and high-school English exams. Gutenberg passages are written for adults, but the examples written for those passages do not show larger gaps than those for MCTest passages. We find a trend in the human performance: the questions of easy-to-read sources (e.g., MCTest and RACE) show higher accuracy and those of difficult-to-read sources (e.g., Gutenberg and Slate) show lower, but this trend is not observed either in the machine performance or human–machine performance gap. These observations are inconsistent with our initial expectations in the introduction.

5 Linguistic Analysis

We analyze how the linguistic aspects of the collected examples correlate with the human–model performance gap computed in the experiments. To get a better estimate of human performance, we use the high-agreement examples (Nie et al., 2020). For ease of comparison, we split these examples into two subsets: easy ($\Delta \leq 20\%$) and hard ($\Delta \geq 40\%$). These subsets have 1,970 and 547 examples, respectively. Appendix F provides the frequency of easy and hard examples across the passage sources and collection methods.

5.1 Readability Measures

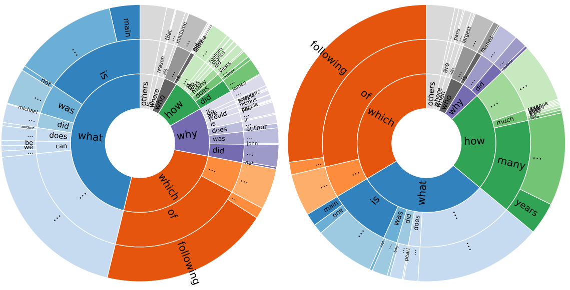
We compute the correlation between the human–model performance gap and readability measures across all valid examples (Pearson's r and p-value) and independence between the distributions of the easy and hard subsets about the measures (p-value in Welch's t-test). Figure 2 shows the density distributions of the easy and hard subsets, while Appendices G to L provide the plots of all valid examples.

Passage Length We use the number of words (except for punctuation) as the passage length (top left in Figure 2). Across all examples, we observe $r = 0.01$ ($p = 0.47$) (the full plot is in Appendix G). The t-test shows $p = 0.51$. We observe no relationship between the passage length and question difficulty. We also analyze question and option length in Appendix H.

Flesch–Kincaid Grade Level We use the Flesch–Kincaid grade level (Kincaid et al., 1975) as a basic metric of text readability (top center in Figure 2). This metric defines readability based on an approximate US grade level with no upper bound (higher is more difficult to read). It is computed for a passage using the average number of words that appear in a sentence and the average number of syllables in a word (Appendix I). The correlation between the grade and human–model performance gap is $r = -0.08$ ($p < 0.001$) and the t-test shows $p < 0.001$. This result demonstrates that passage readability has a small negative effect on the question difficulty, perhaps pointing to an interfering effect whereby our pre-qualified *human* annotators are more likely to make mistakes on more complex passages.

Syntactic and Lexical Surprisal The Flesch–Kincaid grade level only considers sentence length and the number of syllables. To better estimate the passage difficulty in terms of the psycholinguistic modeling of human text processing, we use syntactic and lexical surprisal measures (Roark et al., 2009). These measures are computed using incremental parsing and proved to be useful for predicting human reading time. We observe $r = 0.000$ ($p = 0.99$) for syntactic surprisal and $r = -0.007$ ($p = 0.66$) for lexical surprisal across all examples. We do not observe any statistically significant difference between the easy and hard subsets (syntactic $p = 0.52$ and lexical $p = 0.57$ in the t-test; see top right in Figure 2). Appendix J describes details of the calculation.

Annotation Speed Inspired by the psycholinguistic study of text complexity (Gibson, 1998; Lapata, 2006), we measure the average time crowdworkers spent answering questions in the validation tasks (see bottom left in Figure 2). This measures the elapsed time of both reading a given passage and thinking about its question, which is used as an approximation of reading time (as a proxy of text readability). The correlation coefficient ($r = -0.06$ with $p < 0.001$) and t-test ($p = 0.88$) show that there is only a small negative correlation with question difficulty. We also measure the elapsed time for writing questions as a reference (bottom center in Figure 2 and Appendix K), observing that there is no strong correlation ($r = 0.02$ with $p = 0.27$).



(a) Easy questions

(b) Hard questions

Figure 3: Question words and their two subsequent words in the (a) easy and (b) hard examples.

Word Frequencies Following Chen and Meurers (2016), we analyze the effect of word frequencies on text readability. Using word frequencies per one million words in SUBTLEXus (Brysbaert and New, 2009), we calculate the average frequency of words appearing in a passage as a measure of passage difficulty in terms of vocabulary (a lower average frequency implies greater difficult). We do not observe any statistically significant difference by the t-test $p = 0.14$ (bottom right in Figure 2) or Pearson's $r = 0.02$ with $p = 0.27$ (Appendix L). We observe similar trends even when using the human performance as the difficulty measure (Appendix N).

5.2 Question Types

We analyze how passage sources and collection methods affect question types in this section.

Question Words We automatically extract the first *wh*-words that appear in each valid question; if no *wh*-word is extracted, we count the question as polar. Figure 3 plots the question words and their two subsequent words (except articles) in the easy and hard questions. From this we observe that the hard questions are generic, not specific to given passages (e.g., *which of the following is correct?*) more often than the easy questions. This probably results from the difference between the standard and adversarial data collection. The workers in the adversarial collection tend to write generic questions, while those in the standard collection write questions that are more balanced (e.g., there are more easy *why* and *how* questions). We also notice

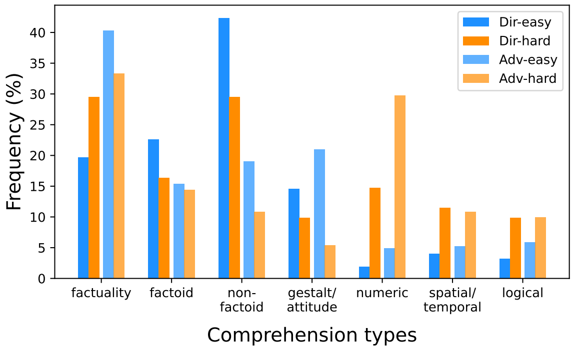


Figure 4: Frequency of comprehension types in the easy and hard examples for each collection method.

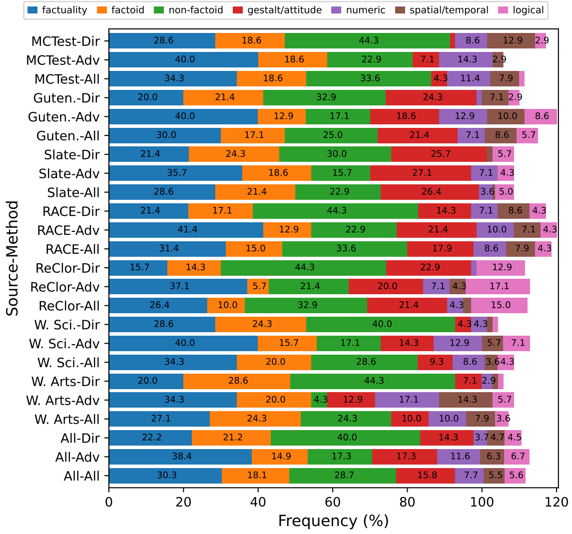

Figure 5: Frequency of comprehension types across passage sources and collection methods. Because a question can have multiple labels, the sum of the frequencies may exceed 100%.

that the hard subset has more *how many* questions. This is likely due to the fact that it is easy for annotators to learn that numeric questions often fool the adversary model. These observations imply that adversarial data collection tends to concentrate the distribution of questions towards a few specific question types (e.g., generic and numeric). This is consistent with the observations in Kaushik et al. (2021). See Appendix M for details.

Comprehension Types Following Bartolo et al. (2020) and Williams et al. (2020), we analyze what kind of comprehension is required to answer the collected questions. We sample a total of 980 high-agreement questions, 70 from each passage source and collection method, and then manually annotate them with one or more labels of seven comprehension types. The definitions of these types, examples, and detailed results are presented in Appendix M. Figure 4 shows the frequency of comprehension types for different question difficulties (676 easy, 172 hard) and the collection methods. We find that 868 questions have one label, 110 have two labels, and two have three labels. We can see that *numeric*, *spatial/temporal*, and *logical* questions appear more often in the hard subset in both collection methods.[2] Looking at the frequency across the passage sources in Figure 5, we find that there are some trends between the sources and comprehension types as follows:

- Technical documents, such as those used in graduate-school-level reading comprehension exams, tend to yield logical reasoning questions (e.g., ReClor and Slate).
- Child-level texts tend to yield numerical reasoning questions in the standard setting (e.g., MCTest and RACE). In the adversarial setting, passages containing many numerical values tend to yield such questions (e.g., MCTest and Wikipedia arts).
- To collect gestalt questions or those considering the author's attitude in a given passage, passages covering subjective or argumentative topics (e.g., Gutenberg, Slate, and ReClor) are suitable. In contrast, expository passages such as Wikipedia articles are not.
- Narratives and related texts (e.g., MCTest, Gutenberg, and part of RACE) involve events with characters, which tend to yield spatial/temporal reasoning questions.

Although the definitions of our comprehension types are coarse and these trends do not ensure that specific kinds of passages always yield the target comprehension type, considering passage sources might be an effective strategy for collecting questions of an intended comprehension type. Adversarial data collection for this purpose might not be useful because it may encourage workers to focus on writing only a few specific types of questions (e.g., numeric).

6 Conclusion

To make an NLU benchmark useful, it has to consist of examples that are linguistically diverse and

---

[2] In contrast, when we use the average human performance as the question difficulty measure, no comprehension type is significantly harder than the others (Appendix N).

difficult enough to discriminate among state-of-the-art models. We crowdsource multiple-choice reading comprehension questions for passages extracted from seven different sources and analyze the effects of passage source on question difficulty and diversity.

Although we expect that the difficulty of a passage affects the difficulty of questions about that passage, the collected questions do not show any strong correlation between the human–machine performance gap and passage source, length, or readability measures. Our manual annotation of comprehension types reveals that questions requiring numerical or logical reasoning are relatively difficult. We also find several trends between passage sources and comprehension types.

These results suggest that when creating a new benchmark dataset, we need to select passage sources carefully, so that the resulting dataset contains questions that require an understanding of the linguistic phenomena that we are interested in. This is especially important in the adversarial setting because it could concentrate the distribution of questions towards a few specific question types.

Ethics Statement

We aim to accelerate scientific progress on robust general question answering, which could translate downstream to useful tools. We are not looking at possible sources of social bias, although this issue should be highly relevant to those considering sources to use as training data for applied systems (Li et al., 2020; Parrish et al., 2022). We are using Amazon Mechanical Turk despite its history of sometimes treating workers unfairly (Kummerfeld, 2021), especially in recourse for unfair rejections. We make sure that our own pay and rejection policies are comparable to in-person employment, but acknowledge that our study could encourage others to use Mechanical Turk, and that they might not be so careful. This work passed review or is exempt from the oversight of the internal review boards of the authors' institutes.

Acknowledgments

We thank Saranya Venkatraman and Ethan Perez for their feedback on early drafts of this paper. For his early contributions to this project, we thank Harsh Trivedi. SS was supported by JST PRESTO Grant No. JPMJPR20C4. This project has benefited from financial support to SB by Eric and Wendy Schmidt (made by recommendation of the Schmidt Futures program), Samsung Research (under the project *Improving Deep Learning using Latent Structure*), and Apple. A Passage Sources

From Project Gutenberg, we use books from the adventure, fiction, humor, novel, and story genres.[3]

From Wikipedia articles, we use articles listed as Level 3 vital articles.[4] For science, we include health, medicine and disease, science, technology, and mathematics categories. For the arts, we include history, arts, philosophy and religion, and society and social sciences categories.

B Dataset Statistics

Table 2 presents the frequencies of valid and high-agreement examples across the passage sources and collection methods.

Source	Method	Valid	High
MCTest	Dir.	91.6	71.3
	Adv.	91.3	73.9
	Total	91.5	72.6
Gutenberg	Dir.	91.3	67.1
	Adv.	89.0	59.4
	Total	90.2	63.2
Slate	Dir.	90.0	66.1
	Adv.	85.5	59.0
	Total	87.7	62.6
RACE	Dir.	94.8	70.3
	Adv.	91.6	67.7

	Adv.	88.7	62.7
	Total	90.3	65.7

Table 2: Frequency of valid and high-agreement examples for different passage sources and collection methods.

C Worker Statistics

Of the 1,050 workers who joined the question-answering phase of the qualification round, 259 workers (24.7%) passed it. From them, 157 workers submitted the question writing task, and 72 workers (36 each for the standard and adversarial collection) qualified for the main writing task, from which 49 workers joined. The workers were allowed to write up to 250 questions. A total of 167 workers participated in the validation task. No worker answered more than 730 questions. Data collection took approximately a month including the qualification round and the validation task.

D Supervised Model Performance

Table 3 shows the supervised performance of the DeBERTa large model.

E Partial-Input Model Performance

Tables 4 and 5 report the zero-shot performance of DeBERTa xlarge and the supervised performance of DeBERTa large (MNLI).

F Easy and Hard Subsets

Table 6 presents the frequency of easy and hard examples across passage sources and collection

Table 3: Supervised performance of DeBERTa large. The accuracy of each row is given by the model trained on the questions of the other rows (leave-one-out training). Subscript values show the difference from its zero-shot accuracy.

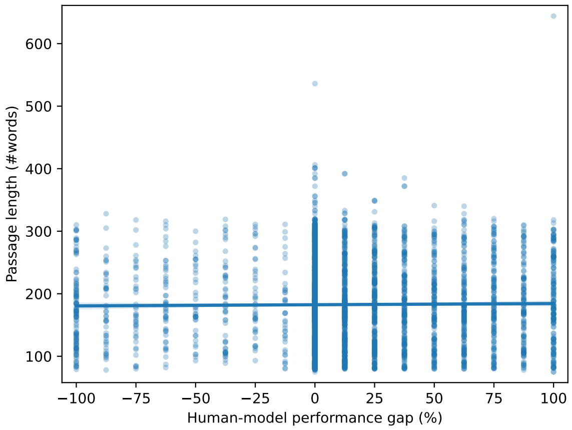

Figure 6: Passage length (number of words) and human–model performance gap. Pearson's $r = 0.01$ with $p = 0.54$.

methods.

G Passage Length

Figure 6 shows the relationship between the passage length and the human–model performance gap.

H Question and Option Length

We plot the average question and option length (the number of words except for punctuation) in the high-agreement examples in Figure 7 across the collection methods and in Figure 8 across the easy and hard subsets. The distributions of question and option length have slightly higher variances in the standard data collection than in the adversarial data collection. This result is consistent with the observation in Nangia et al. (2021).

Table 5: Supervised performance (three-fold cross validation) of DeBERTa large on the partial inputs. Superscripts show standard deviation and subscripts show gains over the zero-shot performance.

I Readability Level

Figure 9 shows the plot between Flesch–Kincaid grade level (Kincaid et al., 1975) and the human–model performance gap. We compute the grade level (L) of a passage using the following formula:

$$L = 0.39 * m + 11.8 * n - 15.59 \qquad (1)$$

where m is the average length of the sentences and n is the average number of syllables of the words in the passage. To estimate the number of syllables in a word, we use the implementation of the sonority sequencing principle (Bartlett et al., 2009) in NLTK

# Questions		1,970	547

Table 6: Distribution (%) of easy and hard questions from each passage source and collection method.

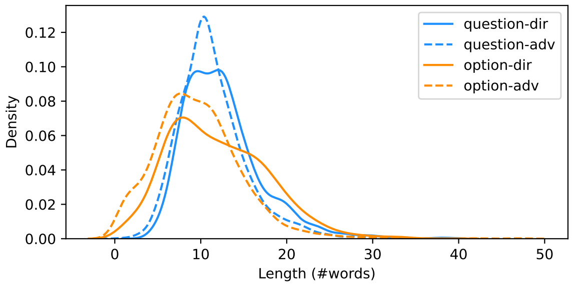

Figure 7: Question and option lengths (number of words) of examples collected in the standard and adversarial methods.

(Bird et al., 2009).[5]

J Syntactic and Lexical Surprisal

Figures 10 and 11 show syntactic and lexical surprisal measures, respectively, for all examples. Following Roark et al. (2009), we compute a surprisal value for each word, then take the average for each sentence, and finally take the average over the whole passage. We use an incremental parser with a lexicalized probabilistic context-free grammar.[6]

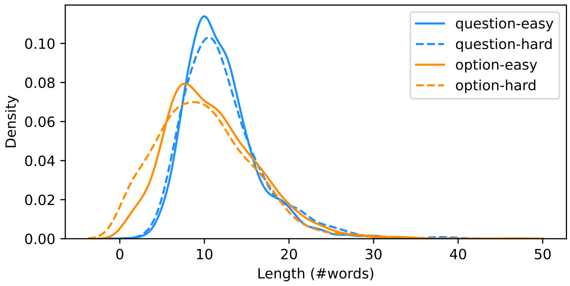

Figure 8: Question and option lengths (number of words) of easy and hard examples.

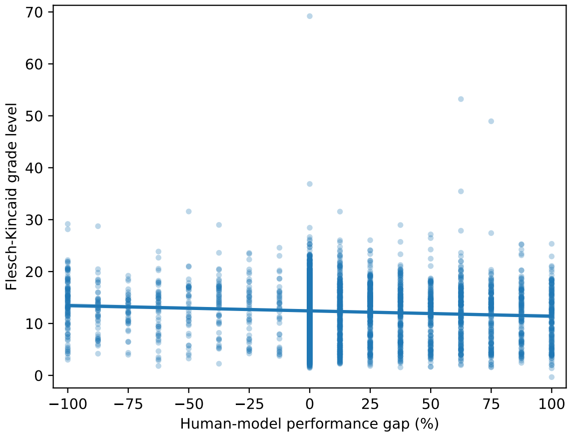

Figure 9: Flesch–Kincaid grade level and human–model performance gap. Pearson's $r = -0.08$ with $p < 0.001$.

K Elapsed Time for Answering Questions

Figure 12 shows the plot of time elapsed by humans while answering questions in the validation task. We measure the elapsed time from when a worker opens a task to when they submit their answer. In addition, we measure the elapsed time for writing questions as a reference (Figure 13). We observe that workers take slightly longer to write hard examples than easy examples.

L Average Word Frequencies

Figure 14 plots the average word frequencies of all examples. We refer to SUBTLEXus (Brysbaert and New, 2009) for the word frequencies per one million words in a corpus of American English subtitles.

M Question and Comprehension Types

Figure 15 shows the frequency of the question words and the two subsequent words for each collection method. Figures 16 and 17 show the box

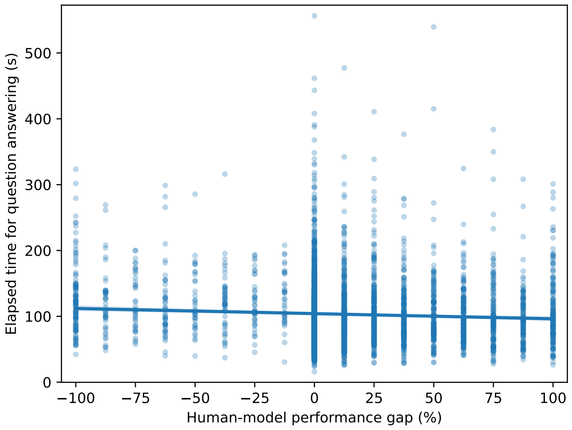

Figure 12: Elapsed time (s) for answering all examples. Pearson's $r = -0.08$ with $p < 0.001$.

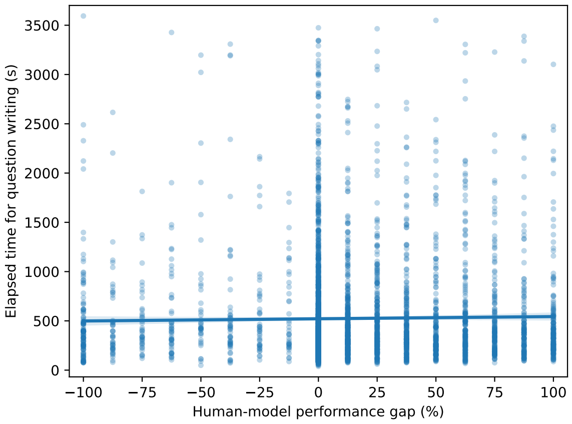

Figure 13: Elapsed time (s) for writing all examples. Pearson's $r = 0.03$ with $p = 0.03$.

plots between human–model performance gap and questions words or comprehension types, respectively. Figures 18 and 5 show the frequency of question words and comprehension types, respectively, across the passage sources and collection methods. In the comprehension types annotation, a question can have multiple labels. Therefore, the sum of the frequencies may exceed 100%.

The definitions of the comprehension types are as follows:

1. **Factuality** (*true/false/likely*) is reasoning of which answer option most (or least) describes facts or events in a given passage.
2. **Factoid** simply asks about described events or entities, typically with typical *what* questions.
3. **Non-factoid** is related to *why* and *how* questions, such as ones asking about causality, a character's attitude, or the process of described events.
4. **Gestalt/Attitude** asks about the summary, theme, or conclusion of the content of a given passage or the author's attitude towards it.
5. **Numeric** indicates questions that require arithmetic reasoning.
6. **Spatial/Temporal** is related to the understanding of places and locations (spatial) or the temporal order or duration (temporal) of described events.
7. **Logical** is pertinent to logical reasoning and arguments described in a passage.

N Human Accuracy as Question Difficulty

We compute a similar linguistic analysis using the average human accuracy as the difficulty of the

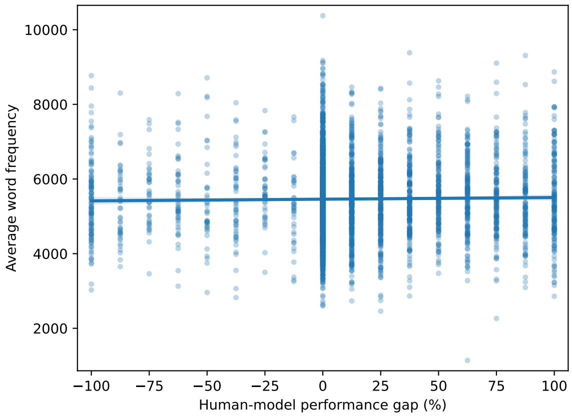

Figure 14: Average word frequencies using SUBTLEXus values. Pearson's $r = 0.02$ with $p = 0.23$.

(a) Standard collection

(b) Adversarial collection

Figure 15: Question words and their two subsequent words in the (a) standard and (b) adversarial collection methods.

questions. Table 7 shows Pearson's correlation r and its p-value between the human accuracy (as the question difficulty) and textual aspects. Just as when using the human–model gap, we do not observe any strong correlations except for the elapsed time for answering that shows a weak negative correlation, which means difficult-for-human questions take slightly longer for answering. Figure 19 shows the frequency of comprehension types in easy and hard examples with regard to the question difficulty for humans.

O Examples of Collected Questions

Table 8 shows examples of questions and options for each comprehension type. After extracting the question words, we review about 100 questions to collect keywords that determine comprehension type (e.g., "reason" for *non-factoid*,"best summarize" for *gestalt/attitude* and "if" for *logical*). We then write simple rules that highlight these keywords, which help us manually annotate the remaining questions within approximately five hours.

P Writing Instructions and Examples

Figures 20, 21, and 22 show the instructions, good and bad examples, and task interface provided to the crowdworkers in our data collection.

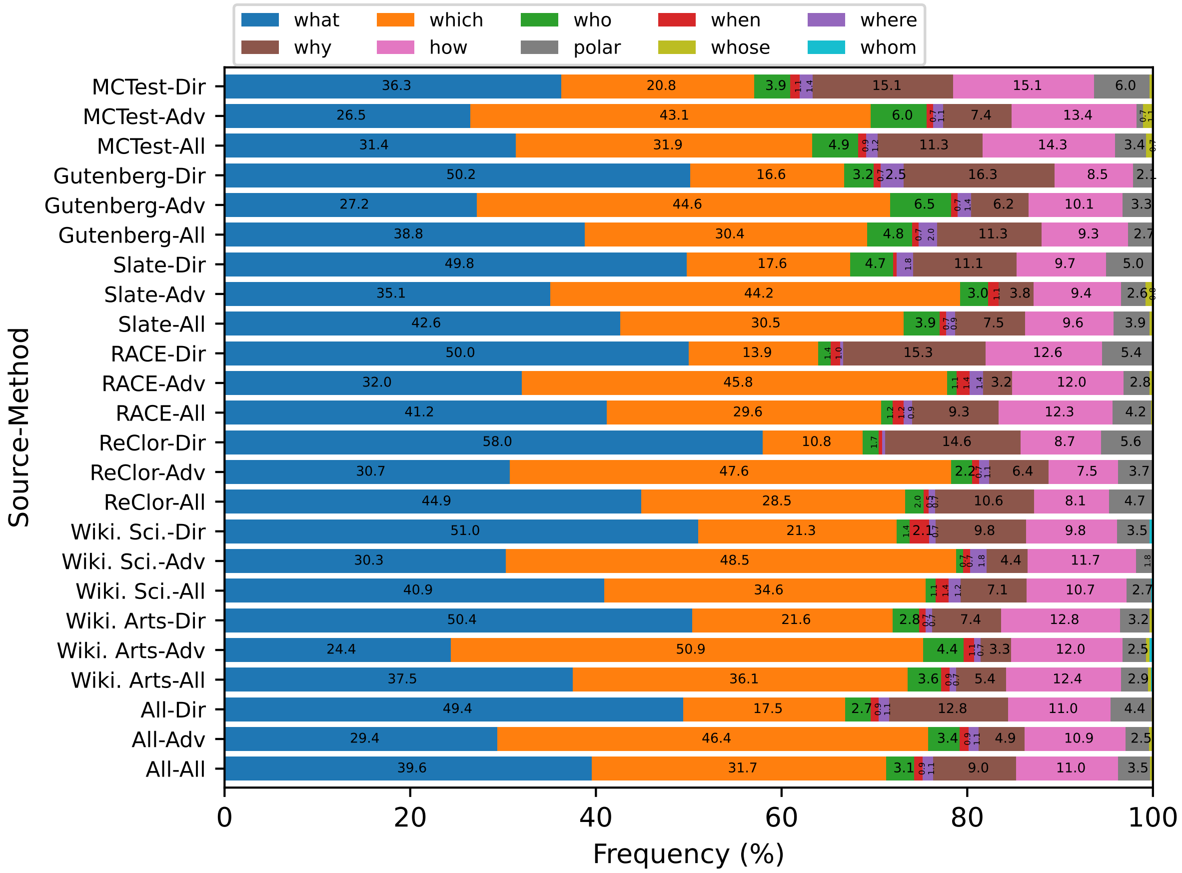

Figure 18: Frequencies of question words (wh-words) across passage sources and collection methods.

Aspects	r	p
Passage length	0.009	0.59
Flesch–Kincaid grade	-0.06	<0.001
Elapsed time for answering	-0.16	<0.001
Elapsed time for writing	-0.04	0.007
Syntactic surprisal	-0.01	0.53
Semantic surprisal	-0.001	0.93
Average word frequency	0.004	0.82

Table 7: Pearson's correlation r and its p-value between the human accuracy and textual aspects.

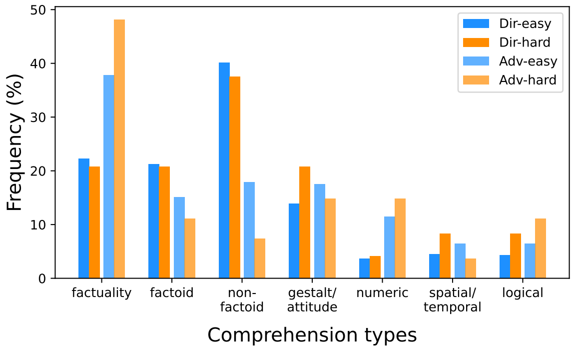

Figure 19: Frequency of comprehension types in easy and hard examples as determined by the question difficulty for humans for each collection method.

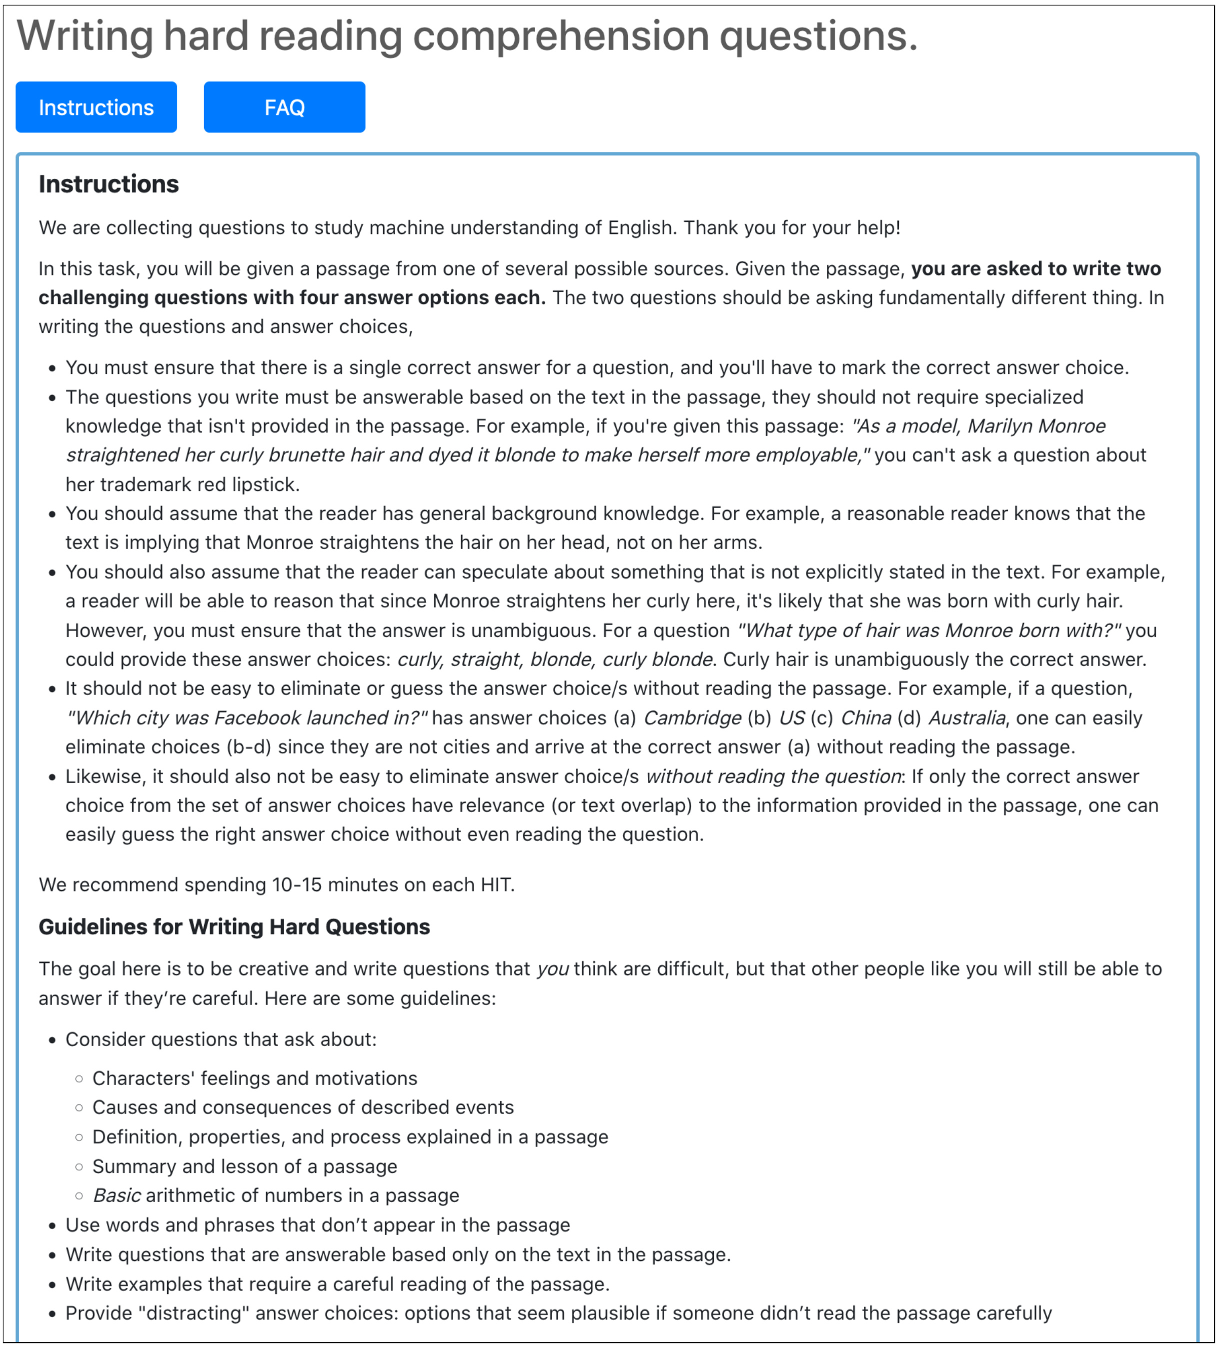
Comprehension Type (source, difficulty)	Example
Factuality (Gutenberg, easy)	Q: Which of the following is not mentioned in the passage? A: ☐ An Earl lived in a house that had a relatively low profile. / ☐ There were some other buildings near the Manor. / ☐ Scroope is a village that is closely linked to an Earl's home. / ☑ Scroope Manor was sold to the village by the Earl.
Factoid (Wiki. science, easy)	Q: What helps many fish keep their buoyancy in water? A: ☐ muscles on either side of the backbone / ☐ fins / ☑ a swim bladder / ☐ a streamlined body
Non-factoid (Wiki. arts, hard)	Q: How did a major portion of English words enter the English language? A: ☐ French speakers can understand many English words without having to undergo any orthographical change. / ☐ Many words in Old English are from Old Norse. / ☑ About one-third of words in English entered the language from the long contact between French and English. / ☐ Romance languages have "Latinate" roots.
Gestalt/Attitude (Slate, easy)	Q: Which of the following is a criticism the author has about Dick Riordan? A: ☐ He's not transparent about his typical lunch looks like, which highlights his lack of wisdom. / ☑ He's okay syphoning resources from elsewhere to himself for personal gain. / ☐ Much like Hillary Clinton, he lacks any sort of coherent persona. / ☐ He is responsible for the vast swaths of one-story buildings that cover the entire landscape of L.A.
Numeric (RACE, hard)	Q: How old was Mary Shelley when she died? A: ☐ Mary Shelley was in her thirties when she died. / ☐ Mary Shelley died when she was forty four years old. / ☑ Mary Shelley died when she was in her fifties. / ☐ Mary Shelley lived well into her eighties before she died.
Spatial/Temporal (MCTest, easy)	Q: When did it start to rain? A: ☑ It started to rain after Will ate his biscuit and jam. / ☐ It started to rain after Will heard the thunder. / ☐ It started to rain while Will was at the store. / ☐ It started to rain on Will's walk home from the store.
Logical (ReClor, hard)	Q: Which statement, if true, would weaken the conclusion of the passage? A: ☐ Archaeologists have found remains of shipwrecks from 2000 BC between Crete and southern Greece. / ☑ The earliest bronze artifacts found in southern Greece date to 3000 BC. / ☐ The Minoans were far more accomplished in producing bronzeware than any other civilization in the area at the time. / ☐ The capacity of Minoan bronze furnaces was extraordinarily large compared to other societies in 2000 BC.

Table 8: Examples of each comprehension type taken from our collected data.



Writing hard reading comprehension questions.

Instructions

We are collecting questions to study machine understanding of English. Thank you for your help!

In this task, you will be given a passage from one of several possible sources. Given the passage, **you are asked to write two challenging questions with four answer options each.** The two questions should be asking fundamentally different thing. In writing the questions and answer choices,

- You must ensure that there is a single correct answer for a question, and you'll have to mark the correct answer choice.
- The questions you write must be answerable based on the text in the passage, they should not require specialized knowledge that isn't provided in the passage. For example, if you're given this passage: *"As a model, Marilyn Monroe straightened her curly brunette hair and dyed it blonde to make herself more employable,"* you can't ask a question about her trademark red lipstick.
- You should assume that the reader has general background knowledge. For example, a reasonable reader knows that the text is implying that Monroe straightens the hair on her head, not on her arms.
- You should also assume that the reader can speculate about something that is not explicitly stated in the text. For example, a reader will be able to reason that since Monroe straightens her curly here, it's likely that she was born with curly hair. However, you must ensure that the answer is unambiguous. For a question *"What type of hair was Monroe born with?"* you could provide these answer choices: *curly, straight, blonde, curly blonde*. Curly hair is unambiguously the correct answer.
- It should not be easy to eliminate or guess the answer choice/s without reading the passage. For example, if a question, *"Which city was Facebook launched in?"* has answer choices (a) *Cambridge* (b) *US* (c) *China* (d) *Australia*, one can easily eliminate choices (b-d) since they are not cities and arrive at the correct answer (a) without reading the passage.
- Likewise, it should also not be easy to eliminate answer choice/s *without reading the question*: If only the correct answer choice from the set of answer choices have relevance (or text overlap) to the information provided in the passage, one can easily guess the right answer choice without even reading the question.

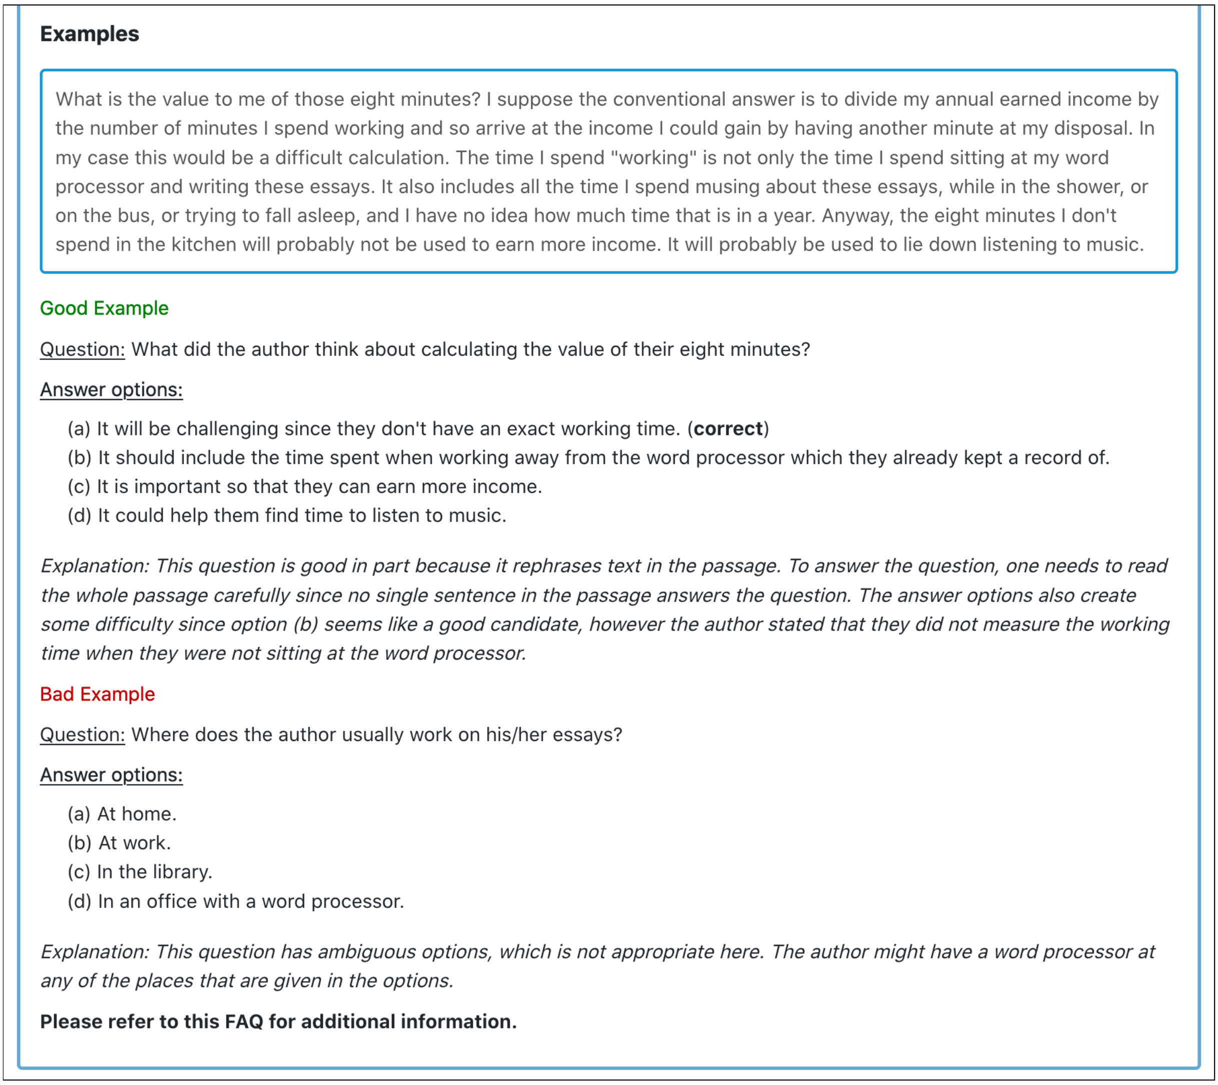
We recommend spending 10-15 minutes on each HIT.

Guidelines for Writing Hard Questions

The goal here is to be creative and write questions that *you* think are difficult, but that other people like you will still be able to answer if they’re careful. Here are some guidelines:

- Consider questions that ask about:
    - Characters' feelings and motivations
    - Causes and consequences of described events
    - Definition, properties, and process explained in a passage
    - Summary and lesson of a passage
    - *Basic* arithmetic of numbers in a passage
- Use words and phrases that don’t appear in the passage
- Write questions that are answerable based only on the text in the passage.
- Write examples that require a careful reading of the passage.
- Provide "distracting" answer choices: options that seem plausible if someone didn’t read the passage carefully

Figure 20: Instructions of the writing task.



Examples

What is the value to me of those eight minutes? I suppose the conventional answer is to divide my annual earned income by the number of minutes I spend working and so arrive at the income I could gain by having another minute at my disposal. In my case this would be a difficult calculation. The time I spend "working" is not only the time I spend sitting at my word processor and writing these essays. It also includes all the time I spend musing about these essays, while in the shower, or on the bus, or trying to fall asleep, and I have no idea how much time that is in a year. Anyway, the eight minutes I don't spend in the kitchen will probably not be used to earn more income. It will probably be used to lie down listening to music.

Good Example

Question: What did the author think about calculating the value of their eight minutes?

Answer options:

(a) It will be challenging since they don't have an exact working time. (**correct**)
(b) It should include the time spent when working away from the word processor which they already kept a record of.
(c) It is important so that they can earn more income.
(d) It could help them find time to listen to music.

Explanation: This question is good in part because it rephrases text in the passage. To answer the question, one needs to read the whole passage carefully since no single sentence in the passage answers the question. The answer options also create some difficulty since option (b) seems like a good candidate, however the author stated that they did not measure the working time when they were not sitting at the word processor.

Bad Example

Question: Where does the author usually work on his/her essays?

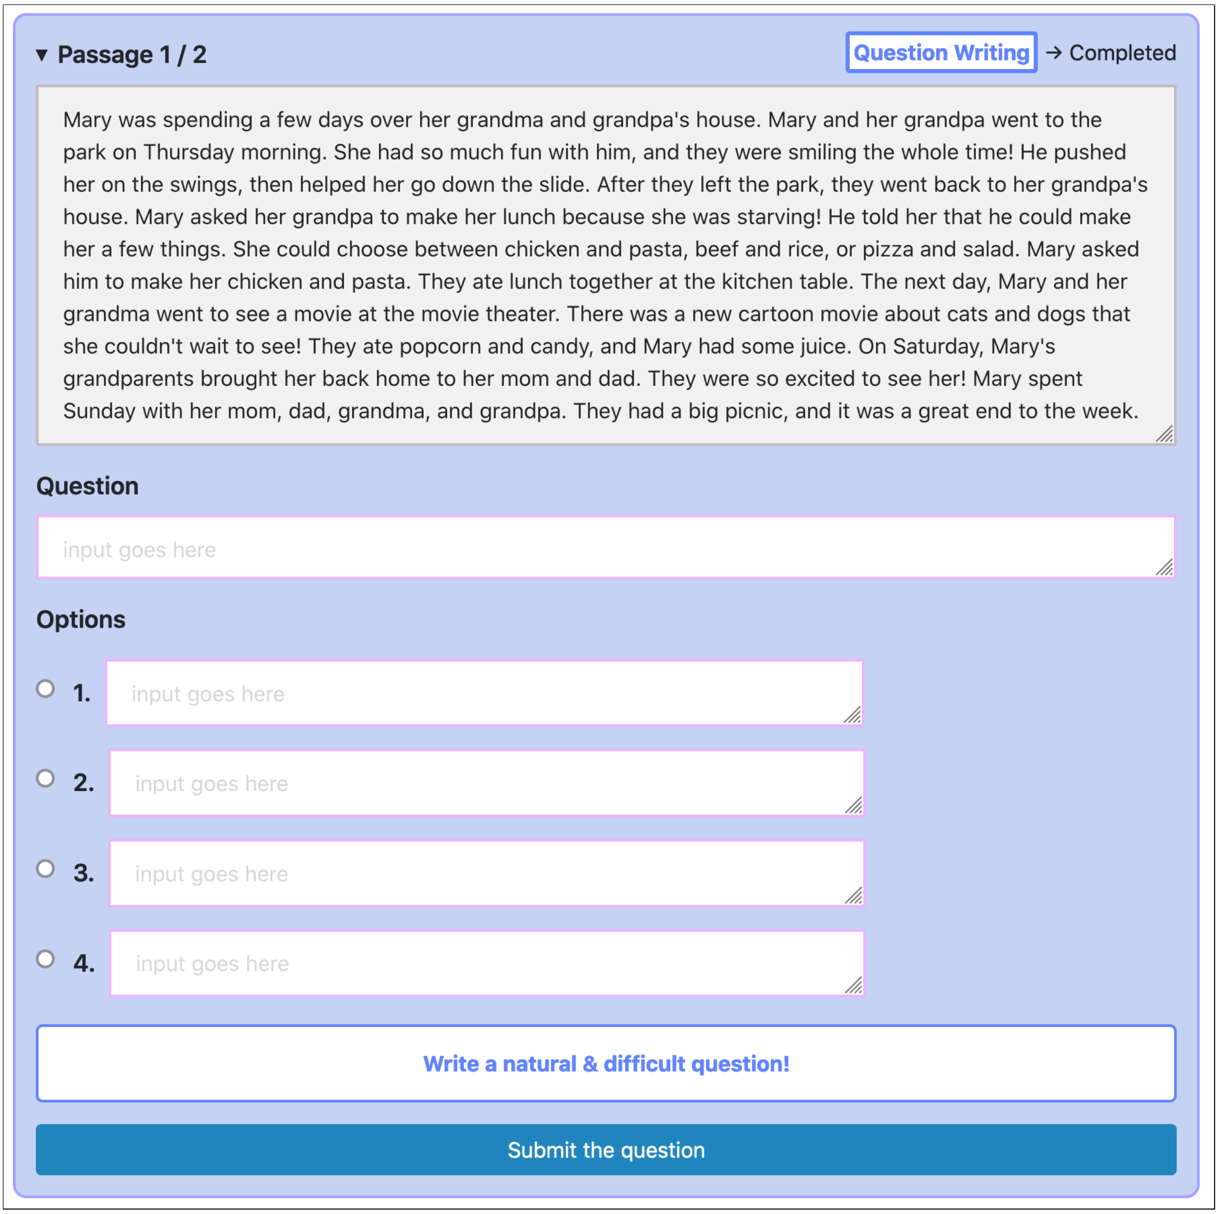
Answer options:

(a) At home.
(b) At work.
(c) In the library.
(d) In an office with a word processor.

Explanation: This question has ambiguous options, which is not appropriate here. The author might have a word processor at any of the places that are given in the options.

Please refer to this FAQ for additional information.

Figure 21: Good and bad examples included in the instructions of the writing task.



Mary was spending a few days over her grandma and grandpa's house. Mary and her grandpa went to the park on Thursday morning. She had so much fun with him, and they were smiling the whole time! He pushed her on the swings, then helped her go down the slide. After they left the park, they went back to her grandpa's house. Mary asked her grandpa to make her lunch because she was starving! He told her that he could make her a few things. She could choose between chicken and pasta, beef and rice, or pizza and salad. Mary asked him to make her chicken and pasta. They ate lunch together at the kitchen table. The next day, Mary and her grandma went to see a movie at the movie theater. There was a new cartoon movie about cats and dogs that she couldn't wait to see! They ate popcorn and candy, and Mary had some juice. On Saturday, Mary's grandparents brought her back home to her mom and dad. They were so excited to see her! Mary spent Sunday with her mom, dad, grandma, and grandpa. They had a big picnic, and it was a great end to the week.

Abstract

Simultaneous Machine Translation is the task of incrementally translating an input sentence before it is fully available. Currently, simultaneous translation is carried out by translating each sentence independently of the previously translated text. More generally, Streaming MT can be understood as an extension of Simultaneous MT to the incremental translation of a continuous input text stream. In this work, a state-of-the-art simultaneous sentence-level MT system is extended to the streaming setup by leveraging the streaming history. Extensive empirical results are reported on IWSLT Translation Tasks, showing that leveraging the streaming history leads to significant quality gains. In particular, the proposed system proves to compare favorably to the best performing systems.

1 Introduction

Simultaneous Machine Translation (MT) is the task of incrementally translating an input sentence before it is fully available. Indeed, simultaneous MT can be naturally understood in the scenario of translating a text stream as a result of an upstream Automatic Speech Recognition (ASR) process. This setup defines a simultaneous Speech Translation (ST) scenario that is gaining momentum due to the vast number of industry applications that could be exploited based on this technology, from person-to-person communication to subtitling of audiovisual content, just to mention two main applications.

These real-world streaming applications motivate us to move from simultaneous to streaming MT, understanding streaming MT as the task of simultaneously translating a potentially unbounded and unsegmented text stream. Streaming MT poses two main additional challenges over simultaneous MT. First, the MT system must be able to leverage the streaming history beyond the sentence level both at training and inference time. Second, the system must work under latency constraints over the entire stream.

With regard to exploiting streaming history, or more generally sentence context, it is worth mentioning the significant amount of previous work in offline MT at sentence level (Tiedemann and Scherrer, 2017; Agrawal et al., 2018), document level (Scherrer et al., 2019; Ma et al., 2020a; Zheng et al., 2020b; Li et al., 2020; Maruf et al., 2021; Zhang et al., 2021), and in related areas such as language modelling (Dai et al., 2019) that has proved to lead to quality gains. Also, as reported in (Li et al., 2020), more robust ST systems can be trained by taking advantage of the context across sentence boundaries using a data augmentation strategy similar to the prefix training methods proposed in (Niehues et al., 2018; Ma et al., 2019). This data augmentation strategy was suspected to boost re-translation performance when compared to conventional simultaneous MT systems (Arivazhagan et al., 2020).

Nonetheless, with the notable exception of (Schneider and Waibel, 2020), sentences in simultaneous MT are still translated independently from each other ignoring the streaming history. (Schneider and Waibel, 2020) proposed an end-to-end streaming MT model with a Transformer architecture based on an Adaptive Computation Time method with a monotonic encoder-decoder attention. This model successfully uses the streaming history and a relative attention mechanism inspired by Transformer-XL (Dai et al., 2019). Indeed, this is an MT model that sequentially translates the input stream without the need for a segmentation model. However, it is hard to interpret the latency of their streaming MT model because the authors observe that the current sentence-level latency measures, Average Proportion (AP) (Cho and Esipova, 2016), Average Lagging (AL) (Ma et al., 2019) and Differentiable Average Lagging (DAL) (Cherry and Foster, 2019) do not perform

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 6972 - 6985

well on a streaming setup. This fact is closely related to the second challenge mentioned above, which is that the system must work under latency constraints over the entire stream. Indeed, current sentence-level latency measures do not allow us to appropriately gauge the latency of streaming MT systems. To this purpose, (Iranzo-Sánchez et al., 2021) recently proposed a stream-level adaptation of the sentence-level latency measures based on the conventional re-segmentation approach applied to the ST output in order to evaluate translation quality (Matusov et al., 2005).

In this work, the simultaneous MT model based on a unidirectional encoder-decoder and training along multiple wait-k paths proposed by (Elbayad et al., 2020a) is evolved into a streaming-ready simultaneous MT model. To achieve this, model training is performed following a sentence-boundary sliding-window strategy over the parallel stream that exploits the idea of prefix training, while inference is carried out in a single forward pass on the source stream that is segmented by a Direct Segmentation (DS) model (Iranzo-Sánchez et al., 2020). In addition, a refinement of the unidirectional encoder-decoder that takes advantage of longer context for encoding the initial positions of the streaming MT process is proposed. This streaming MT system is thoroughly assessed on IWSLT translation tasks to show how leveraging the streaming history provides systematic and significant BLEU improvements over the baseline, while reported stream-adapted latency measures are fully consistent and interpretable. Finally, our system favourably compares in terms of translation quality and latency to the latest state-of-the-art simultaneous MT systems (Ansari et al., 2020).

This paper is organized as follows. Next section provides a formal framework for streaming MT to accommodate streaming history in simultaneous MT. Section 3 presents the streaming experimental setup whose results are reported and discussed in Section 4. Finally, conclusions and future work are drawn in Section 5.

2 Streaming MT

In streaming MT, the source stream X to be translated into Y comes as an unsegmented and unbounded sequence of tokens. In this setup, the decoding process usually takes the greedy decision of which token appears next at the i-th position of the translation being generated

$$\hat{Y}_i = \operatorname*{argmax}_{y \in \mathcal{Y}} p\Big(y \mid X_1^{G(i)}, Y_1^{i-1}\Big) \tag{1}$$

where $G(i)$ is a global delay function that tells us the last position in the source stream that was available when the i-th target token was output, and $\mathcal{Y}$ is the target vocabulary. However, taking into account the entire source and target streams can be prohibitive from a computational viewpoint, so the generation of the next token can be conditioned to the last $H(i)$ tokens of the stream as

$$\hat{Y}_i = \operatorname*{argmax}_{y \in \mathcal{Y}} p\Big(y \mid X_{G(i)-H(i)+1}^{G(i)}, Y_{i-H(i)}^{i-1}\Big) . \tag{2}$$

Nevertheless, for practical purposes, the concept of sentence segmentation is usually introduced to explicitly indicate a monotonic alignment between source and target sentences in streaming MT. Let us consider for this purpose the random variables $\mathbf{a}$ and $\mathbf{b}$ for the source and target segmentation of the stream, respectively. Variables $\mathbf{a}$ and $\mathbf{b}$ can be understood as two vectors of equal length denoting that the n-th source sentence starts at position a_n, while the n-th target sentence does so at position b_n.

In the next sections, we reformulate simultaneous MT in terms of the more general framework of streaming MT. This reformulation allows us to consider opportunities for improvement of previous simultaneous MT models.

2.1 Simultaneous MT with streaming history

In the conventional simultaneous MT setup, the aforementioned variables $\mathbf{a}$ and $\mathbf{b}$ are uncovered at training and inference time, while in streaming MT $\mathbf{a}$ and $\mathbf{b}$ are considered hidden variables at inference time that may be uncovered by a segmentation model. In fact, in conventional simultaneous MT the history is limited to the current sentence being translated, while in streaming MT we could exploit the fact that the history could potentially span over all the previous tokens before the current sentence.

To this purpose, the global delay function $G(i)$ introduced above would replace the sentence-level delay function $g(i)$ commonly used in simultaneous MT. However, it should be noticed that we could express $g(i)$ as $G(i) - a_n$ with $b_n \leq i < b_{n+1}$. Delay functions are defined as a result of the policy being applied. This policy decides what action to take at each timestep, whether to read a token from the input or to write a target token. Policies can be either fixed (Ma et al., 2019; Dalvi et al., 2018) depending only on the current timestep, or adaptive (Arivazhagan et al., 2019; Ma et al., 2020b; Zheng et al., 2020a) being also conditioned on the available input source words. Among those fixed policies, the sentence-level wait-k policy proposed by (Ma et al., 2019) is widely used in simultaneous MT with the simple local delay function

$$g(i) = k + i - 1. \tag{3}$$

This policy initially reads k source tokens without writing a target token, and then outputs a target token every time a source token is read. This is true in the case that the ratio between the source and target sentence lengths is one. However, in the general case, a catch-up factor γ computed as the inverse of the source-target length ratio defines how many target tokens are written for every read token, that generalises Eq. 3 as

$$g(i) = \left\lfloor k + \frac{i-1}{\gamma} \right\rfloor . \tag{4}$$

The wait-k policy can be reformulated in streaming MT so that the wait-k behaviour is carried out for each sentence as

$$G(i) = \left\lfloor k + \frac{i-b_n}{\gamma} \right\rfloor + a_n - 1 \tag{5}$$

where $b_n \leq i < b_{n+1}$.

In streaming MT, we could take advantage of the streaming history by learning the probability distribution stated in Eq. 2, whenever streaming samples would be available. However, training such a model with arbitrarily long streaming samples poses a series of challenges that need to be addressed. Firstly, it would be necessary to carefully define $G(i)$ and $H(i)$ functions so that, at each timestep, the available source and target streams are perfectly aligned. Given that the source-target length ratio may vary over the stream, if one uses a wait-k policy with a fixed γ, there is a significant chance that source and target are misaligned at some points over the stream. Secondly, every target token can potentially have a different $G(i)$ and $H(i)$, so the encoder-decoder representation and contribution to the loss would need to be recomputed for each target token at a significant computational expense. Lastly, current MT architectures and training procedures have evolved conditioned by the availability of sentence-level parallel corpora for training, so they need to be adapted to learn from parallel streams.

To tackle the aforementioned challenges in streaming MT, a compromise practical solution is to uncover the source and target sentence segmentations. At training time, parallel samples are extracted by a sentence-boundary sliding window spanning over several sentences of the stream that shifts to the right one sentence at a time. In other words, each sentence pair is concatenated with its corresponding streaming history that includes previous sentence pairs simulating long-span prefix training. Doing so, we ensure that source and target streams are properly aligned at all times, and training can be efficiently carried out by considering a limited history. The inference process is performed in a purely streaming fashion in a single forward pass as defined in Eq. 2 with $H(i)$ being consistently defined in line with training, so that the streaming history spans over previous sentences already translated.

2.2 Partial Bidirectional Encoder

In simultaneous MT, the conventional Transformer-based bidirectional encoder representation (of the l-th layer) of a source token at any position j is constrained to the current n-th sentence

$$e_j^{(l)} = \text{Enc}\left(e_{a_n:G(i)}^{(l-1)}\right) \tag{6}$$

where $a_n \leq j \leq G(i)$, while the decoder can only attend to previous target words and the encoding of those source words that are available at each timestep

$$s_i^{(l)} = \text{Dec}\left(s_{b_n:i-1}^{(l-1)}, e_{a_n:G(i)}^{(l-1)}\right) . \tag{7}$$

As a result, the encoder and decoder representations for positions j and i, respectively, could be computed taking advantage of subsequent positions to position j up to position $G(i)$ at inference time. However, at training time, this means that this bidirectional encoding-decoding of the source sentence has to be computed for every timestep, taking up to $|y|$ times longer than the conventional Transformer model.

To alleviate this problem, (Elbayad et al., 2020a) proposes a wait-k simultaneous MT model based on a modification of the Transformer architecture that uses unidirectional encoders and multiple values of k at training time. In this way, the model is consistent with the limited-input restriction of simultaneous MT at inference time. The proposed unidirectional encoder can be stated as

$$e_j^{(l)} = \text{Enc}\left(e_{a_n:j}^{(l-1)}\right), \tag{8}$$

that is more restrictive than that in Eq. 6, and it consequently conditions the decoder representation, since $G(i)$ in Eq. 7 depends on the specific k value employed at each training step.

As mentioned above, the unidirectional encoder just requires a single forward pass of the encoder at training time, and therefore there is no additional computational cost compared with a conventional Transformer. However, it does not take into account all possible input tokens for different values of k. Indeed, the encoding of the j-th input token will not consider those tokens beyond the j-th position, even if including them into the encoding process does not prevent us from performing a single forward pass.

A trade-off between the unidirectional and bidirectional encoders is what we have dubbed Partial Bidirectional Encoder (PBE), which modifies the unidirectional encoder to allow the first $k-1$ source positions to have access to succeeding tokens according to

$$e_j^{(l)} = \text{Enc}\left(e_{a_n:\max(a_n+k-1,j)}^{(l-1)}\right). \tag{9}$$

PBE allows for a longer context when encoding the initial positions and is consistent with Eq. 7. At training time a single forward pass of the encoder-decoder is still possible as in the unidirectional encoder, and therefore no additional training cost is incurred. At inference time, we fall back to the bidirectional encoder.

Figure 1 shows a graphical comparison of the attention mechanism in $j = 3$ across the bidirectional (left), unidirectional (center) and PBE (right) encoders with $k = 4$ for two consecutive timesteps $i = 1$ with $G(1) = 4$ (top) and $i = 2$ with $G(2) = 5$ (bottom). As observed, PBE can take advantage of additional positions from $j + 1$ up to k with respect to the unidirectional encoder.

In a streaming setup, the bidirectional encoder-decoder of Eqs. 6 and 7 are not necessarily constrained to the current sentence and could exploit a streaming history of $H(i)$ tokens

$$e_j^{(l)} = \text{Enc}\left(e_{G(i)-H(i)+1:G(i)}^{(l-1)}\right) \tag{10}$$

$$s_i^{(l)} = \text{Dec}\left(s_{i-H(i):i-1}^{(l-1)}, e_{G(i)-H(i)+1:G(i)}^{(l-1)}\right). \tag{11}$$

Likewise, the proposed PBE with streaming history states as follows

$$e_j^{(l)} = \text{Enc}\left(e_{G(i)-H(i)+1:\max(G(i)-H(i)+k,j)}^{(l-1)}\right). \tag{12}$$

3 Experimental setup

Table 1: Basic statistics of the training data from the IWSLT 2020 Evaluation Campaign (M = Millions).

Paracrawl		31.4	465.2	502.9

A series of comparative experiments in terms of translation quality and latency have been carried out using data from the IWSLT 2020 Evaluation Campaign (Ansari et al., 2020), for both German→English and English→German. For the streaming condition, our system is tuned on the 2010 dev set, and evaluated on the 2010 test set for comparison with (Schneider and Waibel, 2020). Under this setting, words were lowercased and punctuation was removed in order to simulate a basic upstream ASR system. Also, a second non-streaming setting is used for the English→German direction to compare our system with top-of-the-line sentence-based simultaneous MT systems participating in the IWSLT 2020 Simultaneous Translation Task.

Table 1 summarizes the basic statistics of the IWSLT corpora used for training the streaming MT systems. Corpora for which document information is readily available are processed for training using the sliding window technique mentioned in Section 2.1. Specifically, for each training sentence, we prepend previous sentences, which are added one by one until a threshold h of history tokens is reached. Sentence boundaries are defined on the presence of special tokens (`<DOC>`, `<CONT>`, `<BRK>`, `<SEP>`) as in (Junczys-Dowmunt, 2019). Byte Pair Encoding (Sennrich et al., 2016) with 40K merge operations is applied to the data after preprocessing.

Our streaming MT system is evaluated in terms of latency and translation quality with BLEU (Papineni et al., 2002). Traditionally, latency evaluation in simultaneous MT has been carried out using

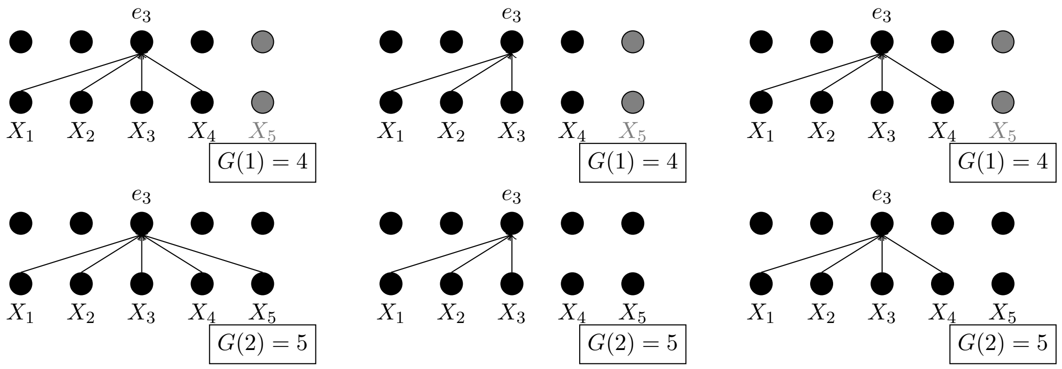

Figure 1: Comparison of attention positions in $j = 3$ for bidirectional (left), unidirectional (center) and PBE (right) encoders with $k = 4$ in two consecutive timesteps $i = 1$ with $G(1) = 4$ (top) and $i = 2$ with $G(2) = 5$ (bottom).

AP, AL and DAL. However, these measures have been devised for sentence-level evaluation, where the latency of every sentence is computed independently from each other and as mentioned before, they do not perform well on a streaming setup. Thus, we revert to the stream-based adaptation of these measures proposed in (Iranzo-Sánchez et al., 2021) unless stated otherwise.

Latency measures for a sentence pair $(\boldsymbol{x}, \boldsymbol{y})$ are based on a cost function $C_i(\boldsymbol{x}, \boldsymbol{y})$ and a normalization term $Z(\boldsymbol{x}, \boldsymbol{y})$

$$L(\boldsymbol{x}, \boldsymbol{y}) = \frac{1}{Z(\boldsymbol{x}, \boldsymbol{y})} \sum_i C_i(\boldsymbol{x}, \boldsymbol{y}) \tag{13}$$

where

$$C_i(\boldsymbol{x}, \boldsymbol{y}) = \begin{cases} g(i) & \text{AP} \\ g(i) - \frac{i-1}{\gamma} & \text{AL} \\ g'(i) - \frac{i-1}{\gamma} & \text{DAL} \end{cases} \tag{14}$$

and

$$Z(\boldsymbol{x}, \boldsymbol{y}) = \begin{cases} |\boldsymbol{x}| \cdot |\boldsymbol{y}| & \text{AP} \\ \underset{i:g(i)=|\boldsymbol{x}|}{\text{argmin}}\ i & \text{AL} \\ |\boldsymbol{y}| & \text{DAL} \end{cases} \tag{15}$$

Latency measures can be computed in a streaming manner by considering a global delay function $G(i)$, that is mapped into a relative delay so that it can be compared with the sentence-level oracle delay. For the i-th target position of the n-th sentence, the associated relative delay can be obtained from the global delay function as $g_n(i) = G(i+b_n)-a_n$. So, the stream-adapted cost function of the latency measures is defined as

$$C_i(\boldsymbol{x}_n, \boldsymbol{y}_n) = \begin{cases} g_n(i) & \text{AP} \\ g_n(i) - \frac{i-1}{\gamma_n} & \text{AL} \\ g'_n(i) - \frac{i-1}{\gamma_n} & \text{DAL} \end{cases} \tag{16}$$

with $g'_n(i)$ defined as

$$\max \begin{cases} g_n(i) & \\ g'_{n-1}(|\boldsymbol{x}_{n-1}|) + \frac{1}{\gamma_{n-1}} & i = 1 \\ g'_n(i-1) + \frac{1}{\gamma_n} & i > 1 \end{cases} \tag{17}$$

This definition assumes that the source and target sentence segmentation of the stream are uncovered, but this is not always the case (Schneider and Waibel, 2020) or they may not match that of the reference translations. However, sentence boundaries can be obtained by re-segmenting the system hypothesis following exactly the same procedure applied to compute translation quality in ST evaluation. To this purpose, we use the MWER segmenter (Matusov et al., 2005) to compute sentence boundaries according to the reference translations.

Our streaming MT models have been trained following the conventional Transformer BASE (German↔English streaming MT) and BIG (English→German simultaneous MT) configurations (Vaswani et al., 2017). As in (Schneider and Waibel, 2020), after training is finished, the models are finetuned on the training set of MuST-C (Di Gangi et al., 2019).

The proposed model in Section 2 assumes that at inference time the source stream has been segmented into sentences. To this purpose, we opt for the text-based DS model (Iranzo-Sánchez et al., 2020), a sliding-window segmenter that moves over the source stream taking a split decision at each token based on a local-context window that extends to both past and future tokens. This segmenter is streaming-ready and obtains superior translation quality when compared with other segmenters (Stolcke, 2002; Cho et al., 2017). As the future window length of the DS segmenter conditions the latency of the streaming MT system, this length was adjusted to find a tradeoff between latency and translation quality. The DS segmenter was trained on the TED corpus (Cettolo et al., 2012).

4 Evaluation

Figure 2 reports the evolution of BLEU scores on the German-English IWSLT 2010 dev set as a function of the k value in the wait-k policy for a range of streaming history lengths ($h = \{0, 20, 40, 60, 80\}$). We show results for the 3 encoders introduced previously. History lengths were selected taking into account that the average sentence length is 20 tokens. A history length of zero ($h = 0$) refers to the conventional sentence-level simultaneous MT model. The BLEU scores for the offline MT systems with a bidirectional encoder are also reported using horizontal lines, in order to serve as reference values. We report offline results for $h = 0$ and the best performing history configuration, $h = 60$. All systems used the reference segmentation during decoding.

As observed, BLEU scores of the simultaneous MT systems leveraging on the streaming history ($h > 0$) are systematically and notably higher than those of conventional sentence-based simultaneous MT system ($h = 0$) over the range of wait-k values. Indeed, as the streaming history increases, BLEU scores also do reaching what it seems the optimal history length at $h = 60$ and slightly degrading at $h = 80$. As expected, when replacing the unidirectional encoder by the PBE, BLEU scores improve as the wait-k value increases, since PBE has additional access to those tokens from $j + 1$ up to k. For instance, for $k = 32$ and $h = 60$, PBE is 0.7 BLEU points above the unidirectional encoder. On the other hand, it can be observed how using an encoder which is not fully bidirectional during training, creates a performance gap with respect to the offline bidirectional model when carrying out inference in an offline manner ($k \geq 32$). It can be also observed how the PBE model is better prepared for this scenario and shows a smaller gap. It is important to keep in mind that although both offline and PBE models behave the same way during inference for a large enough k, during training time the PBE model, trained using the multi-k with k randomly sampled for each batch, has been optimized jointly for low, medium and high latencies.

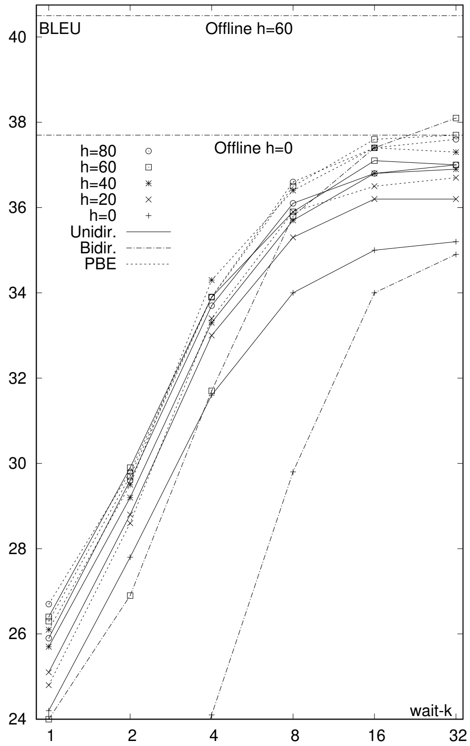

Figure 2: BLEU scores on the German-English IWSLT 2010 dev set as a function of the k value in the wait-k policy for a range of streaming history (h) lengths and encoder type (See Appendix A for a close-up).

In general, the bidirectional encoder shows poor performance for simultaneous MT. This can be explained by the fact that there exists a mismatch between the training condition (whole source available) and the inference condition (only a prefix of the source is available for $k < 32$). These results are consistent with (Elbayad et al., 2020a). Keep in mind that this bidirectional model is different from the offline one because it has been subject to the constraints of Eq. 7 during training. As a result of the BLEU scores reported in Figure 2, the streaming MT system with $h = 60$ and PBE was used in the rest of the German-English experiments.

Following (Schneider and Waibel, 2020)'s setup, the test set is lowercased and concatenated into a single stream. In order to measure the latency of the pipeline defined by the segmenter followed by MT system, it is necessary to take into account not only the latency of the MT system but also that of the segmenter. Thankfully this is straightforward to do in our pipeline, as a segmenter with a

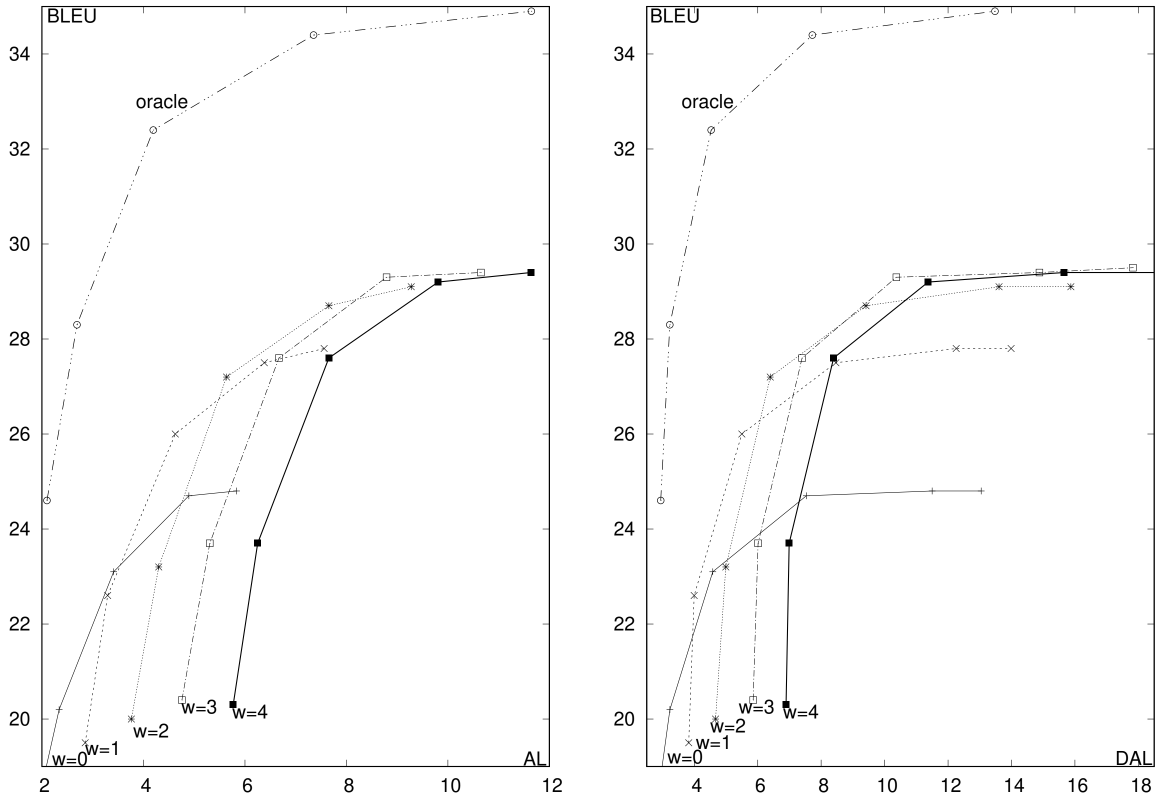

Figure 3: BLEU scores versus stream-adapted AL and DAL (scale s=0.85) with segmenters of future window length $w = \{0, 1, 2, 3, 4\}$ on the IWSLT 2010 test set. Points over each curve correspond to $k = \{1, 2, 4, 8, 16\}$ values of the wait-k policy used at inference time.

future window of length w modifies the pipeline policy so that, at the start of the stream, w READ actions are carried out to fill up the future window. Then, every time the MT system carries out a READ action, it receives one token from the segmenter. Thus, the integration of the segmenter into the pipeline is transparent from a latency viewpoint. Figure 3 shows BLEU scores versus stream-adapted AL and DAL (s scale = 0.85) figures reported with segmenters of future window length $w = \{0, 1, 2, 3, 4\}$ for a streaming evaluation on the IWSLT 2010 test set. Points over each curve correspond to $k = \{1, 2, 4, 8, 16\}$ values of the wait-k policy used at inference time. Results for a $w = 0$ oracle are also shown as an upper-bound.

As shown, stream-adapted AL and DAL figures achieved by our streaming MT system are reasonable, lagging 2-10 tokens behind the speaker for nearly maximum BLEU scores with a best BLEU score of 29.5 points. The same happens with AP figures ranging from 0.6 for $w = 0$ to 1.3 for $w = 4$. These figures highlight the advantages of tying together our translation policy with the sentence segmentation provided by the DS model. Every time the DS model emits an end-of-sentence event, the MT model is forced to catch-up and translate the entire input. In this way, the MT model never strays too far from the speaker, even if the source-target length ratio differs from the γ defined at inference time. See Appendix A for streaming translation results in the reverse direction (English → German).

Next, we compare our proposed streaming MT (STR-MT) model with the $\lambda = 0.3$ ACT system (Schneider and Waibel, 2020) in terms of BLEU score and stream-adapted latency measures on Table 2. Stream-level AL and DAL indicate that the ACT models lags around 100 tokens behind the speaker. Although both MT systems achieve similar translation quality levels, they do so at significantly different latencies, since the ACT model

Table 2: Latency and quality comparison of ACT (Schneider and Waibel, 2020) and the proposed STR-MT on the IWSLT 2010 De-En test set.

Model	BLEU	AP	AL	DAL
ACT	30.3	10.3	100.1	101.8
STR-MT	29.5	1.2	11.2	17.8

lacks a catch-up mechanism to synchronize and keep the pace of the speaker.

The STR-MT model is now compared on the English-German IWSLT 2020 simultaneous text-to-text track (Ansari et al., 2020) with other participants: RWTH (Bahar et al., 2020), KIT (Pham et al., 2020) and ON-TRAC (Elbayad et al., 2020b). This comparison is carried out in order to assess whether the proposed streaming MT system is competitive with highly optimized systems for a simultaneous MT task. Given that the test set of this track remains blind, we use the results reported on the MuST-C corpus as a reference. In order to evaluate all systems under the same conditions, the reference segmentation of the MuST-C corpus is used instead of the DS model. Additionally, given that all other participants translate each sentence independently, the conventional sentence-level AL latency measure is reported. Figure 4 shows the comparison of BLEU scores versus AL measured in terms of detokenized tokens. As defined in the IWSLT text-to-text track, three AL regimes, low ($\text{AL} \leq 3$), medium ($3 < \text{AL} \leq 6$) and high ($6 < \text{AL} \leq 15$) were considered.

ON-TRAC and our streaming MT system exhibit a similar progression, which is to be expected given that they are both based on the multi-k approach. However, our system consistently outperforms the ON-TRAC system by 1-2 BLEU. This confirms the importance of utilizing streaming history in order to significantly improve results, and how the proposed PBE model can take better advantage of the history.

RWTH and KIT systems are closer in translation quality to our proposal than ON-TRAC, for AL between 5 and 7. However, these systems do not show a flexible latency policy and are not comparable to our system at other regimes. Indeed, for that to be possible, these systems need to be re-trained, in contrast to our system in which latency is adjusted at inference time.

5 Conclusions

In this work, a formalization of streaming MT as a generalization of simultaneous MT has been proposed in order to define a theoretical framework in which our two contributions have been made. On the one hand, we successfully leverage streaming history across sentence boundaries for a simultaneous MT system based on multiple wait-k paths that allows our system to greatly improve the results of the sentence-level baseline. On the other hand, our PBE is able to take into account longer context information than its unidirectional counterpart, while keeping the same training efficiency.

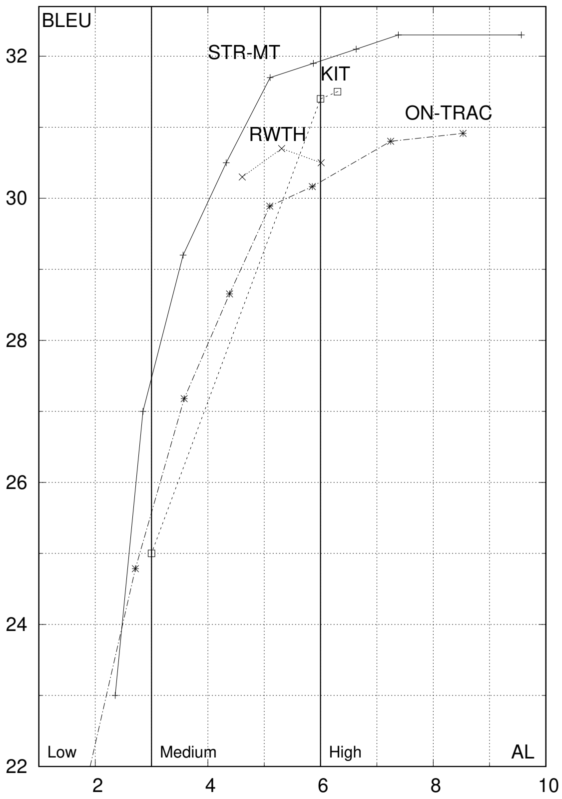

Figure 4: Comparative BLEU scores versus AL at three regimes, low, medium, and high latency, for IWSLT 2020 simultaneous text-to-text track participants, RWTH, ON-TRAC, KIT and our streaming MT (STR-MT) system on the MuST-C corpus.

Our proposed MT system has been evaluated under a realistic streaming setting being able to reach similar translation quality than a state-of-the-art segmentation-free streaming MT system at a fraction of its latency. Additionally, our system has been shown to be competitive when compared with state-of-the-art simultaneous MT systems optimized for sentence-level translation, obtaining excellent results using a single model across a wide range of latency levels, thanks to its flexible inference policy.

In terms of future work, additional training and inference procedures that take advantage of the streaming history in streaming MT are still open for research. One important avenue of improvement is to devise more robust training methods, so that simultaneous models can perform as well as their offline counterparts when carrying out inference at higher latencies. The segmentation model, though proved useful in a streaming setup, adds complexity and can greatly affect translation quality. Thus, the development of segmentation-free streaming MT models is another interesting research topic.

A Extended Streaming Translation Results

Figure 5 shows a close-up of Figure 2, which contains results for the German-English IWSLT 2010 dev set. We can observe how the PBE models obtain consistent quality improvements over their unidirectional counterparts.

Apart from the previously reported German → English streaming MT results, we have also conducted experiments in the reverse direction, English → German. These are shown in Figure 6. The results show a similar trend to previous experiments, with the addition of streaming history allowing our systems to obtain significant improvements over the sentence-based baseline. Unlike the previous case, the optimum history size in this case is $h = 40$ instead of $h = 60$.

In order to enable streaming translation, the best performing $h = 40$ systems has been combined with a German DS system. Similarly to previous experiments, we have conducted tests using different values of w and k in order to balance the

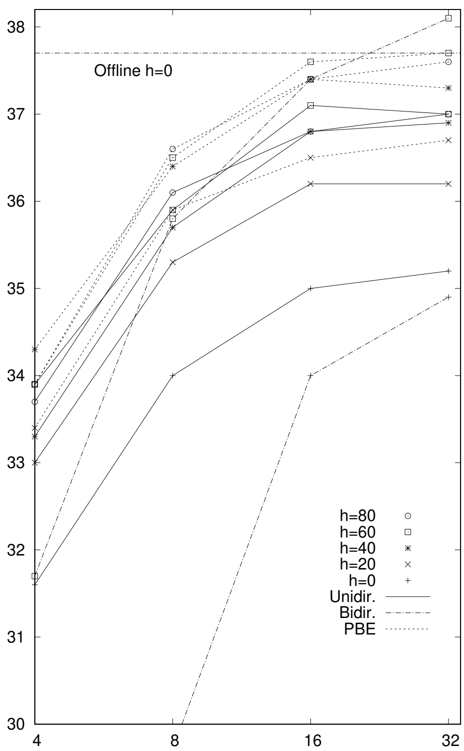

Figure 5: BLEU scores on the German-English IWSLT 2010 dev set as a function of the k value in the wait-k policy for a range of streaming history (h) lengths with a unidirectional encoder (solid lines), PBE (dashed line) or bidirectional (dashed line with points). This is a close-up of Figure 2.

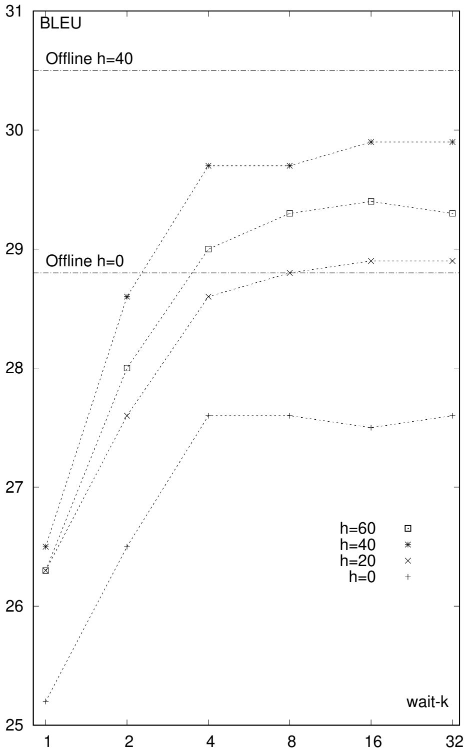

Figure 6: BLEU scores on the English-German IWSLT 2010 dev set as a function of the k value in the wait-k policy for a range of streaming history (h) lengths using a PBE encoder.

latency-quality trade-off, shown in Figure 7. Under the streaming condition, the wait-k policy and DS model allow the model to follow closely the speaker while achieving good quality, with a latency that can be easily adjusted between 4 and 15 tokens depending on the requirements of the task. There are diminishing returns when increasing the latency above 6-7 tokens, as only marginal gains in quality are obtained.

B Efficiency of the proposed models

During training of the unidirectional and PBE encoders, the constraints imposed by Eqs. 8 and 9 are efficiently implemented by full self-attention, as in the bidirectional encoder, followed by an attention mask, for each token to only attend those tokens fulfilling the constraints. The attention mask sets the weights of the other tokens to $-\infty$ before application of the self-attention softmax. This is exactly the same mechanism used in the standard Transformer decoder to prevent the auto-regressive decoder from accessing future information.

This means that the three encoder types have an identical computational behavior. We are not aware of alternative GPU-based acceleration techniques to speed up the training of the unidirectional encoder. If so, this could be also applicable to the training of the standard Transformer decoder.

During inference time, however, the unidirectional encoder has some advantages. Given that the unidirectional encoder is incremental, meaning that the encodings of old tokens do not change when a new token becomes available, the process can be sped up by only computing the encoding of the newly available token. Although encoder self-attention still needs to be computed, a single vector is used as the query instead of the full matrix. Table 3 shows inference statistics for the different components of the En $\rightarrow$ De Transformer Big with h=60. Two setups have been tested: CPU-only inference, and GPU inference. Results were obtained on an Intel i9-7920X machine with an NVIDIA GTX 2080Ti.

The unidirectional encoder is four times faster than the bidirectional encoder when run on a CPU. However, both encoders perform the same when run on a GPU. For the streaming MT scenario considered in this work, no latency reduction is gained

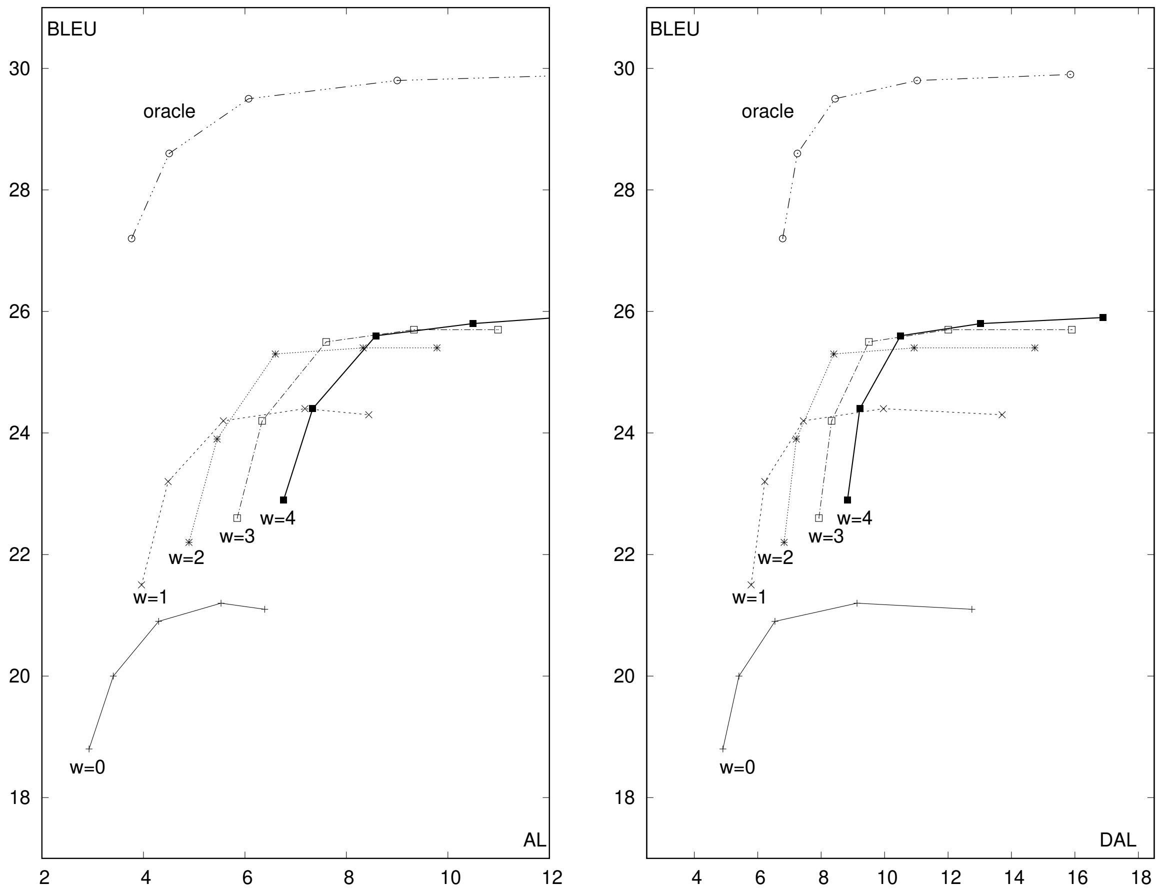

Figure 7: BLEU scores versus stream-adapted AL and DAL (scale s=0.85) with segmenters of future window length $w = \{0, 1, 2, 3, 4\}$ on the English-German IWSLT 2010 test set. Points over each curve correspond to $k = \{1, 2, 4, 8, 16\}$ values of the wait-k policy used at inference time.

Table 3: Latency of translating a token (in seconds) for the proposed En-De h=60 Transformer Big model.

Component	CPU	GPU
Unidir. Encoder	0.034s	0.002s
Bidir. Encoder	0.138s	0.002s
Decoder	0.242s	0.004s

by not re-encoding previous tokens due to the GPU paralellization capability. When run on a GPU, the proposed model works seamlessly under real-time constraints.

C MT System configuration

The multi-k systems have been trained with the official implementation (`https://github.com/elbayadm/attn2d`). Models are trained for 0.5M steps on a machine with 4 2080Ti GPUs. Total training time was 40h for BASE models, and 60h for BIG models. The following command was used to train them:

```
cri=label_smoothed_cross_entropy;
ex=simultaneous_translation
fairseq-train $CORPUS_FOLDER \
-s $SOURCE_LANG_SUFFIX \
-t $TARGET_LANG_SUFFIX \
--user-dir $FAIRSEQ/examples/$ex \
--arch $ARCH waitk_transformer_base \
--share-decoder-input-output-embed \
--left-pad-source False \
--multi-waitk \
--optimizer adam \
--adam-betas ’(0.9, 0.98)’ \
--clip-norm 0.0 \
--lr-scheduler inverse_sqrt \
--warmup-init-lr 1e-07 \
--warmup-updates 4000 \
--lr 0.0005 \
--min-lr 1e-09 \
--dropout 0.1 \
--weight-decay 0.0 \
--criterion $cri \
--label-smoothing 0.1 \
--max-tokens $TOK \
--update-freq 2 \
--save-dir $MODEL_OUTPUT_FOLDER \
--no-progress-bar \
--log-interval 100 \
--max-update 500000 \
--save-interval-updates 10000 \
```

```
--keep-interval-updates 20 \
--ddp-backend=no_c10d \
--fp16
```

with

`ARCH=waitk_transformer_base; TOK=4000`

for the BASE configuration, and

`ARCH=waitk_transformer_big; TOK=2000`

for the BIG one.

For finetuning, we change to the following:

```
--lr-scheduler fixed \
--lr 4.47169e-05 \
```

For the streaming translation scenario, the data is lowercased and all punctuation signs are removed. For the simultaneous scenario (IWSLT 2020 simultaneous text- to-text), it is truecased and tokenized using Moses. We apply language identification to the training data using langid (Lui and Baldwin, 2012) and discard those sentences that have been tagged with the wrong language. SentencePiece (Kudo and Richardson, 2018) is used to learn the BPE units, and we use whitespace as a suffix in order to know when an entire target word has been written during decoding.

In order to obtain samples that can be used for training streaming MT models, a sliding window that moves over whole sentences is used to extract consistent source-target samples. Figure 8 shows an example of corpus construction using $h = 5$. The generated streaming data is upsampled to keep a 1-to-3 ratio with the regular sentence-level data.

D Segmenter System configuration

The Direct Segmentation system has been trained with the official implementation (`https://github.com/jairsan/Speech_Translation_Segmenter`). The following command was used to train the segmenter system:

```
python3 train_text_model.py \
 --train_corpus train.$len_$window.txt \
 --dev_corpus  dev.$len_$window.txt \
 --output_folder $out_f \
 --vocabulary $corpus_f/train.vocab.txt \
 --checkpoint_interval 1 \
 --epochs 15 \
 --rnn_layer_size 256 \
 --embedding_size 256 \
 --n_classes 2 \
 --batch_size 256 \
 --min_split_samples_batch_ratio 0.3 \
 --optimizer adam \
 --lr 0.0001 \
 --lr_schedule reduce_on_plateau \
 --lr_reduce_patience 5 \
 --dropout 0.3 \
 --model_architecture ff-text \
 --feedforward_layers 2 \
 --feedforward_size 128 \
 --sample_max_len $len \
 --sample_window_size $window
```

with the following configurations:

```
(len=11; window=0)
(len=12; window=1)
(len=13; window=2)
(len=14, window=3)
(len=15, window=4)
```

Figure 8: Illustrated example of sample construction with history. Starting from a corpus of ordered sentence pairs (top), streaming samples are constructed (bottom) using $h = 5$. Past history is shown in light gray. Sentence boundary and document tokens (Junczys-Dowmunt, 2019) are not counted for the history size limit. Notice how, for the last sample, the pair $(\boldsymbol{x}_2, \boldsymbol{y}_2)$ is not included in the sample, as the history size limit would have otherwise been exceeded on the source side.

A Rationale-Centric Framework for Human-in-the-loop Machine Learning

Abstract

We present a novel rationale-centric framework with human-in-the-loop – **R**ationales-centric **D**ouble-robustness **L**earning (RDL) – to boost model out-of-distribution performance in few-shot learning scenarios. By using static semi-factual generation and dynamic human-intervened correction, RDL exploits rationales (i.e. phrases that cause the prediction), human interventions and semi-factual augmentations to decouple spurious associations and bias models towards generally applicable underlying distributions, which enables fast and accurate generalisation. Experimental results show that RDL leads to significant prediction benefits on both in-distribution and out-of-distribution tests compared to many state-of-the-art benchmarks—especially for few-shot learning scenarios. We also perform extensive ablation studies to support in-depth analyses of each component in our framework.

1 Introduction

Recent work finds that natural artefacts (Gururangan et al., 2018) or spurious patterns (Keith et al., 2020; Srivastava et al., 2020) in datasets can cause sub-optimal model performance for neural networks. As shown in Figure 1, the bold phrases—***"100% bad"*** and ***"brain cell killing"***—are underlying causes for a negative sentiment prediction that most human readers would recognise. These are defined as *rationales* in this paper. The underlined phrase—"acting and plot"—has been incorrectly recognised as a causal term by the model used fort this example, and is referred to as a *spurious pattern.*

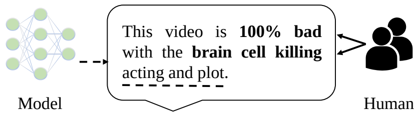

Figure 1: A negative movie review with human annotated causal terms (bold text) and spurious patterns recognised by the model (underlined text).

Spurious patterns (or associations) are caused by natural artefacts or biases in training data (Lertvittayakumjorn and Toni, 2021), and are usually useless, or even harmful, at test time. This issue can be severe in few-shot learning (FSL) scenarios. For instance, Kulesza et al. (2010) suggests that when a model is trained with a small subset of labelled data, it is prone to exploiting spurious patterns leading to poor generalisability that is evident in the performance decay in out-of-distribution (OOD) datasets. In spite of these issues, training deep neural networks using few labelled examples is a compelling scenario since unlabelled data may be abundant but labelled data is expensive to obtain in real-world applications (Lu and MacNamee, 2020; Lu et al., 2021).

There is a strand of research addressing this scenario that seeks to improve model performance by *"introducing methods and resources for training models less sensitive to spurious patterns"* (Kaushik et al., 2020). Most of this work relies on generating counterfactual augmented data (CAD), either manually (Kaushik et al., 2021) or automatically (Feng et al., 2021; Qian et al., 2021; Yang et al., 2021, 2020a; Delaney et al., 2021). For example, Kaushik et al. (2020) proposed a human-in-the-loop framework where human annotators are required to make minimal changes to original movie reviews to produce sentiment-flipped counterfactual reviews, which enables models to learn useful associations between input texts and output labels (Kaushik et al., 2021).

Generating manual counterfactuals, however, is expensive and time-consuming—Kaushik et al. (2020) report the cost of revising $2.5k$ instances at over $10,000. On the other hand, fully automatic methods are task-specific and therefore have weak robustness across domains and less reliabil-

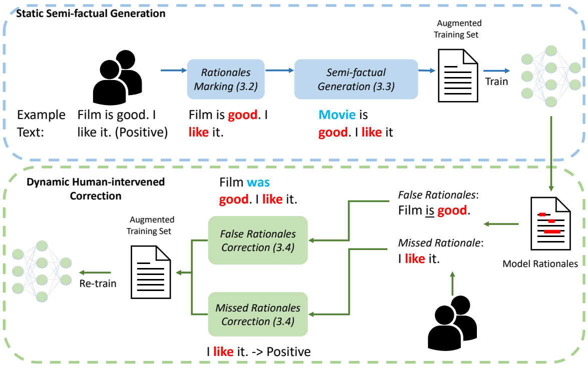

Figure 2: The procedure of the Rationale-centric Double-robustness Learning framework. Red text highlights rationales identified by human annotators. Blue text indicates words replaced in raw text. Underlined text shows spurious patterns identified by the model.

ity compared to manual counterfactuals. To address these issues, we propose **R**ationales-centric **D**ouble-robustness **L**earning (RDL), a human-in-the-loop framework for data augmentation in a few-shot setting, which is efficient, robust, model-agnostic, and general across tasks.

Our main idea is a rationale-centric strategy for eliminating the effect of spurious patterns by leveraging human knowledge as shown in Figure 2. Our double-robustness framework consists of two main modules. The first is a *Static Semi-factual Generation module* that generates a set of semi-factual data automatically for a given instance by using human-identified rationales. Such labelling requires less human input compared to fully manual counterfactual generation (see Section 3.1). In contrast with counterfactuals (Roese, 1997) that rely on what might have been different (i.e. the label would be changed if certain terms have been changed), semi-factuals (McCloy and Byrne, 2002; Kenny and Keane, 2021), as used in our work, aim to guide a model to identify terms less causally related to the label (i.e. even if certain terms had been changed, the label would be kept the same). Second, we apply a *Dynamic Human-intervened Correction module*, where the most salient features are identified for model predictions over a set of training examples, and human workers intervene by checking the correctness of the rationale in case first-round modifications introduce new artefacts. We evaluate the two modules in a few-shot setting, where a minimum number of training instances are labeled for maximum generalisation power, both for in-distribution and OOD predictions.

Results on a sentiment analysis task, which is also used in Kaushik et al. (2020), demonstrate that the double-robust models can be less sensitive to spurious patterns. In particular, models trained with RDL with only 50 labelled examples achieve the same or even better results than fully-supervised training with a full training set of 1,707 examples, and improvements are especially significant for OOD tests. The predictive model trained with RDL using only 100 labelled examples outperforms models trained with manual (Kaushik et al., 2020) and automatic CAD (Yang et al., 2021) using the full augmented training set of 3,414 examples.

To the best of our knowledge, we are the first to exploit the efficacy of semi-factuals and human-intervention for improving the generalisation abilities of deep neural networks in few-shot learning scenarios.[*]

2 Related Work

Data augmentation has been used for resolving artefacts in training datasets before (Gururangan et al., 2018; Srivastava et al., 2020; Kaushik et al., 2021). In particular, previous work (Kaushik et al., 2020) relied on large-scale crowd-sourcing to generate useful augmented data. More recently, Yang et al. (2021), and Wang and Culotta (2021) investigated the efficacy of the automatically generated counterfactuals for sentiment analysis. Similar to our work, these methods also consider the most salient features that a model uses when generating augmented data, which is in line with our rationale definition. However, they use sentiment lexicon matching for identifying rationales, which is task-specific and not necessarily fully relevant. In contrast, we employ human annotators to identify rationales, which can be task-agnostic and robust. Moreover, our method generates semi-factuals instead of counterfactuals used in previous work.

Human-the-loop Machine Learning (Wu et al., 2021) has received increasing research attention. Active learning (Settles, 2009; Margatina et al., 2021), the most common example of human-in-the-loop machine learning, asks human annotators only to provide high-level annotations (i.e. labels) for important examples. There is also some work exploring more explainable AI systems by exploiting feature-based information. Such methods use relatively simple models such as Naïve Bayes (Stumpf

---

[*] All resources are available at https://github.com/GeorgeLuImmortal/RDL-Rationales-centric-Double-robustness-Learning/

et al., 2009; Kulesza et al., 2015) and Linear Regression with bag-of-words features (Jia and Liang, 2017; Teso and Kersting, 2019; Ghai et al., 2021; Shao et al., 2021), because these classifiers are relatively intuitive in generating explanations and amenable to incorporating human feedback.

Some other work uses simple neural networks such as multi-layer perceptrons (Shao et al., 2021) and shallow CNNs (Lertvittayakumjorn et al., 2020; Stammer et al., 2021; Teso et al., 2021) because the predictions of such models can be explained in the form of features. Very recently, Yao et al. (2021) proposed a human-in-the-loop method to inspect more complicated models (e.g. BERT) with the help of model-agnostic post-hoc explanation algorithms (Ribeiro et al., 2018) that can explain predictions of any linear or non-linear model without exploiting its weights. However, previous work focuses on increasing the explainability of AI systems for high-stakes domains such as health and finance (Li et al., 2020; Yang et al., 2020b), instead of improving model robustness or generalisation ability. Also, they assume access to a large amount of labelled data. In contrast, we focus on few-shot learning scenarios which are more compelling.

3 Method

The RDL pipeline is shown in Figure 2 and consists of two modules: *Static Semi-factual Generation* and *Dynamic Human-intervened Correction*.

Static semi-factual generation is a more efficient alternative to manually generated counterfactuals (Kaushik et al., 2020). In the first phase, Rationale Marking (Section 3.1), human annotators review each document in the training set to provide *rationales* (i.e. phrases that support the document classification decisions shown as bold text in Figure 2). The second phase is a semi-factual generation method based on synonym replacement (Section 3.2) that produces augmented examples (blue text in Figure 2 indicates replaced words), which are added into the training set.

Dynamic human-intervened correction (Section 3.3) is a rationales-powered human-in-the-loop framework to dynamically correct the model's behaviours. At the outset, *sampling and sensitivity of contextual decomposition* (SCD) (Jin et al., 2019) is applied to detect the rationales given by the model that is obtained in the previous step. Then, all model-identified rationales (underlined texts in Figure 2) are examined by human annotators to identify *false rationales* (i.e. words or phrases that do not support the classifications but are falsely included by the model) and *missing rationales* (i.e. words or phrases that support the classifications but are not included by the model). Both false rationales and missing rationales are corrected to produce augmented examples. Finally, newly generated examples are added into the training set to re-train the deep learning model.

3.1 Rationale Marking

Following Kaushik et al. (2020) and Yang et al. (2021), we use the *IMDb* movie review dataset (Maas et al., 2011) in our experiments. It consists of positive and negative movie reviews that are easy for human participants to understand, re-annotate, and provide feedback upon (Zaidan et al., 2007).

We use a crowdsourcing company to recruit editors and annotators for marking rationales that support classification decisions. At the outset, annotators were given instructions and examples that gently guided them to annotate rationales. Only adjectives, adverbs, nouns, and verbs were considered as rationales. Besides, rationales were required to carry complete semantic information. For example, for a phrase starting with a negation word such as "*not great*", annotators are instructed to mark the whole phrase "*not great*" as a rationale instead of just marking "*not*". We also limited rationales to at most three consecutive words (i.e. unigrams, bigrams and trigrams). Phrases consisting of numerical scores are not counted as rationales (e.g. 5 or 10 stars) since different datasets may use different rating scales, and annotating digits may hurt OOD performance.

Overall, we encouraged annotators to try their best to mark as many rationales as possible to explain classification labels. However, to guarantee the quality of rationale marking and prevent annotators from over including non-rationales for more payment, we also manually inspected annotated examples and rejected examples that contained incorrect rationales. After inspection, we rejected 10.6% of negative reviews and 7.6% of positive reviews. Editors and annotators re-annotated the rejected examples, which were then presented to us for another inspection. All re-annotated examples were approved only if all authors were happy with the quality of the annotations. Otherwise, the examples were re-annotated again.

Our annotation procedure generated 5,073 rationales in 855 movie reviews involved in Section 3.1 and 3.3 (note that we did not annotate all 1,707 examples in the training set because only 855 examples were necessarily involved in our experiments). Human annotators spent on average 183.68 seconds to identify rationales in a review and our method generated semi-factual examples automatically. On the contrary, workers spent on average 300 seconds to revise a review to generate a counterfactual manually as reported by Kaushik et al. (2020). Note that our approach using 100 labelled examples can outperform manual CAD (Kaushik et al., 2020) using the entire training set of 1,707 examples (see Section 5.3), making our approach $\frac{300\times1707}{183.68\times100} \approx 27.88$ times more efficient than manually generated CAD.

3.2 Static Semi-factual Generation

We take a simple replacement strategy, which has been taken by Yang et al. (2021), to generate semi-factual examples. Given a human-identified rationale, our method constructs augmented examples by automatically replacing non-rationale words, thus leading to examples with the same labels. This augmentation is consistent with semi-factual thinking: even if those non-rationales were changed, the label would not change.

Formally, given a training example $x_i = [t_{i1}, t_{i2}, ..., t_{ij}]$ (where t_{ij} is the j^{th} token of the i^{th} document) and its ground truth label y_i, we create a rationale vector $r_i = [a_{i1}, a_{i2}, ..., a_{ij}]$ where a_{ij} is the value that indicates whether t_{ij} is a rationale or not (we set $a_{ij} = 1$ to indicate that t_{ij} is a rationale and 0 otherwise). To generate a semi-factual example, x'_i, we randomly replace a certain number of non-rationales (where $a_{ij} = 0$), except for punctuation, with synonymous terms. The synonyms can be provided by a human, retrieved automatically from a lexicon such as WordNet (Miller, 1995), or generated using the *mask-filling* function of a pretrained context-aware language model (Liu et al., 2019).

In our experiments, we randomly replace 5% of non-rationales using mask-filling and generate a set of augmented examples, x'_i, with some replaced non-rationales and all the other tokens identical to x_i. The label, y_i, of a newly generated example is the same as the label of the original example, x_i. Examples of generated data are shown in Table 1. Afterwards, the augmented examples are added into the training set used to train the model.

3.3 Dynamic Human-intervened Correction

Dynamic human-intervened correction further improves the robustness of the model by allowing human annotators to correct the model rationales online. Firstly, SCD is applied to detect unigrams, bigrams or trigrams that are salient to the model. SCD is a technique to assess the importance of terms by continuously removing terms and measuring changes in prediction (Jin et al., 2019). Human annotators examine all rationales given by the model from all documents to discover two types of incorrect rationale: false rationales and missing rationales. The next phase allows human feedback to influence the learning process. To this end, for each type of incorrect rationale, we propose a corresponding strategy to correct them.

For false rationales (i.e. phrases that actually do not support classifications but are incorrectly identified by the model), we use synonym replacement again to generate semi-factual examples. Unlike the static semi-factual generation (Section 3.2), in this component we replace all false rationales with their synonyms instead of randomly replacing 5% of non-rationales in a document. Examples of generated data are shown in Table 2.

For missing rationales (i.e. phrases that actually support classifications but are not identified by the model), we take another simple semi-factual generation strategy, that is, extracting sentences that contain missing rationales to form semi-factual data. Specifically, given a sentence containing missing rationales, we use this sentence as a new example, and the label of this newly generated example is identical to that of the document where the sentence is extracted. For example, there is a positive movie review (bold font for rationales) *"Robert Urich was a **fine** actor, and he makes this TV movie **believable** . I remember watching this film when I was 15 ....".* The model fails to identify *"**fine**"* and *"**believable**"* as rationales. Thus we extract the text *""Robert Urich was a **fine** actor, and he makes this TV movie **believable** ."* as a new example, and the class of this example is still positive. We extract the whole sentence rather than just the missing rationales to reserve more semantic information.

Note that the two correction methods in dynamic human-intervened correction can operate in parallel and the generated examples are added to the small training set to re-train the model.

Sentiment	**Examples**
Negative	Origin: The attempt at a "lesbian scene" was **sad**. Augment 1: The hint at a "lesbian scene" was **sad** . Augment 2: The attempt at a "kiss scene" was **sad** .
Positive	Origin: I **recommended** this film a lot, specially in this difficult times for the planet . Augment 1: I **recommended** you film a lot, specially in this difficult times for the planet . Augment 2: I **recommended** this movie a lot, specially in this difficult times for the planet .

Table 1: Fragments of augmented data generated by static semi-factual generation (Original/Augmented, in order). Blue spans were synonyms used as replacements and bold font were rationales identified by human annotators.

Sentiment	Examples
Negative	Origin: but this is **pathetic**! Micawber was nothing more than a mid-nineteenth century Kramer. SCD: but this is **pathetic**! Micawber was nothing more than a mid-nineteenth century Kramer. Augment 1: but this is **pathetic**! Perkins became nothing more than a mid-nineteenth century Kramer. Augment 2: but this is **pathetic**! It had nothing more than a mid-nineteenth century Kramer.
Positive	Origin: Soylent Green is a wild movie that I **enjoyed** very much . SCD: Soylent Green is a wild movie that I **enjoyed** very much . Augment 1: Gang Orange is a wild movie that I **enjoyed** very much . Augment 2: Village Spring is a wild movie that I **enjoyed** very much .

Table 2: Fragments of augmented data generated by false rationale correction (Original/SCD/Augmented, in order). Underlined spans were false rationales given by the model through SCD. Blue spans were synonyms used as replacements, and bold font were rationales identified by human annotators.

4 Why Does RDL Work?

Broadly speaking, our RDL framework takes advantage of invariance that makes a model less sensitive to non-rationale words or spurious patterns (Tu et al., 2020; Wang et al., 2021) in favour of focusing on useful mappings of rationales to labels.

More specifically, by using static semi-factual generation (Section 3.2) and false rationale correction (Section 3.3), we expect to break spurious associations. For example, if a model incorrectly determines that "*Soylent Green*" is associated with positive sentiment (Table 2), the augmented examples that replace "*Soylent Green*" with other phrases such as "*Gang Orange*" break the spurious association. Besides, using synonym replacement can generate examples that are similar to the original one, which is equivalent to adding noisy data to prevent models from overfitting (Wei and Zou, 2019).

Missing rationale correction (Section 3.3) emphasizes the ground truth associations between rationales and labels, enabling the model to better estimate the generally useful underlying distributions for OOD datasets, even in few-shot learning scenarios. In the next section, we present experiments and empirical evidence to demonstrate the utility of the proposed RDL framework in improving model robustness.

5 Experiments

Our intention is to improve the generalisability of models, and we use both in-distribution and OOD performance for evaluation. Our experiments are designed to address the following research questions:

- **RQ1** Can we use static semi-factual generation to achieve better in-distribution and OOD performance?
- **RQ2** Does dynamic human-intervened correction improve generalisability of models?

5.1 Datasets

For fair comparison with previous work (Kaushik et al., 2020; Yang et al., 2021), we use the *IMDb* sentiment classification dataset (Maas et al., 2011) as the in-distribution dataset. Following Kaushik et al. (2020), all models were trained with the *IMDb* dataset predefined training, validation and test partitions containing $1,707$, 245, and 488 reviews respectively and an enforced 50:50 class ratio.

To measure the generalisation ability of different models, we focus on OOD performance. To this end, we test models on another four binary sentiment classification datasets: the sampled *Amazon reviews* dataset (Ni et al., 2019) (100,000 positives and 100,000 negatives) from six genres: beauty, fashion, appliances, gift cards, magazines, and software; the *Yelp review* dataset (Zhang et al., 2015) (19,000 positives and 19,000 negatives); the *SST-2* dataset (Socher et al., 2013) (1,067 positives and 1,143 negatives), and the *SemEval-2017 Twitter* dataset (Rosenthal et al., 2017) (2,339 positives

Training Data	**In-domain**	**SemEval-2017**	**SST-2**	**Yelp**	**Amazon**

and 2,339 negatives). These datasets were sampled to ensure a nearly 50:50 class balance.

5.2 Evaluating Static Semi-factual Generation

To address **RQ1**, we compare the performance of models trained by the **static semi-factual generation** strategy with models trained with the original 50 examples, referred to as **Static**. We also compare to a model trained with the full training set (1,707 labelled examples), referred to as **Full**.

5.2.1 Experiment Setup

To simulate the few-shot training scenario, we randomly sample 50 examples (we also forced a 50:50 class balance) from the *IMDb* dataset as training data. For each experiment, the training is repeated 10 times with training datasets sampled by 10 different random seeds. We report the average result of these 10 repetitions and use accuracy to measure the classification performance. Our experiments rely on an off-the-shelf cased "RoBERTa-base" model implemented by Hugging Face[*] to either perform mask-filling to provide synonyms or as a predictive model. Following Kaushik et al. (2020), we fine-tune RoBERTa for up to 20 epochs and apply early stopping with patience of 5 (i.e. stop fine-tuning when validation loss does not decrease for 5 epochs).

We also explore the impact of the number of semi-factual examples on model performance. To this end, we conduct static semi-factual generation with a different number of augmented examples for each instance: {3, 7, 11, 15, 19, 23}. Considering we have 50 original examples, this would result in {150, 350, 550, 750, 950, 1,150} additional examples in the training set, respectively (we call this **Static+*n***, where *n* is the number of generated semi-factuals).

We use the Adam optimizer (Kingma and Ba, 2014) with a batch size of 4. We found that setting the learning rate to {5e-5, 5e-6 and 5e-6} could optimise Static, Static+*n*, and Full, respectively.

5.2.2 Results and Analysis

As shown in Table 3, all static semi-factual generation (Static+*n*) methods can outperform the baseline method (Static) in both in-distribution and OOD tests, demonstrating the utility of static semi-factual generation. Among all Static+*n* methods, Static+350 seems the best-performing method and exceeds Static with a 1.56% in-distribution improvement in average accuracy. Static+350 also outperforms Static with 3.26%, 1.97%, 1.5%, and 0.46% OOD improvement in the *SemEval-2017*, *SST-2*, *Yelp* and *Amazon* datasets respectively. Although the improvement on the *Amazon* dataset appears modest, given that there are 200,000 examples in the *Amazon* test set, this actually stands for nearly 1,000 documents being correctly classified.

The Static+*n* methods can even outperform Full (i.e. normal training with the full training set) on the *SemEval*, *SST-2*, and *Amazon* datasets and are comparable on the *Yelp* dataset. The performance of models with the full training set is best on the in-distribution dataset but the worst on the *SemEval* dataset, which can be caused by the big difference between underlying distributions of these two datasets. In other words, a model that fits well with one dataset can cause performance decay on others. In this case, training with a smaller training set is more likely to reduce overfitting with the in-distribution dataset and fit well with the *SemEval* dataset, which explains the big improvement. It is interesting to note that models trained with the en-

---

[*] https://huggingface.co/transformers/model_doc/roberta.html

tire training set perform slightly better on the OOD *Yelp* dataset ($93.66_{\pm 0.84}$) than on the in-distribution dataset ($93.23_{\pm 0.46}$), which could also be explained by the high similarity between the underlying distributions of these two datasets.

Benefits of Static Semi-factual Generation

First, we test whether the improvement in model performance is brought about by static semi-factual generation (Static+n) or simply by an increase in the size of the training set. We compare Static+350 (due to its relatively good performance) with another baseline called Duplication (**DP** heareafter). We multiply the original training set (50 examples) up into 400 examples identical to the size of the training set of Static+350, and fine-tune RoBERTa on this dataset with the same hyperparameters as Static+350.

As shown in Table 3, in most cases, DP underperforms other algorithms and is even worse than Static, demonstrating that solely increasing the dataset size cannot improve the performance. We believe that the duplication of original examples increases the risk of overfitting and easily *magnifies* artefacts or spurious patterns hidden in the small training set, which leads to worse models.

Second, synonym replacement has been used previously for data augmentation (Wei and Zou, 2019), and we compare static semi-factual generation with simply replacing any words (i.e. both rationales and non-rationales). Following Wei and Zou (2019), we replace 5% of words at random and set the training set size to 400 to ensure fair comparison (we use RoBERTa and the same hyperparameters of Static+350). We call this Random Replacement (**RR** hereafter).

As shown in Table 3, RR is slightly better than the baseline Static approach. This result is similar to that reported in Wei and Zou (2019), since the augmented data generated by random replacement is similar to the original data, introducing noise that helps prevent overfitting to some extent. However, the magnitude of improvement of the Static+n method is much larger than that of RR, demonstrating the utility of only replacing non-rationales to generate semi-factuals. These observations show that the model trained with Static+n does improve both in-distribution and OOD performance, and the improvement is actually derived from static semi-factual generation.

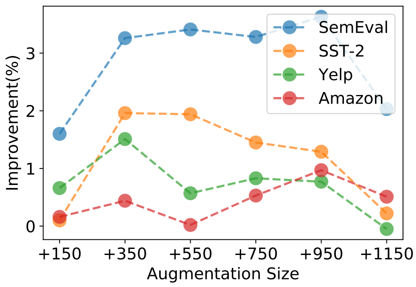

Figure 3: Average performance gain of different static semi-factual generation methods with different augmentation size over four OOD datasets.

5.3 Evaluating Dynamic Human-intervened Correction

As shown in Table 3 and Figure 3, the performance gain of static semi-factual generation (Static+n) marginalises when augmented data is increased. Using too much augmented data even hurts the Static+1150 performance. This observation is consistent with existing work on data augmentation (Wei and Zou, 2019). We believe one reason could be that the use of static augmented examples could also introduce new spurious patterns that degrade model performance, necessitating a method that exploits rationales without generating too many augmented examples. Human-in-the-loop can address this issue by dynamically correcting the model.

To address **RQ2**, we compare the performance of models trained by **dynamic human-intervened correction** with a popular few-shot human-in-the-loop learning framework, Active Learning, as well as two other state-of-the-art CAD-based methods (Kaushik et al., 2020; Yang et al., 2021). Lastly, we provide an ablation study to examine the influence of different correction methods, as well as an analysis regarding model sensitivity to spurious patterns.

5.3.1 Experiment Setup

We build up an active learning procedure as a baseline based on the model trained with Static. In particular, we select another 50 examples by Uncertainty Sampling (i.e. prediction scores for two classes in these examples were close) and add them into the training set (called **AL** hereafter). The training set size of the baseline becomes 100. The best performing static semi-factual generation method Static+350 is also listed as a baseline.

For fair comparison, we also use Uncertainty Sampling to select another 50 examples (i.e. 100 original examples in the training set now) for the proposed dynamic human-intervened correction in-

Baseline Methods	**In-domain**	**SemEval-2017**	**SST-2**	**Yelp**	**Amazon**
Static (50 gold)	88.60±1.11	77.28±9.11	79.29±5.14	91.53±2.06	89.63±1.65
Static + 350 auto (400)	90.16±0.85	80.54±2.81	81.26±1.97	93.03±1.08	90.09±1.79
AL (100 gold)	88.64±1.75	78.61±5.90	80.50±3.37	92.47±0.68	89.80±1.91
CAD-based Methods					
Manual CAD (3,414 gold)	**92.70±0.53**	69.98±3.99	80.30±2.03	91.87±1.09	90.48±1.09
Automatics CAD (1,707 gold+1,707 auto)	91.82±0.74	79.39±5.37	80.60±3.10	91.92±0.97	90.46±1.08
Our Dynamic Methods

Dynamic-FR (100 gold + 700 auto)	89.85±1.38	**82.39±1.88**	81.59±1.82	92.98±0.91	90.12±2.42

Table 4: Results on in-distribution and OOD data. Values in brackets are the training set size. AL: Active Learning. Manual CAD (Kaushik et al., 2020), Automatic CAD (Yang et al., 2021). Our methods are Dynamic-MR: Missing Rationale Correction, Dynamic-FR: False Rationale Correction, Dynamic: Dynamic Human-intervened Correction.

cluding both False Rationale Correction and Missing Rationale Correction (called **Dynamic**). For Dynamic, we control the number of augmented examples for each review to 7 (4 from Missing Rationale Correction and 3 from False Rationale Correction), resulting in 800 examples in the training set. For Automatic CAD (Yang et al., 2021) and Manual CAD (Kaushik et al., 2020), we use the entire training set to produce counterfactuals to build up two challenging baselines (one counterfactual for one example, which is limited by the method), resulting in 3,414 examples in the training set.

To investigate the influence of each correction method, we also construct another two datasets that augment the same 100 original examples to 800 exclusively by False Rationale Correction (**Dynamic-FR** hereafter) and Missing Rationale Correction (**Dynamic-MR** hereafter). Again, experiments all rely on a RoBERTa model and all hyperparameters are identical to those described in Section 5.2.1, except for the learning rate of AL which is set to 1.25e-5 (we found this value optimised AL performance).

5.3.2 Results and Analysis

As shown in Table 4, both AL and Dynamic outperform Static in in-distribution and OOD datasets which makes sense, because we use Uncertainty Sampling to add new labelled data to minimise model uncertainty and increase model performance. However, AL fails to compete with Static+350 even if more original data is added, which again demonstrates the utility of static semi-factual generation. On the contrary, Dynamic does better than Static+350 with a 0.68% in-distribution improvement in average accuracy. Dynamic also outperforms Static+350 with 1.14%, 0.16%, 0.42% OOD improvement in the *SST-2*, *Yelp* and *Amazon* datasets, but no improvement for the *SemEval* dataset. Finally, the performance of our methods is better that the state-of-the-art manual CAD method in few-shot learning scenarios on all OOD datasets.

	Non-rationales	**Rationales**
Static	0.572	0.428
Dynamic	0.433	0.567

Table 5: Static versus Dynamic models on average sensitivity (normalised) to rationales and non-rationales for *IMDb* test samples.

Overall, these observations demonstrate that applying dynamic human-intervened correction (i.e. Missing Rationale Correction and False Rationale Correction) can further increase the robustness of a model on generalisation ability, effectively avoiding the improvement marginalisation caused by the increased volume of augmented data.

Missing Rationales vs. False Rationales

We conduct an ablation study by examining the performance of Dynamic-MR and Dynamic-FR in Table 4. Interestingly, Dynamic-FR is specifically good at improving model performance on the in-distribution and *SemEval* datasets while Dynamic-MR does a good job on the *SST-2* dataset. We believe that it is because Dynamic-MR biases the model to estimate an underlying distribution that is useful for *SST-2* and in-distribution datasets, while Dynamic-FR biases the model to estimate a distribution similar to *SemEval* dataset. The performance of Dynamic can be explained as a compromise of two correction methods.

Sensitivity to Spurious Patterns

We conduct an analysis to explore whether the double-robust models are less sensitive to spurious patterns. We compute models mean sensitivity to all rationales and non-rationales through SCD in the *IMDb* test set. As shown in Table 5, the corrected model is much more sensitive to rationales with 13.9% average increase in the sensitivity to rationales, which demonstrates that our double-robust method can decouple models from spurious patterns.

6 Conclusion

We proposed a rationale-centric human-in-the-loop framework, RDL, for better model generalisability in few-shot learning scenarios. Experimental results show that our method can boost performance of deep neural networks in both in-distribution and OOD datasets and make models less sensitive to spurious patterns, enabling fast generalisation. In the future, we expect to see rationale-centric frameworks defined for different tasks, including NER, question answering, and relation extraction.

7 Ethical Statement

We honor the ACL Code of Ethics. No private data or non-public information was used in this work. All annotators have received labor fees corresponding to the amount of their annotated instances.

Abstract

Various efforts in the Natural Language Processing (NLP) community have been made to accommodate linguistic diversity and serve speakers of many different languages. However, it is important to acknowledge that speakers and the content they produce and require, vary not just by language, but also by culture. Although language and culture are tightly linked, there are important differences. Analogous to cross-lingual and multilingual NLP, cross-cultural and multicultural NLP considers these differences in order to better serve users of NLP systems. We propose a principled framework to frame these efforts, and survey existing and potential strategies.

1 A Framework for Cultural Awareness

Language technology is rapidly advancing for a minority of the world's languages. At the same time, the majority of languages are falling behind (Joshi et al., 2020). It is essential that language technology can serve the speakers of a wide variety of languages, who come from a wide variety of cultures. In this paper, we argue that doing so requires accommodating these speakers not only on a linguistic level, but also on a cultural level.

Culture, like language, is a term that is hard to pin down, but generally describes the way of life of a collective group of people, and distinguishes them from other groups with other cultures (Mora, 2013; Shweder et al., 2007). Culture encompasses both material as well as non-material aspects, such as beliefs and linguistic practices (Kendall et al., 2005). Moreover, since "[c]ulture is the acquired knowledge people use to interpret experience and generate behavior" (Spradley, 1972), it is also the lens through which people understand linguistic messages. Culturally maladapted messages can and will be misinterpreted; NLP must be culturally sensitive in order to avoid doing harm.

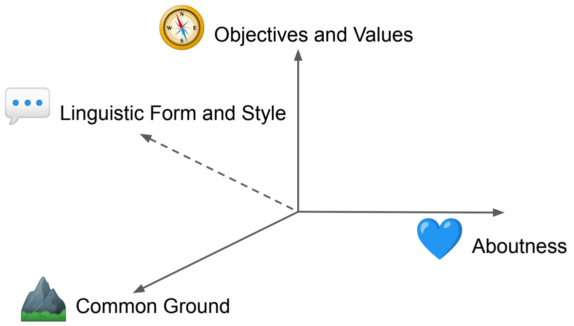

Figure 1: The role of culture in NLP, illustrated by four dimensions along which cultures vary, and for which NLP can be culturally biased: linguistic form and style, common ground, aboutness, and objectives (values).

Language and culture interact in a number of ways (see Figure 1). This paper aims to illuminate these connections, in order to motivate and inform future NLP work. Beyond **linguistic form and style**, *how* things are expressed in language, they include **common ground**, the shared knowledge based on which people reason and communicate; **aboutness**, *what* information people care to convey; and **objectives** or values, the goals people strive for (e.g., when developing language technology).

Since language and culture are intertwined, the different dimensions may be difficult to tease apart (Hovy and Yang, 2021): for example, the lexicon is shaped both by the need to convey information people care about, and by the conceptual categories grounded in the environment. Style is related to values and societal structure: formality levels in Japanese, for example, reflect the hierarchy of Japanese society (Gao, 2005). Nevertheless, language and culture are not interchangeable terms. Culture varies greatly *within* languages (Lin et al.,

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 6997 - 7013
May 22-27, 2022

2018). For example, the assumption that "English" in and of itself carries a single set of worldviews, interests and norms is unjustified (Paul and Girju, 2009; Wilson et al., 2016). On the other hand, a relatively homogeneous culture can span multiple languages, as in the Nordic countries (Sahlgren et al., 2021).

Contributions. We propose a framework for understanding the challenges that cultural diversity poses for NLP to serve all users, as well as the opportunities that NLP creates to understand these differences better. We consider four elements: linguistic form, common ground, aboutness and values. We then survey existing strategies in NLP to address these challenges. Highlighting limitations in current strategies, as well as successful examples, we propose directions for future development of cross-cultural NLP.

2 Linguistic Form and Style

Linguistic form refers to non-semantic questions of *how* to formulate an utterance. Most work on cross-lingual NLP has focused on how linguistic form varies between languages. However, the impact of social and cultural factors on linguistic form and stylistic variations is rarely discussed (Hovy and Yang, 2021).

Variation within language. How to circumscribe and define a particular language is a difficult problem (Eberhard et al., 2021). A language spoken in different countries often becomes standardized in slightly different ways (e.g., German in Austria and Germany). Geo-cultural variation within a language also gives rise to *dialects* (Zampieri et al., 2020; Wolfram and Friday, 1997; Brown et al., 2020), which in turn operate as an important sign of cultural identity (Falck et al., 2012). In addition, *sociolects* vary across social groups, which can include subcultures (McCormack et al., 2011).

Due to these variations, treating "a language" as a homogeneous mass limits cultural adaptation, and runs the risk of privileging certain cultures over others. Zhang et al. (2021) find that pretrained language models (PLMs; see §6) reflect certain sociolects more than others. For example, there are considerable morphosyntactic variations between Spanish spoken in Spain and Argentina (Bentivoglio and Sedano, 2011), but they are not considered separately in a Spanish PLM (Cañete et al., 2020). A PLM specific to the Algerian dialect of Arabic performs better than a multilingual or general Arabic one (Antoun et al., 2020) in sentiment classification (Abdaoui et al., 2021).

Stylistic variation. Factors such as directness and formality are often associated with different communicative styles across cultures. For example, the level of politeness and thus also how offensive something is perceived depends very much on communicative norms (Gao, 2005; Larina, 2015). Misunderstandings that arise from different communicative styles can occur in any interaction between people of different cultural backgrounds. Thomas (1983) refers to this as *pragmatic failure*, namely the "inability to understand 'what is meant by what is said"', due to *how* it is being said. Comparative stylistics (Vinay and Darbelnet, 1995) aims to characterise these differences.

The same intention (e.g., to be polite) can lead to different forms in different cultures. For example, an offer of help can be made in an imperative form in Polish, while in English speaking Anglo-Saxon cultures, this form would be considered rude and so an interrogative form would be used instead (Wierzbicka, 2009). Similarly, German native speakers tend to use a high level of directness, which would be considered offensive in English (House and Kasper, 2011). Based on the observation that such differences exist, Ringel et al. (2019) applied distant supervision by inducing labels for English formality and sarcasm detection based on language—in this case German and Japanese, respectively.

The expression and perception of emotion also varies across cultures, both in text (Kirmayer et al., 2001; Ryder et al., 2008) and in face-to-face communication (Hareli et al., 2015). These differences are critical for cross-cultural sentiment analysis (Bautin et al., 2008) and for text-based recognition of medical conditions such as depression. For example, Loveys et al. (2018) find clear differences in linguistic form across English speakers of different ethnic identities with self-reported depression (e.g., the ratio of positive to negative emotion expression). Not understanding cross-cultural variation could lead to misclassification of movies, or worse, mis-diagnosing people.

3 Common Ground

A culture is in part defined by a shared *common ground*: the shared body of knowledge that can be talked about and that can be assumed as known by others. This common ground varies from culture to culture, and thus cross-cultural language use has to take into account shifts in common ground.

These cross-cultural shifts, often correlating with cross-lingual shifts, are neglected in NLP. An underlying assumption in many approaches to multilingual NLP is that "different languages share a similar semantic structure" (Miceli Barone, 2016). However, the assumption that there is a cross-lingual, cross-culturally common semantics to preserve fails when the common grounding does not match between cultures. Two relevant aspects here are the set of relevant *concepts*, closely identified with problems of lexicalisation, and *common sense*, i.e., the relevant propositional knowledge used in reasoning and entailment.

Conceptualisation. People carve up the world using conceptual categories (Margolis and Laurence, 2021). While some general or even universal patterns exist (Wierzbicka, 1996), these categories can and do differ between languages and cultures: the domain of colour is a famous example (Berlin and Kay, 1969), but cross-cultural differences are also reflected in kinship systems (the lexicalization of family structures Murdock, 1970), spatial relations (Bowerman and Choi, 2001) and basic objects (e.g., where to draw the distinction between a 'cup' and a 'mug', or the 'hand' and the 'arm'; Majid et al., 2015). Translating between languages thus entails translating between conceptualisations, which can be impossible if the conceptual grounding is not available (is this Danish "kop" an English 'cup' or a 'mug?')—this is the motivation behind multimodal, i.e., visually grounded, translation (Specia et al., 2016). Data collected from a single culture may contain concepts that do not easily map across cultures, as for example seen in the recent MarVL dataset (Liu et al., 2021), in which about a quarter of concepts from a sample of non-Western cultures did not map to English concepts (as represented by WordNet).

Commonsense knowledge. "Common sense" is the knowledge that is held *in common* by a community and culture, the communal knowledge bank that can be presumed to be known by everyone. Common sense thus covers a diverse set of knowledge types, from physical and temporal reasoning to psychological, social and moral judgements (Sap et al., 2020). Some aspects of common sense are fairly universal, in particular those that arise from inhabiting a grounded human body on earth (dropping a glass of juice onto a hard surface is likely to cause a mess; the baby might be crying because it's hungry). On the other hand, axioms of social and moral common sense, for example the how and why of rituals such as marriages, vary between cultures (Acharya et al., 2021).

Moving between different banks of common sense can involve different strategies to either provide missing background/common knowledge, or to transfer the content to a target-culture appropriate setting (see §6.3).

4 Aboutness

Cultures promote different topics and issues (Seibert et al., 2002), sometimes by necessity, sometimes by accident.[1] Some of the domains commonly considered in (English-speaking, Anglo-western) NLP are irrelevant to some cultures, while others *mean* different things to different cultures, i.e., they involve completely different practices. An example of the former is beer reviews, a go-to domain in sentiment analysis (Zeng et al., 2019; Ji et al., 2020; Paranjape et al., 2020). Beer reviews are hardly meaningful in cultures with no beer consumption. An example of the latter, i.e., a domain that is used differently across cultures and social groups, is Twitter (Hine, 2020). As an example of multi-domain sentiment analysis, Liu et al. (2018) consider cameras, laptops, restaurants, and movies, within the context of data from U.S. American websites. These domains, however, apply differently in other cultures: restaurants are more important in some cultures (e.g., Copenhagen hipsters) than others (e.g., Sámi); similarly, laptops have not penetrated cultures equally and have in fact been found to *change* culture (Hansen et al., 2014).

Beyond conceptualisation differences (see §3), Liu et al. (2021) point out how the visual concepts at the core of many multimodal NLP tasks reflect a Northern American and Western European bias in the underlying data sources, from which images were scraped. As an alternative, in their new

---

[1] What we, as human beings, are interested in is, in part, a product of our group memberships. Our group membership determines conditions, e.g., our dependence on weather, agriculture, livestock, etc., making some topics vital, and promotes others e.g., through fashion, trends, etc. Heidegger (1927, 1953) refers to the former as the *facticity* aspect of our *caring*; the latter as the *fallenness* aspect. Unbiased treatment of the facticity aspect of what cultures care about, has been argued to be particularly important from an ethical perspective (Nelson, 2008).

dataset (MarVL), they let the selection of both concepts and images be entirely driven by native speakers. This corrects for some existing asymmetries in what our evaluation data tends to be about. For example, Althoff et al. (2014) created a dataset entirely devoted to *pizzas*; in Liu et al. (2021), models' ability to recognise *vadas*, an Indian food, is evaluated.

People describe the same events differently across cultures. News reports emphasise different goals, motivations, methods and content in different parts of the world (Bandura, 1986; Li, 1997; Loo, 2019). However, many news resources used in NLP research reflect only some cultures (Breed, 1955; Galtung and Ruge, 1965; Marcus et al., 1993). As NLP technologies have been widely adopted to build multilingual news generators (Zhang et al., 2016; Xu et al., 2020; Jin et al., 2020), it is important that these differences are taken into account in language generation.

5 Objectives and Values

Common objectives in NLP include progress, accuracy, fairness, robustness and interpretability. They are driven by the research community, and reflect the values of this community: novelty, for example, is highly esteemed, which is not a value held by more conservative, tradition-valuing cultures. Grounding these objectives explicitly in ethical values and norms, and acknowledging that these may differ across cultures, is essential for cross-cultural NLP. Jiang et al. (2021), for example, introduce COMMONSENSE NORM BANK and Delphi, a moral reasoning resource and model, respectively, reflecting "English-speaking cultures of the United States in the 21st century". However, researchers, practitioners, regulators and users may belong to different cultures and have different objectives and values (Talat et al., 2021).

Another common goal in the NLP community is the eventual expansion of all NLP technologies to low-resource languages. However, as Bird (2020) points out, this goal must not overshadow, or be placed above, the specific desires and needs of a given language community, as every community will have their own objectives for what they do and do not want for their language with regards to technology. Without building relationships with the communities for which we aim to develop NLP, there is a serious risk for imposing our own objectives on the community.

Importantly, entire categories of applications and tasks may be driven by cultural assumptions. For example, the main objective of text summarisation is brevity (Jørgensen and Søgaard, 2021). Likewise, while fluency is a common objective of machine translation, it may in fact, be less important than comprehensibility for users (Castilho et al., 2018).

Values differ across cultures. Values are an important part of non-materialistic culture, as these values define what a specific culture deems to be good or valuable, as opposed to bad and undesirable (Kendall et al., 2005). Accordingly, these values help inform what is accepted as normal and ethical behaviour, and shape common cultural attitudes. Aspects that clash against a culture's values, norms, and ethics, may often be taboo or even illegal. As cultures around the world hold different values, their norms and ethics are inevitably different, too (Schäfer et al., 2015; Hanel et al., 2018). For example, in some cultures, alcohol consumption is prohibited for religious reasons, and thus may not be normal or acceptable behaviour; meanwhile drinking alcohol can be seen as normal behaviour by some cultures without this shared value. For this reason, beer reviews in an application, for example, may be seen not only as irrelevant (see §4), but even as offensive. While these values can and do change greatly from culture to culture, *end-users of NLP systems deserve technologies that are suitable to the culture that they belong to*. To this end, the preservation of cultural values, norms, and ethics in models intended for users from different cultures, is another important aspect of cross-cultural NLP (Solaiman and Dennison, 2021).

Fairness and combating biases. Many recent studies in NLP have explored strategies to counteract unwanted biases (according to the community's values, see above) in models, resulting from prejudices present in society. These biases are implicit in the data used to train our models, and become baked into the models themselves (Bolukbasi et al., 2016; Sap et al., 2019; Sun et al., 2019; Blodgett et al., 2020; Bender et al., 2021). Because NLP datasets are composed of utterances from members of a larger culture, the resulting biases constitute a partial reflection of that culture's values, norms, and ethics. For example, work in NLP on gender bias demonstrate that there is a pervasive problem with sexism in models (a direct result of sexist attitudes present in society), and explore ways to remedy this (Friedman et al., 2019; Zhao et al., 2019; Webster et al., 2021; Baker Gillis, 2021). Accordingly, just as members of any culture deserve language technology that truly serves them, *members of vulnerable groups and marginalised members in larger cultures deserve such as well*. Current research in addressing fairness and combating biases in models demonstrates how NLP can be used to tackle the challenge of inequitable cultural attitudes. In other words, the goal of countering bias in NLP can be seen as shifting existing cultures into hopefully more equitable ones.

Conflicting objectives. With regards to cultural values, cross-cultural NLP lies at the intersection of the two important, but potentially conflicting, crossroads of multicultural pluralism and societal equity: cultures will have different values, which should be respected and represented for end-users; meanwhile, cultures will also have some inequitable attitudes that hurt different end-users, and NLP should be part of the solution. Together, these conflicting aspects land cross-cultural NLP in the impossible position of needing to both *preserve* cultural values, while also *minimising* harmful cultural biases. We acknowledge that these issues become increasingly difficult to disentangle, especially for more difficult or taboo aspects of culture. On the one hand, it is dangerous for members of one culture to impose values onto the others (i.e. this would, in fact, contribute to NLP colonisation—see §7), and on the other hand, it is dangerous to leave marginalised groups vulnerable, when we can diminish bias against them. While none of the strategies we discuss in §6 offers a simple solution to this challenge, our goal is to bring this important conundrum in cross-cultural NLP to the community's attention. To help navigate this convoluted space, and thus ensure end-users have access to relevant NLP systems, we encourage people working in this space to collaborate with members of the culture relevant to their work, as they are the best equipped to judge what cultural aspects can appropriately be challenged. Additionally, new works in AI ethics should also be considered (Nanayakkara et al., 2021; Hagendorff, 2020; Prunkl et al., 2021; Pitta et al., 1999; Mohamed et al., 2020). An international regulatory instrument is essential for the responsible development of AI, a task that UNESCO is in the process of undertaking.[2]

6 Strategies

We have identified several challenges along four dimensions of culture. Here, we highlight general strategies for cross-cultural NLP. We identify three main areas where we could direct efforts towards mitigating cross-cultural disparities: data collection, model training, and translation. Data is the backbone of NLP and any efforts towards cross-cultural NLP needs to consider the strategies involved in collecting and annotating it. Transfer learning is central to cross-lingual NLP and can serve an important role in cross-cultural NLP. Finally, translation is used to communicate between languages and will often be necessary when communicating between cultures. We explain what can be done within each of these areas each in turn.

6.1 Data Collection

The most fundamental issue is the representation disparity in our data, i.e., not all cultures are (equally) represented. While the volume of multilingual datasets increases and multilingual NLU benchmarks are becoming available (Hu et al., 2020; Liang et al., 2020; Ruder et al., 2021), this does not guarantee cross-cultural representation. There are two main factors: source of data (e.g., media outlet) and origin of annotations (e.g., automatic vs human-generated). To have truly diverse datasets, we should both ensure that they not only represent diverse sources, but also multiple perspectives in terms of annotations, when applicable.

Data selection and curation. Relevant to the impact of the source of data, Dodge et al. (2021) discuss how the Colossal Clean Crawled Corpus (C4; Raffel et al., 2020), an English web-based corpus, is skewed in favour of US governmental institutions and main-stream US media, while data filtering, which tries to remove slurs, or obscene words, disproportionately removes text from and about minorities (e.g., African American and LGBTQ+). Similarly, data from Wikipedia is heavily used in multilingual NLP even though it has been shown to be culturally biased (Callahan and Herring, 2011). To mitigate the risks associated with using culturally biased data, data selection or curation methods should strive to use data sources that are appropriate for the target culture of downstream NLP applications. Large, general-purpose datasets should be curated so as to be as unbiased as possible, and carefully documented (Jo and Gebru, 2020; Bender et al., 2021).

---

[2] https://en.unesco.org/courier/2018-3/towards-global-code-ethics-artificial-intelligence-research

As examples of culturally diverse data collection, Liu et al. (2021) and Yin et al. (2021) recruit geodiverse annotators from Africa, Asia and the Americas who are tasked with also providing the data (the images) along with the annotations (image descriptions). However, these dataset are small and thus limited to evaluation only; the cost and effort associated with collecting sufficient data to train modern NLP models means that finding culture-specific data to cover the enormous diversity of cultures represented on earth remains a formidable challenge. A diverse and open community, however, facilitates scalability in this regard. Examples for such communities include Universal Dependencies, dedicated to manual annotation of morphosyntactic datasets for over one hundred languages, covering the highest typological diversity to date among such datasets (Nivre et al., 2020). As another example, the Masakhane community aims to strengthen NLP research for African languages. It has created MasakhaNER (Adelani et al., 2021), a Named Entity Recognition dataset for 10 African languages, collected by native speakers of these languages.

Data annotation. With respect to annotation practices, a diverse pool of annotators reduces the risk of cultural bias. In the case of subjective tasks such as detecting affect, aggression, and hate speech, annotators may systematically disagree with one another due to cultural differences that are often reflected by their biases and values (Davani et al., 2021). Annotator disagreements may capture important nuances in such tasks that are often ignored while aggregating annotations to a single (possibly hegemonic) ground truth. Release of all annotations with each dataset, even disagreeing ones, allows training models that generalise better (Plank et al., 2014; Pavlick and Kwiatkowski, 2019; Prabhakaran et al., 2021; Gordon et al., 2022). Careful documentation of the annotation process also plays an important role. In a recent survey of machine learning papers (including NLP ones), Geiger et al. (2020) reported a wide divergence in the level of documentation about methodological practices in human annotation. They advocate for the importance of human annotation within the research process, arguing that it ought to be given as much attention, care, and concern as is currently placed on performance based metrics.

When arguing for an increasingly diverse 'participatory design' (Bodker et al., 2009), however, it is important to consider the values, ideologies, codes, narratives, and power relations which govern the interaction between the assemblies of actors involved in data collection and annotation. This is the perspective of social-cultural studies and other critical viewpoints from the humanities (Mainsah and Morrison, 2014; Gray and Suri, 2019).

Annotation projection. Of course, data collection for many languages and cultures can be costly. Using parallel data and a word alignment tool, annotation (for example a syntactic tree) in a source language can be transferred to a target language without extra annotation (Yarowsky et al., 2001; Hwa et al., 2005). A related method to create multilingual datasets is translating a dataset (typically in English) into other languages (often using machine translation). While not usually called annotation projection, it can be considered a variation of this method, since the source annotation is ported to the translated data. For example, in XNLI (Conneau et al., 2018), the premise and hypothesis pair is translated from English to other languages and the label is reused for the translated pair. These methods help leverage data from high-resource languages to create more data for low-resource languages (Agić, 2017).

However, these methods risk ignoring target culture complexity or forcing the source culture concepts on the target culture. For example, English common sense datasets (Singh et al., 2021) include culture-specific concepts such as food ingredients,[3] rituals and celebrations,[4] and societal expectations.[5] Translating this dataset into other languages will require making decisions about how, and whether, to modify these items to make them more intelligible in the target culture. Lin et al. (2021a) use machine translation to translate two common-sense reasoning datasets from English into 14 other languages. They attempt to deal with difficult cases by automatically flagging and removing examples which contain 'social keywords' from the dataset, or that are (again, automatically) labeled as containing non-neutral sentiment. However, these methods are unlikely to capture all examples of social behaviour and cannot identify examples of cultural over-specificity (sports teams,

[4] *Colt doesn't have any kids. Finley has four kids. Therefore, Finley is more likely to go Trick or Treating.*

[5] *Many people disapproved of the widow waiting one week after his [sic] wife's death to start dating again, rather than one year.*

jalapeños). Automatically translated *training* data can lead to worse performance than native target language data (Liu et al., 2021). However, if *evaluation* data is automatically translated too, we have no trivial way of exposing cultural biases introduced by the projection process. Culturally-aware evaluation thus necessitates data annotated directly in the target language, or at least culturally-sensitive human translations.

Ponti et al. (2020) point out that literal translation of datasets is sometimes impossible or undesirable due to culture-specific concepts in the source that may be missing or unnatural in the target. In their multilingual extension of the English Choice of Plausible Alternatives (COPA; Roemmele et al., 2011) dataset, they therefore asked "carefully chosen" human translators to perform culturally-sensitive translation, and either paraphrase, substitute the original concepts with similar ones that exist in the target language, or leverage phonetically transcribed loan words.

Human translation, or original data from the target culture, is clearly the expensive option, but will often be the only way to avoid cultural bias. Only translating/generating high-quality *evaluation* data is becoming an attractive middle ground option (Liu et al., 2021; Ponti et al., 2020; Yin et al., 2021) that at least allows us to judge the success of cross-lingual transfer in a culturally appropriate way.

6.2 Model Training

Models can be culturally biased even when trained on culturally diverse data. On the other end, diverse cultural representation can in some cases be achieved with specific training strategies, not only data selection and annotation.

Transfer learning and pre-training. A common strategy in machine learning is to *transfer* the knowledge acquired for a task, domain or language to another. It is used extensively in the context of cross-lingual learning, motivated by similarities between languages and cultures: if only the form differs between languages, then models can learn to abstract away from it and transfer from resource-rich languages, obviating task-specific training data in many languages (Agić, 2017; Wu and Dredze, 2019; Blloshmi et al., 2020).

In this context, approaches for creating cross-lingual word embeddings (Klementiev et al., 2012; Ammar et al., 2016) are based on the assumption that the semantic spaces of different languages are approximately *isomorphic*. However, this assumption is violated in practice (Søgaard et al., 2018, 2019). Among linguistic reasons, cultural factors (e.g., conceptualisation) can play a role in the mismatch between the spaces. Though hardly ever considered when selecting the source language for model transfer, considering cultural factors improves performance on target languages in pragmatically motivated tasks (Sun et al., 2021).

In recent years, *model transfer* has been the mainstream paradigm with the advent of pre-trained language models (PLMs), and specifically, multilingual PLMs such as mBERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020). Language models require massive amounts of data to *pre-train*. Since corpora are largely skewed in favour of few languages, this leads to cross-lingual disparities. To mitigate this issue, Conneau and Lample (2019) introduced an exponential smoothing of the language *sampling* rate leading to a less skewed data selection. Conneau et al. (2020) and Xue et al. (2021) further studied the effect of the language sampling rate, and found that more uniform sampling improves performance in low-resource languages, but hurts high-resource languages.

The reliance on pre-training means that what PLMs encode has far-reaching consequences. Several works find differences in culture-specific commonsense knowledge in multilingual PLMs, depending on the language used to probe them. These include differences in factual knowledge (Kassner et al., 2021), grounding of time-of-day expressions (Shwartz, 2022), and social value (Lin et al., 2021b). Understanding these differences better will facilitate cultural adaptation and debiasing of NLP systems.

Training. The common methodology for training machine learning models (e.g., empirical loss minimisation) relies on maximising average performance across training examples (instead of groups, e.g., languages), which often leads to low minority performance, a phenomenon named *representation disparity* (Hashimoto et al., 2018). Model performance for minorities is often disregarded in favour of majority groups, as shown for race (Blodgett and O'Connor, 2017), gender (Jørgensen and Søgaard, 2021), and age (Zhang et al., 2021). Deriving fair models from biased data is a promising countermeasure (Mehrabi et al., 2021). In a cross-cultural setting, methodologies that account for model updates for different groups (Hashimoto et al., 2018; Sagawa et al., 2020; Levy et al., 2020) could potentially reduce cultural biases. Most methods to balance for bias require access to protected demographic attributes (Sagawa et al., 2020), and these only partially reflect culture.

In this direction, Zhou et al. (2021) and Ponti et al. (2021) propose using *Group Distributionally Robust Optimisation* (group DRO; Oren et al., 2019) to optimise worst-case performance across languages. Similarly, de Lhoneux et al. (2022) used Worst-Case-Aware Curriculum Learning (Zhang et al., 2020) to improve group (language) performance parity in cross-lingual dependency parsing. However, Lent et al. (2021) find that group DRO has no benefit in a low-resource settings, namely for Creole languages. Such techniques can potentially be applied to pre-training multilingual language models with better cross-lingual parity, possibly in addition to improved data sampling. Furthermore, a fairer model with respect to other attributes, besides the language dimension, can lead to less culturally biased models. While these measures are widely discussed in a multilingual framework, they are also applicable in a monolingual setting to favour a more equal representation of different cultures in a single language (e.g., a fairer representation of English-speaking communities for English NLP).

Limitations. Nonetheless, cross-lingual countermeasures are *culture-agnostic*. In other words, even if we sample languages equally, cross-cultural disparity persists, as data for a given language is also not balanced in terms of sources, and hence cultures. However, one can directly target a more diverse cross-cultural representation by applying the same principles in terms of cultures instead of languages.

Ideally, methods such as data sampling or group DRO should facilitate generalisation of universally-common knowledge from highly-represented cultures, while granting equal representation to minority cultures. Overemphasising the former is problematic as it contributes to *cultural homogenisation*, while the latter enables mitigation of cross-cultural biases present in the underlying training data and models. There is no substitute for a larger representation of minority cultures in the data used for training and evaluation.

Finally, practical concerns include the level of granularity at which cultural groups are defined and annotated in the data (e.g., as metadata attributes or criteria for splitting text corpora). There is a continuum from representing each individual separately (which may raise privacy concerns) to considering large, culturally diverse groups (such as all Spanish speakers) as a homogeneous mass. Again, NLP dataset creators as well as model developers must be aware of the trade-off between generalisation and adaptation here.

6.3 Translation

Beyond NLP *for* various cultures, cross-cultural NLP can be used for bridging *between* cultures, investigating cross-cultural communication. The classic example is machine translation (MT) between languages. In MT, semantic divergences are usually treated as noise, or in any case, as imperfect translations (Briakou and Carpuat, 2021). A commonly accepted criterion for translation adequacy is that the semantics of the source are preserved in the output (Carl, 1998; Sulem et al., 2015). However, when applied for translation across cultures, translation may have different objectives. The same meaning may be inappropriate in the target culture, regardless of fluency, and require adjustments: this is referred to as *adaptation* in the translation field (Vinay and Darbelnet, 1995). Peskov et al. (2021) observed that translated sentences are often opaque without cultural context (e.g., "I saw Merkel eating a Berliner from Dietsch on the ICE"), and propose adapting entities to the target culture by substituting them with their approximate counterparts. As an alternative strategy, adding explanations, for example in the form of appositives (Kementchedjhieva et al., 2020), can elucidate entities that are known in the source culture but not in the target culture. These are examples of *cross-cultural translation* (Sperber et al., 1994). This kind of adaptation can also be helpful in culturally-situated dialogue, where some users may be less familiar with the common ground of a particular culture; in such cases, Abou-Khalil et al. (2018) propose to explain by analogy to concepts from the user's home culture.

Cross-cultural translation is not necessarily always between languages, but could take the form of style transfer within a language (Shen et al., 2017; Prabhumoye et al., 2018). For example, Jhamtani et al. (2017) transform text from modern English to Shakespearean English. Roy et al. (2015) approach personalised marketing by adapting the style of marketing messages for specific audience segments, defined by geographic location and occupation.

Evaluation of cross-cultural translation is challenging, as the task is not always well-defined. In particular, for style transfer, human evaluation is more reliable than automatic evaluation, but still suffers from non-standard evaluation protocols (Briakou et al., 2021a,b). Reference-based automatic evaluation methods are particularly unreliable in this case, as the assumption that there is just one (or a few) *correct* translations is ostensibly violated (Song et al., 2013; Reiter, 2018). This stresses the need for culture-sensitive human evaluation.

7 Conclusion

In this paper, we have touched on a number of ways in which cultural knowledge, preferences and values can affect NLP practices. It is important to acknowledge the breadth of culture in all of these aspects, if we should aspire to a more cross-cultural NLP. However, we do not pretend to cover all relevant aspects of culture in our taxonomy: many works in sociology posture frameworks to better explain and catalogue the specific elements that compose a culture (Dant, 1999; Hofstede, 2001; Kendall et al., 2005; Woodward, 2007). We encourage further investigation of their impact on NLP.

Finally, present-day computational science have inherited colonising practices, which in NLP are realised as "homogenisation of perspectives" and "algorithmic monoculture" (Kleinberg and Raghavan, 2021; Bommasani et al., 2021). While there is general agreement in the NLP community that we need to represent cultures from outside Western, Educated, Industrialised, Rich, and Democratic (WEIRD) societies (Henrich et al., 2010), representation alone is not enough if we do not also allow them to prioritise their goals and values, rather than the goals and values held by the NLP community. Decolonisation (Bird, 2020; Mohamed et al., 2020; Birhane and Guest, 2021) aims to dismantle harmful power asymmetries and concepts of knowledge, turning us instead towards a "pluriversal epistemology of the future" (Mignolo, 2012) that unlike universalisms, acknowledges and supports a wider radius of socio-political, ecological, cultural, and economic needs (Mohamed et al., 2020).

Acknowledgements

The authors thank Desmond Elliott and Vinit Ravishankar for participating in preliminary discussions about the ideas presented in this paper. We are grateful to Omri Abend, members of the CoAStaL NLP group and the anonymous reviewers for their constructive feedback. This project has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 801199 (*Heather Lent* and *Emanuele Bugliarello*). This work is also partly funded by the Innovation Fund Denmark (IFD)[6] under File No. 0175-00011A (*Ilias Chalkidis* and *Anders Søgaard*). *Miryam de Lhoneux* was funded by the Swedish Research Council (grant 2020-00437).

8 Ethical Aspects and Broader Impact

As discussed in §5, norms and ethics are culture-dependent, and in some cases there is a conflict between maintaining researchers' and practitioners' ethical values (such as social equity) and multicultural acceptance. It is not our place to settle this conflict or to provide answers, but we stress that asking the question, of which values should prevail in each case, is essential for cross-cultural NLP. Furthermore, language technology for local communities must involve the members of those communities in an active, participatory manner, in order to decolonise language technology and respect the sovereignty of local people over their data (Bird, 2020; Mukhija et al., 2021).

Abstract

Prompt-based tuning for pre-trained language models (PLMs) has shown its effectiveness in few-shot learning. Typically, prompt-based tuning wraps the input text into a cloze question. To make predictions, the model maps the output words to labels via a *verbalizer*, which is either manually designed or automatically built. However, manual verbalizers heavily depend on domain-specific prior knowledge and human efforts, while finding appropriate label words automatically still remains challenging. In this work, we propose the prototypical verbalizer (ProtoVerb) which is built directly from training data. Specifically, ProtoVerb learns prototype vectors as verbalizers by contrastive learning. In this way, the prototypes summarize training instances and are able to enclose rich class-level semantics. We conduct experiments on both topic classification and entity typing tasks, and the results demonstrate that ProtoVerb significantly outperforms current automatic verbalizers, especially when training data is extremely scarce. More surprisingly, ProtoVerb consistently boosts prompt-based tuning even on untuned PLMs, indicating an elegant non-tuning way to utilize PLMs. Our codes are avaliable at `https://github.com/thunlp/OpenPrompt`.

1 Introduction

The massive-scale pre-trained language models (PLMs) (Han et al., 2021a) have been proven to be backbones for solving a variety of NLP tasks (Kowsari et al., 2019; Rajpurkar et al., 2016). To further adapt these PLMs to downstream tasks such as classification, traditional approaches fine-tune the language models through an extra classifier (Howard and Ruder, 2018). However, when task-specific data is limited (Bragg et al., 2021), training the extra classifier effectively is challenging due to the gap between pre-training tasks (e.g., masked language modeling) and fine-tuning tasks (e.g., classification and regression). This gap impedes the fast adaptation of PLMs to downstream tasks.

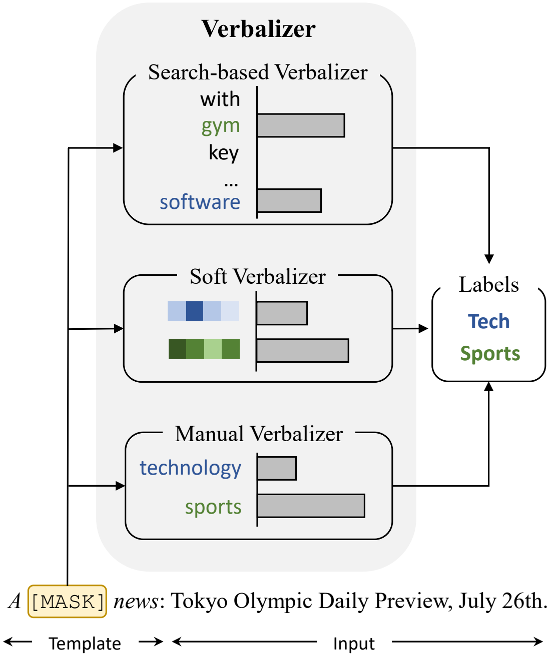

Figure 1: Illustration of three verbalizer construction methods.

Recently, prompt-based tuning (Schick and Schütze, 2021; Liu et al., 2021) has risen to be a powerful way for few-shot learning by bridging the gap between the pre-training stage and downstream task stage. In prompt-based tuning, the input texts are wrapped with task-specific templates to re-formalize the original task as a cloze-style task. For example, in topic classification task, we can use template "`<text>` This topic is about `[MASK]`", where `<text>` is the placeholder for input sentences. The PLMs are asked to infer the words to fill in `[MASK]` and the words are further mapped to corresponding labels through a *verbalizer* (e.g. "sports" for label "Sports"). Verbaliz-

ers are of great importance in prompt-based tuning (Gao et al., 2021) since they are the bridges between model outputs and the final predictions. How to build effective verbalizers for prompt-based tuning—especially for many-class classification, is a critical issue in prompt-based tuning.

Typically, most current works adopt three kinds of verbalizers: manual verbalizers, search-based verbalizers, and soft verbalizers. We show them by an example in Figure 1. Human-designed manual verbalizers pick some label words (e.g. label names) to depict classes. These verbalizers are powerful across multiple tasks (Schick and Schütze, 2021). Despite their success, a major drawback roots in the strong assumption that we own precise understandings of downstream tasks and are able to sum up each class with several words. Without task-specific prior knowledge, selecting appropriate label words is non-trivial. Further, they also need intensive human labors when facing many classes. To mitigate these issues, search-based verbalizers aim at finding suitable label words from vocabulary with algorithms (Schick et al., 2020; Shin et al., 2020; Gao et al., 2021) and soft verbalizers use trainable tokens which are optimized during tuning (Hambardzumyan et al., 2021; Zhang et al., 2021). However, it is challenging to search or optimize adequately in a large vocabulary or embedding space under a low-data regime, making automatic verbalizers suboptimal compared with manual ones.

Intuitively, class proxies in verbalizers should encapsulate class-level semantic features, which are expressed implicitly by instances. To obtain these semantic representatives with few data, one promising approach is computing central points of class instances, namely *prototypes*, as approximation. To this end, we manage to estimate prototype vectors for each class to serve as verbalizer. Summarized from instances, prototypes are supposed to establish concepts similar with human-designed labels.

In this work, we introduce prototypes into this problem and propose prototypical verbalizer (ProtoVerb), which learns class prototypes from training data to build verbalizers automatically. For prototype learning, inspired by the idea of PCL (Li et al., 2021), ProtoVerb trains the prototype vectors by contrastive learning with the InfoNCE estimator (Oord et al., 2018). Specifically, our optimization objective includes two components: The first part is an instance-instance loss to cluster intra-class instances and separate inter-class instances; The second part is an instance-prototype loss which enforces the prototypes to be center points of classes. Compared with other verbalizer construction methods, ProtoVerb learns continuous vectors straight from training instances efficiently, which makes it a plug-in-and-play algorithm with high flexibility.

To verify the effectiveness of ProtoVerb, we conduct extensive experiments on topic classification and entity typing tasks. We study two different settings where ProtoVerb can work: (1) When manual verbalizers are available, ProtoVerb can play as an extra verbalizer in the inference stage. Results show that ProtoVerb consistently improves the classification performance with low cost, and even untuned PLMs benefit largely. (2) Consider a realistic setting where only a limited number of samples are provided with no manual verbalizers, ProtoVerb also produces verbalizers of high quality. Experimental results demonstrate that ProtoVerb significantly outperforms existing search-based and soft verbalizers.

2 Related Work

2.1 Prompt-based Tuning

Despite the success of PLMs (Devlin et al., 2019; Liu et al., 2019; Raffel et al., 2019) in massive NLP tasks, few-shot fine-tuning of PLMs was suboptimal due to the gap between pre-training and downstream tasks. Inspired by the "in context learning" proposed by GPT-3 (Brown et al., 2020), stimulating model knowledge with a few *prompts* has recently received much attention. A series of prompt-based work on knowledge probing (Trinh and Le, 2018; Petroni et al., 2019; Davison et al., 2019), text classification (Schick and Schütze, 2021; Gao et al., 2021), relation extraction (Han et al., 2021b), and entity typing (Ding et al., 2021a) emerge and achieve impressive progress. Typically, a piece of prompt contains a template and a verbalizer. Early prompts employ human-picked prompts which demand human knowledge and manual efforts. To alleviate this issue, later works explore automatic designing and optimizing prompts (Liu et al., 2021; Gao et al., 2021; Zhang et al., 2021). Recently research works further propose continuous prompts to replace the discrete phrases (Lester et al., 2021; Li and Liang, 2021). However, the designation of verbalizers, an important part of prompts, is less explored. In this work, we investigate the automatic verbalizer construction in prompt-based tuning.

2.2 Verbalizer Design

Verbalizers bridge between model outputs and labels and make great impact on prompt-based tuning (Gao et al., 2021). With task-specific knowledge, human-picked words are widely used and proved effective (Schick and Schütze, 2021). The major drawback of manual verbalizers is the assumption that we possess sufficient knowledge of downstream tasks, which is not always satisfied. To avoid intensive human labor and expert knowledge dependency in manual verbalizers, some works explore search-based verbalizers (Schick et al., 2020; Gao et al., 2021; Shin et al., 2020) that identify label words automatically with training data. However, with a large vocabulary and few examples, it is non-trivial to find suitable words. Another line of researches focuses on soft verbalizers (Hambardzumyan et al., 2021; Zhang et al., 2021), which insert continuous embeddings as soft labels. The label embeddings are optimized along with model tuning. Similarly, soft verbalizers require abundant data for sufficient optimization, which can not be satisfied with the few-shot setting. In contrast, our approach learns prototype vectors from scratch, hence is more effective for few-shot tuning.

2.3 Prototype-based Few-shot Learning

In few-shot learning, prototype-based metric-learning methods have been promising approaches for their simplicity and effectiveness. Prototypical Networks (ProtoNet) (Snell et al., 2017) is the pioneering work that introduces prototypes into deep learning. Specifically, ProtoNet calculates prototype vectors by taking the average of instance vectors and makes predictions by metric-based comparisons between prototypes and query instances. A set of following works concentrates on the advancement of prototype estimation (Li et al., 2021; Gao et al., 2019; Ding et al., 2021c). Among them, PCL (Li et al., 2021) achieves remarkable results on self-supervised few-shot learning by using prototypes as latent variables and inspires us in designing training objectives. The success of prototype-based models indicates that prototypes, which are representative embeddings of instances from the same classes, encapsulate some class-level semantic features. Inspired by the intrinsic similarity of prototypes and verbalizers, we find it natural and elegant to introduce prototypes into verbalizer construction for prompt-based tuning.

3 Background

Given a pre-trained language model $\mathcal{M}$, our goal is to tune it for specific downstream tasks. Take N way K shot few-shot text classification as an example, the support set for class n $\mathcal{D}_n = \{x_1^n, \cdots, x_K^n\}$ contains K sentences. We aim to predict the label $y \in \mathcal{Y}$ for each sentence, where $\mathcal{Y}$ is the label set with N distinct classes.

3.1 Fine-tuning

For a sentence concatenated with special tokens $x = \{\texttt{[CLS]}, t_1, \cdots, t_T, \texttt{[SEP]}\}$, language model $\mathcal{M}$ encodes it into hidden representations $\{\mathbf{h}_{\texttt{[CLS]}}, \mathbf{h}_1, \cdots, \mathbf{h}_T, \mathbf{h}_{\texttt{[SEP]}}\}$. Conventional fine-tuning trains an extra classifier F over the `[CLS]` embedding $\mathbf{h}_{\texttt{[CLS]}}$ and output the probability distribution on label set $\mathcal{Y}$.

$$P(\cdot|x) = \text{Softmax}(F(\mathbf{h}_{\texttt{[CLS]}})). \tag{1}$$

The classifier and PLM are tuned by maximizing $\frac{1}{N}\sum_{i=1}^{N} \log P(y_i|x_i)$, where y_i is the label of x_i.

3.2 Prompt-based Tuning

The vanilla prompt-based tuning converts the downstream task to a cloze-style mask language modeling problem. For example, to formulate the text classification task, we can modify the original input x with a template $\mathcal{T}(\cdot) =$ A `[MASK]` news: to get the prompt input $\mathcal{T}(x) =$ A `[MASK]` news: x. With $\mathcal{T}(x)$, $\mathcal{M}$ produces the hidden vector at the `[MASK]` position $\mathbf{h}_{\texttt{[MASK]}}$. To calculate the probability distribution over the label set, a manual verbalizer stores a set of label words $\mathcal{V}$ and the score for label y is

$$P_{\mathcal{M}}(y|x) = g(P_{\mathcal{M}}(\texttt{[MASK]} = v|\mathcal{T}(x))|v \in \mathcal{V}_y), \tag{2}$$

where $\mathcal{V}_y$ is the label words of y and $g(\cdot)$ is to aggregate multiple scores.

4 Prototypical Verbalizer

In previous sections, we introduce the general pipeline of prompt-based tuning. As manually defining or automatically searching for appropriate verbalizers can be challenging, here we propose to learn prototypes directly from training instances. Inspired by PCL (Li et al., 2021), the prototypes are trained with contrastive learning. As shown in

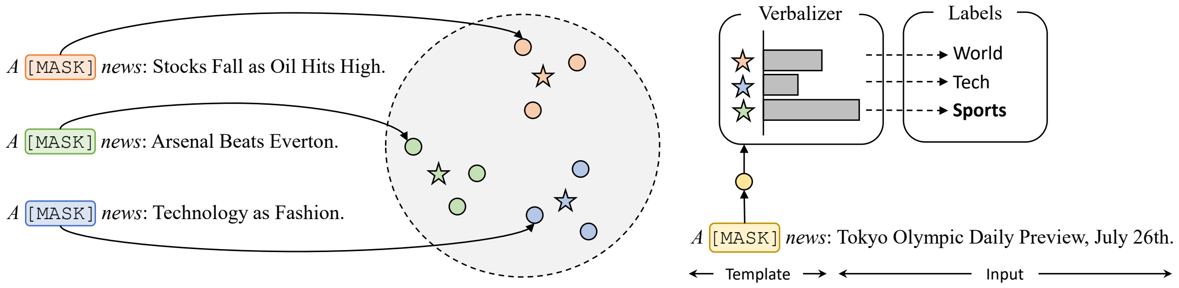

Figure 2: Illustration of ProtoVerb. Left: We project the hidden states of `[MASK]` tokens to the embedding space and learn prototypes. Right: The learned prototypes constitute the verbalizer and map the PLM outputs to corresponding labels.

Figure 2, we first get the hidden states of `[MASK]` tokens to represent instances, then project them to another embedding space for prototype learning. The prototypes are used as verbalizers for prediction. Next, we will introduce the learning and inference stages of ProtoVerb in detail.

4.1 Instance Representation and Similarity Function

Given a piece of training text x wrapped with a template, we take the last layer's hidden state of the `[MASK]` token $\mathbf{h}_{\texttt{[MASK]}}$ as the initial representation of the text. With an encoder $E_\phi(\cdot)$ parameterized by ϕ, the instance representation of x is

$$\mathbf{v} = E_\phi(x) = \mathbf{W}\mathbf{h}_{\texttt{[MASK]}}. \tag{3}$$

In practice, we simply adopt a linear encoder with weight $\mathbf{W}$. To measure the similarity between instances, we adopt cosine similarity function $S(\cdot)$, where

$$S(\mathbf{v}_i, \mathbf{v}_j) = \frac{\mathbf{v}_i}{||\mathbf{v}_i||} \cdot \frac{\mathbf{v}_j}{||\mathbf{v}_j||}. \tag{4}$$

4.2 Loss Function

With the instance representation and similarity function, we discuss how to define our training objective. Denote $\mathcal{C} = \{\mathbf{c}_1, \cdots, \mathbf{c}_N\}$ as the set of prototype vectors. Intuitively, there are two goals we need to achieve by optimization: (1) For instance-instance pairs, intra-class pairs should get higher similarity scores than inter-class pairs. (2) For instance-prototype pairs, the similarity scores between prototype $\mathbf{c}_n$ and instances of class n should be higher than $\mathbf{c}_n$ and other instances. To realize these two goals, we define the objective function based on the InfoNCE estimator (Oord et al., 2018), which is widely adopted in contrastive learning.

For the instance-instance objective, we minimize the following loss function

$$\mathcal{L}_{\text{ins}} = \frac{-1}{N^2K^2}\sum_n\sum_{i,j}\log\frac{\exp S(\mathbf{v}_i^n, \mathbf{v}_j^n)}{\sum_{n',j'}\exp S(\mathbf{v}_i^n, \mathbf{v}_{j'}^{n'})}, \tag{5}$$

where $(\mathbf{v}_i^n, \mathbf{v}_j^n)$ are instance pairs of the same class. This loss function maximizes intra-class similarity and minimizes inter-class similarity between instances.

Similarly, the instance-prototype loss function is defined as

$$\mathcal{L}_{\text{proto}} = \frac{-1}{N^2K}\sum_{i,n}\log\frac{\exp S(\mathbf{v}_i^n, \mathbf{c}_n)}{\sum_{n'}\exp S(\mathbf{v}_i^n, \mathbf{c}_{n'})}, \tag{6}$$

and $\mathbf{v}_i^n$ is of class n. This objective forces each prototype to lie at the center point of its instances.

Overall, combining the instance-instance loss and instance-prototype loss, our final training objective is

$$\mathcal{L} = \mathcal{L}_{\text{ins}} + \mathcal{L}_{\text{proto}}. \tag{7}$$

4.3 Inference

During inference, following the same metric, we calculate the similarity scores of query and prototypes. The probability score for class k is

$$P_{\mathcal{M}}(y_k|x) = \frac{\exp S(\mathbf{v}, \mathbf{c}_k)}{\sum_{k'}\exp S(\mathbf{v}, \mathbf{c}_{k'})}. \tag{8}$$

Then we make prediction by $\arg\max$ function

$$\widetilde{y} = \arg\max_k P_{\mathcal{M}}(y_k|x). \tag{9}$$

When there are other verbalizers (e.g. manual verbalizers), we first process the logits from different verbalizers with a standard scaler (minus mean then divide by standard deviation). Then we take the mean value of the scores to get the final score.

5 Experiments

We conduct extensive few-shot learning experiments to illustrate the effectiveness of ProtoVerb. In this section, we first introduce the experimental settings in use. Then we present and discuss the experiment results.

5.1 Datasets and Templates

Verbalizers in many-class classification tasks are difficult to get precise definitions. Hence we adopt three topic classification datasets: AG's News, Yahoo (Zhang et al., 2015), and DBPedia (Lehmann et al., 2015) and one entity typing dataset: FewNERD (Ding et al., 2021d) as benchmarks, and their statistics are summarized in Table 1.

To focus on the verbalizer and alleviate the influence of templates, we adopt multiple fixed manual templates. For topic classification, following (Hu et al., 2021), we use four templates on each dataset. For entity typing, we use three templates from (Ding et al., 2021a). Details about the templates can be found in Appendix A.

Dataset	Task	#Class	#Test
AG's News	TC	4	7,600
DBPedia	TC	14	70,000
Yahoo	TC	10	60,000
FewNERD	ET	66	96,901

Table 1: Dataset statistics. TC is for topic classification and ET is for entity typing.

5.2 Experimental Settings

Under the few-shot setting, we randomly sample $k = 1, 2, 4, 8, 16$ instances in each class from the training set and test the model on the entire test set. As for the evaluation metric, we use accuracy in all experiments. For the different usages of ProtoVerb, we consider two specific settings:

(1) ProtoVerb as a single verbalizer (§ 5.5). When manual verbalizers are not available, we can tune the model with ProtoVerb. Under this setting, we want to evaluate the performance of ProtoVerb compared with other automatic verbalizer construction methods.

(2) ProtoVerb as an extra verbalizer (§ 5.6). Naturally, we suppose that there exists a manual verbalizer and we append ProtoVerb to strengthen the performance. Under this setting, ProtoVerb is a plug-in-and-play component and does not participate in the tuning process. We compare ProtoVerb with manual verbalizers and other verbalizer ensembles.

5.3 Implementation Details

All our models and baselines are implemented with PyTorch (Paszke et al., 2019) framework, Huggingface transformers (Wolf et al., 2020), and OpenPrompt toolkit (Ding et al., 2021b). We optimize PLMs with AdamW optimizer (Loshchilov and Hutter, 2019). For prototype learning, we set the prototype dimension to 128 and optimize the loss function with Adam optimizer (Kingma and Ba, 2015). For topic classification, we use RoBERTa-large (Liu et al., 2019) as our PLM backbone and tune the model for 5 epochs. The batchsize is 2 and the learning rate is 3e-5. For entity typing, we tune a BERT-base (Devlin et al., 2019) model for 30 epochs and set the batchsize to 16. The learning rate here is 5e-5.

5.4 Baselines

The vanilla prompt-based tuning method fuses the input text with a task-specific template and maps the model outputs to labels through a verbalizer. For fair comparisons, all our baselines and proposed models are built on this pipeline and they merely differ from the verbalizers in use.

Manual verbalizers (ManualVerb) are defined by human with domain knowledge. Here we simply employ the verbalizers provided by OpenPrompt (Ding et al., 2021b).

Search-based verbalizers (SearchVerb) search for suitable words from vocabulary automatically. We adopt the implementation in PETAL (Schick et al., 2020), which finds the words that maximize the likelihood of the training data. To combine SearchVerb with ManualVerb, we merge their verbalizer words together.

Soft verbalizers (SoftVerb) introduce trainable tokens as verbalizers in prompt-based tuning. We follow the approach in WARP (Hambardzumyan et al., 2021) that applies soft tokens as a linear decoding layer, and the token embeddings are learned along with model tuning. Note that the templates in WARP are also trainable, but here we only use its soft verbalizers. In single verbalizer experiments, we initialize the token embeddings randomly for fairness. And in extra verbalizer experiments, they are initialized with label names.

	ProtoVerb	**84.48**	**96.30**	**64.35**	**61.29**

Table 2: Results for single verbalizer experiments. We report the mean accuracy scores (%) over 3 random seeds. *Italic*: results with task-specific knowledge. **Bold**: best results without task-specific knowledge.

5.5 Single Verbalizer Results

Table 2 presents the performance of different verbalizers. Overall, ManualVerb is the most powerful verbalizer, which is reasonable because it is picked by human with domain knowledge. ProtoVerb outperforms SearchVerb and SoftVerb remarkably and consistently, especially when only 1 or 2 instances per class are given. The poor performances of the two baselines under extreme data scarcity corroborate the issues we claim in § 1. As the training data become sufficient, ProtoVerb gets comparable or even exceeding scores compared with ManualVerb, showing that ProtoVerb is able to learn prototypes that well represent the classes. At the same time, the gaps between ManualVerb and other verbalizers narrow, which also indicates that we can summarize data across various ways.

Across tasks, ProtoVerb gets better results on topic classification than entity typing. A possible reason is that FewNERD is a fine-grained entity typing dataset, in which the differences across classes are subtle. For example, it is hard for ProtoVerb to discriminate between "person-artist/author" and "person-director" with only a few instances. However, ProtoVerb can also catch up with ManualVerb with enough samples.

K	Method	AG	DB	Yahoo	Few

Table 3: Results for multiple verbalizer experiments. We report the mean accuracy scores (%) over 3 random seeds. ProtoVerb+ w/o tuning: apply ProtoVerb to untuned PLMs. **Bold**: best results.

5.6 Multiple Verbalizer Results

Table 3 shows the experiment results when we ensemble manual verbalizers with automatic verbalizers. The ensembled versions are denoted as SearchVerb+, SoftVerb+, and ProtoVerb+ respectively. From the table, we have the following observations: (1) Basically, prompt-based tuning outperforms fine-tuning by a large margin with few samples (1∼2 per class). When sufficient training data is available, fine-tuning models will produce comparable results. (2) Overall, ProtoVerb+ certainly improves the performance of prompt-based tuning under most cases, which demonstrates the effectiveness of ProtoVerb+. At the same time, SearchVerb+ and SoftVerb+ seldom show enhancement compared with ManualVerb. As ProtoVerb+ does not introduce any external knowledge, this illustrates that ProtoVerb+ provides a better way to utilize training data.

Finally, we also present the results of applying ProtoVerb+ on untuned PLMs. It is worth noting that even for untuned models, ProtoVerb+ also boosts them considerably on all tasks. For example on DBPedia, showing only one instance per class to PLMs with ProtoVerb+ leads to 11.26% absolute accuracy improvement. On topic classification, when more training samples are given, untuned PLMs achieve competitive scores. This observation indicates a new cost-efficient way to leverage training data, which we highlight as valuable for future study of **none-tuning** methods for PLMs. Compared to the "in context learning" in GPT-3 (Brown et al., 2020), ProtoVerb+ is not limited by input length and can deal with arbitrary number of samples. We further study this "fixed model" scenario in § 6.1.

6 Analysis

In this section, we discuss several analytical topics for further understandings of ProtoVerb. For simplicity, we conduct experiments on AG's News dataset.

6.1 Fixed Model Experiments

In § 5.6, we see ProtoVerb is still powerful with fixed PLMs. For further comparisons, we conduct experiments to quantitatively evaluate verbalizers when PLMs are fixed. Figure 3 gives the results. To clarify, using ManualVerb on fixed PLMs equals the zero-shot setting, which we plot with a dashed line. Meanwhile, different from § 5.6, ProtoVerb here is a single verbalizer. From the figure we can conclude that (1) Similar with § 5.5, ProtoVerb outperforms SoftVerb and SearchVerb by a large margin under low-shot settings. Notably, ProtoVerb exceeds ManualVerb with only 2 shots per class, illustrating the experessive power of prototypes. (2) SoftVerb is also better than SearchVerb under this setting, demonstrating that tunable verbalizers could exploit training data better with PLMs fixed.

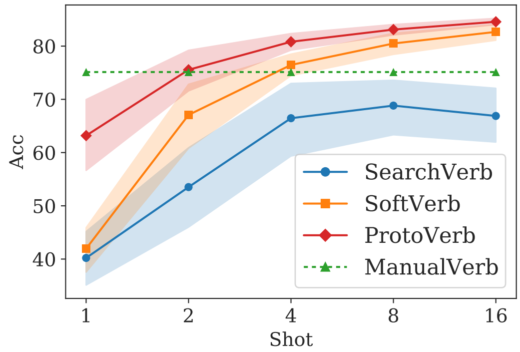

Figure 3: Experiment results with fixed PLMs. We report the mean accuracy (%) with 95% confidence interval on AG's News.

Method	$K=2$	$K=4$	$K=8$
$\mathcal{L}_{\text{ins}} + \mathcal{L}_{\text{proto}}$	**77.34**	**81.65**	**84.03**
$\mathcal{L}_{\text{proto}}$	76.37	81.06	82.91
Instance Mean	73.36	77.76	82.57

Table 4: Ablation study of ProtoVerb on AG's News. Instance Mean: using the mean embeddings of instances as prototype embeddings. **Bold**: best results

K	Method	# Noisy Samples		
		1	2	3

	SoftVerb	4.84	7.80	11.71
	ProtoVerb	**2.34**	**3.11**	**4.37**
16	SearchVerb	0.80	2.93	5.18
	SoftVerb	2.01	4.17	4.58
	ProtoVerb	**0.04**	**2.13**	**3.16**

Table 5: Accuracy drop (%) with noisy samples. Lower is better. **Bold**: best results.

6.2 Ablation Study

To validate the effect of each part in the loss function, we conduct an ablation study on AG's News dataset. For comparison, we consider two variants of prototype calculation methods: (1) ProtoVerb with $\mathcal{L}_{\text{proto}}$ only. (2) Following ProtoNet (Snell et al., 2017), take the average of instance embeddings for prototype embeddings. Table 4 shows the results. Compared to taking the mean embedding

Class	$K = 1$	$K = 16$
World	Qaida, Syria, Iraq, Nusra, TPP	Taliban, Iraq, Afghan, militants, rebellion
Sports	Steelers, Raptors, Knicks, Dodgers	ball, ESPN, baseball, Fifa, Sports
Business	cash, earnings, Securities, NYSE	Dow, dividend, investing, markets
Tech	LTE, Tel, Huawei, Mbps, VPN	Vault, IBM, Qualcomm, Technologies

Table 6: Words that are most similar with prototypes of each class on AG's News.

vectors directly, optimizing the embedding vectors of prototypes using our loss functions leads to better performances and stability. Adding $\mathcal{L}_{\text{ins}}$ is also beneficial, meaning that $\mathcal{L}_{\text{ins}}$ helps ProtoVerb in learning instance embeddings.

6.3 Robustness on Noisy Samples

Noisy data are commonly seen as threats in real-world datasets for few-shot learning systems. For automatic verbalizers, noisy data are more harmful because of the effect on both the quality of verbalizers and the training process. In this section, we evaluate the robustness of different automatic verbalizers against noisy samples on AG's News. For training stability, we set $K = 8, 16$. Table 5 presents the accuracy drop when there are 1, 2, or 3 samples having wrong labels. It is clearly seen that a limited number of noisy samples will hinder the performance greatly, showing the vulnerability of automatic verbalizers. Meanwhile, we can also find that ProtoVerb is more robust than baseline methods when facing noisy samples.

6.4 Prototype Discretization

Since ProtoVerb learns continuous prototype vectors, their meanings are implicit. Here we manage to investigate which words are most similar to the learned prototypes. Due to word embeddings and prototype vectors lying in different embedding spaces, we can not directly calculate their similarity. Hence we use the vocabulary as the input texts (one word at a time) to get the top-scored word for each class. On AG's News dataset, we collect some most similar words for each class and list them in Table 6.

To investigate the property of prototypes learned with different numbers of samples, we present words for $K = 1$ and $K = 16$. With the table, we see that: (1) Even when only one example is available, the learned prototypes are meaningful. Most of the similar words are proper nouns and entity names closely related to class topics. For example, "Steelers", "Raptors", "Knicks", and "Dodgers" are all baseball or basketball teams that appear frequently in sports news. We attribute this to prompt mechanism that allows PLMs to extract the most conclusive information and fill the `[MASK]` with it. Then the relevant words are also included. (2) With more training instances, prototypes show diverse interests. Despite entity names, more "conceptual" words show up on the list, such as "ball" and "Sports" for class Sports. We interpret this as the summarization and abstraction ability of prototypes. Given many instances, prototypes are enforced to capture their common features, hence some abstract concepts are found automatically. In this way, ProtoVerb encapsulates class-level, rather than entity-level, semantics, which leads to better performance on unseen data.

6.5 Is ProtoVerb Similar with ManualVerb?

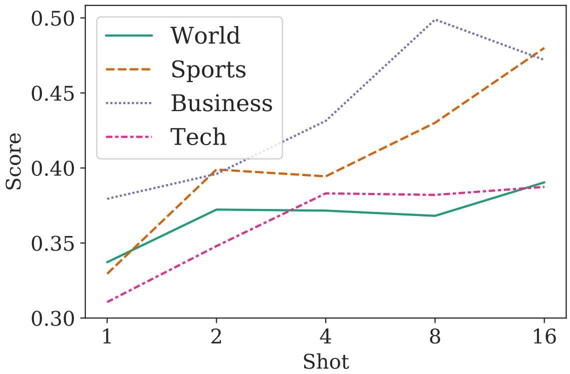

Figure 4: Similarity scores between ProtoVerb and ManualVerb on AG's News.

To give further analyses for the inner workings of prototypes, we measure the similarity between ProtoVerb and ManualVerb to see whether ProtoVerb is able to learn abstract concepts as humans do. On AG's News dataset, we calculate the similarity scores between prototypes and manual verbalizers and normalize the scores using the softmax function across the four classes. In Figure 4 we plot the scores with various shots. It is clearly seen that the similarity of prototypes and corresponding verbalizers are above average (0.25). As shot increases, the scores also gradually grow, which illustrates that prototypes can capture the conceptual information better from more instances. This observation matches our findings in § 6.4. Among the four classes, Business and Sports get higher scores than World and Tech. A reasonable guess is that World and Tech news includes diverse sub-topics that are hard to summarize.

7 Conclusion

In this paper, we propose a novel approach for automatic verbalizer construction in prompt-based tuning. The proposed ProtoVerb learns class prototypes from training instances using contrastive learning. We explore the performance of ProtoVerb on few-shot topic classification and entity typing tasks. As a single verbalizer, ProtoVerb outperforms state-of-the-art automatic verbalizers considerably. Working together with manual verbalizers, ProtoVerb can also consistently improve prompt-based tuning with minor effort. The results validate the effectiveness of ProtoVerb. Our analysis further reveals the intrinsic properties of prototypes. For future work, we will focus on extending ProtoVerb for effective non-tuning algorithms of PLMs and prompt-tuning with soft templates. Moreover, we are finding proper ways to combine label words and prototypes for verbalizer construction.

Acknowledgements

This work is supported by the National Key R&D Program of China (No. 2020AAA0106502), Institute for Guo Qiang at Tsinghua University, Beijing Academy of Artificial Intelligence (BAAI), and International Innovation Center of Tsinghua University, Shanghai, China. Ganqu Cui and Shengding Hu conducted the experiments. Ganqu Cui, Shengding Hu, Ning Ding and Zhiyuan Liu wrote the paper. Longtao Huang provided valuable advices to the research.

Ethical Considerations

Our work explores how to stimulate large PLMs with few samples. We conduct experiments under the few-shot setting, where requires less training time and fewer resources than normal full-data setting. Also, we open up our codes and hyperparameters to facilitate future reproduction without repeated energy cost.

A Templates

For topic classification, we use the default templates and verbalizers in OpenPrompt (Ding et al., 2021b).

AG's News is a news' topic classification dataset. There are four categories: World, Sports, Business, and Tech. We use the following templates.

$$\begin{aligned}
\mathcal{T}_1(x) &= \text{A } \texttt{[MASK]} \text{ news: } x \\
\mathcal{T}_2(x) &= x \text{ This topic is about } \texttt{[MASK]}. \\
\mathcal{T}_3(x) &= [\text{ Category : } \texttt{[MASK]} \text{] } x \\
\mathcal{T}_4(x) &= [\text{ Topic : } \texttt{[MASK]} \text{] } x
\end{aligned}$$

DBPedia is an ontology classification dataset. Each sample contains an article title x and abstract y extracted from Wikipedia, and the task is to classify the subject's ontology class. There are 14 classes in total. We employ four templates shown below:

$$\begin{aligned}
\mathcal{T}_1(x, y) &= x\ y\ x \text{ is a } \texttt{[MASK]}. \\
\mathcal{T}_2(x, y) &= x\ y \text{ In this sentence,} x \text{is a } \texttt{[MASK]}. \\
\mathcal{T}_3(x, y) &= x\ y \text{ The type of} x \text{is } \texttt{[MASK]}. \\
\mathcal{T}_4(x, y) &= x\ y \text{ The category of} x \text{is } \texttt{[MASK]}.
\end{aligned}$$

Yahoo is a question classification dataset with 10 classes. Each piece of text consists of a question and an answer. We use the templates in AG's News where "news" is replaced with "question" in $\mathcal{T}_1(\cdot)$

$$\begin{aligned}
\mathcal{T}_1(x) &= \text{A } \texttt{[MASK]} \text{ question: } x \\
\mathcal{T}_2(x) &= x \text{ This topic is about } \texttt{[MASK]}. \\
\mathcal{T}_3(x) &= [\text{ Category : } \texttt{[MASK]} \text{] } x \\
\mathcal{T}_4(x) &= [\text{ Topic : } \texttt{[MASK]} \text{] } x
\end{aligned}$$

FewNERD is a large-scale fine-grained entity typing dataset with 66 types and we use the official split of its supervised setting. Following (Ding et al., 2021a), we employ 3 templates as below

$$\begin{aligned}
\mathcal{T}_1(x) &= x \ \texttt{[ENT]} \text{ is } \texttt{[MASK]}. \\
\mathcal{T}_2(x) &= x \ \texttt{[ENT]} \text{ is a } \texttt{[MASK]}. \\
\mathcal{T}_3(x) &= x \text{ In this sentence, } \texttt{[ENT]} \text{ is a } \texttt{[MASK]}.
\end{aligned}$$

where `[ENT]` copies the entity mention in the sentence.

Clickbait Spoiling via Question Answering and Passage Retrieval

Matthias Hagen[1] **Maik Fröbe**[1] **Artur Jurk**[1] **Martin Potthast**[2]

[1]Martin-Luther-Universität Halle-Wittenberg
[2]Leipzig University

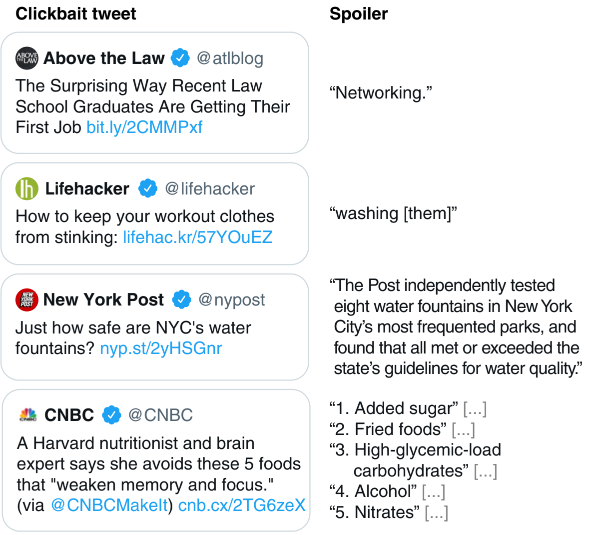
Abstract

We introduce and study the task of clickbait spoiling: generating a short text that satisfies the curiosity induced by a clickbait post. Clickbait links to a web page and advertises its contents by arousing curiosity instead of providing an informative summary. Our contributions are approaches to classify the type of spoiler needed (i.e., a phrase or a passage), and to generate appropriate spoilers. A large-scale evaluation and error analysis on a new corpus of 5,000 manually spoiled clickbait posts—the Webis Clickbait Spoiling Corpus 2022—shows that our spoiler type classifier achieves an accuracy of 80%, while the question answering model DeBERTa-large outperforms all others in generating spoilers for both types.

1 Introduction

Clickbait is the term used to describe posts in social media that are intended to inappropriately entice their readers to visit a web page. This is achieved through formulations such as sensationalism or cataphors that are believed to create a so-called curiosity gap: "a form of cognitively induced deprivation that arises from the perception of a gap in knowledge or understanding" (Loewenstein, 1994). Clickbait is perceived as inappropriate since its resolution is usually ordinary or trivial, comprising little more than a phrase, short passage, or a list of things that could just as easily have been included in the post. This observation motivates us to introduce the task of clickbait spoiling: identifying or generating a spoiler for a clickbait post.

Figure 1 shows four examples of clickbait on Twitter, along with spoilers. The first two tweets explicitly or implicitly promise a surprising resolution to spark curiosity, but their spoilers are brief and trivial. The linked page of the first tweet adds almost nothing, and the spoiler of the second is common sense. The third spoiler is a passage from the linked page, and the fourth is a list of things. Even though there are length limits to the informativeness of tweets, the spoilers in all examples could easily have been part of the original tweets.



Clickbait tweet	Spoiler
Above the Law @atlblog The Surprising Way Recent Law School Graduates Are Getting Their First Job bit.ly/2CMMPxf	"Networking."

Figure 1: Examples of clickbait tweets and spoilers for them extracted from the respective linked web page.

This paper reports about our investigation into clickbait spoiling and the following contributions: (1) The Webis Clickbait Spoiling Corpus 2022 (Webis-Clickbait-22), consisting of 5,000 clickbait posts, their linked pages and a spoiling piece of text therein.[1] (2) A two-step approach to clickbait spoiling that first classifies a clickbait post according to its spoiler type (phrase or passage), and then treats spoiling either as a question answering or as a passage retrieval task. (3) A systematic evaluation of state-of-the-art methods for spoiler type classification, question answering, and passage retrieval.[2] Although the first step of spoiler type classification is not necessary, our results suggest that it can be helpful. Even more so, as we have not yet tackled multipart spoilers (bottom example in Figure 1; 876 cases also part of our corpus) that probably require a different spoiling approach.

2 Related Work

Following an overview of research on clickbait and its operationalization so far, models of question answering and passage retrieval are examined.

2.1 Clickbait and its Operationalization

The underlying assumption of most research on clickbait is that it is a form of data-driven optimization of social media posts to exploit the curiosity gap described by Loewenstein (1994). At least that's what Peter Koechley (2012), the CEO of Upworthy, claimed. Upworthy became one of the first major spreaders of clickbait on Facebook, and their success has prompted Facebook to change its news recommendation algorithms to curb the amount of clickbait, twice (El-Arini and Tang, 2014; Peysakhovich and Hendrix, 2016).

Exploratory and theoretical studies of clickbait and its impact on journalism analyzed its prevalence for more than 150 publishers (Rony et al., 2017); its economics for the news market (Munger, 2020); its impact on perceptions of credibility and quality (overall negative) (Molyneux and Coddington, 2020); and noted a slow decline over the past decade (Lischka and Garz, 2021).

Journalistic studies of this kind rely on clickbait detection technologies. Originally proposed by Rubin et al. (2015) but not followed up, Potthast et al. (2016) and Chakraborty et al. (2016) independently developed the first detectors. Starting from a shared task organized by Potthast et al. (2018) shortly after, more than 50 approaches have been contributed to date. An overview is beyond the scope of our work, but transformer models dominate this task as well. For the clickbait generation task, preceded by a rule-based generator (Eidnes, 2015), only Shu et al. (2018) and Xu et al. (2019) have presented more advanced models, while Karn et al. (2019) generate teaser headlines that are explicitly not meant to be clickbait. So far, no attempt has been made to generate spoilers for clickbait.

2.2 Question Answering

If one considers clickbait spoiling as a question answering problem, there are numerous possible solutions. Among the available question-answering benchmarks (Dzendzik et al., 2021), we select two to choose appropriate state-of-the-art models for our evaluation: (1) SQuAD (Rajpurkar et al., 2016) compiles 107,785 questions and answers based on 536 Wikipedia articles. Although a wide range of questions and answers are included, the vast majority of 93.6% are factual (32% names, 31.8% noun phrases, 19.8% numbers, 5.5% verb phrases, and 3.9% adjective phrases), while the remainder are descriptive (3.7% clauses and 2.7% other). We use SQuAD v1.1, not the v2.0 superset (Rajpurkar et al., 2018), which contains unanswerable questions, since we do not expect clickbait to be "unspoilable". (2) TriviaQA (Joshi et al., 2017) contains 95,000 question–answer pairs, mostly dealing with trivia questions that are supposed to be particularly difficult to answer. These are comparable to clickbait in that many of them address rather trivial things (see Figure 1).

The question answering models used in our experiments are ALBERT (Lan et al., 2020), AllenAI-Document-QA (Clark and Gardner, 2018), BERT (cased/uncased) (Devlin et al., 2019), Big Bird (Zaheer et al., 2020), DeBERTa (large) (He et al., 2021), ELECTRA (Clark et al., 2020), Funnel-Transformer (Dai et al., 2020), MPNet (Song et al., 2020), and RoBERTa (base/large) (Liu et al., 2019). Many of them are or were state of the art on the above benchmarks and implement various different architectural paradigms.

2.3 Passage Retrieval

Passage retrieval relaxes the question answering task a bit in the sense of allowing longer passages of text as answers (e.g., one or more sentences), rather than exact phrases or statements. Neural retrieval models, as surveyed by Guo et al. (2020) and Lin et al. (2021), have been successfully applied to passage retrieval. One of the most important passage retrieval benchmarks is part of MS MARCO, a series of challenges whose first edition was a large question answering task (Nguyen et al., 2016). A passage retrieval dataset of 8.8 million passages was derived for the underlying set of 100,000 questions originally submitted to Bing. This dataset formed the basis for two consecutive shared tasks at the TREC 2019 and 2020 Deep Learning tracks (Craswell et al., 2019, 2020).

The passage retrieval models used in our experiments are MonoBERT (Nogueira and Cho, 2019; Nogueira et al., 2019) and MonoT5 (Nogueira et al., 2020) (both topped the MS MARCO passage retrieval leaderboard once), and the classic baseline models BM25 (Robertson and Zaragoza, 2009) and Query Likelihood (Ponte and Croft, 1998), implemented in Anserini (Yang et al., 2017).

3 Webis Clickbait Spoiling Corpus 2022

To tackle clickbait spoiling for the first time, we created the Webis Clickbait Spoiling Corpus 2022 (Webis-Clickbait-22), a collection of 5,000 clickbait posts and their associated spoilers.

3.1 Corpus Construction

Our corpus is primarily based on five social media accounts on Twitter, Reddit, and Facebook that manually spoil clickbait: r/savedyouaclick, @HuffPoSpoilers, @SavedYouAClick, @UpworthySpoiler, and @StopClickBaitOfficial. With the goal of collecting 5,000 "spoilable" clickbait posts at an expected rejection rate of around 10% of unusable posts, 5,555 were initially collected from the accounts. Each of them was manually reviewed, and those that turned out not to be spoiled clickbait were removed (e.g., funny posts not intended to be spoilers, or posts with unavailable linked documents). The rejection rate was higher than expected, and only 4,204 posts remained.

To reach our goal of 5,000 posts, we then sampled from the Webis-Clickbait-17 corpus used in the Clickbait Challenge 2017 (Potthast et al., 2018). The corpus contains 38,517 tweets, each of which was rated by 5 annotators on a 4-point Likert scale for clickbaitiness: "no clickbait," "slight clickbait," "considerable clickbait," and "heavy clickbait." Of the tweets, 1,845 scored an average of 0.8 or higher and can safely be considered clickbait. We selected tweets from this subset and manually spoiled them based on the linked document until our target size of 5,000 posts was reached.

Thus, our final corpus consists of 4,204 posts from Twitter, Reddit, and Facebook that were spoiled by a third party specializing in this task, and 796 tweets from the Webis-Clickbait-17 corpus with an average clickbaitiness of at least 0.8 that we spoiled ourselves. For each of the 5,000 clickbait posts, we also reviewed and corrected erroneous spoilers and labeled their exact positions in the linked documents. Our internal guidelines dictated that a spoiler should be as short as possible (i.e., if one word is enough, not a whole sentence should be chosen). Since the underlying annotation task is simple, one main annotator was sufficient. Nevertheless, randomly selected as well as ambiguous cases were discussed with two additional experts among the co-authors. No systematic errors or unforeseen difficulties in solving the annotation task were identified during these discussions.

During our annotation, we found that none of the common approaches to main content extraction worked reliably for all the documents linked in the clickbait posts. Yet, clean content is a prerequisite for research on clickbait spoiling to eliminate as many confounding variables as possible. To ensure a clean corpus, one annotator manually extracted the main content of the linked documents, removing (inline) advertisements, links to related articles (e.g., "READ ALSO: [. . .]" or "Also from CNBC [. . .]"), credits (e.g., "Image credit: [. . .]" or "Photo by [. . .]"), and social media links (e.g., "Subscribe to [. . .]" or "Follow us on [. . .]"). A random selection was reviewed to ensure high quality.

Moreover, during spoiler annotation, it turned out that there are basically three types of spoilers: (1) *phrase spoilers* consisting of a single word or phrase from the linked document (e.g., the first two spoilers in Figure 1, but often named entity spoilers as well), (2) *passage spoilers* consisting of one or a few sentences of the linked document (e.g., the third spoiler in Figure 1), and (3) *multipart spoilers* consisting of more than one non-consecutive phrases or passages of the linked document (e.g., the fourth spoiler in Figure 1). Spoiler types were also annotated by the main annotator, and randomly checked by the other two.

In sum, each of the 5,000 posts in our corpus consists of a unique ID, the platform from which it was taken, the respective platform's post ID, the post's text (i.e., the "clickbait"), the URL to the linked document, the manually extracted title and paragraph-divided main content of the linked document, the manually optimized spoiler, the spoiler's character position in the main content, and the type of spoiler (phrase, passage, or multipart). In total, the annotation took about 560 hours, which marked the limit of our budget dedicated for this step.

3.2 Corpus Statistics

Table 1 summarizes the main statistics of our corpus. Most spoiled clickbait posts come from Twitter (47.5%) and Reddit (36%), whereas the Facebook account contributes less (16.5%). Most spoilers are phrases (42.5%) and passages (40%). That there are fewer multi-part spoilers could be due to the fact that spoiler account operators prefer to spoil "simpler" clickbait posts. For the corpus, we also provide a fixed random 80/20/20 train/validation/test split to ensure future reproducibility and comparability with our results.

Table 1: Key statistics of the Webis Clickbait Spoiling Corpus 2022 (Webis-Clickbait-22).

4 Type-dependent Clickbait Spoiling

Our approach to clickbait spoiling is based on the observation that there are three types of spoilers: (1) phrase spoilers, (2) passage spoilers, and (3) multipart spoilers. We assume that different tailored approaches will work best for each spoiler type. However, an important prerequisite for this is the corresponding classification of clickbait. Therefore, we first investigate how well the spoiler type of a clickbait post can be predicted (Section 4.1).

The generation of phrase and passage spoilers for a given clickbait post is similar in that the solution to the problem in both cases amounts to extracting a coherent piece of text from the linked document. To this end, there are a variety of existing approaches in related disciplines whose output is either a phrase or a passage, and which may be adapted to clickbait spoiling. We therefore investigate whether phrase spoilers can be identified by conventional question answering methods (i.e., we treat a clickbait post as a "question" to which a phrase of the linked document should be returned as the "answer"; Section 4.2), and whether passage spoilers can be identified by conventional passage retrieval methods (i.e., we treat a clickbait post as a "query" and the paragraphs of the linked document as the collection from which to retrieve the best "passage"; Section 4.3). In our evaluation, we focus on phrase and passage spoilers and also examine the abilities of the above question answering and passage retrieval methods to serve as one-size-fits-all solutions for phrases and passages. For multipart spoilers, a novel approach will be needed, which is beyond the scope of our current work but an interesting direction for the future.

4.1 Spoiler Type Classification

For the spoiler classification subtask, we experimented with classic feature-based models (Naïve Bayes, Logistic Regression, SVM) and the neural models BERT-, DeBERTa-, and RoBERTa.

As feature types for the classic models, we use tf- and $tf \cdot idf$-weighted word and POS tag uni- and bigrams from the clickbait post and $tf \cdot idf$-weighted word and POS tag uni- and bigrams from the linked document. We include features from the linked document, since it has to be analyzed for the spoiler generation anyway. The idf values are calculated on the OpenWebText corpus (Gokaslan and Cohen, 2019) to prevent any bias from the comparatively small size of our corpus.

The input for the neural models is a post concatenated with the main content of the linked document.

4.2 Phrase Spoiler Generation

Viewing a clickbait post for which a phrase spoiler should be derived as a "question" and the linked document as potentially containing an "answer", phrase spoiler generation can be tackled by question answering methods. We therefore employ ten state-of-the-art question answering methods trained on the SQuAD data and fine-tune them on our new clickbait spoiling training set: ALBERT, BERT (cased/uncased), BigBird, DeBERTa (large), ELECTRA, FunnelTransformer, MPNet, and RoBERTa (base/large).

4.3 Passage Spoiler Generation

Treating the clickbait post whose spoiler type is a passage as a "query" for which the "most relevant" passage from the linked document is to be

Table 2: Effectiveness of spoiler type classification in the multi-class (first column) and one-vs-rest settings on 1000 test posts (training: 3200; validation: 800).

Model	**Balanced accuracy** (0, 1, 2 indicate class labels)				
	Phrase	0	1	0	0
	Passage	1	0	1	0
	Multipart	2	0	0	1
Naïve Bayes		56.15	65.03	62.50	64.82
SVM		59.62	68.03	68.70	70.28
Log. Regression		60.04	68.04	69.33	71.26
BERT		67.84	74.06	75.70	75.56
DeBERTa		**73.63**	78.39	78.65	77.93
RoBERTa		71.57	**80.39**	**79.30**	**79.12**

retrieved, passage spoiler generation can be tackled by passage retrieval methods. We therefore use ten state-of-the-art passage retrieval approaches trained on the MS MARCO data: BM25 and QLD in four variants each (alone or with RM3/Ax/PRF query expansion), MonoBERT, and MonoT5. In addition, we also adapt all of the above question answering models to retrieve passages by simply considering the passage as the returned result from which the question answering model extracts its answer.

5 Evaluation of Spoiler Type Classification

In our evaluation, we assume a setup in which a previous clickbait detection would have (perfectly) identified posts as clickbait. To then evaluate the effectiveness of spoiler type classification on such detected clickbait posts, we conduct three experiments: (1) multi-class, (2) one-vs-rest, and (3) one-vs-one for the types of phrase and passage spoilers.

In all cases, the hyperparameters of the six studied classifiers were optimized based on the validation set of our corpus. For the three feature-based approaches, a chi-square feature selection step selected all post-based features and 70% of the document-based features. The post-based features are weighted 4-times higher than the document-based features. Most hyperparameters of the transformer models were left at their default values, but a grid search was used to find the most effective combination of learning rate (1e-5, 4e-5, 1e-4), warm-up ratio (0.02, 0.06, and 0.1), stack size (8, 16, and 32), number of epochs (1 to 10), and maximum sequence length (256, 384, 512).

Table 2 shows the balanced accuracy of the six classifiers. All are less effective in the multi-class setting than in the one-vs-rest settings and the transformer-based classifiers are clearly more effective than the feature-based ones; DeBERTa is best in the multi-class setting (accuracy of 73.63) and RoBERTa in the one-vs-rest ones (79.12 to 80.39).

Table 3: Effectiveness of spoiler type classification in the one-vs-one (phrase-vs-passage) setting on 826 test posts (training: 2,641; validation: 657).

Model	**Effectiveness**				
	TP	TN	FP	FN	Acc.
Naïve Bayes	298	256	147	125	67.07
SVM	311	264	139	112	69.61
Log. Regression	306	273	130	117	70.10
BERT	315	315	88	108	76.27
DeBERTa	318	335	68	105	79.06
RoBERTa	332	332	71	91	**80.39**

Table 3 shows the accuracy of the six classifiers on the 826 test posts with phrase and passage spoilers (almost balanced setup, since there is hardly any class imbalance). Again, the transformer-based classifiers clearly are more effective than the feature-based ones; with RoBERTa achieving the best accuracy of 80.39.

The substantial improvements of DeBERTa and RoBERTa over the feature-based classifiers in all settings (about 9–10 accuracy points) indicates that classifying the clickbait spoiler type requires more advanced language “understanding” than what is encoded in the basic features that the Naïve Bayes, SVM, or logistic regression classifiers used.

6 Evaluation of Spoiler Generation

To assess the effectiveness of the question answering and passage retrieval methods for clickbait spoiling, we evaluate both for their respective intended spoiler types, but each also for the respective other spoiler type. Multipart spoilers are deferred to future work. We continue to assume that prior clickbait detection (perfectly) identifies clickbait posts as such. Our evaluation of the generated spoilers includes quantitative and qualitative assessments (Section 6.1). In a pilot study with ten question answering and ten passage retrieval models at their default settings, two models in each category dominate the respective others (Section 6.2). The computationally expensive step of hyperparameter optimization is restricted to these four models plus two baselines (Section 6.3). Then, the effectiveness of spoiling clickbait posts dependent on spoiler type is evaluated (Sections 6.4 and 6.5), and compared to an end-to-end clickbait spoiling setup independent of spoiler type (section 6.6).

6.1 Quantitative and Qualitative Assessment

We introduce the measures used to evaluate generated spoilers and how we manually determined thresholds for them above which a generated spoiler is considered as “correct”.

Evaluation measures. To assess the quantitative correspondence between a derived spoiler and the ground truth, we use three question answering-oriented and one passage retrieval-oriented measure: BLEU-4 (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005) in its extended version of Denkowski and Lavie (2014), BERTScore (Zhang et al., 2020), and Precision@1.

The three question answering-oriented measures each calculate a (penalized) harmonic mean of measure-specific definitions of precision and recall when comparing a generated spoiler to the ground truth. In case of BLEU-4, the overlap of word 1- to 4-grams is determined (if the length n of a generated spoiler is less than 4 words, we compute BLEU-n), in case of METEOR the overlap of word 1-grams, and in case of BERTScore the best matching embeddings of word pairs. Note that in their original formulation, BLEU-4 and METEOR penalize the score, the more the n-gram order differs. To arrange the measures on a spectrum from calculating predominantly syntactic (BLEU-4) to predominantly semantic similarity (BERTScore), we omit METEOR’s penalization term.

The question answering-oriented measures are not really suited to assess the effectiveness of passage retrieval models since a retrieved passage is often longer than the ground truth spoiler. Therefore, we also use Precision@1 to measure whether the top-ranked passage contains the ground truth spoiler (all phrase spoilers and 98% of the passage spoilers come from a single passage; for the other passage spoilers, we consider all containing passages as relevant). To calculate the Precision@1 of question answering models, we use the first passage that contains the returned spoiler.

High-confidence thresholds. Candidates with higher scores on the question answering-oriented measures BLEU-4, METEOR, and BERTScore are closer to the ground truth. However, it is unclear what score threshold a particular spoiler candidate has to exceed so that it would be considered a true positive in a manual analysis. Determining such thresholds enables “high confidence” estimations of how many correct spoilers an approach generates without having to manually check its outputs each time with each new variant.

Table 4: Manually determined numbers of false positives/negatives (FP/FN) on 500 sampled clickbait posts with phrase spoilers and 500 with passage spoilers for question answering (top row group) and passage retrieval models (bottom row group), dependent on score threshold (Thresh.), spoiler type, and effectiveness measure (BL4 = BLEU-4, MET = METEOR, BSc. = BERTScore). The thresholds selected for subsequent assessment are indicated by bold FP/FN numbers.

Thresh.	**Phrase Spoilers**						**Passage Spoilers**					
	BL4		MET		BSc.		BL4		MET		BSc.	
	FP	FN	FP	FN	FP	FN	FP	FN	FP	FN	FP	FN
10%	11	11	18	7	238	0	5	44	168	15	399	0
20%	7	14	16	7	234	0	3	48	67	27	325	3
30%	7	14	14	9	165	1	**1**	**51**	31	35	134	21
40%	2	27	8	13	59	6	0	55	15	39	18	38
50%	**2**	**27**	2	28	24	14	0	60	9	42	5	51
60%	2	30	3	31	11	25	0	64	4	57	**1**	**59**
70%	1	33	**2**	**31**	6	36	0	66	**1**	**54**	0	66
80%	1	34	0	37	**1**	**40**	0	66	0	61	0	73
5%	8	40	28	64	208	0	**0**	**95**	225	10	355	0
10%	**4**	**104**	**8**	**108**	180	60	0	95	140	30	355	0
20%	0	184	0	164	44	144	0	95	35	65	305	15
30%	0	188	0	184	**0**	**176**	0	105	**5**	**90**	145	55
40%	0	188	0	188	0	188	0	115	5	105	20	95
50%	0	192	0	188	0	192	0	120	5	110	**5**	**105**
60%	0	192	0	192	0	192	0	125	0	120	5	130

In a pilot study, we thus determined such thresholds by running all question answering models (cf. Section 4.2 and 4.3) on a random sample of 500 clickbait posts with phrase spoilers and 500 with passage spoilers. For each post, a random spoiler generated by a question answering model and a random spoiler generated by a passage retrieval model were manually checked for whether they could be viewed as correct. Table 4 shows the number of manually determined false positives and false negatives for different thresholds of BLEU-4, METEOR, and BERTScore. The manually selected subjective thresholds (FP/FN in bold) for each combination of measure, spoiler type, and model type (question answering or passage retrieval) minimize the false positives at a rate where being more strict would incur too many false negatives. For instance, for phrase spoilers and BLEU-4, we set the question answering model threshold at 50% since a more strict threshold of 60% does not reduce the false positives but increases the false negatives.

In addition to reporting quantitative mean effectiveness scores, applying the determined thresholds helps to estimate how many of the spoilers of a

Table 5: Pilot study spoiling effectiveness of question answering and passage retrieval models on 200 validation posts (models ordered lexicographically). The bracketed numbers indicate the expected number of true positives as per our pre-determined high-confidence score thresholds; P@1 is the Precision@1. The models DeBERTa-large and RoBERTa-large, as well as MonoBERT and MonoT5 are the most effective in their groups.

Type	**Model**	**Phrase Spoilers** (n = 97)				**Passage Spoilers** (n = 103)

model would be perceived as "good" by human readers. This corresponds to a conservative assessment, since we believe that a model should only be deployed to production if it has been tuned to not return a spoiler if in doubt about its correctness; also probably somewhat minimizing the otherwise possible spread of auto-generated misinformation.

6.2 Pilot Study for Model Selection

In a pilot study on 1,000 clickbait posts (800 training, 200 validation), we compare ten question answering and ten passage retrieval models (cf. Table 5) at their default settings to select models for subsequent experiments with more extensive (and expensive) hyperparameter tuning. The question answering models were or are among the most effective in the SQuAD and TriviaQA question answering benchmarks. In our setup, they return a piece of text from the linked document as an "answer" to the clickbait post as the "query". As passage retrieval models, we empoly MonoBERT and MonoT5 using their PyGaggle[3] implementations, and eight variants of the popular baseline retrieval models BM25 and QLD using their Anserini implementations (Yang et al., 2017). These models return the most "relevant" paragraph from the linked document for the clickbait post as the "query".

Using Nvidia A100 GPUs, the question answering models were first fine-tuned on SQuAD v1.1 and then on the pilot training data. This was the most effective setup from an ablation study with other fine-tuning regimes (e.g., the phrase spoiler BERTScore for RoBERTa-large dropped from 84.04 to 69.91 when only fine-tuned on our pilot study data, to 64.61 when only fine-tuned on SQuAD, and to 46.60 without fine-tuning). Interestingly, the models' SQuAD effectiveness does not predict their spoiling effectiveness (e.g., RoBERTa-base and FunnelTransformer were tied on SQuAD, but RoBERTa-base is more effective at spoiling). This indicates the importance of the pilot study.

Table 5 shows the pilot study effectiveness of all models on the 200 validation posts. RoBERTa-large (for phrasal spoilers) and DeBERTa-large (for passage spoilers) are the most effective. Among the passage retrieval models, MonoBERT and MonoT5 achieve the best scores. Contrary to our original assumption that passage retrieval models might be particularly well-suited to identify passage spoilers, MonoBERT and MonoT5 have similar Precision@1 scores on both phrase and passage spoilers and are substantially less effective than the best question answering models (e.g., DeBERTa-large has a Precision@1 of 48.39 for passage spoilers compared to 31.18 for MonoBERT).

---

Table 6: Effectiveness on the 826 test clickbait posts with phrase and passage spoilers. The bracketed numbers indicate the expected number of true positives as per our pre-determined high-confidence score thresholds; P@1 is the Precision@1. Overall, DeBERTa-large and RoBERTa-large are the most effective models.

Type	**Model**	**Phrase Spoilers** ($n = 423$)				**Passage Spoilers** ($n = 403$)			
		BLEU-4	METEOR	BERTScore	P@1	BLEU-4	METEOR	BERTScore	P@1
Question Answering	BERT (baseline)	58.89 (257)	56.75 (266)	71.06 (215)	66.67	21.59 (110)	35.49 (100)	44.38 (109)	42.43
	DeBERTa-large	**68.80 (300)**	**67.93 (298)**	**77.03 (250)**	**75.65**	**31.44 (157)**	**46.06** (142)	**51.06** (161)	**54.84**
	RoBERTa-large	65.70 (290)	66.15 (293)	74.81 (233)	72.58	29.61 (148)	45.20 **(145)**	49.99 **(167)**	53.85
Passage Retrieval	BM25 (baseline)	3.40 (55)	5.06 (83)	19.94 (12)	8.27	7.91 (53)	20.19 (61)	34.71 (42)	4.22
	MonoBERT	4.20 (72)	6.12 (103)	20.66 (11)	42.08	10.43 (74)	22.37 (75)	36.58 (46)	26.05
	MonoT5	4.95 (82)	6.47 (115)	20.98 (16)	43.97	10.58 (74)	22.02 (74)	36.70 (46)	29.03

6.3 Tuning the Selected Models

Given the pilot study results, six models are selected for a more extensive hyperparameter tuning: the best two question answering models (DeBERTa-large was best for phrase spoilers, RoBERTa-large for passage spoilers) plus BERT as baseline, as well as the best two passage retrieval models (MonoBERT and MonoT5) plus BM25 as baseline.

As the ablation study in our pilot study showed that fine-tuning the question answering models on SQuAD first and then on our corpus works best, we apply this fine-tuning regime to DeBERTa-large, RoBERTa-large, and BERT using the clickbait spoiling training data (depending on the experiment, either only the phrase spoilers, only the passage spoilers, or both combined). Most hyperparameters of DeBERTa-large, RoBERTa-large, BERT, MonoBERT, and MonoT5 are left at their defaults, but a grid search is run to find the most effective combination of learning rate (1e-5, 4e-5, 1e-4), warmup ratio (0.02, 0.06, 0.1), batch size (8, 16, 32), number of epochs (1 to 10), and maximum sequence length (256, 384, 512). For BM25, we try combinations of k_1 from 0.1 to 0.4 and b from 0.1 to 1.0 with a step size of 0.1.

6.4 Effectiveness on Phrase Spoilers

The 'Phrase Spoilers' column group in Table 6 shows the effectiveness of the selected question answering and passage retrieval models on the 423 test clickbait posts with phrase spoilers. Given the ground-truth spoiler, we report the predicted spoilers' average BLEU-4, METEOR, BERTScore, and Precision@1 (using 1,367 posts with phrase spoilers for training and 335 posts for validation to tune the hyperparameters; cf. Table 1).

Overall, DeBERTa-large is the most effective model for phrase spoilers. Based on our high-confidence score thresholds, it generates the correct spoiler for 250–300 of the 423 test posts (i.e., for about 60–70% of the cases) according to a BERTScore or BLEU-4 evaluation. Similar to our pilot study, the passage retrieval models are comparably ineffective in identifying phrase spoilers. Among them, MonoT5 achieves the highest scores but is even substantially less effective than the question answering baseline BERT. For instance, with a BLEU-4 of 58.89 and probably 257 correct spoilers (61% of the 423 test posts), BERT is way ahead of MonoT5 with a BLEU-4 of 4.95 and only 82 probably correct spoilers (19% of the 423 posts).

6.5 Effectiveness on Passage Spoilers

The 'Passage Spoilers' column group in Table 6 shows the effectiveness of the selected passage retrieval models on the 403 test clickbait posts with passage spoilers (using 1,274 and 322 posts for training and validation). The numbers of probably correct spoilers are lower for all models compared to the phrase spoilers (even the higher amount of probably correct passage spoilers of the passage retrieval models according to their BERTScore threshold are still worse than the estimated probably correct phrase spoilers according to BLEU-4 or METEOR). Similar to the pilot study, all question answering models are also substantially more effective on passage spoilers than the passage retrieval models. Overall, DeBERTa-large and RoBERTa-large achieve the highest Precision@1 scores and the highest amount of probably correct passage spoilers (about 35–41% of the passage spoilers are correctly identified according to our high-confidence thresholds).

6.6 Effectiveness of the End-to-End System

We evaluate the entire spoiling pipeline using all 826 phrase and passage test posts by comparing two-step pipelines that first classify the spoiler type

Table 7: End-to-end effectiveness on the 826 phrase and passage test posts. Spoiling models that classify the spoiler type to then select an appropriately trained spoiler model ('Classif.', using the most effective spoiler type classifier), models without spoiler type classification ('None'), and unrealistic models with perfect-accuracy type classification ('Oracle').

Model		**End-to-End Effectiveness**			
		BLEU-4	METEOR	BERTScore	P@1
Classif.	BERT	35.95 (311)	34.25 (303)	53.86 (294)	52.66
	DeBERTa	44.98 (392)	44.32 (377)	59.18 (378)	63.44
	RoBERTa	42.70 (374)	43.23 (356)	58.01 (361)	61.86
None	BERT	38.85 (346)	37.80 (330)	54.60 (314)	55.33
	DeBERTa	**46.16 (409)**	**47.01 (407)**	**60.43 (382)**	64.16
	RoBERTa	44.69 (400)	44.72 (395)	59.51 (375)	**65.13**
Oracle	BERT	40.69 (367)	39.02 (366)	58.05 (324)	54.84
	DeBERTa	**50.58 (457)**	**49.40 (440)**	**64.36 (411)**	**65.50**
	RoBERTa	48.10 (438)	48.57 (438)	62.71 (400)	63.44

to then select an appropriately trained spoiler model (trained on the respective type) and single-step approaches that skip the spoiler type classification and simply run the same spoiler model on all posts (trained on the complete training data). For the two-step pipelines, we experiment with two variants: (1) using an artificial classifier that returns perfect oracle-style answers about a post's type, and (2) using the best RoBERTa-based phrase-vs-passage classifier from Section 5.

Since the passage retrieval models were less effective in our spoiler experiments (cf. Table 6), we report results only for pipelines with question answering models. In the two-step pipelines the respective question answering models are fine-tuned on the respective spoiler types, in the single-step approach on the combined training data.

Table 7 shows the achieved end-to-end effectiveness values. The individual two-step pipelines with oracle type classification (row group 'Oracle') are substantially more effective than their single-step counterparts without type classification (row group 'None') that again are more effective than the respective two-step pipelines with "real" RoBERTa-based type classification (row group 'Classif.'). Overall, the DeBERTa pipeline with oracle classifier achieves an estimated amount of about 50–55% correctly spoiled posts (i.e., 411 to 457 of 826). This result confirms that classifying the required spoiler type can be beneficial for clickbait spoiling. Still, among the currently realistically applicable end-to-end spoiling approaches (with RoBERTa type classification or without spoiler type classification), the one-step DeBERTa approach without spoiler type classification is the most effective according to the number of probably correctly spoiled posts (382 to 409 of the 826 posts, i.e., 46–50%). This indicates that the currently best RoBERTa-based spoiler type classifier with its accuracy of 80.39% is still not good enough to result in an end-to-end system that actually benefits from spoiler type classification.

Our results show that effectively spoiling clickbait with question answering models is possible in practice but also that there is still room for improvements (e.g., improved spoiler type classification, improved spoiler generation for the individual types, and taking multipart spoilers into account).

7 Conclusion

Clickbait spoiling is a new task to help social media users who do not want to be manipulated into falling for clickbait links. Unlike clickbait detection, which often involves filtering out clickbait posts from users' timelines, clickbait spoiling subverts the curiosity triggered by clickbait, presenting users with the withheld "punchline" in advance.

We compile the first large resource for clickbait with associated spoilers. By interpreting clickbait spoiling as either a question answering task or a passage retrieval task, many possible approaches are available to extract from the linked document of a clickbait post the phrase or passage that spoils it. We have explored the effectiveness of a number of state-of-the-art solutions for both tasks in a large-scale experiment, including fine-tuning the respective models on our resource to determine their effectiveness for type-specific clickbait spoiling. Our experimental setup considers type-specific spoiling on the one hand, but on the other hand it also includes an end-to-end configuration for comparison. Overall, our results show that type-agnostic question answering-based spoiling is the most effective yet, but also that spoiler type-specific solutions have the potential to outperform them.

In addition to the possibilities explored, there might also be other approaches to clickbait spoiling: for example, paraphrasing technology could be used to directly transform a clickbait post into a version that contains its own spoiler. With respect to multipart spoilers, the use of summarization models could be an interesting direction to select the different parts of the linked document of a clickbait post that make up its multipart spoiler.

Ethics Statement

The spread of clickbait on social media by news publishers to promote click-through to their websites has been empirically found to decrease their perceived credibility in readers (Molyneux and Coddington, 2020). There is, of course, nothing wrong with monitoring and optimizing the effectiveness of marketing a newly published news article, especially in cases where the editors make an honest effort to reach and inform their target audience. But the clickbait in our corpus mostly spreads trivial facts that could have been easily fitted into the length limits of a social media post, which is why we consider these posts to fall short of the journalistic ideal. However, it is as of yet unclear, in terms of journalism ethics, whether clickbait is an acceptable means to an end for publishers (i.e., whether it is "necessary in driving audiences to the journalism they need by giving them the journalism they seem to want."), or whether it serves to "crowding out «real» journalism by reducing quality in favor of the need for a click-through at whatever cost" (Harte, 2021).

Facebook intervened twice with algorithmic filters to reduce the amount of clickbait that people are exposed to in their timelines—even though this probably also lowered Facebook's user engagement metrics. Our technology demonstrates another, complementary way of relatively simply circumventing the purported exploitation of the curiosity gap by giving the audience a choice on whether or not they wish their cognitive "loopholes" to be exploited. If a sufficiently large portion of people decide to adopt spoiling tools, that would send a clear message to publishers and social media platforms alike. Spoiling clickbait, as opposed to removing it, however, still gives publishers the benefit of the doubt, since, as the publishers claim, there are people who enjoy these kinds of trivia.

Abstract

We present Knowledge Distillation with Meta Learning (MetaDistil), a simple yet effective alternative to traditional knowledge distillation (KD) methods where the teacher model is fixed during training. We show the teacher network can learn to better transfer knowledge to the student network (i.e., *learning to teach*) with the feedback from the performance of the distilled student network in a meta learning framework. Moreover, we introduce a pilot update mechanism to improve the alignment between the inner-learner and meta-learner in meta learning algorithms that focus on an improved inner-learner. Experiments on various benchmarks show that MetaDistil can yield significant improvements compared with traditional KD algorithms and is less sensitive to the choice of different student capacity and hyperparameters, facilitating the use of KD on different tasks and models.[1]

1 Introduction

With the prevalence of large neural networks with millions or billions of parameters, model compression is gaining prominence for facilitating efficient, eco-friendly deployment for machine learning applications. Among techniques for compression, knowledge distillation (KD) (Hinton et al., 2015b) has shown effectiveness in both Computer Vision and Natural Language Processing tasks (Hinton et al., 2015b; Romero et al., 2015; Zagoruyko & Komodakis, 2017; Tung & Mori, 2019; Peng et al., 2019; Ahn et al., 2019; Park et al., 2019; Passalis & Tefas, 2018; Heo et al., 2019; Kim et al., 2018; Shi et al., 2021; Sanh et al., 2019; Jiao et al., 2019; Wang et al., 2020b). Previous works often train a large model as the "teacher"; then they fix the teacher and train a "student" model to mimic the behavior of the teacher, in order to transfer the knowledge from the teacher to the student.

However, this paradigm has the following drawbacks: **(1) The teacher is unaware of the student's capacity.** Recent studies in pedagogy suggest student-centered learning, which considers students' characteristics and learning capability, has shown effectiveness improving students' performance (Cornelius-White, 2007; Wright, 2011). However, in conventional knowledge distillation, the student passively accepts knowledge from the teacher, without regard for the student model's learning capability and performance. Recent works (Park et al., 2021; Shi et al., 2021) introduce student-aware distillation by jointly training the teacher and the student with task-specific objectives. However, there is still space for improvement since: **(2) The teacher is not optimized for distillation.** In previous works, the teacher is often trained to optimize its *own* inference performance. However, the teacher is not aware of the need to transfer its knowledge to a student and thus usually does so suboptimally. A real-world analogy is that a PhD student may have enough knowledge to solve problems themselves, but requires additional teaching training to qualify as a professor.

To address these two drawbacks, we propose Knowledge Distillation with Meta Learning (MetaDistil), a new teacher-student distillation framework using meta learning (Finn et al., 2017) to exploit feedback about the student's learning progress to improve the teacher's knowledge transfer ability throughout the distillation process. On the basis of previous formulations of bi-level optimization based meta learning (Finn et al., 2017), we propose a new mechanism called *pilot update* that aligns the learning of the bi-level learners (i.e., the teacher and the student). We illustrate the workflow of MetaDistil in Figure 1. The teacher in MetaDistil is trainable, which enables the teacher to adjust to its student network and also improves its

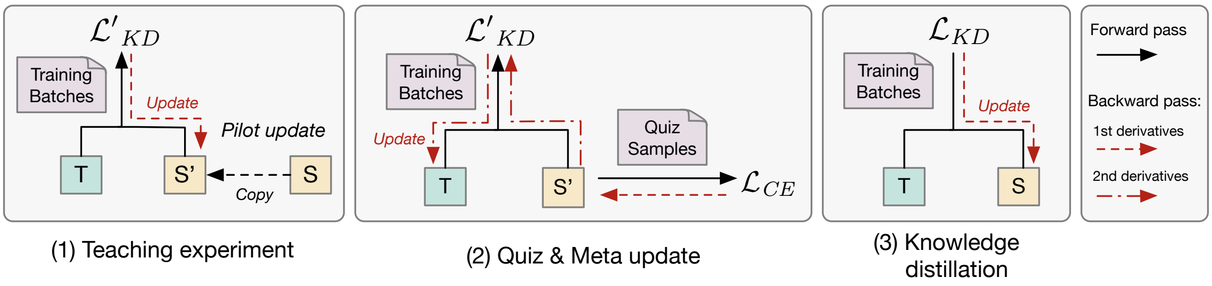

Figure 1: The workflow of MetaDistil. (1) We perform experimental knowledge distillation on a selection of training batches. Instead of updating the student S, we make a temporary copy S' and update S'. (2) We calculate a Cross-Entropy loss $\mathcal{L}_{CE}$ of S' on samples from a separate quiz set. We calculate the gradients of $\mathcal{L}_{CE}$ with respect to the parameters of T and update T by gradient descent. (3) We discard S' and use the updated T to perform actual knowledge distillation and update S.

"teaching skills." Motivated by the idea of student-centered learning, we allow the teacher to adjust its output based on the performance of the student model on a "quiz set," which is a separate reserved data split from the original training set. For each training step, we first copy the student S to S' and update S' by a common knowledge distillation loss. We call this process a "teaching experiment." In this way, we can obtain an experimental student S' that can be quizzed. Then, we sample from the quiz set, and calculate the loss of S' on these samples. We use this loss as a feedback signal to meta-update the teacher by calculating second derivatives and performing gradient descent (Finn et al., 2017). Finally, we discard the experimental subject S' and use the updated teacher to distill into the student S on the same training batches. The use of meta learning allows the teacher model to receive feedback from the student in a completely differentiable way. We provide a simple and intuitive approach to explicitly optimize the teacher using the student's quiz performance as a proxy.

To test the effectiveness of MetaDistil, we conduct extensive experiments on text and image classification tasks. MetaDistil outperforms knowledge distillation by a large margin, verifying the effectiveness and versatility of our method. Also, our method achieves state-of-the-art performance compressing BERT (Devlin et al., 2019) on the GLUE benchmark (Wang et al., 2019) and shows competitive results compressing ResNet (He et al., 2016) and VGG (Simonyan & Zisserman, 2015) on CIFAR-100 (Krizhevsky et al., 2009). Additionally, we design experiments to analyze and explain the improvement. Ablation studies show the effectiveness of our proposed pilot update and dynamic distillation. Also, compared to conventional KD, MetaDistil is more robust to different student capacity and hyperparameters, which is probably because of its ability to adjust the parameters of the teacher model.

2 Related Work

Knowledge Distillation Recently, many attempts have been made to accelerate large neural networks (Xu et al., 2020, 2021b; Zhou et al., 2020, 2021; Xu & McAuley, 2022). Knowledge distillation is a prominent method for training compact networks to achieve comparable performance to a deep network. Hinton et al. (2015b) first introduced the idea of knowledge distillation to exploit the "dark knowledge" (i.e., soft label distribution) from a large teacher model as additional supervision for training a smaller student model. Since its introduction, several works (Romero et al., 2015; Zagoruyko & Komodakis, 2017; Tung & Mori, 2019; Park et al., 2019; Sun et al., 2019; Jiao et al., 2019) have investigated methods that align different latent representations between the student and teacher models for better knowledge transfer. In the context of knowledge distillation, MetaDistil shares some common ideas with the line of work that utilizes a sequence of intermediate teacher models to make the teacher network better adapt to the capacity of the student model throughout the training process, including teacher assistant knowledge distillation (TAKD) (Mirzadeh et al., 2020) and route constraint optimization (RCO) (Jin et al., 2019). However, the intermediate teachers are heuristically selected independently of the training process and the evolution of the teacher network is discrete. In contrast, MetaDistil employs meta learning to make the teacher model adapt to the current state of the student model and provide a continuously evolving meta-teacher that can better teach the student. Concurrently, Park et al. (2021) and Shi et al. (2021) propose to update the teacher model jointly with the student model with task specific objectives (e.g., cross-entropy loss) during the KD process and add constraints to keep student and teacher similar to each other. Their approaches makes the teacher model aware of the student model by constraining the teacher model's capacity. However, the teacher models in their methods are still not optimized for knowledge transfer. In addition, Zhang et al. (2018) introduced deep mutual learning where multiple models learn collaboratively and teach each other throughout the training process. While it is focused on a different setting where different models have approximately the same capacity and are learned from scratch, it also encourages the teacher model to behave similarly to the student model. Different from all aforementioned methods, MetaDistil employs meta learning to explicitly optimize the teacher model for better knowledge transfer ability, and leads to improved performance of the resulting student model.

Meta Learning The core idea of meta learning is "learning to learn," which means taking the optimization process of a learning algorithm into consideration when optimizing the learning algorithm itself. Meta learning typically involves a bi-level optimization process where the inner-learner provides feedback for optimization of the meta-learner. Successful applications of meta learning include learning better initialization (Finn et al., 2017), architecture search (Liu et al., 2019), learning to optimize the learning rate schedule (Baydin et al., 2018), and learning to optimize (Andrychowicz et al., 2016). These works typically aim to obtain an optimized meta-learner (i.e., the teacher model in MetaDistil), while the optimization of the inner-learner (i.e., the student model in MetaDistil), is mainly used to provide learning signal for the meta optimization process. This is different from the objective of knowledge distillation where an optimized student model is the goal. Recently, there have been a few works investigating using this bi-level optimization framework to obtain a better inner-learner. For example, meta pseudo labels (Pham et al., 2020) use meta learning to optimize a pseudo label generator for better semi-supervised learning; meta back-translation (Pham et al., 2021) meta-trains a back-translation model to better train a machine translation model. These methods adapt the same bi-level optimization process as previous works where the goal is to obtain an optimized meta-learner. In these approaches, during each iteration, the meta-learner is optimized for the original inner-learner and then applied to the updated inner-learner in the next iteration. This leads to a mismatch between the meta-learner and the inner-learner, and is therefore suboptimal for learning a good inner-learner. In this paper, we introduce a pilot update mechanism, which is a simple and general method for this kind of problems, for the inner-learner to mitigate this issue and make the updated meta-learner better adapted to the inner-learner.

Meta Knowledge Distillation Recently, some works on KD take a meta approach. Pan et al. (2020) proposed a framework to train a meta-teacher across domains that can better fit new domains with meta-learning. Then, traditional KD is performed to transfer the knowledge from the meta-teacher to the student. Liu et al. (2020) proposed a self-distillation network which utilizes meta-learning to train a label-generator as a fusion of deep layers in the network, to generate more compatible soft targets for shallow layers. Different from the above, MetaDistil is a general knowledge distillation method that exploits meta-learning to allow the teacher to learn to teach dynamically. Instead of merely training a meta-teacher, our method uses meta-learning throughout the procedure of knowledge transfer, making the teacher model compatible for the student model for every training example during each training stage.

3 Knowledge Distillation with Meta Learning

An overview of MetaDistil is presented in Figure 1. MetaDistil includes two major components. First, the meta update enables the teacher model to receive the student model's feedback on the distillation process, allowing the teacher model to "learn to teach" and provide distillation signals that are more suitable for the student model's current capacity. The pilot update mechanism ensures a finer-grained match between the student model and the meta-updated teacher model.

3.1 Background

3.1.1 Knowledge Distillation

Knowledge distillation algorithms aim to exploit the hidden knowledge from a large teacher network, denoted as T, to guide the training of a shallow student network, denoted as S. To help transfer the knowledge from the teacher to the student, apart from the original task-specific objective (e.g., cross-entropy loss), a knowledge distillation objective which aligns the behavior of the student and the teacher is included to train the student network. Formally, given a labeled dataset $\mathcal{D}$ of N samples $\mathcal{D} = \{(x_1, y_1), \dots, (x_N, y_N)\}$, we can write the loss function of the student network as follows,

$$\begin{aligned}\mathcal{L}_S(\mathcal{D}; \theta_S; \theta_T) = \frac{1}{N}\sum_{i=1}^{N}[\alpha\mathcal{L}_{\mathcal{T}}(y_i, S(x_i; \theta_S)) \\ + (1-\alpha)\mathcal{L}_{KD}(T(x_i; \theta_T), S(x_i; \theta_S))]\end{aligned} \tag{1}$$

where α is a hyper-parameter to control the relative importance of the two terms; θ_T and θ_S are the parameters of the teacher T and student S, respectively. $\mathcal{L}_{\mathcal{T}}$ refers to the task-specific loss and $\mathcal{L}_{KD}$ refers to the knowledge distillation loss which measures the similarity of the student and the teacher. Some popular similarity measurements include the KL divergence between the output probability distribution, the mean squared error (MSE) between student and teacher logits, the similarity between the student and the teacher's attention distribution, etc. We do not specify the detailed form of the loss function because MetaDistil is a general framework that can be easily applied to various kinds of KD objectives as long as the objective is differentiable with respect to the teacher parameters. In the experiments of this paper, we use mean squared error between the hidden states of the teacher and the student for both our method and the KD baseline since recent study Kim et al. (2021) finds that it is more stable and slightly outperforms than KL divergence.

3.1.2 Meta Learning

In meta learning algorithms that involve a bi-level optimization problem (Finn et al., 2017), there exists an inner-learner f_i and a meta-learner f_m. The inner-learner is trained to accomplish a task $\mathcal{T}$ or a distribution of tasks with help from the meta-learner. The training process of f_i on $\mathcal{T}$ with the help of f_m is typically called *inner-loop*, and we can denote $f_i'(f_m)$ as the updated inner-learner after the inner-loop. We can express f_i' as a function of f_m because learning f_i depends on f_m. In return, the meta-learner is optimized with a meta objective, which is generally the maximization of expected performance of the inner-learner after the inner-loop, i.e., $f_i'(f_m)$. This learning process is called a *meta-loop* and is often accomplished by gradient descent with derivatives of $\mathcal{L}(f_i'(f_m))$, the loss of updated inner-leaner on some held-out support set (i.e., the quiz set in our paper).

3.2 Methodology

3.2.1 Pilot Update

In the original formulation of meta learning (Finn et al., 2017), the purpose is to learn a good meta-learner f_m that can generalize to different inner-learners f_i for different tasks. In their approach, the meta-learner is optimized for the "original" inner-learner at the beginning of each iteration and the current batch of training data. The updated meta-learner is then applied to the updated inner-learner and a different batch of data in the next iteration. This behavior is reasonable if the purpose is to optimize the meta-learner. However, in MetaDistil, we only care about the performance of the only inner-learner, i.e., the student. In this case, this behavior leads to a mismatch between the meta-learner and the inner-learner, and is therefore suboptimal for learning a good inner-learner. Therefore, we need a way to align and synchronize the learning of the meta- and inner-learner, in order to allow an update step of the meta-learner to have an instant effect on the inner-learner. This instant reflection prevents the meta-learner from catastrophic forgetting (McCloskey & Cohen, 1989). To achieve this, we design a pilot update mechanism. For a batch of training data $\boldsymbol{x}$, we first make a temporary copy of the inner-learner f_i and update both the copy f_i' and the meta learner f_m on $\boldsymbol{x}$. Then, we discard f_i' and update f_i again with the updated f_m on the same data $\boldsymbol{x}$. This mechanism can apply the impact of data $\boldsymbol{x}$ to both f_m and f_i at the same time, thus aligns the training process. Pilot update is a general technique that can potentially be applied to any meta learning application that optimizes the inner-learner performance. We will describe how we apply this mechanism to MetaDistil shortly and empirically verify the effectiveness of pilot update in Section 4.2.

3.2.2 Learning to Teach

In MetaDistil, we would like to optimize the teacher model, which is fixed in traditional KD frameworks. Different from previous deep mutual learning (Zhang et al., 2018) methods that switch the role between the student and teacher

Algorithm 1 Knowledge Distillation with Meta Learning (MetaDistil)

```
Require: student $\theta_S$, teacher $\theta_T$, train set $\mathcal{D}$, quiz set $\mathcal{Q}$
Require: $\lambda$, $\mu$: learning rate for the student and the teacher
while not done do
    Sample batch of training data $\boldsymbol{x} \sim \mathcal{D}$
    Copy student parameter $\theta_S$ to student $\theta'_S$
    Update $\theta'_S$ with $\boldsymbol{x}$ and $\theta_T$: $\theta'_S \leftarrow \theta'_S - \lambda \nabla_{\theta'_S} \mathcal{L}_S(x; \theta_S; \theta_T)$
    Sample a batch of quiz data $\boldsymbol{q} \sim \mathcal{Q}$
    Update $\theta_T$ with $\boldsymbol{q}$ and $\theta'_S$: $\theta_T \leftarrow \theta_T - \mu \nabla_{\theta_T} \mathcal{L}_\mathcal{T}\left(\boldsymbol{q}, \theta'_S(\theta_T)\right)$
    Update original $\theta_S$ with $\boldsymbol{x}$ and the updated $\theta_T$: $\theta_S \leftarrow \theta_S - \lambda \nabla_{\theta_S} \mathcal{L}_S(x; \theta_S; \theta_T)$
end while
```

network and train the original teacher model with soft labels generated by the student model, or recent works (Shi et al., 2021; Park et al., 2021) that update the teacher model with a task-specific loss during the KD process, MetaDistil explicitly optimizes the teacher model in a "learning to teach" fashion, so that it can better transfer its knowledge to the student model. Concretely, the optimization objective of the teacher model in the MetaDistil framework is *the performance of the student model after distilling from the teacher model.* This "learning to teach" paradigm naturally fits the bi-level optimization framework in meta learning literature.

In the MetaDistil framework, the student network θ_S is the inner-learner and the teacher network θ_T is the meta-learner. For each training step, we first copy the student model θ_S to an "experimental student" θ'_S. Then given a batch of training examples $\boldsymbol{x}$ and the learning rate λ, the experimental student is updated in the same way as conventional KD algorithms:

$$\theta'_S(\theta_T) = \theta_S - \lambda \nabla_{\theta_S} \mathcal{L}_S(x; \theta_S; \theta_T). \quad (2)$$

To simplify notation, we will consider one gradient update for the rest of this section, but using multiple gradient updates is a straightforward extension. We observe that the updated experimental student parameter θ'_S, as well as the student quiz loss $l_q = \mathcal{L}_\mathcal{T}(\boldsymbol{q}, \theta'_S(\theta_T))$ on a batch of quiz samples $\boldsymbol{q}$ sampled from a held-out quiz set $\mathcal{Q}$, is a function of the teacher parameter θ_T. Therefore, we can optimize l_q with respect to θ_T by a learning rate μ:

$$\theta_T \leftarrow \theta_T - \mu \nabla_{\theta_T} \mathcal{L}_\mathcal{T}\left(\boldsymbol{q}, \theta'_S(\theta_T)\right) \quad (3)$$

We evaluate the performance of the experimental student on a separate quiz set to prevent overfitting the validation set, which is preserved for model selection. Note that the student is never trained on the quiz set and the teacher only performs meta-update on the quiz set instead of fitting it. We do not use a dynamic quiz set strategy because otherwise the student would have been trained on the quiz set and the loss would not be informative. After meta-updating the teacher model, we then update the "real" student model in the same way as described in Equation 2. Intuitively, optimizing the teacher network θ_T with Equation 3 is maximizing the expected performance of the student network after being taught by the teacher with the KD objective in the inner-loop. This meta-objective allows the teacher model to adjust its parameters to better transfer its knowledge to the student model. We apply the pilot update strategy described in Section 3.2.1 to better align the learning of the teacher and student, as shown in Algorithm 1.

4 Experiments

4.1 Experimental Setup

We evaluate MetaDistil on two commonly used classification benchmarks for knowledge distillation in both Natural Language Processing and Computer Vision (see Appendix A).

Settings For NLP, we evaluate our proposed approach on the GLUE benchmark (Wang et al., 2019). Specifically, we test on MRPC (Dolan & Brockett, 2005), QQP and STS-B (Conneau & Kiela, 2018) for Paraphrase Similarity Matching; SST-2 (Socher et al., 2013) for Sentiment Classification; MNLI (Williams et al., 2018), QNLI (Rajpurkar et al., 2016) and RTE (Wang et al., 2019) for the Natural Language Inference; CoLA (Warstadt et al., 2019) for Linguistic Acceptability. Following previous studies (Sun et al., 2019; Jiao et al., 2019; Xu et al., 2020), our goal is to distill BERT-Base (Devlin et al., 2019) into a 6-layer BERT with the hidden size of 768. We use MSE loss between model logits as the distillation objective. The reported results are in the same format as on the GLUE leaderboard. For MNLI,

Table 1: Experimental results on the development set and the test set of GLUE. Numbers under each dataset indicate the number of training samples. All student models have the same architecture of 66M parameters, 6 Transformer layers and 1.94× speed-up. The test results are from the official test server of GLUE. The best results for the task-specific setting are marked with **boldface**. Results reported by us are average of 3 runs with different seeds. †Results reported by us. The student is initialized with a 6-layer pretrained BERT (Turc et al., 2019) thus has a *better* performance than the original implementation. ‡TinyBERT has data augmentation (DA).

we report the results on MNLI-m and MNLI-mm, respectively. For MRPC and QQP, we report both F1 and accuracy. For STS-B, we report Pearson and Spearman correlation. The metric for CoLA is Matthew's correlation. The other tasks use accuracy as the metric.

Following previous works (Sun et al., 2019; Turc et al., 2019; Xu et al., 2020), we evaluate MetaDistil in a *task-specific* setting where the teacher model is fine-tuned on a downstream task and the student model is trained on the task with the KD loss. We do not choose the pretraining distillation setting since it requires significant computational resources. We implement MetaDistil based on Hugging Face Transformers (Wolf et al., 2020).

Baselines For comparison, we report the results of vanilla KD and patient knowledge distillation (Sun et al., 2019). We also include the results of progressive module replacing (Xu et al., 2020), a state-of-the-art task-specific compression method for BERT which also uses a larger teacher model to improve smaller ones like knowledge distillation. In addition, according to Turc et al. (2019), the reported performance of current task-specific BERT compression methods is underestimated because the student model is not appropriately initialized. To ensure fair comparison, we re-run task-specific baselines with student models initialized by a pretrained 6-layer BERT model and report our results in addition to the official numbers in the original papers. We also compare against deep mutual learning (DML) (Zhang et al., 2018), teacher assistant knowledge distillation (TAKD) (Mirzadeh et al., 2020), route constraint optimization (RCO) (Jin et al., 2019), proximal knowledge teaching (ProKT) (Shi et al., 2021), and student-friendly teacher network (SFTN) (Park et al., 2021), where the teacher network is not fixed. For reference, we also present results of pretraining distilled models including DistilBERT (Sanh et al., 2019), TinyBERT (Jiao et al., 2019), MiniLM v1 and v2 (Wang et al., 2020b,a). Note that among these baselines, PKD (Sun et al., 2019) and Theseus (Xu et al., 2020) exploit intermediate features while TinyBERT and the MiniLM family use both intermediate and Transformer-specific features. In contrast, MetaDistil uses none of these but the vanilla KD loss (Equation 1).

Training Details For training hyperparameters, we fix the maximum sequence length to 128 and the temperature to 2 for all tasks. For our method and all baselines (except those with officially reported numbers), we perform grid search over the sets of the student learning rate λ from {1e-5, 2e-5, 3e-5}, the teacher learning rate μ from {2e-6, 5e-6, 1e-5}, the batch size from {32, 64}, the weight of KD loss from {0.4, 0.5, 0.6}. We randomly split the original training set to a new training set and the quiz set by $9:1$. For RCO, we select four unconverged teacher checkpoints as the intermediate training targets. For TAKD, we use KD to train a teacher assistant model with 10 Transformer layers.

4.2 Experimental Results

We report the experimental results on both the development set and test set of the eight GLUE tasks (Wang et al., 2019) in Table 1. MetaDistil achieves state-of-the-art performance under the task-specific setting and outperforms all KD baselines. Notably, without using any intermediate or model-specific features in the loss function, MetaDistil outperforms methods with carefully designed features, e.g., PKD and TinyBERT (without data augmentation). Compared with other methods with a trainable teacher (Zhang et al., 2018; Mirzadeh et al., 2020; Jin et al., 2019; Shi et al., 2021), our method still demonstrates superior performance. As we analyze, with the help of meta learning, MetaDistil is able to directly optimize the teacher's teaching ability thus yielding a further improvement in terms of student accuracy. Also, we observe a performance drop by replacing pilot update with a normal update. This ablation study verifies the effectiveness of our proposed pilot update mechanism. Moreover, MetaDistil achieves very competitive results on image classification as well, as described in Section A.2.

5 Analysis

5.1 Why Does MetaDistil Work?

We investigate the effect of meta-update for each iteration. We inspect (1) the validation loss of S' after the teaching experiment and that of S after the real distillation update, and (2) the KD loss, which describes the discrepancy between student and teacher, before and after the teacher update.

We find that for 87% of updates, the student model's validation loss after real update (Line 7 in Algorithm 1) is smaller than that after the teaching experiment (Line 4 in Algorithm 1), which would be the update to the student S in the variant without pilot update. This confirms the effectiveness of the pilot update mechanism on better matching the student and teacher model.

Moreover, we find that in 91% of the first half of the updates, the teacher becomes more similar (in terms of logits distributions) to the student after the meta-update, which indicates that the teacher is learning to adapt to a low-performance student (like an elementary school teacher). However, in the second half of MetaDistil, this percentage drops to 63%. We suspect this is because in the later training stages, the teacher needs to actively evolve itself beyond the student to guide the student towards further improvement (like a university professor).

Finally, we try to apply a meta-learned teacher to a conventional static distillation and also to an unfamiliar student. We describe the results in details in Section A.3.

5.2 Hyper-parameter Sensitivity

A motivation of MetaDistil is to enable the teacher to dynamically adjust its knowledge transfer in an optimal way. Similar to Adam (Kingma & Ba, 2015) vs. SGD (Sinha & Griscik, 1971; Kiefer et al., 1952) for optimization, with the ability of dynamic adjusting, it is natural to expect MetaDistil to be more insensitive and robust to changes of the settings. Here, we evaluate the performance of MetaDistil with students of various capability, and

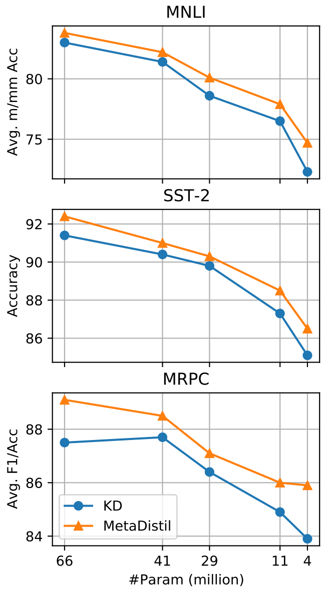

Figure 2: Results with different student architectures.

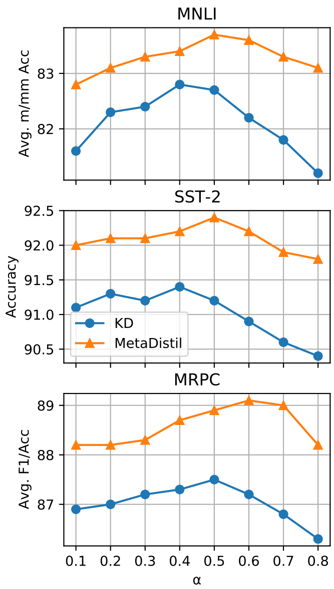

Figure 3: Results with different loss weight α.

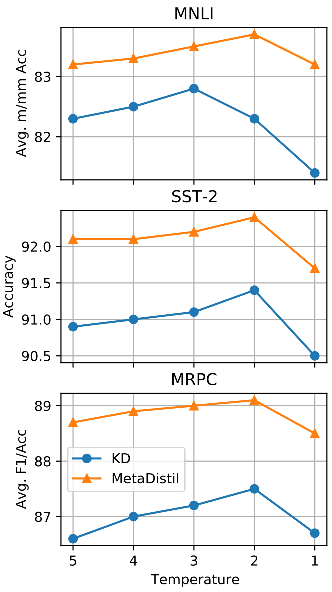

Figure 4: Results with different temperature.

a wide variety of hyperparameters, including *loss weight* and *temperature*.

Student Capability To investigate the performance of MetaDistil under different student capacity, we experiment to distill BERT-Base into BERT-6L, Medium, Small, Mini and Tiny (Turc et al., 2019) with conventional KD and MetaDistil. We plot the performance with the student's parameter number in Figure 2. Additionally, we show results for different compression ratio in Appendix B.

Loss Weight In KD, tuning the loss weight is non-trivial and often requires hyperparameter search. To test the robustness of MetaDistil under different loss weights, we run experiments with different α (Equation 1). As shown in Figure 3, MetaDistil consistently outperforms conventional KD and is less sensitive to different α.

Temperature Temperature is a re-scaling trick introduced in Hinton et al. (2015b). We try different temperatures and illustrate the performance of KD and MetaDistil in Figure 4. MetaDistil shows better performance and robustness compared to KD.

5.3 Limitation

Like all meta learning algorithms, MetaDistil inevitably requires two rounds of updates involving both first and second order derivatives. Thus, MetaDistil requires additional computational time and memory than a normal KD method, which can be a limitation of our method. We compare the computational overheads of MetaDistil with other methods in Table 2. Although our approach takes more time to achieve its own peak performance, it can match up the performance of PKD (Sun et al., 2019) with a similar time cost. The memory use of our method is higher than PKD and ProKT (Shi et al., 2021). However, this one-off investment can lead to a better student model for inference, thus can be worthy.

Method	PKD (2019)	ProKT (2021)	MetaDistil *(ours)*
Training Time (Best)	13 min.	25 min.	31 min.
Training Time (Match)	13 min.	18 min.	16 min.
Memory Cost	4.2 GB	6.8 GB	11.4 GB
Best Acc/F1	89.4/84.7	90.7/86.3	91.1/86.8

Table 2: Comparison of training time and memory cost of MetaDistil with the baselines. "Training Time (Best)" denotes the training time for each method to achieve its own best performance on the development set. "Training Time (Match)" denotes the training time for each method to match the best performance of PKD on the development set. The batch size is 4. All experiments are conducted on a single Nvidia V100 GPU.

6 Discussion

In this paper, we present MetaDistil, a knowledge distillation algorithm powered by meta learning that explicitly optimizes the teacher network to better transfer its knowledge to the student network. The extensive experiments verify the effectiveness and robustness of MetaDistil.

Ethical Consideration

MetaDistil focuses on improving the performance of knowledge distillation and does not introduce extra ethical concerns compared to vanilla KD methods. Nevertheless, we would like to point out that as suggested by Hooker et al. (2020), model compression may lead to biases. However, this is not an outstanding problem of our method but a common risk in model compression, which needs to be addressed in the future.

Acknowledgments

We would like to thank the anonymous reviewers and the area chair for their insightful comments. This project is partly supported by NSF Award #1750063.

A MetaDistil for Image Classification

In addition to BERT compression, we also provide results on image classification. Also, we conduct experiments of static teaching and cross teaching, to further verify the effectiveness of MetaDistil of adapting to different students.

A.1 Experimental Settings

For CV, following the settings in Tian et al. (2020), we experiment with the image classification task on CIFAR-100 (Krizhevsky et al., 2009) with student-teacher combinations of different capacity and architectures, including ResNet (He et al., 2016) and VGG (Simonyan & Zisserman, 2015). Additionally, we run a distillation experiment between different architectures (a ResNet teacher to a VGG student). We report the top-1 test accuracy of the compressed student networks. We inherit all hyperparameters from Tian et al. (2020) except for the teacher learning rate, which is grid searched from {1e-4, 2e-4, 3e-4}. We randomly split the original training set to a new training set and the quiz set by $9:1$. We use the KL loss in Hinton et al. (2015a) as the distillation objective. We compare our results with a state-of-the-art distillation method, CRD (Tian et al., 2020) and other commonly used knowledge distillation methods (Hinton et al., 2015b; Romero et al., 2015; Zagoruyko & Komodakis, 2017; Tung & Mori, 2019; Peng et al., 2019; Ahn et al., 2019; Park et al., 2019; Passalis & Tefas, 2018; Heo et al., 2019; Kim et al., 2018) including ProKT (Shi et al., 2021) which has a trainable teacher.

A.2 Image Recognition Results

We show the experimental results of MetaDistil distilling ResNet (He et al., 2016) and VGG (Simonyan & Zisserman, 2015) with five different teacher-student pairs. MetaDistil achieves comparable performance to CRD (Tian et al., 2020), the current state-of-the-art distillation method on image classification while outperforming all other baselines with complex features and loss functions. Notably, CRD introduces additional negative sampling and contrastive training while our method achieves comparable performance without using these tricks. Additionally, we observe a substantial performance drop without pilot update, again verifying the importance of this mechanism.

A.3 Static Teaching and Cross Teaching

In MetaDistil, the student is trained in a dynamic manner. To investigate the effect of such a dynamic distillation process, we attempt to use the teacher at the end of MetaDistil training to perform a static conventional KD, to verify the effectiveness of our dynamic distillation strategy. As shown in Table 4, on both experiments, dynamic MetaDistil outperforms conventional KD and static distillation with the teacher at the end of MetaDistil training.

As mentioned in Section 3.2, a meta teacher is optimized to transfer its knowledge to a specific student network. To justify this motivation, we conduct experiments using a teacher optimized for the ResNet-32 student to statically distill to the ResNet-20 student, and also in reverse. As shown in Table 4, the cross-taught students underperform the static students taught by their own teachers by 0.27 and 0.12 for ResNet-32 and ResNet-20, respectively. This confirms our motivation that the meta teacher in MetaDistil can adjust itself according to its student.

B Results of Different Compression Ratios

In this section, we present additional experimental results in settings with different compression ratios to further demonstrate the effectiveness of MetaDistil on bridging the gap between the student and teacher capacity. Specifically, we conduct experiments in the following two settings: (1) distilling BERT-base into a 4-layer BERT (110M→52M) and (2) distilling BERT-large into a 6-layer BERT (345M→66M). The results are shown in Table 4 and Table 5, respectively. We can see that MetaDistil consistently outperforms PKD and ProKT in both settings. This confirms the effectiveness of MetaDistil and also show its ability to adapt the teacher model to the student model, since the gap between teacher and student is even larger in these settings.

C Distillation Dynamics

We also investigate why MetaDistil works by conducting experiments on the development sets of MNLI, SST, and MRPC, which are important tasks in GLUE that have a large, medium, and small training set, respectively.

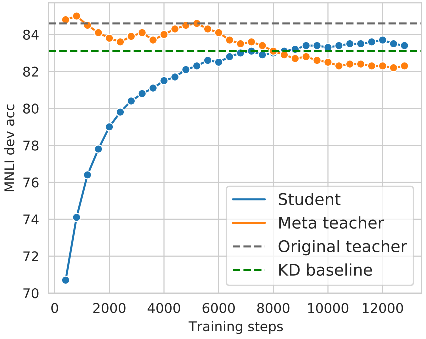

Figure 5: Learning dynamics of the student and teacher in MetaDistil on the development set of MNLI.

We illustrate the validation accuracy curves of the meta teacher and student models with training steps in Figure 5, and compare them to the student performance in conventional KD. We can see that the meta teacher maintains high accuracy in the first 5,000 steps and then begins to slowly degrade. Starting from step 8,000, the teacher model underperforms the student while the student's accuracy keeps increasing. This verifies our assumption that a model with the best accuracy is not necessarily the optimal teacher. Also, MetaDistil is not naively optimizing the teacher's accuracy but its "teaching skills." This phenomenon suggests that beyond high accuracy, there could be more important properties of a good teacher that warrant further investigation.

D Improvement Analysis

While MetaDistil achieves improved student accuracy on the GLUE benchmark, it is still not very clear where the performance improvement comes from. There are two possibilities: (1) the student better mimics the teacher, and (2) the changes of teacher helps student perform better on hard examples that would be incorrectly classified by the student with vanilla KD. We conduct a series of analysis on the MRPC dataset.

For the first assumption, we compute the prediction loyalty (Xu et al., 2021a) of the student model distilled with PKD and MetaDistil, respectively. For MetaDistil, we measure the loyalty with respect to both the original teacher and the final teacher. We find that there is no significant difference between between PKD and MetaDistil. This suggests that the improvement does not come from student better mimicking the teacher.

For the second assumption, we first identify the examples in the quiz set for which our model gives correct predictions while the student distilled by PKD makes a wrong prediction. We then compute

the loss (cross entropy) of the original teacher and the teacher updated by MetaDistil. We find the loss is substantially reduced by MetaDistil. In contrast, the overall loss of teacher on the development set does not decrease. This suggests that MetaDistil can help the teacher concentrate on hard examples that the student struggles in the quiz set and learn to perform better on these examples, thus facilitate student learning.

STEMM: Self-learning with Speech-text Manifold Mixup for Speech Translation

Abstract

How to learn a better speech representation for end-to-end speech-to-text translation (ST) with limited labeled data? Existing techniques often attempt to transfer powerful machine translation (MT) capabilities to ST, but neglect the representation discrepancy across modalities. In this paper, we propose the **S**peech-**TE**xt **M**anifold **M**ixup (STEMM) method to calibrate such discrepancy. Specifically, we mix up the representation sequences of different modalities, and take both unimodal speech sequences and multimodal mixed sequences as input to the translation model in parallel, and regularize their output predictions with a self-learning framework. Experiments on MuST-C speech translation benchmark and further analysis show that our method effectively alleviates the cross-modal representation discrepancy, and achieves significant improvements over a strong baseline on eight translation directions.

1 Introduction

Speech-to-text translation (ST) aims at translating acoustic speech signals into text in a foreign language, which has wide applications including voice assistants, translation for multinational video conferences, and so on. Traditional ST methods usually combine automatic speech recognition (ASR) and machine translation (MT) in a cascaded manner (Sperber et al., 2017; Cheng et al., 2018; Sperber et al., 2019; Dong et al., 2019b; Zhang et al., 2019a; Lam et al., 2021b), which might suffer from error propagation and high latency. To break this bottleneck, end-to-end ST systems attracted much attention recently (Wang et al., 2020b,c; Dong et al., 2021a,b; Han et al., 2021; Inaguma et al., 2021a; Tang et al., 2021a), which learn a unified model to generate translations from speech directly. Some recent work has shown great potential for end-to-end speech translation, even surpassing traditional cascaded systems (Ye et al., 2021; Xu et al., 2021).

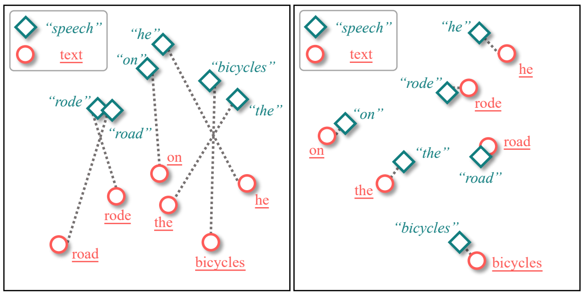

Figure 1: STEMM aims at bridging the modality gap of speech and text. Different modalities with the same meaning are projected to a shared space.

As a cross-modal task, a major challenge in training an end-to-end ST model is the representation discrepancy across modalities, which means there is a modality gap between speech representations and text embeddings, as shown in the left sub-figure of Figure 1. Existing approaches often adopt a sophisticated MT model to help the training of ST, with some techniques like pretraining (Wang et al., 2020c; Ye et al., 2021; Xu et al., 2021), multi-task learning (Ye et al., 2021; Han et al., 2021; Tang et al., 2021a) and knowledge distillation (Liu et al., 2019; Gaido et al., 2020; Inaguma et al., 2021b; Tang et al., 2021a). Although these methods have achieved impressive improvements in ST task, these methods are not necessarily the best way to leverage the MT knowledge. Considering that during training, the input of the translation module only include speech sequences or text sequences, the lack of multimodal contexts makes it difficult for the ST model to learn from the MT model. Inspired by recent studies on some cross-

lingual (Lample and Conneau, 2019; Liu et al., 2020a; Lin et al., 2020) and cross-modal (Li et al., 2021b; Zhou et al., 2020; Dong et al., 2019a) tasks, we suggest that building a shared semantic space between speech and text, as illustrated in the right sub-figure of Figure 1, has the potential to benefit the most from the MT model.

In this paper, we propose the **S**peech-**TE**xt **M**anifold **M**ixup (STEMM) method to bridge the modality gap between text and speech. In order to calibrate the cross-modal representation discrepancy, we mix up the speech and text representation as the input and keep the target sequence unchanged. Specifically, STEMM is a self-learning framework, which takes both the speech representation and the mixed representation as parallel inputs to the translation model, and regularizes their output predictions. Experimental results show that our method achieves promising performance on the benchmark dataset MuST-C (Di Gangi et al., 2019a), and even outperforms a strong cascaded baseline. Furthermore, we found that our STEMM could effectively alleviate the cross-modal representation discrepancy, and project two modalities into a shared space.

2 Method

In this section, we will begin with the basic problem formulation (Section 2.1) and introduce the model architecture (Section 2.2). Then, we introduce our proposed **S**peech-**TE**xt **M**anifold **M**ixup (STEMM) in Section 2.3. Finally, we introduce our proposed self-learning framework with STEMM in Section 2.4 and present two mixup ratio strategies in Section 2.5. Figure 2 illustrates the overview of our proposed method.

2.1 Problem Formulation

The speech translation corpus usually contains *speech-transcription-translation* triples, which can be denoted as $\mathcal{D} = \{(\mathbf{s}, \mathbf{x}, \mathbf{y})\}$. Here $\mathbf{s}$ is the sequence of audio wave, $\mathbf{x}$ is the transcription in the source language, and $\mathbf{y}$ is the translation in the target language. End-to-end speech translation aims to generate translation $\mathbf{y}$ directly from the audio wave $\mathbf{s}$, without generating intermediate transcription $\mathbf{x}$.

2.2 Model Architecture

Inspired by recent works (Dong et al., 2021b; Xu et al., 2021) in end-to-end speech translation, we decompose the ST model into three modules: *acoustic encoder*, *translation encoder*, and *translation decoder*. The *acoustic encoder* first encodes the original audio wave into hidden states, fed into the *translation encoder* to learn further semantic information. Finally, the *translation decoder* generates the translation based on the output of the *translation encoder*.

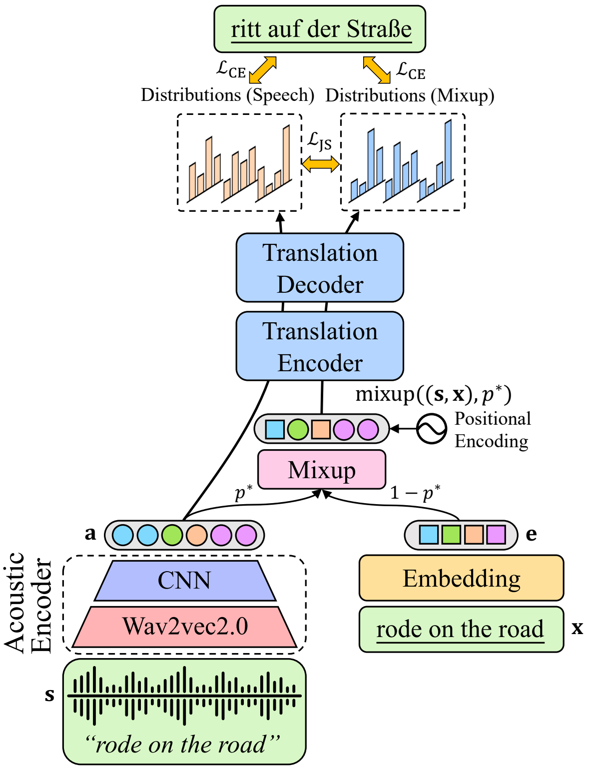

Figure 2: Overview of our proposed self-learning framework with STEMM. We first mix up the sequence of speech representations and word embeddings with STEMM. Then, both the unimodal speech sequence and the multimodal mixed sequence are fed into the shared translation module to predict the translation, and we regularize two output predictions with an additional JS Divergence loss.

Acoustic Encoder As recent works (Ye et al., 2021; Han et al., 2021) show that Wav2vec2.0 (Baevski et al., 2020) can improve the performance of speech translation, we first use a pretrained Wav2vec2.0 to extract speech representations $\mathbf{c}$ from the audio wave $\mathbf{s}$. We add two additional convolutional layers to further shrink the length of speech representations by a factor of 4, denoted as $\mathbf{a} = \text{CNN}(\mathbf{c})$.

Translation Encoder Our *translation encoder* is composed of N_e transformer (Vaswani et al., 2017) encoder layers, which includes a self-attention layer, a feed-forward layer, normalization layers, and residual connections. For MT task, the input of the *translation encoder* is the embedding of transcription $\mathbf{e} = \text{Emb}(\mathbf{x})$. For ST task, it is the output sequence of the *acoustic encoder* $\mathbf{a}$. The input can also be the multimodal mixed sequence with our proposed STEMM (see details in Section 2.3). Generally, for the input sequence $\boldsymbol{\chi}$, we obtain the contextual representations $\mathbf{h}(\boldsymbol{\chi})$ after N_e transformer (Vaswani et al., 2017) layers, which are fed into the *translation decoder* for predicting the translation.

Translation Decoder Our *translation decoder* is composed of N_t transformer decoder layers, which contain an additional cross-attention layer compared with transformer encoder layers. For the input sequence $\boldsymbol{\chi}$, the cross entropy loss is defined as:

$$\mathcal{L}_{\text{CE}}(\boldsymbol{\chi}, \mathbf{y}) = -\sum_{i=1}^{|\mathbf{y}|} \log p_\theta(\mathbf{y}_i | \mathbf{y}_{<i}, \mathbf{h}(\boldsymbol{\chi})). \quad (1)$$

Pretrain-finetune We follow the pretrain-finetune paradigm to train our model. First, we pretrain the *translation encoder* and *translation decoder* with parallel *transcription-translation* pairs, derived from both the speech translation corpus and the external MT dataset. Also, the *acoustic encoder* is pretrained on large amounts of unlabeled audio data in a self-supervised manner. We combine those pretrained modules and finetune the whole model for ST.

2.3 Speech-Text Manifold Mixup (STEMM)

As we mentioned in Section 1, to alleviate the representation discrepancy due to the lack of multimodal contexts, we present the **S**peech-**TE**xt **M**anifold **M**ixup (STEMM) method to mix up the sequence of speech representations and word embeddings. We first introduce STEMM in this section and later show how to use it to help the training of ST.

Note the sequence of sub-word embeddings as $\mathbf{e} = [\mathbf{e}_1, \mathbf{e}_2, ..., \mathbf{e}_{|\mathbf{e}|}]$ and the sequence of speech representations as $\mathbf{a} = [\mathbf{a}_1, \mathbf{a}_2, ..., \mathbf{a}_{|\mathbf{a}|}]$, where the sequence lengths usually follow $|\mathbf{a}| \geq |\mathbf{e}|$. We first perform a word-level forced alignment between speech and text transcriptions to determine when particular words appear in the speech segment. Formally, the aligner recognizes a sequence of word units $\mathbf{w} = [w_1, w_2, ..., w_T]$, and for each word w_i, it returns the start position l_i and end position r_i in the sequence of speech representation $\mathbf{a}$. Meanwhile, we denote the corresponding sub-word span for word w_i as $[x_{m_i} : x_{n_i}]$, with its embeddings matrix $[\mathbf{e}_{m_i} : \mathbf{e}_{n_i}]$, where m_i and n_i are the start position and end position in the sequence of subwords. To mix up both sequences, for each word unit w_i, we choose either the segment of speech representations $[\mathbf{a}_{l_i} : \mathbf{a}_{r_i}]$ or sub-word embeddings $[\mathbf{e}_{m_i} : \mathbf{e}_{n_i}]$ with a certain probability p^*, referred to *mixup ratio* in this paper.

$$\mathbf{m}_i = \begin{cases} [\mathbf{a}_{l_i} : \mathbf{a}_{r_i}] & p \leq p^* \\ [\mathbf{e}_{m_i} : \mathbf{e}_{n_i}] & p > p^* \end{cases}, \quad (2)$$

where p is sampled from the uniform distribution $\mathcal{U}(0, 1)$.

Finally, we concatenate all $\mathbf{m}_i$ together and obtain the mixup sequence:

$$\mathbf{m} = \text{Concat}(\mathbf{m}_1, \mathbf{m}_2, ..., \mathbf{m}_T). \quad (3)$$

Note that in terms of the mixup representation sequence length, we have $|\mathbf{e}| \leq |\mathbf{m}| \leq |\mathbf{a}|$. Considering the positions of tokens have changed after mixup, we add positional encodings to the token embeddings. We further perform layer normalization to normalize the embeddings:

$$\text{Mixup}((\mathbf{s}, \mathbf{x}), p^*) = \text{LayerNorm}(\mathbf{m} + \text{Pos}(\mathbf{m})), \quad (4)$$

where $\text{Pos}(\cdot)$ is the sinusoid positional embedding (Vaswani et al., 2017). $\text{Mixup}((\mathbf{s}, \mathbf{x}), p^*)$ indicates the *mixup sequence* of speech $\mathbf{s}$ and text $\mathbf{x}$ with probability p^*, which is fed into the *translation encoder* for predicting the translation.

2.4 Self-learning with STEMM

With the help of our proposed STEMM, we are now able to access multimodal mixed sequences, in addition to the unimodal speech sequences. We integrate them into a self-learning framework. Specifically, we input both unimodal speech sequences and multimodal mixed sequences into the translation module (*translation encoder* and *translation decoder*). In this way, translation of unimodal speech sequences focuses on the ST task itself, while the translation of multimodal mixed sequences is devoted to capture the connections between representations in different modalities. Besides, we try to regularize above two output predictions by minimizing the Jensen-Shannon Divergence (JSD) between two output distributions, which is

$$\mathcal{L}_{\text{JSD}}(\mathbf{s},\mathbf{x},\mathbf{y},p^*) = \sum_{i=1}^{|\mathbf{y}|} \text{JSD}\{p_\theta(\mathbf{y}_i|\mathbf{y}_{<i},\mathbf{h}(\mathbf{s}))\| \\ p_\theta(\mathbf{y}_i|\mathbf{y}_{<i},\mathbf{h}(\text{Mixup}((\mathbf{s},\mathbf{x}),p^*)))\}, \quad (5)$$

where $\mathbf{h}(\cdot)$ is the contextual representation outputted by the *translation encoder*. $p_\theta(\mathbf{y}_i|\mathbf{y}_{<i},\mathbf{h}(\mathbf{s}))$ is the predicted probability distribution of the i-th target token given the speech sequence $\mathbf{s}$ as input, and $p_\theta(\mathbf{y}_i|\mathbf{y}_{<i},\mathbf{h}(\text{Mixup}((\mathbf{s},\mathbf{x}),p^*)))$ is that given the multimodal mixed sequence as input.

With the cross-entropy losses of two forward passes, the final training objective is as follows:

$$\mathcal{L} = \mathcal{L}_{\text{CE}}(\mathbf{s},\mathbf{y}) + \mathcal{L}_{\text{CE}}(\text{Mixup}((\mathbf{s},\mathbf{x}),p^*),\mathbf{y}) \\ + \lambda\mathcal{L}_{\text{JSD}}(\mathbf{s},\mathbf{x},\mathbf{y},p^*), \quad (6)$$

where λ is the coefficient weight to control $\mathcal{L}_{\text{JSD}}$.

2.5 Mixup Ratio Strategy

When using our proposed STEMM, an important question is how to determine the mixup ratio p^*. Here we try two strategies: *static mixup ratio* and *uncertainty-aware mixup ratio*.

Static Mixup Ratio We use the same mixup ratio p^* for all instances throughout the whole training process. We will show how we determined this important hyper-parameter in Section 4.3.

Uncertainty-aware Mixup Ratio With this strategy, we determine the mixup ratio for each instance according to the prediction uncertainty of the ST task, defined as the average entropy of predicted distributions of all target tokens:

$$u = \frac{1}{|\mathbf{y}|}\sum_{i=1}^{|\mathbf{y}|} \text{Entropy}(p_\theta(\mathbf{y}_i|\mathbf{y}_{<i},\mathbf{h}(\mathbf{s}))), \quad (7)$$

and then we set the mixup ratio p^* as follows:

$$p^* = \sigma\left(\frac{u}{U} - \frac{1}{2}\right), \quad (8)$$

where U is a normalization factor which re-scales u to $[0, 1]$, $\sigma(\cdot)$ is a sigmoid function to prevent p^* from dropping too quickly.

3 Experiments

3.1 Datasets

MuST-C We conduct experiments on MuST-C (Di Gangi et al., 2019a) dataset. MuST-C is a multilingual speech translation dataset, which contains translations from English (En) to 8 languages: German (De), French (Fr), Russian (Ru), Spanish (Es), Italian (It), Romanian (Ro), Portuguese (Pt), and Dutch (Nl). It is one of the largest speech translation datasets currently, which contains at least 385 hours of audio recordings from TED Talks, with their manual transcriptions and translations at the sentence level. We use `dev` set for validation and `tst-COMMON` set for test.

	ST (MuST-C)		MT

Es	504	270K	WMT13	15.2M
Ro	432	240K	WMT16	0.6M
It	465	258K	OPUS100	1.0M
Pt	385	211K	OPUS100	1.0M
Nl	442	253K	OPUS100	1.0M

Table 1: Statistics of all datasets

MT Datasets Our model architecture allows us to utilize external parallel sentence pairs in large-scale machine translation datasets. Therefore, we incorporate data from WMT for En-De, En-Fr, En-Ru, En-Es, En-Ro, and OPUS100[1] for En-Pt, En-It, En-Nl, as pretraining corpora. The detailed statistics of all datasets included are shown in Table 1.

3.2 Experimental setups

Pre-processing For speech input, we use the raw 16-bit 16kHz mono-channel audio wave. To perform word-level force alignment, we use Montreal Forced Aligner[2] toolkit, whose acoustic model is trained with LibriSpeech (Panayotov et al., 2015). For text input, we remove the punctuation from the source texts for the ST dataset. Both source and target texts are case-sensitive. For each translation direction, we use a unigram SentencePiece[3] model to learn a vocabulary on the text data from ST dataset, and use it to segment text from both ST and MT corpora into subword units. The vocabulary is shared for source and target with a size of 10k.

Table 3: Comparison with cascaded baseline on MuST-C En-De `tst-COMMON` set. ** mean the improvements over cascaded baseline is statistically significant ($p < 0.01$).

Model Configuration Our model consists of three modules. For the *acoustic encoder*, we use Wav2vec2.0 (Baevski et al., 2020) following the base configuration, which is pretrained on audio data from LibriSpeech (Panayotov et al., 2015) without finetuning[4]. We add two additional 1-dimensional convolutional layers to further shrink the audio, with kernel size 5, stride size 2, padding 2, and hidden dimension 1024. For the *translation encoder*, we use $N_e = 6$ transformer encoder layers. For the *translation decoder*, we use $N_d = 6$ transformer decoder layers. Each of these transformer layers comprises 512 hidden units, 8 attention heads, and 2048 feed-forward hidden units.

Training and Inference We train our model in a pretrain-finetune manner. During pretraining, we train the MT model i.e., *translation encoder* and *translation decoder*, with *transcription-translation* pairs. The learning rate is 7e-4. We train the model with at most 33k input tokens per batch. During finetuning, the learning rate is set to 1e-4. We finetune the whole model up to 25 epochs to avoid overfitting, with at most 16M source audio frames per batch. The training will early-stop if the loss on *dev* set did not decrease for ten epochs. During both pretraining and finetuning, we use an Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9, \beta_2 = 0.98$, and 4k warm-up updates. The learning rate will decrease proportionally to the inverse square root of the step number after warm-up. The dropout is set to 0.1, and the value of label smoothing is set to 0.1. We use the uncertainty-aware mixup ratio strategy by default, and the mixup ratio p^* is set to 0.4 when using static strategy. The weight λ of JSD loss is set to 1.0.

During inference, We average the checkpoints of the last 10 epochs for evaluation. We use beam search with a beam size of 5. We use sacreBLEU[5] (Post, 2018) to compute case-sensitive detokenized BLEU (Papineni et al., 2002) scores and the statistical significance of translation results with paired bootstrap resampling (Koehn, 2004) for a fair comparison[6]. All models are trained on 8 Nvidia Tesla-V100 GPUs. We implement our models based on fairseq[7] (Ott et al., 2019).

Baseline Systems We compare our method with several strong end-to-end ST systems including:

[7] `https://github.com/pytorch/fairseq`

Fairseq ST (Wang et al., 2020a), AFS (Zhang et al., 2020), DDT (Le et al., 2020), MTL (Tang et al., 2021b), Self-training (Pino et al., 2020), BiKD (Inaguma et al., 2021a), FAT-ST (Zheng et al., 2021a), JT-S-MT (Tang et al., 2021a), SATE (Xu et al., 2021), Chimera (Han et al., 2021) and XSTNet (Ye et al., 2021). Besides, we implement a strong baseline W2V2-Transformer based on Wav2vec2.0. It has the same model architecture as our proposed STEMM and is pretrained in the same way. The only difference is that it is only finetuned on the ST task, while we adopt a self-learning framework during finetuning.

4 Results and Analysis

4.1 Results on MuST-C Dataset

Comparison with End-to-end Baselines As shown in Table 2, our implemented W2V2-Transformer is a relatively strong baseline, which proves the effectiveness of Wav2vec2.0 module and MT pretraining. Without external MT data, our method achieves an improvement of 1.0 BLEU (average over 8 directions) over the strong baseline, which proves our proposed self-learning framework could effectively improve the performance of the ST task. It even outperforms baselines with external MT data on En-Es, En-It, En-Ro, En-Pt, and En-Nl. When we introduce additional MT data, our method also yields a 0.8 BLEU improvement compared with baseline. Note that our performance is slightly worse than XSTNet (Ye et al., 2021). However, our method is orthogonal with theirs, which focuses on the training procedure of end-to-end ST model. We will investigate how to combine them together in the future.

Comparison with Cascaded Baseline We also implement a strong cascaded system, whose ASR part is composed of a pretrained Wav2vec2.0 module and 6 transformer decoder layers, and the MT part is the same as our pretrained MT module. Both cascaded systems and end-to-end models are trained with the same data ($\mathcal{D}$ and $\mathcal{D}_{\text{MT}}$). As shown in Table 3, the end-to-end baseline W2V2-Transformer is inferior to the cascaded system, but our method significantly outperforms it, which shows the potential of our STEMM method.

4.2 Ablation Studies

Is Each Learning Objective Effective? As shown in Equation 6, our training objective contains three terms. Besides the cross-entropy objective $\mathcal{L}_{\text{CE}}(\mathbf{s}, \mathbf{y})$ for speech translation, we investigate the effects of the other two auxiliary training objectives. As shown in Table 4, when we input the additional multimodal mixed sequence into the model and optimize the cross-entropy loss (Line 3), it can already outperform the baseline (Line 4) significantly. When we regularize two output predictions with JSD loss (Line 2), the performance can be further boosted.

Mixup Ratio	STEMM Trans.	JSD	BLEU
uncertainty-aware	✓	✓	**28.7****
static	✓	✓	28.5**
static	✓	×	27.9**
static	×	×	26.9

Table 4: BLEU scores on MuST-C En-De `tst-COMMON` set with different auxiliary training objectives. STEMM Trans. indicates the criterion entropy loss of translation of multimodal mixed sequence $\mathcal{L}_{\text{CE}}(\text{Mixup}((\mathbf{s}, \mathbf{x}), p^*), \mathbf{y})$. ** mean the improvements over W2V2-Transformer baseline (last row in the table) is statistically significant ($p < 0.01$).

The uncertainty-aware strategy reduces the cost for searching mixup ratio and has better performance. We present two different mixup ratio strategies in Section 2.5. To evaluate their impacts, we conduct another ablation study on MuST-C En-De. We observe that the BLEU scores on `tst-COMMON` set are 28.5 and 28.7 for *static strategy* and *uncertainty-aware strategy*, respectively. The *uncertainty-aware strategy* can slightly improve the performance, and more importantly, it lowers the manual cost for searching an optimal mixup ratio to get the best performance.

4.3 What is the Optimal Mixup Ratio?

When using *static mixup ratio strategy*, it is important to choose the mixup ratio p^*. We constrain p^* in $[0.0, 0.2, 0.4, 0.6, 0.8]$ for experiments on MuST-C En-De `tst-COMMON` set, as shown in Figure 3. When $p^* = 0.0$, the translation task with the mixed sequence as input degrades to the MT task. We interestingly find that self-learning with MT tasks performed the worst (i.e. lowest BLEU) than self-learning with STEMM at other mixup ratios. This confirms what we mentioned in Section 1, that the representation discrepancy between speech and text makes the MT task an inferior boost to ST.

Our method achieves the best performance at $p^* = 0.4$. To find a reasonable explanation, we do a more in-depth study of the representation of the speech, text, and their mixup sequence (STEMM).

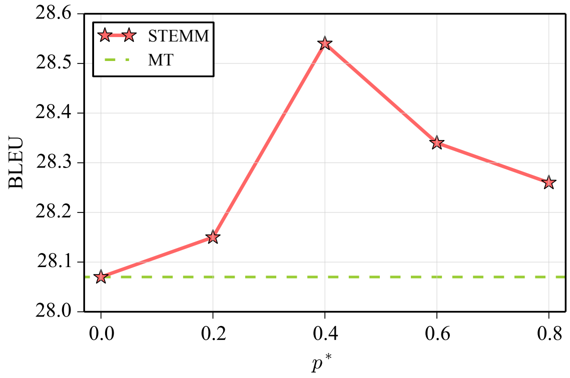

Figure 3: BLEU scores on MuST-C En-De `tst-COMMON` set with different mixup ratio p^*. Our method achieves best performance when $p^* = 0.4$. When $p^* = 0.0$, STEMM will degrade to text-only sequence, which we denote as MT.

In Figure 4, we take out the sequential representation of the speech (output of acoustic encoder), text sequences (output of embedding layer), and the STEMM sequences, average them over the sequence dimension, and apply the T-SNE dimensionality reduction algorithm to reduce the 512 dimensions to two dimensions. We plot the bivariate kernel density estimation based on the reduced 2-dim representation. We find that when $p^* = 0.4$, the mixup representation just lies between the representation of speech and text sequences. That is why it calibrates the cross-modal representation discrepancy more easily and gets the best ST performance.

4.4 Can Our Model Alleviate Cross-modal Representation Discrepancy?

To examine whether our method alleviates the cross-modal representation discrepancy, we conduct some analysis of cross-modal word representations. As described in Section 2.3, for each word unit w_i, we identify the corresponding segment of speech representation $[\mathbf{a}_{l_i} : \mathbf{a}_{r_i}]$ and text embedding $[\mathbf{e}_{m_i} : \mathbf{e}_{n_i}]$. We define the word representation in each modality as follows:

$$\boldsymbol{\alpha}_i = \text{AvgPool}([\mathbf{a}_{l_i} : \mathbf{a}_{r_i}]), \quad (9)$$

$$\boldsymbol{\varepsilon}_i = \text{AvgPool}([\mathbf{e}_{m_i} : \mathbf{e}_{n_i}]), \quad (10)$$

where AvgPool() denotes average-pooling operation across the sequence dimension, $\boldsymbol{\alpha}_i$ and $\boldsymbol{\varepsilon}_i$ denote the representation of word unit w_i in speech and text modalities, respectively.

We calculate the average cosine similarity between $\boldsymbol{\alpha}_i$ and $\boldsymbol{\varepsilon}_i$ over all word units w_i in MuST-C En-De `tst-COMMON` set. As shown in Table 5, our method could significantly improve the similarity of word representations across modalities over baseline. We believe it is because when training with our proposed STEMM, the speech segment and text segment of a word will appear in a similar multimodal context, which leads to similar representations. We also show the visualization of an example in Figure 5, we can observe that our method brings word representations within different modalities closer compared with baseline.

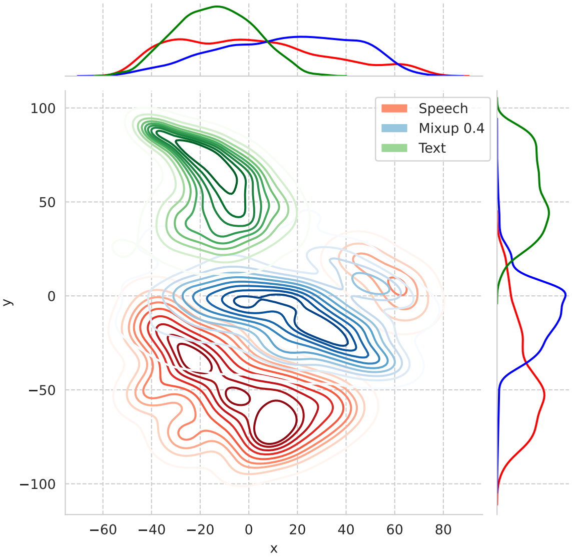

Figure 4: The bivariate kernel density estimation visualization of the averaged sentence representation of the speech, text and STEMM sequences after pretraining. T-SNE algorithm is applied to reduce the 512-dim representations to two dimensions. The green line stands for the averaged sentence embedding. The red line stands for the averaged speech representation. the blue line is the representation for STEMM with mixup ratio $p^* = 0.4$. We observe that the representation of the mixed sequence is in between that of speech and text, which fills the gap between the representation of speech sequences and text sequences. Best view in color.

Models	Similarity (%)
W2V2-Transformer	32.31
STEMM	**51.89**

Table 5: Comparison of word-level representation similarity across modalities.

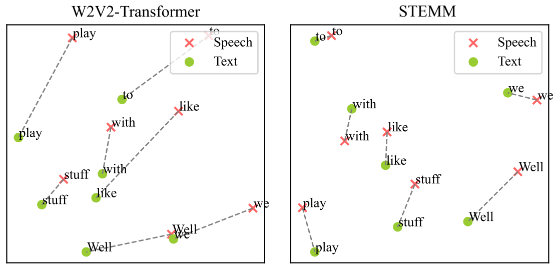

Figure 5: Visualization of word representations in speech and text modalities. We visualize the representations by reducing the dimension with Principal Component Analysis (PCA). Our method brings word representation within different modalities closer.

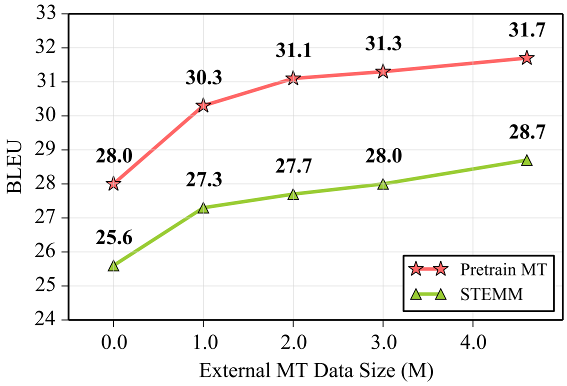

Figure 6: Curve of BLEU scores on MuST-C En-De `tst-COMMON` against the size of external MT data used during pretraining.

4.5 How the Size of MT Data Influences Performance?

One important contributor to our excellent performance is the usage of external MT data. Therefore, how the amount of MT data affects the final performance is an important question. We vary the amount of available external MT data during pretraining on En-De direction. As shown in Figure 6, we observe a continuous improvement of BLEU scores with the increase of MT data, which shows that external MT data is helpful to improve ST.

4.6 Can the Final Model still Perform MT Task?

Our model is first pretrained on the MT task and then finetune for ST. An important question is whether there is a catastrophic forgetting problem during finetuning. We evaluate the model on the MT task and show the result in Table 6. We observe that when we only finetune the model on the ST task (W2V2-Transformer), the ability of text translation will be forgotten a lot. In contrast, when we use our self-learning framework during finetuning, even though there is no MT task, the MT capability can still be preserved.

Models	**BLEU**
Pretrained MT	**31.7**
W2V2-Transformer	19.5
STEMM	31.5

Table 6: BLEU scores of MT task on MuST-C En-De `tst-COMMON` set. Our proposed method almost preserves the text translation capability of pretrained MT model.

5 Related Works

End-to-end ST To overcome the error propagation and high latency in the cascaded ST systems, Bérard et al. (2016); Duong et al. (2016) proved the potential of end-to-end ST without intermediate transcription, which has attracted much attention in recent years (Vila et al., 2018; Salesky et al., 2018, 2019; Di Gangi et al., 2019b,c; Bahar et al., 2019a; Inaguma et al., 2020). Since it is difficult to train an end-to-end ST model directly, some training techniques like pretraining (Weiss et al., 2017; Berard et al., 2018; Bansal et al., 2019; Stoian et al., 2020; Wang et al., 2020b; Pino et al., 2020; Dong et al., 2021a; Alinejad and Sarkar, 2020; Zheng et al., 2021b; Xu et al., 2021), multi-task learning (Le et al., 2020; Vydana et al., 2021; Tang et al., 2021b; Ye et al., 2021; Tang et al., 2021a), curriculum learning (Kano et al., 2017; Wang et al., 2020c), and meta-learning (Indurthi et al., 2020) have been applied. To overcome the scarcity of ST data, Jia et al. (2019); Pino et al. (2019); Bahar et al. (2019b) proposed to generate synthesized data based on ASR and MT corpora. To overcome the modality gap, Han et al. (2021); Huang et al. (2021); Xu et al. (2021) further encode acoustic states which are more adaptive to the decoder. Previous works have mentioned that the modality gap between speech and text is one of the obstacles in the speech translation task, and to overcome such gap, one branch of the works (Liu et al., 2020b; Dong et al., 2021b; Xu et al., 2021) introduced a second encoder based on the conventional encoder-decoder model, to extract semantic information of speech and text. Recently, Han et al. (2021) built a shared semantic projection module that simulates the human brain, while in this work, we explored how to construct an intermediate state of the two modalities via the recent mixup method (*i.e.* **S**peech-**TE**xt **M**anifold **M**ixup) to narrow such gap. Note that our work is orthogonal with Ye et al. (2021)'s study in training procedure of end-to-end ST model.

Mixup Our work is inspired by the mixup strategy. Zhang et al. (2018) first proposed mixup as a data augmentation method to improve the robustness and the generalization of the model, where additional data are constructed as the linear interpolation of two random examples and their labels at the surface level. Verma et al. (2019) extended the surface-level mixup to the hidden representation by constructing *manifold mixup* interpolations. Recent work has introduced mixup on machine translation (Zhang et al., 2019b; Li et al., 2021a; Guo et al., 2022; Fang and Feng, 2022), sentence classification (Chen et al., 2020; Jindal et al., 2020; Sun et al., 2020), multilingual understanding (Yang et al., 2022), and speech recognition (Medennikov et al., 2018; Sun et al., 2021; Lam et al., 2021a; Meng et al., 2021), and obtained enhancements. Our approach is the first to introduce the idea of manifold mixup to the speech translation task with two modalities, speech, and text.

6 Conclusion

In this paper, we propose a **S**peech-**TE**xt **M**anifold **M**ixup (STEMM) method to mix up the speech representation sequences and word embedding sequences. Based on STEMM, we adopt a self-learning framework, which learns the translation of unimodal speech sequences and multimodal mixed sequences in parallel, and regularizes their output predictions. Experiments and analysis demonstrate the effectiveness of our proposed method, which can alleviate the cross-modal representation discrepancy to some extent and improve the performance of ST. In the future, we will explore how to further eliminate this discrepancy and fill the cross-modal transfer gap for ST.

Abstract

Lexically constrained neural machine translation (NMT), which controls the generation of NMT models with pre-specified constraints, is important in many practical scenarios. Due to the representation gap between discrete constraints and continuous vectors in NMT models, most existing works choose to construct synthetic data or modify the decoding algorithm to impose lexical constraints, treating the NMT model as a black box. In this work, we propose to open this black box by directly integrating the constraints into NMT models. Specifically, we vectorize source and target constraints into continuous keys and values, which can be utilized by the attention modules of NMT models. The proposed integration method is based on the assumption that the correspondence between keys and values in attention modules is naturally suitable for modeling constraint pairs. Experimental results show that our method consistently outperforms several representative baselines on four language pairs, demonstrating the superiority of integrating vectorized lexical constraints.[1]

1 Introduction

Controlling the lexical choice of the translation is important in a wide range of settings, such as interactive machine translation (Koehn, 2009), entity translation (Li et al., 2018), and translation in safety-critical domains (Wang et al., 2020). However, different from the case of statistical machine translation (Koehn et al., 2007), it is non-trivial to directly integrate discrete lexical constraints into neural machine translation (NMT) models (Bahdanau et al., 2015; Vaswani et al., 2017), whose hidden states are all continuous vectors that are difficult for humans to understand.

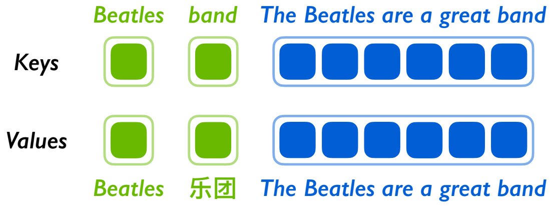

Figure 1: An example of the integration of vectorized lexical constraints into attention proposed in this work. We omit queries for simplicity. Blue and green squares denote the continuous representation of the source sentence and the constraints, respectively. The provided constraints are "Beatles→Beatles" and "band→乐团".

In accordance with this problem, one branch of studies directs its attention to designing advanced decoding algorithms (Hokamp and Liu, 2017; Hasler et al., 2018; Post and Vilar, 2018) to impose hard constraints and leave NMT models unchanged. For instance, Hu et al. (2019) propose a *vectorized dynamic beam allocation* (VDBA) algorithm, which devotes part of the beam to candidates that have met some constraints. Although this kind of method can guarantee the presence of target constraints in the output, they are found to potentially result in poor translation quality (Chen et al., 2021b; Zhang et al., 2021), such as repeated translation or source phrase omission.

Another branch of works proposes to learn constraint-aware NMT models through data augmentation. They construct synthetic data by replacing source constraints with their target-language correspondents (Song et al., 2019) or appending target constraints right after the corresponding source phrases (Dinu et al., 2019). During inference, the input sentence is edited in advance and then provided to the NMT model. The major drawback of data augmentation based methods is that they may suffer from a low success rate of generating target constraints in some cases, indicating that only adjusting the training data is sub-optimal for lexical constrained translation (Chen et al., 2021b).

To make NMT models better learn from and cope with lexical constraints, we propose to lever-

age attention modules (Bahdanau et al., 2015) to explicitly integrate vectorized lexical constraints. As illustrated in Figure 1, we use vectorized source constraints as additional keys and vectorized target constraints as additional values. Intuitively, the additional keys are used to estimate the relevance between the current query and the source phrases while the additional values are used to integrate the information of the target phrases. In this way, each revised attention is aware of the guidance to translate *which source phrase* into *what target phrase*.

Experiments show that our method can significantly improve the ability of NMT models to translate with constraints, indicating that the correspondence between attention keys and values is suitable for modeling constraint pairs. Inspired by recent progress in controlled text generation (Dathathri et al., 2020; Pascual et al., 2021), we also introduce a plug-in to the output layer that can further improve the success rate of generating constrained tokens. We conduct experiments on four language pairs and find that our model can consistently outperform several representative baselines.

2 Neural Machine Translation

Training The goal of machine translation is to translate a source-language sentence $\mathbf{x} = x_1 \dots x_{|\mathbf{x}|}$ into a target-language sentence $\mathbf{y} = y_1 \dots y_{|\mathbf{y}|}$. We use $P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta})$ to denote an NMT model (Vaswani et al., 2017) parameterized by $\boldsymbol{\theta}$. Modern NMT models are usually trained by maximum likelihood estimation (Bahdanau et al., 2015; Vaswani et al., 2017), where the log-likelihood is defined as

$$\log P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}) = \sum_{t=1}^{|\mathbf{y}|} \log P(y_t|\mathbf{y}_{<t},\mathbf{x};\boldsymbol{\theta}), \quad (1)$$

in which $\mathbf{y}_{<t}$ is a partial translation.

Inference The inference of NMT models can be divided into two sub-processes:

- *probability estimation*: the model estimates the token-level probability distribution for each partial hypothesis within the beam;
- *candidate selection*: the decoding algorithm selects some candidates based on the probability estimated by the NMT model.

These two sub-processes are performed alternatively until reaching the maximum length or generating the end-of-sentence token.

3 Approach

This section explains how we integrate lexical constraints into NMT models. Section 3.1 illustrates the way we encode discrete constraints into continuous vectors, Section 3.2 details how we integrate the vectorized constraints into NMT models, and Section 3.3 describes our training strategy.

3.1 Vectorizing Lexical Constraints

Let $\mathbf{s} = \mathbf{s}^{(1)}, \dots, \mathbf{s}^{(N)}$ be the source constraints and $\mathbf{t} = \mathbf{t}^{(1)}, \dots, \mathbf{t}^{(N)}$ be the target constraints. Given a constraint pair $\langle \mathbf{s}^{(n)}, \mathbf{t}^{(n)} \rangle$, lexically constrained translation requires that the system must translate the source phrase $\mathbf{s}^{(n)}$ into the target phrase $\mathbf{t}^{(n)}$. Since the inner states of NMT models are all continuous vectors rather than discrete tokens, we need to vectorize the constraints before integrating them into NMT models.

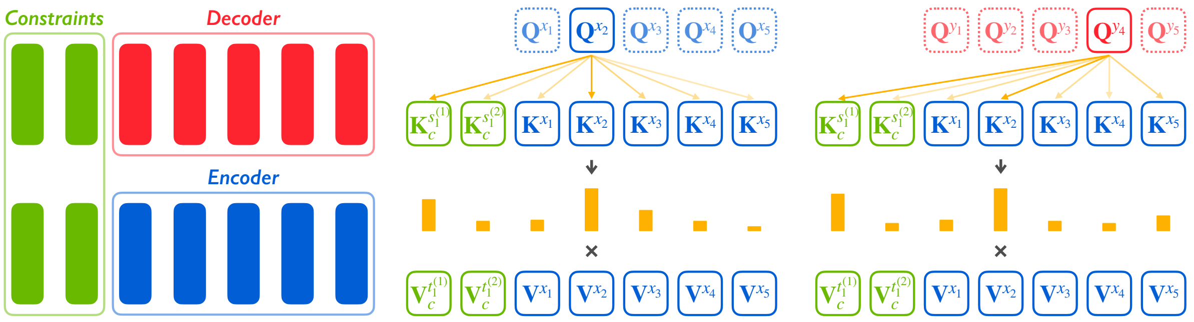
For the n-th constraint pair $\langle \mathbf{s}^{(n)}, \mathbf{t}^{(n)} \rangle$, let $|\mathbf{s}^{(n)}|$ and $|\mathbf{t}^{(n)}|$ be the lengths of $\mathbf{s}^{(n)}$ and $\mathbf{t}^{(n)}$, respectively. We use $\mathbf{S}_k^{(n)} \in \mathbb{R}^{d\times 1}$ to denote the vector representation of the k-th token in $\mathbf{s}^{(n)}$, which is the sum of word embedding and positional embedding (Vaswani et al., 2017). Therefore, the matrix representation of $\mathbf{s}^{(n)}$ is given by:

$$\mathbf{S}^{(n)} = \left[\mathbf{S}_1^{(n)}; \dots; \mathbf{S}_{|\mathbf{s}^{(n)}|}^{(n)}\right], \quad (2)$$

where $\mathbf{S}^{(n)} \in \mathbb{R}^{d\times|\mathbf{s}^{(n)}|}$ is the concatenation of all vector representations of tokens in $\mathbf{s}^{(n)}$. Similarly, the matrix representation of the target constraint $\mathbf{t}^{(n)}$ is $\mathbf{T}^{(n)} \in \mathbb{R}^{d\times|\mathbf{t}^{(n)}|}$. Note that the positional embedding for each constraint is calculated independently, which is also independent of the positional embeddings of the source sentence $\mathbf{x}$ and the target sentence $\mathbf{y}$.

3.2 Integrating Vectorized Constraints

We adopt Transformer (Vaswani et al., 2017) as our NMT model, which is nowadays one of the most popular and effective NMT models (Liu et al., 2020). Typically, a Transformer consists of an encoder, a decoder, and an output layer, of which the encoder and decoder map discrete tokens into vectorized representations and the output layer converts such representations into token-level probability distributions. We propose to utilize the attention modules to integrate the constraints into the encoder and decoder and use a plug-in module to integrate constraints into the output layer. We change the formal representation of our model



(a) Overview (b) Integration into enc. self-attn. (c) Integration into dec. cross-attn.

Figure 2: Illustration of the integration of vectorized lexical constraints into both the encoder and the decoder. Blue, red, and green squares represent vectorized representations for source tokens, target tokens, and tokens of constraint pairs, respectively. The basic idea is to use source constraints as indicators to select the corresponding target constraints for each query. We only plot the attention weights for one query for simplicity.

from $P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta})$ to $P(\mathbf{y}|\mathbf{x},\mathrm{s},\mathbf{t};\boldsymbol{\theta})$ to indicate that the model explicitly considers lexical constraints when estimating probability.

Constraint-Related Keys and Values We propose to map source and target constraints into additional keys and values, which are called *constraint-related keys and values*, in order to distinguish from the original keys and values in vanilla attention modules. In practice, source and target constraints may have different lengths and they are usually not monotonically aligned (Du et al., 2021), making it challenging to directly convert the constraints into keys and values. To fix this problem, We adopt a multi-head attention layer (Vaswani et al., 2017) to align the bilingual constraints. The constraint-related keys and values for the n-th constraint pair are given by

$$\begin{aligned}\mathbf{K}_c^{(n)} &= \mathbf{S}^{(n)},\\ \mathbf{V}_c^{(n)} &= \mathrm{attn}\left(\mathbf{S}^{(n)}, \mathbf{T}^{(n)}, \mathbf{T}^{(n)}\right),\end{aligned} \tag{3}$$

where $\mathbf{K}_c^{(n)} \in \mathbb{R}^{d\times|\mathbf{s}^{(n)}|}$ and $\mathbf{V}_c^{(n)} \in \mathbb{R}^{d\times|\mathbf{s}^{(n)}|}$. $\mathrm{attn}(\mathbf{Q},\mathbf{K},\mathbf{V})$ denotes the multi-head attention function. Note that the resulting $\mathbf{K}_c^{(n)}$ and $\mathbf{V}_c^{(n)}$ are of the same shape. $\mathbf{V}_c^{(n)}$ can be seen as a redistributed version of the representation of target constraints. The constraint-related keys and values of each constraint pair are calculated separately and then concatenated together:

$$\begin{aligned}\mathbf{K}_c &= [\mathbf{K}_c^{(1)};\ldots;\mathbf{K}_c^{(N)}],\\ \mathbf{V}_c &= [\mathbf{V}_c^{(1)};\ldots;\mathbf{V}_c^{(N)}],\end{aligned} \tag{4}$$

where $\mathbf{K}_c \in \mathbb{R}^{d\times|\mathbf{s}|}$ and $\mathbf{V}_c \in \mathbb{R}^{d\times|\mathbf{s}|}$. $|\mathbf{s}|$ is the total length of all the N source constraints.

Integration into the Encoder The encoder of Transformer is a stack of I identical layers, each layer contains a self-attention module to learn context-aware representations. For the i-th layer, the self-attention module can be represented as

$$\mathrm{attn}\left(\mathbf{H}_{\mathrm{enc}}^{(i-1)}, \mathbf{H}_{\mathrm{enc}}^{(i-1)}, \mathbf{H}_{\mathrm{enc}}^{(i-1)}\right), \tag{5}$$

where $\mathbf{H}_{\mathrm{enc}}^{(i-1)} \in \mathbb{R}^{d\times|\mathbf{x}|}$ is the output of the $(i-1)$-th layer, and $\mathbf{H}_{\mathrm{enc}}^{(0)}$ is initialized as the sum of word embedding and positional embedding (Vaswani et al., 2017). For different layers, $\mathbf{H}_{\mathrm{enc}}^{(i-1)}$ may lay in various manifolds, containing different levels of information (Voita et al., 2019). Therefore, we should adapt the constraint-related keys and values for each layer before the integration. We use a two-layer adaptation network to do this:

$$\begin{aligned}\mathbf{K}_{\mathrm{c4enc}}^{(i)} &= [\mathrm{adapt}(\mathbf{K}_c);\mathbf{H}_{\mathrm{enc}}^{(i-1)}],\\ \mathbf{V}_{\mathrm{c4enc}}^{(i)} &= [\mathrm{adapt}(\mathbf{V}_c);\mathbf{H}_{\mathrm{enc}}^{(i-1)}],\end{aligned} \tag{6}$$

where $\mathrm{adapt}(\cdot)$ denotes the adaptation network, which consists of two linear transformations with shape $d \times d$ and a ReLU activation in between. The adaptation networks across all layers are independent of each other. $\mathbf{K}_{\mathrm{c4enc}}^{(i)} \in \mathbb{R}^{d\times(|\mathbf{s}|+|\mathbf{x}|)}$ and $\mathbf{V}_{\mathrm{c4enc}}^{(i)} \in \mathbb{R}^{d\times(|\mathbf{s}|+|\mathbf{x}|)}$ are the constraint-aware keys and values for the i-th encoder layer, respectively. The vanilla self-attention module illustrated in Eq. (5) is revised into the following form:

$$\mathrm{attn}\left(\mathbf{H}_{\mathrm{enc}}^{(i-1)}, \mathbf{K}_{\mathrm{c4enc}}^{(i)}, \mathbf{V}_{\mathrm{c4enc}}^{(i)}\right). \tag{7}$$

Figure 2b plots an example of the integration into the encoder self-attention.

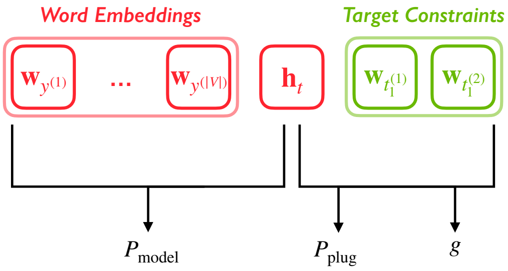


Figure 3: Illustration of the integration into the output layer. Please refer to Eq (11), (12), and (13) for the definition of P_{model}, P_{plug}, and g, respectively.

Integration into the Decoder The integration into the decoder is similar to that into the encoder, the major difference is that we use the cross-attention module to model constraints for the decoder. The decoder of the Transformer is a stack of J identical layers, each of which is composed of a self-attention, a cross-attention, and a feed-forward module. We integrate vectorized constraints into the cross-attention module for the decoder. Formally, the vanilla cross-attention is given by

$$\operatorname{attn}\left(\mathbf{S}_{\text{dec}}^{(j)}, \mathbf{H}_{\text{enc}}^{(I)}, \mathbf{H}_{\text{enc}}^{(I)}\right), \tag{8}$$

where $\mathbf{S}_{\text{dec}}^{(j)} \in \mathbb{R}^{d\times|\mathbf{y}|}$ is the output of the self-attention module in the j-th decoder layer, and $\mathbf{H}_{\text{enc}}^{(I)} \in \mathbb{R}^{d\times|\mathbf{x}|}$ is the output of the last encoder layer. We adapt the constraint-related keys and values to match the manifold in the j-th decoder layer:

$$\begin{aligned}\mathbf{K}_{\text{c4dec}}^{(j)} &= [\operatorname{adapt}(\mathbf{K}_c); \mathbf{H}_{\text{enc}}^{(I)}],\\ \mathbf{V}_{\text{c4dec}}^{(j)} &= [\operatorname{adapt}(\mathbf{V}_c); \mathbf{H}_{\text{enc}}^{(I)}].\end{aligned} \tag{9}$$

Then we revise the vanilla cross-attention (Eq. (8)) into the following form:

$$\operatorname{attn}\left(\mathbf{S}_{\text{dec}}^{(j)}, \mathbf{K}_{\text{c4dec}}^{(j)}, \mathbf{V}_{\text{c4dec}}^{(j)}\right). \tag{10}$$

Figure 2c plots an example of the integration into the decoder cross-attention.

Integration into the Output Layer In vanilla Transformer, an output layer is employed to convert the output of the last decoder layer into token-level probabilities. Let $\mathbf{h}_t \in \mathbb{R}^{d\times 1}$ be the decoder output at the t-th time step, the output probability of the Transformer model is defined as

$$P_{\text{model}}(y|\mathbf{y}_{<t}, \mathbf{x}, \mathbf{s}, \mathbf{t}; \boldsymbol{\theta}) = \operatorname{softmax}\left(\mathbf{h}_t^\top \mathbf{W}\right), \tag{11}$$

where $\mathbf{W} \in \mathbb{R}^{d\times|\mathcal{V}|}$ is the output embedding matrix and $|\mathcal{V}|$ is the vocabulary size. Inspired by the plug-and-play method (Pascual et al., 2021) in the field of controlled text generation (Dathathri et al., 2020; Pascual et al., 2021), we introduce an additional probability distribution over the vocabulary to better generate constrained tokens:

$$\begin{aligned}&P_{\text{plug}}(y|\mathbf{y}_{<t}, \mathbf{x}, \mathbf{s}, \mathbf{t}; \boldsymbol{\theta})\\ &= \begin{cases} 0 & y \notin \mathbf{t} \\ \max\left(0, \cos\left(\frac{\mathbf{w}_y}{|\mathbf{w}_y|}, \frac{\mathbf{h}_t}{|\mathbf{h}_t|}\right)\right) & y \in \mathbf{t} \end{cases},\end{aligned} \tag{12}$$

where $\mathbf{w}_y \in \mathbf{R}^{d\times 1}$ is the word embedding of token y and $\mathbf{t}$ is the sequence of all the target-side constrained tokens. We also use a gating sub-layer to control the strength of the additional probability:

$$\begin{aligned}&g(y, \mathbf{h}_t)\\ &= \operatorname{sigmoid}\left(\tanh\left(\left[\mathbf{w}_y^\top \mathbf{W}_1; \mathbf{h}_t^\top \mathbf{W}_2\right]\right) \mathbf{W}_3\right),\end{aligned} \tag{13}$$

where $\mathbf{W}_1 \in \mathbf{R}^{d\times d}$, $\mathbf{W}_2 \in \mathbf{R}^{d\times d}$, and $\mathbf{W}_3 \in \mathbf{R}^{2d\times 1}$ are three trainable linear transformations. The final output probability is given by

$$\begin{aligned}&P(y|\mathbf{y}_{<t}, \mathbf{x}, \mathbf{s}, \mathbf{t}; \boldsymbol{\theta})\\ &\quad= (1 - g(y, \mathbf{h}_t))\, P_{\text{model}}(y|\mathbf{y}_{<t}, \mathbf{x}, \mathbf{s}, \mathbf{t}; \boldsymbol{\theta})\\ &\quad+ g(y, \mathbf{h}_t) P_{\text{plug}}(y|\mathbf{y}_{<t}, \mathbf{x}, \mathbf{s}, \mathbf{t}; \boldsymbol{\theta}).\end{aligned} \tag{14}$$

3.3 Training and Inference

Training The proposed constraint-aware NMT model should not only generate pre-specified constraints but also maintain or improve the translation quality compared with vanilla NMT models. We thus propose to distinguish between constraint tokens and constraint-unrelated tokens during training. Formally, the training objective is given by

$$\begin{aligned}&L(\mathbf{y}|\mathbf{x}, \mathbf{s}, \mathbf{t}; \boldsymbol{\theta})\\ &\quad= \alpha \sum_{y_t \in \mathbf{y}\cap\mathbf{t}} \log P(y_t|\mathbf{y}_{<t}, \mathbf{x}, \mathbf{s}, \mathbf{t}; \boldsymbol{\theta})\\ &\quad+ \beta \sum_{y_t \in \mathbf{y}\setminus\mathbf{t}} \log P(y_t|\mathbf{y}_{<t}, \mathbf{x}, \mathbf{s}, \mathbf{t}; \boldsymbol{\theta}),\end{aligned} \tag{15}$$

where α and β are hyperparameters to balance the learning of constraint generation and translation.

We can divide the parameter set of the whole model into two subsets: $\boldsymbol{\theta} = \boldsymbol{\theta}_v \cup \boldsymbol{\theta}_c$, where $\boldsymbol{\theta}_v$

is a set of original vanilla model parameters and $\boldsymbol{\theta}_c$ is a set of newly-introduced parameters that are used to vectorize and integrate lexical constraints.[2] Since $\boldsymbol{\theta}_c$ is significantly smaller than $\boldsymbol{\theta}_v$, it requires much less training iterations. Therefore, we adopt the strategy of two-stage training (Tu et al., 2018; Zhang et al., 2018) for model optimization. Specifically, we optimize $\boldsymbol{\theta}_v$ using the standard NMT training objective (Bahdanau et al., 2015; Vaswani et al., 2017) at the first stage and then learn the whole model $\boldsymbol{\theta}$ at the second stage. The second stage is significantly shorter than the first stage, we will give more details in Section 4.1.

Inference As discussed in Section 2, the inference process is composed of two sub-processes: probability estimation and candidate selection. In this work, we aim to improve the probability estimation sub-process and our method is orthogonal to constrained decoding algorithms (Hokamp and Liu, 2017; Post and Vilar, 2018; Hu et al., 2019), which instead focus on candidate selection. Therefore, we can employ not only beam search but also constrained decoding algorithms at inference time. We use VDBA (Hu et al., 2019) as the default constrained decoding algorithm, which supports batched inputs and is significantly faster than most other counterparts (Hokamp and Liu, 2017; Post and Vilar, 2018; Hasler et al., 2018).

4 Experiments

4.1 Setup

Training Data In this work, we conduct experiments on Chinese⇔English (Zh⇔En) and German⇔English (De⇔En) translation tasks. For Zh⇔En, the training set contains 1.25M sentence pairs from LDC[3]. For De⇔En, the training set is from the WMT 2014 German⇔English translation task, which consists of 4.47M sentence pairs. We apply BPE (Sennrich et al., 2016b) with 32K joint merge operations for both Zh⇔En and De⇔En.

Evaluation Data Following Chen et al. (2021b), we evaluate our approach on the test sets with human-annotated alignments, which are widely used in related studies (Chen et al., 2020b, 2021a). We find the alignment test sets have significant overlaps with the corresponding training sets, which is not explicitly stated in previous works. In this work, we remove the training examples that are covered by the alignment test sets. For Zh⇔En, we use the alignment datasets from Liu et al. (2005)[4], in which the validation and test sets both contain 450 sentence pairs. For De⇔En, we use the alignment dataset from Zenkel et al. (2020)[5] as the test set, which consists of 508 sentence pairs. Since there is no human-annotated alignment validation sets for De⇔En, we use `fast-align`[6] to annotate the newstest 2013 as the validation set for De⇔En.

Lexical Constraints In real-world applications, lexical constraints are usually provided by human translators. We follow Chen et al. (2021b) to simulate the practical scenario by sampling constraints from the phrase pairs that are extracted from parallel data using alignments. The script for phrase pair extraction is publicly available.[7] For the validation and test sets of Zh⇔En and the test set of De⇔En, we use human-annotated alignments to extract phrase pairs. For the training corpora in both Zh⇔En and De⇔En, we use `fast-align` to firstly learn an alignment model and then use the model to automatically annotate the alignments. The validation set of De⇔En is also annotated by the alignment model learned on the corresponding training corpus. We use the same strategy as Chen et al. (2021b) to sample constraints from the extracted phrase pairs. More concretely, the number of constraints in each sentence is up to 3. The length of each constrained phrase is uniformly sampled among 1 and 3. For each sentence pair, all the constraint pairs are shuffled and then supplied to the model in an unordered manner.

Model Configuration We use the base setting (Vaswani et al., 2017) for our model. Specifically, the hidden size d is 512 and the depths of both the encoder and the decoder are 6. Each multi-head attention module has 8 individual attention heads. Since our method introduces additional parameters, we use a larger model with an 8-layer encoder and an 8-layer decoder to assimilate the

---

[2] $\boldsymbol{\theta}_c$ includes parameters of the attention presented in Eq (3), the adaptation networks described in Eq (6) and (9), and the gating sub-layer illustrated in Eq (13).

[3] The total training set for Zh⇔En is composed of LDC2002E18, LDC2003E07, LDC2003E14, part of LDC2004T07, LDC2004T08 and LDC2005T06.

Table 1: Results on lexically constrained test sets. "*Z→E*" denotes Zh→En, and "*D→E*" denotes De→En. The **best BLEU** in each column is highlighted in bold, and "$\star$" indicates no significant difference with the method achieving the best BLEU. The *best CSR* in each column is italicized.

parameter count for the baselines. For Zh⇔En, we optimize $\boldsymbol{\theta}_v$ for 50K iterations at the first stage and then optimize $\boldsymbol{\theta}$ for 10K iterations at the second stage. For a fair comparison, we train the baselines for 60K iterations in total. For De⇔En, we optimize $\boldsymbol{\theta}_v$ for 90K iterations then optimize $\boldsymbol{\theta}$ for 10K iterations. The baselines are trained for 100K iterations. All the involved models are optimized by Adam (Kingma and Ba, 2015), with $\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\epsilon = 10^{-9}$. The dropout rate is set to 0.3 for Zh⇔En and 0.1 for De⇔En. Label smoothing is employed and the smoothing penalty is set to 0.1 for all language pairs. We use the same learning rate schedule as Vaswani et al. (2017). All models are trained on 4 NVIDIA V100 GPUs and evaluated on 1 NVIDIA V100 GPU. During training, each mini batch contains roughly 32K tokens in total across all GPUs. We set the values of α and β based on the results on the validation set. Specifically, for models using VDBA, we set $\alpha = \beta = 0.5$, while for models using beam search, we set $\alpha = 0.8$ and $\beta = 0.2$. The beam size is set to 4 during inference.

Baselines We compare our approach with three representative baselines:

- *VDBA* (Hu et al., 2019): dynamically devoting part of the beam for constraint-related hypotheses at inference time;
- *Replace* (Song et al., 2019): directly replacing source constraints in the training data with their corresponding target constraints. The model is also improved with pointer network;
- *CDAlign* (Chen et al., 2021b): explicitly using an alignment model to decide the position to insert target constraints during inference.

Evaluation Metrics We evaluate the involved methods using the following two metrics:

- *BLEU*: we use sacreBLEU[8] (Post, 2018) to report the BLEU score;
- *Copying Success Rate (CSR)*: We follow Chen et al. (2021b) to use the percentage of constraints that are successfully generated in the translation as the CSR, which is calculated at word level after removing the BPE separator.

We use `compare-mt` (Neubig et al., 2019) for significance testing, with $\text{bootstrap} = 1000$ and $\text{prob\_thresh} = 0.05$.

4.2 Main Results

Table 1 shows the results of lexically constrained translation on test sets of all four translation tasks. All the investigated methods can effectively improve the CSR over the vanilla Transformer. The CSR of VDBA on Zh⇔En is not 100.0% for the reason that some target constraints contain out-of-vocabulary tokens. Replace (Song et al., 2019) achieves better BLEU scores on three translation directions (i.e., Zh⇔En and En→De) than VDBA, but its CSR is much lower. CDAlign (Chen et al., 2021b) also performs better than Replace on average regarding CSR. Our method consistently outperforms all the three baselines across the four translation directions in terms of BLEU, demonstrating the necessity of integrating vectorized constraints into NMT models. Decoding with VDBA, we also achieve the highest CSR. To disentangle the effect of integrating vectorized constraints and

VDBA, we also report the result of our model using beam search in Table 2. Decoding with beam search, our model can also achieve a better BLEU score than the baselines and the CSR is higher than both Replace and CDAlign on average.

4.3 Ablation Study

We investigate the effect of different components through an ablation study, the results are shown in Table 3. We find that only integrating lexical constraints into attention can significantly improve the CSR over the vanilla model (91.5% vs. 25.5%), which is consistent with our motivation that the correspondence between keys and values is naturally suitable for modeling the relation between source and target constraints. Plugging target constraints into the output layer can further improve the performance, but the output plug-in itself can only generate 61.9% of constraints. When decoding with VDBA, combining both the two types of integration achieves the best BLEU score, indicating that every component is important for the model to translate with constraints.

4.4 Code-Switched Translation

Task Description and Data Preparation An interesting application of lexically constrained machine translation is code-switched translation, of which the output contains terms across different languages. Figure 1 shows an example of code-switched translation, where the output Chinese sentence should include the English token "Beatles". Code-switched machine translation is important in many scenarios, such as entity translation (Li et al., 2018) and the translation of sentences containing product prices or web URLs (Chen et al., 2021b). In this work, we evaluate the performance of several approaches on code-switched machine translation. The parallel data and extracted constraint pairs for each language pair are the same as those used in the lexically constrained translation task. To construct the training and evaluation data for code-switched translation, we randomly replace 50% of the target constraints with their corresponding source constraints. The target sentence is also switched if it contains switched target constraints.

Method	**BLEU**

w/o VDBA	96.1	94.6	97.6	95.8

(b) CSR on code-switched test sets.

Table 4: Results on the code-switched translation task.

Results Table 4 gives the results of the code-switched translation task. The CSR of Replace (Song et al., 2019) is lower than 50% across all the four translation directions, indicating that simply replacing the training data can not handle the code-switched translation. A potential reason is that it is difficult for the NMT model to decide whether to translate or copy some source phrases in the input sentence. Surprisingly, VDBA, CDAlign,

Method	Batch Size (# Sent.)	
	1	128
Vanilla	1.0×	43.2×
VDBA	0.5×	2.1×

and our method all perform well in this scenario, and our method outperforms the two baselines. These results suggest the capability of our method to cope with flexible types of lexical constraints.

5 Discussion

5.1 Inference Speed

We report the inference speed of each involved approach in Table 5. The speed of Replace is close to that of the vanilla Transformer, but its CSR is much lower than other methods. Since the open-sourced implementation of CDAlign[9] does not support batched decoding, we compare our method with CDAlign with $\text{batch\_size} = 1$. The speed of our method using beam search is faster than that of CDAlign (0.9×vs. 0.7×). When provided with batched inputs, our method can slightly speed up VDBA (2.3×vs. 2.1×). A potential reason is that the probability estimated by our model is more closely related to the correctness of the candidates, making target constraints easier to find.

5.2 Calibration

To validate whether the probability of our model is more accurate than vanilla models, we follow Wang et al. (2020) to investigate the gap between the probability and the correctness of model outputs, which is measured by the inference expected calibration error (ECE). As shown in Table 6, the inference ECE of our method is much lower than that of the vanilla model, indicating that the probability of our model is more accurate than vanilla models. To better understand the calibration of our model and the baseline model, we also estimate the average probability of all the predicted tokens and the constrained tokens. The results show that our model assigns higher probabilities to constrained tokens, which are already known to be correct.

Z→E	*E→Z*	*D→E*	*E→D*	*Avg.*
38.9%	43.4%	27.7%	32.2%	35.6%

Table 7: Overlap ratio of lexical constraints between training and test sets across the four directions.

5.3 Memory vs. Extrapolation

To address the concern that the proposed model may only memorize the constraints seen in the training set, we calculate the overlap ratio of constraints between training and test sets. As shown in Table 7, we find that only 35.6% of the test constraints are seen in the training data, while the CSR of our model decoding with beam search is 94.4%. The results indicate that our method extrapolates well to constraints unseen during training.

5.4 Case Study

Table 8 shows some example translations of different methods. We find Replace tends to omit some constraints. Although VDBA and CDAlign can successfully generate constrained tokens, the translation quality of the two methods is not satisfying. Our result not only contains constrained tokens but also maintains the translation quality compared with the unconstrained model, confirming the necessity of integrating vectorized constraints into NMT models.

6 Related Work

6.1 Lexically Constrained NMT

One line of approaches to lexically constrained NMT focuses on designing advanced decoding algorithms (Hasler et al., 2018). Hokamp and Liu (2017) propose *grid beam search* (GBS), which enforces target constraints to appear in the output by

Table 8: Example translations of different lexically constrained NMT approaches.

enumerating constraints at each decoding step. The beam size required by GBS varies with the number of constraints. Post and Vilar (2018) propose *dynamic beam allocation* (DBA) to fix the problem of varying beam size for GBS, which is then extended by Hu et al. (2019) into VDBA that supports batched decoding. There are also some other constrained decoding algorithms that leverage word alignments to impose constraints (Song et al., 2020; Chen et al., 2021b). Although the alignment-based decoding methods are faster than VDBA, they may be negatively affected by noisy alignments, resulting in low CSR. Recently, Susanto et al. (2020) adopt Levenshtein Transformer (Gu et al., 2019) to insert target constraints in a non-autoregressive manner, for which the constraints must be provided with the same order as that in the reference.

Another branch of studies proposes to edit the training data to induce constraints (Sennrich et al., 2016a). Song et al. (2019) directly replace source constraints with their target translations and Dinu et al. (2019) insert target constraints into the source sentence without removing source constraints. Similarly, Chen et al. (2020a) propose to append target constraints after the source sentence.

In this work, we propose to integrate vectorized lexical constraints into NMT models. Our work is orthogonal to both constrained decoding and constraint-oriented data augmentation. A similar work to us is that Li et al. (2020) propose to use continuous memory to store only the target constraint, which is then integrated into NMT models through the decoder self-attention. However, Li et al. (2020) did not exploit the correspondence between keys and values to model both source and target constraints.

6.2 Controlled Text Generation

Recent years have witnessed rapid progress in controlled text generation. Dathathri et al. (2020) propose to use the gradients of a discriminator to control a pre-trained language model to generate towards a specific topic. Liu et al. (2021) propose a decoding-time method that employs experts to control the generation of pre-trained language models.

We borrow the idea presented in Pascual et al. (2021) to insert a plug-in into the output layer. The difference between our plug-in network and Pascual et al. (2021) is that we use an input-dependent gate to control the effect of the plugged probability.

7 Conclusion

In this work, we propose to vectorize and integrate lexical constraints into NMT models. Our basic idea is to use the correspondence between keys and values in attention modules to model constraint pairs. Experiments show that our approach can outperform several representative baselines across four different translation directions. In the future, we plan to vectorize other attributes, such as the topic, the style, and the sentiment, to better control the generation of NMT models.

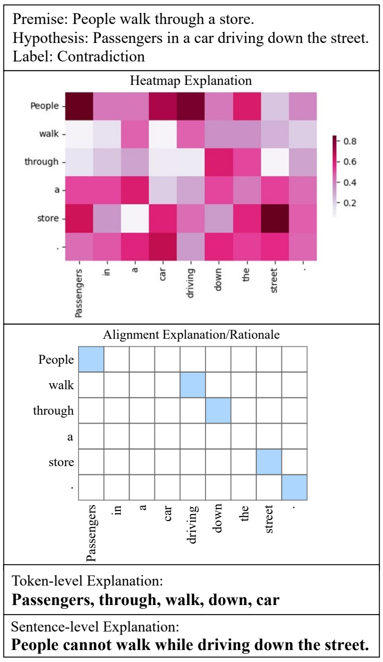
Abstract

In order to better understand the rationale behind model behavior, recent works have exploited providing interpretation to support the inference prediction. However, existing methods tend to provide human-unfriendly interpretation, and are prone to sub-optimal performance due to one-side promotion, i.e. either inference promotion with interpretation or vice versa. In this paper, we propose a multi-level **M**utual **P**romotion mechanism for self-evolved **I**nference and sentence-level **I**nterpretation (MPII). Specifically, from the model-level, we propose a Step-wise Integration Mechanism to jointly perform and deeply integrate inference and interpretation in an autoregressive manner. From the optimization-level, we propose an Adversarial Fidelity Regularization to improve the fidelity between inference and interpretation with the Adversarial Mutual Information training strategy. Extensive experiments on NLI and CQA tasks reveal that the proposed MPII approach can significantly outperform baseline models for both the inference performance and the interpretation quality.[1]

1 Introduction

Recently, the interpretability of neural networks has been of increasing concern. In order to break the black-box of neural networks, many works explore the interpretability of neural networks through providing interpretations to support their inference results (Ribeiro et al., 2016; Chen et al., 2018; Liu et al., 2019; Thorne et al., 2019; Kumar and Talukdar, 2020).

Although prior works have made some progress towards interpretable NLP, they tend to provide interpretations that lack human-readability. Existing interpretable models usually extract prominent features or select input key words as explanations, such as attention distribution (Xu et al., 2015), heatmap (Samek et al., 2017), alignment rationale (Jiang et al., 2021), gradients (Li et al., 2016), magnitude of hidden states (Linzen et al., 2016), etc. Considering readability and comprehensibility for humans, some works turn to generate token-level explanations (Liu et al., 2019; Thorne et al., 2019), which are nevertheless prone to cause ambiguity. Figure 1 shows some prevalent forms of interpretations in NLI task. Obviously, human language interpretations seem more acceptable than those chaotic maps, whether it is heatmap or alignment map. As for the token-level interpretation, several discrete tokens without any logical links are vague and ambiguous. Moreover, Thorne et al. (2019) observed that token-level methods tend to predict common tokens (e.g. people, man, dog)



Premise: People walk through a store.
Hypothesis: Passengers in a car driving down the street.
Label: Contradiction

Token-level Explanation:
Passengers, through, walk, down, car

Sentence-level Explanation:
People cannot walk while driving down the street.

Figure 1: Comparison of different interpretations: heatmap explanation, alignment rationale, token-level NL explanation, and sentence-level NL explanation.

rather than keywords. Intuitively, human language sentence-level interpretations containing reasoning logic are the best form for human to understand.

With annotated natural language interpretation datasets available (Camburu et al., 2018; Rajani et al., 2019), methods of generating sentence-level interpretation have been explored recently. Camburu et al. (2018) proposed to first generate interpretation and then predict the label only based on the generated interpretation. Kumar and Talukdar (2020) proposed to first generate sentence-level interpretations with deep pre-trained language models (such as BERT and GPT), then fed those interpretations as extra knowledge to help improve inference performance. We notice that these methods only include one-side promotion: utilizing information contained in interpretation to improve inference, while ignoring the other-side promotion: using inference logic to enhance interpretation. As claimed in Kumar and Talukdar (2020) that their one-side promotion improves predictions' faithfulness to generated interpretations, then the other-side should be able to improve interpretation's faithfulness to inference process. This has aroused our thinking: *Can we deeply fuse these two relevant tasks with ingenious combination skills and achieve mutual promotion for inference and interpretation?*

In this paper, we propose a multi-level Mutual Promotion mechanism for self-evolved Inference and sentence-level Interpretation (MPII). Specifically, from the model-level, we propose a Stepwise Integration Mechanism (SIM) to iteratively update the inference prediction and generate an interpretation token at each decoding step, and deeply integrate hidden representations of the prediction and the token with two fusion modules. In this way, the model learns to refine the inference conclusion as the interpretation proceeds, and the inference procedure can in turn guide the generation of interpretation at each decoding step. From the optimization-level, we propose an Adversarial Fidelity Regularization (AFiRe) to improve the fidelity between inference and interpretation with the Adversarial Mutual Information (AMI) method (Pan et al., 2020), which extends the maximum mutual information optimization objective with the idea of generative adversarial network (Goodfellow et al., 2014). With this training framework, the model is trained against a smart backward network that learns to reward the inference prediction and interpretation of fidelity, which ensures faithfulness and makes the derived interpretation depict the true profile of how the model works (Jiang et al., 2021).

To verify the effectiveness of MPII, we conduct extensive experiments on two inference tasks: Natural Language Inference (NLI) task and Commonsense Question Answering (CQA) task. Experiment results reveal that compared with baseline models, our method can achieve mutual promotion on both model inference performance and sentence-level interpretation quality. Meanwhile, through providing simultaneous inference prediction and human-comprehensible interpretation with deep integration mechanism and adversarial training strategy, our model can perform inference and interpretation of fidelity and generate more robust explanations. Main contributions of this work include:

- Different from the previous works that only include one-side promotion, we mutually promote the inference and sentence-level interpretation from both the model-level and the optimization-level.
- We propose a Stepwise Integration Mechanism to tightly fuse latent prediction and interpretation information at every decoding step, and an Adversarial Fidelity Regularization to further improve the fidelity with the adversarial training strategy.
- Experiment results show that our method achieves significant improvement in both inference accuracy and interpretation quality compared with baseline models.

2 Methodology

In this section, we introduce Stepwise Integration Mechanism (SIM) and Adversarial Fidelity Regularization (AFiRe) in details. Utilizing the autoregressive nature of Transformer decoder, SIM enables deep interaction at every decoding step between inference and interpretation. With the adversarial training strategy, AFiRe enables further integration of latent semantic information between inference and interpretation, and also improves the quality of explanation sentences by bringing them closer to human expressions.

2.1 Task Description

Transformer model (Vaswani et al., 2017) has been firmly established as the dominant approach in text generation tasks, we therefore adopt the Transformer model as backbone. Given a sequence of tokens as input $\mathbf{X} = \{x_0, x_1, ..., x_m\}$ (e.g. for NLI:

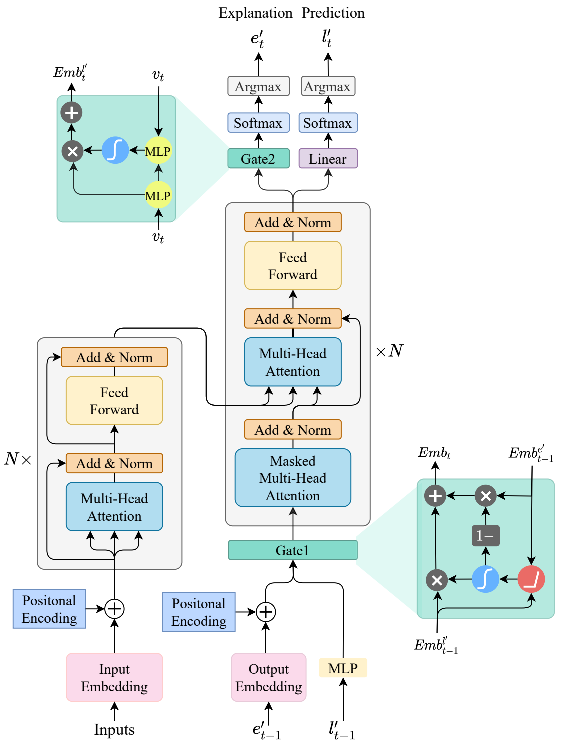

Figure 2: The overall architecture of our model. Both prediction label and explanation token are generated at every decoding step. Two fusion gates are attached to enable deep interaction of their hidden representations.

$\mathbf{X}$ = {[CLS] + Premise + [SEP] + Hypothesis}, for CQA: $\mathbf{X}$ = {[CLS] + Question + [SEP] + Answers}), Transformer encoder produces a sequence of continuous vectors $\mathbf{H}_{enc}$. Conditioned on $\mathbf{H}_{enc}$, on each decoding step, Transformer decoder takes the embedding of words generated by previous steps as input and predicts the word for current step.

With ground truth prediction $\mathbf{L}$ and explanation $\mathbf{E}$ from human-annotated dataset, the interpretable model is required to generate prediction $\mathbf{L}'$ and explanation sentence $\mathbf{E}' = \{e'_0, e'_1, ..., e'_n\}$ simultaneously.

2.2 Stepwise Integration Mechanism

Prevalent interpretable models share the same encoder and separately adopt a MLP and a decoder to generate predictions and explanations. We analogously adopt the standard Transformer encoder, but apply Stepwise Integration Mechanism to deeply integrate standard MLP and Transformer decoder at every decoding step to simultaneously produce predictions and explanations.

As depicted in Figure 2, at decoding step t, decoder takes the last generated token e'_{t-1} and the predicted label l'_{t-1} at previous step as input. At the first decoding step, we pass the encoder hidden state corresponding to [CLS] token into MLP to get the l'_0. We project the label l'_{t-1} with Multi-Layer Perceptrons (MLP) and obtain $\mathbf{v}^p_{t-1}$, which represents the previous step prediction information. We then fuse the prediction information $\mathbf{v}^p_{t-1}$ and the explanation token e'_{t-1} with gate mechanism. The gate probability at t step is computed by:

$$p'_t = \mathrm{ReLU}(\mathbf{W}_1 \, [\mathbf{Emb}^{l'}_{t-1}; \mathbf{Emb}^{e'}_{t-1}] + \mathbf{b}_1) \quad (1)$$

$$p_t = \sigma(\mathbf{W}_2 \, p'_t + \mathbf{b}_2) \quad (2)$$

where ";" means concatenation, $\mathbf{W}_1$, $\mathbf{W}_2$, $\mathbf{b}_1$ and $\mathbf{b}_2$ are trainable parameters. $\mathrm{ReLU}(\cdot)$ here denotes the ReLU activation function (Nair and Hinton, 2010), $\sigma(\cdot)$ represents the sigmoid function. We fuse the prediction and interpretation information as below:

$$\mathbf{Emb}_t = p_t \mathbf{Emb}^{l'}_{t-1} + (1 - p_t)\mathbf{Emb}^{e'}_{t-1} \quad (3)$$

where $\mathbf{Emb}_t$ contains the information of prediction and the overall explanation sub-sequence generated in all previous steps.

We utilize the stack of masked self-attention layers f_{sa} used in Transformer decoder to compute the decoder hidden states:

$$\{\mathbf{h}_0, \mathbf{h}_1, ..., \mathbf{h}_t\} = f_{sa}(\{\mathbf{Emb}_0, \mathbf{Emb}_1, ..., \mathbf{Emb}_t\}) \quad (4)$$

The attention vector referring to the source sequence is computed with multi-head attention:

$$\mathbf{v}_t = f_{mha}(\mathbf{H}_{enc}, \mathbf{h}_t) \tag{5}$$

where $\mathbf{H}_{enc}$ represents the encoder hidden states, f_{mha} denotes the multi-head attention module. The $\mathbf{v}_t$ is further passed into a fully connected layer followed with $softmax$ function to obtain the vocabulary distribution of generated explanation token e'_t at t step:

$$e'_t = argmax(softmax(\mathbf{W}\mathbf{v}_t + \mathbf{b})) \tag{6}$$

where $\mathbf{W}$ and $\mathbf{b}$ are both trainable parameters.

The gate mechanism is then used to integrate the explanation information to update the prediction information:

$$p_t = \sigma(\mathrm{MLP}_1([\mathbf{Emb}^{l'}_{t-1}; \mathrm{MLP}_2(\mathbf{v}_t)])) \tag{7}$$

where the two $\mathrm{MLP}(\cdot)$ use different parameters.

$$\mathbf{Emb}^{l'}_t = \mathbf{Emb}^{l'}_{t-1} + p_t \mathrm{MLP}_3(\mathbf{v}_t) \tag{8}$$

We apply the residual connection (He et al., 2016) here, which is easier to optimize in the scenario of many decoding steps. This is similar to the gate mechanism used in Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) that learns to remember important information obtained on each decoding step. At the last decoding step, the model deduces the eventual decision:

$$L' = argmax(softmax(\mathbf{Emb}^{l'}_n)) \tag{9}$$

where n is the length of the generated explanation $\mathbf{E}'$. With this setting, both prediction and explanation are updated at every decoding step. The step-by-step explanation helps the model to do better inference, and the stepwise inference in turn guides the generation of better explanation.

2.3 Adversarial Fidelity Regularization

From the level of optimization objective, we further introduce the Adversarial Fidelity Regularization (AFiRe) to improve the fidelity of inference and interpretation. We leverage the Adversarial Mutual Information (AMI) method (Pan et al., 2020) to extend the maximum mutual information objective among input, inference prediction and the generated explanation with the idea of generative adversarial network (Goodfellow et al., 2014).

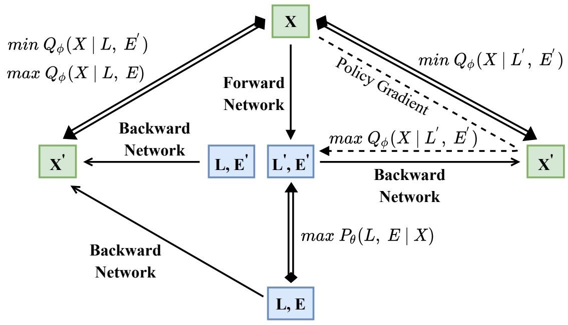

Figure 3: The overview of Adversarial Fidelity Regularization.

Compared to the maximum likelihood estimation (MLE) objective, maximum mutual information (MMI) objective encourages the model to generate the prediction and explanation that are more faithful to the input (Kinney and Atwal, 2014; Stratos, 2019). The mutual information $I(X, L, E)$ among the input X, inference label L and explanation E is formulated as:

$$\begin{aligned} I(X, L, E) &= \mathbb{E}_{P(X,L,E)}\left[\log \frac{P(X, L, E)}{P(X)P(L, E)}\right] \\ &= H(X) - H(X|L, E) \end{aligned}$$

where H denotes the entropy.

Because of the intractability of directly estimating the mutual information in high-dimensional space, we approximate the optimization objective with a Variational Information Maximization lower bound (Chen et al., 2016b; Zhang et al., 2018; Poole et al., 2019):

$$\begin{aligned} \mathrm{I(X, L, E)} &= \mathrm{H(X)} + \mathbb{E}_{P(X,L,E)}\left[\log P(X|L, E)\right] \\ &= \mathrm{H(X)} + \mathbb{E}_{P(X,L,E)}\left[\log Q_\phi(X|L, E)\right] \\ &\quad + \mathbb{E}_{P(L,E)}\left[\mathcal{KL}(P(X|L, E)||Q_\phi(X|L, E))\right] \\ &\geq \mathrm{H(X)} + \mathbb{E}_{P(X)}\mathbb{E}_{P_\theta(L,E|X)}\left[\log Q_\phi(X|L, E)\right] \end{aligned}$$

where $\mathcal{KL}(\cdot||\cdot)$ denotes the Kullback-Leibler (KL) divergence between two distributions. $P_\theta(L, E|X)$ and $Q_\phi(X|L, E)$ denote the forward network (generating L, E conditioned on X) and the backward network (generating X conditioned on L, E) respectively.

Since the entropy term $H(X)$ associates with the training data and does not involve the parameters we optimize, the objective of MMI is equivalent as:

$$\max_{\theta,\phi}\ \mathbb{E}_{(L',E')\sim P_\theta(L',E'|X)}\left[\log Q_\phi(X|L', E')\right]$$

where θ and ϕ are the parameters of the forward and backward network respectively. L' and E' represent the synthetic prediction label and explanation generated by the forward network.

With the MMI optimization objective, the backward network is trained with only the synthetic label and explanation produced by the forward network, and prone to sub-optimal performance if the synthetic text is uninformative. Since the the backward network provides a reward for optimizing the forward network, a biased backward network may provide unreliable reward scores and mislead the forward network optimization.

To remedy this problem, we leverage the Adversarial Mutual Information (AMI) method (Pan et al., 2020) to extend MMI with the idea of generative adversarial network (Goodfellow et al., 2014).

Specifically, we first bring the min-max adversarial game into training procedure and add an additional objective term $\mathrm{Q}_{\phi}(X|L, E)$ to maximize the negative likelihood of Q_{ϕ} when feeding it with the real data:

$$\min_{\phi}\max_{\theta}\ \mathbb{E}_{(L',E')\sim P_{\theta}(L',E'|X)}\left[\log\mathrm{Q}_{\phi}(X|L',E')\right]-\mathrm{Q}_{\phi}(X|L,E)$$

With this interactive training strategy and regularizing the backward network with both the synthetic data and real data, the forward network will be trained against a smarter backward network that only rewards prediction and explanation of fidelity.

Besides, we add an objective term $\mathrm{P}_{\theta}(\mathrm{L},\mathrm{E}|X)$ of maximize the negative likelihood of P_{θ} to balance the positive samples as teacher-forcing algorithm (Li et al., 2017). The final optimization objective is formulated as:

$$\min_{\phi}\max_{\theta}\ \mathrm{P}_{\theta}(\mathrm{L},\mathrm{E}|X)+\underbrace{\overbrace{\mathbb{E}_{(L',E')\sim P_{\theta}(L',E'|X)}\left[\log\mathrm{Q}_{\phi}(X|L',E')\right]}^{\text{Mutual Information}}-\mathrm{Q}_{\phi}(X|L,E)}_{\text{Adversarial Training}}$$

As depicted in Fig 3, to encourage the forward network to learn a stronger connection between generated explanations and model predictions, we also add $Q_{\phi}(X|L, E')$ as negative samples for backward network. This explicitly encourages the backward network to be capable of punishing the P_{θ} when it generates unfaithful explanations.

3 Experiments

We intend to verify the mutual promotion effect of SIM and AFiRe on the inference ability and interpretablity of model. We choose two tasks requiring inference ability: Natural Language Inference (NLI) and Commonsense Question Answering (CQA).

3.1 Datasets

We use six datasets as our testbeds: **SNLI** (Bowman et al., 2015), **e-SNLI** (Camburu et al., 2018), **CQA** (Talmor et al., 2019), **CoS-E** (Rajani et al., 2019), **MultiNLI** (Williams et al., 2018), and **SICK-E** (Marelli et al., 2014).

SNLI is a standard benchmark for NLI task, while e-SNLI extends it with human-annotated natural language explanations for each sentence pair. CoS-E[2] dataset extends CQA dataset with natural language explanations for each QA sample. MultiNLI is another large-scale NLI corpus, which includes a diverse range of genres. SICK-e (Sentences Involving Compositional Knowledge for entailment) provides sentence pairs that are rich in the lexical, syntactic and semantic phenomena. The latter two datasets are used for out-of-domain evaluation.

3.2 Baselines

NLI: We use e-INFERSENT and Transformer as two baseline models for NLI task. The e-INFERSENT model adds a LSTM decoder into INFERSENT (Conneau et al., 2017) for explanations. The classification module and the explanation generation module are separated but share the same encoder. The Transformer model (Vaswani et al., 2017) adds a MLP layer for making predictions. With this baseline, we aim to test whether vanilla transformer without further interaction can achieve good results.

CQA: We use CAGE (Rajani et al., 2019) as the baseline model for CQA task. CAGE adopts the explain-then-predict approach, which firstly finetunes a deep pretrained language model GPT (Radford et al., 2019) to generate explanations, then use a classifier to predict the inference label with the generated explanation and source text as the input.

3.3 Metrics

To evaluate inference performance, we report **Task-specific Accuracy** (NLI Accuracy and CQA Accuracy). To evaluate the quality of generated interpretation, we report **BLEU** (similarity between generation and ground truth), **PPL** (fluency of generated sentences), and **Inter Repetition** (diversity of generated explanations).

3.4 Main Results

Table 1 shows automatic evaluation results on the SNLI and CQA datasets with the annotated explanation from the e-SNLI and CoS-E datasets. Compared with the baseline models, our MPII method can achieve significant performance improvement for both the inference and interpretation on two tasks. It indicates that the inference and interpretation process can be mutually promoted with our proposed method. With the ablation study, we notice a performance degradation of the inference and interpretation if we remove either of them, demonstrating the faithfulness between the generated explanation and the model's prediction.

Inference Promotion: We can achieve 11.73 and 2.06 absolute inference accuracy improvements compared to the baselines for the NLI and CQA task, respectively. For the NLI task, with our MPII framework, the Transformer baseline model can improve over 5 absolute accuracy score. The ablation study shows the contribution comes from not only the mutual interaction of inference and interpretation in the Stepwise Integration Mechanism (SIM), but also the adversarial mutual information training objective introduced in the Adversarial Fidelity Regularization (AFiRe). Moreover, with parameters initialized with the pretrained BART model, the accuracy can be further improved by a 4.53 absolute score. For the CQA task, we observe that better performance is still achieved compared with the CAGE baseline model. If we remove the AFiRe, a significant inference degradation would be witnessed. It also indicates the effectiveness of AFiRe for utilizing interpretability to improve the inference ability.

Transformer	55.92	53.21
Transformer + MPII (w/o AFiRe)	56.42	53.84
Transformer + MPII	**58.73**	**56.54**

Table 2: Out-of-domain NLI evaluation results on MultiNLI and SICK-E datasets.

Interpretation Promotion: The quality of generated interpretation can also be significantly improved with our mutual promotion method on both NLI and CQA tasks. For the NLI task, combined with our MPII, the Transformer baseline model can provide more accurate, fluent and diverse interpretation with much better results in all metrics. Similar with the inference results, the ablation study shows that both SIM and AFiRe contribute to the performance improvement. With the pretrained BART model, we further improve the BLEU and Inter-Rep performance and get comparable PPL compared with the e-INFERSENT model. For the CQA task, our method performs better in terms of BLEU score and the diversity of generated explanations. We notice that the BLEU scores are pretty low for CQA task, which may stem from the free form of expression for explanations in the dataset, i.e. several different explanations share the same

commonsense knowledge. We observe that most of the explanations generated by our method are reasonable enough to interpret the predictions even though the BLEU scores are low. Our method also achieves a smaller Inter-Rep score, which shows that our model can provide more diverse explanations to reveal the inference process of making predictions.

3.5 Out-of-Domain Evaluation

As shown in Table 2, we evaluate our method with the Transformer baseline model on two out-of-domain datasets: MultiNLI and SICK-E. The results show that our mutual promotion method enables the Transformer model to be more robust, and achieves about 3 absolute accuracy improvement on both of the out-of-domain datasets without fine-tuning. It is because with our MPII method, the model can generate more reliable and domain-related interpretation, which helps to make more accurate inference prediction. The ablation results demonstrate both the adversarial mutual information training strategy in AFiRe and deep integration in SIM is very effective to improve the model's generalization and robustness.

3.6 Fidelity Evaluation

We propose a model-based evaluation metric *Critic-Score* to evaluate the fidelity between model's inference predictions and interpretations. Inspired by Shen et al. (2017), which applied a trained model to automatically evaluate the text style transfer accuracy in the absence of parallel dataset, we pre-train a well-performed discriminator model to evaluate the fidelity between the predicted label and the generated explanation.

The discriminator is a binary classifier $f : (X, L, E) \mapsto$ Yes/No , which shares similar architecture with the backward network in our Adversarial Fidelity Regularization (Section 2.3). The training dataset is constructed based on the e-SNLI and CoS-E corpus. Given a sample $\langle X_i, L_i, E_i \rangle$ on e-SNLI that serves as a positive sample, we build the negative sample as $\langle X_i, L_i, E_j \rangle$, where explanation $E_j \neq E_i$ is selected from another e-SNLI sample that shares either the same premise or hypothesis. With this dataset, the discriminator model is trained to learn the intrinsic fidelity between the label and its corresponding explanation. The trained discriminator achieves 97% accuracy on its test set and is able to serve as a quantitative way of evaluating fidelity.

As shown in Table 3, with our proposed mutual promotion method, the Transformer model can achieve significant improvement on Critic-Score between prediction and explanation. The ablation results confirm both the deep interaction design in Stepwise Integration Mechanism and the adversarial training strategy in Adversarial Mutual Information can contribute to the improvement of fidelity and faithfulness.

Input X**:** the premise is : a statue at a museum that no seems to be looking at , while the hypothesis is : the statue is offensive and people are mad that it is on display .
Choices: (0) entailment, (1) neutral, (2) contradiction.

Method	Prediction	Explanation
Human:	(1)	not all statues are ignored because they are offensive .
e-INFERSENT:	(0)	people is _end_ .
MPII (w/o AFiRe):	(1)	just because a statue at a museum that no seems to be looking at does n't imply the statue is offensive and people are mad .
MPII:	(1)	a statue that no seems to be looking at it does not imply the statue is offensive or people are mad .

Input X**:** the premise is : a young family enjoys feeling ocean waves lap at their feet . while the hypothesis is : a family is out at a restaurant .
Choices: (0) entailment, (1) neutral, (2) contradiction.

Method	Prediction	Explanation
Human:	(2)	one says the family is inside the restaurant , while the other says they are feeling ocean waves .
e-INFERSENT:	(2)	a family can not be enjoying their feet out at a restaurant and at the same time
MPII (w/o AFiRe):	(2)	the family can not be at the beach and at a restaurant at the same time .
MPII:	(2)	the family can not be feeling ocean waves and be at a restaurant at the same time .

Table 4: Examples randomly selected from the test set of e-SNLI. "Human" here represents the explanations from dataset. Blue and red indicate good and bad explanations respectively, except for those provided by human.

Input X**:** what do people aim to do at work ?
Choices: (0) complete job, (1) learn from each other, (2) kill animals, (3) wear hats (4) talk to each other.

Method	Prediction	Explanation
Human:	(0)	people aim to complete job in work .
CAGE:	(2)	people aim to kill animals .
BART + MPII (w/o AFiRe):	(0)	people want to complete job .
BART + MPII:	(0)	what people aim to do at work is to complete job .

Input X**:** the lock kept the steering wheel from moving, but the thief still took his chances and began to work on the what ?
Choices: (0) keep cloesd, (1) train, (2) ignition switch, (3) drawer, (4) firearm.

Method	Prediction	Explanation
Human:	(2)	it was more safe .
CAGE:	(0)	the lock kept the steering wheel from moving, but the door kept the door from moving .
BART + MPII (w/o AFiRe):	(2)	the lock kept the steering wheel from moving ignition switch .
BART + MPII:	(2)	the ignition switch is the only thing that would work on a car .

Table 5: Randomly selected examples in CQA task. "Human" here represents the explanations from dataset. Blue and red indicate good and bad explanations respectively, except for those provided by human. Predicted label is presented in the parentheses.

3.7 Analysis

Mutual Promotion Visualization: Figure 4 demonstrates the evolution of the inference prediction as the interpretation proceeds. The input of the model is "[CLS] a couple standing on what looks like a peer or boardwalk [SEP] a couple hugging each other at the park", of which the ground truth label is "contradiction". We observe that the model draws an initial conclusion that the entailment relationship between the premise and the hypothesis is not "entailment", and is not able to tell whether it is "neutral" or "contradiction". As the deliberation proceeds, our model comes to judge that it is "contradiction" with the generated interpretation "a park does not have a peer or boardwalk". From the clear split of the red and blue lines when "does" and "not" are generated, we can see that the prediction is very sensitive to explanation, which demonstrates the faithfulness (Kumar and Talukdar, 2020).

Semantic Similarity Evaluation of Interpretation: To better evaluate the quality of generated explanations, we also measure the cosine similarity between generated explanations and human annotated explanations. The results are presented in Fig 5. The cosine similarity of our method concentrates on 0.9 and achieves higher scores than CAGE, which demonstrates the effectiveness of our MPII for generating better interpretation that are closer to human expression.

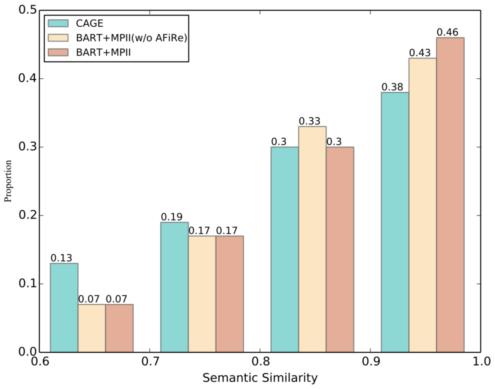

Figure 5: The distribution of cosine similarity with average sentence embedding between human annotation and generated interpretation.

Case Study Table 4 presents examples produced by different models. For the first example, e-INFERSENT fails to make correct prediction and provide reasonable explanation. In contrast, our MPII not only predict the entailment relation correctly, but also produce faithful explanations to

Methods	**Fidelity-C**$^{\uparrow}$	**Fidelity-W**$^{\uparrow}$	**LAcc**$^{\uparrow}$	**Fluency**$^{\uparrow}$
NLI Task				
e-INFERSENT	3.16	2.74	3.34	4.23
Transformer	3.30	3.21	3.65	3.68
Transformer + MPII (w/o AFiRe)	4.01	4.12	4.33	4.36

Table 6: Human evaluation results on Fidelity-C(fidelity between correct prediction and corresponding interpretation), Fidelity-W(fidelity between wrong prediction and corresponding interpretation), LAcc(accuracy of selecting correct lables when only given the generated interpretations), Fluency(fluency of interpretation).

interpret predictions. For the second example, our MPII and MPII with AFiRe removed still capture the entailment relation well, and explain that "at the beach" and "at restaurant" can not be done at the same time. As we can see, these explanations generated by our method are also fluent.

Table 5 shows the randomly selected examples generated by different models in the CQA task. For the first example, CAGE makes wrong prediction, and generates explanation that obviously conflicts with common knowledge. In contrast, our method can make correct predictions and generate more reasonable explanations. Similarly for the second example, CAGE seems to directly copy words from the question that do not actually contain meaningful information. Our MPII still explains well, but fails to explain properly with AFiRe removed, even if the explanation contains the correct answer, which reveals the importance of AFiRe for promotion of interpretation.

Human evaluation: We conduct human evaluation to further evaluate the effectiveness of MPII. We randomly selected 300 examples from the test set of e-SNLI, and asked 4 well-educated annotators to rate every sample with 4 metrics on a 1-5 Likert scale in a strictly blind fashion (Stent et al., 2005). As shown in Table 6, analogous to automatic evaluation results (Section 3.4), our MPII can generate interpretations with best quality and fidelity to corresponding inference predictions, whether correct or wrong.

4 Related Work

With the great success of natual language inference, many recent works explore the interpretability of neural networks through providing interpretation to support their inference results (Ribeiro et al., 2016; Chen et al., 2018; Liu et al., 2019; Thorne et al., 2019; Kumar and Talukdar, 2020). Three forms of interpretation are provided by these works: (1) feature-based interpretation (Chen et al., 2016a, 2018; Ribeiro et al., 2016, 2018; Li et al., 2016; Nguyen, 2018; Feng et al., 2018; Gururangan et al., 2018) such as attention distribution (Xu et al., 2015), heatmap (Samek et al., 2017), alignment rationale (Jiang et al., 2021), gradients (Li et al., 2016), magnitude of hidden states (Linzen et al., 2016), etc.; (2) token-level interpretation that relatively easy to comprehend but prone to ambiguity (Ribeiro et al., 2016; Liu et al., 2019; Thorne et al., 2019), and (3) sentence-level interpretation which has the best human-readability Camburu et al. (2018); Talmor et al. (2019); Kumar and Talukdar (2020). Different from the previous work which only include one-side promotion, we proposed the mutual promotion mechanism that can improve the performance of both inference and sentence-level interpretation.

5 Conclusions

In this work, we propose to mutually promote model inference ability and interpretability from multi-levels. From the model-level, we propose Stepwise Integration Mechanism to enable the model to refine the prediction conclusion as the explaining proceeds and also to guide the generation of better explanation with the inference procedure of reaching prediction conclusion. From the optimization-level, we propose an Adversarial Fidelity Regularization, which leverages the Adversarial Mutual Information method to improve the fidelity between the inference and interpretation, which further guarantees faithfulness. Experiment results show the effectiveness of our proposed method on both NLI and CQA tasks. Future work will involve extending our approaches into other tasks of NLP. We hope that our work can encourage further research in this direction.

Abstract

The Mixture-of-Experts (MoE) technique can scale up the model size of Transformers with an affordable computational overhead. We point out that existing learning-to-route MoE methods suffer from the routing fluctuation issue, i.e., the target expert of the same input may change along with training, but only one expert will be activated for the input during inference. The routing fluctuation tends to harm sample efficiency because the same input updates different experts but only one is finally used. In this paper, we propose **StableMoE** with two training stages to address the routing fluctuation problem. In the first training stage, we learn a balanced and cohesive routing strategy and distill it into a lightweight router decoupled from the backbone model. In the second training stage, we utilize the distilled router to determine the token-to-expert assignment and freeze it for a stable routing strategy. We validate our method on language modeling and multilingual machine translation. The results show that StableMoE outperforms existing MoE methods in terms of both convergence speed and performance. The code is available at `https://github.com/Hunter-DDM/stablemoe`.

1 Introduction

In recent years, large-scale Transformers (Devlin et al., 2019; Dong et al., 2019; Raffel et al., 2020; Clark et al., 2020; Bao et al., 2020; Brown et al., 2020) have shown a striking ability to model languages. However, with the model scale growing, the training speed will go slower, and the extremely large memory requirement also introduces a heavy burden of engineering. Mixture of Experts (MoE) (Jacobs et al., 1991; Jordan and Jacobs, 1994; Shazeer et al., 2017), in a much easier way, enables Transformers to scale up the number of parameters meanwhile introducing an affordable computational overhead. MoE-based Transformers have a set of expert modules, and only a few experts will be activated for each input token. In this way, we can expand the model scale by adding expert modules, which will keep the computational and memory overhead within a tolerable range.

Most existing MoE methods (Lepikhin et al., 2021; Fedus et al., 2021; Lewis et al., 2021) decide the token-to-expert routing according to the dynamically changing token representations. However, we point out that they face the routing fluctuation problem. As shown in Figure 1, the same input may be assigned to different experts along with training. However, during inference, only one expert will be activated for the input. The routing fluctuation problem tends to harm sample efficiency because the same input updates different experts while only one is finally used.

Taking BASE Layer (Lewis et al., 2021) as an example, during the whole training process, we examine the token-to-expert assignment for tokens in the validation set. For an input token, we define the last fluctuation step as the last step where its target expert is different from the final step. We plot the cumulative token percentage with regard to the last fluctuation step (annotated as its percentage accounting for all training steps) in Figure 2. We find that the last fluctuation step of 40.9% tokens exceeds 20%, which means 40.9% tokens do not have a stable target expert when 20% of all training steps have been done. Furthermore, 29.1% tokens still change their target experts after half of the whole training process, and 15.4% tokens even change the target expert after 80% of all training steps, which is nearing the training ending. These statistics prove that the routing fluctuation problem indeed exists in previous MoE methods.

In this paper, we propose **StableMoE** with two training stages to address the routing fluctuation problem. In the first training stage, we follow the learning-to-route paradigm and aim to learn a

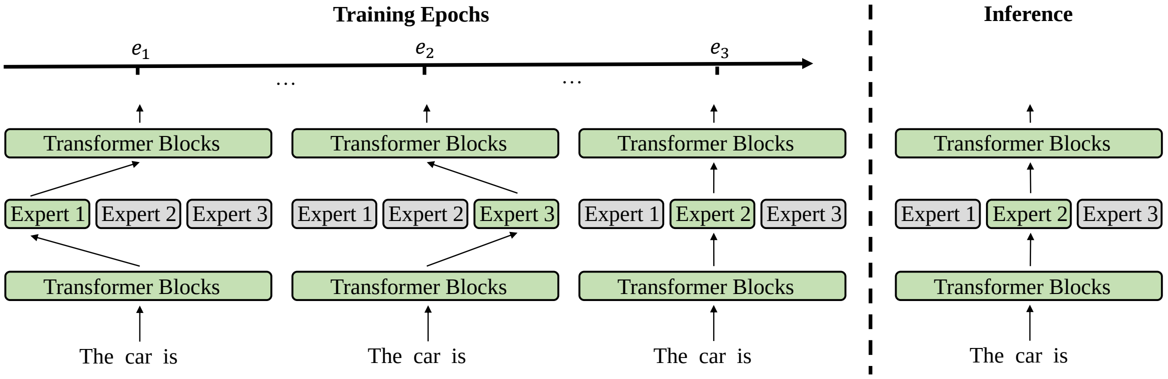

Figure 1: Illustration of the routing fluctuation problem. The same input is assigned to different experts along with training. However, during inference, only one expert is sparsely activated for the input. The routing fluctuation tends to harm sample efficiency because the same input updates different experts while only one is used.

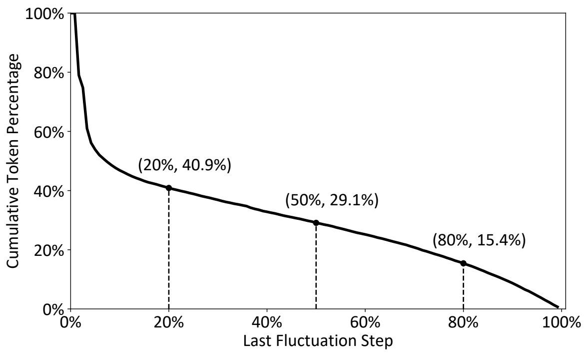

Figure 2: Cumulative token percentage with regard to the last fluctuation step of tokens for BASE Layer (Lewis et al., 2021). A substantial portion of tokens still change their target experts even if the training is nearing the end.

balanced and cohesive routing strategy. We design a balance loss to guarantee the assignment is balanced. In addition, inspired by Lewis et al. (2021), we adopt a sigmoid gating mechanism, which enables the task objective to propagate supervised signal back to the routing strategy, to facilitate learning a more cohesive assignment. As the routing strategy is being learned, we synchronously distill it into a lightweight router decoupled from the backbone model. In the second training stage, we utilize the distilled router to determine the token-to-expert assignment. The distilled router is frozen in this stage to provide a stable routing strategy, which addresses the routing fluctuation problem in the remaining training. We conduct experiments on language modeling and multilingual machine translation. The results show that StableMoE outperforms existing MoE methods in terms of both convergence speed and performance.

Our contributions are summarized as follows: (1) We point out the routing fluctuation problem in existing learning-to-route MoE methods. (2) We propose StableMoE to address the routing fluctuation problem. (3) We conduct substantial experiments under various settings to show the advantages of StableMoE over existing MoE methods.

2 Background: Mixture-of-Experts for Transformers

We first introduce the MoE mechanism designed for Transformers (Vaswani et al., 2017). Given a standard L-layer Transformer model and an input sequence X containing T tokens, the Transformer output H^L is calculated by

$$H^L = [\mathbf{h}_1^L; \mathbf{h}_2^L; ...; \mathbf{h}_T^L], \tag{1}$$

$$\mathbf{h}_t^l = \mathrm{FFN}\left(\mathbf{u}_t^l\right) + \mathbf{u}_t^l, \tag{2}$$

$$\mathbf{u}_{1:T}^l = \text{self-att}\left(\mathbf{h}_{1:T}^{l-1}\right) + \mathbf{h}_{1:T}^{l-1}, \tag{3}$$

where $\mathbf{h}_t^l$ is the hidden state of t-th token after the l-th layer, Self-Att$(\cdot)$ is the self-attention module, and FFN$(\cdot)$ is short for the feed-forward network. For simplicity, we omit the layer normalization.

We implement MoE for Transformers by inserting MoE layers, that are composed of a set of FFNs, into two neighboring Transformer blocks. At an MoE layer, for each input token, only a few or one expert will be activated, controlled by a gating function $g(\cdot)$:

$$\mathbf{h}_t^l = \sum_{i=1}^{N} g_i\left(\mathbf{h}_t^{l-1}\right) \mathrm{FFN}_i\left(\mathbf{h}_t^{l-1}\right) + \mathbf{h}_t^{l-1}, \tag{4}$$

where N is the total number of experts, and FFN_i is the i-th expert. Here, the gating function $g_i(\cdot)$ is sparse for computational efficiency. For simplicity, we omit the layer normalization.

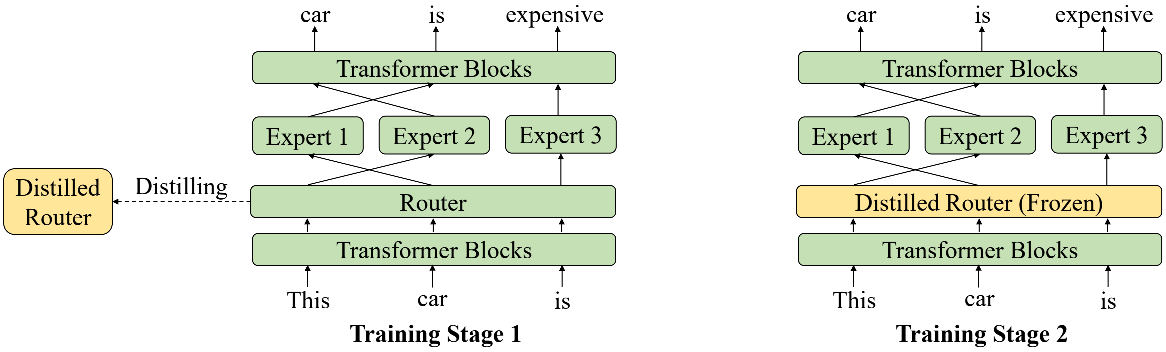

Figure 3: Illustration of two training stages in STABLEMOE. In training stage 1, we learn a routing strategy and distill it into a lightweight router. Then, we freeze the distilled router for stable routing in training stage 2.

3 Method

STABLEMOE has two training stages as illustrated in Figure 3. In the first training stage, we follow the learning-to-route paradigm and aim to learn a balanced and cohesive routing strategy. As the routing strategy is being learned, we synchronously distill it into a lightweight router decoupled from the backbone model. In the second training stage, we utilize the distilled router to determine the token-to-expert assignment. The distilled router is frozen in this stage to provide a stable routing strategy. During inference, we also use the frozen distilled router for consistent routing.

3.1 Training Stage 1: Learn Routing Strategy

Let $\mathbf{h}_t^{l-1} \in \mathbb{R}^d$ be the input representation of token t and $E \in \mathbb{R}^{N\times d}$ be the centroids of N experts. For each MoE layer, we assign each token to one expert FFN (Fedus et al., 2021; Lewis et al., 2021; Roller et al., 2021). The assignment score is:

$$s_{t,i} = E_i^\top \mathbf{h}_t^{l-1}, \tag{5}$$

where $s_{t,i}$ is the assignment score between token t and expert i, indicating their affinity. We use a greedy assignment algorithm, i.e., sending each token to the expert with the highest affinity. Then, we calculate the expert FFN output as:

$$a_t = \arg\max_i (s_{t,i}), \tag{6}$$

$$\mathbf{h}_t^l = \sigma\left(s_{t,a_t}\right) \mathrm{FFN}_{a_t}\left(\mathbf{h}_t^{l-1}\right) + \mathbf{h}_t^{l-1}, \tag{7}$$

where a_t is the expert index that token t is sent to, and σ is the sigmoid gate (Lewis et al., 2021). Considering the sigmoid gate $\sigma\left(s_{t,a_t}\right)$, if FFN_{a_t} is beneficial for token t, optimizing the training objective (e.g., minimizing the cross-entropy loss for language modeling) will urge the gate to be greater; otherwise, the gate will tend to be smaller. The gate signal urges similar tokens to be assigned to the same expert that is beneficial to them, thus producing cohesive token-to-expert assignments.

Balance Loss We design a balance loss $\mathcal{L}_{bal}$ to avoid imbalanced assignments that will result in a high computational bottleneck in the MoE layer and thus limit the computational efficiency:

$$\mathcal{L}_{bal} = \alpha \sum_{i=1}^{N} \left(\frac{(|\mathcal{A}_i| - \overline{n})}{\overline{n}} \sum_{t\in\mathcal{A}_i} \sigma\left(s_{t,i}\right) \right), \tag{8}$$

where α is a hyper-parameter, $\mathcal{A}_i$ denotes the set of tokens assigned to expert i, and $\overline{n}$ denotes the average number of tokens per expert. Intuitively, if an expert is overloaded, the balance loss will urge its assignment scores to be smaller. Otherwise, if an expert is unoccupied, the balance loss will increase its assignment scores to capture more tokens.

Distilled Router As the routing strategy is being learned, we synchronously distill it into a lightweight router decoupled from the backbone model to mimic the original routing strategy. Let X be the input sequence and $\hat{E}$ be the distilled expert centroids, we use word embeddings $\mathrm{D}(\cdot)$ to extract the routing features. We use the cross-entropy loss as the distillation loss $\mathcal{L}_{dis}$:

$$\hat{\mathbf{h}}_t^{l-1} = \mathrm{D}(X_t), \quad \hat{s}_{t,i} = \hat{E}_i^\top \hat{\mathbf{h}}_t^{l-1}, \tag{9}$$

$$\mathcal{L}_{dis} = -\sum_{t=1}^{T} \log \frac{\exp\left(\hat{s}_{t,a_t}\right)}{\sum_{i=1}^{N} \exp\left(\hat{s}_{t,i}\right)}, \tag{10}$$

where $\hat{\mathbf{h}}_t^{l-1}$ is the distilled routing feature of token t, $\hat{s}_{t,i}$ is the distilled assignment score between token t and expert i, and a_t is the expert index that token t is actually sent to. In practice, $\mathrm{D}(\cdot)$

Methods	Assignment Algorithm	Gating Function	Balance Loss
Switch Transformer	Greedy	softmax	Yes
BASE Layer	Auction (Bertsekas, 1992)	sigmoid	No
Hash Layer	Fixed Hashing	$\{0, 1\}$	No
StableMoE			
Training Stage 1	Greedy	sigmoid	Yes
Training Stage 2	Fixed Routing	sigmoid	No

Table 1: Comparison of three core elements among StableMoE and existing MoE-based Transformers.

can also be other feature extractors such as CNNs or Transformers (we investigate other variants of distilled routers in Section 4.4.3), but the word embedding is the fastest one and achieves the best performance. At the end of training stage 1, we freeze all parameters for the distilled router (i.e., $\mathrm{D}(\cdot)$ and $\hat{E}$) to prepare a stable routing strategy for training stage 2 and the inference stage.

Training Objective In training stage 1, the training loss consists of the task loss, the balance loss, and the distillation loss:

$$\mathcal{L}_{S1} = \mathcal{L}_{task} + \mathcal{L}_{bal} + \mathcal{L}_{dis}. \tag{11}$$

3.2 Training Stage 2: Learn with Stable Routing Strategy

Given frozen $\mathrm{D}(\cdot)$ and $\hat{E}$, in training stage 2, we directly use them for a stable routing strategy. Keeping other processes the same as in training stage 1, we calculate the output of the MoE layer as follows:

$$\hat{\mathbf{h}}_t^{l-1} = \mathrm{D}(X_t), \quad \hat{s}_{t,i} = \hat{E}_i^{\top} \hat{\mathbf{h}}_t^{l-1}, \tag{12}$$

$$\hat{a}_t = \arg\max_i(\hat{s}_{t,i}), \tag{13}$$

$$\mathbf{h}_t^l = \sigma\left(s_{t,\hat{a}_t}\right) \mathrm{FFN}_{\hat{a}_t}\left(\mathbf{h}_t^{l-1}\right) + \mathbf{h}_t^{l-1}. \tag{14}$$

Notice that the sigmoid gate $\sigma(\cdot)$ still uses original assignment score $s_{t,\hat{a}_t}$ as input, so the gate signal can also be learned in training stage 2. Since the routing strategy has been fixed in training stage 2, we no longer need the balance loss and distillation loss. Therefore, the training loss for training stage 2 contains only the task loss:

$$\mathcal{L}_{S2} = \mathcal{L}_{task}. \tag{15}$$

3.3 Inference

During inference, we also use the frozen distilled router for routing. The fixed routing strategy, which is consistent with training stage 2, makes information learned in MoE layers be utilized more thoroughly and thus leads to better performance.

3.4 Comparison with Existing MoE Methods

We compare three core elements, including the assignment algorithm, the gating function, and the balance loss, among StableMoE and existing MoE-based Transformers. In Table 1, we summarize their differences.

Assignment Algorithm Switch Transformer and the training stage 1 in StableMoE simply assign each token to the expert with the highest affinity. BASE Layer adopts the auction algorithm (Bertsekas, 1992) to find a global balanced assignment with the maximum affinity sum. Hash layer and the training stage 2 in StableMoE have token-level fixed routing strategies, which have good stability.

Gating Function Hash Layer uses a hard gating function, which means an expert is either fully activated or not activated, no any intermediate state. Switch Layer, BASE Layer, and StableMoE have soft gating functions, which can judge the affinity between a token and its target expert and determine a proper ratio to use the expert. Soft gating mechanisms also urge models to learn a more cohesive token-to-expert assignment.

Balance Loss BASE Layer and Hash Layer do not apply any balance losses. By contrast, Switch Transformer and the training stage 1 in StableMoE design balance losses to control the balance of the token-to-expert assignment.

In summary, combing two training stages, StableMoE has a stable, cohesive, and balanced routing strategy, while the other three MoE methods cannot meet them all simultaneously.

4 Experiments

4.1 Tasks and Datasets

Language Modeling Following (Lewis et al., 2021) and Roller et al. (2021), we use the combination of the corpora in RoBERTa (Liu et al.,

Size	Models	# Shared Params	# Expert Params	FLOPs	Valid PPL	Test PPL
Base	Standard Transformer	124M	N/A	146B	23.02	22.58
	Larger Transformer (deeper)	578M	N/A	610B	17.93	17.63
	Larger Transformer (wider)	578M	N/A	610B	18.31	18.01
	Switch Transformer	124M	454M	160B	19.79	19.20
	BASE Layer	124M	454M	160B	20.04	19.69
	Hash Layer	124M	454M	160B	19.63	19.25
	StableMoE	124M	454M	160B	**19.28**	**18.93**
Large	Standard Transformer	355M	N/A	414B	18.86	18.19
	Switch Transformer	355M	3.22B	465B	16.62	16.21
	BASE Layer	355M	3.22B	465B	16.36	15.75
	Hash Layer	355M	3.22B	465B	16.37	15.79
	StableMoE	355M	3.22B	465B	**16.22**	**15.59**

Table 2: Perplexity results of language modeling. We also report the training FLOPs, and the number of parameters for the shared backbone (# Shared Params) and the expert layers (# Expert Params). "N/A" denotes not applicable. StableMoE consistently outperforms other MoE methods under both the base and the large settings.

2019) and the English subset of the CC100 (Conneau et al., 2020) corpus. The corpus contains about 100B tokens, and we randomly sample 5M tokens for validation and 20M tokens for test.

Multilingual Machine Translation We follow Wang et al. (2020) and Ma et al. (2020) to use a collection of parallel data in different languages from the WMT datasets.[1] The dataset contains 32.5 million parallel data for language pairs between English and other 9 languages, including French (Fr), Czech (Cs), German (De), Finnish (Fi), Latvian (Lv), Estonian (Et), Romanian (Ro), Hindi (Hi), and Turkish (Tr). In our experiments, we combine the original parallel data with 180 million back-translation data as described in (Ma et al., 2020) and call the augmented dataset WMT for short.

4.2 Experimental Setup

We conduct experiments based on fairseq[2]. All experiments are conducted on NVIDIA V100 GPUs with 32 GB memory.

Language Modeling We adopt the tokenizer of GPT-2 (Radford et al., 2019), which uses byte-pair encoding (Sennrich et al., 2016) with a vocabulary size of 50,257. We set up two settings for StableMoE, a base one and a large one. For both settings, we insert one MoE layer after the middle Transformer block. We train the model for 60K steps in total (6K for training stage 1 and 54K for training stage 2). The dimension of the distilled routing features is 50, which brings 2.51M extra parameters for routing. The balance factor α is set to 0.3. We use Adam (Kingma and Ba, 2015) with $\beta_1 = 0.9$ and $\beta_2 = 0.98$ as the optimizer. The rest of the hyper-parameters are summarized in Appendix A.

Multilingual Machine Translation Following (Ma et al., 2020), we use the SentencePiece (Kudo and Richardson, 2018) model to tokenize sentences. The vocabulary is learned from the training set and consists of 64,000 tokens. We insert two MoE layers, one after the third encoder block and one after the third decoder block. We train the model for 352K steps in total (30K for training stage 1 and 322K for training stage 2). The dimension of the distilled routing features is also set to 50. The balance factor α is set to 0.3. We use Adam with $\beta_1 = 0.9$ and $\beta_2 = 0.98$ as the optimizer. The rest of the hyper-parameters are summarized in Appendix B.

4.3 Results

4.3.1 Language Modeling

We compare StableMoE with Switch Transformer, BASE Layer, Hash Layer, and the standard Transformer. All MoE models have the same number of shared parameters as the standard Transformer. Under the base setting, in addition, we compare two larger dense Transformers that add FFNs in a dense manner to achieve the same number of total parameters as MoE models. The deeper model stacks more FFNs, while the wider model uses FFNs with a larger hidden size. The floating point operations (FLOPs) per sequence are profiled by the torchprofile toolkit.

We show the main results of language modeling on the RoBERTa+cc100en corpus in Table 2.

StableMoE	480M	317B	**43.0**	37.4	**34.7**	**31.5**	**29.3**	26.8	24.7	**23.6**	**21.9**	**30.32**

Table 3: X→En test BLEU on WMT. We also report the total number of parameters, and training FLOPs. StableMoE outperforms other MoE-based Transformers across most languages.

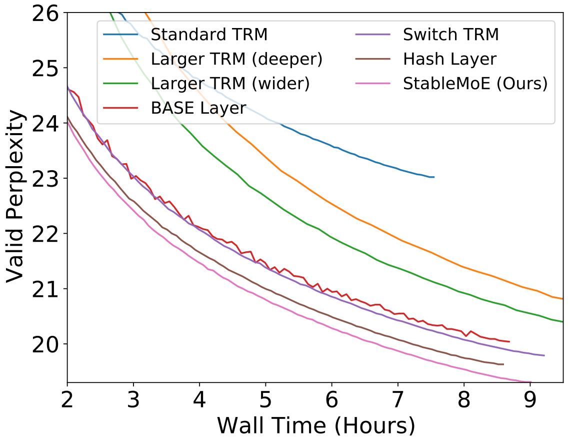

Figure 4: Convergence speed of different models. TRM is a shorthand for Transformer.

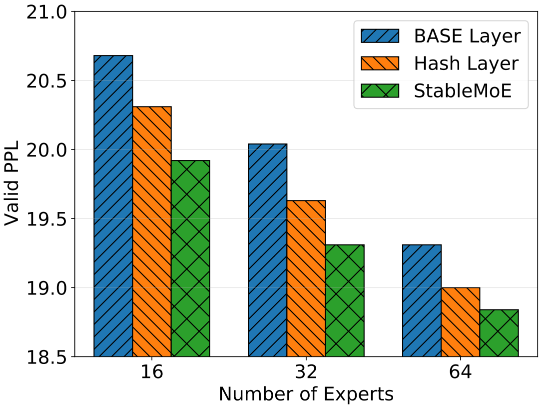

Figure 5: Comparison of MoE-based Transformers with different numbers of experts. Lower perplexity indicates better performance.

Under the base setting, StableMoE outperforms existing MoE methods on both the validation and the test sets by 0.3-0.8 perplexity. Compared with dense models, StableMoE achieves about 3.7 lower perplexity than the standard Transformer, and about 1.3 higher perplexity than the deeper larger model. Under the large setting, consistently, StableMoE outperforms the other MoE methods, and achieves about 2.6 lower perplexity than the standard Transformer.

We also compare the convergence speed of different models under the base setting. The results are plotted in Figure 4, which takes the validation perplexity as y-axis and the training wall time as x-axis. Although larger dense models achieve better validation perplexity at last, their training speed is quite slow. With regard to the convergence speed, MoE-based Transformers usually exceed dense models. Further, among the MoE methods, StableMoE has the fastest convergence speed.

4.3.2 Multilingual Machine Translation

We compare StableMoE with Switch Transformer, BASE Layer, Hash Layer, the standard Transformer, and a larger Transformer. All MoE-based models have the same number of shared parameters as the standard Transformer. Except the standard Transformer, the other models have the same FLOPs.

We translate other languages to English (X→En) and report the test BLEU on WMT in Table 3. StableMoE achieves the best average test BLEU among the compared MoE methods. Keeping the same FLOPs, StableMoE outperforms the dense model by 1.22 test BLEU. With the MoE technique, we expand the number of parameters by 523% and the FLOPs just increase by 9.3%.

4.4 Analysis

4.4.1 Effects of Hyperparameters

On top of the base setting of language modeling, we investigate different settings for the MoE layers in StableMoE.

Number of Experts Figure 5 shows the results of BASE Layer, Hash Layer, and StableMoE with different numbers of experts. As the number of experts goes larger, the validation perplexity of each model tends to further descend. Consistently, StableMoE performs the best with dif-

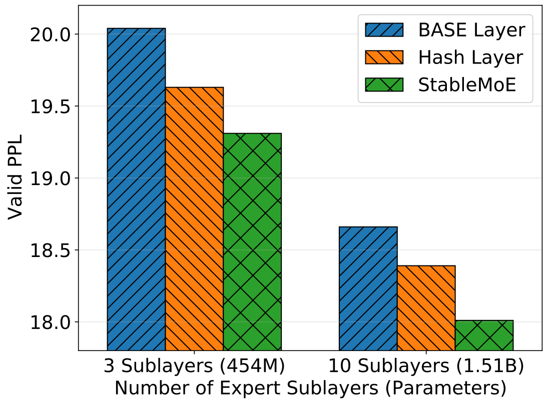

Figure 6: Comparison of MoE models with different numbers of expert sublayers (i.e., number of parameters). Lower perplexity indicates better performance.

Models	**Valid PPL**
StableMoE (stacked, top)	19.55
StableMoE (stacked, middle)	**19.28**
StableMoE (stacked, bottom)	22.82
StableMoE (scattered)	20.56

Table 4: Effects of the position of MoE layers. StableMoE (scattered) scatters 3 MoE sublayers uniformly into the standard Transformer, while the others stack 3 MoE sublayers together.

ferent numbers of experts. In addition, it is worth noting that StableMoE with 16 experts outperforms BASE Layer with 32 experts, and StableMoE with 32 experts achieves a similar perplexity to BASE Layer with 64 experts.

Number of Expert Parameters We compare MoE models with different numbers of expert parameters by setting different expert sublayers. Models with 3 and 10 expert sublayers have 454M and 1.51B expert parameters, respectively. From Figure 6, we observe that more expert parameters bring better performance, and StableMoE consistently performs the best under both settings.

Position of MoE Layers We investigate the effect of the inserting position of the MoE layer. By default, the MoE layer stacks 3 MoE sublayers and is inserted after the $\frac{L}{2}$-th Transformer block (middle). We also attempt to insert the MoE layer before the first Transformer block (bottom), and after the last Transformer block (top). In addition, we also investigate the effect if we scatter 3 MoE sublayers uniformly into the standard Transformer, i.e., after the $\frac{L}{4}$-th, $\frac{2L}{4}$-th, and $\frac{3L}{4}$-th blocks, respectively. As shown in Table 4, among the above four settings, inserting stacked MoE sublayers into the middle position allows StableMoE to achieve the best performance.

Models	**Valid PPL**
BASE Layer	20.04
+ Fixed Routing Strategy (Stage 2)	19.41 (0.63↓)
StableMoE with Only Stage 1	19.48
+ Fixed Routing Strategy (Stage 2)	19.28 (0.20↓)

Table 5: Effects of the fixed routing strategy.

Ratio Between Two Training Stages We investigate the balance point of the ratio between two training stages in StableMoE. Given a fixed number of total steps, allocating more steps to training stage 1 can help to learn and distill a better routing strategy. On the other hand, a larger ratio of training stage 2 means longer stable training. Under the base setting of language modeling, we attempt to allocate 6K, 15K, and 30K steps to training stage 1 and show the results in Table 6. We find that if we use word embeddings as the distilled router, allocating 6K steps (10% of the total steps) to training stage 1 is a good balance point. We speculate that the word embedding is simple enough to be learned fast, so longer stable training is more important to achieve better performance.

4.4.2 Effects of the Fixed Routing Strategy

Based on the base setting of language modeling, we design two experiments to investigate how much performance improvement the fixed routing strategy can bring. On the one hand, we equip BASE Layer with a stable routing strategy to address its routing fluctuation problem. Specifically, as in StableMoE, we use word embeddings to distill the routing strategy of BASE Layer in the first 6K training steps, and freeze the distilled router for stable routing in the remaining training. As shown in Table 5, the fixed routing strategy decreases the validation perplexity of BASE Layer by 0.63. On the other hand, we attempt to disable the training stage 2 in StableMoE and always train the model as in training stage 1. As a result, the validation perplexity of StableMoE becomes 0.20 higher than the full version that has a fixed routing strategy. These two cases support that the fixed routing strategy, which addresses the routing fluctuation problem, can bring better performance for MoE-based Transformers.

In addition, we visualize the fixed routing strat-

Distilled Routers	Stage 1 Steps	Valid PPL
Word Embedding	6K (10%)	**19.28**
Word Embedding	15K (25%)	19.34
Word Embedding	30K (50%)	19.41
CNN	15K (25%)	19.39
1-layer Transformer	15K (25%)	19.42
2-layer Transformer	15K (25%)	19.38
3-layer Transformer	15K (25%)	19.65

Table 6: Results of different ratios of two training stages and different variants of distilled routers.

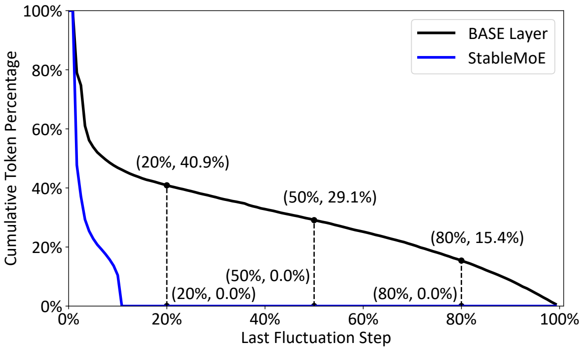

Figure 7: Cumulative token percentage about the last fluctuation step of tokens for BASE Layer and StableMoE. Notice that training stage 2 of StableMoE does not have routing fluctuation compared with BASE Layer.

egy of StableMoE in Appendix C for reference.

4.4.3 Variants of Distilled Routers

In Table 6, in addition to word embedding, we also investigate four variants of the distilled router including CNN and three Transformers with different numbers of layers. We allocate 15K steps to training stage 1 for all of them. From the table, we find that using word embedding achieves the best performance, while the 3-layer Transformer does not perform well. For the routing strategy distillation, the distilling signal from a 32-category classification objective may not be informative enough to learn a complex router. By contrast, it is more suitable for simpler routers. Therefore, we recommend using word embedding, which is simple and effective, as the distilled router in StableMoE.

4.4.4 Analysis of Routing Fluctuations

We compare the degree of routing fluctuations between StableMoE and BASE Layer to show our advantage with regard to the routing stability. During the 60K training steps, we examine the token-to-expert assignment for tokens in the validation set every 500 steps. For each token, we define the last fluctuation step as the last step where its target expert is different from the final step. We plot the cumulative token percentage about the last fluctuation step in Figure 7. For ease of reading, we annotate the x-axis as the percentage it accounts for all training steps. From the figure, we find that the routing fluctuation problem is notable for BASE Layer. By contrast, for StableMoE, there is no routing fluctuation in training stage 2 since we apply a fixed routing strategy.

5 Related Work

Jacobs et al. (1991); Jordan and Jacobs (1994) propose Mixture of Experts (MoE) to compute different examples with independent expert modules. Shazeer et al. (2017) introduce MoE to build large-scale language models based on LSTMs (Hochreiter and Schmidhuber, 1997). Recently, as Transformers become popular, many pieces of work design MoE-version FFNs to build MoE-based Transformers. GShard (Lepikhin et al., 2021), Switch Transformer (Fedus et al., 2021), and BASE Layer (Lewis et al., 2021) follow the learning-to-route paradigm and dynamically learn how to route each input token to experts. However, we point out that these learning-to-route methods face the routing fluctuation problem. Hash Layer (Roller et al., 2021) propose a non-parametric routing strategy, which uses a pre-designed token-level hash table to determine the token-to-expert assignment. The static routing strategy will not fluctuate, but the randomly determined hash table limits the upper bound of its performance. Our work includes the advantages of learning-to-route methods to learn a balanced and cohesive routing strategy, and further addresses the routing fluctuation problem through applying a frozen lightweight router that mimics the original routing strategy.

6 Conclusion

In this paper, we point out the routing fluctuation problem that exists in previous learning-to-route MoE methods. In order to address this problem, we propose StableMoE with two training stages. We first learn a balanced and cohesive routing strategy and synchronously distill it into a lightweight router decoupled from the backbone model. Then, we freeze the distilled router for a stable routing strategy in the remaining training. We validate StableMoE on language modeling and multilingual machine translation. The results show that Sta-

BLEMOE outperforms existing MoE methods in terms of both convergence speed and performance.

Table 9: The most frequent tokens assigned to each expert in the validation set. We present several representative experts. Tokens assigned to the same expert usually share some common features.

C Visualization of the Fixed Routing Strategy of STABLEMOE

We visualize the fixed routing strategy of STABLEMOE in Table 9. On the validation set, for each expert, we demonstrate the most frequent tokens assigned to it along with a text that describes their common features. We find that tokens assigned to the same expert usually share some common features, e.g., Expert 22 captures adjectives and Expert 31 captures conjunctions. These cases show good cohesiveness of the token-to-expert assignment in STABLEMOE.

Boundary Smoothing for Named Entity Recognition

Abstract

Neural named entity recognition (NER) models may easily encounter the over-confidence issue, which degrades the performance and calibration. Inspired by label smoothing and driven by the ambiguity of boundary annotation in NER engineering, we propose *boundary smoothing* as a regularization technique for span-based neural NER models. It re-assigns entity probabilities from annotated spans to the surrounding ones. Built on a simple but strong baseline, our model achieves results better than or competitive with previous state-of-the-art systems on eight well-known NER benchmarks.[1] Further empirical analysis suggests that boundary smoothing effectively mitigates over-confidence, improves model calibration, and brings flatter neural minima and more smoothed loss landscapes.

1 Introduction

Named entity recognition (NER) is one of the fundamental natural language processing (NLP) tasks with extensive investigations. As a common setting, an entity is regarded as correctly recognized only if its type and two boundaries exactly match the ground truth.

The annotation of boundaries is more ambiguous, error-prone, and raises more inconsistencies than entity types. For example, the CoNLL 2003 task contains four entity types (i.e., person, location, organization, miscellaneous), which are easy to distinguish between. However, the boundaries of a entity mention could be ambiguous, because of the "boundary words" (e.g., articles or modifiers). Considerable efforts are required to specify the "gold standard practice" case by case. Table 1 presents some examples from CoNLL 2003 Annotation Guidelines.[2] In addition, some studies have also reported that incorrect boundary is a major source of entity recognition error (Wang et al., 2019; Eberts and Ulges, 2020).

Text	Boundary words
[The [White House]$_{\text{ORG}}$]$_{\text{ORG}}$	Article

[[John Doe]$_{\text{PER}}$, Jr.]$_{\text{PER}}$	Name appositive

Table 1: Examples of CoNLL 2003 Annotation Guidelines and potential alternatives. The gold annotations are marked in blue [*], whereas the alternative annotations are in red [*].

Recently, span-based models have gained much popularity in NER studies, and achieved state-of-the-art (SOTA) results (Eberts and Ulges, 2020; Yu et al., 2020; Li et al., 2021). This approach typically enumerates all candidate spans and classifies them into entity types (including a "non-entity" type); the annotated spans are scarce and assigned with full probability to be an entity, whereas all other spans are assigned with zero probability. This creates noticeable *sharpness* between the classification targets of adjacent spans, and may thus plague the trainability of neural networks. In addition, empirical evidence shows that these models easily encounter the *over-confidence* issue, i.e., the confidence of a predicted entity is much higher than its correctness probability. This is a manifestation of miscalibration (Guo et al., 2017).

Inspired by label smoothing (Szegedy et al., 2016; Müller et al., 2019), we propose boundary smoothing as a regularization technique for span-based neural NER models. By explicitly re-allocating entity probabilities from annotated spans

to the surrounding ones, boundary smoothing can effectively mitigate over-confidence, and result in consistently better performance.

Specifically, our baseline employs the contextualized embeddings from a pretrained Transformer of a `base` size (768 hidden size, 12 layers), and the biaffine decoder proposed by Yu et al. (2020). With boundary smoothing, our model outperforms previous SOTA on four English NER datasets (CoNLL 2003, OntoNotes 5, ACE 2004 and ACE 2005) and two Chinese datasets (Weibo NER and Resume NER), and achieves competitive results on other two Chinese datasets (OntoNotes 4 and MSRA). Such extensive experiments support the effectiveness and robustness of our proposed technique.

In addition, we show that boundary smoothing can help the trained NER models to preserve calibration, such that the produced confidences can better represent the precision rate of a predicted entity. This corresponds to the effect of label smoothing on the image classification task (Müller et al., 2019). Further, visualization results qualitatively suggest that boundary smoothing can lead to flatter solutions and more smoothed loss landscapes, which are typically associated with better generalization and trainability (Hochreiter and Schmidhuber, 1997; Li et al., 2018).

2 Related Work

Named Entity Recognition The mainstream NER systems are designed to recognize flat entities and based on a sequence tagging framework. Collobert et al. (2011) introduced the linear-chain conditional random field (CRF) into neural network-based sequence tagging models, which can explicitly encode the transition likelihoods between adjacent tags. Many researchers followed this work, and employed LSTM as the encoder. In addition, character-level representations are typically used for English tasks (Huang et al., 2015; Lample et al., 2016; Ma and Hovy, 2016; Chiu and Nichols, 2016), whereas lexicon information is helpful for Chinese NER (Zhang and Yang, 2018; Ma et al., 2020; Li et al., 2020a).

Nested NER allows a token to belong to multiple entities, which conflicts with the plain sequence tagging framework. Ju et al. (2018) proposed to use stacked LSTM-CRFs to predict from inner to outer entities. Straková et al. (2019) concatenated the BILOU tags for each token inside the nested entities, which allows the LSTM-CRF to work as for flat entities. Li et al. (2020b) reformulated nested NER as a machine reading comprehension task. Shen et al. (2021) proposed to recognize nested entities by the two-stage object detection method widely used in computer vision.

Recent years, a body of literature emerged on span-based models, which were compatible with both flat and nested entities, and achieved SOTA performance (Eberts and Ulges, 2020; Yu et al., 2020; Li et al., 2021). These models typically enumerate all possible candidate text spans and then classify each span into entity types. In this work, the biaffine model (Yu et al., 2020) is chosen and re-implemented with slight modifications as our baseline, because of its high performance and compatibility with boundary smoothing.

In addition, pretrained language models, also known as contextualized embeddings, were also widely introduced to NER models, and significantly boosted the model performance (Peters et al., 2018; Devlin et al., 2019). They are used in our baseline by default.

Label Smoothing Szegedy et al. (2016) proposed the label smoothing as a regularization technique to improve the accuracy of the Inception networks on ImageNet. By explicitly assigning a small probability to non-ground-truth labels, label smoothing can prevent the models from becoming too confident about the predictions, and thus improve generalization. It turned out to be a useful alternative to the standard cross entropy loss, and has been widely adopted to fight against the over-confidence (Zoph et al., 2018; Chorowski and Jaitly, 2017; Vaswani et al., 2017), improve the model calibration (Müller et al., 2019), and denoise incorrect labels (Lukasik et al., 2020).

Our proposed boundary smoothing applies the smoothing technique to entity boundaries, rather than labels. This is driven by the observation that entity boundaries are more ambiguous and inconsistent to annotate in NER engineering.[3] To the best of our knowledge, this study is the first that focuses on the effect of smoothing regularization on NER models.

---

[3] We note that Shen et al. (2021) also allocate a weight to the non-entity but partially matched spans; however, boundary smoothing additionally regularizes the weight of entity spans, which is intuitively crucial for mitigating over-confidence.

3 Methods

3.1 Biaffine Decoder

A neural network-based NER model typically encodes the input tokens to a sequence of representations $x = x_1, x_2, \ldots, x_T$ of length T, and then decodes these representations to task outputs, i.e., a list of entities specified by types and boundaries.

We follow Yu et al. (2020) and use the biaffine decoder. Specifically, the representations x are separately affined by two feedforward networks, resulting in two representations $h^s \in \mathbb{R}^{T\times d}$ and $h^e \in \mathbb{R}^{T\times d}$, which correspond to the start and end positions of spans. For c entity types (a "non-entity" type included), given a span starting at the i-th token and ending at the j-th token, a scoring vector $r_{ij} \in \mathbb{R}^c$ can be computed as:

$$r_{ij} = (h_i^s)^{\mathrm{T}} U h_j^e + W(h_i^s \oplus h_j^e \oplus w_{j-i}) + b, \tag{1}$$

where $w_{j-i} \in \mathbb{R}^{d_w}$ is the $(j-i)$-th width embedding from a dedicated learnable matrix; $U \in \mathbb{R}^{d\times c\times d}$, $W \in \mathbb{R}^{c\times(2d+d_w)}$ and $b \in \mathbb{R}^c$ are learnable parameters. r_{ij} is then fed into a softmax layer:

$$\hat{y}_{ij} = \mathrm{softmax}(r_{ij}), \tag{2}$$

which yields the predicted probabilities over all entity types.

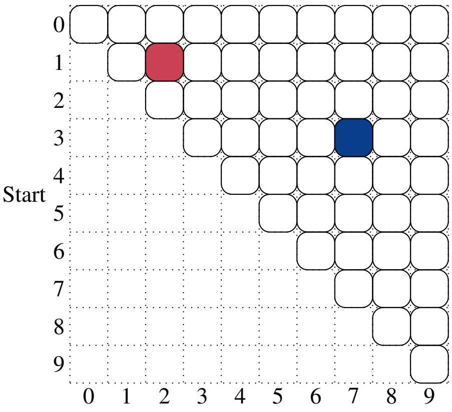
The ground truth $y_{ij} \in \mathbb{R}^c$ is an one-hot encoded vector, with value being 1 if the index corresponds with the annotated entity type, and 0 otherwise. Thus, the model can be optimized by the standard cross entropy loss for all candidate spans:

$$\mathcal{L}_{\mathrm{CE}} = -\sum_{0\le i\le j<T} y_{ij}^{\mathrm{T}} \log(\hat{y}_{ij}). \tag{3}$$

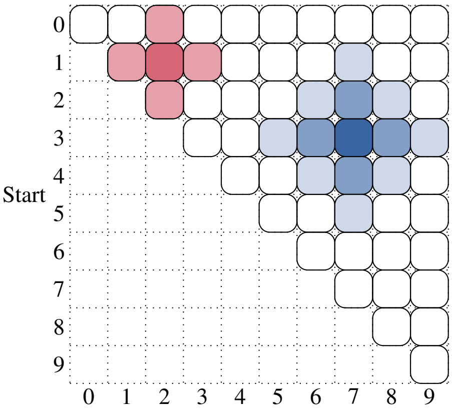
In the inference time, the spans predicted to be "non-entity" are first discarded, and the remaining ones are ranked by their predictive confidences. Spans with lower confidences would also be discarded if they clash with the boundaries of spans with higher confidences. Refer to Yu et al. (2020) for more details.

3.2 Boundary Smoothing

Figure 1a visualizes the ground truth y_{ij} for an example sentence with two annotated entities. The valid candidate spans cover the upper triangular area of the matrix. In existing NER models, the annotated boundaries are considered to be absolutely reliable. Hence, each annotated span is assigned with the full probability to be an entity, whereas all unannotated spans are assigned with zero probability. We refer to this probability allocation as *hard boundary*, which is, however, probably not the best choice.



(a) Hard boundary



(b) Smoothed boundary

Figure 1: An example of hard and smoothed boundaries. The example sentence has ten tokens and two entities of spans (1, 2) and (3, 7), colored in red and blue, respectively. The first subfigure presents the entity recognition targets of hard boundaries. The second subfigure presents the corresponding targets of smoothed boundaries, where the span (1, 2) is smoothed by a size of 1, and the span (3, 7) is smoothed by a size of 2.

As aforementioned, the entity boundaries may be ambiguous and inconsistent, so the spans surrounding an annotated one deserve a small probability to be an entity. Figure 1b visualizes $\tilde{y}_{ij}$, the boundary smoothing version of y_{ij}. Specifically, given an annotated entity, a portion of probability ϵ is assigned to its surrounding spans, and the remaining probability $1-\epsilon$ is assigned to the originally annotated span. With smoothing size D, all the spans with Manhattan distance d $(d \le D)$ to the annotated entity equally share probability ϵ/D. After such entity probability re-allocation, any remaining probability of a span is assigned to be "non-entity". We refer to this as *smoothed boundary*.

Thus, the biaffine model can be optimized by the boundary-smoothing regularized cross entropy loss:

$$\mathcal{L}_{\mathrm{BS}} = - \sum_{0 \leq i \leq j < T} \tilde{y}_{ij}^{\mathrm{T}} \log(\hat{y}_{ij}). \tag{4}$$

Empirically, the positive samples (i.e., ground-truth entities) are sparsely distributed over the candidate spans. For example, the CoNLL 2003 dataset has about 35 thousand entities, which represent only 0.93% in the 3.78 million candidate spans. By explicitly assigning probability to surrounding spans, boundary smoothing prevents the model from concentrating all probability mass on the scarce positive samples. This intuitively helps alleviate over-confidence.

In addition, hard boundary presents noticeable sharpness between the classification targets of positive spans and surrounding ones, although they share similar contextualized representations. Smoothed boundary provides more continuous targets across spans, which are conceptually more compatible with the inductive bias of neural networks that prefers continuous solutions (Hornik et al., 1989).

4 Experiments

4.1 Experimental Settings

Datasets We use four English NER datasets: CoNLL 2003 (Tjong Kim Sang and Veenstra, 1999), OntoNotes 5[4], ACE 2004[5] and ACE 2005[6]; and four Chinese NER datasets: OntoNotes 4[7], MSRA (Levow, 2006), Weibo NER (Peng and Dredze, 2015) and Resume NER (Zhang and Yang, 2018). Among them, ACE 2004 and ACE 2005 are nested NER tasks, and the others are flat tasks.

Hyperparameters For English corpora, we use RoBERTa (Liu et al., 2019) followed by a BiLSTM layer to produce the contextualized representations. For Chinese, we choose the BERT pretrained with whole word masking (Cui et al., 2019). The BiLSTM has one layer and 200 hidden size with dropout rate of 0.5. The biaffine decoder follows Yu et al. (2020), with the affine layers of hidden size 150 and dropout rate 0.2. We additionally introduce a span width embedding of size 25. Note that the pretrained language models are all of the `base` size (768 hidden size, 12 layers), and the model is free of any additional auxiliary embeddings; this configuration is relatively simple, compared with those in related work.

The boundary smoothing parameter ϵ is selected in $\{0.1, 0.2, 0.3\}$; smoothing size D is selected in $\{1, 2\}$.

All the models are trained by the AdamW optimizer (Loshchilov and Hutter, 2018) with a gradient clipping at L2-norm of 5.0 (Pascanu et al., 2013). The models are trained for 50 epochs with batch size of 48. The learning rate is searched between 1e-3 and 3e-3 on the randomly initialized weights, and between 8e-6 and 3e-5 on the pretrained weights; a scheduler of linear warmup in the first 20% steps followed by linear decay is applied.

Evaluation A predicted entity is considered correct if its type and boundaries exactly match the ground truth. Hyperparameters are tuned according to the F_1 scores on the development set, and the evaluation metrics (precision, recall, F_1 score) are reported on the testing set.

4.2 Main Results

Table 2 presents the evaluation results on four English datasets, in which CoNLL 2003 and OntoNotes 5 are flat NER corpora, whereas ACE 2004 and ACE 2005 contains a high proportion of nested entities. Compared with previous SOTA systems, our simple baseline (RoBERTa-base + BiLSTM + Biaffine) achieves on-par or slightly inferior performance. Provided the strong baseline, our experiments show that boundary smoothing can effectively and consistently boost the F_1 score of entity recognition across different datasets. With the help of boundary smoothing, our model outperforms the best of the previous SOTA systems by a magnitude from 0.2 to 0.5 percentages.

Table 3 presents the results on four Chinese datasets, which are all flat NER corpora. Again, boundary smoothing consistently improves model performance against the baseline (BERT-base-wwm + BiLSTM + Biaffine) across all datasets. In addition, our model outperforms previous SOTA

by 2.16 and 0.55 percentages on Weibo and Resume NER datasets, and achieves comparable F_1 scores on OntoNotes 4 and MSRA. Note that almost all previous systems solve these tasks within a sequence tagging framework; this work adds to the literature by introducing a span-based approach and establishing SOTA results on multiple Chinese NER benchmarks.

In five out of the above eight datasets, integrating boundary smoothing significantly increases the precision rate with a slight drop in the recall, resulting in a better overall F_1 score. This is consistent with our expectation, because boundary smoothing discourages over-confidence when recognizing entities, which implicitly leads the model to establish a more critical threshold to admit entities.

Given the use of well pretrained language models, most of the performance gains are relatively marginal. However, boundary smoothing can work effectively and consistently for different languages and datasets. In addition, it is easy to implement and integrate into any span-based neural NER models, with almost no side effects.

4.3 Ablation Studies

We perform ablation studies on CoNLL 2003, ACE 2005 and Resume NER datasets (covering

	CoNLL 2003	ACE 2005	Resume NER
Baseline	93.48	86.56	96.34

LS ($\alpha = 0.3$)	93.26	85.65	96.26

Table 4: Ablation studies of smoothing parameters. F_1 scores are reported. BS and LS mean boundary smoothing and label smoothing, respectively.

flat/nested and English/Chinese datasets), to evaluate the effects of boundary smoothing parameter ϵ and D, as well as other components of our NER system.

Boundary Smoothing Parameters We train the model with ϵ in $\{0.1, 0.2, 0.3\}$ and D in $\{1, 2\}$; the corresponding results are reported in Table 4. Most combinations of the two hyperparameters can achieve higher F_1 scores than the baseline, which suggests the robustness of boundary smoothing. On the other hand, the best smoothing parameters are different across datasets, which are probably related to the languages/domains of the text, the entity types, and the annotation scheme (e.g., flat or nested NER). Hence, if the best performance is desired for a new NER task in practice, hyperparameter tuning would be necessary.

Label Smoothing We replace boundary smoothing with label smoothing in the span classifier. Label smoothing cannot improve, or may even impair the performance of the model, compared with the baseline (see Table 4). As aforementioned, we hypothesize that the semantic differences between the typical entity types are quite clear, so it is ineffective to smooth between them.

Pretrained Language Models We test if the performance gain by boundary smoothing is robust to different baselines. For English datasets, we use BERT (Devlin et al., 2019) of the `base` and `large` sizes, and RoBERTa (Liu et al., 2019) of the `large` size (1024 hidden size, 24 layers). It shows that boundary smoothing can consistently increase the F_1 scores by 0.1–0.2 and 0.4–0.6 percentages for CoNLL 2003 and ACE 2005, respectively. For Chinese, we use MacBERT (Cui et al., 2020) of the `base` and `large` sizes, and boundary smoothing still performs positively and consistently, with an improvement of 0.2–0.3 percentage F_1 scores on Resume NER (see Table 5).

	CoNLL 2003	ACE 2005	Resume NER
Baseline	93.48	86.56	96.34
+ BS	**93.65**	**87.15**	**96.66**
Baseline w/ BERT-base	91.84	84.51	
+ BS	**92.05**	**84.95**

+ BS	**93.08**	**86.33**	
Baseline w/ RoBERTa-large	93.66	87.82	
+ BS	**93.77**	**88.02**	
Baseline w/ MacBERT-base			96.41
+ BS			**96.75**
Baseline w/ MacBERT-large			96.46
+ BS			**96.75**
Baseline w/o BiLSTM	93.13	86.22	96.24
+ BS	**93.30**	**86.58**	**96.56**

Table 5: Ablation studies of model structure. F_1 scores are reported. BS means boundary smoothing.

It is noteworthy that boundary smoothing achieves performance gains roughly comparable to the gains by switching the pretrained language model from the `base` size to the `large` size. This suggests that the effect of boundary smoothing is quite considerable, although the performance improvements seem small in magnitude.

In addition, our results show that RoBERTa substantially outperforms the original BERT on English NER. This is probably because that (1) RoBERTa is trained on much more data; and (2) RoBERTa focuses on the token-level task (i.e., masked language modeling) by removing the sequence-level objective (i.e., next sentence prediction), hence, it is particularly suitable for within-sequence downstream tasks, e.g., NER. This is also the reason why we choose RoBERTa for our baseline.

BiLSTM Layer We remove the BiLSTM layer, directly feeding the output of pretrained language model into the biaffine decoder. The results show that this does not change the positive effect of boundary smoothing (see Table 5). In addition, absence of the BiLSTM layer will result in drops of the F_1 scores by about 0.3, 0.5 and 0.1 percentages on the three datasets.

5 Further In-Depth Analysis

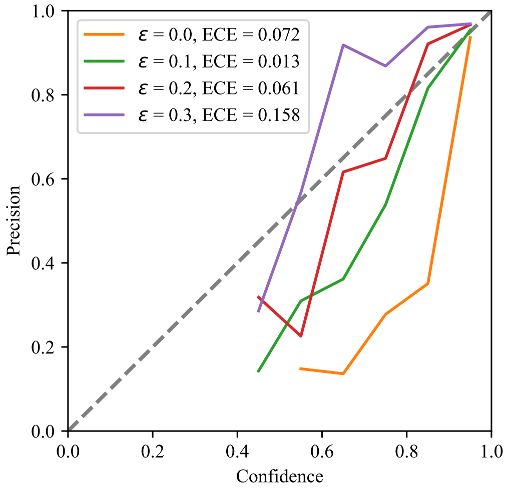
5.1 Over-Confidence and Entity Calibration

The model performance (evaluated by, e.g., accuracy or F_1 score) is certainly important. However, the *confidences* of model predictions are also of interest in many applications. For example, when it requires the predicted entities to be highly reliable (i.e., precision is of more priority than recall), we may filter out the entities with confidences lower than a specific threshold.

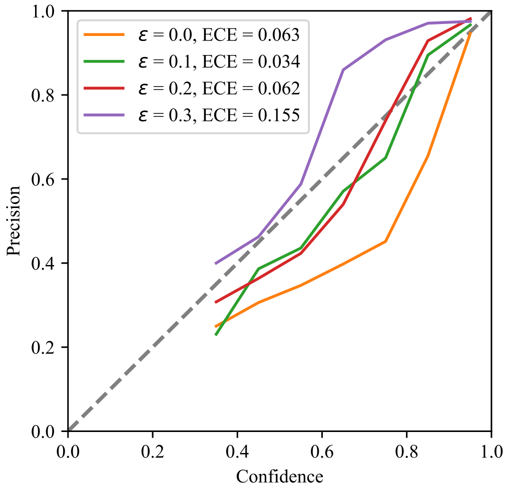
However, Guo et al. (2017) have indicated that modern neural networks are poorly calibrated, and typically over-confident with their predictions. By calibration, they mean the extent to which the prediction confidences produced by a model can represent the true correctness probability. We find neural NER models also easy to become miscalibrated and over-confident. We observe that, with the standard cross entropy loss, both the development loss and F_1 score increase in the later training stage, which goes against the common perception that the loss and F_1 score should change in the opposite directions. This phenomenon is similar to the disconnect between negative likelihood and accuracy in image classification described by Guo et al. (2017). We suppose that the model becomes over-confident with its predictions, including the incorrect ones, which contributes to the increase of loss (see Appendix A for more details).

To formally investigate the over-confidence issue, we plot the reliability diagrams and calculate expected calibration error (ECE). In brief, for an NER model, we group all the predicted entities by the associated confidences into ten bins, and then calculate the precision rate for each bin. If the model is well calibrated, the precision rate should be close to the confidence level for each bin (see Appendix B for more details).

Figure 2 compares the reliability diagrams and ECEs between models with different smoothness ϵ on CoNLL 2003 and OntoNotes 5. For the baseline model ($\epsilon = 0$), the precision rates are much lower than corresponding confidence levels, suggesting significant over-confidence. By introducing boundary smoothing and increasing the smoothness ϵ, the over-confidence is gradually mitigated, and shifted to under-confidence ($\epsilon = 0.3$). In general, the model presents best reliability diagrams when ϵ is 0.1 or 0.2. In addition, the ECEs of the baseline model are 0.072 and 0.063 on CoNLL 2003 and OntoNotes 5, respectively; with ϵ of 0.1, the ECEs are reduced to 0.013 and 0.034.



(a) CoNLL 2003



(b) OntoNotes 5

Figure 2: Reliability diagram of recognized entities on CoNLL 2003 and OntoNotes 5. Results are computed on ten bins.

In conclusion, boundary smoothing can prevent the model from becoming over-confident with the predicted entities, and result in better calibration. In addition, as mentioned previously, spans with lower confidences are discarded if they clash with those of higher confidences when decoding. With the better calibration, the model can obtain a very marginal but consistent increase in the F_1 score.

5.2 Loss Landscape Visualization

How does boundary smoothing improve the model performance? We originally conjectured that boundary smoothing can de-noise the inconsistently annotated entity boundaries (Lukasik et al., 2020), but failed to find enough evidence – the

Figure 3: Visualization of loss landscapes on CoNLL 2003 and OntoNotes 5. Training, development and testing losses are in orange, green and red, respectively. CE and BS mean cross entropy and boundary smoothing, respectively.

performance improvement did not significantly increase when we injected boundary noises into the training data.[8]

As aforementioned, positive samples are very sparse among the candidate spans. Without boundary smoothing, the annotated spans are regarded to be entities with full probability, whereas all other spans are assigned with zero probability. This creates noticeable *sharpness* between the targets of the annotated spans and surrounding ones, although their neural representations are similar. Boundary smoothing re-allocates the entity probabilities across contiguous spans, which mitigates the sharpness and results in more continuous targets. Conceptually, such targets are more compatible with the inductive bias of neural networks that prefers continuous solutions (Hornik et al., 1989).

Li et al. (2018) have shown that residual connections and well-tuned hyperparameters (e.g., learning rate, batch size) can produce flatter minima and less chaotic loss landscapes, which account for the better generalization and trainability. Their findings provide important insights into the geometric properties of non-convex neural loss functions.

Figure 3 visualizes the loss landscapes for models with different smoothness ϵ on CoNLL 2003 and OntoNotes 5, following Li et al. (2018). In short, for a trained model, a direction of the parameters is randomly sampled, normalized and fixed, and the loss landscape is computed by sampling over this direction (refer to Appendix C for more details).

The visualization results qualitatively show that, the solutions found by the standard cross entropy are relatively sharp, whereas boundary smoothing can help arrive at flatter minima. As many theoretical studies regard the flatness as a promising predictor for model generalization (Hochreiter and Schmidhuber, 1997; Jiang et al., 2019), this result may explain why boundary smoothing can improve the model performance. In addition, boundary smoothing is associated with more smoothed landscapes – the surrounding local minima are small, shallow, and thus easy for the optimizer to escape. Intuitively, such geometric property suggests that the underlying loss functions are easier to train (Li et al., 2018).

We believe that the sharpness in the span-based NER targets is probably the reason for the sharp

---

[8] On the other hand, this cannot rule out the de-noising effect of boundary smoothing, because the synthesized boundary noises are distributed differently from the real noises.

and chaotic loss landscape. Boundary smoothing can effectively mitigate the sharpness, and result in loss landscapes of better generalization and trainability.

6 Conclusion

In this study, we propose boundary smoothing as a regularization technique for span-based neural NER models. Boundary smoothing re-assigns entity probabilities from annotated spans to the surrounding ones. It can be easily integrated into any span-based neural NER systems, but consistently bring improved performance. Built on a simple but strong baseline (a `base`-sized pretrained language model followed by a BiLSTM layer, and the biaffine decoder), our model achieves SOTA results on eight well-known NER benchmarks, covering English and Chinese, flat and nested NER tasks.

In addition, experimental results show that boundary smoothing leads to less over-confidence, better model calibration, flatter neural minima and more smoothed loss landscapes. These properties plausibly explain the performance improvement. Our findings shed light on the effects of smoothing regularization technique in the NER task.

As discussed, boundary smoothing typically increases the overall F_1 score at the risk of a slight drop in the recall rate; hence, one may be careful to use it for recall-sensitive applications. Future work will apply boundary smoothing to more variants of span-based NER models, and investigate its effect in a broader range of information extraction tasks.

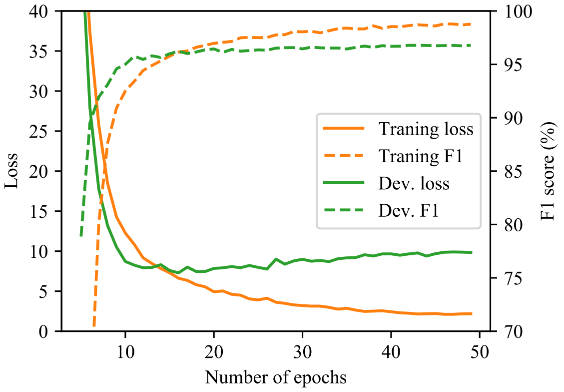
A Disconnect between Development Loss and F_1 Score

For most machine learning tasks, the desired metric (e.g., accuracy or F_1 score) is non-differentiable and thus cannot be optimized via back-propagation. The loss, on the other hand, is a designed differentiable proxy such that minimizing it can increase the original metric.

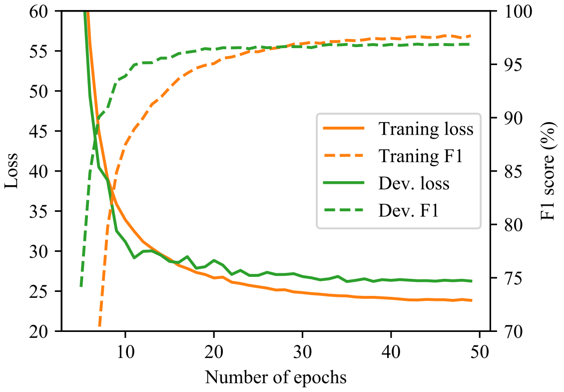
However, as illustrated in Figure 4a, when training an NER model by the standard cross entropy loss, although the development F_1 score keeps increasing throughout, the development loss also increases in the later stage (e.g., after ten epochs) of the training process. Guo et al. (2017) describe this phenomenon as a disconnect – the neural network overfits to the loss without overfitting to the metric. They regard this as indirect evidence for miscalibration.

One plausible explanation is that in the later training stage, the model becomes too confident with its predicted outcomes, including both the correct and incorrect ones. Therefore, although slightly more spans are correctly classified on the development set (as the F_1 score increases), a small portion of incorrectly classified spans is assigned with much more confidence and contributes to the increase of loss.

Figure 4b presents the curves for boundary smoothing loss. The development loss decreases throughout the training process, opposite to the increasing F_1 score. This result suggests that boundary smoothing can help mitigate over-confidence.



(a) Cross entropy loss



(b) Boundary smoothing loss (ϵ=0.2, D=1)

Figure 4: Training/development losses and F_1 scores of models with cross entropy loss and boundary smoothing loss on CoNLL 2003. Both the cross entropy loss and corresponding F_1 score on the development set experience an ascending trend after about ten epochs, suggesting the existence of over-confidence. However, the boundary smoothing loss on the development set keeps decreasing through the whole training process.

B Reliability Diagrams and Expected Calibration Error

We generally follow Guo et al. (2017)'s approach to plot reliability diagrams and calculate expected calibration error (ECE).

Given an NER dataset and a model trained on it, denote the gold and predicted entity sets as $\mathcal{E}$ and $\hat{\mathcal{E}}$, respectively; the model produces a confidence $\hat{p}_e$ for each entity $e \in \hat{\mathcal{E}}$. With K confidence interval bins, the predicted entities are grouped such that those with confidences falling into the k-th bin constitute a subset:

$$\hat{\mathcal{E}}_k = \left\{ e \mid e \in \hat{\mathcal{E}}, \hat{p}_e \in \left(\frac{k-1}{K}, \frac{k}{K} \right] \right\}.$$

The precision rate (equivalent to the accuracy with regard to a predicted set) of k-th group $\hat{\mathcal{E}}_k$ is:

$$\mathrm{Prec}_k = \frac{|\hat{\mathcal{E}}_k \cap \mathcal{E}|}{|\hat{\mathcal{E}}_k|},$$

and the corresponding average confidence is:

$$\mathrm{Conf}_k = \frac{\sum_{e \in \hat{\mathcal{E}}_k} \hat{p}_e}{|\hat{\mathcal{E}}_k|}.$$

The reliability diagrams plot Prec_k against Conf_k for $k = 1, 2, \dots, K$. ECE is estimated by the weighted average of absolute difference between Prec_k and Conf_k:

$$\mathrm{ECE} = \sum_{k=1}^{K} \frac{|\hat{\mathcal{E}}_k|}{|\hat{\mathcal{E}}|} \cdot \left| \mathrm{Prec}_k - \mathrm{Conf}_k \right|$$

By definition, a perfectly calibrated model will have $\mathrm{Prec}_k = \mathrm{Conf}_k$ for $k = 1, 2, \dots, K$. In this case, the reliability diagrams should lie along the identity line, and ECE equals to 0.

C Loss Landscape Visualization

We generally follow Li et al. (2018)'s approach to visualize the loss landscape.

Given a trained model of parameters $\theta^\star$, we sample a random direction δ from a normal distribution, and rescale it by:

$$\delta_i \leftarrow \frac{||\theta_i^\star||}{||\delta_i||}\delta_i,$$

where δ_i is the i-th weight of δ.[9] On a data set/split $\mathcal{D}$, the loss landscape plots the function:

$$f(\alpha) = L(\mathcal{D}; \theta^\star + \alpha\delta),$$

where $L(\mathcal{D}; \theta)$ is the average loss value (in the evaluation mode) on $\mathcal{D}$ if the model takes parameters of θ. In practice, we evenly sample 51 points in the interval $[-1, 1]$ for α, and plot the loss values against α.

---

[9] Li et al. (2018) use filter-wise normalization for convolutional networks, whereas our models have no convolutional layers, so we simplify it as weight-wise normalization.

Incorporating Hierarchy into Text Encoder: a Contrastive Learning Approach for Hierarchical Text Classification

Zihan Wang, Peiyi Wang, Lianzhe Huang, Xin Sun, Houfeng Wang[*]

`{hlz, sunx5, wanghf}@pku.edu.cn`

Abstract

Hierarchical text classification is a challenging subtask of multi-label classification due to its complex label hierarchy. Existing methods encode text and label hierarchy separately and mix their representations for classification, where the hierarchy remains unchanged for all input text. Instead of modeling them separately, in this work, we propose Hierarchy-guided Contrastive Learning (HGCLR) to directly embed the hierarchy into a text encoder. During training, HGCLR constructs positive samples for input text under the guidance of the label hierarchy. By pulling together the input text and its positive sample, the text encoder can learn to generate the hierarchy-aware text representation independently. Therefore, after training, the HGCLR enhanced text encoder can dispense with the redundant hierarchy. Extensive experiments on three benchmark datasets verify the effectiveness of HGCLR.

1 Introduction

Hierarchical Text Classification (HTC) aims to categorize text into a set of labels that are organized in a structured hierarchy (Silla and Freitas, 2011). The taxonomic hierarchy is commonly modeled as a tree or a directed acyclic graph, in which each node is a label to be classified. As a subtask of multi-label classification, the key challenge of HTC is how to model the large-scale, imbalanced, and structured label hierarchy (Mao et al., 2019).

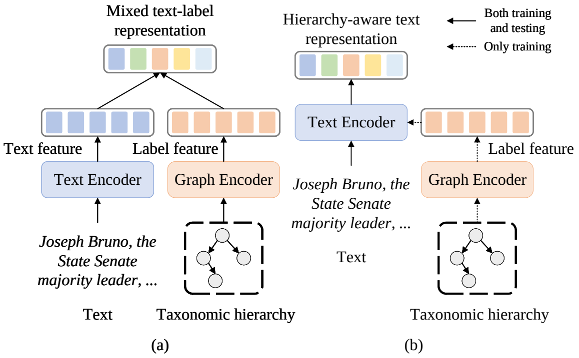

Figure 1: Two ways of introducing hierarchy information. (a) Previous work model text and labels separately and find a mixed representation. (b) Our method incorporating hierarchy information into text encoder for a hierarchy-aware text representation.

The existing methods of HTC have variously introduced hierarchical information. Among recent researches, the state-of-the-art models encode text and label hierarchy separately and aggregate two representations before being classified by a mixed feature (Zhou et al., 2020; Deng et al., 2021). As denoted in the left part of Figure 1, their main goal is to sufficiently interact between text and structure to achieve a mixed representation (Chen et al., 2021), which is highly useful for classification (Chen et al., 2020a). However, since the label hierarchy remains unchanged for all text inputs, the graph encoder provides exactly the same representation regardless of the input. Therefore, the text representation interacts with constant hierarchy representation and thus the interaction seems redundant and less effective. Alternatively, we attempt to inject the constant hierarchy representation into the text encoder. So that after being fully trained, a hierarchy-aware text representation can be acquired without the constant label feature. As in the right part of Figure 1, instead of modeling text and labels separately, migrating label hierarchy into text encoding may benefit HTC by a proper representation learning method.

To this end, we adopt contrastive learning for the hierarchy-aware representation. Contrastive learning, which aims to concentrate positive samples and push apart negative samples, has been considered as effective in constructing meaningful representations (Kim et al., 2021). Previous work on contrastive learning illustrates that it is critical

May 22-27, 2022

to building challenging samples (Alzantot et al., 2018; Wang et al., 2021b; Tan et al., 2020; Wu et al., 2020). For multi-label classification, we attempt to construct high-quality positive examples. Existing methods for positive example generation includes data augmentation (Meng et al., 2021; Wu et al., 2020), dropout (Gao et al., 2021), and adversarial attack (Wang et al., 2021b; Pan et al., 2021). These techniques are either unsupervised or task-unspecific: the generation of positive samples has no relation with the HTC task and thus are incompetent to acquire hierarchy-aware representations. As mentioned, we argue that both the ground-truth label as well as the taxonomic hierarchy should be considered for the HTC task.

To construct positive samples which are both label-guided and hierarchy-involved, our approach is motivated by a preliminary observation. Notice that when we classify text into a certain category, most words or tokens are not important. For instance, when a paragraph of news report about a lately sports match is classified as "basketball", few keywords like "NBA" or "backboard" have large impacts while the game result has less influence. So, given a sequence and its labels, a shorten sequence that only keeps few keywords should maintain the labels. In fact, this idea is similar to adversarial attack, which aims to find "important tokens" which affect classification most (Zhang et al., 2020). The difference is that adversarial attack tries to modify "important tokens" to fool the model, whereas our approach modifies "unimportant tokens" to keep the classification result unchanged.

Under such observation, we construct positive samples as pairs of input sequences and theirs shorten counterparts, and propose Hierarchy-Guided Contrastive Learning (HGCLR) for HTC. In order to locate keywords under given labels, we directly calculate the attention weight of each token embedding on each label, and tokens with weight above a threshold are considered important to according label. We use a graph encoder to encode label hierarchy and output label features. Unlike previous studies with GCN or GAT, we modify a Graphormer (Ying et al., 2021) as our graph encoder. Graphormer encodes graphs by Transformer blocks and outperforms other graph encoders on several graph-related tasks. It models the graph from multiple dimensions, which can be customized easily for HTC task.

The main contribution of our work can be summarized as follows:

- We propose Hierarchy-Guided Contrastive Learning (HGCLR) to obtain hierarchy-aware text representation for HTC. To our knowledge, this is the first work that adopts contrastive learning on HTC.

- For contrastive learning, we construct positive samples by a novel approach guided by label hierarchy. The model employs a modified Graphormer, which is a new state-of-the-art graph encoder.

- Experiments demonstrate that the proposed model achieves improvements on three datasets. Our code is available at https://github.com/wzh9969/contrastive-htc.

2 Related Work

2.1 Hierarchical Text Classification

Existing work for HTC could be categorized into local and global approaches based on their ways of treating the label hierarchy (Zhou et al., 2020). Local approaches build classifiers for each node or level while the global ones build only one classifier for the entire graph. Banerjee et al. (2019) builds one classifier per label and transfers parameters of the parent model for child models. Wehrmann et al. (2018) proposes a hybrid model combining local and global optimizations. Shimura et al. (2018) applies CNN to utilize the data in the upper levels to contribute categorization in the lower levels.

The early global approaches neglect the hierarchical structure of labels and view the problem as a flat multi-label classification (Johnson and Zhang, 2015). Later on, some work tries to coalesce the label structure by recursive regularization (Gopal and Yang, 2013), reinforcement learning (Mao et al., 2019), capsule network (Peng et al., 2019), and meta-learning (Wu et al., 2019). Although such methods can capture the hierarchical information, recent researches demonstrate that encoding the holistic label structure directly by a structure encoder can further improve performance. Zhou et al. (2020) designs a structure encoder that integrates the label prior hierarchy knowledge to learn label representations. Chen et al. (2020a) embeds word and label hierarchies jointly in the hyperbolic space. Zhang et al. (2021) extracts text features according to different hierarchy levels. Deng et al. (2021)

introduces information maximization to constrain label representation learning. Zhao et al. (2021) designs a self-adaption fusion strategy to extract features from text and label. Chen et al. (2021) views the problem as semantic matching and tries BERT as text encoder. Wang et al. (2021a) proposes a cognitive structure learning model for HTC. Similar to other work, they model text and label separately.

2.2 Contrastive Learning

Contrastive learning is originally proposed in Computer Vision (CV) as a weak-supervised representation learning method. Works such as MoCo (He et al., 2020) and SimCLR (Chen et al., 2020b) have bridged the gap between self-supervised learning and supervised learning on multiple CV datasets. A key component for applying contrastive learning on NLP is how to build positive pairs (Pan et al., 2021). Data augmentation techniques such as back-translation (Fang et al., 2020), word or span permutation (Wu et al., 2020), and random masking (Meng et al., 2021) can generate pair of data with similar meanings. Gao et al. (2021) uses different dropout masks on the same data to generate positive pairs. Kim et al. (2021) utilizes BERT representation by a fixed copy of BERT. These methods do not rely on downstream tasks while some researchers leverage supervised information for better performance on text classification. Wang et al. (2021b) constructs both positive and negative pairs especially for sentimental classification by word replacement. Pan et al. (2021) proposes to regularize Transformer-based encoders for text classification tasks by FGSM (Goodfellow et al., 2014), an adversarial attack method based on gradient. Though methods above are designed for classification, the construction of positive samples hardly relies on their categories, neglecting the connection and diversity between different labels. For HTC, the taxonomic hierarchy models the relation between labels, which we believe can help positive sample generation.

3 Problem Definition

Given a input text $x = \{x_1, x_2, ..., x_n\}$, Hierarchical Text Classification (HTC) aims to predict a subset y of label set Y, where n is the length of the input sequence and k is the size of set Y. The candidate labels $y_i \in Y$ are predefined and organized as a Directed Acyclic Graph (DAG) $G = (Y, E)$, where node set Y are labels and edge set E denotes their hierarchy. For simplicity, we do not distinguish a label with its node in the hierarchy so that y_i is both a label and a node. Since a non-root label of HTC has one and only one father, the taxonomic hierarchy can be converted to a tree-like hierarchy. The subset y corresponds to one or more paths in G: for any non-root label $y_j \in y$, a father node (label) of y_j is in the subset y.

4 Methodology

In this section, we will describe the proposed HGCLR in detail. Figure 2 shows the overall architecture of the model.

4.1 Text Encoder

Our approach needs a strong text encoder for hierarchy injection, so we choose BERT (Devlin et al., 2019) as the text encoder. Given an input token sequence:

$$x = \{[\text{CLS}], x_1, x_2, ..., x_{n-2}, [\text{SEP}]\} \qquad (1)$$

where $[\text{CLS}]$ and $[\text{SEP}]$ are two special tokens indicating the beginning and the end of the sequence, the input is fed into BERT. For convenience, we denote the length of the sequence as n. The text encoder outputs hidden representation for each token:

$$H = \text{BERT}(\text{x}) \qquad (2)$$

where $H \in \mathbb{R}^{n \times d_h}$ and d_h is the hidden size. We use the hidden state of the first token ([CLS]) for representing the whole sequence $h_x = h_{[\text{CLS}]}$.

4.2 Graph Encoder

We model the label hierarchy with a customized Graphormer (Ying et al., 2021). Graphormer models graphs on the base of Transformer layer (Vaswani et al., 2017) with spatial encoding and edge encoding, so it can leverage the most powerful sequential modeling network in the graph domain. We organize the original feature for node y_i as the sum of label embedding and its name embedding:

$$f_i = \text{label\_emb}(y_i) + \text{name\_emb}(y_i). \qquad (3)$$

Label embedding is a learnable embedding that takes a label as input and outputs a vector with size d_h. Name embedding takes the advantage of the name of the label, which we believe contains fruitful information as a summary of the entire class. We use the average of BERT token embedding of

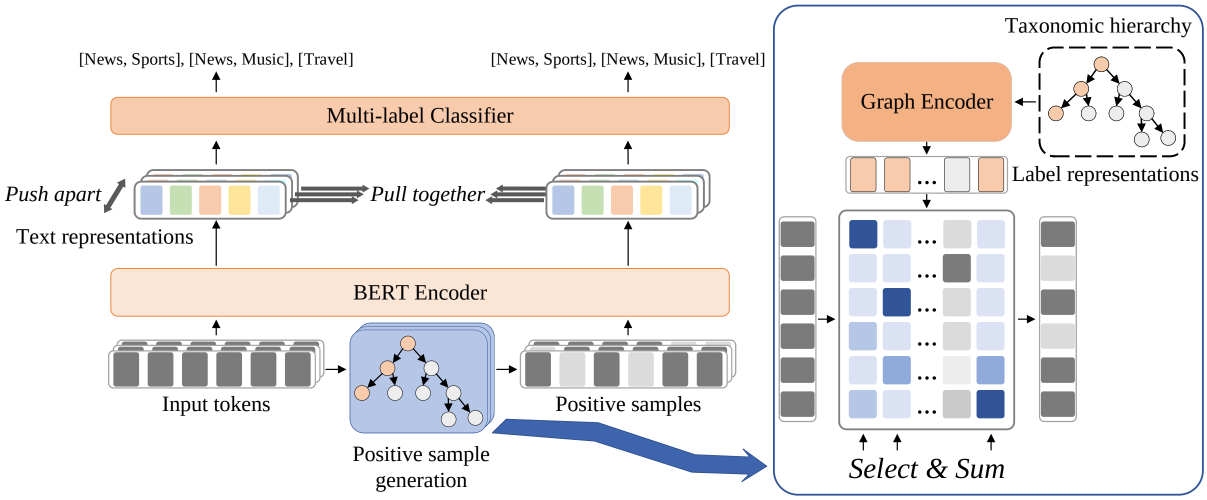

Figure 2: An overview of HGCLR under a batch of 3. HGCLR adopts a contrastive learning framework to regularize BERT representations. We construct positive samples by masking unimportant tokens under the guidance of hierarchy and labels. By pulling together and pushing apart representations, the hierarchy information can be injected into the BERT encoder.

the label as its name embedding, which also has a size of d_h. Unlike previous work which only adopts names on initialization, we share embedding weights across text and labels to make label features more instructive. With all node features stack as a matrix $F \in \mathbb{R}^{k \times d_h}$, a standard self-attention layer can then be used for feature migration.

To leverage the structural information, spatial encoding and edge encoding modify the Query-Key product matrix A^G in the self-attention layer:

$$A^G_{ij} = \frac{(f_i W^G_Q)(f_j W^G_K)^T}{\sqrt{d_h}} + c_{ij} + b_{\phi(y_i,y_j)} \tag{4}$$

where $c_{ij} = \frac{1}{D}\sum_{n=1}^{D} w_{e_n}$ and $D = \phi(y_i, y_j)$. The first term in Equation 4 is the standard scale-dot attention, and query and key are projected by $W^G_Q \in \mathbb{R}^{d_h \times d_h}$ and $W^G_K \in \mathbb{R}^{d_h \times d_h}$. c_{ij} is the edge encoding and $\phi(y_i, y_j)$ denotes the distance between two nodes y_i and y_j. Since the graph is a tree in our problem, for node y_i and y_j, one and only one path $(e_1, e_2, ..., e_D)$ can be found between them in the underlying graph G' so that c_{ij} denotes the edge information between two nodes and $w_{e_i} \in \mathbb{R}^1$ is a learnable weight for each edge. $b_{\phi(y_i,y_j)}$ is the spatial encoding, which measures the connectivity between two nodes. It is a learnable scalar indexed by $\phi(y_i, y_j)$.

The graph-involved attention weight matrix A^G is then followed by Softmax, multiplying with value matrix and residual connection & layer normalization to calculate the self-attention,

$$L = \mathrm{LayerNorm}(\mathrm{softmax}(\mathrm{A^G})\mathrm{V} + \mathrm{F}) \tag{5}$$

We use L as the label feature for the next step. The Graphormer we use is a variant of the self-attention layer, for more details on the full structure of Graphormer, please refer to the original paper.

4.3 Positive Sample Generation

As mentioned, the goal for the positive sample generation is to keep a fraction of tokens while retaining the labels. Given a token sequence as Equation 1, the token embedding of BERT is defined as:

$$\{e_1, e_2, ..., e_n\} = \mathrm{BERT\_emb}(x) \tag{6}$$

The scale-dot attention weight between token embedding and label feature is first calculated to determine the importance of a token on a label,

$$q_i = e_i W_Q, k_j = l_j W_K, A_{ij} = \frac{q_i k_j^T}{\sqrt{d_h}} \tag{7}$$

The query and key are token embeddings and label features respectively, and $W_Q \in \mathbb{R}^{d_h \times d_h}$ and $W_K \in \mathbb{R}^{d_h \times d_h}$ are two weight matrices. Thus, for a certain x_i, its probability of belonging to label y_j can be normalized by a Softmax function.

Next, given a label y_j, we can sample key tokens from that distribution and form a positive sample $\hat{x}$. To make the sampling differentiable, we replace the Softmax function with Gumbel-Softmax (Jang et al., 2016) to simulate the sampling operation:

$$P_{ij} = \mathrm{gumbel\_softmax}(A_{i1}, A_{i2}, ..., A_{ik})_j \tag{8}$$

Notice that a token can impact more than one label, so we do not discretize the probability as one-hot vectors in this step. Instead, we keep tokens for positive examples if their probabilities of being sampled exceed a certain threshold γ, which can also control the fraction of tokens to be retrained. For multi-label classification, we simply add the probabilities of all ground-truth labels and obtain the probability of a token x_i regarding its ground-truth label set y as:

$$P_i = \sum_{j \in y} P_{ij} \tag{9}$$

Finally, the positive sample $\hat{x}$ is constructed as:

$$\hat{x} = \{x_i \text{ if } P_i > \gamma \text{ else } \mathbf{0}\} \tag{10}$$

where $\mathbf{0}$ is a special token that has an embedding of all zeros so that key tokens can keep their positions. The select operation is not differentiable, so we implement it differently to make sure the whole model can be trained end-to-end. Details are illustrated in Appendix A.

The positive sample is fed to the same BERT as the original one,

$$\hat{H} = \text{BERT}(\hat{x}) \tag{11}$$

and get a sequence representation $\hat{h_x}$ with the first token before being classified. We assume the positive sample should retain the labels, so we use classification loss of the positive sample as a guidance of the graph encoder and the positive sample generation.

4.4 Contrastive Learning Module

Intuitively, given a pair of token sequences and their positive counterpart, their encoded sentence-level representation should be as similar to each other as possible. Meanwhile, examples not from the same pair should be farther away in the representation space.

Concretely, with a batch of N hidden state of positive pairs $(h_i, \hat{h_i})$, we add a non-linear layer on top of them:

$$\begin{aligned} c_i &= W_2\text{ReLU}(W_1 h_i) \\ \hat{c_i} &= W_2\text{ReLU}(W_1 \hat{h_i}) \end{aligned} \tag{12}$$

where $W_1 \in \mathrm{R}^{d_h \times d_h}$, $W_2 \in \mathrm{R}^{d_h \times d_h}$. For each example, there are $2(N-1)$ negative pairs, i.e., all the remaining examples in the batch are negative examples. Thus, for a batch of $2N$ examples $\mathbf{Z} = \{z \in \{c_i\} \cup \{\hat{c_i}\}\}$, we compute the NT-Xent loss (Chen et al., 2020b) for z_m as:

$$L_m^{con} = -\log \frac{\exp(\text{sim}(z_m, \mu(z_m))/\tau)}{\sum_{i=1, i\neq m}^{2N} \exp(\text{sim}(z_m, z_i)/\tau)} \tag{13}$$

where sim is the cosine similarity function as $\text{sim}(u, v) = u \cdot v / \|u\|\|v\|$ and μ is a matching function as:

$$\mu(z_m) = \begin{cases} c_i, & \text{if } z_m = \hat{c_i} \\ \hat{c_i}, & \text{if } z_m = c_i \end{cases} \tag{14}$$

τ is a temperature hyperparameter.

The total contrastive loss is the mean loss of all examples:

$$L^{con} = \frac{1}{2N} \sum_{m=1}^{2N} L_m^{con} \tag{15}$$

4.5 Classification and Objective Function

Following previous work (Zhou et al., 2020), we flatten the hierarchy for multi-label classification. The hidden feature is fed into a linear layer, and a sigmoid function is used for calculating the probability. The probability of text i on label j is:

$$p_{ij} = \text{sigmoid}(W_c h_i + b_c)_j \tag{16}$$

where $W_C \in \mathbb{R}^{k \times d_h}$ and $b_c \in \mathbb{R}^k$ are weights and bias. For multi-label classification, we use a binary cross-entropy loss function for text i on label j,

$$L_{ij}^C = -y_{ij}\log(p_{ij}) - (1 - y_{ij})\log(1 - p_{ij}) \tag{17}$$

$$L^C = \sum_{i=1}^{N} \sum_{j=1}^{k} L_{ij}^C \tag{18}$$

where y_{ij} is the ground truth. The classification loss of the constructed positive examples $\hat{L^C}$ can be calculated similarly by Equation 16 and Equation 18 with $\hat{h_i}$ substituting for h_i.

The final loss function is the combination of classification loss of original data, classification loss of the constructed positive samples, and the contrastive learning loss:

$$L = L^C + \hat{L^C} + \lambda L^{con} \tag{19}$$

where λ is a hyperparameter controlling the weight of contrastive loss.

During testing, we only use the text encoder for classification and the model degenerates to a BERT encoder with a classification head.

Dataset	$\lvert Y \rvert$	Depth	Avg($\lvert y_i \rvert$)	Train	Dev	Test
WOS	141	2	2.0	30,070	7,518	9,397
NYT	166	8	7.6	23,345	5,834	7,292
RCV1-V2	103	4	3.24	20,833	2,316	781,265

Table 1: Data Statistics. $\lvert Y \rvert$ is the number of classes. Depth is the maximum level of hierarchy. Avg($\lvert y_i \rvert$) is the average number of classes per sample.

5 Experiments

5.1 Experiment Setup

Datasets and Evaluation Metrics We experiment on Web-of-Science (WOS) (Kowsari et al., 2017), NYTimes (NYT) (Sandhaus, 2008), and RCV1-V2 (Lewis et al., 2004) datasets for comparison and analysis. WOS contains abstracts of published papers from Web of Science while NYT and RCV1-V2 are both news categorization corpora. We follow the data processing of previous work (Zhou et al., 2020). WOS is for single-path HTC while NYT and RCV1-V2 include multi-path taxonomic labels. The statistic details are illustrated in Table 1. Similar to previous work, We measure the experimental results with Macro-F1 and Micro-F1.

Implement Details For text encoder, we use `bert-base-uncased` from Transformers (Wolf et al., 2020) as the base architecture. Notice that we denote the attention layer in Eq. 4 and Eq. 7 as single-head attentions but they can be extended to multi-head attentions as the original Transformer block. For Graphormer, we set the attention head to 8 and feature size d_h to 768. The batch size is set to 12. The optimizer is Adam with a learning rate of $3e-5$. We implement our model in PyTorch and train end-to-end. We train the model with train set and evaluate on development set after every epoch, and stop training if the Macro-F1 does not increase for 6 epochs. The threshold γ is set to 0.02 on WOS and 0.005 on NYT and RCV1-V2. The loss weight λ is set to 0.1 on WOS and RCV1-V2 and 0.3 on NYT. γ and λ are selected by grid search on development set. The temperature of contrastive module is fixed to 1 since we have achieved promising results with this default setting in preliminary experiments.

Baselines We select a few recent work as baselines. HiAGM (Zhou et al., 2020), HTCInfoMax (Deng et al., 2021), and HiMatch (Chen et al., 2021) are a branch of work that propose fusion strategies for mixed text-hierarchy representation. HiAGM applies soft attention over text feature and label feature for the mixed feature. HTCInfoMax improves HiAGM by regularizing the label representation with a prior distribution. HiMatch matches text representation with label representation in a joint embedding space and uses joint representation for classification. HiMatch is the state-of-the-art before our work. All approaches except HiMatch adopt TextRCNN (Lai et al., 2015) as text encoder so that we implement them with BERT for a fair comparison.

5.2 Experimental Results

Main results are shown in Table 2. Instead of modeling text and labels separately, our model can make more use of the strong text encoder by migrating hierarchy information directly into BERT encoder. On WOS, the proposed HGCLR can achieve 1.5% and 2.1% improvement on Micro-F1 and Macro-F1 respectively comparing to BERT and is better than HiMatch even if its base model has far better performance.

BERT was trained on news corpus so that the base model already has decent performance on NYT and RCV1-V2, outperforming post-pretrain models by a large amount. On NYT, our approach observes a 2.3% boost on Macro-F1 comparing to BERT while sightly increases on Micro-F1 and outperform previous methods on both measurements.

On RCV1-V2, all baselines hardly improve Micro-F1 and only influence Macro-F1 comparing to BERT. HTCInfoMax experiences a decrease because its constraint on text representation may contradict with BERT on this dataset. HiMatch behaves extremely well on RCV1-V2 with Macro-F1 as measurement while our approach achieves state-of-the-art on Micro-F1. Besides the potential implement difference on BERT encoder, RCV1-V2 dataset provides no label name, which invalids our name embedding for label representation. Baselines like HiAGM and HiMatch only initialize labl embedding with their names so that this flaw has less impact. We will discuss more on name embedding in next section.

5.3 Analysis

The main differences between our work and previous ones are the graph encoder and contrastive learning. To illustrate the effectiveness of these two parts, we test our model with them replaced or removed. We report the results on the develop-

Model	WOS		NYT		RCV1-V2	
	Micro-F1	Macro-F1	Micro-F1	Macro-F1	Micro-F1	Macro-F1
Hierarchy-Aware Models						
TextRCNN (Zhou et al., 2020)	83.55	76.99	70.83	56.18	81.57	59.25
HiAGM (Zhou et al., 2020)	85.82	80.28	74.97	60.83	83.96	63.35
HTCInfoMax (Deng et al., 2021)	85.58	80.05	-	-	83.51	62.71

BERT+HiAGM (Our implement)	86.04	80.19	78.64	66.76	85.58	67.93
BERT+HTCInfoMax (Our implement)	86.30	79.97	78.75	67.31	85.53	67.09
BERT+HiMatch (Chen et al., 2021)	86.70	81.06	-	-	86.33	**68.66**
HGCLR	**87.11**	**81.20**	**78.86**	**67.96**	**86.49**	68.31

Table 2: Experimental results of our proposed model on several datasets. For a fair comparison, we implement some baseline with BERT encoder. We cannot reproduce the BERT results reported in Chen et al. (2021) so that we also report the results of our version of BERT.

Ablation Models	Micro-F1	Macro-F1
BERT	85.75	79.36
HGCLR	**87.46**	**81.52**
-*r.p.* GCN	87.06	80.63
-*r.p.* GAT	87.18	81.45
-*r.m.* graph encoder	86.67	80.11
-*r.m.* contrastive loss	86.72	80.97

Table 3: Performance when replace or remove some components of HGCLR on the development set of WOS. *r.p.* stands for *replace* and *r.m.* stands for *remove*. We remove the contrastive loss by setting $\lambda = 0$.

(a)

(b)

Figure 3: T-SNE visualization of the label representations on WOS dataset. Dots with same color are labels with a same father. (a) BERT model. (b) Our approach.

ment set of WOS for illustration. We first replace Graphormer with GCN and GAT (*r.p.* GCN and *r.p.* GAT), results are in Table 3. We find that Graphormer outperforms both graph encoders on this task. GAT also involves the attention mechanism but a node can only attend to its neighbors. Graphormer adopts global attention where each node can attend to all others in the graph, which is proven empirically more effective on this task. When the graph encoder is removed entirely (-*r.m.* graph encoder), the results drop significantly, showing the necessity of incorporating graph encoder for HTC task.

The model without contrastive loss is similar to a pure data augmentation approach, where positive examples stand as augment data. As the last row of Table 3, on development set, both the positive pair generation strategy and the contrastive learning framework have contributions to the model. Our data generation strategy is effective even without contrastive learning, improving BERT encoder by around 1% on two measurements. Contrastive learning can further boost performance by regularizing text representation.

We further analyze the effect of incorporating label hierarchy, the Graphormer, and the positive samples generation strategy in detail.

5.3.1 Effect of Hierarchy

Our approach attempts to incorporating hierarchy into the text representation, which is fed into a linear layer for probabilities as in Equation 16. The weight matrix W_C can be viewed as label representations and we plot theirs T-SNE projections under default configuration. Since a label and its father should be classified simultaneously, the representation of a label and its father should be similar. Thus, if the hierarchy is injected into the text repre-

Variants of Graphormer	Micro-F1	Macro-F1
Base architecture	**87.46**	**81.52**
-w/o name embedding	86.40	80.40
-w/o spatial encoding	86.88	80.42
-w/o edge encoding	87.25	80.54

Table 4: Performance with variants of Graphormer on development set of WOS. We remove name embedding, spatial encoding, and edge encoding respectively. "w/o" stands for "without".

Generation Strategy	Micro-F1	Macro-F1
Hierarchy-guided	**87.46**	**81.52**
Dropout	86.94	79.91
Random masking	87.19	81.16
Adversarial attack	86.67	80.24

Table 5: Impact of different positive example generation techniques on the development set of WOS. Hierarchy-guided is the proposed method. We control the valid tokens in positive samples roughly the same for random methods. We select FGSM as the attack algorithm following Pan et al. (2021).

sentation, labels with the same father should have more similar representation to each other than those with a different father. As illustrated in Figure 3, label representations of BERT are scattered while label representations of our approach are clustered, which demonstrates that our text encoder can learn a hierarchy-aware representation.

5.3.2 Effect of Graphormer

As for the components of the Graphormer, we validate the utility of name embedding, spatial encoding, and edge encoding. As in Table 4, all three components contribute to embedding the graph. Edge encoding is the least useful among these three components. Edge encoding is supposed to model the edge features provided by the graph, but the hierarchy of HTC has no such information so that the effect of edge encoding is not fully embodied in this task. Name embedding contributes most among components. Previous work only initialize embedding weights with label name but we treat it as a part of input features. As a result, neglecting name embedding observes the largest drop, which may explain the poor performance on RCV1-V2.

5.3.3 Effect of Positive Example Generation

To further illustrate the effect of our data generation approach, we compare it with a few generation strategies. Dropout (Gao et al., 2021) uses no positive sample generation techniques but contrasts on the randomness of the Dropout function using two identical models. Random masking (Meng et al., 2021) is similar to our approach except the remained tokens are randomly selected. Adversarial attack (Pan et al., 2021) generates positive examples by an attack on gradients.

As in Table 5, a duplication of the model as positive examples is effective but performs poorly. Instead of dropping information at neuron level, random masking drops entire tokens and boosts Macro-F1 by over 1%, indicating the necessity of building hard enough contrastive examples. The adversarial attack can build hard-enough samples by gradient ascending and disturbance in the embedding space. But the disturbance is not regularized by hierarchy or labels so that it is less effective since there is no guarantee that the adversarial examples remain the label. Our approach guided the example construction by both the hierarchy and the labels, which accommodates with HTC most and achieves the best performance.

In Figure 4, we select two cases to further illustrate the effect of labels on positive samples generation. In the first case, word *machine* strongly indicates this passage belongs to *Machine Learning* so that it is kept for positive examples. In the second case, *syndrome* is related to *Medical* and *PRES* occurs several times among *Headache*. Because of the randomness of sampling, our approach cannot construct an example with all keywords. For instance, *learning* in case one or *headache* in case two is omitted in this trial, which adds more difficulties for contrastive examples.

6 Conclusion

In this paper, we present Hierarchy-guided Contrastive Learning (HGCLR) for hierarchy text classification. We adopt contrastive learning for migrating taxonomy hierarchy information into BERT encoding. To this end, we construct positive examples for contrastive learning under the guidance of a graph encoder, which learns label features from taxonomy hierarchy. We modify Graphormer, a state-of-the-art graph encoder, for better graph understanding. Comparing to previous approaches, our approach empirically achieves consistent improvements on two distinct datasets and comparable results on another one. All of the components we designed are proven to be effective.

A Trick for Token Selection

To make sure P_i in Equation 10 can acquire gradients, we choose to modify token embedding instead of the token itself. As in Equation 6, e_i is the token embedding of x_i and can have gradient. The positive counterpart of e_i is denoted as:

$$\hat{e_i} = e_i((P_i + Detach(1 - P_i)) \text{ if } P_i > \gamma \text{ else } 0), \tag{20}$$

where $Detach$ is a function that ignores the gradient of its input. Numerically, $\hat{e_i}$ is either e_i or 0 depending on the threshold γ, which serves the same purpose as Equation 10. As for gradient,

$$\frac{\partial \hat{e_i}}{\partial P_i} = e_i \text{ if } P_i > \gamma \text{ else } 0, \tag{21}$$

which makes P_i can be updated by back-propagation.

Abstract

Natural language processing models learn word representations based on the distributional hypothesis, which asserts that word context (e.g., co-occurrence) correlates with meaning. We propose that n-grams composed of random character sequences, or *garble*, provide a novel context for studying word meaning both within and beyond extant language. In particular, randomly generated character n-grams lack meaning but contain primitive information based on the distribution of characters they contain. By studying the embeddings of a large corpus of garble, extant language, and pseudowords using CharacterBERT, we identify an axis in the model's high-dimensional embedding space that separates these classes of n-grams. Furthermore, we show that this axis relates to structure within extant language, including word part-of-speech, morphology, and concept concreteness. Thus, in contrast to studies that are mainly limited to extant language, our work reveals that meaning and primitive information are intrinsically linked.

1 Introduction

What primitive information do character sequences contain? Modern natural language processing is driven by the *distributional hypothesis* (Firth, 1957), which asserts that the context of a linguistic expression defines its meaning (Emerson, 2020). Because existing words—which represent an extremely small fraction of the space of possible character sequences—appear in context together, the distributional paradigm at this level is limited in its ability to study the meaning of and information encoded by arbitrary character level n-grams (word forms). Furthermore, state-of-the-art computational language models operating within the distributional paradigm, such as BERT (Devlin et al., 2019), are mainly trained on extant words. Yet, a plethora of insights into language learning have emerged from inquiries into language beyond extant words, such as the grammatical errors and inference patterns that children exhibit when distinguishing extant words from non-linguistic auditory signals, including emotional expressions, auditory gestures, and other forms of paralinguistic speech (Yang, 2006; Carey, 2000). We therefore propose that character n-grams (i.e., sequences of alphabetic characters) outside the space of extant language can provide new insights into the meaning of words and how they are represented by these models, beyond that captured by word and subword-based distributional semantics alone. We explore this by studying the embeddings of randomly generated character n-grams (referred to as *garble*), which contain primitive communicative information but are devoid of meaning, using the CharacterBERT model (El Boukkouri et al., 2020). Such randomly generated character n-grams are textual analogues of paralinguistic vocalizations—vocal extra-speech sounds and noises.

Our analyses contribute to the growing understanding of BERTology (Rogers et al., 2020) by identifying a dimension, which we refer to as the *information axis*, that separates extant and garble n-grams. This finding is supported by a Markov

May 22-27, 2022

model that produces a probabilistic information measure for character n-grams based on their statistical properties. Strikingly, this information dimension correlates with properties of extant language; for example, parts of speech separate along the information axis, and word concreteness varies along a roughly orthogonal dimension in our projection of CharacterBERT embedding space. Although the information axis we identify separates extant and randomly generated n-grams very effectively, we demonstrate that these classes of n-grams mix into each other in detail, and that *pseudowords*—i.e., phonologically coherent character n-grams without extant lexical meaning—lie between the two in our CharacterBERT embeddings.

This paper is organized as follows. We first discuss concepts from natural language processing, information theory, and linguistics relevant to our study. We then analyse CharacterBERT representations of extant and randomly generated character sequences and how the relation between the two informs the structure of extant language, including morphology, part-of-speech, and word concreteness. Finally, we ground our information axis in a predictive Markov language model.

2 Modeling n-grams Beyond Extant Language

Models in computational linguistics often represent words in a high-dimensional embedding space based on their co-occurrence patterns according to the distributional hypothesis (Landauer and Dumais, 1997; Mikolov et al., 2013). Embeddings that capture the semantic content of extant words are used for many natural language applications, including document or sentence classification (Kowsari et al., 2019), information retrieval and search (Mitra et al., 2018), language modelling and translation (Devlin et al., 2019), language generation (Brown et al., 2020), and more (Jurafsky and Martin, 2021). In these cases, vector operations performed on word embeddings are used for higher-level tasks such as search or classification.

Word embeddings have largely concerned themselves with extant language—that is, commonly used words which carry consistent meaning—and thus cannot represent character n-grams outside of this space. The few models that encompass *character* n-grams, which naturally include n-grams beyond extant words, often use RNNs (Mikolov et al., 2010) or encoder-decoder architectures (Sutskever et al., 2014) to represent character-level sequences. In parallel, the ubiquitous use of Transformer models has led to studies of their inner representations, weights, and attention mechanism (Rogers et al., 2020; Clark et al., 2019). Most Transformer models are trained using extant words and sub-words, largely focusing on their semantics and syntax; however, some recent models operate at the character level, such as CharacterBERT (El Boukkouri et al., 2020) and CharBERT (Ma et al., 2020). Strikingly, character-level models excel at character-level tasks (e.g., spelling correction; Xie et al. 2016; Chollampatt and Ng 2018) and perform comparably to word-level models at language-modelling tasks (Kim et al., 2016).

Character-level models are therefore an ideal tool for studying the information and meaning encoded in n-grams beyond the realm of extant language. Given that the current state-of-the-art is driven by Transformer-based models, throughout our study, we use the CharacterBERT model. CharacterBERT is uniquely suited for our study as it uses a CharacterCNN module (Peters et al., 2018) to produce single embeddings for any input token, built as a variant to BERT which relies on sub-word tokenization (El Boukkouri et al., 2020).

3 Primitive Information and Meaning Beyond Extant Language

Before presenting our results, we discuss general characteristics of the space beyond extant words; we reiterate that this space is missed by word and sub-word-based models. Due to CharacterBERT's use of English characters, we restrict our analysis to English character n-grams, and we study the properties of CharacterBERT embeddings including English-based n-grams outside of extant language. By studying CharacterBERT's representations of meaning encoded in n-grams that do not appear in consistent (or any) context in its training data, our framework goes beyond the traditional distributional hypothesis paradigm. In this way, we seek to understand core properties of information encoded in n-grams beyond their lexicalized semantics by simultaneously studying n-grams that contain different types of information.[1]

We use randomly generated character sequences to create n-grams that contain primitive informa-

---

[1] In analogy, the theory of ensemble perception in developmental psychology offers a framework to understand the human ability to understand the 'gist' of multiple objects at once (Sweeny et al., 2015).

tion but no meaning. We adapt Marr's notion of primitive visual information for primitive textual information (Marr and Hildreth, 1980), and make the analogue between vision and language because information is substrate independent (Deutsch and Marletto, 2015). In our case, primitive textual information is lower-level communicative information which is present in both text with and without meaning. Being textual, our randomly generated n-grams are not bound by the constraints of human speech, and may be phonologically impossible; these garble n-grams may be seen as an example of textual noise.

In the following subsections, we provide three examples of language—distorted speech, paralanguage, and pseudowords—which motivate our study of character-level embeddings for randomly generated character n-grams. We then describe the complementary information encoded by word morphology.

3.1 Distorted Speech

In popular use, "garble" refers to a message that has been distorted (garbled), such as speech where meaning is corrupted by phonological distortions. For example, the phrase "reading lamp" may become "eeling am" when garbled. Garbled speech contains lesser, or zero, meaning compared to ungarbled speech, but the signal of speech media is nonetheless present as information, which according to Shannon (1951) may contain no meaning at all. Garbled speech satisfies the classical five-part definition of communication provided by Shannon (2001); an *information source* (speaker) can *transmit* (verbalize) an informationally primitive message through the *channel* of speech media through the *receiver* (ears) to the *destination* (listener).

3.2 Paralanguage

Paralinguistic vocalizations are specifically identifiable sounds beyond the general characteristics of speech (Noth, 1990) and present another example of communication beyond lexicalized semantics. Paralinguistic vocalizations include *characterizers*, like moaning; and *segregates*, like "uh-huh" for affirmation. The border between such paralinguistic vocalizations and lexicalized interjections with defined meanings is "fuzzy" (Noth, 1990).

3.3 Pseudowords

Pseudowords are phonologically possible character n-grams without extant lexical meaning. Word-likeness judgments reveal that human distinctions between pseudowords and phonologically impossible nonwords are gradational (Needle et al., 2020). As a unique informational class, pseudowords have been used in language neuronal activation studies (Price et al., 1996), infant lexical-semantic processing (Friedrich and Friederici, 2005), in poetry through nonsense (Ede, 1975), and in literary analyses (Lecercle, 2012). Pseudowords can also elicit similar interpretations and associations across independent participants (Davis et al., 2019a).

To consider pseudowords generatively, it is helpful to note that an alphabetic writing system covers not only every word but every possible word in its language (Deutsch, 2011); pseudowords can thus be thought of as possible-but-uninstantiated (counterfactual) extant words—e.g., "cyberspace" was a pseudoword before the internet. We embed randomly generated pseudowords into our model to study their information content and relation to both extant words and randomly generated n-grams.

3.4 Morphology

Morphology deals with the systems of natural language that create words and word forms from smaller units (Trost, 1992). Embedding spaces and the distributional hypothesis offer insights into the relationship between character combination, morphology and semantics. Notably, morphological irregularities complicate the statistics of global character-level findings in the embedding space, like through *suppletion*—where word forms change idiosynchratically e.g. *go*'s past tense is *went*, or *epenthesis*—where characters are inserted under certain phonological conditions e.g. fox pluralizes as fox*e*s (Trost, 1992); so too do the multiple 'correct' spellings of pseudowords under conventional phoneme-to-grapheme mappings (Needle et al., 2020). Distinctions between morphological phenomena can also be hard to define; for example, the boundary between derivation and compounding is "fuzzy" (Trost, 1992).

4 Character-Level Language Models for Information Analysis

As described above, state-of-the-art language models serve as a tool to study meaning as it emerges though the distributional hypothesis paradigm. Existing work on the analysis of Transformers and BERT-based models have explored themes we are interested in, such as semantics (Ethayarajh, 2019),

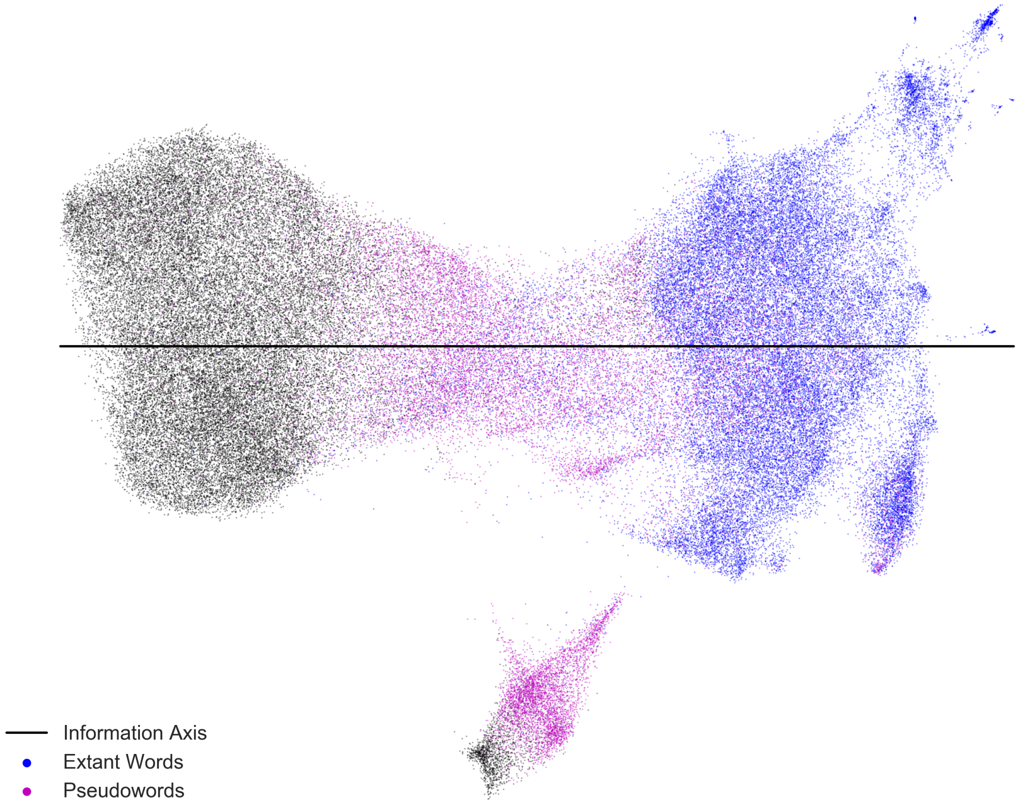

Figure 1: UMAP projection of CharacterBERT embeddings for extant words (blue), pseudowords (magenta), and randomly generated character n-grams (black). The solid black line shows the information axis that we define in this work. The bottom-most cluster of random and pseudoword character n-grams is comprised of character n-grams ending in "s", and the top-most clusters of extant words are comprised of compound words.

syntax (Goldberg, 2019), morphology (Hofmann et al., 2020, 2021), and the structure of language (Jawahar et al., 2019). However, all of this work limits itself to the focus of extant words due to the word and sub-word-based nature of these models.

We study the structure of the largely unexplored character n-gram space which includes extant language, pseudowords and garble character n-grams, seen through the representations created by CharacterBERT, as follows. To explore how the character n-gram space is structured in the context of character based distributional semantics, we embed 40,000 extant English words, 40,000 randomly generated character n-grams, and 20,000 pseudowords. We choose the 40,000 most used English words that have been annotated for concreteness/abstractness ratings (Brysbaert et al., 2014). Randomly generated character n-grams are forced to have a string length distribution that matches the corpus of extant words we analyze. To generate pseudowords, we use a popular pseudoword generator.[2]

The CharacterBERT (El Boukkouri et al., 2020) general model has been trained on nearly 40 GB of Reddit data using character sequences. We leverage this model to create representations of character n-grams that may not have been seen in the training data. This allows us to use the resulting 512 dimensional embeddings for exploration via visualisation, topology modelling via distances and projections, and classification error analysis.

4.1 Identifying the Information Axis

To guide our exploration of the high-dimensional topology of the resulting embeddings, we use the UMAP dimensionality reduction technique (McInnes et al., 2018). UMAP creates a low-dimensional embedding by searching for a low-dimensional projection of the data that has the closest possible equivalent fuzzy topological structure as the original representations, thereby preserving both local and global structure. In Appendix A, we demonstrate that our key results are not sensitive to this choice of dimensionality reduction method.

We use the UMAP embeddings to extract an *in-*

Character n-gram type	Information Axis position
Extant	0.75 ± 0.12
Noun	0.74 ± 0.12
Verb	0.72 ± 0.09
Adjective	0.76 ± 0.11
Adverb	0.87 ± 0.09
Pseudoword	0.50 ± 0.15
Random	0.17 ± 0.11

Table 1: Median and standard deviation of minmax-normalized position along the information axis shown in Figure 1, for extant words (including parts of speech), pseudowords, and randomly generated n-grams.

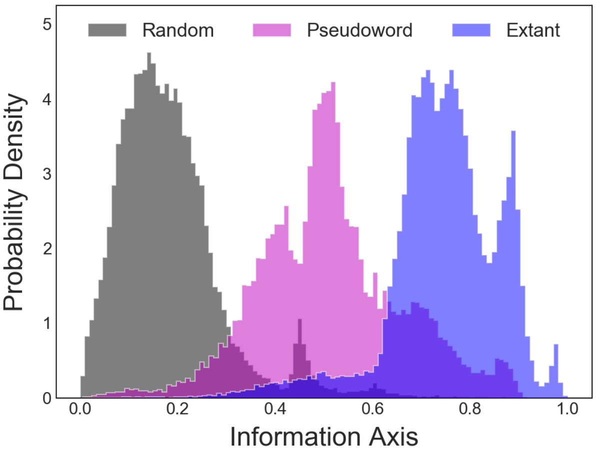

Figure 2: Probability density of CharacterBERT embeddings for extant words (blue), pseudowords (magenta), and randomly generated character n-grams (black) as a function of minmax-normalized position along the information axis shown in Figure 1.

formation axis that captures most variance among extant and randomly generated n-grams. To assign n-grams an 'information axis score,' we minmax-normalize the UMAP coordinates along this axis. Thus, our information axis establishes a link between extant language and garble, thereby connecting meaning and primitive information. Figure 1 shows how CharacterBERT embeddings of extant, pseudoword, and randomly generated character n-grams arrange themselves in this space.

4.2 Statistical Properties of n-grams Along the Information Axis

We perform several statistical tests to differentiate between categories of character n-grams along the information axis. First, Table 1 lists the median and standard deviation of minmax-normalized position along the information axis, demonstrating that extant words, pseudowords, and garble are clearly separated. Note that the scatter within each n-gram class is much smaller than the distances between classes, indicating that our results are robust to variations in the garble and pseudoword samples.

Next, we use the Kolmogorov-Smirnov (KS; Massey Jr 1951) two-sample test to assess differences between the information axis distributions of our n-gram classes. All of the KS tests very significantly indicate differences between types of character n-gram and parts of speech along the information axis ($p \ll 0.001$). Furthermore, the KS statistic score is 0.94 for (extant, random), 0.83 for (pseudoword, random), and 0.70 for (extant, pseudoword), indicating that extant and random n-grams differ most significantly along the information axis (consistent with Figures 1–2).

4.3 Hyperplane Classifier

The visualisation of the character n-grams suggests that a hyperplane classifier is suitable for separating extant words and garble. We use a support vector machine (Cortes and Vapnik, 1995) trained on half of our 40,000 commonly-used extant words and half of our computer-generated garble to classify unseen extant, garble and pseudoword character n-grams. We use this method to explore the information axis in the high-dimensional embedding space.

The classifier achieves an accuracy of 98.9% on unseen extant language and garble character n-grams, suggesting we can learn about the embeddings through error analysis.

In particular, we found similarities among extant words classified as garble. 74.4% (270/363) were compound or derivative words, similar to many extant language terms that lie near the midpoint of the information axis. 19% (69/363) were foreign words like "hibachi" or dialect words like "doohickey."

The garble classification errors—garble classified as extant language—were in small part due to our randomization method inadvertently creating extant language labelled as garble, accounting for 9.5% (36/377) errors we identify. The garble classified as extant language mostly contained phonologically impossible elements, though some were pseudowords.

When pseudowords were forcibly classified into extant or garble character n-grams, more pseudowords were classified as extant language than garble (12894 as extant to 7106 as garble). Labelling affirms these intuitions, with pseudowords like "flought" looking intuitively familiar and being readable. Given CharacterBERT's massive Reddit training data, typos and localized language may account for the classifier's tendency to classify pseudowords as extant language. Also, our embedding space only uses the 40,000 most common English words out of 208,000 distinct lexicalized lemma words (Brysbaert et al., 2016), which may impact spatial structure if included.

5 Structure of Extant Words along the Information Axis

We use this section to discuss the structure of language across the information axis derived from our low-dimensional UMAP space. We structure our analysis across this axis as it organises the relative structure of extant words vs. randomly generated character n-grams, while also distinguishing internal structure within the extant word space.

5.1 Extant vs. Pseudowords vs. Garble

At the scale of global structure, the information axis highlights that extant words are separated from randomly generated character n-grams (Figure 1). We note that the midpoint of all character n-gram classes is 0.5 on our information axis. Pseudowords populate the region near the midpoint of the information axis, and also overlap with both extant English and garble character n-grams (Figure 2). There is no distinct boundary between the three classes of n-grams, consistent with both morphological descriptions of compound and derivational words and descriptions of paralanguage as "fuzzy." This global structure—and the structure internal to extant language (Figure 3)—goes beyond the distributional hypothesis by including n-grams that do not appear in consistent (or any) contexts, like pseudowords and garble. Pseudowords lie between extant and garble character n-grams, but there is no distinct boundary between pseudowords and the other classes of n-grams.

Extant language, pseudoword, and garble regions have different internal structure (Figure 1). The garble region has comparatively less structure than the extant language region, though there is some internal variation, notably a cluster of character n-grams ending in the character "s" separated from the main garble region. We qualitatively explore the classes of garble and pseudoword embeddings revealed by our analysis in Appendix B, which includes supplementary discussion of the potential relevance of these findings for linguistic theory.

5.2 Parts of Speech and Morphology

In our UMAP projection, detailed structure emerges for extant words split by part-of-speech (Figure 3). In particular KS statistics between all part-of-speech pairs significantly indicate that their distributions differ along the information axis. Furthermore, KS statistic values are 0.12 for (noun, verb), 0.11 for (noun, adjective), 0.64 for (noun, adverb), 0.22 for (verb, adjective), 0.72 for (verb, adverb), and 0.64 for (adjective, adverb). This suggests that adverbs are most cleanly separated from other parts of speech along the information axis (consistent with Figure 3), which may indicate that morphemes such as affixes have important effects in embedding space. A detailed investigation is beyond the scope of this paper and may require analyses through alternative heuristics such as pseudomorphology and lexical neighborhood density (Needle et al., 2020).

Many extant words near the midpoint of the information axis are, or may be, compound words; the boundary between derivative and compound words is thought to be fuzzy because many derivational suffixes developed from words are frequently used in compounding (Trost, 1992). Both derivative and compound words populate other spaces of the extant language region, but conflicting definitions hamper straightforward statistical analysis.

Morphological traits such as adjectival suffixes $-ness$, $-ism$, and $-able$, or the adverbial suffix $-ly$ correlate to clear embedding mappings, but the boundaries for morphological classes are not distinct. Garble ending in "s" occupies a closer region to extant language than most other garble, arguably due to the semantic associations of ending in "s" (e.g. regarding pluralization) derived from the suffix $-s$. Note, morphological heuristics like affixation apply to lexicalized words but not garble. Pseudowords ending in "s" share that region of garble ending in "s", however, such seemingly plural pseudowords tend closer to extant language, reflecting the notion that word form similarity increases with semantic similarity (Dautriche et al., 2017). Given the fuzziness of morphology and the opaqueness of English spelling (Needle et al., 2020), pseudowords ending in "s" may or may not be due to affixation.

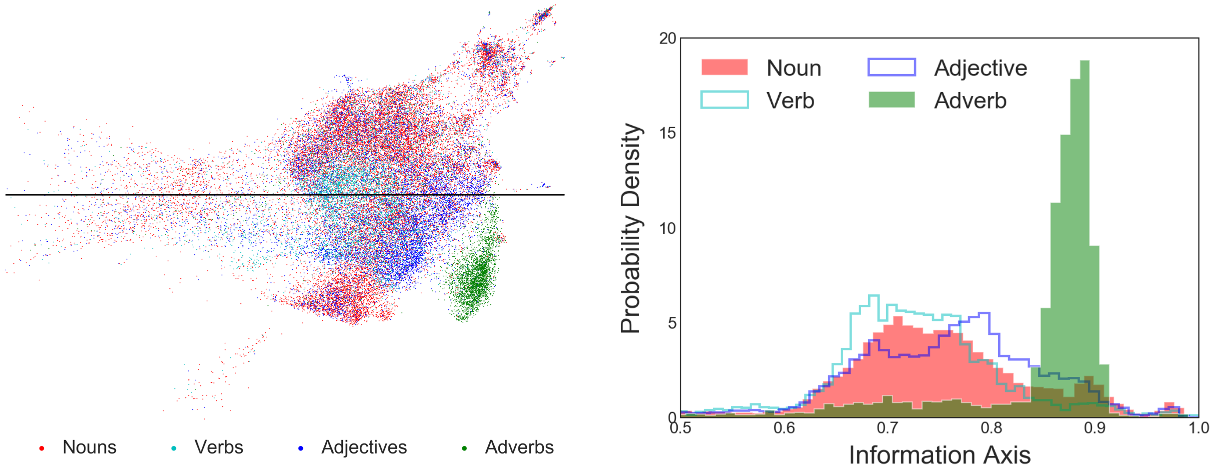

Figure 3: *Left panel*: UMAP projection of CharacterBERT embeddings for extant words split by part-of-speech into nouns (red), verbs (cyan), adjectives (blue), and adverbs (green). *Right panel*: Probability density of extant words, split by part-of-speech, as a function of minmax-normalized position along the information axis shown in Figure 1.

5.3 Concreteness/Abstractness

The internal positioning of different parts-of-speech within the extant language space of our low-dimensional UMAP projection suggests that the representations also capture notions of concreteness (e.g nouns) and abstractness (e.g adverbs) which we explore by projecting concreteness scores from the (Brysbaert et al., 2014) study. We calculate the center of extant UMAP coordinates with no weighting and with weighting by minmax-normalized concreteness and used those points to define a *concreteness axis*, which demonstrates that concreteness varies in a direction roughly orthogonal to our information axis (see Figure 4). The bootstrap-resampled angle distribution between information and concreteness axes is 86.6 ± 1.2 degrees.

Thus, the information axis and word concreteness capture two crucial and largely distinct aspects of the many latent features underlying CharacterBERT representations. This finding is particularly relevant in light of recent work showing not only that word concreteness is a psychologically rich dimension that shapes semantic processing (Brysbaert et al., 2016; Guilbeault et al., 2020), but also that word concreteness is surprisingly effective at enriching the predictive capacities of word embedding models, such as for the purpose of automated metaphor detection (Srinivasa Desikan et al., 2020). We leave a detailed investigation of this finding, including its relation to the visual information (Brysbaert et al., 2016) carried by concrete and abstract words, to future work.

5.4 Markov Chain Model

We also create a language model using the Prediction by Partial Matching (PPM) variable order Markov model (VOMM) to estimate the probability of each of these character n-grams (Begleiter et al., 2004). The model calculates the *logpdf* for each character n-gram in which more commonly occurring character n-grams have a lower score, and less commonly occurring character n-grams receive a higher score. The model is trained on extant words, then used to score all of the extant, pseudowords and garble character n-grams. We use this score to capture the likelihood of character n-grams in our character sequence space (Figure 5).

These Markov model values correlate with our information axis measure. In particular, the Spearman correlation coefficient between information axis and Markov chain information content is 0.4 (highly significant) for randomly generated n-grams, and 0.007 (not significant) for extant words. Thus, for random character n-grams, our information axis measure is correlated with statistical properties of the character n-grams from the Markov model (see the left panel of Figure 5). However, our information axis measure more clearly separates extant and garble n-grams, indicating that it incorporates information beyond purely statistical properties of n-gram classes (see the right panel of Figure 5). This suggests that the CharacterBERT model learns information beyond character-level statistical information, even for n-grams that never explicitly appear in the training data.

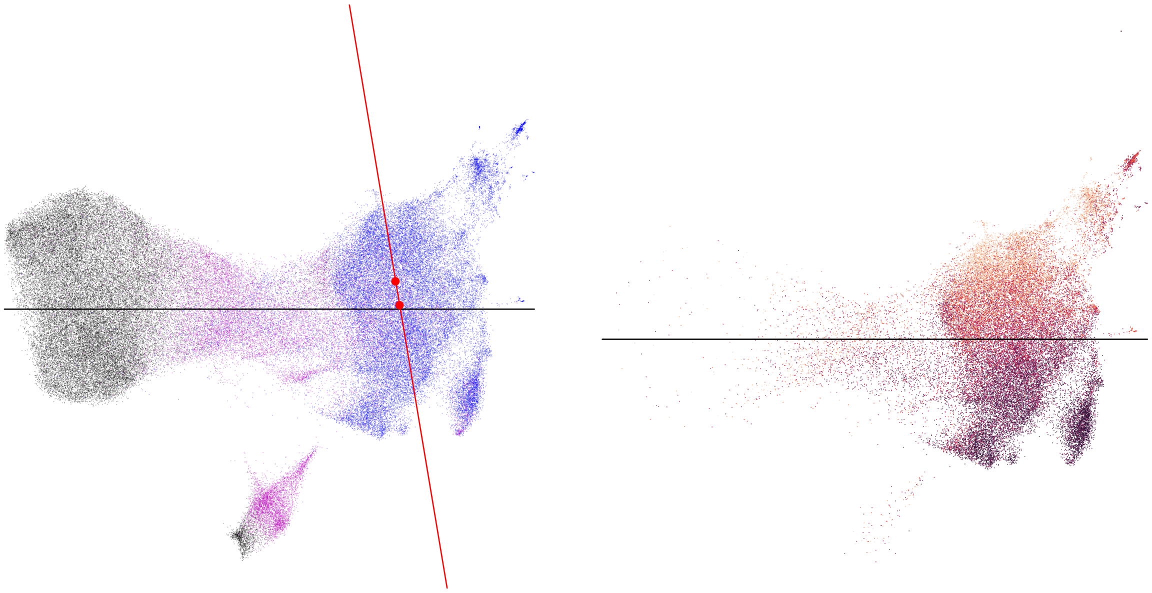

Figure 4: *Left panel*: UMAP projection of CharacterBERT embeddings for extant words (blue), pseudowords (magenta), and randomly generated character n-grams (black). The solid black line shows the information axis that we define in this work, and the red line shows the axis that captures variability in word concreteness, computed by connecting the unweighted average UMAP position for extant words with that weighted by minmax-normalized concreteness (red dots). *Right panel*: UMAP of only extant words, colored by minmax-normalized concreteness, with lighter colors indicating more concrete words.

6 Discussion and Conclusion

Using the CharacterBERT model, we embedded a large corpus of character level n-grams outside of extant language to study how the primitive information they contain relates to the semantic information carried by extant language. The key findings of this paper are:

1. Extant words and randomly generated character n-grams are separated along a particular axis in our UMAP projection of CharacterBERT embedding space (Figures 1–2);
2. Pseudowords lie between extant and randomly generated n-grams along this axis, but there is no distinct boundary between these classes of n-grams (Figures 1–2);
3. The structure of CharacterBERT embeddings of extant language, including structure based on part-of-speech and morphology, is correlated with the information axis (Figure 3);
4. Word concreteness varies along a dimension that is roughly orthogonal to the information axis in our UMAP projection (Figure 4);
5. Separation between extant and randomly generated n-grams captured by CharacterBERT is correlated with and more coherent than that based purely on the statistical properties of n-grams (Figure 5).

These findings suggest that character-based Transformer models are largely able to explore the relation between extant words and randomly generated character strings. In particular, character-level models capture complex structure in the space of words, pseudowords, and randomly generated n-grams. These findings are consistent with work suggesting that character-level and morpheme-aware representations are rich in meaning, even compared to word or sub-word models (Al-Rfou et al., 2019; El Boukkouri et al., 2020; Ma et al., 2020; Hofmann et al., 2020, 2021).

Our study is limited to extant words in English and randomly generated character n-grams using the English alphabet. Given the unique impact of a specific language and alphabet on representation spaces, there is motivation to see whether the relationships we identify generalise to other languages and alphabets. Finally, we reiterate that our analysis was limited to the last embedding layer of the CharacterBERT model; future work may focus on weights in earlier layers, including attention mechanisms explored by other BERTology studies (Clark et al., 2019; Jawahar et al., 2019). By only analysing the final embedding layer, we study

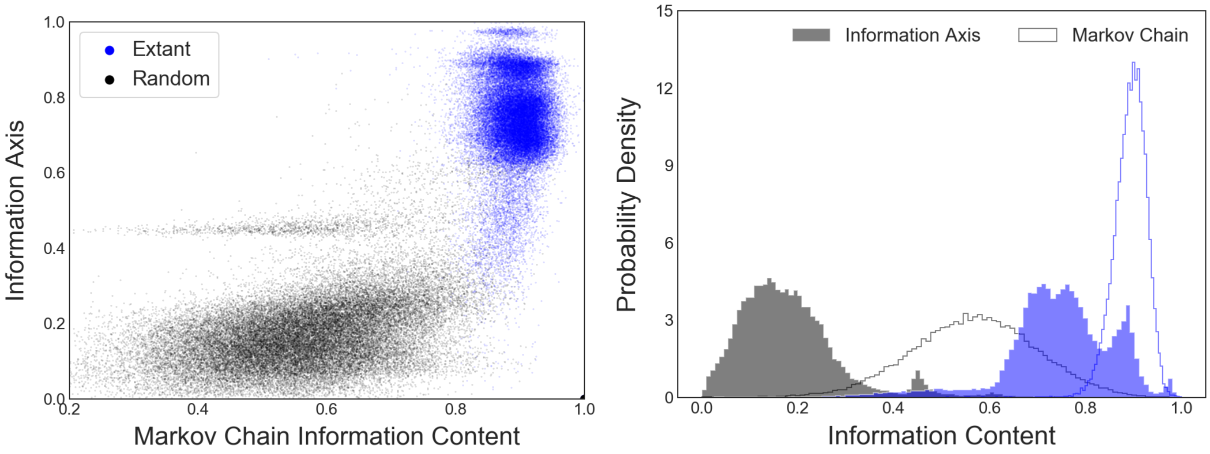

Figure 5: *Left panel*: Minmax-normalized position along the information axis shown in Figure 1 vs. minmax-normalized information content from our Markov Chain model, for extant words (blue) and randomly generated character n-grams (black). *Right panel*: Probability density of minmax-normalized information content measures from our UMAP projection (filled histograms) and Markov Chain model (unfilled histograms).

the 'psychology' of such character-level models; in analogy, much may be gained by studying the 'neuroscience' of such models encoded in their attention weights (Wang, 2020).

Our study also has important practical implications for the widespread use of pseudowords as an experimental tool in psycholinguistic research. Pseudowords are frequently used as stimuli to observe the psychological and neurocognitive processes underlying the interpretation of novel words (Price et al., 1996; Stark and McClelland, 2000; Keuleers and Brysbaert, 2010; Lupyan and Casasanto, 2015; Davis et al., 2019b). However, the lion's share of this research treats all pseudoword stimuli as equivalent in their novelty, based on *prima facie* human judgments. By contrast, our method shows that not all pseudowords are created equal. Due to various features of character sequences, including morphological structure, some pseudowords encode disproportionately more information according to character-aware language models, and are therefore represented as significantly more similar to extant words, whereas other pseudowords are recognized by these models as random character sequences. This variation is especially striking given that the algorithms used to generate pseudowords are highly constrained and designed to produce morphologically coherent words (Keuleers and Brysbaert, 2010); that some pseudowords are evaluated as random by CharacterBERT reveals not only asymmetries in the coherence of pseudowords that may be of psychological relevance, but also assumptions and limitations in terms of which morphological units CharacterBERT and related models recognize as signatures of extant words. Our study thus provides a quantitative method for evaluating pseudoword plausibility, without relying on variable human judgments, while also revealing insights into key differences between how humans and contemporary language models evaluate the plausibility of pseudowords.

To allow for further explorations and replicability, we release all of our data and code on GitHub[3]. Our findings reveal new avenues for future work using character-aware embeddings of extant, pseudoword, and garble n-grams, including analyses of nonsense poetry like Lewis Carroll's "Jabberwocky" or of the innovative idiosyncrasies of rap lyricists and graffiti artists. The embeddings we study may also complement philological studies (especially if dynamic analyses are employed), as well as research into novel category formation (Lupyan and Casasanto, 2015; Guilbeault et al., 2021). Also, language acquisition studies of the distinction between language and noise may benefit from character-level embeddings beyond the realm of extant language (Yang, 2006; Carey, 2000). By investigating a broadened embedding space to include randomly generated n-grams, we found new structures of meaning through the context of meaningless information; further studies may extend our garble-based approach across different media and modes to contribute to more general understandings of human meaning.

A Robustness to Alternative Dimensionality Reduction Techniques

Our main analyses use the UMAP algorithm to project garble, pseudoword, and extant word CharacterBERT embeddings into an interpretable, low-dimensional space. Here, we demonstrate that our key results are not sensitive to this choice of dimensionality reduction technique by recreating our findings using t-SNE, a popular alternative to UMAP. Figure 6 shows the extant, pseudoword, and garble embeddings resulting from the `scikit-learn` t-SNE algorithm (run with $n_{\mathrm{components}} = 2$ and $\mathrm{perplexity} = 10$). The qualitative structure is unchanged relative to the UMAP embedding shown in Figure 1: garble and extant n-grams are separated along a new information axis that captures roughly the same amount of variance as our original UMAP information axis, and pseudowords embeddings connect these two clusters. Furthermore, some particular aspects of the UMAP structure are preserved, including a distinct cluster of garble and pseudoword n-grams ending in “s” near the bottom of Figure 6. In general, the separation among t-SNE n-gram clusters is somewhat less distinct compared to the UMAP case, which we attribute to UMAP’s better preservation of global structure (McInnes et al., 2018).

The results of this t-SNE projection are also quantitatively consistent with our main findings. In particular, the UMAP information axis summary statistics presented in Table 1 become 0.70 ± 0.15, 0.54 ± 0.13, and 0.26 ± 0.12 for extant, pseudoword, and randomly generated n-grams, respectively; these results are all consistent with our UMAP results at the 1σ level. Similarly, KS two-sample tests between the extant, pseudoword, and garble information axis distributions all remain highly significant ($p \ll 0.001$), and their ordering is consistent with our UMAP results: the t-SNE information axis KS statistic scores are 0.86 for (extant, random), 0.76 for (pseudoword, random), and 0.50 for (extant, pseudoword). Relative to our fiducial UMAP results, the slightly larger scatter for the information axis summary statistics and the slightly weaker KS statistic scores are consistent with the increases in scatter orthogonal to the information axis in the t-SNE projection (Figure 6) relative to the UMAP projection (Figure 1). Thus, our main results are not sensitive to the dimensionality reduction method employed.

B Global Structure of Garble and Pseudoword Embeddings

Here, we qualitatively explore the main features of pseudoword and randomly generated n-grams’ structure in our UMAP projection, deferring a more detailed exposition to future work. Figure 7 highlights several distinct groups of randomly generated (black) and pseudoword (magenta) n-grams that we describe in detail below.

Beginning with randomly generated n-grams, we first note that there is a significant correlation between their string length and information axis score, such that randomly generated n-grams with low information axis scores tend to contain more characters, and vice versa. Indeed, the high-information tail of the garble distribution shown in Figure 2 has a power-law exponent that is quantitatively consistent with the low-length tail of the underlying string length distribution.[4] Figure 7 highlights two notable exceptions to this rule: a cluster of randomly generated n-grams with strings that tend to be short and often contain repeated characters, and a garble cluster in which strings tend to end in “s.” We refer to the remaining randomly generated n-grams as “typical garble.” To illustrate, we provide ten examples of n-grams in each category:

- Typical garble: kiwbckodaffzhjxkvpfh, ijhtsfjsu, ojcfere, fsgnwy, qiqa, nevm, uzp, tgj, bv, w;
- Short repeated garble: cureuul, fbxoon, gallm, alln, ffod, ido, obb, tek, aa, hq;
- -s garble: dddgvasbbzaoeuius, wdycrynylhyos, nkeccmosls, ilvtubdts, eoubazos, ptfjqs, hslxls, xwkss, gehs, jgs.

A particularly interesting feature of short repeated garble is that it encodes considerably more information along our axis than the pseudowords in our sample. This is striking because the pseudowords were generated using an algorithm designed to generate morphologically plausible words, whereas the garble is generated purely randomly at the character level. In this way, our garble embeddings provide novel insights into the string patterns that CharacterBERT identifies as information rich and predictive of word plausibility (in terms of proximity to extant words in embedding

---

[4] We remind the reader that our randomly generated string length distribution is matched to that of our extant sample.

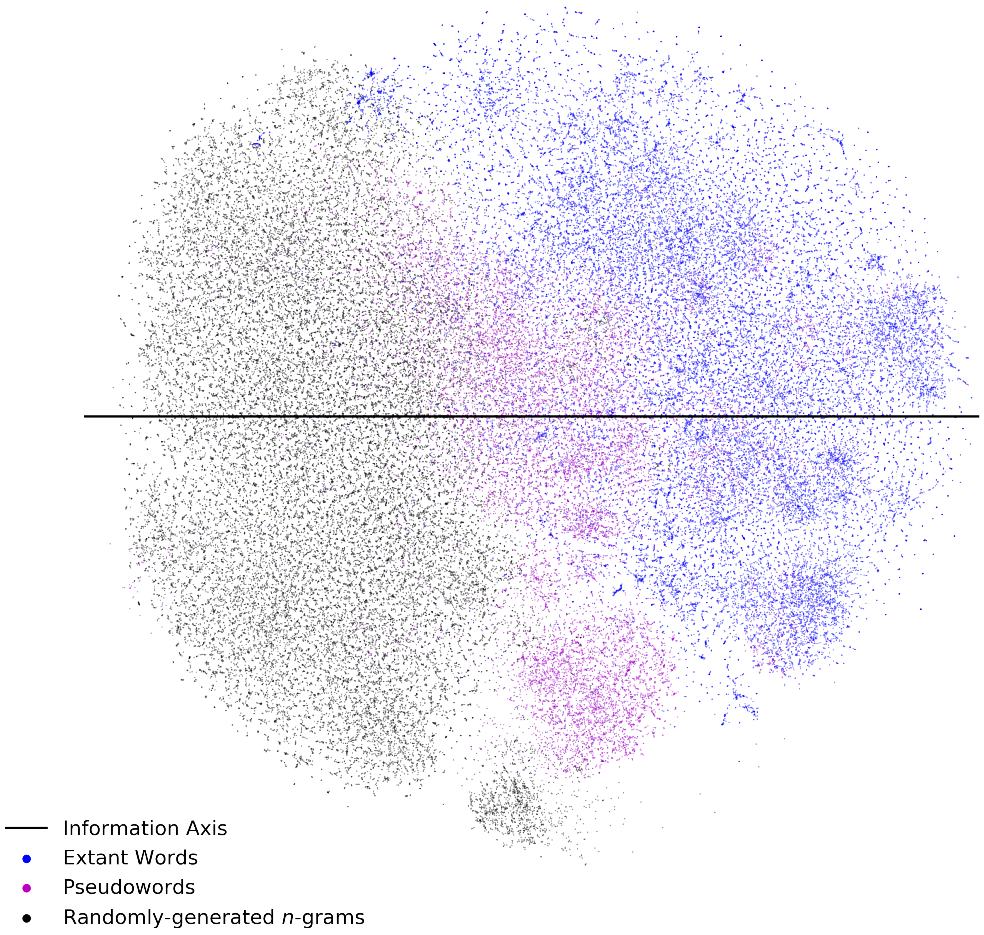

Figure 6: t-SNE projection of CharacterBERT embeddings for extant words (blue), pseudowords (magenta), and randomly generated character n-grams (black). The solid black line shows the information axis that we define in this work. The bottom-most cluster of random and pseudoword character n-grams is comprised of character n-grams ending in "s."

space); specifically, it reveals that CharacterBERT identifies repeated characters in the same string as information rich, even though these repeated character sequences often lack morphological hallmarks of extant words.

These sequences of repeated sounds share similarities with early-childhood vocalizations ("babbling"), as well as stylistic features of child-oriented speech in the context of early word learning, for example, words such as *mama* and *dada*. The role of simple character repetitions in child development is often studied from the phonetic standpoint as a mechanism for a child to become proficient in the diversity of sounds appearing in a language (Davis and MacNeilage, 1995). However, the results from CharacterBERT suggest that repetitive sequences are especially rich in their information at the character-level, which may confer additional syntactic or lexical benefits as children learn to differentiate random sounds from linguistically meaningful units. We leave further investigation of this to future work.

Pseudoword embeddings also display a clear cluster in which strings tend to end in "s." In addition, there is a distinct pseudoword group near extant adverbs (see Figure 3) in which strings tend to end in "ly." We refer to the remaining pseudoword n-grams as "typical pseudowords." To illustrate, we provide ten examples of n-grams in each category:

- Typical pseudowords: hypnostementer, eatmendownwald, eninardister, unalgion, conquing, ambooked, runton, ditity, etbarn;
- -s pseudowords: sacrembelcones, irstuphorries, unnessnells, herepairds, finihips, littoes, warposs, quards, precs, gicass;
- -ly pseudowords: queepecturusly, unbornortardly, remechlocally, expotputtly, musteetly, confully, popubly, ectoily, artfaly, mously.

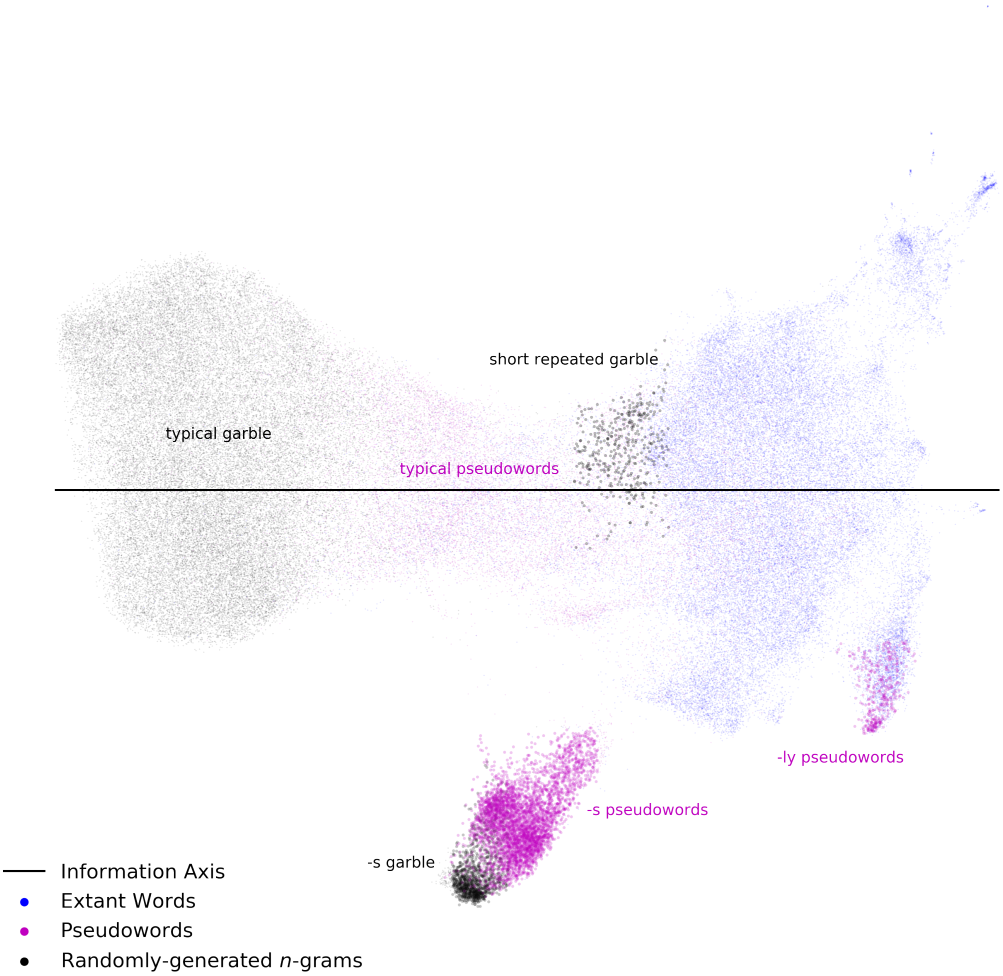

Figure 7: UMAP projection of CharacterBERT embeddings for extant words (blue), pseudowords (magenta), and randomly generated character n-grams (black). The solid black line shows the information axis that we define in this work. We discuss the highlighted clusters of pseudoword and garble n-grams in Appendix B.

Hyperlink-induced Pre-training for Passage Retrieval in Open-domain Question Answering

Abstract

To alleviate the data scarcity problem in training question answering systems, recent works propose additional intermediate pre-training for dense passage retrieval (DPR). However, there still remains a large discrepancy between the provided upstream signals and the downstream question-passage relevance, which leads to less improvement. To bridge this gap, we propose the **H**yper**L**ink-induced **P**re-training (HLP), a method to pre-train the dense retriever with the text relevance induced by hyperlink-based topology within Web documents. We demonstrate that the hyperlink-based structures of *dual-link* and *co-mention* can provide effective relevance signals for large-scale pre-training that better facilitate downstream passage retrieval. We investigate the effectiveness of our approach across a wide range of open-domain QA datasets under zero-shot, few-shot, multi-hop, and out-of-domain scenarios. The experiments show our HLP outperforms the BM25 by up to 7 points as well as other pre-training methods by more than 10 points in terms of top-20 retrieval accuracy under the zero-shot scenario. Furthermore, HLP significantly outperforms other pre-training methods under the other scenarios.

1 Introduction

Open-domain question answering (OpenQA) aims to answer factual open questions with a large external corpus of passages. Current approaches to OpenQA usually adopt a two-stage retriever-reader paradigm (Chen et al., 2017; Zhu et al., 2021) to fetch the final answer span. The performance of OpenQA systems is largely bounded by the retriever as it determines the evidential documents for the reader to examine. Traditional retrievers, such as TF-IDF and BM25 (Robertson and Zaragoza, 2009), are considered incapable of adapting to scenarios where deep semantic understanding is required. Recent works (Lee et al., 2019; Karpukhin et al., 2020; Qu et al., 2021) show that by fine-tuning pre-trained language models on sufficient downstream data, dense retrievers can significantly outperform traditional term-based retrievers.

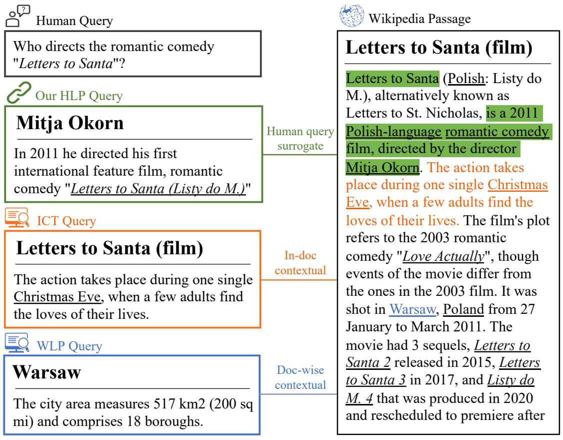

Figure 1: An example of different kinds of pseudo Q-P pairs. Underlined texts are hypertexts that linked to other Wikipedia pages. The ICT query is a random sentence originated from the passage and the WLP query is a sentence from the first section of an out-link document of the given passage. The text highlighted in green gives evidence to answer the human query, and our proposed HLP query can be a better surrogate of the human query.

Considering the data-hungry nature of the neural retrieval models, extensive efforts (Lee et al., 2019; Chang et al., 2019; Sachan et al., 2021) have been made to design self-supervised tasks to pre-train the retriever. However, these pre-training tasks construct relevance signals largely depending on easily attainable sentence-level or document-level contextual relationships. For example, the relationship between a sentence and its originated context (shown by the ICT query in Figure 1) may not be sufficient enough to facilitate question-passage matching for the tasks of OpenQA. We also find that these pre-trained retrievers still fall far behind BM25 in our pilot study on the zero-shot experiment.

Our code and trained models are available at `https://github.com/jzhoubu/HLP`.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 7135 - 7146
May 22-27, 2022

In order to address the shortcomings of the matching-oriented pre-training tasks as mentioned above, we propose a pre-training method with better surrogates of real natural question-passage (Q-P) pairs. We consider two conditions of relevance within Q-P pairs, which is similar to the process of distantly supervised retriever learning (Mintz et al., 2009; Chen et al., 2017).

1) **Evidence Existence** The evidence, such as entities and their corresponding relations, should exist across the query and the targeted passage as they both discuss similar facts or events related to the answer.
2) **Answer Containing** The golden passage should contain the answer of the query, which means that a text span within the passage can provide the information-seeking target of the query.

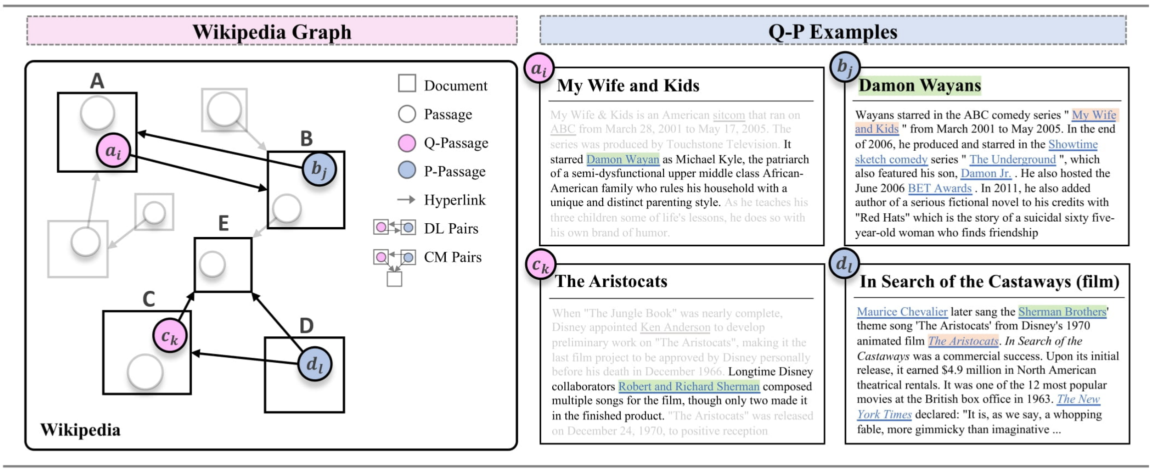
In this paper, we propose **H**yper**L**ink-induced **P**re-training (HLP), a pre-training method to learn effective Q-P relevance induced by the hyperlink topology within naturally-occurring Web documents. Specifically, these Q-P pairs are automatically extracted from the online documents with relevance adequately designed via hyperlink-based topology to facilitate downstream retrieval for question answering. Figure 1 shows an example of comparison between the human-written query and different pseudo queries. By the guidance of hyperlinks, our HLP query hold the relevance of answer containing with the passage (query title occurs in the passage). Meanwhile, the HLP query can introduce far more effective relevance of evidence existence than other pseudo queries by deeply mining the hyperlink topology, e.g., the dual-link structure. In figure 1, both HLP query and the passage both contain information corresponding to the same fact of *"Mitja Okorn directed the film of Letters to Santa"*. This makes our pseudo query low-cost and a good surrogate for the manually written query.

Our contributions are two-fold. First, we present a hyperlink-induced relevance construction methodology that can better facilitate downstream passage retrieval for question answering, and specifically, we propose a pre-training method: Hyperlink-induced Pre-training (HLP). Second, we conduct evaluations on six popular QA datasets, investigating the effectiveness of our approach under zero-shot, few-shot, multi-hop, and out-of-domain (OOD) scenarios. The experiments show HLP outperforms BM25 in most of the cases under the zero-shot scenario and other pre-training methods under all scenarios.

2 Related Work

Dense Retriever Pre-training Previous works have attempted to conduct additional pre-training for dense retrievers on various weakly supervised data. Borisov et al. (2016) and Dehghani et al. (2017) pre-trained ranking models on click-logs and BM25-induced signals respectively for web search. Lee et al. (2019) proposed the inverse cloze task (ICT) to pre-train a dense retrieval model, which randomly selects sentences as pseudo queries, and matched them to the passages that they originate from. Besides, Chang et al. (2019) proposed the pre-training task of wiki link prediction (WLP) and body first selection (BFS) tasks. Similar to our work, the WLP task also leveraged the hyperlinks within Wikipedia to construct relevant text pairs. However, as shown in figure 1, the WLP pseudo query can only ensure the weak doc-wise contextual relationship with the passage. Guu et al. (2020) proposed the masked-salient-span pre-training task which optimizes a retrieval model by the distant supervision of language model objective. As a follow-up, Sachan et al. (2021) combined ICT with the masked-salient-span task and further improved the pre-training effectiveness.

Data Augmentation via Question Generation Ma et al. (2021), Reddy et al. (2021) and Oğuz et al. (2021) all investigate training a dense retriever on questions synthesized by large question generative (QG) models. Targeting on the zero-shot setting, Ma et al. (2021) trained a question generator on general-domain question passage pairs from community platforms and publicly available academic datasets. Reddy et al. (2021) focused more on domain transfer and trained the QG model on QA datasets of Wikipedia articles. Oğuz et al. (2021) uses the synthetically generated questions from PAQ dataset (Lewis et al., 2021) and the post-comment pairs from dataset of Reddit conversations for retrieval pre-training. Recently, Shinoda et al. (2021) reveals that the QG models tend to generate questions with high lexical overlap which amplify the bias of QA dataset. Different to these studies, our method focuses on a more general setting where the retriever is only trained with the naturally occurring web documents, and has no access to any downstream datasets.



a_i **My Wife and Kids**

My Wife & Kids is an American sitcom that ran on ABC from March 28, 2001 to May 17, 2005. The series was produced by Touchstone Television. It starred Damon Wayan as Michael Kyle, the patriarch of a semi-dysfunctional upper middle class African-American family who rules his household with a unique and distinct parenting style. As he teaches his three children some of life's lessons, he does so with his own brand of humor.

b_j **Damon Wayans**

Wayans starred in the ABC comedy series " My Wife and Kids " from March 2001 to May 2005. In the end of 2006, he produced and starred in the Showtime sketch comedy series " The Underground ", which also featured his son, Damon Jr. . He also hosted the June 2006 BET Awards . In 2011, he also added author of a serious fictional novel to his credits with "Red Hats" which is the story of a suicidal sixty five-year-old woman who finds friendship

c_k **The Aristocats**

When "The Jungle Book" was nearly complete, Disney appointed Ken Anderson to develop preliminary work on "The Aristocats", making it the last film project to be approved by Disney personally before his death in December 1966. Longtime Disney collaborators Robert and Richard Sherman composed multiple songs for the film, though only two made it in the finished product. "The Aristocats" was released on December 24, 1970, to positive reception

d_l **In Search of the Castaways (film)**

Maurice Chevalier later sang the Sherman Brothers' theme song 'The Aristocats' from Disney's 1970 animated film *The Aristocats*. *In Search of the Castaways* was a commercial success. Upon its initial release, it earned $4.9 million in North American theatrical rentals. It was one of the 12 most popular movies at the British box office in 1963. *The New York Times* declared: "It is, as we say, a whopping fable, more gimmicky than imaginative ...

Figure 2: The figure on the left shows a partial Wikipedia graph where two types of pseudo Q-P pairs (a_i, b_j) and (c_k, d_l) are presented. The text boxes on the right show two concrete examples of HLP Q-P pairs where text highlighted in green gives evidence while in orange indicates the answer span.

3 Hyperlink-induced Pre-training (HLP)

In this section, we firstly discuss the background of OpenQA retrieval, then our methodology and training framework.

3.1 Preliminaries

Passage Retrieval Given a question q, passage retrieval aims to provide a set of relevant passages p from a large corpus $\mathcal{D}$. Our work adopts Wikipedia as source corpus and each passage is a disjoint segment within a document from $\mathcal{D}$.

OpenQA Q-P Relevance For OpenQA, a passage p is considered relevant to the query q if p conveys similar facts and contains the answer to q. These two conditions of relevance, namely evidence existence and answer containing, are properly introduced into the HLP Q-P pairs under the guidance of desired hyperlink structure. We will discuss more in this section.

To better formulate the relevance of pseudo Q-P pairs, we denote the sequence of passages within a document as $A = [a_1, a_2, ..., a_{n_A}]$ where $A \in \mathcal{D}$. The corresponding topical entity and the title of document A and its passage splits are denoted as e_A and t_A, respectively. We use m_A to indicate a mention of entity e_A, which is a hypertext span linking to document A. Note that the mention span m_A is usually identical to the document title t_A or a variant version of it. Further, we define $\mathcal{F}_{(p)}$ as the entity-level factual information conveyed by the passage p, which is a set consists of the topical entity e_P and the entities mentioned within passage p.

Evidence Existence in HLP With appropriately designed hyperlink topologies, our HLP Q-P pairs guarantee the co-occurrence of entities which are presented as hypertext or topics in q and p. This is considered as evidence across the Q-P pairs:

$$\mathcal{F}_{(q)} \cap \mathcal{F}_{(p)} \neq \emptyset \tag{1}$$

Furthermore, we conjecture that HLP is more likely to achieve fact-level relevance than entity-level overlap. We conduct human evaluation in Section 6.3 and case studies in Appendix G to support this conjecture. Moreover, we demonstrate that any Q-P pair containing hyperlink-induced factual evidence, which can be represented as triples, is included in our proposed topologies, which are included in Appendix E.

Answer Containing in HLP We consider the document title t_Q as the information-seeking target of q. Accordingly, the relevance of answer containing can be formulated as

$$t_Q \subseteq p \tag{2}$$

The rationale behind this is that both the natural question and the Wikipedia document are intended to describe related facts and events regarding a targeted object, whereas the object is an answer for a question but a topical entity for a Wikipedia document. This similarity leads us to take the document title as the information-seeking target of its context.

3.2 Hyperlink-induced Q-P Pairs

Based on analysis of how queries match their evidential passages in the NQ (Kwiatkowski et al.,

2019) dataset, we propose two kinds of hyperlink topology for relevance construction: Dual-link and Co-mention. We present our exploratory data analysis on NQ dataset in Appendix C. Here we discuss the desired hyperlink topologies and the corresponding relevance of the pseudo Q-P pairs.

Dual-link (DL) Among all NQ training samples, 55% of questions mention the title of their corresponding golden passage. This observation motivates us to leverage the topology of dual-link (DL) for relevance construction. We consider a passage pair (a_i, b_j) follows the dual-link topology if they link to each other. An example of a DL pair (a_i, b_j) is shown in Figure 2, in which passage b_j mentions the title of document A as m_A, satisfying the condition of answer containing:

$$t_A \approx m_A \quad \text{and} \quad m_A \subseteq b_j \tag{3}$$

Further, since the passages a_i and b_j both mention the topical entity of the other, the entities e_A and e_B appear in both passages as evidence:

$$\{e_A, e_B\} \subseteq \mathcal{F}_{(a_i)} \cap \mathcal{F}_{(b_j)} \tag{4}$$

Co-mention (CM) Among all NQ training samples, about 40% of questions fail to match the dual-link condition but mention the same third-party entity as their corresponding golden passages. In light of this observation, we utilize another topology of Co-mention (CM). We consider that a passage pair (c_k, d_l) follows the Co-mention topology if they both link to a third-party document E and d_l links to c_k. Figure 2 illustrates a CM pair (c_l, d_k) where answer containing is ensured as the title of c_k occurs in d_l:

$$t_C \approx m_C \quad \text{and} \quad m_C \subseteq d_l \tag{5}$$

Since both c_l and d_k mention a third-party entity e_E, and that e_C is a topical entity in c_l while a mentioned entity in d_k, we have entity-level evidence across c_l and d_k as:

$$\{e_C, e_E\} \subseteq \mathcal{F}_{(c_k)} \cap \mathcal{F}_{(d_l)} \tag{6}$$

In practice, we use sentence-level queries which contain the corresponding evidential hypertext, and we do not prepend the title to the passage in order to reduce the superficial entity-level overlap. To improve the quality of CM pairs, we filter out those with a co-mentioned entity which has a top 10% highest-ranked in-degree among the Wikipedia entity. We also present pseudo code in Appendix D to illustrate how we construct our pseudo Q-P pairs.

Furthermore, we highlight that HLP has the following advantages: 1) it introduces more semantic variants and paraphrasing for better text matching. 2) The hypertext reflects potential interests or needs of users in relevant information, which is consistent to the downstream information-seeking propose.

3.3 Bi-encoder Training

We adopt a BERT-based bi-encoder to encode queries and passages separately into d-dimension vectors. The output representation is derived from the last hidden state of the [CLS] token and the final matching score is measured by the inner product:

$$\begin{aligned} h_q &= \mathrm{BERT_Q}(q)([\mathrm{CLS}]) \\ h_p &= \mathrm{BERT_P}(p)([\mathrm{CLS}]) \\ \mathrm{S}(p,q) &= h_q^{\mathrm{T}} \cdot h_p \end{aligned}$$

Let $B = \{\langle q_i, p_i^+, p_i^- \rangle\}_{i=1}^n$ be a mini-batch with n instances. Each instance contains a question q_i paired with a positive passage p_i^+ and a negative passage p_i^-. With in-batch negative sampling, each question q_i considers all the passages in B except its own gold p_i^+ as negatives, resulting in $2n-1$ negatives per question in total. We use the negative log likelihood of the positive passage as our loss for optimization:

$$\begin{aligned} &L(q_i, p_i^+, p_{i,1}^-, ..., p_{i,2n-1}^-) \\ &= -\,log \frac{e^{S(q_i, p_i^+)}}{e^{S(q_i, p_i^+)} + \sum_{j=1}^{2n-1} e^{S(q_i, p_{i,j}^-)}} \end{aligned}$$

4 Experimental Setup

In this session, we discuss the pre-training corpus preparation, downstream datasets, the hyperparameter and the basic setup for our experiments.

4.1 Pre-training Corpus

We adopt Wikipedia as our source corpus $\mathcal{D}$ for pre-training as it is the largest encyclopedia covering diverse topics with good content quality and linking structures. We choose the snapshot 03-01-2021 of an English Wikipedia dump, and process it with WikiExtractor[2] to obtain clean context. After filtering out documents with blank text or a title less than three letters, following previous work (Karpukhin et al., 2020), we split the remaining documents into disjoint chunks of 100 words as passages, resulting in over 22 million passages in the end.

---

[2] Available at https://github.com/attardi/wikiextractor

4.2 Downstream Datasets

We evaluate our method on several open-domain question answering benchmarks which are shown below.

Natural Questions (NQ) (Kwiatkowski et al., 2019) is a popular QA dataset with real queries from Google Search and annotated answers from Wikipedia.

TriviaQA (Joshi et al., 2017) contains question-answer pairs scraped from trivia websites.

WebQuestions (WQ) (Berant et al., 2013) consists of questions generated by Google Suggest API with entity-level answers from Freebase.

HotpotQA (Fullwiki) (Yang et al., 2018) is a human-annotated multi-hop question answering dataset.

BioASQ (Tsatsaronis et al., 2015) is a competition on biomedical semantic indexing and question answering. We evaluate its factoid questions from task 8B.

MS MARCO (Passage Ranking) (Nguyen et al., 2016) consists of real-world user queries and a large collection of Web passages extracted by Bing search engine.

Retrieval Corpus For downstream retrieval, we use the 21M Wikipedia passages provided by DPR (Karpukhin et al., 2020) for NQ, TriviaQA and WQ. For BioASQ, we take the abstracts of PubMed articles from task 8A with the same split to Reddy et al. (2021)'s work. For HotpotQA and MS MARCO, we use the official corpus.

4.3 Implementation Details

During the pre-training, we train the bi-encoder for 5 epochs with parameters shared, using a batch size of 400 and an Adam optimizer (Kingma and Ba, 2014) with a learning rate 2×10^{-5}, linear scheduling with 10% warm-up steps. Our HLP and all the reproduced baselines are trained on 20 million Q-P pairs with in-batch negative sampling, and the best checkpoints are selected based on the average rank of gold passages evaluated on the NQ dev set. The pre-training takes around 3 days using eight NVIDIA V100 32GB GPUs.

For the downstream, we use the same hyper-parameters for all experiments. Specifically, we fine-tune the pre-trained models for 40 epochs with a batch size of 256 and the same optimizer and learning rate settings to the pre-training. We conduct evaluation on respective dev sets to select best checkpoints, and we use the last checkpoint if there is no dev set or test set (e.g. HotpotQA). More details can be found in the Appendix A.

4.4 Baselines

Most existing baselines have been implemented under different experimental settings, which have a substantial effect on the retrieval performance. To ensure fairness, we reproduce several pre-training methods (ICT, WLP, BFS, and their combination) under the same experimental setting, such as batch size, base model, amount of pre-training data, and so on. The only difference between our method and the re-implemented baselines is the self-supervision signal derived from the respective pre-training samples. Our reproduced BM25 baseline is better than that reported in Karpukhin et al. (2020), and the re-implemented pre-training methods also perform better than those reported by the recent work[3]. In addition, we include the work REALM (Guu et al., 2020) as a baseline which has recently been reproduced by Sachan et al. (2021) using 240 GPUs and is named masked salient spans (MSS). We note that most related works gain improvements from varying downstream setting or synthetic pre-training with access to the downstream data of respective domain, which is out of the scope of our interests.

5 Experiments

5.1 Main Results

Table 1 shows the retrieval accuracy of different models on three popular QA datasets under zero-shot and full-set fine-tuning settings.

Under zero-shot setting, HLP consistently outperforms BM25 except for the top-5 retrieval accuracy of TriviaQA, while all other pre-training baselines are far behind. We attribute the minor improvement over BM25 on TriviaQA to a high overlap between questions and passages, which gives term-based retriever a clear advantage. We investigate the coverage of the question tokens that appear in the gold passage and find that the overlap is indeed higher in TriviaQA (62.8%) than NQ (60.7%) and WQ (57.5%).

After fine-tuning, all models with intermediate pre-training give better results than the vanilla DPR while our HLP achieves the best in nearly all cases.

---

[3] Our reproduced ICT and BFS surpass the reproduction from recent work (Oğuz et al., 2021) by 15 and 12 points, respectively, in terms of top-20 retrieval accuracy on NQ test set under zero-shot setting.

Table 1: Top-k ($k \in \{5, 20, 100\}$) retrieval accuracy, measured as the percentage of top k retrieved passages with the answer contained. The upper block of the table describes the performance under zero-shot setting, while the lower under the full-set fine-tuning setting. †: Our re-implementation.

Among ICT, WLP and BFS, we observe that WLP is the most competitive with or without fine-tuning, and additional improvements can be achieved by combining three of them. This observation indicates that pre-training with diverse relevance leads to better generalization to downstream tasks, while document-wise relevance is more adaptable for the OpenQA retrieval. The advantage of document-wise relevance may come from the fact that texts in different documents are likely written by different parties, providing less superficial cues for text matching, which is beneficial for the downstream retrieval. Our HLP learns both coarse-grained document-wise relationships as well as the fine-grained entity-level evidence, which results in a significant improvement.

5.2 Few-shot Learning

To investigate the retrieval effectiveness in a more realistic scenario, we conduct experiments for few-shot learning. Specifically, we fine-tune the pre-trained models on large datasets (NQ, TriviaQA) with m ($m \in \{16, 256, 1024\}$) samples and present the few-shot retrieval results in Table 2. With only a few hundred labeled data for fine-tuning, all the models with intermediate pre-training perform better than those without, and HLP outperforms the others by a larger margin when m is smaller. Moreover, among three re-implemented baselines, WLP gains the largest improvement with increasing number of samples, outperforming ICT and BFS when a thousand labelled samples are provided for fine-tuning.

Table 2: Few-shot retrieval accuracy on NQ and TriviaQA test sets after fine-tuning with m annotated samples.

5.3 Out-of-domain (OOD) Scenario

While HLP is pre-trained on Wikipedia pages, we conduct additional experiments on BioASQ and MS MARCO datasets with non-Wikipedia corpus to further verify its out-of-domain (OOD) generalization. Following Gururangan et al. (2020), we measure the similarity between corpus by computing the vocabulary overlap of the top 10K frequent words (excluding stopwords). We observe a vocabulary overlap of 36.2% between BioASQ and Wikipedia while 61.4% between MS MARCO and Wikipedia, indicating that these two domains differ considerably from our pre-training corpus.

The results of zero-shot retrieval on BioASQ

Model	Negative	NQ			TriviaQA			WebQ		
		top5	top20	top100	top5	top20	top100	top5	top20	top100

	1	**51.2**	**70.2**	**82.0**	**65.9**	**76.9**	**84.0**	**49.3**	66.9	**80.8**

Table 3: Ablation studies on different types of topologies and negatives. The retrieval accuracy of models trained with different types of Q-P pairs and additional negatives on NQ, TriviaQA, and WebQ datasets.

and MS MARCO datasets are presented in Table 4. For BioASQ, HLP is competitive with both BM25 and AugDPR(Reddy et al., 2021) while significantly outperforming ICT, WLP, and BFS. Note that AugDPR is a baseline that has access to NQ labeled data whereas our HLP is trained in an unsupervised way. For MS MARCO, HLP consistently outperforms other pre-training methods but falls behind BM25 under zero-shot setting. We conjecture the performance degradation on MS MARCO is attributed to two factors: 1) the Q-P lexical overlap of MS MARCO (65.7%) is higher than that in BioASQ (48.7%) as well as other datasets; 2) the information-seeking target of the MS MARCO query is the entire passage rather than a short answer span, which is biased towards our proposed answer containing. we also observe that pre-training exclusively with DL pairs achieves better results in MS MARCO, indicating the generality of relevance induced by DL topology.

	BioASQ		MS MARCO	
	top20	top100	R@20	R@100
BM25	42.1‡	50.5‡	**49.0**	**69.0**

5.4 Multi-hop Retrieval

While HLP aims to acquires the ability in matching document-wise concepts and facts, it raises our interest in its capability for multi-hop scenarios. We evaluate our methods on HotpotQA in a single-hop manner. Specifically, for each query, we randomly selects one golden passage from the two as a positive passage and one additional passage with high TF-IDF scores as a negative passage. Our models are further fine-tuned on the HotpotQA training set and evaluated on the bridge and the comparison type questions from the development set, respectively. The results of our study are shown in Table 5 which reveals that HLP consistently outperforms others methods, with up to a 11-point improvement on top-5 retrieval accuracy of bridge questions. Furthermore, WLP yields a 4-point advantages in average over ICT and BFS on bridge questions, showing that document-wise relevance contributes to better associative abilities. We include a case study in Appendix F.

	Bridge			Comparison		
	top5	top20	top100	top5	top20	top100
No Pre-train	25.0	40.5	58.0	83.0	94.2	97.4
ICT	28.1	43.8	61.8	84.8	94.4	98.3

Table 5: Retrieval accuracy on questions from HotpotQA dev set, measured as the percentage of top-k retrieved passages which include both golds.

6 Analysis

6.1 Ablation Study

To better understand how different key factors affect the results, we conduct ablation experiments with results shown in Table 3.

Hyperlink-based Topologies Our proposed dual-link (DL) and co-mention (CM) Q-P pairs, provide evidence induced by different hyperlink-based topologies. To examine their respective effectiveness, we pre-train retrievers on Q-P pairs derived from each topology and their combinations. We present zero-shot retrieval results in Table 3, which show that retrievers pre-trained on DL pairs has a distinct advantage over that on CM pairs, while combining both gives extra improvement.

Negative Passage In practice, negative sampling is essential for learning a high-quality encoder. Besides in-batch negative, our reported HLP employs one additional negative for each query. We further explore the impact of the additional negatives during pre-training. In our ablation study, pre-training with additional negatives improves the results significantly, which may be attributed to using more in-batch pairs for text matching. More details on implementation and negative sampling strategies can be found in Appendix B.

6.2 Analysis on Q-P Overlap

We carry out extensive analysis on the Q-P lexical overlap in the task of retrieval. Specifically, we tokenize q, p using the BERT tokenizer and measure the Q-P overlap as the proportion of the question tokens that appear in the corresponding passage. Based on the degree of Q-P overlap, we divided the NQ dev set into five categories for further analysis.

Distribution of Q-P Overlap Figure 3 shows both the pre-training and the retrieved pairs of HLP have a more similar overlap distribution with the downstream NQ dataset than the other methods, which implies the consistency between the relevance provided by HLP and that in real information-seeking scenario.

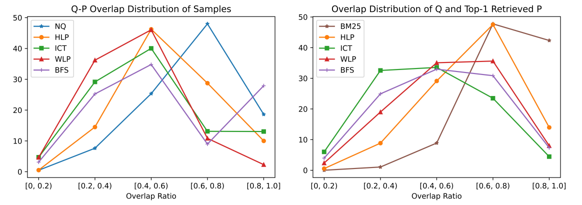

Figure 3: Distribution of overlap on pseudo and downstream Q-P pairs (left), and that between the query and the top-1 passage retrieved by different pre-trained models (right).

Retrieval Performance vs. Q-P Overlap Figure 4 shows the top-20 retrieval accuracy on the samples with varying degrees of Q-P overlap. Both figures show that the retrievers are more likely to return answer-containing passages when there is higher Q-P overlap, suggesting that all these models can exploit lexical overlap for passage retrieval. Under the zero-shot setting, HLP outperforms all the methods except BM25 when r is larger than 0.8, which reflects the strong reasoning ability of HLP and the overlap-dependent nature of the term-based retrievers. After fine-tuning, models with additional pre-training perform better than the vanilla DPR while HLP outperforms all other methods in most of the cases. It is important to note that HLP is pre-trained on more high-overlap text pairs while it performs better than all the other methods when fewer overlaps are provided. We speculate that this is because the overlapping in HLP Q-P pairs mostly comes from the factual information, such as entity, which introduces fewer superficial cues, allowing for better adaptation to the downstream cases.

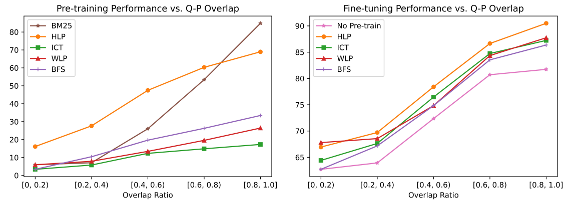

Figure 4: Top-20 retrieval accuracy of pre-training (left) and fine-tuning (right) on the divided NQ dev set.

6.3 Human Evaluation on Q-P pairs

We conduct human evaluation to investigate the proportion of Q-P pairs that convey the similar fact-level information. Specially, we randomly selected one hundred examples from our constructed Q-P pairs and asked annotators to identify whether the query and the corresponding passage convey similar facts. Each case is evaluated by three annotators and the result is determined by their votes. Our results are shown in Table 6, and we further present case studies in Appendix G.

	DL	CM	WLP
Votes	61%	40%	15%

Table 6: Human evaluation on pseudo Q-P pairs constructed by different methods.

7 Conclusion

This paper proposes Hyperlink-induced Pre-training (HLP), a pre-training method for OpenQA passage retrieval by leveraging the online textual relevance induced by hyperlink-based topology. Our experiments show that HLP gains significant improvements across multiple QA datasets under different scenarios, consistently outperforming other pre-training methods. Our method provides insights into OpenQA passage retrieval by analyzing the underlying bi-text relevance. Future work involves addressing tasks like MS MARCO where the granularity of the information-seeking target is at the passage level.

A Parameter Details

For the pre-training, all models we reproduced are trained with 20 million Q-P pairs. Specifically, our reported HLP is trained on the combination of 10 million DL pairs and 10 million CM pairs while the HLP (DL) and HLP (CM) reported in Table 4 are trained on 10 million DL pairs and 10 million CM pairs, respectively. More parameters details are shown in the table below.

Hyperparameter	Pre-training	Fine-tuning
Epoch	5	40
Batch Size	400	256
GPU Resource	32GB GPU × 8	32GB GPU × 8
Learning Rate	2e-5	2e-5
Warmup Ratio	0.1	0.1
Learning Rate Decay	Linear	Linear
Shared Encoder	True	False
Maximum Q Length	150	256
Maximum P Length	256	256

B Negative Sampling

While negative sampling plays an import role in contrast learning, we have explored different types of negatives to pair with queries: (1) Random negatives: passages randomly selected from the corpus (2) Overlap negatives: passages have entity overlap with queries but fail to match either DL or CM topology. Our experimental results in Table 7 show that the model perform better when it adopts random negatives. We conjecture that the overlap negatives may be too hard for the self-supervised pre-training. Thus, we pair one random negative to each query during pre-training.

Negative	NQ			TriviaQA		
Type	top5	top20	top100	top5	top20	top100
None	45.7	66.0	79.9	62.6	75.2	83.0
Random	**51.2**	**70.2**	**82.0**	**65.9**	**76.9**	**84.0**
Overlap	49.7	67.8	80.3	63.1	75.1	83.0

Table 7: Top-k zero-shot retrieval accuracy of HLP using different types of negatives during pre-training.

C Data Analysis on NQ Samples

We discuss how we conduct data analysis to determine the hyperlink-based topology. Driven by a strong interest in what roles the Q-P overlapping spans play, we conduct exploratory data analysis on the widely-used NQ dataset. Specifically, we extract all entities and mentions from the Q-P pairs using TagMe (Ferragina and Scaiella, 2010) for further investigation. We observe about 55% queries

q either explicitly mentions the titles of p or successfully links to the document via TagMe. This observation motivates us to construct the dual-link topology where the pseudo queries q mention p via a hypertext. Moreover, we observe about 45% queries q do not mention the titles of q but instead they share the same mentions. This encourages us to adopt the co-mention topology where the pseudo q and p both mention a third-party document through hypertext.

D Pseudo Code for HLP Pairs

Algorithm 1: HLP Pairs Identification

```
Notation:
    $q, p \leftarrow$ Wikipedia passages
    $t_Q \leftarrow$ Topical entity of passage $q$
    $\mathcal{M}(q) \leftarrow$ The set of entities mentioned in $q$
    $d_{in}(q) \leftarrow$ in-degree of the Wikipedia entity $t_Q$
    $K \leftarrow$ in-degree threshold for CM pairs
Def IsDL($q$, $p$):
    if $t_P \in \mathcal{M}(q)$ & $t_Q \in \mathcal{M}(p)$ then
        return 1
    else
        return 0
;
Def IsCM($q$, $p$):
    foreach $m \in \mathcal{M}(q)$ do
        if $d_{in}(m) < K$ & $m \in M(p)$ & $t_Q \in M(p)$ then
            return 1
        else
            return 0
```

E Fact-level Evidence Reduction

Intuitively, we assume any mentioned entity, let's say e_Y mentioned in a Wikipedia document X, is used to describe the topical entity e_X of this document. In other words, e_Y is likely to attend in a topically relevant fact or event related to e_X, which can be represented as a triple <e_X, r_{XY}, e_Y> where r_{XY} is a latent relation between e_X and e_Y.

Given any passage pair (q, p) from Wikipedia, we consider q and p have fact-level evidence if they both entail a fact that can be represented as a triple, let's say <e_X, r_{XY}, e_Y>. Further, if both passages q and p contain representative hypertext or topic of e_X and e_Y, we consider such fact-level evidence can be induced by hyperlink-based topology, namely hyperlink-induced fact. Below we show that any Q-P pair with hyperlink-induced fact while satisfying answer containing is within either DL or CM hyperlink-based topology.

Following the example above, given q and p containing a factual triple <e_X, r_{XY}, e_Y>, we have facts <e_Q, r_{QX}, e_X>, <e_Q, r_{QY}, e_Y> at q-side while <e_P, r_{PX}, e_X>, <e_P, r_{PY}, e_Y> at p-side. Further, p entails <e_P, r_{PQ}, e_Q> because of the answer containing property.

Case1: $e_P = e_X$ or $e_P = e_Y$. Then q entails facts <e_Q, r_{QP}, e_P>. Note that r_{QP} is likely but not necessarily to be identical to r_{PQ} in p. In this case, (q, p) fits in the Dual-link topology in our definition.

Case2: $e_P \neq e_X$ and $e_P \neq e_Y$. Then given the facts <e_Q, r_{QX}, e_X> at q-side, and <e_P, r_{PX}, e_X> at p-side, (q, p) fits in the Co-mention topology.

F Case Studies on Multi-hop Retrieval

We evaluate HLP on multi-hop scenario where knowledge from different documents need to be associated. Besides significant improvements shown in Table 5, we conduct case study to investigate its capability on knowledge-intensive retrieval. In Table 8, a complex question is proposed, requiring the retriever firstly to retrieve the document *"Apple Remote"* and then *"Front Row (software)"*. HLP successfully retrieves both golds in the top-10 retrieved passages while the vanilla DPR fails. We find 6 items retrieved by HLP are related to the brand *"Apple"* while 4 by DPR, which indicates stronger comprehension and associative ability of HLP.

Question: Aside from the Apple Remote, what other device can control the program Apple Remote was originally designed to interact with?
Evidence Passage: 1. Apple Remote: The Apple Remote is a remote control device ... was originally designed to interact with the Front Row media ... 2. Front Row (software): Front Row is a discontinued media ... is controlled by an Apple Remote or the keyboard function keys ...
Top-10 Retrieved Titles (Ours): Apple Remote; ITunes Remote; Remote computer; Wii Remote; Remote Shell; Kinect; Siri Remote; Front Row (software); Apple TV; Spinning pinwheel;
Top-10 Retrieved Titles (DPR's): Apple Remote; ITunes Remote; Console (video game CLI); Control Panel (Windows); Apple Wireless Keyboard; Chooser (Mac OS); Remote computer; Media player (software); ToggleKeys; Button (computing);

Table 8: Case studies on HotpotQA dataset. Blue gives the titles of gold passages while red gives answer span.

G Case Studies on Q-P Paraphrase

We present case studies on the constructed HLP Q-P pairs in Table 9 and Table 10. As we can see, there are entity- and fact-level paraphrasing across questions and passages, which can be interpreted as factual evidence for passage matching in OpenQA. For example, entity-level variants such as *"Robert and Richard Sherman"* vs. *"Sherman Brothers"*, and fact-level paraphrases such as *"Abby Kelley and Stephen Symonds Foster ... working for abolitionism"* vs. *"... radical abolitionists, Abby Kelley Foster and her husband Stephen S. Foster"* can be found in our examples.

Query	Passage
Title: **Abby Kelley** Liberty Farm in Worcester, Massachusetts, the home of Abby Kelley and Stephen Symonds Foster, was designated a National Historic Landmark because of its association with their lives of working for abolitionism.	Title: **Worcester, Massachusetts** Two of the nation's most radical abolitionists, Abby Kelley Foster and her husband Stephen S. Foster, adopted Worcester as their home, as did Thomas Wentworth Higginson, the editor of The Atlantic Monthly and Emily Dickinson's avuncular correspondent, and Unitarian minister Rev. Edward Everett Hale. Abstract

Recent machine reading comprehension datasets such as ReClor and LogiQA require performing logical reasoning over text. Conventional neural models are insufficient for logical reasoning, while symbolic reasoners cannot directly apply to text. To meet the challenge, we present a neural-symbolic approach which, to predict an answer, passes messages over a graph representing logical relations between text units. It incorporates an adaptive logic graph network (AdaLoGN) which adaptively infers logical relations to extend the graph and, essentially, realizes mutual and iterative reinforcement between neural and symbolic reasoning. We also implement a novel subgraph-to-node message passing mechanism to enhance context-option interaction for answering multiple-choice questions. Our approach shows promising results on ReClor and LogiQA.

1 Introduction

Machine reading comprehension (MRC) has drawn much research attention. Early MRC datasets are not difficult for state-of-the-art neural methods. Indeed, BERT (Devlin et al., 2019) has outperformed humans on SQuAD (Rajpurkar et al., 2016). Recent datasets become more challenging. For example, ReClor (Yu et al., 2020) and LogiQA (Liu et al., 2020) require understanding and reasoning over logical relations described in text, where neural methods showed unsatisfactory performance.

For instance, consider the MRC task in Figure 1. The context consists of a set of textual propositions describing logical relations between elementary discourse units (EDUs) (Mann and Thompson, 1988). For example, the first sentence describes an implication between two EDUs: "the company gets project A" implies that "product B can be put on the market on schedule". With the help of propositional calculus, humans can formalize propositions and then apply inference rules in propositional logic to prove the proposition in option C. However, how can machines solve such a task?

> **Context:** *If* the company gets project A, product B can be put on the market on schedule. Product B is put on schedule *if and only if* the company's fund can be normally turned over. *If* the company's fund *cannot* be turned over normally, the development of product C *cannot* be carried out as scheduled. The fact is that the development of product C is carried out as scheduled.
>
> **Question:** This shows:
>
> **Options:**
> **A.** The company gets project A and product B is put on the market on schedule.
> **B.** The company does not get project A and product B is not put on the market on schedule.
> ✓**C.** Product B is put on the market on schedule and the company's fund is turned over normally.
> **D.** Product B is not put on the market on schedule, and the company's fund turnover is extremely abnormal.

Figure 1: An example MRC task (adapted from a task in LogiQA). Logical connectives are highlighted in italics. ✓marks the correct answer.

Existing Methods and Limitations To solve it, conventional neural models are insufficient for providing the required reasoning capabilities, while symbolic reasoners cannot directly apply to unstructured text. One promising direction is to consider a neural-symbolic solution, such as the recent DAGN method (Huang et al., 2021a). It breaks down the context and each option into a set of EDUs and connects them with discourse relations as a graph. Then it performs graph neural network (GNN) based reasoning to predict an answer.

However, we identify two limitations in this method. **L1:** Despite the graph representation, it is predominantly a neural method over discourse relations. It is debatable whether the required symbolic reasoning over logical relations (e.g., implication, negation) can be properly approximated. **L2:** The graph is often loosely connected and composed of long paths. Node-to-node message passing implemented in existing GNN models (Kipf and Welling, 2017; Schlichtkrull et al., 2018; Velickovic et al., 2018) is prone to provide insufficient interaction be-

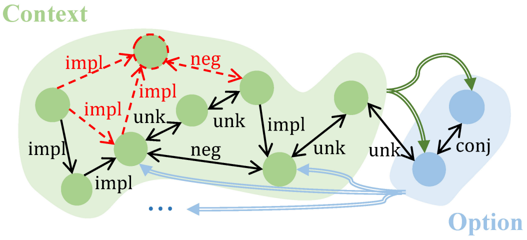
(a) Raw TLG.



(b) Extended TLG. Dashed nodes and edges represent adaptively inferred EDUs and logical relations, respectively. Double edges represent subgraph-to-node message passing.

Figure 2: Two TLGs for exemplifying our approach. For readability, we omit `rev` edges.

tween the context and the option, which is critical to answering a multiple-choice question.

Our Approach. While we follow the general framework of DAGN, i.e., graph construction and then graph-based reasoning, we overcome its two limitations with a novel neural-symbolic approach.

To address L1, Figure 3 sketches out our idea. Specifically, we propose to construct a text logic graph (TLG) representing EDUs and their logical relations as opposed to discourse relations, so we can *explicitly perform symbolic reasoning* to extend the TLG with inferred logical relations, as illustrated in Figure 2. The inferred relations may provide crucial connections to be used in the subsequent graph-based message passing, i.e., *symbolic reasoning reinforces neural reasoning*.

Further, while trivially computing and admitting the deductive closure may extend the TLG with irrelevant connections which would mislead message passing, we leverage signals from neural reasoning to adaptively admit relevant extensions, i.e., *neural reasoning reinforces symbolic reasoning*.

Moreover, we *iterate the above mutual reinforcement* by restarting inference in each iteration with signals from the previous iteration to accommodate corrections to the reasoning process and allow sufficient neural-symbolic interaction.

To address L2, we aggregate the information in the context subgraph of TLG and employ a novel subgraph-to-node message passing mechanism to *enhance the interaction from the holistic context subgraph to each node in the option subgraph, and vice versa*, as illustrated in Figure 2b.

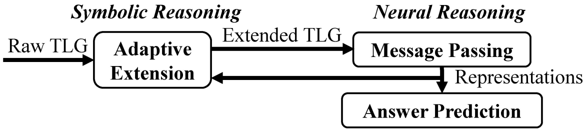


Figure 3: Our main idea: mutual and iterative reinforcement between symbolic and neural reasoning.

We incorporate the above two ideas into our new Adaptive Logic Graph Network (AdaLoGN). To summarize, our technical contributions include

- a novel neural-symbolic approach where neural and symbolic reasoning mutually and iteratively reinforce each other, and
- a novel aggregation-based enhancement of message passing in graph-based neural reasoning.

Outline. We elaborate our approach in Section 2, present experiments in Section 3, discuss related work in Section 4, and conclude in Section 5.

Our code is available on GitHub: `https://github.com/nju-websoft/AdaLoGN`.

2 Approach

A MRC task $\langle c, q, O \rangle$ consists of a context c, a question q, and a set of options O. Only one option in O is the correct answer to q given c. The goal of the task is to find this option.

Figure 4 outlines our implementation. For each option $o \in O$, we generate the representations of c, q, o (i.e., $\mathbf{g}_c, \mathbf{g}_q, \mathbf{g}_o$, respectively) by a pre-trained language model (Section 2.1), and we construct a raw TLG where nodes (i.e., $u_1, \ldots, u_{|V|}$) represent EDUs extracted from c, q, o and edges represent their logical relations (Section 2.2). With their initial representations (i.e., $\mathbf{h}_{u_1}^{(0)}, \ldots, \mathbf{h}_{u_{|V|}}^{(0)}$) obtained from the pre-trained language model, in an iterative manner, we adaptively extend the TLG (i.e., symbolic reasoning) and then pass messages (i.e., neural reasoning) to update node representations (i.e., $\mathbf{h}_{u_1}^{(l+1)}, \ldots, \mathbf{h}_{u_{|V|}}^{(l+1)}$) for generating the representation of the TLG (i.e., $\mathbf{h}_G$) (Section 2.3). Finally, we predict the correctness of o (i.e., $score_o$) based on the above representations (Section 2.4).

2.1 Text Encoding

We use RoBERTa (Liu et al., 2019), a pre-trained language model, to encode three token sequences $c = c_1 \cdots c_{|c|}$, $q = q_1 \cdots q_{|q|}$, and $o = o_1 \cdots o_{|o|}$ which are concatenated by the classifier token <s>

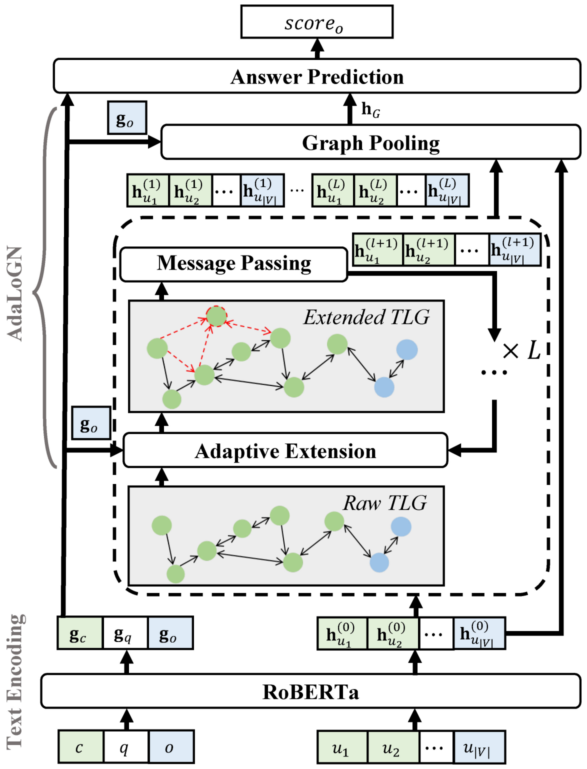

Figure 4: Overview of our approach.

and the separator token </s>:

$$[\mathbf{g}_{\text{<s>}}; \mathbf{g}_{c_1}; \dots; \mathbf{g}_{\text{</s>}}; \mathbf{g}_{q_1}; \dots; \mathbf{g}_{o_1}; \dots; \mathbf{g}_{\text{</s>}}] = \text{RoBERTa}(\text{<s>}\ c_1 \cdots \text{</s>}\ q_1 \cdots o_1 \cdots \text{</s>}) . \tag{1}$$

The output vector representations are averaged to form the representations of c, q, o:

$$\mathbf{g}_c = \frac{1}{|c|}\sum_{i=1}^{|c|} \mathbf{g}_{c_i} , \quad \mathbf{g}_q = \frac{1}{|q|}\sum_{i=1}^{|q|} \mathbf{g}_{q_i} , \quad \mathbf{g}_o = \frac{1}{|o|}\sum_{i=1}^{|o|} \mathbf{g}_{o_i} . \tag{2}$$

2.2 Text Logic Graph (TLG)

Besides directly encoding text, we extract logical relations from text as a graph called TLG.

2.2.1 Definition of TLG

For a piece of text, its TLG is a directed graph $G = \langle V, E \rangle$ where V is a set of nodes representing EDUs of the text (Mann and Thompson, 1988), and $E \subseteq V \times R \times V$ is a set of labeled directed edges representing *logical relations* between EDUs described in the text. We consider six types of common logical relations $R = \{\texttt{conj}, \texttt{disj}, \texttt{impl}, \texttt{neg}, \texttt{rev}, \texttt{unk}\}$:

- conjunction (`conj`), disjunction (`disj`), implication (`impl`), and negation (`neg`) are standard logical connectives in propositional logic;

Rhetorical Relation	Logical Relation
LIST, CONTRAST	`conj`
DISJUNCTION	`disj`
RESULT	`impl`
CAUSE, PURPOSE, CONDITION, BACKGROUND	`rev`

Table 1: Mapping from rhetorical relations in Graphene to logical relations in TLG.

- reversed implication (`rev`) is introduced to represent the inverse relation of `impl`;
- `unk` represents an unknown relation.

Since `conj`, `disj`, `neg`, and `unk` are symmetric relations, edges labeled with them are bidirectional.

Observe the difference between our TLG and the discourse-based logic graph considered in DAGN (Huang et al., 2021a): edges in the former represent logical relations, while those in the latter represent discourse relations. Therefore, we can explicitly perform symbolic reasoning on TLG.

2.2.2 Construction of Raw TLG

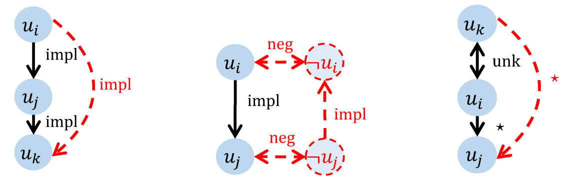
We initialize a raw TLG from c and o. Following Huang et al. (2021a), we ignore q as it is usually uninformative in existing datasets. Specifically, we use Graphene (Cetto et al., 2018) to extract EDUs and their rhetorical relations (Mann and Thompson, 1988) from c and o. Rhetorical relations are converted to logical relations via the mapping in Table 1. Note that each `impl` edge is always paired with an inverse `rev` edge, and vice versa.

We also define a small number of syntactic rules to identify EDUs that negate each other and connect them with `neg`. The rules are based on part-of-speech tags and dependencies. For example, one such rule checks whether two EDUs differ from each other only by an antonym of an adverb.

In addition, for each pair of EDUs that are adjacent in the text (including the last EDU of c and the first EDU of o) but have none of the above logical relations, we connect them with `unk` because Graphene may fail to identify their relation.

2.3 Adaptive Logic Graph Network (AdaLoGN)

Since TLG consists of logical relations, we explicitly perform symbolic reasoning by applying inference rules to extend the TLG with inferred logical relations to benefit the subsequent neural reasoning. However, rather than computing the deductive closure which may undesirably provide many relations that are irrelevant to answering the question



(a) Hypothetical syllogism.

(b) Transposition.

(c) Adjacency-transmission.

Figure 5: Dashed nodes and edges are inferred by applying an inference rule. $\star$ represents any logical relation in $\{\texttt{conj}, \texttt{disj}, \texttt{impl}\}$. We omit `rev` edges.

and mislead neural reasoning, we perform adaptive extension by leveraging signals from neural reasoning to identify and admit relevant extensions. For neural reasoning, we perform message passing to update node representations, which finally are pooled into the representation of the TLG to be used in the subsequent answer prediction. We iterate the above process by restarting inference on the raw TLG in each iteration with signals from the previous iteration to accommodate corrections to the reasoning process and let symbolic and neural reasoning sufficiently interact with each other. We transform the above idea into a new model named AdaLoGN outlined in Figure 4 and detailed below.

2.3.1 Inference Rules

Let $G = \langle V, E \rangle$ be a raw TLG. For symbolic reasoning over the logical relations in G, we apply two *inference rules about implication in propositional logic*. Other rules are left for future work.

- Hypothetical Syllogism:

$$((u_i \rightarrow u_j) \wedge (u_j \rightarrow u_k)) \vdash (u_i \rightarrow u_k)\,. \quad (3)$$

Specifically, if E contains two edges $\langle u_i, \texttt{impl}, u_j \rangle$ and $\langle u_j, \texttt{impl}, u_k \rangle$, we can add two edges $\langle u_i, \texttt{impl}, u_k \rangle$ and $\langle u_k, \texttt{rev}, u_i \rangle$ to E, as illustrated in Figure 5a.

- Transposition:

$$(u_i \rightarrow u_j) \vdash (\neg u_j \rightarrow \neg u_i)\,. \quad (4)$$

Specifically, if E contains an edge $\langle u_i, \texttt{impl}, u_j \rangle$, we can add two edges $\langle \neg u_j, \texttt{impl}, \neg u_i \rangle$ and $\langle \neg u_i, \texttt{rev}, \neg u_j \rangle$ to E, as illustrated in Figure 5b. Note that if u_i (resp. u_j) is not incident from/to any `neg` edge, i.e., $\neg u_i$ (resp. $\neg u_j$) is not a node in V, we will add $\neg u_i$ (resp. $\neg u_j$) to V whose text negates that of u_i (resp. u_j), and then add a bidirectional `neg` edge between u_i and $\neg u_i$ (resp. u_j and $\neg u_j$) to E.

Besides, recall that `unk` represents a potential logical relation between EDUs that are adjacent in text. Considering that an EDU often inherits logical relations from its adjacent EDUs, we heuristically define and apply the following inference rule.

- Adjacency-Transmission:

$$((u_i \star u_j) \wedge (u_i \sim u_k)) \vdash (u_k \star u_j)\,, \quad (5)$$

where $\star \in \{\wedge, \vee, \rightarrow\}$ and $\sim$ represents adjacency in text. For example, if E contains two edges $\langle u_i, \texttt{conj}, u_j \rangle$ and $\langle u_i, \texttt{unk}, u_k \rangle$, we can add a bidirectional `conj` edge between u_k and u_j to E, as illustrated in Figure 5c.

While this rule may generate false propositions, we expect our adaptive reasoner to apply it properly. For example, it is useful for handling the following sentence: "... only 1 person in the group knew 3 of the group (u_k), 3 people knew 2 of the group (u_i), and 4 people know 1 of the group (u_j)." Graphene identifies $\langle u_i, \texttt{conj}, u_j \rangle$ and $\langle u_i, \texttt{unk}, u_k \rangle$ but misses $\langle u_k, \texttt{conj}, u_j \rangle$, which can be generated by applying this rule.

2.3.2 Adaptive Extension of TLG

Our symbolic reasoning is *adaptive*. We rely on signals from neural reasoning to decide which inference steps are relevant to answering the questions and hence are admitted to extend the TLG. Specifically, each candidate extension ϵ applies an inference rule over a set of nodes $V_\epsilon \subseteq V$. We average their vector representations (which will be detailed later) to form the representation of ϵ:

$$\mathbf{h}_\epsilon = \frac{1}{|V_\epsilon|} \sum_{u_i \in V_\epsilon} \mathbf{h}_{u_i}\,. \quad (6)$$

Since ϵ is for predicting the correctness of o, we interact $\mathbf{h}_\epsilon$ with the representation of o, i.e., $\mathbf{g}_o$ in Equation (2), to predict the relevance score of ϵ:

$$rel_\epsilon = \texttt{sigmoid}(\texttt{linear}(\mathbf{h}_\epsilon \,\|\, \mathbf{g}_o))\,, \quad (7)$$

where $\|$ represents vector concatenation. We admit all possible ϵ to extend G such that $rel_\epsilon > \tau$ where τ is a predefined threshold.

Moreover, our neural-symbolic reasoning is *iterative*. In the $(l+1)$-th iteration, we restart symbolic reasoning with the raw TLG and recompute Equation (6) with node representations $\mathbf{h}_{u_i}^{(l)}$ from neural reasoning in the l-th iteration (which will be detailed in Section 2.3.3). The initial node representations $\mathbf{h}_{u_i}^{(0)}$ are obtained from a pre-trained language model. Specifically, we flatten V into a sequence of nodes in the order they appear in the text. Recall that V is divided into $V_c = \{u_1, \dots, u_{|V_c|}\}$ and $V_o = \{u_{|V_c|+1}, \dots, u_{|V|}\}$ representing the nodes extracted from c and o, respectively. Each node u_i is a token sequence $u_i = u_{i_1} \cdots u_{i_{|u_i|}}$. We use RoBERTa to encode V_c and V_o which are concatenated by <s> and </s>, where nodes inside V_c and V_o are separated by a special token "|":

$$\begin{aligned}&[\mathbf{h}_{\text{<s>}}; \mathbf{h}_{u_{1_1}}; \dots; \mathbf{h}_{|}; \dots; \mathbf{h}_{\text{</s>}}; \mathbf{h}_{u_{|V_c|+1_1}}; \dots; \mathbf{h}_{|}; \dots; \mathbf{h}_{\text{</s>}}] \\ &= \text{RoBERTa}(\text{<s>}\ u_{1_1} \cdots \mid \cdots\ \text{</s>}\ u_{|V_c|+1_1} \cdots \mid \cdots\ \text{</s>})\,.\end{aligned} \tag{8}$$

The output vector representations are averaged to form the initial representation of each node $u_i \in V$:

$$\mathbf{h}_{u_i}^{(0)} = \frac{1}{|u_i|} \sum_{j=1}^{|u_i|} \mathbf{h}_{u_{i_j}}\,. \tag{9}$$

2.3.3 Message Passing

To let the nodes in TLG interact with each other and fuse their information, our neural reasoning performs graph-based message passing (Gilmer et al., 2017) to update node representations in each iteration from $\mathbf{h}_{u_i}^{(l)}$ to $\mathbf{h}_{u_i}^{(l+1)}$. Since TLG is a heterogeneous graph containing multiple types of edges, we incorporate the node-to-node message passing mechanism in R-GCN (Schlichtkrull et al., 2018) as a basis. Further, observe that TLG is usually loosely connected and prone to cause insufficient interaction between V_c and V_o via long paths in limited iterations, which cannot be alleviated by simply increasing the number of iterations because it would raise other issues such as over-smoothing (Li et al., 2018; Chen et al., 2020). To enhance such interaction which is critical to predicting the correctness of o, we incorporate a novel *subgraph-to-node message passing mechanism* to holistically pass the information aggregated from a subgraph (e.g., V_c) to a node (e.g., each $u_i \in V_o$).

Specifically, without loss of generality, for each $u_i \in V_o$, we compute the u_i-attended aggregate representation of V_c by an attention-weighted sum of node representations over V_c:

$$\begin{aligned}\mathbf{h}_{V_c,u_i}^{(l)} &= \sum_{u_j \in V_c} \alpha_{i,j} \mathbf{h}_{u_j}^{(l)}\,, \text{ where} \\ \alpha_{i,j} &= \texttt{softmax}_j([a_{i,1}; \dots; a_{i,|V_c|}]^\intercal)\,, \\ a_{i,j} &= \texttt{LeakyReLU}(\texttt{linear}(\mathbf{h}_{u_i}^{(l)} \parallel \mathbf{h}_{u_j}^{(l)}))\,.\end{aligned} \tag{10}$$

Let N^i be the set of neighbors of u_i. Let $N_r^i \subseteq N^i$ be the subset under logical relation $r \in R$. We update the representation of u_i by passing messages to u_i from its neighbors and from V_c:

$$\begin{aligned}\mathbf{h}_{u_i}^{(l+1)} &= \texttt{ReLU}(\sum_{r \in R} \sum_{u_j \in N_r^i} \frac{\alpha_{i,j}}{|N_r^i|} \mathbf{W}_r^{(l)} \mathbf{h}_{u_j}^{(l)} + \mathbf{W}_0^{(l)} \mathbf{h}_{u_i}^{(l)} \\ &\qquad + \beta_i \mathbf{W}_{\text{subgraph}}^{(l)} \mathbf{h}_{V_c,u_i}^{(l)})\,, \text{ where} \\ \alpha_{i,j} &= \texttt{softmax}_{\texttt{idx}(a_{i,j})}([\dots; a_{i,j}; \dots]^\intercal) \text{ for all } u_j \in N^i\,, \\ a_{i,j} &= \texttt{LeakyReLU}(\texttt{linear}(\mathbf{h}_{u_i}^{(l)} \parallel \mathbf{h}_{u_j}^{(l)}))\,, \\ \beta_i &= \texttt{sigmoid}(\texttt{linear}(\mathbf{h}_{u_i}^{(l)} \parallel \mathbf{h}_{V_c,u_i}^{(l)}))\,,\end{aligned} \tag{11}$$

$\mathbf{W}_r^{(l)}, \mathbf{W}_0^{(l)}, \mathbf{W}_{\text{subgraph}}^{(l)}$ are matrices of learnable parameters, and $\texttt{idx}(a_{i,j})$ returns the index of $a_{i,j}$ in the $|N^i|$-dimensional vector $[\dots; a_{i,j}; \dots]^\intercal$.

In an analogous way, for each $u_i \in V_c$, we compute the u_i-attended aggregate representation of V_o denoted by $\mathbf{h}_{V_o,u_i}^{(l)}$ and update $\mathbf{h}_{u_i}^{(l+1)}$.

Observe two differences between Equation (11) and its counterpart in the original R-GCN. First, we incorporate subgraph-to-node message passing and control it by a gating mechanism (i.e., β_i). Second, we weight node-to-node message passing by an attention mechanism (i.e., $\alpha_{i,j}$).

2.3.4 Graph Pooling

After L iterations where L is a hyperparameter, for each node $u_i \in V$, we fuse its representations over all the iterations with a residual connection:

$$\mathbf{h}_{u_i}^{\text{fus}} = \mathbf{h}_{u_i}^{(0)} + \texttt{linear}(\mathbf{h}_{u_i}^{(1)} \parallel \cdots \parallel \mathbf{h}_{u_i}^{(L)})\,. \tag{12}$$

Inspired by Huang et al. (2021a), we feed all $\mathbf{h}_{u_i}^{\text{fus}}$ into a bidirectional residual GRU layer (Cho et al., 2014) to finalize node representations:

$$[\mathbf{h}_{u_1}^{\text{fnl}}; \dots; \mathbf{h}_{u_{|V|}}^{\text{fnl}}] = \texttt{Res-BiGRU}([\mathbf{h}_{u_1}^{\text{fus}}; \dots; \mathbf{h}_{u_{|V|}}^{\text{fus}}])\,. \tag{13}$$

We aggregate these node representations by computing an o-attended weighted sum:

$$\begin{aligned}\mathbf{h}_V &= \sum_{u_i \in V} \alpha_i \mathbf{h}_{u_i}^{\text{fnl}}\,, \text{ where} \\ \alpha_i &= \texttt{softmax}_i([a_1; \dots; a_{|V|}]^\intercal)\,, \\ a_i &= \texttt{LeakyReLU}(\texttt{linear}(\mathbf{g}_o \parallel \mathbf{h}_{u_i}^{\text{fnl}}))\,,\end{aligned} \tag{14}$$

and $\mathbf{g}_o$ is the representation of o in Equation (2). We concatenate $\mathbf{h}_V$ and the relevance scores to form the representation of G:

$$\begin{aligned}\mathbf{h}_G &= (\mathbf{h}_V \parallel \mathit{rel}_{\mathcal{E}^{(1)}} \parallel \cdots \parallel \mathit{rel}_{\mathcal{E}^{(L)}})\,, \text{ where} \\ \mathit{rel}_{\mathcal{E}^{(l)}} &= \frac{1}{|\mathcal{E}^{(l)}|} \sum_{\epsilon \in \mathcal{E}^{(l)}} \mathit{rel}_\epsilon\,,\end{aligned} \tag{15}$$

$\mathcal{E}^{(l)}$ is the set of candidate extensions in the l-th iteration, and rel_ϵ is in Equation (7). In this way, we are able to train the network in Equation (7).

2.4 Answer Prediction

We fuse the representations of c, q, o and the TLG to predict the correctness of o:

$$score_o = \mathtt{linear}(\tanh(\mathtt{linear}(\mathbf{g}_c \parallel \mathbf{g}_q \parallel \mathbf{g}_o \parallel \mathbf{h}_G))) \,, \tag{16}$$

where $\mathbf{g}_c, \mathbf{g}_q, \mathbf{g}_o$ are in Equation (2).

2.5 Loss Function

Let $o_{\text{gold}} \in O$ be the correct answer. We optimize the cross-entropy loss with label smoothing:

$$\mathcal{L} = -(1-\gamma) score'_{o_{\text{gold}}} - \gamma \frac{1}{|O|} \sum_{o_i \in O} score'_{o_i} \,,$$
$$\text{where } score'_{o_i} = \log \frac{\exp(score_{o_i})}{\sum_{o_j \in O} \exp(score_{o_j})} \,, \tag{17}$$

and γ is a predefined smoothing factor.

3 Experiments

3.1 Datasets

We used two reasoning-based MRC datasets.

ReClor (Yu et al., 2020) consists of 6,138 four-option multiple-choice questions collected from standardized exams such as GMAT and LSAT. The questions were divided into 4,638 for training, 500 for development, and 1,000 for testing. The test set was further divided into 440 easy questions (Test-E) where each question could be correctly answered by some strong baseline method using only the options and ignoring the context and the question, and the rest 560 hard questions (Test-H).

LogiQA (Liu et al., 2020) consists of 8,768 four-option multiple-choice questions collected from the National Civil Servants Examination of China, which were translated into English. The questions were divided into 7,376 for training, 651 for development, and 651 for testing.

3.2 Implementation Details

We experimented on NVIDIA V100 (32GB).

We tuned hyperparameters on the development set of each dataset. Specifically, for text encoding, we used RoBERTa-large with hidden layer $= 24$ and hidden units $= 1,024$ implemented by Hugging Face (Wolf et al., 2020). For message passing, our implementation was based on DGL (Wang et al., 2019). For both datasets, we used the Adam optimizer, and set attention heads $= 16$, dropout rate $= 0.1$, epochs $= 10$, batch size $= 16$ selected from $\{8, 16, 24\}$, number of iterations $L = 2$ from $\{2, 3\}$, and maximum sequence length $= 384$. For ReClor, we set warm-up proportion $= 0.1$ from $\{0.1, 0.2\}$, learning rate $= 7e{-}6$ from $\{6e{-}6, 7e{-}6, 8e{-}6, 1e{-}5\}$, and seed $= 123$ from $\{123, 1234, 42, 43\}$. For LogiQA, we set warm-up proportion $= 0.2$ from $\{0.1, 0.2\}$, learning rate $= 8e{-}6$ from $\{6e{-}6, 7e{-}6, 8e{-}6, 1e{-}5\}$, and seed $= 42$ from $\{123, 1234, 42, 43\}$.

For the relevance score threshold τ below Equation (7), we set $\tau = 0.6$ from $\{0.4, 0.5, 0.6, 0.7\}$ for both datasets. For the smoothing factor γ in Equation (17), we set $\gamma = 0.25$ for both datasets.

To fit in our GPU's memory, we restricted a raw TLG to contain at most 25 nodes and 50 edges by, if needed, randomly merging nodes connected by an `unk` edge and/or deleting non-bridge edges while keeping the graph connected.

3.3 Baselines

We compared our approach, referred to as AdaLoGN, with popular pre-trained language models and with other known methods in the literature.

Reasoning-based MRC, like other MRC tasks, can be solved by using a pre-trained language model with a classification layer. Yu et al. (2020) reported the results of BERT$_{\text{LARGE}}$, RoBERTa$_{\text{LARGE}}$, and XLNet$_{\text{LARGE}}$ on ReClor. Huang et al. (2021a) reported the results of BERT$_{\text{LARGE}}$ and RoBERTa$_{\text{LARGE}}$ on LogiQA.

In the literature, we found the results of DAGN (Huang et al., 2021a), Focal Reasoner (Ouyang et al., 2021), and LReasoner (Wang et al., 2021a,b) on both datasets. For a fair comparison with our approach, we presented their results on RoBERTa$_{\text{LARGE}}$, while LReasoner achieved better results with ALBERT. Between the two variants of LReasoner, one without data augmentation (w/o DA) and the other with data augmentation (w/ DA), we presented both of their results but mainly compared with the former because our approach and other baseline methods would also benefit if data augmentation were incorporated.

Method	Dev	Test	Test-E	Test-H
BERT$_{\text{LARGE}}$	53.80	49.80	72.00	32.30
RoBERTa$_{\text{LARGE}}$	62.60	55.60	75.50	40.00
XLNet$_{\text{LARGE}}$	62.00	56.00	75.70	40.50
DAGN	65.80	58.30	75.91	44.46
Focal Reasoner	66.80	58.90	77.05	44.64
LReasoner (w/o DA)	65.20	58.30	78.60	42.30
LReasoner (w/ DA)	66.20	62.40	81.40	47.50
AdaLoGN	65.20	60.20	79.32	45.18
Human	–	63.00	57.10	67.20

Table 2: Comparison with baselines on ReClor.

Method	Dev	Test
BERT$_{\text{LARGE}}$	34.10	31.03
RoBERTa$_{\text{LARGE}}$	35.02	35.33
DAGN	36.87	39.32
Focal Reasoner	41.01	40.25
LReasoner (w/ DA)	38.10	40.60
AdaLoGN	39.94	40.71
Human	–	86.00

Table 3: Comparison with baselines on LogiQA.

3.4 Evaluation Metric

Following the literature, we reported accuracy, i.e., the proportion of correctly answered questions. For our approach we reported the max across 3 runs on the development set of each dataset.

3.5 Comparison with Baselines

On ReClor, as shown in Table 2, AdaLoGN outperformed all the baseline methods on the test set by at least 1.30%, except for LReasoner (w/ DA) which performed data augmentation so that the comparison might be unfair. AdaLoGN and LReasoner (w/ DA) both exceeded 60%, being comparable with human-level performance (63%).

On LogiQA, as shown in Table 3, AdaLoGN outperformed all the baseline methods on the test set, including LReasoner (w/ DA). Still, our result (40.71%) was not comparable with human-level performance (86%).

In particular, on both ReClor and LogiQA, AdaLoGN exceeded DAGN on the test set by 1.39%–1.90%, which demonstrated the effectiveness of our approach in addressing the limitations of DAGN mentioned in Section 1.

3.6 Ablation Study

We conducted an ablation study to evaluate the effectiveness of the two main technical contributions in our approach: adaptive extension of TLG and subgraph-to-node message passing.

Method	Dev	Test	Test-E	Test-H
AdaLoGN	65.20	60.20	79.32	45.18
AdaLoGN$_{\texttt{no-ext}}$	65.80	59.50	77.27	45.54
AdaLoGN$_{\texttt{full-ext}}$	65.00	58.80	78.19	43.57
AdaLoGN$_{\texttt{no-at}}$	64.80	59.40	79.77	43.39
AdaLoGN$_{\texttt{n2n}}$	65.20	57.60	77.95	41.61
AdaLoGN$_{\texttt{n2n+}}$	65.00	58.60	78.64	42.86

Table 4: Ablation study on ReClor.

Method	Dev	Test
AdaLoGN	39.94	40.71
AdaLoGN$_{\texttt{no-ext}}$	37.94	39.02
AdaLoGN$_{\texttt{full-ext}}$	39.63	39.02
AdaLoGN$_{\texttt{no-at}}$	38.56	39.94
AdaLoGN$_{\texttt{n2n}}$	38.40	39.02
AdaLoGN$_{\texttt{n2n+}}$	38.40	38.86

Table 5: Ablation study on LogiQA.

3.6.1 Effectiveness of Adaptive Extension

We compared the standard version of AdaLoGN with two variants removing adaptive extension.

- AdaLoGN$_{\texttt{no-ext}}$ performs no extension.
- AdaLoGN$_{\texttt{full-ext}}$ performs full extension by computing and admitting the deductive closure.

On ReClor, as shown in Table 4, both variants exhibited a fair decrease in accuracy on the test set by 0.70%–1.40%. On LogiQA, as shown in Table 5, the decreases were larger, 1.69% on the test set, possibly because the questions in LogiQA were harder so that the effectiveness of our adaptive extension became more noticeable. Interestingly, on both datasets, AdaLoGN$_{\texttt{full-ext}}$ was not better than AdaLoGN$_{\texttt{no-ext}}$ on the test set, indicating that a naive injection of logical reasoning into neural reasoning might not have positive effects.

We analyzed the distributions of relevance scores of candidate extensions, i.e., rel_{ϵ} in Equation (7). As shown in Figure 6, they approximated a normal distribution on both datasets. By setting the threshold $\tau = 0.6$, we admitted 19.57% and 4.86% of the extensions on ReClor and LogiQA, respectively.

We also compared with a variant of AdaLoGN using a subset of inference rules.

- AdaLoGN$_{\texttt{no-at}}$ ignores the adjacency-transmission rule.

By ignoring the adjacency-transmission rule, AdaLoGN$_{\texttt{no-at}}$ showed a decrease in accuracy on the test sets by 0.77%–0.80%, suggesting the usefulness of this rule despite its heuristic nature.

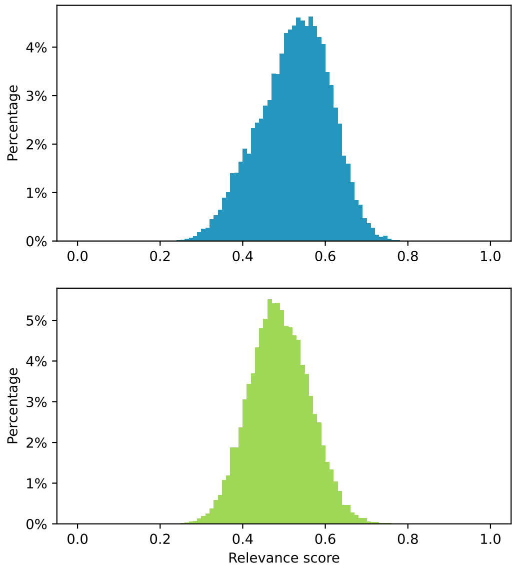


Figure 6: Distributions of relevance scores of candidate extensions. Top: on the development set of Reclor; Bottom: on the development set of LogiQA.

3.6.2 Effectiveness of Subgraph-to-Node Message Passing

We compared the standard version of AdaLoGN with two variants removing subgraph-to-node message passing or implementing it in a different way.

- $\mathrm{AdaLoGN}_{\texttt{n2n}}$ only performs node-to-node message passing in a standard way.
- $\mathrm{AdaLoGN}_{\texttt{n2n+}}$ only performs node-to-node message passing but, as an alternative to our holistic subgraph-to-node message passing, it adds a bidirectional `unk` edge between each node in the context subgraph and each node in the option subgraph to enhance context-option interaction.

On ReClor, as shown in Table 4, both variants exhibited a large decrease in accuracy on the test set by 1.60%–2.60%. On LogiQA, as shown in Table 5, the decreases were also large, 1.69%–1.85% on the test set. The results demonstrated the effectiveness of our subgraph-to-node message passing.

Compared with $\mathrm{AdaLoGN}_{\texttt{n2n}}$, $\mathrm{AdaLoGN}_{\texttt{n2n+}}$ achieved better results on ReClor but worse results on LogiQA on the test set, indicating that a naive enhancement of context-option interaction could have negative effects.

3.7 Error Analysis

From the development set of each dataset, we randomly sampled fifty questions to which our approach outputted an incorrect answer. We analyzed the sources of these errors. Note that an error could have a mixture of multiple sources.

Source of Error	ReClor	LogiQA
Construction of raw TLG	38%	36%
Adaptive extension of TLG	18%	22%
Expressivity of symbolic reasoning	20%	18%
Others (about neural reasoning)	46%	40%

Table 6: Error analysis of AdaLoGN.

As shown in Table 6, we mainly relied on Graphene to extract a raw TLG from text based on syntactic analysis, which accounted for about one third of the errors (36%–38%). Our adaptive extension of TLG constituted about one fifth of the errors (18%–22%), e.g., some excessive extensions produced irrelevant logical relations which might mislead message passing. One fifth of the errors (18%–20%) were due to the limited expressivity of our symbolic reasoning, i.e., a subset of propositional logic, while some questions required quantifiers. Other errors might be related to neural reasoning such as message passing or answer prediction (40%–46%).

3.8 Run Time

On both ReClor and LogiQA, our approach used about 0.8 second for answering a question.

4 Related Work

4.1 Reasoning-Based MRC

While simple MRC tasks have been well studied, complex MRC tasks requiring various reasoning capabilities are receiving increasing research attention. Among others, multi-hop MRC tasks in HotpotQA (Yang et al., 2018) and WikiHop (Welbl et al., 2018) require retrieving and reading multiple supporting passages to answer a question. They can be solved by constructing and reasoning over a graph connecting passages that overlap or co-occur with each other (Qiu et al., 2019; Tu et al., 2020), by implicitly supervising a retriever via word weighting (Huang et al., 2021b), or by iteratively applying dense retrieval (Xiong et al., 2021). MRC tasks in DROP (Dua et al., 2019) require discrete reasoning such as addition, counting, and sorting. Neural networks have been extended to incorporate modules that can perform such reasoning over numbers and dates mentioned in a given context (Gupta et al., 2020). For MRC tasks in CommonsenseQA (Talmor et al., 2019) which are targeted at commonsense knowledge and reasoning, recent methods fuse external commonsense knowledge with pre-trained language models for reasoning (Yan et al., 2021; Xu et al., 2021). There are also studies on MRC tasks requiring spatial/geographical reasoning (Huang et al., 2019; Li et al., 2021) and temporal/causal reasoning (Sun et al., 2018).

Different from the above reasoning capabilities, the MRC tasks considered in this paper require *logical reasoning*, such as reasoning about sufficient and necessary conditions, categorization, conjunctions and disjunctions. Pre-trained language models alone struggled and were far behind human-level performance on such tasks in ReClor (Yu et al., 2020) and LogiQA (Liu et al., 2020) due to their weakness in logical reasoning.

Among existing methods for solving such tasks, DAGN (Huang et al., 2021a) and Focal Reasoner (Ouyang et al., 2021) extract discourse or coreference relations from text and represent as a graph of text units. Then they employ GNN to pass messages and update representations for predicting an answer. Different from their neural nature, our approach *symbolically performs logical reasoning* as required by such tasks, by applying inference rules over extracted logical relations to extend the graph. This feature resembles LReasoner (Wang et al., 2021a,b) which extends the context with inferred logical relations to benefit the subsequent neural reasoning. However, different from LReasoner which computes the deductive closure and identifies relevant extensions by text overlapping with the options in an unsupervised manner, our approach predicts relevance based on signals from neural reasoning *in a supervised manner*, and our prediction *evolves over iterations* after sufficient interaction between symbolic and neural reasoning. All these features helped our approach achieve better performance in the experiments.

4.2 Neural-Symbolic Reasoning

Our approach represents a novel implementation of neural-symbolic reasoning (Raedt et al., 2020), and it differs from the following existing methods.

One paradigm of neural-symbolic reasoning is logic-driven neural reasoning. For example, logical constraints can be compiled into a neural network by augmenting the loss function (Xu et al., 2018) or the network structure (Li and Srikumar, 2019). Logical connectives, quantifiers, and consistency checking can also be approximated by neural networks (Dong et al., 2019; Ren et al., 2020; Gu et al., 2019). While these methods incorporate logical reasoning into neural reasoning via emulation, our approach *explicitly performs logical reasoning* by applying inference rules over logical relations. Such exact inference is more accurate than emulation-based approximation.

Another paradigm is neural-driven logical reasoning. For example, neural networks have been employed to predict the truth of an atom in answering first-order logic queries (Arakelyan et al., 2021), and to implement predicates in probabilistic logic programming (Manhaeve et al., 2021). These methods and our approach cope with different problems, thus using different techniques. Specifically, while these methods complement logical reasoning with extra facts generated by neural reasoning, our approach *filters inferred logical relations* based on signals from neural reasoning.

Moreover, observe that the neural-symbolic interaction in the above methods are unidirectional, i.e., they leverage either symbolic or neural reasoning to reinforce the other. By contrast, we allow *bidirectional neural-symbolic interaction* where neural and symbolic reasoning mutually and iteratively reinforce each other for better performance.

5 Conclusion

To meet the challenge of reasoning-based MRC, we presented a neural-symbolic approach where neural and symbolic reasoning mutually and iteratively reinforce each other via our new AdaLoGN model. We also enhanced graph-based neural reasoning with a novel subgraph-to-node message passing mechanism. Since these ideas are quite general, we believe they have great potential for a variety of applications beyond MRC, e.g., link prediction.

Error analysis has revealed some shortcomings of our approach. Currently we rely on syntactic tools to extract a raw TLG from text. We will explore other extraction methods to achieve a higher quality. We also plan to apply more inference rules and incorporate quantifiers to improve the expressivity of our symbolic reasoning.

Responsible NLP Research Checklist

Members of the ACL are responsible for adhering to the ACL code of ethics. The ARR Responsible NLP Research checklist is designed to encourage best practices for responsible research, addressing issues of research ethics, societal impact and reproducibility.

Please read the Responsible NLP Research checklist guidelines for information on how to answer these questions. Note that not answering positively to a question is not grounds for rejection.

All supporting evidence can appear either in the main paper or the supplemental material. For each question, if you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Please do not modify, reorder, delete or add questions, question options or other wording of this document.

A For every submission

A1 Did you discuss the *limitations* of your work?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification Section 3.7

A2 Did you discuss any potential *risks* of your work?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

N/A

Section or justification Click or tap here to enter text.

A3 Do the abstract and introduction summarize the paper's main claims?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification Abstract, Section 1

B Did you use or create *scientific artifacts*?

If you answer **Yes**, provide the section number; if you answer **No**, you can skip the rest of this section.

Yes

If yes:

B1 Did you cite the creators of artifacts you used?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification   Sections 2.1, Section 2.2.2, Section 3.1, Section 3.2

B2 Did you discuss the *license or terms* for use and/or distribution of any artifacts?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification   The license for our code is available on GitHub.

B3 Did you discuss if your use of existing artifact(s) was consistent with their *intended use*, provided that it was specified? For the artifacts you create, do you specify intended use and whether that is compatible with the original access conditions (in particular, derivatives of data accessed for research purposes should not be used outside of research contexts)?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

N/A

Section or justification   Click or tap here to enter text.

B4 Did you discuss the steps taken to check whether the data that was collected/used contains any *information that names or uniquely identifies individual people* or *offensive content*, and the steps taken to protect / anonymize it?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

N/A

Section or justification   Click or tap here to enter text.

B5 Did you provide documentation of the artifacts, e.g., coverage of domains, languages, and linguistic phenomena, demographic groups represented, etc.?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification   Section 3.1

B6 Did you report relevant statistics like the number of examples, details of train/test/dev splits, etc. for the data that you used/created?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification   Section 3.1

C Did you run *computational experiments*?

If you answer **Yes**, provide the section number; if you answer **No**, you can skip the rest of this section.

Yes

If yes:

C1 Did you report the *number of parameters* in the models used, the *total computational budget* (e.g., GPU hours), and *computing infrastructure* used?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification Section 3.2, Section 3.8

C2 Did you discuss the experimental setup, including *hyperparameter search* and *best-found hyperparameter* values?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification Section 3.2

C3 Did you report *descriptive statistics* about your results (e.g., error bars around results, summary statistics from sets of experiments), and is it transparent whether you are reporting the max, mean, etc. or just a single run?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification Section 3.2, Section 3.4, Section 3.5

C4 If you used existing packages (e.g., for preprocessing, for normalization, or for evaluation), did you report the implementation, model, and parameter settings used (e.g., NLTK, Spacy, ROUGE, etc.)?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification Section 3.2

D Did you use *human annotators* (e.g., crowdworkers) or *research with human subjects*?

If you answer **Yes**, provide the section number; if you answer **No**, you can skip the rest of this section.

No

If yes:

D1 Did you report the full text of instructions given to participants, including e.g., screenshots, disclaimers of any risks to participants or annotators, etc.?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Choose an item.

Section or justification   Click or tap here to enter text.

D2 Did you report information about how you recruited (e.g., crowdsourcing platform, students) and paid participants, and discuss if such *payment is adequate* given the participants' demographic (e.g., country of residence)?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Choose an item.

Section or justification   Click or tap here to enter text.

D3 Did you discuss whether and how consent was obtained from people whose data you're using/curating (e.g., did your instructions explain how the data would be used)?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Choose an item.

Section or justification   Click or tap here to enter text.

D4 Was the data collection protocol *approved* (or *determined exempt*) by an ethics review board?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Choose an item.

Section or justification   Click or tap here to enter text.

D5 Did you report the basic demographic and geographic characteristics of the *annotator* population that is the source of the data?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Choose an item.

Abstract

Model ensemble is a popular approach to produce a low-variance and well-generalized model. However, it induces large memory and inference costs, which are often not affordable for real-world deployment. Existing work has resorted to sharing weights among models. However, when increasing the proportion of the shared weights, the resulting models tend to be similar, and the benefits of using model ensemble diminish. To retain ensemble benefits while maintaining a low memory cost, we propose a consistency-regularized ensemble learning approach based on perturbed models, named CAMERO. Specifically, we share the weights of bottom layers across all models and apply different perturbations to the hidden representations for different models, which can effectively promote the model diversity. Meanwhile, we apply a prediction consistency regularizer across the perturbed models to control the variance due to the model diversity. Our experiments using large language models demonstrate that CAMERO significantly improves the generalization performance of the ensemble model. Specifically, CAMERO outperforms the standard ensemble of 8 BERT-base models on the GLUE benchmark by 0.7 with a significantly smaller model size (114.2M vs. 880.6M).

1 Introduction

Deep Neural Networks (DNNs) have achieved remarkable success in various fields and have become very powerful in learning complicated models (Devlin et al., 2018; Brown et al., 2020; He et al., 2020). However, their remarkable representation powers come at the expense of large model variance, which may hurt the model generalization performance. A popular approach for reducing such variance is model ensemble, where the weights or predictions of a set of models are aggregated to produce the predictions (Yang and Lv, 2021; Dong et al., 2020). For example, Zhang et al. (2018) show that a simple 2-model ensemble leads to notable improvement over a single model in computer vision tasks.

Despite such notable benefits, model ensemble has not been widely applied to large language models. The major barriers are its enormous storage and expensive inference cost, which linearly scales with the size and the number of models. Therefore, it is often not affordable to ensemble large language models for deployment using memory-constrained and low-latency edge devices.

To alleviate the memory burden, recent works have resorted to a weight-sharing strategy, where all models share the same set of bottom-layer weights, on top of which branches out a set of parallel, un-shared top-layer weights (Lan et al., 2018; Chen et al., 2020; Li et al., 2020). Since the shared weights are optimized to accommodate multiple *diverse* un-shared branches, they can learn shared representations with better generalization (Liu et al., 2020; Luong et al., 2015; Ruder et al., 2019).

For large models, however, such a weight-sharing strategy no longer enjoys the same benefits. Due to memory constraints, a significant proportion of bottom-layer weights need to be shared. Accordingly, top-layer branches have only limited capacity, and therefore the resulting models tend to be similar (Chen et al., 2020; Rame and Cord, 2021; Feng et al., 2020; Yang et al., 2021; Wu and Gong, 2021) (Figure 1 (Left)). Due to the lack of the model diversity, their ensemble cannot gain much improvement in generalization. As shown in Figure 1 (Right), both the generalization performance and model variance of the ensemble model are similar to those of a single model when the branch size is small.

To retain a light memory cost while maintaining the ensemble benefits, we propose a new Consistency-regulArized enseMble lEarning ap-

May 22-27, 2022

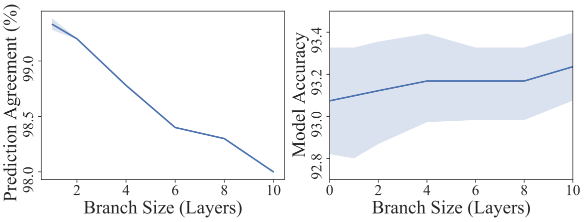

Figure 1: Left: The prediction similarity among branches with different sizes. Right: The average generalization performance and variance of ensembled models over five random seeds. The results are obtained by fine-tuning SST-2 on a BERT-base. A branch size of 0 corresponds to training a single model.

proach based on peRturbed mOdels – CAMERO. Specifically, we share the bottom-layer weights across all models and apply *different* perturbations to the hidden representations for *different* models. Such a perturbation strategy effectively promotes the model diversity. Accordingly, the weights at each layer are optimized to produce consistent outputs given diverse input representations from differently perturbed models. In other words, the shared weights are essentially an on-the-fly ensemble of all perturbed models. In the end, we ensemble all branches on top of the shared weights to produce the final model, which has both a low variance and good generalization performance.

Since we apply perturbations in large models with significant depth, different models' hidden representations may end up being extremely diverse, especially in upper layers. As a result, optimizing the shared weights to accommodate such perturbations can be very challenging. To prevent the models from being over-diverse, we apply a consistency regularizer to reduce variance across different models. Specifically, such a consistency regularizer can be viewed as collaborative distillation across models (Guo et al., 2020; Lan et al., 2018; Zhang et al., 2018; Kim et al., 2021; Chen et al., 2020; Li et al., 2020). By regularizing the discrepancy between each model's output logits and the ensemble of these logits, it encourages all models to be *consistent* in their predictions. We thus adopt consistency regularization to control the perturbed models' diversity from being too large, and thus ease the optimization of the shared weights.

We conduct thorough experiments to demonstrate CAMERO's effectiveness and efficiency in ensembling large number of models with more than hundreds of millions of learning parameters. Specifically, our experiments in fine-tuning the BERT-base model on the GLUE benchmark achieve 0.7 points of gain in terms of task-average score with a significantly smaller parameters over the vanilla ensemble approach (114.2M vs. 880.6M) and achieve 1.2 points of gain with the same amount of learning parameters over the single model. CAMERO also achieves significant improvements in neural machine translation on both low-resource and high-resource language pairs.

Furthermore, we verify that CAMERO can learn shared layers with better generalization and ensemble model with smaller variance. We also investigate the effects of using different types and strengths of perturbation and consistency regularization techniques. In particular, we observe that models created with virtual adversarial perturbation (Jiang et al., 2019a) and neuron dropout (Srivastava et al., 2014) lead to ensemble models with the best generalization performance. Lastly, we demonstrate CAMERO's effectiveness on a larger-scale model, RoBERTa-large (Liu et al., 2019), where it achieves 0.8 and 0.9 points of gain over the vanilla ensemble approach and single model performance, respectively. Our codes are released at `https://github.com/cliang1453/CAMERO`.

2 Background

Notations. We use $f(\cdot;\theta)$ to denote a mapping f associated with the parameter θ from the input sample to an output space, where the output is a multi-dimensional probability simplex for classification tasks and a scalar for regression tasks. We denote the model's final logits as $g(\cdot;\theta)$, where $f(\cdot;\theta) = \sigma(g(\cdot;\theta))$ and $\sigma(\cdot)$ is the Softmax function. We denote n pairs of data samples of the target task as $\{(\boldsymbol{x}_i, y_i)\}_{i=1}^{n}$. The training loss of $f(\cdot;\theta)$ is computed as $\ell(f(\boldsymbol{x}_i;\theta), y_i)$ for any given training instance $(\boldsymbol{x}_i, y_i)$ where $\ell(\cdot;\cdot)$ denotes the loss function. We use $\mathcal{D}_{KL}(P||Q) = \sum_k p_k \log(p_k/q_k)$ to denote the KL-divergence of two discrete distributions P and Q with the associated parameters of p_k's and q_k's, respectively.

Collaborative Distillation. Collaborative distillation approaches train two or more models in parallel while regularizing the consistency of their final prediction distributions (Guo et al., 2020; Lan et al., 2018; Zhang et al., 2018; Kim et al., 2021; Chen et al., 2020; Li et al., 2020). Specifically, we use $\{f(\cdot;\theta_j)\}_{j=1}^{m}$ to denote m individual models with the same architectures with parameters by $\theta_1, ..., \theta_m$, respectively, and denote

$\Theta = \{\theta_1, ..., \theta_m\}$. A typical collaborative distillation approach solves the following optimization problem:

$$\min_{\Theta} \mathcal{L}(\Theta) + \alpha \mathcal{R}(\Theta),$$

where $\alpha > 0$ is a tuning parameter, and $\mathcal{L}(\Theta)$ and $\mathcal{R}(\Theta)$ are defined as

$$\mathcal{L}(\Theta) = \frac{1}{m}\sum_{j=1}^{m} \ell(f(\boldsymbol{x};\theta_j), y),$$

$$\mathcal{R}(\Theta) = \frac{1}{m}\sum_{j=1}^{m} \mathcal{D}(f(\boldsymbol{x};\theta_j), \mathcal{E}(\boldsymbol{x};\Theta)). \qquad (1)$$

For notational simplicity, we will omit the subscript i throughout the rest of the paper. Here, $\mathcal{E}(\boldsymbol{x};\Theta)$ defines a mapping function associated with Θ, which maps the input sample $\boldsymbol{x}$ to a multi-dimensional probability simplex or a scalar depending on the tasks. A commonly adopted ensemble-distillation approach makes $\mathcal{E}(\cdot;\Theta) = \sigma(\sum_{j=1}^{m} w_j g(\boldsymbol{x};\theta_j))$, where $\{w_j\}_{j=1}^{m}$ are non-negative scalars summing to one. $\mathcal{D}(\cdot,\cdot)$ denotes the distance metric of two discrete distributions P and Q or two scalars p and q. $\mathcal{D}(P,Q)$ can take the form of symmetric KL-Divergence, $\frac{1}{2}(\mathcal{D}_{KL}(P||Q)+\mathcal{D}_{KL}(Q||P))$. $\mathcal{D}(p,q)$ or euclidean distance $\|p-q\|_2^2$.

Weight-Sharing. Weight-sharing technique has been adopted in several representation learning scenarios, e.g., multi-task learning (Liu et al., 2020; Luong et al., 2015; Ruder et al., 2019), multi-domain learning (Britz et al., 2017; Zeng et al., 2018; Tars and Fishel, 2018; Jiang et al., 2019b) and multi-lingual tasks (Gu et al., 2018; Aharoni et al., 2019). Weight-sharing strategy can reduce the number of free parameters in the model, which helps prevent overfitting in the training and lead to better generalization abilities.

3 Method

We introduce CAMERO, a weight-sharing ensemble learning approach based on consistency-regularized perturbed models.

3.1 Ensemble Learning w/ Perturbed Models

Based on the multi-layer structures of neural networks, we divide each model into two parts: the bottom-layers and the top-layers. The model parameters in bottom-layers are shared across all models. Specifically, the parameters of the j-th model is denoted as $\theta_j = [\theta_0, \theta_j^{'}]$, where θ_0 denotes the shared weights in bottom-layers, and $\theta_j^{'}$ denotes the top-layer weights of the j-th model. Based on such a compositional structure, the j-th model's output can be denoted as

$$f(\boldsymbol{x};\theta_j) = f_K(f_{K-1}(\dots f_1(\boldsymbol{x};\theta_j^{(1)}) \\ \dots;\theta_j^{(K-1)});\theta_j^{(K)}),$$

where $f_k(\cdot;\theta_j^{(k)})$ is the mapping associated with the k-th layer parameter $\theta_j^{(k)}$, and θ_0 consists of $\{\theta_j^{(k)}\}_{k=1}^{K'}$ for some $K' \in \{1, ..., K\}$, which shares across models.

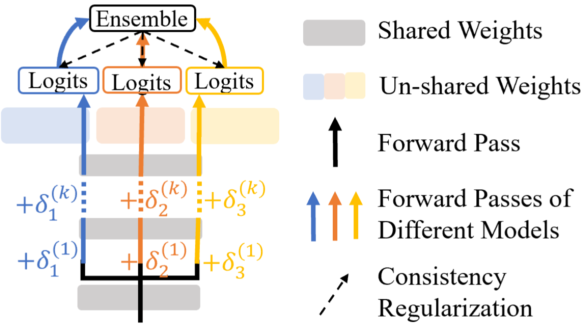

Figure 2: Illustration of CAMERO during training.

A significant proportion of shared weights leads to the models' similarity, which accordingly impairs the ensembled model's performance. To increase the models' diversity, we consider perturbing each layer's hidden representations for different models during training (Figure 2). Specifically, the j-th model's output is denoted as

$$f(\boldsymbol{x};\theta_j,\Delta_j) = f_K(f_{K-1}(\dots f_1(\boldsymbol{x};\theta_j^{(1)}) \\ + \delta_j^{(1)} \dots;\theta_j^{(K-1)}) + \delta_j^{(K-1)};\theta_j^{(K)}),$$

where $\delta_j^{(k)}$ is the perturbation applied at the k-th layer's hidden representations, and $\Delta_j = \{\delta_j^{(k)}\}_{k=1}^{K-1}$, which is sampled from a distribution $\mathcal{P}$. We then train m models with SGD-type algorithms using the following loss:

$$\mathcal{L}_\Delta(\Theta) = \frac{1}{m}\sum_{j=1}^{m} \mathbb{E}_{\Delta_j\sim\mathcal{P}}[\\ \ell(f(\boldsymbol{x};[\theta_0,\theta_j^{'}],\Delta_j),y)]. \qquad (2)$$

Remark 1. We can consider a wide variety of perturbations for hidden representations, input embeddings or data samples, e.g., random perturbation (Aghajanyan et al., 2020), virtual adversarial perturbation (Miyato et al., 2018; Jiang et al., 2019a), neuron dropout (Srivastava et al., 2014) and word dropout (Wei and Zou, 2019).

3.2 Consistency-Regularized Perturbed Models

In large models with significant depth, different models' hidden representations may end up being extremely diverse, especially in upper layers. As a result, optimizing the shared weights to accommodate such diverse inputs can be very challenging. To address this issue, we propose to control model variability through consistency regularization. Specifically, we regularize the consistency among m models' final prediction distributions by minimizing the following loss,

$$\mathcal{R}_{\Delta}(\Theta) = \frac{1}{m}\sum_{j=1}^{m}\mathbb{E}_{\Delta_j\sim\mathcal{P}}[\mathcal{D}(f(\boldsymbol{x};[\theta_0,\theta_j^{'}],\Delta_j),\mathcal{E}(\boldsymbol{x};\Theta,\{\Delta_j\}_{j=1}^{m}))], \tag{3}$$

where $\mathcal{E}(\boldsymbol{x};\Theta,\{\Delta_j\}_{j=1}^{m})$ denotes the final prediction distribution produced by some ensemble method applied upon models with perturbed representations. For example, commonly adopted ensemble methods include logits ensemble, where $\mathcal{E}(\boldsymbol{x};\Theta,\{\Delta_j\}_{j=1}^{m}) = \sigma(\sum_{j=1}^{m} w_j g(\boldsymbol{x};\theta_j,\{\Delta_j\}_{j=1}^{m}))$. In summary, we train m models by minimizing the following overall loss function:

$$\mathcal{L}_{\Delta}(\Theta) + \alpha\mathcal{R}_{\Delta}(\Theta),$$

where $\mathcal{L}_{\Delta}(\Theta)$ is defined in Eq. (2) and $\mathcal{R}_{\Delta}(\Theta)$ is defined in Eq. (3). We adjust the strength of consistency regularization via α, a non-negative hyper-parameter.

Remark 2. Different from existing weight-sharing strategies, which control models' diversity via the amount of shared and un-shared weights, CAMERO controls model diversity via the strength of perturbation and regularization. Such a difference renders significant memory benefits. In practice, we safely share all layers except a single top layer. Accordingly, the memory storage is reduced to that of a single model. This allows us to explore the behaviors of ensemble learning under a larger number of models.

4 Experiment

We verify the effectiveness of CAMERO on widely used benchmarks for natural language understanding and neural machine translation.

4.1 Natural Language Understanding

Model and data. We evaluate the fine-tuning performance of BERT-base (110M) (Devlin et al., 2018) and RoBERTa-large (335M) (Liu et al., 2019) on the General Language Understanding Evaluation (GLUE, Wang et al. (2018)) benchmark. GLUE contains nine NLU tasks, including textual entailment, question answering, sentiment analysis, and text similarity. Details about the benchmark are deferred to Appendix A.1.1.

Baseline methods. We compare CAMERO with Vanilla, where all models are independently trained without consistency regularization. We also compare CAMERO with representative collaborative distillation methods: Deep Mutual Learning (DML, Zhang et al. (2018)), On-the-fly Native Ensemble Learning (ONE, Lan et al. (2018)) and Knowledge Distillation via Collaborative Learning (KDCL, Guo et al. (2020))[1]. DML trains two models with alternating updates while regularizing the consistency between their final prediction distributions. KDCL extends two models to multiple models, training all models concurrently while regularizing the consistency between the prediction distribution of each individual model and of the ensemble of all models. ONE adopts the traditional weight-sharing strategy with a learnable gating factor assigned to each individual branch, which helps to control the model diversity.

Perturbation. We demonstrate the effectiveness of CAMERO using neuron dropout (Srivastava et al., 2014), one of the most straightforward perturbation techniques which randomly zeros out neurons based on a small, fixed ratio. In particular, the ratio adopted in our experiments is 0.1. In Section 5.3, we further demonstrate that a wide variety of perturbations, including virtual adversarial perturbation (Jiang et al., 2019a), random perturbation (Aghajanyan et al., 2020) and word dropout (Wei and Zou, 2019), can all serve the role.

Consistency regularization. We demonstrate the effectiveness of CAMERO using the ensemble consistency defined in Eq. (1). In Section 5.4, we further investigate the effectiveness of different types of consistency regularization techniques.

Initialization. To fine-tune the BERT encoder on downstream tasks, the common initialization approach is to append a randomly initialized, fully connected classification layer on top of the encoder

---

[1] We do not include the data augmentation technique proposed in KDCL for a fair comparison.

Table 2: Single-task fine-tuning dev results on ensembled RoBERTa-large using the GLUE benchmark. "Single" denotes single model performance from Liu et al. (2019); other results are from our own implementation.

(Devlin et al., 2018). For ONE and CAMERO, we append m differently initialized, parallel classification layers on top of the encoder. For other methods, we initialize m individual encoders and append a differently initialized classification layer on top of each.

Inference. For ONE and CAMERO, we conduct a single pass through the encoder and average the predicted logits of m classification layers. For other methods, we average the predicted logits of m models. All results in the following experiments are evaluated based on such a logits ensemble.

Implementation details. Our implementation is based on the MT-DNN code-base[2]. We follow the suggested training and hyper-parameters settings from Liu et al. (2020). Specifically, we adopt Adamax (Kingma and Ba, 2014) as the optimizer with $\beta = (0.9, 0.999)$. We tune α in range of $\{0.5, 1, 2, 5\}$ for all methods. Comprehensive training details are reported in Appendix A.1.2.

Results of BERT-base. Table 1 shows the evaluation results of BERT-base on the GLUE development set. The results are averaged over five random seeds, and all gains are statistically significant[3].

We have the following observations: 1) With significantly less learning parameters, CAMERO achieves a prominent and consistent margin over Vanilla, DML and KDCL. This suggests that CAMERO can produce better-generalized ensemble model with higher parameter efficiency. 2) CAMERO significantly outperforms ONE, suggesting that applying perturbations to models effectively improves the performance of weight-sharing strategy. 3) As the number of models increases from 2 to 8, CAMERO's performance steadily increases for 6 out of 8 tasks, while Vanilla and KDCL fail to do so.

Results of RoBERTa-large. We further verify that CAMERO can benefit an even larger model, RoBERTa-large. As shown in Table 2, CAMERO achieves consistent gains across all tasks[4]. Worth noticing, Vanilla shows limited improvements upon the single model performance (e.g., the gains are

[3] All results have passed a paired student t-test with p-values less than 0.05. The detailed statistics are summarized in Appendix A.1.3.

[4] We present the median of five runs following Liu et al. (2019).

0.0, 0.1 and -0.4 on QNLI, SST-2 and RTE, respectively). We conjecture that the high model variance in large models compromises the ensemble benefits. In contrast, by control the model variance with regularization, CAMERO achieves gains of 0.6, 0.6 and 1.1 on these tasks.

4.2 Neural Machine Translation

Model and data. We further evaluate CAMERO on the Transformer-base NMT model (Vaswani et al., 2017) using widely used IWSLT (Cettolo et al., 2016)[5] and WMT (Bojar et al., 2016)[6] datasets. Specifically, we adopt IWSLT'14 En↔De, IWSLT'16 En↔Fr and WMT'14 En↔De. IWSLT En↔De and En↔Fr are low-resource datasets containing 160k and 236k sentence pairs. WMT En↔De is a rich-resource dataset containing 4.5M sentence pairs. Model and dataset details are deferred to Appendix A.2.1.

Implementation details. Our implementation is based on the fairseq code-base and follows the training and hyper-parameters settings from Ott et al. (2018, 2019). Specifically, we use 5×10^{-4} as the learning rate and employ Adam (Kingma and Ba, 2014) as the optimizer with $\beta = (0.9, 0.98)$. We select α in range of $\{1, 2, 5\}$. For ONE and CAMERO, we randomly initialize multiple parallel decoders's last layers as the un-shared branches. Comprehensive training details are reported in Appendix A.2.2.

Main results. Table 3 shows the BLEU scores on the IWSLT test set and the SacreBLEU scores (Post, 2018) with compound splitting on the WMT test set[7]. WMT's corresponding BLEU scores are reported in Appendix A.2.3.

With a number of learning parameters similar to a single model, CAMERO achieves around 2 and 1 points upon ONE, and improves around 0.4 and 0.4 points upon KDCL, on low-resource and rich-resource datasets, respectively. This suggests that other than fine-tuning, CAMERO also improves the generalization of training-from-scratch models in both low-resource and rich-resource datasets.

5 Analysis

We first verify that CAMERO leads to a well-generalized and low-variance ensemble model. We then demonstrate how the perturbation and consistency regularization strength influences the model diversity and performance. Finally, we demonstrate CAMERO's effectiveness on various types of perturbation and regularization techniques.

5.1 Shared Weights Learn Better Representations

We verify that CAMERO allows the shared weights to learn better-generalized representations. Specifically, we attach a randomly initialized classifier on top of a BERT-base encoder trained by CAMERO. We then fix the encoder and fine-tune the attached classifier only. As shown in Table 4, the encoder trained by CAMERO learns better representations than ONE's consistently across different tasks and under different numbers of models.

5.2 Ensemble Model Has a Low Variance Across Random Seeds

We verify that CAMERO produces an ensemble model that both generalizes well and has a low variance across different random seeds under a light parameter budget. Figure 3 plots the prediction accuracy of 2-model and 4-model ensemble across five seeds. For example, in MNLI, CAMERO's 2-model ensemble (110.7M) achieves similar performance to KDCL's 4-model ensemble (440.2M) and CAMERO's 4-model ensemble (111.9M) achieves an even better performance. Across different tasks, CAMERO's ensemble model has a similar or lower variance than all others. Complete variance statistics are presented in Appendix A.1.3.

5.3 Types and Strength of Perturbations

Types of perturbation. We verify that CAMERO produces well-generalized ensemble models under various types of perturbations. Specifically, we apply virtual adversarial perturbation (Jiang et al., 2019a) and random noise perturbation (Aghajanyan et al., 2020) on the first layer input embeddings, neuron dropout on all layers' input representations (Srivastava et al., 2014), and word dropout on the input sentences (Wei and Zou, 2019). Specifically, we set the dropout ratio to be 0.1 for neuron dropout and 0.05 for word dropout. We set the norm constraint $\epsilon = 1 \times 10^{-5}$ for both virtual adversarial perturbation and random noise perturbation. The random noise is sampled from a normal distribution. As shown in Table 5, CAMERO leads to significant margin of improvement under all types of perturbation. In particular, virtual adversarial

Table 4: Performance of the ensembled BERT-base encoder using the GLUE dev set. We only fine-tune the randomly initialized classification layer on top of a well-trained encoder.

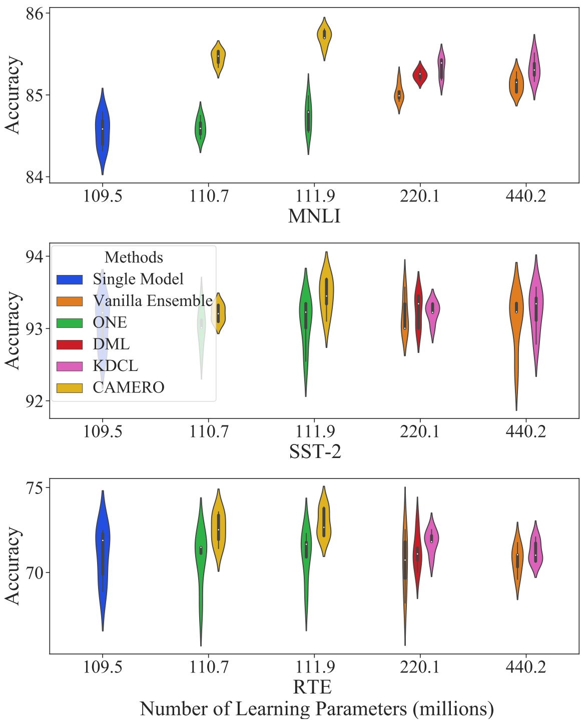

Figure 3: Performance and variance of the ensembled BERT-base on the GLUE dev set.

perturbation and neuron dropout perform consistently well on all tasks. Random noise perturbation performs well on larger tasks (e.g., MNLI, QNLI, SST-2) while the gains shrink on smaller tasks.

Strength of perturbation. We then verify that a larger perturbation strength improves the perturbed models' diversity during training. As consistency loss is computed as the average distance between all perturbed models' output logits to the ensembled logits at each iteration, it directly reflects the model diversity during training. As shown in Figure 4 (Left), a larger neuron dropout ratio leads to larger consistency loss, thus higher model diversity.

Furthermore, we observe that a larger perturbation strength leads to a lower-variance ensemble model. As shown in Figure 4 (Right), as the neuron dropout ratio grows, CAMERO's ensemble model variance decreases. In contrast, ONE has a large variance under all ratios.

5.4 Types and Strength of Consistency Regularization

Types of consistency regularization. We then investigate the effects of using different types of consistency regularization techniques. Specifically, we compare the existing *ensemble consistency*, as defined in Eq. (1), and a newly proposed *pairwise consistency*, which is defined as

$$\mathcal{R}(\Theta) = \frac{2}{m(m-1)} \sum_{j=1}^{m} \sum_{p=j+1}^{m} \mathcal{D}(f(\boldsymbol{x};\theta_j), f(\boldsymbol{x};\theta_p)).$$

The pairwise consistency measures the average distance between *each pair* of models' output logits, thus we expect it to capture the discrepancies among models more accurately. As shown

Perturbation Types	**MNLI** Acc	**QNLI** Acc	**SST-2** Acc	**MRPC** Acc/F1	**CoLA** MCC	**Avg.** Score
None	84.74	91.76	93.10	89.05	58.75	83.48
Neuron Dropout (Srivastava et al., 2014)	85.73	92.30	93.46	89.09	59.50	84.02
Virtual Adversarial Pert. (Jiang et al., 2019a)	85.76	92.33	93.53	89.19	59.49	84.08
Random Noise Pert. (Aghajanyan et al., 2020)	85.78	92.21	93.42	89.07	59.22	83.94
Word Dropout (Wei and Zou, 2019)	85.61	92.00	93.21	89.06	59.19	83.81

Table 5: CAMERO's performance under different types of perturbation. "None" corresponds to ONE, which does not apply different perturbations to different models. We report the 4-model ensembled BERT-base results.

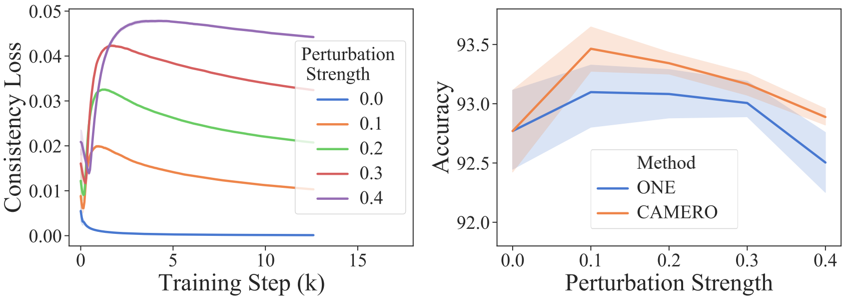

Figure 4: The effect of perturbation strength on models' diversity during training (Left) and the variance of the ensembled model (Right). We fine-tune BERT-base on SST-2 and report the 4-model ensemble results.

Consistency Types	**MNLI** Acc	**QNLI** Acc	**SST-2** Acc	**MRPC** Acc/F1	**CoLA** MCC	**Avg.** Score
None	85.23	91.76	93.30	88.97	58.40	83.48
Ensemble Consistency	85.73	92.30	93.46	89.09	59.50	84.02
Pairwise Consistency	85.73	92.33	93.37	89.40	59.87	84.14

Table 6: CAMERO's performance under different types of consistency regularization. "None" corresponds to $\alpha = 0$, where no regularization is applied. We report the 4-model ensembled BERT-base results.

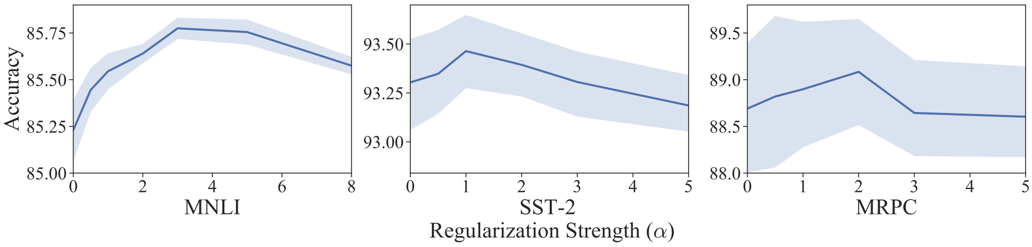

Figure 5: The effect of consistency regularization strength on the generalization and variance of the ensembled model. We fine-tune BERT-base and report the 4-model ensemble results.

in Table 6, CAMERO shows consistent improvements under both types of regularization. In particular, pairwise consistency shows larger advantages on smaller tasks (e.g., 0.3 on MRPC and 0.4 on CoLA).

Strength of consistency regularization. We further investigate how the strength of the regularization factor α affects the ensemble model's performance. As shown in Figure 5, as α increases, the generalization performance of the ensemble model first increases, then decreases. This suggests that regularization can effectively benefits the generalization performance through balancing the model diversity.

6 Conclusion

We propose CAMERO, a consistency-regularized ensemble learning approach based on perturbed models. Such a strategy significantly improves the parameter efficiency of model ensemble in large language models, making it an accessible and powerful technique for learning ensemble models with better generalization performances.

A Appendix

A.1 Natural Language Understanding

A.1.1 Data

GLUE is a collection of nine NLU tasks. The benchmark includes question answering (Rajpurkar et al., 2016), linguistic acceptability (CoLA, Warstadt et al. 2019), sentiment analysis (SST, Socher et al. 2013), text similarity (STS-B, Cer et al. 2017), paraphrase detection (MRPC, Dolan and Brockett 2005), and natural language inference (RTE & MNLI, Dagan et al. 2006; Bar-Haim et al. 2006; Giampiccolo et al. 2007; Bentivogli et al. 2009; Williams et al. 2018) tasks. Details of the GLUE benchmark, including tasks, statistics, and evaluation metrics, are summarized in Table 12.

All the texts were tokenized using wordpieces, and were chopped to spans no longer than 512 tokens.

A.1.2 Training Details

Table 7 presents the hyper-parameter configurations to fine-tune BERT-base and RoBERTa-large models. We apply a linear weight decay rate of 0.01 and a gradient norm clipping threshold of 1 for all experiments. All experiments are conducted on Nvidia V100 GPUs.

A.1.3 Evaluation Results

Statistics of the dev set results. Table 8 shows the standard deviation of the dev set results.

Average score computation formula. For dev set results, we first obtain a score for each task by averaging the scores of all metrics (e.g., Acc and F1) and test sets (e.g., MNLI-m and MNLI-mm) within this task, then compute a task-average score. For test set results, we directly averages scores of all reported metrics following Devlin et al. (2018).

A.2 Neural Machine Translation

A.2.1 Data

For IWSLT'14 En-De and De-En datasets, we follow Ott et al. (2019)[8] to split the train/dev/test set. For IWSLT'16 En-Fr and Fr-En, we adopt the default training set, and use IWSLT16.TED.tst2015 for validation and use IWSLT16.TED.tst2016 for testing. For WMT'14 En-De and De-En, We use the standard newstest-2013 and newstest-2014 for validation and testing, respectively. Table 9 shows the number of sentence pairs in each dataset.

We tokenize all datasets with byte-pair encoding (BPE, Sennrich et al. (2015)) with a vocabulary size of 10k for datasets in IWSLT and 32k for datasets in WMT. We build a joint dictionary upon all source and target sentences for all datasets.

A.2.2 Training Details

We adopt the Transformer-base model for all datasets and share all embeddings. For IWSLT datasets, we follow the training configurations from Ott et al. (2019)[9]. For WMT datasets, we follow the training configurations from Ott et al. (2018)[10]. For all datasets, we use Adam(Kingma and Ba, 2014) as the optimizer with $\beta = (0.9, 0.98)$. We use a inverse square root learning rate schedule. We apply a linear weight decay rate of 1×10^{-4} and a label smoothing ratio of 0.1 for all experiments. All experiments are conducted on Nvidia V100 GPUs. Table 10 presents the training hyper-parameter configurations for all datasets.

For evaluation on IWSLT datasets, we report the BLEU score of the best checkpoint using a beam size of 5 and length penalty of 1. For evaluation on WMT datasets, we average the last 10 checkpoints, decode with a beam size of 4 and length penalty of 0.6, then report the SacreBLEU scores after compound splitting.

A.2.3 BLEU scores for WMT experiments

Table 11 shows the corresponding BLEU scores for WMT datasets.

Interpretability for Language Learners
Using Example-Based Grammatical Error Correction

Abstract

Grammatical Error Correction (GEC) should focus not only on correction accuracy but also on the interpretability of the results for language learners. However, existing neural-based GEC models mostly focus on improving accuracy, while their interpretability has not been explored. Example-based methods are promising for improving interpretability, which use similar retrieved examples to generate corrections. Furthermore, examples are beneficial in language learning, helping learners to understand the basis for grammatically incorrect/correct texts and improve their confidence in writing. Therefore, we hypothesized that incorporating an example-based method into GEC could improve interpretability and support language learners. In this study, we introduce an Example-Based GEC (**EB-GEC**) that presents examples to language learners as a basis for correction result. The examples consist of pairs of correct and incorrect sentences similar to a given input and its predicted correction. Experiments demonstrate that the examples presented by EB-GEC help language learners decide whether to accept or refuse suggestions from the GEC output. Furthermore, the experiments show that retrieved examples also improve the accuracy of corrections.

1 Introduction

Grammatical Error Correction (GEC) models, which generate grammatically correct texts from grammatically incorrect texts, are useful for language learners. In GEC, various neural-based models have been proposed to improve the correction accuracy (Yuan and Briscoe, 2016; Chollampatt and Ng, 2018; Junczys-Dowmunt et al., 2018; Zhao et al., 2019; Kaneko et al., 2020; Omelianchuk et al., 2020). However, the basis on which a neural GEC model makes corrections is generally uninterpretable to learners. Neural GEC models rarely address correction interpretability, leaving language learners with no explanation of the reason for a correction.

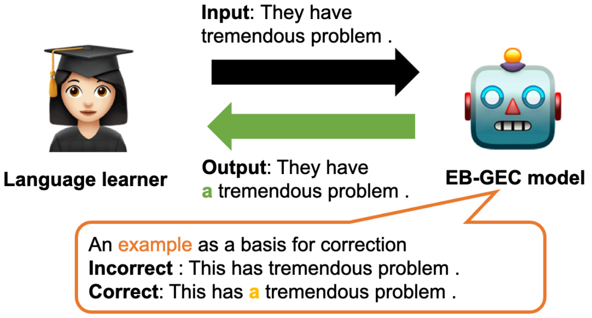

Figure 1: EB-GEC presents not only a correction but also an example of why the GEC model suggested this correction.

Interpretability plays a key role in educational scenarios (Webb et al., 2020). In particular, presenting examples is shown to be effective in improving understanding. Language learners acquire grammatical rules and vocabulary from examples (Johns, 1994; Mizumoto and Chujo, 2015). Presenting examples of incorrect sentences together with correct ones improves the understanding of grammatical correctness as well as essay quality (Arai et al., 2019, 2020).

Recently, example-based methods have been applied to a wide range of natural language processing tasks to improve the interpretability of neural models, including machine translation (Khandelwal et al., 2021), part-of-speech tagging (Wiseman and Stratos, 2019), and named entity recognition (Ouchi et al., 2020). These methods predict labels or tokens by considering the nearest neighbor examples retrieved by the representations of the model at the inference time. Khandelwal et al. (2021) showed that in machine translation, examples close to a target sentence in the representation space of a decoder are useful for translating the source sentence. Inspired by this, we hypothesized that examples corrected for similar reasons are dis-

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 7176 - 7187
May 22-27, 2022

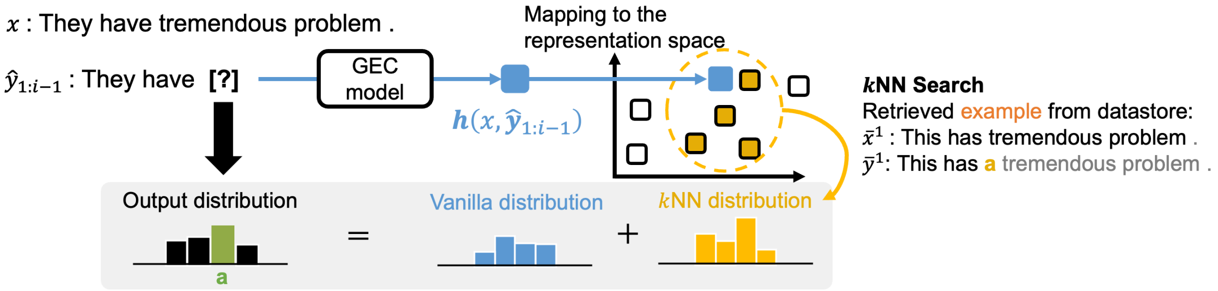

Figure 2: An illustration of how EB-GEC chooses examples and predicts a correction. The model predicts a correction "*They have* __/a *tremendous problem* ." by using the example "*This has* __/a *tremendous problem* ." Hidden states of the decoder computed during the training phase are stored as keys, and tokens of the output sentences corresponding to the hidden states are stored as values. A hidden state of the decoder (blue box) at the time of inference is used as a query to search for k-neighbors (yellow box) of hidden states of the training data. EB-GEC predicts a distribution of tokens for the correction from a combination of two distributions of tokens: a vanilla distribution computed by transforming the hidden state of the decoder; and a kNN distribution by the retrieved k-neighbors.

tributed closely in the representation space. Thus, we assume that neighbor examples can enhance the interpretability of the GEC model, allowing language learners to understand the reason for a correction and access its validity.

In this paper, we introduce an example-based GEC (**EB-GEC**)[1] that corrects grammatical errors in an input text and provides examples for language learners explaining the reason for correction (Figure 1). As shown in Figure 2, the core idea of EB-GEC is to unify the token prediction model for correction and the related example retrieval model from the supervision data into a single encoder-decoder model. EB-GEC can present the reason for the correction, which we hope will help learners decide whether to accept or to refuse a given correction.

Experimental results show that EB-GEC predicts corrections more accurately than the vanilla GEC without examples on the three datasets and comparably on one dataset. Experiments with human participants demonstrate that EB-GEC presents significantly more useful examples than the baseline methods of example retrieval (Matsubara et al., 2008; Yen et al., 2015; Arai et al., 2020). These results indicate that examples are useful not only to the GEC models but also to language learners. This is the first study to demonstrate the benefits of examples themselves for real users, as existing studies (Wiseman and Stratos, 2019; Ouchi et al., 2020; Khandelwal et al., 2021) only showed example utility for improving the task accuracy.

2 EB-GEC

EB-GEC presents language learners with a correction and the related examples it used for generating the correction of the input sentence. k-Nearest-Neighbor Machine Translation (**kNN-MT**; Khandelwal et al., 2021) was used as a base method to consider example in predicting corrections. kNN-MT predicts tokens by considering the nearest neighbor examples based on representations from the decoder at the time of inference. EB-GEC could use any method (Gu et al., 2018; Zhang et al., 2018; Lewis et al., 2020) to consider examples, but kNN-MT was used in this study because it does not require additional training for example retrieval.

Figure 2 shows how the EB-GEC retrieves examples using kNN-MT. EB-GEC performs inference using the softmax distribution of target tokens, referred to as vanilla distribution, hereafter, obtained from the encoder-decoder model and the distribution generated by the nearest neighbor examples. Nearest neighbor search is performed for a cache of examples indexed by the decoder hidden states on supervision data (kNN distribution). EB-GEC can be adapted to any trained autoregressive encoder-decoder GEC model. A detailed explanation of retrieving examples using kNN-MT is provided in Section 2.1, and of presenting examples in Section 2.2.

2.1 Retrieving Examples Using kNN-MT

Let $x = (x_1, ..., x_N)$ be an input sequence and $y = (y_1, ..., y_M)$ be an output sequence of the autoregressive encoder-decoder model. Here, N and M are the lengths of the input and output se-

---

[1] Our code is publicly available at `https://github.com/kanekomasahiro/eb-gec`

quences, respectively.

Vanilla Distribution. In a vanilla autoregressive encoder-decoder model, the distribution for i-th token y_i of the output sequence is conditioned from the entire input sequence x and previous output tokens $\hat{y}_{1:i-1}$, where $\hat{y}$ represents a sequence of generated tokens. The probability distribution of the i-th token $p(y_i|x, \hat{y}_{1:i-1})$ is calculated by a linear translation to the decoder's hidden state $\boldsymbol{h}(x, \hat{y}_{1:i-1})$ followed by the softmax function.

Output Distribution. Let $p_{\mathrm{EB}}(y_i|x, \hat{y}_{1:i-1})$ denote the final probability distribution of tokens from EB-GEC. We define $p_{\mathrm{EB}}(y_i|x, \hat{y}_{1:i-1})$ as a linear interpolation of the vanilla distribution $p(y_i|x, \hat{y}_{1:i-1})$ and $p_{k\mathrm{NN}}(y_i|x, \hat{y}_{1:i-1})$ (explained later), which is the distribution computed using the examples in the datastore,

$$\begin{aligned} p_{\mathrm{EB}}(y_i|x, \hat{y}_{1:i-1}) =& \lambda p_{k\mathrm{NN}}(y_i|x, \hat{y}_{1:i-1}) \\ &+ (1-\lambda) p(y_i|x, \hat{y}_{1:i-1}). \end{aligned} \tag{1}$$

Here, $0 \leq \lambda \leq 1$ is an interpolation coefficient between the two distributions. This interpolation also improves the output robustness when relevant examples are not found in the datastore.

Datastore. In the work of Khandelwal et al. (2021), the i-th hidden state $\boldsymbol{h}(x, y_{1:i-1})$ of the decoder in the trained model was stored as a key, and the corresponding next token y_i was stored as a value. In order to present examples of incorrect/correct sentences, we stored a tuple of the token y_i, the incorrect input sentence x, and the correct output sentence y as a value of the datastore. Thus, we built key-value pairs ($\mathcal{K}$, $\mathcal{V}$) from all decoder timesteps for the entire training data $(\mathcal{X}, \mathcal{Y})$,

$$\begin{aligned} (\mathcal{K}, \mathcal{V}) = \{(\boldsymbol{h}(x, y_{1:i-1}), (y_i, x, y)) \mid \\ \forall y_i \in y, (x, y) \in (\mathcal{X}, \mathcal{Y})\}. \end{aligned} \tag{2}$$

***k*NN Distribution.** During inference, given a source x as input, the model uses the i-th hidden state $\boldsymbol{h}(x, y_{1:i-1})$ of the decoder as the query to search for k-nearest neighbors,

$$\mathcal{N} = \{(\boldsymbol{u}^{(j)}, (v^{(j)}, x^{(j)}, y^{(j)})) \in (\mathcal{K}, \mathcal{V})\}_{j=1}^{k}, \tag{3}$$

where $\boldsymbol{u}^{(j)}$ $(j = 1, \ldots, k)$ are the k-nearest neighbors of the query $\boldsymbol{h}(x, y_{1:i-1})$ measured by squared L^2 distance. The tuple $(v^{(j)}, x^{(j)}, y^{(j)})$ is the value associated with the key $\boldsymbol{u}^{(j)}$ in the datastore $(\mathcal{K}, \mathcal{V})$. Then, the kNN-MT aggregates the retrieved tokens to form a probability distribution $p_{k\mathrm{NN}}(y_i|x, \hat{y}_{1:i-1})$ with a softmax with temperature T to the negative L^2 distances[2],

$$\begin{aligned} & p_{k\mathrm{NN}}(y_i|x, \hat{y}_{1:i-1}) \propto \\ & \sum_{(\boldsymbol{u},(v,\_,\_))\in\mathcal{N}} \mathbb{I}_{v=y_i} \exp\left(\frac{-\|\boldsymbol{u} - \boldsymbol{h}(x, \hat{y}_{1:i-1})\|}{T}\right). \end{aligned} \tag{4}$$

2.2 Presenting Examples

We used a pair of incorrect and correct sentences stored in the value retrieved for the predicted token $\hat{y}_i$ as an example from the correction. Figure 1 depicts an example where the retrieved value consists of the predicted token $v^{(j)}$ = "*a*" and the incorrect/correct sentences $x^{(j)}, y^{(j)}$ corresponding to "*This has _/a tremendous problem .*". In this study, we presented examples for each edited token in an output. For example, when an input or output is "*They have _/a tremendous problem .*", we presented examples for the edit "*_/a*". To extract edit operations from an input/output pair, we aligned the tokens in input and output sentences by using the Gestalt pattern matching (Ratcliff and Metzener, 1988).

There are several ways to decide which examples should be presented to a language learner. For instance, we could use all the examples in k-nearest neighbors $\mathcal{N}$ and possibly filter them with a threshold based on L^2 distance. In this paper, we present an example incorrect/correct sentence pair that is the nearest to the query in $\mathcal{N}$, which is the most confident example estimated by the model.

3 Experiments

This section investigates the effectiveness of the examples via manual evaluation and accuracy on the GEC benchmark to show that the EB-GEC does, in fact, improve the interpretability without sacrificing accuracy. We first describe the experimental setup and then report the results of the experiments.

3.1 Datasets and Evaluation Metrics

We used the official datasets of BEA-2019 Shared Task (Bryant et al., 2019), W&I-train (Granger, 1998; Yannakoudakis et al., 2018),

---

[2] In Equation 4, we do not use the input and output sentences in the value, and thus represent them as _.

NUCLE (Dahlmeier et al., 2013), FCE-train (Yannakoudakis et al., 2011) and Lang-8 (Mizumoto et al., 2011) as training data and W&I-dev as development data. We followed Chollampatt and Ng (2018) to exclude sentence pairs in which the source and target sentences are identical from the training data. The final number of sentence pairs in the training data was 0.6M. We used this training data to create the EB-GEC datastore. Note that the same amount of data is used by EB-GEC and the vanilla GEC model.

We used W&I-test, CoNLL2014 (Ng et al., 2014), FCE-test, and JFLEG-test (Napoles et al., 2017) as test data. To measure the accuracy of the GEC models, we used the evaluation metrics ERRANT (Felice et al., 2016; Bryant et al., 2017) for the W&I-test and FCE-test, M^2 (Dahlmeier and Ng, 2012) for CoNLL2014, and GLEU (Napoles et al., 2015) for the JFLEG-test. M^2 and ERRANT report $\mathrm{F}_{0.5}$ values.

3.2 Implementation Details of EB-GEC

We used Transformer-big (Vaswani et al., 2017) as the GEC model. Note that EB-GEC does not assume a specific autoregressive encoder-decoder model. The beam search was performed with a beam width of 5. We tokenized the data into subwords with a vocabulary size of 8,000 using BPE (Sennrich et al., 2016). The hyperparameters reported in Vaswani et al. (2017) were used, aside from the max epoch, which was set to 20. In our experiments, we reported the average results of five GEC models trained using different random seeds. We used four Tesla V100 GPUs for training.

We considered the kNN and vanilla distributions equally, with λ in Eq. (1) set to 0.5, to achieve both accuracy and interpretability. Based on the development data results, the number of nearest neighbors k was set to 16 and the softmax temperature T to 1,000. We used the final layer of the decoder feedforward network as the datastore key. We used Faiss (Johnson et al., 2021) with the same settings as Khandelwal et al. (2021) for fast nearest neighbor search in high-dimensional space.

3.3 Human Evaluation Settings

We assessed the interpretability by human evaluation based on Doshi-Velez and Kim (2017). The human evaluation was performed to determine whether the examples improved user understanding and helped users to accept or refuse the GEC corrections. To investigate the utility of the examples presented by EB-GEC, we examined the relative effectiveness of presenting examples in GEC as compared to providing none. Moreover, we used two baseline methods for example selection, token-based retrieval and BERT-based retrieval. Note that, unlike EB-GEC, token-based and BERT-based retrievals do not directly use the representations in the GEC model; in other words, these baselines perform the task of choosing examples independently of the GEC model. In contrast, EB-GEC uses examples directly for generating an output. EB-GEC was expected to provide examples more related to GEC input/output sentences than the baseline methods.

Token-based Retrieval. This baseline method retrieves examples from the training data where the corrections of the EB-GEC output match the corrections in the target sentence of the training data. This is a similar method to the example search performed using surface matching (Matsubara et al., 2008; Yen et al., 2015). If multiple sentences are found with matching tokens, an example is selected at random. If the tokens do not match, this method cannot present any examples.

BERT-based Retrieval. This baseline method uses BERT[3] (Devlin et al., 2019) to retrieve examples, considering the context of both the corrected sentence and example from the datastore. This method corresponds to one based on context-aware example retrieval (Arai et al., 2020). In order to retrieve examples using BERT, we create a datastore,

$$(\mathcal{K}_{\mathrm{BERT}}, \mathcal{V}_{\mathrm{BERT}}) = \{(\boldsymbol{e}(y_i), (y_i, x, y)) | \\ \forall y_i \in y, (x, y) \in (\mathcal{X}, \mathcal{Y})\}. \tag{5}$$

Here $\boldsymbol{e}(y_i)$ is the hidden state of the last layer of BERT for the token y_i when the sentence y is given without masking. This method uses $\boldsymbol{e}(y_i)$ as a query for the model output sentence to then search the datastore for k nearest neighbors.

The input and output sentences of the GEC model and the examples from the baselines and EB-GEC were presented to the annotators with anonymized system names. Annotators then decided whether the examples helped to interpret the GEC output or not, or whether they aided understanding of grammar and vocabulary. The example

Method	Human evaluation score
Token-based retrieval	28.8
BERT-based retrieval	52.4
EB-GEC	**68.8**†,‡

Table 1: Results of the human evaluation of the usefulness of Token-based retrieval, BERT-based retrieval and EB-GEC examples. Human evaluation score is the percentage of useful examples among those presented to the language learners. The † and ‡ indicate statistically significant differences of EB-GEC according to McNemar's test ($p < 0.05$) against Token-based retrieval and BERT-based retrieval, respectively.

sentence pair was labeled as 1 if it was "useful for decision-making or understanding the correction" and 0 otherwise. We then computed scores for Token-based retrieval, BERT-based retrieval, and EB-GEC models by counting the number of sentences labeled with 1. We confirm whether corrections with examples were more beneficial for learners than those without, and whether EB-GEC could present more valuable examples than those from the baselines. Since it is not always the case that only corrected parts are helpful for learners (Matsubara et al., 2008; Yen et al., 2015), the uncorrected parts were also considered during annotation.

We manually evaluated 990 examples provided by the three methods for 330 ungrammatical and grammatical sentence pairs randomly sampled from the W&I-test, CoNLL2014, FCE-test, and JFLEG-test. The human evaluation was performed by two annotators with CEFR[4] proficiency level B and one annotator with level C[5]. All three annotators evaluated different examples.

3.4 Results

Human Evaluation of Examples. Table 1 shows the results of human evaluation of Token-based retrieval, BERT-based retrieval, and EB-GEC models. The percentage of useful examples has increased significantly for EB-GEC compared to token-based and BERT-based retrieval baselines. The percentage of useful examples from EB-GEC is greater than 50, which indicates that presenting examples is more useful than providing none. This result is non-trivial because the percentage for token-based retrieval is only 28.8, which indicates that those presented examples were mostly useless. Therefore, the examples for interpretability in EB-GEC support language learners' understanding and acceptance of the model output.

Method	W&I	CoNLL2014	FCE	JFLEG
Vanilla GEC	50.12	49.68	41.49	**53.71**
EB-GEC	**52.45**	**50.51**	**43.00**	53.46

Table 2: Accuracy of vanilla GEC model and EB-GEC model on W&I, CoNLL2014, FCE and JFLEG test data.

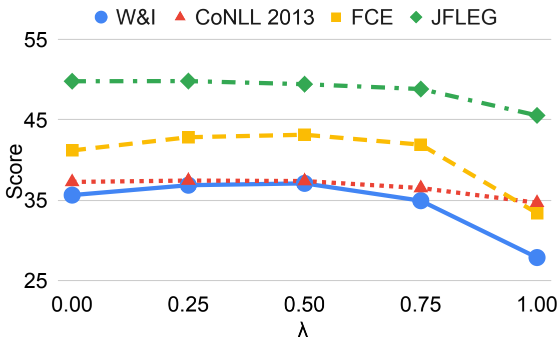

Figure 3: Scores for each development data using different λ values from 0 to 1 in increments of 0.25. The evaluation metrics for each data are the same as for the test data.

GEC Accuracy. We examined the impact of using examples for the prediction of GEC accuracy. Table 2 shows the scores of the vanilla GEC and EB-GEC for the W&I, CoNLL2014, FCE, and JFLEG test data. The accuracy of EB-GEC is slightly lower for JFLEG but outperforms the vanilla GEC for W&I, CoNLL2014, and FCE. This indicates that the use of examples contributes to improving GEC model accuracy.

4 Analysis

4.1 Effect of λ

We analyzed the relationship between the interpolation coefficient λ (in Equation (1)) and the GEC accuracy. A smaller λ value may reduce the interpretability as examples are not considered in prediction. In contrast, a larger λ value may reduce robustness, especially when relevant examples are not included in the datastore; the model must then generate corrections relying more on kNN exam-

---

[4] `https://www.cambridgeenglish.org/exams-and-tests/cefr`

[5] They are not authors of this paper. In this human evaluation, annotators with a middle and high proficiency level are selected in case annotators cannot understand errors/corrections and make a judgment whether the presented example is necessary or unnecessary. Therefore, this study does not focus on whether annotators with lower proficiency levels find it helpful to see examples without explanation.

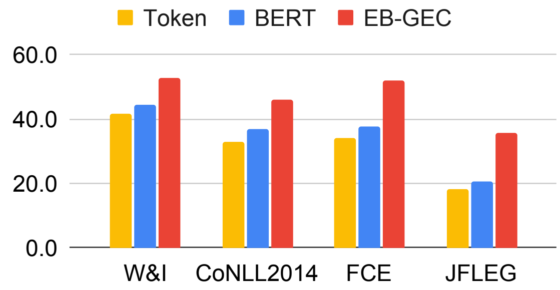

Figure 4: Matching percentage of edits and error types in model outputs and examples.

Error type	Freq.	Vanilla GEC	EB-GEC	Diff.
`PREP`	115K	40.9	44.6	3.7
`PUNCT`	98K	33.5	37.0	3.5
`DET`	171K	46.6	49.8	3.2
`ADJ:FORM`	2K	54.5	38.4	-16.08
`ADJ`	21K	17.0	14.5	-2.42
`SPELL`	72K	68.6	66.8	-1.87

Table 3: The error types with the highest and the lowest EB-GEC accuracy compared to vanilla GEC on FCE-test based on Diff. column. Freq. column is the frequency of the error type in the datastore.

ples, which may not be present in the datastore for some inputs.

Figure 3 shows the accuracy of the GEC for each development data when the λ is changed from 0 to 1 in increments of 0.25. We found that when λ was set to 1, the accuracy for all development datasets was lower than when λ was set to 0.50 or less. It is shown that the highest accuracy was obtained for $\lambda = 0.5$, as this treats the vanilla output distribution and the output distribution equally.

4.2 Matching Error Types of Model Outputs and Examples

In Section 1, we hypothesized that similar error-correcting examples are closely clustered in the representation space. Therefore, we investigated the agreement between the GEC output and the examples for edits and error types. We extracted **edits** and their **error types**, which were automatically assigned by ERRANT (Felice et al., 2016; Bryant et al., 2017) for incorrect/correct sentence pairs. For example, for a GEC input/output pair "*They have* _/a *tremendous problem .*", the example pair is "*This has* _/a *tremendous problem .*", its **edit** is "_/a" and the **error type** is the determiner error (`DET`). We calculated the matching percentage of the edits and error types for EB-GEC outputs and for the examples retrieved using EB-GEC to show their similarity. In addition, we used token-based and BERT-based retrieval as comparison methods for obtaining examples relevant to EB-GEC outputs.

Figure 4 shows the matching percentage of edits and error types between the GEC outputs and the k-nearest neighbors examples. First, we see that EB-GEC has the highest percentage for all test data. This indicates that of the methods tested, EB-GEC retrieves the most relevant examples. This trend is consistent with the human evaluation results. Furthermore, we see that EB-GEC has a lower percentage on JFLEG compared to those on W&I, CoNLL2014, and FCE. This corroborates the results of Table 2, which suggests that the accuracy of GEC improved further when examples more relevant to the corrections could be retrieved.

4.3 EB-GEC and Error Types

We analyzed the accuracy of EB-GEC for different error types to investigate the effect of error type on EB-GEC performance. We used ERRANT to evaluate the accuracy of EB-GEC for each error type on the FCE-test.

Table 3 shows three error types selected as having the most significant increase and decrease in accuracy for EB-GEC compared to the vanilla GEC. The three error types with the largest increases were preposition (`PREP`; e.g. *I think we should book at/_ the Palace Hotel .*), punctuation error (`PUNCT`; e.g. *Yours ./_ sincerely ,*), and article error (`DET`; e.g. *That should complete that/an amazing day .*). The three error types with the largest decreases are adjective conjugation error (`ADJ:FORM`; e.g. *I was very please/pleased to receive your letter .*), adjective error (`ADJ`; e.g. *The adjoining restaurant is very enjoyable/good as well .*), and spelling error (`SPELL`; e.g. *Pusan Castle is locted/located in the South of Pusan .*).

We concluded the following findings from these results. Error types with the largest increase in accuracy have a limited number of tokens used for the edits compared to those with the largest decreases in accuracy (namely, error types referring to adjectives and nouns). Furthermore, these error types are the most frequent errors in the datastore, (excluding the unclassified error type annotated as `OTHER`), and the datastore sufficiently covers such edits. Contrary to the error types with improved accuracy, `ADJ` and `SPELL` have a considerable

	Error type	Error-correction pair	Label
Input/Output	`PREP`	*You will be able to buy them* ***in/at*** *__/a reasonable price .*	-
Token-based retrieval	`PREP`	*Naturally , it 's easier to get a job then/when you were/are good* ***in/at*** *foreign languagers/languages or computers .*	0
BERT-based retrieval	`PREP`	*I could purchase them* ***in/at*** *reasonable price/prices .*	1
EB-GEC	`PREP`	*I could purchase them* ***in/at*** *reasonable price/prices .*	1
Input/Output	`PUNCT`	*for/For example* ***__/,*** *a reasercher that wants to be successfull must take risk .*	-
Token-based retrieval	`PUNCT`	*Today* ***__/,*** *we first/__ met for __/the first time in about four weeks .*	0
BERT-based retrieval	`PUNCT`	*for/For example* ***__/,*** *a kid named Michael .*	1
EB-GEC	`PUNCT`	*for/For example* ***__/,*** *a kid named Michael .*	1
Input/Output	`DET`	*Apart from that __/, it takes* ***__/a*** *long time to go somewhere .*	-
Token-based retrieval	`DET`	*If you have enough time , I recommend* ***__/a*** *bus trip .*	0
BERT-based retrieval	`PREP`	*However , it will take* ***for/__*** *a long time to go abroad in my company .*	0
EB-GEC	`DET`	*So/Because of that , it takes* ***__/a*** *long time to write my journal/entries .*	1

Table 4: Examples retrieved by Token-based retrieval, BERT-based retrieval, and EB-GEC for input/output, and the human evaluation labels. Underlines indicate error-correction pairs in the sentences. **Bold** indicates the edit used as the query to retrieve the example, and error types of the bold edits are assigned by ERRANT.

number of tokens used in edits, and they are not easy to cover sufficiently in a datastore. Moreover, `ADJ:FORM` is the second least frequently occurring error type in the datastore, and we believe such examples cannot be covered sufficiently. These results show that EB-GEC improves the accuracy of error types that are easily covered by examples, as there are fewer word types rarely used for edits and they are better presented in datastore. Furthermore, the results show that the accuracy deteriorates for error types that are difficult to cover, such as word types used for edits and infrequent error types in the datastore.

We investigated the characteristics of the EB-GEC examples by comparing specific examples for each error type with those from token-based and BERT-based retrieval. Table 4 shows examples of Token-based retrieval, BERT-based retrieval and EB-GEC for the top three error types (`PREP`, `PUNCT` and `DET`) with accuracy improvement in EB-GEC. Token-based retrieval showed that the tokens in the edits are consistent, including "***in/at***", "***__/,***", and "***__/a***". However, only surface information is used, and context is not considered. So such unrelated examples are not useful for language learners. BERT-based retrieval presented the same examples as EB-GEC for `PREP` and `PUNCT` error types, and the label for human evaluation was also 1. However, the last example is influenced by the context rather than the correction and so presents an irrelevant example, labeled 0 by human evaluation. This indicates that BERT-based retrieval overly focuses on context, resulting in examples related to the overall output but unrelated to the edits. Conversely, EB-GEC is able to present examples in which the editing pair tokens are consistent for all corrections. Furthermore, the contexts were similar to those of the input/output, for example "*purchase them* ***in/at*** *reasonable price/prices*", "*for/For example* ***__/,***" and "*it takes* ***__/a*** *long time to*", and all the examples were labeled 1 during human evaluation. This demonstrates that EB-GEC retrieves the most related examples that are helpful for users.

5 Related Work

5.1 Example Retrieval for Language Learners

There are example search systems that support language learners by finding examples. Before neural-based models, examples were retrieved and presented by surface matching (Matsubara et al., 2008; Yen et al., 2015). Arai et al. (2019, 2020) proposed to combine Grammatical Error Detection (GED) and example retrieval to present both grammatically incorrect and correct examples of essays written by Japanese language learners. This study showed that essay quality was improved by providing examples. Their method is similar to EB-GEC in that it presents both correct and incorrect examples but incorporates example search systems for GED rather than the GEC. Furthermore, the example search systems search for examples independently of the model. Contrastingly, EB-GEC presents more related examples as shown in Section 3.4.

Cheng and Nagase (2012) developed a Japanese example-based system that retrieves examples using dependency structures and proofread texts.

Proofreading is a task similar to GEC because it also involves correcting grammatical errors. However, this method also does not focus on using examples to improve interpretability.

5.2 Explanation for Language Learners

There is a feedback comment generation task (Nagata, 2019) that can generate useful hints and explanations for grammatical errors and unnatural expressions in writing education. Nagata et al. (2020) used a grammatical error detection model (Kaneko et al., 2017; Kaneko and Komachi, 2019) and neural retrieval-based method for prepositional errors. The motivation of this study was similar to ours, that is, to help language learners understand grammatical errors and unnatural expressions in an interpretable way. On the other hand, EB-GEC supports language learners using examples from the GEC model rather than using feedback.

5.3 Example Retrieval in Text Generation

Various previous studies have used neural network models to retrieve words, phrases, and sentences for use in prediction. Nagao (1984) proposed an example-based MT to translate sequences by analogy. This method has been extended to a variety of other methods for MT (Sumita and Iida, 1991; Doi et al., 2005; Van Den Bosch, 2007; Stroppa et al., 2007; Van Gompel et al., 2009; Haque et al., 2009). In addition, the example-based method has been used for summarization (Makino and Yamamoto, 2008) and paraphrasing (Ohtake and Yamamoto, 2003). These studies were performed before neural networks were in general use, and the examples were not used to solve the neural network black box as was done in this study.

In neural network models, methods using examples have been proposed to improve accuracy and interpretability during inference. Gu et al. (2018) proposed a model that during inference retrieves parallel sentences similar to input sentences and generates translations by the retrieved parallel sentences. Zhang et al. (2018) proposed a method that, during inference, retrieves parallel sentences where the source sentences are similar to the input sentences and weights the output containing n-grams of the retrieved sentence pairs based on the similarity between the input sentence and the retrieved source sentence. These methods differ from EB-GEC using kNN-MT in that they retrieve examples via surface matching, as done in baseline token-based retrieval. Moreover, these studies do not focus on the interpretability of the model.

Several methods have been proposed to retrieve examples using neural model representations and consider them for prediction. Khandelwal et al. (2020, 2021) proposed the retrieval of similar examples using the nearest neighbor examples of pre-trained hidden states during inference and to complement the output distributions of the language model and machine translation with the distributions of these examples. Lewis et al. (2020) combined a pre-trained retriever with a pre-trained encoder-decoder model and fine-tuned it end-to-end. For the input query, they found the top-k documents and used them as a latent variable for final prediction. Guu et al. (2020) first conducted an unsupervised joint pre-training of the knowledge retriever and knowledge-augmented encoder for the language modeling task, then fine-tuned it using a task of primary interest, with supervised examples. The main purpose of these methods was to improve the accuracy using examples, and whether the examples were helpful for the users was not verified. Conversely, our study showed that examples for the interpretability in GEC could be helpful for real users.

6 Conclusion

We introduced EB-GEC to improve the interpretability of corrections by presenting examples to language learners. The human evaluation showed that the examples presented by EB-GEC supported language learners' decision to accept corrections and improved their understanding of the correction results. Although existing interpretive methods using examples have not verified if examples are helpful for humans, this study demonstrated that examples were helpful for learners using GEC. In addition, the results of the GEC benchmark showed that EB-GEC could predict corrections more accurately or comparably to its vanilla counterpart.

Future work would include investigations of whether example presentation is beneficial for learners with low language proficiency. In addition, we plan to improve the datastore coverage by using pseudo-data (Xie et al., 2018) and weight low frequency error types to present diverse examples. We explore whether methods to improve accuracy and diversity (Chollampatt and Ng, 2018; Kaneko et al., 2019; Hotate et al., 2019, 2020) are effective for EB-GEC.

Rethinking Negative Sampling for Handling Missing Entity Annotations

Yangming Li, Lemao Liu, Shuming Shi

`{newmanli,redmondliu,shumingshi}@tencent.com`

Abstract

Negative sampling is highly effective in handling missing annotations for named entity recognition (NER). One of our contributions is an analysis on how it makes sense through introducing two insightful concepts: missampling and uncertainty. Empirical studies show low missampling rate and high uncertainty are both essential for achieving promising performances with negative sampling. Based on the sparsity of named entities, we also theoretically derive a lower bound for the probability of zero missampling rate, which is only relevant to sentence length. The other contribution is an adaptive and weighted sampling distribution that further improves negative sampling via our former analysis. Experiments on synthetic datasets and well-annotated datasets (e.g., CoNLL-2003) show that our proposed approach benefits negative sampling in terms of F1 score and loss convergence. Besides, models with improved negative sampling have achieved new state-of-the-art results on real-world datasets (e.g., EC).

1 Introduction

With powerful neural networks and abundant well-labeled corpora, named entity recognition (NER) models have achieved promising performances (Huang et al., 2015; Ma and Hovy, 2016; Akbik et al., 2018; Li et al., 2020a). However, in many scenarios, available training data is low-quality, which means a portion of named entities are absent in annotations. Fig. 1 depicts a sentence and its incomplete annotations. Fine-grained NER (Ling and Weld, 2012) is a typical case. Its training data is mainly obtained through applying weak supervision to unlabeled corpora. Past works (Shang et al., 2018b; Li et al., 2021a) find missing annotations impact NER models and refer this to *unlabeled entity problem*.

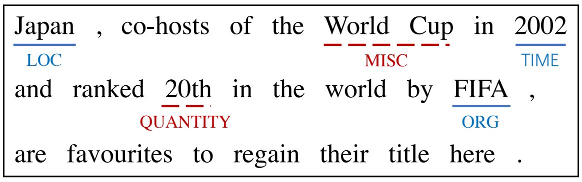

Figure 1: A toy example to show *unlabeled entity problem*. The phrases underlined with dashed lines are the named entities neglected by annotators.

Recently, Li et al. (2021a) find it's the misguidance of unlabeled entities to NER models in training that causes their poor performances. To eliminate this adverse impact, they propose a simple yet effective approach based on negative sampling. Compared with its counterparts (Li and Liu, 2005; Tsuboi et al., 2008; Shang et al., 2018b; Peng et al., 2019), this method is of high flexibility, without relying on external resources, heuristics, etc.

While negative sampling has handled missing annotations well, there is no systematic study on how it works, especially what potential factors are involved. From a number of experiments, we find missampling and uncertainty both worth receiving attention. Missampling means that some unlabeled entities are mistakenly drawn into the set of training negatives by negative sampling. To quantitively describe this, we define missampling rate, the proportion of unlabeled entities in sampled negatives, for a sentence. Uncertainty indicates how hard a sampled negative is for NER models to recognize, and we use entropy to estimate it. Empirical studies show low missampling rate and high uncertainty are both indispensable for effectively applying negative sampling. Besides, based on the observation that entities are commonly sparse, we provide a lower bound for the probability of zero missampling rate with theoretical proof, which is only related to sentence length.

Originally, Li et al. (2021a) adopt uniform sampling distribution for negative sampling. Inspired by former findings, we introduce a weighted sampling distribution to displace the uniform one,

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 7188 - 7197
May 22-27, 2022

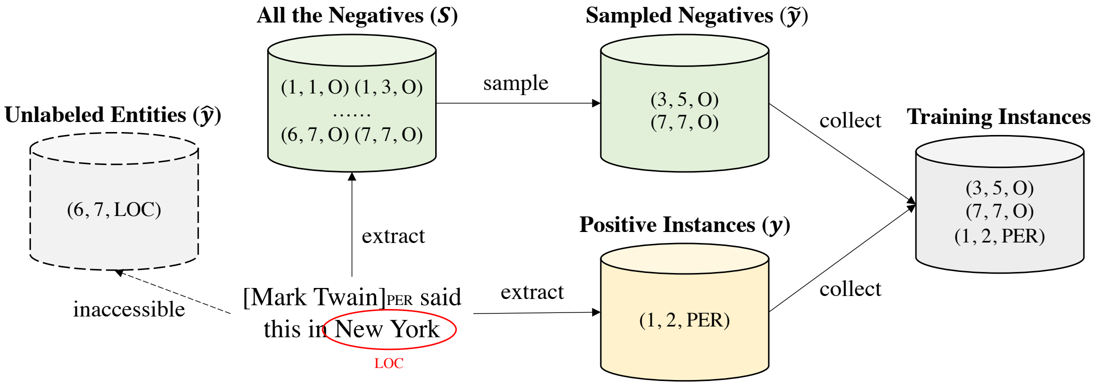

Figure 2: An example to depict how negative sampling collects training negatives given an annotated sentence. The phrase marked by a red circle is an unlabeled entity.

which takes missampling and uncertainty into account. Our distribution is purely computed from the predictions of an NER model. This means it coevolves with the model throughout the training process. The adaptive property of our method is appealing since it doesn't rely on manual annotations or additional models to indicate valuable negatives.

We have conducted extensive experiments to verify the effectiveness of our weighed sampling distribution. Results on synthetic datasets and well-annotated datasets (e.g., OntoNotes 5.0) show that weighted sampling distribution improves negative sampling in performances and loss convergence. Notably, with improved negative sampling, our NER models have established new state-of-the-art performances on real-world datasets, like EC (Yang et al., 2018).

2 Preliminaries

2.1 Unlabeled Entity Problem

Given an n-length sentence, $\mathbf{x} = [x_1, x_2, \cdots, x_n]$, an annotator (e.g., human) will mark a set of named entities from it as $\mathbf{y} = \{y_1, y_2, \cdots, y_m\}$. n is sequence length and m is set size. Every entity, y_k, of the set, $\mathbf{y}$, is denoted as a tuple, (i_k, j_k, l_k). (i_k, j_k) is the span of the entity that corresponds to the phrase, $\mathbf{x}_{i_k,j_k} = [x_{i_k}, x_{i_k+1}, \cdots, x_{j_k}]$, and l_k is its label. *Unlabeled entity problem* occurs when some ground truth named entities, $\widehat{\mathbf{y}}$, are missed by annotators, which means they are not contained in the labeled entity collection, $\mathbf{y}$. In distantly supervised NER (Mintz et al., 2009; Ren et al., 2015; Fries et al., 2017), this is resulted from the limited coverage of external resources, such as predefined ontology. In other situations (e.g., fine-grained NER where manual annotation is extremely hard), the cause may be the negligence of human annotators.

Take Fig. 2 as an example. The set of labeled entities is $\mathbf{y} = [(1, 2, \mathrm{PER})]$, that of unlabeled entities is $\widehat{\mathbf{y}} = \{(6, 7, \mathrm{LOC})\}$, and that of ground-truth entities is $\mathbf{y} \cup \widehat{\mathbf{y}}$.

Let $\mathcal{S}$ denote the set that includes all spans of a sentence, $\mathbf{x}$, except the ones of annotated named entities, $\mathbf{y}$. Every span in this set is labeled with "O", indicating that it's a possible negative. A standard training strategy for NER models is to minimize the loss on annotated positives, $\mathbf{y}$, and all negative candidates, $\mathcal{S}$. Unfortunately, since $\mathcal{S}$ might contain unlabeled entities in $\widehat{\mathbf{y}}$, NER models are seriously misguided in training. To address this problem, (Li et al., 2021a) propose to circumvent unlabeled entities with negative sampling.

2.2 Training with Negative Sampling

The core idea is to uniformly sample a few negative candidates, $\widetilde{\mathbf{y}}$, from $\mathcal{S}$ for reliably training NER models. Under this scheme, the training instances contain sampled negatives, $\widetilde{\mathbf{y}}$, and positives from annotated entities, $\mathbf{y}$. With them, $\mathbf{y} \cup \widetilde{\mathbf{y}}$, a cross-entropy loss is incurred as

$$\mathcal{J} = \sum_{(i,j,l) \in \mathbf{y} \cup \widetilde{\mathbf{y}}} -\log P(l \mid \mathbf{x}_{i,j}; \theta). \qquad (1)$$

$P(l \mid \mathbf{x}_{i,j}; \theta)$ is the probability that the ground truth label of the span, (i, j), is l and θ represents the parameters of a model. Following Li et al. (2021a), our NER models are all span-based, which treat a span, instead of a single token, as the basic unit for labeling.

Negative sampling is probable to avoid models being exposed to unlabeled entities. As Fig. 2 shows, the false negative, $(6, 7, \mathrm{O})$, is not involved

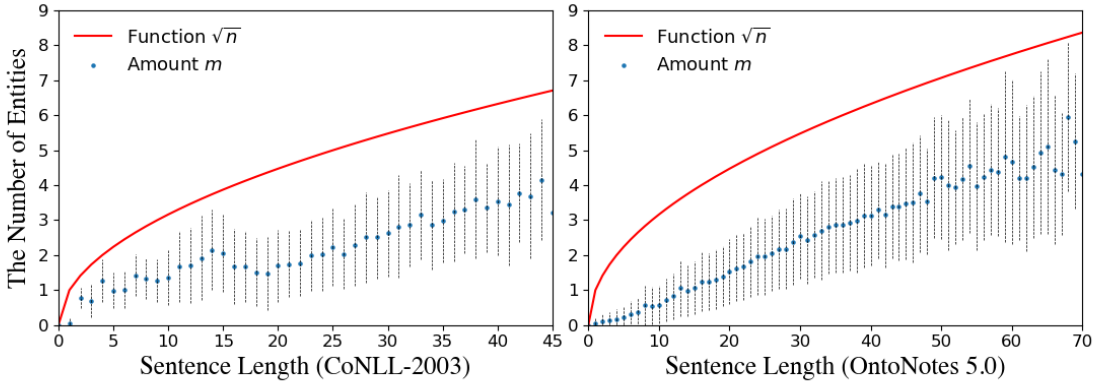

Figure 3: The comparisons between changes of entity number and square root curve.

Average γ	0.76%	1.52%	4.11%
F1 Score	89.86	87.35	83.11

Table 1: The effects of γ on F1.

in training. Li et al. (2021a) have empirically confirmed the effectiveness of negative sampling in handling unlabeled entities. However, there is no systematic study to explain how it works, and what factors are relevant.

3 Analyzing Negative Sampling

We analyze how negative sampling leads NER models that suffer from missing entity annotations to promising results from two angles: missampling and uncertainty.

3.1 Missampling Rate

3.1.1 Definition

Missampling rate, γ, is defined as, for a sentence, the proportion of unlabeled entities contained in sampled negatives, $\widetilde{\mathbf{y}}$. Formally, it's computed as

$$\gamma = 1 - \frac{\#\{(i,j,l) \mid (i,j,l) \in \widehat{\mathbf{y}}; (i,j,\mathrm{O}) \notin \widetilde{\mathbf{y}}\}}{\#\widetilde{\mathbf{y}}},$$

where $\#$ is an operation that measures the size of an unordered set.

The missampling rate γ reflects the quality of training instances, $\mathbf{y} \cup \widetilde{\mathbf{y}}$. A lower averaged rate over the whole dataset means that the NER model meets fewer unlabeled entities in training. Intuitively, this leads to higher F1 scores since there is less misguidance from missing annotations to the model. Hence, missampling is an essential factor for analysis.

3.1.2 Missampling Affects Performance

We design a simulation experiment to empirically verify the above intuition. Like Li et al. (2021a), we build synthetic datasets as follows. We start from a well-labeled dataset, i.e., CoNLL-2003 (Sang and De Meulder, 2003), and then mimic *unlabeled entity problem* by randomly masking manually annotated entities with a fixed probability p (e.g., 0.7). In this way, we can obtain unlabeled entities, $\widehat{\mathbf{y}}$, and annotated entities, $\mathbf{y}$, for every sentence, $\mathbf{x}$.

We can obtain different pairs of a missampling rate and an F1 score through running a negative sampling based model on different synthetic datasets. Table 1 demonstrates several cases, and we can see the trend that lower missamping rates lead to better performances. Therefore, we conclude that missampling affects the effectiveness of negative sampling.

3.1.3 Theoretical Guarantee

We also theoretically prove that negative sampling is very robust to unlabeled entities based on a natural property of named entities.

Entity Sparsity. Unlike other sequence labeling tasks, such as syntactic chunking (Sang and Buchholz, 2000) and part-of-speech tagging (Schmid, 1994), named entities (i.e., non-“O" segments) are commonly sparse in NER datasets.

Fig. 3 depicts some statistics of two common NER datasets, CoNLL-2003 and OntoNotes 5.0. The blue points are the averaged number of entities for sentences of fixed lengths. Every point stands on the center of a dashed line, whose length is the 1.6 variance of the entity numbers. The red curves are the square roots of sentence lengths. To avoid being influenced by “rare events" we erase the points supported by too few cases (i.e., 20).

From the above figure, we can see that the number of ground truth named entities (i.e., unlabeled entities, $\widehat{\mathbf{y}}$, and annotated ones, $\mathbf{y}$) in a sentence is generally smaller than the square root of sentence length, $\sqrt{n}$. Empirically, we have $\#\mathbf{y}+\#\widehat{\mathbf{y}} \leq \sqrt{n}$.

Theorem 1. *For a n-length sentence $\mathbf{x}$, assume $\widetilde{\mathbf{y}}$ is the set of sampled negatives with size $\lceil \lambda n \rceil (0 < \lambda < 1)$ via negative sampling. If the premise of entity sparsity holds, then the probability of zero missampling rate, i.e., $\gamma = 0$, is bounded.*

Proof. Since $\widetilde{\mathbf{y}}$ is uniformly sampled from $\mathcal{S}$ without replacement, the probability q that $\gamma = 0$ for a single sentence $\mathbf{x}$ can be formulated as

$$q = \prod_{0 \leq i < \lceil \lambda n \rceil} \Big(1 - \frac{\#\widehat{\mathbf{y}}}{\frac{n(n+1)}{2} - m - i}\Big),$$

where $m = \#\mathbf{y}$. The i-th product term is the probability that, at the i-th sampling turn, the i-th sampled candidate doesn't belong to unlabeled entity set, $\widehat{\mathbf{y}}$.

Then we can derive the following inequalities:

$$\begin{aligned} q &\geq \prod_{0 \leq i < \lceil \lambda n \rceil} (1 - \frac{\sqrt{n} - m}{\frac{n(n+1)}{2} - m - i}) \\ &\geq \prod_{0 \leq i < \lceil \lambda n \rceil} (1 - \frac{\sqrt{n}}{\frac{n(n+1)}{2} - i}) \\ &> \Big(1 - \frac{2\sqrt{n}}{n(n-1) + 2}\Big)^{\lceil \lambda n \rceil} \end{aligned} .$$

The first inequality holds because of the assumption; the second one holds because $\frac{\sqrt{n}-m}{\frac{n(n+1)}{2}-m-i}$ is monotonically decreases as m increases, and $m \geq 0$; the last inequality hold since $\frac{\sqrt{n}}{\frac{n(n+1)}{2}-i}$ increases with decreasing i, $i < \lceil \lambda n \rceil$, and $\lceil \lambda n \rceil \leq n$.

Because $(1 + a)^b \geq 1 + ba$ for $a \geq -1 \cap b \geq 1$ and $\lceil \lambda n \rceil < \lambda n + 1$, we have

$$\begin{aligned} q &> \Big(1 - \frac{2\sqrt{n}}{n(n-1) + 2}\Big)^{\lceil \lambda n \rceil} \\ &\geq 1 - \frac{2(\lambda n + 1)\sqrt{n}}{n(n-1) + 2} \\ &> 1 - \frac{4\lambda\sqrt{n}}{n - 1} \end{aligned} .$$

The right-most term monotonically increases with the sentence length n, and thus the probability of zero missampling rate for every sentence has a lower bound. □

H	Top-k	Middle-k	Bottom-k
F1 Score	88.82	87.72	85.56

Table 2: The effects of H on F1.

This theorem shows that missampling rates for standard negative sampling are controllable, and implies why negative sampling succeeds in handling missing annotations.

3.2 Uncertainty

3.2.1 Definition

Assume $P_o(l \mid \mathbf{x}_{i,j})$ is an oracle model that accurately estimates a label distribution over every span (i, j). The uncertainty is defined as the entropy of this distribution:

$$H(L \mid \mathbf{X} = \mathbf{x}_{i,j}) = \sum_{l \in L} -P_o(l \mid \mathbf{x}_{i,j}) \log P_o(l \mid \mathbf{x}_{i,j}),$$

where L and $\mathbf{X}$ represent the label space and a span, $\mathbf{x}_{i,j}$, respectively.

Note that the oracle model $P_o(l \mid \mathbf{x}_{i,j})$ is generally unreachable. the common practice is to additionally train a model $P(l \mid \mathbf{x}_{i,j}; \theta)$ (see Sec. 2.2) to approximate it. Besides, the approximate model is learned on held-out training data to avoid overconfident estimation.

Uncertainties essentially measure how difficult a case is for models to make a decision (Jurado et al., 2015). In active learning, uncertainty is used to mine hard unlabeled instances for human annotator (Settles, 2009). In our scenario, we suspect that the uncertainty of sampled negatives plays an important role in our training with negative sampling.

3.2.2 Uncertainty Affects Performances

We design an empirical experiment to verify our hypothesis. Specifically, we first randomly and equally split the entire training data with masked entities into two parts, and the first part is used to train an oracle model P_o. For every sentence $\mathbf{x}$ in the second part, we then sample three subsets from $\mathcal{S}$ as training negatives: the first subset denoted by $\widetilde{\mathbf{y}}^t$ corresponding to the top-k uncertainties, and the second denoted by $\widetilde{\mathbf{y}}^m$ corresponding to middle-k uncertainties, and the third denoted by $\widetilde{\mathbf{y}}^b$ corresponding to the bottom-k uncertainties, with $k = \lceil \lambda n \rceil$. Since missampling affects F1 scores as aforementioned, we eliminate the effect on missampling rate by setting $\gamma = 0$ when constructing both subsets, i.e., neither subset contains any spans included in $\widehat{\mathbf{y}}$. Finally, we respectively train three models on top of three negative subsets according to Eq. 1, and report their performances on test data in Table 2. We can see that the model trained on $\widetilde{\mathbf{y}}^t$ achieves the best performance, which validates our hypothesis.

4 Improving Negative Sampling

The previous section shows that the effectiveness of negative sampling is dependent on two factors: missampling and uncertainty. As a result, if we had considered both quantities when sampling negatives, we should see larger improvements from final models. In this section, we propose an adaptive and weighted sampling distribution based on these two factors.

Unfortunately, since missampling rate is defined on top of the unlabeled entities $\widehat{\mathbf{y}}$ which is unknown in practice, it is not straightforward to apply missampling for improving negative sampling. Therefore, we assume that an oracle model, $z_{i,j,l} = P_o(l \mid \mathbf{x}_{i,j})$, exists, which is likely to predict the ground-truth label for every span $\mathbf{x}_{i,j}$. Then we define a score $v_{i,j}$ as the difference between the score $z_{i,j,\mathrm{O}}$ and the maximum label score on the span (i,j):

$$v_{i,j} = z_{i,j,\mathrm{O}} - \max_{l \in \mathcal{L}} z_{i,j,l}. \tag{2}$$

Intuitively, if $v_{i,j}$ is high, then $z_{i,j,\mathrm{O}}$ is high and $\max_{l \in \mathcal{L}} z_{i,j,l}$ is low. In other words, $\mathbf{x}_{i,j}$ is likely to be with "O" label and thus the missampling rate should be small. Hence sampling such a span as a negative won't hurt NER models. Note that $\max_{l \in \mathcal{L}} z_{i,j,l}$ in the right hand acts as normalization, making $v_{i,j}$ comparable among different spans (i,j).

We also define an uncertainty score, $u_{i,j}$, as the entropy of the label distribution for a span:

$$\begin{aligned} u_{i,j} &= H(L \mid \mathbf{X} = \mathbf{x}_{i,j}) \\ &= -\sum_{l \in \mathcal{L}} z_{i,j,l} \log z_{i,j,l}. \end{aligned} \tag{3}$$

As discussed in Sec. 3.2.2, training a NER model with the negatives of higher uncertainty scores, $u_{i,j}$, brings better performances.

Based on $v_{i,j}$ and $u_{i,j}$, we design the following weighted sampling distribution to displace the uniform one when sampling k negatives from $\mathcal{S}$ without replacement:

$$\begin{cases} r_{i,j} = u_{i,j} * (1 + v_{i,j})^{\mu} \\ e_{i,j} = \dfrac{\exp(r_{i,j}/T)}{\sum_{(i',j',\mathrm{O}) \in \mathcal{S}} \exp(r_{i',j'}/T)} \end{cases}, \tag{4}$$

where $T \geq 1$ is a temperature to control the smoothness of sampling distribution. $\mu \geq 1$ is to make a trade-off between $v_{i,j}$ and $u_{i,j}$: a high μ will ensure a low missampling rate while a low μ will ensure a high uncertainty score.

To make our approach practical for use, we should specify how to approximate the oracle model, $P_o(l \mid \mathbf{x}_{i,j})$. In the simulation experiment in Sec. 3.2.1, the oracle model is a fixed model via standard negative sampling which is learned on held-out training data. It's natural to use such a fixed model to approximate the oracle model here. However, this will cause a side-effect that our approach is not self-contained due to its dependence on an external model.

Consequently, we consider an adaptive style: directly using the NER model, $P(l \mid \mathbf{x}_{i,j}; \theta)$, itself as the oracle model whose parameter θ is learned during the training process. Under this scheme, T is scheduled as $\sqrt{C - c}$, where C is the number of training epochs and $0 \leq c < C$ is the current epoch number. Since the NER model $P(l \mid \mathbf{x}_{i,j}; \theta)$ is not accurate in early epochs of training, a more uniform sampling distribution (i.e., higher T) is safer for sampling negatives.

Finally, we get a weighted sampling distribution with the NER model, $P(l \mid \mathbf{x}_{i,j}; \theta)$, adaptively approximating the oracle model. Our training procedure is the same as that of vanilla negative sampling (see Fig. 2), except for sampling distribution.

5 Experiments

To evaluate our proposed variant (i.e., negative sampling w/ weighted sampling distribution) , we have conducted extensive experiments on under-annotated cases: synthetic datasets and real-world datasets. We also validate its superiority in well-annotated scenarios.

5.1 Settings

The well-annotated datasets are CoNLL-2003 and OntoNotes 5.0. CoNLL-2003 contains 22137 sentences and is split into 14987, 3466, and 3684 sentences for training set, development set, and test set, respectively. OntoNotes 5.0 contains 76714

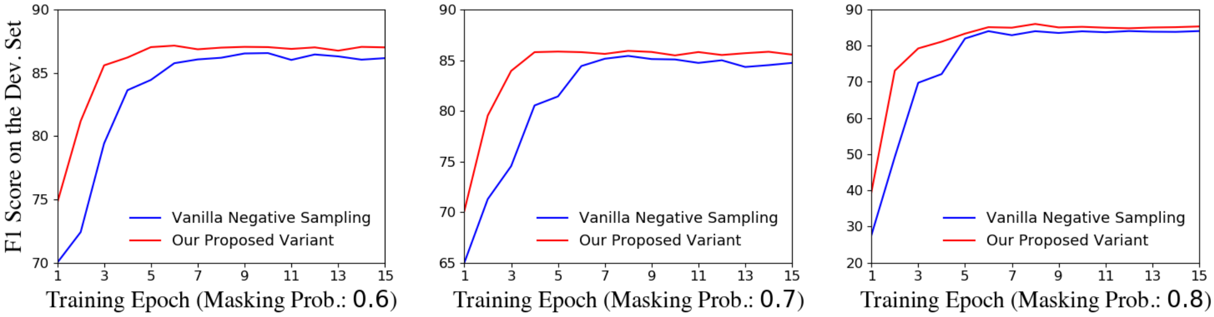

Figure 4: The changes of F1 scores with training epochs on some synthetic datasets.

0.6	87.65	**88.03**	87.53	**88.02**
0.7	86.24	**86.97**	86.42	**86.85**
0.8	78.84	**82.05**	85.02	**86.12**
0.9	51.47	**60.57**	74.26	**80.55**

Table 3: The comparisons of F1 scores on synthetic datasets.

sentences from a wide variety of sources. We follow the same format and partition as in Luo et al. (2020). The construction of synthetic datasets is based on well-annotated datasets and has been already described in Sec. 3.

Following prior works (Nooralahzadeh et al., 2019; Li et al., 2021a), we adopt EC and NEWS as the real-world datasets. Both of them are collected by Yang et al. (2018). The data contains 2400 sentences annotated by human and is divided into three portions: 1200 for training set, 400 for development set, and 800 for test set. Yang et al. (2018) build an entity dictionary of size 927 and apply distant supervision on a raw corpus to get extra 2500 training cases. NEWS is constructed from MSRA (Levow, 2006). Training set is of size 3000, development set is of size 3328, and test set is of size 3186 are all sampled from MSRA. Yang et al. (2018) collect an entity dictionary of size 71664 and perform distant supervision on the remaining data to obtain extra 3722 cases for training. Both EC and NEWS contain massive incomplete annotations. NER models trained on them suffer from *unlabeled entity problem*.

We adopt the same configurations for all the datasets. The dimensions of scoring layers are 256. L2 regularization and dropout ratio are 10^{-5} and 0.4, respectively. We set $\mu = 8$. This setting is obtained via grid search. We use Adam (Kingma and Ba, 2014) to optimize models. Our models run on GeForceRTX 2080T. At test time, we convert the predictions from our models into IOB format and use conlleval[1] script to compute the F1 score. In all the experiments, the improvements of our models over the baselines are statistically significant with a rejection probability lower than 0.01.

5.2 Results on Under-annotated Scenarios

We show how NER models with our proposed approach perform on two types of datasets: synthetic datasets (e.g., CoNLL-2003) and real-world datasets (e.g., EC). Synthetic datasets offer us a chance to qualitatively analyze how our approach reacts to changing mask probabilities. For example, we will show that weighted sampling distribution is beneficial in fast loss convergence. Real-world datasets provide more appropriate cases to evaluate NER models, since missing annotations are caused by limited knowledge resources, rather than intentional masking.

5.2.1 Results on Synthetic Datasets

Fig. 4 shows the changes of F1 scores from vanilla negative sampling and our proposed variant with training epochs. The synthetic datasets are constructed from OntoNotes 5.0. We can see that, compared with vanilla negative sampling, our proposed variant obtains far better performances on

the first few epochs and converges much faster. These results clearly verify the superiority of our weighted sampling distribution.

Table 3 compares vanilla negative sampling with our proposed variant in terms of F1 score. We can draw two conclusions. Firstly, our approach greatly improves the effectiveness of negative sampling. For example, when masking probability p is 0.8, we increase the F1 scores by 4.07% on CoNLL-2003 and 1.29% on OntoNotes 5.0. Secondly, our variant is still robust when *unlabeled entity problem* is very serious. Setting masking probability p from 0.5 to 0.9, our performance on OntoNotes 5.0 only drops by 8.79%. By contrast, it's 32.33% for vanilla negative sampling.

5.2.2 Results on Real-world Datasets

Real-world datasets contain a high percentage of partial annotations caused by distant supervision. Hence, the models trained on them are faced with serious *unlabeled entity problem*.

Table 4 diagrams the results. The F1 scores of negative sampling and Partial CRF are from their papers. We have additionally reported the results of PU Learning[2], Weighted Partial CRF[3], BERT-MRC[4], and BERT-Biaffine Model[5], using their codes. We can draw three conclusions from the table. Firstly, we can see that BERT-MRC and BERT-Biaffine Model both perform poorly on real-world datasets. This manifests the huge adverse impacts of unlabeled entities on models. Secondly, our variant has achieved new state-of-the-art results on the two datasets. Our scores outnumber those of vanilla negative sampling by 1.30% and 0.89% on them. Thirdly, to make fair comparisons, we also report the results of using Bi-LSTM, instead of BERT, as the sentence encoder. This version still notably surpasses prior methods on the two datasets. For example, compared with Weighted Partial CRF, our improvements are 6.57% on EC and 6.55% on NEWS.

5.3 Results on Well-annotated Scenarios

As a by-product, we also evaluate the effectiveness of the proposed method on the well-annotated datasets CoNLL-2003 and OntoNotes 5.0. As shown in Table 5, we have achieved excellent performances on well-annotated datasets. The F1 scores of baselines are copied from Li et al. (2021a). With our weighted sampling distribution, the results of negative sampling are improved by 0.28%

on CoNLL-2003 and 0.64% on OntoNotes 5.0. Our model even outperforms BERT-Biaffine Model by 0.19% on CoNLL-2003. Compared with a strong baseline, Flair Embedding, our improvements of F1 scores are 0.63% and 2.09% on the two datasets. These results further verify the effectiveness of the proposed sampling distribution.

The comparison here is in fact unfair for our model, because negative sampling only utilizes a small part of negatives, $\lceil \lambda n \rceil$ rather than $\frac{n(n+1)}{2} - m$ (see Sec. 2 for the details of these numbers). We also have tried using all the negatives for training our model, and found the resulting performances significantly outnumber those of baselines. The purpose of Table 5 is to confirm that negative sampling even works well for situations with complete entity annotations.

6 Related Work

A number of NER models (Lample et al., 2016; Akbik et al., 2018; Clark et al., 2018; Li et al., 2020b, 2021b) based on end-to-end neural networks and well-labeled data have achieved promising performances. A representative work is Bi-LSTM CRF (Huang et al., 2015). However, in many situations (e.g., distantly supervised NER), these seemingly perfect models severely suffer from *unlabeled entity problem*, where massive named entities are not annotated in training data. There are some techniques developed by earlier works to mitigate this issue. Fuzzy CRF and AutoNER (Shang et al., 2018b) allow NER models to learn from high-quality phrases that might be potential named entities. Mining these phrases demands external resources (Shang et al., 2018a), which is not flexible for practical usage. Moreover, there is no guarantee that unlabeled entities are fully covered by these phrases. PU Learning (Peng et al., 2019; Mayhew et al., 2019) adopts a weighted training loss and assigns low weights to false negative instances. This approach is limited by requiring prior information or heuristics. Partial CRF (Yang et al., 2018; Jie et al., 2019) is an extension of CRF, which marginalizes the loss over all candidates that are compatible with the incomplete annotation. While being theoretically attractive, this approach still needs a portion of well-annotated data to obtain true negatives, which limits its use in real-world applications. For example, in fine-grained NER (Ling and Weld, 2012), all the training data are produced through weak supervision, and its manual annotation is very difficult, so obtaining enough high-quality data is not practical.

Recently, Li et al. (2021a) find that unlabeled entities severely misguide the NER models during training. Based on this observation, they introduce a simple yet effective approach using negative sampling. It's much more flexible than other methods, without resorting to external resources, heuristics, etc. However, Li et al. (2021a) haven't well explained why negative sampling works and there are weaknesses in their principle analysis. In this paper, we first show two factors that affect how negative sampling avoids NER models from being impacted by missing annotations. Notably, a theoretical guarantee is provided for the zero missampling rate. Then, we propose weighted sampling distribution to further improve negative sampling based on our former findings.

7 Conclusion

Negative sampling succeeds in handling missing annotations. In particular, the fine-grained NER module of our online text understanding service, TexSmart (Liu et al., 2021; Zhang et al., 2020), adopts this technique because of its massive low-quality training data.

In this work, we have made two contributions. On the one hand, we analyze why negative sampling succeeds in handling *unlabeled entity problem* from two perspectives: missampling and uncertainty. Empirical studies show both low missampling rates and high uncertainties are essential for applying negative sampling. Based on entity sparsity, we also provide a theoretical lower bound for the probability of zero missampling rate. On the other hand, we propose an adaptive and weighted sampling distribution that takes missampling and uncertainty into account. We have conducted extensive experiments to verify whether this further improves the effectiveness of negative sampling. Results on synthetic datasets and well-annotated datasets show that our approach benefits in performances and loss convergence. With improved negative sampling, our NER models also have achieved new state-of-the-art results on real-world datasets (e.g., NEWS).

Distantly Supervised Named Entity Recognition via Confidence-Based Multi-Class Positive and Unlabeled Learning

Kang Zhou, Yuepei Li, Qi Li

Abstract

In this paper, we study the named entity recognition (NER) problem under distant supervision. Due to the incompleteness of the external dictionaries and/or knowledge bases, such distantly annotated training data usually suffer from a high false negative rate. To this end, we formulate the Distantly Supervised NER (DS-NER) problem via Multi-class Positive and Unlabeled (MPU) learning and propose a theoretically and practically novel CONFidence-based MPU (**Conf-MPU**) approach. To handle the incomplete annotations, Conf-MPU consists of two steps. First, a confidence score is estimated for each token of being an entity token. Then, the proposed Conf-MPU risk estimation is applied to train a multi-class classifier for the NER task. Thorough experiments on two benchmark datasets labeled by various external knowledge demonstrate the superiority of the proposed Conf-MPU over existing DS-NER methods. Our code is available at Github[1].

1 Introduction

Named Entity Recognition (NER) aims to detect entity mentions from text and classify them into predefined types. It is a fundamental task in information extraction and many other downstream tasks (Gábor et al., 2018; Luan et al., 2017; Giorgi et al., 2019). However, the necessity of extensive human efforts to annotate a large amount of training data imposes restrictions on the state-of-the-art supervised deep learning methods, especially in professional fields.

To address this problem, distantly supervised methods spring up (Yang et al., 2018; Shang et al., 2018; Mayhew et al., 2019; Cao et al., 2019; Peng et al., 2019; Liang et al., 2020; Liu et al., 2021; Zhang et al., 2021), which aim to train NER models using automatically annotated training data based on external knowledge such as dictionaries and knowledge bases. Observed by previous DS-NER methods (Shang et al., 2018; Peng et al., 2019), distant labels provided by reliable dictionaries are usually of high precision. However, such distant labeling suffers a major drawback — incomplete labeling. This is due to the fact that most existing dictionaries and knowledge bases have limited coverage on entities. Hence simply treating unlabeled samples (*i.e.*, unmatched tokens) as negative ones will introduce a high false negative rate (*e.g.*, "neutropenia" in Figure 1) compared with human-annotated training data, and further mislead a supervised NER model to overfit to false negative samples and seriously affect its recall.

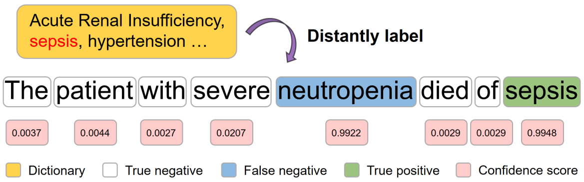

Figure 1: Distant labeling example for the entity type of `Disease` using a dictionary.

Recently, binary Positive and Unlabeled (PU) learning is applied to DS-NER tasks for this challenge (Peng et al., 2019). PU learning performs classification using only limited labeled positive data and unlabeled data, thus naturally suitable for handling distant supervision, where external knowledge often has a limited coverage on positive samples. However, binary PU learning has several drawbacks in real DS-NER tasks. It applies the one-vs-all strategy to convert a multi-class classification problem into multiple binary classification problems, and thus suffers from two weaknesses. First, it is not efficient, especially in the case where there are many entity types. For a NER task with n entity types, n binary classifiers need to be trained. Second, the scale of predicted confidence values may differ among those binary classifiers, which may not guarantee a mutually beneficial inference for the final prediction (Bishop, 2006).

Furthermore, the PU learning theory is built on a fundamental assumption of data distribution that unlabeled data can accurately reveal the overall distribution (*i.e.*, the marginal distribution of the target field) (Bekker and Davis, 2020). In DS-NER tasks, the distantly annotated training data may not fit the assumption well: It depends on the coverage of used dictionaries or knowledge bases on the entities. Our empirical studies validate that violation of this assumption can significantly impact the performance of PU learning.

To address these challenges in DS-NER tasks and PU learning, we propose a CONFidence-based Multi-class Positive and Unlabeled (**Conf-MPU**) learning framework. The proposed Conf-MPU can handle different levels of false negative rates brought by dictionaries of various coverage and does not overfit to the distantly labeled training data. It consists of two steps. Specifically, given the distantly labeled training data, we first carry out a token-level binary classification to estimate the confidence score (a probability value in $[0, 1]$) of a token being an *entity token* (*i.e.*, a token of a named entity). Then, we perform the NER classification using a neural network model with the proposed Conf-MPU risk estimator, which incorporates the confidence scores obtained from the first step in the risk estimation, to alleviate the impact of annotation imperfection. It is worth noting that the two-step strategy of Conf-MPU needs to train only two classifiers for any DS-NER tasks with arbitrary number of entity types, which is more efficient than previous binary PU learning.

In summary, our main contributions are:

- We propose Conf-MPU, a theoretically and practically novel approach for the DS-NER task. Conf-MPU enriches the PU learning theory with solid theoretical analysis.

- We verify that the practical use of traditional PU learning is subject to its theoretical assumption, which can be released by Conf-MPU. As far as we know, this is the first work specially dealing with such a practical problem.

- We empirically demonstrate that Conf-MPU with a two-step strategy can significantly alleviate the impact of incomplete annotations during the model training and outperform the state-of-the-art DS-NER methods on benchmark datasets.

2 Preliminaries

In this section, we briefly review the risk formulations of standard supervised learning and PU learning in the binary classification setting.

2.1 Standard Binary Supervised Learning

Suppose that the data follow an unknown probability distribution with density $p(\boldsymbol{x}, y)$. Let $\boldsymbol{x} \in \mathcal{X} \subseteq \mathbb{R}^d$ and $y \in \mathcal{Y} = \{0, 1\}$, where 0 and 1 indicate negative and positive classes, respectively. The goal is to learn a decision function $f : \mathcal{X} \to \mathcal{Y}$ by minimizing the expected classification risk:

$$\mathrm{R}(f) = \pi \mathrm{R}_{\mathrm{P}}^{+}(f) + (1 - \pi)\mathrm{R}_{\mathrm{N}}^{-}(f). \qquad (1)$$

In this function, $\pi = p(y = 1)$ is the prior of the positive class. $\mathrm{R}_{\mathrm{P}}^{+}(f) = \mathbb{E}_{\boldsymbol{x} \sim p(\boldsymbol{x}|y=1)} [\ell(f(\boldsymbol{x}), 1)]$ and $\mathrm{R}_{\mathrm{N}}^{-}(f) = \mathbb{E}_{\boldsymbol{x} \sim p(\boldsymbol{x}|y=0)} [\ell(f(\boldsymbol{x}), 0)]$ denote the expected classification risks on the positive and negative classes, respectively, where $\mathbb{E}$ denotes expectation and its subscript indicates the data distribution on which the expectation is computed, and the loss function is represented by ℓ.

In supervised learning setting, we are given both labeled positive and negative data that are sampled independently from $p_{\mathrm{P}}(\boldsymbol{x}) = p(\boldsymbol{x} \mid y = 1)$ and $p_{\mathrm{N}}(\boldsymbol{x}) = p(\boldsymbol{x} \mid y = 0)$ as $\mathcal{X}_{\mathrm{P}} = \{\boldsymbol{x}_j^{\mathrm{P}}\}_{j=1}^{n_{\mathrm{P}}}$ and $\mathcal{X}_{\mathrm{N}} = \{\boldsymbol{x}_j^{\mathrm{N}}\}_{j=1}^{n_{\mathrm{N}}}$, respectively. Then Eq. 1 can be estimated by $\hat{\mathrm{R}}_{\mathrm{PN}}(f) = \pi \hat{\mathrm{R}}_{\mathrm{P}}^{+}(f) + (1 - \pi)\hat{\mathrm{R}}_{\mathrm{N}}^{-}(f)$, where $\hat{\mathrm{R}}_{\mathrm{P}}^{+}(f) = \frac{1}{n_{\mathrm{P}}} \sum_{j=1}^{n_{\mathrm{P}}} \ell(f(\boldsymbol{x}_j^{\mathrm{P}}), 1)$ and $\hat{\mathrm{R}}_{\mathrm{N}}^{-}(f) = \frac{1}{n_{\mathrm{N}}} \sum_{j=1}^{n_{\mathrm{N}}} \ell(f(\boldsymbol{x}_j^{\mathrm{N}}), 0)$.

2.2 Binary PU Learning

In PU learning setting, we have only access to labeled positive data $\mathcal{X}_{\mathrm{P}}$ and unlabeled data $\mathcal{X}_{\mathrm{U}} = \{\boldsymbol{x}_j^{\mathrm{U}}\}_{j=1}^{n_{\mathrm{U}}}$ drawn from $p_{\mathrm{U}}(\boldsymbol{x})$ instead of labeled negative data $\mathcal{X}_{\mathrm{N}}$, which indicates that the classification risk Eq. 1 can not be directly estimated as done in supervised learning setting. For this problem, Du Plessis et al. (2014) propose the expected classification risk formulation of PU learning:

$$\mathrm{R}(f) = \pi \mathrm{R}_{\mathrm{P}}^{+}(f) + \mathrm{R}_{\mathrm{U}}^{-}(f) - \pi \mathrm{R}_{\mathrm{P}}^{-}(f), \qquad (2)$$

where $\mathrm{R}_{\mathrm{U}}^{-}(f) = \mathbb{E}_{\boldsymbol{x} \sim p(\boldsymbol{x})} [\ell(f(\boldsymbol{x}), 0)]$ and $\mathrm{R}_{\mathrm{P}}^{-}(f) = \mathbb{E}_{\boldsymbol{x} \sim p(\boldsymbol{x}|y=1)} [\ell(f(\boldsymbol{x}), 0)]$. Here $\mathrm{R}_{\mathrm{U}}^{-}(f) - \pi \mathrm{R}_{\mathrm{P}}^{-}(f)$ can alternatively represent $(1 - \pi)\mathrm{R}_{\mathrm{N}}^{-}(f)$ because $p(y = 0)p(\boldsymbol{x} \mid y = 0) = p(\boldsymbol{x}) - p(y = 1)p(\boldsymbol{x} \mid y = 1)$.

PU learning assumes that unlabeled data $\mathcal{X}_{\mathrm{U}}$ can reflect the true overall distribution, that is, $p_{\mathrm{U}}(\boldsymbol{x}) = p(\boldsymbol{x})$, due to unlabeled data consisting of both positive and negative data, under which Eq. 2 can be approximated by $\hat{\mathrm{R}}_{\mathrm{PU}}(f) = \pi\hat{\mathrm{R}}_{\mathrm{P}}^{+}(f) + \hat{\mathrm{R}}_{\mathrm{U}}^{-}(f) - \pi\hat{\mathrm{R}}_{\mathrm{P}}^{-}(f)$, where $\hat{\mathrm{R}}_{\mathrm{U}}^{-}(f) = \frac{1}{n_{\mathrm{U}}}\sum_{j=1}^{n_{\mathrm{U}}}\ell(f(\boldsymbol{x}_j^{\mathrm{U}}), 0)$ and $\hat{\mathrm{R}}_{\mathrm{P}}^{-}(f) = \frac{1}{n_{\mathrm{P}}}\sum_{j=1}^{n_{\mathrm{P}}}\ell(f(\boldsymbol{x}_j^{\mathrm{P}}), 0)$.

3 Methodology

In this section, we introduce the proposed Conf-MPU learning for DS-NER in the multi-class classification setting with solid theoretical analysis.

3.1 Conf-MPU Learning

Let $y \in \mathcal{Y} = \{0, 1, 2, ..., k\}$, where 0 refers to the negative class and $1, ..., k$ refer to k positive classes. The goal in multi-class classification is to minimize the following expected classification risk:

$$\mathrm{R}(f) = \sum_{i=1}^{k}\pi_i \mathrm{R}_{\mathrm{P}_i}^{+}(f) + (1 - \sum_{i=1}^{k}\pi_i)\mathrm{R}_{\mathrm{N}}^{-}(f), \quad (3)$$

where $\mathrm{R}_{\mathrm{P}_i}^{+}(f) = \mathbb{E}_{\boldsymbol{x}\sim p(\boldsymbol{x}|y=i)}\left[\ell(f(\boldsymbol{x}), i)\right]$ and $\pi_i = p(y = i)$ are the classification risk and the prior of the i-th positive class, respectively. We denote this classification risk as MPN.

Following PU learning setting, there are only labeled positive data $\mathcal{X}_{\mathrm{P}_i} = \{\boldsymbol{x}_j^{\mathrm{P}_i}\}_{j=1}^{n_{\mathrm{P}_i}}$ drawn from $p_{\mathrm{P}_i}(\boldsymbol{x}) = p(\boldsymbol{x} \mid y = i)$ where $i \in \{1, ..., k\}$, and unlabeled data $\mathcal{X}_{\mathrm{U}}$. Thus we can not directly estimate Eq. 3. Here we adopt the same probability principle as applied in binary PU learning to alternatively compute the risk on negative data. Since $p(y = 0)p(\boldsymbol{x} \mid y = 0) = p(\boldsymbol{x}) - \sum_{i=1}^{k} p(y = i)p(\boldsymbol{x} \mid y = i)$, we can further derive Eq. 3 as:

$$\mathrm{R}(f) = \sum_{i=1}^{k}\pi_i \mathrm{R}_{\mathrm{P}_i}^{+}(f) + \mathrm{R}_{\mathrm{U}}^{-}(f) - \sum_{i=1}^{k}\pi_i \mathrm{R}_{\mathrm{P}_i}^{-}(f), \quad (4)$$

where $\mathrm{R}_{\mathrm{U}}^{-}(f) - \sum_{i=1}^{k}\pi_i \mathrm{R}_{\mathrm{P}_i}^{-}(f)$ theoretically plays the role of $(1 - \sum_{i=1}^{k}\pi_i)\mathrm{R}_{\mathrm{N}}^{-}(f)$, and $\mathrm{R}_{\mathrm{P}_i}^{-}(f) = \mathbb{E}_{\boldsymbol{x}\sim p_{\mathrm{P}_i}(\boldsymbol{x})}\left[\ell(f(\boldsymbol{x}), 0)\right]$. We denote this classification risk as MPU, whose estimation requires the same assumption of data distribution as binary PU learning does, namely, $p_{\mathrm{U}}(\boldsymbol{x}) = p(\boldsymbol{x})$. We refer this assumption to **PU assumption** hereinafter for convenience. Under PU assumption, $\mathcal{X}_{\mathrm{U}}$ can be used to estimate $\mathrm{R}_{\mathrm{U}}^{-}(f)$. Specifically, MPU risk estimator is given as:

$$\hat{\mathrm{R}}_{\mathrm{MPU}}(f) = \sum_{i=1}^{k}\frac{\pi_i}{n_{\mathrm{P}_i}}\sum_{j=1}^{n_{\mathrm{P}_i}}\ell(f(\boldsymbol{x}_j^{\mathrm{P}_i}), i) + \max\Bigg\{0,$$
$$\frac{1}{n_{\mathrm{U}}}\sum_{j=1}^{n_{\mathrm{U}}}\ell(f(\boldsymbol{x}_j^{\mathrm{U}}), 0) - \sum_{i=1}^{k}\frac{\pi_i}{n_{\mathrm{P}_i}}\sum_{j=1}^{n_{\mathrm{P}_i}}\ell(f(\boldsymbol{x}_j^{\mathrm{P}_i}), 0)\Bigg\}, \quad (5)$$

with a non-negative constraint inspired by Kiryo et al. (2017) ensuring the risk on the negative class is non-negative.

However, PU assumption can be violated in real distant supervision scenarios. The distribution of unlabeled data $p_{\mathrm{U}}(\boldsymbol{x})$ may be different from the overall distribution $p(\boldsymbol{x})$ especially when the distant supervision has a good coverage. In such cases, the unlabeled data will have a distribution closer to the distribution of the true negative data $p_{\mathrm{N}}(\boldsymbol{x})$ instead of the overall distribution $p(\boldsymbol{x})$. Thus, the risk estimation of $\mathrm{R}_{\mathrm{U}}^{-}(f)$ based on the assumption, in either MPU or binary PU, may be biased.

To alleviate such estimation bias, we derive a novel Conf-MPU risk function from MPU. With the context of NER tasks, we observe that almost any combination of characters could be part of a named entity. Based on this observation, mathematically, we define $\lambda(\boldsymbol{x}) = p(y > 0 \mid \boldsymbol{x})$ to determine the confidence score of a token being an entity token, no matter what entity type it belongs to, and further assume that $\lambda(\boldsymbol{x}) > 0$. Under this assumption, we can further decompose $\mathrm{R}_{\mathrm{U}}^{-}(f)$ in Eq. 4 by involving a threshold parameter $0 < \tau \leq 1$ as follows:

$$\mathrm{R}_{\mathrm{U}}^{-}(f) = \sum_{i=1}^{k}\pi_i \mathrm{R}_{\tilde{\mathrm{P}}_i}^{-}(f) + \mathrm{R}_{\tilde{\mathrm{U}}}^{-}(f), \quad (6)$$

where $\mathrm{R}_{\tilde{\mathrm{P}}_i}^{-}(f) = \mathbb{E}_{\boldsymbol{x}\sim p_{\mathrm{P}_i}(\boldsymbol{x}|\lambda(\boldsymbol{x})>\tau)}\left[\ell(f(\boldsymbol{x}), 0)\frac{1}{\lambda(\boldsymbol{x})}\right]$ and $\mathrm{R}_{\tilde{\mathrm{U}}}^{-}(f) = \mathbb{E}_{\boldsymbol{x}\sim p(\boldsymbol{x}|\lambda(\boldsymbol{x})\leq\tau)}\left[\ell(f(\boldsymbol{x}), 0)\right]$. The detailed proof is shown as follows.

Proof. Since $\lambda(\boldsymbol{x}) > 0$ and $0 < \tau \leq 1$, we have

$$\begin{aligned}
&\mathrm{R}_{\mathrm{U}}^{-}(f) = \mathbb{E}_{\boldsymbol{x}\sim p(\boldsymbol{x})}\left[\ell(f(\boldsymbol{x}), 0)\right] \\
&= \int_{\lambda(\boldsymbol{x})>\tau}\ell(f(\boldsymbol{x}), 0)p(\boldsymbol{x})d\boldsymbol{x} + \int_{\lambda(\boldsymbol{x})\leq\tau}\ell(f(\boldsymbol{x}), 0)p(\boldsymbol{x})d\boldsymbol{x} \\
&= \int_{\lambda(\boldsymbol{x})>\tau}\ell(f(\boldsymbol{x}), 0)\frac{p(\boldsymbol{x})p(\boldsymbol{x}, y > 0)}{p(\boldsymbol{x}, y > 0)}d\boldsymbol{x} + \mathrm{R}_{\tilde{\mathrm{U}}}^{-}(f) \\
&= \int_{\lambda(\boldsymbol{x})>\tau}\ell(f(\boldsymbol{x}), 0)\frac{p(\boldsymbol{x})p(\boldsymbol{x} \mid y > 0)p(y > 0)}{p(y > 0 \mid \boldsymbol{x})p(\boldsymbol{x})}d\boldsymbol{x} + \mathrm{R}_{\tilde{\mathrm{U}}}^{-}(f) \\
&= \int_{\lambda(\boldsymbol{x})>\tau}\ell(f(\boldsymbol{x}), 0)\frac{p(\boldsymbol{x} \mid y > 0)p(y > 0)}{\lambda(\boldsymbol{x})}d\boldsymbol{x} + \mathrm{R}_{\tilde{\mathrm{U}}}^{-}(f) \\
&= \sum_{i=1}^{k}p(y = i)\int_{\lambda(\boldsymbol{x})>\tau}\ell(f(\boldsymbol{x}), 0)\frac{p(\boldsymbol{x} \mid y = i)}{\lambda(\boldsymbol{x})}d\boldsymbol{x} + \mathrm{R}_{\tilde{\mathrm{U}}}^{-}(f) \\
&= \sum_{i=1}^{k}\pi_i\int_{\lambda(\boldsymbol{x})>\tau}\ell(f(\boldsymbol{x}), 0)\frac{1}{\lambda(\boldsymbol{x})}p(\boldsymbol{x} \mid y = i)d\boldsymbol{x} + \mathrm{R}_{\tilde{\mathrm{U}}}^{-}(f) \\
&= \sum_{i=1}^{k}\pi_i \mathrm{R}_{\tilde{\mathrm{P}}_i}^{-}(f) + \mathrm{R}_{\tilde{\mathrm{U}}}^{-}(f).
\end{aligned}$$

Consequently, we obtain the expected classification risk of Conf-MPU by substituting $\mathrm{R}_{\mathrm{U}}^{-}(f)$ in Eq. 4 with Eq. 6 as follows:

$$\mathrm{R}(f) = \sum_{i=1}^{k}\pi_i\big(\mathrm{R}_{\mathrm{P}_i}^{+}(f) + \mathrm{R}_{\tilde{\mathrm{P}}_i}^{-}(f) - \mathrm{R}_{\mathrm{P}_i}^{-}(f)\big) + \mathrm{R}_{\tilde{\mathrm{U}}}^{-}(f). \quad (7)$$

Given a reliable λ and a proper τ, $\lambda(\boldsymbol{x}) > \tau$ indicates $\boldsymbol{x}$ being an entity token (a positive sample), otherwise a non-entity token (a negative sample), which further induces that $p_{\mathrm{P}_i}(\boldsymbol{x} \mid \lambda(\boldsymbol{x}) > \tau) \approx p_{\mathrm{P}_i}(\boldsymbol{x})$, and $p(\boldsymbol{x} \mid \lambda(\boldsymbol{x}) \leq \tau) \approx p_{\mathrm{U}}(\boldsymbol{x} \mid \lambda(\boldsymbol{x}) \leq \tau) \approx p_{\mathrm{N}}(\boldsymbol{x})$ even if $p_{\mathrm{U}}(\boldsymbol{x})$ is different from $p(\boldsymbol{x})$. Thus, empirically $\mathrm{R}^{-}_{\tilde{\mathrm{P}}_i}(f)$ and $\mathrm{R}^{-}_{\tilde{\mathrm{U}}}(f)$ can be estimated with less bias using $\mathcal{X}_{\mathrm{P}_i}$ and $\mathcal{X}_{\mathrm{U}}$, respectively, which further leads to a more precise estimation of $\mathrm{R}^{-}_{\mathrm{U}}(f)$. This is the mechanism that Conf-MPU can significantly reduce estimation bias in practice, even if PU assumption is violated. Specifically, Conf-MPU risk estimator can be expressed as:

$$\hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(f) = \sum_{i=1}^{k} \frac{\pi_i}{n_{\mathrm{P}_i}} \sum_{j=1}^{n_{\mathrm{P}_i}} \max\Bigg\{0, \ell(f(\boldsymbol{x}_j^{\mathrm{P}_i}), i) + \mathbb{1}_{\hat{\lambda}(\boldsymbol{x}_j^{\mathrm{P}_i}) > \tau} \ell(f(\boldsymbol{x}_j^{\mathrm{P}_i}), 0) \frac{1}{\hat{\lambda}(\boldsymbol{x}_j^{\mathrm{P}_i})} - \ell(f(\boldsymbol{x}_j^{\mathrm{P}_i}), 0)\Bigg\} + \frac{1}{n_{\mathrm{U}}} \sum_{j=1}^{n_{\mathrm{U}}} \left[\mathbb{1}_{\hat{\lambda}(\boldsymbol{x}_j^{\mathrm{U}}) \leq \tau} \ell(f(\boldsymbol{x}_j^{\mathrm{U}}), 0)\right], \tag{8}$$

with a constraint to guarantee a non-negative loss on each labeled positive sample, where $\hat{\lambda}$ is an empirical confidence score estimator. In DS-NER tasks, we formulate the sub-task of estimating $\lambda(\boldsymbol{x})$ as a token-level binary classification problem which also uses distant labels. In practice, a classifier with a sigmoid output layer for this sub-task can guarantee $\hat{\lambda}(\boldsymbol{x}) > 0$.

3.2 Insights into Conf-MPU Risk Estimator

Targeting on the challenge of high false negative rates in training data, we give the following analysis to offer some insights into the Conf-MPU risk estimator. For ease of expression, we use letters to denote the terms in Eq. (8): $\mathbb{A} = \ell(f(\boldsymbol{x}_j^{\mathrm{P}_i}), i)$, $\mathbb{B} = \mathbb{1}_{\hat{\lambda}(\boldsymbol{x}_j^{\mathrm{P}_i}) > \tau} \ell(f(\boldsymbol{x}_j^{\mathrm{P}_i}), 0) \frac{1}{\hat{\lambda}(\boldsymbol{x}_j^{\mathrm{P}_i})}$, $\mathbb{C} = \ell(f(\boldsymbol{x}_j^{\mathrm{P}_i}), 0)$, $\mathbb{D} = \mathbb{1}_{\hat{\lambda}(\boldsymbol{x}_j^{\mathrm{U}}) \leq \tau} \ell(f(\boldsymbol{x}_j^{\mathrm{U}}), 0)$. The threshold τ is set to 0.5 by default. We assume that $\hat{\lambda}(\boldsymbol{x})$ of an entity token is close to 1 (*i.e.*, $\hat{\lambda}(\boldsymbol{x}) > \tau$), and $\hat{\lambda}(\boldsymbol{x})$ of a non-entity token is close to 0 (*i.e.*, $\hat{\lambda}(\boldsymbol{x}) \leq \tau$).

For a true positive sample (*e.g.*, "sepsis" distantly labeled in Figure 1), the loss is computed by $\mathbb{A}+\mathbb{B}-\mathbb{C}$, where $\mathbb{B}$ is involved because its confidence score is larger than the threshold. Since $1/\hat{\lambda}(\boldsymbol{x})$ is close to 1, $\mathbb{B}-\mathbb{C}$ is almost 0 but positive, and thus the loss on this sample approximately equals to $\mathbb{A}$, which is very similar with the loss on a positive sample in standard supervised learning. For a true negative sample (*e.g.*, "patient" unlabeled in Figure 1), the loss is calculated by $\mathbb{D}$ due to its confidence score is less than the threshold. So the minimization for $\mathbb{D}$ enables the model to learn from this true negative sample. For a false negative sample (*e.g.*, "neutropenia" unlabeled in Figure 1), the loss is not counted, because its confidence score is larger than the threshold and thus $\mathbb{D}$ is not calculated. It is the mechanism that Conf-MPU handles false negative samples from unlabeled data.

3.3 Estimation Error Bound

Here we establish an estimation error bound for the proposed Conf-MPU risk estimator (Eq. 8) to show the guaranteed performance.

Theorem 1. *Let* $f^* = \arg\min_{f \in \mathcal{F}} \mathrm{R}(f)$ *and* $\hat{f}_{\mathrm{Conf-MPU}} = \arg\min_{f \in \mathcal{F}} \hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(f)$. *Assume that* $\ell(\cdot) \in [0, C_l]$ *and* ℓ *is Lipschitz continuous on the interval* $[-C_g, C_g]$ *with a Lipschitz constant* L_l, *where* $C_l, C_g > 0$. *Also suppose that* $\hat{\lambda}$ *is a fixed function independent of data used to compute* $\hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(f)$ *and* $\tau \in (0, 1]$. *Let* $\zeta = p(\hat{\lambda}(\boldsymbol{x}) \leq \tau)$ *and* $\epsilon = \mathbb{E}_{\boldsymbol{x} \sim p(\boldsymbol{x})}\left[|\hat{\lambda}(\boldsymbol{x}) - \lambda(\boldsymbol{x})|^2\right]$. *Then for any* $\delta > 0$, *with probability at least* $1 - \delta$,

$$\mathrm{R}(\hat{f}_{\mathrm{Conf-MPU}}) - \mathrm{R}(f^*) \leq \sum_{i=1}^{k} 2\pi_i \frac{(\tau+1)C_l}{\tau} + \sum_{i=1}^{k} 2\pi_i \left[\frac{2L_l}{\tau} \mathfrak{R}_{n_{\mathrm{P}_i}, p_{\mathrm{P}_i}(\boldsymbol{x})}(\mathcal{F}) + \frac{(\tau+1)C_l}{\tau} \sqrt{\frac{\log \frac{k+1}{\delta}}{2n_{\mathrm{P}_i}}}\right] + 4L_l \mathfrak{R}_{n_{\mathrm{U}}, p(\boldsymbol{x})}(\mathcal{F}) + 2C_l \sqrt{\frac{\log \frac{k+1}{\delta}}{2n_{\mathrm{U}}}} + \frac{2C_l}{\tau} \sqrt{(1-\zeta)\epsilon}.$$

In Theorem 1, $\mathcal{F}$ is the function class and $\mathfrak{R}_{n_{\mathrm{P}_i}, p_{\mathrm{P}_i}(\boldsymbol{x})}(\mathcal{F})$ is the Rademacher complexity of the function class $\mathcal{F}$ for the sampling of size n_{P_i} from the distribution $p_{\mathrm{P}_i}(\boldsymbol{x})$ and $\mathfrak{R}_{n_{\mathrm{U}}, p(\boldsymbol{x})}(\mathcal{F})$ follows a similar definition. We relegate this proof to the Appendix.

4 DS-NER Classification

In this section, we describe the setup for the DS-NER classification.

4.1 Generation of Distant Labels

In DS-NER tasks, professional dictionaries (*e.g.*, UMLS) and knowledge bases (*e.g.*, Wikidata) are used to automatically generate distant labels. Distant labeling by dictionaries employs some string matching algorithms to map training samples to dictionaries (Ren et al., 2015; Giannakopoulos et al., 2017; Peng et al., 2019), while knowledge bases utilize public APIs to perform such distant labeling.

4.2 Classifiers

The proposed Conf-MPU risk estimator can be applied on any NER classifiers where the task is to predict the label for each token. For example, BERT (Devlin et al., 2019) can be used as the underlying NER model, and then the Conf-MPU risk estimation can be used to calculate the classification risks. We use **Conf-MPU$_{\text{BERT}}$** to denote this method. BiLSTM (Chiu and Nichols, 2016) is another popular choice for NER models. Ratinov and Roth (2009); Passos et al. (2014); Chiu and Nichols (2016) demonstrate that using lexicons as external features can improve NER performance. With the dictionaries, we extract the lexicon features as follows. For each token, we match its contextual words within a window size against entries in the dictionaries. If there is any successful matching, a binary indicator is set to 1, otherwise 0. With the window size of n, we can form an n-bit vector, which is appended to the input embedding. We denote the model of BiLSTM with the lexicon feature engineering as LBiLSTM, and denote **Conf-MPU$_{\text{LBiLSTM}}$** as the LBiLSTM-based classifier with Conf-MPU risk estimation.

For the first step of estimating confidence scores, we build a token-level binary classifier (*i.e.*, λ) based on LBiLSTM to output scores. To be consistent with PU learning setting, this classifier is equipped with a binary PU learning risk estimator (*i.e.*, $\hat{\mathrm{R}}_{\mathrm{PU}}(\lambda)$).

4.3 Prior Estimation

Unlike in supervised learning where priors (*i.e.*, π_i) can be easily obtained from human annotations, we cannot directly acquire them from distant annotations. In PU learning research, there are some methods proposed specifically for estimating the priors (Bekker and Davis, 2018; Jain et al., 2016; Du Plessis and Sugiyama, 2014). Here we adopt the most effective TIcE algorithm from Bekker and Davis (2018) to perform prior estimation.

4.4 Loss Function

Peng et al. (2019) point out that a bounded loss function can help avoid overfitting in PU learning setting. We also confirm this argument in our empirical studies. Thus, instead of using the common unbounded cross entropy loss function, we adopt the mean absolute error (MAE) as the loss function for Conf-MPU and other PU learning methods in our experiments. Given its label $\boldsymbol{y}$ in the one-hot form, the loss on a token $\boldsymbol{x}$ is defined by:

$$\ell(f(\boldsymbol{x}), \boldsymbol{y}) = \frac{1}{k+1} \sum_{i=0}^{k} |\boldsymbol{y}^{(i)} - f(\boldsymbol{x})^{(i)}|,$$

where $f(\boldsymbol{x})$ is the softmax output, and both $\boldsymbol{y}$ and $f(\boldsymbol{x})$ are in $k+1$ dimensions. Note that $\ell(f(\boldsymbol{x}), \boldsymbol{y}) \in [0, \frac{2}{k+1}]$ is bounded.

4.5 Post-Processing

In DS-NER tasks, self-training strategies as post-processing can often further improve the performance, such as iteratively enriching dictionaries based on the model predictions (Peng et al., 2019), or iteratively training a teacher-student framework (Liang et al., 2020). The discussion for self-training framework is out of the scope of this paper and we refer the readers to Zoph et al. (2020) for more information.

5 Experiments

In this section, we evaluate the proposed Conf-MPU and compare with other baseline methods.

5.1 Experimental Setup

5.1.1 Training Data and Evaluation Metrics

We consider two benchmark NER datasets from different domains: (1) **BC5CDR** comes from biomedical domain. It consists of 1,500 articles, containing 15,935 `Chemical` and 12,852 `Disease` mentions; (2) **CoNLL2003** is a well-known open-domain NER dataset. It consists of 1,393 English news articles, containing 10,059 `PER`, 10,645 `LOC`, 9,323 `ORG` and 5,062 `MISC` mentions.

We obtain the following distantly labeled datasets: (1) **BC5CDR (Big Dict)** is labeled using a dictionary[2] released by Shang et al. (2018); (2) **BC5CDR (Small Dict)** is labeled using a smaller dictionary constructed by selecting only the first 20% entries from the previous one; (3) **CoNLL2003 (KB)**[3] is labeled by the knowledge base Wikidata and released by Liang et al. (2020); (4) **CoNLL2003 (Dict)** is labeled using a refined dictionary released by Peng et al. (2019)[4]. For dictionary labeling, we use the strict string matching algorithm presented in Peng et al. (2019). The process of knowledge base labeling can be found in Liang et al. (2020).

All DS-NER methods are trained on the same distantly labeled training data and evaluated on the released human-annotated test sets in terms of span-level precision, recall and F1 score. To avoid the noise induced by the position tag in the distant labels, we do not consider the position of

[3] https://github.com/cliang1453/BOND

[4] https://github.com/v-mipeng/LexiconNER

each token in a named entity. During the prediction phase, a continuous span with the same label is considered as a single entity.

5.1.2 Baseline Methods

We compare the proposed Conf-MPU with different groups of baseline methods.

Fully Supervised Methods. We present the state-of-the-art (SOTA) performance of fully supervised methods on the two benchmark datasets, Wang et al. (2021) on BC5CDR and Wang et al. (2020) on CoNLL2003. For SOTA methods, we report the results from their original papers. We also evaluate the employed BiLSTM and BERT models in fully supervised setting. The performance in this group serves as upper-bound references.

Distantly Supervised Methods. We consider the following distantly supervised NER methods: (1) **Dict/KB Matching** distantly labels the test sets using dictionaries or knowledge bases directly, which is included here as references; (2) **AutoNER** (Shang et al., 2018) trains the model using a "tie-or-break" mechanism to detect entity boundaries and then predicts entity type for each candidate; (3) **BERT-ES** (Liang et al., 2020) adopts early stopping to prevent BERT from overfitting to noisy distant labels; (4) **BNPU** (Peng et al., 2019) built on LBiLSTM (**BNPU$_{\text{LBiLSTM}}$**) applies a binary PU learning risk estimation with MAE as the loss function to each entity type and then infers the final types; (5) **MPU** is the predecessor of the proposed Conf-MPU, which computes the empirical risk using Eq. 5. We also build MPU on both BERT and LBiLSTM models, denoted as **MPU$_{\text{BERT}}$** and **MPU$_{\text{LBiLSTM}}$**. Note that full models in Peng et al. (2019); Liang et al. (2020) contain self-training as post processing steps, which are omitted here. We focus on the evaluation of how well each model can handle incomplete labeling issues in DS-NER tasks.

5.1.3 Method Setups

To evaluate the efficacy of the DS-NER methods in real usage under distantly supervised settings, we do not use any human-annotated validation or test sets in any stage of the training process. The training stopping criteria are set as follows: 100 epochs for BiLSTM-based methods and 5 epochs for BERT-based ones. We report the performance of the final model instead of the best checkpoint. Consequently, the baselines have different performance from their reported results. We use the released code for AutoNER and BERT-ES to reproduce their results. For other methods, we report the results based on our implementations. BiLSTM-based models utilize pretrained `bio-embedding`[5] for BC5CDR and pretrained Stanford's `Glove`[6] embedding for CoNLL2003. BERT-based models use pretrained `biobert-base-cased-v1.1`[7] for BC5CDR and `bert-base-cased`[8] for CoNLL2003. The only exception is that BERT-ES uses `roberta-base`[9] for CoNLL2003 in the original implementation.

Dataset	Type	Precision	Recall
BC5CDR (Big Dict)	Chemical	97.99	63.14
	Disease	98.34	46.73
BC5CDR (Small Dict)	Chemical	98.66	11.43
	Disease	99.25	9.31
CoNLL2003 (KB)	PER	82.36	82.11
	LOC	99.98	65.20
	ORG	90.47	60.59

CoNLL2003 (Dict)	PER	99.78	79.10
	LOC	97.56	34.69
	ORG	95.80	65.47
	MISC	99.24	57.22

Table 1: The quality of distant labels on training sets, stated in token-level precision and recall (in %).

5.2 Experimental Results

5.2.1 Main Results

We first examine the quality of the distantly labeled training data. Table 1 shows the detailed evaluation of distantly labeled training data. The results validate the assumption mentioned in previous work that distant labels generated by dictionaries are often of high precision but low recall.

Table 2 presents the overall span-level precision, recall, and F1 scores for all methods on the test sets. The proposed Conf-MPU shows a clear advantage over baseline methods, especially when accompanying with LBiLSTM. Almost all distantly supervised baselines perform better than Dict/KB Matching on these four datasets, except for a few cases of BNPU and MPU which will be discussed later. Among the baseline methods, AutoNER and BERT-ES show strong correlation with respect to the dictionary quality. On BC5CDR (Small Dict), where the dictionary suffers from extremely low coverage, the two methods have little improvement

on recall. Similarly, this phenomenon can also be observed by comparing their performance on CoNLL2003 (KB) and CoNLL2003 (Dict).

By contrast, all PU learning based methods demonstrate significantly higher recall on all datasets, showing more robustness to the issue of incomplete labeling. However, we can observe that compared with their performances on BC5CDR (Small Dict), BNPU and MPU suffer from low precision on BC5CDR (Big Dict) labeled by a dictionary with high coverage and precision, which is against one's intuition. We will extend the discussion in Section 5.2.3. Note that although BNPU and MPU are derived from the same probability principle, it is not necessary for BNPU and MPU to have similar performance. For example, BNPU$_{\text{LBiLSTM}}$ and MPU$_{\text{LBiLSTM}}$ perform similarly on BC5CDR datasets, but not on CoNLL2003 datasets. We suspect the cause is that they differ in the training process. BNPU is trained with the one-vs-all strategy where the distribution of unlabeled data is different for each entity type, while MPU is simultaneously trained with all types keeping the same distribution of unlabeled data. As mentioned earlier, the distribution of unlabeled data may significantly affect the risk estimation of PU learning. In addition, the inference step also has an unpredictable effect on the overall performance of BNPU.

As the results manifest, Conf-MPU can significantly improve precision compared with BNPU and MPU, and meanwhile maintain a high level of recall on all datasets, which shows that Conf-MPU can significantly alleviate the estimation bias.

We guide readers to the Appendix for the detailed evaluation of prior estimation and the empirical solution to the class imbalance problem.

5.2.2 Confidence Score Estimation

For Conf-MPU, another factor for its performance is the confidence score estimation for each token being an entity token. To evaluate the quality of the confidence scores, we first convert the results as labels where if $\hat{\lambda}(\boldsymbol{x}) > 0.5$ then label $\boldsymbol{x}$ as an

Method	BC5CDR (Big Dict)	BC5CDR (Small Dict)

Table 4: Ablation study on lexicon features on BC5CDR (Small Dict).

entity token, otherwise label as a non-entity token. We present the results in terms of token-level F1 score, precision, and recall in Table 3, where Fully Supervised using human-annotated ground-truth labels provides upper-bound references for this estimation, while Binary PU uses distant labels. We can see that the classifier with the binary PU risk estimation achieves good recall on all of the distantly labeled datasets. High recall indicates that the classifier can recognize most of entity tokens, which can be taken advantage of in the Conf-MPU risk estimation to avoid overfitting to false negative samples in unlabeled data. We also evaluate the proposed Conf-MPU models with the confidence scores given by the fully supervised classifier on the four distantly labeled datasets, where the performances increased by $2 \sim 5$ percentage in terms of F1 score, indicating that the proposed Conf-MPU framework is robust to the confidence score estimation of lesser quality. We leave for future work the optimization of the confidence score estimation.

5.2.3 Impact of Dictionary Coverage

To have a solid recognition to the estimation bias in BNPU and MPU caused by the violation of PU assumption, we construct a series of dictionaries with different coverage on entities. We treat the dictionaries used to generate labels for BC5CDR (Big Dict) and CoNLL2003 (Dict) as two reference standard dictionaries. Then for each of the two benchmark datasets we build a group of dictionaries by selecting the first 20, 40, 60, 80, and 100 (%) entries from the standard ones. We train BNPU, MPU, and Conf-MPU on the distantly labeled datasets generated by these dictionaries. Here we show the results based on LBiLSTM in Figure 2 (`a` - `c` and `f` - `h` on corresponding test sets). Similar trend can be observed on BERT-based settings.

We can see a clear decreasing trend on precision for BNPU and MPU when dictionary size increases (Figures 2 (`a&f`)). These phenomena are caused due to the violation of PU assumption. When a dictionary has higher coverage, the distribution of unlabeled data is more and more similar to the distribution of true negative data, instead of to the overall data distribution. The BNPU and MPU risk estimations bring higher bias, leading to lower precision. Although their recalls remain high, the F1 scores still decrease. By contrast, the proposed Conf-MPU can effectively avoid this limitation and achieve good performance for all dictionary sizes.

5.2.4 Ablation Studies

To further evaluate the Conf-MPU risk estimation, we first conduct ablation studies comparing with MPN risk (Eq. 3) whose estimation simply treats unlabeled data as negative samples in distant supervision, and demonstrate the performance with different epochs. Sub-figures (`d`, `e`, `i`, `j`) in Figure 2 show the trends of F1 scores of LBiLSTM-based models on the validation sets using three risk estimations of Conf-MPU, MPU, and MPN, with respect to different number of epochs. (`d`, `e`) and (`i`, `j`) reflect the performance on BC5CDR and CoNLL2003, respectively. (`d`, `i`) and (`e`, `j`) reflect the performance based on 20% and 100% dictionaries, respectively. The results show that MPN risk estimation can lead to severe overfitting for the model when dictionaries have low coverage. Although MPN still causes overfitting on full dictionaries, its performances are more stable and generally good. By contrast, MPU and Conf-MPU consider the false negative issue during training, and do not overfit even on small dictionaries. Conf-MPU performs stably and consistently well for more scenarios comparing with the other risk estimations.

From Table 2, we can observe that Conf-MPU$_{\texttt{LBiLSTM}}$ outperforms BiLSTM with fully supervised setting on BC5CDR with both big and small dictionaries. To examine the performance gain, we implement three methods, BNPU, MPU, and Conf-MPU based on BiLSTM instead of LBiLSTM to evaluate the impact of lexicon features learned from the dictionaries. The results on BC5CDR (Small Dict) are shown in Table 4. We can see that the lexicon features used in DS-NER tasks can significantly improve the performance. The experiments performed on other distantly labeled datasets also exhibit similar trends. The results suggest that dictionaries in DS-NER tasks can also serve as external features in additional to the distant labels.

6 Related Work

DS-NER. Handling noisy labels (false positives and false negatives) in DS-NER has attracted extensive attention in recent years (Yang et al., 2018; Shang et al., 2018; Mayhew et al., 2019; Cao et al., 2019; Peng et al., 2019; Liang et al., 2020; Liu et al., 2021; Zhang et al., 2021). Here we briefly discuss a few representative approaches.

One line of work focuses on alleviating the impact of false negatives (or incomplete labeling). Our work belongs to this line. AutoNER (Shang et al., 2018) proposes a new tagging scheme to identify entity candidates by determining if the connection of two adjacent tokens should be `tied`, `broken`, or `unknown`, and then decides the type for entity candidates. To handle incomplete labeling, tokens with `unknown` tag are not counted for the loss calculation. Mayhew et al. (2019) introduce a constraint driven iterative algorithm learning to detect false negatives in the noisy data and down-weigh them, resulting in a weighted training set on which a weighted NER model is trained. Peng et al. (2019) employ PU learning to avoid the model overffiting to false negatives, and propose a bounded non-negative positive-unlabeled learning. However, the application of binary PU learning in DS-NER is limited to the underlying PU assumption and its efficiency. Our proposed Conf-MPU can release the limitations and allow PU learning to be utilized in wider distant supervision scenarios.

Another line of work considers the noise of both types, either explicitly or implicitly. Cao et al. (2019) design a data selection scheme to compute scores for annotation confidence and annotation coverage to distinguish high-quality sentences from noisy ones, and then propose a name tagging model that consists of two modules of sequence labeling and classification, focusing on high-quality and noisy portions, respectively. BOND (Liang et al., 2020), leveraging the power of pre-trained language model BERT, first adopts early stopping to prevent overfitting to noisy labels and obtains an initialized model, then further boosts the performance by a teacher-student self-training framework. Liu et al. (2021) propose a calibrated confidence estimation approach for DS-NER and integrate it in an LSTM-CRF model under a self-training framework to reduce the impact of noise. Zhang et al. (2021) study the noise in DS-NER from a novel perspective of dictionary bias. Specifically, they first formulate DS-NER using a structural causal model, then identify the causes of both false positives and false negatives, and finally debias via backdoor adjustment and causal invariance regularizer. We leave for future work enabling Conf-MPU to handle false positives.

PU Learning. PU learning learns a classifier from positive and unlabeled data (Elkan and Noto, 2008; Du Plessis et al., 2014). In a broad sense, PU learning belongs to semi-supervised learning. However, there is a fundamental difference between them: semi-supervised learning requires labeled negative data, but PU learning does not. Recently, a few works significantly enriched PU learning theory. Kiryo et al. (2017) propose a non-negative risk estimator for PU learning, which enables the usage of deep neural networks for classification given limited labeled positive data. Xu et al. (2017) first come up with the concept of multi-positive and unlabeled learning with a margin maximization goal for the multi-class classification problem. However, the objective of margin maximization cannot be easily extended to apply on popular deep learning architectures. Hsieh et al. (2019) propose a novel classification framework incorporating biased negative data in PU learning, which opens up a wider range of the applications of PU learning.

7 Conclusion

In this paper, we present a novel multi-class positive and unlabeled learning method called Conf-MPU for the DS-NER task. Conf-MPU estimates the empirical classification risks using the confidence estimation of a token being an entity token on the distantly labeled training data to prevent the model from overfitting to the false negatives. We empirically show that Conf-MPU can significantly reduce the potential risk estimation bias caused by PU assumption. The extensive experiments illustrate that compared with existing DS-NER methods, Conf-MPU is more robust to various types of dictionaries and can handle the incomplete labeling problem effectively.

Appendix

1 Proof of Theorem 1

Here we determine the difference between $\mathrm{R}(\hat{f}_{\mathrm{Conf-MPU}})$ and $\mathrm{R}(f^*)$ using the error bound between $\hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(f)$ and $\mathrm{R}(f)$. Let us first define the intermediate risk estimators as follows. Each one introduces a new estimation component.

Starting from $\mathrm{R}(f)$ (*i.e.*, Eq. 7), $\bar{\mathrm{R}}(f)$ introduces $\hat{\lambda}(\boldsymbol{x})$ as the estimation of $\lambda(\boldsymbol{x})$,

$$\begin{aligned}\bar{\mathrm{R}}(f) = \sum_{i=1}^{k} \pi_i \mathbb{E}_{\boldsymbol{x}\sim p(\boldsymbol{x}|y=i)} \Big[& \ell(f(\boldsymbol{x}), i) \\ & + \mathbb{1}_{\hat{\lambda}(\boldsymbol{x})>\tau} \ell(f(\boldsymbol{x}), 0) \frac{1}{\hat{\lambda}(\boldsymbol{x})} - \ell(f(\boldsymbol{x}), 0) \Big] \\ & + \mathbb{E}_{\boldsymbol{x}\sim p(\boldsymbol{x})} \left[\mathbb{1}_{\hat{\lambda}(\boldsymbol{x})\leq\tau} \ell(f(\boldsymbol{x}), 0) \right].\end{aligned}$$

Then, $\hat{\mathrm{R}}(f)$ uses empirical means to estimate expectations,

$$\begin{aligned}\hat{\mathrm{R}}(f) = \sum_{i=1}^{k} \frac{\pi_i}{n_{\mathrm{P}_i}} \sum_{j=1}^{n_{\mathrm{P}_i}} \Big[& \ell(f(\boldsymbol{x}_j^{\mathrm{P}_i}), i) \\ & + \mathbb{1}_{\hat{\lambda}(\boldsymbol{x}_j^{\mathrm{P}_i})>\tau} \ell(f(\boldsymbol{x}_j^{\mathrm{P}_i}), 0) \frac{1}{\hat{\lambda}(\boldsymbol{x}_j^{\mathrm{P}_i})} - \ell(f(\boldsymbol{x}_j^{\mathrm{P}_i}), 0) \Big] \\ & + \frac{1}{n_{\mathrm{U}}} \sum_{j=1}^{n_{\mathrm{U}}} \left[\mathbb{1}_{\hat{\lambda}(\boldsymbol{x}_j^{\mathrm{U}})\leq\tau} \ell(f(\boldsymbol{x}_j^{\mathrm{U}}), 0) \right].\end{aligned}$$

$\hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(f)$ restricts the loss on each labeled positive sample to be at least 0,

$$\begin{aligned}\hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(f) = \sum_{i=1}^{k} \frac{\pi_i}{n_{\mathrm{P}_i}} \sum_{j=1}^{n_{\mathrm{P}_i}} \max\Big\{ & 0, \ell(f(\boldsymbol{x}_j^{\mathrm{P}_i}), i) \\ - \ell(f(\boldsymbol{x}_j^{\mathrm{P}_i}), 0) + \mathbb{1}_{\hat{\lambda}(\boldsymbol{x}_j^{\mathrm{P}_i})>\tau} & \ell(f(\boldsymbol{x}_j^{\mathrm{P}_i}), 0) \frac{1}{\hat{\lambda}(\boldsymbol{x}_j^{\mathrm{P}_i})} \Big\} \\ + \frac{1}{n_{\mathrm{U}}} \sum_{j=1}^{n_{\mathrm{U}}} & \left[\mathbb{1}_{\hat{\lambda}(\boldsymbol{x}_j^{\mathrm{U}})\leq\tau} \ell(f(\boldsymbol{x}_j^{\mathrm{U}}), 0) \right].\end{aligned}$$

In the following proof, we will derive the error bounds from $\hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(f)$ to $\hat{\mathrm{R}}(f)$, from $\hat{\mathrm{R}}(f)$ to $\bar{\mathrm{R}}(f)$, and from $\bar{\mathrm{R}}(f)$ to $\mathrm{R}(f)$ in order.

Let us first derive the error bound from $\hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(f)$ to $\hat{\mathrm{R}}(f)$. For ease of notation, let

$$\begin{aligned}A &= \max\left\{0, \ell(f(\boldsymbol{x}), i) + \ell(f(\boldsymbol{x}), 0)\left(\mathbb{1}_{\hat{\lambda}(\boldsymbol{x})>\tau} \frac{1}{\hat{\lambda}(\boldsymbol{x})} - 1\right)\right\}, \\ B &= \ell(f(\boldsymbol{x}), i) + \ell(f(\boldsymbol{x}), 0)\left(\mathbb{1}_{\hat{\lambda}(\boldsymbol{x})>\tau} \frac{1}{\hat{\lambda}(\boldsymbol{x})} - 1\right).\end{aligned}$$

Then we have

$$\left|\hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(f) - \hat{\mathrm{R}}(f)\right| = \sum_{i=1}^{k} \frac{\pi_i}{n_{\mathrm{P}_i}} \sum_{j=1}^{n_{\mathrm{P}_i}} |A - B|.$$

Since $\ell(\cdot) \in [0, C_l]$, we have $A \in \left[0, \frac{C_l}{\tau}\right]$ and $B \in \left[-C_l, \frac{C_l}{\tau}\right]$. Further, we have $|A - B| \leq \left(1 + \frac{1}{\tau}\right) C_l$. So we get the error bound

$$\left|\hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(f) - \hat{\mathrm{R}}(f)\right| \leq \sum_{i=1}^{k} \pi_i \frac{(\tau+1)C_l}{\tau}.$$

Then, we use the following lemma to establish the error bound from $\hat{\mathrm{R}}(f)$ to $\bar{\mathrm{R}}(f)$.

Lemma 1. *Let* $\hat{\lambda}(\cdot) : \mathbb{R}^d \to (0, 1]$ *be a fixed function independent of data used to compute* $\hat{\mathrm{R}}(f)$ *and* $\tau \in (0, 1]$. *For any* $\delta > 0$, *with probability at least* $1 - \delta$,

$$\begin{aligned}\sup_{f\in\mathcal{F}} & \left|\hat{\mathrm{R}}(f) - \bar{\mathrm{R}}(f)\right| \leq \\ & \sum_{i=1}^{k} \pi_i \left[\frac{2L_l}{\tau} \mathfrak{R}_{n_{\mathrm{P}_i}, p(\boldsymbol{x}|y=i)}(\mathcal{F}) + \frac{(\tau+1)C_l}{\tau} \sqrt{\frac{\log\frac{k+1}{\delta}}{2n_{\mathrm{P}_i}}}\right] \\ & + 2L_l \mathfrak{R}_{n_{\mathrm{U}}, p(\boldsymbol{x})}(\mathcal{F}) + C_l \sqrt{\frac{\log\frac{k+1}{\delta}}{2n_{\mathrm{U}}}}.\end{aligned}$$

Proof of Lemma 1. For ease of notation, let

$$\begin{aligned}\bar{\mathrm{R}}_{\mathrm{P}_i}^{+} &= \mathbb{E}_{\boldsymbol{x}\sim p(\boldsymbol{x}|y=i)} \Big[\ell(f(\boldsymbol{x}), i) \\ & \qquad + \ell(f(\boldsymbol{x}), 0)\left(\mathbb{1}_{\hat{\lambda}(\boldsymbol{x})} \frac{1}{\hat{\lambda}(\boldsymbol{x})} - 1\right)\Big], \\ \bar{\mathrm{R}}_{\mathrm{U}}^{-} &= \mathbb{E}_{\boldsymbol{x}\sim p(\boldsymbol{x})} \left[\mathbb{1}_{\hat{\lambda}(\boldsymbol{x})\leq\tau} \ell(f(\boldsymbol{x}, 0))\right], \\ \hat{\mathrm{R}}_{\mathrm{P}_i}^{+} &= \frac{1}{n_{\mathrm{P}_i}} \sum_{j=1}^{n_{\mathrm{P}_i}} \Big[\ell(f(\boldsymbol{x}_j^{\mathrm{P}_i}), i) \\ & \qquad + \ell(f(\boldsymbol{x}_j^{\mathrm{P}_i}), 0)\left(\mathbb{1}_{\hat{\lambda}(\boldsymbol{x}_j^{\mathrm{P}_i})>\tau} \frac{1}{\hat{\lambda}(\boldsymbol{x}_j^{\mathrm{P}_i})} - 1\right)\Big], \\ \hat{\mathrm{R}}_{\mathrm{U}}^{-} &= \frac{1}{n_{\mathrm{U}}} \sum_{j=1}^{n_{\mathrm{U}}} \left[\mathbb{1}_{\hat{\lambda}(\boldsymbol{x}_j^{\mathrm{U}})\leq\tau} \ell(f(\boldsymbol{x}_j^{\mathrm{U}}), 0)\right].\end{aligned}$$

From the sub-additivity of the supremum operator, we have

$$\begin{aligned}\sup_{f\in\mathcal{F}} \left|\hat{\mathrm{R}}(f) - \bar{\mathrm{R}}(f)\right| \leq & \sum_{i=1}^{k} \pi_i \sup_{f\in\mathcal{F}} \left|\hat{\mathrm{R}}_{\mathrm{P}_i}^{+} - \bar{\mathrm{R}}_{\mathrm{P}_i}^{+}\right| \\ & + \sup_{f\in\mathcal{F}} \left|\hat{\mathrm{R}}_{\mathrm{U}}^{-} - \bar{\mathrm{R}}_{\mathrm{U}}^{-}\right|.\end{aligned}$$

It suffices to prove Lemma 1 if we can prove that with probability at least $1 - \frac{\delta}{k+1}$, the following bounds hold separately:

$$\begin{aligned}\sup_{f\in\mathcal{F}} \left|\hat{\mathrm{R}}_{\mathrm{P}_i}^{+} - \bar{\mathrm{R}}_{\mathrm{P}_i}^{+}\right| \leq & \frac{2L_l}{\tau} \mathfrak{R}_{n_{\mathrm{P}_i}, p(\boldsymbol{x}|y=i)}(\mathcal{F}) \\ & + \frac{(\tau+1)C_l}{\tau} \sqrt{\frac{\log\frac{k+1}{\delta}}{2n_{\mathrm{P}_i}}}, \end{aligned} \tag{9}$$

$$\begin{aligned}\sup_{f\in\mathcal{F}} \left|\hat{\mathrm{R}}_{\mathrm{U}}^{-} - \bar{\mathrm{R}}_{\mathrm{U}}^{-}\right| \leq & 2L_l \mathfrak{R}_{n_{\mathrm{U}}, p(\boldsymbol{x})}(\mathcal{F}) \\ & + C_l \sqrt{\frac{\log\frac{k+1}{\delta}}{2n_{\mathrm{U}}}}. \end{aligned} \tag{10}$$

Next, we prove Inequation 9. Inequation 10 is proven similarly.

Let $\phi_{\boldsymbol{x}} : \mathbb{R} \rightarrow \mathbb{R}$ be the function defined by $\phi_{\boldsymbol{x}} : z \mapsto \ell(z, i) + \ell(z, 0)\left(\mathbb{1}_{\hat{\lambda}(\boldsymbol{x})>\tau} \frac{1}{\hat{\lambda}(\boldsymbol{x})} - 1\right)$. For $\boldsymbol{x} \in \mathbb{R}^d$, $f \in \mathcal{F}$, since $\ell(\cdot) \in [0, C_l]$ and $\mathbb{1}_{\hat{\lambda}(\boldsymbol{x})>\tau} \frac{1}{\hat{\lambda}(\boldsymbol{x})} - 1 \in \left[-1, \frac{1}{\tau} - 1\right]$, we have $\phi_{\boldsymbol{x}}(f(x)) \in \left[-C_l, \frac{C_l}{\tau}\right]$. Following the proof of Theorem 3.3 in (Mohri et al., 2018), we can show that with probability at least $1 - \frac{\delta}{k+1}$, it holds that

$$\begin{aligned}&\sup_{f\in\mathcal{F}} \left|\hat{\mathrm{R}}^+_{\mathrm{P}_i} - \bar{\mathrm{R}}^+_{\mathrm{P}_i}\right| \leq \\ &2\mathbb{E}_{\mathcal{X}_{\mathrm{P}_i} \sim p(\boldsymbol{x}|y=i)^{n_{\mathrm{P}_i}}} \mathbb{E}_{\boldsymbol{\theta}} \left[\sup_{f\in\mathcal{F}} \frac{1}{n_{\mathrm{P}_i}} \sum_{j}^{n_{\mathrm{P}_i}} \theta_j \phi_{\boldsymbol{x}_j^{\mathrm{P}_i}}(f(\boldsymbol{x}_j^{\mathrm{P}_i}))\right] \\ &+ \frac{(\tau+1)C_l}{\tau} \sqrt{\frac{\log \frac{k+1}{\delta}}{2n_{\mathrm{P}_i}}},\end{aligned}$$

where $\boldsymbol{\theta} = \{\theta_1, ..., \theta_{n_{\mathrm{P}_i}}\}$ and each θ_i is a Rademacher variable.

We notice that for all $\boldsymbol{x}$, $\phi_{\boldsymbol{x}}$ is a (L_l/τ)-Lipschitz function on the interval $[-C_g, C_g]$. Following the proof of Lemma 26.9 in (Shalev-Shwartz and Ben-David, 2014), we can show that, when the set $\mathcal{X}_{\mathrm{P}_i}$ is fixed, we have

$$\begin{aligned}&\mathbb{E}_{\mathcal{X}_{\mathrm{P}_i} \sim p(\boldsymbol{x}|y=i)^{n_{\mathrm{P}_i}}} \mathbb{E}_{\boldsymbol{\theta}} \left[\sup_{f\in\mathcal{F}} \frac{1}{n_{\mathrm{P}_i}} \sum_{j}^{n_{\mathrm{P}_i}} \theta_j \phi_{\boldsymbol{x}_j^{\mathrm{P}_i}}(f(\boldsymbol{x}_j^{\mathrm{P}_i}))\right] \leq \\ &\quad \frac{L_l}{\tau} \mathbb{E}_{\mathcal{X}_{\mathrm{P}_i} \sim p(\boldsymbol{x}|y=i)^{n_{\mathrm{P}_i}}} \mathbb{E}_{\boldsymbol{\theta}} \left[\sup_{f\in\mathcal{F}} \frac{1}{n_{\mathrm{P}_i}} \sum_{j}^{n_{\mathrm{P}_i}} \theta_j f(\boldsymbol{x}_j^{\mathrm{P}_i})\right].\end{aligned}$$

We can obtain Inequation 9 by substituting the Rademacher complexity. Lemma 1 is proven.

Then, we establish the error bound from $\bar{\mathrm{R}}(f)$ to $\mathrm{R}(f)$ by the following lemma.

Lemma 2. *Let* $\hat{\lambda}(\cdot) : \mathbb{R}^d \rightarrow (0, 1]$, $\tau \in (0, 1]$, $\zeta = p(\hat{\lambda}(\cdot) \leq \tau)$ *and* $\epsilon = \mathbb{E}_{\boldsymbol{x}\sim p(\boldsymbol{x})}\left[|\hat{\lambda}(\boldsymbol{x}) - \lambda(\boldsymbol{x})|^2\right]$. *For all* $f \in \mathcal{F}$, *it holds that*

$$\left|\bar{\mathrm{R}}(f) - \mathrm{R}(f)\right| \leq \frac{C_l}{\tau}\sqrt{(1-\zeta)\epsilon}.$$

Proof of Lemma 2. We notice that the difference between $\bar{\mathrm{R}}(f)$ and $\mathrm{R}(f)$ is actually the difference between $\bar{\mathrm{R}}^-_{\mathrm{U}}$ and $\mathrm{R}^-_{\mathrm{U}}$, where

$$\begin{aligned}\bar{\mathrm{R}}^-_{\mathrm{U}} &= \sum_{i=1}^{k} \pi_i \mathbb{E}_{\boldsymbol{x}\sim p(\boldsymbol{x}|y=i)}\left[\mathbb{1}_{\hat{\lambda}(\boldsymbol{x})>\tau} \ell(f(\boldsymbol{x}), 0) \frac{1}{\hat{\lambda}(\boldsymbol{x})}\right] \\ &\quad + \mathbb{E}_{\boldsymbol{x}\sim p(\boldsymbol{x})}\left[\mathbb{1}_{\hat{\lambda}(\boldsymbol{x})\leq\tau} \ell(f(\boldsymbol{x}), 0)\right], \\ \mathrm{R}^-_{\mathrm{U}} &= \sum_{i=1}^{k} \pi_i \mathbb{E}_{\boldsymbol{x}\sim p(\boldsymbol{x}|y=i)}\left[\mathbb{1}_{\lambda(\boldsymbol{x})>\tau} \ell(f(\boldsymbol{x}), 0) \frac{1}{\lambda(\boldsymbol{x})}\right] \\ &\quad + \mathbb{E}_{\boldsymbol{x}\sim p(\boldsymbol{x})}\left[\mathbb{1}_{\lambda(\boldsymbol{x})\leq\tau} \ell(f(\boldsymbol{x}), 0)\right].\end{aligned}$$

We can rewrite $\bar{\mathrm{R}}^-_{\mathrm{U}}$ and $\mathrm{R}^-_{\mathrm{U}}$ in the form of integral

$$\begin{aligned}\bar{\mathrm{R}}^-_{\mathrm{U}} &= \sum_{i=1}^{k} \pi_i \int \mathbb{1}_{\hat{\lambda}(\boldsymbol{x})>\tau} \ell(f(\boldsymbol{x}), 0) \frac{1}{\hat{\lambda}(\boldsymbol{x})} p(\boldsymbol{x} \mid y = i) d\boldsymbol{x} \\ &\quad + \int \mathbb{1}_{\hat{\lambda}(\boldsymbol{x})\leq\tau} \ell(f(\boldsymbol{x}), 0) p(\boldsymbol{x}) d\boldsymbol{x}, \\ \mathrm{R}^-_{\mathrm{U}} &= \sum_{i=1}^{k} \pi_i \int \mathbb{1}_{\hat{\lambda}(\boldsymbol{x})>\tau} \ell(f(\boldsymbol{x}), 0) \frac{1}{\lambda(\boldsymbol{x})} p(\boldsymbol{x} \mid y = i) d\boldsymbol{x} \\ &\quad + \int \mathbb{1}_{\hat{\lambda}(\boldsymbol{x})\leq\tau} \ell(f(\boldsymbol{x}), 0) p(\boldsymbol{x}) d\boldsymbol{x},\end{aligned}$$

where for $\mathrm{R}^-_{\mathrm{U}}$, we replace the subscript $\lambda(\boldsymbol{x})$ of the indicator function with $\hat{\lambda}(\boldsymbol{x})$, which does not change the value of $\mathrm{R}^-_{\mathrm{U}}$.

According to the sub-additivity of the supremum operator, we have

$$\begin{aligned}&\left|\bar{\mathrm{R}}(f) - \mathrm{R}(f)\right| = \left|\bar{\mathrm{R}}^-_{\mathrm{U}} - \mathrm{R}^-_{\mathrm{U}}\right| \leq \\ &\sum_{i=1}^{k} \pi_i \int \mathbb{1}_{\hat{\lambda}(\boldsymbol{x})>\tau} \ell(f(\boldsymbol{x}), 0) \left|\frac{1}{\hat{\lambda}(\boldsymbol{x})} - \frac{1}{\lambda(\boldsymbol{x})}\right| p(\boldsymbol{x} \mid y = i) d\boldsymbol{x} \\ &= \int \mathbb{1}_{\hat{\lambda}(\boldsymbol{x})>\tau} \ell(f(\boldsymbol{x}), 0) \left|\frac{1}{\hat{\lambda}(\boldsymbol{x})} - \frac{1}{\lambda(\boldsymbol{x})}\right| p(\boldsymbol{x}, y > 0) d\boldsymbol{x} \\ &= \int \mathbb{1}_{\hat{\lambda}(\boldsymbol{x})>\tau} \ell(f(\boldsymbol{x}), 0) \frac{\left|\hat{\lambda}(\boldsymbol{x}) - \lambda(\boldsymbol{x})\right|}{\hat{\lambda}(\boldsymbol{x})\lambda(\boldsymbol{x})} p(\boldsymbol{x}, y > 0) d\boldsymbol{x} \\ &\leq \frac{C_l}{\tau} \int \mathbb{1}_{\hat{\lambda}(\boldsymbol{x})>\tau} \frac{\left|\hat{\lambda}(\boldsymbol{x}) - \lambda(\boldsymbol{x})\right|}{\lambda(\boldsymbol{x})} p(\boldsymbol{x}, y > 0) d\boldsymbol{x} \\ &= \frac{C_l}{\tau} \int \mathbb{1}_{\hat{\lambda}(\boldsymbol{x})>\tau} \frac{\left|\hat{\lambda}(\boldsymbol{x}) - \lambda(\boldsymbol{x})\right|}{p(y > 0 \mid \boldsymbol{x})} p(y > 0 \mid \boldsymbol{x}) p(\boldsymbol{x}) d\boldsymbol{x} \\ &= \frac{C_l}{\tau} \int \mathbb{1}_{\hat{\lambda}(\boldsymbol{x})>\tau} \left|\hat{\lambda}(\boldsymbol{x}) - \lambda(\boldsymbol{x})\right| p(\boldsymbol{x}) d\boldsymbol{x} \\ &\leq \frac{C_l}{\tau} \sqrt{\int \mathbb{1}^2_{\hat{\lambda}(\boldsymbol{x})>\tau} p(\boldsymbol{x}) d\boldsymbol{x}} \sqrt{\int \left|\hat{\lambda}(\boldsymbol{x}) - \lambda(\boldsymbol{x})\right|^2 p(\boldsymbol{x}) d\boldsymbol{x}} \\ &= \frac{C_l}{\tau} \sqrt{(1-\zeta)\epsilon},\end{aligned}$$

where the last inequality is obtained after applying the Cauchy-Schwarz inequality. Lemma 2 is proven.

Combining the above three error bounds, we know that with probability at least $1 - \delta$, the following holds:

$$\begin{aligned}&\sup_{f\in\mathcal{F}} \left|\hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(f) - \mathrm{R}(f)\right| \leq \sum_{i=1}^{k} \pi_i \frac{(\tau+1)C_l}{\tau} \\ &+ \sum_{i=1}^{k} \pi_i \left[\frac{2L_l}{\tau} \mathfrak{R}_{n_{\mathrm{P}_i}, p(\boldsymbol{x}|y=i)}(\mathcal{F}) + \frac{(\tau+1)C_l}{\tau} \sqrt{\frac{\log \frac{k+1}{\delta}}{2n_{\mathrm{P}_i}}}\right] \\ &+ 2L_l \mathfrak{R}_{n_{\mathrm{U}}, p(\boldsymbol{x})}(\mathcal{F}) + C_l \sqrt{\frac{\log \frac{k+1}{\delta}}{2n_{\mathrm{U}}}} + \frac{C_l}{\tau}\sqrt{(1-\zeta)\epsilon}.\end{aligned}$$

Finally, with probability at least $1 - \delta$,

$$\begin{aligned}&\mathrm{R}(\hat{f}_{\mathrm{Conf-MPU}}) - \mathrm{R}(f^*) \\ &= \mathrm{R}(\hat{f}_{\mathrm{Conf-MPU}}) - \hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(\hat{f}_{\mathrm{Conf-MPU}}) \\ &\quad + \hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(\hat{f}_{\mathrm{Conf-MPU}}) - \hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(f^*) \\ &\quad + \hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(f^*) - \mathrm{R}(f^*) \\ &\leq \mathrm{R}(\hat{f}_{\mathrm{Conf-MPU}}) - \hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(\hat{f}_{\mathrm{Conf-MPU}})\end{aligned}$$

$$
\begin{aligned}
&+ \hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(f^*) - \mathrm{R}(f^*) \\
\leq &\left|\mathrm{R}(\hat{f}_{\mathrm{Conf-MPU}}) - \hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(\hat{f}_{\mathrm{Conf-MPU}})\right| \\
&+ \left|\hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(f^*) - \mathrm{R}(f^*)\right| \\
\leq &\, 2 \sup_{f \in \mathcal{F}} \left|\hat{\mathrm{R}}_{\mathrm{Conf-MPU}}(f) - \mathrm{R}(f)\right| \\
\leq &\sum_{i=1}^{k} 2\pi_i \frac{(\tau+1)C_l}{\tau} + \sum_{i=1}^{k} 2\pi_i \left[\frac{2L_l}{\tau}\mathfrak{R}_{n_{\mathrm{P}_i}, p(\boldsymbol{x}|y=i)}(\mathcal{F}) \right. \\
&\left. + \frac{(\tau+1)C_l}{\tau}\sqrt{\frac{\log \frac{k+1}{\delta}}{2n_{\mathrm{P}_i}}}\right] + 4L_l \mathfrak{R}_{n_{\mathrm{U}}, p(\boldsymbol{x})}(\mathcal{F}) \\
&+ 2C_l\sqrt{\frac{\log \frac{k+1}{\delta}}{2n_{\mathrm{U}}}} + \frac{2C_l}{\tau}\sqrt{(1-\zeta)\epsilon}.
\end{aligned}
$$

Theorem 1 is proven.

2 Evaluation of Prior Estimation

As mentioned in Section 4.3, we apply the TIcE algorithm to estimate the prior for each class without using ground-truth annotations. In Table 5, we compare the priors estimated on distantly annotated BC5CDR (Big Dict) and CoNLL2003 (Dict) with the true priors for each class of the two datasets. We also conduct the prior estimation on BC5CDR (Small Dict) and CoNLL2003 (KB), and we find that the priors estimated with different dictionaries are not significantly different. Table 5 shows that the estimated priors by TIcE algorithm are close to the true priors. We further trained Conf-MPU models using the true priors and do not observe significant differences in the performances. This experiment indicates that Conf-MPU is not sensitive to the prior estimations and TIcE algorithm can be applied for prior estimation without ground-truth labels.

Dataset	Type	Estimated Prior	True Prior
BC5CDR	Chemical	0.0503	0.0601
(Big Dict)	Disease	0.0504	0.0601
CoNLL2003 (Dict)	PER	0.1052	0.0547
	LOC	0.0331	0.0407
	ORG	0.0630	0.0492
	MISC	0.0371	0.0226

Table 5: The results of prior estimation.

3 Study on Class Imbalance Problem

NER tasks often suffer from the problem of class imbalance, where most tokens are not entity tokens. In our experiments, we introduce a hyper-parameter γ as a class weight in risk estimations to balance the risks on positive and unlabeled data.

We empirically investigate the effect of this parameter by evaluating Conf-MPU and MPU with different values of γ on BC5CDR (Big Dict) and CoNLL2003 (KB), and show the span-level F1 scores on test sets in Figure 3. We can see that if the class imbalance issue is ignored (*i.e.*, $\gamma = 1$), the two methods achieve very low F1 scores on the two distantly labeled datasets. When γ increases to a certain value (*e.g.*, $\gamma = 15$), both methods can achieve good performances. As γ increases, the F1 scores fluctuate a little within a certain range but stay high. It indicates that the two methods are not sensitive to the value of the class weight γ if it is properly large. Similar results can also be observed on the other distantly labeled datasets. Therefore, for a fair comparison, we uniformly set γ to 28 and 15 for distantly labeled BC5CDR datasets and CoNLL2003 datasets, respectively, in our experiments.

Abstract

Pre-trained models for programming languages have recently demonstrated great success on code intelligence. To support both code-related understanding and generation tasks, recent works attempt to pre-train unified encoder-decoder models. However, such encoder-decoder framework is sub-optimal for auto-regressive tasks, especially code completion that requires a decoder-only manner for efficient inference. In this paper, we present UniXcoder, a unified cross-modal pre-trained model for programming language. The model utilizes mask attention matrices with prefix adapters to control the behavior of the model and leverages cross-modal contents like AST and code comment to enhance code representation. To encode AST that is represented as a tree in parallel, we propose a one-to-one mapping method to transform AST in a sequence structure that retains all structural information from the tree. Furthermore, we propose to utilize multi-modal contents to learn representation of code fragment with contrastive learning, and then align representations among programming languages using a cross-modal generation task. We evaluate UniXcoder on five code-related tasks over nine datasets. To further evaluate the performance of code fragment representation, we also construct a dataset for a new task, called zero-shot code-to-code search. Results show that our model achieves state-of-the-art performance on most tasks and analysis reveals that comment and AST can both enhance UniXcoder.

1 Introduction

Pre-trained models such as GPT (Radford et al.) and BERT (Devlin et al., 2018) have substantially advanced the state of the art across numerous natural language processing (NLP) tasks. These pre-trained models are pre-trained on large amounts of text data with self-supervised objectives, and can be fine-tuned to adapt to downstream tasks. Inspired by the success of pre-trained models in NLP, pre-trained models for programming languages (PL) (Kanade et al., 2019; Feng et al., 2020; Svyatkovskiy et al., 2020) have been proposed to promote the development of code intelligence. Svyatkovskiy et al. (2020) proposes GPT-C that employs a left-to-right Transformer (Vaswani et al., 2017) to support generation tasks such as code completion, but the unidirectional framework is sub-optimal for understanding tasks. In contrast, other works (Kanade et al., 2019; Feng et al., 2020) pre-train a bidirectional Transformer encoder on source code, which significantly improves the performance of code-related understanding tasks. However, its bidirectionality nature requires an additional decoder when applied to generation tasks, where this decoder initializes from scratch and cannot benefit from the pre-training.

In this work, we present UniXcoder, a unified cross-modal pre-trained model for programming languages to support both code-related understanding and generation tasks. UniXcoder is based on a multi-layer Transformer and follows Dong et al. (2019) to utilize mask attention matrices with prefix adapters to control the access to context for each token. Compared with current unified encoder-decoder models (Ahmad et al., 2021; Wang et al., 2021) on code intelligence, UniXcoder can be better applied to auto-regressive tasks such as code completion that requires a decoder-only manner to perform efficient inference in practice. Instead of taking code as the only input, we also consider multi-modal contents like code comment and abstract syntax tree (AST) to enhance code representation. Generally, user-written code comments provide crucial semantic information about source code like *"Sort a given list"* and AST contains rich syntax information like types of statements and nested relationship among them, which helps the

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 7212 - 7225

model better understand source code. To encode AST that is represented as a tree in parallel, we propose a one-to-one mapping method to transform AST in a sequence structure that retains all information of the tree and then the sequence can be used as the input to enhance code representation.

We pre-train UniXcoder using three types of language modeling tasks: masked language modeling (Devlin et al., 2018), unidirectional language modeling (Radford et al.) and denoising objective (Raffel et al., 2019), which can enable the model to support various types of downstream tasks. Furthermore, we introduce two pre-training tasks to learn a embedding that can represent semantics of a code fragment. One is multi-modal contrastive learning that leverages AST to enhance semantics of code fragment embeddings, and the other is cross-modal generation that utilizes code comment to align embeddings among programming languages.

We evaluate UniXcoder on five tasks over nine public datasets, including two understanding tasks: clone detection and code search, two generation tasks: code summarization and code generation, and an auto-regressive task: code completion. To further test code fragment embeddings, we propose a new task, called zero-shot code-to-code search, and construct a new dataset from CodeNet corpus (Puri et al., 2021) for this task. Experimental results show that our model achieves state-of-the-art performance on most tasks. Further analysis reveals that AST and code comment can both enhance UniXcoder to better capture code semantics.

In summary, the contributions of this paper are: (1) We propose a unified cross-modal pre-trained model that leverages multi-modal contents, i.e. code comment and AST, to support code-related understanding, generation tasks and auto-regressive tasks. (2) We propose a one-to-one mapping function that converts AST into a sequence that retains all information of AST and can be encoded with source code and comment in parallel. (3) We further propose to utilize code comment to learn code fragment representation and construct a new dataset for zero-shot code-code search to evaluate the quality of code fragment representation. (4) Experimental results show that UniXcoder provides significant improvement on most downstream tasks.[1]

2 Related Works

With the great success of pre-training in natural language (NL) processing (Devlin et al., 2018; Lewis et al., 2019; Raffel et al., 2019; Brown et al., 2020), pre-trained models for programming languages have been proposed to promote the development of code intelligence. These pre-trained models can be generally divided into three categories: encoder-only, decoder-only, and encoder-decoder models.

Encode-only models (Kanade et al., 2019; Buratti et al., 2020; Feng et al., 2020; Guo et al., 2020; Wang et al., 2022) pre-train a bidirectional Transformer in which each token can attend to each other. Kanade et al. (2019) pre-train CuBERT on a corpus of Python source codes by masked language modeling and next sentence prediction objectives. CodeBERT(Feng et al., 2020) is pre-trained on NL-PL pairs in six programming languages with a new pre-training task, namely replace token detection. GraphCodeBERT (Guo et al., 2020) leverages data flow to enhance code representation, while SYNCOBERT (Wang et al., 2022) incorporates abstract syntax tree by AST edge prediction and contrastive learning. However, encoder-only models require an additional decoder for generation tasks, where this decoder initializes from scratch and cannot benefit from the pre-training.

As for decoder-only pre-trained models, Svyatkovskiy et al. (2020) and Lu et al. (2021) respectively propose GPT-C and CodeGPT, which are both pre-trained using unidirectional language modeling that only allows tokens to attend the previous tokens and itself to predict the next token. Decoder-only models are good at auto-regressive tasks like code completion, but the unidirectional framework is sub-optimal for understanding tasks.

Some recent works explore encoder-decoder models to support both understanding and generation tasks. PLBART (Ahmad et al., 2021) is based on the BART (Lewis et al., 2019) architecture and pre-trained on NL and PL corpus using denoising objectives. CodeT5 (Wang et al., 2021) adapts the T5 (Raffel et al., 2019) model that considers the crucial token type information from identifiers and allow for multi-task learning on downstream tasks. TreeBERT (Jiang et al., 2021) follows the encoder-decoder transformer framework but utilizes the tree structural information by modeling AST paths.

Different from current unified models, UniXcoder is based on a multi-layer Transformer and utilizes mask attention matrices with prefix adapters

```
# Return the sample arithmetic mean of data
def mean(data):
    n = len(data)
    return sum(data) / n
```

Figure 1: A Python code with its comment and AST.

to control the behavior of the model for supporting both understanding and generation tasks. Compared with the encoder-decoder architecture, UniXcoder can be better applied to auto-regressive tasks like code completion that is widely used in IDEs, since the task requires a decoder-only manner to perform efficient inference in practice. Liu et al. (2020) also pre-train a similar model CugLM with multi-task learning, but they only focus on code completion rather than various tasks. Besides, we incorporate syntax information from AST by a one-to-one mapping function that converts an AST into a sequence to enhance code representation. Different from previous pre-trained models that utilize AST, the mapping function retains all structural information from AST and does not require additional pre-training tasks (such as edge prediction) to implicitly learn the AST structure.

3 UniXcoder

In this section, we describe UniXcoder, a unified cross-modal pre-trained model that leverages multi-modal data (i.e. code comment and AST) to pretrain code representation. The model is based on Transformer and utilizes mask attention matrices (Dong et al., 2019) with prefix adapters to control the behavior of the model. In the following, we first introduce how to unify multi-modal data as the input of UniXcoder (§3.1), and then the model architecture (§3.2) and pre-training tasks (§3.3).

3.1 Input Representation

We give an example of a python code with its comment and AST in Figure 1. From the figure, we can see that the comment *"Return the sample arithmetic mean of data"* highly describes the function of the source code, which provides crucial semantic information about the source code. Besides, AST provides rich syntax information, for example, the subtree *"parameters $\rightarrow$ (data)"* indicates the type (i.e., `parameters`) of the term `(data)` in the function definition. Both of them can be used as additional knowledge to enhance code representation in pre-trained models. However, AST is usually expressed as a tree and cannot be used directly as input to Transformer. In order to encode AST in parallel with code comments, we propose a one-to-one mapping function $\mathcal{F}$, described in Algorithm 1, to transform an AST into a sequence that retains all structural information.

Algorithm 1 AST Mapping Function $\mathcal{F}$

Input: The root node $root$ of AST
Output: A flattened token sequence

```
 1: function $\mathcal{F}(root)$
 2:     $seq$ = an empty list
 3:     $name$ = the name of $root$
 4:     if $root$ is a leaf then
 5:         $seq.append(name)$
 6:     else
 7:         $seq.append(name :: left)$
 8:         for $child$ in children of $root$ do
 9:             $seq.extend(\mathcal{F}(child))$
10:         end for
11:         $seq.append(name :: right)$
12:     end if
13: end function
```

Specially, given a root node $root$ of AST, the algorithm recursively applies the same function $\mathcal{F}$ to its children and then add its name with two special suffixes (i.e. $left$ and $right$, respectively) on both sides (line 6-11 of Algorithm 1). If the root node is a leaf, we directly produce its name (line 4-5). Taking *"parameters $\rightarrow$ (data)"* as an example, the mapping function $\mathcal{F}$ transforms the subtree to *"<parameters,left> (data) <parameters,right>"*.

There can be various ways to transform a tree to a sequence of tokens, e.g. pre-order traversal. However, a particular transformation should be a one-to-one mapping function. Otherwise, the mapping may confuse a tree with another structure. Our mapping function $\mathcal{F}$ satisfies this requirement (see Appendix A for a proof). Finally, given a source code C, we take its comment $W = \{w_0, w_1, ..., w_{m-1}\}$ and the flattened AST token sequence $\mathcal{F}(\mathcal{T}(C)) = \{c_0, c_1, ..., c_{k-1}\}$ as input, where $\mathcal{T}(C)$ is the root of the AST of the code. For input format, we concatenate them with a prefix as an input sequence, as shown at the bottom of Figure 2, where the prefix represents the work mode of the model and will be discussed next.

3.2 Model Architecture

Figure 2 shows the model architecture of UniXcoder. The model applies N transformer layers over code comment and flattened AST with a prefix to produce hidden states $H^N = \{h_0^N, h_1^N, ..., h_{n-1}^N\}$, where the prefix $p \in \{[Enc], [Dec], [E2D]\}$ indicates the behavior of the model, e.g. $[E2D]$ means that UniXcoder works as a encoder-decoder model. Each transformer layer contains an architecturally identical transformer that uses a multi-headed self-attention operation (Vaswani et al., 2017) followed by a feed forward layer over the output of the previous layer. For the l-th transformer layer, the output of the multi-headed self-attention is computed via:

$$Q = H^{l-1}W^Q, K = H^{l-1}W^K, V = H^{l-1}W^V \tag{1}$$

$$head = \mathrm{softmax}(\frac{\mathrm{QK^T}}{\sqrt{\mathrm{d_k}}} + \mathrm{M})\mathrm{V} \tag{2}$$

where previous layer's output $H^{l-1} \in \mathbb{R}^{n \times d_h}$ is linearly mapped to a triplet of queries, keys and values respectively. d_k is the dimension of a head, and $M \in \mathbb{R}^{n \times n}$ is a mask matrix to control the context a token can attend to when computing its contextual representation, as shown in the middle of Figure 2. If the i-th token is allowed to attend to the j-th token, then M_{ij} is set to 0 otherwise $-\infty$.

For encoder-only mode, we add a special token $[Enc]$ as the prefix in front of the input and set all elements of the mask matrix as 0 to allow all tokens attend to each other. For decoder-only mode, a prefix $[Dec]$ is used and the upper triangular part of the mask is set to $-\infty$ to indicate that each token can only attend to itself and previous tokens. For encoder-decoder mode, tokens in the source input are allowed to attend to each other, while tokens in the target input only attend to itself and previous tokens in both source and target inputs. We use the $[E2D]$ prefix to indicate that UniXcoder works as an encoder-decoder model. During the pre-training phase, model parameters are shared in different modes and optimized with several objectives to support various types of downstream tasks.

3.3 Pre-training Tasks

We describe the pre-training tasks used in UniXcoder in this section. As shown on the right side of Figure 2, we first pre-train UniXcoder using three tasks, including masked language modeling (Devlin et al., 2018), unidirectional language modeling (Radford et al.) and denoising objective (Raffel et al., 2019). These tasks are designed for different modes, enabling UniXcoder to support various types of code-related downstream tasks. We then propose to utilize multi-modal data to learn code fragment embeddings through contrastive learning with cross-modal generation, as shown in Figure 3.

Masked Language Modeling For encoder-only mode, we follow Devlin et al. (2018) to apply masked language modeling (MLM) pre-training task. Specially, we sample 15% of the tokens S_m from the input sequence, and then replace 80% (10%) of them with a [MASK] (random) token and leave another 10% of them unchanged. The task is to predict original tokens of masked tokens based on their bidirectional contextual tokens, as illustrated in Figure 2 (a). In particular, the model can leverage semantic information from comment and syntax information from AST to infer masked code tokens, which encourages the model to learn code representations from different knowledge resources. The objective is calculated as Equation 3, where X^{mask} is the masked input sequence.

$$loss_{MLM} = -\sum_{x_i \in S_m} logp(x_i|X^{mask}) \tag{3}$$

Unidirectional Language Modeling We use unidirectional language modeling (ULM) pre-training task to pre-train decoder-only mode for supporting auto-regressive tasks like code completion, as shown in Figure 2 (b). The task predicts the next token x_i one by one conditioned on previous tokens and itself $\{x_0, x_1, .., x_{i-1}\}$, which can be done using a triangular matrix for attention mask.

$$loss_{ULM} = -\sum_{i=0}^{n-1} logp(x_i|x_{t<i}) \tag{4}$$

Denoising Objective **De**N**oi**S**ing** (DNS) pre-training objective has been shown to be quite effective for encoder-decoder models like BART (Lewis et al., 2019) and T5 (Raffel et al., 2019) in NLP. The task randomly masks spans with arbitrary lengths and then generates these masked spans in encoder-decoder mode. To better support generation tasks

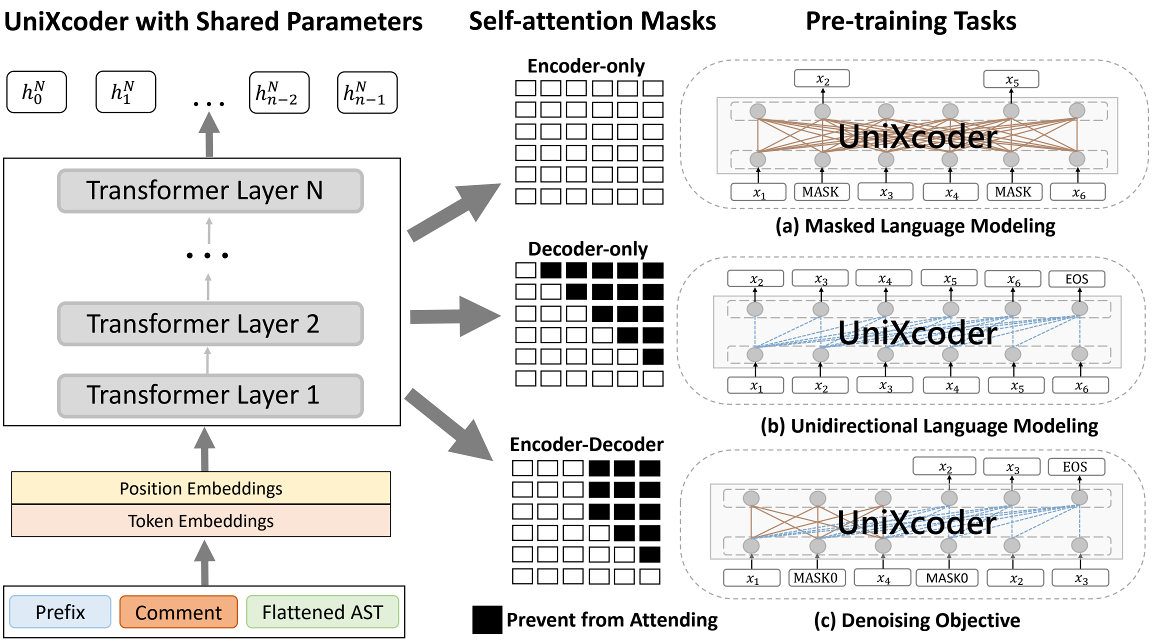

Figure 2: Model architecture of UniXcoder. The model takes comment and flattened AST as the input (more specific input examples can be found in Figure 3). Model parameters are shared in different modes. We use different self-attention masks to control the behavior of the model and use various tasks to pre-train the model, including masked language modeling, unidirectional language modeling, and denoising objective.

like code summarization, we utilize similar denoising objective as T5 for encoder-decoder mode, as illustrated in Figure 2 (c). Specially, we first split the input sequence into $max(\lfloor \frac{n \times r}{l} \rfloor, 1)$ chunks and then randomly mask a span of from 1 to $2l$-1 tokens for each chunk, where n is the length of the input, r is corruption rate and l is the average length of masked spans. We set corruption rate as 15% and the average length as 5, respectively. The concatenation $\{y_0, y_1, ..., y_{n-1}\}$ of all masked spans with special tokens $[MASK_k]$ in front of the k-th span will be used as the output:

$$loss_{DNS} = -\sum_{i=0}^{n-1} logp(y_i|X^{mask}, y_{t<i}) \qquad (5)$$

Code Fragment Representation Learning In addition to the above three pre-training tasks designed for different modes, we propose to utilize multi-modal data to learn semantic embedding $\widetilde{h}_i$ of a code fragment C_i. As shown in Figure 3, we first use UniXcoder to encode a mapped AST sequence and then apply a mean pooling layer over the hidden states of the source input to obtain semantic embedding $\widetilde{h}_i$. In order to learn the semantic embedding, we propose two pre-training tasks. One is multi-modal contrastive learning (MCL), and another is cross-modal generation (CMG).

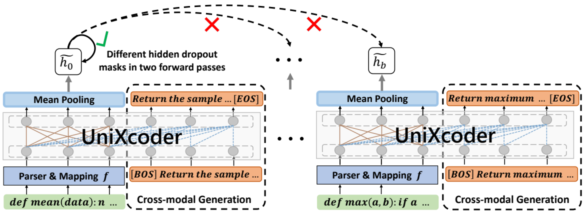

Figure 3: Code fragment representation learning.

For multi-modal contrastive learning, we follow Gao et al. (2021) to forward the same input using different hidden dropout mask as a positive example $\widetilde{h}_i^+$ and use other representations in the same batch as negative examples. The loss is calculated as Equation 6, where b is batch size, τ is a temperature hyperparameter, and $cos(\cdot, \cdot)$ is the cosine similarity between two vectors.

$$loss_{MCL} = -\sum_{i=0}^{b-1} log \frac{e^{cos(\widetilde{h}_i, \widetilde{h}_i^+)/\tau}}{\sum_{j=0}^{b-1} e^{cos(\widetilde{h}_i, \widetilde{h}_j^+)/\tau}} \qquad (6)$$

For cross-modal generation, we ask the model to generate its comment $W = \{w_0, w_1, ..., w_{m-1}\}$. The comment describes the function of the code, which can help the model not only understand the code semantics but align representations among different programming languages by a unified natural language description as a fulcrum. Since the generation of the comment is conditioned on the code, it will force the model to fuse semantic information from the comment into the hidden states of the code. The loss is calculated as Equation 7, where X is the flattened AST token sequence.

$$loss_{CMG} = -\sum_{i=0}^{m-1} logp(w_i|X, w_{t<i}) \quad (7)$$

In order to learn the semantic embedding of natural language, we randomly exchange the source input and the target input with a probability of 50%.

Considering that explicitly adding AST in downstream tasks will introduce extra costs like parsing time and increasing input length (70% longer input length after tokenization), we implicitly learn knowledge from AST by pre-training and only keep leaves of AST (i.e. source code) in the fine-tuning phase. This gap can be alleviated by randomly drop all non-terminal symbols of AST with a probability of 50% in the pre-training phase. More details about pre-training dataset and settings can be found in the Appendix B.

4 Experiments

We evaluate UniXcoder on five tasks over nine public datasets, including two understanding tasks (§4.2), two generation tasks (§4.3) and an auto-regressive task (§4.4). To further evaluate the performance of code fragment embeddings, we also propose a new task called zero-shot code-to-code search (§4.5). More details about datasets and fine-tuning can be found in the Appendix C.

4.1 Baselines

We compare UniXcoder with state-of-the-art pre-trained models, including **encoder-only**, **decoder-only** and **encoder-decoder** models.

For **encoder-only** models, we consider Roberta (Liu et al., 2019) pre-trained on text corpus with MLM, CodeBERT (Feng et al., 2020) pre-trained on NL-PL pairs using both MLM and replaced token detection, GraphCodeBERT (Guo et al., 2020) that leverages data flow to enhance code representation, and SYNCOBERT that incorporates AST by edge prediction and contrastive learning.

For **decoder-only** models, we consider GPT-2 (Radford et al., 2019) and CodeGPT (Lu et al., 2021), where the former one is pre-trained on text corpus and the latter one is pre-trained on CodeSearchNet dataset. Both use ULM as the objective.

For **encoder-decoder** models, we mainly compare the current unified models PLBART (Ahmad et al., 2021) and CodeT5 (Wang et al., 2021). PLBART is based on BART and pre-trained on 470M Python and 210M Java functions, and 47M NL posts from StackOverflow using denoising objective. CodeT5, adapted from T5, considers the crucial token type information from identifiers and allows multi-task learning on downstream tasks.

4.2 Understanding Tasks

Clone Detection The task is to measure the similarity between two code fragments. We conduct experiments on POJ-104 (Mou et al., 2016) and BigCloneBench (Svajlenko et al., 2014) datasets. The first dataset is to predict whether two codes have the same semantics and uses F1-score as the evaluation metric, while the second aims to retrieve semantically similar codes given a code as the query with the Mean Average Precision (MAP) as the metric.

Code Search The task aims to find the most relevant code from a collection of candidates given a natural language query. We conduct experiments on three datasets, namely CSN (Guo et al., 2020), AdvTest (Lu et al., 2021) and CosQA (Huang et al., 2021). CSN dataset is constructed from CodeSearchNet dataset of six programming languages, and low-quality queries are filtered by handcrafted rules. AdvTest normalizes python function and variable names to better test the understanding and generalization capabilities of models. The code base of CosQA is also from CodeSearchNet corpus but queries come from the search logs of Microsoft Bing search engine. We use Mean Reciprocal Rank (MRR) evaluation metric for the task.

Results The results are shown in Table 1. Compared with encoder-only pre-trained models (i.e. the first group) and encoder-decoder models (i.e. the second group), UniXcoder outperforms them and achieves state-of-the-art performance on two tasks on all five datasets. By comparing with the results of ablation studies in the last six rows, we can see that the improvement mainly comes from contrastive learning and the use of multi-modality.

4.3 Generation Tasks

Code Summarization The task aims to generate an NL summary of a code snippet. We use the dataset provided by the CodeXGLUE team (Lu et al., 2021) for this task. We use the smoothed BLEU-4 (Lin and Och, 2004) as the evaluation metric and report overall score of six PLs, including Ruby, JavaScript, Go, Python, Java, and PHP.

Model	Clone Detection				Code Search		
	POJ-104	BigCloneBench			CosQA	AdvTest	CSN
	MAP@R	Recall	Precision	F1-score	MRR		
RoBERTa	76.67	**95.1**	87.8	91.3	60.3	18.3	61.7

Table 1: Results on understanding tasks. **contras** is contrastive learning, **cross-gen** indicates cross-modal generation, and **BFS** (**DFS**) means that our mapping function is replaced by breath-first (deep-first) search algorithm.

Code Generation The task is to generate a code snippet based on an NL description. we use CONCODE (Iyer et al., 2018) dataset, where the input consists of an NL description and code environments. For this task, we use exact match (EM) and BLEU-4 as evaluation metrics.

Model	Summarization	Generation	
	BLEU-4	EM	BLEU-4
RoBERTa	16.57	-	-
CodeBERT	17.83	-	-
GPT-2	-	17.35	25.37
CodeGPT	-	20.10	32.79
PLBART	18.32	18.75	36.69
CodeT5-small	19.14	21.55	38.13

UniXcoder	19.30	**22.60**	38.23
-w/o contras	19.20	22.10	37.69
-w/o cross-gen	19.27	22.20	35.93
-w/o comment	18.97	21.45	37.15
-w/o AST	19.33	22.60	38.52
-using BFS	19.24	21.75	38.21
-using DFS	19.25	22.10	38.06

Table 2: Results on two generation tasks, including code summarization and code generation.

Results From Table 2, UniXcoder achieves comparable performance on generation tasks compared with CodeT5-base and brings a 0.3% improvement in code generation accuracy. However, UniXcoder has slightly worse BLEU-4 scores on both code summarization and generation tasks. The main reasons may come from two aspects. One is the amount of NL-PL pairs in the pre-training data. As shown in the ablation study (see **w/o comment**) in the table, NL-PL pairs bring significant improvement on two tasks. Wang et al. (2021) collect 50% more NL-PL pairs from Github to pre-train CodeT5. Since the collected data is not public, we cannot use it to pre-train UniXcoder for fair comparison. Anothor reason is the model size. CodeT5-base uses a 12-layer encoder and a 12-layer decoder, which is twice larger than other baselines and UniXcoder. Therefore, we also list the results of CodeT5-small using a 6-layer encoder and a 6-layer decoder. We can see that UniXcoder outperforms CodeT5-small.

4.4 Code Completion

We use **PY150** (Raychev et al., 2016) and **Github Java Corpus** (Allamanis and Sutton, 2013) datasets in CodeXGLUE (Lu et al., 2021) for line-level code completion tasks. The task entails the completion of a whole-line of code, and is evaluated using exact match accuracy and Levenshtein edit similarity (Svyatkovskiy et al., 2020).

Model	PY150		JavaCorpus	
	EM	Edit Sim	EM	Edit Sim
Transformer	38.51	69.01	17.00	50.23
GPT-2	41.73	70.60	27.50	60.36
CodeGPT	42.37	71.59	30.60	63.45
PLBART	38.01	68.46	26.97	61.59

-using DFS	42.61	71.97	32.87	65.75

Table 3: Results of code completion task.

In practice, the task requires a decoder-only manner to perform efficient inference. Therefore, we first compare our UniXcoder with decoder-only models (the first group) in Table 3. As we can see, UniXcoder achieves comparable performance on

Model	Ruby			Python			Java			Overall
	Ruby	Python	Java	Ruby	Python	Java	Ruby	Python	Java	
CodeBERT	13.55	3.18	0.71	3.12	14.39	0.96	0.55	0.42	7.62	4.94

Table 4: MAP score (%) of zero-shot setting on code-to-code search task.

both datasets and brings absolute 2.3% gain of accuracy on java corpus, which demonstrates the effectiveness of our model for code completion. Besides, we also compare with current unified models (the second group). Since they are based the encoder-decoder framework, we fine-tune their decoders by feeding a placeholder into the encoder. Results show that UniXcoder outperforms PLBART and CodeT5, which demonstrates our model framework is better applied to code completion tasks.

4.5 Zero-shot Code-to-Code Search

To further evaluate the performance of code fragment embeddings, we also propose a new task called zero-shot code-to-code search. Given a source code as the query, the task aims to retrieve codes with the same semantics from a collection of candidates in zero-shot setting. The task can help users translate from one PL to another by retrieving source codes with the same semantics. We collect 11,744/15,594/23,530 functions from the CodeNet corpus (Puri et al., 2021) in Ruby/Python/Java PL. Each function solves one of 4,053 problems. We take each function as a query and retrieve all functions that solve the same problem from each PL. We use average MAP score as the evaluation metric. More details about the dataset and an example can be found in Appendix C.6.

We re-implement the publicly released pre-trained models on this task using the mean vector or CLS vector of last hidden states and report the results in Table 4. The first row is the query PL and the second row is the target PL. From the table, we can see that UniXcoder achieves state-of-the-art performance and about 11 points improvement on the overall score compared with GraphCodeBERT. Ablation studies further show that both multi-modal data and code fragment representation pre-training tasks can enhance UniXcoder.

4.6 Model Analysis

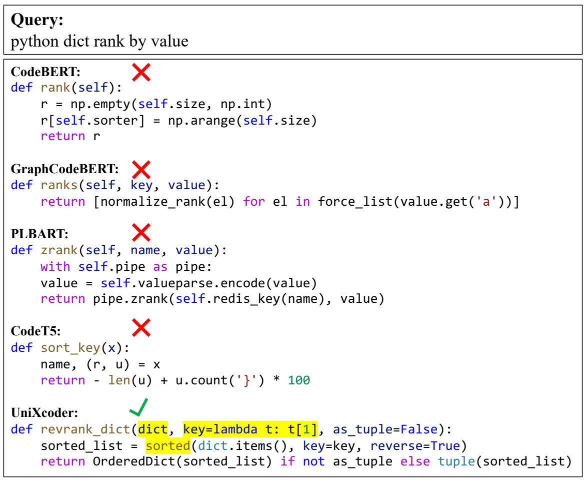
The Effect of Representation Pre-training We conduct ablation study to analyze the effect of code fragment representation pre-training tasks by removing contrastive learning task (**w/o constras**) and cross-modal generation task (**w/o cross-gen**). As we can see in Table 1 and 4, two pre-training tasks significantly improve understanding tasks. Taking zero-shot code-code search task as an example, after removing contrastive learning, the performance drops from 20.45% to 13.73%. Besides, the two pre-training tasks also bring a small improvement on generation tasks, as shown in Table 2 and 3. Overall, the ablation study demonstrates the effectiveness of the two pre-training tasks.

The Effect of Multi-modal Data We also study the effect of multi-modal data. By removing comment (**w/o comment**), the results from Tables indicate that code comment plays an important role in both understanding and generation tasks. For AST (**w/o AST**), we observe that injecting AST can boost the performance on all code understanding tasks. However, AST does not bring improvements on generation tasks, which may require a better way to incorporate AST for generation tasks. Overall, AST and comment can both improve UniXcoder.

Comparison of Traversal Algorithms We compare our mapping function with other mapping functions used to map a tree into a sequence, namely BFS and DFS algorithms. As we can see, after replacing our mapping function by BFS or DFS algorithms, the performance of UniXcoder drops on both understanding and generation tasks, which demonstrates the effectiveness of our mapping function. In particular, using BFS or DFS algorithms even hurt the performance of UniXcoder on some tasks by comparing **w/o BFS (DFS)** with

w/o AST. The main reason may be that BFS and DFS algorithms are not one-to-one mapping functions and can confuse a tree with another structure.

Case Study We also conduct a case study to intuitively demonstrate the effectiveness of UniXcoder, as shown in Figure 4. We give an example for code search task on CosQA dataset and output predictions from different models. The input query from the search logs of Microsoft Bing search engine is *"python dict rank by value"*. We know that the intent of the user is to sort a dictionary by its value in Python language. Although the prediction from PLBART has higher lexical overlap than UniXcoder like *"rank"* and *"value"*, the function is incorrect since the input of the ground truth should be a dictionary. We can see that UniXcoder retrieves a correct function whose input is a dictionary. Besides, although the *"value"* in the query is expressed as the statement *"key=lambda t: t[1]"* in the function definition, UniXcoder can understand the code semantics and successfully retrieves the ground truth, which demonstrates the effectiveness of UniXcoder.



Query:
python dict rank by value

CodeBERT: ✗
```python
def rank(self):
    r = np.empty(self.size, np.int)
    r[self.sorter] = np.arange(self.size)
    return r
```

GraphCodeBERT: ✗
```python
def ranks(self, key, value):
    return [normalize_rank(el) for el in force_list(value.get('a'))]
```

PLBART: ✗
```python
def zrank(self, name, value):
    with self.pipe as pipe:
    value = self.valueparse.encode(value)
    return pipe.zrank(self.redis_key(name), value)
```

CodeT5: ✗
```python
def sort_key(x):
    name, (r, u) = x
    return - len(u) + u.count('}') * 100
```

UniXcoder: ✓
```python
def revrank_dict(dict, key=lambda t: t[1], as_tuple=False):
    sorted_list = sorted(dict.items(), key=key, reverse=True)
    return OrderedDict(sorted_list) if not as_tuple else tuple(sorted_list)
```

Figure 4: An examples for code search task on CosQA dataset and predictions from different models. Key clues are marked in yellow.

5 Conclusion

To support both code-related understanding and generation tasks, we present UniXcoder, a unified pre-trained model that incorporates semantic and syntax information from code comment and AST. We propose a one-to-one mapping method to transform AST to a sequence structure and two new pre-training tasks to learn code fragment representation. To further investigate the performance of code representation, we propose a new downstream task of zero-shot code-to-code search and create a dataset for this task. Experiments show that UniXcoder significantly outperforms previous works on most tasks. Further ablation studies also show that both AST and code comment can enhance UniXcoder and reveal the effectiveness of our proposed mapping function and pre-training tasks.

A Proof for Mapping Function

In this section, we show that the function $\mathcal{F}$ described in Algorithm 1 is a one-to-one mapping function. using a **proof by induction**.

Lemma 1: Given a tree $\mathcal{T}$ and the mapped sequence $\mathcal{F}(\mathcal{T}) = \{x_1, x_2, ..., x_m\}$, the first element x_0 is the root of $\mathcal{T}$ with a *left* suffix and the last element x_m is the root of $\mathcal{T}$ with a *right* suffix.

Lemma 2: An internal node only occurs twice in the mapped sequence $\mathcal{F}(\mathcal{T})$. One is with *left* suffix, and the other is with *right* suffix. Therefore, the sequence has the same number of elements with *left* suffix and *right* suffix.

Lemma 3: Since a node with a *left* suffix occurs before the same node with a *right* suffix (see line 7 and 11 of the Algorithm), an element x_i with a *right* suffix must match another element x_j with a *left* suffix (i.e. coming from the same node in the tree) in the left side, i.e. $j < i$.

Proof: In order to prove $\mathcal{F}$ is a one-to-one function, given two trees $\mathcal{T}_1$ and $\mathcal{T}_2$, we need to prove that $\mathcal{F}(\mathcal{T}_1) \neq \mathcal{F}(\mathcal{T}_2)$ if $\mathcal{T}_1 \neq \mathcal{T}_2$. For easier proof, we prove its equivalent contrapositive statement, i.e. $\mathcal{T}_1 = \mathcal{T}_2$ if $\mathcal{F}(\mathcal{T}_1) = \mathcal{F}(\mathcal{T}_2)$.

Base case: When the depth h of $\mathcal{T}_1$ is 1, $\mathcal{T}_1$ only has a node r and $\mathcal{F}(\mathcal{T}_1) = \{r\}$. Since $\mathcal{F}(\mathcal{T}_2) = \mathcal{F}(\mathcal{T}_1)$, $\mathcal{T}_2$ contains one node, otherwise the length of $\mathcal{F}(\mathcal{T}_2)$ will be more than 2. Since $\mathcal{F}(\mathcal{T}_2) = \{r\}$, the root of $\mathcal{T}_2$ is also r. Therefore, $\mathcal{T}_1 = \mathcal{T}_2$ and $\mathcal{F}$ is a one-to-one function for $h = 1$.

Inductive hypothesis: When $h = 2, 3, .., n$, suppose $\mathcal{F}$ is a one-to-one function.

Inductive step: Now, we prove that the hypothesis is true for $h = n + 1 \geq 2$.

We let $\mathcal{F}(\mathcal{T}_1) = \{x_1, x_2, ..., x_m\}$, where x_j is a leaf or a node with a *left* (or *right*) suffix. Since $\mathcal{F}(\mathcal{T}_1) = \mathcal{F}(\mathcal{T}_2)$, the first elements of two mapped sequences are same as each other. According to Lemma 1, $\mathcal{T}_1$ and $\mathcal{T}_2$ have the same root.

Let the leftmost subtree of $\mathcal{T}_1$ and $\mathcal{T}_2$ as $\mathcal{T}_{s_1}$ and $\mathcal{T}_{s_2}$, respectively. We prove $\mathcal{T}_{s_1} = \mathcal{T}_{s_2}$ now. According to the Algorithm, we know that $\mathcal{F}(\mathcal{T}_{s_1})$ and $\mathcal{F}(\mathcal{T}_{s_2})$ start with x_2 and end with one element. Suppose $\mathcal{F}(\mathcal{T}_{s_1}) = \{x_2, .., x_i\}$ and $\mathcal{F}(\mathcal{T}_{s_2}) = \{x_2, .., x_j\}$. According to Lemma 1 and 2, $S = \{x_3, .., x_i\}$ has one more element with a *right* suffix. Therefore, x_0 must match one element x_k ($3 \leq k \leq i$) in S, otherwise there will be an element with a *right* suffix that cannot match any element. If $i \neq j$ (suppose $j > i$), x_0 will match x_j according to Lemma 1. However, the root node occurs three times x_0, x_k and x_j, which will contradict Lemma 2. Therefore, we get that $i = j$ and $\mathcal{F}(\mathcal{T}_{s_1}) = \mathcal{F}(\mathcal{T}_{s_2})$. According to the hypothesis, we get that $\mathcal{T}_{s_1} = \mathcal{T}_{s_2}$, since the depth of $\mathcal{F}(\mathcal{T}_{s_1})$ is less than $n + 1$. In the same way, it can be proved that other subtrees of $\mathcal{T}_1$ and $\mathcal{T}_2$ are also the same. Thus, we get that $\mathcal{T}_1 = \mathcal{T}_2$.

Conclusion: By the principle of induction, it follows that the hypothesis is true for all $h \geq 2$ and our mapping function is one-to-one.

B Pre-training Setting

UniXcoder uses 12 layers of Transformer with 768 dimensional hidden states and 12 attention heads. We follow Liu et al. (2019) to train a byte-pair encoding vocabulary (Sennrich et al., 2015) with 50K subword units for programming languages and add 1,416 additional special tokens into the vocabulary to represent non-terminal symbols in AST. The pre-training multi-modal data we use includes 2.3M functions paired with comments from CodeSearchNet dataset (Husain et al., 2019) for six programming languages (i.e. ruby, java, python, php, go and javascript). We leverage tree-sitter[2] as the parser to extract AST from PL.

We pre-train the model on 4 DGX-2 machines, each having 16 NVIDIA Tesla V100 with 32GB memory. During pre-training, we set both the max length of input sequence and batch size as 1024, and use the Adam optimizer to update model parameters with 2e-4 learning rate. As proven in Feng et al. (2020), unimodal data like text is also useful for code-related downstream tasks. Therefore, we first pre-train our UniXcoder with MLM, ULM and denoising objective on C4 dataset (Raffel et al., 2019) and 4.1M unimodal code from CodeSearchNet for 500k and 200k steps, respectively.

---

Table 5: Results of code search task over six programming languages.

We further pre-train on the multi-modal data with all pre-training objectives for 100k steps. The total time for pre-training UniXcoder is about 8 days. At each iteration, we alternate each objective to pre-train the model and follow Guo et al. (2020) to sample each batch from the same programming language according to a distribution $\{q_i\}_{i=1...N}$ as Equation 8, where n_i is number of examples for i-th programming language and α=0.7. Sampling with this distribution could alleviates the bias towards high-resource languages.

$$q_i = \frac{p_i^\alpha}{\sum_{N}^{j=1} p_j^\alpha}, \quad p_i = \frac{n_i}{\sum_{N}^{k=1} n_k} \tag{8}$$

C Fine-tuning Setting

C.1 Clone Detection

Clone detection aims to measure the similarity between two code fragments. We conduct experiments on POJ-104 (Mou et al., 2016) and BigCloneBench (Svajlenko et al., 2014) datasets.

For POJ-104 dataset, it consists of 104 problems and includes 500 C/C++ programs for each problem. The datasets are splited into 64/16/24 problems for training, validation, and testing, and the task aims to retrieve other programs that solve the same problem given a program. The probability of true clone is calculated by cosine similarity between two mean vectors of last hidden states of UniXcoder. We set the learning rate as 2e-5, the batch size as 8, and the max sequence length as 400. We use the Adam optimizer to fine-tune the model for 2 epochs.

For BigCloneBench dataset, we use the dataset provided by Lu et al. (2021), which includes 901,724/416,328/416,328 examples from 10 different functionalities for training/validation/testing. Following previous works, we also treat the task as a binary classification to fine-tune UniXcoder. The true clone probability of two inputs is calculated by cosine similarity between the mean vectors of last hidden states. In the fine-turning step, we set the learning rate as 5e-5, the batch size as 16, and the max sequence length as 512. We update model parameters using the Adam optimizer and perform early stopping on the development set.

C.2 Code Search

Code search aims to search the most relevant code from a collection of candidates given a natural language query. We conduct experiments on three datasets, namely CSN (Guo et al., 2020), AdvTest (Lu et al., 2021) and CosQA (Huang et al., 2021).

Language	Training	Dev	Testing	Candidates
Go	167,288	7,325	8,122	28,120
Java	164,923	5,183	10,955	40,347
JavaScript	58,025	3,885	3,291	13,981
PHP	241,241	12,982	14,014	52,660
Python	251,820	13,914	14,918	43,827
Ruby	24,927	1,400	1,261	4,360

Table 6: Data statistics about CSN dataset provided by Guo et al. (2020). **Training/Dev/Testing** means the number of query for training/validation/testing dataset.

For CSN dataset, it is constructed from CodeSearchNet dataset for six languages but filter lowquality queries by handcrafted rules. We list data statistics about the dataset in Table 6. We set the learning rate as 2e-5, the batch size as 64, and the max sequence length of PL and NL as 256 and 128, respectively. We use the Adam optimizer to fine-tune the model for 10 epochs and perform early stopping on the development set. In Table 5, we also give more detailed results of different models for each programming language.

For AdvTest dataset, it comes form Python lan-

Model	Ruby	Javascript	Go	Python	Java	Php	Overall
RoBERTa	11.70	11.90	17.72	18.14	16.47	24.02	16.57
CodeBERT	12.16	14.90	18.07	19.06	17.65	25.16	17.83
GraphCodeBERT	12.39	14.81	18.41	18.06	19.00	25.59	18.04
PLBART	14.11	15.56	18.91	19.30	18.45	23.58	18.32
CodeT5-base	**15.24**	**16.16**	**19.56**	**20.01**	20.31	26.03	**19.55**
UniXcoder	14.87	15.85	19.07	19.13	20.31	26.54	19.30
-w/o contras	14.72	15.41	19.16	19.01	20.30	26.60	19.20
-w/o cross-gen	14.90	15.96	18.60	19.06	**20.50**	26.62	19.27
-w/o comment	14.25	15.50	18.80	18.83	20.25	26.17	18.97
-w/o AST	15.09	15.97	19.04	19.16	20.07	**26.67**	19.33
-using BFS	14.74	15.69	18.97	19.03	20.58	26.45	19.24
-using DFS	14.81	15.88	18.98	19.15	20.26	26.40	19.25

Table 7: Results of code summarization task over six programming languages.

guage of CSN dataset but Lu et al. (2021) normalizes python function and variable names to better test the understanding and generalization abilities of models. We use the same hyper-parameters as CSN dataset but fine-tune the model for 2 epochs.

For CosQA dataset, Huang et al. (2021) use 20,604 search logs of the Microsoft Bing search engine as queries and each log is annotated by at least 3 human annotators. We use the same hyper-parameters as CSN dataset but fine-tune the model.

For the three datasets, we all use cosine similarity between two mean vectors of last hidden states as relevant scores and take other vectors in the same batch as negative examples.

C.3 Code Summarization

Code summarization aims to generate an NL summary of a code snippet. We use the dataset provided by CodeXGLUE team (Lu et al., 2021) for this task. The dataset includes six programming languages, including Ruby, JavaScript, Go, Python, Java, and PHP. We list data statistics about the dataset in Table 8. We set the learning rate as 5e-5, the batch size as 48, and the max sequence length of source and target as 256 and 128, respectively. We use the Adam optimizer to fine-tune the model for 10 epochs and perform early stopping on the development set. For inference, we set beam size as 10. In Table 7, we also give more detailed results of different models for each programming language.

Language	Training	Dev	Testing
Go	167,288	7,325	8,122
Java	164,923	5,183	10,955
JavaScript	58,025	3,885	3,291
PHP	241,241	12,982	14,014
Python	251,820	13,914	14,918
Ruby	24,927	1,400	1,261

Table 8: Data statistics about the dataset for the code summarization task.

C.4 Code Generation

Code generation aims to generate a code snippet based on an NL description. We use CONCODE (Iyer et al., 2018) dataset, which is collected from about 33k Java projects on GitHub. It contains 100k/2k/2k examples for training/validation/testing. Each example consists of an NL description, code environments and code snippets. The environment is provided by the rest of the class, including member variables and member functions in the class. We set the learning rate as 5e-5, the batch size as 32, and the max sequence length of source and target as 350 and 150, respectively. We use the Adam optimizer to fine-tune the model for 30 epochs and perform early stopping on the development set. For inference, we set beam size as 3.

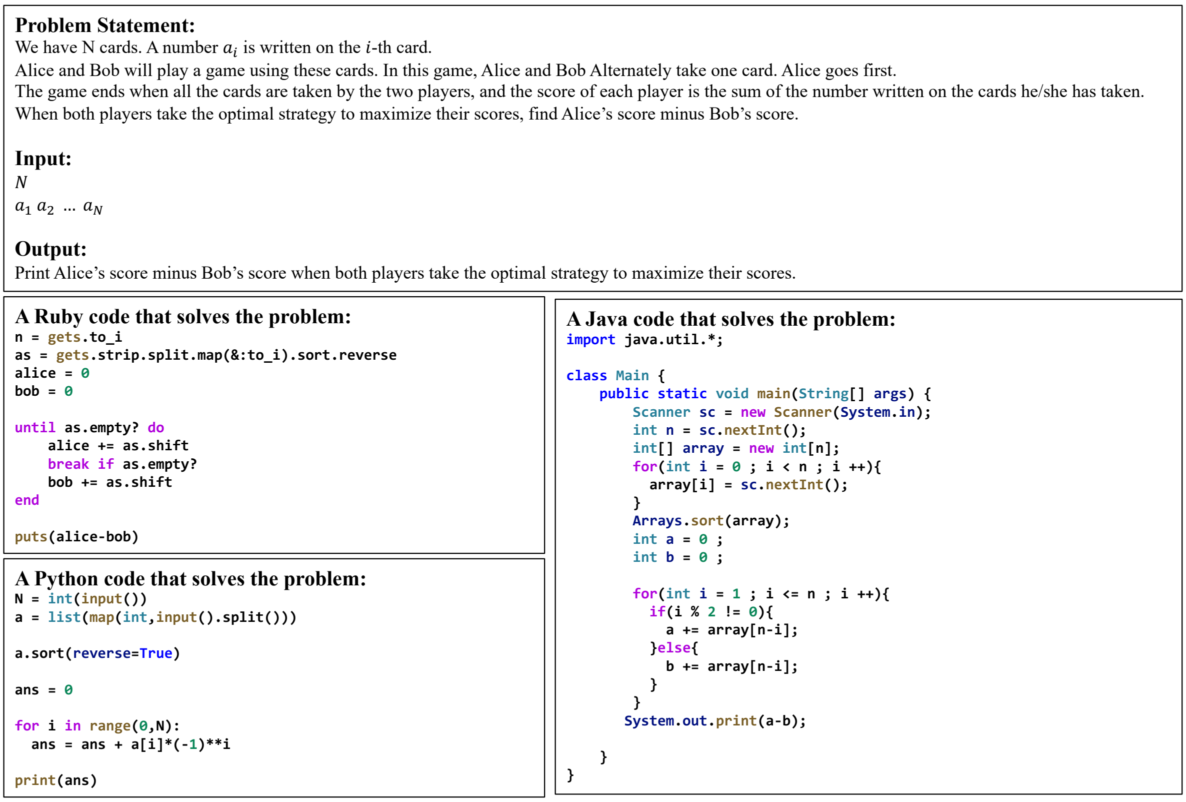
C.5 Code Completion

In this paper, we mainly focus on line-level code completion. We use **PY150** (Raychev et al., 2016) and **Github Java Corpus** (Allamanis and Sutton, 2013) provided by CodeXGLUE (Lu et al., 2021).

PY150 is a Python dataset (Raychev et al., 2016) containing 150,000 Python source files collected from Github. Lu et al. (2021) create 10,000 examples from different files in the test set of PY150 for testing and select lines to be predicted at random. The average number of tokens in input and output are 489.11 and 6.56, respectively.

Github Java Corpus is collected by Allamanis and Sutton (2013) over 14 thousand Java projects from Github. Lu et al. (2021) create 3,000 examples for testing from different files in the test set of the corpus. The average numbers of tokens are 350.62 and 10.49 in input and output, respectively.

For two datasets, we both follow Lu et al. (2021) to use the same CodeSearchNet dataset to fine-tune



Problem Statement:

We have N cards. A number a_i is written on the i-th card.

Alice and Bob will play a game using these cards. In this game, Alice and Bob Alternately take one card. Alice goes first.

The game ends when all the cards are taken by the two players, and the score of each player is the sum of the number written on the cards he/she has taken.

When both players take the optimal strategy to maximize their scores, find Alice's score minus Bob's score.

Input:

N

$a_1\ a_2\ \dots\ a_N$

Output:

Print Alice's score minus Bob's score when both players take the optimal strategy to maximize their scores.

A Ruby code that solves the problem:

```ruby
n = gets.to_i
as = gets.strip.split.map(&:to_i).sort.reverse
alice = 0
bob = 0

until as.empty? do
    alice += as.shift
    break if as.empty?
    bob += as.shift
end

puts(alice-bob)
```

A Python code that solves the problem:

```python
N = int(input())
a = list(map(int,input().split()))

a.sort(reverse=True)

ans = 0

for i in range(0,N):
  ans = ans + a[i]*(-1)**i

print(ans)
```

A Java code that solves the problem:

```java
import java.util.*;

class Main {
    public static void main(String[] args) {
        Scanner sc = new Scanner(System.in);
        int n = sc.nextInt();
        int[] array = new int[n];
        for(int i = 0 ; i < n ; i ++){
          array[i] = sc.nextInt();
        }
        Arrays.sort(array);
        int a = 0 ;
        int b = 0 ;

        for(int i = 1 ; i <= n ; i ++){
          if(i % 2 != 0){
            a += array[n-i];
          }else{
            b += array[n-i];
          }
        }
       System.out.print(a-b);

    }
}
```

Figure 5: An example for zero-shot code-to-code search. Three codes for Ruby, Python and Java all solve the same problem mentioned in the Figure. Therefore, they have same semantics in different programming languages.

UniXcoder for 10 epochs. We set the learning rate for **PY150** as 2e-4 and for **Java Corpus** as 2e-5. The batch size is 32 and the max sequence length is 1024. For inference, we set beam size as 5.

C.6 Zero-shot Code-to-Code Search

To evaluate the performance of code fragment embeddings, we propose a new task, called zero-shot code-to-code search. Given a source code as the query, the task aims to retrieve codes with the same semantics from a collection of candidates in zero-shot setting. We give an example in Figure 5.

We collect 11,744/15,594/23,530 functions from CodeNet corpus (Puri et al., 2021) for Ruby/Python/Java PL. Each function solves one of 4,053 problems. The task is to take each function as the query and retrieve functions that solves the same problem from each PL. In zero-shot testing, we set the max sequence length as 512 and use cosine similarity between two mean vectors of last hidden states as relevant scores. We then sort the candidates by the scores to calculate MAP score.

One Country, 700+ Languages: NLP Challenges for Underrepresented Languages and Dialects in Indonesia

Abstract

NLP research is impeded by a lack of resources and awareness of the challenges presented by underrepresented languages and dialects. Focusing on the languages spoken in Indonesia, the second most linguistically diverse and the fourth most populous nation of the world, we provide an overview of the current state of NLP research for Indonesia's 700+ languages. We highlight challenges in Indonesian NLP and how these affect the performance of current NLP systems. Finally, we provide general recommendations to help develop NLP technology not only for languages of Indonesia but also other underrepresented languages.

1 Introduction

Research in natural language processing (NLP) has traditionally focused on developing models for English and a small set of other languages with large amounts of data (see Figure 1, bottom right). While the lack of data is generally cited as the key reason for the lack of progress in NLP for underrepresented languages (Hu et al., 2020; Joshi et al., 2020), we argue that another factor relates to the diversity and the lack of understanding of the linguistic characteristics of such languages. Through the lens of the languages spoken in Indonesia, the world's second-most linguistically diverse country, we seek to illustrate the challenges in applying NLP technology to such a diverse pool of languages.

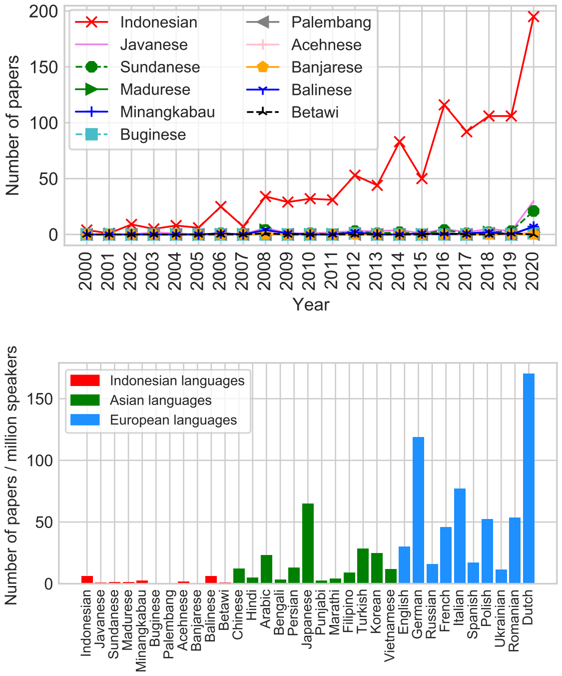

Figure 1: Following Joshi et al. (2020), we compile ACL Anthology to count the distribution of published works that mention languages spoken in Indonesia. **Top:** Distribution of papers in 20 years. **Bottom:** Number of papers per a million speakers. We compare languages spoken in Europe, Asia, and Indonesia.

Indonesia is the 4th most populous nation globally, with 273 million people spread over 17,508 islands. There are more than 700 languages spoken in Indonesia, equal to 10% of the world's languages, second only to Papua New Guinea (Eberhard et al., 2021). However, most of these languages are not well documented in the literature; many are not formally taught, and no established standard exists across speakers (Novitasari et al., 2020). Many of them are decreasing in use, as Indonesian (*Bahasa Indonesia*), the national language, is more frequently used as the primary language across the country. This process may ultimately result in a monolingual society (Cohn and Ravindranath, 2014).

Among more than 700 Indonesian local languages, many are threatened. 440 languages are listed as endangered and 12 as extinct according to data from Ethnologue (Eberhard et al., 2021) illustrated in Figure 2. Anindyatri and Mufidah (2020) found nearly half of a sample of 98 Indonesian local languages to be endangered while van Esch et al. (2022) observed 71 among 151 Indonesian local languages to have less than 100k speakers.

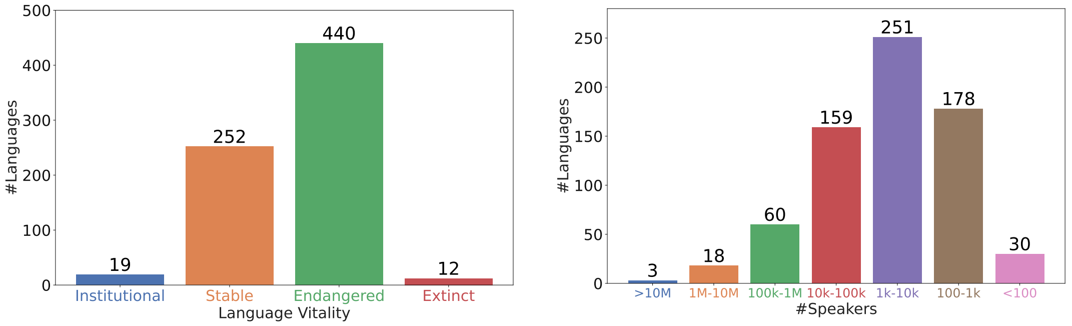

Figure 2: Distribution of 700+ languages spoken in Indonesia according to Ethnologue (Eberhard et al., 2021). **Left:** Language vitality. **Right:** Speaker count.

Language	**ISO**	**# Speakers**
Indonesian	ind	198 M
Javanese	jav	84 M
Sundanese / Sunda	sun	34 M
Madurese / Madura	mad	7 M
Minangkabau	min	6 M
Buginese	bug	6 M
Betawi	bew	5 M
Acehnese / Aceh	ace	4 M
Banjar	bjn	4 M
Balinese	ban	3 M
Palembang Malay (Musi)	mus	3 M

Table 1: The number of speakers for Indonesian and top-10 most spoken local languages in Indonesia (Eberhard et al., 2021).

Table 1 lists the names of the 10 most spoken local languages in Indonesia (Eberhard et al., 2021). Javanese and Sundanese are at the top with 84M and 34M speakers, respectively, while Madura, Minangkabau, and Buginese each have around 6M speakers. Despite their large speaker populations, these local languages are poorly represented in the NLP literature. Compared to Indonesian, the number of research papers mentioning these languages has barely increased over the past 20 years (Figure 1, top). Furthermore, compared to their European counterparts, Indonesian languages are drastically understudied (Figure 1, bottom). This is true even for Indonesian, which has nearly 200M speakers.

Language technology should be accessible to everyone in their native languages (European Language Resources Association, 2019), including Indonesians. In the context of Indonesia, language technology research offers some benefits. First, language technology is a potential peacemaker tools in a multi-ethnic country, helping Indonesians understand each other better and avoid the ethnic conflicts of the past (Bertrand, 2004). On a larger scale, language technology promotes language use (European Language Resources Association, 2019) and helps language preservation. Despite these benefits, following Bird (2020), we recommend a careful assessment of individual usage scenarios of language technology, so they are implemented for the good of the local population.

For language technology to be useful in the Indonesian context, it additionally has to account for the dialects of local languages. Language dialects in Indonesia are influenced by the geographical location and regional culture of their speakers (Vander Klok, 2015) and thus often differ substantially in morphology and vocabulary, posing challenges for NLP systems. In this paper, we provide an overview of the current state of NLP for Indonesian and Indonesia's hundreds of languages. We then discuss the challenges presented by those languages and demonstrate how they affect state-of-the-art systems in NLP. We finally provide recommendations for developing better NLP technology not only for the languages in Indonesia but also for other underrepresented languages.

2 Background and Related Work

2.1 History and Taxonomy

Indonesia is one of the richest countries globally in terms of linguistic diversity. More than 400 of its languages belong to the Austronesian language family, while the others are Papuan languages spoken in the eastern part of the country. As shown in Figure 3, the Austronesian languages in Indonesia belong to three main groups: Western-Malayo-Polynesian (WMP), Central-Malayo-Polynesian (CMP), and South-Halmahera-West-New-Guinea (SHWNG) (Blust, 1980). WMP languages are Malay, Indonesian, Javanese, Sundanese, Balinese, and Minangkabau, among others. All languages mentioned in Table 1 are in this group. Lan-

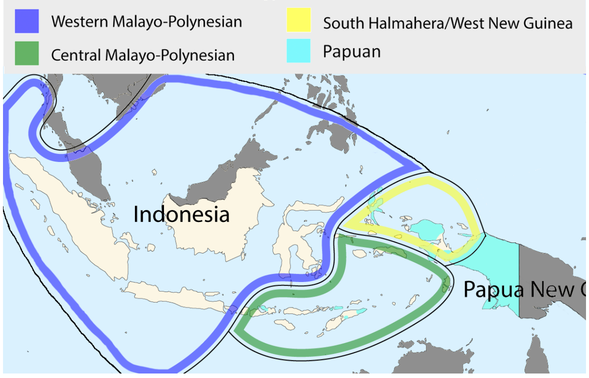

Figure 3: Map of Austronesian and Papuan languages in Indonesia.

guages belonging to CMP are languages of the Lesser Sunda Islands from East Sumbawa (with Bimanese) onwards to the east, and languages of the central and southern Moluccas (including the Aru Islands and the Sula Archipelago). The SHWNG group consists of languages of Halmahera and Cenderawasih Bay, and further-flung regions such as the Mamberamo River and the Raja Ampat Islands. Meanwhile, the Papuan languages are mainly spoken in Papua, such as Dani, Asmat, Maybrat, and Sentani. Some Papuan languages are also spoken in Halmahera, Timor, and the Alor Archipelago (Palmer, 2018; Ross, 2005).

Most Austronesian linguists and archaeologists agree that the original 'homeland' of Austronesian languages must be sought in Taiwan and, prior to Taiwan, in coastal South China (Adelaar, 2005; Bellwood et al., 2011). In the second millennium CE, the Austronesian people moved from Taiwan to the Philippines. From the Philippines, they moved southward to Borneo and Sulawesi. From Borneo, they migrated to Sumatra, the Malay Peninsula, Java, and even to Madagascar. From Sulawesi, they moved southward to the CMP area and eastward to the SHWNG area. From there, they migrated to Oceania and Polynesia, as far as New Zealand, Easter Island, and Hawaii (Gray and Jordan, 2000). The people that lived in insular Southeast Asia, such as in the Philippines and Indonesia, before the arrival of Austronesians were Australo-Melanesians (Bellwood, 1997). Gradual assimilation with Austronesians occurred, although some pre-Austronesian groups still survive, such as Melanesian people in eastern Indonesia (Ross, 2005; Coupe and Kratochvíl, 2020).

At the time of the arrival of the first Europeans, Malay had become the major language (lingua franca) of interethnic communication in Southeast Asia and beyond (Steinhauer, 2005; Coupe and Kratochvíl, 2020). It functioned as the language of trade and the language of Islam because Muslim merchants from India and the Middle East were the first to introduce the religion into the harbor towns of Indonesia. After the arrival of Europeans, Malay was used by the Portuguese and Dutch to spread Catholicism and Protestantism. When the Dutch extended their rule over areas outside Java in the nineteenth century, the importance of Malay increased, and thus, the first standardization of the spelling and grammar occurred in 1901, based on Classical Malay (Abas, 1987; Sneddon, 2003). In 1928, the Second National Youth Congress participants proclaimed Malay (henceforth called Indonesian) as the unifying language of Indonesia. During World War II, the Japanese occupying forces forbade all use of Dutch in favor of Indonesian, which from then onward effectively became the new national language. From independence until the present, Indonesian has functioned as the primary language in education, mass media, and government activities. Many local language speakers are increasingly using Indonesian with their children because they believe it will aid them to attain a better education and career (Klamer, 2018).

2.2 Efforts in Multilingual Research

Recently, pretrained multilingual language models such as mBERT (Devlin et al., 2019), mBART (Liu et al., 2020), and mT5 (Xue et al., 2021b) have been proposed. Their coverage, however, focuses on high-resource languages. Only mBERT and mT5 include Indonesian local languages, i.e., Javanese, Sundanese, and Minangkabau, but with comparatively little pretraining data.

Some multilingual datasets for question answering (TyDiQA; Clark et al., 2020), common sense reasoning (XCOPA; Ponti et al., 2020), abstractive summarization (Hasan et al., 2021), passage ranking (mMARCO; Bonifacio et al., 2021), cross-lingual visual question answering (xGQA; Pfeiffer et al., 2021), language and vision reasoning (MaRVL; Liu et al., 2021), paraphrasing (ParaCotta; Aji et al., 2021), dialogue systems (XPersona & BiToD; Lin et al., 2021a,b), lexical normalization (MultiLexNorm; van der Goot et al., 2021), and machine translation (FLORES-101; Guzmán et al., 2019) include Indonesian but most others do not, and very few include Indonesian local languages. An exception is the weakly supervised named entity recognition dataset, WikiAnn (Pan et al., 2017), which covers several Indonesian local languages, namely Acehnese, Javanese, Minangkabau, and Sundanese.

Parallel corpora including Indonesian local languages are: (i) CommonCrawl; (ii) Wikipedia parallel corpora like MediaWiki Translations;[1] and WikiMatrix (Schwenk et al., 2021) (iii) the Leipzig corpora (Goldhahn et al., 2012), which include Indonesian, Javanese, Sundanese, Minangkabau, Madurese, Acehnese, Buginese, Banjar, and Balinese; and (iv) JW-300 (Agić and Vulić, 2019), which includes dozens of Indonesian local languages, e.g., Batak language groups, Javanese, Dayak language groups, and several languages in Nusa Tenggara. Recent studies, however, have raised concerns regarding the quality of such multilingual corpora for underrepresented languages (Caswell et al., 2022).

2.3 Progress in Indonesian NLP

NLP research on Indonesian has occurred across multiple topics, such as POS tagging (Wicaksono and Purwarianti, 2010; Dinakaramani et al., 2014), NER (Budi et al., 2005; Rachman et al., 2017; Gunawan et al., 2018), sentiment analysis (Naradhipa and Purwarianti, 2011; Lunando and Purwarianti, 2013; Wicaksono et al., 2014), hate speech detection (Alfina et al., 2017; Sutejo and Lestari, 2018), topic classification (Winata and Khodra, 2015; Kusumaningrum et al., 2016), question answering (Mahendra et al., 2008; Fikri and Purwarianti, 2012), machine translation (Yulianti et al., 2011; Simon and Purwarianti, 2013; Hermanto et al., 2015), keyphrases extraction (Saputra et al., 2018; Trisna and Nurwidyantoro, 2020), morphological analysis (Pisceldo et al., 2008), and speech recognition (Lestari et al., 2006; Baskoro and Adriani, 2008; Zahra et al., 2009). However, many of these studies either did not release the data or used non-standardized resources with a lack of documentation and open source code, making them extremely difficult to reproduce.

Recently, Wilie et al. (2020), Koto et al. (2020b, 2021), and Cahyawijaya et al. (2021) collected Indonesian NLP resources as benchmark data. Others have also begun to create standardized labeled data for Indonesian NLP, e.g. the works of Kurniawan and Aji (2018), Guntara et al. (2020), Koto et al. (2020a), Khairunnisa et al. (2020), and Mahendra et al. (2021).

On the other hand, there has been very little work on local languages. Several works studied stemming (Sundanese (Suryani et al., 2018); Balinese (Subali and Fatichah, 2019)) and POS Tagging (Madurese; Dewi et al., 2020). Koto and Koto (2020) built a Indonesian Minangkabau parallel corpus and also sentiment analysis resources for Minangkabau. Other works developed machine translation systems between Indonesian and local languages, e.g., Sundanese (Suryani et al., 2015), Buginese (Apriani et al., 2016), Dayak Kanayatn (Hasbiansyah et al., 2016), and Sambas Malay (Ningtyas et al., 2018).

Tanaya and Adriani (2016, 2018) studied Javanese character segmentation in non-Latin script. Safitri et al. (2016) worked on spoken data language identification in Minangkabau, Sundanese, and Javanese, while Azizah et al. (2020) developed end-to-end neural text-to-speech models for Indonesian, Sundanese, and Javanese. Nasution et al. (2017, 2021) proposed an approach for bilingual lexicon induction and evaluated the approach on seven languages, i.e., Indonesian, Malay, Minangkabau, Palembang Malay, Banjar, Javanese, and Sundanese.

Cahyawijaya et al. (2021) established a machine translation benchmark in Sundanese and Javanese using Bible data. Wibowo et al. (2021) studied a family of colloquial Indonesian, which is influenced by some local languages via morphological transformation, and Putri et al. (2021) worked on abusive language and hate speech detection on Twitter for five local languages, namely Javanese, Sundanese, Madurese, Minangkabau, and Musi.

3 Challenges for Indonesian NLP

3.1 Limited Resources

Monolingual Data Unlabeled corpora are crucial for building large language models, such as GPT-2 (Radford et al., 2019) or BERT (Devlin et al., 2019). Available unlabeled corpora such as Indo4B (Wilie et al., 2020), and Indo4B-Plus (Cahyawijaya et al., 2021) mainly include data in Indonesian, with the latter containing ≈10% of data in Javanese and Sundanese.

In comparison, in multilingual corpora such as CC–100 (Conneau et al., 2020), Javanese and Sundanese data accounts for only 0.001% and 0.002% of the corpus size respectively while in mC4 (Xue

---

[1] https://mediawiki.org/wiki/Content_translation

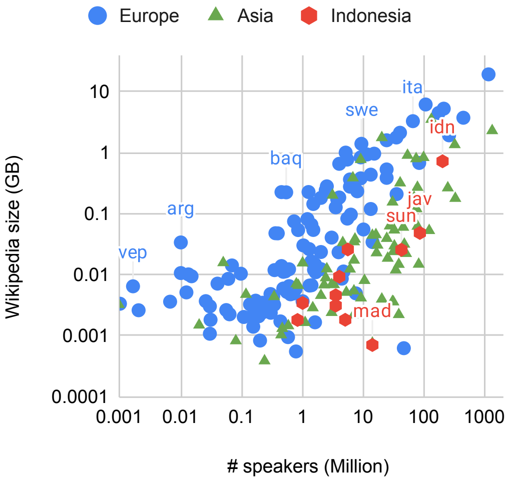

Figure 4: Relationship between the number of speakers and the size of data in Wikipedia for languages spoken in Europe, Asia, and Indonesia.

et al., 2021b), there are only 0.6M Javanese and 0.3M Sundanese tokens out of a total of 6.3T tokens. In addition, we measure data availability in Wikipedia compared to the number of speakers in Figure 4.[2] Much less data is available for the languages spoken in Indonesia, compared to European languages with similar numbers of speakers. For example, Wikipedia contains more than 3 GB of Italian articles but less than 50 MB of Javanese articles, despite both languages having a comparable number of speakers. Similarly, Sundanese has less than 25 MB of articles, whereas languages with comparable numbers of speakers have more than 1.5 GB of articles. Similar trends hold for most other Asian languages. Languages in Africa are even more underrepresented in terms of Wikipedia data (see Appendix B).

Beyond the highly spoken local languages, most other Indonesian local languages do not have Wikipedia instances, in contrast to European languages with few speakers. It is very difficult to find alternative sources for high-quality text data for other local languages of Indonesia (such as news websites), as most such sources are written in Indonesian. Resources in long-tail languages are even more scarce due to a very low number of speakers. Moreover, most of the languages in the long tail are mainly used in a spoken context, making text data challenging to obtain. These statistics demonstrate that collecting unlabeled corpora for Indonesian local languages is extremely difficult. This makes it impractical to develop strong pretrained language models for these languages, which have been the foundation for many recent NLP systems.

Labeled Data Most work on Indonesian NLP (see §2) has not publicly released the data or models, limiting reproducibility. Although recent Indonesian NLP benchmarks are addressing this issue, they mostly focus on the Indonesian language (see Appendix F). Some widely spoken local languages such as Javanese, Sundanese, or Minangkabau have extremely small labeled datasets compared to Indonesian, while others have barely any.

The lack of such datasets makes NLP development for the local languages difficult. However, constructing new labeled datasets is still challenging due to: (1) the lack of speakers of some languages; (2) the vast continuum of dialectical variation (see §3.2.1); and (3) the absence of writing standard in most local languages (see §3.3).

3.2 Language Diversity

The diversity of Indonesian languages is not only reflected in the large number of local languages but also the large number of dialects of these languages (§3.2.1). Speakers of local languages also often mix languages in conversation, which makes colloquial Indonesian more diverse (§3.2.2). In addition, some local languages are more commonly used in conversational contexts, so they do not have consistent writing forms in written media (§3.3).

3.2.1 Regional Dialects and Style Differences

Indonesian local languages often have multiple dialects, depending on the geographical location. Local languages of Indonesian spoken in different locations might be different (have some lexical variation) to one another, despite still being categorized as the same language (Fauzi and Puspitorini, 2018). For example, Anderbeck (2008) showed that villages across the Jambi province use different dialects of Jambi Malay. Similarly, Kartikasari et al. (2018) showed that Javanese between different cities in central and eastern Java could have more than 50% lexical variation, while Purwaningsih (2017) showed that Javanese in different districts in the Lamongan has up to 13% lexical variation. Similar studies have been conducted on other languages, such as Balinese (Maharani and Candra, 2018) and Sasak (Sarwadi et al., 2019).

---

[2] The number of speakers is collected from Wikidata (Vrandečić and Krötzsch, 2014), from the `number of speakers (P1098)` property as of Nov 7th, 2021, while the size is collected from the 20211101 Wikipedia dump.

English	**Mudung Laut**	**Dusun Teluk**	**Mersam**	**Suo Suo**	**Teluk Kuali**	**Lubuk Telau**	**Bunga Tanjung**	**Pulau Aro**

he/she	dioʔ	dioʔ, ɲo	ɲo	kau	ɲo	ɲo	ɲo	iɲo
if	kalu	jiko, kalu	kalu	bilao	kalu	jiko	koʔ	kalu
one	satu	sekoʔ	sekoʔ	sekoʔ	ciʒʔ	sekoʔ	sekoʔ, so	sekoʔ

Table 2: Lexical variation of Jambi Malay across different villages in Jambi (Anderbeck, 2008).

English	**Context**	**Ngoko**			**Krama**
		Western	Central	Eastern	Eastern
I/me	I like to eat fried rice.	inyong, enyong	aku	aku	kulo
You	Where will you go?	rika, kowe, ko	kowe, siro, sampeyan	koen, awakmu, sampeyan	panjenengan
How	How do I read this?	priwe	piye	yo'opo	pripun
Why	Why is this door broken?	ngapa	ngopo	opo'o	punapa
Will	Where will you go?	arep	arep	kate, ate	badhe
Not/no	The calculation is not correct.	ora	ora	gak	mboten

Table 3: Lexical variations of Javanese dialects and styles across different regions of the Java island. Native speakers are asked to translate the words, given the context.

Style	**Region**	**Model**				
		langid.py		**FastText**		**CLD3**
		Top-1	Top-3	Top-1	Top-3	Top-1
Ngoko	Western	0.241	0.621	0.069	0.379	0.759
Ngoko	Central	0.345	0.690	0.379	0.724	0.828
Ngoko	Eastern	0.276	0.552	0.103	0.379	0.552
Krama	Eastern	0.345	0.759	0.379	0.586	0.897

Table 4: Language identification accuracy based on different Javanese dialects and styles. Systems do not perform equally well across dialects and styles.

Moreover, Indonesian and its local languages have multiple styles, even within the same dialect. One factor that affects style is the level of politeness and formality—similar to Japanese and other Asian languages (Bond and Baldwin, 2016). More polite language is used when speaking to a person with a higher social position, especially to elders, seniors, and sometimes strangers. Different politeness levels manifest in the use of different honorifics and even different lexical terms.

To illustrate the distinctions between regional dialects and styles, we highlight common words and utterances across dialects and styles in Jambi Malay and Javanese in Tables 2 and 3 respectively. For Jambi Malay, we sample the result from a prior work (Anderbeck, 2008). For Javanese, we ask native speakers to translate basic words into three regional dialects: Western, Central, and Eastern Javanese, and two different styles: *Ngoko* (standard, daily-use Javanese) and *Krama* (polite Javanese, used to communicate to elders and those with higher social status). However, since contemporary *Krama* Javanese is not very different among regions, we only consider *Krama* from the Eastern speakers' perspective.

Jambi Malay has many dialects across villages. As shown in Table 2, many common words are spoken differently across dialects and styles. Similarly, Javanese is also different across regions. Not every Javanese speaker understands *Krama*, since its usage is very limited. Moreover, the number of Javanese speakers who can use *Krama* is declining (Cohn and Ravindranath, 2014).[3] Examples from other languages are shown in Appendix D.

Case Study in Javanese

Dialectical and style differences pose a challenge to NLP systems. To explore the extent of this challenge, we conduct an experiment to test the robustness of NLP systems to variations in Javanese dialects. We ask native speakers[4] to translate 29 simple sentences into Javanese according to the specified dialect and style. We then evaluate several language identification systems on those instances. Language identification is a core part of multilingual NLP and a necessary step for collect-

---

[3] *Krama* is used to speak formally (e.g., with older or respected people). However, people prefer to use Indonesian more in a formal situation. People who move from sub-urban areas to bigger cities tend to continue to use *Ngoko* and thus also pass *Ngoko* on to their children.

[4] Our annotators are based in Banyumas, Jogjakarta, and Jember for Western, Central, and Eastern Javanese respectively. Using dialects from different cities might yield different results.

Colloquial Indonesian	Translation
Ada yang **ngetag** foto **lawas** di FB	Someone is tagging old photos in FB
Quotenya Andrew Ng ini relevan **banget**	This Andrew Ng quote is very relevant
Bilo kita pergi main lagi?	When will we go play again?
Ini **teh** aksara jawa kenapa susah **banget**?	Why is this Javanese script very difficult?

Table 5: Colloquial Indonesian code-mixing examples from social media. Color code: English, Betawinese, Javanese, Minangkabau, Sundanese, Indonesian.

Language	Meaning	Written Variation	IPA
Javanese (Eastern–*Ngoko*)	what	apa / opo	/ɔpɔ/
	there is	ana / ono / onok	/ɔnɔʔ/
	you	kon / koen	/kɔn/
Balinese (Alus–*Singgih*)	yes	inggih / nggih	/ʔŋgih/
	I / me	tiang / tyang	/tiaŋ/
	<greeting>	swastyastu / swastiastu	/swastiastu/
Sundanese (Badui–*Loma*)	please / sorry	punten / punteun	/puntən/
	red	beureum / berem	/bərɨm/
	salivating	ngacai / ngacay	/ŋacaɪ/

Table 6: Written form variations in several local languages, confirmed by native speakers.

ing textual data in a language. Despite its importance, it is an open research area, particularly for underrepresented languages (Hughes et al., 2006, Caswell et al., 2022).

We compare langid.py (Lui and Baldwin, 2012), FastText (Joulin et al., 2017), and CLD3.[5] The results can be seen in Table 4. In general, the language identification systems are more accurate in detecting Javanese texts in the *Ngoko*-Central dialect, or *Krama*, since the systems were trained on Javanese Wikipedia data, which is written in either the *Ngoko*-Central or *Krama* dialects and styles. If an NLP system can only detect certain dialects, then this information should be conveyed explicitly. Problems arise if we assume that the model works equally well across dialects. For example, in the case of language identification, if we use the model to collect datasets automatically, then Javanese datasets with poor-performing dialects will be underrepresented in the data.

3.2.2 Code-Mixing

Code-mixing is an occurrence where a person speaks alternately in two or more languages in a conversation (Sitaram et al., 2019, Winata et al., 2018, 2019b, Doğruöz et al., 2021). This phenomenon is common in Indonesian conversations (Barik et al., 2019, Johanes et al., 2020, Wibowo et al., 2021). In a conversational context, people sometimes mix their local languages with standard Indonesian, resulting in colloquial Indonesian (Siregar et al., 2014). This colloquial-style Indonesian is used daily in speech and conversation and is common on social media (Sutrisno and Ariesta, 2019). Some frequently used code-mixed words (especially on social media) are even intelligible to people that do not speak the original local languages. Interestingly, code-mixing can also occur in border areas where people are exposed to multiple languages, therefore mixing them together. For example, people in Jember (a regency district in East Java) combine Javanese and Madurese in their daily conversation (Haryono, 2012).

Indonesian code-mixing not only occurs at the word level but also at the morpheme level (Winata, 2021). For example, *quotenya* (“his/her quote”, see Table 5) combines the English word *quote* and the Indonesian suffix *-nya*, which denotes possession; similarly, *ngetag* combines the Betawinese prefix *nge-* and the English word *tag*. More examples can be found in Table 5.

3.3 Orthography Variation

Many Indonesian local languages are mainly used in spoken settings and have no established standard orthography system. Some local languages do originally have their own archaic writing systems that derive from the Jawi alphabet or Kawi script, and even though standard transliteration into the Roman alphabet exists for some (e.g., Javanese and Sundanese), they are not widely known and practiced (Soeparno, 2015). Hence, some words have multiple romanized orthographies that are mutually intelligible, as they are pronounced the same. Some examples can be seen in Table 6. Such a variety of written forms is common in local languages in Indonesia. This variation leads to a significantly larger vocabulary size, especially for NLP systems that use word-based representations, and presents a challenge to constrain the representations for different spellings of the same word to be similar.

3.4 Societal Challenges

Language evolves together with the speakers. A more widely used language may have a larger digital presence, which fosters a more written form of communication, while languages that are used only

---

[5] https://github.com/google/cld3

within small communities may emphasize the spoken form. Some languages are also declining, and speakers may prefer to use Indonesian rather than their local language. In contrast, there are isolated residents that use the local language daily and are less proficient in Indonesian (Nurjanah et al., 2018, Jahang and Meirina, 2021). These variations give rise to different requirements, and there is no single solution for all.

Technology and education are not well-distributed within the nation. Internet penetration in Indonesia is 73.7% in 2020 but is mainly concentrated on Java. Among the non-Internet users, 39% explain that they do not understand the technology, while 15% state that they do not have a device to access the Internet.[6] In some areas where the Internet is not seen as a basic need, imposing NLP technology on them may not necessarily be relevant. At the same time, general NLP development within the nation faces difficulties due to the lack of funding, especially in universities outside of Java. GPU servers are still scarce, even in top universities in the country.[7]

The dynamics of population movement in Indonesia also need to be taken into consideration. For example, urban communities transmigrate to remote areas for social purposes, such as teaching or becoming doctors for underdeveloped villages. Each of these situations might call for various new NLP technologies to be developed to facilitate better communication.

4 Opportunities

Based on the challenges for Indonesian NLP highlighted in the previous section, we formulate proposals for improving the state of Indonesian NLP research, as well as of other underrepresented languages. Our proposals cover several aspects including metadata documentation; potential research directions; and engagement with communities.

4.1 Better Documentation

In line with studies promoting proper data documentation for NLP research (Bender and Friedman, 2018, Rogers et al., 2021, Alyafeai et al., 2021, McMillan-Major et al., 2022), we recommend the following considerations.

Regional Dialect Metadata We have shown that a local language can have large variation depending on the region and the dialect. Therefore, we suggest adding regional dialect metadata to NLP datasets and models, not only for Indonesian but also for other languages. This is particularly important for languages with large dialectical differences. It also helps to clearly communicate NLP capabilities to stakeholders and end-users as it will help set an expectation of what dialects the systems can handle. Additionally, regional metadata can indirectly inform topics present in the data, especially for crawled data sources.

Style and Register Metadata Similarly, we also suggest adding style and register metadata. This metadata can capture the politeness level of the text, not only for Indonesian but also in other languages. In addition, this metadata can be used to document the formality level of the text, so it may be useful for research on modeling style or style transfer.

4.2 Potential Research Directions

Among the most spoken local languages, a lot of research has been done on mainstream NLP tasks such as hate-speech detection, sentiment analysis, entity recognition, and machine translation. Some research has even been deployed in production by industry. Many of the languages, however, are not widely spoken and under-explored. Focusing on these languages, we suggest future research direction as follows.

Data-Efficient NLP Pretrained language models, which have taken the NLP world by storm, require an abundance of monolingual data. However, data collection has been a long-standing problem for low-resource languages. Therefore, we recommend more exploration into designing data-efficient approaches such as adaptation methods (Artetxe et al., 2020, Aji et al., 2020, Gururangan et al., 2020, Koto et al., 2021, Kurniawan et al., 2021), few-shot learning (Winata et al., 2021, Madotto et al., 2021, Le Scao and Rush, 2021), and learning from related languages (Khanuja et al., 2021, Khemchandani et al., 2021). The goal of these methods is effective resource utilization, that is, to minimize the financial costs for computation and data collection as advocated by Schwartz et al. (2020), Cahyawijaya (2021), and Nityasya et al. (2021).

---

[6] The Indonesian Internet Providers Association (APJII) survey: https://apjii.or.id/survei2019x

[7] For instance, we estimate the whole CS Faculty of the country's top university to have fewer than 10 GPUs.

Data Collection Data collection efforts need to be commenced as soon as possible, despite all the challenges (§3.1). Here, we suggest collecting parallel data between Indonesian and each of the local languages for several reasons. First, a lot of Indonesians are bilingual (Koto and Koto, 2020), that is, they speak both Indonesian and their local language, which facilitates data collection. Moreover, the fact that the local languages have some vocabulary overlap with Indonesian (see Table 7 in the Appendix) might help facilitate building translation systems with relatively little parallel data (Nguyen and Chiang, 2017). Finally, having such parallel data, we can build translation systems for synthetic data generation. In line with this approach, the effectiveness of models trained on synthetic translated data can be explored.

Compute-Efficient NLP The costly GPU requirement for current NLP models hinders adoption by local research institutions and industries. Instead of focusing on building yet another massive model, we suggest focusing on developing lightweight and fast neural architectures, for example through distillation (Kim et al., 2019; Sanh et al., 2019; Jiao et al., 2020), model factorization (Winata et al., 2019a) or model pruning (Voita et al., 2019). We also recommend research on more efficient training mechanisms (Aji and Heafield, 2017; Diskin et al., 2021). In addition, non-neural methods are still quite popular in Indonesia. Therefore, further research on the trade-off between the efficiency and quality of the models is also an interesting research direction.

Robustness to Code-mixing and Non-Standard Orthography Languages in Indonesia are prone to variations due to code-mixing and non-standard orthography, which occurs on the morpheme or even grapheme level. Models that are applied to Indonesian code-mixed data need to be able to learn morphologically faithful representations. Therefore, we recommend more explorations on methods derived from subword tokenization (Gage, 1994; Kudo, 2018) and token-free models (Gillick et al., 2016; Tay et al., 2021; Xue et al., 2021a) to deal with this problem. This problem is also explored by Tan and Joty (2021) in an adversarial setting.

NLP Beyond Text For many Indonesian local languages that are rarely if ever written, speech is a more natural communication format. We thus recommend more attention on less text-focused research, such as spoken language understanding (Chung et al., 2021; Serdyuk et al., 2018), speech recognition (Besacier et al., 2014; Winata et al., 2020a,b), and multimodality (Dai et al., 2020, 2021) in order to improve NLP for such languages.

4.3 Engagement with Communities

As discussed in §3.4, it is difficult to generalize a solution across local languages. We thus encourage the NLP community, such as the Indonesian Association of Computational Linguistics (INACL)[8] to work more closely with native speakers and local communities. Local communities who work on linguistics such as *Polyglot Indonesia*,[9] *Merajut Indonesia*,[10] and *Masyarakat Linguistik Indonesia*[11] would be relevant collaborators to provide solutions and resources that support use cases benefiting the native speakers and communities of underrepresented languages. We advise the involvement of linguists, for example, to aid the language documentation process (Anastasopoulos et al., 2020). We also support open-science movements such as BigScience[12] or ICLR CoSubmitting Summer[13] to help start collaborations and reduce the barrier to entry to NLP research.

5 Conclusion

In this paper, we highlight challenges in Indonesian NLP. Indonesia is one of the most populous countries and the second-most linguistically diverse country of the world, with over 700 local languages, yet Indonesian NLP is underrepresented and underexplored. Based on the observed challenges, we also present recommendations to improve the situation, not only for Indonesian but also for other underrepresented languages.

Acknowledgments

We are grateful to Alexander Gutkin and Ling-Yen Liao for valuable feedback on an earlier draft of this paper. We also thank the anonymous reviewers for their helpful feedback. Lastly, we acknowledge the support of Kata.ai in this work.

A Language Statistics

In Figure 5, we contrast the count of publications related to Indonesian languages compared to European languages. Although there are many more Indonesian speakers than most European languages, the amount of published research relating to Indonesian is still comparatively lower than for European languages.

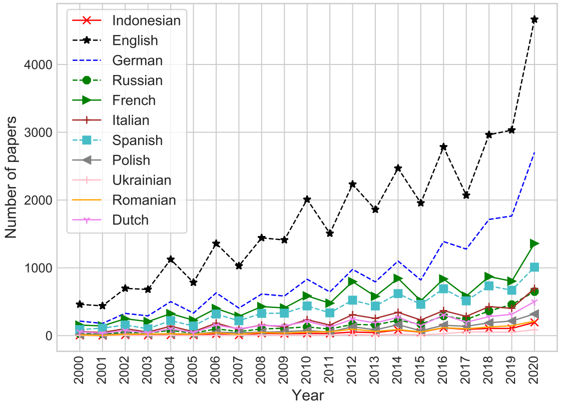

Figure 5: Count of published papers per year on Indonesian and European languages from 2000 to 2020.

B Wikipedia Availability

In Figure 6, we compare Wikipedia size (in GB file size) compared to the number of speakers for various languages. We show that some African and indigenous American languages are even more under-resourced.

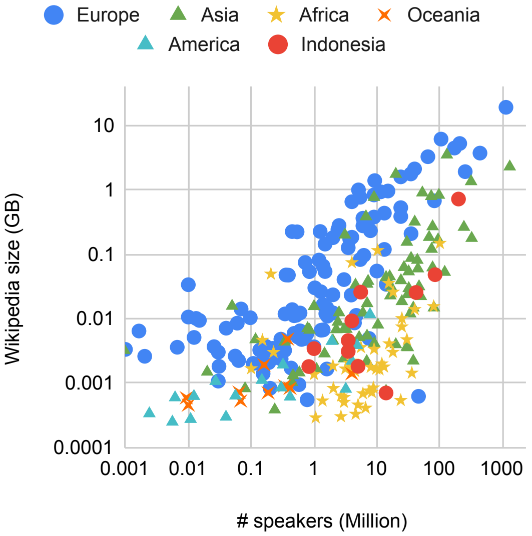

Figure 6: Wikipedia data size (in GB) compared to the number of speakers among Indonesia and different regions across the world.

C Wikipedia Vocabulary Overlap

In Table 7, we present vocabulary statistics for Indonesian languages based on Wikipedia. Due to the noisy nature of Wikipedia, we use "*Kamus Besar Bahasa Indonesia*" (KBBI) third edition,[14] the official dictionary for the Indonesian language to filter out the top 1% and top-100 most frequent words. As expected, the top 1% words are less reliable, with only 59.3% of vocabulary overlap between `id` and KBBI. In the top-100 words, there is a 96% word overlap with KBBI, making this set more reliable. Previous work on Minangkabau by Koto and Koto (2020) also showed that `id-min` words have a 55% overlap in a manually curated bilingual dictionary, closer to the top-100 value for `min` in Table 7.

Lang	**# Vocab**		
	All (k)	Top 1% ∩ KBBI (%)	Top 100 ∩ KBBI (%)
ind	2023	59.3	**96**
jav	435	46.8	43
sun	286	44.3	47
min	252	30.3	41
bug	23	35.7	27
map-bms	14	76.7	79
gor	12	40.5	49
ace	12	37.6	46
ban	10	43.3	46
bjn	4	62.9	69
nia	1	25.9	30
mad	1	26.9	24

Table 7: Vocabulary of Indonesian languages in Wikipedia, filtered with KBBI third edition.[15]

D Dialect Differences

In this section, we present more examples of lexical variations in local Indonesian languages. Maharani and Candra (2018) and Sarwadi et al. (2019) show lexical variations in Balinese and Sasak, respectively, where they asked locals to translate general/common words. Then, they compared the vocabulary across different locations (in this case, villages) to each other. Some of the examples can be seen in Tables 8 and 9. Unfortunately, they did not provide quantitative results. Pamolango (2012) conducted a similar experiment in the Banggai district of South Sulawesi across 31 observation points for the Saluan language. While Pamolango (2012)

---

[15] KBBI is the official Indonesian dictionary.

English	Kedonganan	Jimbaran	Unggasan
I/me	Tyang	Tyang	Aku
You	Béné	Béné	Éngko
Umbrella	Pajéng	Pajéng	Pajong
Hat	Capil	Topong	Cecapil, Tetopong
How	Engken	Engken	Kengen
Where	Dijé	Dijé	Di joho
All	Konyangan	Onyé	Konyangan, onyang
Swallow (vb)	Gélék, ngélék	Gélék, ngélék	Ngélokang
Scratch (vb)	Gagas	Gagas	Gauk
Cough (vb)	Kokoan	Dékah	Kohkohan
Dawn	Plimunan	Plimunan	Sémongan
Afternoon	Sanjé	Sanjé	Sanjano

Table 8: Lexical variation of Balinese across different villages in South Kuta district, Bali (Maharani and Candra, 2018)

English	Pemenang Timur	Jenggala	Genggelang	Kayangan	Akar-Akar
Here	Ite	ite	ite	ite	tinI
There	Ito	ito	ito	ito	tinO
You	diʔ	sita	diʔ	sita	diʔ
Husband	kurənan	sawa	sawa	sawa	sawa
No	deʔ	deʔ	deʔ	deʔ	soraʔ
Paddle	bose	bose	dayung	dayung	bose
Spear	tɜr	cinəkan	tɜr	tombak	tombak
Black	birəɳ	birəɳ	birəɳ	birəɳ	pisak
Red	bənəɳ	bənəɳ	bənəɳ	bənəɳ	abaɳ
White	putɜʔ	putɜʔ	putɜʔ	putɜʔ	pətak
Worm	gumbər	loɳa	gumbər	gumbər	gumbər

Table 9: Lexical variation of Sasak across different villages in North Lombok district (Sarwadi et al., 2019)

did not provide full examples, they reported up to 23.5% lexical variation among 200 basic vocabulary items.

E Local Language Classification

As shown in Table 10, some Javanese texts are misidentified as Indonesian, English, and Malay. This is because Javanese and Indonesian (which is similar to Malay) share some words. We believe English misclassification is due to the data size bias.

F Indonesian NLP Resources

In Table 11, we present the list of existing monolingual and parallel corpora in Indonesian and local languages. Table 12 shows the list of publicly available NLP datasets for Indonesian. Table 13 shows the list of NLP tools and resources for Indonesian. Table 14 shows the list of publicly available NLP datasets for local languages spoken in Indonesia.

Although the volume of data in local languages is much smaller than that for Indonesian, these resource collections are arguably beneficial for constructing resources in other local languages. This is because: (1) Indonesian can be used as a pivot language with regard to local languages, due to the large vocabulary overlap (see Table 7); and 2) most Indonesians are bilingual, speaking both Indonesian and their local language (Koto and Koto, 2020).

Dialect/		**Class**

Is GPT-3 Text Indistinguishable from Human Text?
SCARECROW: A Framework for Scrutinizing Machine Text

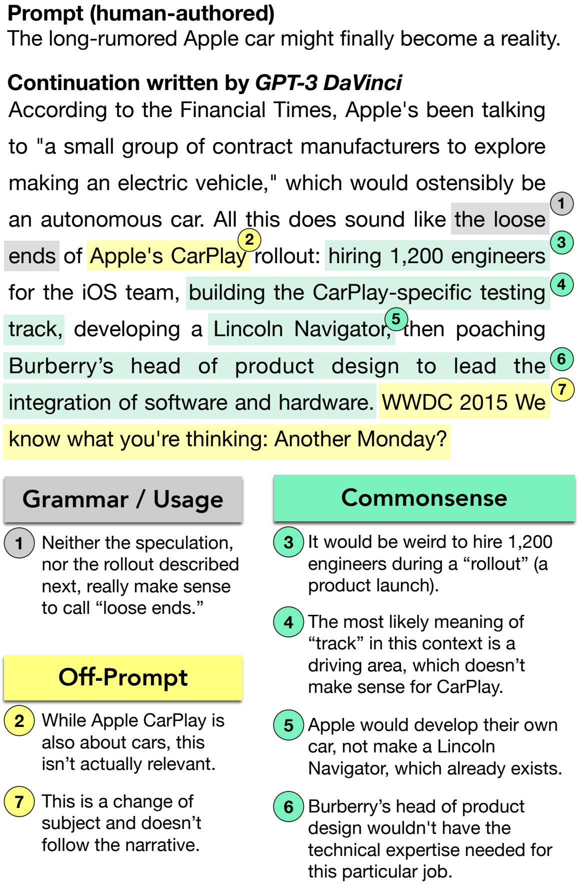
Abstract

Modern neural language models can produce remarkably fluent and grammatical text. So much, in fact, that recent work by Clark et al. (2021) has reported that conventional crowdsourcing can no longer reliably distinguish between machine-authored (GPT-3) and human-authored writing. As errors in machine generations become ever subtler and harder to spot, it poses a new challenge to the research community for robust machine text evaluation.

We propose a new framework called SCARECROW for scrutinizing machine text via crowd annotation. To support the broad range of real machine errors that can be identified by laypeople, the ten error categories of SCARECROW—such as **redundancy**, **commonsense errors**, and **incoherence**—are identified through several rounds of crowd annotation experiments without a predefined ontology.

We then use SCARECROW to collect over 41k error spans in human-written and machine-generated paragraphs of English language news text. We isolate factors for detailed analysis, including parameter count, training data, and various decoding-time configurations. Our approach successfully quantifies measurable gaps between human authored text and generations from models of several sizes, including fourteen configurations of GPT-3. In addition, our analysis unveils new insights, with detailed rationales provided by laypeople, e.g., that the commonsense capabilities have been improving with larger models while math capabilities have not, and that the choices of simple decoding hyperparameters can make remarkable differences on the perceived quality of machine text. We release our training material, annotation toolkit and dataset at **`https://yao-dou.github.io/scarecrow/`**.

1 Introduction



Prompt (human-authored)
The long-rumored Apple car might finally become a reality.

Continuation written by *GPT-3 DaVinci*
According to the Financial Times, Apple's been talking to "a small group of contract manufacturers to explore making an electric vehicle," which would ostensibly be an autonomous car. All this does sound like the loose ① ends of Apple's CarPlay ② rollout: hiring 1,200 engineers ③ for the iOS team, building the CarPlay-specific testing ④ track, developing a Lincoln Navigator, ⑤ then poaching Burberry's head of product design to lead the ⑥ integration of software and hardware. WWDC 2015 We ⑦ know what you're thinking: Another Monday?

Grammar / Usage

① Neither the speculation, nor the rollout described next, really make sense to call "loose ends."

Off-Prompt

② While Apple CarPlay is also about cars, this isn't actually relevant.

⑦ This is a change of subject and doesn't follow the narrative.

Commonsense

③ It would be weird to hire 1,200 engineers during a "rollout" (a product launch).

④ The most likely meaning of "track" in this context is a driving area, which doesn't make sense for CarPlay.

⑤ Apple would develop their own car, not make a Lincoln Navigator, which already exists.

⑥ Burberry's head of product design wouldn't have the technical expertise needed for this particular job.

Figure 1: After a model (here, GPT-3 DaVinci) has read the prompt (top sentence) and generated a continuation (next paragraph), the SCARECROW annotation framework provides a systematic way for humans to mark issues throughout the text and explain what is wrong. Our own annotations are pictured here.

Clark et al. (2021) demonstrated the challenges of human evaluation in the era of GPT-3 (Brown et al., 2020), as crowd workers are no longer able to reliably distinguish GPT-3's generations from human-written text.

Or are they? In this paper, we propose a new framework for systematically scrutinizing machine text so that even crowd workers, despite the known challenges reported by recent literature, can successfully critique seemingly fluent generations. We not only quantify a measurable gap between ma-

Commonsense	Violates basic understanding of the world	The dress was made at the **spa.**
Reader Issues		
Needs Google	Search needed to verify claim	***Jose Celana, an artist based in Pensacola, FL***, ...
Technical Jargon	Text requires expertise to understand	... *an 800-megawatt* ***photovoltaic*** *plant was built* ...

Table 1: Error types in the SCARECROW framework, grouped into three categories. The categories are explained further in §4.4, and detailed definitions and examples for each error type is provided in Appendix A.

chine text and human text, but reveal the distributions of specific categories of issues, and pinpoint their occurrences in text written by several sizes of language models as well as humans.

To achieve this, we develop SCARECROW, a methodology for eliciting categorical judgements of errors in machine-generated text from crowd workers. One goal in natural language generation (NLG) is to produce fluent outputs which can be read by laypeople. As such, we propose that important errors to address are those which are recognized by readers without NLP expertise. Our framework allows crowd workers to annotate problems in model outputs at the span level. A single such annotation is shown in Figure 1.

To make this possible, we establish a categorization of shortcomings commonly found in machine generated text (Table 1). This error schema covers a broad scope of problems as identified by experts, but has been honed according to what is salient to non-expert readers through several pilot rounds of crowd annotation without a fixed label set. The result is a framework that is usable by everyday people with minimal training, but covers the error phenomena found in real machine-generated text. Labeling spans of text using specific error types creates a picture of contemporary model generations with an unprecedented level of detail. In contrast to judging text holistically (Celikyilmaz et al., 2021), insights from this method are specific and practical, as it measures exactly how and where problems arise.

We conduct a large-scale analysis of human-written and machine-generated text using SCARECROW, collecting 13k annotations of 1.3k paragraphs, amassing 41k spans labeled with error type, severity, and an explanation. Through this, we characterize in which ways GPT-3's generations are better than those of previous models, and which aspects do not improve with increased data and parameters. We also provide a rigorous error analysis of text generated by several other contemporary language models, examining the impact of model size, training data, and decoding strategy.

We provide our detailed annotator training system and task interface so that future researchers may employ and refine them for error analyses of machine-generated text. We hope this will contribute to the standardization of NLG human evaluation (Howcroft et al., 2020).

2 Key Findings

We perform a large-scale annotation of errors in English news text generated by five sources (four

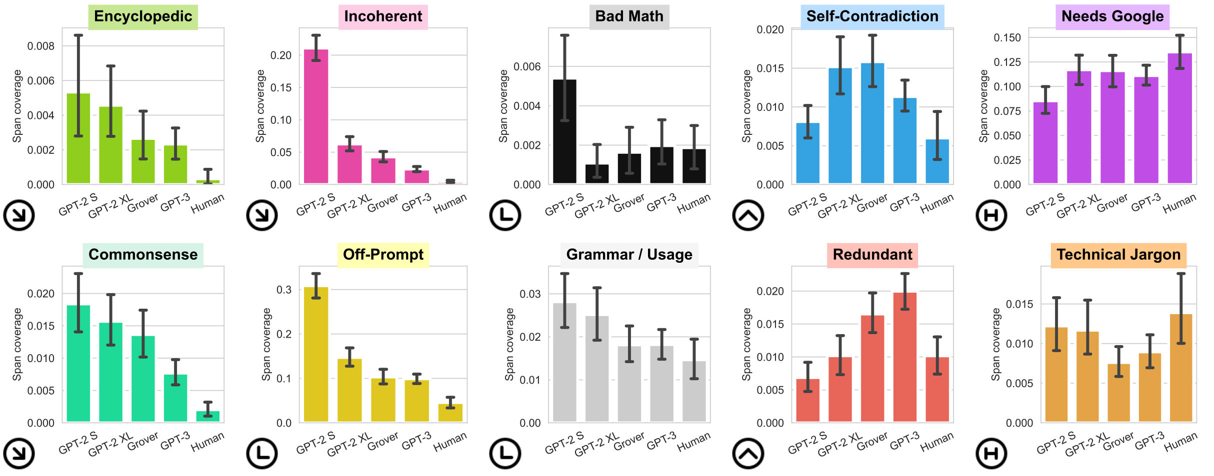

Figure 2: Average portion of tokens annotated with each error type (y-axis) across models (x-axis), with 95% confidence intervals. We group the trends into several broad categories. ↘**Decreasing:** fine-tuning and increasing model size improves performance. Ⓛ**Model plateau:** increasing model size to GPT-3 does not correlate with further improvements. ⌃**Rising and falling:** errors become more prevalent with some models, then improve. Ⓗ**Humans highest:** these spans are labeled most on human-authored text; both are *reader issues* (distinct from *errors*; see Table 1). Details: all models, including GPT-3, use the same "apples-to-apples" decoding hyperparameters: top-p=0.96, temperature=1, and no frequency penalty.

models and ground truth articles). We present Figures 2, 3, and 4 as summaries of our main results. As a reminder to readers, Grover (Zellers et al., 2019) is the same model size and architecture as GPT-2 XL (Radford et al., 2019), but trained in-domain (on news text). As such, our results cover three increasing model sizes (GPT-2 Small, XL, and GPT-3 (Brown et al., 2020)), one change in domain (Grover), and ground-truth text (Human). For GPT-3, we also study a variety of decoding configurations (Figure 4).

The main quantity we measure (on y-axes) is *span coverage*, which is the average portion of tokens that ends up covered by annotations of a particular error type. Since it is possible that multiple spans nest or overlap, there is no upper bound for this quantity. (See Figure 12 for a comparison of span coverage with other measurement alternatives.) Figure 2 measures span coverage for each type of span separately, Figure 3 stacks them, and Figure 4 removes non-error spans (reader issues) before adding them (as in Figure 3, but without showing the individual types).

The following are our key findings.

1. Scaling pays off to improve Encyclopedic, Commonsense, and Incoherent errors (Fig. 2). These error categories ↘**decrease** with in-domain training (Grover) and larger model size (GPT-3). Human text still shows the fewest of these kinds of errors.

2. Scaling benefits plateau for Off-Prompt, Bad Math, and Grammar and Usage errors (Fig. 2). These three error categories see a Ⓛ**model plateau** in error reduction when scaling to GPT-3. Of these error types, humans still commit fewer **Off-Prompt** (more: §E.1) and **Grammar and Usage** errors, but **Bad Math** appears saturated for our domain.

3. Self-Contradiction and Redundant errors exhibit more complex scaling behavior (Fig. 2). We roughly categorize these trends as ⌃**rising and falling**: increasing for medium or large-scale models, but dropping for human-authored text. Text generated by GPT-2 Small is so often incoherent that there is little possibility for **Self-Contradiction** (more: §E.2), and the increase in **Redundant** errors varies based on how errors are counted (more: §E.3).

4. Human-authored text produces the most reader issues (Figs. 2 and 3). The **Needs Google** and **Technical Jargon** span categories both have a Ⓗ**humans highest** trend, and both fall under *reader issues*: problems that are not necessarily *errors*, but that still prevent full comprehension

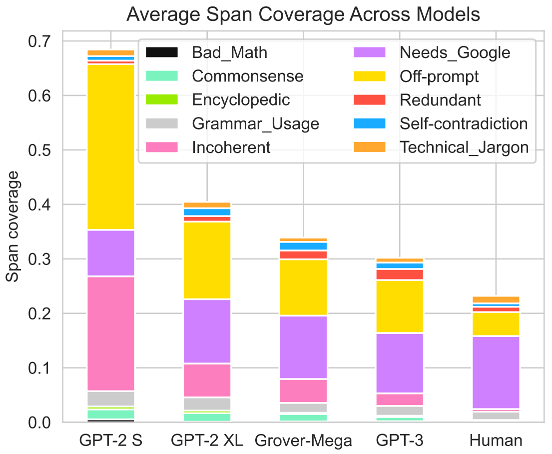

Figure 3: Average portion of tokens covered by span annotations, broken down by error type. All models, including GPT-3, use the same apples-to-apples decoding hyperparameters: top-p=0.96, temperature=1, and no frequency penalty. We scale each span by its token length, normalize by generation token lengths, and remove severity-1 **Grammar and Usage** errors (see §C).

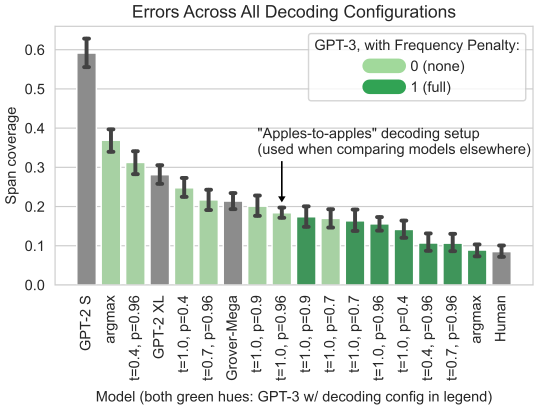

Figure 4: Taking the average span coverage (Figure 3) and removing reader issues (**Technical Jargon** and **Needs Google**), we plot values and 95% confidence intervals for all models, including all decoding hyperparameters we tested for GPT-3. We find a surprisingly large change in annotated errors depending on the decoding setting used.

or factual verification of the text (more: §E.4).

Furthermore, human-authored text is not free from error annotations (Figure 3). This can serve either as a control for baseline error rates (more: §E.6), or as a mechanism for critiquing human writing.

5. Decoding hyperparameters have a huge impact (Figure 4). For the previous findings, we fix the sampling configuration for all models to an apples-to-apples setup for fair comparison: top-p = 0.96, (softmax) temperature = 1, and no frequency penalty (i.e., word repetition penalty; defined precisely in §5.2, Equation 1). To study the effects of these decoding settings, we annotate text generated by GPT-3 using a variety of values for top-p and temperature, both with and without a frequency penalty.

To our surprise, the decoding hyperparameters considerably affected error rates (more: §E.5). As seen in Figure 4, the worst sampling procedure for GPT-3 (argmax sampling with no frequency penalty) performed even worse than GPT-2 XL. But the best sampling procedure (surprisingly, also argmax sampling, but with a frequency penalty) produced text with as few apparent SCARECROW error spans as those authored by humans (more: §E.6).

All of these findings are discussed in more detail in Appendix E.

3 Evaluation of Natural Language Generation

We make our study in the area of open-ended natural language generation, a loose term for generating longer texts with an increased level of creative freedom. The common factor in all open-ended generation tasks such as story, blog, and dialog generation is the wide and diverse nature of target outputs. Lexically and even semantically dissimilar responses to the same prompt could be equally valid. For example, a model prompted with the blog title “Recipes for success this Holiday season” could describe how to roast a turkey or strategies for dealing with the stresses of holiday travel.

This allowable variation poses a particular difficulty for the evaluation of generation systems. Traditionally, text generation quality for tasks like machine translation or graph-to-text generation has been measured by word overlap with human-authored references (Papineni et al., 2002; Lin, 2004). Though measures like BLEU allow for multiple references, they break down when the space of allowable outputs is large, as in open-ended generation. Recently introduced metrics seek to remedy this problem (Hashimoto et al., 2019; Pillutla et al., 2021), but the gold standard for evaluating generated text is still human judgment.

However, current approaches to eliciting human judgement of generated text often do not provide detailed insight into where models are making progress, where they are failing, and the scope of these failures. A/B-style testing allows for directly comparing one system against others (Clark and Smith, 2021), but can only express relative improvements. Simple Likert scale judgements can assess text quality, but do not explain why a generated text receives a given rating, or which segment of the text is problematic. Insights into model failures often come instead from a small scale expert analysis of outputs. However, these "error analyses," once a staple of NLP research, have become less common in recent years, perhaps due to their small size and high variance.

A hypothesis of the current work is that a well designed error analysis annotation framework could be used by crowdworkers to annotate large amounts of text, thereby providing detailed information about model progress and failures as well as actionable directions for future research. Such a framework would be easy to learn, reusable, and independent of particular models or experimental conditions. In what follows, we outline the details of such a method.

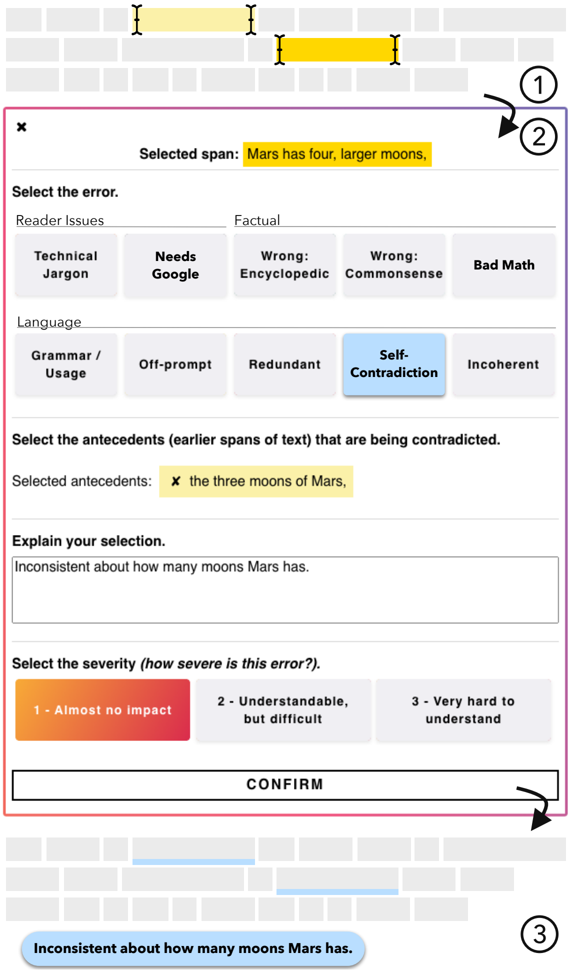
4 SCARECROW Annotation Methodology

This section describes the high-level annotation methodology for SCARECROW.

4.1 Prompt and Generation

Our annotations consider two segments of text: a one-sentence prompt, and a one-paragraph generation. The prompt is human-written. It provides both starting tokens for model generation, as well as context for humans to evaluate whether a model is able to stay on-prompt—both topically and factually. Annotators know that the prompt is written by a human.

The generation is either text sampled from a language model, or the human-authored continuation to the prompt. Annotators, who do not know whether the generation came from a model or humans, assess this text. A paragraph length (80–145 tokens) is chosen to balance expressiveness with scope. For expressiveness, models must be given a sufficient number of tokens to express their capabilities lexically, syntactically, and semantically. One paragraph allows for significantly more variation than a single sentence. On the other hand, assessing multiple paragraphs is challenging, both as a crowdsourcing task itself, and because it broadens the kinds of errors to include larger narrative scope. We leave extensions of SCARECROW to longer narrative lengths for future work.



Selected span: Mars has four, larger moons,

Selected antecedents: × the three moons of Mars,

Inconsistent about how many moons Mars has.

Inconsistent about how many moons Mars has.

Figure 5: SCARECROW interface for annotating a single span: (1) highlighting a span (and later, an antecedent); (2) completing the annotation, with the error type, explanation, and severity; (3) the error annotation is saved—interactive controls allow detailed viewing and editing of spans (not shown).

4.2 Span Labeling

Annotators select spans that contain problems in the generation. The spans are automatically snapped to word boundaries. We choose spans to balance specificity (i.e., vs. simply commenting on the text as a whole) with ease of use (vs. imposing a more structured annotation schema).

4.3 Span Selection

We instruct workers to select the smallest span—minimally a single word—that contains an issue. Sometimes this involves an entire phrase, sentence, or multiple sentences. We aim for specificity because during aggregation, it is possible to "back off" annotations to larger spans, but not the inverse.

Once they select a span, workers (1) label the error type, (2) choose a severity level, and (3) explain their reasoning behind the error. Workers use the annotation interface shown in Figure 5 to mark a span with these three steps. We describe each step in greater detail in the next three sections.

4.4 Error Types

Each selected span is labeled with exactly one error type. Multiple errors may be marked with partially or fully overlapping spans in the case that one text segment contains multiple problems.

We chose ten error types to balance three criteria: linguistic analysis, observed errors in generated text, and capabilities of everyday people with one to two hours of training.[1] We developed the schema by starting with the first two criteria (linguistic analysis and observed errors), and refining it over several pilot annotation studies, with 30 crowd workers performing 750 total annotations of 60 paragraphs before beginning data collection.

We broadly group the errors into three categories: language errors, factual errors, and reader issues. Language errors are issues with internal and external structure of text: which ideas are expressed, and whether they are expressed coherently and consistently. Factual errors denote that the information presented is known to be incorrect. Reader issues, on the other hand, are cases where the text is too technical or obscure to assess its factuality. Hence, reader issues are not errors, per se, but regions where a reader would need assistance outside of the text itself for comprehension.

We present the ten error types in Table 1 (several pages back). Appendix A provides more details, examples, and explanations for all error types.

4.5 Severity

Errors naturally vary in how jarring they are to a reader. We define three error severity levels, and ask annotators to pick one for each error.

The severity levels are as follows. **(1)** Almost no impact on quality; just a small problem. **(2)** Understandable, but difficult; what's written is still comprehensible, but there's clearly an issue. **(3)** Very difficult to understand; the error almost completely ruins the text.

We provide examples of each severity in Appendix B.1. In this paper, we omit an analysis of the severity labels (except for an illustration in Figure 12), but include it in our data release for future work to explore.

4.6 Explanation

Finally, we ask annotators to explain their reasoning behind each error in natural language. We provide example explanations during training, but do not impose strict guidelines. This paper primarily focuses on quantitative error analysis, but we anticipate the error explanations may warrant future investigation.

4.7 Annotation Process

We use Amazon Mechanical Turk (AMT) for all data collection.

Training We first pay each worker \$40 to take an extensive qualification task, which both trains them in the span categorization scheme and quizzes their understanding. We pass workers if they score ≥ 90 points out of 100 points (details in Appendix B.2).

Annotation Workers annotate each paragraph using a custom annotation interface (shown partially in Figure 5), for which we pay \$3.50. We calculated \$3.50 per annotation by aiming to pay workers at least \$15/hour. After several annotation rounds, we observed considerable variation in time per annotation,[2] so this cost should not be necessarily seen as a requirement for SCARECROW annotations.

5 Data Collection

We collect 13k human annotations of 1.3k paragraphs using SCARECROW, resulting in over 41k spans.

5.1 Models

We consider four model configurations to test recent state-of-the-art transformer-based (Vaswani et al., 2017) models.

GPT-2 Small (Radford et al., 2019) The 117M parameter variant of GPT-2, which is pretrained on WebText, without additional fine-tuning.

GPT-2 XL (Radford et al., 2019) The 1.5B parameter variant of GPT-2, (WebText, no fine-tuning).

---

[1] The complete training material is available for download.

[2] Median: 212s, mean: 265s, std. dev.: 199s.

Grover-Mega (Zellers et al., 2019) The 1.5B parameter variant of Grover, a model with the same architecture and parameter count of GPT-2, trained on news articles and their metadata.

GPT-3 DaVinci (Brown et al., 2020) The 175B parameter variant of GPT-3, which is trained on a version of the Common Crawl web scrape with additional filtering and deduplicating.

In addition, we also use the actual human-written text from the data sources we draw from, which we denote as **Human**.

5.2 Decoding strategies

We consider three main hyperparameters when sampling from models: p for *top-p* or *nucleus sampling* (Holtzman et al., 2020), an alternative to *top-k*;[3] t for the *softmax temperature*; and *f.p.* for *frequency penalty*. The frequency penalty scales a token's likelihood based on how many times it was already generated by applying the following modification to the model's output:

$$\ell_i(t) \leftarrow \ell_i(t) - c_{<i}(t) \cdot \alpha_f \qquad (1)$$

where $\ell_i(t)$ is the model's output for token t at the i-th position,[4] $c_{<i}(t)$ is the count of token t's sampled occurrences prior to the i-th position, and α_f is the frequency penalty. We omit studying *presence penalty*, another hyperparameter offered for GPT-3, simply due to annotation budget constraints.

To compare models as consistently as possible, we set identical decoding strategies for our primary data collection. We refer to this as the "apples-to-apples" decoding setup throughout the paper:

$$p = 0.96 \qquad t = 1.0 \qquad \textit{f.p.} = 0$$

However, we also wish to study the effects of these decoding strategies. We annotate generations from the strongest available model (currently, GPT-3) varying the following parameters:

$$\begin{aligned} p &\in \{0.4, 0.7, 0.9, 0.96\} \\ t &\in \{0.0\ \textit{(argmax)}, 0.4, 0.7, 1.0\} \\ \text{f.p.} &\in \{0\ \text{(none)}, 1\ \text{(full)}\} \end{aligned}$$

For budget reasons, we only vary p and t independently—i.e., we set $p = 0.96$ when varying t, and $t = 1.0$ when varying p.

5.3 Prompt Selection

We use news articles as the sources of prompts for models to condition on for generation. Specifically, we use news articles found in the Common Crawl. We select the first sentence as the prompt.

Our use of news text is constrained by two factors. First GPT-3 is trained on the Common Crawl, from 2016 through 2019. We wish to avoid testing GPT-3 by generating from articles it saw during training, due to the possibility of copying (Carlini et al., 2021). Second, news articles began heavily covering the COVID-19 pandemic beginning around February 2020. Though testing models' capabilities to generate text about unseen events is a valuable line of study, the distribution shift caused by COVID-19 in news writing about all aspects of life is difficult to overstate.

As such, to make the comparison more amenable to models' training data, we consider news articles from January 2020. We select articles where there is a known topic—such as *Food* or *Sports*—from the Common Crawl metadata, to allow for studying any effect of coarse-grained subject.

5.4 Generation

We generate between 80 and 145 tokens[5] from each model as a continuation to the first sentence of the news article. We stop generating when we heuristically detect the first sentence boundary after 80 tokens. If the model does not end a sentence between 80 and 145 tokens, we sample again. For the *Human* setting, we use the remainder of the article, similarly stopping after the first sentence boundary after 80 tokens.

5.5 Annotation

Crowdsourcing Workers first complete training and qualification tasks. We provide more details in 4.7. From pilot studies, we discovered that each error, depending on its severity and clarity, has only a

---

[3] We omit separate studies of *top-k*, due to results presented by Holtzman et al. (2020), and OpenAI's removal of *top-k* from the GPT-3 API.

[4] While $\ell_i(t)$ is defined to be *"logits (un-normalized log-probabilities),"* because it is un-normalized, we anticipate that it is simply the model's output before the $\log(\text{softmax}(\cdot))$ is applied. See OpenAI's description of frequency and presence penalties: `https://beta.openai.com/docs/api-reference/parameter-details`

[5] Counted by Stanza tokenization (Qi et al., 2020), not byte-pair encoding (BPE) or whitespace-separated tokens.

low to moderate chance of being identified by each worker. However, most worker-identified errors were truly problems. In other words, annotators labeled issues with high precision and low recall. To account for this, we have **10 workers** annotate each paragraph. We examine the agreement and variability of annotations in Appendix C.

Dataset statistics We provide detailed dataset statistics in Appendix D.

6 Error Prediction

A natural question is: using this data, can machines learn to detect and classify errors in machine generated text?

Task We frame this problem as a span classification task. Given a span from a generated text, the goal is to classify its error type or output "No Error" if there is none. Positive examples for each error class are taken from our data. We sample random spans that were not labeled with any error type as negative examples. To ensure a breadth of span lengths, we sample 3 negative spans for every length of error span in the generated text. We split the generated texts into train, development, and test sets using 1063 texts (28029 error spans), 100 texts (2538 spans) and 100 texts (2677 spans) respectively.

Model We use a standard span classification model inspired by Wadden et al. (2019). This model encodes every generated text using a pretrained language model (RoBERTa-large). Spans are represented with the final layer of this encoding. Following previous work, we concatenate the start and end tokens with a task-specific learned length embedding. The resulting vector is passed through a feedforward network which reduces its dimensionally to the number of error categories plus a "No Error" option. The resulting model has 357M trainable parameters. The model is trained to minimize the cross entropy of the correct span category. We train for 15 epochs using AdamW with a learning rate of 10^{-6}. We validate after each epoch and use the checkpoint with the lowest validation loss (epoch 8).

Evaluation To evaluate the error prediction model, we use per-token precision, recall, and F_1 score per error category. We classify every span up to length 30 in a generated text. We take as gold labels the aggregated human error spans collected in our data. In other words, models predict the combined spans of all 10 annotators. For comparison, we also report as *Human* the average metrics of one annotator versus the others (i.e., 1-vs-9).[6]

Error	Model			Human		
	P	R	F_1	P	R	F_1
Bad Math	–	0	–	0.72	0.14	**0.24**
Commonsense	0.77	0.06	**0.10**	0.17	0.02	0.04
Encyclopedic	–	0	–	0.22	0.03	**0.05**
Grammar and Usage	0.29	0.23	**0.26**	0.30	0.04	0.08
Incoherent	0.59	0.34	**0.43**	0.69	0.15	0.24
Off-Prompt	0.67	0.29	0.41	0.88	0.31	**0.46**
Redundant	0.23	0.82	0.36	0.88	0.35	**0.50**
Self-Contradiction	0.08	0.23	0.12	0.51	0.09	**0.16**
Technical Jargon	0.18	0.74	**0.29**	0.61	0.12	0.20
Needs Google	0.59	0.96	**0.73**	0.78	0.20	0.32

Table 2: Model prediction results against combined spans of 10 annotators, compared with humans scored as one-vs-rest (i.e., 1-vs-9). Bold F_1 scores denote the higher average; values marked "–" cannot be computed due to division by zero. **Takeaway:** Humans have higher precision in every error type except **Commonsense**, but relatively sparse annotations lead to lower computed recall. This allows the model to achieve higher F_1 scores for half of the span categories.

Results Table 2 shows the error prediction capability of this model in terms of precision and recall. As we noted earlier, a single human annotator can be thought of as a high precision, low recall judge. These results bear out this claim. For all but one category, humans have higher precision annotations. However, the models trained on the aggregation of human labels can achieve considerably higher recall. For half of the error categories, this leads to higher model F_1 scores than the human annotators.

We see that the model is successful at identifying information that human's would have to manually verify (**Needs Google**), achieving nearly perfect recall with precision close to 0.6. The model can also identify **Grammar and Usage**, **Incoherent**, and **Redundant** errors with higher recall than an individual human annotator, though at the cost of precision (sometimes in the .20s).

7 Related Work

Automated evaluation metrics such as BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), METEOR (Banerjee and Lavie, 2005), and BERTScore

---

[6] The difference in available references (10 for models, 9 for humans) mean this setup makes it easier for models to score higher in precision, and for humans to score higher in recall. Despite this, humans still achieve higher precision, and models still achieve higher recall.

(Zhang et al., 2019) compute a generation's score based on a (set of) reference(s). Their use is well-established in tasks like machine translation and summarization, but they are less helpful in open-ended text generation, where there is a vast diversity of possible high-quality continuations.

Recent studies propose automated metrics for open-ended text generation evaluation such as: Perception Score (Gu et al., 2021), which diffuses evaluation onto a multidimensional space and assigns a single score; UNION (Guan and Huang, 2020), which learns to distinguish human-written stories from negative samples by generating perturbations of human-written stories; and MAUVE (Pillutla et al., 2021), which compares the distribution of machine-generated text to that of human language.

An alternate recent approach to assessing open-ended text generation was presented in TuringAdvice (Zellers et al., 2021), where crowd workers assess machine-generated advice in response to Reddit posts. In their error analysis, Zellers et al. connect problems in generated text to core NLP tasks, such as **Self-Contradiction** errors as instances of failed natural language inference (Monz and de Rijke, 2001), or **Off-Prompt** errors as cases of failed reading comprehension (Richardson et al., 2013). While past work has attempted to guide text generation using discriminative models trained for such tasks (Holtzman et al., 2018), it remains an open challenge.

Comparative human evaluations of natural language generations ask annotators to rank system outputs relative to each other. Text is typically evaluated using a few global criteria, such as fluency and relevance, using discrete (e.g., 5-point) (Sai et al., 2020) or continuous scales (Novikova et al., 2018). Recent work even automates this approach, running a human evaluation alongside automatic metrics on leaderboard submissions (Khashabi et al., 2021). In the RoFT system (Dugan et al., 2020), annotators attempt to detect the boundary between human- and machine-written text as a proxy for assessing quality. Table 3 summarizes the differences between these schemes and SCARECROW. See Celikyilmaz et al. (2021) for a recent survey of text generation evaluation techniques across both human and automatic metrics.

While these approaches may be helpful—sometimes (Card et al., 2020)—at ranking systems, they do not give us insight into exactly *which* parts of a generation fall short, and *why*. One approach related to or annotation method is pursued by Wood et al. (2018), who develop a collaborative mobile app where users draw "graffiti" commentary on news articles. SCARECROW aims to assess model generations the way we would critique human-written text: by locating, coarsely categorizing, and explaining problems.

Method	**GC**	**SET**	**DE**	**RR**	**EE**	**RS**	**SA**
Likert-Scale	✓		✓			✓	
RankME	✓			✓		✓	
RoFT	✓		✓		✓		
SCARECROW		✓	✓		✓		✓

Table 3: Comparison of different natural language generation human evaluations. Here, **GC** : General Criteria, **SET** : Specific Error Type, **DE** : Direct Evaluation, **RR** : Relative Ranking, **EE** : Error Explanation, **RS** : Rating Scale, **SA** : Span Annotation.

8 Conclusion

We present SCARECROW, a method for identifying and explaining issues in generated text. Along with the annotation framework, we present an analysis of the SCARECROW method applied to several large neural language models in an open-ended news generation task. We release our data and methodology to the community.

A SCARECROW Annotation Schema

Here, we present in greater detail the SCARECROW annotation error types.[7] A visual summary is shown in Figure 6.

While we annotate using this schema, the essence of our study is to embrace language users' abilities to detect when something may be wrong with text. In other words, we do not wish for our span definitions to get in the way of humans describing problems with text. To this end, we encourage researchers to embrace label back off (to coarser categories), merging labels (based on empirical observations), and refining the annotation ontology over time. The central goal is to collect what people find wrong with text.

A.1 Language Errors

We define five categories of language errors, which concern the selection of ideas in a text and how they are expressed. These range from grammar and syntax problems to issues of semantics and pragmatics.

A.1.1 Grammar and Usage

This category of errors includes missing words, extra words, and incorrect or out of order words.

> EXAMPLE
> A PhD student from the University of Kent in the UK claims to have discovered a clever way to explain the positive **emoticons** in cats.
>
> ***Explanation:*** *The word should probably be "emotions."*

We also label **Grammar and Usage** for inserted words or small phrases that could be deleted to resolve the issue:

> A couple is facing criticism for their extravagant birthday party. The bewitching pair had first stripped down to fishnets **and backward.**
>
> ***Explanation:*** *This phrase can simply be deleted.*

We avoid partitioning **Grammar and Usage** errors into more detailed categories based on the observation that large language models produce fewer issues of syntax and diction (aside from **Redundant** errors, described next). As such, we focus instead on semantic and pragmatic errors, captured by the upcoming error types.

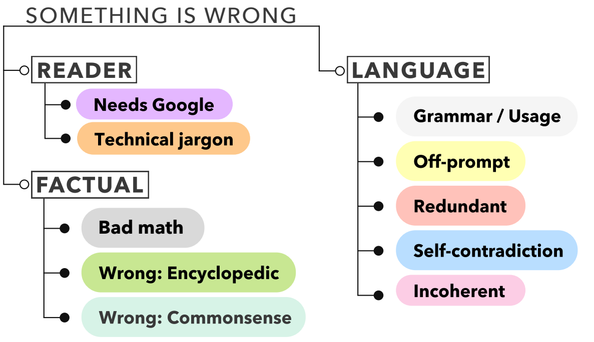

Figure 6: A visualization of SCARECROW spans: three categories (reader, language, and factual) composed of ten types. Annotators choose directly from the ten error types.

A.1.2 Redundant

While "redundant" can also include extra unnecessary information, we specifically use the **Redundant** label to mark repetition. In identifying redundant text, our schema annotates both the **antecedent** (first mention) and the **redundant text** (when the repetition occurs). Sometimes the exact word or phrase will be repeated.

> EXAMPLE
> Many merchants worry about the possibility of **poor service** **or service** for certain categories of customers.

Other times, generated text expresses the same idea repeatedly using different words.

> EXAMPLE
> They then made decisions based on Kondo's instructions, to the extent that they **created decluttered spaces** **and got rid of clutter and clutter-filled spaces**.

A.1.3 Off-Prompt

The prompt is a human-written sentence used as context from which the model generates a continuation. Models sometimes generate text that is unrelated to the prompt.

> EXAMPLE
> **Prompt:** Dogs are the new kids.
> **Generation:** Statistics suggest that most Americans would be happier with dogs than children. **In fact, four out of five don't even visit the dentist annually, much less every six months.** Dog owners report much higher rates of happiness than non-dog owners.

Other times, the text may be related, but it contradicts what is stated in the prompt.

> EXAMPLE
> **Prompt:** China sets new record for Economic Growth
> **Generation:** The Chinese economy **fell 10% this month, the third such loss this year.**

---

[7] All example annotations here are our own. Many are provided to annotators during training.

A.1.4 **Self-Contradiction**

When a model generates text that contradicts the prompt, that is labeled as **Off-Prompt** . But when a model generates text that contradicts itself, that is labeled as **Self-Contradiction** . We also mark the **antecedent** (original statement).

EXAMPLE
McDonald's is considering a design which will replace the **cardboard packaging.** Mr Gore-Cotter said: "We recognise the concern around waste. We are now looking at a new design that minimises the **plastic bag."**

Explanation: *The idea of minimizing the plastic bag contradicts the stated goal of replacing cardboard packaging.*

EXAMPLE
Mall of America plans to **lay off and furlough hundreds of its employees.** **It has no plans to restrict the number of hours workers can work.**

Explanation: *Furloughed workers are explicitly restricted from working.*

A.1.5 **Incoherent**

Generated text is sometimes grammatical, not redundant, on prompt, and not contradictory, but still confusing. We provide the **Incoherent** label for such sentences.

EXAMPLE
Melody Mitsugi, 28, had never given her kids cheese toast before her husband **drew a map of it on her toast.**

Explanation: *One can't exactly draw a map of Cheese Toast, and one probably wouldn't draw it on toast itself.*

EXAMPLE
Cats naturally show anxiety and fear by at times **breaking apart different parts of the brain in an attempt to keep the others from escaping.**

Explanation: *It's difficult to even imagine what is happening in this passage.*

A.2 Factual Errors

We define three categories of factual errors, which encompass known incorrect statements.

A.2.1 **Bad Math**

Generated text will sometimes have issues with basic mathematical operations of known quantities (e.g., *"half of ten apples is four"*), problems converting fixed units (e.g., *m to cm*).

EXAMPLE
One account, @Iain_Rowling1, had over 500,000 followers at one point, but in just four days they fell by **around half - some 4,000.**

We also include problems converting currencies that are wildly implausible under modern assumptions (e.g., *£1 = $18 US*).

EXAMPLE
... compared with just over £1,000 **($18,868)** for previous versions of Samsung's flagship phone.

A.2.2 **Commonsense**

These errors mark spans that violate our everyday basic understanding of the world. Though it is challenging to precisely define *commonsense knowledge* (Liu and Singh, 2004), we include non-encyclopedic knowledge and basic reasoning.

The following example concerns broadly sensible numerical ranges.

EXAMPLE
The picture is from high above the South Pole, where close to **100,000** Astronauts live and work.

Explanation: *Even if we don't know the exact number of astronauts in space, it is common knowledge that 100k is far too many.*

The next example involves world knowledge, akin to scripts (Schank and Abelson, 1977).

EXAMPLE
You can get the dress custom-made and stitched at your favorite **spa.**

Explanation: *Spas don't offer stitching.*

The following example involves lexical entailment.

EXAMPLE
The thinness of our bodies isn't an answer to all common human health problems like **obesity** or diabetes

Explanation: *While most of the statement is acceptable, it's impossible to be "thin" and "obese" at the same time.*

The final example involves time.

EXAMPLE
Now in 2021, NASA is measuring California wildfire temperatures using an instrument on the International Space Station. This year's record-shattering heat has had global repercussions in **2017** , forcing sea level rise on California and increasing the risk of deadly wildfires.

Explanation: *Events in 2021 can't affect events in 2017.*

A.2.3 **Encyclopedic**

These errors are ones that we *know* are factually wrong, and that we could look up in, say, Wikipedia.

EXAMPLE
Japanese Prime Minister Justin Trudeau said he will be halting all imports and exports until the current situation can be contained.

Explanation: *Justin Trudeau is the Prime Minister of Canada, not Japan.*

The distinction between **Encyclopedic** errors, and the upcoming **Technical Jargon** and **Needs Google** issues, depends on the reader's knowledge.

EXAMPLE
The gas contains something known as **phyto-romatic acid, a common chemical element in the periodic table.**

Explanation: *Acids aren't elements.*

A.3 Reader Issues

We define two categories of reader issues. These are words or statements a reader cannot verify without using an external resource.

A.3.1 Technical Jargon

Sometimes generated text includes specific words from a field that requires expertise to understand.

EXAMPLE
In Chile, an 800-megawatt **photovoltaic** plant was built for a record low cost of $129 per megawatt-hour last year.

Which words are jargon depends on the reader's particular expertise. This means **Technical Jargon** spans are more accurately thought of as potential issues rather than known errors.

EXAMPLE
He uses a spirit **mash** made from white corn and malted barley and a **neutral grain**, which he describes as a "whiskey grain."

A.3.2 Needs Google

Many facts—especially those involving specific people, events, dates, or numbers—could be categorized as encyclopedic knowledge. However, whether the fact is accurate may require additional verification by the everyday reader. To make this distinction between *known* encyclopedic knowledge and *trivia*, we introduce this label to denote that a reader would need to search online to verify whether it is true.

We instruct annotators to not look up facts marked with the **Needs Google** span. We do this to keep the focus of the task on classification, rather than factuality detection. As a result, **Needs Google** spans mark *statements that would need to be verified*, rather than known errors.

EXAMPLE
It was promoted by **Dr. Michael Fanning, the Executive Director of the Foundation for Mental Health Awareness, Inc.**

Explanation: *A reader would likely need to look up whether there is a Dr. Fanning who holds this position.*

EXAMPLE
... an **800-megawatt photovoltaic plant** was built for a **record low cost of $129 per megawatt-hour** last year.

Explanation: *In addition to potential* ***Technical Jargon*** *spans, there are at least two* ***Needs Google*** *spans: 1. whether such a plant can be roughly 800-megawatt, 2. whether $129/megawatt-hour is a sensible cost measure, and the value is reasonable.*

To illustrate the annotation methodology and schema in practice, we present four complete example annotations in Figure 7. This figure also illustrates how much variation we see across models.

B Annotation Details

B.1 Error Severity

We provide here examples for each of the three error severity levels, which we also give to annotators during training.

EXAMPLE
Paul Campbell-Hughes, from the University of Aberdeen, explains how **she** managed to locate colonies of honey bees in Kent.

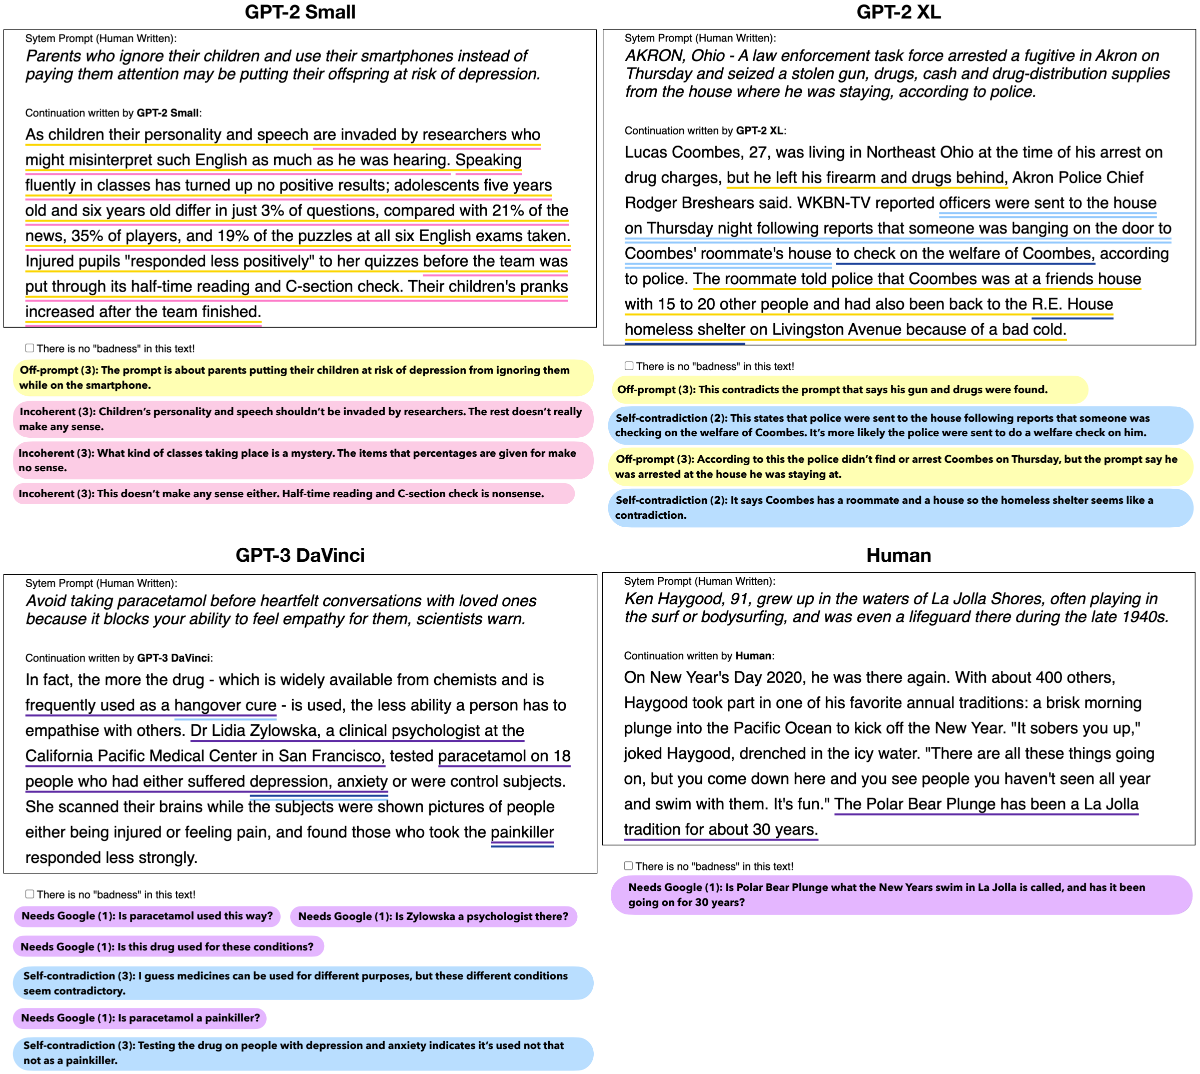
Severity: 1. *Since Paul is usually a male name, the model should have used "he." But this error is pretty minor.*

EXAMPLE
Paul Campbell-Smith, a PhD student from the University of Kent in the UK, claims to have discovered a clever way to explain the positive **emoticons** in cats.

Severity: 2. *The word should probably be "emotions." We can guess what was being said, but it's definitely wrong.*

EXAMPLE
Prompt: Whether you're on Facebook, Instagram, Snapchat or TikTok, many people make huge efforts to curate the best version of themselves online.
Generation: **This year we've got something for you: a Love Match Custom Size Poster featuring Mather, Phoenix, Kashun and all her friends, divided among six different covers, creating a beautiful custom size poster for your own personal high school reunion.**

Severity: 3. *Even ignoring the end of the generation (a poster for a personal high school reunion?), this whole generation is way off the prompt and does not make sense.*



GPT-2 Small

Sytem Prompt (Human Written):

Parents who ignore their children and use their smartphones instead of paying them attention may be putting their offspring at risk of depression.

Continuation written by **GPT-2 Small**:

As children their personality and speech are invaded by researchers who might misinterpret such English as much as he was hearing. Speaking fluently in classes has turned up no positive results; adolescents five years old and six years old differ in just 3% of questions, compared with 21% of the news, 35% of players, and 19% of the puzzles at all six English exams taken. Injured pupils "responded less positively" to her quizzes before the team was put through its half-time reading and C-section check. Their children's pranks increased after the team finished.

☐ There is no "badness" in this text!

Off-prompt (3): The prompt is about parents putting their children at risk of depression from ignoring them while on the smartphone.

Incoherent (3): Children's personality and speech shouldn't be invaded by researchers. The rest doesn't really make any sense.

Incoherent (3): What kind of classes taking place is a mystery. The items that percentages are given for make no sense.

Incoherent (3): This doesn't make any sense either. Half-time reading and C-section check is nonsense.

GPT-2 XL

Sytem Prompt (Human Written):

AKRON, Ohio - A law enforcement task force arrested a fugitive in Akron on Thursday and seized a stolen gun, drugs, cash and drug-distribution supplies from the house where he was staying, according to police.

Continuation written by **GPT-2 XL**:

Lucas Coombes, 27, was living in Northeast Ohio at the time of his arrest on drug charges, but he left his firearm and drugs behind, Akron Police Chief Rodger Breshears said. WKBN-TV reported officers were sent to the house on Thursday night following reports that someone was banging on the door to Coombes' roommate's house to check on the welfare of Coombes, according to police. The roommate told police that Coombes was at a friends house with 15 to 20 other people and had also been back to the R.E. House homeless shelter on Livingston Avenue because of a bad cold.

☐ There is no "badness" in this text!

Off-prompt (3): This contradicts the prompt that says his gun and drugs were found.

Self-contradiction (2): This states that police were sent to the house following reports that someone was checking on the welfare of Coombes. It's more likely the police were sent to do a welfare check on him.

Off-prompt (3): According to this the police didn't find or arrest Coombes on Thursday, but the prompt say he was arrested at the house he was staying at.

Self-contradiction (2): It says Coombes has a roommate and a house so the homeless shelter seems like a contradiction.

GPT-3 DaVinci

Sytem Prompt (Human Written):

Avoid taking paracetamol before heartfelt conversations with loved ones because it blocks your ability to feel empathy for them, scientists warn.

Continuation written by **GPT-3 DaVinci**:

In fact, the more the drug - which is widely available from chemists and is frequently used as a hangover cure - is used, the less ability a person has to empathise with others. Dr Lidia Zylowska, a clinical psychologist at the California Pacific Medical Center in San Francisco, tested paracetamol on 18 people who had either suffered depression, anxiety or were control subjects. She scanned their brains while the subjects were shown pictures of people either being injured or feeling pain, and found those who took the painkiller responded less strongly.

☐ There is no "badness" in this text!

Needs Google (1): Is paracetamol used this way?

Needs Google (1): Is Zylowska a psychologist there?

Needs Google (1): Is this drug used for these conditions?

Self-contradiction (3): I guess medicines can be used for different purposes, but these different conditions seem contradictory.

Needs Google (1): Is paracetamol a painkiller?

Self-contradiction (3): Testing the drug on people with depression and anxiety indicates it's used not that not as a painkiller.

Human

Sytem Prompt (Human Written):

Ken Haygood, 91, grew up in the waters of La Jolla Shores, often playing in the surf or bodysurfing, and was even a lifeguard there during the late 1940s.

Continuation written by **Human**:

On New Year's Day 2020, he was there again. With about 400 others, Haygood took part in one of his favorite annual traditions: a brisk morning plunge into the Pacific Ocean to kick off the New Year. "It sobers you up," joked Haygood, drenched in the icy water. "There are all these things going on, but you come down here and you see people you haven't seen all year and swim with them. It's fun." The Polar Bear Plunge has been a La Jolla tradition for about 30 years.

☐ There is no "badness" in this text!

Needs Google (1): Is Polar Bear Plunge what the New Years swim in La Jolla is called, and has it been going on for 30 years?

Figure 7: Example SCARECROW annotations (for a single annotator) of three model generations and one ground truth continuation, demonstrating the shift in number, type, and severity of errors. The entirety of the **GPT-2 Small** generation is **Off-Prompt** and/or **Incoherent**, with high severity (3/3). **GPT-2 XL** is instead only about two-thirds covered by errors—still sometimes **Off-Prompt**, but also **Self-Contradiction**, and with high severity (2–3/3). In contrast, **GPT-3 DaVinci** receives several **Needs Google** marks—less severe than errors, as they only indicate that fact-checking is needed—though it also commits two high-severity **Self-Contradiction** errors by generating inconsistent claims. The **Human** (ground-truth) continuation only receives one **Needs Google** span.

B.2 Grading Details

In the training material, there are 10 annotation exercises, 10 multiple choice questions, and 1 real task question to test workers' understanding.

Annotation Exercise After going through each error type, there is an annotation exercise. Workers are asked to mark the span with that particular error in a short text. Each exercise is worth 5 points.

Multiple Choice Question After going through all language errors, and going through all factual errors and reader issues, there is a language error label quiz and a reader and factual error label quiz respectively. Each label quiz consists of 5 multiple choice questions, where workers are asked to choose the error type of a marked span in a short text. Each multiple choice question is worth 3 points.

Real Task Question At the end of the whole training material, workers are asked to apply what they learn in an actual task where they annotate a given paragraph with full tool like ones shown in Figure 7. This question is worth 20 points. We mark 7 error spans as the solution. As long as they can mark 5 of 7 error spans, they get a full 20 points. Otherwise, 4 points will be deducted for each missing error span.

In total, there are 100 points. We pass workers if they score $\geq$ 90 points, and then they are provided with the solution to review.

C Data Quality

Identifying and classifying errors in potentially noisy machine-generated text is a challenging task. How consistent are the annotations collected from crowd workers? In this section, we examine the agreement and variability of the collected annotations.

At a high level, we observe either acceptable or high inter-annotator agreement across error categories. For rare error types such as **Bad Math**, high agreement stems from the prevalence of spans with no error. For such categories, *we recommend treating each annotator as a high precision, low recall judge*, and considering the information from their aggregate annotations. Figure 8 gives an example of the perspective gained by viewing all 10 annotations of a single generation.

Error	Krippendorff's α	*Two Agree* (%)
Bad Math	0.99	30
Commonsense	0.88	20
Encyclopedic	0.98	12
Grammar and Usage $^{>1}$	0.72	30
Incoherent	0.73	49
Off-Prompt	0.71	61
Redundant	0.88	38
Self-Contradiction	0.87	26

Table 4: Per-token inter-annotator agreement metrics by error category. The $^{>1}$ indicates that we omit severity-1 **Grammar and Usage** errors in all analyses in this paper due to higher variance; including them would drop the Krippendorf's α to 0.56.

Agreement Table 4 shows token-level inter-annotator agreement statistics aggregated over all collected data. Since a single annotator can label a single span with multiple errors, we break the agreement statistics down by error category. We report Krippendorff's α coefficient, a chance-corrected measure of agreement for multiple annotators (Krippendorff, 2018). Due to computational constraints, we calculate this coefficient per generation and report the average across the dataset. The agreement shown here is high for most categories (>0.8) and acceptable (>0.6) for all error types.

The Krippendorff measure may be deceptively high for some error types such as **Bad Math**, where 99% of tokens are not annotated with this error. The *Two Agree* measure in Table 4 gives a different characterization of this data. *Two Agree* for a given error label is the percentage of tokens labeled by at least one annotator that were also labeled by one or more additional annotators. This metric allows us to see where annotators agree that particular errors exist while ignoring the majority of tokens (for most error categories) which annotators agree are not errors. *Two Agree* shows significantly lower rates for sparse errors with high Krippendorff scores, such as **Encyclopedic**. However, it reveals stronger agreement among **Incoherent** and **Off-Prompt** errors than might be expected given the Krippendorff coefficient.

A limitation for both metrics is the use of token-based overlap.

Bootstrap One issue we face is high variance of annotations. To determine the impact of this variance for lower-data settings, we perform a bootstrap analysis using largest subset of our data (GPT-3, top-p = 0.96, t = 1, f.p.= 0, for which we have annotations of 200+ generations). We choose 50 generations (roughly 500 annotations) and calculate the error statistics therein. We repeat this process 1000 times and report the mean, standard deviation, and coefficient of variation in Table 5. We also calculate the coefficient of variation for different numbers of samples, shown in Figure 9. We see that as the number of samples increases, the coefficient of variation decreases as expected, though less precipitously after 30 examples. These results show that with as few as 50 documents, the SCARECROW error analysis should yield relatively robust results. However, this varies by error type: rare errors like **Bad Math** and **Encyclopedic** show greater variance. Here, again we repeat our recommendation to treat annotations for these categories in aggregate. These results motivate our collection of at least 500 annotations per condition studied.

D Dataset Statistics

We list the data collection quantities in Table 6, and plot visualizations of three aspects: prompt topic and annotated span proportions are shown in Figure 10, and average span lengths are shown in Figure 11.

E Detailed Analysis

In this section we perform a detailed analysis of the trends of individual error types and decoding

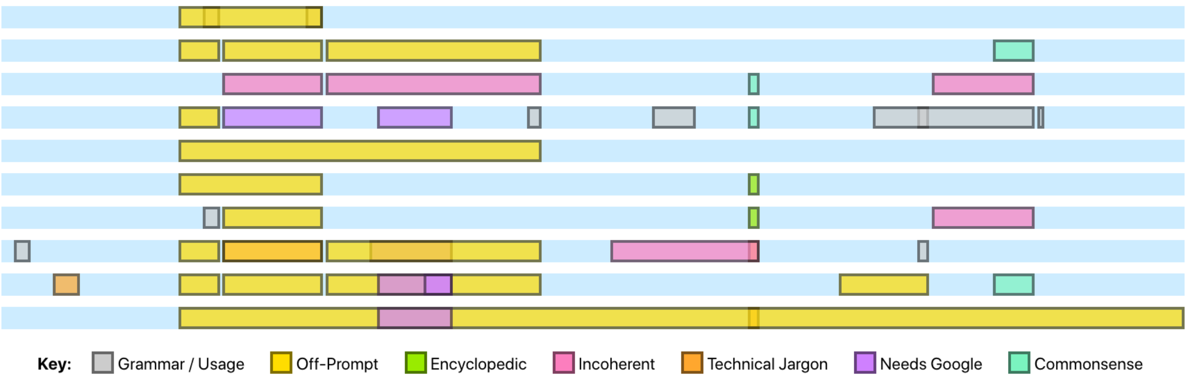


Figure 8: A visual representation of the 10 annotations we collected for one paragraph. Each blue bar represents one annotator, where the width of the bar represents the text of the paragraph. Colored bars drawn on top of the blue bar represent spans marked as errors. We draw bars semi-transparently to show overlapping errors. We can see that some problematic spans (e.g., the **Off-Prompt** section) are marked by almost all workers and given the same label. Other spans are marked by only a subset of the workers (e.g., **Commonsense** and **Incoherent** spans on the right side), or have some label disagreement.

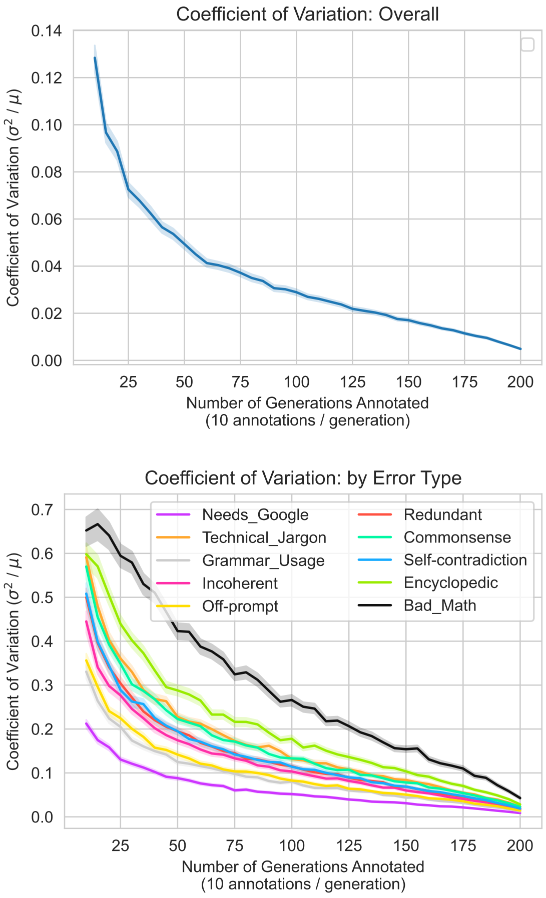

Figure 9: Change in coefficient of variation as number of bootstrap samples increases overall (top), and by error type (bottom), with 95% confidence intervals. Data shown for GPT-3 with apples-to-apples decoding configuration (top-$p = 0.96$, $t = 1$, no *f.p.*).

Error	mean	std.	c.v. (%)
Bad Math	8.51	3.78	44.5
Commonsense	39.40	8.67	22.0
Encyclopedic	13.56	3.94	29.1
Grammar and Usage	126.19	16.81	13.3
Incoherent	96.89	16.58	17.1
Off-Prompt	167.29	23.39	14.0
Redundant	114.77	22.53	19.6
Self-Contradiction	60.54	11.94	19.7
Technical Jargon	100.95	24.09	23.9
Needs Google	482.84	42.22	8.7
Total errors	1268.48	55.59	19.72

Table 5: Bootstrap analysis (sampling 50 generations) of error *counts*, by category (c.v. is the coefficient of variation).

configurations.

To begin, we consider apples-to-apples model decoding configurations. To expand on these results, originally presented in Figure 2, we also present two additional ways of counting error spans, which we show in Figure 12. While our method for counting errors throughout the paper takes into account the number of tokens covered in each span (*span coverage*), we also show plots for scaling each span by its severity level (*span coverage* × *severity*), and by ignoring both severity and token length (simply *span counts*). These changes in measurement further illuminate model error characters, which we discuss in the upcoming sections (refer to Figure 12).

MODEL	top-p	t	F.P.	GENS	ANNS	SPANS
GPT-2 S	0.96	1.00	0	81	809	3694
GPT-2 XL	0.96	1.00	0	81	806	3087
GROVER-MEGA	0.96	1.00	0	80	796	3006
GPT-3	0.40	1.00	0	66	660	2064
	0.70	1.00	0	65	648	1841
	0.90	1.00	0	63	629	1794
	n/a	argmax	0	66	659	2153
	0.96	0.40	0	65	650	2249
	0.96	0.70	0	61	610	1865
	0.96	1.00	0	206	2055	6234
	0.40	1.00	1	50	500	1280
	0.70	1.00	1	53	530	1481
	0.90	1.00	1	54	540	1717
	n/a	argmax	1	51	509	1384
	0.96	0.40	1	53	530	1401
	0.96	0.70	1	50	498	1369
	0.96	1.00	1	84	838	2947
HUMAN				79	789	2296
TOTAL				1308	13056	41862

Table 6: Statistics of data annotated with SCARECROW. t is the (softmax) temperature, and F.P. is a frequency penalty for already-generated words (explained in §5.2). GENS, ANNS, and SPANS are then number of generations, annotations over those generations, and error spans marked during the annotations, respectively. We perform the most annotations on the strongest available generative model (GPT-3).

E.1 **Off-Prompt**

Under initial analysis of *span coverage*, **Off-Prompt** errors show a 🕒*model plateau* at GPT-3. Measuring *span counts* offers barely perceptible improvement, indicating that scaling language models over more in-domain training does not guarantee topicality.

This observation is consistent with growing work on *prompt programming* as a new technique for attempting to steer large pretrained models to complete the desired task (Branwen, 2020; Gao et al., 2020; Reynolds and McDonell, 2021). In practice, we observe that while GPT-3 will sometimes continue a prompt by writing an article, other times, it may elaborate on the prompt itself:

> **PROMPT**
> Do you prefer the idea of being outdoors in the fresh air to being stuck inside with phones ringing and messages pinging?
>
> **GPT-3**
> Can you leave work at work? Are you flexible enough to **cover holidays or take on additional responsibilities? Can you prioritize tasks? If your boss comes to you on Tuesday to confirm the new social media strategy, are you able to pick up the ball and get the messaging hammered out by Thursday?** ...

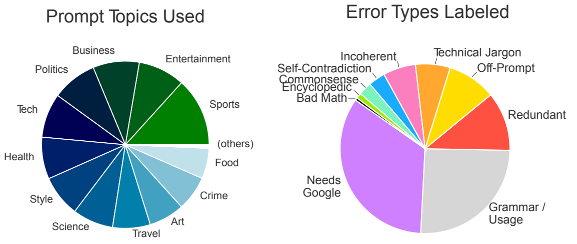

Figure 10: Visual overviews of the distribution of prompt topics used for generating the 1.3k paragraphs used in the annotation (left), and the types of the 41k spans labeled during the annotation (right).

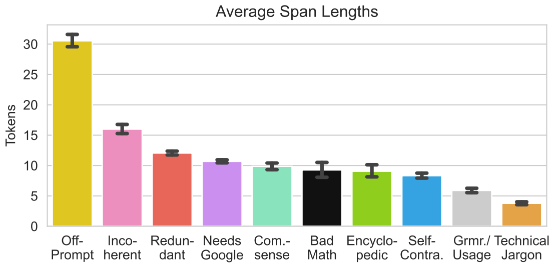

Figure 11: Average number of tokens covered by each annotated span. We observe span length correlates with how abstract the error category is, from word-level issues (**Technical Jargon**), through phrase-level semantics (e.g., **Commonsense**), and into problems of pragmatics (**Off-Prompt**).

Of course, this generation is not *literally* **Off-Prompt**, but it is out of place when other generations are continuations of the prompt, rather than further elaborations of it.

While avoiding **Off-Prompt** errors for language models is worth exploring with prompt programming and other avenues, an investigation of these techniques is outside the scope of this work.

Finally, we note that **Off-Prompt** spans are the most prevalent *error* (not reader issue) marked for human-authored text. We suggest that a higher rate of false positives for this error type, coupled with its prevalence in model-generated text, makes further refinement of this error a compelling avenue for further study.

E.2 **Self-Contradiction**

While changing from *span coverage* to *span counts* alters the relative order of GPT-2 XL and Grover (though still within confidence bounds), the puzzling question is why GPT-2 Small performs better than most (or all) other models. Why would the smallest model produce the fewest **Self-Contra-**

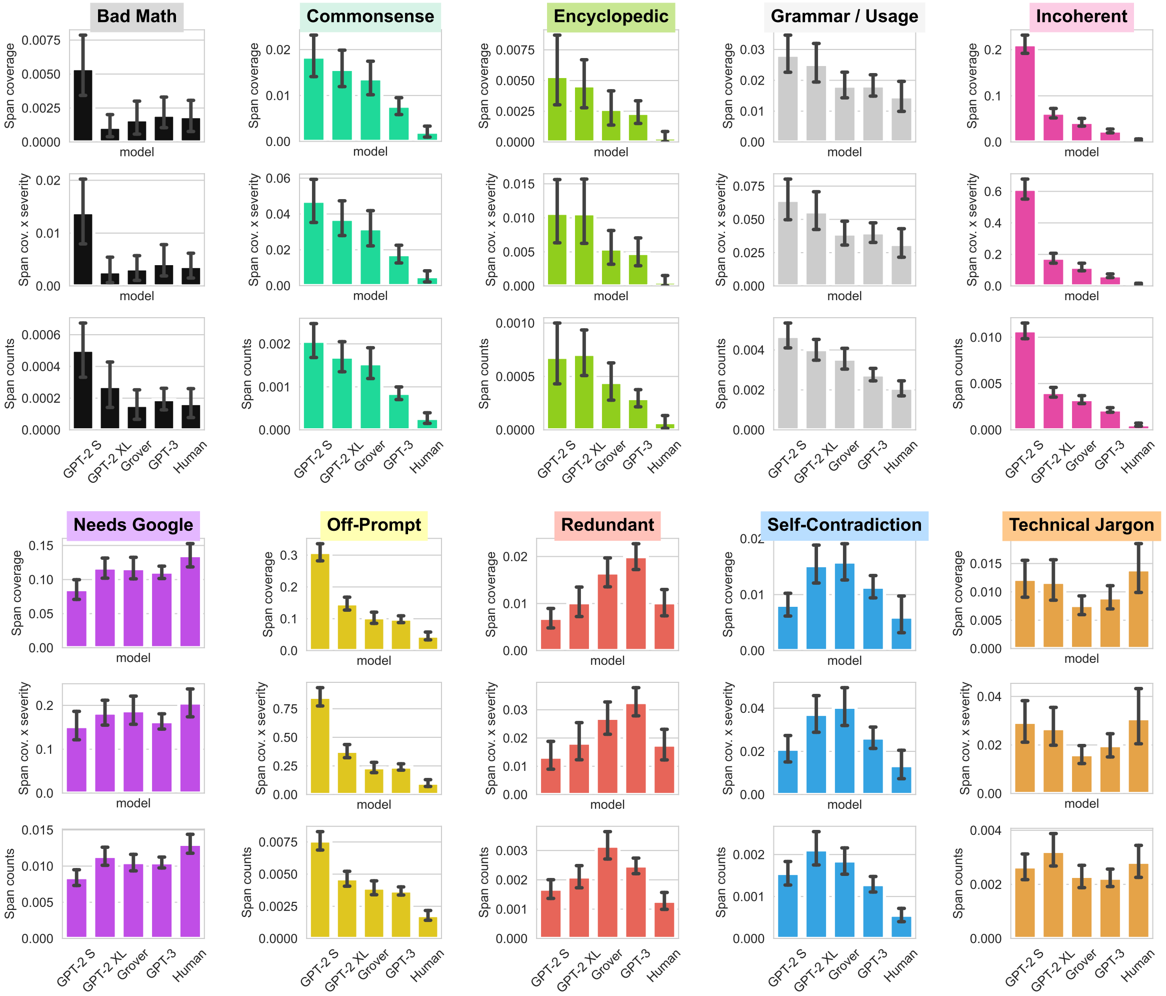

Figure 12: Comparison of three different ways of measuring quantities of error span annotations, shown per label. (The top plot for each error type is identicial to the one shown in Figure 2.) The top method (*span coverage*) is used in the rest of the paper; we provide the comparisons here to illustrate how this decision affects analysis. **Top subplots:** *span coverage*, where the number of tokens annotated as the error span are divided by the length of each annotation. (Annotations with no spans count as 0.) Intuitively, this measures the expected portion of tokens that will be covered by an error span. **Middle subplots:** *span coverage* × *severity*, like the top measure, but each span's token count is multiplied by its severity, more harshly penalizing errors intuitively marked as worse. **Bottom subplots:** *span counts*, where each error span simply counts as 1, regardless of the span length. In all cases, model configurations are set as closely as possible (top-$p = 0.96$, $t = 1.0$, no frequency penalty), severity-1 grammar errors are removed (see §C), and 95% confidence intervals are shown as bands. **Takeaways:** Compared to the approach used in the rest of the paper (*span coverage;* top), scaling by severity (middle) does not affect the relative model ordering, primarily widening confidence intervals. However, ignoring span lengths (bottom) does affect the results in several cases. **Grammar and Usage** and **Encyclopedic** develop clearer ↘*decreasing* shapes, previously suffering from various levels of ◷*model plateau* at GPT-3. Furthermore, the relative model ordering is changed for **Redundant**, **Self-Contradiction**, and **Technical Jargon** spans.

diction errors?

We posit the reason is that GPT-2 generations are so **Incoherent** and **Off-Prompt** that there is little opportunity for relevant, comprehensible points to be made and then reversed. For example, see the GPT-2 Small annotated generation in the top left of Figure 7. The entire text is covered by **Off-Prompt** and **Incoherent** errors.[8] If we look at GPT-2 Small's error distribution in Figure 3, we see most of its added density comes from significantly

---

[8] The high double-error coverage reveals another consideration: to what *depth* (i.e., number of overlapping spans) will annotators mark? By the design of our framework, **Incoherent** errors serve as a fall-back, but without it, we might imagine poor generations splatter-painted by other error types.

more **Off-Prompt** and **Incoherent** tokens.

E.3 **Redundant**

The different counting methods shown in Figure 12 reveal a change in the results for **Redundant** errors. Rather than repetition simply increasing as models grow larger, we observe that GPT-3 repeats in a similar number of cases (lower span *counts*), but for more tokens (higher span coverage). This matches the qualitative observation that GPT-3 produces larger *topically* repetitive blocks, rather than simple word or phrase repetitions generated by GPT-2-sized models:

> **GPT-2 Small**
> ... owners have started growing their own breeds and dogs are **starting to start** so there's really ...
>
> **GPT-3**
> The focus of your thoughts should be on the task at hand, **not on your productivity. You shouldn't be thinking about how you can be more productive. You should be thinking about how you can be productive right now.**
> ...

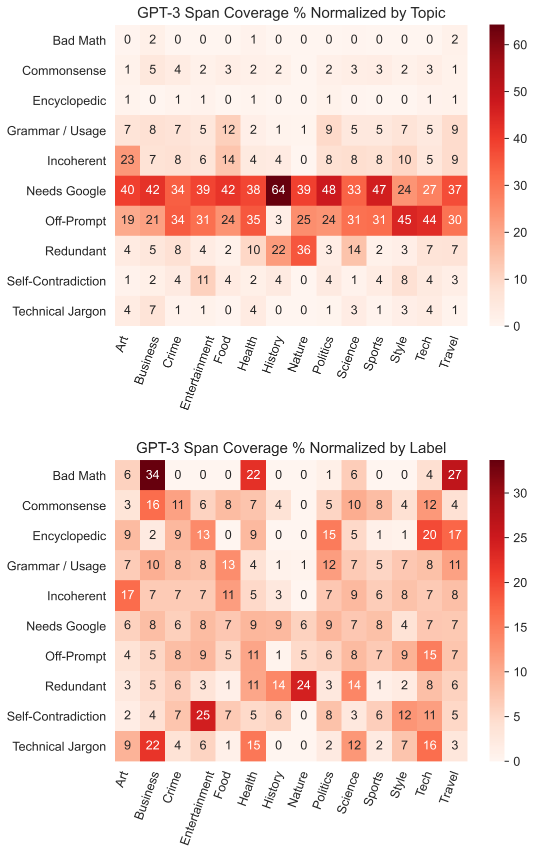
Such repetitions can be more difficult to clearly isolate, because even slight wording changes produce variations in tone and connotation. Rather than being identical *semantically*, we observe GPT-3 will seem stuck on a particular *topic*, elaborating on and rephrasing similar ideas more times than a human writer (hopefully) would.

E.4 Reader Issues

We observe the highest number of **Needs Google** and **Technical Jargon** issues in human-authored text.

Needs Google issues broadly represent any specific claim that could be fact-checked. In our domain (news articles), these are primarily whether an event happened on a particular day, whether a person holds a role, or whether a mechanism works as described (e.g., chemical or technical). As seen in Figure 13 (which shows GPT-3's span distribution), **Needs Google** issues happen roughly equally for all topics. We believe this trend is due to the news article domain, which is prone to a high density of specific information. As such, for other domains, this trend may be less prevalent, more difficult to label (e.g., subtle claims assumed to be true in long running text), or both.

We observe that **Technical Jargon** issues are influenced by topic (Figure 13, bottom), occurring significantly more frequently in *Business, Health, Science,* and *Technology* topics than in others. This trend displays a clear topic-dependence even within a single broader domain (news). These results indicate that both reader issues are characteristics of natural text. Of course, one might wish to measure or minimize potential reader issues for a particular application—for example, claim verification, or controlling for reading level.



GPT-3 Span Coverage % Normalized by Topic

	Art	Business	Crime	Entertainment	Food	Health	History	Nature	Politics	Science	Sports	Style	Tech	Travel

Figure 13: Span coverage across both topic (x-axis) and span label (y-axis) for GPT-3 generated spans (*apples-to-apples* decoding: $p = 0.96, t = 1$, and no frequency penalty). **Top:** normalized by topic (column); **bottom:** normalized by error type (row).

E.5 Decoding Hyperparameters

We discuss the effects of the decoding hyperparameters we consider—top-p, temperature, and frequency penalty—on generation quality. For the sake of annotation cost, we only vary these parameters for the strongest model available, GPT-3.

First, we show the effect of varying top-p and temperature alone (i.e., with no frequency penalty) on different error types. Figure 14 shows the effect on two salient spans: **Off-Prompt** and **Redundant**. (We omit others for space.) We observe that annotators naturally label errors the way we would

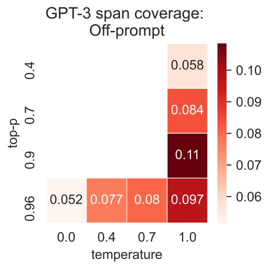

Figure 14: GPT-3 span coverage for **Off-Prompt** (left) and **Redundant** (right) for values of top-p and temperature ($t = 0$ is argmax; both plots with no frequency penalty; argmax sampling is agnostic to the top-p value, so we simply plot it in the $p = 0.96$ cell). **Takeaway:** Our annotation confirms intuitive expectations of the effect of sampling on two error categories. When sampling from a larger pool of words (higher p and t), a model is more likely to veer **Off-Prompt**, but less likely to produce **Redundant** text.

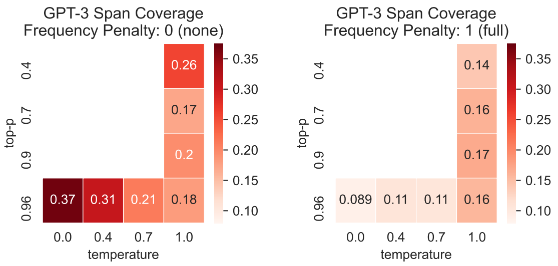

Figure 15: Comparison of *frequency penalty* off (left) and full (right) for GPT-3 (removing reader issues and severity-1 **Grammar and Usage** errors; argmax sampling is agnostic to the top-p value, so we simply plot it in the $p = 0.96$ cell). We observe the frequency penalty improves average span coverage for all values of top-p and temperature. Furthermore its trend is reversed: with a frequency penalty, the least diverse sampling mechanisms (low temperature and low top-p) now produce text with the fewest error spans, rather than the most. (See Figure 4 for confidence intervals on each value.)

intuitively expect the model to produce them, given the hyperparameter changes. The bottom-right corner of each subplot, where $t = 1$ and $p = 0.96$, is the configuration with the highest amount of randomness from sampling. As we move away from that corner—either left by lowering temperature, or up by lowering top-p—we lower the amount of randomness. We observe a positive correlation with randomness and **Off-Prompt** errors, and an inverse correlation with **Redundant** errors. In other words, sampling from a larger set of words makes the model more prone to changing topics, but less likely to repeat itself, and vice versa.

After confirming these intuitive measures, we turn our attention to Figure 15, which investigates the overall error spans for GPT-3 both without (left) and with (right) the frequency penalty. (Note that unlike Figure 14, both heatmaps in Figure 15 have the same color scale.) We observe that introducing the frequency penalty lowers error rates for every value of temperature and top-p that we try. Furthermore, it appears to reverse the trend seen without a frequency penalty: that sampling from a larger set of words produces fewer errors.

The overall results for all decoding configurations were shown previously in Figure 4. In the next section, we focus on the GPT-3 decoding configuration that produced the fewest number of errors, and compare it to human authored text.

E.6 Best GPT-3 vs. Humans

The best GPT-3 configuration shown in Figure 4—argmax sampling with frequency penalty = 1—appears to match error rates seen in human text. Is the text generated by this model truly as error-free as news articles?

We first look at the error composition of both sets of annotations. To get a clear picture of the potential problems, we plot only error spans (ignoring reader issues), and we omit length scaling, instead plotting span counts. This breakdown is shown in the left plot of Figure 16. The error compositions are similar, the largest differences being more **Redundant** errors for GPT-3, and more **Grammar and Usage** errors for human-authored text.

Next, we perform a manual analysis of 160 errors, sampling 10 at random from each of the 8 error types for each model (GPT-3 and human-authored text). We show the results in the center plot of Figure 16. We notice that a greater portion of errors in human-authored text were due to artifacts present in the text-only format of the Common Crawl. For example, links to other articles or advertisements sometimes appear in the middle of an article's text. While annotators were quick to mark these spans, they reflect errors in formatting, not in writing. We partition these errors separately and exclude them from the subsequent calculations.[9]

---

[9] GPT-3's generations also sometimes exhibited what appeared to be formatting errors due to training on web-scraped

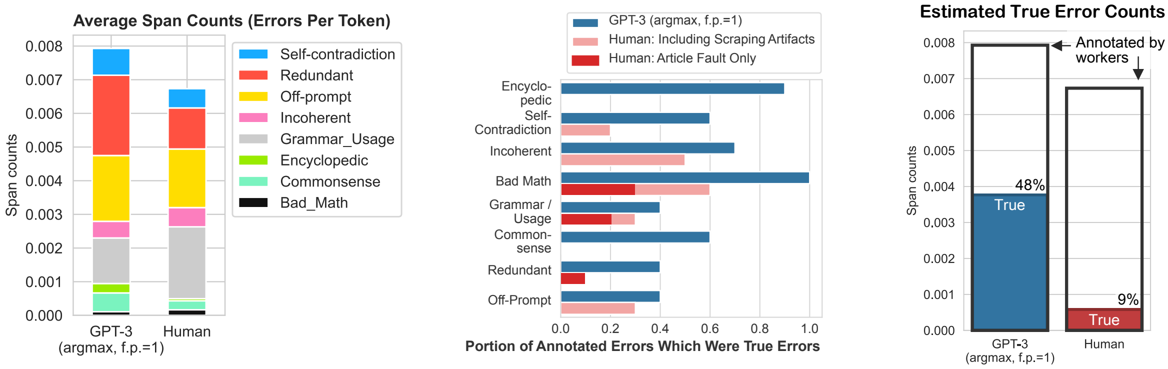

Figure 16: Analysis of the best GPT-3 configuration (*argmax, freq. penalty = 1*) vs. human-authored text. **Left:** A breakdown of errors by type. **Center:** Results of manually annotating 10 random spans from each type with whether the error was legitimate. For human-authored text, we also show errors marked on scraping artifacts that were present in the Common Crawl data. **Right:** Scaling each error type (*left plot*, now shown in black outline) by the portion of errors found to be legitimate (*center plot*), we estimate the true errors counts for each model (color-filled portions). **Takeaway:** Humans have more difficulty spotting errors in higher quality text; accounting for this difference dramatically increases the gap between model-authored and human-authored text. For simplicity, all plots use error *counts* rather than error *coverage*—i.e., they count the number of error spans, rather than scaling by the number of tokens covered.

Finally, we scale each error type's prevalence for each model (i.e., the left plot of Figure 16) by the portion of errors that we estimate to be legitimate based on our manual annotation (i.e., Figure 16, center) to produce the right plot of Figure 16. After taking into account each error type's frequency, we estimate that 48% of GPT-3's worker-annotated errors overall are legitimate, compared to 9% for human-written articles.

This analysis suggests two findings. First, human-authored news paragraphs contain many times fewer issues than text authored by GPT-3 using the best decoding configuration we tested. Second, the noise of error annotations may be as high as 90% when assessing high-quality text. Though it would require further manual annotation to verify, we conjecture that the trend of GPT-3's error spans being more reliable (only 50% noise) would continue, and that text generated by GPT-2 would contain even fewer false positives. We note that such rates are not fixed—after all, the manual annotations were done by one of the authors simply by reading carefully—but that more realistic text may require correspondingly more effort by human annotators.

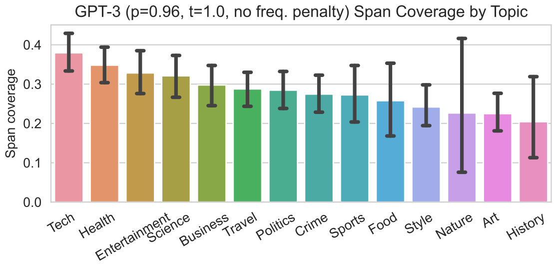

Figure 17: Average span coverage for different topics (GPT-3 generations with apples-to-apples decoding configuration), with 95% confidence intervals. While the majority of topics display no significant trend, we observe that more technical topics such as *Tech* and *Health* are covered by a higher density of error spans than *Style* and *Art*.

E.7 Topics

As noted in §5.3, we collect data using prompts drawn primarily from 12–14 news topics. For conciseness, we show results only for GPT-3, and only for the standard apples-to-apples decoding configuration.

Figure 17 plots, based on the prompt topics, the average portion of the generation that is covered by error spans. While there is no significant difference between most topics, the results do indicate that generating text in more technical domains leads to higher span counts.

Figure 13 shows individual span prevalence by topic. The top heatmap normalizes each topic (col-

---

text, though more rarely. For example, some generations contained *Which?* after vague noun phrases, which appear to be learned from Wikipedia, where under-specified information is tagged by an editor with this word. For fairness, we removed these errors from GPT-3's tally as well, though they were few enough we do not plot them separately.

umn) independently. **Needs Google** issues and **Off-Prompt** errors dominate the error types, with a few exceptions: for *History*, and *Nature* articles, **Redundant** trumps **Off-Prompt** as a source of errors.

For the bottom, if we instead normalize by error label (row), we can observe which topics are more prone to certain error types than others. For example, we can see **Bad Math** errors are most common in *Business* and *Health* generations; *Entertainment* causes the most **Self-Contradiction** errors; and **Technical Jargon** issues appears more frequently in articles about *Business, Technology,* or *Health*.

E.8 Error explanations

Figure 18 displays word clouds for common unigrams and bigrams found in the error explanations for each error type, and Figure 19 shows the average explanation lengths for each error type. For **Technical Jargon**, **Redundant**, and **Needs Google** error types, the prominent words do not provide much illumination and they have short average explanation length, indicating that the explanations are straightforward affirmations of the category (*"I think this is financial jargon," "The information is repeated,"* or *"I would need Google to check this."*). But for categories like **Encyclopedic** and **Bad Math**, we observe some coarse trends: "year" is prevalent in both, "movie" appears in **Encyclopedic**, and "million" is present in **Bad Math**, which suggests that the explanations are more likely from outside knowledge and needs some calculation (*"The iPhone uses a lightening connector not a L-shaped connector," or "5000 feet is 1524 meters."*)

Figure 20 presents a few representative explanations for four error types, taking particular note of their explanation lengths (Figure 19). Both **Self-Contradiction** and **Redundant** errors have antecedents, but their explanations are markedly different. Explanations for **Self-Contradiction** contain more information describing the particular semantics that is reversed, which are less obvious at first glance than other errors. On the other hand, **Redundant** errors are more straightforward to spot, often involving simple lexical overlap, and so don't require elaboration.

Explanations for **Commonsense** contain the true commonsense knowledge that the text violates, which may take several words to explain. But an explanation for a **Grammar and Usage** error simply corrects the error; as these errors are easier to fix, the explanation lengths are often short.

F Future Work

We outline several further directions of study centering around the SCARECROW annotation framework, considering both natural implications and broader steps.

F.1 SCARECROW Studies: Simple

Find the best-performing GPT-3 decoding hyperparameters. We observed that for GPT-3, a frequency penalty value of 1 with argmax sampling produced fewer error spans than any other configuration (Fig. 4). We have not tried varying the frequency penalty to values *between* 0 and 1, or adding any *presence penalty* (§5.2), both of which then allow for fresh explorations of top-p and temperature.

Study decoding parameters in smaller models. How good can (a finetuned) GPT-2 get? We saw decoding parameters considerably impacted GPT-3's performance, moving it from edging out Grover to error rates close to humans (Fig. 4). Could such decoding changes have a similar effect on a GPT-2-sized model? Or might a smaller model favor different decoding hyperparameteres?

Back-off annotations. We observed good annotator agreement given the complexity of the task, but the odds that two annotators agree exactly on each span's type and boundaries remains only moderate (§C). We did not try backing-off (a) error types into coarser categories (e.g., language, factual, reader issue) or even to binary presence; (b) span boundaries into phrase or sentence-level annotations. Applying a type of back-off could also allow clustering methods to discover different error ontologies.

Improve automatic error detection. While we present baseline results for automatic span error detection (§6), we anticipate that significant progress is still available in this new task.

F.2 SCARECROW Studies: Complex

Align multiple annotations. In the current work, we largely treat annotators independently, with the exception of measuring their overlap to study agreement (§C) or taking their union to train prediction model (§6). However, we might consider other

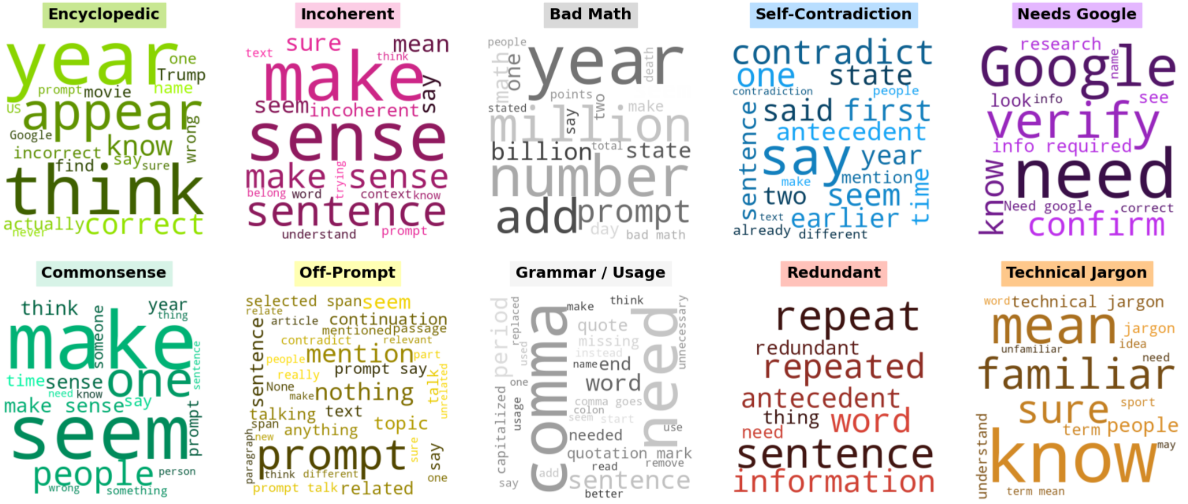

Figure 18: Common unigrams and bi-grams observed in the explanations written for each annotated span, grouped by error type.

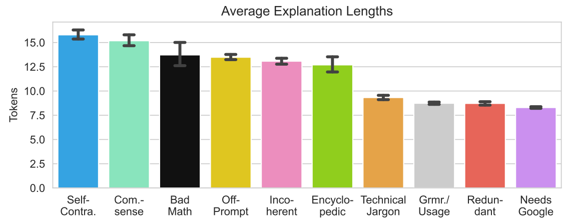

Figure 19: Average number of tokens in explanation for each error type. We observe explanation length correlates with how obvious the error type is, where categories like **Grammar and Usage** and **Technical Jargon** are easier to find and explain than **Self-Contradiction** and **Commonsense**.

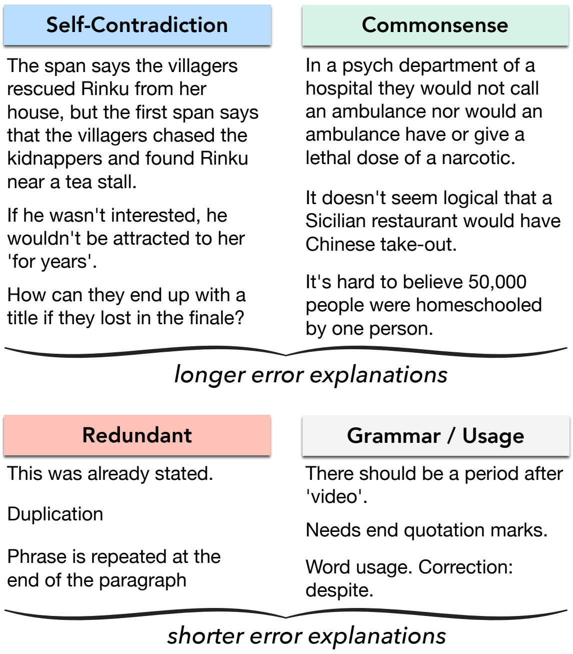
ways of viewing the 10 annotations for each generation together. For example, we might consider the aggregate decision of *whether* a token is labeled with *any* span a measure of how noticeable or jarring an error is. This measure may be related to error severity, but may be distinct from it.

One might also consider formal methods for computing annotation alignments. The Gamma measure, proposed by Mathet et al. (2015), satisfies the long list of criteria needed to align and measure SCARECROW annotations: spans of multiple types, with gaps, full and partial span overlap, more than three annotators, and the potential to merge or split annotations (which we have not addressed in this paper). While we performed experiments with this measure, we experienced difficulties producing intuitive alignments with the authors' software, which disallows configuring parameters of



Self-Contradiction

The span says the villagers rescued Rinku from her house, but the first span says that the villagers chased the kidnappers and found Rinku near a tea stall.

If he wasn't interested, he wouldn't be attracted to her 'for years'.

How can they end up with a title if they lost in the finale?

Commonsense

In a psych department of a hospital they would not call an ambulance nor would an ambulance have or give a lethal dose of a narcotic.

It doesn't seem logical that a Sicilian restaurant would have Chinese take-out.

the mixed-integer programming problem.[10] Emerging concurrent work (Titeux and Riad, 2021) offers a reimplementation of this measure that exposes additional parameters, which may be a promising avenue. However, it is possible that aligning annotations is a challenging task on its own that might

---

[10] The mixed-integer programming approach is also computationally intensive; e.g., memory alone prevented us from computing alignments for pilot studies with twenty annotators, even on a machine with 500GB of RAM.

require use of the explanations.

Characterize error nuance. Related to the previous point about error alignment, one might study whether model size affects span agreement. Anecdotally, errors from larger models like GPT-3—even of the same type, like **Commonsense** errors—are more difficult to describe without careful consideration, and may also be more difficult to identify.

Characterize repetition. Our quantitative studies of **Redundant** errors (e.g., Figs. 14 and 12) point to semantic repetition as the major issue that emerges as models are scaled. Though this effect may be mitigated by changes to the decoding algorithm (like the frequency penalty), we still observe that models have difficulty striking a balance of repetition. With excessive paraphrasing, generated text seems *stuck* on an idea. But equally, if a generation moves too quickly between ideas without linking them together or to an overall theme, the text lacks coherence. We posit that the issue of **Redundant** text emerges as the shadow of encompassing issues of narrative structure and discourse.

F.3 Broadening SCARECROW

Constrained generation This paper focuses on open-ended generation, but a natural extension of this method would be to assessing constrained generation tasks, such as machine translation.

New error types Especially if considering a novel task setting, new error types may prove useful. For example, in constrained generation, one might consider an **Adequacy** error, which—as in machine translation—would indicate that the meaning of a span diverges from what is expected given the generation constraints. Furthermore, one might need to introduce annotations on the provided (not generated) text to account for desired semantic components that are *missing* from the generated text. Or, perhaps for a dialog setting, one might introduce a **Generic** label, which would indicate that a portion of the generation is otherwise coherent and correct, but offers a lack of new information.[11]

Corpus-level evaluation Other work has considered the evaluation of natural language generations at-scale, looking at distributional properties of the text (Caccia et al., 2020; Pillutla et al., 2021). We suggest that these views are complementary to instance-based, human evaluation proposed here, and combining the approaches could lead towards a more holistic view of generative evaluation. For example, while all **Self-Contradiction** errors right now are *within-document*, one could similarly identify *cross-document* contradiction errors, where a model is inconsistent at a more global scale.

F.4 Applications

Detecting factuality One potential application of the SCARECROW data could be using the **Needs Google** spans as a dataset of its own. In addition to training models to identify spans that require verification, one could go a step further and consider *evidence retrieval* for each span, and even propose a classification task.[12]

Editing errors One errors can be detected, can they be fixed? The difficulty and scope of fixing SCARECROW-identified errors may depend on the error type, as error fixes may have cascading effects in the rest of the document.

---

[11] Such generic language may be seen as violating Grice's Maxims (Grice, 1975), for example, by providing a dearth of information *quantity*, or by flouting improper *manner* by lacking brevity.

[12] Minimally, **Needs Google** spans from human-authored reputable news text should (hopefully) all be factually correct.

Transkimmer: Transformer Learns to Layer-wise Skim

Abstract

Transformer architecture has become the de-facto model for many machine learning tasks from natural language processing and computer vision. As such, improving its computational efficiency becomes paramount. One of the major computational inefficiency of Transformer-based models is that they spend the identical amount of computation throughout all layers. Prior works have proposed to augment the Transformer model with the capability of skimming tokens to improve its computational efficiency. However, they suffer from not having effectual and end-to-end optimization of the discrete skimming predictor. To address the above limitations, we propose the Transkimmer architecture, which learns to identify hidden state tokens that are not required by each layer. The skimmed tokens are then forwarded directly to the final output, thus reducing the computation of the successive layers. The key idea in Transkimmer is to add a parameterized predictor before each layer that learns to make the skimming decision. We also propose to adopt reparameterization trick and add skim loss for the end-to-end training of Transkimmer. Transkimmer achieves 10.97× average speedup on GLUE benchmark compared with vanilla $\text{BERT}_{\text{base}}$ baseline with less than 1% accuracy degradation.

1 Introduction

The Transformer model (Vaswani et al., 2017) has pushed the accuracy of various NLP applications to a new stage by introducing the multi-head attention (MHA) mechanism (Lin et al., 2017). Further, the BERT (Devlin et al., 2019) model advances its performances by introducing self-supervised pre-training, and has reached the state-of-the-art accuracy on many NLP tasks.

Compared to the recurrent fashion models, e.g. RNN (Rumelhart et al., 1986), LSTM (Hochreiter and Schmidhuber, 1997), the Transformer model leverages the above attention mechanism to process all the input sequence. By doing so, extremely large scale and long span models are enabled, resulting in a huge performance leap in sequence processing tasks. However, the computation complexity of the attention mechanism is $O(N^2)$ with the input length of N, which leads to the high computation demand of the Transformer model.

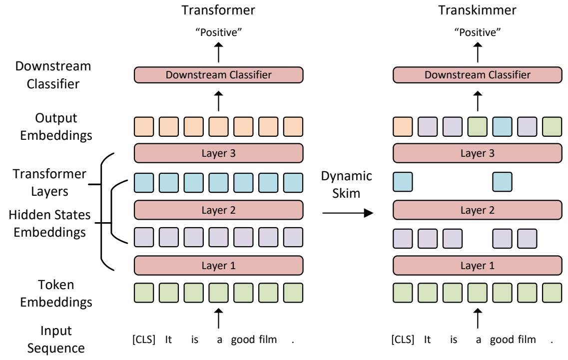

Figure 1: Overview of Transkimmer dynamic token skimming method. Tokens are pruned during the processing of Transformer layers. Note that actually we don't need all the tokens given to the downstream classifier in this sequence classification example. We show the full length output embedding sequence to demonstrate the forwarding design of Transkimmer.

Some prior works (Goyal et al., 2020; Kim and Cho, 2021; Kim et al., 2021; Ye et al., 2021) explore the opportunity on the dynamic reduction of input sequence length to improve the Transformer's computational efficiency. Its intuition is similar to the human-being's reading comprehension capability that does not read all words equally. Instead, some words are focused with more interest while others are skimmed. For Transformer models, this means adopting dynamic computation budget for different input tokens according to their contents. To excavate the efficiency from this insight, we propose to append a skim predictor module to the Transformer layer to conduct fine-grained dynamic token pruning as shown in Fig. 1. When processed by the Transformer layers, the sequence of token

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 7275 - 7286
May 22-27, 2022

hidden state embeddings are pruned at each layer with reference to its current state. Less relevant tokens are skimmed without further computation and forwarded to the final output directly. Only the significant tokens are continued for successive layers for further processing. This improves the Transformer model inference latency by reducing the input tensors on the sequence length dimension.

However, the optimization problem of such skim decision prediction is non-trivial. To conduct pruning of dynamic tensors, non-differentiable discrete skim decisions are applied. Prior works have proposed to use soft-masking approximation or reinforcement learning to resolve, which leads to approximation mismatch or nonuniform optimization. Transkimmer propose to adopt reparameterization technique (Jang et al., 2017) to estimate the gradient for skim prediction. As such, we can achieve the end-to-end joint optimization obejective and training paradigm. By jointly training the downstream task and skim objective, the Transformer learns to selectively skim input contents. In our evaluation, we show Transkimmer outperforms all prior input reduction works on inference speedup gain and model accuracy. Specifically, BERT$_{\text{base}}$ is accfelerated for $10.97\times$ on GLUE benchmark and $2.81\times$ without counting the padding tokens. Moreover, we also demonstrate the method proposed by Transkimmer is generally applicable to pre-trained language models and compression methods with RoBERTa, DistillBERT and ALBERT models.

This paper contributes to the following 3 aspects.

- We propose the Transkimmer model which accelerates the Transformer inference with dynamic token skimming.
- We further propose an end-to-end joint optimization method that trains the skim strategy together with the downstream objective.
- We evaluate the proposed method on various datasets and backbone models to demonstrate its generality.

2 Related Works

Recurrent Models with Skimming. The idea to skip or skim irrelevant sections or tokens of input sequence has been studied in NLP models, especially recurrent neural networks (RNN) (Rumelhart et al., 1986) and long short-term memory network (LSTM) (Hochreiter and Schmidhuber, 1997). When processed recurrently, skimming the computation of a token is simply jumping the current step and keep the hidden states unchanged. LSTM-Jump (Yu et al., 2017), Skim-RNN (Seo et al., 2018), Structural-Jump-LSTM (Hansen et al., 2019) and Skip-RNN (Campos et al., 2018) adopt this skimming design for acceleration in recurrent models.

Transformer with Input Reduction. Unlike the sequential processing of the recurrent models, the Transformer model calculates all the input sequence tokens in parallel. As such, skimming can be regarded as the reduction of hidden states tensor on sequence length dimension. Universal Transformer (Dehghani et al., 2019) proposes a dynamic halting mechanism that determines the refinement steps for each token. DeFormer (Cao et al., 2020) proposes a dual-tower structure to process the question and context part separately at shallow layers specific for QA task. The context branch is preprocessed off-line and pruned at shallow layers. Also dedicated for QA tasks, Block-Skim (Guan et al., 2021) proposes to predict and skim the irrelevant context blocks by analyzing the attention weight patterns. Progressive Growth (Gu et al., 2021) randomly drops a portion of input tokens during training to achieve better pre-training efficiency.

Another track of research is to perform such input token selection dynamically during inference, which is the closest to our idea. POWER-BERT (Goyal et al., 2020) extracts input sequence at token level while processing. During the fine-tuning process for downstream tasks, Goyal et al. proposes a soft-extraction layer to train the model jointly. Length-Adaptive Transformer (Kim and Cho, 2021) improves it by forwarding the inflected tokens to final downstream classifier as recovery. Learned Token Pruning (Kim et al., 2021) improves POWER-BERT by making its pre-defined sparsity ratio a parameterized threshold. TR-BERT (Ye et al., 2021) adopts reinforcement learning to independently optimize a policy network that drops tokens. Comparison to these works are discussed in detail in Sec. 3. Moreover, SpAttn (Wang et al., 2021) facilitate POWER-BERT design with a domain-specific hardware design for better acceleration and propose to make skimming decisions with attention values from all layers.

Early Exit Early exit (Panda et al., 2016; Teerapittayanon et al., 2016) is another method to execute the neural network with input-dependent computational complexity. The idea is to halt the execution during model processing at some early exits. Under the circumstance of processing sequential inputs, early exit can be viewed as a coarse-grained case of input skimming. With the hard constraint that all input tokens are skimmed at the same time, early exit methods lead to worse accuracy and performance results compared to input skimming methods. However, the early exit method is also generally applicable to other domains like convolutional neural networks (CNN). DeeBERT (Xin et al., 2020), PABEE (Zhou et al., 2020), FastBERT (Liu et al., 2020) are some recent works adopting early exit in Transformer models. Magic Pyramid (He et al., 2021) proposes to combine the early exit and the input skimming ideas together. Tokens are skimmed with fine-grained granularity following POWER-BERT design and the whole input sequence is halted at some early exits.

Efficient Transformer. There are also many efforts for designing efficient Transformers (Zhou et al., 2020; Wu et al., 2020; Tay et al., 2020). For example, researchers have applied well studied compression methods to Transformers, such as pruning (Guo et al.), quantization (Wang and Zhang, 2020; Guo et al., 2022), distillation (Sanh et al., 2019), and weight sharing. Other efforts focus on dedicated efficient attention mechanism considering its quadratic complexity of sequence length (Kitaev et al., 2020; Beltagy et al., 2020; Zaheer et al., 2020) or efficient feed-forward neural network (FFN) design regarding its dominant complexity in Transformer model (Dong et al., 2021). Transkimmer is orthogonal to these techniques on the input dimension reduction.

3 Input Skimming Search Space

In this section, we discuss the challenges of dynamic input skimming idea in details. Moreover, we compare techniques and design decisions from prior works described in Tbl. 1.

3.1 Optimization Method

The first challenge of input skimming is the optimization with discrete skimming decisions. In specific, the decision for pruning the hidden state tensors (i.e., reducing their sequence length) is a binary prediction. As such, the skim prediction model is non-differentiable and unable to be directly optimized by gradient back propagation. Prior works handle the discrete binary skimming decision by using a set of complicated training techniques, which we categorize in Tbl. 1.

Models	Optimization	Input	Discard	Strategy
POWER-BERT (Goyal et al., 2020)	Soft-Masking	Attention	Discard	Searched
LAT (Kim and Cho, 2021)	Soft-Masking	Attention	Forward	Searched
LTP (Kim et al., 2021)	Soft-Masking	Attention	Discard	Learned
TR-BERT (Ye et al., 2021)	RL	Embedding	Forward	Searched
Transkimmer	Reparameterize	Embedding	Forward	Learned

Table 1: Summary of prior token reduction works and their design choices including POWER-BERT, Length-Adaptive Transformer (LAT), Learned Token Pruning (LTP) and TR-BERT. The design details are discussed in Sec. 3.

Soft-Masking. Some works (Goyal et al., 2020; Kim and Cho, 2021; Kim et al., 2021) propose to use the soft-masking training trick which uses a continuous value for predicting the skimming prediction. During the training process, the predicted value is multiplied to the hidden states embedding vectors so that no actual pruning happens. In the inference phase, this continuous skimming prediction value is binarized by a threshold-based step function. The threshold value is pre-defined or determined through a hyper-parameter search process. Obviously, there exists a training-inference paradigm mismatch where the actual skimming **only** happens at the inference time. Such a mismatch leads to a significant accuracy degradation.

Reinforcement Learning. TR-BERT (Ye et al., 2021) proposes to use the reinforcement learning (RL) to solve the discrete skimming decision problem. It uses a separated policy network as the skimming predictor, and the backbone Transformer model is considered as the value network. At first, the backbone Transformer is fine-tuned separately. It then updates the skimming policy network by using the RL algorithm. This multi-step training paradigm is tedious. And training the backbone Transformer and skimming policy network separately is sub-optimal compared to the joint optimization paradigm. Moreover, the large search space of such RL objective is difficult to converge especially on small downstream datasets.

Reparameterization. In this work, we propose to use the reparameterization technique to address the discrete skimming decision challenge. Its core idea is to sample the backward propagation gradient during training, whose details we describe in Sec. 4. The advantage of our method is that it enables the joint optimization of skim predictor and backbone Transformer model and therefore achieves the optimal solution. For example, we will later demonstrate in Fig. 4 that the different tasks or datasets prefer different layer-wise skimming strategies, which are learned by our method. We will further explain the results in Sec. 5.4.

3.2 Design Choices

In our work, we also jointly consider other design choices regarding the skimming optimization, which includes the choice of input to the skimming module and how to deal with the skimmed input. We first explain the choices made by prior works, and then explain the choice of our method.

Strategy. For the skimming optimization methods described above, there can be different strategies regarding the implementation details. Generally, the skimming strategy can be categorized into search-based or learning-based approach, as described in Tbl. 1. However, when applied to various downstream NLP tasks and datasets, the dynamic skimming scheme prefers different layer-wise strategies as we mentioned above. This layer-wise skimming characteristics makes the search-based approach not scalable and generally applicable. In contrast, our method enables the joint training of skimming strategy and downstream task , which leads to better skimming decisions with reference to both efficiency and accuracy. LTP is the only by prior works adopting learning-based method, which, however, uses the soft-masking approach and suffers from the training-inference mismatch.

Input for Skimming. POWER-BERT, LAT and LTP treat the attention weight value as importance score and utilize it as the criterion for making the skimming decision. Compared to this value-based method (Guan et al., 2020), TR-BERT uses hidden state embeddings as input feature. In our work, we use the hidden state embeddings because they enclose contextual information of the corresponding input token. Our work shows that the joint training of skimming module and backbone Transformer model leads to that the embeddings also learn to carry features for skimming prediction.

Skimming Tokens. For the tokens pruned dynamically by the skimming decision during processing, it is natural to remove them from all the successive layers. However, LAT and TR-BERT propose to forward such tokens to the final output of the Transformer encoder, which keeps the dimension of the Transformer output unchanged. Our work adopts the forward-based design because it is more friendly for the Transformer decoder module on downstream tasks.

4 Transkimmer Methodology

4.1 Transformer with Skim Predictor

To predict which tokens to be pruned, we append an extra prediction module before each layer as shown in Fig. 2. This prediction module outputs a skimming mask M, which is used to gather the hidden state embedding H at the sequence length dimension. The pruned embedding is then feed to the Transformer layer as its input.

$$\begin{aligned} H^{i+1} &= Transkimmer^{i}(H^{i}) \\ &= Transformer^{i}(Gather(H^{i}, M^{i})) \end{aligned} \tag{1}$$

In the skim mask, we use output 1 to denote remaining tokens and 0 to denote pruned tokens. The gathering operation is to select the input tensor with a provided mask. By optimizing this stand-alone skim module, syntactically redundant and semantically irrelevant tokens are skimmed and pruned. The proposed skim predictor module is a multi-layer perceptron (MLP) network composed of 2 linear layers with a layer norm operation (Ba et al., 2016) and GeLU activation (Hendrycks and Gimpel, 2016). The activation function is an arbitrary function with discrete output as skim decision.

$$\begin{aligned} M^{i} &= SkimPredictor(H^{i}) \\ &= Activation(MLP(H^{i})) \\ \text{where } MLP &= Linear(GeLU(LN(Linear))) \end{aligned} \tag{2}$$

This skim predictor introduces extra model parameters and computation overhead. However, both of them are very small compared to the vanilla Transformer model, which are about 7.9% and 6.5% respectively. We demonstrate later that the computation overhead of skim module is much smaller than the benefits brought by the reduction of input tensor through skimming.

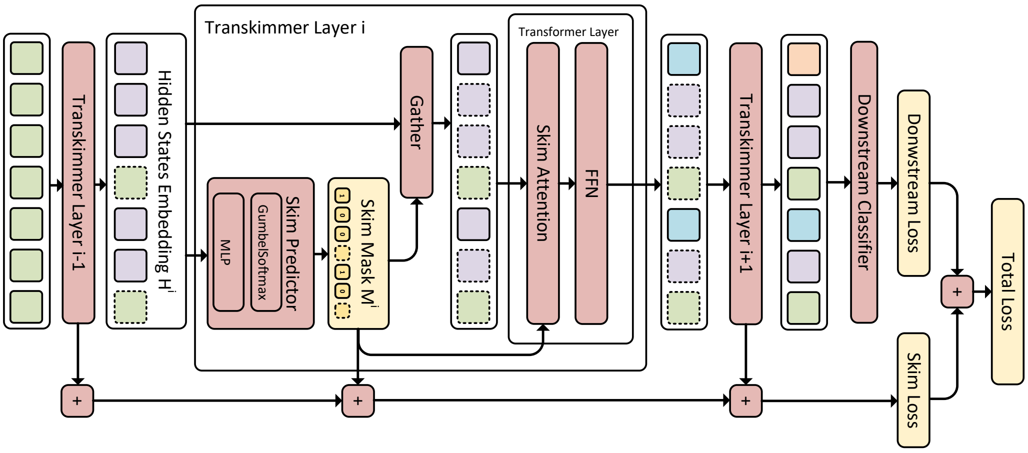

Figure 2: Architecture and end-to-end optimization objective of Transkimmer. The dashed token embeddings are directly forwarded to the final output of Transformer layers without further processing.

For the tokens pruned by the skim module at each layer, we forward the these pruned hidden state embeddings to the last Transformer layer. As such, the final output of the whole Transformer model is composed of token embeddings skimmed at all layers and the ones processed by all layers without being skimmed.

$$H^L = \sum_{i=0}^{L-1} H^i \cdot M^i \tag{3}$$

And this output is used for classification layers on various downstream tasks. This makes the skimming operation also compatible for token classification tasks such as extractive question answering (QA) and named entity recognition (NER). This also restores the once abandoned information for downstream tasks.

4.2 End-to-End Optimization

In the above discussion, we have described that Transkimmer can be easily augmented to a backbone model without modification to its current structure. Furthermore, Transkimmer is also capable to utilize the pre-trained model parameters and finetune the Transkimmer activated Transformer-based models on downstream tasks. With an extra skim loss appended to the optimization object, this fine-tuning process is also performed end-to-end without changing its origin paradigm.

Skim Attention. In the training procedure, Transkimmer does not prune the hidden state tensors as it does in the inference time. Because the gathering and pruning operation of a portion of tokens prevents the back-propagation of their gradients. The absence of error signal from negative samples interference the convergence of the Transkimmer model. Therefore, we propose skim-attention to mask the reduced tokens in training instead of actually pruning them. The attention weights to the skimmed tokens are set to 0 and thus unreachable by the other tokens.

$$SkimAttn(H^i) = Attn(H^i) \cdot M^i \tag{4}$$

By doing so, the remaining tokens will have the identical computational value as actually pruning. And the gradient signal is passed to the skim predictor module from the skim attention multiplication.

Gumbel Softmax. Following the discussion in Sec. 3.1, the output decision mask of skim predictor is discrete and non-differentiable. To conquer this inability of back propagation, we use the reparameterization method (Jang et al., 2017) to sample the discrete skim prediction from the output probability distribution π^i of the MLP. The gradient of the non-differentiable activation function is estimated from the Gumbel-Softmax distribution during back propagation.

$$\begin{aligned} M_j^i &= Activation(\pi_j^i) \text{ ,for j = 0,1} \\ &= GumbelSoftmax(\pi_j^i) \\ &= \frac{exp((log(\pi_j^i) + g_j^i)/\tau)}{\sum_{k=0}^{1} exp((log(\pi_k^i) + g_k^i)/\tau)} \end{aligned} \tag{5}$$

g_j^i are independent and identically sampled from $Gumbel(0, 1)$ distribution. τ is the temperature hyper-parameter controlling the one-hot prediction distribution. We take $\tau = 0.1$ for all experiments.

Dataset	CoLA	RTE	QQP	MRPC	SST-2	MNLI	WNLI	QNLI	STS-B	SQuAD	IMDB	YELP	20News

Harmony Coefficient	0.3	0.8	0.2	0.5	0.3	0.2	0.5	0.1	0.3	0.8	0.5	0.5	0.5

Table 2: Summary of evaluation datasets. The input sequence length matches the setting of prior works POWER-BERT and LTP. It is determined by covering 99 percentile of input samples without truncation.

To achieve better token sparsification ratio, we further add a skim loss term to the overall optimization objective as follows

$$Loss_{skim} = \frac{1}{L}\sum_{L-1}^{1}\frac{sum(M^i)}{len(M^i)}. \tag{6}$$

The skim loss is essentially the ratio of tokens remained in each layer thus representing the computation complexity speedup. By decreasing this objective, more tokens are forced to be pruned during processing. To collaborate with the original downstream task loss, we use a harmony coefficient λ to balance the two loss terms. As such, the total loss used for training is formulated as

$$Loss_{total} = Loss_{downstream} + \lambda Loss_{skim}. \tag{7}$$

With the use of the previous settings, the Transkimmer model is trained end-to-end without any change to its original training paradigm.

Unbalanced Initialization. Another obstacle is that skimming tokens during the training process makes it much unstable and decreases its accuracy performance. With the pre-trained language modeling parameters, the skim predictor module is random initialized and predicts random decisions. This induces significant processing mismatch in the backbone Transformer model, where all tokens are accessible. Consequently, the randomly initialized skim predictor makes the training unstable and diverged. We propose an unbalance initialization technique to solve this issue. The idea is to force positive prediction at first and learn to skim gradually. Generally, parameters are initialized by zero mean distribution as

$$\omega \sim N(0, \sigma). \tag{8}$$

We propose to initialize the bias vector of the last linear layer in the skim predictor MLP with unbalanced bias as

$$\beta_i \sim N((-1)^{i+1}\mu_0, \sigma), \tag{9}$$

where i stands for the bias vector for prediction 1 or 0. Consequently, the skim predictor tends to reserve tokens rather than skimming them when innocent. The mean value μ_0 of the unbalanced distribution set to 5 for all the experiments.

5 Evaluation

5.1 Setup

Datasets. We evaluate the proposed Transkimmer method on various datasets. We use the GLUE(Wang et al., 2019) benchmark including 9 classification/regression datasets, extractive question answering dataset SQuAD-v2.0, and sequence classification datasets 20News (Lang, 1995), YELP (Zhang et al., 2015) and IMDB (Maas et al., 2011). These datasets are all publicly accessible and the summary is shown in Tbl. 2. The diversity of tasks and text contexts demonstrates the general applicability of the proposed method.

Models. We follow the setting of the BERT model to use the structure of the Transformer encoder and a linear classification layer for all the datasets. We evaluate the base setting with 12 heads and 12 layers in prior work (Devlin et al., 2019). We implement Transkimmer upon BERT and RoBERTa pre-trained language model on downstream tasks.

Baselines. We compare our work to prior token reduction works including POWER-BERT (Goyal et al., 2020), Length-Adaptive Transformer (LA-Transformer) (Kim and Cho, 2021), Learned Token Pruning (LTP) (Kim et al., 2021), DeFormer (Cao et al., 2020) and TR-BERT (Kim et al., 2021). We also compare our method with model compression methods of knowledge distillation and weight sharing. Knowledge distillation uses a teacher model to transfer the knowledge to a smaller student model. Here we adopt DistilBERT (Sanh et al., 2019) setting to distill a 6-layer model from the BERT$_{\text{base}}$ model. By sharing weight parameters among layers, the amount of weight parameters reduces. Note that weight sharing does not impact the computa-

Table 4: Performance and FLOPs evaluation on several downstream tasks and datasets with BERT$_{\text{base}}$ as backbone model. The speedup results are emphasized considering the padding setting.

tion FLOPs (floating-point operations). We evaluate Transkimmer on ALBERT (Lan et al., 2020) that shares weight parameters among all layers. To express that token reduction method is compatible with these model compression methods, we further implement Transkimmer method with this works to demonstrate their cooperation effect. Besides, DeeBERT(Xin et al., 2020) is a Transformer early exit baseline which can be regarded as coarse-grained input skimming.

Padding. While processing batched input samples, Transformer models perform a padding operation on the input sequences to align the input length. Sequences are appended with a special padding token *[PAD]* to a predefined sequence length for the convenience of successive computing. This is a trivial setting for general evaluation but could lead to possible pseudo speedup for token reductions works. Because the padded tokens can be pruned without prediction. For the prior works, there are three evaluation settings with reference to padding, padding to a fixed sequence length, padding to mini-batch maximum length and no padding (denoted as **Sequence**, **Batch** and **No** in Fig. 3 & 4). We indicate the padding methods of prior works and evaluate Transkimmer with different padding settings for a fair comparison. The speedup of padding to mini-batch maximum length setting is related to batch size and processing order of input samples. So it is difficult to make a direct comparison under this setting. However, it can be estimated with padding to fixed sequence length as upper bound and no padding as lower bound. The sequence length on different datasets is determined following prior works' settings (Goyal et al., 2020; Kim et al., 2021). We measure the inference FLOPs as a general measurement of the model computational complexity on all platforms. We use the TorchProfile(**?**) tool to calculate the FLOPs for each model.

Training Setting. We implement the proposed method based on open-sourced library from Wolf et al. (2020)[1]. For each baseline model, we use the released pre-trained checkpoints [2]. We follow the training setting used by Devlin et al. (2019) and Liu et al. (2019) to perform the fine-tuning on the above datasets. We perform all the experiments reported with random seed 42. We use four V100 GPUs for training experiments.

The harmony coefficient λ is determined by hyper-parameter grid search on development set with 20% data random picked from training set set. The search space is from 0.1 to 1 with a step of 0.1.

5.2 Overall Results

We show the overall results on several datasets and demonstrate our observations. Tbl. 3 demonstrates the accuracy and speedup evaluated on GLUE benchmark. And Tbl. 4 further demonstrates the results on other datasets with longer input.

---

[1] The source code is available at `https://github.com/ChandlerGuan/Transkimmer`.

[2] We use pre-trained checkpoints from Wolf et al. (2020).

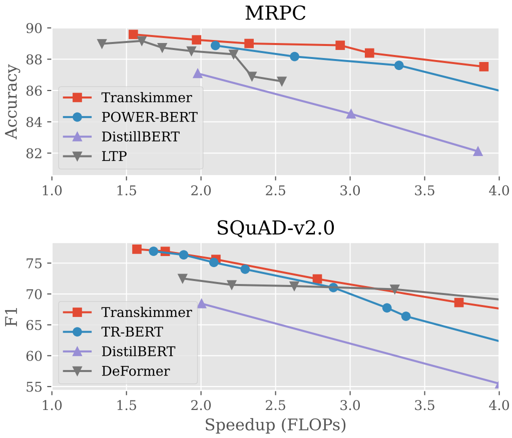

Figure 3: Trade-off results between accuracy and speedup of MRPC and SQuAD-v2.0 datasets by tuning the harmony coefficient. Note that different padding settings are used for each baseline while Transkimmer doesn't count any padding.

Comparison to vanilla model baseline. Generally, Transkimmer achieves considerably speedup to the vanilla models with a minor accuracy degradation, which is less than 1% for nearly all cases. The average speedup is 2.81× on GLUE benchmark and over 2× on the other datasets. This demonstrates the inference efficiency improvement of the Transkimmer input reduction method. We also evaluate Transkimmer with RoBERTa model as backbone and reach 3.24× average speedup on GLUE benchmark. This result further expresses the general applicability of Transkimmer with different Transformer-based pre-trained language models. Among all the datasets we evaluated, Transkimmer tends to have better acceleration ratio on the easier ones. For example, sequence classification tasks like QQP and STS-B are better accelerated than QA or NLI datasets. We suggest that the Transformer backbone is able to process the information at shallower layers and skim the redundant part earlier. This is also demonstrated in the following post-hoc analysis Sec. 5.4.

Comparison to input reduction prior works. As shown in Tbl. 3, Transkimmer outperforms all the input reduction methods by a margin on GLUE benchmark. To make a fair comparison, we evaluate Transkimmer with two padding settings, padding to fixed sequence length or no padding. For most cases, Transkimmer has better accuracy performance and higher speedup ratio at the same time. When taking the special padding token into account, Transkimmer is able to accelerate $\text{BERT}_{\text{base}}$ model for 10.97× on GLUE benchmark. Transkimmer also outperforms the other methods on tasks shown in Tbl. 4. TR-BERT has the closet performance compared with Transkimmer but with a much complicated RL paradigm and larger search space.

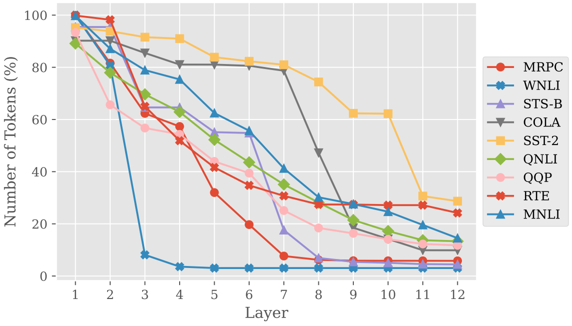

Figure 4: Layer-wise skim strategies analysis of datasets from GLUE benchmark. The normalized area under curve is viewed as an approximate speedup ratio with reference to sequence length.

Comparison to model compression methods. The comparison to two model compression methods is shown in Tbl. 3. Transkimmer outperforms the knowledge distillation and weight sharing baseline by a margin. Besides, the dynamic skimming idea itself is orthogonal to this existing model compression methods. To elaborate, we further adopt the proposed Transkimmer method on DistilBERT and ALBERT models. With the proposed end-to-end training objective, Transkimmer is easily augmented to these methods. There is also no need to change the original training process. The result shows that the Transkimmer method further accelerates the inference efficiency of compressed models with nearly no extra accuracy degradation.

5.3 Accuracy and Performance Trade-Off

Fig. 3 demonstrates the accuracy and performance trade-off analysis by tuning the harmony coefficient. We show the results on MRPC and SQuAD-v2.0 datasets to give comparisons with different baselines. It is shown that Transkimmer achieves a better accuracy to speedup Pareto curve compared to prior works. Transkimmer is able to provide better acceleration gain with less accuracy degradation. Especially, Transkimmer has a 1.5× speedup without accuracy loss. The result validates our design decisions analyzed in the input reduction search space choices.

Dataset	Example
SST-2	[CLS] Even horror fans will most likely not find what they're seeking with trouble every day; the movie lacks both thrills and humor. [SEP]
SQuAD	Question: [CLS] In what country is Normandy located? [SEP] Context: The Normans (Norman: Nourmands; French: Normands; Latin: Normanni) were the people who in the 10th and 11th centuries gave their name to Normandy, a region in France. They were descended from Norse ("Norman" comes from "Norseman") raiders and pirates from Denmark, Iceland and Norway who, under their leader Rollo, agreed to swear fealty to King Charles III of West Francia. Through generations of assimilation and mixing with the native Frankish and Roman-Gaulish populations, their descendants would gradually merge with the Carolingian-based cultures of West Francia. The distinct cultural and ethnic identity of the normans emerged initially in the first half of the 10th century, and it continued to evolve over the succeeding centuries. [SEP] Answer: France

Table 5: Post-hoc case study of SST-2 sentimental analysis and SQuAD QA tasks from Transkimmer model with BERT$_{\text{base}}$ setting. The color indicated by the colorbar represents the Transformer layer index where the token is pruned. Specifically, the black tokens are fully processed without being skimmed.

5.4 Post-hoc Analysis

Skim Strategy. Fig. 4 is the result of the number of tokens remained for the processing of each Transformer layer. The normalized area under each curve is a rough approximation of the speedup ratio with reference to the tokens number. By end-to-end optimization, Transkimmer learns significant distinguished strategies on different tasks. On WNLI dataset, over 90% of tokens are pruned within the first 3 layers and guarantees a high acceleration gain. The steer cliff at layer 7 on COLA demonstrates a large portion of skimming at this particular position. We suggest that this is because the processing of contextual information is sufficient for the skimming decision at this specific layer.

Post-Hoc Case Study. Moreover, several post-hoc case studies are demonstrated with Tbl. 5. In the SST-2 sentimental analysis example, the definite articles and apostrophes are discarded at the beginning. And all words are encoded in contextual hidden states embeddings and gradually discarded except for a few significant key words. Only the special token *[CLS]* is fully processed in this example for final sentimental classification. However, on the token classification task example from SQuAD dataset, all tokens are given to the downstream classifier to predict the answer position. The answer tokens are processed by all Transformer layers. Similarly, the question part is also kept with tokens containing enough information. Another detail worth mentioning is that we use subword tokenization for the SQuAD dataset. As such, subword tokens of the same word might be discarded at different layers. For instance, the word *Francia* is tokenized into *fran-* and *-cia* two subword tokens, which are pruned at layer 4 and 6 respectively.

6 Conclusion

Input skimming or dynamic input reduction is an emerging Transformer model acceleration method studied by many works recently. This idea utilizes the semantic structure of language and the syntactic information of the input context for inference acceleration. Compared to static model weight compression methods, input skimming explores the redundancy in the input and hidden state tensors. As such, it is orthogonal and compatible with those model compression algorithms with its dynamic feature.

In this work, we propose an accurate and efficient Transformer inference acceleration method by teaching it how to skim input contents. The proposed Transkimmer method is trained with an easy and end-to-end paradigm. Furthermore, Transkimmer is also generally applicable to various Transformer-based model structures. It is even compatible with the static model compression methods like knowledge distillation and weight sharing. We believe that the above features guarantee the Transkimmer method a wide range of applicable production scenarios.

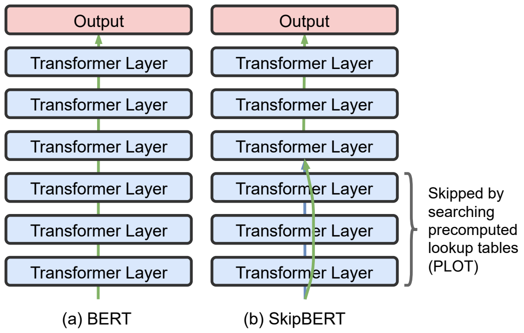
Abstract

In this paper, we propose SkipBERT to accelerate BERT inference by skipping the computation of shallow layers. To achieve this, our approach encodes small text chunks into independent representations, which are then materialized to approximate the shallow representation of BERT. Since the use of such approximation is inexpensive compared with transformer calculations, we leverage it to replace the shallow layers of BERT to skip their runtime overhead. With off-the-shelf early exit mechanisms, we also skip redundant computation from the highest few layers to further improve inference efficiency. Results on GLUE show that our approach can reduce latency by 65% without sacrificing performance. By using only two-layer transformer calculations, we can still maintain 95% accuracy of BERT.[1]

1 Introduction

Pre-trained language models, such as ELMo (Peters et al., 2018), GPT (Radford et al., 2018), BERT (Devlin et al., 2019), XLNet (Yang et al., 2019), and RoBERTa (Liu et al., 2019), have yielded significant improvements to NLP tasks. Despite the gain in accuracy, these models have significant demands in computation and inference time, limiting their use in resource-constrained or latency-sensitive applications. Therefore, it is desirable to reduce the computational overhead of these models while retaining acceptable accuracy.

Knowledge distillation (KD, Hinton et al. 2015) facilitates the transfer of knowledge embedded in pre-trained language models into small student models (Sanh et al., 2019; Sun et al., 2019; Jiao et al., 2020), which usually reduces the redundant parameters of BERT in a uniform manner. Early exit mechanisms (Xin et al., 2020; Zhou et al., 2020; Liu et al., 2020) then use an adaptive number of transformer layers during inference, aiming to reduce redundant calculations from the highest few layers. However, since they build the sequence representation from scratch for each forward pass, they require a certain number of lower layers to capture basic syntactic and semantic information, making it difficult to further reduce inference costs. This naturally raises a question: Can we reduce the computation at the lower transformer layers?



(a) BERT (b) SkipBERT

Figure 1: Comparison of inference between BERT and SkipBERT. The computation of shallow (lower) layers of SkipBERT are skipped by searching PLOT.

In this paper, we propose SkipBERT, a novel scheme that skips the computation at the shallow transformer layers of BERT. As revealed by Jawahar et al. (2019); Rogers et al. (2020), the lower layers of BERT mainly focus on short-distance context, while the higher layers are able to capture long-range dependencies. Therefore, it is reasonable to assume that, at lower layers, even if distant tokens are masked, the representation for each token will not vary dramatically. Here, by sweeping over the input text, we get short chunks (n-grams) and use their representations to approximate the hidden states of BERT's lower layers. We then precompute and store representations of text chunks in a *precomputed lookup table* (PLOT). Thus, during inference we only need to *access* PLOT to get the representations of short chunks, which is inexpen-

sive compared with transformer computation.

Fig. 1 compares the inference procedure between vanilla BERT and our proposed SkipBERT. In BERT, the input text needs to be processed by a large number of transformer layers in turn, leading to high latency in inference. In comparison, SkipBERT precomputes the hidden states of lower transformer layers, which are accessed via table lookups, rather than computed in inference-time.

Moreover, SkipBERT exhibits effective compatibility with early exit mechanisms: Since the initial sequence representation in our work is partially contextualized (thanks to PLOT) rather than individual word embeddings, SkipBERT allows exiting from a relatively earlier layer than typical BERT variants, while maintaining good accuracy. We empirically verify this in Section 4.5. Therefore, our approach can skip the calculations of lower and higher layers for the same input, thereby further improving the inference speed.

Our contributions are listed as follows:

- We present SkipBERT to avoid computation at BERT's lower layers during inference. Instead, we construct PLOT and use it to approximate their hidden states.
- We incorporate early exit mechanisms as an enhancement to skip redundant computation, leading to further network acceleration.
- We conduct extensive experiments on GLUE. Compared with BERT, SkipBERT is capable of accelerating inference by up to 65% without compromising GLUE score, or accelerating by 82% while retaining 95% accuracy.

2 Related Work

Knowledge Distillation (Hinton et al., 2015) provides an effective way to transfer the knowledge embedded in a teacher network to a student network. The student network is usually more lightweight than the teacher network and thus more computationally efficient. The student network can be structurally identical to the teacher but contains fewer layers or hidden units, e.g. BERT-PKD (Sun et al., 2019), DistilBERT (Sanh et al., 2019), TinyBERT (Jiao et al., 2020), MiniLM (Wang et al., 2020), and BERT-EMD (Li et al., 2020). Meanwhile, some work adopts specifically designed networks, e.g. SqueezeBERT (Iandola et al., 2020) and MobileBERT (Sun et al., 2020), to reduce the computation per layer.

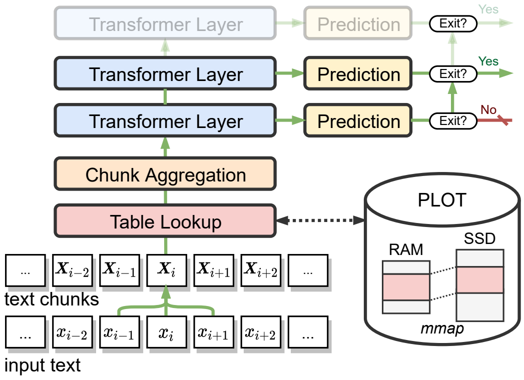

Figure 2: The overview of our system during inference. PLOT stores hidden states of the local transformer layers. The global transformer layers are enhanced with early exit mechanisms.

Input-adaptive inference allows models to choose different computational paths according to the input during inference. In this way, simpler input samples usually require less calculation to make predictions. Recently, DeeBERT (Xin et al., 2020) adapts confidence-based BranchyNet (Teerapittayanon et al., 2016), which uses entropy as an early-exit criterion. FastBERT (Liu et al., 2020) uses self-distillation to train the branch classifiers. RightTool (Schwartz et al., 2020) leverages the same early-exit criterion as in the Shallow-Deep Network (Kaya et al., 2019), i.e., softmax scores of predictions. PABEE (Zhou et al., 2020) stops inference when the intermediate predictions of the internal classifiers remain unchanged consecutively.

Precomputation has also been studied in information retrieval, where documents are assumed to be stored at local database so their representation can be precomputed (Gao et al., 2020). However, this method may not be suitable for other tasks where the input text is unknown before inference.

3 Model

During training, SkipBERT consists of two groups of transformer layers, *local* transformer layers for encoding short-distance context, and *global* transformer layers for leveraging the full context. Once pre-training finishes, our approach will replace local transformer layers with PLOT, which stores the hidden states of local transformer layers; we also enhance global transformer layers with early exit mechanisms to further accelerate inference speed. Fig. 2 presents the overview of our system.

3.1 Preparing Inputs

We define the input text as a sequence of tokens $\boldsymbol{x} = [x_i]_{0 \le i < n}$ in BERT's input style, where n is the number of input tokens.

As shown in Fig. 3, we sweep over the input text to get three-token chunks (tri-grams, $\boldsymbol{X}_i = [x_{i-1}, x_i, x_{i+1}]$), which will also be taken as the index entries of PLOT later. We let cross-border tokens be padding tokens, i.e. $x_{-1} = x_n = x_{[\text{PAD}]}$.

We show in Section 4.8.2 that using longer text chunks (e.g. 5-grams) will improve accuracy since they can bring more context information than tri-grams. However, the number of 5-grams is too large to be enumerated and stored, and thus it is hard to use them in actual applications.

3.2 Leveraging Local Context

Fig. 3 illustrates our procedure to leverage local context. By mapping each word to a d-dimensional embedding, we denote the chunk embeddings by $\tilde{\boldsymbol{X}}_i \in \mathbb{R}^{3 \times d}$. For local transformer layers, we inject position embeddings $\boldsymbol{P} \in \mathbb{R}^{3 \times d}$, and define the initial chunk representations as follows:

$$\boldsymbol{H}_i^{(0)} = \text{LN}(\tilde{\boldsymbol{X}}_i + \boldsymbol{P}) \qquad (1)$$

where $\text{LN}(\cdot)$ is layer normalization.

We use L_{loc} transformer layers to leverage the local context of each text chunk. For layer $0 \le m < L_{\text{loc}}$, we have:

$$\boldsymbol{H}_i^{(m+1)} = \text{Transformer}^{(m)}(\boldsymbol{H}_i^{(m)}). \qquad (2)$$

Note that since each chunk is short enough, it would be possible to precompute these representations before inference. More importantly, these representations are good approximations of those produced by the respective shallow layers of BERT. Thus, given a tri-gram, the embedding produced from $(L_{\text{loc}} - 1)$-th layer is taken as its respective data entry stored in PLOT. We also precompute bi-grams and uni-grams following the same procedure of tri-grams. When a lookup of tri-gram fails (out-of-vocabulary, OOV), the system will resort to bi-grams or uni-grams as an alternative.

Specifically, we randomly replace $\delta\%$ of tri-grams by bi-grams during training. On the one hand, such random replacement allows the model to encounter bi-grams during training, so as to better handle OOVs in inference; on the other hand, it can also be considered a variant of Dropout (Srivastava et al., 2014), which drops tokens rather than hidden units, thereby improving the robustness of our approach. Section 4.7 shows $\delta = 10\%$ works well with different OOV rates. We also show in Section 4.8.2 that even bi-grams have a clear advantage over the baseline, which can be seen as an extreme case when all tri-gram lookups fail.

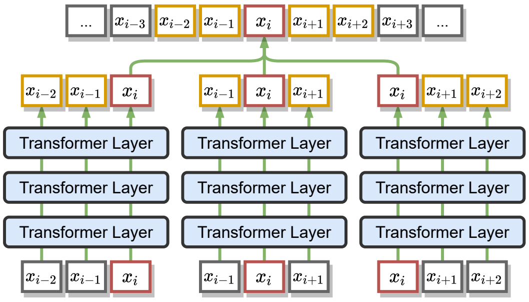

Figure 3: Illustration of how we leverage the local context for token x_i. Yellow-bordered boxes indicate embeddings that interact with token x_i; grey-bordered boxes are independent of x_i.

3.3 Aggregating Text Chunks

Now we get a list of contextualized chunk embeddings. Here we aggregate them to form a feature sequence corresponding to the original input text.

Each token occurs at three consecutive tri-grams, as shown in Fig. 3. By calculating a weighted sum of embeddings that correspond to the same token, we can leverage its context of five tokens:

$$\tilde{h}_i = \sum_{j=-1,0,1} H^{(L_{\text{loc}})}_{i+j,1-j} \cdot \text{Gate}(H^{(L_{\text{loc}})}_{i+j,1-j}), \qquad (3)$$

where $\text{Gate}(\cdot)$ is a sigmoid-based gating mechanism such that $\text{Gate}(x) = \sigma(v_{\text{G}} \cdot x + b_{\text{G}})$, where v_{G} is a learnable vector and b_{G} is a learnable scalar.

Note that these embeddings do not have a sense of the order of the sequence. So we need to inject position and segment embeddings before sending them to the subsequent transformer layers:

$$h_i^{(0)} = \begin{cases} \text{LN}(\tilde{h}_i + \tilde{p}_i + \tilde{s}_A), \text{if } x_i \in A, \\ \text{LN}(\tilde{h}_i + \tilde{p}_i + \tilde{s}_B), \text{if } x_i \in B, \end{cases} \qquad (4)$$

where $\tilde{p}_i$ and $\tilde{s}_{A/B}$ are position and segment embeddings respectively as in Devlin et al. (2019).

3.4 Leveraging Global Context

We denote by $\boldsymbol{h}^{(0)} = [h_i^{(0)}]_{0 \le i < n}$ the aggregated sequence representation. We use L_{glo} transformer layers to further contextualize it. For layer $0 \le m < L_{\text{glo}}$, we have:

$$\boldsymbol{h}^{(m+1)} = \text{Transformer}^{(m+L_{\text{loc}})}(\boldsymbol{h}^{(m)}). \qquad (5)$$

Since we focus on text classification and regression tasks, we use the representation corresponding to token $x_{\text{[CLS]}}$ to compute logit scores:

$$z = \text{Classifier}(h_{\text{[CLS]}}^{(L_{\text{glo}})}) \tag{6}$$

where Classifier$(\cdot)$ is a two-layer feedforward neural network.

When an early exit mechanism is activated, we compute logit scores for each global transformer layer as follows:

$$z^{(m)} = \text{Classifier}^{(m)}(h_{\text{[CLS]}}^{(m)}) \tag{7}$$

We adopt a simple confidence-based early exit mechanism, i.e., once the prediction's maximum logit score is higher than a pre-defined threshold, the result will be returned without passing through the next transformer layers.

3.5 Training

We mainly adopt the two-stage learning procedure proposed in TinyBERT (Jiao et al., 2020). It includes *general distillation* (GD) conducted on large-scale unlabeled corpora, and *task-specific distillation* (TD) to learn from fine-tuned BERT.

General Distillation We perform distillation on the hidden states and attention scores. We compute loss on the chunk aggregation layer and global transformer layer. The local transformer layers are trained with supervision signals from upper layers. The loss is defined as follows:

$$\mathcal{L}_{\text{GD}} = \mathcal{L}_{\text{att}} + \mathcal{L}_{\text{hid}} \tag{8}$$

and we define $\mathcal{L}_{\text{att}}$ and $\mathcal{L}_{\text{hid}}$ as the mean-squared error (MSE) of attention scores and hidden states between the teacher (T) and student (S):

$$\mathcal{L}_{\text{att}} = \sum_{m=1}^{L_{\text{glo}}} \text{MSE}(\boldsymbol{a}_{\text{S}}^{(m)}, \boldsymbol{a}_{\text{T}}^{(g_{\text{att}}(m))}) \tag{9}$$

$$\mathcal{L}_{\text{hid}} = \sum_{m=0}^{L_{\text{glo}}} \text{MSE}(\boldsymbol{h}_{\text{S}}^{(m)} \boldsymbol{W}_{\text{hid}}, \boldsymbol{h}_{\text{T}}^{(g_{\text{hid}}(m))}) \tag{10}$$

where $\boldsymbol{a}^{(m+1)}$ and $\boldsymbol{h}^{(m+1)}$ represent the attention score matrix and hidden states of the m-th transformer layer; $\boldsymbol{h}^{(0)}$ is the outputs of chunk aggregation layer; $\boldsymbol{W}_{\text{hid}}$ is a learnable matrix to transform the hidden states of the student into the same space as the teacher; $g_{\text{att}}(\cdot)$ and $g_{\text{hid}}(\cdot)$ define the layer mapping function between the student and teacher.

For attention-based distillation, we use the uniform mapping strategy to leverage the heterogeneous attention patterns across different layers. For hidden states-based distillation, we use top mapping strategy since the initial sequence representation (outputs of chunk aggregation) are already partially contextualized. The detailed illustration of layer mapping is presented at Appendix E.

Task-Specific Distillation We start from the generally distilled SkipBERT, and use fine-tuned BERT as the teacher for task-specific distillation. The loss is defined as follows:

$$\mathcal{L}_{\text{TD}} = \beta(\mathcal{L}_{\text{att}} + \mathcal{L}_{\text{hid}}) + \mathcal{L}_{\text{pred}} \tag{11}$$

where β is a factor to control the loss weight; $\mathcal{L}_{\text{pred}}$ is the prediction loss that will be defined below.

For classification, the loss function $\mathcal{L}_{\text{pred}}$ is calculated via cross entropy:

$$\mathcal{L}_{\text{pred}} = \text{CE}(z_{\text{S}}/\tau, z_{\text{T}}/\tau) \tag{12}$$

where z_{S} are the logits predicted by the student; z_{T} are the logits predicted by the teacher; τ is the temperature to smooth the probability distribution to facilitate distillation training. For regression, the loss is instead calculated by MSE, i.e., $\mathcal{L}_{\text{pred}} = \text{MSE}(z_{\text{S}}, z_{\text{T}})$.

Early Exit Specifically, when SkipBERT enables early exit mechanisms, we need to train internal classifiers to predict based on the hidden states of their respective layers. Overall, we train the model to minimize a weighted average loss as follows:

$$\mathcal{L}_{\text{pred}} = \frac{\sum_{m=1}^{L_{\text{glo}}} m\mathcal{L}_{\text{pred}}^{(m)}}{\sum_{m=1}^{L_{\text{glo}}} m} \tag{13}$$

where $\mathcal{L}_{\text{pred}}^{(m)}$ is the loss between the predictions of the teacher and the m-th intermediate classifier of the student.

3.6 Constructing PLOT

Considering that the local transformer layers mostly capture generalized knowledge, which do not vary significantly across different tasks, we *do not* update the local transformer layers during fine-tuning. Therefore, once general distillation is finished, we can compute their hidden states to construct PLOT.

To ensure fast response, PLOT should ideally be loaded in the server's RAM during inference. However, such a table could be too large to fully fit into

Model	MACs	Latency	GLUE Score	CoLA (8.5k)	SST-2 (67k)	MRPC (3.5k)	STS-B (5.7k)	QQP (364k)	MNLI (393k)	QNLI (108k)	RTE (2.5k)	WNLI (0.6k)

Table 1: Results on the GLUE benchmark. MACs are multiply–accumulate operations of text with 128 tokens. The results of DistilBERT$_4$, BERT-PKD, TinyBERTv2 are taken from Li et al. (2020). The results of BERT$_{\text{mini4/small4}}$ are taken from google-research/bert. The result of DistilBERT$_6$ is taken from (Jiao et al., 2020). Others are taken from the official GLUE website. "w/ exit": enabling the early exit mechanism.

RAM. Hence we propose to adopt memory-mapped files (*mmap*), which allows for file access via the virtual memory mechanism. By using *mmap*, the frequently used chunk embeddings reside in RAM for fast lookup, while the rare chunks can be stored on SSD, and will be loaded to RAM only when the system demand-pages them. Appendix D presents a simple implementation of PLOT.

4 Experiments

4.1 Data

We use the corpora of Wikipedia[2] and BooksCorpus[3] (Zhu et al., 2015) to perform general distillation. For task-specific distillation, we mainly evaluate SkipBERT and compare it with other baselines on the GLUE benchmark (Wang et al., 2018). Appendix F provides some details.

4.2 Setup

We denote by SkipBERT$_{6+6}$ the scheme with 6 local transformer layers (converted to PLOT) and 6 global transformer layers, each having a hidden size of 768 and intermediate size of 3072. For direct comparisons with 4-layer baselines, we instantiate SkipBERT$_{6+4}$ with 4 thin global transformer layers (hidden size of 312 and intermediate size of 1200). We also instantiate SkipBERT$_{6+2}$ with only 2 global transformer layers to further reduce the latency. Appendix C presents detailed settings.

Training For general distillation, we randomly initialize SkipBERT, and pre-train it with Lamb optimizer (You et al., 2019). We use linear learning rate decay with the peak learning rate of 1e-3 and a batch size of 2048 for around 80k steps, including 4000 warm-up steps.

For task-specific distillation, under the supervision of a fine-tuned BERT, we use AdamW (Kingma and Ba, 2015) to train 20 epochs with a learning rate of 2e-5. We slightly tune the hyperparameters across different tasks, and the details can be found in Appendix B. We do not use any data augmentation strategies.

Inference Following prior work, we evaluate *latency* by performing inference on a per-instance basis, i.e. the batch size for inference is set to 1. This is a common latency-sensitive scenario when processing individual requests from different users. We note that latency on modern GPUs is not sensitive to the hidden size, but mainly depends on the number of sequential operations, i.e. the number of network layers. We report the median performance over 5 runs with different random seeds.

4.3 Results on GLUE

We submitted our model predictions to the official GLUE evaluation server[4] to obtain results on the

---

[2] `https://dumps.wikimedia.org/`

[3] `https://yknzhu.wixsite.com/mbweb`

[4] `https://gluebenchmark.com/`

test set, as summarized in Table 1. We present the results of TinyBERT v2 reported by Li et al. (2020) as the v2 model employs more training corpora than v1, and they eliminate the data augmentation strategy for a fair comparison.

By comparing with baselines (we compare with 6-layer models and 4-layer models separately), we can see that SkipBERT outperforms all compared approaches in terms of GLUE score. Compared with TinyBERT, as we mainly follow their distillation process, our approach shows clear advantages on all tasks. BERT-EMD employs a more sophisticated task-specific distillation process based on general-distilled TinyBERT, and further improves the overall performance. Nevertheless, SkipBERT still maintains an advantage in the overall score.

Specifically, SkipBERT$_{6+4}$ has a similar inference speed to the 4-layer baselines, but achieves higher accuracy on most tasks. We consider that a 4-layer model is somewhat too shallow to capture complex dependencies from scratch. In contrast, SkipBERT effectively compensates by adding "more layers" in effect, even though their computation is skipped by PLOT search during inference. These layers are useful to capture the basic linguistic information, thereby reducing the burden on subsequent layers. Moreover, our method can further reduce the latency with only a slight loss in accuracy. SkipBERT$_{6+2}$ which performs only two-layer transformer calculations maintains accuracy comparable to 4-layer models.

For the 6-layer track, TinyBERT and BERT-EMD both achieve performance comparable to the teacher model. However, SkipBERT$_{6+6}$ also shows competitive results, especially for the challenging CoLA task (predicting linguistic acceptability judgments), on which previous methods do not work well. The local transformer layers of SkipBERT can effectively capture the short-distance grammatical knowledge, e.g. subject-verb-object word order and verbal argument structure, etc., which is considered crucial to CoLA (Warstadt et al., 2019).

The early exit mechanism, tagged by "w/ exit" in Table 1, provides a flexible way to tune the speed-accuracy tradeoff. With early exit enabled, both SkipBERT$_{6+6}$ and SkipBERT$_{6+4}$ achieve further improvements on inference speed with only a minor decrease in accuracy. More exploration will be done in Section 4.5.

Model	EM	F1

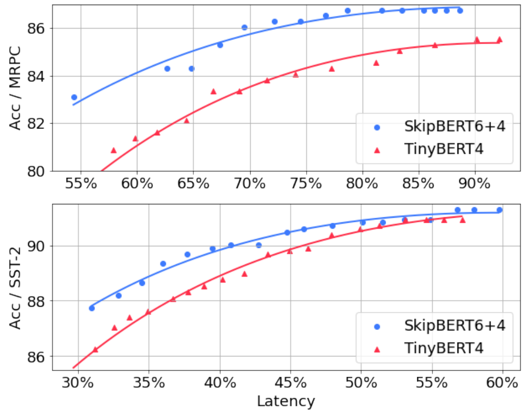

Figure 4: Accuracy-latency curve on the development set of MRPC and SST-2. Both models are equipped with the same early exit mechanism.

4.4 Results on SQuAD

We also investigate the effectiveness of SkipBERT on the reading comprehension task, SQuAD v1.1 (Rajpurkar et al., 2016a). Following previous work, we treat this task as sequence labeling and predict the possibility of each token as the start or end of answer span. Table 2 shows that SkipBERT outperforms all the baselines with large margins. This experiment shows that our approach also works well for relatively complicated task forms.

4.5 Accuracy-Latency Curve

Here we investigate the compatibility between early exit mechanisms and SkipBERT. We draw the accuracy-latency curve by tuning the early exit threshold. The goal is to enlarge the area under the curve – so the model can maintain good accuracy when the average exit layer is small. Fig. 4 compares the results of TinyBERT$_4$ v2 and SkipBERT$_{6+4}$, both using the same early exit mech-

Operation	MACs $d = 768$ / 312	Latency $d = 768$ / 312
Retrieve Text Chunks	-	155 µs / 114 µs
- Chunks to IDs	-	31.4 µs
- Retrieve from *mmap**	-	22.8 µs / 18.4 µs
- Send to GPU	-	101 µs / 64.1 µs
Aggregate Text Chunks	-	48.4 µs / 42.7 µs
Each Transformer Layer	**906M / 146M**	**1.22 ms / 1.18 ms**
Each Classifier	591K / 98K	116 µs / 112 µs

Table 3: Breakdown of computation and average latency of text with 128 tokens (including padding tokens). * varies depending on the input and cache memory, and we report the average value here.

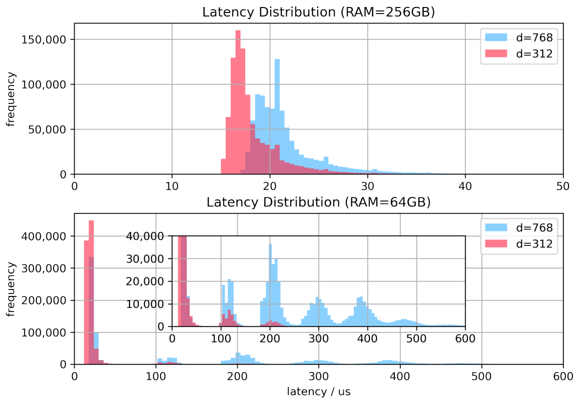

Figure 5: Latency distribution of reading from *mmap*. We evaluate on GLUE training sets, which include text from various sources, to simulate realistic workloads. We zoomed in on the long tail with RAM size of 64GB.

anism. We observe that SkipBERT consistently outperforms TinyBERT on both MRPC and SST-2. Specifically, the curve of SkipBERT is “flatter” than that of TinyBERT, which indicates that even if SkipBERT is forced to exit at a relatively shallow layer, it can still maintain a desirable accuracy. Compared with baselines, our approach starts inference based on PLOT search results rather than from scratch, so even at a lower layer, the representation is well-learned for making predictions.

4.6 Breakdown of Computation and Latency

Table 3 presents the breakdown of computation and average latency of SkipBERT. Detailed hardware information can be found at Appendix A. We can observe that the transformer layers account for the majority of inference time.

We note that there may be some variation in the latency of retrieving data from *mmap*, depending on the cache memory managed by the operating system. Fig. 5 presents the latency distribution of retrieving chunks contained in a text sequence with 128 tokens under different RAM sizes. We perform experiments in Docker containers to limit the RAM size; more results can be found in Appendix G. The upper half of Fig. 5 shows that with enough RAM, the system can directly collect chunk embeddings from RAM, yielding latencies clustered around 20 µs. Meanwhile, with a smaller RAM as shown in the lower half of Fig. 5, most of the latency is still around 20 µs but a small portion of items take several hundred µs due to cache misses. We also observe that the long tail of latency is distributed in several clusters, mainly due to I/O queuing. However, even under heavy I/O load, retrieving data from *mmap* takes less time than the computation of a single transformer layer.

OOV: PLOT size:	0% -	11.2% 168G	14.5% 59.2G	24.7% 12.1G
$\delta = 0\%$	88.0/91.4	87.0/90.6	86.3/90.1	85.8/89.6
$\delta = 5\%$	88.2/91.4	**88.2/91.7**	88.0/91.3	87.3/91.0
$\delta = 10\%$	**88.2/91.6**	88.0/91.4	**88.0/91.4**	**88.0/91.2**
$\delta = 20\%$	88.0/91.4	87.7/91.2	88.0/91.3	88.0/91.2

Table 4: Influence of space costs on the model accuracy. An OOV here means a tri-gram which can not be found at PLOT. We randomly replace $\delta\%$ of tri-grams with bi-grams during training. We evaluate on MRPC.

4.7 Space Costs and OOV

The previous sections prioritize accuracy and efficiency by sacrificing space. Reducing the space costs (by dropping less frequent chunks) allows users to use more economical hardware, but it will lead to OOV issues which may compromise accuracy. Here we only count OOV for tri-grams, since OOVs for bi-grams rarely occur (<0.5%) and have little impact on the final performance.

We collect tri-grams on news corpora[5] and training sets of GLUE to construct PLOT.

Table 4 shows results by reducing the space costs. $\delta = 0\%$ means that the model does not see any bi-grams during training. In this case, if the model encounters a tri-gram lookup failure and reverts to bi-grams, the performance will suffer to some extent. When we randomly replace $\delta\%$ of tri-grams with bi-grams during training, the model becomes more robust to OOVs, and can even slightly improve accuracy. We find $\delta = 10\%$ works well for all cases, and thus we use it as the default value.

Generally, our method can maintain the advan-

Table 5: Effect of the number/type of skipped layers.

Model	r.f.	CoLA	MRPC	MNLI
BERT$_4$	-	23.7	85.0/89.6	79.8/79.6
SkipBERT$_{6+4}$				
w/ 1-gram	1	23.5	85.3/89.5	79.8/79.5
w/ 2-gram	3	29.1	86.3/90.1	80.8/81.0
w/ 3-gram ctr. only	3	32.3	86.0/90.0	80.7/81.1
w/ 3-gram	5	32.9	86.3/90.4	80.9/81.1
w/ 5-gram ctr. only	5	31.9	**87.5/91.2**	**81.2/81.4**
w/ 5-gram	9	**34.5**	86.8/90.7	81.1/81.3

Table 6: Effect of short context. r.f.: receptive field of local layers; ctr. only: only use the embedding of the center token of each chunk; 5-gram results are computed on the fly without using PLOT.

tage even if the OOV rate is at a moderate level. As we will see later at Section 4.8.2, if we only use bi-gram embeddings, i.e. the OOV rate is 100%, our approach is still better than the baseline that does not apply PLOT.

To understand why the backoff strategy, namely to replace tri-grams with bi-grams for OOVs, does not hurt accuracy, we investigate the similarity between them. As shown in Fig. 6, most of them are similar, confirming the feasibility of our backoff strategy; but there is also a long tail where bi-grams cannot well compensate for the missing tri-grams. Fig. 6 also shows some examples with different similarities. Generally, auxiliary tokens that do not contain much meaning by themselves tend to rely more on context. Meanwhile, tokens rich in semantics, e.g. noun phrases, do not vary much in embedding under different ranges of context.

4.8 Ablation Study

We conduct an ablation study in this subsection. We only pre-train SkipBERT on the Wikipedia corpus for 1 epoch for fast validation. We also prepare a generally distilled small BERT$_4$ (the model architecture is identical to TinyBERT$_4$) with the same setup and corpus as a baseline. We report the results on the development set.

4.8.1 Tuning the Number of Skipped Layers

Table 5 compares the results with different numbers of local transformer layers. BERT$_4$ is a baseline that does not employ any skipping mechanism. We can see that all settings that use additional local transformer layers have better performance than BERT$_4$, indicating the effectiveness of our approach. In general, the performance increases when we gradually enlarge the number of local transformer layers. CoLA benefits most from the local transformer layers due to better modeling of short-distance context. However, when it reaches a certain number of local transformer layers, the improvement becomes minimal. We believe that since each token only has the context of five tokens, too many layers may increase the risk of overfitting, which harms the performance. Thus we adopt 6 layers as our default setting.

We also construct variants that replace local transformer layers with a single-layer FFN or CNN, which are computationally lightweight and thus may not need precomputation. However, their accuracy improvement against BERT$_4$ is very limited, which shows that even for short-distance context, using a relatively complex and deep network is beneficial to the final performance.

4.8.2 Effect of Short Context

We investigate the effect of short-distance context leveraged in the local transformer layers of SkipBERT. Table 6 presents the comparisons of using different ranges of short-context in local transformer layers. 1-grams are equivalent to conventional word embeddings, and the performance is similar to the baseline. When using 2-grams, SkipBERT obtains notable improvements since each token can now access its direct neighbors in local transformer layers. 3-grams and 5-grams bring consistent improvements to all tasks. Generally, the results are improved when we broaden the receptive field of local transformer layers, showing that more contexts are always beneficial. However, due to its large number, it would be hard to enumerate n-grams with $n > 3$. It might require certain pruning or compression strategies, which we leave as future work.

In addition, we also study the effect of the weighted sum used in chunk aggregation, Eq. (3). We add comparison against a variant that only uses the embedding of the central token of each chunk, denoted "ctr. only". Table 6 shows that the weighted sum brings improvements over all tasks for the 3-gram setting. However, it is not as effective for the 5-gram setting on MRPC and MNLI. We believe using a weighted sum for five chunks may confuse important semantics and thus affect the accuracy; while for 3-gram setting, this problem is not as serious, and using a weighted sum for neighbor chunks can bring more context information to improve the accuracy.

4.8.3 Effect of Distillation Objective

Model	CoLA	MRPC	MNLI
SkipBERT$_{6+4}$	**32.9**	**86.3/90.4**	80.9/81.1
w/o GD-att	29.9	81.9/87.2	**81.3/81.6**
w/o GD-hid	28.7	85.5/90.0	80.9/81.1
w/o TD-att	31.3	85.8/89.6	80.1/80.1
w/o TD-hid	30.5	85.8/89.9	80.4/80.1

Table 7: Effect of different distillation objectives.

We here show the effects of different distillation objectives. We try to eliminate attention-based or hidden state-based distillation. Results in Table 7 indicate that all distillation objectives are helpful both in the general distillation and task-specific distillation process. In general distillation, both attention and hidden states-based distillation are critical to the final performance of relatively small datasets, e.g. CoLA and MRPC. But for large-scale datasets, e.g. MNLI, removing attention based distillation even improves the performance, which may imply that the student model can benefit more from a fine-tuned teacher model as long as the downstream task has enough data.

In the task-specific distillation, the two distillation objectives are marginally helpful for CoLA and MRPC, while acting more importantly for MNLI. The original TinyBERT uses a data augmentation strategy for all tasks during fine-tuning, which significantly enlarges the training set and makes the effect of task-specific distillation more significant.

5 Conclusion

In this paper, we proposed SkipBERT, a straightforward yet effective approach to skip the computation of BERT's shallow layers. We used representations of short text chunks to approximate BERT's shallow representation, and stored them in PLOT for fast retrieval during inference. Empirical results showed that SkipBERT could achieve performance comparable to BERT while significantly reducing inference time. In the future, we would like to leverage discontinuous text chunks to further improve the accuracy and inference speed. We will also try to reduce storage requirements with appropriate pruning and compression strategies.

A Hardware Information

Computation Related We test on *Intel(R) Xeon(R) Gold 6240C* CPU with 24.75M Cache and 2.60 GHz (3.90 GHz maximum). The GPU model is *Tesla V100* with 32GB Graphics RAM.

Data Retrieval Related The server has 384GB RAM. We store PLOT as *mmap* files and read them from SSD. The SSD used is *Toshiba PX04PMC160* 1.6TB with NVMe driver. It contains four caches of Micron's 5ME77 D9QBJ, DDR3L 1600 MHz. Each one has 512MB capacity, and thus the four make up a 2GB cache capacity. We also note that the CPU used in the experiments contains 48 lanes of PCIe 3.0 bandwidth and throughput for demanding I/O-intensive workloads.

We attach below the results of random 4k read benchmark on our SSD with *fio*,[6] and it takes 107.24 μs on average to retrieve 4k data randomly, which is in line with our latency tests.

B Fine-tuning Details

In this section, we introduce the detailed settings during fine-tuning. We set the maximum sequence length to 128 for the GLUE benchmark. We train 20 epochs with a learning rate of 2e-5. We choose batch sizes from {16, 32}, and β from {0.1, 0.2}.

According to TinyBERT (Jiao et al., 2020), it is useful to first perform the intermediate layer distillation (i.e. with no prediction loss) on the augmented dataset using a fine-tuned teacher model for several epochs. In our experiments, without data augmentation, this strategy is still useful for CoLA, SST-2, MRPC, STS-B, and RTE but not as useful for other tasks. Specifically, we train additional 10 epochs with no prediction loss for CoLA and STS-B, and 1 epoch for SST-2, MRPC, and RTE.

C Model Architecture

Table 8 presents the neural network architecture of SkipBERT$_{6+6}$, SkipBERT$_{6+4}$ and SkipBERT$_{6+2}$, and we compare with BERT$_{12}$ as a reference. The local transformer layers of SkipBERT only appear in the training phase, and we replace them with PLOT in inference-time. We use the same settings of local transformer layers for SkipBERT$_{6+6}$, SkipBERT$_{6+4}$ and SkipBERT$_{6+2}$, since they do not affect inference speed. We reduce the hidden size of SkipBERT$_{6+4}$ so as to be able to compare with recent 4-layer counterparts, and we add a linear layer between local and global transformer layers to match their hidden size. We also instantiate SkipBERT$_{6+2}$ with only 2 global transformer layers to further reduce the latency, where the hidden size setting is the same to SkipBERT$_{6+6}$.

D PLOT Implementation

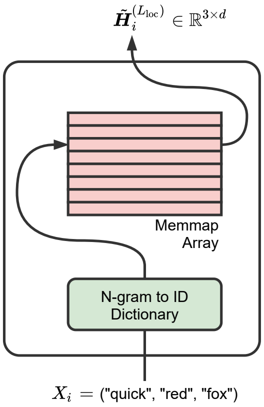

Figure 7: Simple Implementation of PLOT

We here provide a simple implementation of PLOT, as shown in Fig. 7. We store chunk representations in a *mmap* file as a huge numpy array[7]. We use python built-in dictionary to map text chunks (n-grams) to their corresponding IDs, which are the offsets to their corresponding representations in the *mmap* file. By such a two-step procedure, we can get the chunk representation without transformer layer computation.

Table 8: The detailed model architecture of BERT$_{12}$, SkipBERT$_{6+6}$, SkipBERT$_{6+4}$ and SkipBERT$_{6+2}$. MHA: Multi-Head Attention. FFN: Feed-Forward Networks. d_{emb}, d_{in}, d_{out}, d_{ffn}, and n_{head} denote the embedding size, input hidden size, output hidden size, FFN intermediate size, number of attention heads.

We note that the implementation of PLOT can be extended to a distributed key-value store to support parallel accesses and larger keys (longer n-grams) with reasonable engineering efforts. We welcome community participation to further optimize the structure in the future.

E Distillation Layer Mapping

Fig. 8 presents the layer mapping of different SkipBERT variants.

We use the uniform mapping strategy for attention-based distillation to leverage the heterogeneous attention patterns across different layers. For SkipBERT$_{6+6}$, we match the student's attention scores with the attention scores of every two transformer layers of the teacher (BERT-base). For SkipBERT$_{6+4}$, we match with every three transformer layers of the teacher. And for SkipBERT$_{6+2}$, we match the 3rd and 7th transformer layer of the teacher.

We use the top mapping strategy for hidden states-based distillation. That it, we match the student's hidden states with the top few transformer layers of the teacher. Since the initial sequence representation (outputs of chunk aggregation) are already partially contextualized, SkipBERT can learn from higher transformer layers of the teacher while skipping shallow layers.

F Data and Tasks

We evaluate our approach on the GLUE benchmark. This benchmark consists of a diverse set of 9 NLU tasks:

CoLA Corpus of Linguistic Acceptability, a single-sentence classification task to predict whether a sentence can be accepted a grammatically correct one. (Warstadt et al., 2019)

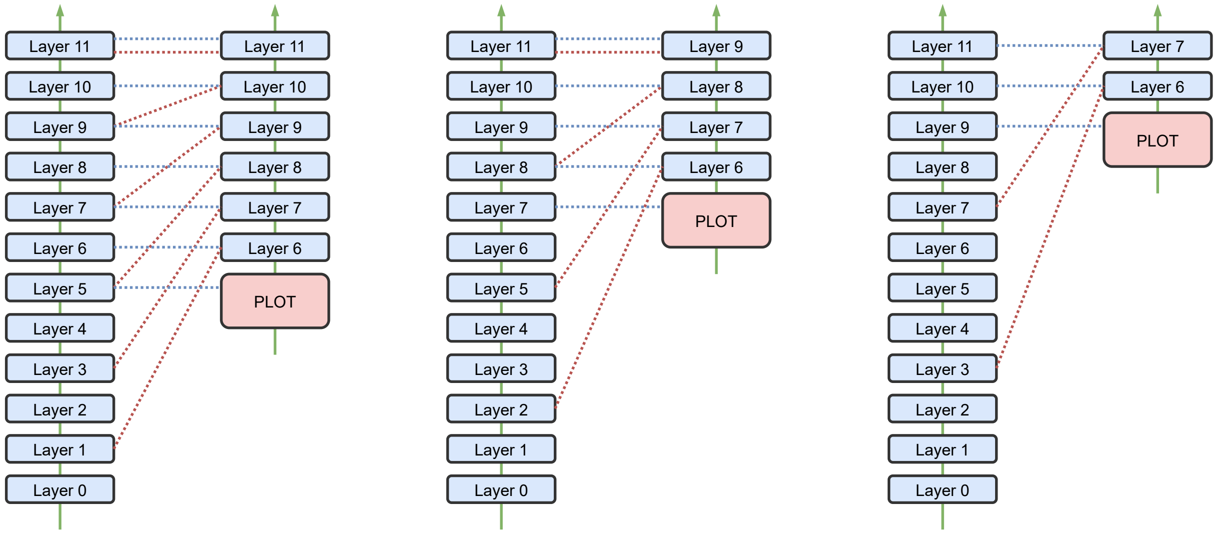
SST-2 Stanford Sentiment Treebank, a single-sentence classification task to predict the sentiment of movie reviews. (Socher et al., 2013)

MRPC Microsoft Research Paraphrase Corpus, a paraphrase identification task to predict whether two sentences are paraphrases of each other. (Dolan and Brockett, 2005)

STS-B Semantic Textual Similarity Benchmark, a regression task to evaluate the similarity of two pieces of texts by a score from 1 to 5. (Cer et al., 2017)

QQP Quora Question Pairs, a bi-sentence classification task to determine whether two questions are semantically equivalent. (Chen et al., 2018)

MNLI Multi-Genre Natural Language Inference, a bi-sentence classification task. Given a pair of premise and hypothesis, the task aims to predict whether the hypothesis is an entailment, contradiction, or neutral with respect to the premise.



(a) SkipBERT$_{6+6}$ (b) SkipBERT$_{6+4}$ (c) SkipBERT$_{6+2}$

Figure 8: Mapping between the teacher (BERT-base) and student. Red dotted lines indicate the layer mapping for attention-based distillation; blue dotted lines indicate the layer mapping for hidden states-based distillation.

(Williams et al., 2018)

QNLI Question Natural Language Inference, a bi-sentence classification task. Given a pair of question and context, the task aims to predict whether the context contains the answer to the question. (Rajpurkar et al., 2016b)

RTE Recognizing Textual Entailment, a bi-sentence classification task, determining whether the meaning of one sentence is entailed from the other sentence. (Bentivogli et al., 2009)

WNLI Winograd Schema Challenge, aiming to predict if the original sentence entails the sentence with the pronoun substituted. (Levesque et al., 2011)

G Latency Distribution of Retrieving Data from Mmap

We perform experiments in Docker containers with different RAM limitations, including 256GB, 128GB, 64GB, and 32GB. We evaluate cases with different hidden sizes, and the results are shown in Fig. 9 and Fig. 10.

Pretraining with Artificial Language: Studying Transferable Knowledge in Language Models

Ryokan Ri and Yoshimasa Tsuruoka
The University of Tokyo
7-3-1 Hongo, Bunkyo-ku, Tokyo, Japan
`{li0123,tsuruoka}@logos.t.u-tokyo.ac.jp`

Abstract

We investigate what kind of structural knowledge learned in neural network encoders is transferable to processing natural language. We design *artificial languages* with structural properties that mimic natural language, pretrain encoders on the data, and see how much performance the encoder exhibits on downstream tasks in natural language. Our experimental results show that pretraining with an artificial language with a nesting dependency structure provides some knowledge transferable to natural language. A follow-up probing analysis indicates that its success in the transfer is related to the amount of encoded contextual information and what is transferred is the knowledge of *position-aware context dependence* of language. Our results provide insights into how neural network encoders process human languages and the source of cross-lingual transferability of recent multilingual language models.

1 Introduction

Pretrained language models (Devlin et al., 2019; Yang et al., 2019; Raffel et al., 2020) have demonstrated strong empirical performance not only within a language but also *across* languages. Language models pretrained with a mix of monolingual corpora, such as multilingual BERT, exhibit a decent zero-shot cross-lingual transfer capability, *i.e.*, a model fine-tuned in a single source language (L1) can solve the task in another language (L2) (Conneau et al., 2020a; Xue et al., 2021). Surprisingly, the transfer happens without lexical overlaps between L1 and L2 (Karthikeyan K and Roth, 2020; Conneau et al., 2020b) or even without joint pretraining (Artetxe et al., 2020): an encoder only pretrained on L1 can be transferred to L2 without any parameter updates. These results suggest that, whether the encoder is trained on single or multiple languages, it learns some *transferable knowledge* about language.

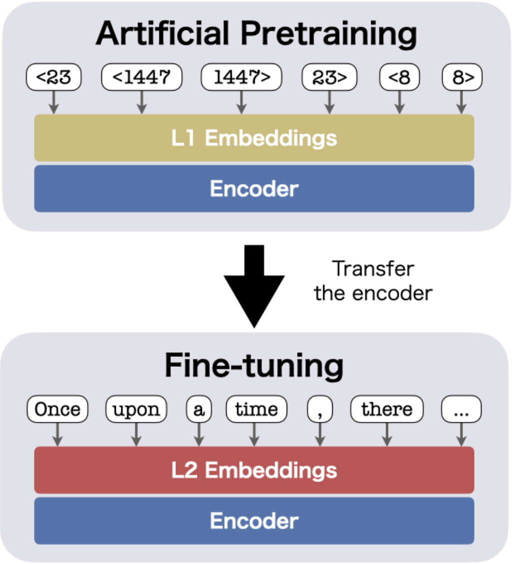

Figure 1: Transfer from artificial language to natural language. The artificial language encodes some structural properties (*e.g.*, token distributions, dependency structures) and we study how the learning of such properties can be transferred to natural language.

However, the characteristics of such transferable knowledge are still underexplored. Recent studies with the probing methodology (Hupkes and Zuidema, 2018; Conneau et al., 2018) have revealed that multilingual BERT captures language-independent linguistic structures such as universal dependency relations (Chi et al., 2020) and subjecthood (Papadimitriou et al., 2021), but it remains unknown whether learning such linguistic properties actually contributes to the performance, and whether there exists more abstract knowledge transferred across languages.

In this study, we try to shed light on these questions with the framework of the Test for Inductive Bias via Language Model Transfer (Papadimitriou and Jurafsky, 2020), focusing on designing *artificial languages* with natural-language-like structural properties (Figure 1). We pretrain encoders

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics Volume 1: Long Papers, pages 7302 - 7315
May 22-27, 2022

with artificial languages and transfer the encoders to natural language tasks with their parameters frozen. This enables us to see how learning the specific structural properties of the artificial language affects the downstream performance.

Specifically, we explore whether it is beneficial for the encoder to know the following two characteristics of natural language: word distributions and latent dependency structures. We design artificial languages that represent such characteristics and perform an extensive study with different encoder architectures (LSTM and Transformer) pretraining objectives (causal and masked language modelings).

The contribution is summarized as follows:

- We first start by complementing the study in Papadimitriou and Jurafsky (2020). We train LSTM and Transformer encoders with the sentence-level causal language modeling task and evaluate the encoders in English. We show that an artificial language that models simple statistical dependency within a sentence provides decent transferable knowledge on natural language modeling. Furthermore, we find that the inductive bias of a nesting head-to-tail dependency structure is more useful than a flat one.

- We then proceed to investigate transfer learning in masked language modeling (Devlin et al., 2019), one of the current dominant pretraining paradigms. We evaluate pretrained Transformer encoders with dependency parsing and confirm that the nesting dependency structure is important to learn the structure of natural language.

- We hypothesize that the transfer performance of pretrained encoders is related to the way the encoder preserves the input contextual information in the output vectors. We perform a probing experiment and find that the artificial language with the nesting dependency structure trains encoders to encode the information on adjacent tokens into the output vector of each token. We conclude this paper with the hypothesis that a part of transferable knowledge in language models could be explained by the knowledge of *position-aware context dependence* of language.

2 Related Work

2.1 Transferable Structural Knowledge in Pretrained Encoders

Multilingual language models trained with masked language modeling objective (Devlin et al., 2019; Doddapaneni et al., 2021) have demonstrated a surprisingly strong cross-lingual transfer capability (Liu et al., 2020), given the model is only trained with a mix of monolingual corpora. This leads to several studies investigating the source of the cross-lingual capability of multilingual models.

An early common hypothesis was that the models take advantage of a common word-piece vocabulary across languages (Wu and Dredze, 2019; Pires et al., 2019), which provides cross-lingual alignment signals to learn useful multilingual representations. However, this hypothesis has been questioned by recent studies (Karthikeyan K and Roth, 2020; Conneau et al., 2020b) which show that shared word-pieces only play a minor role in the performance. These studies suggest that the model can exploit abstract structures of languages to learn shared multilingual representations.

Another line of research suggests that the learning of transferable knowledge happens even in monolingual pretraining. Artetxe et al. (2020) showed that a Transformer encoder pretrained only on L1 exhibits strong cross-lingual transfer performance simply by aligning the L2 embeddings to the encoder. Papadimitriou and Jurafsky (2020) pretrained LSTM encoders with natural languages and non-linguistic data (*e.g.*, code, music, and artificial data) to demonstrate that the encoders achieve reasonable performance in Spanish language modeling. These studies provide additional evidence for the existence of transferable linguistic knowledge learned in the model.

Then what is such knowledge? Probing studies (Hupkes and Zuidema, 2018; Conneau et al., 2018) have revealed that the model captures language-independent structures such as universal dependency relations (Chi et al., 2020) and subjecthood (Papadimitriou et al., 2021). However, the probing methodology does not answer whether such linguistic knowledge contributes to the performance in cross-lingual transfer.

In this study, we shed light on this question by studying transfer learning from artificial language with the Test for Inductive Bias via Language Model Transfer (TILT) (Papadimitriou and Jurafsky, 2020). This framework enables us to assess if abstract features generalizable to L2 (natural language) are encoded in L1. Here we explicitly design artificial languages with some structural properties as L1 to investigate their transferability.

2.2 Studying Language Models with Artificial Language

To study the behavior of language models, several studies have employed a specific type of *artificial language*: artificial variants of natural languages. A typical experimental framework is as follows: (1) create an artificial language that differs from a natural language in one linguistic property, such as word orders (Sinha et al., 2021b; Dufter and Schütze, 2020; Sinha et al., 2021a), scripts (Karthikeyan K and Roth, 2020; Dufter and Schütze, 2020; Conneau et al., 2020b), or morphology (Ravfogel et al., 2019); (2) train or evaluate the natural/artificial language models and compare the performance to analyze the model's sensitivity to the linguistic property.

However, this methodology is limited to studying linguistic properties that are easily editable to create artificial variants and also offers limited control over the experiments. To overcome this problem, White and Cotterell (2021) created artificial languages by defining their own probabilistic context-free grammars (PCFG). As the concurrent work, Chiang and yi Lee (2022) trained Transformer encoders on artificial data with token dependencies in the sequences and showed that they perform reasonably well on the GLUE benchmark (Wang et al., 2019). In this research, we design artificial languages with certain structural properties from scratch to study knowledge transferable to natural language.

3 Approach

3.1 Experimental Framework

We first describe the experimental framework used throughout this paper, the Test for Inductive Bias via Language Model Transfer (TILT) introduced by Papadimitriou and Jurafsky (2020). TILT consists of pretraining and transfer steps:

1. Pretrain an encoder with a pretraining task in the source language (L1). We explore pretraining with causal language modeling in §4 and masked language modeling in §5.

2. Transfer the encoder to the target language (L2) in a downstream task. As we are interested in structural prior knowledge learned in the encoder, we discard the learned L1 word embeddings and initialize the embedding layer with the L2 vocabulary. We then train the model with the encoder parameters frozen and evaluate the task performance.

TILT reveals how transferrable the computation induced to solve the L1 pretraining task is to processing L2. In this study, we are interested in the transferability of certain types of structures to natural language, and thus we primarily use hand-designed artificial languages with the structural properties as L1 and natural language as L2.

3.2 Designing Artificial Languages

Artificial languages are designed to mimic a certain property of natural language. After providing a formal definition of artificial language, we introduce several languages used in this paper.

3.2.1 Formulation of Artificial Language

A artificial language refers to a set of a vocabulary and algorithms to generate sequential data for pretraining. Each language has a sentence-length distribution $p_{len}(l)$, token vocabulary $\{w | w \in \mathcal{V}\}$, and sentence-sampling function $f(l) : l \mapsto \mathcal{V}^l$. The training data is generated sentence by sentence as follows: we first sample a sentence length ($l \sim p_{len}(l)$) and then sample a sequence of tokens of that length ($[w_1, ..., w_l] \sim f(l)$).

In this study, the token vocabulary V simply consists of integers (or integers with a special symbol) and is not intended to correspond to a vocabulary of any natural language. Also the sentence-length distribution $p_{len}(l)$ is fitted with a baseline dataset in each experiment. The focus is how to design the sentence-sampling function $f(l)$. This determines what kind of characteristics we want to encode in the artificial dataset.

3.2.2 Modeling Word Distribution

Words in natural language are distributed in non-trivial fashions. We will study whether prior knowledge of token distribution facilitates learning from natural language. We first present the simplest artificial language that serves as a baseline.

Uniform language samples each token in a sentence independently and uniformly. Specifically, the probability of a token w being sampled is

$$p(w) = \frac{1}{|\mathcal{V}|}. \quad (1)$$

However, this deviates from the token distribution of natural language. Natural language is empirically known to follow the Zipf's law (Zipf, 1949), *i.e.*, the relation between the frequency of a word and its rank is given by $\text{frequency}(w) \propto \text{rank}(w)^{-\alpha}$. The coefficient α is typically around 1, although the coefficient shows some variation according to the corpus domain (Zanette and Montemurro, 2005).

Zipf language captures this property and samples each token w from the following probability distribution assuming $\alpha = 1$:

$$p(w) \propto \frac{1}{rank(w)}. \tag{2}$$

The two languages introduced so far generate tokens in a sentence independently. However, words within a sentence of natural language are known to have statistical dependencies, *i.e.*, specific cooccurrence patterns (Church and Hanks, 1989). Consider the sentence "*The cat and dog are fighting over food.*" The words *the* and *cat* would cooccur much more often than by chance because *cat* (noun) is dependent on *the* (determinant); so would *dog* and *cat* because they are topically related. The words in a sentence are usually coherent according to some syntactic and semantic dependencies.

Log-linear language is designed to capture this property. Inspired by the log-linear model in Arora et al. (2016), tokens in a sentence s are drawn from the following probability distribution:

$$p(w|s) \propto \exp(\vec{c}_s \cdot \vec{v}_w), \tag{3}$$

where $\vec{c}_s$ is the discourse vector of the sentence and $\vec{v}_w$ is the word vector of the token w. Intuitively, we can imagine that the discourse vector represents the *topic* of the sentence and determines the unigram distribution over the vocabulary (Blei et al., 2003). Sampling tokens this way, non-trivial cooccurrence patterns within sentences emerge in the language.

We speculate that pretraining with the Log-linear language will endow the model with an inductive bias to aggregate the context in a sentence to predict the identity or property of tokens, which is likely to benefit natural language processing.

In the experiments, the word vectors $\vec{v}_w$ are initialized with the normal distribution, and the discourse vector $\vec{c}_s$ is also drawn from the normal distribution each time we generate a sentence. We set the dimension of the word and discourse vector to 10 as we empirically find that this makes the entire token distribution close to the Zipfian distribution.

3.2.3 Modeling Latent Dependency Structure

Sentences in natural language are known to have latent structures, which are often described in the form of trees (Chomsky, 1957) or dependency graphs (Mel'čuk, 1988). Now we consider how to endow the sampled tokens with such structures.

In this study, we adopt a dependency-based latent structure. Words in sentences of natural language often have dependency relations and the existence of a certain word can be predictive of another word (*e.g.*, the verb *am* always cooccurs with *I*). We hypothesize that, pretrained on such data, language models may acquire inductive bias towards finding relations between tokens in the input, which is presumably important in processing natural language.

Inspired by Papadimitriou and Jurafsky (2020), we design algorithms that generate structured sentences given a set of tokens sampled with any of the strategies described in §3.2.2. The general idea is that half of the tokens (heads) in the vocabulary are all paired with another half of tokens (tails). A pair of head and tail can be represented in right and left brackets with the same integer (*e.g.*, "`<123`", "`123>`"). The pairs always appear together in a sentence and express simple dependency relations. After determining the sentence length $l \sim f(l)$, we first sample $\frac{l}{2}$ (rounded to an integer) pairs of head and tail and then arrange them with one of the following structures.

Flat Dependency structure simply arranges the tokens randomly while keeping the right order of the brackets (*e.g.*, ["`<5`", "`<84`", "`5>`", "`<123`", "`123>`", "`84>`"]). The dependency arcs are allowed to be crossed and thus often result in a non-projective dependency structure.

Nesting Dependency language, by contrast, does not allow any dependency arcs to be crossed, and the brackets are nested hierarchically (*e.g.*, ["`<5`", "`<84`", "`84>`", "`5>`", "`<123`", "`123>`"]). The sentences are generated from the stack-based algorithm described in Appendix A.

These structures are similar to the **Parenthesis** languages used to study the inductive bias of language models in Papadimitriou and Jurafsky (2020). However, our Dependency languages differ from them in how to represent the head and tail tokens. In the Parenthesis language, the head and tail are represented with the same token (*e.g.*, [“`5`”, “`84`”, “`84`”, “`5`”, “`123`”, “`123`”]), which we argue deviates from the dependency structure in natural language, because in natural language, dependency relations usually hold between different words (*e.g.*, *I* and *am*). We will show that this difference is in fact crucial and draw a different conclusion from Papadimitriou and Jurafsky (2020) on the importance of the nested structure (§4.2).

4 Causal Language Model Pretraining with Artificial Language

In this section, we complement the study of Papadimitriou and Jurafsky (2020). While they studied the inductive bias learned in LSTM encoders with some artificial languages, here we provide additional studies with the newly introduced Log-linear and Dependency artificial languages, and the Transformer encoder.

4.1 Experimental Setups

Task. We study sentence-level causal (left-to-right) language modeling (CLM), where the model needs to predict the next word given the previous context in the sentence. Note that, Papadimitriou and Jurafsky (2020) experiment with language modeling across sentences, but we adopt sentence-level modeling because we would like to focus on the learning of sentence structures here. As we will see in §4.2, we observe the same tendency in regard to the effect of artificial pretraining where we share the setups. The task performance is measured by the average perplexity scores for each token.

Model. We study two encoder architectures: LSTM (Hochreiter and Schmidhuber, 1997) and Transformer (Vaswani et al., 2017). These architectures are known to exhibit different abilities in capturing the underlying hierarchical structure of sequential data (Tran et al., 2018).

The size of word embeddings is set to 300. For both LSTM and Transformer encoders, the number of layers is set to 3, and the number of parameters is configured to be the same (6.9M parameters) to enable a fair comparison between architectures (for further details, see Appendix B).

Pretraining Data. We generate artificial corpora with three unstructured languages, which randomly arrange the tokens sampled from Uniform, Zipf, and Log-linear languages, and four structured languages which combine the Zipf sampling strategy with the structures of Flat Parenthesis, Nesting Parenthesis, Flat Dependency, and Nesting Dependency.

We also experiment with natural language corpora. We create training corpora from Wikipedia dumps of English, Japanese, and Spanish. The sentences are tokenized with the `Moses` tokenizer[1] for English and Spanish and `MeCab`[2] for Japanese.

The sentence lengths of artificial data were sampled from the empirical distribution of the English Wikipedia corpus. The size of the vocabulary $|V|$ is set to 32,000 for both artificial and natural corpora, and out-of-vocabulary words in natural language are replaced with the OOV token. For each corpus, we sample 12.8 M sentences and train the model with one iteration over the corpus.

Evaluation Data. We evaluate the pretrained encoders on the Penn Treebank (PTB) corpus (Marcus et al., 1993) with preprocessing from Mikolov et al. (2010). Note that, when we train language models with the pretrained encoders, the parameters of the encoder are not updated and only the English word embeddings are learned from scratch (optimization details in Appendix B.2).

4.2 Results

We provide two baseline models trained on the L2 training corpus from scratch and trained with frozen random weights in the encoder to compare with pretrained encoders. For each configuration, we pretrain three encoders with different random seeds, and for each encoder fine-tuned three models, which results in nine models in total. We summarize the average scores and standard deviations in Figure 2.

The Transformer encoder is more flexible than LSTM. We start by discussing overall trends. We observe that the Transformer encoders give lower perplexity scores compared to LSTM regardless of pretraining language. This tendency is in line with the observations on the surprisingly good transferability or pretrained Transformer encoders to other languages (Conneau et al., 2020a), or even other modalities (Lu et al., 2021; Reid et al., 2022). We think that this is because Transformer encoders are better at aggregating and preserving the context information at each time step, as we will see in §6, presumably because the Transformer architecture has self-attention and residual connections.

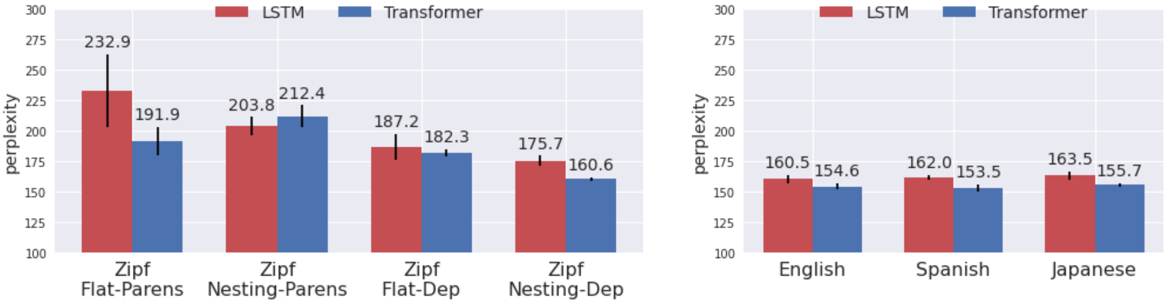
[2] `http://taku910.github.io/mecab/`

(a) Comparison of token distributions.



(b) Comparison of dependency structures.

(c) Comparison of natural languages.

Figure 2: The perplexity scores (the lower the better) on the sentence-level causal language modeling task with the English Penn Treebank dataset. The two baselines (From scratch and Random weights) are not pretrained, and the others are the results of pretrained encoders.

Natural languages are better than the artificial languages. As expected, pretraining with natural languages (English, Spanish and Japanese) provides better encoders for language modeling than the artificial languages both with LSTM and Transformer. However, the performance differences between natural languages seem to be negligible, indicating that there is not much difference in the way the encoders process these different languages, conforming with the observation of cross-lingual transferability of pretrained encoders (Artetxe et al., 2020).

The Uniform and Zipf languages degrade the encoders. Looking at the difference among unstructured languages (Figure 2a), Uniform and Zipf languages give higher perplexities than the Random weights baseline particularly with LSTM. In hindsight, it is natural that encoders would be degraded even from random weights when trained with sequences where tokens are drawn independently from each other because the encoders are not incentivized to use contextual information and will even learn to discard the input information. We will demonstrate this with a follow-up probing experiment in §6.

The Log-linear language provides a useful inductive bias to language modeling. On the contrary, the Log-linear language gives reasonably lower perplexities compared to Random weights (Figure 2a). This indicates that knowing the existence of statistical dependency within a sentence, or learning to predict tokens from the cooccurrence information, is a useful inductive bias even though the cooccurrence statistics is not necessarily in line with L2.

We do not observe the importance of the nested structure in the Parenthesis languages. Papadimitriou and Jurafsky (2020) showed that LSTM encoders trained on the Flat Parenthesis and Nesting Parenthesis structures do not provide a significant difference in perplexity, and concluded that simple non-hierarchical head-dependent-type relations are important in LSTM language processing. A similar observation can be made in Figure 2b: although the Nesting Parenthesis exhibits the lower average score, there is no significant difference between Flat Parenthesis and Nesting Parenthesis (232.9 ± 30.0 vs. 203.8 ± 7.7, $p > 0.01$ in Welch's t-test) with the unstable results of Flat Parenthesis. Also, the trend of the average scores is reversed in Transformer: the Nesting Parenthesis exhibits the higher average score (212.4 ± 8.8) than Flat Parenthesis (191.9 ± 11.8), which makes it difficult to draw a consistent conclusion from here.

However, **the Dependency languages suggest that the nested structure is actually important in language modeling.** While the Parenthesis language represents dependency relations with two identical tokens (*e.g.*, "`4543`" and "`4543`"), our Dependency language represents relations with two different tokens (*e.g.*, "`<4543`" and "`4543>`"). We expect that expressing dependency relations with two different tokens is closer to natural language and thus provides more viable insights into natural language. When we compare the scores of the Dependency languages, Nesting Dependency provides the lower and more stable perplexity than Flat Dependency with LSTM (175.7 ± 4.3 vs. 187.2 ± 10.7) and the significantly lower score with Transformer (160.6 ± 1.6 vs. 175.7 ± 4.3, $p > 0.01$ in Welch's t-test). Overall, Nesting Dependency performs best among other artificial languages, indicating our Dependency language is closer to natural language and the nested structure is useful for language modeling.

5 Masked Language Model Pretraining with Artificial Language

We proceed to investigate transfer learning from artificial languages in one of the most successful pretraining paradigms, masked language modeling (MLM) (Devlin et al., 2019) to see if we can observe similar trends to what we see in the CLM experiment (§4).

5.1 Experimental Setups

Pretraining. To allow for fast experimentation, we train small Transformer encoders. The size of word embeddings is set to 300 and the encoders have three layers (further details in Appendix C). The pretraining datasets are the same as in §4.1.

Downstream Task. We evaluate the pretrained encoders with dependency parsing to see if the structural knowledge learned with artificial language is beneficial to predict the structure of natural language. We use the English EWT dataset from Universal Dependencies (UD) v2.8 (Nivre et al., 2020)[3].

Model. We adopt the biaffine graph-based parser (Dozat and Manning, 2017) with the Transformer encoder. The input word representations are the concatenation of word embeddings and character features computed by a character-level bidirectional LSTM encoder (Ling et al., 2015). For the details on fine-tuning these models, please refer to Appendix C.

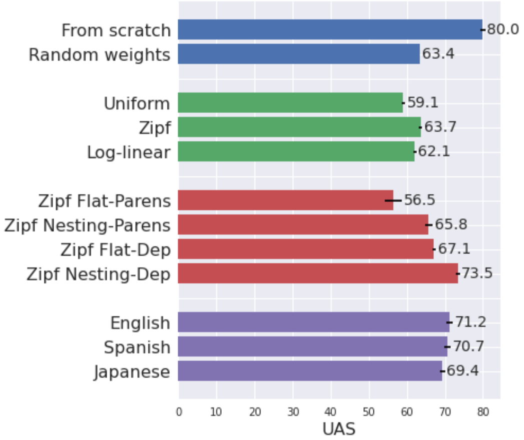


Figure 3: The downstream performance on two syntactic tasks with the English EWT dataset. The two baselines (From scratch and Random weights) are not pretrained, and the others are the results of encoders pretrained with masked language modeling.

5.2 Results

We provide two baseline models trained from scratch and trained with random encoder weights. For each pretraining language, we again train three encoders and fine-tune three models for each, and take the mean and standard deviation of the nine models. Figure 3 shows the results.

The unstructured languages do not provide useful transferable knowledge for dependency parsing. The Uniform, Zipf, and Log-linear encoders perform comparably to or worse than the Random weights baseline. This is in contrast with the causal language modeling task, where the Log-linear language at least outperforms the Random weights baseline (§4.2).

On the other hand, **learning from structured languages seems to be important in dependency parsing.** The Dependency encoders outperform the Random weights baseline, and also we can observe that learning from the nesting structure is more effective than the flat structure, and Dependency languages outperform Parenthesis languages, as observed in the CLM in §4.

6 How much contextual information do the pretrained encoders capture?

In the previous sections, we have seen that the encoders pretrained with different artificial languages exhibit various degrees of transferability to natural

---

[3] https://universaldependencies.org/

language. In this section, we try to explain why pretraining with some artificial languages is better or worse for the transfer to natural language from the perspective of the amount of contextual information in the encoder outputs.

The intuition is, for example, if a pretrained encoder has learned to discard the input information, we cannot expect the encoder to perform well when transferred to any tasks. Also, existing studies show that neural language models assign more importance to local context when they make predictions (Khandelwal et al., 2018; Lai et al., 2020). Can we observe that encoders pretrained with artificial languages exhibit similar patterns to natural languages regarding how they encode the contextual information?

6.1 Experimental Setups

We investigate how much contextual information can be extracted from the outputs of the pretrained encoders by setting up a simple probing task. In this task, the encoder is asked to recover the identity of the contextual words given the contextualized vector of a target word.

Specifically, we first randomly generate 100K sequences of integers with the length of $15 \sim 25$ (close to most frequent sequence lengths in the pretrained corpus) with the vocabulary size 100 and split them into training (90K sequences), validation (5K) and test (5K) sets.

Then we simultaneously train several linear classifiers, each of which predicts the ID of the context word at a fixed relative position to the target word in the sequence, on top of a frozen pretrained encoder. For the encoders pretrained with CLM in §4, the target word is the last word in sequences and the classifiers predict the words at the positions of [-9, -4, -3, -2, -1, 0]; for the encoders pretrained with MLM in §5, the target word is the middle word and the classifiers predict the words at [-6, -3, -2, -1, 0, 1, 2, 3, 6].

After training, we measure the accuracy of predicting the words at each position on the test set and interpret this as how much information on each contextual word the encoder preserves.

6.2 Results

Figure 4 summarizes the results of the encoders trained in §4 and §5.

The amount of the encoded contextual information can explain the transfer performance in some obvious cases. In the experiment of CLM (Figure 2a), we observed that the Uniform and Zipf encoders tend to perform worse even than Random weights. Figure 4a and 4d demonstrate that their poor performance is because the encoders are trained to discard the input information. The Uniform and Zipf encoders tend to preserve less contextual information even than Random weights because capturing the contextual information does not lead to solving the pretraining task in these languages.

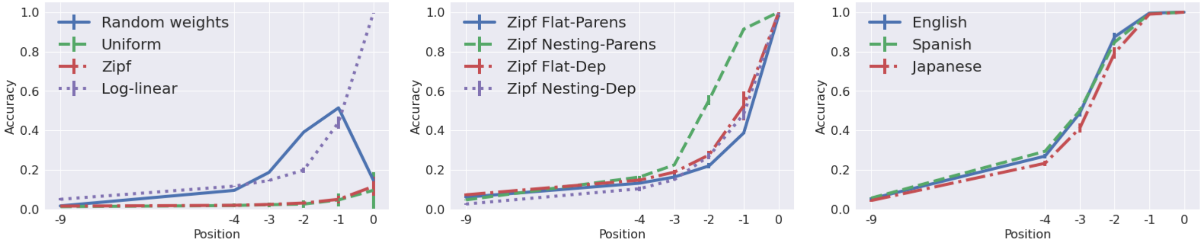
On the other hand, if words are predictable from the context, encoders are encouraged to learn to preserve the contextual information. The Log-linear encoders trained with CLM encode a decent amount of the contextual information (Figure 4a and 4d) and also performed best among the unstructured artificial languages in CLM (Figure 2a). Moreover, encoders trained with natural languages (Figure 4c, 4f and 4i) capture not only the local context well (at distance $0 \sim 2$) but also a modest amount of the farther context (at distance $3 \sim$), which is consistent with the existing observation that LSTM encoders trained with natural language are better at memorizing the inputs than ones trained with randomly sampled data (Liu et al., 2018). In these cases, the downstream performance and the amount of the encoded contextual information seem to be correlated.

However, this trend is not as clear when comparing the structured artificial languages. For example, the Nesting Dependency encoders perform the best for the downstream tasks among the structured artificial languages but do not necessarily in the probing task (Figure 4b and 4e).

The nesting structure seems to facilitate encoders to remember the local context with MLM. The difference between the Nesting and Flat languages is striking in Figure 4f. The Nesting encoders are consistently better at capturing the local contextual information (at positions $-2 \sim 2$) than their flat counterparts, which may explain the better performance of the Nesting encoders in dependency parsing (Figure 3), given that the local contextual information is particularly important to predict the syntactic characteristics of words (Levy and Goldberg, 2014; Ri and Tsuruoka, 2020).

7 Discussion and Future Work

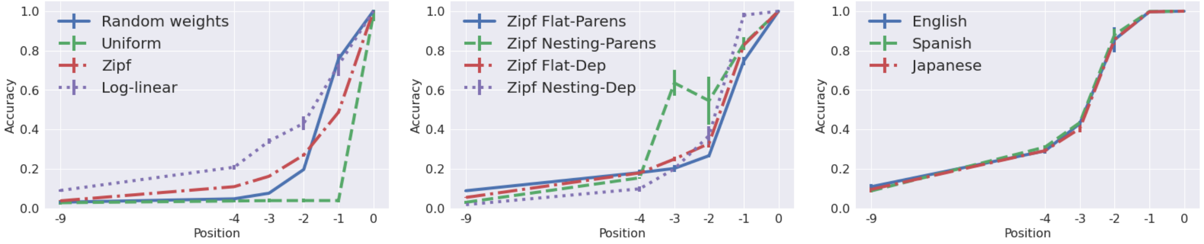
In this paper, we studied what kind of structural properties in pretraining data is useful to train encoders for natural language tasks. We have found



(a) LSTM-CLM.

(b) LSTM-CLM.

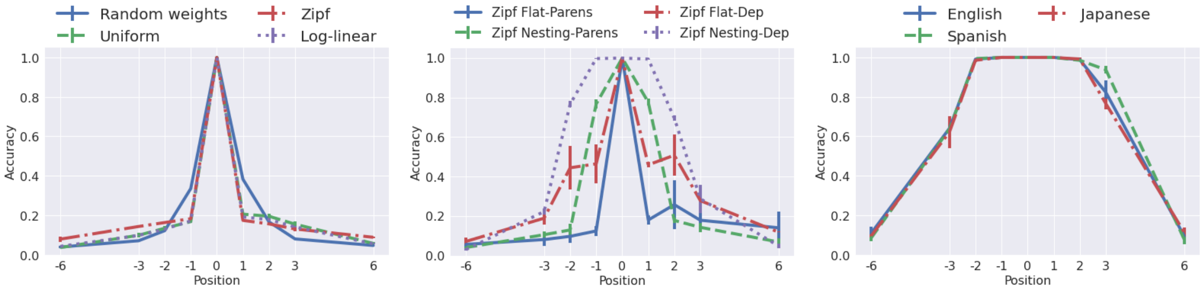
(c) LSTM-CLM.



(d) Transformers-CLM.

(e) Transformers-CLM.

(f) Transformers-CLM.



(g) Transformers-MLM.

(h) Transformers-MLM.

(i) Transformers-MLM.

Figure 4: The accuracy of the task of recovering the contextual words from the encoder output of target words.

that to achieve decent results, L1 needs at least statistical dependency in a sentence (§4), and having the head-to-tail dependency with the nesting structure is further beneficial (§4 and §5). The probing experiment in §6 suggests that the encoders trained with languages with the above characteristics are good at capturing the positions and identities of the context words.

From these observations, we suggest a tentative answer to the initial research question: what knowledge in pretrained encoders are transferred across different languages? That is *position-aware context dependence* of language, in other words, **"tokens in a sequence can be characterized by its neighbor tokens at specific positions"**.

We think that it can explain the success of transferring the encoder across languages to some extent. To solve natural language tasks, it is often useful to characterize words in a sentence by the words around them. For example, to understand the semantics of a sentence, it would be useful to look for the subject by looking for a noun that precedes the word *is*; to parse a sentence, a word can be identified as a noun because it follows the article *the*. If the encoder computes the output representation of a word in a sentence by aggregating the information from its surrounding words, that should be a useful inductive bias to solve most NLP tasks in any language. Also, it is easy to imagine that the knowledge of position-aware context dependence gives a reasonable prior for solving sequence modeling problems in other domains, which may explain the success of cross-modality transfer of language models (Lu et al., 2021; Reid et al., 2022).

Of course, we do not expect that the knowledge of position-aware context dependence explains every aspect of the success of cross-lingual transfer. As future work, we need further investigation for a more fine-grained view of the transferred knowledge. Important questions include how much the model size affects the transferability of the encoder or if there is any difference in the knowledge transferred among different downstream tasks.

A Generating the Nesting Structure

In the Nesting languages introduced in §3.2.3, tokens are ordered in a way that any dependency arcs in a sequence are not crossed. This is realized by the stack-based algorithm in Algorithm 1. We set the probability of closing a dependency pair to 0.4 following Papadimitriou and Jurafsky (2020).

Algorithm 1 Generating a sentence from the Nesting Dependency language.

```
Input: input_pairs: Stack[($w$, $w$)]]
Output: sentence: List[$w$]
closing_stack = []
while not input_pairs.is_empty() do
    Uniform sampling $p \sim [0, 1]$
    if closing_stack.is_empty() or $p < 0.4$ then
        head, tail = input_pairs.pop()
        sentence.append(head)
        closing_stack.push(tail)
    else
        tail = closing_stack.pop()
        sentence.append(tail)
    end if
end while
while not closing_stack.is_empty() do
    tail = closing_stack.pop()
    sentence.append(tail)
end while
return sentence
```

B Details of Causal Language Modeling Task

B.1 Model configuration

For the experiment with causal language modeling (§4), we set the number of layers of the LSTM and Transformer encoders to 3 and configure them so that they have the same number of parameters (2.1 M parameters without the embedding and output projection layers). The details of configuration are shown in Table 1 and Table 2.

The weights of the output projection layer are tied with the word embedding layer (Press and Wolf, 2017). Note that, to enable this, the LSTM encoder has an additional linear layer to project the hidden vector (294 dim) to the input size (300 dim), which the Transformer encoder does not have.

# of layers	3
input size	300
hidden size	294

Table 1: Configuration of the LSTM encoder.

# of layers	3
size	300
feedforward size	600
# of attention heads	4

Table 2: Configuration of the Transformer encoder.

B.2 Optimization

We optimize the pretrained models for 10k steps with 12.8 M sentences and the batch size of 128 using AdamW (Loshchilov and Hutter, 2019). We use the the Noam Learning rate scheduler described in Vaswani et al. (2017) with the warmup steps of 4000, and the other hyper-parameter details are shown in Table 3. We use the same hyper-parameters for fine-tuning with the L2 language.

Name	Value
Pretraining minimum sentence length	6
Pretraining maximum sentence length	60
Dropout	0.1
Weight decay	0.01
Adam β_1	0.9
Adam β_2	0.98
Adam ϵ	1e-9
Gradient clipping	0.25

Table 3: Hyper-parameters for pretraining.

C Details of Masked Language Modeling Task

C.1 Model configuration

For the experiment with masked language modeling (§5), we set the number of layers of the Transformer encoders to 3. The details of configuration are shown in Table 4 (2.1 M parameters without the embedding and output projection layers).

The hyper-parameters for the masked language modeling task is shown in Table 5. For optimization, we used the same hyper-parameters as in Appendix B.2.

# of layers	3
size	300
feedforward size	600
# of attention heads	4

Table 4: Model configuration of the Transformer encoder.

Mask probability for words	15%
Random-word probability for words	10%
Unmasked probability for words	10%

Table 5: The hyper-parameters for masked language modeling.

D Computing Infrastructure

We ran the experiments on a server with a Intel(R) Xeon(R) CPU E5-2698 v4 @ 2.20GHz CPU and 10 NVIDIA TITAN Xp GPUs. Each pretraining and finetuning were run with a single GPU.

mLUKE: The Power of Entity Representations in Multilingual Pretrained Language Models

Abstract

Recent studies have shown that multilingual pretrained language models can be effectively improved with cross-lingual alignment information from Wikipedia entities. However, existing methods only exploit entity information in pretraining and do not explicitly use entities in downstream tasks. In this study, we explore the effectiveness of leveraging entity representations for downstream cross-lingual tasks. We train a multilingual language model with 24 languages with entity representations and show the model consistently outperforms word-based pretrained models in various cross-lingual transfer tasks. We also analyze the model and the key insight is that incorporating entity representations into the input allows us to extract more language-agnostic features. We also evaluate the model with a multilingual *cloze prompt* task with the mLAMA dataset. We show that entity-based prompt elicits correct factual knowledge more likely than using only word representations. Our source code and pretrained models are available at `https://github.com/studio-ousia/luke`.

1 Introduction

Pretrained language models have become crucial for achieving state-of-the-art performance in modern natural language processing. In particular, multilingual language models (Conneau and Lample, 2019; Conneau et al., 2020a; Doddapaneni et al., 2021) have attracted considerable attention particularly due to their utility in cross-lingual transfer.

In zero-shot cross-lingual transfer, a pretrained encoder is fine-tuned in a single resource-rich language (typically English), and then evaluated on other languages never seen during fine-tuning. A key to solving cross-lingual transfer tasks is to obtain representations that generalize well across languages. Several studies aim to improve multilingual models with cross-lingual supervision such as bilingual word dictionaries (Conneau et al., 2020b) or parallel sentences (Conneau and Lample, 2019).

Another source of such information is the cross-lingual mappings of Wikipedia entities (articles). Wikipedia entities are aligned across languages via inter-language links and the text contains numerous entity annotations (hyperlinks). With these data, models can learn cross-lingual correspondence such as the words *Tokyo* (English) and 東京 (Japanese) refers to the same entity. Wikipedia entity annotations have been shown to provide rich cross-lingual alignment information to improve multilingual language models (Calixto et al., 2021; Jian et al., 2022). However, previous studies only incorporate entity information through an auxiliary loss function during pretraining, and the models do not explicitly have entity representations used for downstream tasks.

In this study, we investigate the effectiveness of entity representations in multilingual language models. Entity representations are known to enhance language models in mono-lingual settings (Zhang et al., 2019; Peters et al., 2019; Wang et al., 2021; Xiong et al., 2020; Yamada et al., 2020) presumably by introducing real-world knowledge. We show that using entity representations facilitates cross-lingual transfer by providing language-independent features. To this end, we present a multilingual extension of LUKE (Yamada et al., 2020). The model is trained with the multilingual masked language modeling (MLM) task as well as the masked entity prediction (MEP) task with Wikipedia entity embeddings.

We investigate two ways of using the entity representations in cross-lingual transfer tasks: (1) perform entity linking for the input text, and append the detected entity tokens to the input sequence. The entity tokens are expected to provide language-independent features to the model. We evaluate this approach with cross-lingual question answering (QA) datasets: XQuAD (Artetxe et al., 2020)

May 22-27, 2022

and MLQA (Lewis et al., 2020); (2) use the entity `[MASK]` token from the MEP task as a language-independent feature extractor. In the MEP task, word tokens in a mention span are associated with an entity `[MASK]` token, the contextualized representation of which is used to train the model to predict its original identity. Here, we apply similar input formulations to tasks involving mention-span classification, relation extraction (RE) and named entity recognition (NER): the attribute of a mention or a pair of mentions is predicted using their contextualized entity `[MASK]` feature. We evaluate this approach with the RELX (Köksal and Özgür, 2020) and CoNLL NER (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003) datasets.

The experimental results show that these entity-based approaches consistently outperform word-based baselines. Our analysis reveals that entity representations provide more language-agnostic features to solve the downstream tasks.

We also explore solving a multilingual zero-shot *cloze prompt* task (Liu et al., 2021) with the entity `[MASK]` token. Recent studies have shown that we can address various downstream tasks by querying a language model for blanks in prompts (Petroni et al., 2019; Cui et al., 2021). Typically, the answer tokens are predicted from the model's word-piece vocabulary but here we incorporate the prediction from the entity vocabulary queried by the entity `[MASK]` token. We evaluate our approach with the mLAMA dataset (Kassner et al., 2021) in various languages and show that using the entity `[MASK]` token reduces language bias and elicits correct factual knowledge more likely than using only the word `[MASK]` token.

2 Multilingual Language Models with Entity Representations

2.1 Model: mulitlingual LUKE

To evaluate the effectiveness of entity representations for cross-lingual downstream tasks, we introduce a new multilingual language model based on a bidirectional transformer encoder: Multilingual LUKE (mLUKE), a multilingual extension of LUKE (Yamada et al., 2020). The model is trained with the masked language modeling (MLM) task (Vaswani et al., 2017) as well as the masked entity prediction (MEP) task. In MEP, some of the input entity tokens are randomly masked with the special entity `[MASK]` token, and the model is trained to predict the original entities. Note that the entity `[MASK]` token is different from the word `[MASK]` token for MLM.

The model takes as input a tokenized text ($w_1, w_2, ..., w_m$) and the entities appearing in the text ($e_1, e_2, ..., e_n$), and compute the contextualized representation for each token ($\mathbf{h}_{w_1}, \mathbf{h}_{w_2}, ..., \mathbf{h}_{w_m}$ and $\mathbf{h}_{e_1}, \mathbf{h}_{e_2}, ..., \mathbf{h}_{e_n}$). The word and entity tokens equally undergo self-attention computation (*i.e.*, no entity-aware self-attention in Yamada et al. (2020)) after embedding layers.

The word and entity embeddings are computed as the summation of the following three embeddings: token embeddings, type embeddings, and position embeddings (Devlin et al., 2019). The entity tokens are associated with the word tokens through position embeddings: the position of an entity token is defined as the positions of its corresponding word tokens, and the entity position embeddings are summed over the positions.

Model Configuration. The model configurations of mLUKE follow the *base* and *large* configurations of XLM-RoBERTa (Conneau et al., 2020a), a variant of BERT (Devlin et al., 2019) trained with CommonCrawl data from 100 languages. Before pretraining, the parameters in common (*e.g.*, the weights of the transformer encoder and the word embeddings) are initialized using the checkpoint from the Transformers library.[1]

The size of the entity embeddings is set to 256 and they are projected to the size of the word embeddings before being fed into the encoder.

2.2 Training Corpus: Wikipedia

We use Wikipedia dumps in 24 languages (Appendix A) as the training data. These languages are selected to cover reasonable numbers of languages that appear in downstream cross-lingual datasets. We generate input sequences by splitting the content of each page into sequences of sentences comprising $\leq$ 512 words with their entity annotations (*i.e.*, hyperlinks). During training, data are sampled from each language with n_i items with the following multinomial distribution:

$$p_i = \frac{n_i^\alpha}{\sum_{k=1}^{N} n_k^\alpha}, \qquad (1)$$

where α is a smoothing parameter and set to 0.7 following multilingual BERT.[2]

---

[1] `https://huggingface.co/transformers/`

[2] `https://github.com/google-research/bert/blob/master/multilingual.md`

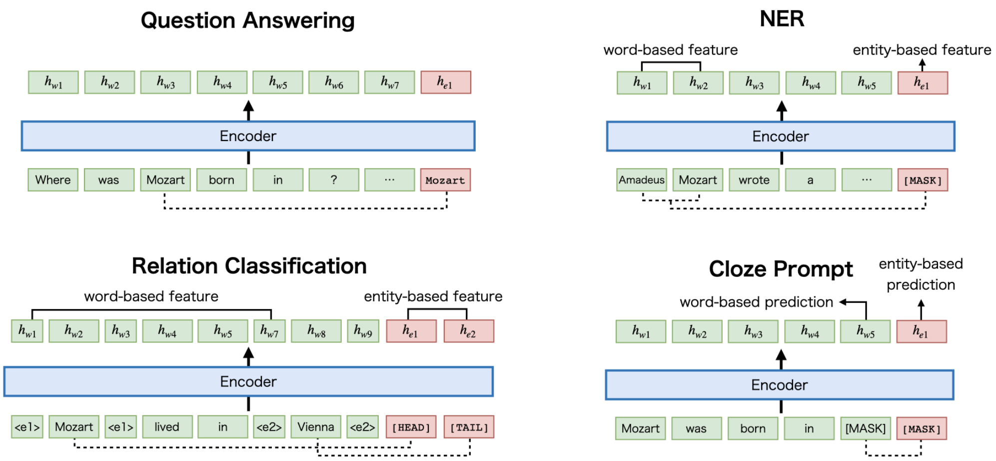

Figure 1: How to use entity representations in downstream tasks. The input entity embeddings are associated with their mentions (indicated by dotted lines) via positional embeddings.

Entity Vocabulary. Entities used in mLUKE are defined as Wikipedia articles. The articles from different languages are aligned through inter-language links[3] and the aligned articles are treated as a single entity. We include in the vocabulary the most frequent 1.2M entities in terms of the number of hyperlinks that appear across at least three languages to facilitate cross-lingual learning.

Optimization. We optimize the models with a batch size of 2048 for 1M steps in total using AdamW (Loshchilov and Hutter, 2019) with warmup and linear decay of the learning rate. To stabilize training, we perform pretraining in two stages: (1) in the first 500K steps, we update only those parameters that are randomly initialized (e.g., entity embeddings); (2) we update all parameters in the remaining 500K steps. The learning rate scheduler is reset at each training stage. For further details on hyperparameters, see Appendix A.

2.3 Baseline Models

We compare the primary model that we investigate, multilingual LUKE used with entity representations (**mLUKE-E**), against several baselines pretrained models and an ablation model based on word representations:

mBERT (Devlin et al., 2019) is one of the earliest multilingual language models. We provide these results as a reference.

XLM-R (Conneau et al., 2020a) is the model that mLUKE is built on. This result indicates how our additional pretraining step and entity representation impact the performance. Since earlier studies (Liu et al., 2019; Lan et al., 2020) indicated longer pretraining would simply improve performance, we train another model based on XLM-R$_{\text{base}}$ with extra MLM pretraining following the same configuration of mLUKE.

mLUKE-W is an ablation model of mLUKE-E. This model discards the entity embeddings learned during pretraining and only takes word tokens as input as with the other baseline models. The results from this model indicate the effect of MEP only as an auxiliary task in pretraining, and the comparison with this model will highlight the effect of using entity representations for downstream tasks in mLUKE-E.

The above models are fine-tuned with the same hyperparameter search space and computational budget as described in Appendix B.

We also present the results of **XLM-K** (Jiang et al., 2022) for ease of reference. XLM-K is based on XLM-R$_{\text{base}}$ and trained with entity information from Wikipedia but does not use entity representations in downstream tasks. Notice that their results are not strictly comparable to ours, because the pretraining and fine-tuning settings are different.

3 Adding Entities as Language-Agnostic Features in QA

We evaluate the approach of adding entity embeddings to the input of mLUKE-E with cross-lingual extractive QA tasks. The task is, given a question and a context passage, to extract the answer span from the context. The entity embeddings provide language-agnostic features and thus should facilitate cross-lingual transfer learning.

Table 1: F1 scores on the XQuAD and MLQA dataset in the cross-lingual transfer settings. The scores without reference are from the best model tuned with the English development data.

3.1 Main Experiments

Datasets. We fine-tune the pretrained models with the SQuAD 1.1 dataset (Rajpurkar et al., 2016), and evaluate them with the two multilingual datasets: XQuAD (Artetxe et al., 2020) and MLQA (Lewis et al., 2020). XQuAD is created by translating a subset of the SQuAD development set while the source of MLQA is natural text in Wikipedia. Besides multiple monolingual evaluation data splits, MLQA also offers data to evaluate generalized cross-lingual transfer (G-XLT), where the question and context texts are in different languages.

Models. All QA models used in this experiment follow Devlin et al. (2019). The model takes the question and context word tokens as input and predicts a score for each span of the context word tokens. The span with the highest score is predicted as the answer to the question.

mLUKE-E takes entity tokens as additional features in the input (Figure 1) to enrich word representations. The entities are automatically detected using a heuristic string matching based on the original Wikipedia article from which the dataset instance is created. See Appendix C for more details.

Results. Table 1 summarizes the model's F1 scores for each language. First, we discuss the *base* models. On the effectiveness of entity representations, mLUKE-E$_{\text{base}}$ performs better than its word-based counterpart mLUKE-W$_{\text{base}}$ (0.6 average points improvement in the XQuAD average score, 0.1 points in MLQA) and XLM-K (0.2 points improvement in MLQA), which indicates the input entity tokens provide useful features to facilitate cross-lingual transfer. The usefulness of entities is demonstrated especially in the MLQA's G-XLT setting (full results available in Appendix F); mLUKE-E$_{\text{base}}$ exhibits a substantial 1.6 point improvement in the G-XLT average score over mLUKE-W$_{\text{base}}$. This suggests that entity representations are beneficial in a challenging situation where the model needs to capture language-agnostic semantics from text segments in different languages.

We also observe that XLM-R$_{\text{base}}$ benefits from extra training (0.4 points improvement in the average score on XQuAD and 2.1 points in MLQA). The mLUKE-W$_{\text{base}}$ model further improves the average score from XLM-R$_{\text{base}}$ with extra training (1.2 points improvement in XQuAD and 2.1 points in MLQA), showing the effectiveness of the MEP task for cross-lingual QA.

By comparing *large* models, we still observe substantial improvements from XLM-R$_{\text{large}}$ to the mLUKE models. Also we can see that mLUKE-E$_{\text{large}}$ overall provides better results than mLUKE-W$_{\text{large}}$ (0.4 and 0.3 points improvements in the MLQA average and G-XLT scores; comparable scores in XQuAD), confirming the effectiveness of entity representations.

3.2 Analysis

How do the entity representations help the model in cross-lingual transfer? In the mLUKE-E model, the input entity tokens annotate mention spans on which the model performs prediction. We hypothesize that this allows the encoder to inject language-agnostic entity knowledge into span representations, which help better align representations across languages. To support this hypothesis, we compare the degree of alignment between span representations before and after adding entity embeddings in the input, *i.e.*, mLUKE-W and mLUKE-E.

Task. We quantify the degree of alignment as performance on the contextualized word retrieval (CWR) task (Cao et al., 2020). The task is, given a word within a sentence in the query language, to find the word with the same meaning in the context from a candidate pool in the target language.

Dataset. We use the MLQA dev set (Lewis et al., 2020). As MLQA is constructed from parallel sentences mined from Wikipedia, some sentences and answer spans are aligned and thus the dataset can be easily adapted for the CWR task. As the query and target word, we use the answer span[4] annotated in the dataset, which is also parallel across the languages. We use the English dataset as the query language and other languages as the target. We discard query instances that do not have their parallel data in the target language. The candidate pool is all answer spans in the target language data.

Models. We evaluate the mLUKE-W$_{\text{base}}$ and mLUKE-E$_{\text{base}}$ models without fine-tuning. The retrieval is performed by ranking the cosine similarity of contextualized span representations, which is computed by mean-pooling the output word vectors in the span.

Results. Table 2 shows the retrieval performance in terms of the mean reciprocal rank score. We observe that the scores of mLUKE-E$_{\text{base}}$ are higher than mLUKE-W$_{\text{base}}$ across all the languages. This demonstrates that adding entities improves the degree of alignment of span representations, which may explain the improvement of mLUKE-E in the cross-lingual QA task.

	ar	de	es	hi	vi	zh	avg.
mLUKE-W$_{\text{base}}$	55.6	66.1	68.4	60.4	69.7	56.1	62.7
mLUKE-E$_{\text{base}}$	56.9	68.1	70.4	61.5	71.2	60.0	64.7

Table 2: The mean reciprocal rank score of the CWR task with the MLQA dev set.

4 The Entity MASK Token as Feature Extractor in RE and NER

In this section, we evaluate the approach of using the entity `[MASK]` token to extract features from mLUKE-E for two entity-related tasks: relation extraction and named entity recognition.

We formulate both tasks as the classification of mention spans. The baseline models extract the feature of spans as the contextualized representations of word tokens, while mLUKE-E extracts the feature as the contextualized representations of the special language-independent entity tokens associated with the mentions (Figure 1). We demonstrate that this approach consistently improves the performance in cross-lingual transfer.

4.1 Relation Extraction

Relation Extraction (RE) is a task to determine the correct relation between the two (head and tail) entities in a sentence. Adding entity type features have been shown to be effective to cross-lingual transfer in RE (Subburathinam et al., 2019; Ahmad et al., 2021), but here we investigate an approach that does not require predefined entity types but utilize special entity embeddings learned in pretraining.

Datasets. We fine-tune the models with the English KBP-37 dataset (Zhang and Wang, 2015) and evaluate the models with the RELX dataset (Köksal and Özgür, 2020), which is created by translating a subset of 502 sentences from KBP-37's test set into four different languages. Following Köksal and Özgür (2020), we report the macro average of F1 scores of the 18 relations.

Models. In the input text, the head and tail entities are surrounded with special markers (`<ent>`, `<ent2>`). The baseline models extract the feature vectors for the entities as the contextualized vector of the first marker followed by their mentions. The two entity features are concatenated and fed into a linear classifier to predict their relation.

For mLUKE-E, we introduce two special entities, `[HEAD]` and `[TAIL]`, to represent the head and tail entities (Yamada et al., 2020). Their embeddings are initialized with the entity `[MASK]` embedding. They are added to the input sequence being associated with the entity mentions in the input, and their contextualized representations are extracted as the feature vectors. As with the word-based models, the features are concatenated and input to a linear classifier.

---

[4] Answer spans are not necessarily a word, but here we generalize the task as span retrieval for our purpose.

Table 3: F1 scores on relation extraction (RE) and named entity recognition (NER).

4.2 Named Entity Recognition

Named Entity Recognition (NER) is the task to detect entities in a sentence and classify their type. We use the CoNLL-2003 English dataset (Tjong Kim Sang and De Meulder, 2003) as the training data, and evaluate the models with the CoNLL-2003 German dataset and the CoNLL-2002 Spanish and Dutch dataset (Tjong Kim Sang, 2002).

Models. We adopt the model of Sohrab and Miwa (2018) as the baseline model, which enumerates all possible spans in a sentence and classifies them into the target entity types or *non-entity* type. In this experiment, we enumerate spans with at most 16 tokens. For the baseline models, the span features are computed as the concatenation of the word representations of the first and last tokens. The span features are fed into a linear classifier to predict their entity type.

The input of mLUKE-E contains the entity `[MASK]` tokens associated with all possible spans. The span features are computed as the contextualized representations of the entity `[MASK]` tokens. The features are input to a linear classifier as with the word-based models.

4.3 Main Results

The results are shown in Table 3. The mLUKE-E models outperform their word-based counterparts mLUKE-W in the average score in all the comparable settings (the *base* and *large* settings; the RE and NER tasks), which shows entity-based features are useful in cross-lingual tasks. We also observe that XLM-R$_{\text{base}}$ benefits from extra training (1.8 average points improvement in RE and 0.3 points in NER), but mLUKE-E still outperforms the results.

	de	es	fr	tr
mLUKE-W$_{\text{base}}$	0.71	0.74	0.74	0.84
mLUKE-E$_{\text{base}}$	0.25	0.28	0.24	0.36

Table 4: The modularity of word and entity features computed with the same mLUKE model. The data are from pairs of English and the other languages in the RELX dataset.

4.4 Analysis

The performance gain of mLUKE-E over mLUKE-W can be partly explained as the entity `[MASK]` token extracts better features for predicting entity attributes because it resembles how mLUKE is pretrained with the MEP task. We hypothesize that there exists another factor for the improvement in cross-lingual performance: language neutrality of representations.

The entity `[MASK]` token is shared across languages and their contextualized representations may be less affected by the difference of input languages, resulting in features that generalize well for cross-lingual transfer. To find out if the entity-based features are actually more language-independent than word-based features, we evaluate the *modularity* (Fujinuma et al., 2019) of the features extracted for the RELX dataset.

Modularity is computed for the k-nearest neighbor graph of embeddings and measures the degree to which embeddings tend to form clusters within the same language. We refer readers to Fujinuma et al. (2019) for how to compute the metric. Note that the maximum value of modularity is 1, and 0 means the embeddings are completely randomly distributed regardless of language.

We compare the modularity of the word features from mLUKE-W$_{\text{base}}$ and entity features from mLUKE-E$_{\text{base}}$ before fine-tuning. Note that the features here are concatenated vectors of head and tail features. Table 4 shows that the modularity of mLUKE-E$_{\text{base}}$ is much lower than mLUKE-W$_{\text{base}}$,

	ar	en	fi	fr	id	ja	ru	vi	zh	avg.
mBERT	17.1	36.8	24.0	24.3	42.9	14.3	19.5	39.4	26.2	27.2
XLM-R$_{\text{base}}$	14.2	27.2	16.2	14.9	28.2	11.9	11.7	25.1	17.6	18.5
+ extra training	21.2	35.0	23.0	22.2	46.8	19.6	17.5	34.4	30.7	27.8
mLUKE-W$_{\text{base}}$	22.3	31.3	18.4	19.6	46.7	18.4	16.7	31.9	29.3	26.1
mLUKE-E$_{\text{base}}$ (`[Y]`)	27.8	37.5	30.4	28.4	44.2	28.9	25.8	42.1	33.4	33.2
mLUKE-E$_{\text{base}}$ (`[X] & [Y]`)	**42.4**	**47.5**	**44.2**	**35.9**	**56.2**	**40.3**	**35.5**	**55.2**	**46.7**	**44.9**

Table 5: The top-1 accuracies from 9 languages from the mLAMA dataset.

demonstrating that entity-based features are more language-neutral. However, with entity-based features, the modularities are still greater than zero. In particular, the modularity computed with Turkish, which is the most distant language from English here, is significantly higher than the others, indicating that the contextualized entity-based features are still somewhat language-dependent.

5 Cloze Prompt Task with Entity Representations

In this section, we show that using the entity representations is effective in a cloze prompt task (Liu et al., 2021) with the mLAMA dataset (Kassner et al., 2021). The task is, given a cloze template such as "*`[X]` was born in `[Y]`*" with `[X]` filled with an entity (*e.g.*, *Mozart*), to predict a correct entity in `[Y]` (*e.g., Austria*). We adopt the typed querying setting (Kassner et al., 2021), where a template has a set of candidate answer entities and the prediction becomes the one with the highest score assigned by the language model.

Model. As in Kassner et al. (2021), the word-based baseline models compute the candidate score as the log-probability from the MLM classifier. When a candidate entity in `[Y]` is tokenized into multiple tokens, the same number of the word `[MASK]` tokens are placed in the input sequence, and the score is computed by taking the average of the log-probabilities for its individual tokens.

On the other hand, mLUKE-E computes the log-probability of the candidate entity in `[Y]` with the entity `[MASK]` token. Each candidate entity is associated with an entity in mLUKE's entity vocabulary via string matching. The input sequence has the entity `[MASK]` token associated with the word `[MASK]` tokens in `[Y]`, and the candidate score is computed as the log-probability from the MEP classifier. We also try additionally appending the entity token of `[X]` to the input sequence if the entity is found in the vocabulary.

To accurately measure the difference between word-based and entity-based prediction, we restrict the candidate entities to the ones found in the entity vocabulary and exclude the questions if their answers are not included in the candidates (results with full candidates and questions in the dataset are in Appendix G).

Results. We experiment in total with 16 languages which are available both in the mLAMA dataset and the mLUKE's entity vocabulary. Here we only present the top-1 accuracy results from 9 languages on Table 5, as we can make similar observations with the other languages.

We observe that XLM-R$_{\text{base}}$ performs notably worse than mBERT as mentioned in Kassner et al. (2021). However, with extra training with the Wikipedia corpus, XLM-R$_{\text{base}}$ shows a significant 9.3 points improvement in the average score and outperforms mBERT (27.8 vs. 27.2). We conjecture that this shows the importance of the training corpus for this task. The original XLM-R is only trained with the CommonCrawl corpus (Conneau et al., 2020a), text scraped from a wide variety of web pages, while mBERT and XLM-R + training are trained on Wikipedia. The performance gaps indicate that Wikipedia is particularly useful for the model to learn factual knowledge.

The mLUKE-W$_{\text{base}}$ model lags behind XLM-R$_{\text{base}}$ + extra training by 1.7 average points but we can see 5.4 points improvement from XLM-R$_{\text{base}}$ + extra training to mLUKE-E$_{\text{base}}$ (`[Y]`), indicating entity representations are more suitable to elicit correct factual knowledge from mLUKE than word representations. Adding the entity corresponding to `[X]` to the input (mLUKE-E$_{\text{base}}$ (`[X] & [Y]`)) further pushes the performance by 11.7 points to 44.9 %, which further demonstrates the effectiveness of entity representations.

Analysis of Language Bias. Kassner et al. (2021) notes that the prediction of mBERT is biased by the input language. For example, when queried in Italian (*e.g.*, "*`[X]` e stato creato in `[MASK]`.*"), the model tends to predict entities that often appear in Italian text (*e.g., Italy*) for any question to answer

	en	ja	fr
mBERT	The Bahamas, 41% (355/870)	Japan, 82% (361/439)	Pays-Bas, 71% (632/895)
XLM-R$_{\text{base}}$	London, 78% (664/850)	Japan, 99% (437/440)	Allemagne, 96% (877/916)
+ extra training	Australia, 27% (247/899)	Japan, 99% (437/442)	Allemagne, 93% (854/917)
mLUKE-W$_{\text{base}}$	Germany, 22% (198/895)	Japan, 97% (428/442)	Allemagne, 99% (906/918)
mLUKE-E$_{\text{base}}$ (`[Y]`)	London, 37% (310/846)	Japan, 56% (241/430)	Suède, 40% (362/908)
mLUKE-E$_{\text{base}}$ (`[X]` & `[Y]`)	London, 27% (213/797)	Japan, 44% (176/401)	Suède, 30% (266/895)

Table 6: The top incorrect predictions in three languages for the template "*[X] was founded in [Y].*" for each model. The predictions in the original language are translated into English.

location. We expect that using entity representations would reduce language bias because entities are shared among languages and less affected by the frequency in the language of questions.

We qualitatively assess the degree of language bias in the models looking at their incorrect predictions. We show the top incorrect prediction for the template "*[X] was founded in [Y].*" for each model in Table 6, together with *the top-*1 *incorrect ratio*, that is, the ratio of the number of the most common incorrect prediction to the total false predictions, which indicates how much the false predictions are dominated by few frequent entities.

The examples show that the different models exhibit bias towards different entities as in English and French, although in Japanese the model consistently tends to predict *Japan*. Looking at the degree of language bias, mLUKE-E$_{\text{base}}$ (`[X]` & `[Y]`) exhibits lower top-1 incorrect ratios overall (27% in fr, 44% in ja, and 30% in fr), which indicates using entity representations reduces language bias. However, lower language bias does not necessarily mean better performance: in French (fr), mLUKE-E$_{\text{base}}$ (`[X]` & `[Y]`) gives a lower top-1 incorrect ratio than mBERT (30% vs. 71%) but their numbers of total false predictions are the same (895). Language bias is only one of several factors in the performance bottleneck.

6 Related Work

6.1 Multilingual Pretrained Language Models

Multilingual pretrained language models have recently seen a surge of interest due to their effectiveness in cross-lingual transfer learning (Conneau and Lample, 2019; Liu et al., 2020). A straightforward way to train such models is multilingual masked language modeling (mMLM) (Devlin et al., 2019; Conneau et al., 2020a), i.e., training a single model with a collection of monolingual corpora in multiple languages. Although models trained with mMLM exhibit a strong cross-lingual ability without any cross-lingual supervision (K et al., 2020; Conneau et al., 2020b), several studies aim to develop better multilingual models with explicit cross-lingual supervision such as bilingual word dictionaries (Conneau et al., 2020b) or parallel sentences (Conneau and Lample, 2019). In this study, we build a multilingual pretrained language model on the basis of XLM-RoBERTa (Conneau et al., 2020a), trained with mMLM as well as the masked entity prediction (MEP) (Yamada et al., 2020) with entity representations.

6.2 Pretrained Language Models with Entity Knowledge

Language models trained with a large corpus contain knowledge about real-world entities, which is useful for entity-related downstream tasks such as relation classification, named entity recognition, and question answering. Previous studies have shown that we can improve language models for such tasks by incorporating entity information into the model (Zhang et al., 2019; Peters et al., 2019; Wang et al., 2021; Xiong et al., 2020; Févry et al., 2020; Yamada et al., 2020).

When incorporated into multilingual language models, entity information can bring another benefit: entities may serve as anchors for the model to align representations across languages. Multilingual knowledge bases such as Wikipedia often offer mappings between different surface forms across languages for the same entity. Calixto et al. (2021) fine-tuned the top two layers of multilingual BERT by predicting language-agnostic entity ID from hyperlinks in Wikipedia articles. As our concurrent work, Jian et al. (2022) trained a model based on XLM-RoBERTa with an entity prediction task along with an object entailment prediction task. While the previous studies focus on improving cross-lingual language representations by pretraining with entity information, our work investigates a multilingual model not only pretrained with entities but also explicitly having entity representations and how to extract better features from such model.

7 Conclusion

We investigated the effectiveness of entity representations in multilingual language models. Our pretrained model, mLUKE, not only exhibits strong empirical results with the word inputs (mLUKE-W) but also shows even better performance with the entity representations (mLUKE-E) in cross-lingual transfer tasks. We also show that a cloze-prompt-style fact completion task can effectively be solved with the query and answer space in the entity vocabulary. Our results suggest a promising direction to pursue further on how to leverage entity representations in multilingual tasks. Also, in the current model, entities are represented as individual vectors, which may incur a large memory footprint in practice. One can investigate an efficient way of having entity representations.

			Total	31.4G	8,374,722

Table 7: Training Data Statistics: the size of training data, and the number of entities found in the 1.2M entity vocabulary.

Optimization. We optimize the mLUKE models for 1M steps in total using AdamW (Loshchilov and Hutter, 2019) with learning rate warmup and linear decay of the learning rate. The pretraining consists of two stages: (1) in the first 500K steps, we update only those parameters that are randomly initialized (e.g., entity embeddings); (2) we update all parameters in the remaining 500K steps. The learning rate scheduler is reset at each training stage. The detailed hyper-parameters are shown in Table 8.

Maximum word length	512	Mask probability for entities	15%
Batch size	2048	The size of word token embeddings	768
Peak learning rate	1e-4	The size of entity token embeddings	256
Peak learning rate (first 500K steps)	5e-4	Dropout	0.1
Learning rate decay	linear	Weight decay	0.01
Warmup steps	2500	Adam β_1	0.9
Mask probability for words	15%	Adam β_2	0.999
Random-word probability for words	10%	Adam ϵ	1e-6
Unmasked probability for words	10%	Gradient clipping	none

Table 8: Hyper-parameters used to pretrain mLUKE.

Computing Infrastructure. We run the pretraining on NVIDIA's PyTorch Docker container 19.02 hosted on a server with two Intel Xeon Platinum 8168 CPUs and 16 NVIDIA Tesla V100 GPUs. The training takes approximately 2 months.

B Details of Downstream Experiments

Hyperparameter Search. For each downstream task, we perform hyperparameter searching for all the models with the same computational budget to ensure a fair comparison. For each task, we use the final evaluation metric on the validation split of the training English corpus as the validation score. The models are optimized with the AdamW optimizer (Loshchilov and Hutter, 2019) with the weight decay term set to 0.01 and a linear warmup scheduler. The learning rate is linearly increased to a specified value in the first 6 % of training steps, and then gradually decreased to zero towards the end. Table 9 summarizes the task-specific hyperparameter search spaces.

	QA (SQuAD)	Relation Classification (KBP37)	NER (CoNLL 2003)
Learning rate	2e-5	2e-5	2e-5
Batch size	{16, 32}	{4, 8, 16}	{4, 8, 16}
Epochs	2	5	5
# of random seeds	3	3	3
Validation metric	F1	F1	F1

Table 9: The hyperparameters search spaces and other details of downstream experiments.

Computing Infrastructure. We run the fine-tuning on a server with a Intel(R) Core(TM) i7-6950X CPU and 4 NVIDIA GeForce RTX 3090 GPUs.

C Detecting Entities in the QA datasets

For each question–passage pair in the QA datasets, we first create a mapping from the entity mention strings (e.g., "U.S.") to their referent Wikipedia entities (e.g., United States) using the entity hyperlinks on the source Wikipedia page of the passage. We then perform simple string matching to extract all entity names in the question and the passage and treat all matched entity names as entity annotations for their referent entities. We ignore an entity name if the name refers to multiple entities on the page. Further, to reduce noise, we also exclude an entity name if its link probability, the probability that the name appears as a hyperlink in Wikipedia, is lower than 1%.

The XQuAD datasets are created by translating English Wikipedia articles into target languages. For each translated article, we create the mention-entity mapping from the source English article by the following procedure: for all the entities found in the source article, we find the corresponding entity in the target language through inter-language links, and then collect its possible mention strings (*i.e.,* hyperlinks to the entity) from a Wikipedia dump of the target language; the entity and the collected mention strings form the mention-entity mapping for the translated article.

D The Model Size

	# of layers	hidden size	# of heads	vocabulary size	# of parameters
mBERT	12	768	12	120K	177M
XLM-$\mathrm{R}_{\mathrm{base}}$	12	768	8	250K	278M
mLUKE-$\mathrm{E}_{\mathrm{base}}$	12	768	8	250K	585M
XLM-$\mathrm{R}_{\mathrm{large}}$	24	1024	16	250K	559M
mLUKE-$\mathrm{E}_{\mathrm{large}}$	24	1024	16	250K	867M

E Ablation Study of Entity Embeddings

In Section 3 and 4, we have shown that using entity representations in mLUKE improves the cross-lingual transfer performance in QA, RE, and NER. Here we conduct an additional ablation study to investigate whether the learned entity embeddings are crucial to the success of our approach. We train an ablated model of mLUKE-E whose entity embeddings are re-initialized randomly before fine-tuning (-ablation). Table 11 and Table 12 show that the ablated model performs significantly worse than the full model (mLUKE-E), indicating that using pretrained entity embeddings is crucial rather than applying our approach during fine-tuning in an ad-hoc manner without entity-aware pretraining.

Abstract

Automated *simplification* models aim to make input texts more readable. Such methods have the potential to make complex information accessible to a wider audience, e.g., providing access to recent medical literature which might otherwise be impenetrable for a lay reader. However, such models risk introducing errors into automatically simplified texts, for instance by inserting statements unsupported by the corresponding original text, or by omitting key information. Providing more readable but inaccurate versions of texts may in many cases be worse than providing no such access at all. The problem of factual accuracy (and the lack thereof) has received heightened attention in the context of summarization models, but the factuality of automatically simplified texts has not been investigated. We introduce a taxonomy of errors that we use to analyze both references drawn from standard simplification datasets and state-of-the-art model outputs. We find that errors often appear in both that are not captured by existing evaluation metrics, motivating a need for research into ensuring the factual accuracy of automated simplification models.

1 Introduction

Simplification methods aim to make texts more readable without altering their meaning. This may permit information accessibility to a wide range of audiences, e.g., non-native speakers (Yano et al., 1994), children (De Belder and Moens, 2010), as well as individuals with aphasia (Carroll et al., 1998) and dyslexia (Rello et al., 2013). Simplification may also help laypeople digest technical information that would otherwise be impenetrable (Damay et al., 2006; Devaraj et al., 2021).

Recent work has made substantial progress by designing sequence-to-sequence neural models that "translate" complex sentences into simplified versions (Xu et al., 2016; Alva-Manchego et al., 2020).

(1) **[Original]** There was no difference in operating time or perioperative complication rates.
[Model simplified] However, there was not enough evidence to determine if there was an important difference in operative time or complication rates when compared to conventional surgery.

(2) **[Original]** All studies were associated with methodological limitations.
[Model simplified] All studies were of poor quality and had limitations in the way they were conducted.

(3) **[Original]** On June 24 1979 (the 750th anniversary of the village), Glinde received its town charter.
[Model simplified] On June 24 1979, the 750th anniversary of the village was renamed.

(4) **[Original]** Others agreed with the federal court; they started marrying people in the morning.
[Model simplified] Others agreed with the federal court; they started trying in morning.

(5) **[Original]** In 2014, Mary Barra became CEO of General Motors, making her the first female CEO of a major automobile company.
[Model simplified] Also, just one woman leads a major automobile company. *Omitted main subject.*

Table 1: Original texts from the Wiki, news, and medical domains with corresponding outputs from simplification systems. Models introduce factual errors.

An important but mostly overlooked aspect of automated simplification—especially in the conditional text generation regime—is whether outputs are *faithful* to the inputs that they are simplifying. Consider, for example, automatically simplifying medical texts (Devaraj et al., 2021): Presenting individuals with readable medical information that contains factual errors is probably worse than providing no such access at all.

Recent work has acknowledged factuality and faithfulness as key issues to be addressed in other conditional generation tasks like summarization (Kryscinski et al., 2020a; Maynez et al., 2020; Pagnoni et al., 2021; Goyal and Durrett, 2021), yet so far little research has thoroughly studied the kinds of errors that simplification datasets and system outputs exhibit. This work seeks to close this research gap.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics

Table 1 shows examples of generated outputs from existing simplification systems, and these clearly illustrate that factuality is an issue. We conduct multi-dimensional analyses based on the edit nature of simplification (Xu et al., 2015; Dong et al., 2019) and define a small typology of (potential) factual errors in the context of simplification. *Inserting* information can be useful to define jargon and provide explanatory content, but introducing irrelevant or erroneous content ("hallucinating") is bad (e.g., examples 1-2 in Table 1). *Omitting* information related to the main entity or event could lead to a change in how the text is understood (e.g., example 5 in Table 1). Finally, making inappropriate *substitutions* can result in inconsistencies (e.g., examples 3-4 in Table 1). Together these dimensions represent the precision, recall, and accuracy of information conveyed in simplified texts.

We collect human ratings of factuality for these aspects on two widely used simplification corpora: Wikilarge (Zhang and Lapata, 2017) and Newsela (Xu et al., 2015). Automatically aligned sentences from these two datasets are typically used to train and evaluate supervised simplification systems. We find that errors occur frequently in the validation and test sets of both datasets, although they are more common in Newsela (Section 6).

We then evaluate outputs from several modern simplification models (Zhang and Lapata, 2017; Dong et al., 2019; Martin et al., 2020; Maddela et al., 2021), as well as a fine-tuned T5 (Raffel et al., 2020) model. Compared to RNN-based models, Transformer-based ones tend to have less severe deletion and substitution errors; however, the pre-trained T5 produced more hallucinations on the more abstractive Newsela dataset. We find that existing quality metrics for simplification such as SARI (Xu et al., 2016) correlate poorly with factuality. Although deletion errors correlate with existing semantic similarity measures, they fail to capture insertion and substitution.

As an initial step towards automatic factuality assessment in simplification, we train RoBERTa (Liu et al., 2019)-based classification models using our annotated data, and use synthetically generated data to supplement training. We demonstrate that this is a challenging task.

Our code and data can be found at https://github.com/AshOlogn/Evaluating-Factuality-in-Text-Simplification.

2 Related Work

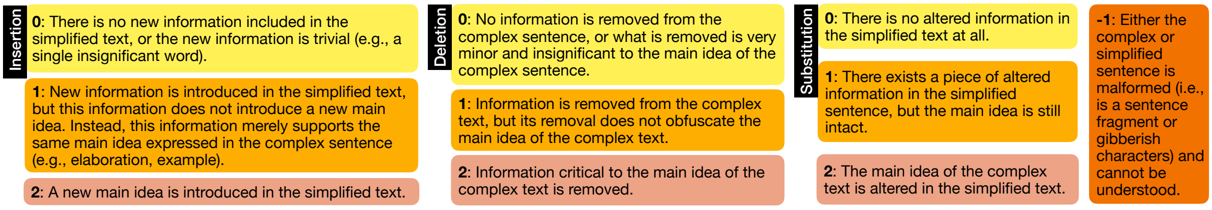
Factuality (and the lack thereof) has been identified as critical in recent work in unsupervised simplification (Laban et al., 2021) and medical simplification (Devaraj et al., 2021). Guo et al. (2018) incorporated textual entailment into their simplification task via an auxillary loss. They showed that this improved simplifications with respect to standard metrics and human assessments of output fluency, adequacy, and simplicity, but they did not explicitly evaluate the resultant factuality of outputs, which is our focus.

Given the paucity of prior work investigating factuality in the context of automated simplification, the most relevant thread of research to the present effort is work on measuring (and sometimes improving) the factuality in outputs from neural *summarization* systems. Falke et al. (2019a) proposed using textual entailment predictions as a means to identify errors in generated summaries. Elsewhere, Kryscinski et al. (2020a) used weak supervision—heuristic transformations used to intentionally introduce factual errors—to train a model to identify inaccuracies in outputs.

Maynez et al. (2020) enlisted humans to evaluate *hallucinations* (content found in a summary but not in its corresponding input) in automatically generated outputs. They report that for models trained on the XSUM dataset (Narayan et al., 2018), over 70% of summaries contain hallucinations. This corroborates other recent work (Falke et al., 2019a; Wallace et al., 2021), which has also found that ROUGE is a weak gauge of factuality. Wang et al. (2020a) proposed *QAGS*, which uses automated question-answering to measure the consistency between reference and generated summaries. Elsewhere, Xu et al. (2020) proposed evaluating textual factuality independent of surface realization via Semantic Role Labeling (SRL). Finally, Pagnoni et al. (2021) introduced the FRANK (meta-)benchmark for evaluating factuality metrics for summarization. While FRANK is tailored towards summarization-specific error categories including discourse, our ontology broadly reflects the goal of simplification (retaining content with simpler language) from the perspective of information precision, recall, and accuracy.

3 Information Errors in Simplification

Above we reviewed various recently proposed frameworks and methods for assessing the factual



0: There is no new information included in the simplified text, or the new information is trivial (e.g., a single insignificant word).

1: New information is introduced in the simplified text, but this information does not introduce a new main idea. Instead, this information merely supports the same main idea expressed in the complex sentence (e.g., elaboration, example).

2: A new main idea is introduced in the simplified text.

0: No information is removed from the complex sentence, or what is removed is very minor and insignificant to the main idea of the complex sentence.

1: Information is removed from the complex text, but its removal does not obfuscate the main idea of the complex text.

2: Information critical to the main idea of the complex text is removed.

0: There is no altered information in the simplified text at all.

1: There exists a piece of altered information in the simplified sentence, but the main idea is still intact.

2: The main idea of the complex text is altered in the simplified text.

-1: Either the complex or simplified sentence is malformed (i.e., is a sentence fragment or gibberish characters) and cannot be understood.

Figure 1: The full annotation scheme: 0: no/trivial change; 1: nontrivial but preserves main idea; 2: does not preserve main idea; -1: gibberish. The -1 label is applicable to all three categories.

accuracy of automatically-generated *summaries*. We aim in this work to similarly codify content errors in *simplification*.

Category	**Original/Simplified Sentences**
Insertion	*I went on a trip last week.* *I went on a trip to Alaska last week.*
Deletion	*Yesterday I bought a bagel.* *I bought it.*
Substitution	*The shelter houses 100 cats and 200 dogs.* *The shelter houses 200 cats and 200 dogs.*

Table 2: Illustrative examples of the three categories of information errors. Not from a real dataset.

Below we describe broad categories of errors[1] we observed in simplification datasets and system outputs, and then use these to design annotation guidelines that formalize accuracy assessment (Section 5). Our analysis revealed three broad categories, illustrated in Table 2:

(1) Information Insertion: This occurs when information not mentioned in the complex sentence is inserted into—or *hallucinated* in—its simplified counterpart. The insertion may be as small as mentioning a proper noun not in the complex sentence, or as large as introducing a new main idea. This category is similar to *extrinsic hallucination* in the summarization literature (Maynez et al., 2020; Goyal and Durrett, 2021).

(2) Information Deletion: This is when information in the complex sentence is omitted from the simplified sentence. A minor example of this is the reverse of the insertion case above, where an entity is mentioned by name in the complex sentence but only by pronoun in the simplified sentence.

(3) Information Substitution: This is when information in the complex sentence is modified in the simplified sentence such that it changes the meaning. This category is broad, encompassing both alterations to the simplified sentence that directly contradict information in the complex sentence, and those that do not.

Because errors can co-occur, we adopt a multi-dimensional labeling scheme that requires a different label to be provided for each category. Each category label specifies the severity of the error: **0–no/trivial change; 1–nontrivial but preserves main idea; 2–doesn't preserve main idea; -1–gibberish, specified in Figure 1.** Table 1 shows level-2 examples from system outputs for insertion (examples 1-2), substitution (examples 3-4), and deletion (example 5). Reference examples are discussed in Section 6.

Interpretation as Precision and Recall In simplification one attempts to rewrite a given complex sentence to be simpler while preserving most of the information that it contains. The categories above can be interpreted as errors in information precision (the fraction of content that also appears in the complex sentence) and recall (the fraction of content in the complex sentence preserved during simplification). With this interpretation, a "false positive" (affecting *precision*) occurs when the simplified sentence contains information not present in the source, i.e., introduces a "hallucination". And a "false negative" (hindering *recall*) is where the simplified sentence omits key information in the source.

4 Data and Models

We annotate data from the simplification datasets themselves (we will call these *reference* examples), as well as from model-generated text. Thus we assess how the distribution of errors in the references compares to that of errors in system outputs and glean insights that might relate model architecture and training choices to the kinds of errors produced.

Datasets. We annotated examples from the Wikilarge and Newsela (Xu et al., 2015; Zhang and

---

[1] We adapt a graded labeling scheme based on content and meaning preservation. For brevity, we use the word "error" as a generic term to refer to all the phenomena captured by our labeling scheme, even those that may be considered acceptable in some simplification systems.

Lapata, 2017) datasets. These are commonly used in the literature, and so results have been reported on these corpora for a diverse collection of models. Wikilarge comprises 296K roughly-aligned sentences pairs from English Wikipedia and Simple English Wikipedia. Newsela (Xu et al., 2015) consists of 96K sentence pairs extracted from a dataset of news stories rewritten at 4 reading levels by professionals. To make analysis tractable in this work, we examine the simplest level for Newsela.

We annotated 400 pairs of (complex, simplified) sentences each from the validation and test sets for Newsela. For Wikilarge, we annotated 400 pairs from the validation set and 359 from the test set (this constitutes the entire test set).

Simplification Models. We annotated outputs generated by a collection of models on the same validation and test examples from Wikilarge and Newsela, respectively. We selected a set of models intended to be representative of different architectures and training methods.

More specifically, for RNN-based models we considered `Dress` (Zhang and Lapata, 2017) and `EditNTS` (Dong et al., 2019). `Dress` is an LSTM model trained using REINFORCE (Williams, 1992) to minimize a reward function consisting of meaning preservation, simplicity, and fluency terms. `EditNTS` represents each sentence pair as a sequence of edit operations and directly learns these operations to perform simplification.

For Transformer-based architectures we evaluated two previously proposed models: `Access` (Martin et al., 2020) and `ControlTS` (Maddela et al., 2021). `Access` trains a randomly-initialized Transformer to generate simplifications parametrized by control tokens influencing traits like lexical complexity and length compression. `ControlTS` is a hybrid method that generates simplification candidates using grammatical rules and then applies a BERT-based (Devlin et al., 2019) paraphrasing model. In addition, we also fine-tuned `T5` (Raffel et al., 2020) for the simplification task, detailed in Appendix A. `T5` is a Transformer-based model jointly pretrained both on unsupervised language modeling objectives and a host of supervised tasks including summarization and translation, all framed as text-to-text problems.

5 Labeling with Mechanical Turk

Annotation Procedure We use Amazon Mechanical Turk to acquire labels for reference examples from datasets, and for model-generated simplifications. To ensure that only annotators who understood our labeling scheme would be included, we released a qualification task consisting of 10 sentence pairs with perfect agreement among two of the authors, with detailed explanation of the labeling scheme, and required that annotators achieve at least 75% accuracy on this set.

Category	% Majority Agreement	% Majority Agr. (non-zero)
Insertion	96	77
Deletion	96	92
Substitution	95	74

Table 3: Percentage of examples with majority annotator agreement for each category and percentage of examples with a majority nonzero label in which the majority of annotators agreed on the specific label.

After worker qualification, examples were released to only qualified workers, and each example was annotated by 3 workers. The final label for each category (insertion, deletion, substitution) was set to the majority label if one existed. If every annotator provided a different label for a given category, we removed this example for purposes of this category. For example, if annotators provided insertion labels of $\{1, 1, 2\}$ and deletion labels of $\{2, 1, 0\}$ for a specific instance, then this would not be assigned a deletion label, but would receive a "final" insertion label of 1. Workers were compensated $10.00 per hour on the annotation task.

Inter-annotator Agreement. We quantified the degree of inter-annotator agreement using 3 metrics, each capturing a different dimension of labeling consistency for each category: First, we report the percentage of examples that had a well-defined majority label for each category. Most annotators agreed on labels for the majority of examples (first column in Table 3), meaning that very few annotations had to be discarded for any category.

Because 0 was the most common label for all 3 categories, especially for the reference examples from the datasets, we also recorded the percentage of examples with *majority non-zero annotations* that also have a well-defined majority label. For example, the labels $\{0, 1, 2\}$ are majority non-zero but do not correspond to a well-defined majority label, while $\{0, 1, 1\}$ satisfies both conditions. Table 3 (column 2) indicates that even among examples where most annotators agree that there is an error, the majority agree on a specific label of 1, 2, or -1.

Category	Dataset	0	1	2	-1
Insertion	Wikilarge	91.1	6.3	0.3	2.3
	Newsela	68.2	20.2	11.1	0.5
Deletion	Wikilarge	76.2	18.0	3.5	2.3
	Newsela	15.8	40.8	42.9	0.5
Substitution	Wikilarge	90.1	6.7	0.9	2.3
	Newsela	94.9	3.8	0.8	0.5

Table 4: Insertion, deletion, and substitution error distributions (%) in Wikilarge and Newsela test datasets.

We also measured Krippendorff's alpha (Krippendorff, 1970) with an ordinal level of measurement (assigning the -1 label a value of 3 to indicate maximum severity). Dataset annotations for insertion enjoy moderate agreement ($\alpha = 0.425$), those for deletion imply substantial agreement ($\alpha = 0.639$), and those for substitution exhibit fair agreement ($\alpha = 0.200$) (Artstein and Poesio, 2008). The latter is possibly due to the clear majority label of 0 among substitution labels.

The % majority agreement scores indicate that although the annotation scheme involves a degree of subjectivity in distinguishing between minor and major errors, with proper screening crowdsource workers can label text pairs with our annotation scheme consistently enough so that a well-defined label can be assigned to the vast majority of examples.

6 Factuality of Reference Examples

Quantitative Analysis Table 4 reports distributions of acquired labels for information insertion, deletion, and substitution errors over the annotated reference examples. Deletion errors are far more common than insertion errors in both datasets, though Wikilarge has fewer of both than Newsela. This is unsurprising, as one of the motivations for introducing the Newsela dataset was that it contains shorter and less syntactically-complex simplifications. Reassuringly, there were very few substitution errors found in either dataset.

Table 5 shows a clear positive correlation between length reduction and the severity of deletion errors present. As expected, sentences are shortened more substantially in Newsela than in Wikilarge. One the other hand, while Table 5 indicates that the examples with nonzero insertion labels collectively see a greater increase in length than those with no insertion errors, the mean length increase for level 2 examples is smaller than that for level 1.

Simplifications in Newsela are more abstractive (Xu et al., 2015), i.e., simplified sentences copy fewer phrases verbatim from inputs. This can be quantified via normalized edit distance (Levenshtein, 1965), which yielded a median of 0.46 for Newsela examples compared to the 0.38 for Wikilarge (after noise filtering described in Appendix B). Table 5 indicates that on average the more erroneous the insertion or deletion, the greater the normalized edit distance between the original and simplified sentences.

These results suggest that while reducing sentence length and rewording can be beneficial (Klare, 1963), too much can negatively impact factuality.

Qualitative Analysis We also manually inspected insertion and deletion errors in both datasets, revealing clear patterns of deletion errors. Label 1 deletions by definition involve omissions of nonsalient details that do not much affect the meaning of the sentence, e.g.:

> **Original:** Mayfield wrote and sang on a string of message-oriented records, *including "Keep on Pushing" and "People Get Ready."*
> **Simplified:** Mayfield wrote and sang on records that had a message. (*Newsela, deletion-1*)

Label 2 deletions have two common manifestations across the datasets. The first involves deletion of the main clause and subsequent promotion of a secondary clause:

> **Original:** "Until you know how the sausage is made, you don't know how expensive it is to make that sausage," said Josh Updike, creative director of Rethink Leisure & Entertainment, *which is working on several projects in China and elsewhere in Asia.*
> **Simplified:** The company is working on several projects in China and Asia. (*Newsela, deletion-2*)

Another common type of label 2 deletion involves removing a key (though often small) phrase that effectively reframes the entire sentence, e.g.:

> **Original:** You may add a passage of up to five words as a Front-Cover Text, and a passage of up to 25 words as a Back-Cover Text, to the end of the list of Cover Texts *in the Modified Version.*
> **Simplified:** You may add a passage of up to five words as a Front-Cover Text and a passage of up to 25 words as a Back-Cover Text to the end of the list of Cover Texts. (*Wikilarge, deletion-2*)

By deleting *in the Modified Version* (emphasis ours), the simplified sentence erroneously states that one may add front- and back-cover passages to the list of cover texts to the unmodified version, which is implicitly forbidden in the original.

Because of the small number of insertion errors on Wikilarge, we were unable to identify any meaningful trends. However, we observed patterns in

		% length change			Normalized edit distance		
		Level 0	**Level 1**	**Level 2**	**Level 0**	**Level 1**	**Level 2**
Insertion	Wikilarge	-5.0 (17.0)	22.4 (36.9)	7.1 (0.0)	0.20 (0.20)	0.55 (0.40)	0.58 (0.0)
	Newsela	-39.4 (23.8)	-19.0 (36.9)	-38.3 (29.0)	0.41 (0.17)	0.51 (0.21)	0.54 (0.04)
Deletion	Wikilarge	2.8 (15.8)	-22.3 (18.9)	-35.9 (15.9)	0.19 (0.23)	0.35 (0.18)	0.39 (0.14)
	Newsela	1.5 (27.6)	-34.8 (23.1)	-49.6 (22.8)	0.34 (0.31)	0.46 (0.13)	0.53 (0.10)

Table 5: % length change (left) and normalized edit distances (right) in simplified sentences in each insertion and deletion error category (mean ± standard deviation).

Newsela for both levels 1 and 2 of insertions, pertaining to quotative phrases (e.g., inserting *"experts said"* to the beginning of a sentence even though the original sentence did not mention an expert), and temporal phrases, e.g.:

> **Original:** They could not afford to pay their son's roughly \$10,000 cost for classes at the University of Texas at Austin.
> **Simplified:** *When he grew up,* they could not afford to pay \$10,000 for him to go to the University of Texas at Austin. (*Newsela, insertion-1*)

Another error trend pertains to a change in specificity:

> **Original:** Mutanabbi Street has always been *a hotbed of dissent*.
> **Simplified:** Mutanabbi Street has always been *a place where protest marches are held*. (*Newsela, insertion-2*)

We observed more contextually related errors for Newsela due to its style and its simplification process. Newsela documents were edited by professionals who rewrote the entire original document, and so information inserted or deleted could move from or to adjacent sentences. This preserves information for the whole document but causes problems at the sentence level. Also, compared to Wikilarge, Newsela's news articles naturally involve more complex discourse (Van Dijk, 2013). These factors lead to relatively underspecified sentences (Li et al., 2016) in the simplified text when they are taken out-of-context during training and evaluation. This observation calls for the inclusion of document context during simplification (Sun et al., 2020), or performing decontextualization (Choi et al., 2021) before simplifying.

7 Factuality of System Outputs

Table 6 shows the distributions of insertion, deletion, and substitution errors annotated in system outputs.[2] It also shows the standard simplification evaluation metric—SARI scores (Xu et al., 2016)—for the annotated set. For the three models that reported both Wikilarge and Newsela outputs, the relative frequency of deletion errors between the two datasets appears to be preserved in model outputs, though for the RNN models errors are milder on Newsela and amplified on Wikilarge.

A clear relationship between dataset and system output distributions does not exist for insertion and substitution errors. For `Dress` and `EditNTS`, this is due to the fact that the minor differences in insertion errors are dwarfed by the larger number of -1 (gibberish) labels assigned to Newsela outputs. Interestingly, outputs from the `T5` model were rarely labeled as -1 errors, so the difference in insertion errors is more apparent. In the case of substitution, the Newsela outputs for `Dress` and `T5` models show much higher rates of substitution errors than the Wikilarge outputs, despite the opposite being true for the datasets themselves. `EditNTS` does not show the same pattern, but again, the high rate of -1 errors subsumes every other trend. One possible reason for this phenomenon could be that the higher abstractiveness of Newsela encourages models to rewrite the input sentence to a greater extent and destroy the original meaning in the process. In general the models produce substitution errors more frequently than are found in the dataset, meaning that they are introduced by the models themselves and not merely learned from the data.

Model comparisons There are a few differences in error distributions between the RNN-based and Transformer-based models, and between pretrained vs. non-pretrained Transformer models. All three Transformer models have less severe deletion errors than the RNN models on Wikilarge, and in addition `T5` has lower deletion error rates on Newsela. Perhaps the most striking trend is that the Transformer models have far lower -1 gibberish errors than RNN-based models, even `Access`, which is not pre-trained on the language modeling task. `T5`—which has been pre-trained on large amounts of data—produced more insertion errors, while `Access` produced more substitution errors.

---

[2] `DRESS` only released their Wikilarge outputs; `ControlTS` had different data splits for Newsela. We could not successfully reproduce their results for Newsela.

			Insertion				**Deletion**				**Substitution**			
Model	**Dataset**	**SARI**	**0**	**1**	**2**	**-1**	**0**	**1**	**2**	**-1**	**0**	**1**	**2**	**-1**
Dress	Wikilarge	34.9	91.9	0.8	0.8	6.5	42.6	24.6	26.2	6.6	84.4	4.1	4.9	6.6
	Newsela	34.5	90.5	0.0	0.0	9.5	29.9	29.2	32.1	9.7	67.4	6.5	15.9	10.1

Table 6: SARI and error distributions in system outputs manually evaluated.

Quantitative Analysis We explore the relationships between the factuality annotations of system outputs and both length reduction and normalized edit distance. We briefly describe our findings here and defer numerical details to Appendix C.

For every model except `Access`, there is a clear positive correlation between the severity of deletion errors and the degree of length reduction between the complex input and generated simplification. This is consistent with the trend observed for the datasets. No consistent relationships between length change and levels of insertion and substitution errors are exhibited by the system outputs. As in the case of length reduction, mean edit distances increase with the severity of deletion error with no consistent trends found for insertion and substitution labels.

Qualitative analysis We also manually inspect model outputs, detailed in Appendix D, and summarize main observations here. As in the data, models also produce deletions ranging from single words and short phrases to clauses. For the two RNN models, `DRESS` and `EditNTS`, level 1 errors primarily consist of shorter deletion errors, which include pronoun errors and modifiers. Level 2 errors are almost always longer deletions, yet we did not observe the promotion of a subordinate clause to a main one as in the references, suggesting that models tend to follow syntactic rules more strictly. For `T5`, we additionally observe level 2 errors in which the model deletes a semantically critical word. We observed more error variability in the other two transformer models, `Access` and `ControlTS`. Models introduced varying numbers of insertion and substitution errors, but in inspection we did not observe any clear properties of these as a function of model type.

Model	**Dataset**	**I**	**D**	**S**
Dress	Wikilarge	0.038	−0.041	0.156
	Newsela	0.105	0.267	0.258

	Newsela	−0.020	−0.124	0.078
Access	Wikilarge	0.035	−0.026	0.057
ControlTS	Wikilarge	0.002	−0.054	0.262

Table 7: Spearman's rank correlation coefficients for SARI vs. each information error category (**I**nsertion, **D**eletion, **S**ubstitution).

8 Comparison with Existing Metrics

Relationship to SARI. SARI is the most popular metric used to evaluate text simplification models (Xu et al., 2016). For each model, we report Spearman's rank correlation coefficient (Spearman, 1904) between SARI and each error category. As Table 7 reports, there is only a weak correlation between SARI and the prevalence of information errors, and both the direction and magnitude of the correlation are highly dependent on model and dataset. This lack of correlation is unsurprising since SARI uses lexical overlap between the generated text with the reference text pair to judge simplification quality. This parallels the case with ROUGE in summarization (Falke et al., 2019a; Maynez et al., 2020; Wallace et al., 2021).

Measures of Semantic Similarity. Many existing text simplification systems attempt to address the problem of meaning preservation by using a semantic similarity score either directly in their loss/reward function or in a candidate ranking step (Zhang and Lapata, 2017; Kriz et al., 2019; Zhao et al., 2020; Maddela et al., 2021). Additionally, some of these metrics have been included in recent factuality evaluation platforms in summarization (Pagnoni et al., 2021). We explore the extent to which existing similarity methods detect

Similarity Measure	I	D	S
Jaccard Similarity	-0.385	-0.695	-0.101
Cosine (GloVe)	-0.315	-0.620	-0.066
Cosine (ELMo)	-0.325	-0.582	-0.065
Cosine (Sentence BERT)	-0.375	-0.724	-0.182
BERTScore	-0.400	-0.748	-0.125

Table 8: Spearman's rank correlation coefficients for semantic similarity measures vs. each information error category (**I**nsertion, **D**eletion, **S**ubstitution).

Factuality Measure	I	D	S
Fact-CC	0.311	0.418	0.165
DAE, $k=1$	0.109	0.217	0.277
DAE, $k=3$	0.110	0.213	0.271
DAE, $k=5$	0.115	0.217	0.271

Table 9: Spearman's rank correlation coefficients for factuality measures vs. each information error category (**I**nsertion, **D**eletion, **S**ubstitution).

information errors as outlined in our annotation scheme. We consider: (1) Jaccard similarity; (2) cosine similarity between averaged GloVe (Pennington et al., 2014) or ELMo (Peters et al., 2018) embeddings of the original and simplified sentences; (3) cosine similarity between Sentence-BERT (Reimers and Gurevych, 2019) embeddings; and (4) BERTScore (Zhang et al., 2019).

As Table 8 indicates, the semantic similarity measures explored capture deletion errors quite well, while being a moderate indicator of insertion errors and a very weak one for substitution errors. Since deletion and substitution errors are common in most of the models we evaluated, the results indicate that better methods are needed to detect unacceptable deletions and intrinsic hallucinations in simplification outputs.

Measures of Factuality. As in text simplification, the most common evaluation metrics used in text summarization like ROUGE do not adequately account for the factuality of model generations with respect to the input texts (Kryscinski et al., 2019). For this reason, recent works have proposed model-based metrics to automatically assess factuality (Falke et al., 2019b; Durmus et al., 2020; Wang et al., 2020b; Kryscinski et al., 2020b; Goyal and Durrett, 2020). We consider the following systems: (1) Fact-CC, which is a BERT-based model trained on a synthetic dataset to classify text pairs as being factually inconsistent or not (Kryscinski et al., 2020b), and (2) DAE, which is another BERT-based model that classifies each dependency arc in the model output as entailing the source text or not (Goyal and Durrett, 2020). More specifically, for Fact-CC we use the model's probability that each simplification example is inconsistent. For DAE we use the average of the lowest k probabilities that a dependency arc in the target sentence does not entail the source for $k = 1, 3, 5$.

As Table 9 indicates, both Fact-CC and DAE's outputs correlate less with insertion and deletion annotations than even surface-level measures of semantic similarity like Jaccard similarity, though DAE scores correlate better with substitution errors than do Fact-CC and all evaluated measures of semantic similarity.

9 Automatic Factuality Assessment

Since manual annotation is costly and time-consuming, as a first step towards large-scale evaluation, we present an initial attempt at automating factuality assessment by training a model on human annotations. To supplement training, we explore methods of generating synthetic data to improve model performance.

We framed automatic factuality assessment as a classification task in which a separate classifier is trained for each category (Insertion, Deletion, and Substitution), for each of the levels 0, 1, and 2. We treat the annotations used in our previous analyses as the test set and have additional data annotated to function as the training set for this task. We therefore collected a total of 1004 additional examples annotated across Wikilarge, Newsela, `Access` outputs on Wikilarge, and `T5` outputs on Newsela and Wikilarge. We fine-tuned RoBERTa (Liu et al., 2019) with a classification head.

Synthetic Data Generation As Table 10 indicates, the validation dataset is both small and highly imbalanced, with very few level 2 insertion and substitution errors. To alleviate this issue, we experimented with a few methods of generating synthetic insertion and substitution errors on which to pretrain the model. We accomplished this by modifying each of the complex sentences in the validation set. To generate insertion errors, we replace names with pronouns and remove phrases from the source text to create target texts (information deletions) and then swap the source and target to produce information insertions. To generate substitutions, we change numbers in the source text, negate statements, and used BERT masking to perturb information in the sentence. We generated 10K examples in total; Appendix E.1 describes these

Category	Level 0 #	Level 0 F1	Level 1 #	Level 1 F1	Level 2 #	Level 2 F1
Insertion	823	87.9	104	36.6	40	30.4
Deletion	413	84.2	356	57.1	204	52.1
Substitution	810	82.7	110	19.8	33	9.5

Table 10: Annotated label counts in the training set, and F1 on the test set.

methods in greater detail.

Training and Evaluation The model is evaluated using the F1-scores with respect to each class (0,1,2), and when selecting checkpoints during training, the average of the label 1 and 2 F1 scores is used. The deletion model was trained directly on its training data, whereas the insertion and substitution models were initially pretrained on the synthetic datasets. Training details are provided in Appendix E.3.

Results Table 10 shows the test F1 scores achieved by the three classifiers. As expected, the deletion classifier achieved the best 1 and 2 F1 scores, likely due to the fact that the training dataset had plenty of level 1 and 2 deletion errors. Although the insertion and substitution datasets are similarly skewed, the insertion classifier significantly outperforms the substitution one. We found that using synthetic data is useful: without it, F1s for levels 1 and/or 2 are near 0 for insertion and substitution. Even with data augmentation, however, detecting errors is a challenging task.

10 Conclusion

We have presented an evaluation of the factuality of automated simplification corpora and model outputs, using an error typology with varied degrees of severity. We found that errors appear frequently in both references and generated outputs. In the datasets, deletion errors are quite frequent, with Newsela containing more than Wikilarge. The system outputs indicate that the models also tend to delete information, which is likely a behavior learned from the training data. Model outputs contain more substitution errors than the datasets, so that behavior is probably a model bias rather than something picked up from the data.

Although we examined the two commonly used sentence-level datasets, factuality errors do extend to other domains and larger units of text. Our initial analysis of factuality in medical text simplification (Devaraj et al., 2021) found errors of all three types, an indication that factual simplification is an open problem in such high-stake areas. The details of our analysis are in Appendix F.

We also found that factuality errors are not well captured by existing metrics used in simplification such as SARI (Xu et al., 2016). While semantic similarity metrics correlate with deletion errors, they poorly correlate with insertion or substitution. We further present an initial model for automatic factuality assessment, which we demonstrate is a challenging task.
