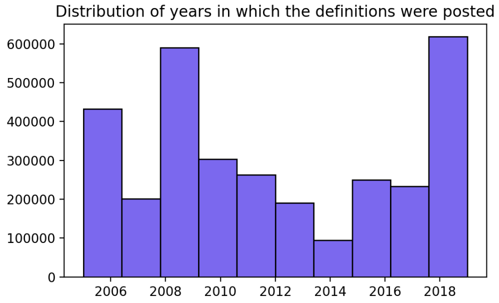

Figure 5: Frequency counts over years in Urban Dictionary data

A Appendix – Fine-tuning with Urban Dictionary data

A.1 Preprocessing

The full Urban Dictionary data contains $3,534,966$ word definitions. In the dataset provided by Wilson et al. (2020), each entry contains a definition, examples in which the word occurs, number of upvotes & downvotes from website visitors, username of the submitter and a timestamp. As the data is crowd-sourced, many of these entries are noisy and of low quality. We therefore filter the lower quality definitions out before fine-tuning RoBERTa. After performing data exploration, we came up with two criteria that we found the most indicative of a definition's quality: the number of upvotes it got, and its upvote/downvote ratio. The distribution of upvotes, downvotes and the upvote/downvote ratios in the dataset can be seen in Figure 6 below. We also note that the number of submissions to Urban Dictionary is relatively well-spread, see Figure 5. This implies that we do not have a strong bias towards more recently popularized slang terms in the dataset, and that we do have representation of the entire time span of interest; $2010 - 2020$.

We keep the entries having more than 20 upvotes and an upvote/downvote ratio of at least 2. This leaves us with $488,010$ Urban Dictionary entries, out of which we randomly sample $100,000$ to reduce the computation time in the fine-tuning process. We use both the definitions and the word usage examples for fine-tuning, producing a final dataset of $200,000$ sequences.

A.2 Training

We randomly split the data into 80% train and 20% test, before training for 10 epochs with an early stopping with patience 3. The batch size was set to 1 in the interest of memory constraints. Following

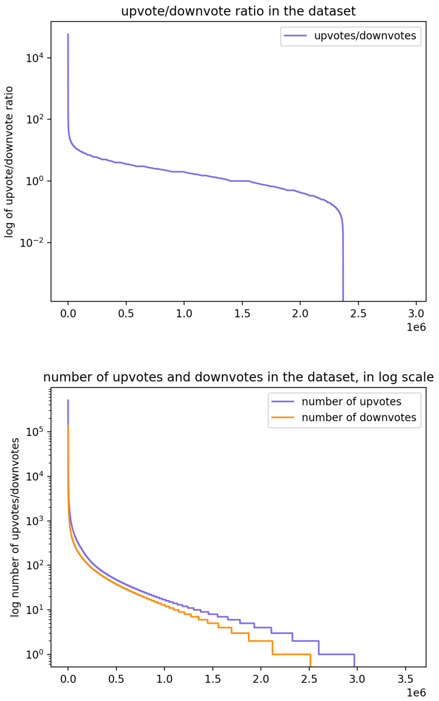

Figure 6: The distributions of (a) upvote/downvote ratio, (b) number of upvotes and number of downvotes among definitions in the dataset in log-scale.

the setup from the pre-training stage as explained in Liu et al. (2019), we use the Adam optimizer (Kingma and Ba, 2015) with $\epsilon = 10^{-6}, \beta_1 = 0.9$ & $\beta_2 = 0.98$ and a linear learning rate decay. For the learning rate, we argue that since the initialized parameters should provide a solution which is already close to the optimum when evaluating on our dataset (our fine-tuning being the very same masked language modeling task as RoBERTa has already been trained on), the learning rate should be smaller. Thus, instead of picking the learning rate $\gamma = 6 \cdot 10^{-4}$ as was done by Liu et al. (2019), we experiment with $\gamma \in \{10^{-4}, 10^{-5}, 10^{-6}, 10^{-7}\}$. Training was done using an NVIDIA GeForce GTX 1080 8GB GPU and took around 1 to 1.5 days per model.

B Appendix – Experiments on SemEval-2020

B.1 Distribution-based Metrics

Method: In addition to the distance-based APD metrics, we experiment with two distribution-based ones, namely entropy difference (ED) & Jensen-Shannon Divergence (JSD) (Giulianelli et al., 2020).

We assume a categorical distribution over a set of K_w word senses for word w and time period t. The word sense s_i^w of an occurrence i is then given by:

$$s_i^{wt} \sim Cat(\alpha_1^{wt}, ..., \alpha_{K_w}^{wt}) =: P^{wt}$$

Given two time periods of word sense distributions, we define the ED metric as

$$|H(s^{wt_2}) - H(s^{wt_1})|$$

with entropy $H(\cdot)$. The JSD is given as:

$$\frac{1}{2} KL(P^{wt_1} || M) + \frac{1}{2} KL(P^{wt_2} || M)$$

with $M = \frac{P^{wt_1} + P^{wt_2}}{2}$ and $KL(\cdot||\cdot)$ being the KL-divergence.

We obtain the word sense distributions via a clustering of the representations from both time periods. We experiment with K-Means and Gaussian Mixture Models (GMMs), the latter proposed due to its ability to find more general cluster shapes. We also experiment briefly with Affinity Propagation, which has been used in previous semantic change detection work (Martinc et al., 2020; Kutuzov and Giulianelli, 2020; Montariol et al., 2021). However, we find it to be ill-suited for our purposes since it results in an excessive amount of clusters in comparison to how a human would classify word senses.

For both K-means and GMM, we experiment with selecting the optimal $K_w \in [1, 10]$ through two different procedures. The first one is a slight extension of the method from Giulianelli et al. (2020) – we select the K_w which optimizes the silhouette score (Rousseeuw, 1987) for a set of different initializations. Their approach does not consider the single cluster case however, so we extend it by setting $K_w = 1$ when the best silhouette score is below a threshold of 0.1. For K-Means, we further experiment with an automatic elbow method[6] for

---

[6] See https://kneed.readthedocs.io/en/stable/index.html

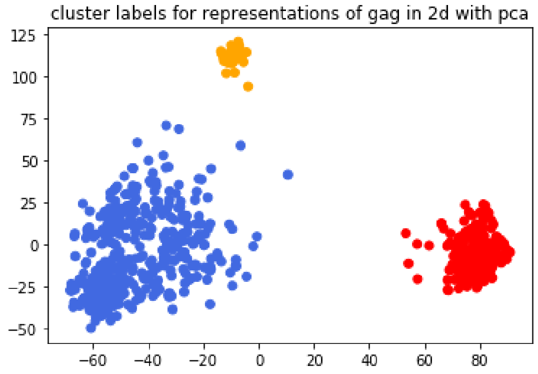

Figure 7: Clusters found with GMM from 2-dimensional PCA representations of the word **gag**.

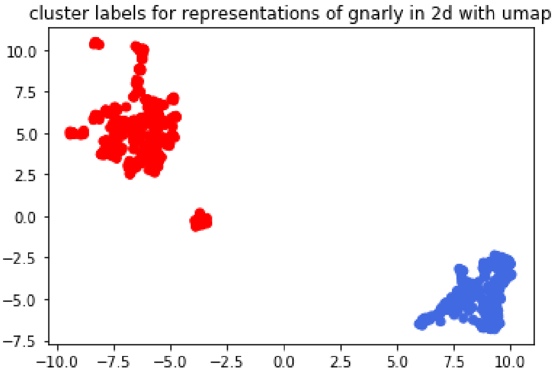

Figure 8: Clusters found with GMM from 2-dimensional UMAP representations of the word **gnarly**.

the sum of squared distances to the cluster centroids, which decreases monotonically with the number of clusters. We again select the cluster assignments with the largest silhouette score for multiple random initalizations. For GMM, we further experiment with taking the model which corresponds to the best Bayesian Information Criterion (Schwarz, 1978).

Clustering examples: In Figure 7 we see three clusters found for "gag." They do not seem to correspond to word senses however: An example from the first cluster is "user i need a pic of you begging if i ' m boiling these because boiled eggs make me gag . :d," an example from the second cluster is "lmao rt user user user so i tried that tuna with cheese and my gag reflexes were in full affect !" and an example from the third cluster is "gag me with a spoon" – all seemingly referring to the sensation of being about to vomit.

We show another example in Figure 8 of the word "gnarly," this time reduced to 2 dimensions using UMAP. Gnarly has three meanings according to the Online Slang Dictionary: It can either mean very good / excellent / cool, gross / disgusting or painful / dangerous. These three word senses are not separated by UMAP and GMM, for instance both "its a good thing one of my roomies is a dude , who else would kill gnarly spiders in my room when i start to hyperventilate" and "rt user bro my wreck on the scooter was so gnarly like it was fun i love shit like that . i wish i could've been on jackass" are put in the first cluster.

B.2 Variance Explained by PCA components

Consider Figure 9 for example plots of how much variance is preserved with PCA on the contextualized representations.

Baseline	Score
Combined APD PCA100	0.489
Kutuzov and Giulianelli (2020)	0.605
Kaiser et al. (2020)	0.461
Rother et al. (2020)	0.440

Table 2: Comparison to the three highest performing previous works on the SemEval-2020 Task 1 subtask 2 for the English dataset.

B.3 Results

We further present more results of the experimentation on the SemEval-2020 Task 1 Subtask 2. All tables show the Spearman's rank-order correlation between the change metrics and the ground truths.

In Table 2 we compare our best performing setup to the three best performing previous approaches on SemEval-2020 Task 1 Subtask 2. We see that only Kutuzov and Giulianelli (2020) display a higher score, which might be partially explained by the fact that they fine-tune their model on the SemEval test corpora. We do not do this since our main goal is not to beat state-of-the-art on the shared task, but rather to find a good enough model to detect semantic change in slang.

The results comparing the layer representations can be observed in Table 3. As a side observation we also note that the less isotropic first layer representations seem to perform better than the more isotropic last layer representations.

In Table 4 we present a comparison across different layer representations for both APD-based and distribution-based metrics. We observe that none of the distribution-based metrics give significant results, even when used with dimensionality reduction techniques. While a few of them do have a

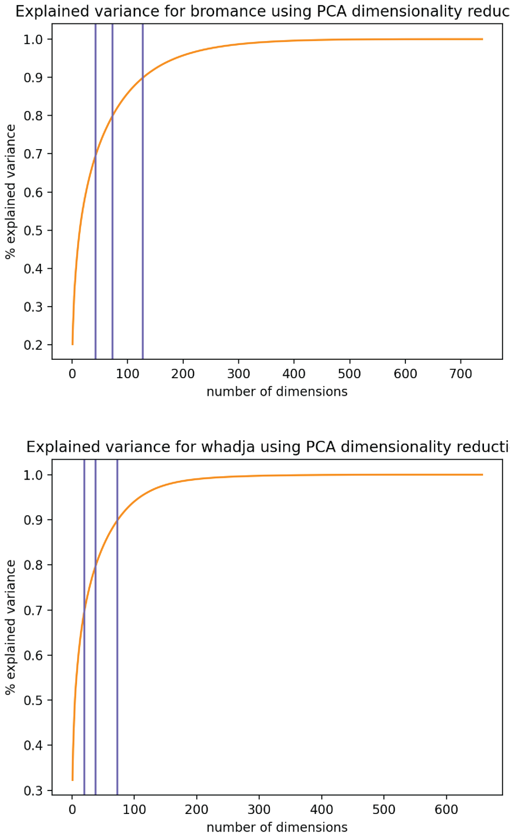

Figure 9: Explained variance by number of components used in PCA for the slang words *bromance* and *whadja*

slight positive correlation, we omit this approach altogether. The APD results on the other hand show a high correlation for many of the configurations, providing an indication of the APD's robustness in detecting semantic change. We show a selection of these in Table 6.

	d_2 **APD**	$d_{\cos}$ **APD**

Table 4: Comparison across different layer representations with APDs and distribution metrics, with K_w selected through silhouette scores.

C Appendix – Hybrid Words

We define hybrid words as words that have both a slang and nonslang meaning, i.e., occurring in both Online Slang Dictionary (OSD) and Merriam Webster (MW). In this section, we compare the polysemy, semantic change, frequency shift as well as the absolute frequency change patterns of hybrid words to slang and nonslangs.

Polysemy is collected for hybrid words from OSD and MW separately. Since the MW dictionary may also contain slang meanings, we filter out definitions labeled as *slang*, *informal* or *vulgar* from these scores. The mean polysemy scores of the slang words are (2.074 ± 2.568) and the mean OSD polysemy scores of the hybrid words are (2.580 ± 2.178), with a non-significant difference ($p > 0.05$) in distribution according to a permutation test. This tells us that we are not skewing

APD	Score	p
d_2	0.336	0.042
$d_{\cos}$	0.332	0.045
d_1	0.409	0.012
d_2 and $d_{\cos}$	0.345	0.037
$d_2, d_{\cos}$ and d_1	0.398	0.015

Table 5: Comparison across APD metrics for original representations. Representations are sums across all layers.

Dim	APD	Score	p
PCA2	d_2	-0.153	0.367
UMAP2	$d_{\cos}$	-0.136	0.424
PCA5	$d_{\cos}$	0.209	0.215
PCA5	d_2 and $d_{\cos}$	0.268	0.109
UMAP5	$d_2, d_{\cos}$ and d_1	-0.146	0.39
PCA20	d_2 and $d_{\cos}$	0.42	0.010
PCA50	d_2	0.26	0.121
PCA50	$d_{\cos}$	0.394	0.016
PCA50	d_2 and $d_{\cos}$	0.478	0.003
PCA50	$d_2, d_{\cos}$ and d_1	0.344	0.037
UMAP50	d_2	-0.158	0.35
PCA100	d_1	0.297	0.074
PCA100	d_2 and $d_{\cos}$	0.489	0.002
UMAP100	$d_{\cos}$	-0.133	0.433

Table 6: Comparison across different dimensions with PCA and UMAP for APD metrics. Representations are sums across all layers.

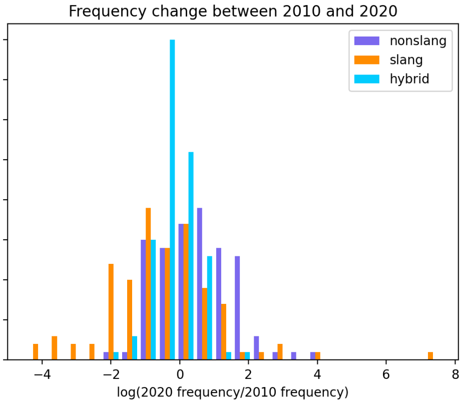

Figure 10: Relative difference in frequency between 2020 and 2010, for slang, nonslang and hybrid words, where a positive score corresponds to an increase in frequency.

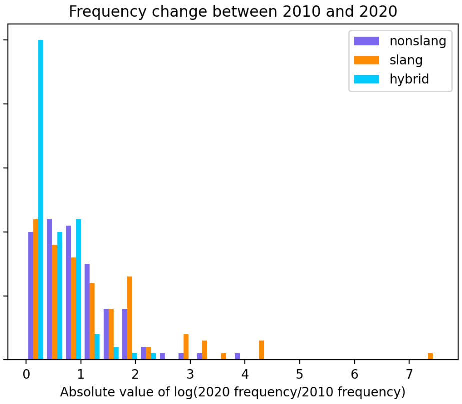

Figure 11: Absolute value of relative difference in frequency between 2020 and 2010, for slang, nonslang and hybrid words, where a larger score corresponds to a larger absolute increase in frequency.

the polysemy score distribution of the slang words by excluding hybrid words.

As for the nonslang meanings of the hybrid words, we get a mean polysemy score of (6.880 ± 6.080) which is significantly different $(p < 0.001)$ from those of the nonslang words (3.079 ± 2.780). This is an interesting observation, implying that had we included nonslang words with hybrid meaning in our nonslang words sample, the difference in polysemy between slang and nonslang words would have been larger. Some example words from this category with high MW polysemy scores include “split,” “down” and “walk.”

For the relative frequency changes, we present the results as histograms in Figure 10. The frequency changes in hybrid words seem to fall between those of the slang words and the nonslang words. We observe a mean and standard deviation of -0.154 and 0.608 respectively.

In addition, we compare the absolute relative frequency changes as described in Section 5.3 across slang, nonslang and hybrid words. The histograms are presented in Figure 11. We observe, respectively, a mean and standard deviation of 1.246 & 1.180 for the slang words, 0.950 & 0.724 for the nonslang words and 0.482 & 0.402 for the hybrid words. The difference in mean is significant between the slang and nonslang words $(p < 0.05)$, indicating that slang words have undergone a larger absolute change in frequency. Furthermore, we note a highly significant difference $(p < 0.001)$ in the mean of the hybrid words compared to both the slang and nonslang word means.

We compare the normalized semantic change scores between the slang, nonslang and hybrid words. Histograms over the semantic change scores are shown in Figure 12. We observe that the dis-

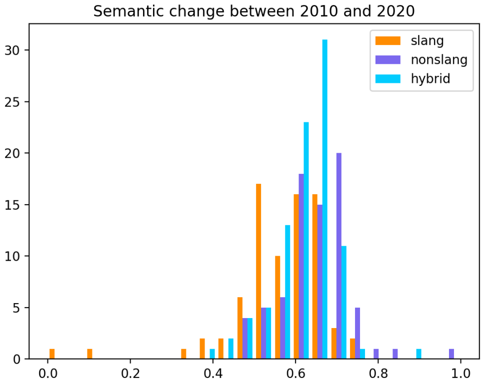

Figure 12: Difference in semantic change score between 2010 and 2020 for slang, nonslang and hybrid words, where a larger score corresponds to a more pronounced semantic change.

tribution over hybrid change scores seem again to be centered between the slang and nonslang distributions, with mean 0.621 ± 0.073. According to a permutation text, there is a significant difference in semantic change both between hybrid and slang words ($p < 0.001$) and between hybrid and nonslang words ($p < 0.05$).

D Appendix – Causal Analysis

D.1 Preliminary on Constraint-based Causal Discovery

Assumptions The constraint-based causal discovery algorithms make use of two main assumptions, namely the global Markov assumption and the faithfulness assumption. The global Markov property (Peters et al., 2017) holds if all d-separations (defined below) encoded in the causal graph imply conditional independencies in the distribution over the variables contained in the graph. More formally, for a graph $G = (V, E)$ and distribution $\mathbb{P}$ over the variables $\mathbf{X}_V$ it holds that for any disjoint subsets A, B and C of V

$$\mathbf{X}_A \perp_d \mathbf{X}_B | \mathbf{X}_C, \quad \text{in } G$$

$$\Rightarrow \mathbf{X}_A \perp\!\!\!\perp \mathbf{X}_B | \mathbf{X}_C, \quad \text{in } \mathbb{P}$$

The faithfulness assumption states the converse of the global Markov assumption: All conditional independencies in the distribution are encoded by d-separations in the graph.

d-separation Two nodes $A, B \in V$ are said to be *d-separated* (Geiger et al., 1990), by a set of nodes $Z \subset V$ if for all paths between A and B, at least one of the following holds:

- The path contains a directed chain $A \cdots \to C \to \cdots B$ or $A \cdots \leftarrow C \leftarrow \cdots B$ such that $C \in Z$
- The path contains a fork $A \cdots \leftarrow C \to \cdots B$ such that $C \in Z$
- The path contains a collider $A \cdots \to C \leftarrow \cdots B$ such that $C \notin Z$ or $C' \notin Z \quad \forall C' \in desc(C)$ (i.e., neither C nor any of its descendants is in Z)

We would then denote $X_A \perp_d X_B | X_Z$.

Markov Equivalence Constraint-based algorithms use conditional independence tests in order to identify a *Markov equivalence class* of DAGs. Two DAGs are defined to be Markov equivalent if they have the same skeleton (edges omitting direction) and v-structures. The three vertices A, B and C form a v-structure if $A \to B \leftarrow C$ and A and C are not directly connected by an edge. Alternatively, two DAGs are Markov equivalent if they describe the same set of d-separation relationships. A Markov equivalence class is the set of all Markov equivalent DAGs.

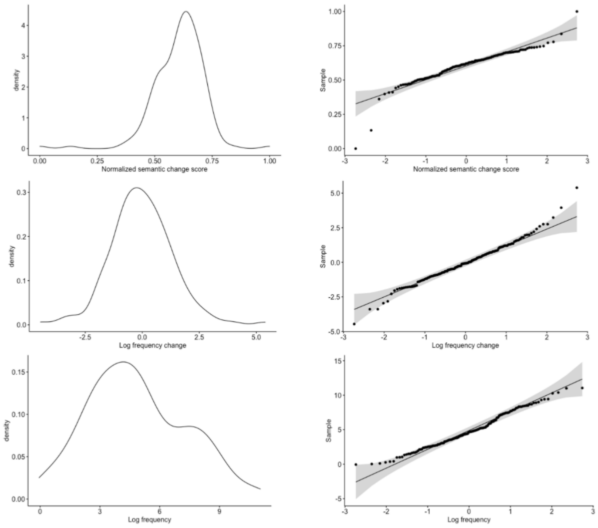

Figure 13: Diagnostic plots for continuous variables, displaying approximate Gaussian shape.

PC Algorithm One common constraint-based algorithm is the PC algorithm (Spirtes et al., 2000). Starting with a full DAG, it eliminates an edge between adjacent vertices i and j if X_i and X_j are conditionally independent given some subset of the remaining variables. This process, including the conditional independence tests, is conducted iteratively starting from a conditioning set of size $k = 0$ to $k = |V| - 2$. In addition to the global Markov and faithfulness assumptions, the PC algorithm also assumes causal sufficiency, namely the absence of unobserved confounders. With these assumptions satisfied and access to correct conditional independence relations, the PC algorithm is guaranteed to be sound, complete and uniformly consistent (Kalisch and Bühlmann, 2007).

PC-stable PC-stable is an order-independent extension with the same guarantees as the original (Colombo and Maathuis, 2014).

D.2 Diagnostic Plots

In Figure 13 we present the density and Q-Q plots for semantic change score, log of word frequency and log of frequency change.

D.3 Sensitivity Analysis on Polysemy

Polysemy is a discrete variable which we treat as an ordered factor in the analysis by splitting it into categories. Since polysmey can be plausibly categorized in different ways, we experiment with 9 different categorizations of it and examine the stability of the resulting graphs. For each categorization, we run PC-stable with the three significance levels $\alpha \in \{0.05, 0.03, 0.01\}$. In Figure 14 we present the results of this sensitivity analysis. We see that the edges between word type and polysemy, from word type to frequency change, as well as the edge from polysemy to frequency, are apparent in all of the configurations. The edge from word type to semantic change is apparent in 21/27 (77.8%) of the configurations. We also observe a few edges very rarely, and therefore label them as noise and do not take them into account for the causal analysis. These consist of an edge from the POS *Noun* to semantic change in 3/27 (11.1%) of the configurations, and edges from polysemy to frequency shift and from polysemy to semantic change each apparent in 1/27 (3.7%) of the configurations.

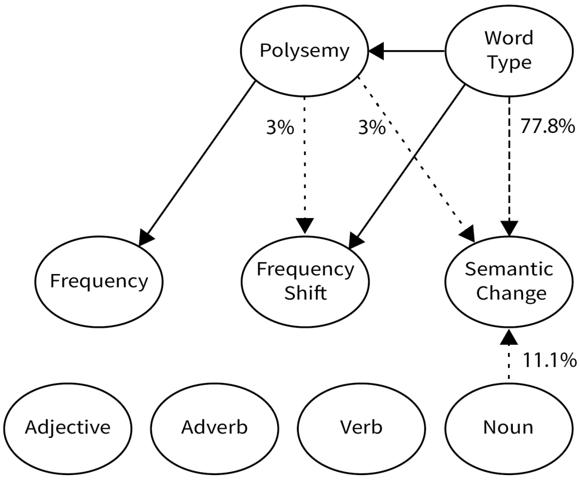

Figure 14: DAG of causal relationships, with the percentage of experiments that found each edge, across different configurations of α and different categorizations of the polysemy score. Solid edges appeared in 100% of the output graphs.

By inferring the causal graph from a set of categorizations, we make up for the possible noise in the polysemy variable and ensure that the graph is not sensitive to small variations in the words' polysemy scores.

D.4 Causal Inference

Given the causal DAG in Figure 4, we derive the expression for the average causal effect of word type on semantic change. Define the following random variables: T = word type, X = polysemy, Y = frequency, Z = frequency shift and S = semantic change, with respective probability mass functions P_T & P_X and probability density functions f_Y, f_Z & f_S.

Note that the possible values for T lie in

$\{\text{slang}, \text{nonslang}\}$. By the truncated factorization for the connected component of the causal DAG (i.e., excluding POS), we have that

$$\mathbb{P}(s,t,x,y,z|do(T=t')) =$$

$$f_{Y|X}(y|x)f_{Z|T}(z|t)f_{S|T}(s|t)P_{X|T}(x|t)\mathbb{1}_{\{t=t'\}}$$

Marginalizing over T, we get

$$\mathbb{P}(s,x,y,z|do(T=t')) =$$

$$= f_{Y|X}(y|x)f_{Z|T}(z|t')f_{S|T}(s|t')P_{X|T}(x|t')$$

Next, marginalize over the continuous random variables Y and Z to get

$$\mathbb{P}(s,x|do(T=t')) =$$

$$\int_y \int_z f_{Y|X}(y|x)f_{Z|T}(z|t')f_{S|T}(s|t')P_{X|T}(x|t')dzdy =$$

$$\int_y f_{Y|X}(y|x)f_{S|T}(s|t')P_{X|T}(x|t') \underbrace{\left(\int_z f_{Z|T}(z|t')dz\right)}_{=1} dy =$$

$$f_{S|T}(s|t')P_{X|T}(x|t') \underbrace{\int_y f_{Y|X}(y|x)dy}_{=1} =$$

$$f_{S|T}(s|t')P_{X|T}(x|t')$$

Finally

$$\mathbb{P}(s|do(T=t')) =$$

$$\sum_x f_{S|T}(s|t')P_{X|T}(x|t') = f_{S|T}(s|t')$$

Taking the expectation, we get

$$\mathbb{E}[S|do(T=t')] = \mathbb{E}_{S|T}[S|t']$$

E Appendix – Selected Words

In Appendix E we list all the slang and nonslang words used in this study.

Slang	**Nonslang**	**Hybrid**
a-list	admitting	annihilated
badass	adulterous	balling
blankie	agenda	bastard
bling	allotted	beef
blowjob	anticlockwise	bloody
blumpkin	avoiders	bomb
bonehead	awesome	book
bro	banzai	bookmark
bromance	bright	booty
bumfuck	butane	bounce
bupkis	calorie	bowl
chillax	chug	brains

Spurious Correlations in Reference-Free Evaluation of Text Generation

Esin Durmus[1*] **Faisal Ladhak**[2*] **Tatsunori Hashimoto**[1]

thashim@stanford.edu

Abstract

Model-based, reference-free evaluation metrics have been proposed as a fast and cost-effective approach to evaluate Natural Language Generation (NLG) systems. Despite promising recent results, we find evidence that reference-free evaluation metrics of summarization and dialog generation may be relying on spurious correlations with measures such as word overlap, perplexity, and length. We further observe that for text summarization, these metrics have high error rates when ranking current state-of-the-art abstractive summarization systems. We demonstrate that these errors can be mitigated by explicitly designing evaluation metrics to avoid spurious features in reference-free evaluation.

1 Introduction

Building reliable automated evaluation metrics is a key factor for quick development of better NLG systems. Recent work has proposed reference-free evaluation metrics as a way to judge the quality of generated outputs without the need for human references (Celikyilmaz et al., 2020). Many of these reference-free evaluations achieve remarkably high correlations with human evaluations, raising hopes that they may soon become a viable alternative to expensive human evaluations (Kryscinski et al., 2020; Goyal and Durrett, 2020; Sinha et al., 2020; Phy et al., 2020; Gao et al., 2020).

However, simply looking at correlation with human scores may not be sufficient to determine the efficacy and robustness of an evaluation metric. In our work, we study recently proposed reference-free evaluation metrics of text summarization and dialog generation. We find that it is possible to achieve similar levels of correlation with human judgment, using simple spurious correlates such as word overlap, length, and perplexity. Furthermore, we find that the learned metrics have a relatively high correlation with the spurious correlates as compared to human scores, which suggests that these metrics may rely heavily on spurious correlations. This may be a potential explanation for the robustness issues that are observed in recent work, despite the seemingly high reported correlations with human judgements (Gabriel et al., 2021; Yeh et al., 2021).

We further analyze reference-free faithfulness evaluation metrics and show that the reliance on spurious correlations leads to errors in model selection and development. First, we show that word overlap, a spurious correlate for the task, does as well as recently proposed reference-free metrics at system-level ranking. Then, we look at rankings amongst systems that are relatively abstractive and faithful, i.e., the current state of the art, and find that these learned metrics perform significantly worse for these systems. This is because word-overlap is not a good measure for ranking these systems in terms of their faithfulness since all of these systems have similarly low word overlap. This suggests that we need metrics that are not overly reliant on word overlap in their faithfulness prediction.

Finally, we explore whether a simple mitigation strategy of adversarially training a faithfulness evaluation metric to avoid spurious correlates can lead to a more robust metric. We find that our adversarially trained metric performs well at overall pairwise ranking while having a significantly lower correlation with the spurious correlate of word-overlap. Crucially, we show that our proposed metric has improved performance in ranking between abstractive and faithful systems, which is a failure mode for existing reference-free faithfulness evaluation metrics.

2 Reference-free Evaluation of Text Generation

We begin by defining the task of reference-free evaluation, as well as the *example-level* and *systems-*

---

[*] Equal contribution.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1443 - 1454

level evaluation of these metrics.

We define a reference-free evaluation metric as a function $F(x, y)$ that can assign a quality score to an output sequence y for a given input sequence x. The goal of a reference-free evaluation metric $F(x, y)$ is to assign high scores to desirable outputs y for some attribute, such as the faithfulness of a summary. Measuring the quality of this metric is challenging, and prior work has relied upon correlation to human judgments $H(x, y)$.

Example-level evaluation: A number of existing reference free evaluations rely upon a procedure which we call *example-level* human correlations (Fabbri et al., 2020; Phy et al., 2020; Sinha et al., 2020), which measures the effectiveness of a metric by computing a Pearson or Spearman correlation $\text{corr}_{p_{\text{eval}}}(H(x, y), F(x, y))$ over some sampled evaluation data $p_{\text{eval}}(x, y)$.

System-level evaluation: An alternative approach to evaluation is *systems-level* rankings (Mathur et al., 2020; Kocmi et al., 2021), which we define as the ability to identify which model is better amongst a set of models M. F is evaluated via its accuracy in matching human evaluation H on all pairs $(m_i, m_j) \in M \times M$ where $m_i \neq m_j$.

The definitions of example and system level correlations suggest that evaluations of these metrics may have a strong dependence on the example and systems distributions $p_{\text{eval}}(x, y)$ and M. As an example, consider an evaluation for dialogue response quality. Building a truly accurate predictor for dialogue response quality is challenging, but if $p_{\text{eval}}(x, y)$ consists of all either professionally written examples or ungrammatical nonsense, a simple grammar checker would perform exceedingly well.

This is an instance of what is called a spurious correlate. More formally, we define this as some attribute $S(x, y)$ which is correlated with H in $p_{\text{eval}}(x, y)$ but is not correlated with H for a carefully constructed test distribution $p_{\text{test}}(x, y)$. We say that F is *spuriously correlated* with S if:

1. F and H are highly correlated under $p_{\text{eval}}(x, y)$ but not under $p_{\text{test}}(x, y)$.

2. F remains correlated with S under $p_{\text{test}}(x, y)$.

3 Example-level Analysis of Learned Evaluation Metrics

In this section, we look at example-level Spearman correlations with human judgements for reference-free evaluation metrics that have been proposed for summarization and dialog generation. We compare the metrics to spurious correlates such as word-overlap, length and perplexity, in order to understand whether the metrics can perform better than these simple measures. We also measure to what extent the proposed metrics are correlated with these spurious measures.

3.1 Faithfulness Evaluation in Text Summarization

State-of-the-art text summarization models are capable of producing fluent summaries. However, they suffer from generating information that is not consistent (i.e., unfaithful) with the information in the source article (Cao et al., 2018). Prior work showed that reference-based metrics are not able to capture such consistency errors (Falke et al., 2019). This motivated researchers to build evaluation metrics to capture these faithfulness issues since collecting human evaluations for faithfulness is expensive and time-consuming (Wang et al., 2020; Durmus et al., 2020; Kryscinski et al., 2020; Goyal and Durrett, 2020).

In this section, we analyze recently proposed reference-free faithfulness evaluation metrics and compare their performance against the spurious correlate of word overlap. Furthermore, we analyze the correlation between the learned metrics and word overlap to understand to what extent these metrics rely on spurious correlations. We focus on learned entailment-based faithfulness evaluation metrics due to their high performance in identifying faithfulness issues (Pagnoni et al., 2021). In particular we evaluate FactCC (Kryscinski et al., 2020) and DAE (Goyal and Durrett, 2021), which have been shown to achieve higher example-level correlations with human judgements than existing faithfulness evaluation metrics (Pagnoni et al., 2021).

FactCC. Kryscinski et al. (2020) proposed an entailment-based method where they train a BERT-based model to predict whether or not the source article entails a summary. To train this model, they generate synthetic training data by applying a set of transformations to source article sentences in order to get article, summary pairs. They evaluate their approach on the CNN/DM dataset (See et al., 2017) and report a high accuracy on example-level comparisons on a human-annotated test set.

DAE. Goyal and Durrett (2021) collected human annotations at the word-level and arc-level to study faithfulness at a finer granularity. They also trained

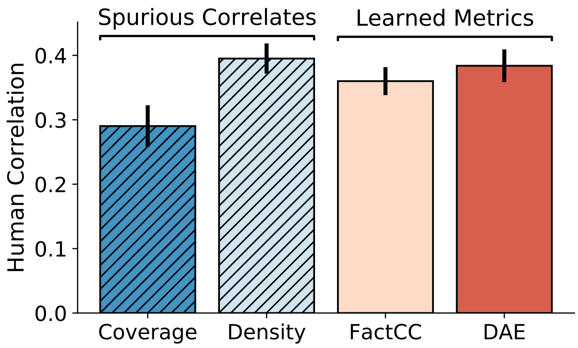

Figure 1: Correlation of the spurious correlates and learned metrics with human scores. Density, a spurious correlate, achieves similar performance as DAE and performs significantly better than FactCC.

Metric	Human	Density
FactCC	0.36	**0.59**
DAE	0.38	**0.76**

Table 1: Correlation of FactCC and DAE scores with humans vs density. Both learned metrics have a significantly higher correlation with density than human scores.

a dependency arc entailment model for faithfulness detection (Goyal and Durrett, 2020). They evaluate on the same test set as Kryscinski et al. (2020) and report improved results over FactCC.

We look at how these learned, reference-free metrics compare with word overlap – a simple spurious correlate. One simple measure of whether a generated summary is faithful is to look at its word overlap with the source article; summaries with a higher word overlap are more likely to be faithful (Ladhak et al., 2021). However, this measure of faithfulness is spurious because it cannot distinguish between faithful and unfaithful summaries that have similar word overlap. In particular, we look at two metrics of word-overlap following Grusky et al. (2018): *coverage* and *density*. *Coverage* measures the percentage of the words in the summary that are also present in the article. *Density* instead looks at the average length of the segments in the summary that are extracted from the article.

Results. We use the large-scale faithfulness human annotations collected by Fabbri et al. (2020) for 16 summarization models on the CNN/DM dataset (See et al., 2017) for our analysis. Figure 1 shows the example-level correlations with human scores for each of the factuality metrics as well as the spurious correlates. We note that *density* has a similar correlation with human scores as DAE, and is significanlty[1] better than FactCC. This result is alarming because *density* is a spurious correlate, yet it can achieve similar performance as the metrics that have been trained for faithfulness evaluation.

Moreover, we also see that both FactCC and DAE have a significantly higher correlation with *density* than they do with human scores (Table 1). This indicates that these metrics may rely upon spurious correlations and are not yet capturing a deeper understanding of faithfulness.

3.2 Learned Metrics for Dialog Generation

Dialog generation systems need to be able to generate a response given the dialog context. The ability to automatically evaluate the quality of a response is essential for building dialogue systems. Liu et al. (2016) show that referenced-based evaluation metrics do not correlate well with human judgments of response quality. This has led to an increased interest in reference-free evaluation metrics for evaluating dialogue response quality.

Similar to our analysis in § 3.1, we aim to look at recently proposed metrics for reference-free evaluation, along with spurious correlates for dialog response quality, and compare them against human judgments.

DialogRPT. Gao et al. (2020) finetune GPT-2 to predict the different types of human feedback (replies, upvotes, etc.) in Reddit threads and combine these to form a composite score for response quality. They evaluate their approach on the Reddit data that they collected and show that their method achieves higher example-level agreement with human judgments than baseline metrics.

MAUDE. Sinha et al. (2020) propose a model that encodes each utterance in the dialog context using a pre-trained BERT model and leverages the temporal transitions between them to score a response. They add noise to existing dialog responses to create negative examples and train their system to distinguish them from valid responses using noise contrastive estimation (NCE). They evaluate their model on the PersonaChat (Zhang et al., 2018) dataset and report improved example-level Spearman correlation with human judgments compared to existing baseline metrics.

---

[1] All numbers reported in the paper are bootstrap means over 1000 bootstrap samples. We use a one-tailed percentile bootstrap test to determine significance at $\alpha = 0.05$.

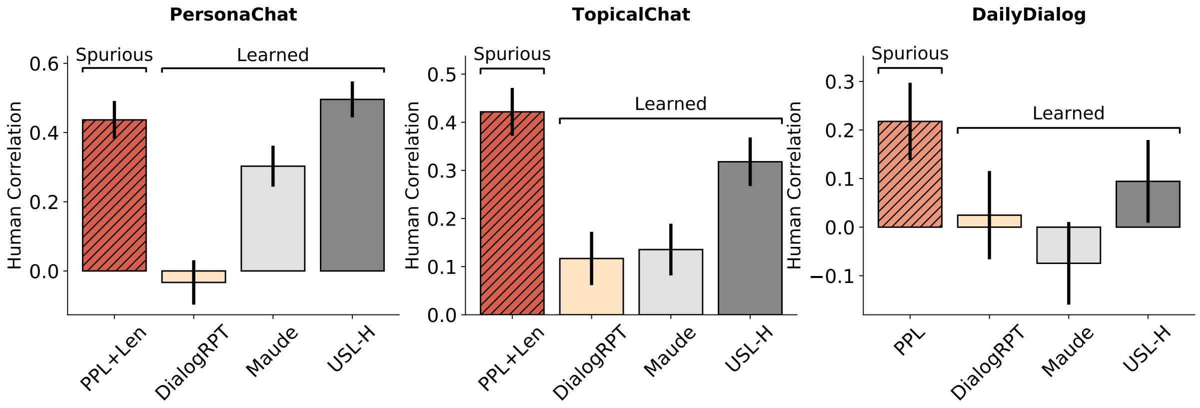

Figure 2: Correlation of the spurious correlates and learned metrics with human scores. PPL+Len represents a simple combination of perplexity (PPL) and length features. The best spurious correlate performs significantly better than all learned metrics on TopicalChat, and performs similarly to the best learned metric on PersonaChat and DailyDialog.

		Human	Perplexity	Length	PPL+Len
PersonaChat	DialogRPT	-0.033	-0.017	**0.086**	0.068
	Maude	0.303	**0.373**	-0.089	0.137
	USL-H	0.496	0.092	**0.506**	0.469
TopicalChat	DialogRPT	0.117	-0.011	0.272	**0.276**
	Maude	0.135	**0.243**	-0.191	-0.148
	USL-H	0.318	0.037	**0.359**	0.355
DailyDialog	DialogRPT	0.025	-0.182	**0.359**	0.270
	Maude	-0.074	-0.076	**0.102**	0.033
	USL-H	0.094	0.048	-0.208	**-0.236**

Table 2: Correlation of the metrics with human scores and spurious correlates. Reference-free evaluation metrics have higher correlation with spurious correlates than the human scores.

USL-H. Phy et al. (2020) decompose response quality into three aspects and train a model to score a response along each of these aspects. They then combine the scores hierarchically into one composite score for response quality. They evaluate their metric on the DailyDialog (Li et al., 2017) dataset and report significantly higher example-level correlations than previous baseline metrics.

MNLI+Adv. Dziri et al. (2021) introduce an entailment-based metric that evaluates the groundedness of a dialog response, i.e., whether the generated response is consistent with the information in the provided external context, such as a Wikipedia article. They trained their metric on automatically generated adversarial data by applying perturbations to the evidence. They further collect human annotations for the various aspects of dialog generation, such as entailment, genericness, etc., and show that their method is more effective in accurately categorizing the generations than existing entailment models.

To assess these metrics, we look at two spurious correlates for dialog quality – perplexity and length of the generated output – as well as a simple combination of two measures. We compute perplexity using a pre-trained GPT-2 language model (Radford et al., 2019). Perplexity (PPL) and length are spurious correlates since they do not account for the dialog context, and therefore it is possible to have high-quality and low-quality responses with similar perplexities/lengths. For groundedness evaluation, we look at the same word overlap measures, as we did for summarization, i.e., *density* and *coverage*, and we measure overlap between the response and the provided external evidence.

Results. We evaluate metrics[2] for response quality estimation on three popular multi-turn dialog datasets – DailyDialog, which contains dialogs

---

[2] We use the code provided by Yeh et al. (2021) for these experiments.

about everyday topics (Li et al., 2017), TopicalChat, which contains dialogs conditioned on a set of 8 broad topics (Gopalakrishnan et al., 2019), and PersonaChat, which contains dialogs conditioned on personas (Zhang et al., 2018).

To evaluate the recently proposed metric for response groundedness, we use human annotations collected by Dziri et al. (2021) on Wizard of Wikipedia (Dinan et al., 2019), a dataset that consists of dialogues conditioned on information from Wikipedia articles. In particular, we use their entailment annotations, where human annotators judge whether or not the external evidence entails a generated response.

Figure 2 shows the correlations with the human scores and the spurious correlates for the dialog generation evaluation metrics. In DialyDialog, we find that perplexity achieves a similar correlation with human judgments as USL-H. In TopicalChat, perplexity or length alone does not beat out any of the learned metrics; however, combining the two measures achieves a significantly better correlation with humans than learned metrics. In PersonaChat, USL-H achieves the highest correlation with human judgment, though the combined PPL+Len score is close. We observe that USL-H is more consistent than the other reference-free metrics and achieves significantly higher correlations with human scores than MAUDE and DialogRPT for PersonaChat and TopicalChat. We further find that the reference-free metrics have a higher correlation with the spurious correlates than the human scores (Table 2), which again suggests that these learned metrics may be relying upon spurious correlations.

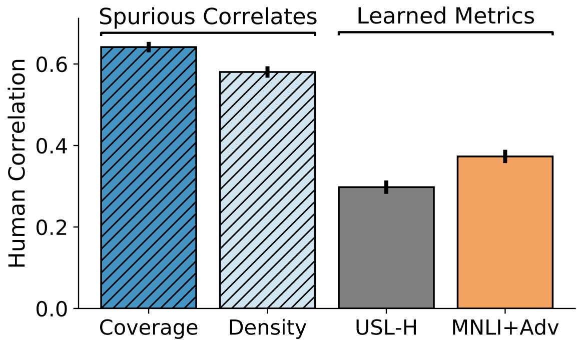

Figure 3: Correlation of the spurious correlates and learned metrics with human scores on groundedness evaluation. Both coverage and density get significantly higher correlations with human scores than the learned metrics.

Metric	Human	Coverage	Density
USL-H	0.298	0.467	**0.515**
MNLI+Adv	0.373	0.451	**0.514**

Table 3: Correlation of USL-H and MNLI+Adv scores with humans vs coverage and density. Both learned metrics have a significantly higher correlation with density than human scores.

For groundedness evaluation[3], both *coverage* and *density* achieve significantly higher correlation with human scores than MNLI+Ad and USL-H. Furthermore, MNLI+Ad and USL-H get a higher correlation with these spurious correlates than human scores (Figure 3).

Despite relatively high correlations on their original datasets, these metrics seem to perform similarly to simple spurious correlations on other datasets. In order to better understand the effectiveness of these reference-free evaluation metrics, we suggest that future research includes comparisons to potential spurious correlates and that research communities come up with a set of potential standard spurious correlates.

4 Learned Metrics in System-level Evaluation

4.1 Pairwise Ranking of Systems

Our example-level analysis demonstrates that recently proposed learned evaluation metrics achieve worse correlations with human scores than spurious correlates for almost all the settings. Since an important goal of building these metrics is to be able to rank arbitrary systems, we analyze whether these concerns we observe at the example level manifest into harms at the system level (i.e., ranking systems incorrectly). In order to study this, we need a large collection of human evaluation data across a wide range of systems. Fabbri et al. (2020) have recently released human evaluations for faithfulness across 16 summarization systems on CNN/DM. Therefore, we focus on system-level rankings of faithfulness for the remainder of the paper.

We first measure pairwise ranking accuracy for all the systems shown in Figure 4.[4] We find that system-level rankings suffer from a similar issue as the example level correlations: density and cover-

---

[3] We do not include MAUDE and DialogRPT results for this task since they perform significantly worse.

[4] Citations corresponding to these systems are included in Appendix A.

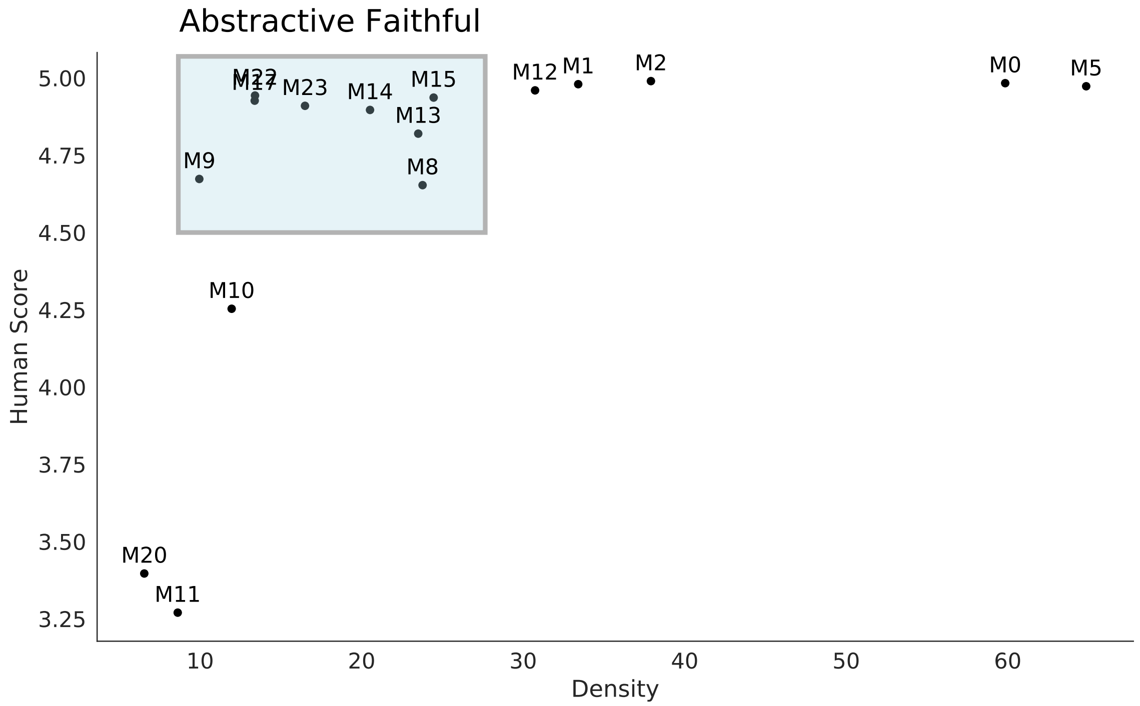

Figure 4: Density and human scores for summarization systems. We analyze the accuracy of the metrics in ranking all the systems vs. ranking the systems within abstractive faithful group, shown in the blue box. Abstractive faithful systems have faithfulness score higher than 4.5 (out of 5) and density lower than 30.

	All Pairs	Within AF
Coverage	56.54	26.60
Density	**81.01**	**40.45**
FactCC	78.87	38.26
DAE	80.39	37.88

Table 4: Accuracy of pairwise ranking across all the systems and within Abstractive Faithful (AF). We observe that the ranking accuracy of all metrics is significantly lower for systems within AF compared to all pairs. Density performs as well as the best learned metric (DAE) in both cases.

age appear as spurious correlations (Table 4). From this observation, we perform a finer-grained analysis and show that these factuality metrics fail on the most important subset of model comparisons: abstractive but faithful summarization system (AF) – where the current state-of-the-art abstractive summarization systems fall.

4.2 Results

Both faithfulness metrics perform relatively well when we look at pairwise ranking accuracy across all pairs of models (Table 4). However, they are unable to improve over *density*, which achieves the highest overall accuracy. When we look at ranking within the abstractive faithful group, we see *density* is no longer a good measure for the faithfulness of a system since these systems are relatively close in terms of density. Similarly, the performance of the learned metrics drops significantly, which is an expected result since our analysis in § 3.1 showed that both FactCC and DAE are spuriously correlated with density. We claim that our system-level analysis is further evidence that these metrics may be relying heavily on simple spurious measures such as word overlap.

These results highlight the importance of performing analyses across different distributions of systems. If we were looking at just the overall ranking accuracy of the metrics, we would conclude that DAE and FactCC correctly measure faithfulness. However, on closer examination, we see that both metrics perform relatively poorly in ranking AF systems, which is arguably the most crucial group since most state-of-the-art systems operate in this regime, and there is substantial interest in building abstractive and faithful summarization systems.

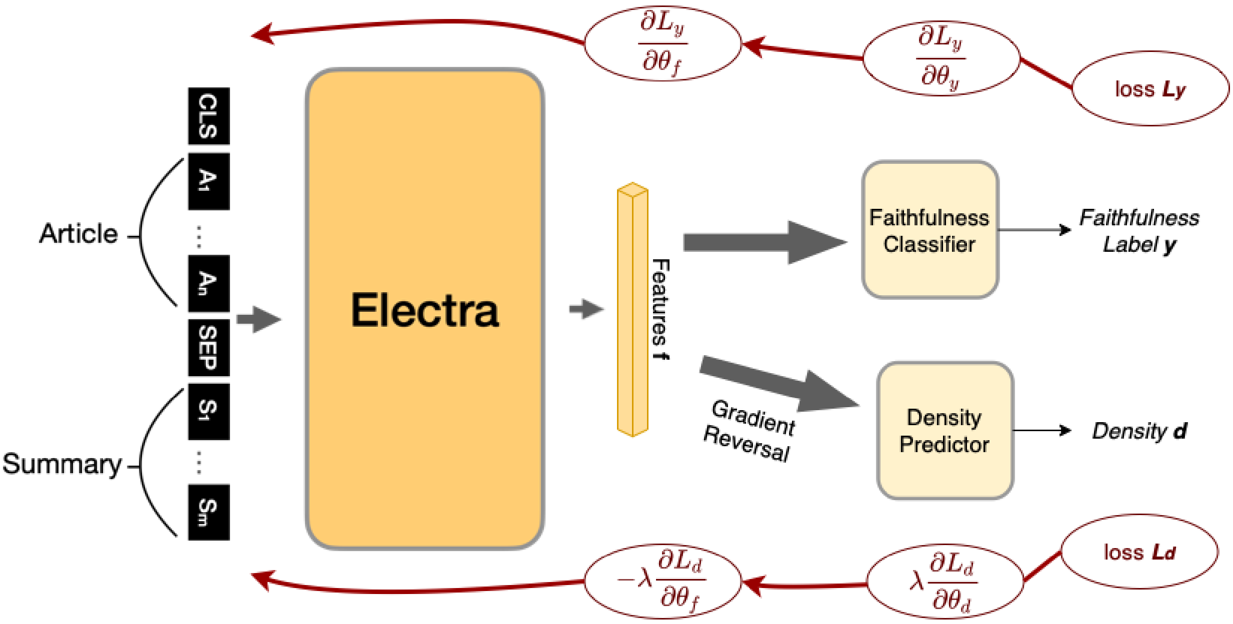

Figure 5: Architecture of adversarial model. The input sequence is first encoded via a pre-trained Electra model, and the representation is used for both faithfulness classification and density prediction. Gradients from the density predictor are reversed in order to make updates to the encoder's parameters, forcing the model to learn representations that are not predicitve of density.

	All Pairs	Within AF
FactCC-Electra	77.85	27.70
FactCC	78.87	38.26
DAE	80.39	37.88
Adversarial	**85.27**	**59.20**

Table 5: Pairwise ranking accuracy for systems across All Pairs vs. Within Abstractive Faithful (AF) for DAE and Adversarial. Adversarially trained metric performs significantly better for the systems within AF than previously proposed metrics.

5 Adversarial Model

In our earlier example-level analysis, we found that learned metrics have higher correlation with spurious correlates than human judgment. We further saw in our system-level analysis that learned metrics for faithfulness are unable to outperform density. One natural question that follows is whether we can build metrics that do well at the systems level by learning representations that rely less on spurious correlates.

In order to do this, we train an entailment based model using the synthetically generated data from FactCC in an adversarial setup similar to Ganin et al. (2016). In particular, our approach augments the standard faithfulness predictor with a density predictor that tries to predict the density of the summary from the model's internal representation. We use this density predictor as an adversary, and our goal is to predict faithfulness while ensuring that it is difficult to predict density using this same representation. To achieve this, the gradients from the density predictor are reversed, which makes it harder to predict the density from the encoder's representation, and thus makes the faithfulness predictions less reliant on density. The model architecture is shown in Figure 5. We initialize the parameter λ to 0 and gradually increase it to 1, following the schedule detailed in Ganin et al. (2016).

We fine-tune a pre-trained Electra model (Clark et al., 2020) using the transformers library (Wolf et al., 2020) for this task. We chose Electra in order to match the model architecture in DAE. Since the original FactCC metric was fine-tuned on BERT, we also fine-tune our own version of FactCC on Electra (FactCC-Electra) as an ablation. Our adversarially trained model is essentially the same as FactCC-Electra, but with an additional adversarial head for predicting density.

Results. We note that the FactCC-Electra model performs worse than the original FactCC, which is consistent with the findings in Goyal and Durrett (2021). Our adversarially trained metric has a significantly lower example-level correlation with density (27.71%), as compared to FactCC (59.10%)

and DAE (76.37%). We find that the adversarial model[5] can achieve a significantly better performance than existing learned evaluation metrics in ranking systems within the abstractive faithful (AF) group (Table 5). This suggests that it is possible to learn effective metrics that are not overly reliant on spurious correlates. Furthermore, our metric is also effective in overall pairwise ranking of the systems achieving 85.27% accuracy.

6 Related Work

Most existing work on assessing the evaluation methodology of evaluation metrics has focused on reference-based evaluation. For example, Mathur et al. (2020) take a critical look at the use of example-level correlations to measure reference-based evaluation metrics in Machine Translation. They show that evaluating these metrics using example-level correlations can be sensitive to the presence of outliers which can lead to false conclusions about a metric's efficacy. Furthermore, Kocmi et al. (2021) show that proper assessment of evaluation metrics is crucial as uninformed use of automated metrics such as BLEU can lead to bad deployment decisions. Caglayan et al. (2020) has shown that automated reference-based evaluation metrics have robustness issues which can cause them to score generated outputs higher than human written outputs. Furthermore, Bhandari et al. (2020) has studied the limitations of reference-based evaluation metrics of text summarization, comparing these metrics across different datasets and application scenarios. In contrast, our work focuses on analyzing learned, reference-free evaluation metrics in summarization and dialog generation, accounting for potential spurious correlates for these evaluation tasks.

There has been some recent work comparing existing reference-free evaluation metrics for text summarization and dialog generation. Pagnoni et al. (2021) has measured the efficacy of existing reference-free faithfulness evaluation metrics of summarization on two different summarization datasets relying on example-level correlations. Similarly, Gehrmann et al. (2021) has evaluated automated metrics of text summarization across a wide range of datasets. Gabriel et al. (2021) has proposed a meta-evaluation framework to evaluate the evaluation metrics looking at certain aspects of these metrics such as robustness, sensitivity, high correlation with human scores, etc., and measured existing evaluation metrics across these aspects. Yeh et al. (2021) perform a comprehensive study of existing dialog generation metrics across several different datasets and find that the performance of metrics varies widely across datasets.

Gabriel et al. (2021) and Yeh et al. (2021) are the most related to our work since they study robustness of these metrics looking at their performance across different datasets. In our work, however, we explicitly study spurious correlations and show that these may potentially be contributing to the robustness issues. We further present initial promising results suggesting that controlling for these spurious correlates may result in more robust evaluation metrics.

7 Conclusion

In conclusion, we study reference-free evaluation metrics for summarization and dialog generation and show that simply looking at overall example-level correlation with human judgment paints an incomplete picture of the effectiveness of a metric. In particular, we show that these metrics are unable to do better than simple spurious correlates for the task. We see that this trend carries over in system-level ranking for summarization systems, where a spurious correlate for the task performs as well as existing learned evaluation metrics. We find that despite the relatively high overall system-level ranking performance, the learned metrics are not robust to distribution shifts. We show that they fail to properly rank abstractive and (relatively) faithful systems, which is where the current state of the art operates. Finally, we train a faithfulness metric that scores the faithfulness of a summary without relying on the spurious overlap correlate. We show that our metric is more robust across distribution shifts and does better at ranking abstractive, faithful summarization systems.

We suggest that future work in designing reference-free evaluation metrics should be mindful of the distribution of the evaluation data. In particular, metrics should be assessed across different distributions of systems in order to test for robustness and failure modes. Simple spurious correlates can be used as a tool to indicate potential overestimates of the effectiveness of proposed metrics. Finally, we highlight the importance of collecting large-scale human evaluation datasets across a wide

---

range of systems, similar to Fabbri et al. (2020), to enable more comprehensive analyses of evaluation metrics.

Abstract

Semantic parsers map natural language utterances into meaning representations (*e.g.* programs). Such models are typically bottlenecked by the paucity of training data due to the laborious annotation efforts. Recent studies have performed zero-shot learning by synthesizing training examples of canonical utterances and programs from a grammar, and further paraphrasing these utterances to improve linguistic diversity. However, such synthetic examples cannot fully capture patterns in real data. In this paper we analyze zero-shot parsers through the lenses of the *language* and *logical* gaps (Herzig and Berant, 2019), which quantify the discrepancy of language and programmatic patterns between the synthetic canonical examples and real-world user-issued ones. We propose bridging these gaps using improved grammars, stronger paraphrasers, and efficient learning methods using canonical examples that most likely reflect real user intents. Our model achieves strong results on the SCHOLAR and GEO benchmarks with *zero* labeled data.[1]

1 Introduction

Semantic parsers translate natural language (NL) utterances into formal meaning representations. In particular, task-oriented semantic parsers map user-issued utterances (*e.g. Find papers in ACL*) into machine-executable programs (*e.g.* a database query), play a key role in providing natural language interfaces to applications like conversational virtual assistants (Gupta et al., 2018; Andreas et al., 2020), robot instruction following (Artzi and Zettlemoyer, 2013; Fried et al., 2018), as well as querying databases (Li and Jagadish, 2014; Yu et al., 2018) or generating Python code (Yin and Neubig, 2017).

Learning semantic parsers typically requires parallel data of utterances annotated with programs, which requires significant expertise and cost (Berant et al., 2013). Thus, the field has explored alternative approaches using supervisions cheaper to acquire, such as the execution results (Clarke et al., 2010) or unlabeled utterances (Poon, 2013). In particular, the seminal OVERNIGHT approach (Wang et al., 2015) synthesizes parallel data by using a synchronous grammar to align programs and their canonical NL expressions (*e.g.* `Filter(paper,venue=`$\boxed{?}$`)` ↔ *papers in* $\boxed{?}$ and `acl`↔*ACL*), then generating examples of compositional utterances (*e.g. Papers in ACL*) with programs (*e.g.* `Filter(paper,venue=acl)`). The synthesized utterances are paraphrased by annotators, a much easier task than writing programs.

Recently, Xu et al. (2020b) build upon OVERNIGHT and develop a *zero-shot* semantic parser replacing the manual paraphrasing process with an automatic paraphrase generator (§2). While promising, there are still several open challenges. First, such systems are not truly zero-shot — they still require labeled validation data (*e.g.* to select the best checkpoint at training). Next, to ensure the quality and broad-coverage of synthetic canonical examples, existing models rely on heavily curated grammars (*e.g.* with 800 production rules), which are cumbersome to maintain. More importantly, as suggested by Herzig and Berant (2019) who study OVERNIGHT models using manual paraphrases, such systems trained on synthetic samples suffer from fundamental mismatches between the distributions of the automatically generated examples and the *natural* ones issued by real users. Specifically, there are two types of gaps. First, there is a *logical gap* between the synthetic and real programs, as real utterances (*e.g. Paper coauthored by Peter and Jane*) may exhibit logic patterns outside of the domain of those covered by the grammar (*e.g. Paper by Jane*). The second is the *language gap* between the synthetic and real utterances, as paraphrased utterances (*e.g.* u'_1 in Fig. 1) still follow similar linguistic patterns as the canonical ones they are

May 22-27, 2022

paraphrased from (*e.g.* $\boldsymbol{u}_1$), while user-issued utterances are more linguistically diverse (*e.g.* $\boldsymbol{u}_2$).

In this paper we analyze zero-shot parsers through the lenses of language and logical gaps, and propose methods to close those gaps (§3). Specifically, we attempt to bridge the language gap using stronger paraphrasers and more expressive grammars tailored to the domain-specific idiomatic language patterns. We replace the large grammars of previous work with a highly compact grammar with only 46 domain-general production rules, plus a small set of domain-specific productions to capture idiomatic language patterns (*e.g.* $\boldsymbol{u}_2$ in Fig. 1, §3.1.1). We demonstrate that models equipped with such a smaller but more expressive grammar catered to the domain could generate utterances with more idiomatic and diverse language styles.

On the other hand, closing the logical gap is non-trivial, since canonical examples are generated by exhaustively enumerating all possible programs from the grammar up to a certain depth, and increasing the threshold to cover more complex real-world examples will lead to exponentially more canonical samples, the usage of which is computationally intractable. To tackle the exponentially exploding sample space, we propose an efficient sampling approach by retaining canonical samples that most likely appear in real data (§3.1.2). Specifically, we approximate the likelihood of canonical examples using the probabilities of their utterances measured by pre-trained language models (LMs). This enables us to improve logical coverage of programs while maintaining a tractable number of highly-probable examples as training data.

By bridging the language and logical gaps, our system achieves strong results on two datasets featuring realistic utterances (SCHOLAR and GEO). Despite the fact that our model uses *zero* annotated data for training and validation, it outperforms other supervised methods like OVERNIGHT and GRANNO (Herzig and Berant, 2019) requiring manual annotation. Analysis shows that current models are far from perfect, suggesting logical gap still remains an issue, while stronger paraphrasers are needed to further close the language gap.

2 Zero-shot Semantic Parsing via Data Synthesis

Problem Definition Semantic parsers translate a user-issued NL utterance $\boldsymbol{u}$ into a machine-executable program $\boldsymbol{z}$ (Fig. 1). We consider a zero-shot learning setting without access to parallel data in the target domain. Instead, the system is trained on a collection of machine-synthesized examples.

Overview Our system is inspired by the existing zero-shot semantic parser AUTOQA (Xu et al., 2020b). Fig. 1 illustrates our framework. Intuitively, we automatically create training examples with canonical utterances from a grammar, which are then paraphrased to increase diversity in language style. Specifically, there are two stages. First, a set of seed canonical examples (Fig. 1b) are generated from a **synchronous grammar**, which defines compositional rules of NL expressions to form utterances (Fig. 1a). Next, in the iterative training stage, a **paraphrase generation** model rewrites the canonical utterances to more natural and linguistically diverse alternatives (Fig. 1c). The paraphrased examples are then used to train a semantic parser. To mitigate noisy paraphrases, a filtering model, which is the parser trained on previous iterations, rejects paraphrases that are potentially incorrect. This step of paraphrasing and training could proceed for multiple iterations, with the parser trained on a dataset with growing diversity of language styles.[2]

Synchronous Grammar Seed canonical examples are generated from a synchronous context free grammar (SCFG). Fig. 1a lists simplified production rules in the grammar. Intuitively, productions specify how utterances are composed from lower-level language constructs and domain lexicons. For instance, given a database entity `alan_turing` with a property `citations`, $\boldsymbol{u}_3$ in Fig. 1 could be generated using r_1. Productions could be applied recursively to derive more compositional utterances (*e.g.* $\boldsymbol{u}_2$ using r_2, r_4 and r_6). Our SCFG is based on Herzig and Berant (2019), consisting of domain-general rules of generic logical operations (*e.g.* `superlative`, r_3) and domain-specific lexicons of entity types and relations. Different from Xu et al. (2020b) which uses a complex grammar with 800 rules, we use a compact grammar with only 46 generic rules plus a handful of idiomatic productions (§3.1.1) to capture domain-specific language patterns (*e.g.* *"most recent"* in $\boldsymbol{u}_2$, *c.f.*, $\boldsymbol{u}_1$). Given the grammar, examples are enumerated exhaustively up to a threshold of number of rule applications, yielding a large set of seed canonical

---

[2] This process is similar to expert iteration in reinforcement learning (Anthony et al., 2017), where a model is iteratively re-trained on newly discovered action trajectories.

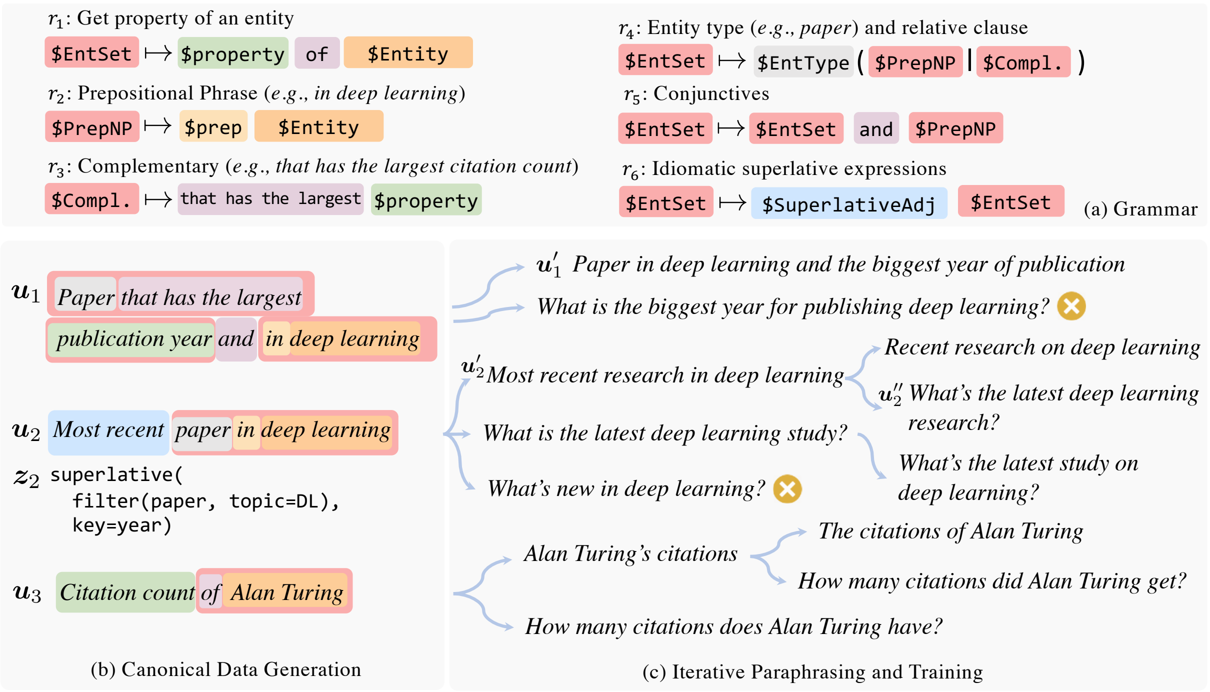

Figure 1: Illustration of the learning process of our zero-shot semantic parser with real model outputs. **(a)** Synchronous grammar with production rules. **(b)** Canonical examples of utterances with programs (only $\boldsymbol{z}_2$ is shown) are generated from the grammar (colored spans show productions used). Programs are shown in simplified, illustrative form. Refer to Appendix B for real examples. Unnatural utterances like $\boldsymbol{u}_1$ can be discarded, as in §3.1.2 **(c)** At each iteration, canonical examples are paraphrased to increase diversity in language style, and a semantic parser is trained on the paraphrased examples. Potentially noisy or vague paraphrases are filtered (marked as ⊗) using the parser trained on previous iterations.

examples $\mathbb{D}_{\text{can}}$ (Fig. 1b) for paraphrasing.[3]

Paraphrase Generation and Filtering The paraphrase generation model rewrites a canonical utterance $\boldsymbol{u}$ to more natural and diverse alternatives $\boldsymbol{u}'$. $\boldsymbol{u}'$ is then paired with $\boldsymbol{u}$'s program to create a new example. We finetune a BART model on the dataset by Krishna et al. (2020), which is a subset of the PARANMT corpus (Wieting and Gimpel, 2018) that contain lexically and syntactically diverse paraphrases. The model therefore learns to produce paraphrases with diverse linguistic patterns, which is essential for closing the language gap when paraphrasing from canonical utterances. To further improve the syntactic diversity of paraphrases from imperative utterances (*e.g.* $\boldsymbol{u}_2$, Fig. 1), we apply forced decoding such that half of the generated paraphrases start with questions with WH-prefixes (*e.g.* $\boldsymbol{u}_3$ in Fig. 1). Refer to Appendix A for details. Still, some paraphrases are noisy or potentially vague (⊗ in Fig. 1c). We follow Xu et al. (2020b) and use the parser trained on previous iterations as the filtering model, and reject paraphrases for which the parser cannot predict their programs.

3 Bridging the Gaps between Canonical and Natural Data

Language and Logical Gaps The synthesis approach in §2 will yield a large set of paraphrased canonical data (denoted as $\mathbb{D}_{\text{par}}$). However, as noted by Herzig and Berant (2019) (hereafter HB19), the synthetic examples cannot capture all the language and programmatic patterns of real-world natural examples from users (denoted as $\mathbb{D}_{\text{nat}}$). There are two mismatches between $\mathbb{D}_{\text{par}}$ and $\mathbb{D}_{\text{nat}}$. First, there is a **logical gap** between real programs in $\mathbb{D}_{\text{nat}}$ and the synthetic ones in $\mathbb{D}_{\text{par}}$, which are exhaustively composed up to a certain compositional depth and therefore cannot capture more complex programs in $\mathbb{D}_{\text{nat}}$. Next, there is a **language gap** between paraphrased canonical utterances and real-world user-issued ones. Real utterances (*e.g.* $\boldsymbol{u}_2$ in Fig. 1, which is from $\mathbb{D}_{\text{nat}}$ but can be modeled as a canonical sample later in §3.1.1) enjoy more lexical and syntactic diversity, while the auto-paraphrased ones (*e.g.* $\boldsymbol{u}'_1$) are typically biased towards the clunky language style of their canonical source (*e.g.* $\boldsymbol{u}_1$). While we could increase diversity via iterative rounds of paraphras-

---

[3] SCFGs could not generate utterances with context-dependent rhetorical patterns such as anaphora. Our model could still handle simple domain-specific context-dependent patterns (*e.g.* *Paper by A and B*, where *A* and *B* are different authors) by first generating all the canonical samples and then filtering those that violate the constraints.

ing (*e.g.* $\boldsymbol{u}_2 \mapsto \boldsymbol{u}'_2 \mapsto \boldsymbol{u}''_2$), the paraphraser could still fail on canonical utterances that are not natural English sentences at all, like $\boldsymbol{u}_1$.

3.1 Bridging Language and Logical Gaps

We introduce improvements to the system to close the language (§3.1.1) and logical (§3.1.2) gaps.

3.1.1 Idiomatic Productions

To close language gaps, we augment the grammar with productions capturing domain-specific idiomatic language styles. Such productions compress the clunky canonical expressions (*e.g.* $\boldsymbol{u}_1$ in Fig. 1) to more succinct and natural alternatives (*e.g.* $\boldsymbol{u}_2$), inspired by prior studies on how human experts revise canonical utterances (Wang et al., 2015), as well as by studying samples in real data. Specifically, we focus on two language patterns:

Non-compositional expressions for multi-hop relations Compositional canonical utterances typically feature chained multi-hop relations that are joined together (*e.g. Author that writes paper whose topic is NLP*), which can be compressed using more succinct phrases to denote the relation chain, where the intermediary pivoting entities (*e.g.* `paper`) are omitted (*e.g. Author that works on NLP*). The pattern is referred to as sub-lexical compositionality in Wang et al. (2015) and used by annotators to compress verbose canonical utterances, while we model them using grammar rules. Refer to Appendix B for more details.

Idiomatic Comparatives and Superlatives The general grammar in Fig. 1a uses canonical constructs for comparative (*e.g. smaller than*) and superlative (*e.g. largest*) utterances (*e.g.* $\boldsymbol{u}_1$), which is not ideal for entity types with special units (*e.g.* time, length). We therefore create productions specifying idiomatic comparative and superlative expressions (*e.g. paper published before 2014*, and $\boldsymbol{u}_2$ in Fig. 1). Sometimes, answering a superlative utterance requires reasoning with other pivoting entities. For instance, the relation in *"venue that X publish mostly in"* between authors and venues implicitly involves counting the papers that *X* publishes. For such cases, we create "macro" productions, with the NL phrase mapped to a program that captures the computation involving the pivoting entity (Appendix B).

Discussion Our SCFG uses idiomatic productions that capture domain-specific language expressions, together with simple domain-general rules (Herzig and Berant, 2019) to combine those idiomatic constructs to form compositional utterances. As we show in §4, both the base and idiomatic grammar sets are relatively compact, and we resort to strong paraphrasers to further "naturalize" synthetic utterances and bridge the language gap. In line with Su and Yan (2017) and Marzoev et al. (2020), we remark that such *functionality*-driven grammar engineering to cover representative patterns in real data using a small set of curated production rules is more efficient and cost-effective than example-driven annotation in classical supervised learning of semantic parsers, which requires labeling a sufficient number of parallel samples to effectively train a data-hungry neural model over a variety of underlying meanings and surface language styles.

Our approach is also orthogonal with the prior work Xu et al. (2020b), which uses large curated general-purpose grammars to attempt to model English syntax, while using weak domain-specific rules that are much easier to specify than our SCFG, but might not be as effective to capture idiomatic language patterns in the domain. On the other hand, grammar engineering can be potentially costly. Ideally, one could study representative samples from real data and come up with a small set of idiomatic productions in the above categories that are expressive enough for domains like GEO and SCHOLAR (§4). Still, the exact the amount of effort this process takes remains difficult to estimate. We present more discussion in §5.

3.1.2 Naturalness-driven Data Selection

To cover real programs in $\mathbb{D}_{\text{nat}}$ with complex structures while tackling the exponential sample space, we propose an efficient approach to sub-sample a small set of examples from this space as seed canonical data $\mathbb{D}_{\text{can}}$ (Fig. 1b) for paraphrasing. Our core idea is to only retain a set of examples $\langle \boldsymbol{u}, \boldsymbol{z} \rangle$ that most likely reflect the intents of real users. We use the probability $p_{\text{LM}}(\boldsymbol{u})$ measured by a language model to approximate the "naturalness" of canonical examples.[4] Specifically, given all canonical examples allowed by the grammar, we form buckets based on their derivation depth d. For each bucket $\mathbb{D}^{(d)}_{\text{can}}$, we compute $p_{\text{LM}}(\boldsymbol{u})$ for its examples, and group the examples using program templates as the key (*e.g.* $\boldsymbol{u}_1$ and $\boldsymbol{u}_2$ in Fig. 1 are grouped together). For each group, we find the example $\langle \boldsymbol{u}^*, \boldsymbol{z} \rangle$ with the highest $p_{\text{LM}}(\boldsymbol{u}^*)$, and discard other examples $\langle \boldsymbol{u}, \boldsymbol{z} \rangle$ if $\ln p_{\text{LM}}(\boldsymbol{u}^*) - \ln p_{\text{LM}}(\boldsymbol{u}) >$

---

[4] We use the GPT-2 XL model (Radford et al., 2019).

δ ($\delta = 5.0$), removing unlikely utterances from the group (*e.g.* $\boldsymbol{u}_1$).[5] Finally, we rank all groups in $\mathbb{D}_{\text{can}}^{(d)}$ based on $p_{\text{LM}}(\boldsymbol{u}^*)$, and retain examples in the top-K groups. This method offers trade-off between program coverage and efficiency and, more surprisingly, we show that using only $0.2\% \sim 1\%$ top-ranked examples also results in significantly better final accuracy (§4).

3.2 Generating Validation Data

Zero-shot learning is non-trivial without a high-quality validation set, as the model might overfit on the (paraphrased) canonical data, which is subject to language and logical mismatch. While existing methods (Xu et al., 2020b) circumvent the issue using real validation data, in this work we create validation sets from paraphrased examples, making our method truly labeled data-free. Specifically, we consider a two-stage procedure. First, we run the iterative paraphrasing algorithm (§2) without validation, and then sample $\langle \boldsymbol{u}, \boldsymbol{z} \rangle$ from its output with a probability $p(\boldsymbol{u}, \boldsymbol{z}) \propto p_{\text{LM}}(\boldsymbol{u})^{\alpha}$ ($\alpha = 0.4$), ensuring the resulting sampled set $\mathbb{D}_{\text{par}}^{\text{val}}$ is representative. Second, we restart training using $\mathbb{D}_{\text{par}}^{\text{val}}$ for validation to find the best checkpoint. The paraphrase filtering model is also initialized with the parser trained in the first stage, which has higher precision and accepts more valid paraphrases. This is similar to iterative training of weakly-supervised semantic parsers (Dasigi et al., 2019), where the model searches for candidate programs for unlabeled utterances in multiple stages of learning.

4 Experiments

We evaluate our zero-shot parser on two datasets.

SCHOLAR (Iyer et al., 2017) is a corpus of user-issued queries to an academic database (Fig. 1). We use the version from HB19 with programs represented in λ-calculus logical forms. The sizes of the train/test splits are 577/211. Entities in utterances and programs (*e.g.* *Parsing paper in ACL*) are canonicalized to slots (*e.g.* `keyphrase0`, `venue0`), and are recovered before executing the programs. We found in the dataset by HB19, slots are paired with with random entities for execution (*e.g.* `keyphrase0`$\mapsto$*Optics*). Therefore reference programs are likely to execute to empty results, making metrics like answer accuracy more prone to false-positives. We fix all such examples in the dataset, as well as those with execution errors.

System	Supervision	SCHOLAR	GEO
Supervised†	Labeled Examples	79.7 $\pm$2.2	81.9 $\pm$5.3
OVERNIGHT†	Manual Paraphrases	41.0 $\pm$3.8	55.8 $\pm$6.4
GRANNO†	Real Utterances, Manual Paraphrase Detection	68.3 $\pm$1.6	69.4 $\pm$1.9
Our System	–	**75.5** $\pm$1.6	**74.1** $\pm$2.3

Table 1: Averaged denotation accuracy and standard deviation on TEST sets. Results are averaged with five random restarts. †Models originally from Herzig and Berant (2019) and run with five random restarts. Results from our model are tested *v.s.* GRANNO using permutation test with $p < 0.05$.

GEO (Zelle and Mooney, 1996) is a classical dataset with queries about U.S. geography (*e.g. Which rivers run through states bordering California?*). Its database contains basic geographical entities like cities, states, and rivers. We also use the release from HB19, of size 596/278.

Models and Configuration Our neural semantic parser uses a BERT$_{\text{Base}}$ encoder (Devlin et al., 2019) and an LSTM decoder with copy mechanism. The paraphraser is a BART$_{\text{Large}}$ model (Lewis et al., 2020). We use the same set of hyper-parameters for both datasets. Specifically, we synthesize canonical examples from the SCFG with a maximal program depth of 6, and collect the top-K ($K = 2,000$) GPT-scored sample groups for each depth as the seed canonical data $\mathbb{D}_{\text{can}}$ (§3.1.2), with two rounds of iterative paraphrasing and training (§2). The beam size for the paraphraser is 20. We create validation sets of size $2,000$ following §3.2. Refer to Appendix C for more details. Note that our model only uses the natural examples in both datasets for evaluation purposes, and the training and validation splits are *not* used during learning.

Measuring Language and Logical Gaps We measure the language mismatch between utterances in the paraphrased canonical ($\mathbb{D}_{\text{par}}$) and natural ($\mathbb{D}_{\text{nat}}$) data using **perplexities** of natural utterances in $\mathbb{D}_{\text{nat}}$ given by a GPT-2 LM fine-tuned on $\mathbb{D}_{\text{par}}$. For logical gap, we follow HB19 and compute the **coverage** of natural programs $\boldsymbol{z} \in \mathbb{D}_{\text{nat}}$ in $\mathbb{D}_{\text{par}}$.

Metric We report **denotation accuracy** on the execution results of predicted programs.[6]We ran all experiments with five random restarts and report the mean and standard deviation.

4.1 Results

In experiments, we first compare our model with existing approaches using labeled data. Next, we analyze how our proposed methods close the lan-

[5] δ chosen in pilot studies, similar to Zhang et al. (2019).

[6] We use `SEMPRE` (Berant et al., 2013) to execute λ-calculus logical forms in parallel.

guage and logical gaps. Tab. 1 reports test accuracies of various systems on the test sets, as well as their form of supervision. Specifically, the **supervised** parser uses a standard parallel corpus $\mathbb{D}_{\text{nat}}$ of real utterances annotated with programs. **OverNight** uses paraphrased synthetic examples $\mathbb{D}_{\text{par}}$ like our model, but with manually written paraphrases. **Granno** uses unlabeled real utterances $\boldsymbol{u}_{\text{nat}} \in \mathbb{D}_{\text{nat}}$, and manual paraphrase detection to pair $\boldsymbol{u}_{\text{nat}}$ with the canonical examples $\mathbb{D}_{\text{can}}$. Our model outperforms existing approaches without using any labeled data, while Granno, the currently most cost-effective approach, still spends $155 in manual annotation (besides collecting real utterances) on the two datasets (Herzig and Berant (2019), HB19). This demonstrates that our zero-shot parser is a data-efficient and cost-effective paradigm to train semantic parsers for emerging domains. Still, our system falls behind supervised models trained on natural corpora $\mathbb{D}_{\text{nat}}$, due to language and logical gaps between $\mathbb{D}_{\text{par}}$ and $\mathbb{D}_{\text{nat}}$. Next, we explore whether our proposed methods are effective at narrowing the gaps and improving accuracy. Since the validation splits of the two datasets are small (< 100), we evaluate on the full training/validation splits (around 600 examples) to get more reliable results.

More expressive grammars narrow language and logical gaps We capture domain-specific language patterns using idiomatic productions to close language mismatch (§3.1.1). Tables 2 and 3 list the results when we gradually augment the grammar with different categories of idiomatic productions. More expressive grammars help close the language gap, as indicated by the decreasing perplexities. This is especially important for Scholar, which has diverse NL expressions hard to infer from plain canonical utterances. For instance, it could be non-trivial to paraphrase canonical utterances with multi-hop (*e.g. Author that cites paper by X*) or superlative relations (*e.g. Topic of the most number of* ACL *paper*) to more idiomatic alternatives (*e.g.* "*Author that cites X*", and "*The most popular topic for* ACL *paper*"), while directly including such patterns in the grammar (+**Multihop Rel.** and +**Superlative**) is helpful. We also remark that the number of idiomatic productions we created is fairly compact (See Appendix B for a complete list).[7] We are able to improve the accuracy by 11% absolute with 26 rules on Scholar, while achieving 8% gain using only 13 idiomatic productions on the simpler Geo domain with fewer entity types and relations.

Grammar	Size	Acc.	PPL	Logical Cov. $\mathbb{D}_{\text{can}}$	$\mathbb{D}_{\text{par}}$
Base	46	66.3 ±3.7	23.0	80.6	75.8
+Multihop Rel.[8]	11	67.0 ±1.1	22.0	87.7	81.2
+Comparison	2	67.3 ±2.4	21.7	86.5	80.2
+Superlative	13	77.8 ±2.2	20.9	90.6	86.1
−Multihop Rel.	2	75.8 ±3.4	20.8	83.9	81.1

Grammar	Size	Acc.	PPL	Logical Cov. $\mathbb{D}_{\text{can}}$	$\mathbb{D}_{\text{par}}$
Base	68	64.5 ±4.6	8.2	84.4	79.7
+Multihop Rel.	4	67.9 ±4.0	8.1	83.6	79.7
+Superlative	9	72.8 ±2.8	8.0	84.1	79.4
−Multihop Rel.	4	66.5 ±3.7	8.2	84.1	80.0

Table 3: Ablation study of grammar categories on Geo.

Additionally, more expressive grammars also improve logical coverage. The last columns (**Logical Cov.**) of Tables 2 and 3 report the percentage of real programs that are covered by the seed canonical data before ($\mathbb{D}_{\text{can}}$) and after ($\mathbb{D}_{\text{par}}$) iterative paraphrasing. Intuitively, a single idiomatic production often captures compositional computations like multi-hop queries, allowing the grammar to generate more compositional programs under the same threshold on the derivation depth. Notably, with all the full grammar on Scholar, the number of exhaustively generated examples with a depth of 6 is tripled ($530K \mapsto 1,700K$).

Moreover, recall that the seed canonical dataset $\mathbb{D}_{\text{can}}$ contains examples with highly-likely utterances under the LM (§3.1.2). Therefore, examples created by idiomatic productions are more likely to be included in $\mathbb{D}_{\text{can}}$. However, this could also be counter-productive, as such examples could dominate $\mathbb{D}_{\text{can}}$, "crowding out" other useful examples with lower LM scores. This likely explains the slightly decreased logical coverage on Geo (Tab. 3), as more than 30% samples in the LM filtered $\mathbb{D}_{\text{can}}$ include idiomatic multi-hop relations directly connecting geographic entities with their countries (*e.g.* "*City in US*"), while such examples only account for $\sim 8\%$ of real data. While the over-representation issue might not negatively impact accuracy, we leave generating more balanced synthetic data as important future work.

---

[7] The base grammar is adapted from HB19, which defines entity types, example entities and (synonyms of) relations in each domain.

[8] This category only considers merging relation chains, and does not include superlative rules involving multiple relations.

	K	TRAIN Size		ACC	PPL	Logical Coverage

Table 6: Systems with different paraphrasers. We report end-to-end denotation accuracy, as well as F_1 and Kendall's τ rank coefficient between utterances and their paraphrases.

Finally, we note that the logical coverage drops after paraphrasing ($\mathbb{D}_{\text{can}}$ *v.s.* $\mathbb{D}_{\text{par}}$ in Tables 2 and 3). This is because for some samples in $\mathbb{D}_{\text{can}}$, the paraphrase filtering model rejects all their paraphrases. We provide further analysis later in §5.

Do smaller logical gaps entail better performance? As in §3.1.2, to make learning tractable in face of the exponential space of canonical samples, the seed canonical data $\mathbb{D}_{\text{can}}$ used in iterative paraphrasing only consists of top-K highest-scoring examples under GPT-2 for each program depth. However, using a smaller cutoff threshold K might sacrifice logical coverage, as fewer examples are in $\mathbb{D}_{\text{can}}$. To investigate this trade-off, we report results with varying K in Tab. 12. Notably, with $K = 1,000$ and around $3K$ seed canonical data $\mathbb{D}_{\text{can}}$ (before iterative paraphrasing), $\mathbb{D}_{\text{can}}$ already covers 88% and 80% natural programs on SCHOLAR and GEO, resp. This small portion of samples only account for 0.2% (1%) of the full set of $1.7M+$ $(0.27M)$ canonical examples exhaustively generated from the grammar on SCHOLAR (GEO). This demonstrates our data selection approach is effective in maintaining learning efficiency while closing the logical gap.

More interestingly, while larger K further closes the logical gap, the accuracy might not improve accordingly. This is possibly because while the coverage of real programs increases, the percentage of such programs in paraphrased canonical data $\mathbb{D}_{\text{par}}$ (numbers in parentheses) actually drops. Out of the remaining $90\%+$ samples in $\mathbb{D}_{\text{par}}$ not covered in $\mathbb{D}_{\text{nat}}$, many have unnatural intents that real users are unlikely to issue (*e.g.* "*Number of titles of papers with the smallest citations*", or "*Mountain whose elevation is the length of Colorado River*"). Such *unlikely* samples are potentially harmful to the model, causing worse language mismatch, as suggested by the increasing perplexity when $K = 8,000$. Similar to HB19, we observe around one-third of samples in $\mathbb{D}_{\text{can}}$ and $\mathbb{D}_{\text{par}}$ are unlikely. As we later discuss in §5, such unlikely utterances often have noisier paraphrases, which hurts the quality of $\mathbb{D}_{\text{par}}$.

Comparing Data Selection Methods Next, we compare our proposed canonical data selection approach using GPT-2 with several baselines (Tab. 5 *Upper Half*). First, randomly choosing examples from each level of program depth instead of using the top-K GPT-scored ones results is less effective with higher variance. Further simplifying the procedure without constraining on equal sample size across program depths leads to significantly worse results, due to the scarcity of likely examples with simpler programs in the resulting sample set.

Impact of Validation Data We generate validation data from samples of the paraphrased data in an initial run (§3.2). Tab. 5 (*Lower Half*) compares this strategy with a baseline approach, which randomly splits the seed canonical examples in $\mathbb{D}_{\text{can}}$ into training and validation sets, and runs the iterative paraphrasing algorithm on the two sets in parallel, with paraphrases from both sets filtered by the filtering model. This approach underperforms, since some canonical samples with program patterns in the natural data $\mathbb{D}_{\text{nat}}$ can be partitioned into the validation split, and not used for training.

Impact of Paraphrasers We rely on strong paraphrasers to generate diverse utterances to close the language gap. Tab. 6 compares the system using our paraphraser and the one in Xu et al. (2020b). Both are based on BART, while ours is fine-tuned to encourage lexically and syntactically diverse outputs (Appendix A). We measure lexical diversity using token-level F_1 between the original and para-

	Example 1 (Uncommon Concept)	
$\boldsymbol{u}_1$	*Venue of paper by* $\texttt{author}_0$ *and published in* $\texttt{year}_0$

	Example 4 (Unlikely Example)	
$\boldsymbol{u}_4$	*Paper in* $\texttt{year}_0$ *and whose author is not the most cited author*	
$\boldsymbol{u}'_{4,1}$	*A paper published in* $\texttt{year}_0$ *that isn't the most cited author*	☑
$\boldsymbol{u}'_{4,2}$	*What's not the most cited author in* $\texttt{year}_0$	☑
$\boldsymbol{u}'_{4,3}$	*In* $\texttt{year}_0$*, he was not the most cited author*	☑

Table 7: Case Study on SCHOLAR. We show the seed canonical utterance $\boldsymbol{u}_i$, the paraphrases $\boldsymbol{u}'_{i,j}$, and the relevant natural examples $\boldsymbol{u}^*_{\text{nat}}$. ✅ and ❌ denote the correctness of paraphrases. ⊗ denotes false negatives of the filtering model (correct paraphrases that are filtered), ☑ denotes false positives (incorrect paraphrases that are accepted). Entities are canonicalized with indexed

phrased utterances $\langle \boldsymbol{u}, \boldsymbol{u}' \rangle$ (Rajpurkar et al., 2016; Krishna et al., 2020). For syntactic divergence, we use Kendall's τ (Lapata, 2006) to compute the ordinal correlation of $\boldsymbol{u}$ and $\boldsymbol{u}'$. Our paraphraser outputs more diverse paraphrases (*e.g. What is the biggest state in US?*) from the source (*e.g. State in US and that has the largest area*), as indicated by lower token-level overlaps and ordinal coefficients, comparing to the existing paraphraser (*e.g. The state in US with the largest surface area*). Still, our paraphraser is not perfect, as discussed next.

5 Limitations and Discussion

Our parser still lags behind the fully supervised model (Tab. 1). To understand the remaining bottlenecks, we show representative examples in Tab. 7.

Low Recall of Filter Model First, the recall of the paraphrase filtering model is low. The filtering model uses the parser trained on the paraphrased data generated in previous iterations. Since this model is less accurate, it can incorrectly reject valid paraphrases $\boldsymbol{u}'$ (⊗ in Tab. 7), especially when $\boldsymbol{u}'$ uses a different sentence type (*e.g.* questions) than the source (*e.g.* statements). Empirically, we found the recall of the filtering model at the first iteration of the second-stage training (§3.2) is only around 60%. This creates logical gaps, as paraphrases of examples in the seed canonical data $\mathbb{D}_{\text{can}}$ could be rejected by the conservative filtering model, leaving no samples with the same programs in $\mathbb{D}_{\text{par}}$.

Imperfect Paraphraser The imperfect paraphraser could generate semantically incorrect predictions (*e.g.* $\boldsymbol{u}'_{1,1}$), especially when the source canonical utterance contains uncommon or polysemic concepts (*e.g. venue* in $\boldsymbol{u}_1$), which tend to be ignored or interpreted as other entities (*e.g. sites*). Besides rare concepts, the paraphraser could also fail to rewrite canonical utterances using more idiomatic syntax, like changing the mentioning of a conference using prepositional phrases ($\boldsymbol{u}_2$) to compound nouns ($\boldsymbol{u}^*_{\text{nat}}$ in Example 2). While the model might still correctly answer $\boldsymbol{u}^*_{\text{nat}}$, $\boldsymbol{u}^*_{\text{nat}}$'s perplexity is high, suggesting language mismatch.

Unnatural Canonical Utterances While we have attempted to close the language gap by generating more idiomatic canonical utterances, some of them are still not natural enough for the paraphraser to rewrite. This is especially problematic for relations not covered by our idiomatic productions, such as the co-authorship relation in Example 3. While this issue could be mitigated using additional production rules, grammar engineering could still remain challenging, as elaborated later.

Unlikely Examples Besides the unnatural canonical utterances with clunky surface expressions but are still logically plausible, $\mathbb{D}_{\text{can}}$ also contains around 30% unlikely examples with both unnatural utterances and convoluted meanings that almost certainly will not appear in real data (*e.g.* $\boldsymbol{u}_4$). Similar to unnatural utterances, their paraphrases are also much noisier (*e.g.* $\boldsymbol{u}'_{4,*}$), with only around 30% paraphrasing accuracy, compared to 70% for the likely ones. The filtering model is also less effective on unlikely examples (false positives ☑). These noisy samples will eventually hurt performance of the parser. We leave modeling utterance naturalness as important future work.

Cost of Grammar Engineering Our approach relies on an expressive SCFG to bridge the language and logical gaps between synthetic and real data. While we have attempted to standardize the process of grammar construction by designing idiomatic productions following a set of representative grammar categories, grammar engineering still remains a non-trivial task. One need to have a good sense of the idiomatic language patterns that would frequently appear in real-world data, which requires performing user study or access to sampled data. Encoding those language patterns as production rules could also take a reasonable amount of time, depending on various factors, such as the complexity of the target domain and the proficiency of the user in the grammar formalism (λ-calculus) used by our system.

Still, we remark that most of the curated productions have simple syntactic constructs (a single verb, preposition, or adjective phrase, more in Appendix B.2.2), and we are able to significantly improve the performance over the base grammar (Tables 2 and 3) using a relatively compact idiomatic grammar ($10 \sim 30$ rules on two datasets). Additionally, considering that the size of those idiomatic rules is orders of magnitude smaller than the size of the annotated parallel examples in the original datasets (around 800), it is safe to assume that for users familiar with the grammar formalism, curating such a small set of grammar rules for domains similar to SCHOLAR and GEO is more efficient than labeling parallel samples in the original datasets. For the latter task the user would have to consider other factors, such as the coverage of compositional logical form patterns and language expressions, while our system automatically synthesizes compositional samples with diverse language style by composing (idiomatic) productions and iterative paraphrasing. Moreover, the paraphrased canonical examples synthesized from a compact curated grammar could also be used to bootstrap the collection of high-quality parallel data. Finally, creation of grammar rules could potentially be simplified by defining them using natural language instead of logical forms, reminiscent of studies on naturalizing programs using canonical language (Wang et al., 2017; Shin et al., 2021; Herzig et al., 2021).

6 Related Work

To mitigate the paucity of labeled data, the field has explored various supervision signals. Specifically, **weakly-supervised** methods leverage the denotations of utterances as indirect supervision (Clarke et al., 2010; Krishnamurthy and Mitchell, 2012), with programs modeled as latent variables (Berant et al., 2013; Pasupat and Liang, 2015). Optimization is challenging due to the noisy binary reward of execution correctness (Agarwal et al., 2019), calling for better learning objectives (Guu et al., 2017; Wang et al., 2021a) or efficient search algorithms for latent programs (Krishnamurthy et al., 2017; Liang et al., 2017, 2018; Muhlgay et al., 2019). Next, **semi-supervised** models leverage extra unlabeled utterances, using techniques like self-training (Konstas et al., 2017) or generative models (Kociský et al., 2016; Yin et al., 2018). As a step further, **unsupervised** methods only use unlabeled utterances (Cao et al., 2019), and leverage linguistic scaffolds (*e.g.* dependency trees) to infer programs with similar structures (Poon, 2013). Like our model, such methods use lexicons to capture alignments between NL phrases and logical predicates (Goldwasser et al., 2011), while our method does not require real utterances. Finally, methods based on OVERNIGHT (Wang et al., 2015) synthesize parallel corpora from SCFGs (Cheng et al., 2019; Xu et al., 2020a) or neural sequence models (Guo et al., 2018), and attempt to bridge the gaps between canonical and real utterances via paraphrase detection (Herzig and Berant, 2019) and generation (Su and Yan, 2017; Shin et al., 2021; Wu et al., 2021), or representation learning (Marzoev et al., 2020).

7 Conclusion and Future Work

In this paper, we propose a zero-shot semantic parser that closes the language and logical gaps between synthetic and real data. on SCHOLAR and GEO, our system outperforms other annotation-efficient approaches with zero labeled data.

There are several import avenues for future work. First, dedicated approaches to generate syntactically diverse paraphrases using latent variable models, such as Hosking and Lapata (2021) and Hosking et al. (2022), could potentially improve performance. Additionally, systematic comparison with AUTOQA could help elucidate the impact of grammar quality to zero-shot semantic parsing, although this was not covered in this study due to complexities in porting λ-calculus logical forms to the specialized formalism in AUTOQA. Next, careful human studies to understand the amount of efforts required for grammar engineering would provide more insights on the practicality of our approach. Finally, generalizing our approach to domains with more complex schemas (*e.g.* ATIS) is an important direction, which traditionally relies on careful feature engineering to reduce the amount of annotated data (Poon, 2013).

Acknowledgements

We are grateful to Jonathan Herzig for sharing the code for GRANNO, and Silei Xu and Giovanni Campagna for questions regarding AUTOQA. Pengcheng Yin was supported in part by an IBM Ph.D. fellowship. We thank our anonymous reviewers for their insightful comments.

On The Ingredients of an Effective Zero-shot Semantic Parser

Supplementary Materials

A Paraphraser

Central to our approach is a paraphrase generation model $p(\boldsymbol{u} \mapsto \boldsymbol{u}')$, which paraphrases a canonical utterance $\boldsymbol{u}$ to an alternative sentence $\boldsymbol{u}'$ that is possibly more natural and linguistically diverse. To improve the diversity of generated paraphrases, we paraphrase $\boldsymbol{u}$ to multiple candidate rewrites $\{\boldsymbol{u}'\}$ using beam search. We tested multiple strategies (*e.g.* nucleus sampling) to improve diversity of paraphrases via ensuring quality, and found beam search yields the best end-to-end performance.

To generate high-quality paraphrases for open-domain utterances, we parameterize $p(\boldsymbol{u} \mapsto \boldsymbol{u}')$ using generative pre-trained LMs (BART$_{\text{Large}}$).[9] The LM is fine-tuned on a corpus of $70K$ high-quality paraphrases sub-sampled from PARANMT (Wieting and Gimpel, 2018) released by Krishna et al. (2020), where samples are carefully constructed to ensure the lexical and syntactical diversity of target paraphrases. To further improve the syntactic diversity of paraphrases from statement-style inputs (*e.g.* $\boldsymbol{u}_2$, Fig. 1), we apply force decoding with WH-prefixes (*e.g.* *What*, *When*, *How many*, based on the answer type) to half hypotheses in the beam to generate question paraphrases (*e.g.* paraphrases prefixed with *"How many"* for $\boldsymbol{u}_3$ in Fig. 1).

Filtering Paraphrases While our paraphraser is strong, it is still far from perfect, especially when tasked with paraphrasing utterances found in arbitrary down-stream domains. For example, two ambiguous utterances "*Author that cites A*" and "*Author cited by A*" could get the same paraphrase "*Who cites A?*". Such noisy paraphrases will bring noise to learning and hurt performance. To filter potentially incorrect outputs, we follow Xu et al. (2020b) and use the parser trained on the paraphrased data generated in the preceding iteration (or the seed canonical data at the beginning of training) to parse each paraphrased utterance, and only retain those for which the parser could successfully predict its program. Admittedly such a stringent criterion will sacrifice recall, but empirically we found it works well. We present more analysis in the case study in §4.

B Synchronous Grammar

Our synchronous grammar is adapted from Herzig and Berant (2019) and Wang et al. (2015), which specifies alignments between NL expressions and logical form constituents in λ-calculus s-expressions.[10] The grammar consists of a set of domain-general production rules (Appendix B.1), plus domain-specific rules specifying domain lexicons (Appendix B.2.1) and idiomatic productions (Appendix B.2.2). Specifically, domain-general productions define (1) generic logical operations like `count` and `superlative` (*e.g.* r_3, Fig. 1), and (2) compositional rules to construct utterances following English syntax (*e.g.* r_1, Fig. 1). Domain-specific rules, on the other hand, are typically used to define task-dependent lexicons like types (*e.g.* `author`), entities (*e.g.* `alan_turing`), and relations (*e.g.* `citations`) in the database. This work also introduces idiomatic productions to specific common NL expression catered to a domain, as outlined in §3.1.1 and detailed later.

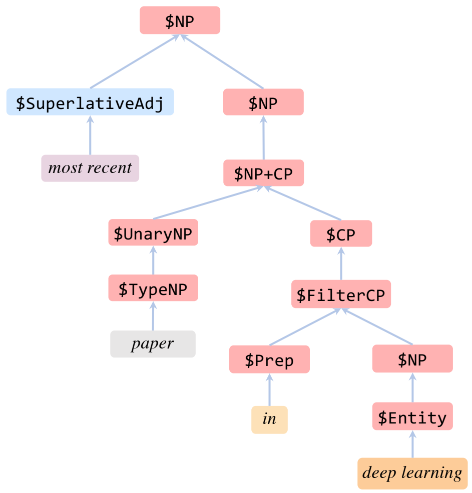
B.1 Domain-General Grammar

Tab. 8 lists example domain-general productions in our SCFG. Fig. 2 shows the derivation that applies those productions to generate an example utterance and program. Each production has a syntactic body, specifying how lower-level syntactic constructs are composed to form more compositional utterances, as well as a *semantic function*, which defines how programs of child nodes are composed to generate a new program. For instance, the production r_3 in Tab. 8 generates a noun phrase from a unary noun phrase `UnaryNP` (*e.g. paper*) and a complementary phrase `CP` (*e.g. in deep learning*) by concatenating the child nodes `UnaryNP` and `CP` (*e.g. paper in deep learning*). On the program side, the programs of two child nodes on Fig. 2 are:

---

[9] We use the official implementation in `fairseq`, https://github.com/pytorch/fairseq.

[10] We use the implementation in `Sempre`, https://github.com/percyliang/sempre



Most recent paper in deep learning

```
(
 call listValue (
   call superlative
    (
     call filter
     (
       call getProperty
       (call singleton fb:en.paper)
       (string ! type)
     )
     (string paper.keyphrase)
     (string =)
     fb:en.keyphrase.deep_learning
    )
   (string max)
   (string paper.publication_year)
  )
)
```

Figure 2: (a) The derivation tree (production rule applications) to generate the example utterance and its program. (b) The program defined in s-expression.

```
# Get all entities whose type is paper
$UnaryNP: call getProperty (call singleton fb:en.paper) (string !type)
# A lambda function that returns entities in x whose relation paper.keyphrase is deep_learning
$CP: lambda x (call
          filter (x)
          (string paper.keyphrase)
          (string =)
          (fb:en.keyphrase.deep_learning))
```

where the program of `UnaryNP` is an entity set of papers, and the program of `NP` is a lambda function with a variable `x`, which filters the entity set. The semantic function of r_3 specifies how these two programs should be composed to form the program of their parent node NP+CP, which performs β reduction, assigning the entity set returned by `UnaryNP` to the variable `x`:

```
# Get all papers whose keyphrase is deep learning
$NP+CP: (call
           filter (
             call getProperty (call singleton fb:en.paper) (string !type)
           )
           (string paper.keyphrase)
           (string =)
           (fb:en.keyphrase.deep_learning))
```

B.2 Domain-specific Grammar

B.2.1 Lexicons and Base Productions

The domain-specific grammar uses a set of base productions to define the task-dependent lexicon, which specifies the mapping between database elements and their natural language expressions. There are three types of elements in the database of a domain: entity types (*e.g.* `author`), entities (*e.g.* `alan_turing`) and relations (*e.g.* `author.paper`), each associated with a base production rule to map them into NL phrases (*e.g.* “*author*”, “*Alan Turing*”, and “*writes*”). A DB element (*e.g.* the entity type `keyphrase`) could also have multiple base productions describing their synonyms (*e.g.* “*keyphrase*” and “*topic*”). The base lexicon in our system is adapted from GRANNO (Herzig and Berant, 2019)[11].

---

Id	Productions (Syntactic Body and Semantic Function)	Description
r_1	`NP↦SuperlativeAdj NP`	*e.g. most recent* $\boxed{?}$
	`lambda rel, sub (` `  call superlative (var sub) (string max) (var rel))`	lambda function to get the subject `sub` with the largest relation `rel`
r_2	`NP↦NP+CP`	A noun phrase head `NP` and a complementary phrase body `CP` (*e.g. paper in deep learning*)
	`IdentityFn`	An identity function returning child program
r_3	`NP+CP↦UnaryNP CP`	*e.g. paper in deep learning*
	`Lambda Beta Reduction: f(var x)`	Perform beta reduction, applying the function from `CP` (*e.g. in deep learning*) to the value of `UnaryNP` (*e.g. paper*)
r_4	`UnaryNP↦TypeNP CP` `IdentityFn`	Entity types, *e.g. paper*
r_5	`CP↦FilterCP` `IdentityFn`	—
r_6	`FilterCP↦Prep NP`	*e.g. in deep learning*
	`lambda rel, obj, sub (` `  call filter (var sub) (var rel) (string =) (var obj))`	Create a lambda function, which filters entities in a list `sub` such that its relation `rel` (*e.g. topic*) equals `obj` (*e.g. deep learning*)
r_5	`NP↦Entity` `IdentityFn`	Entity noun phrases *e.g. deep learning*

Table 8: Example domain-general productions rules in the SCFG

B.2.2 Idiomatic Productions

Here we describe the two categories of idiomatic productions. Readers are referred to Tables 9 and 11 for the list of productions used in SCHOLAR and GEO.

Multi-hop Relations We create idiomatic productions for non-compositional NL phrases of multi-hop relations (*e.g. Author that writes paper in ACL*). We augment the database with entries for those multi-hop relations (*e.g.* ⟨X, `author.publish_in`, `acl`⟩), and then create productions in the grammar aligning those relations with their NL phrases (*e.g.* r_1 in Tab. 9).

Note that the productions defining different relations might have the same syntactic body, for example, r_1 and r_2 in Tab. 9. Since our synthesis algorithm based on Herzig and Berant (2019) performs type checking before composing productions, when it generates an utterance like *Author that publish in ACL*, only r_1 will be used, because the entity span *ACL* has a type (conference) `venue`, not `journal`.

Comparatives and Superlatives We also create productions for idiomatic comparatives and superlative expressions. Those productions specify the NL expressions for the comparative/superlative form of some relations. For example, for the relation `paper.publication_year` with objects of date time, its superlative form would be *most recent* and *first* (r_{14} in in Tab. 9), while its comparative form could be prepositional phrases like *published before* (r_{12}) and *published after*. Those productions define the lexicons for comparative/superlative expressions, and could be used by the domain-general rules like r_1 in Tab. 8 to compose utterances (*e.g.* Fig. 2).

Besides superlative expressions for relations whose objects are measurable, we also create idiomatic expressions for relations with countable subjects or objects. As an example, the utterance "*The most popular topic for papers in ACL*" involves grouping ACL papers by topic and return the most frequent one. Such computation is captured by the `CountSuperlative` operation in our SCFG based on Wang et al. (2015), and we create productions aligning those relations with the idiomatic noun phrases describing their superlative form (*e.g.* r_{16} in Tab. 9).

Perhaps the most interesting form of superlative relations are those involving reasoning with additional entities. For instance, the relation in *"venue that X publish mostly in"* between the entity `author` and `venue` implicitly involves counting the `papers` that the author *X* publishes. For those relations, we create "macro" productions (*e.g.* r_{20} in Tab. 10), which defines the lambda function that computes the answer (*e.g.* return the publication venue where *X* publishes the most number of papers) given the arguments

Id	Production Body (LHS↦RHS and Semantic Function)	Description
	Multi-hop Relations	
	Entity Tyle: `Author`	
r_1	`RelVP`↦*publish in* `ConstantFn (string author.publish_in)`	Verb phrase for multi-hop relation *author that writes paper in ACL*
r_2	`RelVP`↦*publish in* `ConstantFn (string author.publish_in_journal)`	Similar relation for journal publications.
r_3	`RelNP`↦*keyphrase | topic* `ConstantFn (string author.keyphrase)`	Noun phrase for multi-hop relation *keyphrase|topic of Alan Turing*, chaining the two relations *topic of paper by Alan Turing*
r_4	`RelVP`↦*works on* `ConstantFn (string author.keyphrase)`	Verb phrase for the same relation
r_5	`RelVP`↦*cites* `ConstantFn (string author.cites)`	Verb phrase ofr the multi-hop relation *author who cites Alan Turing*, chaining the three relations: *author of paper that cites paper by Alan Turing*
r_6	`RelVP`↦*cites* `ConstantFn (string author.cites_paper)`	Verb phrase chaining the relations *author of paper that cites paper_name*
	Entity Type: `Paper`	
r_7	`RelVP`↦*cites* `ConstantFn (string paper.cites_author)`	Verb phrase chaining the relations *Paper that cites paper by Alan Turing*
	Entity Type: `Venue`	
r_8	`RelNP`↦*topic* `ConstantFn (string venue.keyphrase)`	Noun phrase in multi-hop relation *topic of ACL*, chaining the two relations *topic of paper published in ACL*
r_9	`Prep`↦*in* `ConstantFn (string venue.keyphrase)`	Prepositional phrase describing the same relation (*e.g. Venue in NLP*)
	Entity Type: `Journal`	
r_{10}	`RelNP`↦*topic* `ConstantFn (string venue.keyphrase)`	Noun phrase in multi-hop relation *topic of Nature*, similar to the one for venues.
r_{11}	`Prep`↦*in* `ConstantFn (string venue.keyphrase)`	Prepositional phrase describing the same relation
	Comparative Relations	
r_{12}	`ComparativeLtPREP`↦*published before* `ConstantFn (string paper.publication_year)`	Comparative prepositions to describe publication dates
r_{13}	`ComparativeGtPREP`↦*published after* `ConstantFn (string paper.publication_year)`	Comparative prepositions to describe publication dates
	Superlative Relations	
	Entity Type: `Paper`	
r_{14}	`SuperlativeAdj`↦*most recent | first* `ConstantFn (string paper.publication_year)`	Superlative adjectives to describe publication dates
r_{15}	`SuperlativeMinAdj`↦*most cited* `ConstantFn (string paper.citation_count)`	Superlative adjectives to describe the a paper's citations
	Entity Type: `Keyphrase`	
r_{16}	`CountSuperlativeNP`↦*the most popular topic for* `ConstantFn (string keyphrase.paper)`	Superlative form to refer to the most frequent keyphrase for a set of paper, *e.g. the most popular topic for paper in ACL*
	Entity Type: `Venue`	
r_{17}	`MultihopCountSuperlativeNP`↦*the most popular venue for* `ConstantFn (string venue.keyphrase)`	Superlative form to refer to the most popular venue for paper about a topic, *e.g. the most popular venue for paper in deep learning*
	Entity Type: `Dataset`	
r_{18}	`MultihopCountSuperlativeNP`↦*the most popular dataset for* `ConstantFn (string dataset.paper)`	Superlative form to refer to the most popular dataset used by a set of paper

Table 9: List of example idiomatic productions used in SCHOLAR (to be continued in Table 10).

(*e.g.* an author *X*).

Id	Production Body (LHS↦RHS and Semantic Function)	Description
	Superlative Relations (cont'd)	
	Entity Tyle: `Author`	
r_{19}	`SuperlativeMinAdj`↦*most cited* `ConstantFn (string author.citation_count)`	Superlative adjectives to describe the an authors citations, *e.g.*, *most cited author in deep learning*
r_{20}	`MacroVP`↦*publish mostly in*	Superlative form of the verb relational phrase *Author that publish mostly in ACL* with complex computation. `countSuperlative` returns the entity `x` in `venue` for which the papers in `x` (via relation `venue.paper`) has the largest intersection with papers by `author` (via realtion `author.paper`)

```
lambda author, venue (
  call countSuperlative
    (var venue)
    (string max)
    (string venue.paper)
    (call getProperty (var author) (string author.paper))
  )
```

Id	Production Body (LHS↦RHS and Semantic Function)	Description
r_{21}	`MacroVP`↦*publish mostly in* `lambda author, journal ...`	Similar relation for journals.
r_{22}	`MacroVP`↦*publish mostly in* `lambda author, keyphrase ...`	Similar relation for topics of paper.
r_{23}	`MacroVP`↦*cites `$NP` the most* `lambda author, author ...`	*e.g. Author that cites Alan Turing the most.*
r_{24}	`MacroVP`↦*cites `$NP` the most* `lambda author, paper ...`	*e.g. Author that cites semantic parsing paper the most.*
r_{25}	`MacroVP`↦*cites the most* `lambda author, paper ...`	Similar expression in reversed form.*e.g. Author that semantic parsing paper cites the most.*
r_{26}	`MacroNPPrep`↦*The most productive author for* `lambda author, paper ...`	*e.g. The most productive author for paper in deep learning*

Table 10: List of example idiomatic productions used in SCHOLAR (continued). Semantic functions are simplified for illustration purpose. Refer to `https://github.com/percyliang/sempre/blob/master/TUTORIAL.md` for more details on λ-calculus SCFGs.

Id	Production Body (LHS↦RHS and Semantic Function)	Description
	Multi-hop Relations	
r_1	`RelPrep`↦*in* `ConstantFn (string city.located_in_country)`	Prepositional phrase for multi-hop relation *cities in the US*, chaining the two relations *city in state in the US*
r_2	`RelPrep`↦*in* `ConstantFn (string mountain.located_in_country)`	Prepositional phrase for multi-hop relation *mountains in the US*
r_3	`RelPrep`↦*in* `ConstantFn (string river.located_in_country)`	Prepositional phrase for multi-hop relation *rivers in the US*
r_4	`RelPrep`↦*in* `ConstantFn (string place.located_in_country)`	Prepositional phrase for multi-hop relation *places in the US*
	Superlative Relations	
r_5	`SuperlativeAdj`↦*longest* `ConstantFn (string river.length)`	Superlative adjectives to describe the length of rivers.
r_6	`SuperlativeMinAdj`↦*shortest* `ConstantFn (string river.length)`	Superlative adjectives to describe the length of rivers.
r_7	`SuperlativeAdj`↦*highest* `ConstantFn (string mountain.elevation)`	Superlative adjectives to describe the elevation of mountains.
r_8	`SuperlativeMinAdj`↦*lowest* `ConstantFn (string mountain.elevation)`	Superlative adjectives to describe the length of rivers.
r_9	`SuperlativeAdj`↦*highest* `ConstantFn (string place.elevation)`	Superlative adjectives to describe the elevation of mountains.
r_{10}	`SuperlativeMinAdj`↦*lowest* `ConstantFn (string place.elevation)`	Superlative adjectives to describe the length of rivers.
r_{11}	`SuperlativeNP`↦*the longest length* `ConstantFn (string river.length)`	Noun phrase used in superlative queries for the length of rivers, *e.g.*, *river in Washington that has the longest length*
r_{12}	`SuperlativeNP`↦*the highest elevation* `ConstantFn (string mountain.elevation)`	For querying the elevations of mountains.
r_{13}	`SuperlativeNP`↦*the highest elevation* `ConstantFn (string place.elevation)`	For querying the elevations of places.

Table 11: List of idiomatic productions used in GEO

C Model Configurations

Paraphraser We finetune the paraphraser using a batch size of $1,024$ tokens for $5,000$ iterations (500 for warm-up), with a learning rate of $3e-5$ using ADAM. We apply label smoothing with a probability of 0.1.

Semantic Parser Our semantic parser is a neural sequence-to-sequence model with dot-product attention (Luong et al., 2015), using a BERT$_{\text{Base}}$ encoder and an LSTM decoder, augmented with copying mechanism. The size of the LSTM hidden state is 256. We decode programs using beam search with a beam size of 5. Following Herzig and Berant (2019), we remove hypotheses from the beam that leads to error executions.

Iterative Training As described in §3.1.1, we first run the iterative paraphrasing and training algorithm for one pass to generate the validation set. In the first iteration of this stage, we train a semantic parser on the (unparaphrased) seed canonical data ($\mathbb{D}_{\text{can}}$) as the initial paraphrase filtering model. In the second stage, we restart the learning process using the generated validation set, and initialize the paraphrase filtering model using the previously trained semantic parser. For each stage, we run the iterative learning algorithm (§2) for two iterations. We generate 10 paraphrases for each example. In each iteration, we train the semantic parser for 30 epochs with a batch size of 64. We use separate learning rates for the BERT encoder ($3e-5$) and other parameters (0.001) in the model (Shaw et al., 2019). For each iteration in the second stage, we perform validation by finding the model checkpoint that achieves the lowest perplexity on the validation set. We perform validation using perplexity for efficiency reasons, as evaluating denotation accuracy requires performing beam search decoding and querying the database, which could be slow.

Evaluation Metric For the perplexity metric to evaluate language gaps, we fine-tune a GPT-2 language model on the paraphrased canonical data $\mathbb{D}_{\text{par}}$ for $1,500$ steps (150 steps for warm-up) with a batch size of 64 and a learning rate of $1e-5$. We use the following equation to compute perplexity

$$\text{PPL}(\mathbb{D}_{\text{nat}}) = \exp\big(\frac{1}{|\mathbb{D}_{\text{nat}}|} \sum_{\langle \boldsymbol{u},\boldsymbol{z}\rangle \in \mathbb{D}_{\text{nat}}} \frac{-\log p(\boldsymbol{u})}{|\boldsymbol{u}|}\big) \tag{1}$$

This is slightly different from the standard corpus-level perplexity. We use this metric because it is more sensitive (larger Δ) on our small ($< 1K$) evaluation sets, and always correlates with the corpus-level perplexity. For reference, here is the sequence of perplexities using Eq. (1) in the upper half of Tab. 12 compared to the corpus-level ones:

Eq. (1)	22.0	21.4	20.9	20.7	21.5
Corpus-PPL	19.3	18.8	18.4	18.2	18.8

D Does the Model Generalize to Out-of-Distribution Samples?

We also investigated whether the model could generalize to utterances with out-of-distribution program patterns not seen in the training data $\mathbb{D}_{\text{par}}$. We report accuracies on the splits whose program templates are covered (**In Coverage**) and not covered (**Out of Coverage**) by $\mathbb{D}_{\text{par}}$. Not surprisingly, the model performs significantly better on the in-coverage sets with less language mismatch. An exception is $K{=}500$ on SCHOLAR, where the perplexity on out-of-coverage samples is slightly lower. This is because utterances in SCHOLAR tend to use compound nouns to specify compositional constraints (*e.g. ACL 2021 parsing papers*), a language style common for in-coverage samples but not captured by the grammar. With smaller K and $\mathbb{D}_{\text{can}}$, it is less likely for the paraphrased data $\mathbb{D}_{\text{par}}$ to capture similar syntactic patterns. Anther factor that makes the out-of-coverage PPL smaller when $K = 500$ is that there are more (simpler) examples in the set compared to $K > 500$, and the relatively simple utterances will also bring down the PPL.

Our results are also in line with recent research in compositional generalization of semantic parsers (Lake and Baroni, 2018; Finegan-Dollak et al., 2018), which suggests that existing models generalize poorly to utterances with novel compositional patterns (*e.g.* conjunctive objects like *Most cited paper by X and Y*) not seen during training. Still surprisingly, our model generalizes reasonably to compositionally novel (out-of-coverage) splits, registering $30\%{\sim}50\%$ accuracies, in contrast to HB19 reporting accuracies smaller than 10% on similar benchmarks for OVERNIGHT. We hypothesize that synthesizing compositional samples increases the number of unique program templates in training, which could be helpful for compositional generalization (Akyürek et al., 2021). As an example, the number of unique program templates in $\mathbb{D}_{\text{par}}$ when $K = 2,000$ on SCHOLAR and GEO is $1.9K$ and $1.7K$, resp, compared to only 125 and 187 in $\mathbb{D}_{\text{nat}}$. This finding is reminiscent of data augmentation strategies for supervised parsers using synthetic samples induced from (annotated) parallel data (Jia and Liang, 2016; Wang et al., 2021b).

	K	ACC	In Coverage ACC	 PPL	Out of Coverage ACC	 PPL
SCHOLAR	500	74.0 ±3.7	82.3	23.4	47.6	18.2
	1,000	75.9 ±1.7	81.4	21.3	50.6	21.7
	2,000	77.8 ±2.2	82.2	20.7	50.2	22.7
	4,000	78.4 ±1.7	83.2	20.5	45.3	22.0
	8,000	75.5 ±2.1	79.8	21.4	43.4	22.4
GEO	500	61.6 ±5.4	79.2	7.6	29.8	9.9
	1,000	68.5 ±7.7	81.4	7.4	28.8	11.3
	2,000	72.8 ±2.8	82.0	7.4	37.6	10.8
	4,000	67.5 ±6.3	75.5	7.6	38.8	11.2
	8,000	67.9 ±4.5	75.5	7.5	41.3	11.2

Table 12: Results on SCHOLAR and GEO with varying amount of canonical examples in the seed training data. We report results on **In Coverage** splits where the program templates of evaluation samples appear in the canonical training data, as well as on **Out of Coverage** splits with disjoint program templates.

Bias Mitigation in Machine Translation Quality Estimation

Abstract

Machine Translation Quality Estimation (QE) aims to build predictive models to assess the quality of machine-generated translations in the absence of reference translations. While state-of-the-art QE models have been shown to achieve good results, they over-rely on features that do not have a causal impact on the quality of a translation. In particular, there appears to be a partial input bias, i.e., a tendency to assign high-quality scores to translations that are fluent and grammatically correct, even though they do not preserve the meaning of the source. We analyse the partial input bias in further detail and evaluate four approaches to use auxiliary tasks for bias mitigation. Two approaches use additional data to inform and support the main task, while the other two are adversarial, actively discouraging the model from learning the bias. We compare the methods with respect to their ability to reduce the partial input bias while maintaining the overall performance. We find that training a multitask architecture with an auxiliary binary classification task that utilises additional augmented data best achieves the desired effects and generalises well to different languages and quality metrics.

1 Introduction

Despite the great advances of Machine Translation (MT) models over the past years, the adequacy and fluency of the translations cannot be guaranteed. Without access to a gold-standard reference translation, it can be difficult to validate the reliability of the MT model's predictions. To address this issue, the field of MT Quality Estimation (QE) emerged, aiming to develop models that can approximate the quality of machine-generated translations in a scalable way. However, recent research suggests that state-of-the-art QE approaches tend to over-rely on features that do not have a causal impact on the quality of a translation. In particular, there appears to be a partial input bias, i.e. a tendency to assign high quality scores to translations that are fluent and grammatical, even though they do not resemble the actual meaning of the source (Sun et al., 2020).

Building upon these findings, the objective of our work is to characterise and, most importantly, mitigate the partial input bias of QE models. We focus on the use of auxiliary training tasks to specifically target the observed biases while avoiding strong modifications of the original model as well as the expensive collection and manual labelling of additional training data. Our efforts concentrate on testing and improving *MonoTransQuest*, the best-performing architecture in the shared task on sentence-level QE hosted as part of the *Fifth Conference on Machine Translation (WMT 2020)* (Specia et al., 2020). We work with the recently published multilingual QE dataset *MLQE-PE* (Fomicheva et al., 2020), allowing us to test the generalisability of our approaches across different languages and quality scores.

Our main **contributions** are as follows:

- **Bias analysis.** We expand on previous research which suggested the partial input bias in QE and find that the model as well as the annotators tend to over-rate the quality of fluent but inadequate translations.
- **Bias mitigation.** To the best of our knowledge, we are the first to explore the mitigation of biases with auxiliary tasks in the field of QE. We group our approaches into four categories: Multitask training with mixed languages, multitask training with additional augmented data, training with adversarial tasks and training with debiased focal loss.
- **New architectures.** We implement and compare several multitask architectures and find that iteratively training the tasks with two optimisers is better suited for our objective than backpropagating a weighted sum of the losses. Further, we reformulate focal loss for regres-

May 22-27, 2022

sion tasks, a technique that is traditionally based upon the cross-entropy loss.

- **Results.** Utilising the multitask architecture, we successfully reduce the partial input bias while maintaining the same performance as the benchmark model and examine the best model's robustness.

In the subsequent sections, we first present related work, followed by the analysis of the partial input bias. Building upon the findings, we explain the four bias mitigation approaches in Section 4 and discuss the results in Section 5.

2 Related Work

2.1 Machine Translation Quality Estimation

QE is an area of research concerned with the development of models for the prediction of the quality of machine-generated translations when gold standard translations are not available. QE is normally addressed as a supervised machine learning task, which may take as input general information from the source and translated texts, as well as from the MT system. The quality is typically assessed at sentence level, but word- and document-level QE are also possible (Specia et al., 2018, pp. 2). Sentence-level QE has evolved from the first feature-heavy prediction models (Blatz et al., 2004) to neural architectures such as RNNs and Transformers (Vaswani et al., 2017), which accelerated the developments in the field by reducing the work of manual feature engineering and improving contextual representations (Kim et al., 2017; Wang et al., 2018; Fan et al., 2019).

A prominent state-of-the-art QE architecture is MonoTransQuest, proposed by Ranasinghe et al. (2020). It builds upon XLM-R, a popular pretrained cross-lingual language model with a good ability to generalise to low-resource languages (Conneau et al., 2020). MonoTransQuest achieved the best results for sentence-level direct assessment score prediction in the WMT 2020 shared task on QE (Specia et al., 2020).

Sun et al. (2020) showed that QE models like MonoTransQuest have a tendency to over-rely on spurious correlations, which is partially due to skewed label distributions and statistical artifacts in QE datasets. In particular, they show the existence of a partial input bias, i.e. the tendency to predict the quality of a translation based on just the target sentence (Poliak et al., 2018). While the fluency and grammatical correctness of the output is a factor influencing the quality, the original meaning should be preserved, which is only possible if the model takes both source and target into consideration. Following their work, in an attempt to reduce statistical artifacts, MLQE-PE (Fomicheva et al., 2020) – a new QE dataset diversifying the topics and languages covered – was created, which forms the basis of this work and will be described in more detail in Section 3.1.

2.2 Bias Mitigation with Auxiliary Tasks

We define auxiliary tasks in a broad sense, using the term to refer to settings where a main task is trained alongside one or more helper tasks used to improve the main task's performance and generalisability. Most commonly, the tasks are trained in a multitask-setting, where some layers are shared across the tasks and some layers are task-specific. The auxiliary tasks can either be *related* to the main task or *adversarial* (Ruder, 2017). In addition, we consider the concept of *debiased focal loss*, where the main and auxiliary task are trained in separate models which are connected via the loss function (Karimi Mahabadi et al., 2020).

Related Tasks: In settings where the data is limited, noisy or high-dimensional, using additional tasks is a way of introducing an inductive bias that prevents the model from overfitting to noise (Caruana, 1997). In addition, the model might be able to use new features that were learned through an auxiliary task for the main task as well (Ruder, 2019). MT models, for example, have been shown to benefit from auxiliary tasks such as named entity recognition, part-of-speech tagging and dependency parsing (Niehues and Cho, 2017; Kiperwasser and Ballesteros, 2018).

Adversarial Tasks: Adversarial tasks can be used to actively discourage the model from overfitting to domain-specific, spurious cues. The technique was introduced by Ganin and Lempitsky (2015) and used for domain adaptation. More recently, it has been successfully used to reduce partial input biases in different fields of NLP, such as natural language inference (NLI) (Belinkov et al., 2019; Stacey et al., 2020) and visual question answering (VQA) (Ramakrishnan et al., 2018). The core idea is to train the auxiliary task using just the partial input. During backpropagation, the gradient is reversed. Consequently, the shared layers are updated such that the adversary's loss is maximised;

the undesired behaviour is penalised. The methodology chapter illustrates the architectural design in more detail.

Debiased Focal Loss: Another approach that has recently been used to mitigate known biases, particularly partial input biases, is debiased focal loss. The notion of focal loss was first introduced by Lin et al. (2017) as a means to improve classification results on imbalanced classes by weighing down the impact of samples that the model had already learned to classify well. In the field of NLI, Karimi Mahabadi et al. (2020) have shown that it is possible to adapt the notion of focal loss to mitigate partial input biases. They train the main model alongside a bias model that learns to predict the label based on the hypothesis only. In this scenario, the bias model's predictions are used to weight the main model's cross-entropy loss. Intuitively, samples that are classified well by the bias model are weighted down so that the main model primarily learns from less biased inputs. The bias model is updated separately and discarded after training.

3 Bias Analysis

In the following, we will describe the dataset and baseline model used, show benchmark results and analyse the partial input bias in more detail.

3.1 Dataset

We work with the MLQE-PE dataset (Fomicheva et al., 2020) which was specifically designed for the training of MT QE models. Published in 2020, it formed the basis for the WMT 2020 and 2021 shared tasks on Quality Estimation (Specia et al., 2020).[1] It consists of 6 high-, mid- and low-resource language pairs which originate from Wikipedia articles: English-German and English-Chinese, Romanian-English and Estonian-English as well as Nepalese-English and Sinhala-English. A seventh dataset, Russian-English, was curated from Reddit posts and WikiQuotes. The translations were generated using Transformer-based Neural MT models. For each language, 9000 sentence pairs (7000 train, 1000 dev, 1000 test) were annotated on two different scales:

- **Human-targeted Translation Edit Rate (HTER)**: Each sentence-pair was edited by two independent translators. The reported HTER score is the averaged edit rate comparing the machine-generated translations and the post-edited versions. The score ranges between 0 (perfect translation) to 1 (everything was edited).
- **Direct Assessment Scores (DA)**: Each sentence pair was judged on a scale from 0-100 by at least 3 evaluators. The reported DA score is the mean of the individual judgements. Different than the HTER scores, the DA scale provides a measure of the severity of the errors, where inadequate (i.e. non-meaning preserving) translations should not receive a score higher than 70, even if only one word is incorrect.

3.2 Benchmark

We use the XLM-R based architecture MonoTransQuest as our baseline model, which fine-tunes XLM-R for sentence-level QE (Ranasinghe et al., 2020). While there are alternative candidates with a good performance on QE tasks, MonoTransQuest was chosen for several reasons: State-of-the-art performance, availability and replicability (all hyperparameters and the source code are open-sourced), as well as the generic design of the architecture which is transferable to related NLP domains.

We train separate MonoTransQuest models for each combination of language pair and quality score using the originally proposed architecture and fine-tuned hyperparameters specified in the TransQuest GitHub repository.[2] All experiments were conducted on a 16GB Nvidia Tesla P100 GPU and averaged across five trainings on the seeds 555, 666, 777, 888 and 999. Our results are shown in Table 3 in the Appendix. In QE, the best practice is to use Pearson's r to measure performance (Specia et al., 2018, pp. 58). Most notably, the Pearson correlation between the predictions and the labels is lowest for the high-resource languages English-German and English-Chinese. This has also been observed in the QE shared task findings (Specia et al., 2020). A possible explanation is the high average quality of the generated translations, making the labelling significantly harder and the annotations less consistent, i.e. more noisy.

3.3 Partial Input Bias

We examine the partial input bias by training the model on the combined representation of source

(a) DA predictions

(b) HTER predictions

Figure 1: Relative decrease of the correlation between prediction and labels when testing with source or target, only.

and target and testing how the performance changes when the prediction is based on only one of the two. If the performance does not significantly decrease, the model has likely learned to base its predictions mostly on one part of the input. Figure 1 shows the results from this experiment. A clear target sentence bias can be observed for the English-German and English-Chinese language pairs. One reason could be the good quality of the translations that MT systems generate for high-resource languages: The occurrence of adequacy errors is lower, so that the target sentence may suffice for a decent prediction. In contrast, the mid-resource Romanian-English model, which shows the best overall performance, appears to be most dependent on both inputs. Figure 1 shows a clear performance deterioration when the model is tested on just the source or target sentence. One particularity of the RO-EN dataset is the high abundance of fluent, but clearly inadequate translations and hallucinations which require both the source and translation to be detected (Specia et al., 2020). The Russian-English dataset is an exception where the source sentence is a good predictor for the translation quality, most likely due to the distinct nature of Reddit data and WikiQuotes (both user-generated). This source sentence bias could best be mitigated by curating a new dataset which is why we chose not to focus our efforts on the Russian-English dataset.

To further examine the nature of the partial input bias, an in-depth analysis of the strongly affected English-German translations was conducted. In particular, the aim was to better understand how MonoTransQuest, but also the annotators, judge the quality of fluent but inadequate translations. To achieve this, one of the authors, a German native speaker, manually annotated translations in the test set that are grammatically correct but do not preserve the meaning of the source.[3]

In total, 145 out of 1000 translations were marked as fluent but inadequate. A key takeaway from the labelling process was that it is not only the models that have a partial input bias – human annotators clearly seem to over-rely on the target fluency, too. Even if the instructions clearly specify that a DA score below 70 should be assigned to inadequate translations,[4] annotators tended to give higher scores if the sentence was fluent and appeared logical. Figure 2 shows that more than half of the fluent but inadequate translations were given a score higher than 70, with an average rating of 81.[5] A likely reason is that adequacy-related mistakes are easy to miss when considering several quality factors, i.e. spelling, grammar and content, at the same time.

4 Methodology

Based on the bias analysis, our goal is to find an effective and feasible way to reduce the impact of spurious correlations and overly dominant features. As outlined in the previous section, the two high-resource datasets (EN-DE and EN-ZH) clearly show the strongest partial input bias. They will therefore be at the centre of the bias mitigation efforts. All four methods presented hereinafter share the core idea of using auxiliary tasks to achieve this aim: The main task – QE – is combined with helper tasks designed to reduce known

---

[3] The annotated dataset is available via `https://github.com/agesb/TransQuest`

[4] The DA annotation guidelines used in the MLQE-PE data dictate that a score in 70–90 indicates a translation that closely preserves the semantics of the source sentence.

[5] The HTER score was not examined in this analysis since it does not explicitly account for the adequacy of the translation.

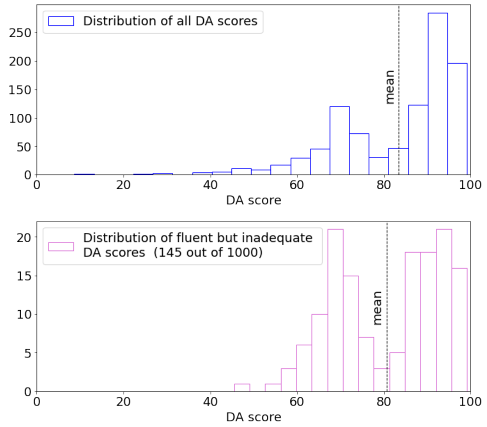

Figure 2: DA label and prediction distribution of fluent but inadequate translations.

biases. At test time, the auxiliary tasks can be discarded. Hereinafter, we introduce four approaches and the corresponding model architectures. The first two methods are tailored to combat the biased behaviour by supporting the model with additional data. In contrast, the two alternative, restrictive approaches actively penalise the model for learning unwanted behaviour. We define three criteria to ensure comparability between the approaches: A good solution should 1) mitigate the observed biases, 2) retain the prediction quality of the benchmark model, and 3) avoid computational overhead and interference with the original model's design.

4.1 Supportive Approaches

We experiment with two different supporting tasks, each combining the main task and the auxiliary task in a multitask setup. The first approach is to train with different language pairs, aiming to transfer information between the language domains. Instead of mixing the languages arbitrarily, we build upon the bias analysis and examine if using a less biased language (RO-EN) to train the auxiliary task can help to reduce biases in the main task (EN-DE or EN-ZH). The bias analysis clearly showed that the models trained on the RO-EN dataset performed poorly when using just the source or target as input, indicating that the predictive power of the individual sentences is low. Thus, the incentive for the multitask model to over-rely on the target should be reduced. In this scenario, both tasks are regression problems and optimise the MSE loss.

The second approach is to collect additional translations originating from the same topic and language domain and use it as the input for the auxiliary task. We choose WikiMatrix (Schwenk et al., 2021), a large parallel sentence corpus based on Wikipedia articles, as data source for the experiments. Without further preprocessing, the vast majority of these sentence pairs would qualify as good translations. While labelling on a continuous scale would require manual annotations, augmenting the data to achieve "bad" translations is more feasible. Hence, we augment 50% of the data to obtain bad translations. We experiment with two augmentation strategies: First, we shuffle the sentences to create mismatched sentence pairs. Second, we augment the sentence to mimic fluent but inadequate translations as seen in the original MLQE-PE dataset and discussed in Section 3.3. To do so, we implement a contextual augmentation pipeline that uses a language model (XLM-R) to replace 30% of the nouns, adjectives, verbs and adverbs such that the meaning of the sentence is changed while the grammatical correctness is preserved in the majority of cases.[6] In both cases, the main task optimises the MSE loss, and the auxiliary task is a binary classification problem using the binary cross-entropy loss.

4.2 Restrictive Approaches

We experiment with two setups that directly penalise the biased behaviour. First, we combine the main task with an adversarial task in a multitask architecture. Intuitively, the adversary is incentivised to predict the quality scores based on the target sentence only. The shared layers, on the other hand, are penalised for learning a mapping between target sentence and scores. The risk of working with an adversarial task setup is that it optimises towards eliminating all cues associated with the adversary. In QE, however, the target sentence provides relevant information, such as grammar and spelling. As a result, the overall model performance might suffer. As an alternative to training with adversarial tasks and a multitask architecture in general, we repurpose the concept of debiased focal loss for regression. While model architecture and training method are different, the underlying idea to use the partial input based predictions to influence the learning remains the same. The subsequent section explains the multitask architecture used for the first three approaches as well as the re-formulated debiased focal loss technique in more detail.

---

[6] The augmentation pipeline was published as part of the NL-Augmenter library (Dhole et al., 2021): `https://github.com/GEM-benchmark/NL-Augmenter/tree/main/transformations/contextual_meaning_perturbation`

4.3 Architecture & Training

4.3.1 MultiTransQuest

To realise the first three approaches, we propose the architecture *MultiTransQuest*, expanding on the MonoTransQuest baseline. The pre-trained language model XLM-R remains at the core and is entirely shared between tasks. The two key changes affect the final layers and the optimisation strategy: Firstly, we exchange the original prediction head to support multiple tasks. As illustrated in Figure 3, the final layers and loss functions are separate per task, thus allowing the mixing of regression and classification tasks. The figure exemplarily shows the adversarial setup, where the gradients are reversed during back-propagation, i.e. weighted with -1. For the two supportive tasks, we use the same setup but remove the weighted gradient layers and adjust the input and loss function for the auxiliary tasks accordingly. We experiment with different numbers of shared and separate layers. Secondly, we adapt the training procedure to support multiple tasks. The data loader is designed so that it alternates between the tasks per training step, with each batch containing only samples for one task which are then passed through the shared layers and the corresponding task-specific layers. We compare two optimisation strategies:

- Training the tasks in turns, where backpropagation is performed per batch and task. Each task works with a separate AdamW optimizer to avoid averaging gradients across tasks.
- Performing one forward pass for every task and combining the calculated losses as a weighted sum which is backpropagated through all layers using a single optimizer.

4.3.2 Debiased Focal Loss Architecture

In contrast to the previously discussed multitask approaches, debiased focal loss enables a complete separation of the main model and bias model, thus requiring no changes to the core MonoTransQuest architecture. To the best of our knowledge, (debiased) focal loss has only been applied to classification tasks so far as it explicitly modifies the cross-entropy loss function. Since our QE task is formulated as a regression problem, we attempt to find an equivalent strategy to weigh down biased examples when working with MSE loss. In our scenario, the bias model is trained on partial inputs, receiving the translated sentence only. The better the bias model's prediction, the lower the MSE and the more biased the sample. In line with the original debiased focal loss idea, we can therefore use the bias model's loss as an indication for the bias per sample.

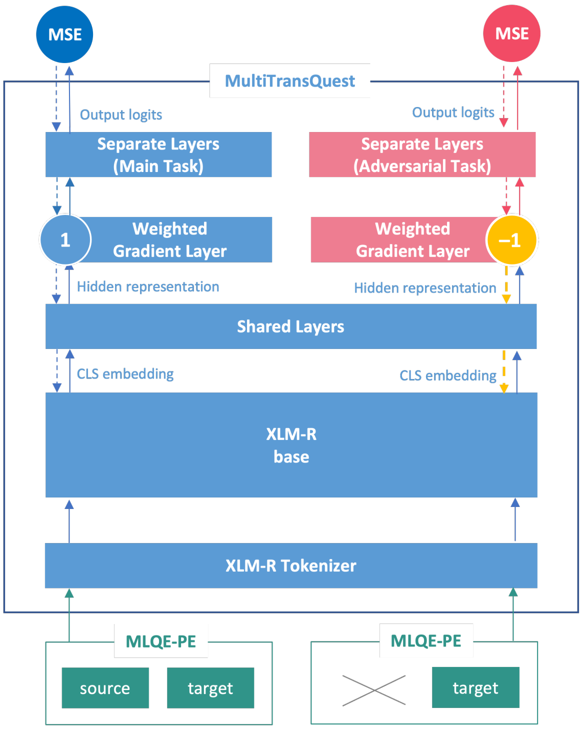

Figure 3: Multitask architecture with gradient reversal.

As the MSE loss can vary greatly during training, we decide against training both models in an end-to-end approach. First, the trained bias model is used to predict the respective quality scores for the training set, using only the target. Next, the absolute error for each of the training samples is calculated. We use the error to approximate the partial input bias: The lower the error, the easier it is for the bias model to predict the sample's quality score correctly. To control the scale of the weights, we normalise the error value between 0 and 1. The resulting weights w are used to scale the MSE loss of the main model f_M before backpropagation. We use the hyperparameter β to exponentially scale the loss (Eq. 1). We further experiment with a sigmoid-shaped function scaled between 0 and 1 (Eq. 2).

$$\mathcal{DFL} = w^{\beta}\left(f_M^{y_i}(\boldsymbol{x_i}) - \hat{y}_i\right)^2 \qquad (1)$$

$$\mathcal{DFL} = \frac{1}{1+\left(\frac{w}{1-w}\right)^{-\beta}}\left(f_M^{y_i}(\boldsymbol{x_i}) - \hat{y}_i\right)^2 \qquad (2)$$

Table 1: **Results**. Comparison of the four bias mitigation approaches. Column *r* shows the mean Pearson correlation of labels and predictions and the standard deviation over 5 runs, each training for 3 epochs = 15 minutes. Column *MSE* is the average mean squared error. Column *r target* measures the performance when testing on the target sentence only and thus approximates the bias mitigation effect, where a smaller correlation is better.

5 Results

In the following, we present and discuss the results of the experiments conducted. Based on the analysis in Section 3.3, the experiments concentrate on the two most biased datasets English-German and English-Chinese, each in combination with the DA and HTER scores. For each of the four sections, we assess different hyperparameter configurations on the EN-DE validation set. A configuration is considered to be good if the bias is reduced and the overall performance is at least maintained. The most promising variant is then evaluated on the EN-DE and EN-ZH test set, to see if the method generalises across language domains. Finally, we compare the four methods against one another and provide further analyses on the robustness of the best-performing model. [7]

5.1 Hyperparameters and Design Choices

Within each of the four approaches, we experiment with different hyperparameter configurations and design choices. While each setup requires individual fine-tuning, observed trends, backed by Table 4, 5, 6, 7 and 8 in the Appendix, include:

- For the multitask architecture, training the tasks in turns with separate optimisers results in a good balance between bias reduction and maintaining performance. Backpropagating the weighted loss is also possible, but requires more task-specific fine-tuning.
- For supportive auxiliary tasks, more separate layers, i.e. a larger degree of freedom, and a larger batch size improve the performance, for adversarial tasks the opposite is the case.
- When augmenting additional WikiMatrix data, shuffling the sentence pairs achieves better results than mimicking fluent but inadequate translations with contextual augmentation.
- The effect of the debiased focal loss technique is limited. A sigmoid-shaped weight distribution does not improve the results.

5.2 Comparison of the Four Approaches

Table 1 summarises the results obtained for each of the four methods. With respect to the choice of architecture, MultiTransQuest, used for methods 1-3, reduces the partial input bias more effectively than MonoTransQuest trained with focal loss. A key advantage of the multitask architecture is that the model is able to learn a balance between the tasks. In contrast, the degree of freedom is significantly limited for the focal loss architecture, where the main hyperparameter is how to scale the weights. We believe that this limitation is what makes the model even more sensitive to the inseparability of the bias and helpful features.

Contrasting the multitask-training with related or adversarial tasks, we find that the two supportive methods maintain a solid performance across all four constellations, while also reducing the bias. Compared to this, the adversarial approach gen-

---

[7] For reproducibility of the experiments, the source code incl. configurations is published under `https://github.com/agesb/TransQuest`. All hyperparameters not explicitly mentioned in the paper were kept constant.

eralises less well, despite its successful application in NLI and VQA. We hypothesise that this discrepancy is rooted in the nature of the partial inputs: In VQA as well as NLI, the task can only be solved when considering both question and image or premise and hypothesis, respectively. In contrast, the translation provides information that is valuable for the QE model regardless of the source, such as the fluency of the generated sentence. Hence, it is difficult to isolate the bias from valuable information, an assumption that both adversarial training and the focal loss technique rely on. Without an unbiased reference dataset (which is hard to acquire due to the subjective nature of the annotation process) the line between desired information and bias is difficult to quantify. The lower the correlation between the existence of the bias and the performance of the adversarial task, the noisier the feedback that is propagated into the shared layers.

The best trade-off between overall performance and bias reduction is achieved with MultiTransQuest when combining the main task with a binary classification task trained on shuffled WikiMatrix data. The binary classification task is simple to learn, yet impossible to solve without paying equal attention to source and translation. For better illustration of the model behaviour and improvements, Figure 6 in the Appendix directly compares the performance and bias reduction achieved by the best model to the benchmark. In addition, Figures 7 and 8 show the distribution of DA and HTER predictions generated by the debiased model.

Since the reduction of the performance on the target sentence is only considering the reduction of the partial input bias, we additionally aim to test the model's ability to generalise better on datasets that barely exhibit the partial input bias. As a feasible alternative to collecting an unbiased reference dataset in the same language domain, we assess the models' robustness in a zero-shot setting on less biased RO-EN data. As elaborated on in Section 3.3, the RO-EN dataset provokes the partial input bias significantly less than the other language pairs. Consequently, a model with reduced partial input bias should perform better when tested on the dataset, indicating improved robustness. We train the MonoTransQuest benchmark and debiased MultiTransQuest architecture on the EN-DE and EN-ZH datasets and use these models to predict the respective scores on the RO-EN dataset. Since this is an out-of-domain setting, we do not expect the models to reach a performance that can compete with the models trained on Romanian-English data. However, the debiased MultiTransQuest models should outperform MonoTransQuest in this zero-shot scenario, which is indeed the case as can be seen from Table 2.

	EN-DE model		**EN-ZH model**	
	DA	**HTER**	**DA**	**HTER**
MonoTQ	0.3756	0.3466	0.494	0.3650
MultiTQ	0.5601	0.3543	0.5226	0.4334

Table 2: Zero-shot prediction quality on the RO-EN dataset (Measured with Person's r).

6 Future Work

Building upon the previously discussed results, we propose ideas for future work. Considering the experimental design, the multitask architecture provides additional degrees of freedom that were not explored extensively, yet. For example, one could vary the amount of training per task or learn the training schedule as a parameter which adapts dynamically during the training process (Kiperwasser and Ballesteros, 2018; Zaremoodi et al., 2018). In addition, the number of auxiliary tasks could be increased to two or more, mixing different task types. To further evaluate the generalisability of the proposed methods, experiments with additional datasets, low-resource language pairs as well as alternative QE architectures and language models could be conducted, too.

Going beyond the field of Machine Translation Quality Estimation, it would be interesting to see the methods applied in adjacent areas of NLP. For example, this could entail closely related settings, such as quality estimation for machine-generated text summaries, as well as the fields of NLI and VQA, both of which face partial input biases. Other observable biases could also be considered as candidates for the use of targeted bias reduction techniques, provided that it is possible to design a counterbalancing auxiliary task or isolate the bias well enough to deploy adversarial approaches. We think that if the latter scenario applies, the adapted debiased focal loss technique for regression could be worth further exploration, too.

7 Conclusion

This paper expands on recent research which suggests that QE models are susceptible to learning spurious correlations. Based on additional analysis, and inspired by related work in the fields of NLI and VQA, we propose a range of auxiliary tasks that inform the main Quality Estimation task during training and are discarded at test time. First, we train the main Quality Estimation task together with additional, less biased data in a multitask setting. Then, we explore adversarial training and debiased focal loss to directly target the partial input bias. We find that the former approaches yield more stable results than the latter and conjecture that this is due to the difficulty of isolating partial input bias effects from useful predictive information encoded in the translation. We show that our proposed multitask architecture MultiTransQuest, especially when trained with additional shuffled WikiMatrix data, generalises well across the two most biased language pairs and the two different quality scores. Our method retains the overall prediction quality, reduces the observed biases significantly and increases the models' robustness in a zero-shot setting.

Abstract

We describe a method to jointly pre-train speech and text in an encoder-decoder modeling framework for speech translation and recognition. The proposed method incorporates four self-supervised and supervised subtasks for cross modality learning. A self-supervised speech subtask leverages unlabelled speech data, and a (self-)supervised text to text subtask makes use of abundant text training data. Two auxiliary supervised speech tasks are included to unify speech and text modeling space. Our contribution lies in integrating linguistic information from the text corpus into the speech pre-training. Detailed analysis reveals learning interference among subtasks. Two pre-training configurations for speech translation and recognition, respectively, are presented to alleviate subtask interference. Our experiments show the proposed method can effectively fuse speech and text information into one model. It achieves between 1.7 and 2.3 BLEU improvement above the state of the art on the MuST-C speech translation dataset and comparable WERs to wav2vec 2.0 on the LIBRISPEECH speech recognition task. [1]

1 Introduction

Pre-training can learn universal feature representations from a large training corpus and is beneficial for downstream tasks with limited amounts of training data (Peters et al., 2018; van den Oord et al., 2018; Chung et al., 2018; Zoph et al., 2020). With the advancement of computational power and self-supervised pre-training approaches, large volumes of unlabeled data may now be used in pre-training. Methods, such as BERT (Devlin et al., 2019), BART (Lewis et al., 2020b) and wav2vec2.0 (Baevski et al., 2020b), have emerged as the backbone of many speech and natural language processing tasks.

The aforementioned pre-training methods focus on learning feature representation either from text or speech. Many speech applications combine information learnt from both speech and text corpora to achieve state of the art results. In speech processing, transcribed speech training data is generally very scarce for many languages. It is difficult to build robust linguistic knowledge representation solely based on labeled speech training data. Jia et al. (2019); Chen et al. (2021) propose to generate synthetic data from text to augment speech training corpus. Li et al. (2021) demonstrate that models initialized with pre-trained wav2vec2.0 and mBART (Liu et al., 2020) modules are competitive for the multilingual speech to text translation task. Chuang et al. (2020) propose to concatenate the acoustic model and BERT model for speech Q&A. Chung et al. (2021b) align speech utterance representation to the corresponding text sentence representation, in which both representations are generated from unsupervised pre-trained models, for speech understanding.

In this study, we are interested in pre-training for speech to text tasks using the Attention based Encoder-Decoder (AED) framework. In particular, we seek to answer the question whether the integration of data from different modalities is beneficial for representation learning. To answer this question, we propose Speech and Text joint Pre-Training (STPT), a multi-task learning framework to combine different modalities, i.e., speech and text, in the pre-training stage. A self-supervised speech subtask and a (self-)supervised text to text subtask dominate the pre-training computation to leverage large amounts of unlabelled speech data and abundant text training corpus. Two auxiliary supervised speech subtasks are used to unify different modalities in the same modeling space. The proposed method fuses information from the text and speech training corpus into a single model, and it effectively improves the performance of down-

stream tasks, such as speech to text translation (ST) and automatic speech recognition (ASR). Our contributions are summarized as follows:

1. We propose a multi-task learning framework to learn four speech and text subtasks in one model and successfully integrate linguistic information from the text corpus into the speech pre-training.
2. We conduct detailed analyses on the proposed pre-training method, which reveal the interference among different subtasks.
3. Two joint pre-training configurations are proposed to alleviate learning interference for ASR and ST respectively.
4. State-of-the-art results are achieved on the downstream tasks. We obtain at least 1.7 BLEU improvement compared with the best MuST-C ST system reported and comparable WERs as wav2vec 2.0 in the LIBRISPEECH ASR task.

2 Related work

Pre-training: Self-supervised pre-training is usually optimized with two different criteria: contrastive loss (van den Oord et al., 2018; Chung and Glass, 2020; Baevski et al., 2020b) and masked prediction loss (Devlin et al., 2019). Contrastive loss focuses on distinguishing the positive samples from the negative ones given the reference sample and it has achieved great success for speech recognition (Baevski et al., 2020b). Masked prediction loss has been first studied for natural language processing tasks (Devlin et al., 2019; Lewis et al., 2020b) with subsequent application to speech processing (Baevski et al., 2020a; Hsu et al., 2021). Chung et al. (2021a) combine contrastive loss and masked prediction loss, which shows good performance for the downstream ASR task. The optimization of our self-supervised speech task is more related to the masked prediction loss. Instead of predicting the hard discretized label for the masked frames, which is error prone, we use KL divergence to minimize the distribution difference between the same feature frames with and without masking. Please refer to subsection 3.2 for more details.

Self-training (or iterative pseudo labelling): self-training is another widely used approach to take advantage of unlabelled speech data to improve the ASR performance (Kahn et al., 2020; Xu et al., 2020; Pino et al., 2020; Zhang et al., 2020; Wang et al., 2021a; Xiao et al., 2021; Wang et al., 2021b). A seed model, which usually is trained with a small amount of supervised speech training data, is employed to generate pseudo labels for the unlabelled speech data. The speech data with pseudo labels is augmented into the training dataset to build another model, which is expected to outperform the seed model due to more training data exposure. Similar to self-training, we also use small amounts of supervised data to unify the speech and text modeling space. However, the self-supervised speech training in this work avoids making hard predictions and uses KL divergence to maximize the mutual information between masked span and observed feature frames.

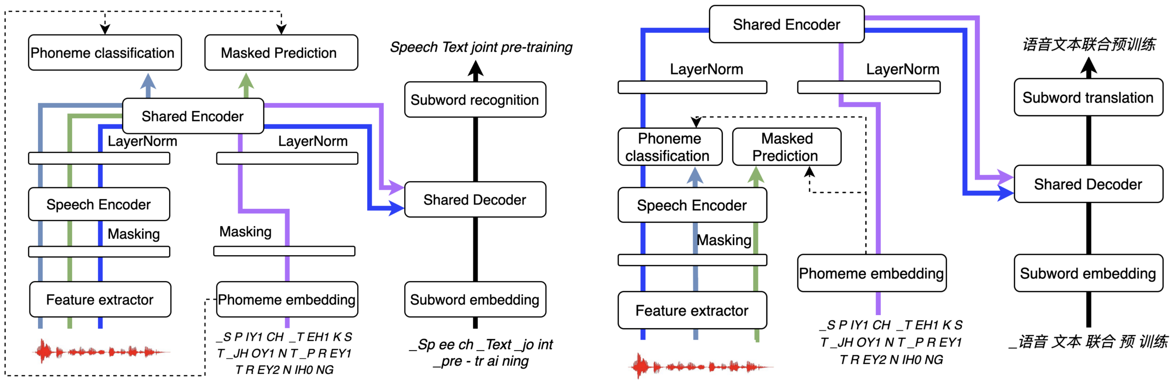
Multi-task learning: Due to data scarcity, multi-task learning is widely adopted to leverage parallel text training data for ST (Weiss et al., 2017; Anastasopoulos and Chiang, 2018; Tang et al., 2021b; Ye et al., 2021). Those methods primarily use supervised speech data sets during multi-task learning, whereas our method can leverage large amounts of unlabeled speech data during the pre-training stage, which has the potential to improve performance even further.

A concurrent work from Ao et al. (2021) also proposes to jointly pre-train speech and text for ASR and text to speech application, which is fully unsupervised. Our method focuses on taking advantage of the supervised speech data, which could be the same data used for fine-tuning, to improve the joint speech text pre-training. Our results demonstrate the efficacy of supervised speech data in pre-training. Another concurrent work is from Bapna et al. (2021), which focuses on speech encoder pre-training using both speech and text data. Our method emphasizes the encoder-decoder framework and training both encoder and decoder in the pre-training stage.

3 Method

ASR and ST are the two main downstream tasks for the proposed pre-training method. Figure 1 depicts our joint pre-training framework, which consists of four subtasks:

1. (Self-)supervised **T**ext to **T**ext subtask (T2T)
2. **S**elf-supervised **S**peech **L**earning subtask (SSL)



(a) Fully shared encoder (FSE) for ASR pre-training. (b) Partially shared encoder (PSE) for ST pre-training.

Figure 1: Speech text joint pre-training framework. The purple, green, steelblue and blue lines depict the data flow in encoders for the **T**ext to **T**ext (T2T), **S**elf-supervised **S**peech **L**earning (SSL), supervised **S**peech to **P**honeme classification (S2P) and supervised AED based **S**peech to **T**ext (S2T) subtasks respectively. The black lines show data flow in the decoder model for the T2T and S2T subtasks. The dotted lines indicate the phoneme embedding is applied in the SSL and S2P subtasks.

3. Supervised **S**peech to **P**honeme classification subtask (S2P)

4. Supervised AED based **S**peech to **T**ext subtask, which is the same as the downstream task, i.e., ST or ASR (S2T)

The choice of the T2T subtask depends on the downstream task. For ASR, the T2T subtask is a denoising autoencoder task (BART) (Lewis et al., 2020a) while ST utilizes a text based neural machine translation task. The SSL subtask is a self-supervised speech learning task to leverage large amounts of unlabelled speech data optimized by the masked prediction loss. The last two supervised speech tasks (S2P and S2T) unify two modalities, i.e., speech and text, into one modeling space.

In this study, we find that the subtasks for the ASR pre-training are complementary, while subtask interference is observed in the ST pre-training at some encoder layers. We propose two different configurations: fully shared encoder (FSE) (Figure 1(a)) for the ASR pre-training, and partially shared encoder (PSE) (Figure 1(b)) for the ST pre-training. The FSE configuration aims to encourage information sharing between different subtasks while the PSE configuration tries to minimize the information sharing between encoder only subtasks, i.e., SSL and S2P, and sequence to sequence AED tasks, i.e., subtask T2T and S2T. More subtask interference analysis is presented in subsection 5.2. We describe the details of each subtask in the following subsections.

3.1 (Self-)supervised text to text subtask

In the sequence to sequence ASR and ST tasks, the decoder is a text generator conditioned on the encoder outputs. Large amounts of training samples are required to cover different linguistic aspects of the target language. Abundant text is an ideal supplement to the limited supervised speech data corpus. Assume the target text sequence is $Y = (y_1, y_2, \cdots, y_N)$, its corresponding corrupted version, $X = \textsc{Noise}(Y) = (x_1, x_2, \cdots, x_M)$, can be created by masking or replacing token spans in Y (Lewis et al., 2020a) for the ASR pre-training. If the downstream task is ST, X is the corresponding source token sequence. The task is optimized by maximizing cross entropy

$$\mathcal{L}_{\text{T2T}} = -\sum_{i}^{N} \log p(y_i | y_{1:i-1}, X) \qquad (1)$$

In this subtask, we also convert the input text into the corresponding pronunciation form, i.e., phoneme sequence, as it would be easier to align the encoder outputs from speech and text (Tang et al., 2021b). The purple and black lines in Figure 1 describe the data flow in the T2T subtask.

3.2 Self-supervised speech subtask

The SSL subtask aims to leverage vast amounts of unlabelled speech data and learn general speech representations. The model configuration follows wav2vec2.0 (Baevski et al., 2020b) where the speech model includes a feature extractor and a context encoder. The context encoder corresponds to the speech encoder in Figure 1(b) in the ST pre-training. If ASR is the downstream task, the context encoder includes one extra shared encoder as shown in Figure 1(a). We use different frameworks for the ST and ASR pre-training to reduce interference among subtasks. The detailed subtask interference is discussed in subsection 5.2.

We propose a masked KL divergence loss to optimize the SSL subtask. It consists of two-pass computation. Given the speech input $S = (s_1, s_2, \cdots, s_T)$, the feature extractor and context encoder outputs are $Z = (z_1, z_2, \cdots, z_{T'})$ and $O = (o_1, o_2, \cdots, o_{T'})$ respectively, where the speech input is down-sampled by the feature extractor and $T > T'$. In the first pass, the output O is compared with the phoneme embedding $E = (e_1, e_2, \cdots, e_I)$, which is from the T2T subtask described in subsection 3.1. I is the phoneme vocabulary size. The predicted phoneme distribution $p(o_j|e_i)$ is defined as

$$p(o_j|e_i) = \frac{\exp({o_j}^\intercal \cdot e_i)}{\sum_{i'} \exp(o_j^\intercal \cdot e_{i'})} \tag{2}$$

In the second pass, speech feature spans $\hat{Z} \subset Z$ are selected and corrupted as wav2vec2.0 (Baevski et al., 2020b). $\hat{O}$ is the corresponding context encoder output from $\hat{Z}$. We train the model to infer the corrupted $p(\hat{o}_j|e_i)$ being similar as $p(o_j|e_i)$ by minimizing KL divergence.

$$\mathcal{L}_{\text{SSL}} = -\sum_{\hat{o}_j \in \hat{O}} \sum_i p(o_j|e_i) \log \frac{p(\hat{o}_j|e_i)}{p(o_j|e_i)} \tag{3}$$

Compared with the masked prediction loss, instead of predicting the hard discretized label for the masked frames, we use the soft label prediction, i.e., predicted phoneme distribution from the first pass, to learn speech representation and avoid the hard prediction errors.

3.3 Supervised speech to phoneme classification

The S2P subtask is employed to unify the self-supervised trained speech and text models. It shares the same model as in the SSL subtask. In this subtask, a transcribed ASR data set is used and the goal of this task is to predict the frame level phoneme labels. A HMM-GMM model is trained with the same transcribed dataset using Kaldi (Povey et al., 2011) to generate the frame-level labels with forced-alignment.

The phoneme classification task is optimized with the cross entropy loss,

$$\mathcal{L}_{\text{S2P}} = -\sum_{o_j \in O} \log p(o_j|e_{a(j)}) \tag{4}$$

where $a(j)$ is the phoneme label associated with the context encoder output o_j. The data flow in the S2P subtask is depicted with steelblue lines in Figure 1.

3.4 Supervised AED based speech to text subtask

Besides the S2P subtask mentioned in the previous subsection, we include the potential downstream AED based task, i.e. ASR or ST, as another auxiliary subtask during the pre-training stage. In many speech translation datasets, such as MuST-C (Gangi et al., 2019) or CoVoST (Wang et al., 2020), we have both speech transcription and translation labels. The speech transcription is used in the S2P subtask while the S2T subtask can make use of the corresponding translation labels. We hope this auxiliary task would make the transition from pre-training to fine-tuning smooth and result in better performance in downstream tasks. The components involved during optimization are connected with blue lines in encoder and black lines in decoder as shown in Figure 1. They are trained with cross entropy criterion,

$$\mathcal{L}_{\text{S2T}} = -\sum_t \log p(y_i|y_{i-1}, O) \tag{5}$$

where O is the input speech and $Y = (y_1, \cdots, y_N)$ is the target labels.

The overall pre-training loss is defined as the combination of four losses discussed above

$$\mathcal{L} = \mathcal{L}_{\text{T2T}} + \alpha\mathcal{L}_{\text{SSL}} + \beta\mathcal{L}_{\text{S2P}} + \gamma\mathcal{L}_{\text{S2T}} \tag{6}$$

where α, β and γ are task weights for the SSL, S2P and S2T subtasks respectively.

During the pre-training, the shared encoder inputs come from two sources, either from speech encoder outputs in the S2T subtask or phoneme embeddings in the T2T subtask. The shared encoder inputs might be in different numerical scales. In order to stabilize the multi-task training, a LayerNorm (Ba et al., 2016) is applied to the shared encoder inputs and places those inputs in the same numerical scale as shown in Figure 1.

4 Experimental setting

In the pre-training, we first train modules with the T2T subtask until they are converged. It helps to stabilize the training and achieve a better result. Then the entire model is jointly optimized with all subtasks mentioned in section 3. Finally, the pre-trained model is fine-tuned on the downstream tasks. In the fine-tuning stage, we keep optimizing the model with the T2T and S2T subtasks. Two encoder-only subtasks (SSL and S2P) are dropped, since the model has learnt good speech representation from the unlabeled speech data in pre-training.

Two downstream tasks, ASR and ST, are examined. The ASR system is evaluated on four LIBRISPEECH (Panayotov et al., 2015) evaluation sets: dev-clean, dev-other, test-clean and test-other. WER is reported in the experiments. ST models are evaluated on two translation directions: English-Spanish (EN-ES) and English-French (EN-FR). Case-sensitive detokenized SACREBLEU (Post, 2018) is reported on the tst-COMMON testset from MUST-C (Gangi et al., 2019).

For both ASR and ST pre-training, 60k hours of unlabelled English speech data from Librilight (Kahn et al., 2020) is used to build the self-supervised speech task if not specifically mentioned. We employ the same labelled data for the supervised learning in pre-training and fine-tuning, i.e., LIBRISPEECH training data for ASR and MUST-C for ST. For ASR pre-training, the LIBRISPEECH language model (LM) training dataset is used to build the monolingual BART model. For ST pre-training, we take the parallel training corpus from WMT. More details about the training data could be found in Appendix A.

4.1 Model configuration

The model takes raw speech audio as input. The feature encoder contains seven blocks and the temporal convolutions in each block have 512 channels with strides (5,2,2,2,2,2,2) and kernel widths (10,3,3,3,3,2,2). The speech encoder, shared encoder and shared decoder are all with 6 transformer layers, model dimension 768, inner dimension (FFN) 3,072 and 8 attention heads. We adopt Pre-LN in the transformer block as Xiong et al. (2020). The total number of parameters is 169 million.

The task weight for each subtask is set by the number of mini-batches used during training. In the pre-training, the ratio of mini-batch numbers for each subtasks are 1.0, 7.0, 0.5 and 0.5 for the T2T, SSL, S2P and S2T subtasks respectively.

We mask 30% tokens in the T2T BART subtask in ASR pre-training, and no masking is applied for the T2T NMT subtask in the ST pre-training. 7% of the feature frames in the SSL subtask and 3% of the feature frames in the two supervised speech subtasks are randomly selected as the mask span starting time-step. The mask span length is 10. The masking percentage is selected via grid search ($(20, 30)$ for text masking, $(6, 6.5, 7)$ and $(2, 3)$ for speech masking). Additional experimental details such as optimization hyper-parameters are included in Appendix B.

5 Experimental results

5.1 Main results

We present the LIBRISPEECH recognition results in Table 1. Recognition results without/with an decoding LM are reported. The WERs obtained with LM are displayed within "()". The second column shows the dataset used as unlabeled data in pre-training. "LS-960" stands for LIBRISPEECH training dataset and "LV-60k" is the 60,000 hours Librilight dataset. The decoding LM is built with the LIBRISPEECH text training corpus , which is the text corpus used by the T2T subtask in the ASR pre-training and fine-tuning.

The first part of the table shows results from the wav2vec 2.0 base model, which is a CTC based ASR system. Second part of the table presents results from two AED based ASR systems, and we mainly compare the proposed method with those two AED systems. LAS is a LSTM based system trained with the LIBRISPEECH data only. Transformer (Tang et al., 2021b) is based on multi-task learning and jointly trained with a text task.

The results from STPT models are presented in the third part of the table. The fourth row shows results from a model that uses 960 hours LIBRISPEECH training data as the unlabelled pre-training data while the model in the fifth row is pre-trained with the 60k hours Librilight data. STPT outperforms all previous reported AED-based systems. On average, there is a 1.2 absolute WER reduction obtained compared to the jointly trained transformer model (Tang et al., 2021b). STPT also reduces 2.2 WER compared with the CTC based wav2vec model if no external LM is applied and achieves comparable WERs when it is decoded with a LM. One interesting observation is the decoding LM is not very helpful for the STPT model,

Data set	Unlabeled	Dev		Test		ave.
	data	clean	other	clean	other	
wav2vec 2.0 (Baevski et al., 2020b)	LS-960	3.2 (1.8)	8.9 (4.7)	3.4 (2.1)	8.5 (4.8)	6.0 (3.4)
LAS (Park et al., 2019)	-	-	-	2.8 (2.5)	6.8 (5.8)	-
Transformer (Tang et al., 2021b)	-	2.8	7.0	3.1	7.2	5.0
STPT	LS-960	2.1 (1.9)	5.4 (5.2)	2.3 (2.2)	5.6 (5.3)	3.8 (3.6)
STPT	LV-60k	2.0 (2.1)	4.4 (4.2)	2.1 (2.1)	4.6 (4.5)	3.3 (3.2)

Table 1: WER results on Librispeech. “()” indicates the WER is measured with an external LM.

Data corpus	EN-ES	EN-FR
Inaguma et al. (2020)	28.0	32.7
Tang et al. (2021a)	31.0	37.4
Zheng et al. (2021)	30.8	-
Ye et al. (2021)	30.8	38.0
STPT	33.1	39.7

Table 2: BLEU results of two language pairs on the MuST-C tst-COMMON.

that only 0.2 WER reduction is observed when a decoding LM is applied. Other systems, on the other hand, show a considerable WER reduction when the LM is applied during decoding. It indicates that our multi-task learning in the pre-training and fine-tuning stages can effectively fuse linguistic information in the text data corpus into the ASR model. LM might not be required if it is trained on the same text corpus. We also report results from model pre-trained with 60k hours Librilight data at the fifth row. Compared with the LS-960 STPT model, Librilight data helps to reduce the WER in two difficult “other” datasets. In the following experiments, we will use Librilight as unlabelled data in pre-training.

In Table 2, we present the speech translation results on the MuST-C datasets. Row one to four are the latest results from literature. Row one shows the results by training a speech to text translation task alone. Row two and three present results from two multi-task systems with speech and text jointly trained together. Row four is the best system reported, which is initialized with the pre-trained wav2vec 2.0 and machine translation model, then fine-tuned with the joint speech and text training. Our method achieves 2.3 and 1.7 more BLEU scores for EN-ES and EN-FR translation directions compared with the best system (Ye et al., 2021).

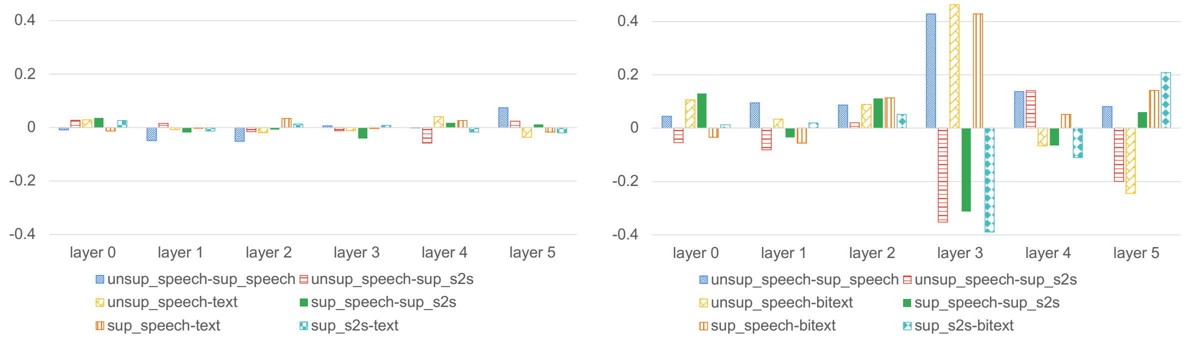
5.2 Impact of model structure

Interference among subtasks may impede the progress of multi-task learning and lead to inferior results. In this study, we examine the task interference via comparing the gradient similarity between pair subtasks. We choose the pre-trained models using the FSE configuration discussed in section 3 and accumulate gradients from one of four jointly trained subtasks. We prepare 20 batches of training samples for each subtask, and retrieve the accumulated gradients by sending these batches to the models. Then we calculate the pairwise cosine similarity between gradients from any two subtasks.

The pairwise subtask gradient similarity from the shared encoder are presented in Figure 2. The Figure 2(a) demonstrates the gradient similarity in ASR pre-training. In most layers, the gradient similarities are small. No serious gradient interference is observed. The Figure 2(b) depicts the gradient similarity from the ST pre-training. Compared with the ASR pre-training, the S2T and T2T subtasks are replaced by speech translation and text based neural machine translation subtasks in pre-training. The interference between different subtasks is significant as large positive and negative gradient similarities are observed in the third and fifth layers in Figure 2.

Similarly, we compare task gradients in the speech encoder and no obvious task interference is observed within the speech encoder for both ASR and ST pre-training. Detailed analysis on the speech encoder is included in the Appendix C.

In order to alleviate the task interference, the PSE configuration is proposed for the ST pre-training. Table 3 presents the performance comparison between two configurations on both ASR and ST pre-training. On the left part of the table, we list the ASR results using 100 hours labelled speech data (train-clean-100) in pre-training and fine-tuning. While the right part of the table shows the BLEU evaluated on the MuST-C dataset. As we expected, the FSE configuration encourages information sharing among tasks and it achieves lower WER for the ASR task. It indicates subtasks in the ASR pre-training are complementary to each other. On the other hand, the PSE configuration



(a) Gradient similarity for the ASR pre-training.

(b) Gradient similarity for the ST pre-training.

Figure 2: Gradient similarity for different subtasks on the shared text encoder.

Config.	Librispeech (WER ↓)		MuST-C (BLEU ↑)	
	dev clean	dev other	EN-ES	EN-FR
FSE	3.2	6.8	31.4	38.3
PSE	3.1	8.3	33.1	39.7

Table 3: Comparison of two pre-training configurations for ASR and ST.

PT (h)	FT (h)	Dev		Test	
		clean	other	clean	other
960	960	2.0	4.4	2.1	4.6
100	960	2.3	4.9	2.2	5.1
	100	3.2	6.8	3.5	7.2
10	960	2.7	5.3	2.8	5.3
	100	3.8	7.8	4.0	7.7
	10	19.9	27.5	22.0	28.8

Table 4: Impact of the amounts of supervised data. "PT" and "FT" stand for pre-training and fine-tuning respectively.

minimizes the information sharing between AED subtasks and encoder only subtasks, and it leads to higher BLEU for the ST task.

5.3 Impact of training data

The supervised speech data connects the text and speech modeling and unifies the representation from different modalities. An interesting question we want to investigate is how much supervised data is enough to learn a good cross modality representation. In this experiment, we choose different amounts of labelled data for ASR pre-training and fine-tuning, varied from 960 hours (the full dataset), 100 hours (train-clean-100) and 10 hours as (Kahn et al., 2020), to answer this question.

In Table 4, the first column shows the amounts of supervised speech data available during the pre-training and the second column presents the amount of labelled data used in the fine-tuning stage. In pre-training, the same supervised speech data is used in the S2P and S2T subtasks.

The first observation is that more supervised speech data in the pre-training stage is always helpful to get smaller WER. For example, if the models are fine-tuned with the full LIBRISPEECH training dataset, the average WER are 3.3 (row one), 3.6 (row two) and 4.0 (row four) for experiments with 960, 100 and 10 hours labelled data in the pre-training stage. The second observation is that we are still able to obtain good speech representations even with small amounts of labelled data. In row four, the model is pre-trained with 10 hours labelled data, then fine-tuned with 960 hours supervised speech data. It can achieve an average 4.0 WER, which is better than the results of the AED systems in Table 1. However, we also notice the performance degrades quickly if only small amounts of labelled speech data are available. The average WER is increased to 24.6 (row six) when only 10 hours of supervised speech data is employed in both pre-training and fine-tuning.

Another question we are interested is the generalizability of the pre-trained model. There are two data partitions in LIBRISPEECH: "clean" and "other". The "clean" partition is supposed to be "higher recording quality and with accents closer to US English" while the "other" partition is difficult speakers with high WER (Panayotov et al., 2015). We create four data partitions for pre-training and fine-tuning to simulate the mismatched training conditions. "train-clean-100" is used as the pre-training "clean" data set ("PT C") and the first 30,000 utterance from "train-clean-360" as the fine-tuning "clean" dataset ("FT C"). The first 30,000 ut-

	FT C		FT O	
	clean	other	clean	other
PT C	3.0	6.7	*3.2*	*5.9*
PT O	*3.0*	*5.9*	3.2	5.8

Table 5: WER comparison under mismatched pre-training and fine-tuning conditions. "C" and "O" represent the "clean" and "other" labelled data; "PT" and "FT" stand for pre-training and fine-tuning. WERs obtained under mismatched conditions are shown as *italic*.

terances and the following 30,000 utterances from "train-other" are used as the pre-training ("PT O") and fine-tuning "other" ("FT O") datasets. Each dataset includes approximately 100 hours speech data. In Table 5, models are trained under 4 different combinations with different supervised pre-training and fine-tuning data sets. We report average WER on the "dev-clean" and "test-clean" test sets as "clean", and average WER on the"dev-other" and "test-other" as "other" to reduce the result variation. From Table 5, we have following observations. 1) a model achieves the best results on the matched condition. The model "PT C + FT C" achieves the lowest WER on the "clean" set while "PT O + FT O" achieves the best results on the "other" set. 2) training and test on totally different conditions could increase WER significantly. The model "PT C + FT C" increases 0.9 WER on the "other" set compared with the "PT O + FT O" model. 3) mismatched pre-training and fine-tuning might slightly increase the WER, 0.1 to 0.2 in this experiment.

5.4 Masked KL divergence loss v.s. contrastive loss

In the SSL subtask, we optimize the model to reduce the KL divergence loss between input without masking and with masking as described in subsection 3.2. It is a variant of the masked prediction loss (Baevski et al., 2020a) and no target labels are required in our implementation. Contrastive loss is another widely used method for the self-supervised speech learning (Baevski et al., 2020b). We compare the both criteria in Table 6. The number of distractors in the contrastive loss is 100 as (Baevski et al., 2020b). Both ASR and ST results are reported in Table 6, where the masked KL divergence loss achieves about 0.6 lower WER in the Librispeech dev sets and $0.7 \sim 1.4$ more BLEU scores in the MuST-C tst-COMMON sets. It demonstrates the effectiveness of the proposed masked KL divergence loss for the SSL subtask.

Loss	Librispeech (WER ↓)		MuST-C (BLEU ↑)	
	dev clean	dev other	EN-ES	EN-FR
Cont.	2.6	5.0	31.7	39.0
KL	2.0	4.4	33.1	39.7

Table 6: Comparison of the masked KL divergence loss and contrastive loss for the SSL subtask. "Cont." stands for the contrastive loss.

5.5 Ablation study

In Table 7, we present an ablation study by removing different steps/tasks in the pre-training stage.

In order to make the pre-training more stable, the model training adopts a three-stage optimization strategy: 1) pre-training the T2T subtask to have a good initialization on the phoneme embeddings 2) joint pre-training with four subtasks to leverage large amounts of unlabelled speech data and abundant text data and 3) fine-tuning the model on the downstream task for best performance. In the second row, we skip the T2T pre-training step and initialize the model randomly for the joint pre-training. 0.5 WER increase is observed in average on two LIBRISPEECH dev sets. It also has more impact on the EN-ES translation direction where 1.2 BLEU score is lost without proper initialization.

In the third row, we present the results without the S2T subtask. For both ASR and ST, significant performance degradation is observed, with an average 1.1 WER increase for two ASR tests and 1.8 BLEU decrease for two ST directions. We also try removing the S2P subtask while still keeping the S2T subtask. The training doesn't converge. The SSL subtask is with very small or zero cost since all predictions collapse into one or two target phonemes. Also, little progress has been made for the S2T subtask even though it is co-trained with the SSL and T2T subtasks.

In the last row, the model is trained without pre-training, i.e., only the T2T and S2T subtasks are optimized. Compared with the STPT results, there is about 1.4 WER increase for two LIBRISPEECH test sets and 3.4 BLEU decrease for the two ST directions on average.

6 Conclusion

In this work, we present a method to jointly pre-train speech and text in one model for speech translation and recognition under the AED framework.

Config.	Librispeech (WER ↓)		MuST-C (BLEU ↑)	
	dev clean	dev other	EN-ES	EN-FR
STPT	2.0	4.4	33.1	39.7
- T2T PT	2.4	5.0	31.9	39.2
- AED task	2.9	5.6	31.3	38.0
- Joint PT	2.8	6.4	30.6	35.4

Table 7: Ablation study for STPT."PT" stands for "pre-training".

It includes four self-supervised and supervised subtasks from two different input modalities, hence the proposed method can leverage large amounts of unlabelled speech data and abundant text data in the pre-training stage. We conduct detailed analysis on the interference among different subtasks and propose two model configurations for the ASR and ST pre-training respectively to alleviate the subtask interference. Our experimental results show STPT can effectively fuse information within text and speech training data into one model. We achieves between 1.7 and 2.3 BLEU improvement over the state of the art on the MuST-C EN-FR and EN-ES speech translation tasks, and comparable WERs as wav2vec 2.0 in the LIBRISPEECH ASR task.

7 Acknowledgments

We want to thank the anonymous reviewers for their insightful comments and suggestions.

8 Broader Impact

We highlight the potential that this work has positive impact in the society: augmenting speech processing tasks with text corpus, and improving speech related applications. At the same time, this work may have some negative consequences if the text data is not handled in a proper way. Before using the text data to train a speech system, one should evaluate fairness in the collected data, and make sure not to train on offensive or any type of inappropriate data.

A Pre-training data setting

T2T: For ASR pre-training, the language model (LM) training dataset [2] for LIBRISPEECH (Panayotov et al., 2015) is used to build the monolingual BART model. It has about 800 million words. For ST pre-training, we take the parallel training corpus from WMT. We examine our methods on two translation directions in MUST-C: English-Spanish (EN-ES), which uses WMT13 training corpus, and English-French (EN-FR), which takes the WMT14 training data. There are 370 million and 1 billion English words in the EN-ES and EN-FR parallel training datasets respectively.

We use "g2p_en" Python package (Lee and Kim, 2018) to convert the training text into the corresponding phoneme representation, which is based on the CMU English dictionary. We further extend the phoneme set by distinguishing the first phoneme in the word with an additional "_" mark appended, which is similar to the notation in the SentencePiece process. The input phoneme vocabulary size is 134.

SSL: For both ASR and ST pre-training, 60k hours of unlabelled English speech data from Librilight (Kahn et al., 2020) is used to build the self-supervised speech task if not specifically mentioned. We set the maximum utterance duration to 37.5 seconds and minimum duration to 4 seconds. We randomly sample audio segments with maximum duration if utterances are longer than the maximum duration. No voice activity detection is applied.

S2P: We use the transcribed LIBRISPEECH dataset for ASR pre-training. In ST pre-training, the MUST-C training dataset is used, where the corresponding English transcription is used as the training target labels after it is converted into phoneme representation. The phoneme level segmentation is obtained via force-alignment, which is conducted using HMM/GMM trained from the same speech data with the Kaldi toolkit (Povey et al., 2011).

S2T: We use the same labelled data in the S2P subtask for the S2T subtask, i.e., LIBRISPEECH training data for the ASR pre-training and MUST-C data for the ST pre-training. Instead of using phoneme representation, the target labels are encoded with SentencePiece (Kudo and Richardson, 2018). For both ASR and ST tasks, the vocabulary is an Unigram model with size 10k and full

(a) Gradient similarity for the ASR pre-training.

(b) Gradient similarity for the ST pre-training.

Figure 3: Gradient similarity for different subtasks on the speech encoder.

character coverage on the training text data.

B Optimization setting

The models are optimized with Adam (Kingma and Ba, 2014) for both pre-training and fine-tuning. The final results are evaluated using an averaged model from checkpoints of the last 10 epochs.
T2T subtask pre-training The T2T model is pre-trained with learning rate 0.01 using Adam optimization. The maximum tokens per mini-batch is 2048 with 8 V100 GPU cards. The model is updated 400,000 until fully converged.
Pre-training with all subtasks The model then keeps optimizing with all four subtasks: T2T, SSL, S2P and S2T, with learning rate 0.001. The model is trained using 16 A100 GPU cards with update frequency 12. The maximum token number per batch for the T2T subtask is 2048 while the maximum sample number is 750,000 (46s) for the speech input in three speech subtasks. The maximum update number is 800,000 and 200,000 for the ASR pre-training and the ST pre-training respectively.
Fine-tuning The model is fine-tuned on the downstream task with learning rate 0.0003 and 8 V100 GPU cards. The update frequency set to 3. The maximum update numbers are dependent on the amounts of supervised speech data available. We choose 100,000 for the ASR task with 960 hours training data and 20,000 for 100 or 10 hours training data. For the ST task, the maximum update number is set to 50,000.

C Gradient similarity of the speech encoder

Three subtasks: SSL, S2P, and S2T, share the speech encoder during the joint pre-training. Similar pairwise gradient similarity analysis is conducted on these three subtasks at the speech encoder, as shown in Figure 3. The gradient similarity analysis for the ASR pre-training is presented in the left subfigure while the ST-pretraining is listed in the right. In both cases, the gradient similarities for different subtask pairs are small, i.e., absolute values of the gradient similarities are all below 0.2. It indicates the task interference between different subtasks are not significant.

Match the Script, Adapt if Multilingual: Analyzing the Effect of Multilingual Pretraining on Cross-lingual Transferability

Abstract

Pretrained multilingual models enable zero-shot learning even for unseen languages, and that performance can be further improved via adaptation prior to finetuning. However, it is unclear how the number of pretraining languages influences a model's zero-shot learning for languages unseen during pretraining. To fill this gap, we ask the following research questions: (1) How does the number of pretraining languages influence zero-shot performance on unseen target languages? (2) Does the answer to that question change with model adaptation? (3) Do the findings for our first question change if the languages used for pretraining are all related? Our experiments on pretraining with *related* languages indicate that choosing a diverse set of languages is crucial. *Without* model adaptation, surprisingly, increasing the number of pretraining languages yields better results up to adding related languages, after which performance plateaus. In contrast, *with* model adaptation via continued pretraining, pretraining on a larger number of languages often gives further improvement, suggesting that model adaptation is crucial to exploit additional pretraining languages.[1]

1 Introduction

Pretrained multilingual language models (Devlin et al., 2019; Conneau et al., 2020) are now a standard approach for cross-lingual transfer in natural language processing (NLP). However, there are multiple, potentially related issues on pretraining multilingual models. Conneau et al. (2020) find the "curse of multilinguality": for a fixed model size, zero-shot performance on target languages seen during pretraining increases with additional pretraining languages only until a certain point, after which performance decreases. Wang et al. (2020b) also report "negative interference", where monolingual models achieve better results than multilingual models, both on subsets of high- and low-resource languages. However, those findings are limited to target languages seen during pretraining.

Current multilingual models cover only a small subset of the world's languages. Furthermore, due to data sparsity, monolingual pretrained models are not likely to obtain good results for many low-resource languages. In those cases, multilingual models can zero-shot learn for unseen languages with an above-chance performance, which can be further improved via model adaptation with target-language text (Wang et al., 2020a), even for limited amounts (Ebrahimi and Kann, 2021). However, it is poorly understood how the number of pretraining languages influences performance in those cases. Does the "curse of multilinguality" or "negative interference" also impact performance on unseen target languages? And, if we want a model to be applicable to as many unseen languages as possible, how many languages should it be trained on?

Specifically, we ask the following research questions: (1) How does pretraining on an increasing number of languages impact zero-shot performance on unseen target languages? (2) Does the effect of the number of pretraining languages change with model adaptation to target languages? (3) Does the answer to the first research question change if the pretraining languages are all related to each other?

We pretrain a variety of monolingual and multilingual models, which we then finetune on English and apply to three zero-shot cross-lingual downstream tasks in unseen target languages: part-of-speech (POS) tagging, named entity recognition (NER), and natural language inference (NLI). Experimental results suggest that choosing a diverse set of pretraining languages is crucial for effective transfer. Without model adaptation, increasing the number of pretraining languages im-

proves accuracy on unrelated unseen target languages at first and plateaus thereafter. Last, with model adaptation, additional pretraining languages beyond English generally help.

We are aware of the intense computational cost of pretraining and its environmental impact (Strubell et al., 2019). Thus, our experiments in Section 4 are on a relatively small scale with a fixed computational budget for each model and on relatively simple NLP tasks (POS tagging, NER, and NLI), but validate our most central findings in Section 5 on large publicly available pretrained models.

2 Cross-lingual Transfer via Pretraining

Pretrained multilingual models are a straightforward cross-lingual transfer approach: a model pretrained on multiple languages is then fine-tuned on target-task data in the *source* language. Subsequently, the model is applied to target-task data in the *target* language. Most commonly, the target language is part of the model's pretraining data. However, cross-lingual transfer is possible even if this is not the case, though performance tends to be lower. This paper extends prior work exploring the cross-lingual transfer abilities of pretrained models for *seen* target languages depending on the number of pretraining languages to *unseen* target languages. We now transfer via pretrained multilingual models and introduce the models and methods vetted in our experiments.

2.1 Background and Methods

Pretrained Language Models Contextual representations such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019) are not just useful for monolingual representations. Multilingual BERT (Devlin et al., 2019, mBERT), XLM (Lample and Conneau, 2019), and XLM-RoBERTa (Conneau et al., 2020, XLM-R) have surprisingly high cross-lingual transfer performance compared to the previous best practice: static cross-lingual word embeddings (Pires et al., 2019; Wu and Dredze, 2019). Multilingual models are also practical—why have hundreds of separate models for each language when you could do better with just one? Furthermore, Wu and Dredze (2020) report that models pretrained on 100+ languages are better than bilingual or monolingual language models in zero-shot cross-lingual transfer.

Model Adaptation to Unseen Languages Adapting pretrained multilingual models such as mBERT and XLM-R to unseen languages is one way to use such models beyond the languages covered during pretraining time. Several methods for adapting pretrained multilingual language models to unseen languages have been proposed, including continuing masked language model (MLM) training (Chau et al., 2020; Müller et al., 2020), optionally adding Adapter modules (Pfeiffer et al., 2020), or extending the vocabulary of the pretrained models (Artetxe et al., 2020; Wang et al., 2020a). However, such adaptation methods assume the existence of sufficient monolingual corpora in the target languages. Some spoken languages, dialects, or extinct languages lack monolingual corpora to conduct model adaptation, which motivates us to look into languages unseen during pretraining. We leave investigation on the effect of target language-specific processing, e.g., transliteration into Latin scripts (Muller et al., 2021), for future work.

2.2 Research Questions

A single pretrained model that can be applied to any language, including those unseen during pretraining, is both more efficient and more practical than pretraining one model per language. Moreover, it is the only practical option for unknown target languages or for languages without enough resources for pretraining. Thus, models that can be applied or at least easily adapted to unseen languages are an important research focus. This work addresses the following research questions (RQ), using English as the source language for finetuning.

RQ1*: How does the number of pretraining languages influence zero-shot cross-lingual transfer of simple NLP tasks on unseen target languages?*

We first explore how many languages a model should be pretrained on if the target language is unknown at test time or has too limited monolingual resources for model adaptation. On one hand, we hypothesize that increasing the number of pretraining languages will improve performance, as the model sees a more diverse set of scripts and linguistic phenomena. Also, the more pretraining languages, the better chance of having a related language to the target language. However, multilingual training can cause interference: other languages could distract from English, the finetuning source language, and thus, lower performance.

RQ2: *How does the answer to RQ1 change with model adaptation to the target language?*

This question is concerned with settings in which we have enough monolingual data to adapt a pretrained model to the target language. Like our hypothesis for RQ1, we expect that having seen more pretraining languages should make adaptation to unseen target languages easier. However, another possibility is that adapting the model makes any languages other than the finetuning source language unnecessary; performance stays the same or decreases when adding more pretraining languages.

RQ3: *Do the answers to RQ1 change if all pretraining languages are related to each other?*

We use a diverse set of pretraining languages when exploring RQ1, since we expect that to be maximally beneficial. However, the results might change depending on the exact languages. Thus, as a case study, we repeat all experiments using a set of closely related languages. On the one hand, we hypothesize that benefits due to adding more pretraining languages (if any) will be smaller with related languages, as we reduce the diversity of linguistic phenomena in the pretraining data. However, on the other hand, if English is all we use during fine-tuning, performance might increase with related languages, as this will approximate training on more English data more closely.

3 Experimental Setup

Pretraining Corpora All our models are pretrained on the CoNLL 2017 Wikipedia dump (Ginter et al., 2017). To use equal amounts of data for all pretraining languages, we downsample all Wikipedia datasets to an equal number of sequences. We standardize to the smallest corpus, Hindi. The resulting pretraining corpus size is around 200MB per language.[2] We hold out 1K sequences with around 512 tokens per sequence after preprocessing as a development set to track the models' performance during pretraining.

Corpora for Model Adaptation For model adaptation (RQ2), we select unseen target languages contained in both XNLI (Conneau et al., 2018b) and Universal Dependencies 2.5 (Nivre et al., 2019): Farsi (FA), Hebrew (HE), French (FR), Vietnamese (VI), Tamil (TA), and Bulgarian (BG). Model adaptation is typically done for low-resource languages not seen during pretraining because monolingual corpora are too small (Wang et al., 2020a). Therefore, we use the Johns Hopkins University Bible corpus by McCarthy et al. (2020) following Ebrahimi and Kann (2021).[3]

Table 1: Languages used in our experiments.

Tasks We evaluate our pretrained models on the following downstream tasks from the XTREME dataset (Hu et al., 2020): POS tagging and NLI. For the former, we select 29 languages from Universal Dependencies v2.5 (Nivre et al., 2019). For the latter, we use all fifteen languages in XNLI (Conneau et al., 2018b). We follow the default train, validation, and test split in XTREME.

Models and Hyperparameters Following Conneau et al. (2020)'s XLM-R Base model, we train transformers (Vaswani et al., 2017) with 12 layers, 768 units, 12 attention heads, and a maximum of 512 tokens per sequence. To accommodate all

---

[2] Micheli et al. (2020) show that corpora of at least 100MB are reasonable for pretraining.

[3] In cases where multiple versions of the Bible are available in the target language, we select the largest one.

languages and facilitate comparability between all pretraining setups, we use XLM-R's vocabulary and the SentencePiece (Kudo and Richardson, 2018) tokenizer by Conneau et al. (2020).

We use masked language modeling (MLM) as our pretraining objective and, like Devlin et al. (2019), mask 15% of the tokens. We pretrain all models for 150K steps, using Adam W (Loshchilov and Hutter, 2019) with a learning rate of 1×10^{-4} and a batch size of two on either NVIDIA RTX2080Ti or GTX1080Ti 12GB, on which it approximately took four days to train each model. When pretraining, we preprocess sentences together to generate sequences of approximately 512 tokens. For continued pretraining, we use a learning rate of 2×10^{-5} and train for forty epochs, otherwise following the setup for pretraining. For finetuning, we use a learning rate of 2×10^{-5} and train for an additional ten epochs for both POS tagging and NER, and an additional five epochs for NLI, following Hu et al. (2020).

Languages Table 1 shows the languages used in our experiments. English is part of the pretraining data of all models. It is also the finetuning source language for all tasks, following Hu et al. (2020). We use two different sets of pretraining languages: "Diverse (Div)" and "Related (Rel)" (Table 2). We mainly focus on pretraining on up to five languages, except for POS tagging where the trend is not clear and we further experiment on up to ten.

For POS tagging and NER, we regard seventeen of the twenty-nine languages available in XTREME as *unseen*, while the remaining twelve languages are pretraining languages for at least one model. For NLI, six languages are *seen* and the rest are *unseen*. The order in which we add pretraining languages follows the size of their original CoNLL 2017 Wikipedia dumps, with larger sizes being added first.

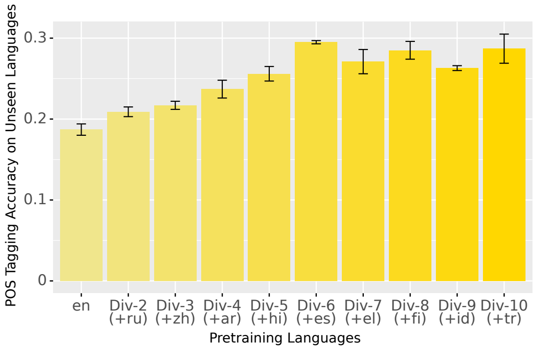

Figure 1: POS tagging accuracy after pretraining on a diverse set of up to 10 languages and finetuning on English. The accuracy improves until six languages on the given target languages.

4 Results

We now present experimental results for each RQ.

4.1 Findings for RQ1

POS Tagging Figure 1 shows the POS tagging accuracy averaged over the 17 languages unseen during pretraining. On average, models pretrained on multiple languages have higher accuracy on unseen languages than the model pretrained exclusively on English, showing that the model benefits from a more diverse set of pretraining data. However, the average accuracy only increases up to six languages. This indicates that our initial hypothesis "the more languages the better" might not be true.

Figure 2 provides a more detailed picture, showing the accuracy for different numbers of pretraining languages for all seen and unseen target languages. As expected, accuracy jumps when a language itself is added as a pretraining language. Furthermore, accuracy rises if a pretraining language from the same language family as a target language is added: for example, the accuracy of Marathi goes up by 9.3% after adding Hindi during pretraining, and the accuracy of Bulgarian increases by 31.2% after adding Russian. This shows that related languages are indeed beneficial for transfer learning. Also, (partially) sharing the same script with a pretraining language (e.g., ES and ET, AR and FA) helps with zero-shot cross-lingual transfer even for languages which are not from the same

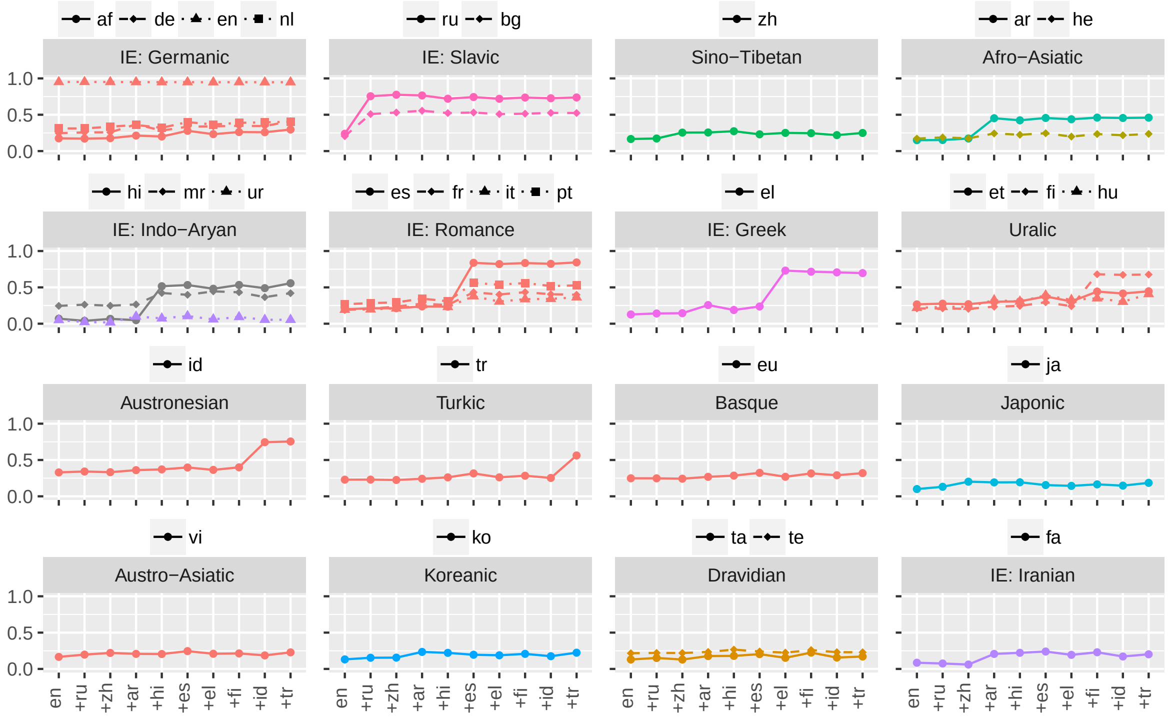

Figure 2: POS tagging accuracy using models pretrained on a diverse set of languages (EN, RU, ZH, AR, HI, ES, EL, FI, ID, TR) grouped by families of target languages, with Indo-European (IE) languages further divided into subgroups following XTREME. The colors represent the script type of the languages. The accuracy gain is larger when a pretraining language from the same family or using the same script is added.

family. These results are consistent with the outcome of Müller et al. (2020) and partially support the hypothesis by Pires et al. (2019) that shared scripts are effective on unseen languages.

But how important are the scripts compared to other features? To quantify the importance of it, we conduct a linear regression analysis on the POS tagging result. Table 3 shows the linear regression analysis results using typological features among target and pretraining languages. For the script and family features, we follow Xu et al. (2019) and encoded them into binary values set to one if a language with the same script or from the same family is included as one of the pretraining languages. For syntax and phonology features, we derive those vectors from the URIEL database using lang2vec (Littell et al., 2017) following Lauscher et al. (2020). We take the maximum cosine similarity between the target language and any of the pretraining languages. Table 3 further confirms that having a pretraining language which shares the same script contributes the most to positive cross-lingual transfer.

Features	**Coef.**	**p-value**	**CI**
Script	**.061**	$<$ .001	[.050, .073]
Family	.022	.004	[.007, .036]
Syntax	.001	.905	[-.016, .018]
Phonology	.021	$<$ .001	[.009, .033]
# pretrain langs	.011	.044	[.000, .022]

Table 3: Regression analysis on the POS tagging accuracy with coefficients (Coef.), p-value, and 95% confidence interval (CI). A large coefficient with a low p-value indicates that the feature significantly contributes to better cross-lingual transfer, which shows that the same script is the most important feature.

We sadly cannot give a definitive optimal number of pretraining languages. One consistent finding is that, for the large majority of languages, using only English yields the worst results for unseen languages. However, adding pretraining languages does not necessarily improve accuracy (Figure 1). This indicates that, while we want more than one pretraining language, using a smaller number than the 100 commonly used pretraining languages is likely sufficient unless we expect them to be closely related to one of the potential target languages.

NER Our NER results show a similar trend. Therefore, we only report the average performance in the main part of this paper (Figure 3), and full

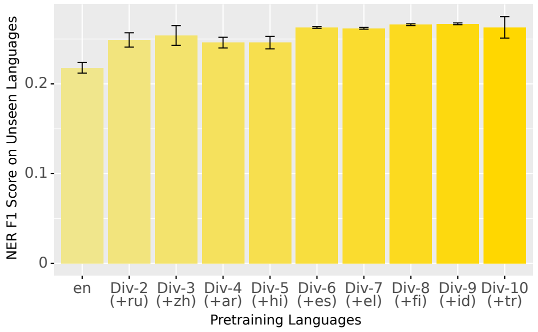

Figure 3: NER F1 score after pretraining on a diverse set of up to 10 languages and finetuning on English.

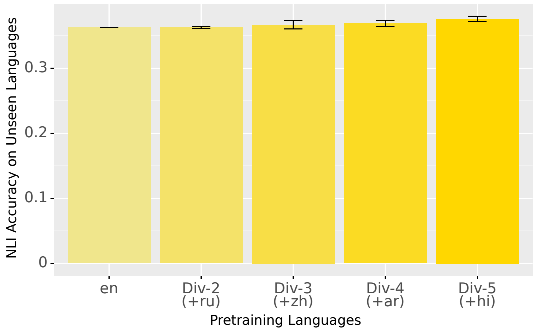

Figure 4: XNLI accuracy after pretraining on a diverse set and finetuning on English.

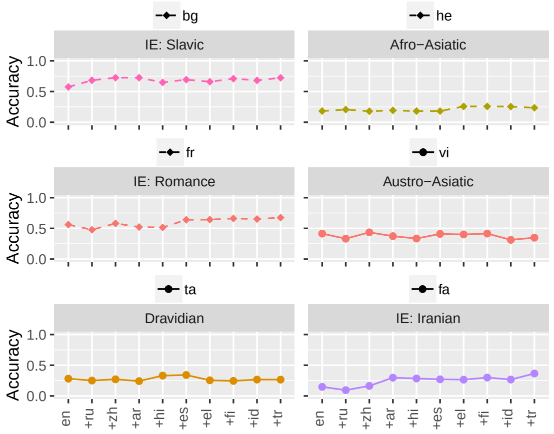
details are available in Appendix A. For NER, transfer to unseen languages is more limited, likely due to the small subset of tokens which are labeled as entities when compared to POS tags.

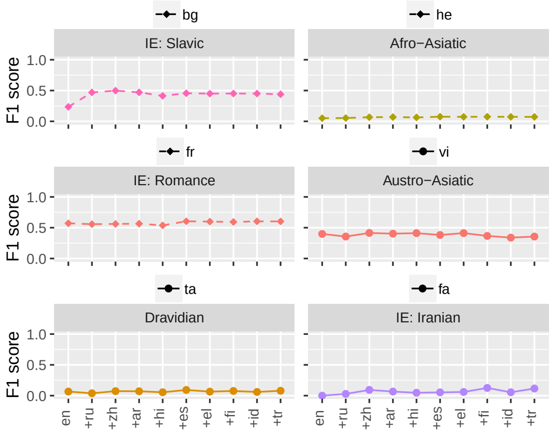
NLI Our NLI results in Figure 4 show a similar trend: accuracy on unseen languages plateaus at a relatively small number of pretraining languages. Specifically, Div-4 has the highest accuracy for 8 target languages, while Div-5 is best only for two target languages. Accuracy again increases with related languages, such as an improvement of 3.7% accuracy for Bulgarian after adding Russian as a pretraining language. Full results are available in Appendix B.

4.2 Findings for RQ2

POS Tagging Figure 5a shows the POS tagging results for six languages after adaptation of the pretrained models via continued pretraining. As expected, accuracy is overall higher than in Figure 2. Importantly, there are accuracy gains in Farsi when adding Turkish (+9.8%) and in Hebrew when adding Greek (+7.7%), which are not observed before adapting models. We further investigate it in Section 5.



(a) POS tagging accuracy.



(b) NER F1 scores.

Figure 5: Results after continued training on the Bible of each target language. The continued training gives limited improvement on NER for most languages when compared to POS tagging.

NER NER results in Figure 5b show similarities between POS tagging (e.g., improvement on Bulgarian after adding Russian). However, there is limited improvement on Farsi after adding Arabic despite partially shared scripts between the two languages. This indicates that the effect of adding related pretraining languages is partially task-dependent.

NLI For NLI, accuracy increases slightly after adding a second pretraining language. Results for two to five pretraining languages are similar for all target languages and, for Greek and Turkish, still similar to the English-only model. This indicates that, similar to our findings for POS tagging, a few pretraining languages could be sufficient for model adaptation. Full results are available in Appendix B. Finally, our NLI results are low overall. This is likely due to the size of the pretraining corpus being one of the top correlated features for NLI (Lauscher

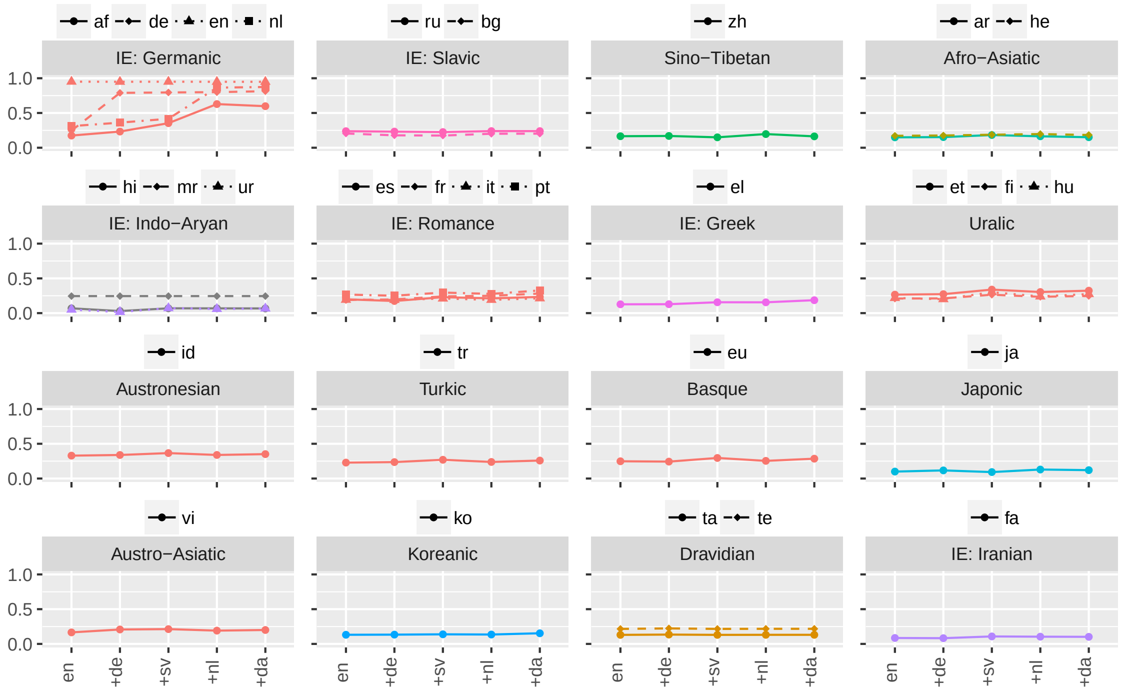


Figure 6: POS tagging accuracy using related pretraining languages (EN, DE, SV, NL, DA) grouped by families of target languages, with Indo-European (IE) languages further divided into subgroups following the XTREME dataset. A change in accuracy can mainly be observed for Germanic, Romance, and Uralic languages due to only using pretraining languages from the Germanic language family.

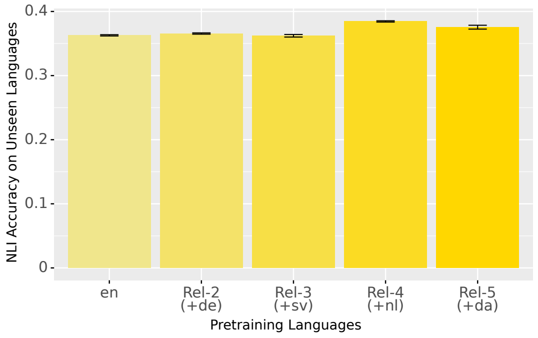

Figure 7: XNLI accuracy on 10 unseen languages after pretraining on a set of related languages and finetuning on English.

et al., 2020), unlike for POS tagging (Hu et al., 2020).

4.3 Findings for RQ3

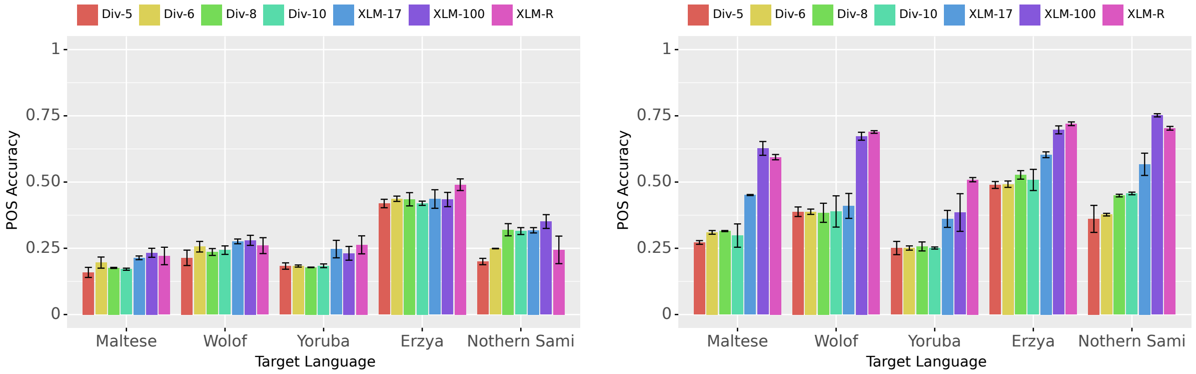
POS Tagging In contrast to RQ1, POS tagging accuracy changes for most languages are limited when increasing the number of pretraining languages (Figure 6). The unseen languages on which we observe gains belong to the Germanic, Romance, and Uralic language families, which are relatively (as compared to the other language families) close to English. The accuracy on languages from other language families changes by $< 10\%$, which is smaller than the change for a diverse set of pretraining languages. This indicates that the models pretrained on similar languages struggle to transfer to unrelated languages.

NER F1 scores of EN, Rel-2, Rel-3, Rel-4, and Rel-5 are .218, .219, .227, .236, and .237 respectively. Compared to Div-X, pretraining on related languages also improves up to adding five languages. However, these models bring a smaller improvement, similar to POS tagging.

NLI Figure 7 shows a similar trend for NLI: when adding related pretraining languages, accuracy on languages far from English either does not change much or decreases. In fact, for nine out of thirteen unseen target languages, Rel-5 is the worst.

5 More Pretraining Languages

Our main takeaways from the last section are: (RQ1) without model adaptation, increasing the number of pretraining languages does not improve accuracy on unrelated unseen target languages; (RQ2) model adaptation largely helps exploiting models pretrained on more languages; and (RQ3)



(a) Before model adaptation.

(b) After model adaptation.

Figure 8: POS tagging accuracy of our models pretrained on a diverse set of languages, XLM-17, XLM-100, and XLM-R after finetuning on English. The models before adaptation are roughly on par regardless of the number of pretraining languages, and the models after adaptation are more affected by related pretraining languages.

when using more than one pretraining language, diversity is important.

However, there are limitations in the experimental settings in Section 4. We assume the following: (1) relatively small pretraining corpora; (2) the target languages are included when building the model's vocabulary; (3) fixed computational resources; and (4) only up to ten pretraining languages. We now explore if our findings for RQ1 and RQ2 hold without such limitations. For this, we use two publicly available pretrained XLM models (Lample and Conneau, 2019), which have been pretrained on full size Wikipedia in 17 (XLM-17) and 100 (XLM-100) languages, and XLM-R base model trained on a larger Common Crawl corpus (Conneau et al., 2020) in 100 languages. We conduct a case study on low-resource languages unseen for all models, including unseen vocabularies: Maltese (MT), Wolof (WO), Yoruba (YO), Erzya (MYV), and Northern Sami (SME). All pretraining languages used in Div-X are included in XLM-17 except for Finnish, and all 17 pretraining languages for XLM-17 are a subset of the pretraining languages for XLM-100. We report the averages with standard deviations from three random seeds.

5.1 Results

RQ1 For models without adaptation, accuracy does not improve for increasing numbers of source languages (Figure 8a). Indeed, the accuracy on both XLM-17 and XLM-100 are on par even though the former uses 17 pretraining languages and the latter uses 100. One exception is Northern Sami (Uralic language with Latin script) due to XLM-17 not seeing any Uralic languages, but XLM-100 does during pretraining. When further comparing Div-10 and XLM-17, increase in accuracy by additional pretraining languages is limited. Erzya remains constant from five to 100 languages (except for XLM-R), even when increasing the pretraining corpus size from downsampled (Div-X) to full Wikipedia (XLM-17 and XLM-100).

RQ2 For the models with adaptation (Figure 8b), there is a significant gap between XLM-17 and XLM-100. This confirms our findings in the last section: more pretraining languages is beneficial if the pretrained models are adapted to the target languages. Thus, a possible explanation is that one or more of XLM-100's pretraining languages is similar to our target languages and such languages can only be exploited through continued pretraining (e.g., Ukrainian included in XLM-100 but not in Div-X). Therefore, having the model see more languages during pretraining is better when the models can be adapted to each target language.

6 Related Work

Static Cross-lingual Word Embeddings Static cross-lingual word embeddings (Mikolov et al., 2013; Conneau et al., 2018a) embed and align words from multiple languages for downstream NLP tasks (Lample et al., 2018; Gu et al., 2018), including a massive one trained on 50+ languages (Ammar et al., 2016). Static cross-lingual embedding methods can be classified into two groups: supervised and unsupervised. Supervised methods use bilingual lexica as the cross-lingual supervision signal. On the other hand, pretrained multilingual language models and unsupervised cross-lingual embeddings are similar because they do not use a bilingual lexicon. Lin et al. (2019) explore the selection of transfer language using both data-independent (e.g., typological) features, and data-dependent features (e.g., lexical overlap). Their work is on static supervised cross-lingual word embeddings, whereas this paper explores pretrained language models.

Analysis of Pretrained Multilingual Models on Seen Languages Starting from Pires et al. (2019), analysis of the cross-lingual transferability of pretrained multilingual language models has been a topic of interest. Pires et al. (2019) hypothesize that cross-lingual transfer occurs due to shared tokens across languages, but Artetxe et al. (2020) show that cross-lingual transfer can be successful even among languages without shared scripts. Other work investigates the relationship between zero-shot cross-lingual learning and typological features (Lauscher et al., 2020), encoding language-specific features (Libovický et al., 2020), and mBERT's multilinguality (Dufter and Schütze, 2020). However, the majority of analyses have either been limited to large public models (e.g., mBERT, XLM-R), to up to two pretraining languages (K et al., 2020; Wu and Dredze, 2020), or to target languages seen during pretraining. One exception is the concurrent work by de Vries et al. (2022) on analyzing the choice of language for the task-specific training data on unseen languages. Here, we analyze the ability of models to benefit from an increasing number of pretraining languages.

7 Conclusion

This paper explores the effect which pretraining on different numbers of languages has on unseen target languages after finetuning on English. We find: (1) if not adapting the pretrained multilingual language models to target languages, a set of diverse pretraining languages which covers the script and family of unseen target languages (e.g., 17 languages used for XLM-17) is likely sufficient; and (2) if adapting the pretrained multilingual language model to target languages, then one should pretrain on as many languages as possible up to at least 100.

Future directions include analyzing the effect of multilingual pretraining from different perspectives such as different pretraining tasks and architectures, e.g., mT5 (Xue et al., 2021), and more complex tasks beyond classification or sequence tagging.

A NER Results

We show additional experimental results on NER in Figures 9 and 10.

B NLI Results

Tables 5 and 6 shows the results without model adaptation, and Table 4 shows the full results with model adaptation.

C Notes on the Experimental Setup for Model Adaptation

Following are the additional notes on the setup of the model adaptation:

- No vocabulary augmentation is conducted unlike Wang et al. (2020a). We use XLM-R's vocabulary throughout all experiments in this paper.
- The Bible is used instead of Wikipedia for the continued pretraining or model adaptation to minimize the corpus size and contents inconsistency across languages.

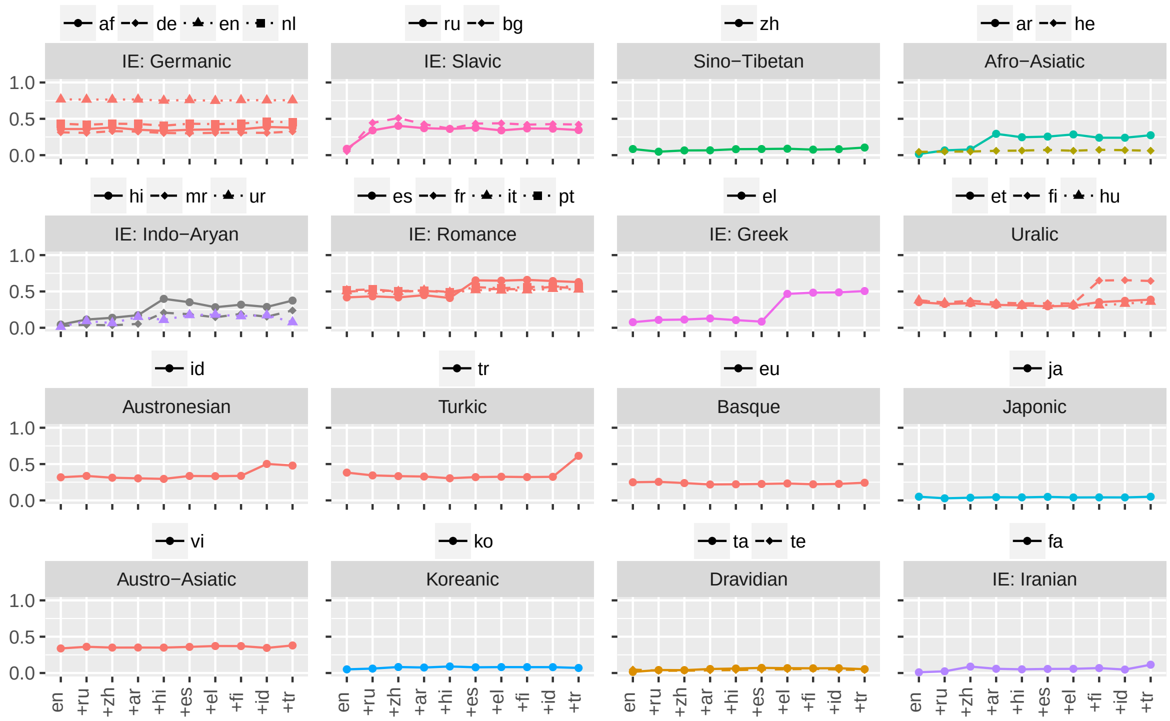

Figure 10: NER F1 score on diverse pretraining languages (EN, RU, ZH, AR, HI, ES, EL, FI, ID, TR) grouped by families of target languages, with Indo-European (IE) languages further divided into subgroups following XTREME. The accuracy gain is significant for seen pretraining languages, and also the languages from the same family of the pretraining languages when added.

Structured Pruning Learns Compact and Accurate Models

Mengzhou Xia **Zexuan Zhong** **Danqi Chen**
Princeton University
`{mengzhou,zzhong,danqic}@cs.princeton.edu`

Abstract

The growing size of neural language models has led to increased attention in model compression. The two predominant approaches are *pruning*, which gradually removes weights from a pre-trained model, and *distillation*, which trains a smaller compact model to match a larger one. Pruning methods can significantly reduce the model size but hardly achieve large speedups as distillation. However, distillation methods require large amounts of unlabeled data and are expensive to train. In this work, we propose a task-specific structured pruning method CoFi[1] (**Co**arse- and **Fi**ne-grained Pruning), which delivers highly parallelizable subnetworks and matches the distillation methods in both accuracy and latency, without resorting to any unlabeled data. Our key insight is to jointly prune coarse-grained (e.g., layers) and fine-grained (e.g., heads and hidden units) modules, which controls the pruning decision of each parameter with masks of different granularity. We also devise a layerwise distillation strategy to transfer knowledge from unpruned to pruned models during optimization. Our experiments on GLUE and SQuAD datasets show that CoFi yields models with over 10× speedups with a small accuracy drop, showing its effectiveness and efficiency compared to previous pruning and distillation approaches.[2]

Table 1: A comparison of state-of-the-art distillation and pruning methods. *U* and *T* denote whether *U*nlabeled and *T*ask-specific are used for distillation or pruning. The inference speedups (↗) are reported against a BERT$_{\text{base}}$ model and we evaluate all the models on an NVIDIA V100 GPU (§4.1). The models labeled as ‡ use a different teacher model and are not a direct comparison. Models are one order of magnitude faster.[3]

1 Introduction

Pre-trained language models (Devlin et al., 2019; Liu et al., 2019a; Raffel et al., 2020, *inter alia*) have become the mainstay in natural language processing. These models have high costs in terms of storage, memory, and computation time and it has motivated a large body of work on model compression to make them smaller and faster to use in real-world applications (Ganesh et al., 2021). The two predominant approaches to model compression are pruning and distillation (Table 1).

Pruning methods search for an accurate subnetwork in a larger pre-trained model. Recent work has investigated how to structurally prune Transformer networks (Vaswani et al., 2017), from removing entire layers (Fan et al., 2020; Sajjad et al., 2020), to pruning heads (Michel et al., 2019; Voita et al., 2019), intermediate dimensions (McCarley et al., 2019; Wang et al., 2020b) and blocks in weight matrices (Lagunas et al., 2021). The trend of structured pruning leans towards removing fine-grained units to allow for flexible final structures. However, thus far, pruned models rarely achieve large speedups (2-3× improvement at most).

By contrast, distillation methods usually first

May 22-27, 2022

specify a fixed model architecture and perform a *general distillation* step on an unlabeled corpus, before further fine-tuning or distillation on task-specific data (Sanh et al., 2019; Turc et al., 2019; Sun et al., 2019; Jiao et al., 2020). Well-designed student architectures achieve compelling speedup-performance tradeoffs, yet distillation to these randomly-initialized student networks on large unlabeled data is prohibitively slow.[4] For instance, TinyBERT (Jiao et al., 2020) is first trained on 2,500M tokens for 3 epochs, which requires training 3.5 days on 4 GPUs (Figure 1).[5]

In this work, we propose a task-specific, structured pruning approach called CoFi (**Co**arse and **Fi**ne-grained Pruning) and show that structured pruning can achieve highly compact subnetworks and obtain large speedups and competitive accuracy as distillation approaches, while requiring much less computation. Our key insight is to jointly prune coarse-grained units (e.g., self-attention or feed-forward layers) and fine-grained units (e.g., heads, hidden dimensions) simultaneously. Different from existing works, our approach controls the pruning decision of every single parameter by multiple masks of different granularity. This is the key to large compression, as it allows the greatest flexibility of pruned structures and eases the optimization compared to only pruning small units.

It is known that pruning with a distillation objective can substantially improve performance (Sanh et al., 2020; Lagunas et al., 2021). Unlike a fixed student architecture, pruned structures are unkown prior to training and it is challenging to distill between intermediate layers of the unpruned and pruned models (Jiao et al., 2020). Hence, we propose a layerwise distillation method, which dynamically learns the layer mapping between the two structures. We show that this strategy can better lead to performance gains beyond simple prediction-layer distillation.

Our experiments show that CoFi delivers more accurate models at all levels of speedups and model sizes on the GLUE (Wang et al., 2019) and SQuAD v1.1 (Rajpurkar et al., 2016) datasets, compared to strong pruning and distillation baselines. Concretely, it achieves over 10× speedups and a 95% sparsity across all the datasets while preserving more than 90% of accuracy. Our results suggest that task-specific structured pruning is an appealing solution in practice, yielding smaller and faster models without requiring additional unlabeled data for general distillation.

2 Background

2.1 Transformers

A Transformer network (Vaswani et al., 2017) is composed of L blocks and each block consists of a multi-head self-attention (MHA) layer, and a feed-forward (FFN) layer. An MHA layer with N_h heads takes an input X and outputs:

$$\mathrm{MHA}(X) = \textstyle\sum_{i=1}^{N_h} \mathrm{Att}(W_Q^{(i)}, W_K^{(i)}, W_V^{(i)}, W_O^{(i)}, X),$$

where $W_Q^{(i)}, W_K^{(i)}, W_V^{(i)}, W_O^{(i)} \in \mathbb{R}^{d \times d_h}$ denote the query, key, value and output matrices respectively and $\mathtt{Att}(\cdot)$ is an attention function. Here d denotes the hidden size (e.g., 768) and $d_h = d/N_h$ denotes the output dimension of each head (e.g., 64).

Next comes a feed-forward layer, which consists of an up-projection and a down-projection layer, parameterized by $W_U \in \mathbb{R}^{d \times d_f}$ and $W_D \in \mathbb{R}^{d_f \times d}$:

$$\mathrm{FFN}(X) = \mathrm{gelu}(XW_U) \cdot W_D.$$

Typically, $d_f = 4d$. There is also a residual connection and a layer normalization operation after each MHA and FFN layer.

MHAs, FFNs account for $1/3$ and $2/3$ of the model parameters in Transformers (embeddings excluded). According to Ganesh et al. (2021), both MHAs and FFNs take similar time on GPUs while FFNs become the bottleneck on CPUs.

2.2 Distillation

Knowledge distillation (Hinton et al., 2015) is a model compression approach that transfers knowledge from a larger teacher model to a smaller student model. *General distillation* (Sanh et al., 2019; Sun et al., 2020; Wang et al., 2020a) and *task-specific distillation* (Sun et al., 2019) exploit unlabeled data and task-specific data respectively for knowledge transfer. A combination of the two leads to increased performance (Jiao et al., 2020). General distillation or pre-training the student network on unlabeled corpus is essential for retaining performance while being computationally expensive (Turc et al., 2019; Jiao et al., 2020).

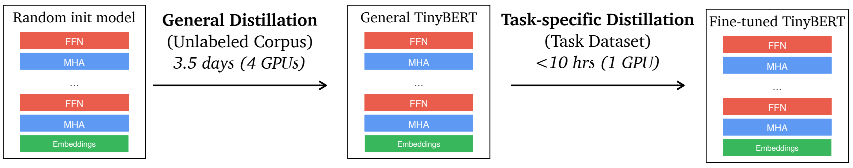
Different distillation objectives have been also explored. Besides standard distillation from the

---

[4] There are exceptions like DistillBERT (Sanh et al., 2020), which initializes the student from the teacher by taking one layer out of two, yet it is unclear how to generalize this initialization scheme to other compact structures.

[5] See training time measurement details in Appendix J.

(a) **TinyBERT**



(b) **CoFi (Ours)**

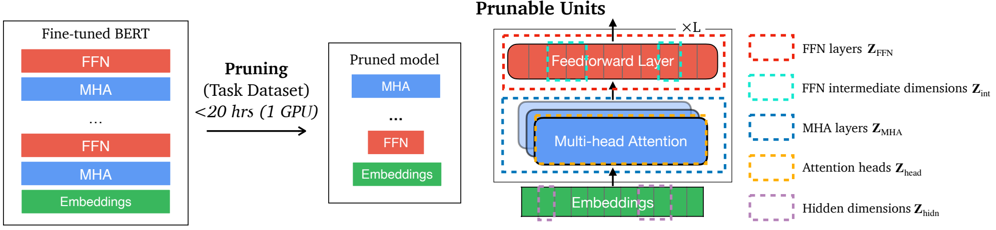


Figure 1: Comparison of (a) TinyBERT (Jiao et al., 2020) and (b) our pruning approach CoFi. TinyBERT trains a randomly-initialized network through two-step distillation: (1) general distillation on a large unlabeled corpus, which takes 3.5 days to finish on 4 GPUs, and (2) task-specific distillation on the task dataset. CoFi directly prunes the fine-tuned BERT model and jointly learn five types of mask variables (i.e., $\mathbf{z}_{\text{FFN}}, \mathbf{z}_{\text{int}}, \mathbf{z}_{\text{MHA}}, \mathbf{z}_{\text{head}}, \mathbf{z}_{\text{hidn}}$) to prune different types of units (Section 3.1). CoFi takes at most 20 hours to finish on 1 GPU on all the GLUE datasets (smaller datasets need $<$ 3 hour).[6]

prediction layer (Hinton et al., 2015), transferring knowledge layer-by-layer from representations (Jiao et al., 2020; Sun et al., 2020) and multi-head attention matrices (Wang et al., 2020a; Jiao et al., 2020; Sun et al., 2020) lead to significant improvements. Most distillation approaches assume a fixed student structure prior to training. Hou et al. (2020) attempt to distill to a dynamic structure with specified widths and heights. Yin et al. (2021) adopt a one-shot Neural Architecture Search solution to search architectures of student networks.

2.3 Pruning

Pruning gradually removes redundant parameters from a teacher model, mostly producing task-specific models. Previous works focus on pruning different components in Transformer models, from coarse-grained to fine-grained units.

Layer pruning Fan et al. (2020) and Sajjad et al. (2020) explore strategies to drop entire Transformer blocks (a pair of MHA and FFN layer) from a pre-trained model. Empirical evidence suggests that 50% of layers can be dropped without big accuracy drop, resulting in a 2× speedup.

Head pruning Voita et al. (2019); Michel et al. (2019) show that only a small subset of heads are important and the majority can be pruned. We follow these works to mask heads by introducing variables $\mathbf{z}_{\text{head}}^{(i)} \in \{0, 1\}$ to multi-head attention:

$$\text{MHA}(X) = \sum_{i=1}^{N_h} \mathbf{z}_{\text{head}}^{(i)} \text{Att}(W_Q^{(i)}, W_K^{(i)}, W_V^{(i)}, W_O^{(i)}, X).$$

Only removing heads does not lead to large latency improvement—Li et al. (2021) demonstrate a 1.4× speedup with only one remaining head per layer.

FFN pruning The other major part—feed-forward layers (FFNs)—are also known to be overparameterized. Strategies to prune an FFN layer for an inference speedup include pruning an entire FFN layer (Prasanna et al., 2020; Chen et al., 2020b) and at a more fine-grained level, pruning intermediate dimensions (McCarley et al., 2019; Hou et al., 2020) by introducing $\mathbf{z}_{\text{int}} \in \{0, 1\}^{d_f}$:

$$\text{FFN}(X) = \text{gelu}(XW_U) \cdot \text{diag}(\mathbf{z}_{\text{int}}) \cdot W_D.$$

Block and unstructured pruning More recently, pruning on a smaller unit, blocks, from MHAs and FFNs have been explored (Lagunas et al., 2021). However, it is hard to optimize models with blocks pruned thus far: Yao et al. (2021) attempt to optimize block-pruned models with the block sparse MatMul kernel provided by Triton (Tillet et al., 2019), but the reported results are not competitive. Similarly, *unstructured pruning* aims to remove individual weights and has been extensively studied in the literature (Chen et al., 2020a; Huang et al., 2021). Though the sparsity reaches up to 97%

---

[6] CoFi requires slightly longer training time compared to the task-specific distillation of TinyBERT, as CoFi searches model structures and learns parameters simultaneously.

(Sanh et al., 2020), it is hard to obtain inference speedups on the current hardware.

Combination with distillation Pruning is commonly combined with a prediction-layer distillation objective (Sanh et al., 2020; Lagunas et al., 2021). Yet it is not clear how to apply layerwise distillation strategies as the pruned student model's architecture evolves during training.

3 Method

We propose a structured pruning approach CoFi, which jointly prunes **Co**arse-grained and **Fi**ne-grained units (§3.1) with a layerwise distillation objective transferring knowledge from unpruned to pruned models (§3.2). A combination of the two leads to highly compressed models with large inference speedups.

3.1 Coarse- and Fine-Grained Pruning

Recent trends in structured pruning move towards pruning smaller units for model flexibility. Pruning fine-grained units naturally entails pruning coarse-grained units—for example, pruning N_h (e.g., 12) heads is equivalent to pruning one entire MHA layer. However, we observe that this rarely happens in practice and poses difficulty to optimization especially at a high sparsity regime.

To remedy the problem, we present a simple solution: we allow pruning MHA and FFN layers explicitly along with fine-grained units (as shown in §2.3) by introducing two additional masks z_{MHA} and z_{FFN} for each layer. Now the multi-head self-attention and feed-forward layer become:

$$\begin{aligned}\text{MHA}(X) &= z_{\text{MHA}} \cdot \sum_{i=1}^{N_h} (\mathbf{z}_{\text{head}}^{(i)} \cdot \\ &\qquad \text{Att}(W_Q^{(i)}, W_K^{(i)}, W_V^{(i)}, W_O^{(i)}, X), \\ \text{FFN}(X) &= z_{\text{FFN}} \cdot \text{gelu}(XW_U) \cdot \text{diag}(\mathbf{z}_{\text{int}}) \cdot W_D.\end{aligned}$$

With these layer masks, we explicitly prune an entire layer, instead of pruning all the heads in one MHA layer (or all the intermediate dimensions in one FFN layer). Different from the layer dropping strategies in Fan et al. (2020); Sajjad et al. (2020), we drop MHA and FFN layers separately, instead of pruning them as a whole.

Furthermore, we also consider pruning the output dimensions of $\text{MHA}(X)$ and $\text{FFN}(X)$, referred to as 'hidden dimensions' in this paper, to allow for more flexibility in the final model structure. We define a set of masks $\mathbf{z}_{\text{hidn}} \in \{0, 1\}^d$, shared across layers because each dimension in a hidden representation is connected to the same dimension in the next layer through a residual connection. These mask variables are applied to all the weight matrices in the model, e.g., $\text{diag}(\mathbf{z}_{\text{hidn}})W_Q$. Empirically, we find that only a small number of dimensions are pruned (e.g., 768 → 760), but it still helps improve performance significantly (§4.3).

CoFi differs from previous pruning approaches in that multiple mask variables jointly control the pruning decision of one single parameter. For example, a weight in an FFN layer is pruned when the entire FFN layer, or its corresponding intermediate dimension, or the hidden dimension is pruned. As a comparison, a recent work Block Pruning (Lagunas et al., 2021) adopts a hybrid approach which applies a pruning pruning strategy on MHAs and FFNs separately.

To learn these mask variables, we use l_0 regularization modeled with hard concrete distributions following Louizos et al. (2018). We also follow Wang et al. (2020b) to replace the vanilla l_0 objective with a Lagrangian multiplier to better control the desired sparsity of pruned models.[7] We adapt the sparsity function accordingly to accommodate pruning masks of different granularity:

$$\begin{aligned}\hat{s} = &\tfrac{1}{M} \cdot 4 \cdot d_h \cdot \textstyle\sum_i^L \sum_j^{N_h} \sum_k^d \mathbf{z}_{\text{MHA}}^{(i)} \cdot \mathbf{z}_{\text{head}}^{(i,j)} \cdot \mathbf{z}_{\text{hidden}}^{(k)} \\ &+ \tfrac{1}{M} \cdot 2 \cdot \textstyle\sum_i^L \sum_j^{d_f} \sum_k^d \mathbf{z}_{\text{FFN}}^{(i)} \cdot \mathbf{z}_{\text{int}}^{(i,j)} \cdot \mathbf{z}_{\text{hidden}}^{(k)},\end{aligned}$$

where $\hat{s}$ is the expected sparsity and M denotes the full model size. All masking variables are learned as real numbers in $[0, 1]$ during training and we map the masking variables below a threshold to 0 during inference and get a final pruned structure where the threshold is determined by the expected sparsity of each weight matrix (see Appendix B for more details).

3.2 Distillation to Pruned Models

Previous work has shown that combining distillation with pruning improves performance, where the distillation objective only involves a cross-entropy loss between the pruned student's and the teacher's output probability distributions $\mathbf{p}_s$ and $\mathbf{p}_t$ (Sanh et al., 2020; Lagunas et al., 2021):

$$\mathcal{L}_{\texttt{pred}} = D_{\texttt{KL}}(\mathbf{p}_s \parallel \mathbf{p}_t).$$

---

[7] We also tried a straight-through estimator as proposed in Sanh et al. (2020) and found the performance comparable. We choose l_0 regularization because it is easier to control the sparsity precisely.

In addition to prediction-layer distillation, recent works show great benefits in distillation of intermediate layers (Sun et al., 2019; Jiao et al., 2020). In the context of distillation approaches, the architecture of the student model is pre-specified, and it is straightforward to define a layer mapping between the student and teacher model. For example, the 4-layer TinyBERT$_4$ model distills from the 3, 6, 9 and 12-th layer of a 12-layer teacher model. However, distilling intermediate layers during the pruning process is challenging as the model structure changes throughout training.

We propose a layerwise distillation approach for pruning to best utilize the signals from the teacher model. Instead of pre-defining a fixed layer mapping, we dynamically search a layer mapping between the full teacher model and the pruned student model. Specifically, let $\mathcal{T}$ denote a set of teacher layers that we use to distill knowledge to the student model. We define a layer mapping function $m(\cdot)$, i.e., $m(i)$ represents the student layer that distills from the teacher layer i. The hidden layer distillation loss is defined as

$$\mathcal{L}_{\texttt{layer}} = \sum_{i \in \mathcal{T}} \texttt{MSE}(W_{\texttt{layer}} \mathbf{H}_s^{m(i)}, \mathbf{H}_t^i),$$

where $W_{\texttt{layer}} \in \mathbb{R}^{d \times d}$ is a linear transformation matrix, initialized as an identity matrix. $\mathbf{H}_s^{m(i)}, \mathbf{H}_t^i$ are hidden representations from $m(i)$-th student FFN layer and i-th teacher FFN layer. The layer mapping function $m(\cdot)$ is dynamically determined during the training process to match a teacher layer to its closest layer in the student model:

$$m(i) = \arg\min_{j: \mathbf{z}_{\texttt{FFN}}^{(j)} > 0} \texttt{MSE}(W_{\texttt{layer}} \mathbf{H}_s^j, \mathbf{H}_t^i).$$

Calculating the distance between two sets of layers is highly parallelizable and introduces a minimal training overhead. To address the issue of layer mismatch, which mostly happens for small-sized datasets, e.g., RTE, MRPC, we add a constraint to only allow matching a teacher layer to a lower student layer than the previously matched student layer. When pruning with larger sized datasets, layer mismatch rarely happens, showing the superiority of dynamic matching—layers between student and teacher models match in a way that benefits the pruning process the most.

Finally, we combine layer distillation with the prediction-layer distillation:

$$\mathcal{L}_{\texttt{distil}} = \lambda \mathcal{L}_{\texttt{pred}} + (1 - \lambda) \mathcal{L}_{\texttt{layer}},$$

where λ controls the contribution of each loss.

4 Experiments

4.1 Setup

Datasets We evaluate our approach on eight GLUE tasks (Wang et al., 2019) and SQuAD v1.1 (Rajpurkar et al., 2016). GLUE tasks include SST-2 (Socher et al., 2013), MNLI (Williams et al., 2018), QQP, QNLI, MRPC (Dolan and Brockett, 2005), CoLA (Warstadt et al., 2019), STS-B (Cer et al., 2017) and RTE (see Appendix D for dataset sizes and metrics).

Training setup In our experiments, *sparsity* is computed as the number of pruned parameters divided by the full model size (embeddings excluded). Following Wang et al. (2020b); Lagunas et al. (2021), we first finetune the model with the distillation objective, then we continue training the model with the pruning objective with a scheduler to linearly increase the sparsity to the target value. We finetune the pruned model until convergence (see Appendix A for more training details). We train models with target sparsities of $\{60\%, 70\%, 75\%, 80\%, 85\%, 90\%, 95\%\}$ on each dataset. For all the experiments, we start from the BERT$_{\text{base}}$ model[8] and freeze embedding weights following Sanh et al. (2020). We report results on development sets of all datasets.

Baselines We compare CoFi against several baselines: DistillBERT$_6$ (Sanh et al., 2019), TinyBERT$_6$ and TinyBERT$_4$ (Jiao et al., 2020), DynaBERT (Hou et al., 2020), and Block Pruning (Lagunas et al., 2021) (see Appendix C for details). We also compare to other pruning methods such as FLOP (Wang et al., 2020b), LayerDrop (Fan et al., 2020), Movement Pruning (Sanh et al., 2020) and distillation methods such as MobileBERT (Sun et al., 2020) and AutoTinyBERT (Yin et al., 2021) in Appendix F.[9]

For TinyBERT and DynaBERT, the released models are trained with task-specific augmented data. For a fair comparison, we train these two models with the released code without data augmentation.[10] For Block Pruning, we train models

---

[8] We also experiments CoFi on RoBERTa models (Liu et al., 2019a). Please refer to Appendix I for details.

[9] We show these results in Appendix F as they are not directly comparable to CoFi.

[10] For TinyBERT, the augmented data is 20× larger than the original data, making the training process significantly slower.

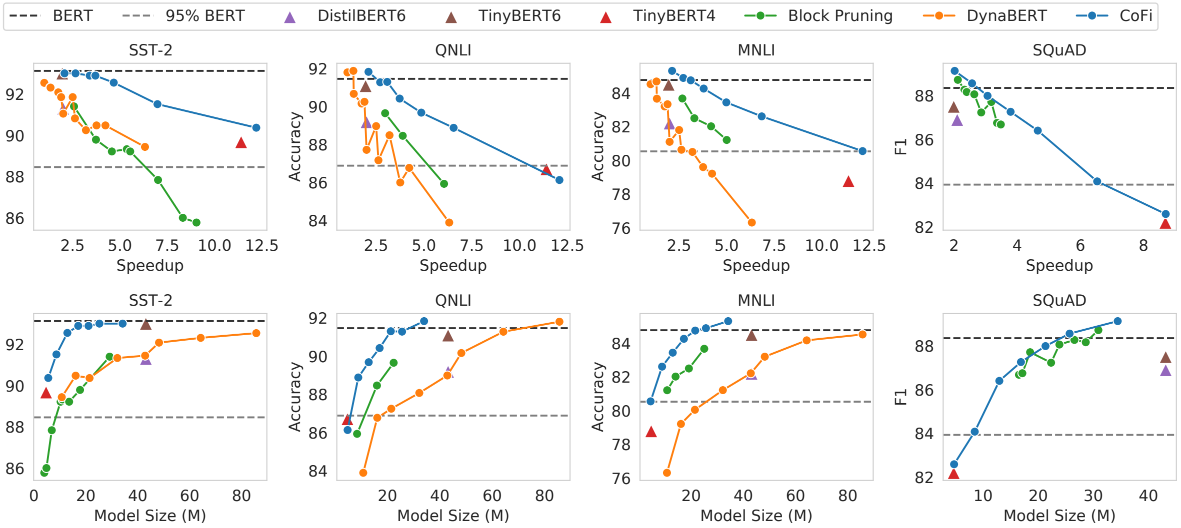

Figure 2: Accuracy v.s. speedup (top) or model size (bottom). We compare CoFi against state-of-the-art distillation and pruning baselines. Note that we exclude embedding size when calculating model size following previous work, as forwarding through the embedding layer has little effect on inference time.

Task	SST-2 (67k)	QNLI (105k)	MNLI (393k)	QQP (364k)	CoLA (8.5k)	RTE (2.5k)	STS-B (7k)	MRPC (3.7k)	SQuAD (88k)	Train Time

Speedup ↗	12.0×	12.1×	12.1×	11.0×	11.5×	11.9×	12.9×	11.9×	8.7×	-

Table 2: CoFi v.s. TinyBERT$_4$ (Jiao et al., 2020) models with a ∼10× speedup. GD: general distillation, which distills the student model on a large unlabeled corpus. Train time is measured in GPU hours (see Appendix J for details). The number of parameters for both models are around 5M (around 95% sparsity). CoFi closes the gap between distillation and pruning with significantly less computation. Note that we remove data augmentation from TinyBERT for a fair comparison, see Table 3 for experiments with augmented data.

Task	TinyBERT$_4$	CoFi (ours)
SST-2	89.7 → 91.6	90.6 → **92.4**
QNLI	86.7 → **87.6**	86.1 → 86.8
RTE	63.2 → 62.5	64.7 → **67.5**
MRPC	81.4 → 83.6	82.6 → **84.6**

Table 3: CoFi v.s. TinyBERT$_4$ trained with task-specific data augmentation introduced in Jiao et al. (2020). All models have around 5M parameters (95% sparsity) and achieve similar speedups (11-12×). The numbers before → are without data augmentation.

with their released checkpoints on GLUE tasks and use SQuAD results from the paper.

Speedup evaluation Speedup rate is a primary measurement we use throughout the paper as the compression rate does not necessarily reflect the actual improvement in inference latency [11]. We use an unpruned BERT$_{\text{base}}$ as the baseline and evaluate all the models with the same hardware setup on a single NVIDIA V100 GPU to measure inference speedup. The input size is 128 for GLUE tasks and 384 for SQuAD, and we use a batch size of 128. Note that the results might be different from the original papers as the environment for each platform is different.

4.2 Main Results

Overall performance In Figure 2, we compare the accuracy of CoFi models to other methods in terms of both inference speedup and model size. CoFi delivers more accurate models than distillation and pruning baselines at every speedup level

---

[11] Models with the same compression rate could have considerably different speedups.

and model size. Block Pruning (Lagunas et al., 2021), a recent work that shows strong performance against TinyBERT$_6$, is unable to achieve comparable speedups as TinyBERT$_4$. Instead, CoFi has the option to prune both layers and heads & intermediate units and can achieve a model with a comparable or higher performance compared to TinyBERT$_4$ and all the other models. Additionally, DynaBERT performs much worse speed-wise because it is restricted to remove at most half of the MHA and FFN layers.

Comparison with TinyBERT$_4$ In Table 2, we show that CoFi produces models with over $10\times$ inference speedup and achieves comparable or even better performance than TinyBERT$_4$. General distillation (GD), which distills information from a large corpus, is essential for training distillation models, especially for small-sized datasets (e.g., TinyBERT$_4$ w/o GD performs poorly on CoLA, RTE and STS-B). While general distillation could take up to hundreds of GPU hours for training, CoFi trains for a maximum of 20 hours on a task-specific dataset with a single GPU. We argue that pruning approaches—trained with distillation objectives like CoFi—are more economical and efficient in achieving compressed models.

We further compare CoFi with TinyBERT$_4$ under the data augmentation setting in Table 3. As the augmented dataset is not publicly released, we follow its GitHub repository to create our own augmented data. We train CoFi with the same set of augmented data and find that it still outperforms TinyBERT$_4$ on most datasets.[12]

4.3 Ablation Study

Pruning units We first conduct an ablation study to investigate how additional pruning units such as MHA layers, FFN layers and hidden units in CoFi affect model performance and inference speedup beyond the standard practice of pruning heads and FFN dimensions. We show results in Table 4 for models of similar sizes. Removing the option to prune hidden dimensions ($\mathbf{z}_{\text{hidn}}$) leads to a slightly faster model with a performance drop across the board and we find that it removes more layers than CoFi and does not lead to optimal performance under a specific sparsity constraint. In addition, removing the layer masks ($\mathbf{z}_{\text{MHA}}$, $\mathbf{z}_{\text{FFN}}$) brings a significant drop in speedup on highly compressed models (95%, 5M). This result shows that even with the same amount of parameters, different configurations for a model could lead to drastically different speedups. However, it does not affect the lower sparsity regime (60%, 34M). In short, by placing masking variables at different levels, the optimization procedure is incentivized to prune units accordingly under the sparsity constraint while maximizing the model performance.

Distillation objectives We also ablate on distillation objectives to see how each part contributes to the performance of CoFi in Table 5. We first observe that removing distillation entirely leads to a performance drop up to 1.9-6.8 points across various datasets, showing the necessity to combine pruning and distillation for maintaining performance. The proposed hidden layer distillation objective dynamically matches the layers from the teacher model to the student model. We also experiment with a simple alternative i.e., “fixed Hidden Distillation”, which matches each layers from the teacher model to the corresponding layer in the student model – if a layer is already pruned, the distillation objective will *not* be added. We find that fixed hidden distillation underperforms the dynamic layer matching objective used for CoFi. Interestingly, the proposed dynamic layer matching objective consistently converges to a specific alignment between the layers of the teacher model and student model. For example, we find that on QNLI the training process dynamically matches the 3, 6, 9, 12 layers in the teacher model to 1, 2, 4, 9 layers in the student model.[13] Moreover, as shown in the table, removing it hurts the performance for all the datasets except SST-2.

4.4 Structures of Pruned Models

Finally, we study the pruned structures produced by CoFi. We characterize the pruned models of sparsities $\{60\%, 70\%, 80\%, 90\%, 95\%\}$ on five datasets. For each setting, we run CoFi three times. Figure 3 demonstrates the number of remaining heads and intermediate dimensions of the pruned models for different sparsities.[14] Interestingly, we discover common structural patterns in the pruned models: (1) Feed-forward layers are significantly pruned

---

[12] We only conduct experiments with data augmentation on four datasets because training on augmented data is very expensive. For example, training on the augmented dataset for MNLI takes more than 200 GPU hours in total. See more details in Appendix E.

[13] Please refer to subsection G.1 for more details.

[14] We show more layer analysis in Appendix H.

$-\mathcal{L}_{\texttt{layer}}$	**91.1**	85.1	79.7	82.5
$-\mathcal{L}_{\texttt{pred}}, \mathcal{L}_{\texttt{layer}}$	86.6	84.2	78.2	75.8
Fixed Hidn Distil.	90.0	85.8	80.5	80.9

Table 5: Ablation study of different distillation objectives on pruned models with sparsity = 95%. Fixed hidden distillation: simply matching each layer of the student and the teacher model, see §4.3 for more details. In subsection G.2, we show that the dynamic layer distillation objective improves model performance more significantly on lower sparsity rates.

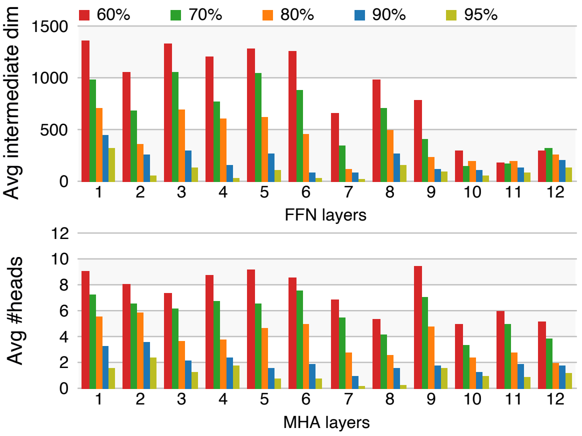

Figure 3: The average intermediate dimensions at each FFN layer and the average number of heads at each MHA layer in the pruned models across five datasets (SST-2, MNLI, QQP, QNLI, and SQuAD 1.1). We study different sparsities $\{60\%, 70\%, 80\%, 90\%, 95\%\}$.

across all sparsities. For example, at the 60% sparsity level, the average number of intermediate dimensions in FFN layers after pruning is reduced by 71% ($3,072 \rightarrow 884$), and the average number of heads in MHA is reduced by 39% ($12 \rightarrow 7.3$). This suggests FFN layers are more redundant than MHA layers. (2) CoFi tends to prune submodules more from upper layers than lower layers. For example, upper MHA layers have fewer remaining heads than lower layers on average.

Furthermore, we study the number of remaining FFN and MHA layers and visualize the results in Table 6 for highly compressed models (sparsity = 95%). Although all the models are roughly of the same size, they present different patterns across datasets, which suggests that there exist different optimal sub-networks for each dataset. We find that on SST-2 and QNLI, the first MHA layer is preserved but can be removed on QQP and SQuAD. We also observe that some layers are particularly important across all datasets. For example, the first MHA layer and the second MHA layer are preserved most of the time, while the middle layers are often removed. Generally, the pruned models contain more MHA layers than FFN layers (see Appendix H), which suggests that MHA layers are more important for solving downstream tasks. Similar to Press et al. (2020), we find that although standard Transformer networks have interleaving FFN layers and MHA layers, in our pruned models, adjacent FFN/MHA layers could possibly lead to a better performance.

5 Related Work

Structured pruning has been widely explored in computer vision, where channel pruning (He et al., 2017; Luo et al., 2017; Liu et al., 2017, 2019c,b; Molchanov et al., 2019; Guo et al., 2020) is a standard approach for convolution neural networks. The techniques can be adapted to Transformer-based models as introduced in subsection 2.3. Unstructured pruning is another major research direction, especially gaining popularity in the theory of Lottery Ticket Hypothesis (Frankle and Carbin, 2019; Zhou et al., 2019; Renda et al., 2020; Frankle

Table 6: Remaining layers in the models pruned by CoFi on different datasets. All models are pruned at a sparsity of 95%. For each setting, we run the experiments three times to obtain three different pruned models. M represents a remaining MHA layer and F represents a remaining FFN layer.

et al., 2020; Chen et al., 2020a). Unstructured pruning produces models with high sparsities (Sanh et al., 2020; Xu et al., 2021; Huang et al., 2021) yet hardly bring actual inference speedups. Developing computing platform for efficient sparse tensor operations is an active research area. DeepSparse[15] is CPU inference engine that leverages unstructured sparsity for speedup. Huang et al. (2021) measure the real inference speedup induced by unstructured pruning on Moffett AI's latest hardware platform ANTOM. We do not directly compare to these methods because the evaluation environments are different.

While all the aforementioned methods produce task-specific models through pruning, several works explore upstream pruning where they prune a large pre-trained model with the masked language modeling task. Chen et al. (2020a) show a 70%-sparsity model retains the MLM accuracy produced by iterative magnitude pruning. Zafrir et al. (2021) show the potential advantage of upstream unstructured pruning against downstream pruning. We consider applying CoFi for upstream pruning as a promising future direction to produce task-agnostic models with flexible structures.

Besides pruning, many other techniques have been explored to gain inference speedups for Transformer models, including distillation as introduced in subsection 2.2, quantization (Shen et al., 2020; Fan et al., 2021), dynamic inference acceleration (Xin et al., 2020) and matrix decomposition (Noach and Goldberg, 2020). We refer the readers to Ganesh et al. (2021) for a comprehensive survey.

6 Conclusion

We propose CoFi, a structured pruning approach that incorporates all levels of pruning, including MHA/FFN layers, individual heads, and hidden dimensions for Transformer-based models. Coupled with a distillation objective tailored to structured pruning, we show that CoFi compresses models into a rather different structure from standard distillation models but still achieves competitive results with more than 10× speedup. We conclude that task-specific structured pruning from large-sized models could be an appealing replacement for distillation to achieve extreme model compression, without resorting to expensive pre-training or data augmentation. Though CoFi can be directly applied to structured pruning for task-agnostic models, we frame the scope of this work to task-specific pruning due to the complexity of the design choices for upstream pruning. We hope that future research continues this line of work, given that pruning from a large pre-trained model could possibly incur less computation compared to general distillation and leads to more flexible model structures.

A Reproducibility & Hyperparameters

We report the hyperparameters that we use in our experiments in Table 7.

Hyperparameter	
λ	$0.1, 0.3, 0.5$
distillation temperature t	2
finetuning epochs	20
finetuning learning rate	$1e-5, 2e-5, 3e-5$
training learning rate	$2e-5$ (GLUE), $3e-5$ (SQuAD)
batch size	32 (GLUE), 16 (SQuAD)

Table 7: Hyperparemeters in the experiments.

For four relatively larger GLUE datasets, MNLI, QNLI, SST-2 and QQP, and SQuAD, we train the model for 20 epochs in total and finetune the finalized sub-network for another 20 epochs. In the first 20 epochs, following Lagunas et al. (2021) and Wang et al. (2020b), we first finetune the model with the distillation objective for 1 epoch, and then start pruning with a linear schedule to achieve the target sparsity within 2 epochs. For the four small GLUE datasets, we train the model for 100 epochs in total and finetune for 20 epochs. We finetune the model with the distillation objective for 4 epochs and prune till the target sparsity within the next 20 epochs. Note that even if the final sparsity is achieved, the pruning process keeps searching better performing structures in the rest of the training epochs. In addition, we find that finetuning the final subnetwork is essential for high sparsity models. Hyperparameters like λ, batch size, and learning rate do not generally affect performance much.

B Optimization Details

Louizos et al. (2018) propose l_0 optimization for model compression where the masks are modelled with hard concrete distributions as follows:

$$\begin{aligned}
&\mathbf{u} \sim U(0,1) \\
&\mathbf{s} = \text{sigmoid}\left(\frac{1}{\beta}\log\frac{\mathbf{u}}{\mathbf{1}-\mathbf{u}} + \log\alpha\right) \\
&\tilde{\mathbf{s}} = \mathbf{s} \times (r-l) + l \\
&\mathbf{z} = \min(1, \max(0, \tilde{\mathbf{s}})).
\end{aligned}$$

$U(0,1)$ is a uniform distribution in the interval $[0,1]$; $l < 0$ and $r > 0$ are two constants that stretch the sigmoid output into the interval (l,r). β is a hyperparameter that controls the steepness of the sigmoid function and $\log\alpha$ is the main learnable parameter. We learn the masks through updating the learnable parameters of the distributions from which the masks are sampled in the forward pass.

In our preliminary experiments, we find that optimizing $\lambda\|\mathbf{z}\|_0$ with different learning rates and pruning schedules may converge to models of drastically different sizes. Hence, we follow Wang et al. (2020b) to add a Lagrangian term, which imposes an equality constraint $\hat{s} = t$ by introducing a violation penalty:

$$\mathcal{L}_c = \lambda_1 \cdot (\hat{s} - t) + \lambda_2 \cdot (\hat{s} - t)^2,$$

where $\hat{s}$ is the expected model sparsity calculated from $\mathbf{z}$ and t is the target sparsity.

C Details of Baseline Methods

We compare against several strong pruning and distillation models, including 1) **DistillBERT$_6$** (Sanh et al., 2019); 2) **TinyBERT$_6$** and **TinyBERT$_4$** (Jiao et al., 2020) both include general distillation for pretraining and task-specific distillation; 3) **DynaBERT** (Hou et al., 2020): a method that provides dynamic-sized models by specifying width and depth; 4) **Block Pruning** (Lagunas et al., 2021): a pruning method coupled with prediction-layer distillation. We choose their strongest approach "Hybrid Filled" as our baseline.

D Data Statistics

We show train sizes and metrics for each dataset we use in Table 8.

Task	Train Size	Metric
SST-2	67k	accuracy
QNLI	105k	accuracy
MNLI	393k	accuracy
QQP	364k	accuracy
CoLA	8.5k	Matthews corr.
RTE	2.5k	accuracy
STS-B	7k	Spearman corr.
MRPC	3.7k	accuracy
SQuAD	88k	F1

Table 8: Data statistics of GLUE and SQuAD datasets.

E TinyBERT$_4$ w/ Data Augmentation

We conduct task-specific distillation with the script provided by the TinyBERT repository.[16] However, our reproduced results are slightly lower than the reported results in (Jiao et al., 2020). The difference between these two sets of scores may stem from augmented data or teacher models. Note that the authors of TinyBERT did not release the augmented dataset. We run their codes to obtain augmented datasets. We compare CoFi and TinyBERT under the same setting where we use the same teacher model and the same set of augmented data.

	SST-2	QNLI	RTE	MRPC
TinyBERT$_4$ reimpl.	91.6	87.6	62.5	83.6
Jiao et al. (2020)	92.7	88.0	65.7	85.7

Table 9: Re-implemented (TinyBERT$_4$ reimpl.) results and the results reported in Jiao et al. (2020).

F Additional Comparisons

F.1 Comparison to Movement Pruning

We compare CoFi with a state-of-the-art **unstructured pruning** method, Movement Pruning (Sanh et al., 2020) in Figure 4. As Movement Pruning is trained with prediction-layer (logit) distillation only, we also show results of CoFi trained with the same distillation objective. We observe that CoFi largely outperforms Movement Pruning even without layerwise distillation on MNLI and is comparable to SQuAD on models with a size over $10M$ parameters. CoFi, as a structured pruning method, is less performant on models of a sparsity up to 95%, as pruning flexibility is largely restricted by the smallest pruning unit. However, pruned models from CoFi achieve $2 - 11\times$ inference speedups while no speedup gains are achieved from Movement Pruning.

F.2 Comparison to Block Pruning

In Figure 6, we compare CoFi with Block Pruning while unifying the distillation objective. Without the layer distillation objective, CoFi still outperforms or is on par with Block Pruning. Block Pruning never achieves a speedup of 10 even the pruned model is of a similar size as CoFi (SST-2), backing up our argument that pruning layers for high sparsity models is the key to high speedups.

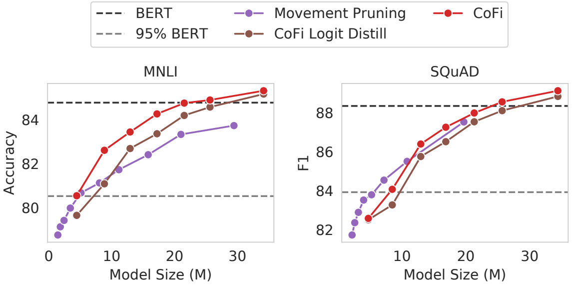

Figure 4: CoFi v.s. Movement Pruning (unstructured pruning). CoFi Logit Distill denotes that we run CoFi with prediction-layer distillation only as Movement Pruning.

F.3 More Baselines

We show additional pruning and distillation methods that are not directly comparable to CoFi in Table 10. CoFi still largely outperforms these baselines even though these methods hold an inherent advantage due to a stronger teacher or base model.

	↗	SST-2	QNLI	MNLI	SQuAD
Wang et al. (2020b)‡	1.5×	92.1	89.1	-	85.4
Sajjad et al. (2020)	2.0×	90.3	-	81.1	-
Fan et al. (2020)‡	2.0×	93.2	89.5	84.1	-

CoFi (ours)	2.0×	93.0	91.8	85.3	89.1
CoFi (ours)	4.6×	92.6	89.7	83.4	86.4

Table 10: More pruning and distillation baselines. ↗: speedup. ‡ denotes that the model prunes from a RoBERTa$_{\text{base}}$ model. ♠: AutoTinyBERT is distilled from an ELECTRA$_{\text{base}}$ model. ◇: MobileBERT (Sun et al., 2020) has specialized architecture designs and trains their own teacher model from the scratch. CoFi models have a model size of 34M and 13M respectively, corresponding to a 60% and 85% sparsity.

G More Analyses on Layer Distillation

G.1 Layer Alignment

We find that the alignment between the layers of the student model and the teacher model shifts during the course of training. To take SST-2 for an example, as the training goes on, the model learns the alignment to match the $7, 9, 10, 11$ layers of the student model to the $3, 6, 9, 12$ layers of the teacher model. For QQP, the model eventually learns to map $2, 5, 8, 11$ layers to the four layers of the teacher model. The final alignment shows that our dynamic layer matching distillation objective can find task-specific alignment and improve

---

[16] https://github.com/huawei-noah/Pretrained-Language-Model/tree/master/TinyBERT

performance.

G.2 Ablation on Distillation Objectives

In Table 11, we show ablation studies on adding the dynamic layer distillation onto prediction distillation across all sparsities. Using the layer distillation loss clearly helps improve the performance on all sparsity rates and different tasks.

H FFN/MHA Layers in Pruned Models

Figure 5 shows the average number of FFN layers and MHA layers in the pruned models by CoFi. We study different sparsities $\{60\%, 70\%, 80\%, 90\%, 95\%\}$. It is clear that when the sparsity increases, the pruned models become shallower (i.e., the number of layers becomes fewer). Furthermore, we find that the pruned models usually have more MHA layers than FFN layers. This may indicate that MHA layers are more important for solving these downstream tasks than FFN layers.

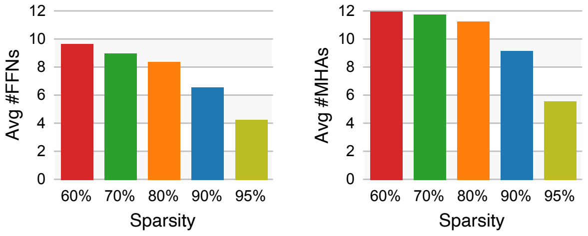

Figure 5: The average number of FFN layers and MHA layers in the pruned models at different sparsities.

I RoBERTa Pruning

We show CoFi results with RoBERTa in Figure 7 across sparsities from 60% to 95%. Similar to BERT, models with 60% weights pruned are able to maintain the performance of a full model. Pruning from RoBERTa outperforms BERT on sparsities lower than 90% but as the sparsity further increases, BERT surpasses RoBERTa. Similar patterns are observed from DynaBERT (Hou et al., 2020).

J Training Time Measurement

We use NVIDIA RTX 2080Ti GPUs to measure the training time of TinyBERT. For the general distillation step of TinyBERT, we measure the training time on a small corpus (containing 10.6M tokens) on 4 GPUs and estimate the training time on the original corpus (containing 2500M tokens) by scaling the time with the corpus size difference. Specifically, it takes 430s to finish one epoch on 10.6M tokens with 4 GPUs, and we estimate that it will take 338 GPU hours (or 3.5 days with 4 GPUs) to finish three epochs on 2500M tokens.

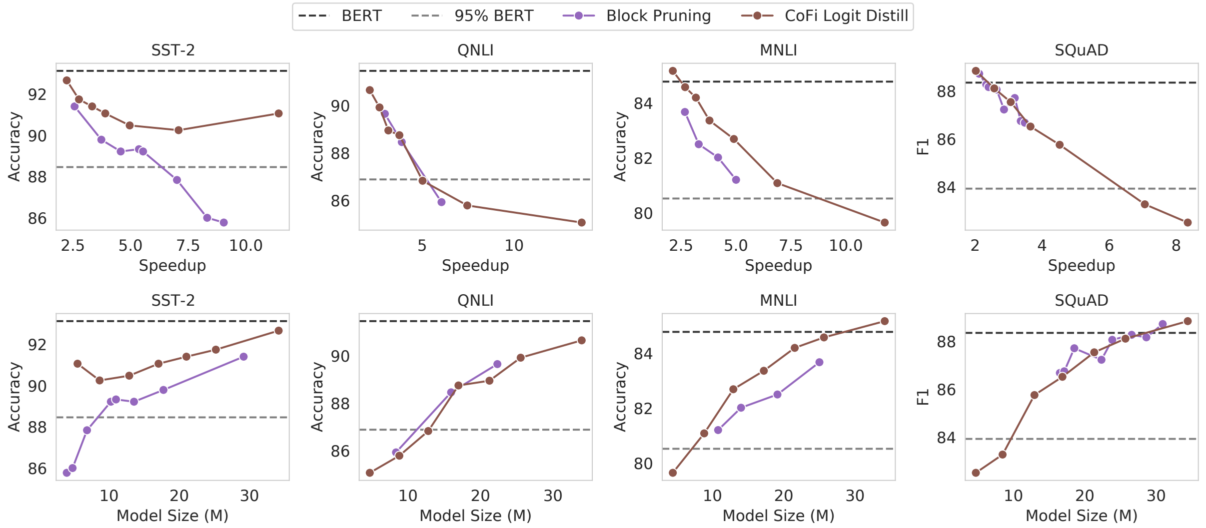

Figure 6: CoFi v.s. Block Pruning with the same distillation objective – prediction-layer distillation (Logit Distill). CoFi still outperforms or is on par with Block Pruning.

How can NLP Help Revitalize Endangered Languages? A Case Study and Roadmap for the Cherokee Language

Shiyue Zhang, Benjamin E. Frey, and Mohit Bansal
UNC Chapel Hill
`{shiyue, mbansal}@cs.unc.edu`; `benfrey@email.unc.edu`

Abstract

More than 43% of the languages spoken in the world are endangered, and language loss currently occurs at an accelerated rate because of globalization and neocolonialism. Saving and revitalizing endangered languages has become very important for maintaining the cultural diversity on our planet. In this work, we focus on discussing how NLP can help revitalize endangered languages. We first suggest three principles that may help NLP practitioners to foster mutual understanding and collaboration with language communities, and we discuss three ways in which NLP can potentially assist in language education. We then take Cherokee, a severely-endangered Native American language, as a case study. After reviewing the language's history, linguistic features, and existing resources, we (in collaboration with Cherokee community members) arrive at a few meaningful ways NLP practitioners can collaborate with community partners. We suggest two approaches to enrich the Cherokee language's resources with machine-in-the-loop processing, and discuss several NLP tools that people from the Cherokee community have shown interest in. We hope that our work serves not only to inform the NLP community about Cherokee, but also to provide inspiration for future work on endangered languages in general.[1]

1 Introduction

There are an estimated 6000 to 7000 spoken languages in the world, and at least 43% of them are endangered.[2] Throughout history, languages have naturally shifted and declined into dormancy. The current speed of language loss, however, is far beyond "natural". Some linguists estimate that between 50% and 90% of languages will be severely endangered or dead by the end of this century (Austin and Sallabank, 2011). This acceleration of language endangerment owes largely to cultural, political, and economic marginalization and the rise of global imperialism. Worldwide, indigenous people have suffered from colonization or conquest and given up their mother tongues in favor of another language. In order to achieve a higher social status, indigenous people have had to capitulate to colonizers' linguistic norms. Following Ladefoged (1992), we acknowledge that burdens such as raw material survival outweigh the more abstract concerns of maintaining a language. In other words, we cannot blame or fault indigenous people for giving up their languages in order to secure a better life under intense socioeconomic pressures. As linguists and NLP researchers, we have the responsibility to address these power imbalances and create a society where space exists for indigenous languages. Moreover, language loss is memory loss, identity loss, culture loss, and knowledge loss, and it even affects the health of indigenous people (Whalen et al., 2016).

Endangered languages are even more underrepresented in the NLP literature. Joshi et al. (2020) point out that more than 88% of the world languages spoken by around 1.2 billion people are *left behind*, i.e., they have been and are still ignored in the aspect of language technologies. Blasi et al. (2021) show that linguistic NLP tasks (e.g., morphology analysis) are more language inclusive than user-facing NLP tasks (e.g., machine translation). In this information age, NLP techniques are widely applied on the Internet. Much Internet content that we are exposed to daily is processed or even created by NLP techniques. Hence, the lack of NLP technology support for endangered languages reduces the degree to which users are exposed to them. Unfortunately, this exacerbates the problem of linguistic marginalization, as frequent language exposure is critical to language acquisi-

May 22-27, 2022

tion. At worst, it can generate a downward spiral: since fewer speakers create content using these languages, the scarcity of resources will in turn hinder the development of NLP technologies. On the other hand, the majority of NLP research is biased towards high-resource languages, neglects diverse linguistic typologies (Joshi et al., 2020), and often relies on the availability of large-scale data. Including endangered languages can help diagnose NLP models' generalizability (Bender, 2011) and push towards universal and data-efficient approaches.

In this work, we address three important steps on the roadmap of NLP for language revitalization: starting from "before NLP" to "NLP for language education" to "language-specific NLP research". Before diving into NLP research, we first suggest that NLP practitioners, who are often "outsiders" of indigenous communities, become aware of three important principles: *understand and respect first*, *decolonize research*, and *build a community*. We especially want to promote *building a community*. Since few people are speaking, learning, or studying an endangered language, the knowledge of each individual, the collected resources, and the developed models should be shared as widely and sustainably as possible. Hence, we need a community to support this (see Section 2).

Second, language revitalization is an attempt to reverse the decline of a language (Tsunoda, 2013). Fundamentally, this requires an increase in the number of active speakers to bring the language back to day-to-day use (Austin and Sallabank, 2011). Due to the lack of inter-generation transmission, language education in school or online is important. We introduce three approaches for applying NLP techniques in assisting language education (Section 3): *automated quiz generation*, *automated assessment*, and *community-based language learning*. The last approach connects to our previous point about building a community.

Next, we introduce the case study of Cherokee; an endangered[3] Native American language with only 2,000 fluent first-language speakers remaining. We first review its history (Section 4.1) to understand how social, political, and economic repression have harmed the Cherokee people and their language. Then, we discuss a few linguistic distinctions of Cherokee (Section 4.2), including polysynthesis, word order, etc., which can help us design linguistically informed NLP models. In Section 5, we review some existing high-quality Cherokee resources and propose two methods to enrich resources: *community-based resource collection* (which also relates to our previous point of building a community) and *automatic data mining*. Lastly, based on conversations with some Cherokee speakers/researchers, we dive deep into several NLP tools that seem advantageous for community members and may be able to create new usage domains for the language, and we point out the key challenges of their development (Section 6).

In summary, we propose suggestions to NLP practitioners, approaches of NLP-assisted language education, and directions for Cherokee language processing. We hope that our work can increase awareness of Cherokee and encourage more work on minority languages.

Last but not the least, the authors of this work come from both the Cherokee community (Benjamin E. Frey) and the NLP community (Shiyue Zhang and Mohit Bansal). Prof. Benjamin E. Frey is a proficient second-language Cherokee speaker and a citizen of the Eastern Band of Cherokee Indians. He has been teaching Cherokee and contributing to Cherokee revitalization for more than 10 years. He initiated our collaboration and continues bridging the gap between the Cherokee language and language technologies. In addition, we have been talking with some other Cherokee community members, including David Montgomery and Eva Marie Garroutte. Prof. Eva Marie Garroutte from Boston College said: "As a citizen of the Cherokee Nation, I am very concerned for the preservation of my tribe's endangered language and I am convinced that Dr. Frey's work represents the most promising project known to me for advancing this goal." Though by no means the views of this paper can represent the whole Cherokee community, our proposals are strongly initiated/motivated by Cherokee community members and grounded by NLP practitioners.

2 Before Diving into NLP Research

We suggest NLP practitioners, who are often "outsiders" of the indigenous communities, three general principles to follow before conducting NLP research on endangered indigenous languages.

Understand and Respect First. Meaningful advances in building speech and language technologies for under-resourced languages hinge upon be-

---

[3] UNESCO has identified the dialect of Cherokee in Oklahoma is "definitely endangered", and the one in North Carolina is "severely endangered".

ing able to understand those languages' speaker communities and their needs. Although the initial temptation among NLP researchers might be to dive in with questions about particular computational tools, that conversation cannot unfold until the speaker communities' more basic needs are met: *the need for respect, reciprocity, and understanding*. It may be tempting to say "this is outside the scope of our current research," yet these kinds of behaviors and assumptions are the very behaviors that led to the disenfranchisement of these groups. When we ignore someone's common humanity and assume that our need for control over the narrative and the situation is greater than their need to be seen and respected, we participate in the same marginalizing and dehumanizing behaviors that led to the problem we are purporting to address. Therefore, it is instrumental that we address the cultural practices and social norms of endangered language communities before assuming we know how to position ourselves, them, and our research within their communities.

Decolonize Research. Decolonizing research is to place indigenous voices and needs in the center of the research process (Smith, 1999; Datta, 2018; Bird, 2020a). As NLP researchers, we are used to certain methodologies. When it comes to questions about endangered languages, it is tempting for us to formulate the new problems we encounter as what we are familiar with. However, we should always question ourselves: Is the formulation suitable for the language we conduct research on? Are the methodologies we familiar with the only true ways to solve the problems? Unquestioned focus on typical methodologies can make us treat languages as commodities and start to play a "number game" (e.g., the size of the data) and forget the real problem, language revitalization, we intend to solve in the first place (Dobrin et al., 2007). At every research step, it is critical to weigh the burden we put upon the speakers against the benefit that the research can bring back to their community. If the research outcome conveys no new knowledge, information, or benefit to the community, it is no different from "taking" indigenous knowledge that has occurred over the centuries. That is exactly why the word "research" is sometimes the direst (i.e., conjuring up bad memories) word in indigenous world's vocabulary (Smith, 1999). Finally, it is important to carefully deal with copyright and data governance; meanwhile, we advocate open-sourced and community-contributed works.

Build a Community. Fundamentally, we want to work together with people from the indigenous communities (Bird, 2020a, 2021). It is the most effective way to foster mutual understanding. We should communicate with the indigenous people and get to know their priorities. Common attitudes need to be fostered, common interests need to be found, and common goals need to be set up, before performing the research. These all lead to a community. We would imagine that there is an online community (a website) where native speakers can share their knowledge and language learners can find resources and learn the language together (see Section 3). People can share resources and participant in machine-in-the-loop resource collection projects (see Section 5). NLP researchers can evaluate and share their models in this community. Entertaining language learning or resource collection games can be launched. We hope the community can support wide and sustainable collaborations between indigenous speakers, language learners, and NLP practitioners. Compared to local communities of the speakers, this community will be greatly supported by technologies. A few NLP communities, e.g., MasakhaneNLP (focusing on African languages) and SIGEL (special interest group endangered languages), have been built. Differently, the community we promote here will support both NLP research and language learning. Lastly, compared to Telegram groups (we are in a few different Telegram groups with Cherokee community members), we want to build a more open community that everyone can have access to.

3 NLP-Assisted Language Education

Since little inter-generation language transmission is happening, language education is an essential requirement of language revitalization. Computer-assisted language learning has a long-standing history (Higgins, 1983) and two workshops, BEA[4] and NLP4CALL[5], are held for research on applying NLP for language education. Here, we discuss three ways in which NLP can potentially assist language education of endangered languages.

Automated Quiz Generation. The most direct way, in which NLP can help, is automatically generating quizzes for language learners. Practicing

---

[4] `https://aclanthology.org/venues/bea/`

[5] `https://aclanthology.org/venues/nlp4call/`

and producing the language in questions are critical to language acquisition (Gass and Mackey, 2013). Usually, language instructors manually design the quizzes, which is tedious and time-consuming; not to mention, there are not a lot of instructors for endangered languages. However, given the available text of endangered languages, NLP can easily and automatically generate cloze questions. It can also help find distracting wrong answers that happen in a similar context and thus form multi-choice questions (Hill and Simha, 2016; Susanti et al., 2018). To increase playfulness, language learning games, e.g., crossword puzzles and flashcards, can also be automatically generated (Rigutini et al., 2012; Xu and Ingason, 2021). Since these applications involve very basic language processing steps, NLP techniques can be reliably and easily applied.

Automated Assessment. Another widely studied topic is NLP-supported automatic assessment. Though a lot of advanced assessments, e.g., grammar error correction (Bryant et al., 2019), essay grading (Chen et al., 2016), are difficult to be applied for endangered languages, we argue that some easier assessments are feasible. For example, automatic error analysis and template-based feedback can be provided for language learning quizzes. Another challenging but feasible assessment is to assess the readability or difficulty of language learning materials to provide suitable learning plans for learners of different levels. Using statistic and linguistic features, such as word frequency, morphology or syntactic complexity, etc., readability and difficulty can be automatically predicted (Schwarm and Ostendorf, 2005; Vajjala and Meurers, 2012). However, basic NLP tools, like POS tagger, dependency parser, morphology analyzer, need to be developed before these applications can be realized. The development of these tools requires small but highly-curated data (Blasi et al., 2021).

Community-based Language Learning. Free online language learning platforms that integrate automated quiz generation and assessment have been developed, e.g., Oahpa (Uibo et al., 2015). Taking one step further, we believe that a more effective approach of supporting endangered language education is to build an online and collaborative language learning platform, following the *human computation* technique (Von Ahn, 2008). When using technologies to assist in language revitalization, we often face a dilemma. On the one hand, due to the endangerment, there is not a lot of resources available and it is very expensive (in terms of time, effort, and cost) to collect resources from speakers. On the other hand, machines struggle to reach “useable” and “helpful” performances without a decent amount of training data. *Human computation* aims at combining human and computer to solve problems neither of them could solve alone (Von Ahn, 2008; Garcia, 2013). The most famous example is Wikipedia where Internet users contribute their knowledge together, and incredibly high-quality content has been created. Other successful cases are Duolingo and Tatoeba. Both are for language learners to translate web text and rate each other’s translations. Then, the translated text can serve as learning materials and training data for NLP models. However, Tatoeba only has an English interface, and mixes languages on the same site, making it hard to find peer learners of under-resourced languages. Though Duolingo has language-specific sites, it supports 23 languages so far. Therefore, how to make use of collaborative language learning platforms for endangered languages is a big challenge. Nonetheless, we believe that it is a promising path to take for teaching endangered languages to the young generation in this information age.

4 The Cherokee Language

Starting from this section, we illustrate the situation of endangered languages through the example of Cherokee. We first review its history and linguistics. In the NLP area, we hardly get to know the languages and often let the model learn statistical patterns automatically from the data. However, it is critical to have basic knowledge of the language when contributing to its revitalization.

4.1 History of the Cherokee People and Their Language

Tribal Sovereignty. Before encountering Europeans, American Indians were already governing themselves. By drafting treaties with indigenous nations, the colonial powers implicitly recognized their sovereignty. Those treaties are still valid today, and tribal peoples are very much operating as sovereign nations, separate from the US (NCAI, 2020). There are three federally recognized nations of Cherokee people: Cherokee Nation of Oklahoma (CN), United Keetoowah Band of Cherokee Indians (UKB), and Eastern Band of Cherokee Indians (EBCI). Traditional Cherokee homeland covered parts of what are now eight US states.[6] EBCI is composed of those Cherokees who were able to remain in their homeland. CN is largely comprised of the descendants of those who were forcibly removed to Indian Territory along the infamous Trail of Tears in 1838 (Perdue and Green, 2007), while the UKB is composed largely of those whose ancestors chose to remove themselves west of the Mississippi. Although the three nations are politically independent, they all descend from the same Cherokee people, and maintain common interests, cultural elements, and language.

The Language and its Dialects. Cherokee is the only surviving member of the Southern Iroquoian language family, which have separated from the Northern Iroquoian languages about 4,000 years ago (Julian, 2010). James Mooney identified three main dialects of Cherokee: the Overhill dialect, the Underhill dialect (has died out), and the Middle, or Kituwah dialect. The Overhill dialect is primarily spoken in Oklahoma, and the Middle dialect is predominantly spoken in North Carolina today. Although according to UNESCO, both dialects are endangered, Cherokee is comparatively well-reported among American Indian languages. This is partially due to its writing system known as the 85-character Cherokee syllabary. It was invented in the early 1820s by Sequoyah (Britannica, 2021). The Cherokees have a newspaper written in their own language: the Cherokee Phoenix. The Phoenix, alongside the Cherokee New Testament, formed cornerstones of the Cherokee language in the 1800s on which many current language preservations and archiving projects rest.

Language Endangerment. Cherokee was robustly spoken until around the 1930s. The primary factor being responsible is the US government's "civilization" policy, which aimed to remove American Indians' cultural distinctions (Spring, 2016). Federal boarding schools were created on the model of military institutions by Richard H. Pratt under the philosophy of "kill the Indian, save the man" (Pratt, 2013). American Indian children were sent to residential schools to be educated in how to live in ways more similar to their white contemporaries. School overseers cut their hair, forced them to abandon their traditional dress, and punished them for speaking their traditional languages. Beyond the trauma, when they returned to communities, banks, post offices, factories, and grocery stores were all controlled non-locally. People working in them either no longer spoke Cherokee because they were not from Cherokee communities or because their employers were not Cherokee speakers. This transition contributed to the decline of the language in daily use, until the first generation grew up with only English as the language of the home around 1950s (Gulick, 1958; Frey, 2013). Recently, the larger project of language revitalization, of which this paper is a part, endeavors to return the language to regular day-to-day use in the Cherokee communities.

4.2 Cherokee Linguistics

Polysynthetic. Cherokee, like most American Indian languages, is polysynthetic. This means that words are primarily composed of a root whose meaning is modified by multiple prefixes and suffixes. The word **ᎨᎦ**, *gega*, can be divided up: *g-*, *-e-*, *-ga*. The *g-* prefix indicates that the subject of the verb is 1st person singular while the *-ga* suffix indicates that the action happens in the present tense and the aspect is progressive. The verb root *-e-* conveys the idea of motion. The simplest verb form in Cherokee will contain at minimum a root, a pronominal prefix, and a tense/aspect suffix. One oft-noted aspect of Cherokee grammar is its classificatory system, wherein verbs with direct objects must conjugate to indicate the physical shape of the direct object. The verb "I have," for instance, could appear in any of the following ways: *Agiha* (I have (solid)), *Agineha* (I have (liquid)), *Agwvya* (I have (long & rigid)), *Agina'a* (I have (flexible)), *Agikaha* (I have (animate)). Cherokee also has pre-pronominal prefixes that can specify the geographical location of particular events, such as *wi-* (translocative), which indicates that the action will happen at a distance away from the speaker, and *di-* (cislocative), which indicates the action will happen at a distance approaching the speaker.

Word Order. Word order in Cherokee is dependent on the larger pragmatic context in which the sentence appears, with new information or timeframes occurring before the verb and old or established information occurring post-verbally. Subject-object agreement is handled largely via the dual-argument pronominal prefixes. E.g., in "I see it," **ᏥᎪᏩᏘᎭ** (*tsigowatiha*), the pronominal

---

[6] North Carolina, South Carolina, Georgia, Kentucky, Tennessee, Alabama, Virginia, and West Virginia.

prefix *tsi-* indicates 1st person singular ("I") acting on 3rd person singular ("it"). In ᎠᎩᎪᏩᏗᎭ (*agigowatiha*), we change *tsi-* to *agi-*, which means 3rd person singular acting on 1st person singular.

Person & Number. Although English has only two categories of number: *singular* and *plural*, Cherokee has a third, *dual* category. Therefore, a verb in Cherokee can be conjugated in first, second, or third person and specified for either singular, dual, or plural subjects. Dual and plural prefixes in the first person must then be further subdivided by clusivity, yielding 1st-person dual inclusive (you & I) or exclusive (she/he & I), 1st-person plural inclusive (all of us) or exclusive (they & I). The second person can inflect for dual (you two) or plural (you all). Cherokee does not have a third-person dual form, and speakers usually use the plural form when referring to two third persons.

Verb-centric. Cherokee is very verb-centric, and verbs comprise 75% of Cherokee (Feeling, 1975). Cherokee nouns are divided into root nouns (have no verbal inflection attached to them) and derived nouns (carry verbal morphology). Similarly, Cherokee adjectives can be distinguished from verbs in that their forms cannot carry the tense/aspect morphology typical of actual verbs. Thus, to say someone is skinny, ᎤᎴᏐᏓ (*ulesoda*) carries the pronominal prefix *u-*, indicating 3rd person singular, while ᎤᎴᏐᏓ ᎨᏒᎢ (*ulesoda gesv'i*) marks past tense by adding a separate copula ("to be") that carries the tense/aspect suffix *-v'i*.

Evidentiality. Cherokee is also marked by a system of evidentiality (indicating whether one has firsthand knowledge of past events, or if one is reporting on hearsay). E.g., one might say ᎠᎦᏍᎬᎢ (*agasgv'i*), "it was raining (and I have firsthand knowledge of this)" vs. ᎠᎦᏍᎨᎢ (*agasge'i*), "it was raining (from what I understand)." Interestingly, this phenomenon applies regardless of the assumed truth of the statement in question.

Phoneme. Cherokee's phoneme inventory is, like other Iroquoian languages, almost completely bereft of bilabial sounds. It entirely lacks the *p* or *b* phonemes, along with *f*/*v*, *θ*/*ð*, and any *r* sound. It has six vowels: *a*, *e*, *i*, *o*, *u*, and *v*, and are generally pronounced with continental values, as in Spanish, except for *v*. Consonant inventory is small, at only 13, and most will be familiar to English speakers. The main exception is the voiceless alveolar fricative ɬ, likely more familiar to Icelandic speakers.

5 Cherokee Language Resources

The availability of language resources is not only important for language education but also determines the development of NLP technologies. Cherokee is categorized into "The Scraping-Bys" by Joshi et al. (2020), which means it has some amount of data but solid movements still need to be taken to increase the awareness of the language.

Existing Resources Online. It is not easy to locate a lot of Cherokee resources on the Internet, compared to other high-resource languages. Here, we point to a few places where high-quality Cherokee resources for language learning or NLP model training can be found: (1) Cherokee-English Dictionary[7] has online Cherokee-English dictionaries, a transliteration tool, a grammar guide, and a few Cherokee text or audio corpora; (2) Cherokee Nation website[8] contains Cherokee online classes, learning materials, fonts and keyboards, etc. (3) UNC Cherokee Program website[9] has UNC Cherokee class resources and pointers to external resources; (4) Cherokee Language Github group[10] gathers a lot of Cherokee text and audio data, as well as initial attempts for speech synthesis and some other NLP tools. (5) The Cherokee Phoenix[11] publishes all-Cherokee issues as well as some bilingual articles with Cherokee audios.[12] (6) We released around 17K Cherokee-English parallel data (Zhang et al., 2020).[13] In addition, Cherokee Wikipedia is available but its content is noisy. A Cherokee resource catalog can be built up in the future for easier locating resources.

Community-based Resource Collection. Besides existing resources, we suggest collaborative resource collection, which can be integrated with the community-based language learning platform we introduced in Section 3. A simple feature of this platform could be a dropbox where people who are willing to contribute their resources can drop in the files they have.[14] The back-end program can support any kind of data processing based on the contributor's request and permission. Then, the

[14] An example can be found at `https://cherokee.web.unc.edu/submit-materials-to-database`.

resources can be shared back with the community as language learning and model training resources. Second, for more complex data annotation tasks, like POS tagging, dependency parsing, we suggest setting up *game with a purpose* (GWAP) applications on this website. GWAP is introduced by Luis Von Ahn (Von Ahn, 2006; Von Ahn and Dabbish, 2008) who is also the founder of Duolingo. One famous example is his *ESP game* (Von Ahn and Dabbish, 2004) which formulates the *image recognition* task as a game. Following this idea, NLP practitioners can design diverse games on the platform to increase the fun and engagement of language learning and resource collection. In addition, this platform will focus more on what kind of materials the Cherokee community members consider important to preserve instead of what the NLP researchers find most valuable.

Automatic Resource Mining. As NLP practitioners, we should try to make the most use of computers for collecting resources automatically. A lot of automatic *data mining* methods have been proposed to mine monolingual or bilingual text from the noisy web or Wikipedia (Guo et al., 2018; Artetxe and Schwenk, 2019; Schwenk et al., 2019; Wenzek et al., 2020; Schwenk et al., 2021; Arkhangelskiy, 2019). Though the mined text has many errors or noises, previous works demonstrate that neural NLP models are surprisingly good at using noisy data for training. However, some additional NLP components, like language identifier and multilingual embeddings, need to be developed to support the data mining. For instance, to mine Cherokee-English parallel text, we will need to map English and Cherokee sentences to the same representation space to compute their similarity. However, existing tools of getting multilingual sentence embeddings, like LASER,[15] do not support Cherokee, and Cherokee is not related to or sharing scripts with any supported languages. But, given the existing Cherokee-English parallel data (Zhang et al., 2020), we can re-train these tools and have Cherokee being supported. Note that these automatic text miners can start with both crawled web text and OCR-processed text (Section. 6.2).

6 NLP Tools for Cherokee Language Processing

Based on our conversation with a few Cherokee speakers, they agree that some NLP tools are good to have and hold the potentials to be useful in Cherokee language revitalization. Thus, some initial attempts have been made by the Cherokee Language Github group and us (Zhang et al., 2020, 2021). Hence, we dive deep into several specific NLP tools for Cherokee language processing in this section. And for any NLP tool we develop, we want to evaluate it by the Cherokee speakers, and we suggest open-sourcing it for free usage. Connecting to our "build a community" proposal, we hope that NLP models can also be shared and used widely and sustainably in the community.

6.1 Machine Translation.

Ideally, a good machine translation (MT) system can automatically translate the big amount of English text to Cherokee; or it can assist human translators. Dr. David Montgomery, a citizen of Cherokee Nation and a Cherokee language learner, commented on MT: "It would be a great service to Cherokee language learners to have a translation tool as well as an ability to draft a translation of documents for first-language Cherokee speakers to edit as part of their translation tasks. If these tools can be made to work accurately, they would be transformative for the Cherokee language." Previously, we collected parallel text and developed an MT online translation demo between Cherokee and English (Zhang et al., 2020, 2021). However, our system can *translate fragments of the source sentence but make major mistakes*, which is far from being practically useful. The first challenge of MT development is the lack of data. Automatic data mining can help enrich MT training data (Section 5). But we still need high-quality and diverse evaluation data because existing evaluation sets (Zhang et al., 2020) are from limited domains (the majority is the Bible). Recently, Flores101, an MT evaluation benchmark covering 101 languages, has been created (Goyal et al., 2021). Though it has not yet covered Cherokee, we hope it can happen in the future.

The second challenge is processing and producing Cherokee text. Cherokee has rich morphology (see Section 4.2). One Cherokee word can be translated into one English sentence. Intuitively, we would think subword tokenization (Sennrich et al., 2016; Kudo, 2018) is helpful. However, previously, we (Zhang et al., 2020) showed that applying subword tokenization for English to Cherokee translation is harmful. We argue that it is be-

OCR tools	Original		Screenshot	
	WER	CER	WER	CER
Tesseract	0.355	0.230	0.151	0.063
Google Vision	0.533	0.199	0.468	0.074

Table 1: OCR performance of two OCR tools on our evaluation sets. WER: word error rate, CER: character error rates. For both WER and CER, lower is better.

cause we processed Cherokee text in its syllabary rather than in transliterated Latin script, however, morphemes are easier to be learned from the latter. E.g., in ᏣᏆᏛᏏᏗᏒ, *tsaquadvsidisv* (when I was growing up), the prefix *ts*- marks relative clauses, but Ꮳ is *tsa*. We suspect that character-level generation (in Latin script) would work better for Cherokee. Additionally, Cherokee has flexible word order that is often determined by whether the information is new or old in relation to the larger discourse (Section 4.2). Thus, document-level translations are more reasonable than typical sentence-level translations.

6.2 Optical Character Recognition.

The majority of Cherokee text is in the format of manuscripts or books, so as many other endangered languages (Joshi et al., 2020; Bustamante et al., 2020). Though humans can read them, they are not machine-readable, which restricts the flexibility of their use, e.g., automatically creating language learning quizzes. Optical character recognition (OCR) (Smith, 2007) can help extract plain text from PDFs or images. Fortunately, existing OCR tools, like Tesseract-OCR[16] and Google Vision OCR API[17], support Cherokee and have decent accuracy. However, OCR accuracy is highly influenced by image quality. If the image has a noisy background or the text is surrounded by colorful pictures (which often happens in children books), the OCR accuracy will drop significantly.

To prove this, we create two evaluation sets from Cherokee books (including Cherokee New Testament, children books, Cherokee narratives): (1) *Original* has 20 images, and each image is one complete page from a book; (2) *Screenshot* is obtained by manually conducting screenshots and cutting out text from the 20 images, i.e., removing background noises. For each image in two sets, we manually annotate the corresponding text. Table 1 shows the results of Tesseract-OCR and Google Vision OCR API. Both OCR tools achieve significantly lower error rates on the *Screenshot* set than on the *Original* set, which demonstrates the importance of cleaning the images. Tesseract-OCR shows better performance than Google Vision OCR, especially it is better at detecting word boundaries. Although ways to improve image quality are available,[18] an easy-to-use tool need to be developed. OCR post-correction methods can also be applied (Rijhwani et al., 2020).

	audio to phonetic text	audio to syllabic text
WER	0.64	0.21

Table 2: The ASR results of finetuned XLSR-53 (Conneau et al., 2020) models. WER: word error rate.

6.3 Speech Recognition and Synthesis.

Automatic speech recognition (ASR) (Povey et al., 2011) can help language documentation, though indigenous community members may prefer unassisted transcription (Prud'hommeaux et al., 2021). Moreover, ASR holds the potential to automatically transcript audio data and thus enrich text corpus. A good amount of Cherokee audio data can be found from the "Cherokee Voices, Cherokee Sounds" radio, Cherokee Phoenix, and recorded meetings. ASR can automatically transcript these audios to produce valuable Cherokee text data. Recently, models that are first pre-trained on audio data and then finetuned on audio-text data have shown great advantages in performing ASR (Baevski et al., 2020). Especially, Conneau et al. (2020) pretrain and finetune a model on 53 languages and release XLSR-53 (supports ASR for 53 languages). It shows reasonable generalizability to unseen and low-resource languages. This sheds light on developing ASR for endangered languages.

Hence, we test its performance for Cherokee ASR. Using the audio-text data open-sourced[19] or shared privately by Michael Conrad, we build two ASR models: (1) audio to phonetic text, (2) audio to syllabic text. See more details in Appendix A.1. As shown in Table 2, we get surprisingly good performances, especially for the audio-to-syllabic-text model.[20] This is very promising,

BPE	14.4	16.5	15.4
Morfessor	16.6	16.3	16.5

Table 3: The alignment between subwords and gold morphemes.

especially when knowing the fact that more self-training strategies can be applied, e.g., pretrain the speech encoder with Cherokee audio data, and more audio-text training data can be compiled. Text-to-speech synthesis (TTS) is more difficult to develop than ASR; nevertheless, following the pretrain-then-finetune paradigm, TTS models for extremely low-resource languages have been introduced (Xu et al., 2020).

6.4 Tokenization and Morphology Parsing.

Tokenization is an essential pre-processing step of most NLP models, and it is related to morphology parsing. Subword tokenization has become *de facto* (Sennrich et al., 2016; Kudo, 2018). It segments a word into frequent subwords, and subwords are supposed to align with morphemes. Better alignment with morphemes can lead to better downstream performance (Bostrom and Durrett, 2020), while current subword tokenization methods struggle to perform well in morphologically rich languages (Amrhein and Sennrich, 2021).

Here, we evaluate how well subword tokenization can learn real morphemes for Cherokee. We train two subword tokenizers,[21] Unigram LM (Kudo, 2018) and BPE (Sennrich et al., 2016), and one morphology parser, Morfessor (Smit et al., 2014), on our previous MT training set (Zhang et al., 2020). Instead of using the original syllabic text, we transliterate text into Latin script to make it easier to learn morphemes. We collect gold (expert-labeled) morphemes of 372 Cherokee words from Cherokee Narratives (Feeling, 2018). Then, we use the pretrained tokenizers or parser to tokenize these 372 words and evaluate the alignment between subwords and gold morphemes. As shown in Table 3, subwords are poorly aligned with gold morphemes. Nonetheless, Unigram LM (Kudo, 2018) demonstrates better ability of inducing morphemes, which is consistent with the observation made by Bostrom and Durrett (2020). We think better representation methods need to be introduced for Cherokee, and the labeled data from Feeling (2018) can provide supervision.

6.5 POS-Tagging and Dependency Parsing.

More basic NLP tools like POS tagger and dependency parser are under-developed for Cherokee. These tools can not only support the development of other NLP tools but also be used to predict the readability of language learning materials (Section 3). Moreover, data for these tasks can serve as language learning materials for understanding Cherokee linguistics. Though unsupervised methods have been proposed (Stratos et al., 2016; Kim et al., 2019), usually small but high-quality labeled data, like Universal Dependencies (Nivre et al., 2016), is needed (Blasi et al., 2021). Therefore, data annotation by experts is required and community-based data collection strategies can be applied (Section 5). Moreover, the parallel English data and English tagger/parser can assist the annotation on the Cherokee side, which will also produce English-Cherokee word/phrase-level alignments as by-products. These alignments are valuable Cherokee language education resources, e.g., asking students when you have “structure X” in English, what is the corresponding “structure Y” in Cherokee?

7 Conclusion & Future Work

In this work, we discuss how NLP can help revitalize endangered languages. We first suggest general principles to NLP practitioners and propose ways of NLP-assisted language education. Especially, we promote building a (online) community that support collaborative language learning, resource collection, and knowledge sharing. Second, we conduct a case study for Cherokee (a severely-endangered Native American language). After reviewing Cherokee history and linguistics, we propose two methods of enriching Cherokee resources and discuss the developments of several NLP models that people from the Cherokee community are interested in. We hope our work can encourage future work to think and plan the path forward for other endangered languages. In the future, we hope to broaden our collaboration to even more Cherokee community members and build meaningful relationships with tribal governments, so that we can develop more useful applications through NLP techniques for supporting Cherokee revitalization.

8 Broader Impact Statement

The content of this paper is based on and inspired by our practice in Cherokee Language Revitalization. The conclusions and suggestions may or may not generalize to other endangered languages. For example, since Cherokee has its own syllabary and can be written down, we are interested in speech recognition for audio transcription. Even though some methods can directly translate audio to text of another language, we do not want to skip the transcription step. However, for some oral languages, they may want to prioritize translation over transcription to tackle the transcription bottleneck (Bird, 2020b). On the other hand, our position is influenced by Crystal (2014), who thinks using electronic technology is important for language revitalization. Therefore, a lot of our proposals, like "building an online community", may have an assumption that computers and the Internet have been or can be widely accepted and used in the indigenous community. However, it may not be true in every indigenous community.

Acknowledgments

We thank the reviewers for their helpful comments. We thank Archiki Prasad and Zhiyuan Tang for providing guidance on developing ASR models. We thank Michael Conrad for providing Cherokee audios and transcriptions. We thank David Montgomery and Eva Marie Garroutte for providing their statements. We thank the Kituwah Preservation and Education Program (KPEP), the Eastern Band of Cherokee Indians, and the Cherokee Nation. This work was supported by NSF-CAREER Award 1846185, ONR Grant N00014-18-1-2871, NSF-AI Engage Institute DRL-2112635, and a Bloomberg Data Science Ph.D. Fellowship. A Appendix

A.1 Data and Implementation Details of ASR

(1) audio to phonetic text: Given the audio, the model outputs text showing its pronunciation, e.g., *Sǔ:dáli* (means "six"). It follows Uchihara's Modified Community Orthography (Uchihara, 2013). (2) audio to syllabic text: Given the audio, the model outputs text showing the Cherokee syllabary, e.g., ᏑᏓᎵ (means "six").

We split our ASR data into training, development, and testing sets. Table 4 lists the statistics. It can be seen that we have more data for the audio to syllabic text model, which probably causes its good performance shown in Table 2.

We follow the ASR recipe provided by Huggingface's Transformers[22] (Wolf et al., 2020) to finetune the pretrained XLSR-53 model (Conneau et al., 2020). Specifically, we use learning rate=3e-4, epoch=15, mask_time_prob=0.01. We run each experiment for 3 times and report the average performance on the testing set in Table 2.

Abstract

The IMPRESSIONS section of a radiology report about an imaging study is a summary of the radiologist's reasoning and conclusions, and it also aids the referring physician in confirming or excluding certain diagnoses. A cascade of tasks are required to automatically generate an abstractive summary of the typical information-rich radiology report. These tasks include acquisition of salient content from the report and generation of a concise, easily consumable IMPRESSIONS section. Prior research on radiology report summarization has focused on single-step end-to-end models – which subsume the task of salient content acquisition. To fully explore the cascade structure and explainability of radiology report summarization, we introduce two innovations. First, we design a two-step approach: extractive summarization followed by abstractive summarization. Second, we additionally break down the extractive part into two independent tasks: extraction of salient (1) sentences and (2) keywords. Experiments on English radiology reports from two clinical sites show our novel approach leads to a more precise summary compared to single-step and to two-step-with-single-extractive-process baselines with an overall improvement in F1 score of 3-4%.

FINDINGS
$^{\psi}$there is no evidence of *midline shift* or *mass effect*.
there is soft tissue swelling or hematoma in the right frontal or supraorbital region.
underlying sinus walls and calvarium are intact.
there is no obvious *laceration*.
$^{\psi}$there is subtle thickening of the *falx* at the high convexity with its mid to posterior portion.
there is no associated subarachnoid hemorrhage.
$^{\psi}$this likely reflects normal prominence of the *falx* in a patient of this age.
$^{\psi}$remote consideration would be a very thin *subdural collection*.
IMPRESSIONS
1) no definite acute intracranial process. 2) mild prominence of the falx is likely normal for this patient. 3) remote possibility of very thin subdural collection has not been entirely excluded.

Table 1: FINDINGS (top) and IMPRESSIONS (bottom) sections of a radiologist's report. ψ indicates a sentence in FINDINGS that overlaps with sentences in IMPRESSIONS. Italicized words in FINDINGS are core concepts (e.g., disorder and procedure) that assist in answering clinical questions.

1 Introduction

A diagnostic radiology report about an examination includes FINDINGS in which the radiologist describes normal and abnormal imaging results of their analysis (Dunnick and Langlotz, 2008). It also includes IMPRESSIONS or a summary that communicates conclusions about the findings and suggestions for the referring physician; a sample report is shown in Table 1. FINDINGS are often lengthy and information-rich. According to a survey of referring physicians, IMPRESSIONS may be the only part of the report that is read (Wallis and McCoubrie, 2011). Overall, referring physicians seem to appreciate the explainability (or self-explanitoriness) of IMPRESSIONS as it helps them evaluate differential diagnoses while avoiding additional conversations with the radiologist or the need for repeat procedures.

A well known end-to-end method for text summarization is *two-step*: extractive summarization followed by abstractive summarization. For instance, Chen and Bansal (2018) initially train extractive and abstractive systems separately and then use the extractive system as an agent in a single-agent reinforcement learning (RL) setup with the abstractive system as part of the environment. Their extractive system extracts salient sentences and the abstractive system paraphrases these sentences to produce a summary. This summary is in turn used to compute the reward for RL training. However, this single-agent setup often fails to extract some

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1542 - 1553
May 22-27, 2022

salient sentences or it extracts irrelevant ones, leading to the generation of incomplete/incorrect IMPRESSIONS. We hypothesize that granular categories of core concepts (e.g., abnormalities, procedures) can be leveraged for generating more comprehensive summaries. Thus, a separate RL agent is dedicated to the task of extracting salient keywords (core concepts) in the two-step system. The novelty in this approach is that the new, second agent can now collaborate with the first one and the two can influence each other in their extraction decisions.

Multiagent reinforcement learning (MARL) requires that an agent coordinate with the other agents to achieve the desired goal. MARL often has centralized training and decentralized execution (Foerster et al., 2016; Kraemer and Banerjee, 2016). There are several protocols for MARL training, such as sharing parameters between agents and explicit (Foerster et al., 2016, 2018; Sukhbaatar et al., 2016; Mordatch and Abbeel, 2018) or implicit (Tian et al., 2020) communication between agents by using an actor-critic policy gradient with a centralized critic for all agents (Foerster et al., 2018). The aim of these protocols is to correctly assign credits so that an agent can deduce its contribution to the team's success. To train our cooperative agents that extract salient sentences and keywords, we propose a novel Differentiable Multiagent Actor-Critic (DiMAC) RL learning method. We learn independent agents in an actor-critic setup and use a communication channel to allow agents to coordinate by passing real-valued messages. As gradients are pushed through the communication channel, DiMAC is end-to-end trainable across agents.

The novelties in the paper are threefold:

- a summarization system that leverages core concepts via keywords, refines them and makes them the basis for more fine-grained explainability
- a multi-agent RL (MARL) based extractive component for a two-step summarization framework,
- a Differentiable Multi-agent Actor-Critic (DiMAC) with independent actors leveraging a communication channel for cooperation

The remaining paper is structured as follows. In Section 2, we provide a detailed description of our two-step framework. In Section 3, we introduce the DiMAC training algorithm. In Section 4, we describe training data and experiments. In Section 5, we discuss the results. In Section 6, we discuss related work. In Section 7, we present our conclusions.

Notations					
General		MLE		RL	
F	FINDINGS	E	encoder network	a	agent (actors)
I	IMPRESSIONS	D	pointer network	c	critic
K	Keywords	$w2w$	word LSTM	u	action
w	word	$s2s$	sentence LSTM	m	message value
s	sentence	α	attention score	r	reward
p	position	c	context vector	G	discounted reward
m	total words	v	trainable vector	V	value function
n	total sentences	q	switch value	Q	action value function
h	hidden vector	W	trainable matrix	A	advantage function
y	train label	$Conv$	CNN network		

Table 2: Notation used in this paper: general notation and notation for two-step maximum likelihood estimation (MLE) and reinforcement learning (RL). Notations are often combined, e.g., $h^{E_{w2w}}$ refers to the word encoder's hidden state vector and a_w to the word agent.

2 Model

Problem statement. We design a two-step summarization framework that takes the FINDINGS (F) section of a radiology report (consisting of a sequence of sentences) and a set of keywords (K) as input and produces an IMPRESSIONS (I) section (consisting of a sequence of sentences).

In the first step of the framework, the two extractors independently select words and sentences from FINDINGS F but also coordinate such that the selection of salient words is followed by the selection of the sentence comprising these words. In the next step, a seq2seq abstractor paraphrases the selected sentences to generate IMPRESSIONS I. Figure 1 illustrates the proposed framework. We refer to Table 2 for basic notations used in this paper. We often combine notations to indicate a framework component concisely.

Two-step summarization framework. The proposed system includes encoder networks to encode words and sentences into vector representations. It also includes two pointer extractor networks (Vinyals et al., 2015) to determine salient words and sentences by selecting their indices. Both extractor networks run for the same number of steps; however, at each step, the output index of one extractor network is chosen while the other is set as empty ($\emptyset$). When the input is $\emptyset$, an extractor pauses its activity and guides the other extractor in an optimal direction.

Encoder. A bi-directional LSTM based word

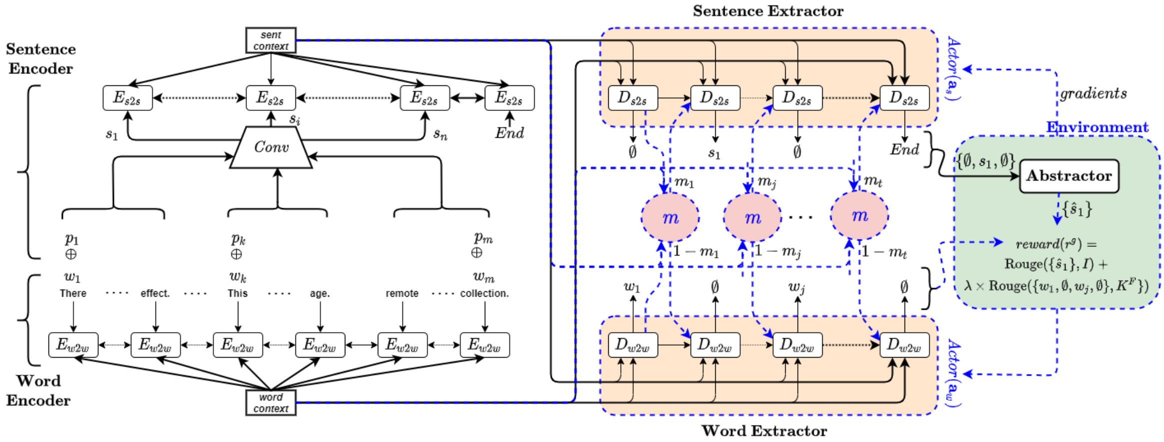

Figure 1: Our two-step summarization framework. DiMAC components (actors/extractors, communicator (*m*), environment and communication between them) are indicated by blue dashed lines and arrows. (i) The first step of the framework consists of encoder-extractor networks. Left side: sentence (E_{s2s}) and word (E_{w2w}) encoders. Right side: sentence (D_{s2s}) and word (D_{w2w}) extractors. Word and sentence encoders are bi-directional LSTMs with word (v^w) and sentence (h^s) embeddings as input. A convolutional network (*Conv*) obtains a sentence embedding (h^s) from word (v^w) and position (v^p) embeddings. An extractor is an LSTM pointer network with context vectors as input and either empty ($\emptyset$) or a source position as output at each step. (ii) In the second step of the framework, the seq2seq abstractor paraphrases selected sentences. During DiMAC reinforcement learning, the communicator takes contexts and actor hidden states and sends them back messages (m). The critic is omitted. Abstracted sentences ($\hat{s}$) and selected words are used to compute rewards. Figure best viewed in color.

encoder, E_{w2w}, is run on m word embeddings of FINDINGS sentences to obtain word representations, $\{h_1^{E_{w2w}}, \cdots, h_m^{E_{w2w}}\}$. A convolutional network ($Conv$) is run on concatenated word (v^w) and position (v^p) embeddings in a sentence to obtain an intermediate sentence representation (h^s). Then, a bi-directional LSTM sentence encoder, E_{s2s}, leverages the intermediate representations to obtain the final sentence representations, $\{h_1^{E_{s2s}}, \cdots, h_n^{E_{s2s}}\}$.

Extractors. Two LSTM based pointer extractors, i.e., word, D_{w2w}, and sentence, D_{s2s}, select a source word and sentence index at each step of decoding respectively. At any step j of decoding, each extractor independently uses its hidden state $h_j^{D_{w2w}}$ and $h_j^{D_{s2s}}$ to compute an attention score over its source item w_i and s_k as:

$$\alpha_{i,j}^w = \text{softmax}(v^T \phi(W^D h_j^{D_{w2w}} + W^E h_i^{E_{w2w}}))$$
$$\alpha_{k,j}^s = \text{softmax}(\hat{v}^T \phi(\hat{W}^D h_j^{D_{s2s}} + \hat{W}^E h_k^{E_{s2s}}))$$

where W^D, W^E, v, $\hat{W}^D$, $\hat{W}^E$ and $\hat{v}$ are trainable parameters, T and ϕ are transpose and $\tanh$ functions respectively, and softmax normalizes the scores. Word and sentence context vectors are computed using attention scores and encoder representations as $c_j^w = \sum_{i=1}^m \alpha_{i,j}^w h_i^{E_{w2w}}$ and $c_j^s = \sum_{k=1}^n \alpha_{k,j}^s h_k^{E_{s2s}}$ respectively.

Additionally, at step j, the decision on whether word or sentence extractor output is set to $\emptyset$ is based on a switch probability $q_j = \sigma(\text{switch}(h_j^{D_{w2w}}, c_j^w, h_j^{D_{s2s}}, c_j^s))$, where switch is a feed-forward network (omitted in Figure 1). The switch value of 0 or 1 indicates whether to set the output of sentence or word extractor to $\emptyset$.

Based on its current cell state $h_j^{D_{s2s}}$, D_{s2s} computes the next cell state, both the context vectors c_j^w and c_j^s and the selected source item encoder representation, $h_{\cdot}^{E_{s2s}}$. Sharing context vectors between extractors is similar to the cross attention mechanism as described by Jadhav and Rajan (2018). In case D_{s2s} is at pause (i.e., q_j=0), the E_{s2s} end representation is taken as the selected item representation. D_{w2w} follows the same approach to compute its next state.

As we lack gold standard FINDINGS keywords and sentence-wise one-to-one match between IMPRESSIONS and FINDINGS to train networks to perform selection, we heuristically obtain such labels. See Section 4.2 for details. We perform a maximum-likelihood (ML) end-to-end training of the encoder-extractor networks to minimize the following loss; $\sum_{j=1}^t -(1 - y_j^q)(y_j^w \log \alpha_j^w) - y_j^q(y_j^s \log \alpha_k^s) - y_j^q \log q_j$, where t is the step when D_{s2s} selects a dummy *END*, which indicates end of the extraction, and y_j^q, y_j^s and y_j^w are heuristically obtained switch, word and sentence selection labels at step j respectively.

Abstractor. The abstractor condenses each selected sentence to a concise summary. We employ a pointer generator network (See et al., 2017) for this purpose. It uses a copy mechanism to solve the out-of-vocabulary (OOV) problem and a coverage mechanism to solve the repetition problem. See (See et al., 2017) for details. We independently train the abstractor using heuristically obtained one-to-one matches between FINDINGS and IMPRESSIONS sentences.

3 DiMAC

As extractor and abstractor are separately trained in a two-step framework, Chen and Bansal (2018) proposed using RL training with the extractor assuming the agent role and the abstractor as part of the environment to address the separation. Furthermore, as RL loss is computed out of final summary and ground-truth IMPRESSIONS, RL training addresses the error due to heuristic labels in the pretrained networks. Unlike Chen and Bansal (2018), our setup involves multiple extractors, so we use MARL for the coordination. In other words, the word and sentence extractors D_{w2w} and D_{s2s} operate as RL agents a_w and a_s (Figure 1, right sidie).

In (Foerster et al., 2018), an actor-critic MARL has a centralized critic and parameter-sharing actors. In contrast, our extractors have different characteristics, e.g., amount of selection (salient words greater than sentences) and size of source representations; therefore, we exclude parameter sharing between actors. Additionally, to not have actors influence each other's policies, we have a critic that estimates the value function by not conditioning on the actions of other agents, thereby ensuring actor independence. Furthermore, we introduce a communicator (m) that coordinates actors through message passing. The dedicated channel m addresses the issue of the environment appearing non-stationary due to independent agents; see (Foerster et al., 2016; Sukhbaatar et al., 2016; Mordatch and Abbeel, 2018). The channel allows gradients to flow between actors, transforming the setup into an end-to-end Differentiable Multi-agent Actor Critic (DiMAC). The actors and the communicator are initialized with the maximum-likelihood (ML) trained extractors and switch network, respectively.

Actions. Actors a_w and a_s have action spaces of source words $\{w_1, \cdots, w_m\}$ and sentences $\{s_1, \cdots, s_n\}$, respectively. At any decoding step j, actors choose actions (i.e., source selection) $u_j^{a_w}$ and $u_j^{a_s}$ by using policy networks π^{a_w} and π^{a_s} and hidden states $h_j^{a_w}$ and $h_j^{a_s}$. Due to the communication between actors in DiMAC training, we intuitively expect some correlation in the actions.

Reward. For any decoding step j, if the communicator indicates sentence selection ($m = 0$), a sentence reward $r_j^{a_s}$ is computed using R_1 (ROUGE unigram recall) between the abstract summary $\hat{s}_j^{a_s}$ of selected sentence $s_j^{a_s}$ (out of action $u_j^{a_s}$) from the abstractor and a ground-truth IMPRESSIONS sentence. We sequentially match summary and IMPRESSIONS sentences such that a_s learns to select relevant sentences sequentially. Similarly, word reward $r_j^{a_w}$ for selected word $w_j^{a_w}$ out of action $u_j^{a_w}$ is 1 if the word is in the subset of keywords in FINDINGS, K^F, else it is 0. Again, we match selected and FINDINGS keywords sequentially. When an agent selects extra items, the reward for those selections is 0, and thus, the agent learns to select only relevant sentences and keywords.

In addition, joint actions of actors eventually generate a global reward in a multi-agent cooperative setting as: $r^g = R_1(\{\hat{s}_1^{a_s}, \cdots, \emptyset, \cdots, \hat{s}_t^{a_s}\}, I) + \lambda R_1(\{w_1^{a_w}, \cdots, \emptyset, \cdots, w_t^{a_w}\}, K^F)$, where t is the step when a_s selects *END* and λ is a hyperparameter to adjust the global word reward contribution. As K^F keywords are not gold-standard, we set $\lambda = 0.1$; this means that generated summary sentences drive most of the global learning. r^g is included as the reward at the last step t for both actors.

Action value functions $Q_j^{a_w}$ and $Q_j^{a_s}$ for actions $u_j^{a_w}$ and $u_j^{a_s}$ are estimated as $\mathbb{E}_{u_{j:t}^{a_w}, h_{j:t}^{a_w}}[G_j^{a_w} \mid h_j^{a_w}, u_j^{a_w}]$ and $\mathbb{E}_{u_{j:t}^{a_s}, h_{j:t}^{a_s}}[G_j^{a_s} \mid h_j^{a_s}, u_j^{a_s}]$, respectively, where $G_j^{a_w}$ and $G_j^{a_s}$ are discounted rewards computed as $\sum_{l=0}^{t-j} \gamma^l r_{j+l}^{a_w}$ and $\sum_{l=0}^{t-j} \gamma^l r_{j+l}^{a_s}$ and $\gamma = 0.99$ is a hyperparameter.

Critic. Like the actors, the critic c is an LSTM based network. It runs for the same number of steps as the actors and estimates gradients to train them. As the critic is used only in training, at each step j, the critic conditions on the actors' ground-truth selection indices, y_j^s and y_j^w, as the actions and uses these indices to obtain word and sentence encoder representations. In addition to source representations, it uses its state, h_j^c, and attends to all encoder states, $\{h_1^{E_{w2w}}, \cdots\}$ and $\{h_1^{E_{s2s}}, \cdots\}$) to estimate a value function V_j. V_j is then used to compute advantage functions $A_j^{a_w}$

Algorithm 1 Differentiable Multi-Agent Actor Critic

```
procedure TRAIN-DIMAC
    Initialize parameters of actors ($a_w$ and $a_s$), critic ($c$) & communicator ($m$) as $\theta^{a_s} := D_{s2s}$, $\theta^{a_w} := D_{w2w}$, $\theta^c := D_{w2w}$ & $\theta^m := switch$
    for each training episode $i$ do
        step $j \leftarrow 1$
        while action $u_j^{a_s} \neq$ END do
            compute actors & critic states
            sample actions $u_j^{a_s}$ & $u_j^{a_w}$
            compute rewards $r_j^{a_w}$ & $r_j^{a_s}$ for $u_j^{a_s}$ & $u_j^{a_w}$
            compute message $m_j$ & value function $V_j$
            $j \leftarrow j + 1$
        compute global reward $r^g$
        for $j = t$ to 1 do
            compute discounted reward $G_j^{a_s}$ and $G_j^{a_w}$
            estimate action-value functions $Q_j^{a_w}$ & $Q_j^{a_s}$
            compute advantages $A_j^{a_s}$ & $A_j^{a_w}$
            accumulate critic gradient $\Delta\theta^c$
            accumulate actor gradients $\Delta\theta^{a_s}$&$\Delta\theta^{a_w}$
        update critic $\theta_{i+1}^c = \theta_i^c - \alpha\Delta\theta^c$
        update actors as $\theta_{i+1}^{a_s} = \theta_i^{a_s} + \alpha\Delta\theta^{a_s}$ & $\theta_{i+1}^{a_w} = \theta_i^{a_w} + \alpha\Delta\theta^{a_w}$
    return $\theta^{a_s}$, $\theta^{a_w}$ & $\theta^m$
```

and $A_j^{a_s}$ for actors as $Q_j^{a_w} - V_j$ and $Q_j^{a_s} - V_j$. At any step, one of the two ground-truth actions y_j^s / y_j^w is empty. Therefore, the computed value and action-value functions V_j and Q_j at that step intuitively become agent-specific, resulting in independent agent learning. Finally, agent specific advantage functions are used to compute actor gradients as $\nabla_{\theta^{a_w}} \log \pi_j^{a_w} A_j^{a_w}$ and $\nabla_{\theta^{a_s}} \log \pi_j^{a_s} A_j^{a_s}$. Importantly, value, action-value and advantage can be calculated in a single forward pass of the actor and critic for each agent. See appendix for details and proofs.

Communication. The communicator *m* (Figure 1, red circles) passes messages between the actors. Actor previous hidden states and contexts, $h_j^{a_s}$, $h_j^{a_w}$, c_j^s and c_j^w, are fed to *m* and a sigmoidal m_j is obtained. Value m_j is fed to a_s while $1 - m_j$ is fed to a_w. The gradient of m_j flows between actors during backpropagation and provides rich training signal that minimizes the learning effort.

See Algorithm 1 for DiMAC training algorithm details.

4 Experiments

4.1 Dataset

We preprocessed and filtered radiology reports from two medical centers in the USA (Courtesy of Princeton Radiology, Princeton and University of Colorado Health). [1] The resulting dataset comprises 37,408 radiology reports, which we randomly split into training (31,808), validation (3,740) and test sets (1,860). Table 3 gives dataset statistics.

	FINDINGS	IMPRESSIONS
#w per sentence	10.54 (06.53)	8.52 (05.80)
#s per report	8.23 (04.68)	1.75 (01.16)
#w per report	86.77 (64.72)	14.89 (15.81)

Table 3: Dataset statistics: number of words/sentences per sentence/report. Standard deviation in parentheses.

4.2 Experimental Setup

Training labels. Given an IMPRESSIONS sentence, we find a unique FINDINGS sentence with the highest sentence similarity score. We follow Chen and Bansal (2018) and Liu and Lapata (2019) and use ROUGE-L as the sentence similarity scorer. Furthermore, they use a greedy matching algorithm that takes similarity scores of all IMPRESSIONS and FINDINGS sentence combinations and yields a sequence of unique FINDINGS indices $\{y_1^s, \cdots\}$ of size equivalent to the length of IMPRESSIONS. There is a 1-to-1 correspondence between FINDINGS sentences at indices and IMPRESSIONS sentences. We refer to the papers for more details. These 1-to-1 correspondence are used for abstractor pretraining.

We use AutoPhrase (Shang et al., 2018) to extract keywords from training reports automatically. We select only high-quality keywords, K, and avoid too frequent ones as these can bias the system to only perform keyword selection. We implement an empirical threshold determined by hyperparameter search experiments.[2] We then find a subset of keywords, K^F, in FINDINGS F and compile their indices $\{y_1^w, \cdots\}$.

As the two extractors run for the same number of steps, we interleave the above sentence and word indices $\{y^s, \cdots\}$ and $\{y^w, \cdots\}$ into one sequence. In more detail, given a sentence index, all keywords indices within that sentence are placed in the sequence, followed by its index. A binary switch variable y^q (with values 0 and 1) distinguishes the

---

[1] Sentences split using Stanford CoreNLP (Manning et al., 2014). The following reports are excluded: (a) no FINDINGS and/or IMPRESSIONS; (b) FINDINGS has fewer than 3 words; (c) FINDINGS has fewer words or fewer sentences than IMPRESSIONS. We replace special tokens like numbers, dates and abbreviations and used scispacy lemmatization.

[2] AutoPhrase ranks keywords using a quality score based on frequency. The threshold is set on this score.

index type in the sequence, i.e., index refers to sentence vs. keyword. Both extractors require, during a decoding step j, training labels y_j^s and y_j^w; we set the value of "non-available type" as indicated by y_j^q to $\emptyset$. For example, when y_j^q is 0, y_j^w is $\emptyset$. Overall, an element in the final sequence is a tuple of y^q, y^s and y^w and provides training labels for the switch, word and sentence extractor networks. See Appendix A for details on the interleaving of indices.

Hyperparameters. Included in Appendix C.

Evaluation measure. We follow standard practice and evaluate the quality of generated IMPRESSIONS by comparing against ground-truth IMPRESSIONS using ROUGE (Lin, 2004).

4.3 Baseline Models

In this section we describe the baselines we compare our model against: a wide variety of extractive and abstractive systems.

Extractive systems

LexRank (Erkan and Radev, 2011) is a graph-based method for computing relative importance in extractive summarization.

Abstractive systems

PTGEN (See et al., 2017) introduces an encoder-decoder model that can copy words from the source text via pointing, while retaining the ability to produce novel words through the generator.

PTGEN+Coverage (See et al., 2017) introduces a coverage mechanism to the original PTGEN model to avoid repetition.

Zhang et al. (2018) provides an automatic generation system for radiology IMPRESSIONS using neural seq2seq learning. The model encodes background information of the radiology study and uses this information to guide the decoding process.

Self supervised learning has recently gained popularity as parameters of large models can be trained with little to no labeled data. Pre-trained language models in which a transformer encoder is trained to reconstruct the original text from masked text, e.g., BERT (Devlin et al., 2018), have become an important component in recent summarization models (Liu and Lapata, 2019; Zhang et al., 2020; Zaheer et al., 2020). **We also present results from experiments using these summarization models**. Additionally, we experimented with a **pre-trained seq2seq model** which is learned using different self supervised techniques to reconstruct the original text, e.g., BART (Lewis et al., 2019).

BertSumExtAbs (Liu and Lapata, 2019) is an encoder-decoder summarization framework that adopts BERT as its encoder. BERT is replaced by ClinicalBERT (Alsentzer et al., 2019) in all our experiments as it is adapted for the medical domain. At the first stage, a model with the BERT encoder accomplishes an extraction task. Then, the trained BERT encoder and a 6-layered transformer (Vaswani et al., 2017) are combined to form an abstractive system. As the encoder in the abstractive system is pre-trained multiple times in comparison to the decoder, two separate Adam optimizers (each with different warm-up steps and learning rates) are used during training. As the training is performed in two stages, **BertSumExtAbs** serves as the two-stage abstractive summarization system baseline for our experiments.[3] We also include results from **BERTSUMAbs**, a single-stage version in which encoder and decoder are trained only on the abstractive task.

BART (Lewis et al., 2019) is a state of the art transformer-based seq2seq model similar to BERTSUMAbs. However, unlike BERTSUMAbs's fine-tuning of the encoder and denovo training of the decoder, for BART, both encoder and decoder are only fine-tuned.

Sentence Rewrite (Chen and Bansal, 2018) is a two-step summarization model that initially extracts and then rewrites the sentences. This model serves as a two-step single agent baseline system for our experiments.

5 Results

In this section, we compare results from our model and various baselines using both automatic and human evaluation.

Automatic Evaluation. Table 4 shows report summarization results of various models trained and tested on the same data. Our DiMAC model surpasses extractive-only and abstractive-only baselines, including LexRank and PTGEN+Coverage. It also outperforms the two-step single agent baseline model (Sentence Rewrite (Chen and Bansal, 2018)) and the two-stage BERTSUMExtAbs (Liu and Lapata, 2019). Besides the pre-trained encoder

---

[3] We require hyperparameters somewhat different from the standard setup due to the small radiology report data size. Hyperparameter tuning yielded the following values. Batch size and initial learning rate of BERTSumExt are set to 16 and 5e-4, batch size in BERTSumExtAbs is 8 and initial learning rates of BERT and transformer decoder in BERTSumExtAbs are 0.0005 and 0.005.

Models	ROUGE-1	ROUGE-2	ROUGE-L
LexRank (Erkan and Radev, 2011)	27.33	14.78	29.8
PTGEN (See et al., 2017)	39.82	17.35	38.04
PTGEN+Coverage (See et al., 2017)	41.22	19.61	40.87
Zhang et al. (2018)	44.16	22.67	43.07
BERTSUMAbs (Liu and Lapata, 2019)	49.82	41.02	49.39
BERTSUMExtAbs (Liu and Lapata, 2019)	52.70	43.21	52.19
BART (Lewis et al., 2019)	41.23	29.02	40.02
Sentence Rewrite (Chen and Bansal, 2018)	59.82	48.54	59.11
DiMAC	**62.65**	**51.55**	**61.06**

Table 4: Results for baseline methods and DiMAC on the test split of the medical reports. The experimental setup is the same for all methods, i.e., the same train/validation/test split of the medical reports was used. Additionally, as DiMAC is a multi-agent two-step system built on top of Sentence Rewrite (Chen and Bansal, 2018) (a single-agent two-step setup), we keep abstractor and all hyperparameters except those specific to DiMAC the same for a fair comparison. All ROUGE scores have a 95% confidence interval of at most ±0.50 as calculated by the official ROUGE script.

of BertSumExtAbs, which is an advantage compared to other baselines, a denovo training of a large size decoder with a relatively small number of radiology reports may have led to overfitting. This might explain the scores compared to the two-step systems. Furthermore, a highly sophisticated semi-supervised training of the encoder and decoder of BART-base resulted in lower performance compared to our model, despite the relatively larger size (100x) of BART. We hypothesize that pre-training mostly on a different domain text (e.g., Wikipedia, Books Corpus and News) and fine-tuning on small data could have adversely affected BART's performance in our setting. The domain difference may also contribute to the relatively lower performance of BART-base versus BERTSUMExtAbs, thereby signifying the importance of pre-training with relevant domain text.

Moreover, DiMAC offers approximately 18 to 28% performance gains over (Zhang et al., 2018), a single-step single-agent summarization system designed specifically for the radiology domain. In our opinion, the performance improvements observed with DiMAC are likely driven by the extract-then-abstract mechanism combined with auxiliary (and salient) information from keywords, which mimics the actual reasoning process of radiologists.

It is important to note that our model supports user-level validation by linking the predicted IMPRESSIONS sentences to sentences in FINDINGS, making the results explainable to radiologists and referring physicians.

Human Evaluation. To assess the overall quality and factual correctness (Zhang et al., 2019) of the IMPRESSIONS generated by DiMAC, we obtained evaluations from two board-certified radiologists. We randomly selected 16 radiology reports from the test set. For each radiology report, we presented to the evaluators its FINDINGS and three (blinded) versions of the summary, i.e., IMPRESSIONS: (1) the ground truth, (2) Sentence Rewrite (Chen and Bansal, 2018) and (3) DiMAC. As Sentence Rewrite has a similar two-step approach, i.e., extract-then-abstract, we evaluate the qualitative performance of DiMAC with Sentence Rewrite as the base model (instead of BERTSUMExtAbs as it is a two-stage single-step system and also had lower Rouge scores compared to Sentence Rewrite).

	Win	Tie	Lose	Gwet AC1
DiMAC vs. Base model				
Overall quality	25.00	59.37	15.63	.305
Factual correctness	12.50	84.37	03.13	.711
DiMAC vs. Ground Truth				
Overall quality	25.00	46.87	28.13	.082
Factual correctness	21.87	53.13	25.00	-.080

Table 5: Percentage of 16 radiology reports for which human evaluators rated DiMAC better than (win), the same as (tie) or worse than (lose) the base model and ground truth on overall quality and factual correctness. We also provide Gwet's Agreement Coefficient as a measure of agreement between raters; values below 0.2 indicate poor agreement, values above 0.8 indicate very good agreement.

We shuffled the three summaries such that the order cannot be guessed. Each radiologist rated the summaries on two measures in relation to the FINDINGS: (1) overall quality and (2) factual correctness and completeness. For example, the phrase "pleural effusions" is a fact (or imaging finding); but the phrase "small bilateral pleural effusions" is a more precise description and should therefore have a better overall quality score. For each measure, we asked the radiologists to score the summary as 1, 2 or 3 for bad, borderline or good. Then we combined the assigned scores under two comparisons: (1) our model versus the base model and (2) our model versus ground truth.

We have 32 evaluations in total: 2 radiologists × 16 reports. We compared the scores provided by the radiologists to determine if they were the same (tie), higher (win) or lower (lose) for our model vs. ground truth and our model vs. base model. Table 5 shows that DiMAC has clearly better factual correctness than the base model: 12.5% of cases are better, 3.13% are worse; gwet AC1 (Gwet, 2008) inter-rater agreement for this result is strong. DiMAC exceeds the base model in 25% (vs. 15.6% "lose") of evaluations for overall quality with moderate inter-rater agreement. DiMAC is only slightly worse than ground truth in overall quality (win: 25%, lose: 28.13%) and factual correctness (win: 21.87%, lose: 25%) – although inter-rater agreement is low in this case.

5.1 Qualitative Results Analysis

Table 6 shows a radiology report from our dataset (FINDINGS and IMPRESSIONS) and IMPRESSIONS generated by DiMAC and the base model. Due to the hierarchical connections between words and sentences, there is significant overlap between the extracted sentences and words. This phenomenon eventually contributes to the RL sentence extraction reward and helps to extract sentences with more keywords. The keywords include disease or clinical diagnoses (e.g., nodule, lymphadenopathy, effusion), anatomical concepts (e.g., hepatic) and qualifiers (e.g., recent, multiple, bilateral). The baseline model (Chen and Bansal, 2018) erroneously states "right greater than left pleural effusions", i.e., it hallucinates. In the sentence "There is no axillary or hilar lymphadenopathy", the sentence reward is low and eventually it is not extracted despite having the keyword "lymphadenopathy".

FINDINGS from the report from a medical site
There are **multiple bilateral** lung **nodules** , most consistent with metastatic disease . There are more nodules on the right than the left . An enlarged prevascular lymph node measures 0.6 x 0.4 cm . There is no axillary or hilar **lymphadenopathy** . No pleural or pericardial **effusion** is seen . There is calcification in the aortic valve and coronary arteries . There are numerous large **hepatic** masses which have been better described on **recent** ct scan of the abdomen . There is degenerative disease in the thoracic spine with mild compression of the superior endplate of a lower thoracic vertebral body . No suspicious osseous lesion is seen .
IMPRESSIONS from the report from a medical site
Multiple bilateral lung nodules , consistent with metastatic disease . Mediastinal lymphadenopathy . Multiple liver masses .
IMPRESSIONS generated by DiMAC
Multiple bilateral lung nodules , most consistent with metastatic disease . No pleural effusions . Numerous hepatic masses , better described on recent ct scan of the abdomen .
IMPRESSIONS generated by base model
Multiple bilateral lung nodules, most consistent with metastatic disease . right greater than left pleural effusions . enlarged right paratracheal lymph node . numerous hepatic masses .

Table 6: FINDINGS and IMPRESSIONS of a radiology report from the report from a medical site and IMPRESSIONS generated by base model and DiMAC. Extracted sentences are highlighted in blue. Extracted words are shown in bold and underlined. The base model (Chen and Bansal, 2018) erroneously states "right greater than left pleural effusions", i.e., it hallucinates.

6 Related Works

Abstractive Summarization. An abstractive summary is a text consisting of novel phrases describing the content of the original text. Abstractive summarization involves a cascade of topic fusion and text generation (Hovy et al., 1999). Each task in this cascade typically requires expert-derived annotations, which is labor-intensive and time-consuming. Thus, many recent abstractive summarization approaches focus on supervised/semi-supervised single-step end-to-end trainable models that implicitly address the sub-tasks of content acquisition and paraphrasing.

As part of two-stage but single step abstractive summarization, a pretrained encoder first learns the extraction task independently. Then the pretrained encoder is embedded into an encoder-decoder abstractive summarization model to assist in better referencing the source content, e.g., Liu and Lapata (2019); Hsu et al. (2018). On the other hand, in two-step abstractive summarization, extractive summarization is followed by abstractive summarization and is trained end-to-end, e.g., Chen and Bansal (2018). Contrary to the two-stage single-step approach, both extractive and abstractive summarization are pretrained (and function) separately in a two-step approach; however, an RL-based end-to-end training enables alignment between them to generate better summaries. DiMAC is a two-step abstractive system.

Multi-agent Reinforcement Learning (MARL). In a single-agent actor-critic (Sutton et al., 1999; Konda and Tsitsiklis, 2000) policy gradient method, an agent policy θ^{π} is optimized by following a gradient computed using a value function estimated by a critic. The simplest MARL setup applies policy gradients independently (each agent with its own actor and critic) and thereby restricts each agent to learn only from its own action history (Tan, 1993). From each agent's point of view in this setting, the environment is not stationary and therefore, the RL stationary environment assumption is violated.

MARL with communication or collaboration protocols. Foerster et al. (2018) proposed counterfactual policy gradients, which is an actor-critic policy gradient that leverages a centralized counterfactual critic that estimates value function for each actor by using actions performed by the other agents. However, unlike our setting, actors in (Foerster et al., 2018) are similar and share parameters. Additionally, the parameter sharing scheme has the limitation that the agents lack tighter coordination. Foerster et al. (2016), Sukhbaatar et al. (2016) and Mordatch and Abbeel (2018) proposed to tightly coordinate independent agents rather than use a dedicated channel. As incorporating an explicit communication channel mimics human (bidirectional) interactions, we design a similar Differentiable Multi-agent Actor-Critic (DiMAC) RL for our setup. In DiMAC, each agent selects one of its actions and communicates with the others at every point in time. Thus, the resulting joint action (influenced by the agents' communication) would aim to reach the desired (optimal) goal. In the future, we will experiment with more variations of MARL (such as counter-factual critic) and transformer-based networks.

7 Conclusion

In this work, we introduce a novel extractive approach into a two-step RL-based summarization task (extractive-then-abstractive). This approach is a MARL (rather than the traditional single-agent RL) which includes a new agent that extracts salient keywords from the source text and collaborates with an agent that extracts salient sentences. We also present a Differentiable Multi-agent Actor-Critic (DiMAC) learning method, a novel yet simple MARL training for independent agents communicating via a dedicated channel. We apply the proposed two-step summarization model with DiMAC MARL training to English radiology reports. Results from our experiments indicate, based on automatic and human expert evaluations, that the DiMAC summarization model can outperform existing baseline models for text summarization. Our summarization model generates the IMPRESSIONS to reflect human-level inference and actionable information (e.g., salient sentences and keywords) towards supporting improved workflow efficiency and better-informed clinical diagnosis based on medical imaging findings.

Appendix

A Training Labels

In any training episode, we use Rouge-L and compute similarity scores between sentences in FINDINGS and IMPRESSIONS. Then, for each IMPRESSIONS sentence, we find the FINDINGS sentence that has the highest similarity score, and we compile its index. Furthermore, index compilation is a selection without replacement process, i.e., each sentence will only be selected once. This yields a sequence of unique sentence indices $\{y_1^s, \cdots\}$ of a size equivalent to the length of IMPRESSIONS. Additionally, we flatten FINDINGS sentences $\{s_1, \cdots, s_n\}$ to a long sequence of words $\{w_1, \cdots, w_m\}$. We then find words that are in the given keywords set K and compile their indices $\{y_1^w, \cdots\}$. For example, in Table 1, salient sentence and word indices are $\{1, 7, 8\}$ and $\{6, 7, 9, 10, \cdots, 81, 82\}$ respectively.

Finally, we interleave sentences and word indices $\{y_1^s, \cdots\}$ and $\{y_1^w, \cdots\}$ into one sequence to train extractors. Basically, given a sentence index, all keywords indices within that sentence are placed in the sequence. In addition, we use a binary switch variable y^q (with values 0 and 1) to distinguish the index type in the sequence, i.e., y^q=0 implies sentence index and y^q=1 implies word index. Thus, the length of the binary switch variables sequence is the same as the interleaved indices. As extractors run for the same number of steps, training requires the labels y_j^s and y_j^w at any step j. However, the interleave sequence at any step includes only one out of the two. So, we set the value of "non-available type" as indicated by y_j^q to $\emptyset$. Overall, an element in the final sequence is a tuple of y^q, y^s and y^w. For Table 1, the final sequence of training labels is $\{(1, \emptyset, 6), (1, \emptyset, 7), (1, \emptyset, 9), (1, \emptyset, 10), (0, 1, \emptyset), \cdots, (1, \emptyset, 81), (1, \emptyset, 82), (0, 8, \emptyset)\}$.

B Encoder-Extractor Training

Algorithm. 2 shows the training of word encoder (E_{w2w}), sentence convolutional network (*Conv*), sentence encoder (E_{s2s}), word extractor (D_{w2w}), sentence extractor (D_{s2s}) and switch network (*switch*).

Algorithm 2 Encoder-Extractor Training

```
procedure TRAIN-JOINT-EXTRACTORS
    Random Initialize: $E_{w2w}, Conv, E_{s2s}, D_{w2w}, D_{s2s}$ & switch
    for 1 to | Reports | do
        $\{h_1, \cdots, h_n\} \leftarrow Conv(\{s_1, \cdots, s_n\})$
        $\{h_1^{E_{s2s}}, \cdots\} \leftarrow E_{s2s}(\{h_1, \cdots\})$
        $\{h_1^{E_{w2w}}, \cdots, \} \leftarrow E_{w2w}(\{w_1, \cdots\})$
        $Loss \leftarrow Array()$
        $h_1^{D_{w2w}}, h_1^{D_{s2s}} \leftarrow h_m^{E_{w2w}}, h_n^{E_{s2s}}$
        for $j = 1$ to $t$ do
            $\boldsymbol{\alpha}^w \leftarrow Attn(h_j^{D_{w2w}}, \{h_1^{E_{w2w}}, \ldots\})$
            $c_j^w \leftarrow \sum_{i=1}^{m} \alpha_i^w \times h_i^{E_{w2w}}$
            $\boldsymbol{\alpha}^s \leftarrow Attn(h_j^{D_{s2s}}, \{h_1^{D_{s2s}}, \ldots\})$
            $c_j^s \leftarrow \sum_{k=1}^{n} \alpha_k^s \times h_k^{E_{s2s}}$
            $q_j \leftarrow switch(h_j^{D_{w2w}}, c_j^w, h_j^{D_{s2s}}, c_j^s))$
            $h_{j+1}^{D_{w2w}} \leftarrow D_{w2w}(h_j^{D_{w2w}}, c_j^w, c_j^s)$
            $h_{j+1}^{D_{s2s}} \leftarrow D_{s2s}(h_{j-1}^{D_{s2s}}, c_j^w, c_j^s)$
            $Loss.\text{ADD}(-(1 - y_j^q)(y_j^w \log \boldsymbol{\alpha}^w))$
            $Loss.\text{ADD}(-y_j^q(y_j^s \log \boldsymbol{\alpha}^s))$
            $Loss.\text{ADD}(-y_j^q \log q_j)$
        compute gradients, $\{\Delta_{E_{w2w}} Loss, \cdots\}$
        update $E_{w2w}, Conv, E_{s2s}, D_{w2s}, D_{s2s}$ & switch
    return $E_{w2w}, Conv, E_{s2s}, D_{w2s}, D_{s2s}$ & switch
```

C Hyperparameter

We set the maximum limit for words in a report to 800 tokens, and the maximum number of sentences is truncated to 60 per report. We use word2vec (Mikolov et al., 2013) on the training set to generate word embeddings of 128 dimensions. The vocabulary is 50,000 most common words in the training set. The dimension of each intermediate sentence representation is 300 after using 1-D convolution filters with 3 different windows sizes (i.e. 3, 4, and 5). The dimension of all the LSTMs in our framework is 256. The optimizer used is Adam with a learning rate of 0.001 in the pre-training phase and 0.0001 in the RL training phase. We apply gradient clipping to alleviate gradient explosion using a 2-norm of 1.5. We adopt the early stopping method on the validation set. In the RL setting, the discounted factor γ is set as 0.95. At test time, we use beam size 5 for beam search.

D Single Agent Actor-Critic

In the case of a single agent actor-critic RL, for any training episode, actor a uses its policy network π^a and samples actions $\{u_1^a, \cdots, u_t^a\}$ for t time steps with each action u_k^a receiving a reward r_j^a. Furthermore, at step j, a discounted reward is computed as $G_j^a = \sum_{l=0}^{t-j} \gamma^l r_{j+l}^a$.

A batch of training episodes is used to estimate the actor's action value at step j as $Q_j^a = \mathbb{E}_{u_{j:t}^a, h_{j:t}^a}[G_j^a \mid h_j^a, u_j^a]$. Similarly, the critic (c) estimates a value function for step j as $V_j = \mathbb{E}_{h_j^a}[G_j^a \mid h_j^a]$. An advantage function is computed as $A_j^a = Q_j^a - V_j$. Policy gradient theorem computes the gradient to update the actor parameter θ^a as

$$\Delta\theta^a = \mathbb{E}_{\theta^a}\left[\sum_{j=1}^{t} \nabla_{\theta^a} \log \pi_j^a A_j^a\right] \tag{1}$$

The value function component V_j in the policy gradient helps to reduce the variance without changing the expectation as

$$\begin{aligned}
&-\mathbb{E}_{\theta^a}\left[\nabla_{\theta^a} \log \pi_j^a V_j\right] \\
&= -\sum_h d^{\pi_j^a}(h) \sum_{u^a} \nabla_{\theta^a} \pi_j^a V_j \\
&= -\sum_h d^{\pi_j^a}(h) V_j \nabla_{\theta^a} \sum_{u^a} \pi_j^a \\
&= 0
\end{aligned}$$

where $d^{\pi_j^a}(h)$ is the discounted ergodic state distribution (Sutton et al., 1999). V_j is a function of state and not action, thus moved outside ∇, and since $\sum_{u^a} \pi_j^a$=1, the gradient becomes 0. $\Delta\theta^a$ is empirically estimated using N episodes in a training batch as

$$\Delta\theta^a \approx \frac{1}{N} \sum_{i=1}^{N} \left[\sum_{j=1}^{t} \nabla_{\theta^a} \log \pi_j^a A_j^a\right] \tag{2}$$

E Multi Agent Actor-Critic

In the case of multi-agent actor-critic RL with a set of actors, $\boldsymbol{a}$=$\{\cdots, a_k, \cdots\}$, for any training episode, an actor a_k uses its policy network π^{a_k} and samples actions $\{u_1^{a_k}, \cdots, u_t^{a_k}\}$ for t time steps with each action $u_j^{a_k}$ receiving a reward $r_j^{a_k}$. Furthermore, at step j, a discounted reward for a_k is computed as $G_j^{a_k} = \sum_{l=0}^{t-j} \gamma^l r_{j+l}^{a_k}$.

Like the single agent actor-critic, a batch of training episodes is used to estimate the action value of a_k at step j as $Q_j^{a_k} = \mathbb{E}_{u_{j:t}^{a_k}, h_{j:t}^{a_k}}[G_j^{a_k} \mid h_j^{a_k}, u_j^{a_k}]$.

The contribution of value function from a centralized critic at any step j in the overall gradient is computed as

$$-\mathbb{E}_{\theta^{\boldsymbol{a}}}\left[\nabla_{\theta^{\boldsymbol{a}}} \log \pi_j^{\boldsymbol{a}} V_j\right]$$

where $\theta^{\boldsymbol{a}}$ and $\boldsymbol{\pi}^{\boldsymbol{a}}$ are the actors' $\boldsymbol{a}$ joint parameters and policies respectively. V_j is the value function computed by the critic at step j. We drop the step notation j subsequently as all notations are specific to step j. The agent-wise break of policies and the contribution of the value function in the overall gradient is

$$\begin{aligned}
&= -\sum_h d^{\pi^{\boldsymbol{a}}}(h) \sum_{a_k} \sum_{u^{a_k}} \nabla_{\theta^{a_k}} \pi^{a_k} V \\
&= 0
\end{aligned}$$

where $d^{\pi^{\boldsymbol{a}}}$ is the discounted ergodic state distribution, u^{a_k} is agent a_k action and V is the estimated value function by the critic. Although two actors are running at each step in our DiMAC training, only one of them is active while the other is on pause ($\emptyset$ selection). Therefore, the contribution of the term $\sum_{\boldsymbol{a}} \sum_{u^{a_k}} \nabla_{\theta^{a_k}} \pi^{a_k} V$ is similar to a single-agent scenario, and therefore, the gradient is 0. Furthermore, the critic estimated value ensures that the active agent gets rewarded for its action leading to the overall success.

Online Semantic Parsing
for Latency Reduction in Task-Oriented Dialogue

Abstract

Standard conversational semantic parsing maps a complete user utterance into an executable program, after which the program is executed to respond to the user. This could be slow when the program contains expensive function calls. We investigate the opportunity to reduce latency by predicting and executing function calls while the user is still speaking. We introduce the task of *online semantic parsing* for this purpose, with a formal latency reduction metric inspired by simultaneous machine translation. We propose a general framework with first a learned prefix-to-program prediction module, and then a simple yet effective thresholding heuristic for subprogram selection for early execution. Experiments on the SMCalFlow and TreeDST datasets show our approach achieves large latency reduction with good parsing quality, with a 30%–63% latency reduction depending on function execution time and allowed cost.

1 Introduction

In task-oriented dialogue systems, a software agent typically translates a user's intent into a program, executes it to query information sources (e.g., find a person in the user's contact list) or effect external actions (e.g., schedule a meeting or send an email), then communicates the results back to the user. If an agent waits to begin this process until the user finishes speaking, there is a noticeable lag before the user receives a response. The complex intents in the datasets SMCalFlow (Semantic Machines et al., 2020) and TreeDST (Cheng et al., 2020), for example, can be slow to execute, nesting up to 7 slow function calls that cannot be parallelized. Inspired by simultaneous machine translation, we ask: How much can latency be reduced by interpreting and executing early, before the user finishes speaking?

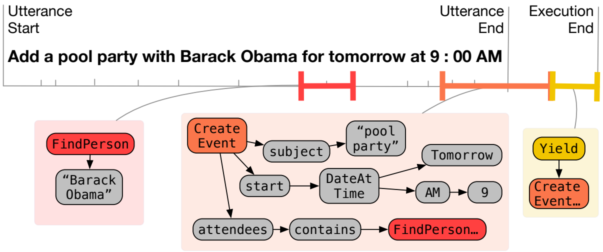

Figure 1: A possible execution timeline for *"Add a pool party with Barack Obama for tomorrow at 9:00 AM"*. `FindPerson` was predicted and executed after the token *"Obama."* `CreateEvent` was predicted and executed after the token *"9"* (`AM` was guessed). `Yield` was also predicted after the token *"9"*, but could not begin until `CreateEvent` finished. Because `FindPerson` and `CreateEvent` started execution before the end of the utterance, the top-level node `Yield` was able to finish early, and overall latency was reduced. Gray nodes have near-instantaneous execution, and do not contribute to the timeline. Edge labels were omitted to save space.

In general, an agent could begin speculatively executing any subprogram at any instant while a user is speaking, based on partial results from automatic speech recognition (ASR) and the current state of execution. Take Figure 1 for a hypothetical example. If partial programs can be identified while the user is still speaking, they can be pre-executed and the final response to the user could be expedited.

This is an online decision problem: decisions to invoke particular functions on particular arguments can be made before all information has arrived. Thus, we refer to it as **online semantic parsing**. This requires spotting user intents that have already been expressed (without the help of aligned training data) and—even harder—anticipating user intents that have not been expressed yet. To assess an online semantic parser, we propose reporting the reduction in latency of the agent's final response (relative to an offline agent), as measured by real or simulated execution of the function calls.

[*] Work performed during a research internship at Microsoft Semantic Machines.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1554 - 1576
May 22-27, 2022

We propose two approaches. Our first system is built on a neural graph-based semantic parser, which is specially trained to parse an incomplete utterance into a full program. Our second system is a pipeline that uses a language model (LM) to predict how a user will finish the incomplete utterance, and then parses the predicted completed utterance. In either case, a subprogram is selected for execution as soon as the semantic parser predicts that it has a high probability of being in the correct parse. Experiments on both SMCalFlow and TreeDST datasets show that both approaches achieve high latency reduction with a small number of excess function calls. We make three main contributions: First, we propose a new task for online semantic parsing and a realistic evaluation metric for latency reduction. Second, we present a neural graph-based semantic parser that matches or surpasses the state-of-the-art on SMCalFlow and TreeDST, and extend it to support two novel approaches to map utterance prefixes to programs. Third, we show our approaches achieve estimated latency reductions of 30%–63%, setting up a good benchmark for future explorations.

2 Background

Simultaneous Translation Our task is inspired by the online version of machine translation (MT), known as **simultaneous MT**, which aims to translate a source sentence in real time into a target language (Wahlster, 1993). The latency of such a system is assessed by counting how many source tokens it has observed before it produces the first, second, third, etc. target token. These counts are aggregated into an overall latency metric—a measure either of "waiting," such as Average Proportion (AP) (Cho and Esipova, 2016) and Consecutive Wait (CW) (Gu et al., 2017), or of "lagging" (in comparison with an ideally paced system), such as Average Lagging (AL) (Ma et al., 2019) and Differentiable Average Lagging (DAL) (Cherry and Foster, 2019; Arivazhagan et al., 2019). We discuss the relationship of our proposed metric to DAL and other existing metrics in Section 4.3.

Approaches to simultaneous MT include explicit source word prediction (Grissom II et al., 2014), discrete decision sequence modeling with reinforcement learning (Satija and Pineau, 2016; Gu et al., 2017), latency-controllable wait-k systems with fixed scheduling (Ma et al., 2019), learned adaptive scheduling (Arivazhagan et al., 2019), and retranslation (Arivazhagan et al., 2020a,b).

Executable Programs as Semantic Graphs Semantic parsing maps natural language to structured meaning representations (MRs) that can be executed or reasoned about. These include general-purpose MRs (Clark and Curran, 2007; Banarescu et al., 2013), database queries (Tang and Mooney, 2001; Zettlemoyer and Collins, 2005; Yu et al., 2018), and source code in general-purpose programming languages (Yin and Neubig, 2017), etc. Despite formal differences, these representations can generally be represented as graphs. We will focus on the dataflow graph (Semantic Machines et al., 2020), which represents an executable program in response to a user's utterance in a task-oriented dialogue system (Zettlemoyer and Collins, 2009). Each function invocation is represented by a node, whose label specifies the function, and whose outgoing[1] edges indicate its arguments, which may be constants or other function invocations.

Preliminaries Formally, we represent a program as a labeled directed acyclic graph $G = (V, E)$, where each node $v \in V$ represents a function invocation or a constant value, and each directed edge $u \xrightarrow{\ell} v \in E$ represents that v fills the ℓ argument of the function u. Positional arguments are given edge labels `arg0`, `arg1`, etc. We use "graph" and "program" interchangeably hereon.

In task-oriented dialogue systems, an executable program G is generated in response to a user utterance $\mathbf{u}$ with possible context $\mathbf{c}$ from the dialogue history. The utterance is a token sequence $\mathbf{u} = (u_1, u_2, \ldots, u_{|\mathbf{u}|})$ and the context is also encoded as a sequence $\mathbf{c} = (c_1, c_2, \ldots, c_{|\mathbf{c}|})$.

We use $\mathbf{u}_{[m]}$ to denote the m^{th} prefix presented to the online system, and t_m to denote the time at which it is presented. t denotes the time at which the complete utterance $\mathbf{u}$ is presented. In our experiments, each $\mathbf{u}_{[m]}$ is some prefix of the gold utterance $\mathbf{u}$. A real system could use the noisy partial outputs returned by an ASR system from successively longer speech prefixes. Each partial ASR output $\mathbf{u}_{[m]}$ is returned at some time $t_m \in \mathbb{R}$. It may append one or more words to the previous output $\mathbf{u}_{[m-1]}$, and may also revise some words.

An *offline* system models $p(G \mid \mathbf{c}, \mathbf{u})$, predicting the program only after the user utterance $\mathbf{u}$ has been fully received. But our online system aims

---

[1] Our description has reversed the edge directions from Semantic Machines et al. (2020).

to *simultaneously* parse $\mathbf{u}$ as the user utters it, so as to pre-execute subprograms to reduce the final response time. Our setting differs from simultaneous MT in an important way: we currently do not show the user any output until their utterance is complete. So speculatively executing a predicted subprogram, silently, does not commit to using it in the final result. Our parse of $\mathbf{u}_{[m-1]}$ therefore does not constrain our parse of $\mathbf{u}_{[m]}$.[2] Indeed, in this work, we re-parse each prefix from scratch.

We distinguish between the time or times at which a function invocation is *selected* by the system for execution, the time it is actually *executed*, and the time it *returns*. A selected function invocation is not actually executed until its arguments have returned from execution. But by that point, the system may have deselected it (and so will not execute it), since the system's predictions may have changed based on additional input.

3 Methods

After each successive utterance prefix $\mathbf{u}_{[m]}$, we perform the following two steps (see Figure 2):

1. **propose**: Predict the complete graph G from only the current prefix $\mathbf{u}_{[m]}$ and context $\mathbf{c}$.
2. **select**: Select the graph nodes (function invocations) that are worth executing at this time. This is an update that replaces the former list of selected nodes; so any formerly selected nodes that were still waiting for their arguments have lost their chance to execute until they are selected again.[3]

In the first step, we currently search for the single most probable G. More generally, one could construct an estimate of the distribution $p(G \mid \mathbf{c}, \mathbf{u}_{[m]})$. In the second step, we select nodes that are probably correct, using a heuristic approximation to their marginal probability. In future work, selecting a node should also consider the predicted execution cost and the predicted effect on overall latency.

An alternative design would collapse propose and select into a single step that directly predicts some graph fragments to execute. But as gold fragments are not defined, this would require a more complicated training objective. Predicting complete programs may also yield more accurate fragments, by making latent structure explicit.

We first describe our general approach for graph prediction (Section 3.1), followed by two different approaches for propose (Section 3.2–3.3), and finally our heuristic for select (Section 3.4).

3.1 Graph Generation Model

We encode any graph G as a sequence $\mathbf{a} = (v_1, \mathbf{e}_1, v_2, \mathbf{e}_2, \ldots, v_{|V|}, \mathbf{e}_{|E|})$. Each element of $\mathbf{a}$ can be regarded as an *action* that adds a node or a sequence of edges to the graph. Note that the subgraphs selected in Section 3.4 below will not necessarily correspond to contiguous substrings of $\mathbf{a}$.

This representation is borrowed from the action-pointer mechanism in Zhou et al. (2021a), but they are operating with graph-utterance alignments in a transition-based model, whereas we develop a more general alignment-free model. Each v_k is a node, representing a constant value or function invocation, while each $\mathbf{e}_k$ is a subsequence that lists all edges between v_k and earlier nodes. At training time, graphs are converted to action sequences to enable us to train a sequence-to-sequence model. At inference time, the model outputs the action sequence, from which the graph can be constructed.

In our action sequence representation, each node and each edge in G corresponds to one token in $\mathbf{a}$, with the only exception being string literals, which can span multiple action tokens. A token of a string literal can appear directly as an action or can be copied from the j^{th} token of the source via a special $\textsc{CopyInput}(j)$ action. The details of the formulation of the action sequence and the model parametrization can be found in Appendix A.

For an offline parser, the model learns $p(G \mid \mathbf{c}, \mathbf{u}) = \prod_{n=1}^{|\mathbf{a}|} p(a_n \mid \mathbf{c}, \mathbf{u}, \mathbf{a}_{1:n-1})$, where the input to the encoder is the concatenation of the context and the full utterance. We call this standard setup FULLTOGRAPH.

3.2 Approach 1: PREFIXTOGRAPH

The FULLTOGRAPH model achieves very strong performance when trained and tested on the standard offline benchmark (see Table 1). We could simply run this trained model on utterance prefixes for our propose step, but that would suffer from a train-test mismatch. Thus, we replace it with a PREFIXTOGRAPH model $p(G \mid \mathbf{c}, \mathbf{u}_{[m]})$ that we explicitly train to map from each prefix of $\mathbf{u}$ to the complete graph. Every $((\mathbf{c}, \mathbf{u}), G)$ pair in the original training data is multiplied into many training pairs $((\mathbf{c}, \mathbf{u}_{[m]}), G)$. Notice that we always use

---

[2] The corresponding setup in simultaneous MT is re-translation (Arivazhagan et al., 2020b; Han et al., 2021).

[3] Ongoing executions of formerly selected nodes will be allowed to finish, however.

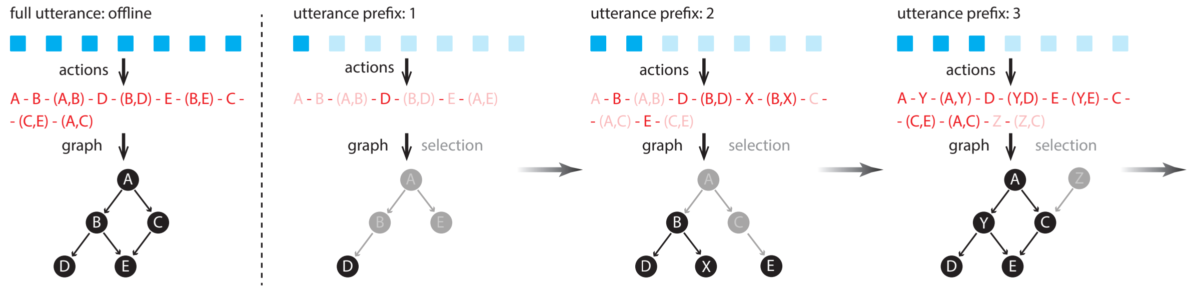

Figure 2: Our framework for simultaneous semantic parsing. Graph nodes and edges are represented as actions in the target (following a depth-first traversal order). Left is the baseline FULLTOGRAPH scenario. For the online scenario, at each prefix position, our model first proposes a full graph which is then pruned based on predicted probabilities. The surviving (selected) nodes, in black, can be executed once their children have returned.

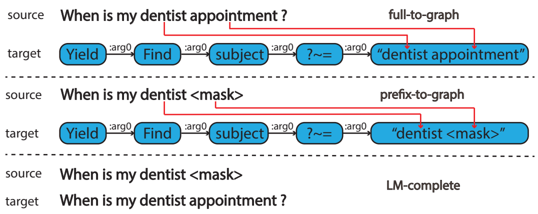

Figure 3: Example of source utterance/prefix and target training data for different models. The red link marks copying from source.

the full graph as the target, rather than attempting to predict only the part of the graph that aligns to the prefix. Hence our method requires no alignment. It tries to predict any function calls that are likely given the prefix, even if they have not been explicitly mentioned yet.

A problem with this setup is that the target graph is often unreachable because it contains string literals that have not been seen yet. This happens when the gold action sequence includes COPYINPUT(j) and j is a position beyond the current prefix. To handle such cases, we modify the target action sequence to instead copy the final position of the prefix, where we have appended a special MASK token as a placeholder for all future tokens. Such a modified training example is shown in the second row of Figure 3. In this way, we disable hallucination of free text by the model, while keeping the graph structure intact with the MASK placeholder.

3.3 Approach 2: LMCOMPLETE then FULLTOGRAPH

Alternatively, propose can first predict the full utterance from the prefix, and use FULLTOGRAPH to parse this completed utterance.[4] Specifically, we fine-tune a pretrained BART model (Lewis et al., 2020) so that it can map an utterance prefix (terminated with the MASK symbol, just as in BART's pre-training recipe) to the full utterance (freely hallucinating content words). As before, the training data includes one example for each prefix of each utterance, so the fine-tuning objective is to maximize the sum of $\log p(\mathbf{u} \mid \mathbf{c}, \mathbf{u}_{[m]})$ over all prefixes $\mathbf{u}_{[m]}$ of all utterances $\mathbf{u}$.

3.4 Subgraph Selection

Let $\hat{G}_m$ be the graph proposed from $\mathbf{u}_{[m]}$. We wish to execute only its probable subgraphs. Recall that we predicted $\hat{G}_m$ by attempting to maximize $\prod_{n=1}^{|\mathbf{a}|} p(a_n \mid \mathbf{c}, \mathbf{u}_{[m]}, \mathbf{a}_{1:n-1})$ (approach 1) or $p(\mathbf{u} \mid \mathbf{c}, \mathbf{u}_{[m]}) \cdot \prod_{n=1}^{|\mathbf{a}|} p(a_n \mid \mathbf{c}, \mathbf{u}, \mathbf{a}_{1:n-1})$ (approach 2). The probability of a subgraph could be obtained by marginalizing over all possible action sequences (and also all completions $\mathbf{u}$ in approach 2), which could be approximated by sampling from the models. For simplicity and efficiency, we instead approximate the probability of a subgraph of $\hat{G}_m$ by the product of the conditional probabilities of the predicted actions that actually built that subgraph[5]—that is, each subgraph of the predicted $\hat{G}_m$ was built by a subset of the predicted actions $\mathbf{a}$. This essentially approximates the marginal probability of the relevant action subsequence by its conditional probability given preceding actions. In practice we found that this simplified heuristic works relatively well, with action-level likelihoods

---

[4] To avoid training-test mismatch, we could have retrained FULLTOGRAPH to predict the gold graphs from these noisily completed utterances, instead of from the gold utterances. However, this learning problem might be too difficult. Instead, we will consider the uncertainty of completion during select.

[5] In approach 2, this includes the probabilities of the predicted unseen tokens of $\mathbf{u}$. We cannot limit to the tokens that contributed to the subgraph because *all* tokens potentially did so: we do not have an alignment. Thus, when $p(\mathbf{u} \mid \mathbf{c}, \mathbf{u}_{[m]})$ is small, *all* subgraphs will be regarded as uncertain.

being decently calibrated (Section 6.4).

We then select the nodes $v \in \hat{G}_m$ such that the subgraph rooted at v has probability above a constant threshold τ.[6] There are three exceptions: (1) Of course we do not select any node whose subgraph we have previously executed (after predicting and selecting it from a previous prefix). That is unnecessary: we already know the result or are waiting for it. (2) Until the utterance is complete, we do not select any nodes whose function invocations have side effects, as they are unsafe to pre-execute. (In particular, we do not show final results to the user.) (3) But once the utterance is complete, we select *all* unexecuted nodes of the final predicted graph, $\hat{G}$, since now they are both safe and necessary to execute.

4 Evaluation

To quantify the latency improvements for online semantic parsing methods, we propose a new metric, final latency reduction.

4.1 Program Execution Process

We assume that functions can be executed, in parallel, as soon as their arguments are available. Given a graph G, any node $v \in G$ is the root of an executable subgraph. Let $g(v)$ be the time that this subgraph is selected.[7] Let $e(v) \geq 0$ be the time it takes to execute just the function at v on its given arguments.[8] The return time $r(v)$ of node v is

$$r(v) = \max[g(v), \max_{w \in \text{children}(v)} r(w)] + e(v) \quad (1)$$

where children(v) is the set of nodes that return the arguments of v. This is a recursive definition—a node can only be executed after it is selected and all its children (if any) have finished executing—and so $r(v) \geq r(w)$ for $w \in$ children(v). The program G finishes executing at time[9]

$$r(G) = \max_{v \in G} r(v) \quad (2)$$

We assume that our own system's computation time is negligible, so $g(v) = t_m$ if the subgraph rooted at v was predicted and selected from $\mathbf{u}_{[m]}$. In our fully simulated experiments, we set $t_m = m$, which measures time in units of input tokens. These practices follow the simultaneous machine translation literature (Cho and Esipova, 2016; Gu et al., 2017; Ma et al., 2019; Cherry and Foster, 2019). In Section 5, we will also explore using real-time measurements to define t_m.

4.2 Final Latency Reduction

We compute the time at which the system completes executing the *gold* graph G^*, namely $r(G^*)$. Thus, the system cannot achieve a good completion time simply by predicting a small graph. The system's **final latency** is $r(G^*) - t$. Note that $r(G^*) \geq t$, since at least the root node that shows final results to the user has to wait until the utterance is complete (section 3.4).

If the system's final prediction $\hat{G} \neq G^*$, then there may be nodes $v \in G^*$ whose subgraph was never executed. Then $r(G^*) \geq r(v) = \infty$, properly speaking—but we keep it finite by defining $g(v) = t$ for these nodes v. That is, for purposes of latency evaluation, we generously consider the worst case for $v \in G^*$ to be that v is selected for execution when the utterance is complete (rather than that v is *never* executed).

We also compute a baseline: $r_o(G^*)$ is the completion time $r(G^*)$ achieved by the offline parser, which is a *batch* system that sees no prefixes before seeing the full utterance at time t. It is found by setting $g(v) = t$ for all $v \in G^*$ in equations (1)–(2).

We now define our **final latency reduction**

$$\text{FLR} = r_o(G^*) - r(G^*) \geq 0 \quad (3)$$

An *oracle* system would have $g(v) = 0$ for all $v \in G^*$, achieving the best possible final latency of $\max(r_o(G^*) - t, t)$ and the best possible FLR of $\min(t, r_o(G^*) - t)$. This is the FLR upper bound.

4.3 Relationship to Existing Metrics

FLR focuses on how much sooner the user can see results from the target program *after* the user

---

[6] As Section 3 noted, this strategy is not optimal. All subgraphs with the same probability do have the same risk of being useless work, but they do not all represent the *same amount* of useless work: some incorrect subgraphs require more computation. And they have the same probability of being useful work, but they are not all *equally useful*: some correct subgraphs can be postponed for longer without affecting the overall latency, because they will run more quickly or will not be needed as soon. In both cases, it would be appropriate to raise the subgraph's threshold and wait for more evidence that the subgraph is actually correct.

[7] More precisely, the final time that this happens; it may have previously been selected but not executed (section 3).

[8] $e(v)$ could be modeled as a random variable with some distribution learned from data, so that FLR becomes a random variable whose expectation we would report. In our simulated experiments we model it by a constant Δ for all "slow" function calls, and 0 otherwise.

[9] In the literature on job-shop scheduling (Applegate and Cook, 1991), the quantity $r(G)$ is known as the **makespan**.

has finished speaking. This is different from simultaneous MT, whose focus is how far the target is lagging behind *while* the user is speaking. Therefore, instead of measuring the average over different subprograms, our metric attends to the final completion of the whole program. This allows flexibility in execution order, compared to the translation scenario, where target generation always follows a linear order.

We share with other simultaneous generation applications the assumption that the model inference time is negligible, compared to slower spoken input and program execution (which may involve system and database interactions).

Separate from the final form of our FLR metric, our latency measurement of subprogram return time $r(v)$ can be seen as a generalization of the target time measurement in DAL (Cherry and Foster, 2019) for simultaneous MT. Our program execution time is analogous to the target speaking time in DAL, but DAL operates in a narrower spectrum with a linear chain structured target, and a fixed constant estimate for the target speaking rate.

5 Experimental Setup

Data We make use of two recently released large-scale conversational semantic parsing datasets, SMCalFlow v2.0 (Semantic Machines et al., 2020) and the version of TreeDST (Cheng et al., 2020) released by Platanios et al. (2021). Table 1 and Appendix B provide statistics about the datasets.

Model Training We use the training splits of these datasets to train our FULLTOGRAPH, PREFIXTOGRAPH, and LMCOMPLETE models, and evaluate them on the corresponding validation data. From each training example $(\mathbf{u}, G)$, we extract prefixes of different relative lengths, obtaining $(\mathbf{u}_{0\%}, G), (\mathbf{u}_{10\%}, G), \ldots, (\mathbf{u}_{90\%}, G), (\mathbf{u}_{100\%}, G)$.[10] The prefix-graph pairs of the same percentage length are then stacked to form different training sets, denoted as {prefix0%, prefix10%, ..., prefix90%, prefix100%}. The FULLTOGRAPH parser is trained only using the prefix100% data. For our PREFIXTOGRAPH parser, we experiment with training on different mixtures of the prefix datasets, to quantify the effect on parsing accuracy. For LMCOMPLETE we train on all pairs $(\mathbf{u}', G)$ where $\mathbf{u}'$ is a prefix of $\mathbf{u}$ of *any* length (not limited to the above percentages).

Model Details All of our parsers are based on the Transformer architecture (Vaswani et al., 2017), adapted to the graph action sequence (see Appendix A). The LMCOMPLETE is based on fine-tuning the pre-trained BART large model (Lewis et al., 2020). One turn of dialogue history is included as the context $\mathbf{c}$. We use greedy decoding for all models. See more details in Appendix E.[11]

Model Evaluation We directly evaluate the parsers FULLTOGRAPH and PREFIXTOGRAPH using exact match accuracy (Semantic Machines et al., 2020; Cheng et al., 2020; Platanios et al., 2021). We also report a finer-grained metric, graph tuple match (Anderson et al., 2016): the F1 score of the set of labeled nodes and labeled edges in the predicted parse. We evaluate LMCOMPLETE using BLEU score (Papineni et al., 2002).

Online Parsing Evaluation For online parsing, we simulate the program execution procedure described in Section 4.1, presenting the system with all prefixes of $\mathbf{u}$ in order: that is, $\mathbf{u}_{[m]} = (u_1, \ldots, u_m)$. We experiment with different probability thresholds τ. For each τ, we report the benefit of our approach as FLR, versus the cost as the number of excess function calls (on top of gold).

When computing FLR, we consider two definitions of t_m: an **intrinsic** one with everything measured by the number of source tokens ($t_m = |\mathbf{u}_{[m]}|$), and an **extrinsic** one with real utterance speaking times in milliseconds. For the latter we recorded human speech data and timing information of the ASR output for 300 randomly sampled examples from SMCalFlow data.[12] When computing FLR, we also assume $e(v) = \Delta$ for all slow function nodes v,[13] and sweep over the constant Δ to see its effects, where Δ is measured either in number of source tokens or in milliseconds.

6 Results and Analysis

6.1 FULLTOGRAPH and LMCOMPLETE

We evaluated our offline parser FULLTOGRAPH and utterance completion model LMCOMPLETE on all prefixes of all utterances in validation data.

---

[10] We omit the context $\mathbf{c}$ here as it remains the same.

[11] Our code is available at `http://aka.ms/simulsp`.

[12] More details in Appendix C. We also extended this evaluation to the full validation data (Appendix D), by using a linear model of t_m fit on recorded speech.

[13] We follow descriptions in `https://github.com/microsoft/task_oriented_dialogue_as_dataflow_synthesis` to identify the set of slow functions. For fast functions, we assume $e(v) = 0$.

Dataset	**SMCalFlow**	**TreeDST**
# utterances in training	121,024	121,652
# utterances in validation	13,496	22,910
Best reported accuracy†	80.4	88.3
FULLTOGRAPH accuracy	80.7	90.8
Prefix BLEU (no completion)	38.04	37.54
LMCOMPLETE BLEU	53.51	55.93

Table 1: Dataset statistics (more in Table 3), offline parser exact-match accuracy, and language model prefix completion performance on corresponding validation data. † both from Platanios et al. (2021).

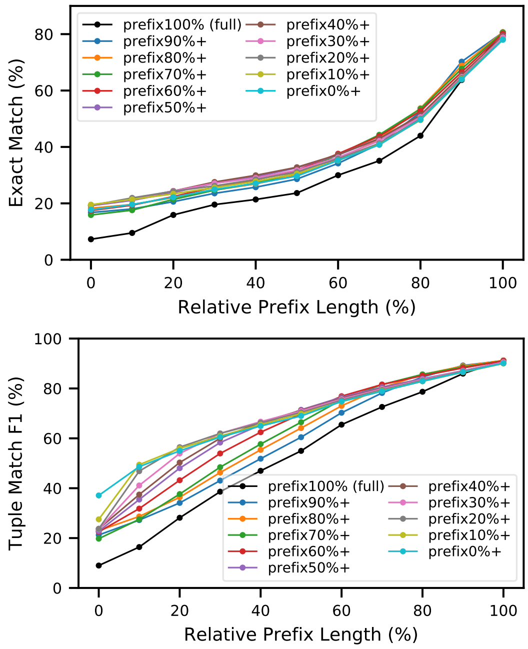

Figure 4: PREFIXTOGRAPH performance on SMCalFlow validation data of varying prefix lengths, by models trained with varying prefix data. E.g., the model with “prefix80%+” is trained on the prefix data with 80%+ relative lengths. We show exact match accuracy on top and graph tuple match F1 scores at the bottom. The larger the area under the curve, the better.

The parser achieves state-of-the-art accuracy on both validation sets. Completing the sentences using our fine-tuned BART model achieves a rather high corpus BLEU score, much higher than if we do not complete them. These models provide a strong foundation for our online parsing methods.

6.2 PREFIXTOGRAPH Quality

In Figure 4 we plot the PREFIXTOGRAPH parser performance when tested on different prefix lengths,[14] with models trained with different mixtures of the prefix training sets. Parsing performance of course degrades for shorter prefixes, but degrades most rapidly for the offline parser (the prefix100% curve). Gradually mixing in shorter prefix data does not affect offline parsing results much (the scores at prefix length 100%, on the top-right), but significantly lifts the curve for earlier prefixes, making the parser better at *anticipating*. The trend is more obvious under the graph tuple match metric, suggesting that PREFIXTOGRAPH succeeds at predicting useful *subgraphs* from short prefixes.

6.3 Final Latency Reduction and Cost

We obtain FLR vs. cost tradeoff curves by varying the threshold τ in our method. Results on the two datasets are shown in Figure 5 under the intrinsic source-timing setup, and results with extrinsic source-timing are shown in Figure 6. The offline approach, FULLTOGRAPH, operates with no latency reduction and no extra calls. The ideal system would have high latency reduction with few excessive function calls, thus the upper left region is desired. We compare our proposed methods with the baseline that directly applies the offline parser on utterance prefixes, which under-performs our methods across all evaluation setups. Between the PREFIXTOGRAPH[15] and LMCOMPLETE + FULLTOGRAPH approaches, we observe that: 1) on SMCalFlow the latter performs better in most cost regions, but on TreeDST they are much closer; 2) when the function execution time Δ is longer, PREFIXTOGRAPH tends to show more advantages in low-cost regions, which is perhaps due to the fact that its early prediction is better when the execution time dominates the source speaking time. Results are similar with the real utterance timing information. Overall, we reduce the final latency by 30%–63%. In fast execution regimes, we obtain 50%–65% of the “best possible” reduction (achieved by the oracle), and 30%–50% in slow execution regimes. Although the FLR metric does not consider model inference time, the LMCOMPLETE + FULLTOGRAPH approach does have higher inference time, since it requires two steps per prefix.

6.4 Analysis and Discussion

PREFIXTOGRAPH Parsing Example In Figure 7, we show the model log-probabilities of individual actions. In (a), the model guesses a complete program structure, but one that finds the next event

---

[14] This is similar to the latency-BLEU curve in Grissom II et al. (2014) for simultaneous machine translation.

[15] We show results of the model trained with prefix30%+ data, as different training setups result in similar curves.

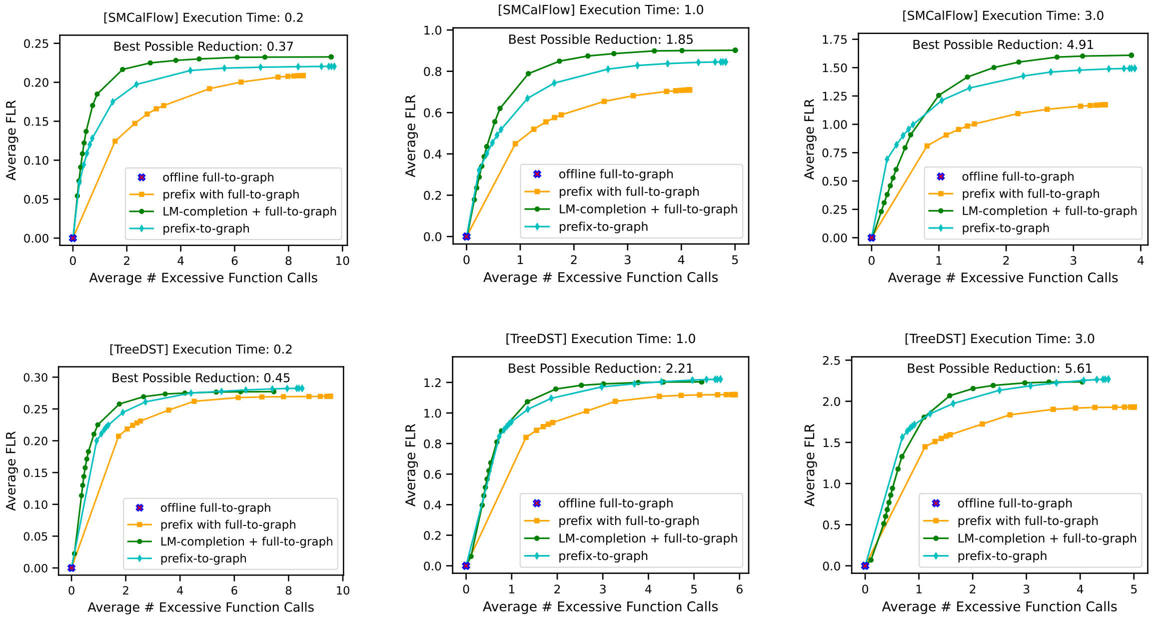

Figure 5: Intrinsic latency reduction vs. cost as we vary the selection threshold τ, with timing measured by number of soure tokens. Columns show different function execution times Δ. The upper left region is desired for better tradeoff. The top row shows results on SMCalFlow dataset, and bottom row is on TreeDST dataset, both on the whole validation data. The average number of gold "slow" function calls (footnote 8) is 1.93 and 2.28, respectively.

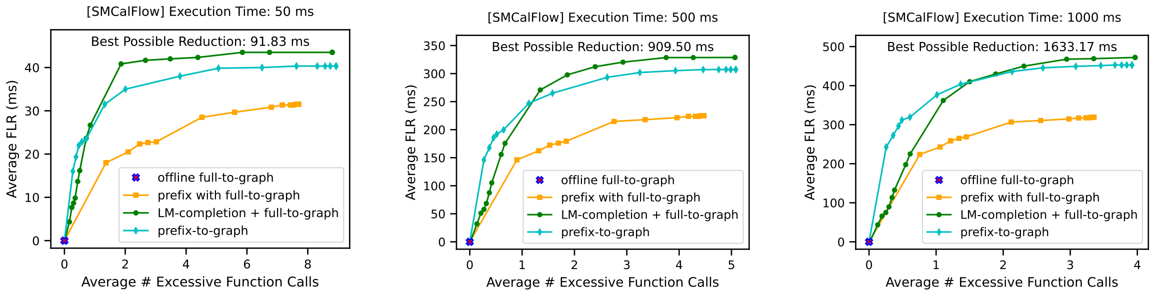

Figure 6: Extrinsic latency reduction vs. cost as we vary the selection threshold τ, with real utterance timing from ASR outputs for 300 examples from SMCalFlow validation data. Columns show different function execution times Δ. The upper left region is desired for better tradeoff. There are on average 1.84 "slow" gold function calls.

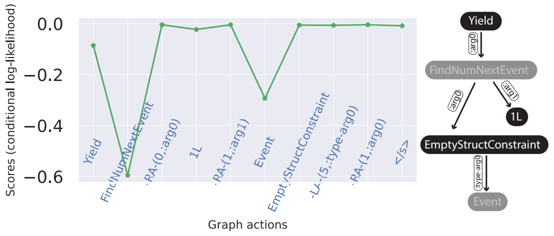
instead of finding the supervisor's name. The uncertainty of this guess is reflected in the low probabilities of the actions, and our simple thresholding heuristic can filter out the incorrect subgraphs. But once the new word *"supervisor"* arrives in (b), the model anticipates the correct program even before seeing the final tokens, and all actions have higher scores. Appendix F traces a complete example.

Action-level Probability Calibration In Figure 8 we plot the actual probability of a node's being in the true graph against the (binned) model probability of the action that predicted it. Perfectly calibrated model probabilities would fit the dotted diagonal. Ours are slightly overconfident, likely because they are conditional (on action history), whereas we are treating them as marginal. But they roughly follow the true likelihoods, which empirically justifies our use of action-level probabilities to assess subgraph probabilities.[16]

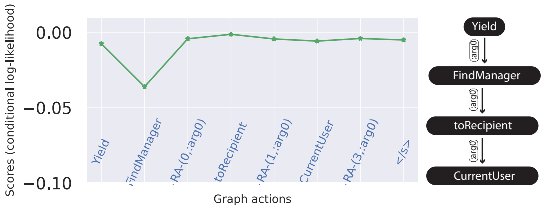
Latency Reduction per Function We inspect the absolute latency reduction (allowing an earlier finish time than the user utterance) for each function type in Figure 9. The largest gains are obtained for `RecipientWithNameLike` and `FindManager`, likely because invocations of these functions tend to have less structure, often having a string literal as their only argument.

---

[16] Section 3.4 proposed a *product* of action probabilities. We found that min worked equally well, and used min throughout our experiments (Sections 6.3–6.4).



(a) Prefix: *What is my*



(b) Prefix: *What is my supervisor*

Figure 7: PREFIXTOGRAPH's action-level scores and parsed programs for two prefixes of *What is my supervisor 's name ?* Gray nodes have lower action-level scores (whereas in Figure 2, gray nodes were the roots of subgraphs with lower scores).

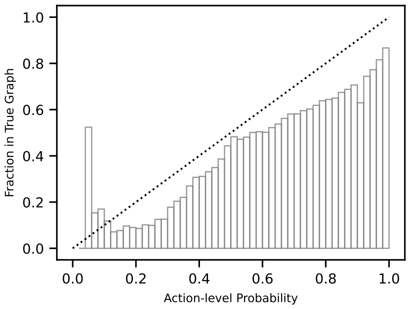


Figure 8: Action-level probability calibration plot from the PREFIXTOGRAPH model, over all prefix data.

7 Related Work

An **incremental** algorithm for computing the function f updates $f(x)$ efficiently each time x grows. In this spirit, incremental parsing updates a partial parse or parse chart each time a new word arrives (e.g. Earley, 1970; Huang and Sagae, 2010; Ambati et al., 2015; Damonte et al., 2017). An **online** algorithm *may commit to possibly suboptimal decisions* before it has seen all the input, as in simultaneous MT or online sequence-to-sequence transduction (Jaitly et al., 2016; Yu et al., 2016). By analogy, an online parser might be expected to start *printing the parse* early. However, when we speak of online semantic parsing in this paper, we really mean online semantic *interpretation*—parsing into a program *and* executing that program—and our algorithm starts *executing* early. It commits early to incurring execution costs, but not to any parse (we rapidly reparse each prefix from scratch) nor to any output (only side-effect-free functions execute early).

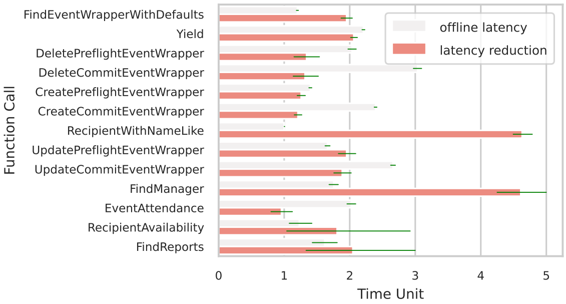

Figure 9: Average latency reduction in SMCalFlow from PREFIXTOGRAPH parsing, when $\Delta = 1$ token and τ allows 3 excessive calls. The gray bar shows how long the offline system takes to return a value for this type of function call once the utterance is complete. The pink bar shows the reduction in this latency.

Ma et al. (2019) directly trained a model to generate from source prefixes for simultaneous MT. However, they used a prefix-to-prefix paradigm whereas we trained a prefix-to-full model, in which more aggressive anticipation is not blocked by target reordering. Also, we allow updating the target history by reparsing at each prefix. We masked the unseen source with copying to avoid excessive hallucination in program prediction. Arivazhagan et al. (2020b) adopted a similar idea but only used a crude heuristic to mask the last k target tokens.

More recently, Deng et al. (2021) also explored parsing an utterance prefix into a full program (in their case an SQL query). They focus on saving user effort in formulating questions, while we focus on reducing latency. Accordingly, our task does not stop at predicting the full program; we also decide which subprograms to execute and when.

8 Conclusion

We propose a new task, online semantic parsing, with an accompanying formal evaluation metric, final latency reduction. We show that it is possible to reduce latency by 30%–63% using a strong graph-based semantic parser—either trained to parse prefixes directly or combined with a pre-trained language model for utterance completion—followed by a simple heuristic for subgraph selection. Our general framework can work with different types of parsers and executable semantic representations. In future work, the subgraph selection decisions could be made by a learned model that considers the cost and benefit of each call, instead of using a fixed threshold. The parser could also condition on the execution status, instead of operating separately.

Ethical Considerations

Our paper describes an enabling technology that can expedite a dialogue system's response for a better user experience. It could also assist people who have trouble interacting with the system by reducing their effort in completing the query utterance.

Caution must be taken when pre-executing program calls before the user intent is fully revealed, as there may be an unacceptable cost to mistakenly executing state-changing programs (for example, sending emails or scheduling meetings) without user confirmation. In this work, we only pre-execute "safe" function calls, which retrieve or compute information *without* changing the state of the environment.

Another concern, if training on real user data, is leaking private information to other users. This is especially pressing when predicting with incomplete intent, as the model is encouraged to hallucinate, and may hallucinate information that it has memorized from other users' data. For PREFIXTOGRAPH, we use an explicit MASK token for unrevealed future tokens, and force the model to copy MASK to the predicted program instead of freely generating text. We could easily completely remove the model's ability to hallucinate free text. LMCOMPLETE, on the other hand, can and will leak text from the training data directly into an utterance completion, which can then be copied into a string literal in the predicted program. Thus PREFIXTOGRAPH may be closer to suitable for production use.

A Graph Generation Model

We encode the graph G as a sequence $\mathbf{a} = (v_1, \mathbf{e}_1, v_2, \mathbf{e}_2, \dots, v_{|V|}, \mathbf{e}_{|E|})$. This enables us to train a sequence-to-sequence model to predict G. Each element of $\mathbf{a}$ can be regarded as an *action* that adds a vertex or edge to the graph. Each v_k is a vertex, representing a constant value or function invocation, while each $\mathbf{e}_k$ is a subsequence that lists all edges between v_k and earlier vertices.

The vertices $v_1, \dots, v_{|V|}$ are enumerated in the same order that they appear in the dataset, which is a top-down DFS order.[17] The edges in each $\mathbf{e}_k$ are sorted such that edges from/to more recent vertices come first, i.e., an edge $v_j \xrightarrow{\ell} v_k$ (or $v_j \xleftarrow{\ell} v_k$) precedes an edge $v_i \xrightarrow{\ell'} v_k$ (or $v_i \xleftarrow{\ell'} v_k$) if $i < j$.

Borrowing from the action-pointer mechanism (Zhou et al., 2021a,b), an edge $v_i \xrightarrow{\ell} v_k$ in the subsequence $\mathbf{e}_k$ is represented in the form $\textsc{RightArc}(n, \ell)$ where n is the position in $\mathbf{a}$ such that $\mathbf{a}_n = v_i$. Similarly $v_i \xleftarrow{\ell} v_k$ in the subsequence $\mathbf{e}_k$ is represented in the form $\textsc{LeftArc}(n, \ell)$.

Thus, each node and each edge in G corresponds to one token in $\mathbf{a}$. As an exception, a vertex v_i that is labeled with a string literal is encoded as multiple tokens, e.g., `<str> lunch meeting </str>` (and the vertex's position n is taken to be the position of the initial `<str>` token). Within such a string literal, we include tokens of the form $\textsc{CopyInput}(j)$ action wherever possible, meaning to copy token j of the source sequence. Constructing the program graph from the actions is straightforward—read off the nodes and edges, and append them to the graph. This provides an efficient and compact sequential representation of the graph, with structural well-formedness maintained. An example of the program graph (derived from the original Lispress format[18]) and the action sequence is shown in Table 2.

We model the action sequence generation with a Transformer encoder-decoder network (Vaswani et al., 2017), augmented with two pointer networks—target-side pointing for the edges and source-side pointing for the copied node values. See Appendix E for details. Similar to Zhou et al. (2021a,b), we do not introduce new modules for the pointer networks but directly re-purpose the decoder self-attention head and source-attention head respectively. The actions, edge pointers and copy pointers are supervised together during training and are decoded and combined during inference to reconstruct the complete actions and thus graphs. For each parser, we model $p(G \mid \mathbf{u}, \mathbf{c}) = \prod_{n=1}^{|\mathbf{a}|} p(a_n \mid \mathbf{c}, \mathbf{u}, \mathbf{a}_{1:n-1})$, where the source to the encoder is the concatenation of the context and the full utterance. We decode greedily, incorporating both edge pointers (as in Zhou et al. (2021a)) and source-copy pointers into the action space.

B Prefix Data Length Distribution

We provide basic dataset statistics in Table 3. We further display the length distribution of the complete utterances and their prefixes in Figure 10, for both SMCalFlow and TreeDST training data.

C Real Utterance Timing from ASR

To obtain real utterance speaking timing information for Figure 6, we randomly sampled 300 utterances from the SMCalFlow validation data and recruited two volunteers to each read a portion of the utterances with their normal voice and pace. An ASR system was run to process the 300 recordings and output word segmentations with timing information. The audio was processed using off-the-shelf models in the Microsoft real-time ASR system.[19] Running with the appropriate flags exposes word-level time markings, which allows us to factor recognition latency into the overall computation.

As the ASR outputs are associated with tokens recognized from the human voice, they are not fully consistent with the original utterance text. We map the ASR output tokens back to the original utterance tokens with the dynamic time warping (DTW) algorithm using edit distance as the distance metric. This gives a sequence of segmentation boundaries of the ASR output tokens, where each segmentation contains zero, one, or a few consecutive words with recorded ASR timing information, that align with one token in the original utterance. The times are then mapped back to the original utterance based on the DTW alignments. On average, each word of the original utterance takes 0.386 seconds to

---

[17] We experimented with other vertex orders, including bottom-up, but found that this made little difference.

Table 2: Graph representation and action sequence of the program formulated by our model. `-RA-` represents RIGHTARC and `-LA-` represents LEFTARC. For example, `-RA-(1,:arg0)` constructs an edge between `UpdatePreflightEventWrapper` (the most recent node) and `UpdateCommitEventWrapper` (the node previously generated at action index `1`), with the edge direction being rightward (from previous node to current node) and the label being `:arg0`. The original Lispress format[18] is shown in the upper left. The action sequence is obtained by converting the Lispress into a graph (upper right) and traversing the graph.

Dataset	**SMCalFlow**	**TreeDST**

# utterances in validation	13,496	22,910
Avg. length of full utterance **u**	8.5	8.6
Avg. length of target sequence **a**	22.5	39.1

Table 3: Dataset statistics.

speak. We show the distribution of the voice duration of words in Figure 11. For the corresponding experiments, the real utterance timing of the 300 utterances is used in the execution process for each prefix (whereas the function execution times Δ are still simulated).

D FLR Evaluation with Extrinsic Timings

To simulate realistic speaking rates on the full SMCalFlow and TreeDST corpora, we took a private corpus of 1000 spoken utterances with ASR output, and fit a linear model predicting word duration based on the number of characters in the word. The fit model had the form `len(word) * 0.05502014s + 0.11375083s`. Using this model, we were then able to simulate speaking rates on our full text-only data.

For slow function calls (see footnote 8), we swept over various execution times Δ in milliseconds. Under the extrinsic setting, the FLR vs. cost tradeoff curves for various Δ values are shown in Figure 12.[20] Our proposed methods consistently outperform the baseline with the FULLTOGRAPH directly applied on the utterance prefix. Overall we achieved 30%–63% final latency reduction relative to the offline parser, depending on Δ and τ.

---

[20] Its top row is similar to Figure 6, but it evaluates on the full SMCalFlow validation dataset, by using simulated utterance timings. Also, it shows a different range of Δ values. The bottom row evaluates on the full TreeDST validation dataset. Thus, Figure 12 evaluates on the same data as Figure 5.

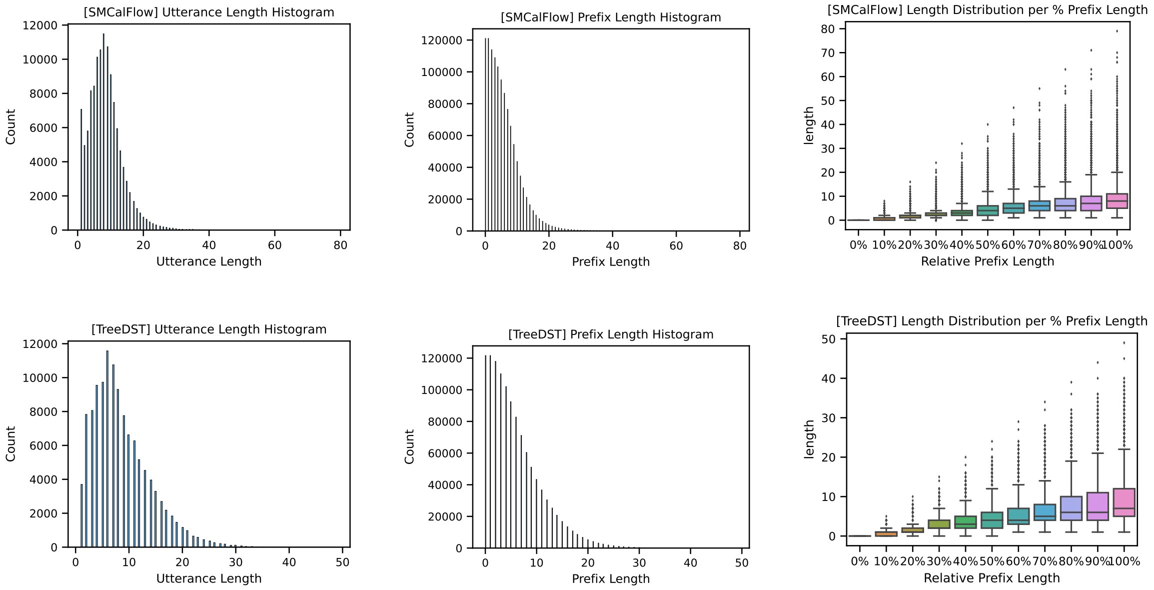

Figure 10: Utterance and prefix length distribution for SMCalFlow (top row) and TreeDST (bottom row) training data. The left column shows the length distribution of the complete utterances, the middle column shows the length distribution of the extracted all possible prefixes, and the right column shows the length distribution for each relative prefix length group (corresponding to our different prefix training subsets {prefix0%, prefix10%, . . ., prefix90%, prefix100%} mentioned in Section 5). Tokenization is considered in all lengths.

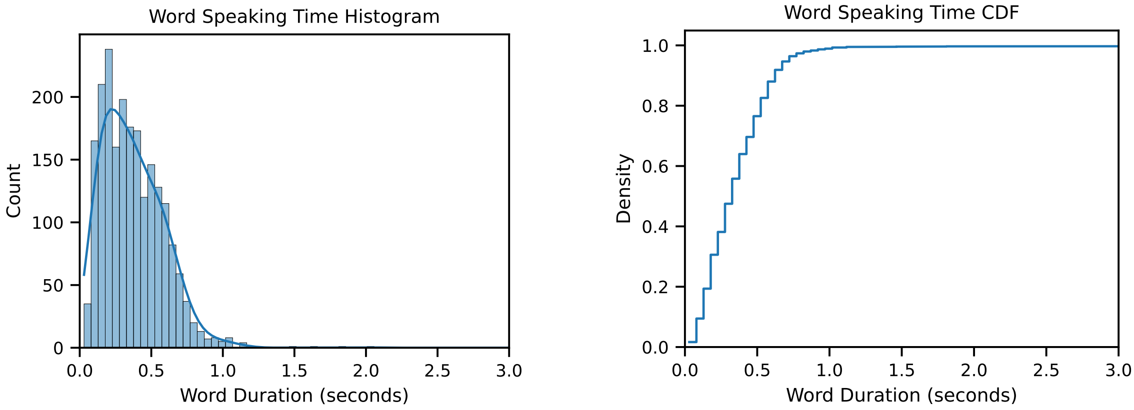

Figure 11: Utterance word voice duration distribution from real ASR outputs, collected from normal human reading voices on 300 randomly sampled utterances in SMCalFlow validation data (2118 words in total, with 0 duration tokens such as punctuation marks removed). The left shows the histogram with the smooth kernel density estimation curve, and the right shows the CDF curve (both with zoomed x-axis to ignore outliers for better visualization). The average voice duration from ASR for a word is 0.386 seconds, and the 0%, 25%, 50%, 75%, 100% quantiles are 0.03, 0.20, 0.34, 0.52, 6.16 seconds, respectively.

E Implementation Details

All of our parsers are based on a 6-layer-4-head Transformer architecture (Vaswani et al., 2017), with 256 hidden dimensions and 512 dimensions for fully connected layers, without additional modules. Pointers for edges are modeled by a self-attention head on the decoder's top layer, and the source copy mechanism is modeled by a cross-attention head of the penultimate decoder layer. The LMComplete model is based on fine-tuning the pre-trained BART large model (Lewis et al., 2020). The context $\mathbf{c}$ includes 1 previous turn of dialogue history, consisting of the user utterance and agent response. We encode the source ($\mathbf{c}$ followed by $\mathbf{u}$) with the fixed RoBERTa (Liu et al.,

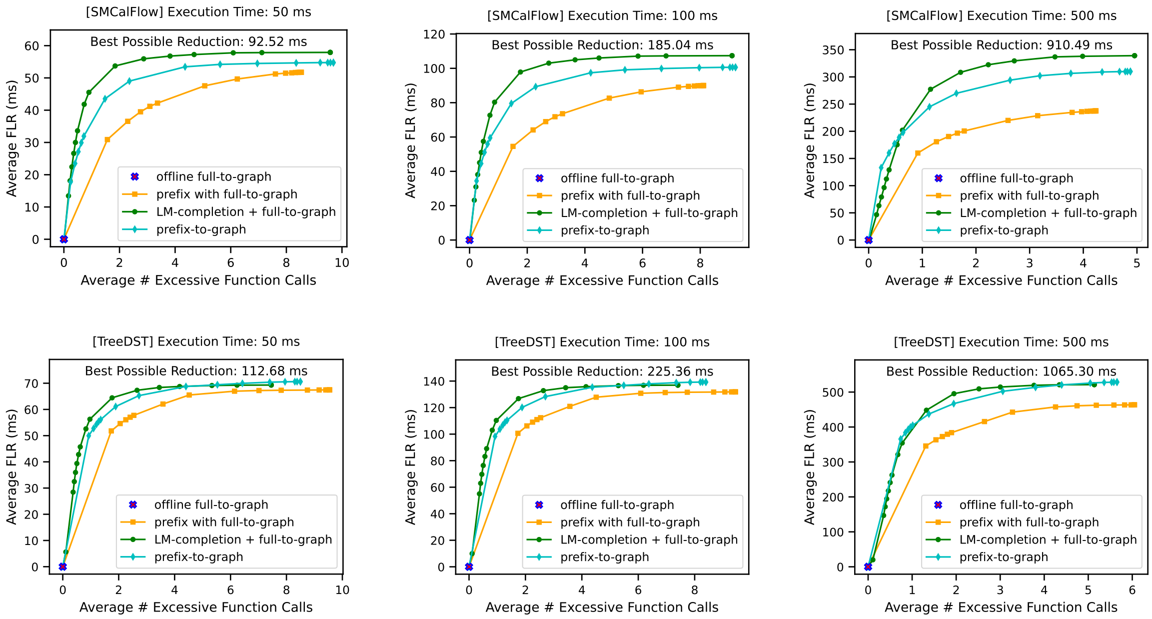

Figure 12: Extrinsic latency reduction vs. cost as we vary the selection threshold τ, with utterance timing estimated as a linear function of length in characters. Columns show different execution times Δ. The upper left region is desired for better tradeoff. The top row shows results on SMCalFlow dataset, and bottom row is on TreeDST dataset, both on the whole validation data. There are on average 1.93 and 2.28 “slow” gold function calls, respectively.

2019) large model for contextualized embeddings (averaged over all RoBERTa layers) to be input to our encoder. For both parsers, FULLTOGRAPH and PREFIXTOGRAPH, we train with the Adam optimizer with batch size 2048 tokens and gradient accumulation of 4 steps. Learning rate is $5e{-}4$ for FULLTOGRAPH and $1e{-}4$ for PREFIXTOGRAPH as there is more data, both with 4000 warm-up steps using the inverse-sqrt scheduling scheme (Vaswani et al., 2017). They are trained for 50 epochs and we use the last checkpoint for all evaluations without model averaging and ensemble decoding. Training takes about 3 hours on a single Nvidia Titan RTX GPU with 24 GB memory with floating-point 16 mixed precision training for the FULLTOGRAPH parser, and the time increases proportionally for PREFIXTOGRAPH with the prefix data size when combining different prefix lengths. For the LMCOMPLETE model, we fine-tune BART-large for 12 epochs and take the best checkpoint, following the standard recipe from FAIRSEQ. For all the models, we use greedy decoding at inference time. All the models are implemented and trained with the FAIRSEQ toolkit (Ott et al., 2019).

F Example of Parsing and Execution

Table 4 illustrates the behavior of our PREFIXTOGRAPH system on an utterance from the SMCalFlow dataset, showing the detailed parsing and execution process for each step. The utterance timings in milliseconds were obtained from real ASR output on a human-spoken version of the utterance. The program graphs are printed in the Lispress format.[18]

We implicitly add an extra root node to the top of every graph G, representing the function that shows the result to the user. Since this function has side effects, it can only be selected for execution after time t, when the utterance is complete (see Section 3.4). As a result, the graph’s completion time $r(G) \geq t$. However, this root node is not shown in our graphs—and in this dataset, the remaining nodes are safe since any other side effects (such as adding the requested event to the calendar) are actually deferred until the root node executes. As a result, all nodes that are shown in Table 4 can be selected at any time.

At each time when a new prefix token arrives, our model first proposes a full graph and then uses a thresholding heuristic to select more probable subgraphs (marked as blue). The threshold is $\tau = \exp(-1.0) \approx 0.368$ in this example. In our experiments, the score of a subgraph is computed as the minimum action-level probability among all actions that construct the subgraph (footnote 16). Hence if a larger subgraph is selected, all its subgraphs must have also been selected.

F.1 Simulated Execution Process

The program execution process (simulated) happens in the background as the user speaks. At the end of the execution the benefit (final latency reduction) is known, along with its cost (count of excessive function calls). We review here some details about the execution process that were already explained in the main paper:

- We assume a constant execution time Δ for all non-trivial ("slow") function calls. All other graph nodes are assumed to have 0 execution time.
- The execution of a selected function must wait until all its dependent functions have finished executing.[21]
- Identical subgraphs that are predicted at different times are treated as the same: there is no need to execute both of them.[22] (E.g., the predicted graphs after seeing the token *friday* and after seeing the token *for* are considered to be the same graph.)
- The selected set is refreshed every time when a new prefix $\mathbf{u}_{[m]}$ arrives, as the new prefix provides new information that may change the predicted subgraphs or their probabilities. Therefore, unexecuted calls in the old selection will be discarded: e.g., after the token *night* arrives, the previously selected functions are no longer selected in the new predicted graph.
- Despite this, ongoing executions are never interrupted or canceled.
- Our method does not affect the accuracy of the semantic parser, but only its latency. This is because our final result is derived from the root node of our parse of the complete utterance $\mathbf{u}$, just as it was for the offline parser.[23] The earlier parses based on prefixes are only used for speculative pre-execution of subprograms, whose results will only be used if they appear in the final parse.
- However, the FLR metric does reflect accuracy to some degree. Recall that it is computed on the gold program calls. In the example, our parser predicts the gold graph G^* successfully—but when it does not, our FLR metric will still require the system to execute any remaining nodes of G^* once the utterance completes. A consequence is that FLR generally suffers somewhat when the parser is inaccurate, since subgraphs of G^* that are never predicted cannot be pre-executed to reduce final latency; indeed, they must be correctly predicted *before* t in order to be pre-executed.

Following the data descriptions in `https://github.com/microsoft/task_oriented_dialogue_as_dataflow_synthesis`, we consider the following function calls to be non-trivial ("slow") function calls. They are marked with colored background in the graphs when they are selected.

SMCalFlow: `Yield`, `RecipientAvailability`, `FindReports`, `FindManager`, `UpdatePreflightEventWrapper`, `CreatePreflightEventWrapper`, `DeletePreflightEventWrapper`, `FindEventWrapperWithDefaults`, `RecipientWithNameLike`, `DeleteCommitEventWrapper`, `UpdateCommitEventWrapper`, `CreateCommitEventWrapper`, `EventAttendance`.

---

[21] In future work, however, we should relax this requirement to allow short-circuit evaluation. A node can sometimes be executed when some but not all of its children have returned. Examples include if-then-else once the boolean condition has returned, a multiplication when one argument has returned with a zero value, or any function when one argument has returned with an exception that is not caught by the function. (Exceptions can be regarded as special return values, as described by Semantic Machines et al. (2020).)

[22] A predicted node $v \in \hat{G}_m$ has a well-defined return value provided that it is the root of a sub-DAG. Any other predicted node that is the root of an identical sub-DAG can be rapidly identified, for example by the technique of hash consing, allowing it to share this return value. (Ordinarily v is indeed the root of a sub-DAG; indeed, the decoder can optionally ensure this by disallowing edge actions that would create a cycle in $\hat{G}_m$, on the grounds that G^* is acyclic.)

[23] It is true that our first approach (Section 3.2) parses $\mathbf{u}$ using a different parser than the offline parser—it uses PREFIXTOGRAPH rather than FULLTOGRAPH—which could have a slight effect on accuracy. If it had harmed accuracy, then we would have had our online parser switch to using FULLTOGRAPH at the final step when it finally sees the complete utterance $\mathbf{u}$. We did not do this because Figure 4 shows that in practice, the various PREFIXTOGRAPH parsers are as accurate as FULLTOGRAPH on complete utterances.

TreeDST: `plan`, `Create`, `Find`, `Update`, `Delete`, `Book`, `CheckExistence`, `reference`, `revise`, `refer`, `someSalient`.

F.2 Discussion of the Example

In the example, the function execution time (500 ms) spans 1 to 2 utterance token times. We could expect faster execution time to result in an earlier finish time.

Our approach achieves an FLR of 880 ms (see the very end of Table 4). This is largely due to the fact that we predict the correct program before the utterance ends, at prefix steps *for*, *2*, and *hours*. The PREFIXTOGRAPH model learns to anticipate the correct information even before seeing it. For example, *2 hours* is predicted in the program as the duration even before seeing the last two tokens *2 hours*, and *friday* and *7 pm* are predicted after seeing only *Add date night for next* _. Therefore, these function calls can be successfully pre-executed in the background, reducing the final latency of the response.

Not all of our speculative executions were useful. We executed 4 excess functions that are not in the gold program, which induces a computational cost. These were due to overconfident early predictions, when we lacked most of the information in the utterance. Future work could attempt to improve selection by better assessing the probability, expected cost, and expected future benefit of each speculative execution (see footnotes 6 and 21).

An interesting phenomenon is that as new words arrive, subgraphs are often corrected to incorporate the new information. In our example, consider how the graph is updated after the token *for*: the call to `CreatePreflightEventWrapper` is almost identical, but a (guessed) duration has been added. Our present system would execute a whole new call to `CreatePreflightEventWrapper`, discarding the results of the previous call. However, as the change to the call was small, a future opportunity would be to keep and modify the result of the previous call, which might be faster than executing a new call from scratch.

The execution ① invokes the `PersonName.apply` function on an argument that is the special token MASK (see Section 3.2). As MASK denotes a value that is not yet known from the prefix, we define such function invocations to return an exception value (see footnote 21).

Indeed, *any* subgraph that contains MASK—such as all of the selected subgraphs at the time of ①—is guaranteed to return an exception value. These subgraphs are also guaranteed to be wrong, as G^* never contains MASK, so we could have assigned them probability 0, overriding the heuristic of Section 3.4. This would have reduced our execution cost—that is, the number of excessive function calls.

Table 4: An example of simultaneous parsing and pre-execution from our PREFIXTOGRAPH system, for the utterance *Add date night for next friday at 7 for 2 hours*. For this particular example, we achieve FLR of 880 ms with 4 excess function calls. For subgraph selection a constant threshold of $\tau = \exp(-1.0) \approx 0.368$ is used. The source prefix timing is from real ASR outputs of human speaking (Appendix C): the "DUR" column shows token duration, and the "Time" column shows the total time elapsed so far. We assume that non-trivial function calls execute in $\Delta = 500$ time. We use circled numbers (e.g. ①, ②, $\cdots$) to denote unique function calls being executed (`in exec.` means ongoing execution, `done` means finished execution). The selected set of subgraphs for execution is refreshed every time a new prefix token arrives, but ongoing executions are allowed to finish.

Few-Shot Tabular Data Enrichment Using Fine-Tuned Transformer Architectures

Asaf Harari, Gilad Katz
Ben-Gurion University of the Negev,

`{hsaf,giladkz}@post.bgu.ac.il`

Abstract

The enrichment of tabular datasets using external sources has gained significant attention in recent years. Existing solutions, however, either ignore external unstructured data completely or devise dataset-specific solutions. In this study, we proposed Few-Shot Transformer based Enrichment (FeSTE), a generic and robust framework for the enrichment of tabular datasets using unstructured data. By training over multiple datasets, our approach is able to develop generic models that can be applied to additional datasets with minimal training (i.e., few-shot). Our approach is based on an adaptation of BERT, for which we present a novel fine-tuning approach that reformulates the tuples of the datasets as sentences. Our evaluation, conducted on 17 datasets, shows that FeSTE is able to generate high quality features and significantly outperform existing fine-tuning solutions.

1 Introduction

Tabular data is the most diverse format of data representation, spanning domains from nutrition to banking. It does, however, suffer from a lack of contextual information that could make its analysis more effective. Data scientists seek to overcome this limitation by using feature engineering (FE), which involves applying transformations on existing features to create additional representations of the data. When the available data is not sufficiently diverse (or when additional improvement is sought), one may attempt to use external information sources to enrich the data. We refer to this process as external enrichment of datasets (EED).

The use of external sources for feature engineering is both computationally-heavy and time consuming. The process first involves matching entities in the data to those in the external source, a process known as Entity Linking (Shen et al., 2014). Once entities in the external source have been matched, candidate features need to be generated, evaluated, and finally integrated into the tabular dataset. While multiple studies in recent years (Paulheim and Fümkranz, 2012; Ristoski et al., 2015; Friedman and Markovitch, 2018; Mountantonakis and Tzitzikas, 2017; Galhotra et al., 2019; Harari and Katz, 2022) have sought to automate the EED process, a large majority focuses solely on *structured* external sources, e.g., DBpedia tables, and do not attempt to use the large amounts of available unstructured data (i.e., free text).

In this study, we present Few-Shot Transformer based Enrichment (FeSTE) a generic and robust framework for the enrichment of tabular datasets using unstructured data. Our approach utilizes transformer-based, pre-trained Language Models (LM) (Devlin et al., 2018) to identify and prioritize promising candidate features in the external data source. FeSTE then applies a novel process of analyzing the relationships between the unstructured features and the dataset's target class values, and automatically generating new tabular features.

To overcome the difficulty imposed by datasets of limited size, we train FeSTE on multiple datasets in order to create a generic model that can later be applied to additional datasets. Additionally, we propose a novel fine-tuning (FT) process that enables pre-trained LM to quickly adapt to new datasets (i.e., perform few-shot learning). The result of this process is a more robust model that is also more effective on small datasets.

While previous studies—TAPAS (Herzig et al., 2020), TaBERT (Yin et al., 2020), TURL (Deng et al., 2020), and TPN (Wang et al., 2021)—have attempted to use Transformers for analyzing tabular data, FeSTE focuses on analyzing the connection between external texts and the dataset's entities. We are therefore able to leverage the Transformer architecture to generate additional features and fine-tune the generation process in a novel way.

We evaluate FeSTE on 17 tabular datasets with

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1577 - 1591
May 22-27, 2022

diverse characteristics (number of samples, feature composition, etc.). For our evaluation, we use BERT as the Transformer architecture and Wikipedia as the external source, with its page abstracts as our unstructured texts. Our results show that FeSTE outperforms existing BERT fine-tuning strategies and that FeSTE is highly effective, achieving an average improvement of 9.2% when combined with the datasets' original features. Finally, we show FeSTE performs well even when it is applied on its own (without any original features), achieving an average AUC of 0.664. To summarize, our contributions in this study are as follows:

- Our work is the first to propose a generic and fully-automated approach for tabular data enrichment using unstructured external sources.
- We propose a novel "few-shot" fine-tuning approach for transformer-based pre-trained LM, which performs well even for training sets consisting of as little as tens of samples.
- We make our code publicly available.

2 Related Work

2.1 Features Generation from External Sources

The large majority of work in the field of automated features generation from external information sources mainly focuses on leveraging structured data. For example, (Paulheim and Fümkranz, 2012) uses structured data from knowledge bases (KB) such as DBpedia to generate new features, which are then used to augment tabular datasets. RapidMiner (Ristoski et al., 2015) processes KB of structured tabular and graphical data by modeling the relations among their entities.

Friedman et al. (Friedman and Markovitch, 2018) focus on features generation for text classification problems. They leverage structured data from two KBs: FreeBase (Bollacker et al., 2008) and YAGO2 (Hoffart et al., 2013). The authors first identify each entity in the text, and then recursively explore the KB to extract new features. The LodsyndesisML framework (Mountantonakis and Tzitzikas, 2017) leverages KB's (e.g DBpedia) to create thousands of new features for classification tasks using nine operators. Each operator creates different types of features, which are then used to enrich the original data. Galhotra et el. (Galhotra et al., 2019) use structured web data to generate new features for classification and regression tasks. Their approach generates thousands of candidate features, then selects the final set using information theory-based measures such as Information Gain and Pearson correlation.

To the best of our knowledge, the only study to utilize both structured and unstructured sources is the recently proposed FGSES framework (Harari and Katz, 2022). FGSES extracts features from both structured and unstructured DBpedia content, generates thousands of candidate features, and then uses a meta learning-based approach to rank them and return a small final set. While this approach is the most similar to the one proposed in this study, there are significant differences: FeSTE focuses on the analysis of the texts, performs fine-tuning rather than relying on a general model, and takes into account the context of analyzed datasets. Moreover, our approach generates a small set of features and is, therefore, more computationally efficient.

2.2 Wikipedia as an External Information Source

Wikipedia is widely used as an external source of information due to its availability, richness, and diversity (Lehmann et al., 2015). An important addition to Wikipedia from an entity linking standpoint is DBpedia, a project that extracts Wikipedia data and makes it accessible in a more structured form. DBpedia is used as an external data source for feature engineering by multiple studies (Paulheim and Fümkranz, 2012; Ristoski et al., 2015; Galhotra et al., 2019; Mountantonakis and Tzitzikas, 2017) because of its accessible format.

To utilize DBpedia for feature engineering in tabular data, one should first link the entities in the analyzed dataset to unique DBpedia entities. DBpedia Spotlight (Mendes et al., 2011) is a tool for automatically identifying and linking textual entities to ones on DBpedia. Unfortunately, DBpedia Spotlight tends to capture entities whose name consists only of one or two words, while ignoring entities composed of longer sequences.

In recent years, Transformers (Vaswani et al., 2017) and other deep learning-based approaches are being applied in the field of semantic relatedness, in order to link free texts to DBpedia. Blink (Wu et al., 2020) is a BERT-based (Devlin et al., 2018) approach which receives a mention and its surrounding text, and links the mention to its corresponding DBpedia entity. It should be noted, however, that the names of DBpedia entities tend to be shorter than in free text, which hampers Blink's performance. Recently, (Harari and Katz, 2022) developed an entity linking algorithm whose aim is to link entities in tabular datasets with Wikipedia pages. We analyze the performance of this approach in Section 5.3.

2.3 Pre-trained Language Models

One of the most influential developments in the field of NLP in recent years is the emergence of Transformer-based LM (Vaswani et al., 2017). BERT (Devlin et al., 2018) and its various extensions, GPT (Radford et al., 2018) and XLnet (Yang et al., 2019) achieve state-of-the-art (SOTA) performance on a variety of tasks, including text classification, question answering, next word prediction, and more. Unfortunately, training these models requires expensive hardware and very large amounts of data. For this reasons, the large majority of studies and applications use pre-trained versions of these models. However, fine tuning (FT) these models, i.e., additional limited training on data from the task at hand, has been shown to improve performance (Gururangan et al., 2020).

Studies such as (Sun et al., 2019) and (Gururangan et al., 2020) propose three FT strategies: (1) *Task-specific*, in which one trains the pre-trained LM on similar ML task (e.g text classification); (2) *Domain-specific*, where the pre-trained LM is trained on a similar domain (e.g biology), and; (3) *Target task-specific*, where the final training step is performed on the targeted dataset directly. The aforementioned studies report a significant improvement in BERT's performance, especially where multi-phase FT was performed.

Another fine-tuning strategy called Multi-Task Deep Neural Network (MT-DNN) training was proposed by (Liu et al., 2019): for each task in each training step, the approach modifies the output layer but keeps the lower layers unchanged. This approach can also be applied in cases where the training and target datasets have different characteristics, e.g., different number of classes. One significant drawback of MT-DNN is the need to replace and train the final layer (e.g., the softmax layer) whenever it is applied to a new problem. This approach has two potential shortcomings: first, given that FT mainly affect BERT's final layers (Gururangan et al., 2020), some loss of earlier knowledge may occur. Secondly, MT-DNN needs to maintain separate final layers for each task during training (three different heads in the original study). In cases where MT-DNN is training on a large number of datasets, this could pose problems in terms of memory consumption.

A different FT approach that does not require task-specific layers was proposed by (Wei et al., 2021), who used an "instruction FT" phase. The authors added instructions (i.e., statements) to the text, and required the model to determine whether the statements are correct. While effective, analysis shows that the approach is only applicable to very large datasets, and the addition of over 8B parameters to the already large architecture of 137B.

In contrast to all the aforementioned studies, FeSTE uses a single architecture for its training process, regardless of the number of datasets used. Moreover, we propose a novel dataset reformulation process that enables us to apply the same architecture on all datasets, regardless of their number of classes. This approach enables a much more efficient FT process, as shown in Section 5.3.

3 Problem Definition

For our task of feature generation from the free text of external sources, we assume a target tabular dataset D_t with a classification tasks. Additionally, we assume a set of pre-analyzed tabular datasets with different classification tasks (i.e. different number of classes) $D = \{D_1 ... D_n\}$. For each dataset, let there be target class values tc_i and original features F_i. Of F_i, let there be at least one feature representing entities $e_i = \{e_{i,1} ... e_{i,m}\}$. For the purpose of generating new features, we assume an external data source EX which consists of entities e^{ex} and text related to these entities. We denote this set of texts as T. For the purpose of linking e_i and e^{ex}, we assume an entity linking function Γ. We generate a set of new features f_t^{new} from T using a Language Model LM.

4 The Proposed Method

Overview. Our proposed approach is presented in Figure 1 and Algorithm 1. FeSTE consists of three main phases: a) *entity linking*; b) *fine-tuning*, and; c) *features generation*. In the entity linking phase, FeSTE automatically matches entity names in the tabular dataset to their corresponding entries in the external data source. In the fine-tuning phase, we fine-tune a pre-trained LM for the task of feature generation. This phase consists of two stages: a preliminary stage where we fine-tune the model "offline" on multiple datasets, and an "online" stage where we fine-tune the model on the training samples of the analyzed dataset. Finally, in the *features generation* phase, we add the newly-generated features to the original features of the tabular dataset.

4.1 The Entity Linking Phase

The goal of this phase is to link entities from our analyzed dataset D_t to entries/entities in the external data source EX (Figure 1 step #1). The identification of relevant entities is a necessary first step, since the entities selected in this phase will be processed in the following phases.

In this study we use Wikipedia as our external source of information, and Google Search as our linking and disambiguation tool. Obviously, other external sources of information (e.g., Reuters news or Yago (Hoffart et al., 2013)) will require a different linking strategy, but our approach can easily be adapted to support them.

Our chosen entity linking process is straightforward: for each dataset entity in e_i in D_i we query Google Search, focusing on Wikipedia and taking into account the domain of the entity:

<lookup> is a <domain> site:en.wikipedia.org

where *<lookup>* is the entity $e_{i,j}$ mention and *<domain>* is the entities domain (entities column name). for example:

USA is a country site:en.wikipedia.org .

Each of our queries returns a list of Wikipedia pages which are most likely to represent the entity. FeSTE then extracts the Wikipedia page referenced in the first entry. This step also serves as a form of automatic disambiguation, because we pair $e_{i,j}$ with its most popular interpretation. At the end of this phase, each dataset D_i entity $e_{i,j}$ has a linked Wikipedia entity $e^{ex}_{i,j}$. FeSTE then extracts the abstracts of those entities using DBpedia.

4.2 The Fine-Tuning Phase

The goal of this phase is to adapt current state-of-the-art NLP architectures, (e.g., GPT, BERT, and their extensions) to the task of selecting the most relevant features from each of our linked external source entities e^{ex}. As explained in Section 2.3, two common FT approaches are *task-specific fine-tuning*, which is performed on the target dataset, and *preliminary fine-tuning*, which is applied on other datasets. While the former is more common, recent studies (Sun et al., 2019; Gururangan et al., 2020) have shown that applying both—the latter and then the former—yields better results.

The main difficulty in applying preliminary FT to tabular datasets stems from their diversity: tabular datasets differ greatly in their domains, number of classes, feature composition, etc. These differences make the training of a generic features engineering tool very difficult. To overcome this challenge, we propose a novel FT approach (Figure 1 step #2), which consists of two stages: first, we perform *preliminary FT with dataset task reformulation*. Then, we perform *Target Dataset Fine-Tuning* using only the target dataset's training set, i.e., *task-specific FT*.

Preliminary FT with dataset task reformulation. The main challenge in learning from multiple tabular datasets, aside from their highly diverse content and characteristics, is their different number of classes. Such a setup makes using a single output layer with a fixed number of entries impossible. We overcome this challenge as follows:

For each dataset D_i let there be a set of free texts T_i, each associated with an entity $e_{i,j}$ in D_i. For each $T_{i,j}$, we create a Cartesian product $T_{i,j}XTC_i$, where TC_i consists of all the target classes of the dataset D_i. Namely, we pair the text $T_{i,j}$ with all possible target class values. We can now treat the problem as one of *Sentence-pairs classification*. In this setting, we are presented with a set consisting of three elements $\{T^r_i, tc^r_i, l^r_i\}$, where T^r_i is the text (first sentence),tc^r_i is a possible target class value (second sentence) and l^r_i the label. l^r_i set to True if $\{T^r_i, tc^r_i\} \in \{\mathrm{T}_i, tc_i\}$.

This setting, which is presented in full in Algorithm 2, creates a unified representation for all tabular datasets *regardless of their original number of classes*. Simply put, we reformulated the original task of each dataset into a NLP downstream task whose goal is to classify whether a given text T^r_i is related to a given class value tc^r_i.

Once we have reformulated our problem, we can use it to perform a *preliminary-FT of BERT*. The input we provide consists of two sentences, a classification token and a separation token:

$$[CLS] < T^r_{i,j} > [SEP] < tc^r_{i,j} > [SEP]$$

Figure 1: FeSTE's phases *entity linking*, *Fine-Tuning*, and *features generation*, an example based on AAUP dataset.

where $T_{i,j}^r$ is the free text, $tc_{i,j}^r$ is the assigned target class value, and $[CLS]$ and $[SEP]$ are BERT's special tokens. An example from the dataset "AAUP", whose task is to predict whether a university is ranked as "high" or "low", is presented below:

[CLS] Alaska Pacific University (APU) is a private university in Anchorage, Alaska ... [SEP] Low [SEP]

This phase of our FT process is similar to BERT's standard auxiliary training task, where the architecture is tasked with determining whether the class assigned to a sentence is correct (i.e., is it the one that appeared in the dataset?). For our fine-tuning, we use the same loss function that is used by the original BERT architecture's auxiliary task.

Our data formulation enables us to fine-tune BERT simultaneously over a large set of datasets, thus creating a generic model that can then be effectively applied to additional datasets. It should be noted that a similar process of including the class value as part of the input was previously used in the domain of zero-shot Text Classification (Yin et al., 2019), to address the possibility of new classes appearing in mid-training.

Target dataset fine-tuning. The goal of the preliminary FT was to adapt the pre-trained LM for the general task of feature generation for tabular datasets. Now we perform additional FT, designed to optimize the LM for the currently analyzed dataset. To this end, *we now repeat the process described above for the target dataset*. The process repeats all the steps of the preliminary FT, including the reformulation into a classification task.

The deep architecture used for the two fine-tuning phases is presented in Figure 2. We partition the training set of the target dataset $D_{t,train}$ into two equal parts. One half is used for the target dataset FT, while the second is used for the *features generation process*, which we describe next.

4.3 The Features Generation Phase

The goal of this phase is to produce the generated features that will augment the target dataset. The features generation process is as follows: for each sample (i.e., dataset tuple), we provide the pre-trained LM with an input consisting of: *a)* all the free text associated with the tuple's entity $T_{t,j}^r$, and; *b)* the possible target class values we generated $tc_{t,j}^r$. Simply put, we task the LM with predicting the likelihood of the text belonging to each of the target dataset's classes. The output of this process is a set of values, equal in length to the number of classes in the target dataset. Each of these values is added as a new feature to the target dataset.

An example of this process is presented in Figure 1, step #3. The dataset presented in the example has only two class values—high and low—so FeSTE creates only two additional features that are added to the original features set. It should be noted that because of the varying number of target class values in our analyzed datasets, we use the Sigmoid function and evaluate each class individually (which is why our values for a given entity don't add up to 1, as shown in Figure 1). Once the new features F_t^{new} have been generated, we apply the Softmax function row-wise to receive a distribution over each target class value.

The process described above is first applied to the target dataset's training set (i.e., the half that is retained for this purpose). We then train our classifier and apply it to the test set. Before each tuple in the test set is classified, we use the LM to generate the same set of features as the training set. In addition to the efficacy of our proposed approach, on which we elaborate in the following section, another advantage of FeSTE is the small number of features it generates. Unlike previously-proposed approaches such as (Harari and Katz, 2022), which generate thousands of features, the small number of features generated by FeSTE does not result in a large computational overhead.

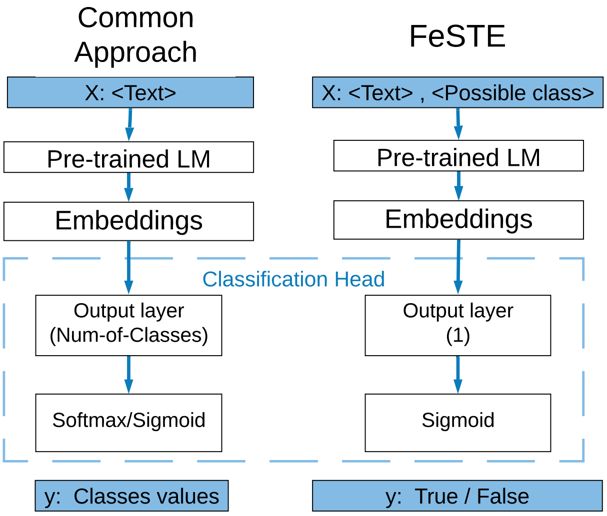

Figure 2: The fine-tuning architectures employed by our approach (right) and current SOTA (left). While previous studies receive the text and solve a standard multi-class classification problem, FeSTE's reformulation process transforms the process into a Sentence-pairs classification problem.

5 Evaluation

5.1 The Evaluated Algorithms

We compare FeSTE to the two leading fine-tuning methods: *target dataset FT* and *MT-DNN FT*:

Target dataset FT. For this baseline, we fine-tune a BERT-based architecture (Figure 2, left side) on the target dataset and the texts *without reformulation nor preliminary FT* (Algorithem 1, lines 1,9-11). This approach is the commonly used FT strategy.

Algorithm 1: FeSTE

```
input      : Target dataset $D_t$, datasets $D$, external
             source $EX$, pre-trained $LM$
1  $T \leftarrow$ EntityLinking$(D, EX)$
2  for $d_i \in D$ do
3      $\{T_i^r, tc_i^r, l_i^r\} \leftarrow$ Reformulation$(D_i, T_i)$
4  end
5  $X^r \leftarrow ConcatTuples(T^r, tc^r, l^r)$
6  $LM \leftarrow$ PreliminaryFT$(LM, X^r)$
7  $\{T_t^r, tc_t^r, l_t^r\} \leftarrow$ Reformulation$(D_t, T_t)$
8  $X_t^r \leftarrow \{T_t^r, tc_t^r, l_t^r\}$
9  $LM \leftarrow$ TargetDatasetFT$(LM, X^r_{t,train})$
10 $LabelsPred \leftarrow LM(X^r_{t,test})$
11 $F_t^{new} \leftarrow TranSoftmax(LabelsPred)$
   return  : Set of new features $F_t^{new}$
```

Algorithm 2: Dataset task reformulation

```
input      : Dataset $d_i$, linked texts $T_i$
$tc^i \leftarrow ExtractUniqueClasses(D_t)$
$tc_i^r, T_i^r \leftarrow tc^i \times T_i$ \\Cartesian product
Initialize empty labels vector $l_i^r$
$j = 0$
for tuple in $tc_i^r, T_i^r$ do
    if tuple is in $\{tc^i, T_i\}$ then
        $l_{i,j}^r = True$
    else
        $l_{i,j}^r = False$
    end
    j++
end
return     : Reformulated $\{tc_i^r, T_i^r, l_i^r\}$
```

MT-DNN FT. For this baseline, we first execute MT-DNN (Liu et al., 2019) as a preliminary FT step for the BERT-based architecture (Figure 2, left side). Then, we fine-tune BERT again using Target Dataset FT (Algorithm 1, lines 1,6,9-11). *No reformulation is performed.*

It is important to note that all baselines, as well as FeSTE, are evaluated using the same experimental settings. *The only difference between the approaches is their fine-tuning methods.* For full details on our baselines, see Section 2.

5.2 Experimental Setup

Datasets and evaluated classifiers. We evaluate our approach on 17 classification datasets with a large variance in their characteristics. The datasets were obtained from public repositories such as Kaggle, UCI (Dua and Graff, 2017), OpenML (Vanschoren et al., 2013), and relevant studies (Ristoski et al., 2016). The datasets and their characteristics are presented in the Appendix. When applying the classifiers on each dataset (after its features have already been augmented), we used four-fold cross-validation, where we train on three folds and evaluate the fourth. We repeat the evaluation four times and report the average results.

We use the following five classifiers to evaluate the performance of FeSTE and the baselines: RandomForest, MLP, SVC, KNeighbors, and GradientBoosting. We used the implementations available in Scikit-learn, with the default hyper-parameter settings. The only preprocessing we perform is feature normalization. *Since results are consistent for all algorithms, we present the average results.* Individual results are presented in the Appendix.

Architectures and parameter tuning. All evaluated models (FeSTE and baselines) use a pre-trained BERT architecture with 12 transformer blocks, 12 attention heads, and 110 million parameters (Hugging Face Tensorflow implementation). Additionally, the loss functions used by all fine-tuning approaches were either binary cross-entropy or multi-class cross-entropy, depending on the number of target classes. Finally, only the embedding [CLS] vector was passed to the output layer.

When evaluating the performance of our approach on dataset $D_t = D_i$, we trained the BERT-based architecture on the remaining datasets, i.e., $d_i \in D$ where $i \neq t$. Since we evaluate FeSTE on 17 datasets, our architecture was fine-tuned on 16 datasets and tested on the 17th. This form of training was also performed for MT-DNN.

FeSTE's preliminary and target-dataset fine-tuning settings were as follows: 20 training epochs with early stopping, mini-batches of 8 samples, a warm-up period of one epoch, no dropout, and the Adam optimizer. We used a learning rate of 1e-5 and 2e-5 for preliminary and target-dataset FTs, respectively. We also used a linear learning rate decay. For all experiments we used an Intel Xeon Gold 6140 2.3GHz Processor and 192GB RAM.

5.3 Evaluation Results

We conducted two sets of experiments. The goal of the first is to evaluate the efficacy of our novel FT approach compared to the two leading baselines: target-dataset FT, and MT-DNN. The second set of experiments is designed to determine whether FeSTE is generic by evaluating its performance when using a different entity linking approach.

Evaluating the efficacy of our FT method. In this experiment we focus on the efficacy of the features generated from the external data source (i.e., DBpedia unstructured text). We, therefore, train our classifiers only on the generated features and ignore the original features of the dataset. This evaluation enables us to more accurately quantify the performance of each FT approach. The setup of this evaluation is as follows: the FeSTE algorithm is used in all experiments, but the FT phases of our approach is either the Reformulation method presented in Section 4.2 (Algorithm 1, lines 2-8) , or one of the two baselines.

Table 1: The AUC results obtained by our full proposed approach (‘Reformulated‘), and by versions of our approach that utilize the baseline FT methods for the fine-tuning phase.

The results of this experiment are presented in Table 1. While it is clear that FeSTE performs well with all FT approaches, our proposed reformulation approach outperforms the baselines, achieving the highest results in 10 out of 17 datasets. In terms of AUC, Reformulated FT improves upon the baselines by 4.7%-6.8%. Using the paired t-test, we were able to determine that Reformulated FT outperforms both baselines with $p < 0.001$.

While Reformulated FT outperforms the baselines across all dataset sizes, it is noteworthy our approach achieves a larger relative improvement for smaller datasets. Improving the performance of such datasets is more difficult because of the limited amount of data available for the FT of the model. For example, the "Zoo" and "Country Codes" datasets contain only 35 and 75 records in their training set, respectively. Nonetheless, Reformulated FT outperforms the other baselines by 37% and 8.9% in terms of AUC—well above the overall average. These results demonstrate the effectiveness of our novel tuning approach, which leverages

Table 2: An evaluation of FeSTE when it uses our Google-based entity linking approach, and when it implements the entity linking approach proposed by the recent FGSES framework. multiple tabular datasets in its FT process.

Evaluating the efficacy of our FT method with the original features. We now evaluate all approaches on the joint set of original and generated features. The only preprocessing we apply is feature normalization (no feature selection or engineering). We consider this setup the most realistic.

The results of this experiment are presented in Table 3. Again, FeSTE performs well with all FT approaches and our reformulation approach outperforms the baselines, achieving the highest results in 9 out of 17 datasets. In terms of AUC, Reformulated FT improves upon the baselines by 1.4%, 2.3%, and 9.2%. Using the paired t-test, we were able to determine that Reformulated FT outperforms the three baselines with $p < 0.001$.

Evaluating FeSTE using additional entity linking approaches. In the previous experiment we demonstrated the efficacy of the features generated by FeSTE. Our goal now is to determine whether our approach is sufficiently generic to be applied with additional forms of entity linking. We, therefore, evaluate FeSTE's performance when our Google-based entity linking approach is replaced by the recently proposed FGSES approaches presented in (Harari and Katz, 2022).

The results of this experiment are presented in Table 2. We present the results for the two FeSTE versions—Google and FGSES-based—where the generated features are added to the original features set. To provide a meaningful point of reference, we also include the results obtained by using only the original features set for each dataset. It is clear that both versions of FeSTE outperform the original set of features. Our approach achieved better performances in 10 out of 17 datasets, with the original features achieving top performance in only 6 datasets. On average, FeSTE outperforms the results obtained by the original features by 9.2% and 5.2% for the Google-based and FGSES-based entity linking, respectively. Using the paired-t statistical tests, we were once again shown that FeSTE superior performance is statistically significant, with $p < 0.001$, compare to the original set of features.

6 Discussion

Cases where the original features outperformed the augmented features set. The results in Section 5.3 clearly show that FeSTE significantly outperforms the baselines in a large majority of the evaluated datasets. In this section, however, we focus on datasets where our approach did not perform well compared to the original set of features.

As shown in Table 2, there are six datasets in which the original features set outperformed FeSTE. We analyzed these datasets in an attempt to determine the causes of our approach's lower performance. Our conclusion is that FeSTE is in greater danger of underperforming in cases of "specialized" datasets, i.e., datasets that are dedicated to highly specific topics that are not of general interest. In such use-cases, information extracted from a "general" data source like DBPedia might not be adequate. An example of such a use case is the WDI dataset, whose goal is to determine the income groups of various countries. Our analysis shows that the abstracts of the linked entities simply do not elaborate on the topic of income.

Finally, we compare the performance achieved using only FeSTE's generated features (Table 1) to the performance of the original features (Table 2). Note that our generated features outperform the original features in 10 out of 17 datasets—an impressive accomplishment given that the original features are often highly informative. On average for all datasets, features generated by our approach outperform the original features by 2%. Moreover, in some datasets our approach significantly outperforms the original features by as much as 192%.

Analyzing FeSTE's Generalization Capabilities. In all our previous experiments, FeSTE was fine-tuned on 16 datasets. We now analyze our approach's ability to generalize as a function of the number of its fine-tuning datasets. Figure 3 presents FeSTE's relative improvement compared to preliminary FT. The results show that even four FT datasets yields an improvement (1.8%) compared to this baseline, with the gap rapidly expanding as new datasets are added. This analysis highlights FeSTE's generic nature and its ability to leverage knowledge from multiple sources.

Analyzing FeSTE Relative Efficiency.

In this analysis we compare FeSTE both to target dataset FT and to MT-DNN (see Section 2). Target dataset FT is clearly the most efficient of the three approaches, as it constitutes a part of the other approaches. While FeSTE and MT-DNN were implemented using identical architectures (with one minor difference, described below), their comparison requires us to consider two aspects of their respective implementations:

(1) While FeSTE employs the same architecture for all datasets, MT-DNN must train a new output layer for each new task, as well as for datasets with the same task but with a different number of classes. In our experiments, for example, we trained seven output layers for MT-DNN. In addition to the need to constantly re-train the model, MT-DNN incurs significant storage costs because of the need to maintain multiple architectures.

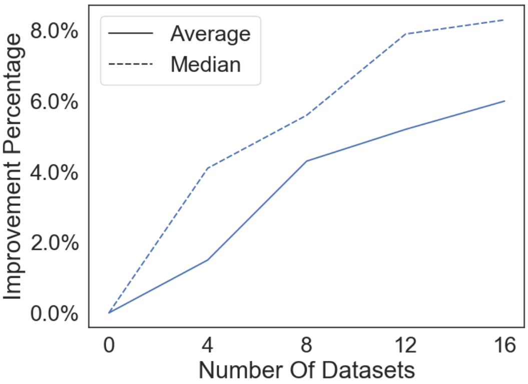

Figure 3: FeSTE's relative performance to preliminary FT, as a function of the number of datasets on which our approach performs its fine-tuning.

(2) FeSTE incurs an additional computational cost due to its reformulation phase. The cost of reformulation consists of two parts: the first is the reformulation process itself, and the other is the additional FT as a results of the larger number of samples. The computational cost of both tasks is $\mathcal{O}(|C| * |UniqueEntities|)$. Please note, however, that in tabular dataset both number of classes and the number of unique entities is relatively small.

To summarize, MT-DNN will likely be more efficient for a small number of tasks/datasets, each consisting of a large number of training samples. FeSTE, on the other hand, will be more effective on a diverse set of datasets and tasks, possibly containing a relatively smaller number of samples.

7 Conclusions

We present FeSTE, a framework for generating new features for tabular datasets from unstructured sources. Our approach uses a novel two-step fine-tuning process that enables it to effectively apply transformer based LM for the extraction of useful features even when the target dataset is limited in size. Our FT approach significantly outperforms the existing SOTA.

A Appendix

In this chapter, we present additional tables with information that can assist the reader to further explore our evaluation results. The list of tables is as follows:

1. The detailed characteristics of the evaluated datasets are presented in Section A.1 and Table 4.
2. The full results for each of the five evaluated classifiers which were used in the evaluation of the FT method are presented in Section A.2 and Table 5.
3. The results for FeSTE's evaluation when using an additional entity linking approach is presented in Section A.3 and Table 6.

A.1 Full Details of the Evaluated Datasets

We evaluate our approach on 17 classification datasets with a large variance in their characteristics. The datasets were obtained from public repositories such as Kaggle, UCI (Dua and Graff, 2017), OpenML (Vanschoren et al., 2013), and relevant studies (Ristoski et al., 2016). The datasets and their characteristics are presented in Table 4.

A.2 Evaluation results for each evaluation classifier

In Section 5.3 we present the average AUC of five classifiers for our two experiments (Tables 1 & 2). We now present the full results of (both AUC and F-score) for each of our classifiers: RandomForestClassifier, MLPClassifier, SVC, KNeighborsClassifier, and GradientBoostingClassifier. The results for each classifier are presented in Table 5.

A.3 FeSTE's Performance Using an Additional Entity Linking Approach

The results in Table 6 present the performance of each of our five classifiers when FeSTE is evaluated using the entity linking approach proposed in (Harari and Katz, 2022). The results also include the performance obtained using only the original dataset features.

Table 4: The characteristics of the datasets used in our experiments.

Abstract

Text summarization helps readers capture salient information from documents, news, interviews, and meetings. However, most state-of-the-art pretrained language models (LM) are unable to efficiently process long text for many summarization tasks. In this paper, we propose SUMM^N, a simple, flexible, and effective multi-stage framework for input texts that are longer than the maximum context length of typical pretrained LMs. SUMM^N first splits the data samples and generates a coarse summary in multiple stages and then produces the final fine-grained summary based on it. Our framework can process input text of arbitrary length by adjusting the number of stages, while keeping the LM input size fixed. Moreover, it can deal with both single-source documents and dialogues, and it can be used on top of different backbone abstractive summarization models. To the best of our knowledge, SUMM^N is the first multi-stage split-then-summarize framework for long input summarization. Our experiments demonstrate that SUMM^N outperforms previous state-of-the-art methods by improving ROUGE scores on three long meeting summarization datasets AMI, ICSI, and QMSum, two long TV series datasets from SummScreen, and a long document summarization dataset GovReport. Our data and code are available at `https://github.com/psunlpgroup/Summ-N`.

1 Introduction

Abstractive summarization helps readers capture salient information from various sources such as documents, news, interviews, and meetings. Previous work has primarily focused on short texts of news (Gehrmann et al., 2018; Zhang et al., 2019) and short conversations (Gliwa et al., 2019; Chen and Yang, 2021). Recently proposed longer dialogue and document summarization tasks (Zhong et al., 2021b; Huang et al., 2021; Chen et al., 2021; Zhu et al., 2021a) pose challenges for current large pretrained language models due to the time and memory complexity of training, as well as limited input lengths these models can consume.

A common method to handle long text reduces the input to a shorter one. This can be accomplished by truncating inputs (Lewis et al., 2020) or employing retrieve-then-summarize pipelines (Zhong et al., 2021b). However, these methods break the dependency of the context and decrease the number of tokens that the model can read, i.e., the receptive field of the model. The cutting-off model depends on the lead bias of the source text, while the retrieve-then-summarize models heavily rely on the independence of retrieved units (turns or sentences) which are usually scattered throughout the source text.

Another approach optimizes the attention mechanism in Transformers to accommodate longer inputs by reducing the impact of quadratic complexity of the attention process using Locality-sensitive hashing (LSH) attention (Kitaev et al., 2020) and Sinkhorn attention (Tay et al., 2020). Additionally, HMNet (Zhu et al., 2020) and HAT-BART (Rohde et al., 2021) use hierarchical self-attention to extend the input limitation of typical self-attention models. However, the simplified attention mechanism weakens the power of pretrained Transformer models, e.g., HMNet is not pretrained on external large-scaled unsupervised datasets as BART did.

In this paper, we propose SUMM^N, a multi-stage framework for long dialogue and document summarization. Figure 1 shows the structure of SUMM^N. First, it divides each source text into segments so that each can be completely fed into the backbone abstractive summarization model. Then, it matches each of them with the subset of target text using a ROUGE-based greedy algorithm. Next, each stage generates a coarse summary for each segment and concatenates them together as the input to the

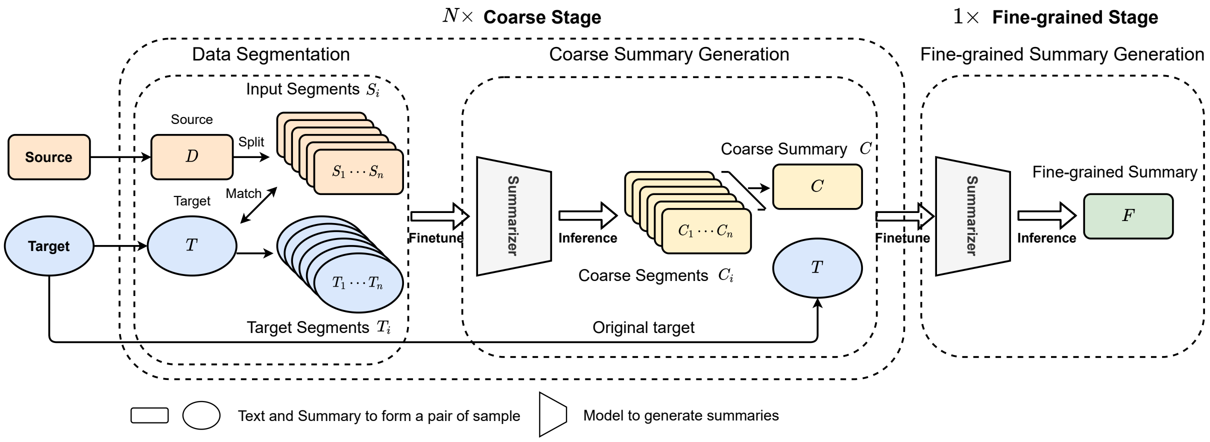

Figure 1: Workflow of the proposed SUMM^N framework. It contains N coarse stages and 1 fine-grained stage. At each coarse stage, source and target text is segmented and paired using a ROUGE-based greedy algorithm, and then a backbone summarization model is used to generate the summary for each segment. After multiple coarse stages, the last fine-graded stage produces the final summary output.

next stage. After multiple stages of compression and summarization, the final stage produces a fine-grained summary. The process expands the model context to the full reception field, meaning that the proposed model can read the full input no matter how long the input is. Additionally, retrieve-then-summarize pipelines (Zhang et al., 2019) extract sentences individually, leading to the loss of the context information for understanding utterances. By contrast, SUMM^N only cuts the source text at the end of each segment, so that the context of most sentences are retained.

It does not assume lead bias because each part of the source is fully used. In addition, in each stage, it leverages a backbone abstractive summarization model to recursively generate the summaries. Therefore, it enjoys the full power of the pretrained language models because the framework preserves the intact structure of Transformers.

SUMM^N is flexible to inputs with different lengths by adjusting the number of stages. SUMM^N can change the number of coarse stages according to the compression ratio between source and target, the input limit of the backbone model, and the input source length. We give the empirical formula to decide the number of needed stages for every tested dataset. Our experiments show that ROUGE increases on all datasets when increasing the number of stages from one to the appropriate number. Additionally, SUMM^N is flexible because it can be applied to different backbone summarization models. For example, we found that the ROUGE scores increase sharply on the AMI dataset when replacing the backbone BART model with T5 (Raffel et al., 2020) and PEGASUS (Zhang et al., 2019).

We conduct extensive experiments on long-input summarization datasets in multiple domains. The results demonstrate that the proposed model significantly outperforms previous state-of-the-art methods according to automatic and human evaluations on three long meeting summarization datasets (AMI, ICSI, QMSum) and one long TV series summarization dataset (SummScreen). It also achieves state-of-the-art performance on a long document summarization dataset (GovReport). These datasets include document summarization as well as both query-based and query-independent long dialogue summarization tasks.

Our contributions are: (1) We propose SUMM^N, a simple, flexible, and effective framework for long dialogue and document summarization. To the best of our knowledge, SUMM^N is the first multi-stage split-then-summarize framework to solve long text summarization tasks. (2) We evaluate SUMM^N on both dialogue and document domains and improve the baseline model by a large margin. (3) We analyze and compare the proposed framework with baselines and discuss its merits in detail.

2 Related Work

Long Document Summarization Long document summarization has been studied in multiple domains, such as news (Liu et al., 2021; Zhu et al., 2021b), patterns (Trappey et al., 2009), books (Kryściński et al., 2021; Wu et al., 2021), scientific publications (Qazvinian and Radev, 2008; Mao et al., 2021), and medical records (Cohan et al., 2018). Gidiotis and Tsoumakas (2020) proposed a divide-and-conquer method by splitting the input into multiple segments, summarizing them separately, and combining the summary pieces. Grail et al. (2021) proposed a hierarchical neural model to process segmented input blocks. Compared with SUMM^N, these models only split the input once, implying the lack of flexibility when handling longer input.

The GovReport dataset was recently introduced containing documents with more than 9000 words, thus greatly challenging the capabilities of current models such as PEGASUS (Zhang et al., 2019), TLM (Pilault et al., 2020), and BIGBIRD (Zaheer et al., 2020). To handle this dataset, Huang et al. (2021) proposed head-wise positional strides to reduce the cost of the encoder-decoder attention. Similarly, models such as Longformer (Beltagy et al., 2020) and Reformer (Kitaev et al., 2020) adjust attention mechanisms in Transformers to consume longer inputs. However, these models sparsify the attention structure of the pretrained model to fit the longer source text. By contrast, SUMM^N is able to maintain the full structure of various pretrained models.

Long Dialogue Summarization Various models have also been proposed to handle long dialogue summarization. HMNet (Zhu et al., 2020) and HAT-BART (Rohde et al., 2021) leverage a two-level transformer-based model to obtain word level and sentence level representations. DialLM (Zhong et al., 2021a), Longformer-BART-arg (Fabbri et al., 2021) use finetuning or data augmentation to incorporate the external knowledge to maintain the accuracy of lengthy input. Different from these models, SUMM^N is a framework without modifying the structure of the backbone attention model.

Multi-Stage Text Generation Multiple multi-stage coarse-to-fine frameworks have been studied in many other text generation tasks, such as dialogue state tracking (Chen et al., 2020), neural story generation (Fan et al., 2018), and extractive summarization (Xu and Lapata, 2020). In a summarization task, a two-stage extract-and-summarize pipeline is commonly used (Zhang et al., 2019; Pilault et al., 2020; Zhao et al., 2020). However, unlike that work, our framework aims at long input summarization with fully abstractive intermediate summaries, meaning that SUMM^N can be viewed as a summarize-then-summarize pipeline.

3 Method

Figure 1 shows the workflow of SUMM^N. The workflow includes two types of stages, N coarse stages, and one fine-grained stage. Coarse stages include the data segmentation and coarse summary generation, while the fine-grained stage directly generates the summary as the final result. Besides, we have $N+1$ separate models for each stage and each was separately trained. Our experiments show that the performance drops if different stages share the parameters (Section 4.2). SUMM^N can adjust and compute the number of coarse stages N according to the stats of dataset and model.

To formulate our task, we denote one sample of the source text as $D = \{D_1, D_2, \cdots, D_m\}$, where D_i indicates one sentence in a document or one turn in a dialogue. For query-based summarization, there is also a query Q. The goal is to generate a summary T, given D and the optional Q.

3.1 Data Segmentation

In long text summarization, the number of tokens in the source data usually exceeds the limit of the backbone summarization models, thus reducing the quality of the summary. To make sure that the model can capture information about all source tokens, we apply a segmentation algorithm for long input summarization datasets. First, we segment the source text so that the data input to the backbone model does not exceed the length limit. Then, we apply a greedy algorithm to find the best target summary that matches the source segments.

Source Segmentation Assume that the number of the maximum input tokens of the backbone model is K. To completely input the source information, we cut the input D (between sentences) into multiple segments, each of them containing fewer than K tokens. Given the input D, we will have n segments $S = \{S_1, S_2, \cdots, S_n\}$ where $S_i \in D$ is a segment in D. For query-based summarization tasks, we simply concatenate the query to the beginning of the S, i.e. $S_i \leftarrow Q \bigoplus S_i$. In both cases, the number of tokens in each segment is less than the hyper-parameter K.

Target Matching Segmenting the source text results in n source pieces S_i. We match each S_i with a target segment $T_i \in T$ to form the new pair (S_i, T_i) for the next step. We use a greedy algorithm for target matching. We first split T into separate sentences $T_s = \{T_{s_1}, T_{s_2}, \cdots, T_{s_k}\}$.

Algorithm 1 Greedy Target Matching

```
Input: $S_i, T_s = \{T_{s_1}, T_{s_2}, \cdots, T_{s_k}\}$
Output: $(S_i, T_i)$
  $T_i \leftarrow \Phi$
  loop
    $T_i' \leftarrow T_i$
    for $T_s' \in T_s - T_i$ do
      $\tau' \leftarrow \text{ROUGE}_1(S_i, T_i')$
      $\tau \leftarrow \text{ROUGE}_1(S_i, T_i \bigoplus T_s')$
      if $\tau' < \tau$ then
        $T_i' \leftarrow T_i \bigoplus T_s'$
      end if
    end for
    if $T_i' = T_i$ then
      Break the loop.
    else
      $T_i \leftarrow T_i'$
    end if
  end loop
  return $(S_i, T_i)$
```

Then, each segment S_i is matched with a subset of T_s such that the ROUGE-1 score between the subset and S_i is maximized. However, it is not feasible to find the optimal set due to the considerable running time. We apply a simple greedy approximation to find such a subset. From a null set T_i, we iteratively add to the subset the sentence with the highest ROUGE-1 gain between T_i and S_i. Algorithm 1 shows how we obtain the new training pair (S_i, T_i). $\bigoplus$ indicates the concatenation of sentences while keeping them in the same order as in the original text. We use ROUGE-1 as the matching criterion because the higher ROUGE-1 score usually implies higher scores on the other metrics such as ROUGE-2 or ROUGE-L, while ROUGE-1 enjoys lower time complexity compared with other ROUGE metrics.

This matching algorithm also ensures $T_i \neq \emptyset$ so that each S_i can be matched to at least one target sentence. A sentence $t \in T_s$ can be added to multiple subsets T_i because one sentence of summary may need the information from multiple segments.

3.2 Coarse Summary Generation

In coarse summary generation, we train a summarization model, that takes the segmented data as input. We first collect the training samples (S_i, T_i) generated by data segmentation to form a new dataset. This augments the source data to d_1/K times compared with the cut-off methods, where $d_1 = |D^1|$ indicates the averaged number of tokens of original source text. Thus, data segmentation helps the summarizer to better learn the task of the current stage. Additionally, because we incorporate the full input using segmentation, it does not rely on the leading bias in the cut-off method that only considers the first segment S_1. Afterward, we use these data to train a neural summarizer. This way, our model treats each part of the source text as equally important.

Given a source segment S_i and an optional query Q, we obtain the coarse summary segments using a backbone summarization model:

$$C_i^l = \text{SUMM}_l(Q, S_i)$$

Where $l \in [1, N]$ is the index of the current stage. Then, the n coarse summaries corresponding to the original source $S = \{S_1, S_2, \cdots, S_n\}$ are concatenated: $C^l = C_1^l \bigoplus C_2^l \bigoplus \cdots \bigoplus C_n^l$. We use C^l as the new source text of next stage, which compresses the input source data D^l. i.e. $D^{l+1} = C^l$. To pair with the D^{l+1}, the target to the next stage is copied from the original dataset, i.e. $T^{l+1} = T$.

The proposed framework is applicable to different backbone models $\text{SUMM}_l(*)$, such as BART (Lewis et al., 2020) and T5 (Raffel et al., 2020). We pick BART as the backbone model because it can best illustrate the benefits of our framework (Section 4.2).

3.3 Estimation of the Number of Coarse Stages N

The number of stages can be estimated by data stats and model characteristics. In SUMM^N, each coarse stage compresses the input to a shorter length. After N turns of coarse stages, the averaged length of source text is below K, the dataset is then fed into the fine-grained stage. Hence, the number of coarse stages can be computed by the following equation (details can be found in Appendix A):

$$\hat{N} = \lceil \frac{\log K - \log d_1}{\log c_1 - \log K} \rceil$$

where d_1 and c_1 are the average length of source text and coarse segments in stage 1. In Section 5.7 and Table 9, we demonstrate this estimation is close to the empirical number of coarse stages.

The greedy algorithm in SUMM^N for target matching is critical to the performance. Consider a duplication algorithm where each segment S_i is simply paired with the target T, i.e. $T_i = T$. Since the target text is longer than the text segmented by Algorithm 1, the generated summary of each coarse stage will be longer as well, leading to a lower compression speed and larger N. Besides,

Dataset	Type	Domain	Size	Source length	Target length	Query	$N+1$
AMI	Dialogue	Meetings	137	6007.7	296.6	✗	2
ICSI	Dialogue	Meetings	59	13317.3	488.5	✗	3
QMSum	Dialogue	Meetings	1808	9069.8	69.6	✓	2
SummScreen	Dialogue	TV shows	26851	6612.5	337.4	✗	2
GovReport	Document	Reports	19466	9409.4	553.4	✗	3

Table 1: The summarization datasets for evaluation. The source length and target length is the averaged number across the dataset. N indicates the number of coarse stages we use.

the duplication of the target will confuse the model, because some source segments will probably be paired with the same target, causing the model to generate duplicated content. Experiments (Table 7, "- stage 2" versus "- stage 2 & tar. seg.") show that ROUGE scores declines a lot when greedy target segment is replaced by the duplication algorithm .

3.4 Fine-Grained Summary Generation

When the input source of D^l is shorter than K, we can proceed to the fine-grained stage. In this stage, D^l is used to train a summarization model from scratch to obtain the final summary. The fine-grained stage works the same way as the vanilla backbone model. In fact, SUMM^N with $N = 0$ is the backbone summarizer. In the fine-grained stage, the model is directly trained on dataset (D^N, T) from the last coarse stage, and obtain the summary as the final output of SUMM^N:

$$F = \text{SUMM}_{N+1}(Q, D^N)$$

It is worth noting that, although source text may be shorter than 2 segments, i.e. $d^i \leq K$, we still add them in all stages, so that each summarization model can be trained on the full dataset.

4 Experiment Setup

We first list the datasets and metrics to evaluate the model. Then, we introduce the backbone model and baselines for comparisons. Finally, we present some implementation details.

4.1 Datasets and Metrics

Table 1 shows data statistics for the datasets[1].

AMI & ICSI (McCowan et al., 2005; Janin et al., 2003) are meeting scripts generated by Automatic Speech Recognition (ASR) systems. AMI is collected from product design meetings in a company while ICSI is collected from academic group meetings. Because the transcript is produced by ASR, there is a word error rate of 36% for AMI and 37% for ICSI.

QMSum (Zhong et al., 2021b) is a query-based meeting summarization dataset. It consists of meetings from three domains, including AMI and ICSI, and the committee meetings of the Welsh Parliament and the Parliament of Canada. Each query and sample are written by experts.

SummScreen (Chen et al., 2021) consists of community-contributed transcripts of television show episodes from The TVMegaSite, Inc. (TMS) and ForeverDream (FD). The summary of each transcript is the recap from TMS, or a recap of the FD shows from Wikipedia and TVMaze.

GovReport (Huang et al., 2021) is a large-scale long document summarization dataset with 19,466 long reports published by the U.S. Government Accountability Office on national policy issues.

We use ROUGE (Lin, 2004) as the automatic evaluation metric.[2] We split summary outputs into sentences to calculate the ROUGE-L score. If not specified, F1 scores are used in all results.

4.2 Backbone Model

We pick BART (Lewis et al., 2020) as our backbone summarization model because it performs well on short text summarization but not as good on longer texts, illustrating the benefits of our framework. Compared with other pretrained parameters, the BART-large model pretrained on the CNN/DM dataset yields the best performance (Zhang et al., 2021). So we use the BART-large-cnn parameter as a better starting point.

It is worth noting that we use separate backbone models for each stage and each was separately trained. We experimented with reusing the model parameters in multiple stages but obtained a lower

---

[1] Both QMSum and SummScreen can be accessed through SummerTime (Ni et al., 2021).

[2] We use `pyrouge`, a Python wrapper for the ROUGE: https://github.com/bheinzerling/pyrouge

Table 2: ROUGE scores on three meeting summarizing tasks, AMI, ICSI, and QMSum. QMSum-ALL uses inputs with all turns while MSum-Gold uses inputs with only the gold turns. * denote the ROUGE-L scores without sentence split.

score, e.g. the ROUGE-1 score of stage 2 on the QMSum dataset decreases around two points if we use the best parameters of stage 1 summarizer as the starting point of training stage 2 summarizer. This is because the tasks of the different stages differ significantly. For instance, the input to the first stage of dialogue summarization is the dialogue turn while the input to the latter stages is the document.

4.3 Baselines

We compare the proposed framework with various baselines. **PGNet** (See et al., 2017) uses a pointer mechanism to copy the token from the training sample. **TopicSeg** (Li et al., 2019) is a multi-modal model jointly learning the segmentation and summarization. **HMNet** (Zhu et al., 2020) uses a hierarchical attention structure and cross-domain pre-training for meeting summarization. **TextRank** (Mihalcea and Tarau, 2004) is a graph-based ranking model for text processing. **HAT-BART** (Rohde et al., 2021) is a new hierarchical attention transformer-based architecture that outperforms standard Transformers. **DDAMS** (Feng et al., 2021) uses a relational graph to model the interaction between utterances by modeling different discourse relations.

For the SummScreen dataset, we use the neural and hybrid model scores reported by Chen et al. (2021). We rename these two baselines as **Longformer+ATT** and **NN+BM25+Neural** to clarify the difference between other baselines.

The baseline scores we report on GovReport are from the original paper (Huang et al., 2021). **BART Variant** indicates self-attention variants with full attention. **BART HEPOS** indicates encoder variants with head-wise positional strides (HEPOS) encoder-decoder attention.

4.4 Implementation Details

We fit all models into a single RTX A6000 GPU with a 48 GiB memory. We adopt the fairseq[3] implementation for BART. The learning rate is set to 2e-5 and the beam width is set to 2 for coarse stages and 10 for fine-grained stages. The maximum number of tokens in each batch is set to 2048. The maximum number of tokens in each source text is set to 1024 because we tried to extend the positional embeddings to 2048 or longer but obtained worse performance. We stop the coarse stage and start the fine-grained stage when the averaged source length is shorter than 2048 rather than 1024 to obtain a better performance (Section 5.7). For the output of each intermediate stage, we use <s> and </s> to separate each generated target segments C_i^l.

5 Results and Analysis

We discuss the evaluation results and effects of each component of Summ^N in this section.

5.1 Overall Results

Meeting Summarization Table 2 shows the ROUGE scores on AMI, ICSI, and QMSum. Compared with the baseline models, Summ^N achieves state-of-the-art results on almost all metrics. Specifically, Summ^N improves SOTA on ICSI by **0.83**, and **1.96** ROUGE-2/L scores, improves SOTA on QMSum-Gold by **4.14**, **3.96**, and **4.35** ROUGE-1/2/L scores. These results demonstrate the effectiveness of Summ^N on long dialogue summarization tasks.

SUMM^N	56.77	**23.25**	**53.90**

Table 4: ROUGE scores on GovReport. For each baseline model, the number in parentheses is the maximum input length.

TV Series Summarization Table 3 shows ROUGE scores on SummScreen. SUMM^N outperforms on almost all metrics on two SummScreen datasets. Specifically, we improve **6.58**, **1.65**, and **3.75** ROUGE-1/2/L scores on the SummScreen-FD dataset. This result demonstrates the generalizability of SUMM^N over various domains including meetings and TV series.

Document Summarization Table 4 shows ROUGE scores on GoveReport. SUMM^N achieves state-of-the-art performance on ROUGE-2 and ROUGE-L, and compatible results on ROUGE-1. The results show that SUMM^N is applicable to both long dialogue and document summarization tasks.

5.2 Effects of Number of Stages

We also notice that the performance increases consistently when the number of stages goes up until the predefined number of stages. Figure 2 shows the ROUGE-1 scores of different tasks across stages. **Stage 1** indicates the model with only one coarse stage and no fine-grained stage. In this model, We directly use the first segment of the coarse summary as the output, i.e. C_1^1 of each sample. **Stage i** ($i > 1$) model contains $i - 1$ coarse stages and one fine-grained stage, the generated summary is from fine-grained summarization models, i.e. F.

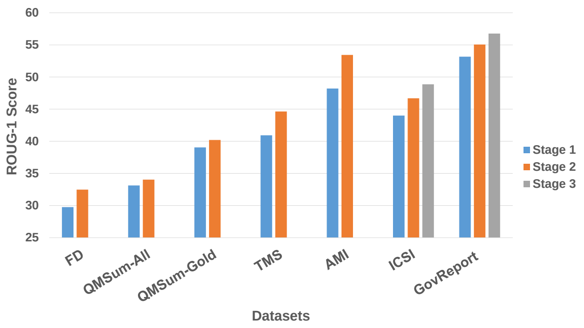

Figure 2: ROUGE-1 scores of various datasets at different stages. ICSI and GovReport have 3 stages, while the others have 2 stages. In all datasets, ROUGE-1 score increases with the increasing number of stages.

Although stage 2 of SUMM^N on the ICSI dataset has already outperformed the baselines, the scores can be further improved by adding one more coarse stage. In fact, on all datasets, increasing the number of stages leads to a performance gain. This gain can be explained as the following: if the output of the current stage is longer than K tokens, adding one more coarse stage will help since the model will receive more information from the source text compared with simply truncating them. On the contrary, if the input is smaller than K, there is no need to add more stages, because there is only one segment.

5.3 Improvements over Backbone Models

SUMM^N also boosts the performance of a backbone model by a large margin. As shown in Table 5, it improves the BART-large model by **6.87**, **3.89**, **6.78** ROUGE-1/2/L on AMI. This indicates the capability of SUMM^N to boost the performance of a weak learner on long summarization tasks. In particular, when the backbone model is well pretrained on short input texts and performs well on short summarization tasks, SUMM^N could greatly increase the capability of the backbone model to process and read long source texts. Also, the backbone of SUMM^N can be easily replaced by some other models, and models do not necessarily have to be identical at every stage. For example, one can try different learners such as T5 as the backbone model and replace the model in stage 1 with a dialogue-to-document model.

		R1	R-2	R-L
AMI	Backbone	46.57	16.41	44.61
	SUMM^N	**53.44**	**20.30**	**51.39**
ICSI	Backbone	39.91	9.98	38.17
	SUMM^N	**45.57**	**11.49**	**43.32**
QMSum-All	Backbone	29.20	6.37	25.49
	SUMM^N	**34.03**	**9.28**	**29.48**
QMSum-Gold	Backbone	32.18	8.48	28.56
	SUMM^N	**40.20**	**15.32**	**35.62**

Table 5: Improvements of SUMM^N over backbone BART models on AMI, ICSI, and QMSum datasets.

		R-1	R-2	R-L	Input
BART-base	Backbone	41.54	13.80	38.75	1024
	SUMM^N	46.60	18.80	45.23	1024
T5-large	Backbone	47.81	16.06	45.77	512
	SUMM^N	51.85	19.40	49.94	512
PEGASUS-cnn_dailymail	Backbone	46.37	16.21	44.75	1024
	SUMM^N	50.15	19.07	48.28	1024

Table 6: ROUGE scores of different backbone models on AMI. For all backbone models with various maximum input lengths, ROUGE scores increase with the help of proposed framework. Input indicates the maximum number of tokens the model can take.

5.4 Generalizability over Backbone Models

To demonstrate our framework can generalize to different backbone summarization models, we replace the BART-large-cnn model in previous experiments with other neural summarization models including T5 (Raffel et al., 2020) and PEGASUS (Zhang et al., 2019) using Hugging Face. Table 6 shows the ROUGE scores of three different models that are trained and evaluated on AMI. In all models, SUMM^N improves the performance of backbone models by a large margin. For instance, although BART-base is a weaker summarizer compared with the BART-large model, the framework is still able to improve the ROUGE-1 score by 5.06.

5.5 Ablations

Table 7 shows the ablation study results of SUMM^N on the AMI test set. Removing stage 2 (using the first segment of the coarse summary C_1^1 as the generated summary) leads to a 5.23 ROUGE-1 score drop. Without data segmentation, the ROUGE-1 score decreases by 6.61 using the same fine-grained stage. Removing both stage 2 and target matching (use duplication algorithm instead) further decreases the performance. It even hurts the performance of the original BART model because the duplication of targets will introduce some biases towards the common part of the targets.

	R-1	R-2	R-L
SUMM^N	**53.44**	**20.30**	**51.39**
- stage 2	48.21	18.59	46.46
- data seg.	46.83	15.91	45.00
- stage 2 & tar. seg.	46.24	16.03	44.45
only BART	46.57	16.41	44.61

Table 7: Ablations on the test set of AMI. "- data seg." indicates removing data segmentation (the same as cutoff at limitation), "- tar. seg." indicates source segmentation paired with duplicated targets.

	AMI			ICSI		
	Read.	Conc.	Cove.	Read.	Conc.	Cove.
HMNet	3.93	4.05	4.15	3.21	3.33	3.84
SUMM^N	**4.45**	**4.13**	**4.23**	**4.12**	**3.55**	**4.06**

Table 8: Human evaluation scores. Read. indicates *Readability*, Conc. indicates *Conciseness*, and Cove. indicates *Coverage*.

5.6 Human Evaluation

We conduct a human evaluation to assess the following: *Readability* takes into account word and grammatical error rate to evaluate how fluent the summary language is; *Conciseness* measures how well the summary discards the redundant information; *Coverage* measures how well the summary covers each part of the dialogue.

We compare the results of SUMM^N and HMNet because HMNet is a baseline model with the good capability to read whole input. For each meeting in AMI and ICSI dataset, we ask 3 different annotators with English expertise to label the summaries. Each annotator was asked to read the meeting transcript, gold summaries, and generated summaries using the SummVis (Vig et al., 2021) toolkit. They were asked to rate each summary from 1 to 5 (higher is better) for each metric. We also shuffle the summaries of two models to reduce the bias.

Table 8 shows that SUMM^N achieves higher scores in *Readability*, *Conciseness*, and *Coverage* than HMNet in both AMI and ICSI dataset. Specifically, the *Readability* of SUMM^N greatly surpasses the baseline by around 0.5/1 point on AMI/ICSI dataset. This is because BART is well-pretrained and is able to generate more readable text and SUMM^N successfully maintains this capability.

	Avg. $\lvert D^i \rvert$	Avg. $\lvert C_i \rvert$	Comp. R	$\hat{N}_{val}$	N
Stage 1	7996.01	377.02	- -	1.41	2
Stage 2	3582.47	373.29	0.45	0.55	1
Stage 3	1517.02	492.89	0.42	-0.41	0

Table 9: Comparison of the empirical number of coarse stage N and the corresponding estimation $\hat{N}_{val}$ on the GovReport test set. Avg. $|D^i|$ and Avg. $|C_i|$ are averaged number of tokens in source text and coarse segments of stage i (Section 3.3). Comp. R is the compression rate R of the stage.

5.7 Intermediate Result Analysis

To gain more understanding of the multi-stage mechanism of SUMM^N, we analyze the number of coarse stages and the compression rate through statistics of intermediate stages.

Early Stopping of the Coarse Stage Although the ideal input of the final fine-grained stage should be shorter than K, the experiment results show that compressing input from $2K$ to $1K$ tokens usually hurts the performance of the model. This is probably because generating too many short segments which are hard to summarize confuses the model.

Thus, we increase the length of input to the final fine-grained stage from K to $2K$ to prevent noises in the training set. The modified formula to estimate the number of coarse stages $\hat{N}$ is shown as follows (details in Appendix A).

$$\hat{N}_{val} = \frac{1 + \log K - \log d_1}{\log c_1 - \log K}$$

$$\hat{N} = \lceil \hat{N}_{val} \rceil$$

Number of Coarse Stages To verify that our estimation $\hat{N}$ is close to the empirical number of coarse stages N, we use GovReport to compare the two as shown in Table 9. We choose this dataset because it contains the most number of samples among all five datasets, with completely three coarse stages as well.

Table 9 shows the empirical/estimated number of coarse stages. To clearly show the $\hat{N}$ value, we display the float number $\hat{N}_{val}$ as the estimated number, and N as the empirical number of "remaining coarse stages" (Table 1). As can be seen, $N = \hat{N} = \lceil \hat{N}_{val} \rceil$ holds for all stages, meaning that the estimated $\hat{N}$ is capable of estimating the correct N value. It is worth noting that, for stage 2 and stage 3, using this formula can also estimate "how many additional coarse stage do we need".

	Transformers	SUMM^N
Time	$O(n^2)$	$O(nK/(1-R))$
Gen. Tokens	$O(n)$	$O(n/(1-R))$

Table 10: Time complexity of inference and the number of tokens generated during inference (Gen. Tokens) by comparing Transformers and SUMM^N. n is the number of tokens in the source text. K is the maximum input length of the backbone model of SUMM^N. R is the averaged compression rate.

Compression Rate We analyze the change of compression rate across different stages. In SUMM^N, compression rate R_i is defined as the averaged source length of stage i divided by source length of stage $i-1$. As shown in Table 9, both compression rates in stage 2 and stage 3 of GovReport are around 0.4, this shows that the compression rate of SUMM^N across different stages are stable, meaning that the number of segments will decrease to around 40% of the previous stage steadily.

5.8 Time Complexity

Table 10 shows the time cost of inferring one sample using vanilla transformer versus SUMM^N. Although the SUMM^N needs to generate more tokens due to multi-stage pipeline, SUMM^N reduces the inference time from quadratic to lower, i.e., from $O(n^2)$ to $O(Cn)$, $C = K/(1-R)$. Regarding training the model, SUMM^N also need to infer $O(n)$ additional tokens on the train/dev/test sets (details in Appendix B).

6 Conclusion

In this paper, we propose SUMM^N, a simple, flexible, and effective framework for long dialogue and document summarization. It consists of multiple coarse stages and one fine-grained stage to iteratively compress the long source input. It enjoys the full power of backbone models while ensuring the full receptive field of the summarization model. We evaluate the model on various datasets and improve the baselines by a large margin.

A Computing the Number of Stages

With regard to text length, the source text of each stage needs to be compressed gradually to ensure that the summary with proper length can be generated in the final stage. Also, the compression level determines the required number of stages, which is a significant indicator of time cost.

Suppose one sample of the source of stage i contains $d_i = |D^i|$ words, while the source of next stage D_{i+1} contains $d_{i+1} = |D^{i+1}|$ words. Also because the input of next stage is the coarse summary of current stage, $D^{i+1} = C^i$, thus $d_{i+1} = |D^{i+1}| = |C^i|$. The maximum input length of the model is K, $c_i = \sum_{j=0}^{n} |C_j^i|/n$ indicates the averaged number of tokens in the segmented predictions. d_{i+1} can be expressed by the length of coarse summary which is the number of segment $\frac{d_i}{K}$ times the length of coarse segments c_i.

In each stage, we have:

$$d_{i+1} = \frac{d_i}{K} \times c_i$$

By iterating this equation for N time, the number of needed coarse stages N for a dataset can be decided in this way:

$$d_1 \times \prod_{i=1}^{N} \frac{c_i}{K} \leq K$$

Empirically, c_i are similar in different stages , thus we replace the production of c_i with c_1 to the N, i.e.

$$c_1^N \approx \prod_{i=1}^{N} c_i$$

Thus, the estimation of N value can be calculated as follows:

$$d_1 \times \frac{c_1^N}{K^N} \leq K$$

$$\hat{N} = \lceil \frac{\log K - \log d_1}{\log c_1 - \log K} \rceil$$

We also call c_i/K the compression rate of stage i, denoted as R_i. For target matching, the compression rate of duplication segmentation is 1 and greedy segmentation is less than 0.5. So that target segmentation algorithm helps reduce number of coarse stages.

After using the early stopping of coarse stage, the estimation formula changes as follows:

$$d_1 \times \frac{c_1^N}{K^N} \leq 2K$$

$$\hat{N} = \lceil \frac{1 + \log K - \log d_1}{\log c_1 - \log K} \rceil$$

B Time Complexity

Suppose the length of the input is n, by segmenting the source text into n/K segments, the time cost of forwarding of one segment is K^2, thus the total time cost of stage 1 is $n/K \times K^2 = nK$. Then, in the next stage, the length of the source text is reduced to nR, thus the time complexity of stage 2 is nKR. We can list the total time cost by adding them together:

$$T(n) = \sum_{i=0}^{\infty} nKR^i = \frac{nK}{1-R}$$

	ICSI
SUMM^N	The project manager opens the meeting by recapping the events of the previous meeting. The marketing expert presents the results of market research , which shows that users want a fancy-looking remote control that is easy to use and has a fancy look and feel. The user interface designer presents the user interface concept for the remote , which is based on the idea that a remote should be simple and user-friendly. The industrial designer presents about the internal components of a remote control. The group discusses using kinetic energy to power the device , using a simple battery for the LCD screen , and using an advanced chip for the advanced chip. The project manager closes the meeting , telling the team members what their tasks will be for the next meeting. $\cdots$ The Marketing Expert will research how to produce a remote that is technologically innovative. The User Interface Designer will look at how to make a remote out of wood or plastic with either a wooden or plastic cover. The Group will not work with teletext. There was a lack of information on the cost of components and materials.
Gold	The project manager opened the meeting and recapped the decisions made in the previous meeting. The marketing expert discussed his personal preferences for the design of the remote and presented the results of trend-watching reports , which indicated that there is a need for products which are fancy , innovative , easy to use , in dark colors , in recognizable shapes , and in a familiar material like wood. The user interface designer discussed the option to include speech recognition and which functions to include on the remote. The industrial designer discussed which options he preferred for the remote in terms of energy sources , casing , case supplements , buttons , and chips. The team then discussed and made decisions regarding energy sources , speech recognition , LCD screens , chips , case materials and colors, case shape and orientation , and button orientation.$\cdots$ The case covers will be available in wood or plastic. The case will be single curved. Whether to use kinetic energy or a conventional battery with a docking station which recharges the remote. Whether to implement an LCD screen on the remote. Choosing between an LCD screen or speech recognition. Using wood for the case.

Table 11: Sample output summary SUMM^N on the ICSI dataset. Tokens marked in grey indicate the out-of-boundary contents of truncation models. Brown tokens are some topic words (manually selected) emerged in the gold summary. Tokens marked in red indicate the concepts of out-of-boundary text.

Similarly, in training phrase, stage 1 generates $O(n)$ tokens while stage 2 generates $O(nR)$ tokens for each sample in train/dev/test set. We can list the total generated tokens by adding them together:

$$T(n) = \sum_{i=0}^{\infty} nR^i = \frac{n}{1-R}$$

Thus the time cost of forwarding reduces. For instance, the inference time of SummScreen-TMS dataset reduces to $1024/(1-0.27)/6420.64 = 21.8\%$, and GovReport dataset reduces to $1024/(1-0.43)/7890.46 = 22.8\%$ of original time cost, compared with $O(n^2)$ transformers. This shows the efficiency of SUMM^N. On the other hand, since the training phrase needs to generate the target for each sample in the train/dev/test set, the training time of SUMM^N also includes the additional generation of $O(\frac{n}{1-R})$ tokens for each sample in the dataset.

C Case Study

Table 11 shows a concrete sample summary generated by SUMM^N. It captures the topics of the source text and smoothly follows the outline of the gold summary. Also, SUMM^N is able to evenly generate the information of the whole summary, including the last part of source text which is truncated in the standard BART-large models.

Open Domain Question Answering with A Unified Knowledge Interface

Abstract

The retriever-reader framework is popular for open-domain question answering (ODQA) due to its ability to use explicit knowledge. Although prior work has sought to increase the knowledge coverage by incorporating structured knowledge beyond text, accessing heterogeneous knowledge sources through a unified interface remains an open question. While data-to-text generation has the potential to serve as a universal interface for data and text, its feasibility for downstream tasks remains largely unknown. In this work, we bridge this gap and use the data-to-text method as a means for encoding structured knowledge for ODQA. Specifically, we propose a *verbalizer-retriever-reader* framework for ODQA over data and text where verbalized tables from Wikipedia and graphs from Wikidata are used as augmented knowledge sources. We show that our **U**nified **D**ata and **T**ext **QA**, `UDT-QA`, can effectively benefit from the expanded knowledge index, leading to large gains over text-only baselines. Notably, our approach sets the single-model state-of-the-art on Natural Questions. Furthermore, our analyses indicate that verbalized knowledge is preferred for answer reasoning for both adapted and hot-swap settings.

1 Introduction

Pretrained language models (Devlin et al., 2019; Brown et al., 2020) have been shown to store certain knowledge (linguistic or factual) implicitly in parameters (Manning et al., 2020; Petroni et al., 2019; Roberts et al., 2020), partially explaining the superior generalization abilities over downstream tasks. However, besides the well-known hallucination issue, the *implicit knowledge* learned through language modeling objective over text struggles at reflecting up-to-date knowledge from text and structured data for answering open-domain questions. To overcome this, recent work on open domain question answering (ODQA) focuses on the semi-parametric method (Karpukhin et al., 2020; Guu et al., 2020) where the pretrained language models can leverage external *explicit knowledge* sources for reasoning. For example, in the *retriever-reader* framework (Min et al., 2021, *inter alia*), the reader produces answers by grounding on the relevant evidence from the retriever, the interface to the explicit knowledge source (Wikipedia text passages). In this work, we focus on the semi-parametric approach for ODQA going beyond textual knowledge. Specifically, we are interested in the question: *Can we develop a viable unified interface over a realistic heterogeneous knowledge source containing both data and text?*

Recent retriever-reader models (Oguz et al., 2020; Agarwal et al., 2021) have demonstrated that expanding the textual knowledge source with more structured data is beneficial. However, only knowledge base (KB) is considered in (Agarwal et al., 2021), limiting the applicability of their method to other structured data. In (Oguz et al., 2020), both tables and KB triples are simply linearized as inputs to the reader, but different retrievers are required for individual cases. Here, we propose a *verbalizer-retriever-reader* semi-parametric framework, `UDT-QA`, which provides a unification of both representation and model for ODQA over data and text. The key idea is to augment the retriever with a data-to-text verbalizer for accessing heterogeneous knowledge sources, *i.e.* KB graphs from WikiData, tables and passages from Wikipedia.

Given its potential in providing a universal interface for data and text, data-to-text generation is increasingly popular (Gardent et al., 2017; Parikh et al., 2020; Nan et al., 2021) with various methods developed recently for converting structured knowledge into natural language (Wang et al., 2020; Ribeiro et al., 2020; Chen et al., 2020b). Nevertheless, most existing work has focused on *intrinsic*

evaluations exclusively, i.e. the quality of generated text measured by metrics like BLEU (Papineni et al., 2002), leaving its usefulness on downstream tasks largely unknown. Moreover, it remains unclear whether a single data-to-text model is able to verbalize heterogeneous structured data effectively. To bridge the gap, we develop a novel data-to-text generation paradigm for our framework. We introduce data filtering and beam selection to maximize the faithful coverage of the input information. To remedy the lack of in-domain data, we further propose an iterative training approach to augment the existing data-to-text training set with high quality outputs selected from the target domain. With this verbalizer, we convert all tables from Wikipedia (10x more than (Oguz et al., 2020)) and sub-graphs from Wikidata together with Wikipedia text passages as the knowledge source for ODQA.

We first validate our data-to-text method using intrinsic metrics on DART (Nan et al., 2021) and additional faithfulness evaluation on the target ODQA data. We show that our data-to-text approach can effectively improve the target-domain faithful metric without compromising too much on the intrinsic metrics. To further evaluate the end-to-end effectiveness, we experiment with `UDT-QA` on the ODQA task using a recent state-of-the-art (SOTA) retriever-reader pipeline, including DPR (Karpukhin et al., 2020) and UnitedQA (Cheng et al., 2021b). Consistent with previous work, our results also suggest that extra knowledge source is beneficial for ODQA. Notably, we find that the verbalized knowledge is favored by the reader compared to the raw format (linearization), especially when the structured data size is comparable to text, leading to more pronounced improvements. Overall, `UDT-QA` shows large improvements over text-only baselines and performs competitively with more complicated methods on both Natural Questions (NQ) (Kwiatkowski et al., 2019) and WebQuestions (WebQ) (Berant et al., 2013). In particular, `UDT-QA` achieves new SOTA on NQ under the single-model open-book setting.[1]

2 Overview of `UDT-QA`

In this section, we present the overall pipeline of our `UDT-QA` framework for ODQA over data and text (Figure 1). The major difference between our approach and the popular *retriever-reader* ODQA systems (Min et al., 2021, *inter alia*) is the use of a data-to-text verbalizer (§3) for converting structured data into natural language text, *i.e.* virtual documents, as the universal knowledge source. Here, we consider two types of structured knowledge (§4.2) — tables and KB sub-graphs. After verbalizing the structured knowledge, a subsequent pipeline consisting of a DPR retriever and a UnitedQA-E reader is used for answer inference. Since the retriever and reader are not the main focus of this work, we only briefly describe them below.

The DPR retriever (Karpukhin et al., 2020) is a bi-encoder model consisting of a question encoder and a context encoder, which is used for data and text retrieval. Following previous work (Karpukhin et al., 2020; Oguz et al., 2020), we use the uncased BERT-base (Devlin et al., 2019) model as the encoder, where the `[CLS]` token representation is used as the document/question vector. During training, positive and negative pairs of (question, context) are used to update the model. For inference, the entire document index is encoded with context encoder and the encoded question vector is used to retrieve the top documents with highest dot-product scores.

The UnitedQA-E (Cheng et al., 2021b) is an extractive reader based on ELECTRA (Clark et al., 2020) trained with enhanced objectives (Cheng et al., 2021a, 2020) for answer inference. Here, a pair of a question and a support passage is jointly encoded into neural text representations. These representations are used to compute scores of possible answer begin and end positions, which are then used to compute probabilities over possible answer spans. Finally, the answer string probabilities are computed based on the aggregation over all possible answer spans from the entire set of support passages.

3 Verbalizer: Data-to-text Generation

Here, we formally describe the data-to-text model developed in this paper, including the input format (§3.1) and the adaptation for ODQA (§3.2).

3.1 Input Format

Given a structured data input D, the data-to-text generator G aims to generate a natural language passage P that faithfully describes the information presented in D. In the literature, the structured data input can be in the form of a set of triples (Nan et al., 2021), a few highlighted cells from

---

[1] Data and code available at `https://github.com/Mayer123/UDT-QA`

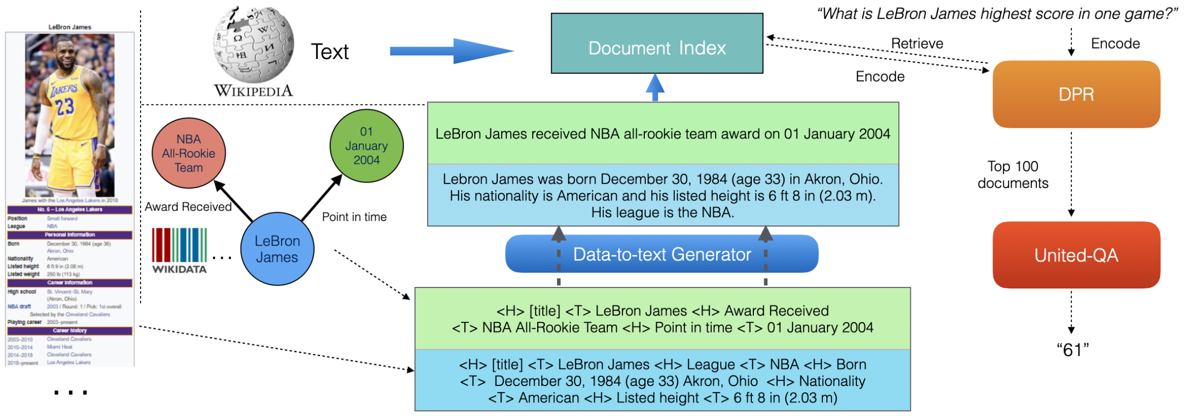

Figure 1: An overview of `UDT-QA` based on the *verbalizer-retriever-reader* pipeline.

a table (Parikh et al., 2020) or a full table (Chen et al., 2020a). Correspondingly, P could a simple surface-form verbalization of D (*e.g.* when D is a triple set) or a high-level summarization in case of a full table or a large KB graph. Since we consider (noisy) tables/KB sub-graphs of arbitrary size in this paper, directly feeding the entire input into the generator is not feasible, likely incurring significant computation challenges. Moreover, it is also desirable to maximize the information coverage of P so that most relevant information in D can be leveraged by the downstream QA retriever and reader. Based on this, we verbalize both tables and KB graphs at a fine-grained level.

In this work, we verbalize tables row by row, i.e. input each table row to G individually, where each row is a set of cells $r = \{c_i\}_{i=1}^{k}$, and k is the number of cells in the corresponding row. Most relevant to our setting, recent work (Nan et al., 2021) represents each cell in a triple. To form such triples, they manually annotate the tree ontology of column headers and then create triples using table title, headers, cell value and header relations, *e.g.* (`[TABLECONTEXT]`, `[title]`, `LeBron James`), (`LeBron James`, `League`, `NBA`) where `LeBron James` is the parent cell. Although such triples with fine-grained ordering may help guide the generator, directly applying such a generator to a target domain with no ontology annotation (our case) likely results in degradation. To overcome this, we propose to convert the triple set to pairs, *e.g.* (`[title]`, `LeBron James`), (`League`, `NBA`). We find such conversion has little impact on the intrinsic evaluation (§5). After all rows are verbalized, we assemble the text outputs back to form the verbalized table.

For KB, we follow previous work (Agarwal et al., 2021) and break the KB into small sub-graphs based on subject entity. Here, each sub-graph contains one central entity and its neighbors. Although this conversion would inevitably create undesirable artifacts (*e.g.* hurdles for multi-hop reasoning across sub-graphs), this preprocessing allows us to unify the input representations for both table and KB graphs, making it possible for a single verbalizer to convert structured knowledge into text format. Specifically, we convert all KB sub-graphs into the same format as table cell sets above, where the subject entity is treated as the title and all the edges are represented using pairs in the form of (`relation`, `object`). Then we verbalize each sub-graph with the generator G. Examples of input and output for table rows and KB sub-graphs are shown in Figure 1.

3.2 Improved Data-to-Text Model Training

A known problem in data-to-text generation is that the model tends to hallucinate or neglect information in the input (Wang et al., 2020; Agarwal et al., 2021). Faithfulness and information coverage is especially important when we apply the verbalized output to knowledge-intensive downstream tasks like ODQA. To address this, we subsample training data `T` such that the instances are filtered out if they are likely to steer model towards missing information. In particular, we compute ROUGE-1 (Lin, 2004) scores between the input and target of training instances and filter out those whose scores are below a certain threshold. We denote the filtered version as `T-F`. Examples of the filtered instances can be found in Table 11, as we discuss more in Appendix F, these instances may bias the model towards unwanted behaviors.

Another challenge we face is that most data-to-text training examples have succinct structured inputs. In other words, the cells in the structured input are usually single words or short phrases with corresponding short target sentences as well. In our case, a number of tables contain large cells with dozens of words. Models trained with existing data likely have a hard time verbalizing such inputs faithfully. To alleviate this domain-mismatch issue, we propose an iterative training set-up. In the first iteration, we train a generator on `T-F`. Then we apply the generator to our data. We then find high quality verbalized outputs based on the ROUGE-1 score between the model inputs and model outputs, and sample instances with score higher than a threshold for the next-round training. We sample instances up to the same size of `T-F`, and denote this set as `ID-T` (examples shown in Table 11). Finally, we mix the `ID-T` with `T-F` and train a second generator for verbalization.

Following recent work (Nan et al., 2021), we use the pretrained T5-Large (Raffel et al., 2020) model as our generator. Given paired training examples consisting of a structured data input and a target sentence, we finetune the T5 model to maximize the log-likelihood of generating the corresponding target sentences. Here, we follow the same experimental setup as (Ribeiro et al., 2020).

4 Experiment Setup

In this section, we describe the data used for experiments and sources of structured knowledge.

4.1 Datasets

In this paper, we use DART (Nan et al., 2021) to train our verbalizer (data-to-text) and two ODQA datasets, NQ and WebQ, to train and evaluate our pipeline, with the same split as in (Lee et al., 2019) provided by (Karpukhin et al., 2020). Below we provide a brief description of each dataset and refer readers to their papers for details.

DART is a data-to-text dataset containing pairs of (triple-set, sentences) collected from WebNLG (Gardent et al., 2017), E2E (Novikova et al., 2017) and crowdsourcing based on tables found in WikiSQL (Zhong et al., 2017) and WikiTableQuestions (Pasupat and Liang, 2015).

Natural Questions contains questions mined from Google search queries and the answers are annotated in Wikipedia articles by crowd workers.

WebQuestions consists of questions from Google Suggest API and the answers are annotated as entities in Freebase.

We collect **knowledge-answerable questions** from NQ and WebQ in order to evaluate our verbalizer and construct the retrieval training data. Specifically, we find questions in the original NQ training set that can be answered by a table. For each question, we search through tables in its associated HTML page to locate exact answer matches. In total, we collected 14,164 triples of (question, answer, gold table) from NQ train and dev sets as `NQ-table-Q`. On WebQ, we find questions that can be answered by KB via expanding from question entities and search for their 1-hop neighbors. If an answer entity is matched, we keep this sub-graph. In total, we collected 2,397 triples of (question, answer, sub-graph) from WebQ train and dev set as `WebQ-KB-Q`.

4.2 Structured Knowledge Sources

In addition to regular Wikipedia text passages, we consider two types of structured knowledge — tables from Wikipedia and KB graphs from Wikidata.

For tables from Wikipedia, we follow OTT-QA (Chen et al., 2021b) with slight modifications. Chen et al. (2021b) only consider tables in good format, *i.e.* tables with no empty cell, multi-column or multi-row, and restrict the tables to have at most 20 rows or columns. Instead, we remove such constraints and keep everything with the `<table>` tag, resulting in a larger and noisier table set. We denote this more realistic set of tables as `OTT-tables`.

Note Oguz et al. (2020) only consider tables from the original NQ HTMLs. In addition to the size difference, `OTT-tables` are crawled from a more recent Wikipedia dump than the NQ version. To study the impact of knowledge source size, we also process tables from the NQ HTML pages with the heuristic suggested by (Herzig et al., 2021) to de-duplicate tables and filter lengthy cells (>80 words). We denote this set of tables as `NQ-tables`. To avoid overlap, we remove tables from `OTT-tables` whose page title are in `NQ-tables` set. In total, we have a `All-tables` set with 2.2M tables from `OTT-tables` and 210K tables from `NQ-tables`, respectively.

For KB graphs, we consider using the English Wikidata (Vrandečić and Krötzsch, 2014) as our KB due to its broad coverage and high quality, not-

		Intrinsic Eval						Extrinsic Eval
Training Set	**# Examples**	**BLEU**	**METEOR**	**TER**	**MoverScore**	**BERTScore**	**BLEURT**	**Ans Cov**

Table 1: Intrinsic and extrinsic evaluations of verbalization approaches on DART test and `NQ-table-Q` (§4.1), respectively. "Ans Cov" refers to Answer coverage. All metrics are higher the better except for TER.

ing its predecessor Freebase is no longer maintained despite its popularity in research. In order to be comparable with recent work (Agarwal et al., 2021), we directly use their partitioned KB graphs from WikiData in our experiments, which is denoted as `WD-graphs`.

5 Experiments: Data-to-Text

In this section, we evaluate our data-to-text model with both intrinsic and extrinsic metrics. Since intrinsic metrics are probably less correlated with the downstream performance, we use them only as a sanity check for generation quality and focus on using an extrinsic metric for selecting models.

Intrinsic Evaluation: Since our model is developed mainly on DART, we first conduct the intrinsic evaluation on the DART test set to measure the impact of our improved data-to-text methods, *i.e.* data filtering and iterative training. Following (Nan et al., 2021), we use the official evaluation metrics including BLEU, METEOR (Banerjee and Lavie, 2005), TER, MoverScore (Zhao et al., 2019), BERTScore (Zhang et al., 2020) and BLEURT (Sellam et al., 2020). Table 1 summarizes different data-to-text models on DART test. As we can see, the resulting model trained with our data conversion (row 2) performs on par with the model using the original format (row 1). More interestingly, filtering short samples has almost no impact on the verbalizer performance (row 3). Lastly, iterative training with additional target domain data (row 4) slightly hurts on BLEU and TER and achieves similar performances on other metrics. Overall, our verbalizer with the proposed data conversion and improved training remains very effective on DART.

Extrinsic Evaluation: Since we are interested in applying verbalized knowledge for ODQA, the QA model is more likely to predict the correct answer only if the answer still exists after the verbalization. Therefore, we also evaluate each generator using a metric more related with the downstream task performance: **answer coverage**. Specifically, we compute the answer coverage as the percentage of examples that the answer present in the raw structured knowledge is still preserved in the corresponding verbalized output.

First, we compute the answer coverage of different generators discussed in the previous section on `NQ-table-Q` where tables are known to contain question-triggering content. The scores are reported in the last column of Table 1. Due to more lengthy tables in `NQ-table-Q`, data filtering improves the answer coverage as expected. Moreover, model trained with our iterative training demonstrates substantial improvements in answer coverage, indicating that our approach is highly effective for converting tables into text. Examples for comparing different verbalizer outputs are shown in Table 12 in Appendix F. Later, we use this best generator to verbalize `All-tables`. We use beam search of size 10 and save all beams. To retain as much input information as possible, a re-ranking stage is carried out over these predictions based on the ROUGE-1 score between the model inputs and model outputs. The highest ranked prediction is then used as the final output.

Lastly, we directly apply our best generator (DART T-F + ID-T) for verbalizing KB graphs. To evaluate the performance, we compare our model with the recent method KELM-verbalizer (Agarwal et al., 2021) using answer coverage on the set `WebQ-KB-Q` where KB sub-graphs are known to contain answer entities. Although never tuned for KB graph inputs, our model achieves 99.6 on answer coverage, outperforming the KELM-verbalizer (97.8 on answer coverage) by a large margin. This suggests that our data-to-text approach is highly effective for both tables and KB sub-graphs.

6 Experiments: QA over Data and Text

Here we present our main experiments on ODQA over data and text. For regular Wikipedia text, we use the same index containing 21M passages as

Model	NQ	WebQ

`UDT-QA` *w/* Verbalized Single Data	**55.2**	52.0
`UDT-QA` *w/* Verbalized Hybrid Data	55.1	52.5

Table 2: End-to-end open-domain QA evaluation of `UDT-QA` in comparison to recent state-of-the-art models on the test sets of NQ and WebQ. Exact match scores are reported (highest scores shown in **bold**).

in (Karpukhin et al., 2020). To augment text, two settings are considered, *i.e.* the *single data* setting and the *hybrid data* setting.

In the single data setting for NQ, we augment the text index with tables from the `All-tables` set (§4.2). For comparison, we also experiment with the raw representations using a simple linearization of tables similar to (Oguz et al., 2020). In single data setting for WebQ, we consider combining text with KB graphs from `WD-graphs` in the single data setting. Different from (Oguz et al., 2020) where a separate entity-linking based retriever is used for KB, we use a single model over the text index with either linearization of raw KB graphs or our verbalized KB graphs. Hence, in our case, both text and data (tables and KB graphs) can be handled by a unified retriever-reader pipeline. In the hybrid data setting for both NQ and WebQ, we use text, `All-tables` and `WD-graphs` for retrieval. The statistics of our document index are shown in Table 7 in Appendix A.

We create additional retriever training data from `NQ-Table-Q` and `WebQ-KB-Q` in a similar fashion as in the text-only setting, so that DPR can better handle additional knowledge. Following (Oguz et al., 2020), we also use the iterative training setup for retriever training. More training details can be found in Appendix B.

To evaluate the effectiveness of our `UDT-QA` for ODQA, we first include recent state-of-the-art ODQA models using text as the only knowledge source, DPR and UnitedQA. We also compare our `UDT-QA` with recent models using additional structured knowledge, KEALM and UnitK-QA. Following the literature, we report the exact match (EM) score for evaluation. The results are in Table 2.

Source	Format	R20	R100	EM
text	-	80.8	86.1	49.6
+`NQ-tables`	raw	85.2	90.1	51.1
+`NQ-tables`	V	85.5	90.2	51.2
+`All-tables`	raw	85.8	**90.7**	52.1
+`All-tables`	V	**86.0**	**90.7**	**52.5**
text	-	78.9	82.3	52.6
+`WD-graphs-WebQ`	raw	**83.4**	86.1	**57.1**
+`WD-graphs-WebQ`	V	**83.4**	85.0	55.7
+`WD-graphs`	raw	82.8	86.1	54.3
+`WD-graphs`	V	82.8	**86.7**	55.4

Table 3: Impact of document index size over separately trained retriever-reader models (Top for NQ and bottom for WebQ). All metrics are computed on the corresponding dev set. V stands for Verbalized here and on-wards.

As we can see, models with additional structured knowledge achieve better performance than text-only models. This indicates that both KB graphs and tables contain complementary knowledge which is either absent in text or harder to be reasoned over. For NQ, although we consider a significantly larger structured knowledge source which is likely to be more challenging, all our models substantially outperform UnitK-QA. As for WebQ, our model achieves competitive performance, although worse than UnitK-QA. We attribute this gap to two possible reasons. First, UnitK-QA uses a separate entity-linking based retriever for KBs which might lead to higher retrieval recall. Second, since WebQ is fully based on FreeBase, using WikiData only in our models likely suffers from mismatch (Pellissier Tanon et al., 2016). Nevertheless, our verbalizer-based models achieve better performances than the corresponding raw format models on both datasets, indicating that the proposed verbalizer is highly effective for tables and KB graphs.

7 Analysis

In this section, we present analyses over the impact of document index size, the use of additional structured knowledge in a hot-swap setting, comparison to a recent KB-only data-to-text approach in an end-to-end fashion, and manual exam of the verbalized/raw tables for their impact on ODQA.

How does the size of document index affect retriever and reader performance? More knowledge is likely to have better coverage of relevant information. On the other hand, larger and noisier index also increases the reasoning complexity.

Source	Format	R20	R100	EM
`Text-only`		81.3	87.3	51.8
`+NQ-tables`	raw	83.9	90.3	51.7
`+NQ-tables`	V	84.3	90.4	52.5
`+All-tables`	raw	84.0	**90.6**	51.7
`+All-tables`	V	**84.5**	**90.6**	**52.7**

Table 4: Hot-swap evaluation of raw vs verbalized table using a text-only retriever-reader model on NQ test.

To understand the impact of the increased document index size, we conduct experiments with a restricted setting where only relevant subset of knowledge to the corresponding dataset (a prior) is used for retrieval. Similar to (Oguz et al., 2020), we experiment with the combined document index of text and `NQ-tables` for NQ. As for WebQ, we keep documents from `WD-graphs` that contain any of the question entity in WebQ to build `WD-graphs-WebQ`, and experiment with using text + `WD-graphs-WebQ`. In addition to EM, we report R20 and R100, evaluating the retrieval accuracy of gold passages in the top-20 and top-100 documents, respectively. The results are reported in Table 3.

For NQ, in spite of being more challenging, we see that using `All-tables` yield substantial improvement in both recall and answer exact match compare to using `NQ-tables`. This indicates that, with proper training, ODQA models are likely to benefit from enriched knowledge. Although the larger raw form index brings in decent improvement (+1 EM) in terms of reader performance (`+All-tables` vs`+NQ-tables`), our verbalized knowledge is more friendly for answer reasoning leading to a more notable QA improvement (+1.3 EM). Different from NQ, we observe that on WebQ the restricted setting with `WD-graphs-WebQ` achieves better results. We hypothesize that this is likely due to the scale of WebQ dataset. The small amount of WebQ training makes the retriever insufficient to handle large-scale document index. We leave the verification of this hypothesis for future work.

Does a text-only retriever-reader model benefit more from verbalized knowledge compare to raw format (hot-swap)? Since both retriever and reader are based on pretrained language models, we hypothesize that they would probably benefit more from the verbalized knowledge due to its similar style as text. This can be particularly useful for a hot-swap setting where both retriever and reader have only seen textual knowledge during training. To verify that verbalized knowledge is more amenable, we carry out a hot-swap experiment here. Specifically, we directly use a DPR model trained on NQ text-only data for additionally indexing both `NQ-tables` and `All-tables`. Then, the inference retrieval is performed on the augmented document index for an input question, and a text-only United-QA-E reader trained on NQ is applied for answer inference afterwards. The results are summarized in Table 4. Similar to the previous fully fine-tuned settings, we see that additional knowledge still provide substantial improvements for text-only retriever using either raw or verbalized knowledge. However, the improvement in recall is not reflected in the later reader performance for the raw format, whereas the hot-swap answer inference performance is notably improved with verbalized knowledge. This observation further validates our hypothesis that verbalized knowledge is more beneficial, especially for reader.

Source	R20	R100	EM
`KELM`	78.2	85.3	51.5
`WD-graphs` (Ours)	**78.5**	**85.5**	**52.0**

Table 5: Comparison of verbalized knowledge from our verbalizer and KELM for retriever and reader on WebQ test. Dev results can be found in Table 9 in Appendix D.

How does the proposed verbalizer compare to recent data-to-text models? Lastly, we compare our verbalizer with the recently proposed data-to-text generator for converting KB graphs only, KELM (Agarwal et al., 2021). Since both KELM generator and our verbalizer are based on the same partitioned Wikidata, this evaluation can fully reflect their corresponding generation impacts on ODQA in an end-to-end fashion. Here, we evaluate using our verbalized `WD-graphs` and the KELM corpus as additional knowledge on WebQ. In particular, we follow the same procedure to train and evaluate our retriever and reader except that we swap the `WD-graphs` with KELM corpus in data construction and retrieval. Both retriever and reader performances are reported in Table 5. Note that the KELM data-to-text model is customized solely for converting KB graphs and trained with a much larger dataset (about 8M training instances),

Table 6: Examples of tables/chunks retrieved by our model given the question, where the evidence is bolded. In raw table, | is the row separator and empty is the filler token used by our table parsing heuristic (to make the table in good shape)

whereas our verbalizer is applicable to both tables and KB graphs with a smaller training data (only 110K instances). Nevertheless, consistent with its better extrinsic performance (§5), our verbalizer again outperforms the KELM generator in both retrieval and reading, which provides further support for the effectiveness of our approach as a unified interface for ODQA over data and text.

What is the impact of verbalized/raw table on ODQA? We manually analyze examples of verbalized and raw tables and the details of annotation can be found in Appendix E. We showcase the examples of verbalized tables and their raw counterpart in Table 6 and discussion their effect on our `UDT-QA` system. We identify 2 common patterns where raw tables are inferior to verbalized tables, as shown in the first 2 rows of Table 6. In the first example, *the concatenated numbers in the raw table can be hard to interpret*, and we have to carefully align the row with the header, which is very far away. In the second example, *the raw infobox can be in ill-format and very long*, making it hard to understand. On the other hand, the verbalized row clearly states the answer evidence by connecting the information in the headers with cell values, making it straightforward to find the answer.

At the same time, we also notice the limitation of verbalized tables: table structure loss. We found that raw tables are better at answering ranking questions, as the examples shown in row 3&4 of Table 6. When asked about the top or bottom ranked subject, the model can directly look for evidence from the starting or the end of the table. On the other hand, when the table is verbalized, the model can not rely on such shortcuts because the boundary of rows is not clear and *the original structure of the tables are lost.* This also suggests a possible direction for future work: to better incorporate the table structure information in verbalization.

8 Related Work

Data-to-Text Generating text from structured data has been a popular task in NLP. Many dataset have been proposed for this task such as Wikibio (Lebret et al., 2016), Rotowire (Wiseman et al., 2017), WebNLG (Gardent et al., 2017) and E2E (Novikova et al., 2017), where each dataset focuses on a particular domain. More recently, large-scale datasets that contains open-domain examples have been proposed including DART (Nan et al., 2021), TOTTO (Parikh et al., 2020), WikiTableT (Chen et al., 2021a) and GenWiki (Jin et al., 2020). On the modeling side, finetuning the pretrained models typically achieves promising performance (Ribeiro et al., 2020). Wang et al. (2020) propose customized loss functions to reduce model hallucination during generation. Muti-task learning is used to improve model's robustness towards input variations (Hoyle et al., 2021). Chen et al. (2020b) introduce a generalized format and a pretrained model that can generate text from both table rows and knowledge graphs. Most previous work on data-to-text generation have only conducted internal evaluation, using typical generation metrics such as BLEU and ROUGE, hence the data-to-text is considered the target task. In this paper, we argue that different training strategies and evaluation metrics should be adapted when applying data-to-text models to downstream tasks, i.e. ODQA. Related to our work, Agarwal et al. (2021) convert the entire Wikidata to natural language using a finetuned T5 model (Raffel et al., 2020). In this work, we generalize the data-to-text approach for verbalizing both tables and KB graphs in a unified fashion and study the verbalized knowledge on ODQA.

QA with Data and Text As the knowledge required to answer the questions may not be available in textual corpus, previous studies have sought to incorporate knowledge from difference sources such as tables and knowledge bases. Min et al. (2019) use Wikidata to expand seed passages found by the retriever and enhance encoded passage representations in the reader. Li et al. (2021) propose a hybrid framework that takes both text and tables as inputs to produce answers and SQL queries. Recently, Chen et al. (2021b) develop the OTT-QA dataset containing questions that require joint reasoning over both tables and text, where the tables and text come from entire Wikipedia. There is also a line of work that studies model architectures for tables specifically or joint encoding of tables and text (Yin et al., 2020; Herzig et al., 2020; Zayats et al., 2021; Glass et al., 2021). However, their focus is not on open-domain QA tasks. Most similar to our work is (Oguz et al., 2020), where they use both tables and Wikidata/Freebase knowledge graph along with Wikipedia text for ODQA. However, they simply linearized structured data without using any verbalizer, thus may suffer from suboptimal input representation. Also, their tables are only mined from original NQ HTMLs, *i.e.* a constrained setting. In contrast, we consider tables from full Wikipedia which is a much larger set. Additionally, separate retrieval models are used for tables and KB in (Oguz et al., 2020) whereas we develop a unified model over text and data.

9 Conclusion

In this paper, we demonstrated that a unified *verbalizer-retriever-reader* framework, `UDT-QA`, for open-domain QA over data and text. We proposed a novel data-to-text paradigm that can largely improve the verbalization effectiveness for downstream knowledge-intensive applications, *i.e.* open-domain QA, when attaining good intrinsic performances. With the verbalized knowledge, we achieved a new state-of-the-art result for NQ. Remarkably, we showed that simply augmenting the text index with the verbalized knowledge improve the performance without retraining the model.

In addition to our method, there are many recently proposed approaches for open-domain QA that are orthogonal. For example, language models specifically optimized for dense retrieval (Gao and Callan, 2021), pretraining on large-scale QA data (Oğuz et al., 2021) and hybrid system that consists of retriever, reranker, extractive reader and generative reader (Fajcik et al., 2021). Incorporating those methods may further improve the performance for open-domain QA, and we leave that exploration for future work. Lastly, instead of only considering a *sanitized* collection of knowledge sources, it is an interesting future direction to scale up the knowledge to web-scale (Nakano et al., 2021; Piktus et al., 2021).

Table 7: Statistics of Document Index

A Document Index Statistics

To be consistent with text passages, we also cut tables and KB sub-graphs (raw or verbalized) into chunks that has about 100 words. Hence the verbalized knowledge will have larger index size than raw format (see Table 7).

B Training Details

To train the retriever to better handle knowledge from tables and KB, we create additional training data from `NQ-Table-Q` and `WebQ-KB-Q`. Given a (question, answer, gold table) from `NQ-Table-Q`, we create a positive passage by concatenating rows containing the answer. Then we randomly sample and concatenate other rows in the table if the passage has less than 100 words. To find negative passages for training, we build a index consists of all the tables and use BM25 to retrieve relevant tables. Ones that do not contain the answer are considered as negative tables. Then we sample rows from the table to build negative passages. For the raw tables, the process is the same except that we also concatenate headers in the beginning to build positive and negative passages. We combine NQ training data with this set to train DPR.

For `WebQ-KB-Q`, we use the verbalized gold sub-graphs as positive passages. For the raw format, this is replaced by flattening the gold sub-graph. Then we build an index with all documents in `WD-graphs` and the top ranked documents by BM25 that do not contain the answer are treated as negatives. Here the documents refer to concatenated triples set for raw setting and sentences produced by the generator in verbalized setting. Additionally, we search through answer entities and their neighbors in the graph to find documents that has word overlap with the question. Then we build training instances in a similar fashion.

As pointed by previous work (Oguz et al., 2020), mining harder negative passages using DPR and iterative training leads to better performance. We also adopted this approach in our experiments. After the first DPR is trained, we used it to retrieve passages from a joint index of text+`structured knowledge`. Then the negative passages are paired with the positive passages from the first round to build new sets of training data. Then we train a second DPR using the iteration1 data combined with the new training sets.

Table 8: Impact of document index size over separately trained retriever-reader models (Top for NQ and bottom for WebQ). All metrics are computed on the corresponding test set.

For retriver training, we follow the experiment set-up as specified by (Karpukhin et al., 2020). Specifically, we use the Adam optimizer and a per-gpu batch size of 32 for NQ and 24 for WebQ, respectively. All trainings are done with a fixed learning rate of $2e-5$ and 40 epochs using 8 V100 GPUs. We select the best model based on the retrieval accuracy on the corresponding dev set.

For reader training, we follow the experiment set-up as described in (Cheng et al., 2021b). Specifically, we use the Adam optimizer and a batch size of 16 for NQ and 8 for WebQ, respectively. We use 16 and 8 V100 GPUs for NQ and WebQ respectively. We select the learning rate in $\{3e-5, 5e-5\}$ and number of training epochs in $\{6, 8\}$. The best model is selected based on EM on the corresponding dev set. All of our reported results are obtained from a single run.

Regarding the number of parameters in the model, our verbalizer is based on T5-large, which has 770M parameters. Our retriever is a bi-encoder model based on bert-base, which has 220M parameters. Our reader model is based on ELECTRA-large, which has 330M parameters.

C Impact of Document Index Size

We report the test set results of models trained with different document index in Table 8 (corresponding

to Table 3). Overall, we observe similar trends. For NQ, the model benefits more from a larger document index while for WebQ the restricted setting yield better performance.

D Comparison betweeh Our Verbalizer and KELM-verbalizer

We report the dev set results of WebQ models trained with our verbalized `WD-graphs` in comparison with KELM in Table 9 (corresponding to Table 5).

E Case Study on Raw vs Verbalized Tables

For manual analysis of verbalized and raw tables, we start by computing the error matrix of the NQ models trained with text+`All-tables` in both format, as shown in Table 10. We then manually annotated 100 examples where only 1 format of knowledge successfully answered the question (50 for each format), and we select examples where at least 1 table chunk is marked as positive by the retriever. Out of 50 examples where verbalized tables contain the answer span, 40 of them are true positives that provide direct evidence to the questions. In 35 out of 40 questions, the retriever for the raw model actually find the same table/chunks that provide the answer. However, the model failed to extract answer for those cases and we think it's mainly because the raw format of the noisy tables can be hard for the model to reason over, as discussed in section 7.

We then looked at the other group of 50 questions (raw format). 37 of them are true positives that contain direct evidence. Then in 30 out of 37 questions, the verbalized retriever is able to find the corresponding verbalized table/chunks that also contain the answer. The remaining cases are all due to retriever failed to find the true positive table chunks. In these 30 cases, the most noticeable pattern is that the model is able to leverage structural shortcut to arrive at the answer, suggesting the limitation of verbalized tables.

F Data-to-text Examples

In the top half of Table 11 we show examples from DART that are filtered out by our method, i.e. low ROUGE scores between input and target. In the first example, information from 2 cells are completely omitted from the target. The model may learn to omit information from this kind of examples, which is problematic when we consider QA as our downstream task. Our filtering method is also able to prune noisy examples, as shown in row 2&3, where there is little correspondence between input and target. In row 4, we show an example where the target contains the information not exist in the input. This kind of examples may teach the model to hallucinate which is also an unwanted behavior, hence they are also filtered out.

In the bottom half of Table 11 we show examples from `ID-T` set, i.e. good quality input-output pairs produced by the verbalizer trained on `T-F` set, when applied to our table sets. These examples often have longer inputs and/or larger table cells and the information coverage rate in target is very high. By combining `ID-T` set with `T-F` set to train a new verbalizer, the model can more effectively learn to generate faithful description of the input.

Finally, in Table 12 we show examples of question-answer pairs along with their associated gold tables(rows). For each raw input, we show its corresponding output generated by the verbalizer trained on `T` and the verbalizer trained on `T-F+ID-T`. We can see that the direction evidence to the answer is present in one of the raw table cells, however in all 3 cases the verbalizer(`T`) failed to generate that piece of information. On the other hand, the verbalizer(`T-F+ID-T`) faithfully described all information presented in the input, showing the effectiveness of our proposed method.

Abstract

Round-trip Machine Translation (MT) is a popular choice for paraphrase generation, which leverages readily available parallel corpora for supervision. In this paper, we formalize the implicit similarity function induced by this approach, and show that it is susceptible to non-paraphrase pairs sharing a single ambiguous translation. Based on these insights, we design an alternative similarity metric that mitigates this issue by requiring the entire translation distribution to match, and implement a relaxation of it through the Information Bottleneck method. Our approach incorporates an adversarial term into MT training in order to learn representations that encode as much information about the reference translation as possible, while keeping as little information about the input as possible. Paraphrases can be generated by decoding back to the source from this representation, without having to generate pivot translations. In addition to being more principled and efficient than round-trip MT, our approach offers an adjustable parameter to control the fidelity-diversity trade-off, and obtains better results in our experiments.

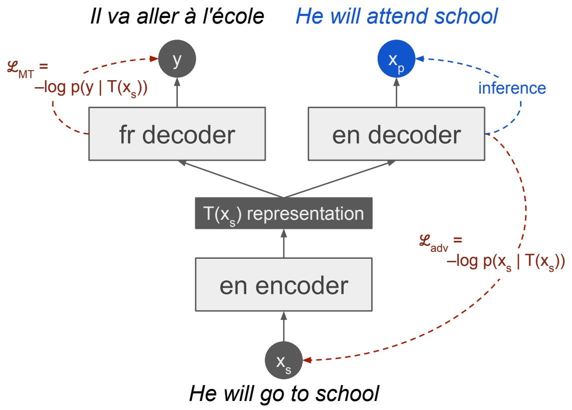

Figure 1: **Proposed system.** Given the input x_s, we aim to learn a representation $T(x_s)$ that encodes as much information as possible about it's reference translation y (ensuring that the meaning is preserved), and as little information as possible about x_s itself (ensuring that surface information is removed). We achieve this through adversarial learning, where the encoder minimizes $\lambda\mathcal{L}_{MT} - (1-\lambda)\mathcal{L}_{adv}$ and the two decoders minimize $\mathcal{L}_{MT}$ and $\mathcal{L}_{adv}$. At inference time, we couple the English encoder and decoder to generate a paraphrase x_p which, being conditioned on $T(x)$, will preserve the meaning of x_s but use a different surface form.

1 Introduction

Paraphrase generation aims to generate alternative surface forms expressing the same semantic content as the original text (Madnani and Dorr, 2010), with applications in language understanding and data augmentation (Zhou and Bhat, 2021). One popular approach is to use an MT system to translate the input text into a pivot language and back (Wieting and Gimpel, 2018; Mallinson et al., 2017; Roy and Grangier, 2019). While it intuitively makes sense that translating to another language and back should keep the meaning of a sentence intact while changing its surface form, it is not clear what exactly would be considered a paraphrase by such a system.

In this work, we show that the probability of a paraphrase x_p given a source sentence x_s under a round-trip MT system can be naturally decomposed as $P(x_p|x_s) = P(x_p)S(x_p, x_s)$, where S is a symmetric similarity metric over the paraphrase space and $P(x_p)$ the probability of x_p. We argue that this similarity function is not appropriate in the general case, as it can assign a high score to sentence pairs that share an ambiguous translation despite not being paraphrases of each other. This phenomenon is illustrated in Figure 2, where x_s and x_p share a confounding translation without gender marker.

So as to address this issue, we design an alternative similarity function that requires the entire translation distribution to match, and develop a relaxation of it through the Information Bottleneck (IB) method. We implement this approach using an adversarial learning system depicted in Figure 1.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1621 - 1638
May 22-27, 2022

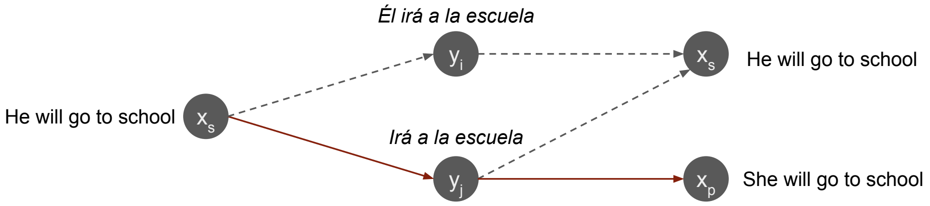

Figure 2: **Confounding translation problem in round-trip MT.** *"Irá a la escuela"* does not mark the gender of the subject due to ellipsis, and it is thus a valid translation of both *"He will go to school"* and *"She will go to school"*. As a consequence, round-trip MT could generate *"She will go to school"* as a paraphrase of *"He will go to school"*. Our approach mitigates this issue by requiring the full translation distribution to match.

Our model combines an encoder that, for a given sentence, removes the information that is not relevant to predict its translation, and a decoder that reconstructs a paraphrase from this encoding. In addition to being more principled, our approach is more efficient than round-trip MT at inference, can be tuned to favor fidelity or diversity, and achieves a better trade-off between the two. Our code is freely available [1].

2 Related Work

We next review the paraphrase generation literature (§2.1), and describe the information bottleneck method (§2.2), which is the basis of our proposal.

2.1 Paraphrase generation

Early work on paraphrasing focused on retrieval methods, either extracting plausible sentences from large corpora for generation (Barzilay and McKeown, 2001; Bannard and Callison-Burch, 2005), or identifying paraphrase pairs from weakly aligned corpora to create paraphrase datasets (Coster and Kauchak, 2011; Dolan et al., 2004). More recently, neural approaches for paraphrase generation have dominated the field. We classify these methods according to the type of supervision they use.

Monolingual corpora. These systems are trained in an unsupervised fashion using unlabeled monolingual corpora. They usually employ an information bottleneck, with the goal of encoding semantic information in the latent space. Approaches include Variational Autoencoders (VAE) (Bowman et al., 2016), VAEs with Vector Quantization (Roy and Grangier, 2019), and latent bag-of-words models (Fu et al., 2019). Huang and Chang (2021) disentangle semantic and syntactic content in the latent space through a bag of words representation, which allows for syntactically controllable generation.

Parallel corpora. These systems are trained on pairs of parallel sentences in two languages. Most of these methods are based on round-trip MT, where a sentence is translated to a pivot language and back in order to obtain a paraphrase. Hu et al. (2019) add lexical constraints to the MT decoding procedure to obtain better paraphrases. Mallinson et al. (2017) generate not one but multiple pivot sentences and use a fusion-in-decoder strategy.

Paraphrase corpora. These systems are trained in a supervised manner over pairs or clusters of paraphrases. When such data is available, training a regular sequence-to-sequence model is a strong baseline (Egonmwan and Chali, 2019). Kumar et al. (2019) add submodular optimization to improve paraphrase diversity. Some VAE-based methods also leverage paraphrase clusters to learn a latent representation that disentangles meaning and form (Iyyer et al., 2018; Kumar et al., 2020; Hosking and Lapata, 2021; Chen et al., 2019). Most of these methods require a syntactic exemplar for generation, and assume that all surface forms are valid for all sentences. Hosking and Lapata (2021) do away with this assumption in the context of question paraphrasing, predicting a valid syntactic embedding from a discrete set at test time.

While it is paraphrase corpora that offers the strongest supervision, such data is hard to obtain and usually restricted to narrow domains like Quora Question Pairs, WikiAnswers and Twitter (Hosking and Lapata, 2021; Kumar et al., 2019; Egonmwan and Chali, 2019). In contrast, parallel corpora is widely available, while offering a stronger training signal than monolingual corpora. For that reason, round-trip MT is a common choice when paraphrases are needed for downstream tasks (Xie et al.,

---

[1] `https://github.com/aitorormazabal/paraphrasing-from-parallel`

2020; Artetxe et al., 2020), as well as a common baseline in the paraphrasing literature (Hosking and Lapata, 2021; Roy and Grangier, 2019).[2] Our work focuses on this class of systems, identifying the limitations of round-trip MT and proposing a more principled alternative.

2.2 The Information Bottleneck Method

Given two random variables X, Y, the Information Bottleneck (IB) method (Tishby et al., 1999) seeks to learn a representation $T(X)$ that minimizes the Mutual Information (MI) between T and X, while preserving a minimum MI between T and Y. That is, the objective $I(X,T)\ s.t.\ I(T,Y) \geq \gamma$ is minimized. Since the MI is usually impossible to calculate exactly for neural representations, a common approach is to use variational methods, that turn the estimation problem into an optimization one. This can be done by adding a neural decoder on top of the representation, and training the entire system end-to-end (Poole et al., 2019). This is the approach we follow in this work.

3 Characterizing Round-trip MT

Let X be a random variable representing a sequence in the source language, and Y be a random variable representing its translation into a pivot language.[3] Given an input sequence $x_s \in X$, we can use round-trip MT to generate a paraphrase $x_p \in X$ by translating x_s into the pivot language and back, according to the forward and backward translation models $P(y|x_s)$ and $P(x_p|y)$. As such, we can formulate the probability of round-trip MT generating a particular paraphrase x_p by marginalizing over the set of possible pivot translations:

$$P(x_p|x_s) = \sum_{y \in Y} P(y|x_s) P(x_p|y) \tag{1}$$

In what follows, we will characterize the paraphrases produced by this approach, i.e. the properties that x_p needs to meet in relation to x_s for $P(x_p|x_s)$ to be high.[4]

By applying Bayes' rule, we can rewrite Eq. 1 as follows:

$$P(x_p|x_s) = P(x_p) \underbrace{\sum_{y \in Y} \frac{P(y|x_s)P(y|x_p)}{P(y)}}_{S_{MT}(x_p, x_s)} \tag{2}$$

The sum on the right hand side can be interpreted as a symmetric similarity function, $S_{MT}(x_p, x_s) = S_{MT}(x_s, x_p) = \sum_y \frac{P(y|x_s)P(y|x_p)}{P(y)}$, which measures the likelihood of two sentences to be actual paraphrases. The probability of x_p given x_s then becomes $P(x_p|x_s) = P(x_p) S_{MT}(x_p, x_s)$, which is the similarity between x_s and x_p, weighted by the marginal probability of x_p.

But when are x_s and x_p considered similar according to the above definition of $S_{MT}(x_s, x_p)$? Intuitively, S_{MT} is a measure of the *overlap* between the conditional distributions that x_s and x_p induce over Y. This will be highest when $P(y|x_s)P(y|x_p)$ is as large as possible for as many y as possible. At the same time, $P(y|x_s)P(y|x_p)$ will be high when both $P(y|x_s)$ and $P(y|x_p)$ are high, that is, when y is a probable translation of both x_s and x_p. This captures the intuition that two sentences are similar when they can be translated into the same text in the pivot language.

But what if x_s and x_p have one particular high-probability translation y_j in common, but differ in the rest? As illustrated in Figure 2, this can happen when y_j is ambiguous in the target language and can mean both x_s and x_p, even if x_s and x_p are not equivalent (e.g., when x_s uses the masculine form, x_p the feminine form, and y_j does not mark the gender). In this case, the sum $\sum_y \frac{P(y|x_s)P(y|x_p)}{P(y)}$ will be dominated by $\frac{P(y_j|x_s)P(y_j|x_p)}{P(y_j)}$, which will be high when both $P(y_j|x_s)$ and $P(y_j|x_p)$ are high.

We can thus conclude that the implicit similarity function underlying round-trip MT is flawed, as it assigns a high score to a pair of sequences (x_s, x_p) that have an ambiguous translation in common. As a consequence, round-trip MT will generate x_p as a paraphrase of x_s with a high probability, even if the two sequences have a different meaning.

4 Principled Paraphrasing

As shown in the previous section, the implicit similarity function induced by round-trip MT is not adequate in the general case, as it assigns a high score to pairs of sequences that share a single translation, despite differing in the rest. So as to address

---

[2] Round-trip MT has also been used to generate synthetic paraphrase corpora (Wieting and Gimpel, 2018).

[3] For convenience, we will also use X and Y to refer to the set of source and target language sequences, and abbreviate probabilities of the form $P(X = x)$ as $P(x)$.

[4] Some round-trip MT systems do not consider all possible translations into the pivot language, but only a subset of them (Mallinson et al., 2017). In that case, the sum in Eq. 1 goes over $y \in \{y_1, ..., y_K\}$, and we need to introduce a partition $Z = \sum_{y \in \{y_1,...,y_K\}} P(y|x_s)$ to normalize the probabilities. However, the fundamental analysis in this section still applies. Refer to Appendix A for more details.

this, we can define an alternative similarity function that requires the entire translation distribution to match:

$$S(x_p, x_s) = \begin{cases} 1 & P(y|x_p) = P(y|x_s) \forall y \in Y \\ 0 & \text{otherwise} \end{cases} \tag{3}$$

and use it to replace S_{MT} in Eq. 2 so that $P(x_p|x_s) \propto P(x_p)S(x_p, x_s)$. However, this definition is too strict, as it is virtually impossible that $P(y|x_p)$ and $P(y|x_s)$ are exactly the same for all $y \in Y$.[5] In 4.1, we define a relaxation of it through the IB method, which introduces an adjustable parameter β to control how much we deviate from it. In 4.2, we characterize the paraphrases generated by this approach, showing that they are less susceptible to the problem of confounding translations described in the previous section.

4.1 IB-based relaxation

So as to implement the similarity function in Eq. 3, we will use the IB method to learn an encoding T for X such that the following holds:

$$S(x_p, x_s) = \frac{P(x_p|T(x_s))}{P(x_p)Z(x_s)} \tag{4}$$

where $Z(x_s)$ is a normalizer that does not depend on the paraphrase candidate x_p.

As seen in §2.2, given a source variable X and a target variable Y, the IB method seeks to find an encoding $T(X)$ that minimizes the MI with X (maximizing compression), while preserving a certain amount of information about Y:

$$\min_T I(X, T) \; s.t \; I(T, Y) \geq \gamma. \tag{5}$$

This constrained minimization is achieved by introducing a Lagrange multiplier β and minimizing

$$\min_T I(X, T) - \beta I(T, Y). \tag{6}$$

As $\beta \to \infty$, all the information about Y is preserved and the IB method learns a minimal sufficient statistic T, that is, an encoding that satisfies $I(T, Y) = I(X, Y)$ while achieving the lowest $I(T, X)$ possible. The following theorem states that such a minimal sufficient statistic T induces the similarity function in Eq. 3 (proof in Appendix C):

Theorem 1. *Suppose the random variable X represents a sentence in the source language, Y represents its translation, and T is a minimal sufficient statistic of X with respect to Y. Let* x_p *and* x_s *be a pair of sentences in the source language. Then,* $P(x_p|T(x_s)) = P(x_p)\frac{S(x_p,x_s)}{Z(x_s)}$, *where S is given by Equation 3, and Z is a normalizing factor that does not depend on* x_p.

Thus, as $\beta \to \infty$ the IB method approximates the similarity metric S. In practice, when β is set to a fixed finite number, losing some information about the target variable is allowed, and a relaxation of the metric S is learned instead.

4.2 Characterizing IB-based paraphrasing

We will next analyze the relaxation of S induced by the IB method. We will characterize what kind of sentences are considered paraphrases by it, showing that it is less susceptible to the problem of confounding translations found in round-trip MT (§3). Derivations for the results in this section, as well as alternative bounds and broader discussion can be found in Appendix B.

As seen in §4.1, we define paraphrase probabilities given an encoding T as $P(x_p|T(x_s)) = P(X = x_p|T(X) = T(x_s))$, which can only be non-zero if $T(x_p) = T(x_s)$. This means that the encoding T will partition the source space into a collection of paraphrase clusters according to its value. Mathematically, given the equivalence relation $x_1 \sim x_2 \iff T(x_1) = T(x_2)$, only sentence pairs within the same equivalence class will have non-zero paraphrase probabilities. We then have the following theorem:

Theorem 2. *Suppose* T *is a solution of the IB optimization problem* $\min_T I(X, T) \; s.t \; I(T, Y) \geq \gamma$, *and* $\epsilon = I(X, Y) - \gamma$. *If* $\mathcal{A}$ *is the partition on* X *induced by* T, *we have:*

$$\sum_{A \in \mathcal{A}} \max_{x_1, x_2 \in A} \frac{P(x_1)P(x_2)}{2(P(x_1) + P(x_2))} \cdot D_1(P_{Y|x_1}, P_{Y|x_2})^2 \leq \epsilon, \tag{7}$$

where D_1 *is the* L_1 *norm distance.*

It is easy to see that, when $\epsilon = 0$, corresponding to $\gamma = I(X, Y)$ and $\beta \to \infty$, this forces all distances to be zero. In that case, only sentences with identical translation distributions are considered paraphrases, in accordance with Theorem 1.

In the general case, Theorem 2 states that the L_1 distance between the translation distributions of

---

[5] One reason is that we use empirical estimates of $P(y|x_p)$ and $P(y|x_s)$, which will deviate from the ground truth.

sentences that are considered paraphrases cannot be high, as it will be bounded by a function of ϵ. While the S_{MT} metric in §3 can be dominated by a high-probability term and effectively ignore differences in probability for the less likely translations, the L_1 norm gives equal importance to differences in probability for every translation candidate. Thanks to this, the resulting system will be less susceptible to the problem of confounding translations.

5 Proposed System

In this section, we describe a practical implementation of the IB-based paraphrasing approach defined theoretically in §4.

As illustrated in Figure 1, our system can be seen as an extension of a regular encoder-decoder MT architecture with an additional adversarial decoder, which is trained with an auto-encoding objective to reconstruct the original sentence x_s from the encoder representation $T(x_s)$. The encoder is trained to minimize the cross-entropy loss of the MT decoder, while maximizing the loss of the adversarial decoder. This way, the encoder is encouraged to remove as much information about x_s as possible, while retaining the information that is necessary to predict its reference translation y. Thanks to this, $T(x_s)$ should capture the semantic content of x_s (which is relevant to predict y), without storing additional surface information (which is not relevant to predict y). Once the model is trained, the adversarial decoder can be used to generate paraphrases of x_s from this representation $T(x_s)$.

This adversarial architecture can be interpreted as an implementation of the IB method as follows. Following Poole et al. (2019), we start by adding a decoder $q(y|t)$ on top of the encoder $T(x)$, and rewrite the $I(T, Y)$ term as:

$$\begin{aligned} I(T,Y) &= \mathbb{E}_{P(y,t)}\left[\log \frac{q(y|t)}{P(y)}\right] \\ &\quad + \mathbb{E}_{P(t)}[KL(P(y|t)||q(y|t))] \\ &\geq \mathbb{E}_{P(y,t)}\Big[\log q(y|t)\Big] + h(Y), \end{aligned} \tag{8}$$

where equality will hold if q is the true conditional distribution $q(y|t) = P(y|t)$, and h is the differential entropy. If we parametrize T and q by a neural network encoder-decoder architecture the $\mathbb{E}_{P(y,t)}\Big[\log q(y|t)\Big]$ term in Eq. 8, can be rewritten as $\mathbb{E}_{P(y,x)}\Big[\log q(y|T(x))\Big]$, which is precisely the log likelihood of the data distribution of X, Y given by P. In other words, by training the encoder-decoder to maximize Eq. 8, we are implicitly maximizing the mutual information $I(T, Y)$.

Similarly, one can approximate

$$\begin{aligned} I(X,T) &\geq \mathbb{E}_{P(x,t)}\Big[\log q(x|t)\Big] + h(X) \\ &= \mathbb{E}_{P(x)}\Big[\log q(x|T(x))\Big] + h(X), \end{aligned} \tag{9}$$

where equality will hold when q is the true conditional distribution and $q(x|T(x)) = P(x|T(x))$. Thus, given an ideal decoder q that perfectly approximates the conditional distributions $q(x|T(x))$ and $q(y|T(x))$, the IB minimization problem is equivalent to minimizing

$$\begin{aligned} &\mathbb{E}_{p(x)}\Big[\log q(x|T(x))\Big] - \beta\mathbb{E}_{P(y,t)}\Big[\log q(y|t)\Big] \\ &= \mathbb{E}_{P(x,y)}\Big[\log q(x|T(x)) - \beta \log q(y|T(x))\Big]. \end{aligned} \tag{10}$$

In practice, we parametrize both the encoder T and the decoder q with transformer neural networks, and learn them from a parallel corpus. Since $\log q(y|T(x))$ is a lower bound of $I(T, Y) - h(Y)$, maximizing this term is theoretically sound. Minimizing $\mathbb{E}_{P(x)}\Big[\log q(x|T(x))\Big]$, on the other hand, amounts to minimizing a lower bound, which, while not as theoretically solid, is common practice in the variational optimization literature (Chen et al., 2018; Kim and Mnih, 2018).

Finally, we reparametrize Eq. 10 by setting $\lambda = \frac{\beta}{1+\beta}$ to obtain the equivalent minimization objective

$$\begin{aligned} \mathcal{L}(T,q) &= \mathbb{E}_{P(x,y)}[-\lambda \log q(y|T(x)) \\ &\quad +(1-\lambda) \log q(x|T(x))] = \\ &\quad \lambda\mathcal{L}_{MT}(T,q) - (1-\lambda)\mathcal{L}_{Adv}(T), \end{aligned} \tag{11}$$

where $\mathcal{L}_{MT}$ is the regular MT loss of cross-entropy with the translation target, and $\mathcal{L}_{Adv}$ is the cross-entropy with the source sentence (see Figure 1).[6] We thus observe that the proposed adversarial training architecture approximates the IB method. The

---

[6] We make the adversarial term a function of T only in the minimization objective, as the gradient from the adversarial term is only propagated to the encoder. The adversarial decoder is independently trained to predict the source from the encoded representation.

setting $\beta \to \infty$ corresponds to $\lambda \to 1$, where the optimal solution is a minimal sufficient statistic.

During training, the expectation in Eq. 11 is approximated by sampling batches from the training data. Care must be taken when optimizing the loss, as we do not want to propagate gradients of the adversarial loss to the adversarial decoder. If we did, a trivial way to minimize $(1-\lambda)\log q(x|T(x))$ would be to make the decoder bad at recovering x, which would not encourage $T(x)$ to encode as little information as possible. To prevent this, we use a percentage K of the batches to learn the adversarial decoder $\log q(x|T(x))$, where the encoder is kept frozen. The rest of the batches are used to optimize the full term $-\lambda \log q(y|T(x)) + (1-\lambda)\log q(x|T(x))$, but the gradients for the second term are only propagated to the encoder.

6 Experimental Design

We experiment with the following systems:

- **Proposed.** Our system described in §5. We share the weights between the MT decoder and the adversarial decoder, indicating the language that should be decoded through a special language ID token. Unless otherwise indicated, we use $\lambda = 0.73$ and $K = 0.7$, which performed best in the development set.[7]
- **Round-trip MT.** A baseline that uses two separate MT models to translate into a pivot language and back (see §3).
- **Copy.** A baseline that copies the input text.

We use mBART (Liu et al., 2020) to initialize both our proposed system and round-trip MT, and train them using the same hyper-parameters as in the original work.[8] In both cases, we use the English-French WMT14 dataset (Bojar et al., 2014) as our parallel corpus for training.[9] We report results for two decoding strategies: beam search with a beam size of 5, and top-10 sampling with a temperature of 0.9 (optimized in the development set).[10]

Model	Self-BLEU ↓ (diversity)	BLEU ↑ (fidelity)	iBLEU ↑ (combined)
Copy	100.0	23.0	-13.9
MT (beam)	51.1	18.8	-2.17
MT (sampling)	41.4	15.8	-1.36
Ours (beam)	33.0	15.5	0.95
Ours (sampling)	27.3	13.2	**1.05**
Human	18.1	19.8	8.43

Table 1: **Results on the MTC dataset for three baselines (top rows), our two systems, and human performance.** ↓ smaller is better, ↑ larger is better.

We consider two axes when evaluating paraphrases: *fidelity* (the extent to which the meaning of the input text is preserved) and *diversity* (the extent to which the surface form is changed). Following common practice, we use a corpus of gold paraphrases to automatically measure these. More concretely, given the source sentence s, the reference paraphrase r and the candidate paraphrase c, we use BLEU(c, r) as a measure of fidelity, and BLEU(c, s)—known as self-BLEU—as a measure of diversity. An ideal paraphrase system would give us a high BLEU, with as low a self-BLEU as possible. Given that there is generally a tradeoff between the two, we also report iBLEU = α BLEU $-(1-\alpha)$ self-BLEU, which combines both metrics into a single score (Mallinson et al., 2017). Following Hosking and Lapata (2021), we set $\alpha = 0.7$.

For development, we extracted 156 paraphrase pairs from the STS Benchmark dataset (Cer et al., 2017), taking sentence pairs with a similarity score above 4.5. For our final evaluation, we used the Multiple Translations Chinese (MTC) corpus (Huang et al., 2002), which comprises three sources of Chinese journalistic text translated into English by multiple translation agencies. We extract the translations of the first two agencies to obtain an test set of 993 paraphrase pairs, where one is the source and the other the reference paraphrase. The third sentence if kept as an additional paraphrase for estimating human performance.

7 Results

We next report our main results (§7.1), followed by a qualitative analysis (§7.2).

7.1 Main results

We report our main results in Table 1. As it can be seen, our proposed system outperforms all baselines in terms of iBLEU, indicating that it achieves

---

[7] We performed a grid search, where $\lambda \in \{0.7, 0.73, 0.8\}$ and $K \in \{0.7, 0.8\}$, and chose the checkpoint with best iBLEU with $\alpha = 0.7$.

[8] 0.3 dropout, 0.2 label smoothing, 2500 warm-up steps, $3e-5$ maximum learning rate, and $100K$ total steps.

[9] We filter the dataset by removing sentence pairs with a source/target length ratio that exceeds 1.5 or are longer than 250 words.

[10] In the case of round-trip MT, we always use beam search to generate the pivot translation, and compare the two approaches to generate paraphrases from it.

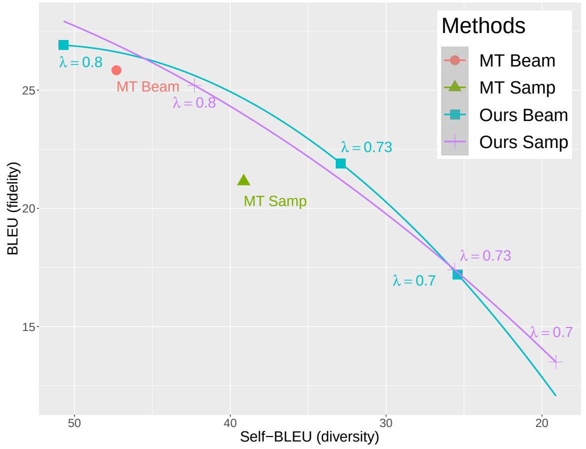

Figure 3: **Effect of varying the λ parameter on the development set.** BLEU in the vertical axis. The horizontal self-BLEU axis is mirrored, so systems toward the top right have the best trade-off between diversity and fidelity.

a better trade-off between diversity and fidelity. This advantage comes from a large improvement in diversity as measured by self-BLEU, at a cost of a small drop in fidelity as measured by BLEU. Both for round-trip MT and our proposed system, beam search does better than sampling in terms of fidelity, at the cost of sacrificing in diversity. Finally, the human reference scores show ample room for improvement in both axes.

While our proposed system achieves the best combined score, our results also show that different approaches behave differently in terms of diversity and fidelity. In practice, it would be desirable to have a knob to control the trade-off between the two, as one may want to favor diversity or fidelity depending on the application. One additional advantage of our approach over round-trip MT is that it offers an adjustable parameter λ to control the trade-off between these two axes. So as to understand the effect of this parameter, we tried different values of it in the development set, and report the resulting curve in Figure 3 together with the MT baselines. BLEU and Self-BLEU scores of the best checkpoints for each λ (0.7,0.73,0.8) and plot the results together with the MT baselines for our systems in Figure 3.

As expected, higher values of λ yield systems that tend to copy more, being more faithful but less diverse. Consistent with our test results, we find that, for a given value of λ, beam search does better than sampling in terms of fidelity, but worse in terms of diversity, yet both decoding strategies can be adjusted to achieve a similar trade-off. More importantly, we observe that both curves are above round-trip MT, the gap being largest for the sampling variant. We can thus conclude that our proposed approach does better than round-trip MT for a comparable trade-off between diversity and fidelity, while offering a knob to adjust this trade-off as desired.

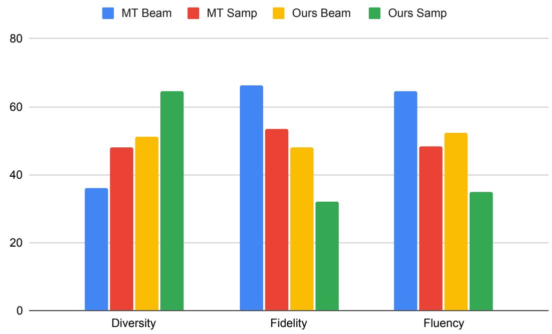

Figure 4: **Human evaluation results (larger is better).** Refer to §7.2 for more details.

7.2 Qualitative analysis

So as to better understand the behavior of our approach in comparison with round-trip MT, we carried out a human evaluation through Amazon Mechanical Turk. Following the setup of Hosking and Lapata (2021), we sample 200 sentences from the MTC corpus and generate a pair of paraphrases for each of them, randomly choosing two systems to generate them. We then ask human evaluators to compare the two sentences according to three criteria: diversity, fidelity and fluency. More details about the judging criteria can be found in Appendix D.

Figure 4 reports the percentage of head-to-head comparisons that each system has won. The results that we obtain are consistent with the trends observed in §7.1. More concretely, we observe that the beam search variant of round-trip MT achieves the best results in terms of fluency and fidelity, but does worst in diversity, indicating a tendency to copy. Our method with beam search does slightly better than the sampling MT variant in terms of diversity and slightly worse in terms of fidelity —indicating a tendency to favor diversity over fidelity— while also being more fluent. Finally, the sampling variant of our method achieves the best diversity, but has the worst fidelity and fluency.

So as to further contrast these results, we manu-

Table 2: Sample paraphrases generated by the different methods.

ally analyzed some paraphrases,[11] and report some examples in Table 2. Just in line with our previous results, we observe that the beam search variant of round-trip MT tends to deviate the least from the original sentence, while the sampling variant of our method generates the most diverse paraphrases (e.g., changing *"sales of vehicles were not included"* to *"vehicles were not included in sales"*). At the same time, we observe that this tendency to improve diversity can cause artifacts like paraphrasing named entities (e.g., changing *"National Youth League"* to *"National League of Youth"*), which can partly explain the drop in fidelity.

8 Conclusions

In this work, we have shown that the implicit similarity function present in round-trip MT is not appropriate in the general case, as it considers sentence pairs that share a single ambiguous translation to be paraphrases. We address this issue by designing an alternative similarity function that requires the entire translation distribution to match, and develop a relaxation of it through the IB method, which we prove to be less susceptible to the problem of confounding translations. We implement this approach through adversarial learning, training an encoder to preserve as much information as possible about the reference translation, while encoding as little as possible about the source. Not only is our approach more principled than round-trip MT, but it is also more efficient at inference, as it does not need to generate an intermediate translation. In addition, it offers a knob to adjust the fidelity-diversity trade-off through the λ parameter, and obtains strong results in our experiments, outperforming round-trip MT.

A Round-trip MT with restricted sampling

Our formulation in Section 3 considers all possible translations into the pivot language. In practice, some round-trip MT systems use restricted sampling, considering only a subset of Y. For example, ParaNET (Mallinson et al., 2017) takes the K highest probability translations given by beam search. As we show next, the fundamental analysis in Section 3 still holds in that case, and the problem of confounding translations can even be exacerbated by it.

More concretely, using this pivot selection strategy yields the following adjusted paraphrase probability:

$$P(x_p|x_s) = P(x_p) \sum_{y\in\{y_1,...,y_K\}} \frac{P(y|x_s)P(y|x_p)}{ZP(y)}, \tag{12}$$

where $\{y_1, ..., y_K\}$ are the top translation candidates and $Z = \sum_{y\in\{y_1,...,y_K\}} P(y|x_s)$. In general, if a subset $S(x_s) \in Y$ of the translation space is considered as pivots, the paraphrase probability will be

$$P(x_p|x_s) = P(x_p) \sum_{y\in S(x_s)} \frac{P(y|x_s)P(y|x_p)}{Z(x_s)P(y)} = \frac{P(x_p)}{Z(x_s)} S'_{MT}(x_p, x_s), \tag{13}$$

where $Z(x_s) = \sum_{y\in S(x_s)} P(y|x_s)$ is a normalizing factor that doesn't depend on the paraphrase x_p, and $S'_{MT}(x_p, x_s)$, is the same similarity function as S_{MT}, with the sum over y restricted to $S(x_s)$.

Using restricted pivot selection strategies such as beam search, top-K sampling, or nucleus sampling (Holtzman et al., 2020) will yield different pivot subsets $S(x_p)$, which will lead to paraphrase probabilities being assigned based on a limited subset of the entire translation distribution. This can exacerbate the issues outlined in Section 3, where the similarity metric can be dominated by a single shared high-probability translation. For example, in the case of translating from a gendered to a genderless language, while the highest probability translation will be genderless, a lower probability candidate might identify the gender, so skipping this translation sampling would increase the similarity of sentences that differ only in gender.

B Characterizing the encoding learned through the IB method

Since we will not learn a perfect minimal sufficient statistic in practice, it is desirable to characterize what the relaxation of S implemented by the IB method can learn.

To that end, we will characterize the kind of encoding T that is allowed by a given γ. Since T is a function of X, we know that $I(X,Y) \geq I(T,Y)$, and thus the condition $I(T,Y) \geq \gamma$ can be rewritten as $I(X,Y) - I(T,Y) \leq \epsilon$, where $\epsilon \geq 0$, which is the form we use throughout this section.

Now, for matters of conditional translation probabilities $P(y|T(x))$, the encoding T can be fully characterized by the equivalence relation it defines on X, where $x_1 \sim x_2$ iff $T(x_1) = T(x_2)$. Two sentences will induce the same conditional translation distribution $P(y|T(x))$ when they are clustered into the same equivalence class by T.

Theorem 3. *Let $\mathcal{S}$ denote the partition of X induced by the encoding T. We denote the elements of a cluster $S \in \mathcal{S}$ by $S = \{x_1^S, ..., x_{m_S}^S\}$. Then, the information loss $I(X,Y) - I(T,Y)$ is given by:*

$$I(X,Y) - I(T,Y) = \sum_{S\in\mathcal{S}} P(x_1^S) KL(P_{Y|x_1^S} || P_{Y|S}) + ... + P(x_{m_S}^S) KL(P_{Y|x_{m_S}^S} || P_{Y|S}), \tag{14}$$

and the translation probabilities conditioned on a cluster are given by the mixture distribution $P(y|T(x)) = P(y|x \in S) = \alpha_1 P(y|x_1^S) + ... + \alpha_{m^S} P(y|x_{m^S}^S)$, where $\alpha_i = \frac{P(x_i^S)}{P(x_1^S)+...+P(x_{m^S}^S)}$.

The proof can be found in Section C.2. This theorem expresses the information loss of an encoding T, $I(X,Y) - I(T,Y)$, in terms of the KL divergences between the translation distributions of source sentences $P(y|x)$ and the translation distributions given their encodings $P(y|T(x)) = P(y|x \in S)$. Intuitively, if T clusters together two sentences x_1 and x_2 (i.e. $T(x_1) = T(x_2)$ holds), such that $P_{Y|x_1}$ and $P_{Y|x_2}$ are very different, then the mixture distribution $P_{Y|S}$ will be different from both, and thus the information loss will be large.

We will now obtain more intuitive bounds for the information loss. As seen before, the translation distribution given a cluster $P(y|x \in S)$ can be expressed as a mixture of the individual translation distributions for sentences in the cluster:

$$P(y|x \in S) = \frac{P(x_1^S)}{P(x_1^S) + ... + P(x_{m^S}^S)} P(y|x_1^S) + ... + \frac{P(x_{m^S}^S)}{P(x_1^S) + ... + P(x_{m^S}^S)} P(y|x_{m_S}^S). \tag{15}$$

We can also define mixtures of all the distributions $P(y|x_i^S)$ except one, with the same weights as in $P(y|x \in S)$, except for a re-normalization constant. Explicitly, we define:

$$P_j^S(y) = \sum_{i=1, i\neq j}^{m_S} \frac{P(x_i^S) P(y|x_i^S)}{P(x_1^S) + ... + \widehat{P(x_j^S)} + ... + P(x_{m^S}^S)}, \tag{16}$$

where the hat indicates that that element is skipped. Then, we have the following theorem:

Theorem 4. *Let $\mathcal{S}$ be the partition imposed by the encoding function T on X. We denote the elements of a cluster $S \in \mathcal{S}$ by $S = \{x_1^S, ..., x_{m_S}^S\}$. We define the partial mixtures $P_j^S(y)$ as above. Then, if the information loss satisfies $I(X,Y) - I(T,Y) \leq \epsilon$, we have*

$$\sum_{S\in\mathcal{S}} \sum_{i=1}^{m^S} \frac{P(x_i^S)(\beta_i^S)^2}{2} D_1(P_{Y|x_i^S}, P_i^S)^2 \leq \epsilon, \tag{17}$$

where $\beta_j^S = \frac{P(x_1^S)+...+\widehat{P(x_j^S)}+...+P(x_{m^S}^S)}{P(x_1^S)+...+P(x_{m^S}^S)}$ and D_1 is the L^1 norm distance.

The proof can be found in Section C.3. Intuitively, this states that, if the encoding T clusters a set of sentences $x_1, ..., x_n \in S$ together, then the translation distribution for an element $x_i \in S$, $P_{Y|x_i}$, cannot be too far from the mixture of the rest of the distributions $P_{Y|x_j}$, with $j \neq i$.

In the scenario where there are only two sentences in a cluster, $m^S = 2$, we have $P_1 = P_{Y|x_2^S}$ and $P_2 = P_{Y|x_1^S}$, and the inner sum reduces as follows (the derivation is shown in Section C.4):

$$\sum_{i=1}^{m^S} \frac{P(x_i^S)(\beta_i^S)^2}{2} D_1(P_{Y|x_i^S}, P_i^S)^2 = \frac{P(x_1^S)P(x_2^S)}{2(P(x_1^S) + P(x_2^S))} D_1(P_{Y|x_1^S}, P_{Y|x_2^S})^2 \tag{18}$$

Since clustering all the elements of a set S leads to a bigger information loss than only clustering any two elements $x_1, x_2 \in S$, combining Equation 18 and Theorem 4 we obtain Theorem 2 from §4.2 as a corollary:

Theorem 2. *Suppose T is a solution of the IB optimization problem $\min_T I(X,T)$ s.t $I(T,Y) \geq \gamma$, and $\epsilon = I(X,Y) - \gamma$. If $\mathcal{S}$ is the partition on X induced by T, we have:*

$$\sum_{S \in \mathcal{S}} \max_{x_1, x_2 \in S} \frac{P(x_1)P(x_2)}{2(P(x_1)+P(x_2))} D_1(P_{Y|x_1}, P_{Y|x_2})^2 \leq \epsilon, \tag{19}$$

where D_1 is the L_1 norm distance.

This bound is the easiest to interpret intuitively, as it bounds the pairwise distances between the translation distributions of any two sentences that are considered paraphrases by the encoding T. To sum up the results from this section, the information loss allowance when learning with the IB method bounds the L^1 norm distance between the translation distributions of paraphrases. Thus the entire translation distribution is considered when learning paraphrases, potentially alleviating the problems discussed in Section 3

C Proofs

C.1 Proof of Theorem 1

We know that T is a minimal sufficient statistic of Y if and only if the following condition is satisfied:

$$\frac{P(x|y)}{P(x'|y)} \text{ independent of y} \iff T(x) = T(x')\ \forall x, x' \in X \tag{20}$$

Rewriting $P(x|y) = \frac{P(y|x)P(x)}{P(y)}$ and cancelling terms, the LHS becomes:

$$\frac{P_y(x)}{P_y(x')} = \frac{P(y|x)}{P(y|x')}\frac{P(x)}{P(x')}. \tag{21}$$

Since $\frac{P(x)}{P(x')}$ does not depend on y, the entire term will not depend on y if and only if $\frac{P(y|x)}{P(y|x')}$ is independent of y. It is easy to see that the ratio of two distributions of y will be independent of y if and only if they are the exact same distribution, and thus we can conclude that if T is a minimal sufficient statistic of Y then $T(x) = T(x') \iff P(y|x) = P(y|x') \forall y \in Y$, or, equivalently, $T(x) = T(x') \iff S(x,x') = 1$.

Thus, we have

$$\begin{aligned}
P(x_p|T(x_s)) &= P(X = x_p|T(X) = T(x_s)) \\
&= P(X = x_p|S(X, x_s) = 1) \\
&= \frac{P(X = x_p, S(X, x_s) = 1)}{P(S(X, x_s) = 1)} \\
&= \frac{P(X = x_p)P(S(X, x_s) = 1)|X = x_p)}{P(S(X, x_s) = 1)} \\
&= \frac{P(x_p)S(x_p, x_s)}{Z},
\end{aligned} \tag{22}$$

where $Z = P(S(X, x_s) = 1)$ is the normalizer that does not depend on x_p, as we wanted to prove. □

C.2 Proof of Theorem 3

We first expand the information loss:

$$\begin{aligned}
&I(X,Y) - I(T,Y) \\
&= \mathbb{E}_X KL(P_{Y|X}||P_Y) \\
&- \mathbb{E}_T KL(P_{Y|T}||P_Y) = \sum_x P(x) \\
&\Big[\sum_y P(y|x) log(P(y|x)) \\
&- P(y|x) log(P(y))\Big] \\
&- \sum_x P(x) \Big[\sum_y P(y|T(x)) log(P(y|T(x))) \\
&- P(y|T(x)) log(P(y))\Big]
\end{aligned} \tag{23}$$

Now, for matters of conditional translation probabilities $P(y|T(x))$, the encoding T can be fully characterized by the equivalence class it defines on X, where $x_1 \sim x_2$ iff $T(x_1) = T(x_2)$. We let $\mathcal{S}$ denote the partition on X induced by this equivalence class. Then, we can rewrite:

$$
\begin{aligned}
&I(X,Y) - I(T,Y) \\
&= \sum_x P(x)\Big[\sum_y P(y|x)log(P(y|x)) \\
&- \ P(y|x)log(P(y))\Big] \\
&- \sum_x P(x)\Big[\sum_y P(y|T(x))log(P(y|T(x))) \\
&- P(y|T(x))log(P(y))\Big] \\
&= \sum_{S\in\mathcal{S}}\sum_{x\in S} P(x)\Big[\sum_y P(y|x)log(P(y|x)) \\
&- P(y|x)log(P(y))\Big] \\
&- \sum_{S\in\mathcal{S}}\sum_{x\in S} P(x)\Big[\sum_y P(y|x\in S)log(P(y|x\in S)) \\
&- P(y|x\in S)log(P(y))\Big]
\end{aligned} \tag{24}
$$

For a certain $S \in \mathcal{S}$, we denote its elements by $S = \{x^S_1, ..., x^S_{m_S}\}$. Then, we have

$$
\begin{aligned}
P(y|x\in S) &= \frac{P(y, x\in S)}{P(x\in S)} \\
&= \frac{P(y, x^S_1) + ... + P(y, x^S_{m_S})}{P(x^S_1) + ... + P(x^S_{m_S})} \\
&= \alpha^S_1 P(y|x^S_1) + ... + \alpha^S_{m_S} P(y|x^S_{m_S}),
\end{aligned} \tag{25}
$$

where $\alpha^S_i = \frac{P(x^S_i)}{P(x^S_1)+...+P(x^S_{m_S})}$. We also define $\beta^S = P(x^S_1) + ... + P(x^S_{m_S})$. Now, we can rewrite the first expression of the RHS in Equation 24:

$$
\begin{aligned}
&\sum_{S\in\mathcal{S}}\sum_{x\in S} P(x)\sum_y \big[P(y|x)log(P(y|x)) \\
&- P(y|x)log(P(y))\big] \\
&= \sum_{S\in\mathcal{S}}\Big[P(x^S_1)\sum_y P(y|x^S_1)log(P(y|x^S_1)) + ... \\
&+ P(x^S_{m_S})\sum_y P(y|x^S_{m_S})log(P(y|x^S_{m_S}))\Big] \\
&- \Big[\sum_y P(x^S_1)P(y|x^S_1)log(P(y)) + ... \\
&+ P(x^S_{m_S})P(y|x^S_{m_S})log(P(y))\Big] \\
&= \sum_{S\in\mathcal{S}}\Big[P(x^S_1)\sum_y P(y|x^S_1)log(P(y|x^S_1)) + ... \\
&+ P(x^S_{m_S})\sum_y P(y|x^S_{m_S})log(P(y|x^S_{m_S}))\Big] \\
&- \Big[\sum_y \beta^S\alpha^S_1 P(y|x^S_1)log(P(y)) + ... \\
&+ \beta^S\alpha^S_{m_S} P(y|x^S_{m_S})log(P(y))\Big] \\
&= \sum_{S\in\mathcal{S}}\Big[P(x^S_1)\sum_y P(y|x^S_1)log(P(y|x^S_1)) + ... \\
&+ P(x^S_{m_S})\sum_y P(y|x^S_{m_S})log(P(y|x^S_{m_S}))\Big] \\
&- \Big[\beta^S\sum_y P(y|x\in S)log(P(y))\Big]
\end{aligned} \tag{26}
$$

And now we rewrite the second term in the RHS of Equation 24:

$$
\begin{aligned}
&\sum_{S\in\mathcal{S}}\sum_{x\in S}P(x)\sum_{y}\big[P(y|x\in S)log(P(y|x\in S))\\
&-P(y|x\in S)log(P(y))\big]\\
&=\sum_{S\in\mathcal{S}}\Bigg[P(x_1^S)\sum_{y}P(y|x\in S)log(P(y|x\in S))\\
&+P(x_{m_S}^S)\sum_{y}P(y|x\in S)log(P(y|x\in S))\Bigg]\\
&-\Bigg[P(x_1^S)\sum_{y}P(y|x\in S)log(P(y))\\
&+P(x_{m_S}^S)\sum_{y}P(y|x\in S)log(P(y))\Bigg]\\
&=\sum_{S\in\mathcal{S}}\Bigg[\beta^S\sum_{y}P(y|x\in S)log(P(y|x\in S))\Bigg]\\
&-\Bigg[\beta^S\sum_{y}P(y|x\in S)log(P(y))\Bigg]\\
&=\sum_{S\in\mathcal{S}}\Bigg[P(x_1^S)\sum_{y}P(y|x_1^S)log(P(y|x\in S))\\
&+P(x_{m_S}^S)\sum_{y}P(y|x_{m_S}^S)log(P(y|x\in S))\Bigg]\\
&-\Bigg[\beta^S\sum_{y}P(y|x\in S)log(P(y))\Bigg],
\end{aligned}
\tag{27}
$$

where we have used Equation 25 in the last equality.

Substituting (26) and (27) into (24), we get:

$$
\begin{aligned}
&I(X,Y)-I(T,Y)\\
&=\sum_{S\in\mathcal{S}}\Bigg[P(x_1^S)\sum_{y}P(y|x_1^S)log(P(y|x_1^S))+...\\
&+P(x_{m_S}^S)\sum_{y}P(y|x_{m_S}^S)log(P(y|x_{m_S}^S))\Bigg]\\
&-\sum_{S\in\mathcal{S}}\Bigg[P(x_1^S)\sum_{y}P(y|x_1^S)log(P(y|x\in S))\\
&+P(x_{m_S}^S)\sum_{y}P(y|x_{m_S}^S)log(P(y|x\in S))\Bigg]\\
&=\sum_{S\in\mathcal{S}}P(x_1^S)\sum_{y}\Bigg[P(y|x_1^S)log(P(y|x_1^S))\\
&-P(y|x_1^S)log(P(y|x\in S))\Bigg]+...\\
&+P(x_{m_S}^S)\sum_{y}\Bigg[P(y|x_{m_S}^S)log(P(y|x_{m_S}))\\
&-P(y|x_{m_S}^S)log(P(y|x\in S))\Bigg]\\
&=\sum_{S\in\mathcal{S}}P(x_1^S)KL(P_{Y|x_1^S}||P_{Y|S})+...\\
&+P(x_{m_S}^S)KL(P_{Y|x_{m_S}^S}||P_{Y|S})
\end{aligned}
\tag{28}
$$

As we wanted to show. □

C.3 Proof of Theorem 4

By Theorem 3, it is enough to show that

$$
\begin{aligned}
&\sum_{S\in\mathcal{S}}P(x_1^S)KL(P_{Y|x_1^S}||P_{Y|S})\\
&\qquad+...+P(x_{m_S}^S)KL(P_{Y|x_{m_S}^S}||P_{Y|S})\\
&\qquad\geq\sum_{S\in\mathcal{S}}\sum_{i=1}^{m^S}\frac{P(x_i^S)(\beta_i^S)^2}{2}D_1(P_{Y|x_i^S},P_i^S)^2
\end{aligned}
\tag{29}
$$

For that, it is enough to show that

$$
\begin{aligned}
&P(x_i^S)KL(P_{Y|x_i^S}||P_{Y|S})\\
&\qquad\geq\frac{P(x_i^S)(\beta_i^S)^2}{2}D_1(P_{Y|x_i^S},P_i^S)^2
\end{aligned}
\tag{30}
$$

for every i. Now, by Pinsker's inequality, for a given i, we have that

$$\begin{aligned}
&P(x_i^S)KL(P_{Y|x_i^S}||P_{Y|S}) = P(x_i^S)\\
&\quad KL(P_{Y|x_i^S}||\alpha_1 P_{Y|x_1^S} + ... + \alpha_{m^S} P_{Y|x_{m^S}^S})\\
&\quad \geq \frac{P(x_i^S)}{2} D_1(\alpha_1 P_{Y|x_1^S} + ...\\
&\quad + \alpha_{m^S} P_{Y|x_{m^S}^S}, P_{Y|x_i^S})^2\\
&\quad = \frac{P(x_i^S)}{2(P(x_1^S) + ... + P(x_{m^S}^S))^2} ||_1(P(x_1)P_{Y|x_1^S} + ...\\
&\quad + P(x_{m^S})P_{Y|x_{m^S}^S}\\
&\quad - (P(x_1^S) + ... + P(x_{m^S}^S))P_{Y|x_i^S}||^2\\
&\quad = \frac{P(x_i^S)}{2(P(x_1^S) + ... + P(x_{m^S}^S))^2}\\
&\quad ||_1(P(x_1^S)P_{Y|x_1^S} + ...P(\widehat{x_i^S)P}_{Y|x_i^S} + ...\\
&\quad + P(x_{m^S}^S)P_{Y|x_{m^S}^S}\\
&\quad - (P(x_1^S) + ... + \widehat{P(x_i^S)} + ... + P(x_{m^S}))P_{Y|x_i^S}||^2\\
&\quad = \frac{P(x_i^S)(P(x_1^S) + ... + \widehat{P(x_i^S)} + ... + P(x_{m^S}))^2}{2(P(x_1^S) + ... + P(x_{m^S}^S))^2}\\
&\quad ||_1 P_i^S - P_{Y|x_i^S}||^2\\
&\quad = \frac{P(x_i^S)(\beta_i^S)^2}{2} D_1(P_i^S(Y), P_{Y|x_i^S})^2
\end{aligned} \tag{31}$$

where the hat represents that element of the sum being skipped, as we wanted to show. ☐

C.4 Derivation of Equation 18

$$\begin{aligned}
&\sum_{i=1}^{m^S} \frac{P(x_i^S)(\beta_i^S)^2}{2} D_1(P_{Y|x_i^S}, P_i^S)^2\\
&= \left[\frac{P(x_1^S)(\beta_1^S)^2}{2} + \frac{P(x_2^S)(\beta_2^S)^2}{2}\right] D_1(P_{Y|x_1^S}, P_{Y|x_2^S})^2\\
&= \left[\frac{P(x_1^S)P(x_2^S)^2}{2(P(x_1^S) + P(x_2^S))^2} + \frac{P(x_2^S)P(x_1^S)^2}{2(P(x_1^S) + P(x_2^S))^2}\right]\\
&D_1(P_{Y|x_1^S}, P_{Y|x_2^S})^2\\
&= \left[\frac{P(x_1^S)P(x_2^S)(P(x_1^S) + P(x_2^S))}{2(P(x_1^S) + P(x_2^S))^2}\right]\\
&D_1(P_{Y|x_1^S}, P_{Y|x_2^S})^2\\
&= \frac{P(x_1^S)P(x_2^S)}{2(P(x_1^S) + P(x_2^S))} D_1(P_{Y|x_1^S}, P_{Y|x_2^S})^2
\end{aligned} \tag{32}$$

D Human evaluation judging criteria

We ask human evaluators to compare systems on three different dimensions, according to the following instructions:

Meaning. Which of the paraphrases better preserves the meaning of the original, without adding or losing information?

Surface similarity. Which of the paraphrases is more similar compared to the original, using more similar phrasing or words? You should chose the text using more similar words or phrasing, regardless of meaning.

Fluency. Which text is a more fluent English sentence? You should choose the sentence that contains the least grammatical mistakes, and sounds more natural.

E Full paraphrase sample

We present the full list of 20 sampled paraphrases in Table 3.

Original	MT (beam)	MT (sampling)	Ours (beam)	Ours (sampling)
As of August 30th, the city had allocated a labor force of 158,300 per day in the project, with the aggregate labor contribution amounting to 936,500, and had completed 730,000 cubic meters of earth and stone.	As at 30 August, the city had allocated 158,300 persons per day to the project, with an overall contribution of 936,500 persons, and had completed the construction of 730,000 cubic metres of land and stone.	It had assigned 158,300 employees per day to the project as of 30 August, with a total staff contribution of 936,500, and it had concluded the construction of 730,000 cubic metres of earth and rock.	As of 30 August, the city had employed 158,300 persons per day for the project, a total of 936,500 of whom had been allocated for the construction of 230,000 square meters of earth and stone.	On 30 August, the City had a staff of 158,300 people per day in the project, a total of 936,500 of whom had been provided for the construction of 330,000 square foot of earth andstone work.

Abstract

Over the last few years, there has been a move towards data curation for multilingual task-oriented dialogue (ToD) systems that can serve people speaking different languages. However, existing multilingual ToD datasets either have a limited coverage of languages due to the high cost of data curation, or ignore the fact that dialogue entities barely exist in countries speaking these languages. To tackle these limitations, we introduce a novel data curation method that generates **GlobalWoZ** — a large-scale multilingual ToD dataset globalized from an English ToD dataset for three unexplored use cases of multilingual ToD systems. Our method is based on translating dialogue templates and filling them with local entities in the target-language countries. Besides, we extend the coverage of target languages to 20 languages. We will release our dataset and a set of strong baselines to encourage research on multilingual ToD systems for real use cases.[1]

1 Introduction

One of the fundamental objectives in pursuit of artificial intelligence is to enable machines with the ability to intelligently communicate with human in natural languages, with one of the widely-heralded applications being the task-oriented dialogue (ToD) systems (Gupta et al., 2006; Bohus and Rudnicky, 2009). Recently, ToD systems have been successfully deployed to assist users with accomplishing certain domain-specific tasks such as hotel booking, alarm setting or weather query (Eric et al., 2017; Wu et al., 2019; Lin et al., 2020; Zhang et al., 2020), thanks to the joint advent of neural networks and availability of domain-specific data. However, most existing ToD systems are predominately built for English, limiting their service for *all* of the world's citizens. The reason of this limitation lies in the stark lack of high-quality multilingual ToD datasets due to the high expense and challenges of human annotation (Razumovskaia et al., 2021).

One solution to this is annotating conversations in other languages from scratch, e.g., CrossWoZ (Zhu et al., 2020) and BiToD (Lin et al., 2021). However, these methods involve expensive human efforts for dialogue collection in the other languages, resulting in a limited language/domain coverage. The other major line of work focused on translating an existing English ToD dataset into target languages by professional human translators (Upadhyay et al., 2018; Schuster et al., 2019; van der Goot et al., 2021; Li et al., 2021). Despite the increasing language coverage, these methods simply translated English named entities (e.g., location, restaurant name) into the target languages, while ignored the fact that these entities barely exist in countries speaking these languages. This hinders a trained ToD system from supporting the real use cases where a user looks for local entities in a target-language country. For example in Figure 1, a user may look for the British Museum when traveling to London (A.), while look for the Oriental Pearl Tower when traveling to Shanghai (B.).

In addition, prior studies (Cheng and Butler, 1989; Kim, 2006) have shown that code-switching phenomena frequently occurs in a dialogue when a speaker cannot express an entity immediately and has to alternate between two languages to convey information more accurately. Such phenomena could be ubiquitous during the cross-lingual and cross-country task-oriented conversations. One of the reasons for code-switching is that there are no exact translations for many local entities in the other languages. Even though we have the translations, they are rarely used by local people. For example in Figure 1 (C.), after obtaining the recommendation from a ToD system, a Chinese speaker traveling to London would rather use the English

Figure 1: Examples of four use cases for multilingual ToD systems: A. Use Case E&E: A English speaker travels to a country of English. B. Use Case F&F: A foreign language speaker travels to a country of the foreign language. C. Use Case F&E: A foreign language speaker travels to a country of English. D. Use Case E&F: A English speaker travels to a country of a foreign language.

entity "British Museum" than its Chinese translation to search online or ask local people. To verify this code-switching phenomena, we have also conducted a case study (§6.1) which shows that searching the information about translated entities online yields a much higher failure rate than searching them in their original languages. Motivated by these observations, we define *three unexplored use cases*[2] of multilingual ToD where a foreign-language speaker uses ToD in the foreign-language country (**F&F**) or an English country (**F&E**), and an English speaker uses ToD in a foreign-language country (**E&F**). These use cases are different from the traditional **E&E** use case where an English speaker uses ToD in an English-speaking country.

To bridge the aforementioned gap between existing data curation methods and the real use cases, we propose a novel data curation method that *globalizes* an existing multi-domain ToD dataset beyond English for the three unexplored use cases. Specifically, building on top of MultiWoZ (Budzianowski et al., 2018) — an English ToD dataset for dialogue state tracking (DST), we create GlobalWoZ, a new multilingual ToD dataset in three new target-languages via machine translation and crawled ontologies in the target-language countries.

Our method only requires minor human efforts to post-edit a few hundred machine-translated dialogue templates in the target languages for evaluation. Besides, as cross-lingual transfer via pre-trained multilingual models (Devlin et al., 2019; Conneau et al., 2020; Liu et al., 2020; Xue et al., 2021) has proven effective in many cross-lingual tasks, we further investigate another question: *How do these multilingual models trained on the English ToD dataset transfer knowledge to our globalized dataset?* To answer this question, we prepare a few baselines by evaluating popular ToD systems on our created test datasets in a *zero-shot* cross-lingual transfer setting as well as a *few-shot* setting.

Our contributions include the following:

- To the best of our knowledge, we provide the first step towards analyzing three unexplored use cases for multilingual ToD systems.
- We propose a cost-effective method that creates a new multilingual ToD dataset from an existing English dataset. Our dataset consists of high-quality test sets which are first translated by machines and then post-edited by professional translators in three target languages (Chinese, Spanish and Indonesian). We also leverage machine translation to extend the language coverage of test data to another 17 target languages.
- Our experiments show that current multilingual systems and translate-train methods fail in zero-shot cross-lingual transfer on the dialogue state tracking task. To tackle this problem, we propose several data augmentation methods to train strong baseline models in both zero-shot and few-shot cross-lingual transfer settings.

---

[2] See comparisons of these use cases in Appendix A

2 Data Curation Methodology

In order to globalize an existing English ToD dataset for the three aforementioned use cases, we propose an approach consisting of four steps as shown in Figure 2: (1) we first extract dialogue templates from the English ToD dataset by replacing English-specific entities with a set of general-purpose placeholders (§2.1); (2) we then translate the templates to a target language for both training and test data, with one key distinction that we only post-edit the test data by professional translators to ensure the data quality for evaluation (§2.2); (3) next, we collect ontologies (Kiefer et al., 2021) containing the definitions of dialogue acts, local entities and their attributes in the target-language countries (§2.3); (4) finally, we tailor the translated templates by automatically substituting the placeholders with entities in the extracted ontologies to construct data for the three use cases (§2.4).

2.1 Automatic Template Creation

We start with MultiWoZ 2.2 (Zang et al., 2020) – a high-quality multi-domain English ToD dataset with more accurate human annotations compared to its predecessors MultiWoZ 2.0 (Budzianowski et al., 2018) and MultiWoz 2.1 (Eric et al., 2020). For the sake of reducing human efforts for collecting ToD context in the target languages, we re-use the ToD context written by human in MultiWoZ as the dialogue templates. Specifically as shown in Figure 2, we replace the English entities in MultiWoz by a set of general-purpose placeholders such as `[attraction-name0]` and `[attraction-postcode1]`, where each placeholder contains the entity's domain, attribute and ID. To do so, we first build a dictionary with entity-placeholder pairs by parsing the annotations of all dialogues. For example, from a dialogue text —*"I recommend Whale of a time and the post code is cb238el."*, we obtain two entity-placeholder pairs from its human annotations, i.e., (*Whale of a time*, `[attraction-name0]`) and (*cb238el*, `[attraction-postcode1]`). Next, we identify entities in the dialogue by their word index from the human annotations, replace them with their placeholders in the dictionary, and finally obtain dialogue templates with placeholders. Notably, we skip the entities with their attributes of `[choice]` and `[ref]` that represent the number of choices and booking reference number, as these attributes could be used globally.

2.2 Labeled Sequence Translation

Following Liu et al. (2021) that translates sentences with placeholders, we use a machine translation system[3] to translate dialogue templates with our designed placeholders. As we observe, a placeholder containing an entity domain, attribute and ID (e.g., `attraction-name0`) is useful to provide contextually meaningful information to the translation system, thus usually resulting in a high-quality translation with the placeholder unchanged [4]. This also enables us to easily locate the placeholders in the translation output and replace them with new entities in the target language.

To build a high-quality test set for evaluation, we further hire professional translators to post-edit a few hundred machine-translated templates, which produces natural and coherent sentences in the target languages.[5] With the goal of selecting representative test templates for post-editing, we first calculate the frequency of all the 4-gram combinations in the MultiWoZ data, and then score each dialogue in the test set by the sum of the frequency of all the 4-gram combinations in the dialogue divided by the dialogue's word length. We use this scoring function to estimate the representiveness of a dialogue in the original dataset. Finally, we select the top 500 high-scoring dialogues in the test set for post-editing.[6] We also use the same procedure to create a small high-quality training set for few-shot cross-lingual transfer setting.

2.3 Collection of Local Ontology

Meanwhile, we crawl the attribute information of local entities in three cities from public websites (e.g., tripadvisor.com, booking.com) to create three ontologies for the three corresponding target languages respectively. As shown in Table 8 in Appendix E, we select Barcelona for Spanish (an Indo-European language), Shanghai for Mandarin (a Sino-Tibetan language) and Jakarta for Indonesian (an Austronesian language), which cover a set of typologically different language families.

Given a translated dialogue template, we can easily sample a random set of entities for a domain of interest from a crawled ontology and assign the entities to the template's placeholders to obtain a

---

[3] We use Google Translate (`https://cloud.google.com/translate`), an off-the-shelf MT system.

[4] Appendix B has an example of label sequence translation.

[5] Appendix C shows the bleu scores between MT test data and MTPE test data.

[6] Appendix D shows the English test data distribution.

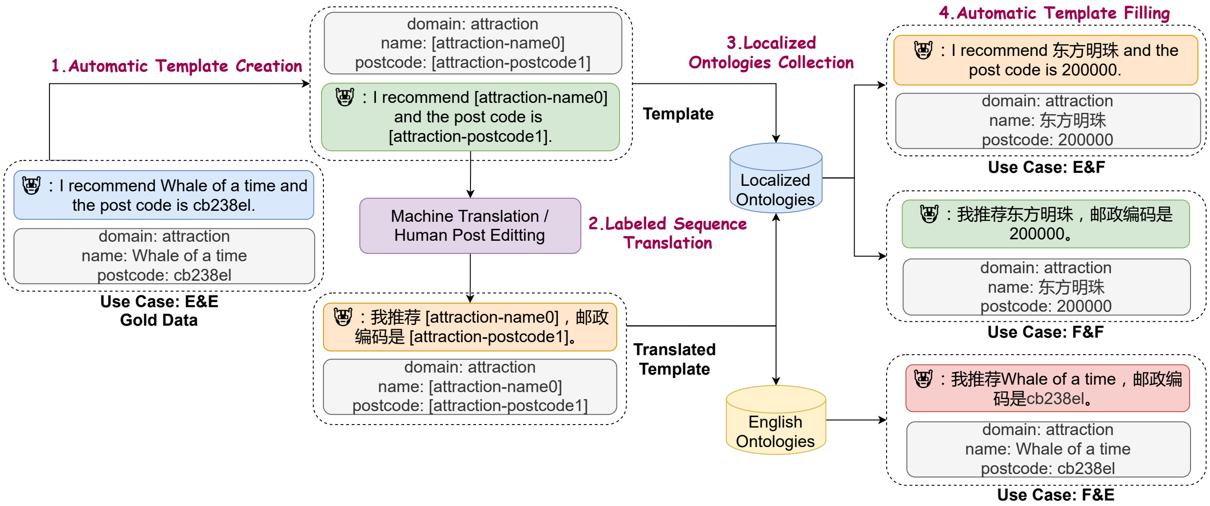

Figure 2: Illustration of our proposed pipeline: 1. Automatic Template Creation 2. Labeled Sequence Translation 3. Localized Ontologies Collection 4. Automatic Template Filling

new dialogue in the target language. Repeating this procedure on each dialogue template, we can easily build a high-quality labeled dataset in the target language. Table 9 in Appendix F shows the statistics of our collected entities in the target languages compared with the English data. The number of our collected entities are either larger than or equal to those in the English data except for the "train" domain; we collected the information about only 100 "trains" for each languages due to the complexity in collecting relevant information.

2.4 Template Filling for Three Use Cases

After the above steps, we assign entities in a target language to the translated templates in the same target language for the F&F case, while assigning target-language entities to the English (source-language) templates for the F&E case. As for the E&F case, we keep the original English context by skipping the translation step and replace the placeholders with local entities in the target language (see Figure 2 for examples).

To sum up, our proposed method has three key properties: (1) our method is *cost-effective* as we only require a limited amount of post-editing efforts for a test set when compared to the expensive crowd-sourced efforts from the other studies; (2) we can easily sample entities from an ontology to create *large-scale machine-translated data* as a way of data augmentation for training; (3) our method is *flexible* to update entities in a ToD system whenever an update of ontology is available, e.g., extension of new entities. We refer the readers to Table 10 for the data statistics of GlobalWoZ and Figure 9 for dialogue examples in the appendix.

3 Task & Settings

3.1 Dialogue State Tracking

Our experiments focus on the dialogue state tracking (DST), one of the fundamental components in a ToD system that predicts the goals of a user query in multi-turn conversations. We follow the setup in MultiWoZ (Budzianowski et al., 2018) to evaluate ToD systems for DST by the joint goal accuracy which measures the percentage of correctly predicting all goals in a multi-turn conversation.

3.2 Experimental Settings

Zero-Shot Cross-lingual Transfer: Unlike prior studies that annotate a full set of high-quality training data for a target language, we investigate the *zero-shot cross-lingual transfer* setting where we have access to only a high-quality human-annotated English ToD data (referred to as gold standard data hereafter). In addition, we assume that we have access to a machine translation system that translates from English to the target language. We investigate this setting to evaluate how a multilingual ToD system transfers knowledge from a high-resource source language to a low-resource target language.

Few-Shot Cross-lingual Transfer: We also investigate few-shot cross-lingual transfer, a more practical setting where we are given a small budget to annotate ToD data for training. Specifically, we include a small set (100 dialogues) of high-quality training data post-edited by professional translators

(§2.2) in a target language, and evaluate the efficiency of a multilingual ToD on learning from a few target-language training examples.

4 Proposed Baselines

We prepare a base model for GlobalWoZ in the zero-shot and few-shot cross-lingual transfer settings. We select Transformer-DST (Zeng and Nie, 2020) as our base model as it is one of the state-of-the-art models on both MultiWoZ 2.0 and MultiWoZ 2.1[7]. In our paper, we replace its BERT encoder with an mBERT encoder (Devlin et al., 2019) for our base model and propose a series of training methods for GlobalWoZ. As detailed below, we propose several data augmentation baselines that create different training and validation data for training a base model. Note that all the proposed baselines are model agnostic and the base model can be easily substituted with other popular models (Heck et al., 2020; Lin et al., 2020). For each baseline, we first train a base model on its training data for 20 epochs and use its validation set to select the best model during training. Finally we evaluate the best model of each baseline on the same test set from GlobalWoZ. We will release GlobalWoZ and our pre-trained models to encourage faster adaptation to future research. We refer the readers to Table 11 and Table 12 in Appendix I while reading the subsequent methods for a better understanding.

4.1 Pure Zero-Shot (E&E)

We train a base model on the gold standard English data (E&E) and directly apply the learned model to the test data of the three use cases in GlobalWoZ. With this method, we simulate the condition of having labeled data only in the source language for training, and evaluate how the model transfers knowledge from English to the three use cases. We use **Zero-Shot (E&E)** to denote this method.

4.2 Translate-Train

We use our data curation method (§2) to translate the templates by an MT system but replace the placeholders in the translated templates with machine-translated entities to create a set of pseudo-labeled training data. Next, we train a base model on the translated training data without local entities, and evaluate the model on the three use cases. We denote this method as **Translate-Train**.

4.3 Single-Use-Case Training

By skipping the human post-editing step in our data curation method (§2), we leverage a machine translation system to automatically create a large set of pseudo-labeled training data with local entities for the three use cases. In the F&F case, we translate the English templates by the MT system and replace the placeholders in the translated templates with foreign-language entities to create a training dataset. In the F&E case, we replace the placeholders in the translated templates with the original English entities to create a code-switched training dataset. In the E&F case, we use the original English templates and replace the placeholders in the English templates with foreign-language entities to create a code-switch training dataset. With this data augmentation method, we can train a base model on each pseudo-labeled training dataset created for each use case. We denote this method as **SUC** (Single-Use-Case).

4.4 Bi-/Multi-lingual Bi-Use-Case Training

We investigate the performance of combining the existing English data and the pseudo-labeled training data created for one of the three use cases (i.e., F&F, F&E, E&F), one at a time, to do bi-use-case training. In the bilingual training, we only combine the gold English data (E&E) with the pseudo-labeled training data in one target language in one use case for joint training. We denote this method as **BBUC** (Bilingual Bi-Use-Case). In the multilingual training, we combine gold English data (E&E) and pseudo-labeled training data in all languages in one use case for joint training. We denote this method as **MBUC** (Multilingual Bi-Use-Case).

4.5 Multilingual Multi-Use-Case Training

We also propose to combine the existing English data (E&E) and all the pseudo-labeled training data in all target languages for all the use cases (F&F, F&E, E&F). We then train a single model on this combined multilingual training dataset and evaluate the model on test data in all target languages for all three use cases . We denote this method as **MMUC** (Multilingual Multi-Use-Case).

5 Experiment Results

In this section, we show the results of all methods in the zero-shot (§5.1) and few-shot (§5.2) settings.

---

[7] According to the leaderboards of Multi-domain Dialogue State Tracking on MultiWoZ 2.0 and MultiWoZ 2.1 on paperwithcode.com as of 11/15/2021.

5.1 Zero-shot Cross-lingual Transfer

5.1.1 Use Case F&F, F&E and E&F

Table 1 reports the joint goal accuracy of all proposed methods on the three different sets of test data in the F&F, F&E, and E&F use cases[8]. Both Zero-Shot (E&E) and Translate-Train struggle, achieving average accuracy of less than 10 in all use cases. Despite its poor performance, Zero-Shot (E&E) works much better in F&E than F&F, while its results in F&F and E&F are comparable, indicating that a zero-shot model trained in E&E can transfer knowledge about local English entities more effectively than knowledge about English context in downstream use cases. Besides, we also find that Zero-Shot (E&E) performs better on the Spanish or Indonesian context than the Chinese context in F&E. One possible reason is that English is closer to the other Latin-script languages (Spanish and Indonesian) than Chinese.

Our proposed data augmentation methods (SUC, BBUC, MBUC) perform much better than non-adapted methods (Zero-Shot (E&E) and Translate-Train) that do not leverage any local entities for training. In particular, it is worth noting that even though Translate-Train and SUC both do training on foreign-language entities in F&F and E&F, there is a huge gap between these two methods, since Translate-Train has only access to the machine-translated entities rather than the real local entities used by SUC. This huge performance gaps not only show that Translate-Train is not an effective method in practical use cases but also prove that having access to local entities is a key to building a multilingual ToD system for practical usage.

Comparing our data augmentation methods SUC and BBUC, we find that the base model can benefit from training on additional English data (E&E), especially yielding a clear improvement of up to 5.58 average accuracy points in F&E. Moreover, when we increase the number of languages in the bi-use-case data augmentations (i.e., MBUC), we observe an improvement of around 1 average accuracy points in all three use cases w.r.t. BBUC. These observations encourage a potential future direction that explores better data augmentation methods to create high-quality pseudo-training data.

Case	Methods	zh	es	id	avg
F&F	Zero-Shot (E&E)	1.22	1.38	1.26	1.28
	Translate-Train	2.61	2.59	5.74	3.65
	SUC (F&F)	36.97	24.66	25.26	28.96
	BBUC (E&E + F&F)	37.32	25.52	26.39	29.74
	MBUC (E&E + F&F)	**38.01**	**26.03**	**28.22**	**30.76**
F&E	Zero-Shot (E&E)	6.92	11.34	9.09	9.12
	Translate-Train	2.28	4.97	4.67	3.97
	SUC (F&E)	56.28	41.94	47.93	48.71
	BBUC (E&E + F&E)	59.87	48.20	54.79	54.29
	MBUC (E&E + F&E)	**60.37**	**53.56**	**54.93**	**56.28**
E&F	Zero-Shot (E&E)	1.69	1.81	1.82	1.77
	Translate-Train	1.39	1.76	1.86	1.67
	SUC (E&F)	38.56	28.00	43.82	36.79
	BBUC (E&E + E&F)	39.87	27.29	45.48	37.54
	MBUC (E&E + E&F)	**40.20**	**29.22**	**47.06**	**38.83**

Table 1: Zero-shot cross-lingual accuracy on DST over three target languages in three use cases.

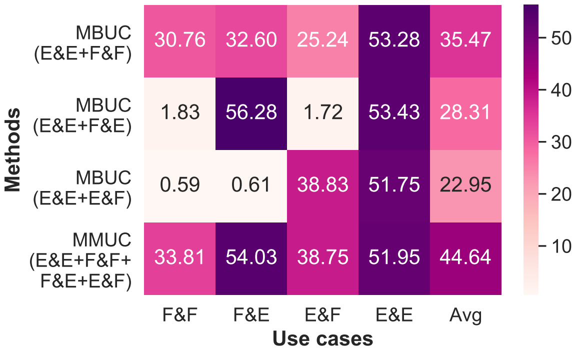

Figure 3: Performance of MMUC vs MBUC on the test data of the four use cases, F&F, F&E, E&F and E&E.

5.1.2 One Model for All

Notice that we can train a single model by MMUC for all use cases rather than training separate models, one for each use case. In Figure 3, we compare MMUC and MBUC (rows) on the test data in the four use cases (columns). Although MMUC may not achieve the best results in each use case, it achieves the best average result over the four use cases, indicating the potential of using one model to simultaneously handle all the four use cases.

5.2 Few-shot Cross-lingual Transfer

In few-shot experiments, we use the same scoring function based on frequency of all 4-gram combinations (§2.2) to select 100 additional dialogues from train set for human-post editing, and create high-quality training data for each of the three use cases. To avoid overfitting on this small few-shot dataset, we combine the few-shot data with the existing English data for training a base model (Few-Shot+Zero-Shot (E&E)). Next, we also investigate a model trained with additional synthetic data created by our proposed SUC. In Figure 4, we find that our proposed SUC without additional few-shot

---

[8] Appendix J reports the results in the E&E use case.

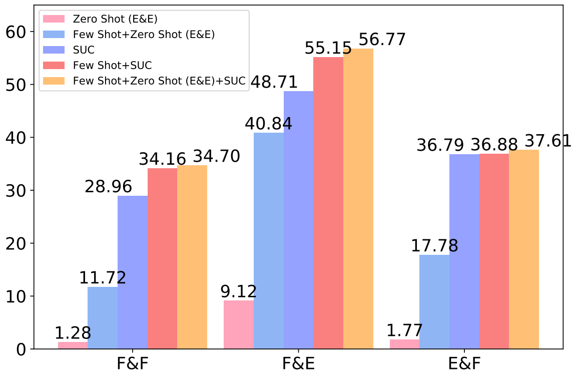

Figure 4: Few-shot cross-lingual average joint accuracy on DST over three target languages in three use cases.

data has already outperformed the model trained with few-shot data and English data (Few-shot + Zero-Shot (E&E)), indicating that the model benefit more from a large amount of pseudo-labeled data than a small set of human-labeled data. If we combine the data created by SUC with the few-shot data or with both few-shot and English data to train the model, we observe improvements over SUC, especially with a clear gain of 8.06 accuracy points in F&E. We refer the readers to Table 14 in the appendix for detailed scores in all target languages.

6 Discussion

6.1 Motivation for Code-Switched Use Cases

One key research question is to validate whether code-switched use cases with local entities (i.e., F&E, E&F) are practically more useful for information seeking. To answer this question, we compare the failure rate of using local entities and machine-translated entities in information search, which is a proxy to the efficiency of using these two types of entities in conversations. We first randomly select 100 entities (33 attractions, 33 hotels and 34 restaurants) of Cambridge, Shanghai, Barcelona and Jakarta. We translate the English entities into Mandarin, Spanish and Indonesian and the foreign-language entities into English via Google Translate. We then manually search the translated entities on Google to check whether we can find the right information of the original entities. Notice that the failure of the above verification partially come from the translation error made by Google Translate, or the search failure due to the fact that this entity does not have a bilingual version at all. In Table 2, we observe a high failure rate of around 60% for almost all translated directions (except Zh→En) due to translation and search failures, significantly exceeding the low failure rate of searching original entities online. Besides, even if we can find the right information of the translated entities, local people may not recognize or use the translated entities for communication, thus this results in inefficient communication with local people.

Translate	Search	En→Zh	En→Es	En→Id	Zh→En	Es→En	Id→En
✔	✔	35	42	36	62	30	31
✔	✗	61	34	51	18	18	15
✗	✔	0	24	13	11	50	54
✗	✗	4	0	0	8	2	0
Failure Case (MTed Entities)		65	58	64	37	70	69
Failure Rate (MTed Entities)		65%	58%	64%	37%	70%	69%
Failure Rate (Original Entities)		3%	3%	3%	0%	1%	0%

Table 2: The search and translation results of 100 translated entities on Google. En→Zh refers to the translation of English entities to Mandarin and Zh→En refers to the translation of Mandarin entities to English.

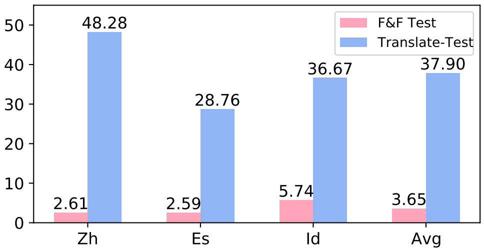

Figure 5: Joint accuracy of Translate-Train for DST on the F&F Test vs Translate-Test data.

6.2 Overestimate of Translate-Train

In previous translation-based work, a multilingual ToD system is usually built based on the translation of English training data (Translate-Train), and is evaluated on translated test data without any local entities (Translate-Test). To verify whether this procedure is reliable to build a multilingual ToD system, we also create a test dataset with translated entities instead of local entities in the target languages. As shown in Figure 5, we find the Translate-Train model performs well on the test data with translated entities, but performs badly on the test data with real local entities. To the best of our knowledge, we provide the first analysis to identify this performance gap between the translated test data and data with real local entities in a more realistic use case [9]. Our work sheds light on the development of a globalized multilingual ToD system in practical use cases. We can tackle

---

[9] Please refer to Appendix L for concrete examples where Translate-Train fails in predicting real local entities.

the challenge of localization issues by exploring new data augmentation method. Alternatively we can also explore new methods from the model level by building modular network to update the entities or perform transfer learning to adapt to new case without retraining.

6.3 Local Context vs. Local Entities

We compare the impact of training a model on data with either local contexts or local entities when the model is evaluated on monolingual test data in F&F and E&E. Specifically, when the train set has access to local context only, all the entities in the train set are replaced by entities in non-target languages. Similarly, when the train set has access to local entities only, the contexts in the train set are replaced by context in the non-target languages. Table 3 shows that both local contexts and local entities are essential to building ToD systems in the target language. A further analysis in Table 15 and Table 16 in the appendix shows that training with local entities is more important if the entities and contexts are written in the same type of language script (e.g. Latin script).

Train Set	E&E (en)	F&F (zh)	F&F (es)	F&F (id)	avg
Local Context Only	5.46	1.77	2.37	2.40	3.20
Local Entities Only	6.39	0.36	2.41	2.75	3.05
Local Context & Entities	**52.78**	**36.97**	**24.66**	**25.26**	**38.13**

Table 3: Comparison of training with local context or/and local entities on the joint accuracy for DST in E&E (en) and F&F (zh, es, id).

6.4 Scaling up to 20 Languages

With our proposed data curation method, it is possible to extend the dataset to cover more languages without spending extra costs if we skip the human post-editing step. Before doing so, one key question is whether the evaluation on the translated data without human post-editing is reliable as a proxy of the model performance. Thus, we conduct the experiments by evaluating the model performance of all baselines (§4) on two sets of test data built with local entities: (1) **MT** test data where translated template is created by machine translation only (§2.2); (2) **MTPE** test data where translated template is first translated by machines and post-edited later by professional translators. As shown in Table 4, the overall reported results on MT test data are higher than those reported on MTPE test data, which is expected because the distribution of the MT test data is more similar to the MT training data. Although there are some differences on individual languages, the conclusions derived from the evaluations on the MT test data remain the same as those derived from the evaluation on the MTPE test data. We also calculate the Spearman rank correlation coefficient between the average results reported on MTPE test data and MT test data in Table 4, which shows a statistically high correlation between the system performance on the MT test data and MTPE test data[10]. Therefore, we show that the MT test data can be used as a proxy to estimate the model performance on the real test data for more languages. Thus we build MT test data for another 17 languages that are supported by Google Translate, Trip Advisor and Booking.com at the same time, as stated in Table 8 and Table 9 in the appendix. Table 5 shows the results of Zero-Shot (E&E) and SUC on the test data of F&F, F&E and E&F in 20 languages. The results show that the model has the best performance in the F&E use case compared with the other two use cases, which is consistent with our findings in Table 1.

Use Case	F2F		F2E	
Methods	**MT Test**	**MTPE Test**	**MT Test**	**MTPE Test**
Zero-Shot (E&E)	1.29	1.28	9.64	9.12
Translate-Train	3.71	3.65	4.17	3.97
SUC	35.78	28.96	56.15	48.71
BBUC	36.31	29.74	57.84	54.29
MBUC	**37.89**	**30.76**	**58.76**	**56.28**
Spearman's correlation	**1.0**		**1.0**	

Table 4: Comparison of average joint accuracy on DST reported on MT test data and MTPE test data for use case F&F and F&E

Case	Method	Avg
F&F	Zero-Shot (E&E)	1.48
	SUC	**16.12**
F&E	Zero-Shot (E&E)	9.03
	SUC	**34.20**
E&F	Zero-Shot (E&E)	1.97
	SUC	**23.40**

Table 5: Average results of Zero-Shot (E&E) on test data of F&F, F&E and E&F in 20 languages. Please refer to Table 18 in Section O for the break down results of 20 languages.

7 Related Work

Over the last few years, the success of ToD systems is largely driven by the joint advent of neural network models (Eric et al., 2017; Wu et al., 2019; Lin et al., 2020) and collections of large-

---

[10] Table 17 in the appendix shows detailed scores.

scale annotation corpora. These corpora cover a wide range of topics from a single domain (e.g., ATIS (Hemphill et al., 1990), DSTC 2 (Henderson et al., 2014), Frames (El Asri et al., 2017), KVRET (Eric et al., 2017), WoZ 2.0 (Wen et al., 2017), M2M (Schatzmann et al., 2007)) to multiple domains (e.g., MultiWoZ (Budzianowski et al., 2018), SGD (Rastogi et al., 2020)). Most notably among these collections, MultiWoZ is a large-scale multi-domain dataset that focuses on transitions between different domains or scenarios in real conversations (Budzianowski et al., 2018). Due to the high cost of collecting task-oriented dialogues, only a few monolingual or bilingual non-English ToD datasets are available (Zhu et al., 2020; Quan et al., 2020; Lin et al., 2021). While there is an increasing interest in data curation for multilingual ToD systems, a vast majority of existing multilingual ToD datasets do not consider the real use cases when using a ToD system to search for local entities in a country. We fill this gap in this paper to provide the first analysis on three previously unexplored use cases.

8 Conclusions

In this paper, we provide an analysis on three unexplored use cases for multilingual task-oriented dialogue systems. We propose a new data curation method that leverages a machine translation system and local entities in target languages to create a new multilingual TOD dataset, GlobalWoZ. We propose a series of strong baseline methods and conduct extensive experiments on GlobalWoZ to encourage research for multilingual ToD systems. Besides, we extend the coverage of languages on multilingual ToD to 20 languages, marking the one step further towards building a globalized multilingual ToD system for all of the world's citizen.

9 Ethical Review

In this section, we would like to address the ethical concerns. All the professional translators in this project have been properly compensated. For Chinese and Spanish, we have followed the standard procurement requirements and engaged three translation companies for quality and price comparison. A small sample of the data had been given to them for MTPE and we then compared their translation results. Following that, we selected the company that produced the best sample translation, and submitted the full translation orders according to the agreed price quotations. For Indonesian, three translation companies were also requested to provide sample MTPE, but our quality check found the quality of these samples to be unsatisfactory. So, no company was engaged, and our in-house Indonesian linguistic resources were used instead. These Indonesian linguists were assigned to work on this project during normal working hours and given proper compensation complying with the local labor laws.

Acknowledgements

This research is partly supported by the Alibaba-NTU Singapore Joint Research Institute, Nanyang Technological University. All the costs for machine translation post-editing are funded by DAMO Academy, Alibaba Group. We would like to thank the help from our Alibaba colleagues, Haiyun Peng, Zifan Xu and Ruidan He, and our NTU-NLP team member, Chengwei Qin in this work as well.

Table 9: Statistics of entities in the collected ontology in different languages. We count the number of entities in the database of each domain. Noticed that in the Taxi database of MultiWoZ, it only list down the taxi colors, taxi types and taxi phones. The taxi destination and departure refer to the entities in the restaurant, hotel and attraction domains. Thus, we use the sum of the number of entities in Restaurant, Hotel and Attraction domains as a proxy of the total number of entities in taxi domain. Besides, we follow MultiWoZ to collect one hospital and one police station for each city.

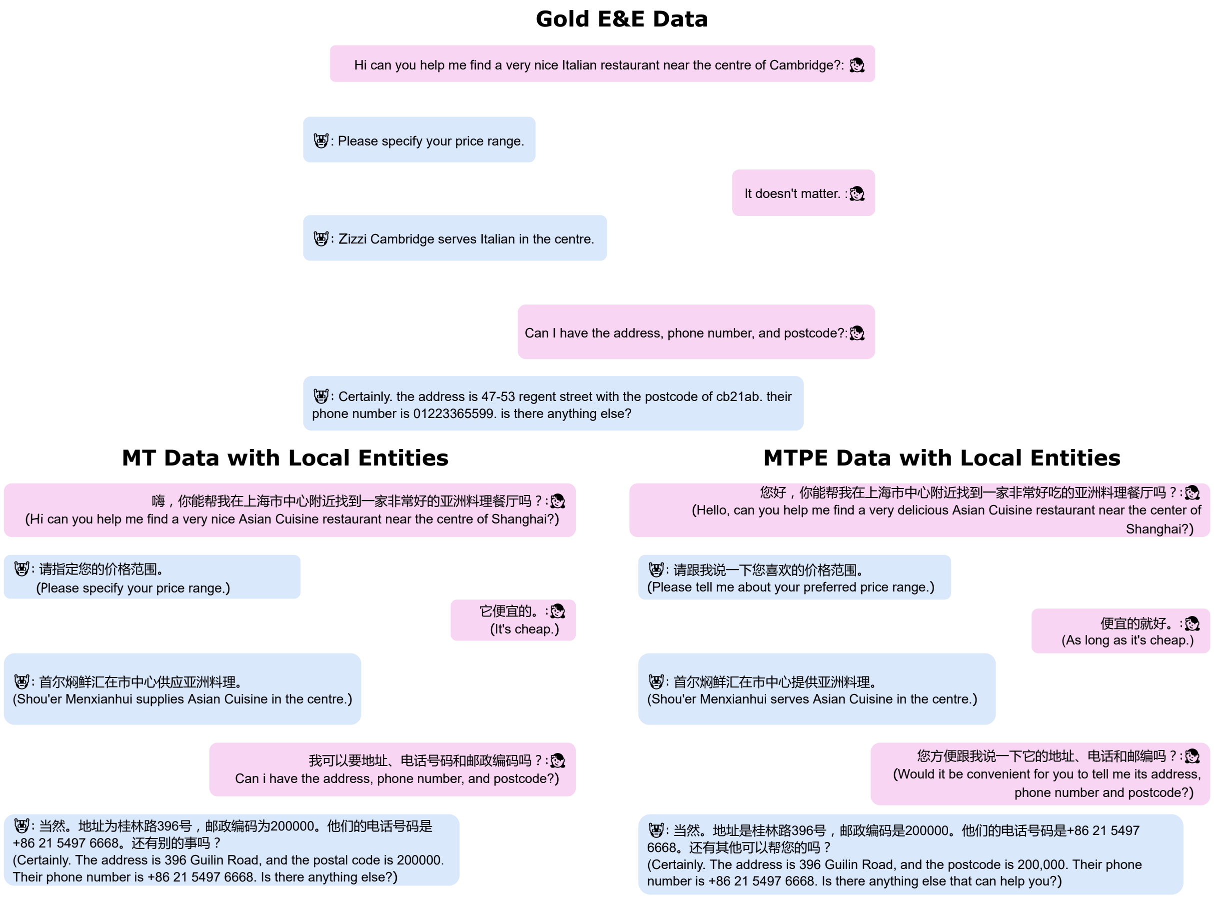
Table 10: Statistics of created dataset, GlobalWoZ for each use case in each target language. For E&F, as the context is the original Engish data, we consider it is created by human. For test data of zh, es and id, we replace the entities twice to boostrap the test data to 1000 dialogues. We are currently preparing the post editing of the other 500 dialogues in test data. Meanwhile, we are leveraging machine translation to prepare the train data for the 17 languages and will release it with baselines in the next version soon.

H Dialogue Examples



Gold E&E Data

Hi can you help me find a very nice Italian restaurant near the centre of Cambridge?:

: Please specify your price range.

It doesn't matter. :

: Zizzi Cambridge serves Italian in the centre.

Can I have the address, phone number, and postcode?:

: Certainly. the address is 47-53 regent street with the postcode of cb21ab. their phone number is 01223365599. is there anything else?

MT Data with Local Entities

嗨，你能帮我在上海市中心附近找到一家非常好的亚洲料理餐厅吗？:
(Hi can you help me find a very nice Asian Cuisine restaurant near the centre of Shanghai?)

: 请指定您的价格范围。
(Please specify your price range.)

它便宜的。:
(It's cheap.)

: 首尔焖鲜汇在市中心供应亚洲料理。
(Shou'er Menxianhui supplies Asian Cuisine in the centre.)

我可以要地址、电话号码和邮政编码吗？:
Can i have the address, phone number, and postcode?)

: 当然。地址为桂林路396号，邮政编码为200000。他们的电话号码是+86 21 5497 6668。还有别的事吗？
(Certainly. The address is 396 Guilin Road, and the postal code is 200000. Their phone number is +86 21 5497 6668. Is there anything else?)

MTPE Data with Local Entities

您好，你能帮我在上海市中心附近找到一家非常好吃的亚洲料理餐厅吗？:
(Hello, can you help me find a very delicious Asian Cuisine restaurant near the center of Shanghai?)

: 请跟我说一下您喜欢的价格范围。
(Please tell me about your preferred price range.)

便宜的就好。:
(As long as it's cheap.)

: 首尔焖鲜汇在市中心提供亚洲料理。
(Shou'er Menxianhui serves Asian Cuisine in the centre.)

您方便跟我说一下它的地址、电话和邮编吗？:
(Would it be convenient for you to tell me its address, phone number and postcode?)

: 当然。地址是桂林路396号，邮政编码是200000。他们的电话号码是+86 21 5497 6668。还有其他可以帮您的吗？
(Certainly. The address is 396 Guilin Road, and the postcode is 200,000. Their phone number is +86 21 5497 6668. Is there anything else that can help you?)

Table 12: Accessibility of data in each use case for each method. Noticed that Translate-Train doesn't have access to the data of the four use cases. Translate-Train has access to a set of pseudo-labeled training data created by replacing the placeholders in the translated template with machine-translated entities instead of local entities.

J Use Case E&E

We also compare the performance of all methods on the original E&E test data. As **Zero-Shot (E&E)** is trained on monolingual English training data, it gets a high accuracy of 52.78 on the English test data. In contrast, **Translate-Train** and **SUC** (F&F) perform poorly on the English test data, because both of them have no access to any English data. Comparing to **SUC** (F&F), **SUC** (F&E) and **SUC** (E&F) achieve higher accuracy scores as they either have access to English context or English entities. When we perform bilingual and multilingual joint training (i.e., **BBUC** and **MBUC**), the base model has a performance increase except **MBUC** (E&E + E&F). This shows that bilingual and multilingual joint training may be used to improve the performance on source language. Further research can be done in this line.

Methods	**En**
Zero-Shot (E&E)	52.78
Translate-Train	2.27

L Concrete Examples where Translate-Train Performs Badly on the Test Data with Real Local Entities.

Through investigation, we found that the Translate-Train method usually performed badly in two main scenarios. Figure 9 is the illustrations of the two scenarios. Scenario 1 is when the Translate-Train can predict values that are close to the meaning of the ground truth values but suffer from the problems of translationese. For example, model trained with Translate-Train may predict "美食酒吧" (gastropub), which is a direct translation of gastropub and not commonly used in Chinese instead of "酒吧餐" (bar). Scenario 2 is when Translate-Train needs to predict the name of real localized entities which Translate-Train doesn't have access to. For example, trained with Translate-Train may predict "冈维尔酒店" (Gonville Hotel) which is a direct translation of Gonville Hotel, instead of "汉庭酒店" (Hanting Hotel) which is unseen in Translate-Train training data.

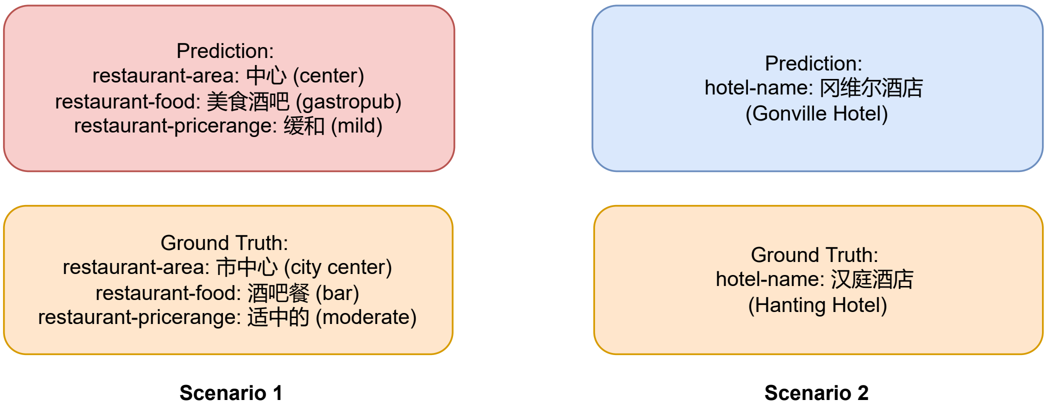

Figure 9: Concrete examples where Translate-Train performs badly on the test data with real local entities.

M Breakdown of the Results of Local Context vs Local Entities by Languages

E&E (en)				
Context vs Entities	Zh	Es	Id	Avg
En_Context	5.37	5.33	5.67	5.46
En_Entites	3.49	7.78	7.90	6.39
F&F (zh)				
Context vs Entities	En	Es	Id	Avg

	SUC	**38.56**	**28.00**	**43.82**	**22.98**	**43.00**	**23.71**	**5.73**	**22.61**	**10.65**	**32.07**	**20.05**	**2.13**	**44.03**	**44.61**	**22.19**	**20.13**	**16.52**	**5.24**	**16.83**	**5.07**	**23.40**

Table 18: Results of Zero-Shot (E&E) on test data of F&F, F&E and E&F in 20 languages. Test data of F&F and F&E in the three languages highlight in pink color are built with MTPE data and the rest are built with MT data.

We observe that there are a few languages like Thai and Vietnamese have low results than other languages. Through investigation, we found that it was caused by failing to predict the tone marks in most of cases. For example, the model may predict *"nha khach"* for hotel type while *" nhà khách"* is the ground truth. We may explore options for post-processing or other models to improve the performance on these languages upon the release of the data.

Domain Knowledge Transferring for Pre-trained Language Model via Calibrated Activation Boundary Distillation

Dongha Choi[1], **HongSeok Choi**[2], and **Hyunju Lee**[1,2*]

Abstract

Since the development and wide use of pre-trained language models (PLMs), several approaches have been applied to boost their performance on downstream tasks in specific domains, such as biomedical or scientific domains. Additional pre-training with in-domain texts is the most common approach for providing domain-specific knowledge to PLMs. However, these pre-training methods require considerable in-domain data and training resources and a longer training time. Moreover, the training must be re-performed whenever a new PLM emerges. In this study, we propose a domain knowledge transferring (DoKTra) framework for PLMs without additional in-domain pre-training. Specifically, we extract the domain knowledge from an existing in-domain pre-trained language model and transfer it to other PLMs by applying knowledge distillation. In particular, we employ activation boundary distillation, which focuses on the activation of hidden neurons. We also apply an entropy regularization term in both teacher training and distillation to encourage the model to generate reliable output probabilities, and thus aid the distillation. By applying the proposed DoKTra framework to downstream tasks in the biomedical, clinical, and financial domains, our student models can retain a high percentage of teacher performance and even outperform the teachers in certain tasks. Our code is available at https://github.com/DMCB-GIST/DoKTra.

1 Introduction

Recently, transformer (Vaswani et al., 2017)-based language models have been successfully applied in the field of natural language processing (NLP). In particular, the two-stage approach of "pre-training and fine-tuning," such as BERT (Devlin et al., 2019), has become the standard for NLP applications. Generally, a transformer-based model is pre-trained with a large amount of text data in an unsupervised manner, and then fine-tuned with a small dataset for several downstream tasks. Further, advanced pre-trained language models (PLMs) with improved architectures or training methods continue to emerge, including ALBERT (Lan et al., 2019) or RoBERTa (Liu et al., 2019).

However, these models must be further improved for tasks requiring domain knowledge, such as those in the biomedical or financial domains, as the pre-training data usually consist of general domain text (e.g., Wikipedia). Additional pre-training with in-domain text has been proposed to provide the PLMs with domain-specific knowledge. For example, in the biomedical domain, several domain-specific PLMs trained with large biomedical texts, such as BioBERT (Lee et al., 2020), PubMedBERT (Gu et al., 2020) and BlueBERT (Peng et al., 2019), have been successfully used as strong baselines for several downstream tasks. Nevertheless, additional pre-training has several limitations, such as the need for sufficient training data and resources, and a longer training time. Furthermore, whenever a new PLM emerges, it must be re-trained to create more advanced domain-specific models.

To address this issue, we propose an efficient domain-knowledge transferring framework that does not require additional pre-training steps. Specifically, we focus on the applicability of knowledge distillation (Hinton et al., 2015) as a domain-knowledge transfer method, not only for model compression. Knowledge distillation is a well-known knowledge transfer method that is primarily used for model compression. The knowledge from a larger and more effective teacher model is distilled to a smaller student model by encouraging it to mimic the teacher characteristics, such as soft probabilities (Hinton et al., 2015) or hidden representations (Kim et al., 2018; Sun et al., 2019).

In this study, we propose a domain knowledge transfer (DoKTra) framework for an advanced PLM via calibrated activation boundary distilla-

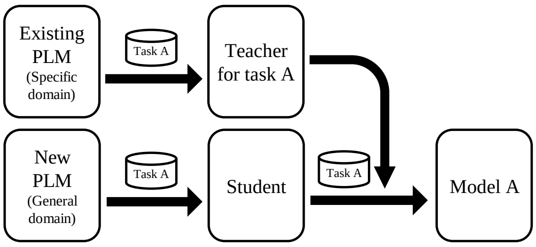
(a) Further in-domain pre-training



(b) DoKTra framework

Figure 1: Comparison between (a) an existing domain transfer method and (b) a proposed framework. The thickness of the arrow is proportional to the required training time.

tion. In contrast to the existing in-domain pre-training methods, we transfer domain knowledge to a new language model using only an existing in-domain pre-trained model, and without a time-consuming pre-training on the new model. For instance, BioBERT was pre-trained for 23 days on 8 NVIDIA V100 GPUs (Lee et al., 2020). We can estimate that if a new, larger language model is pre-trained with a large number of biomedical texts, its training duration would be longer than that of BioBERT. However, our framework can be executed in a few hours on a single 24 GB GPU. The comparison between our framework and a conventional approach is visualized in Figure 1.

Specifically, we apply the calibration method to generate a reliable and well-supervising teacher model. Then, we apply activation boundary distillation (Heo et al., 2019) to distill the domain knowledge to the student, which is more efficient with a small amount of training data. Moreover, by selecting language models more advanced than the teacher as students, we allow the student models to acquire additional domain knowledge while preserving its superiority.

We apply our framework to the biomedical domain and verify its effectiveness by conducting experiments on several biomedical and clinical downstream tasks. Consequent to applying our framework to ALBERT and RoBERTa student models, we were able to obtain models that retained most of the teacher model's performance with fewer model parameters (ALBERT), and models with a higher performance than both students and teachers (RoBERTa). We also investigate the general applicability of our framework by applying it to a financial domain PLM and downstream tasks. The contributions of this study can be summarized as follows:

- We propose a DoKTra framework for advanced PLM via calibrated activation boundary distillation, without additional time-consuming pre-training steps.

- We conduct experiments to demonstrate the efficacy of DoKTra, resulting in obtaining the student models that retain most of the performances of the teacher model while utilizing fewer parameters or achieve even higher performances than the teacher model.

2 Related Work

2.1 Pre-trained language model (PLM)

Most modern language models are based on the transformer (Vaswani et al., 2017) architecture. The PLMs generally use only the encoder block of the transformer, which consists of two sublayers: a self-attention layer and a feed-forward layer. BERT (Devlin et al., 2019) is the most widely used PLM, which consists of several layers of transformer encoders. It was pre-trained for 4 days with a large amount of text data, which consisted of 3.3 billion words, using masked language modeling and a next sentence prediction task in an unsupervised manner. This pre-trained model can be easily used in various downstream tasks by fine-tuning it with a labeled dataset. Following the success of BERT, a variety of similar PLMs have emerged. Lan et al. (2019) proposed ALBERT, which outperformed BERT with considerably fewer parameters. ALBERT's architecture is more complex than BERT's; however, by applying factorized embedding parameterization and cross-layer parameter sharing, the number of parameters can be reduced. Liu et al. (2019) observed that BERT is significantly undertrained, and proposed RoBERTa, a more robust and better-performing model, which is obtained by a longer pre-training with a larger dataset (approximately 10 times that of BERT) and the removal of next sentence prediction.

2.2 Domain knowledge transferring for PLMs

Despite the PLMs' excellent performances in several downstream tasks in the general domain, they have not exhibited a superior performance in specific domain tasks, such as in biomedicine. To provide domain-specific knowledge to PLMs, additional pre-training with in-domain data has been applied. BioBERT (Lee et al., 2020) further pre-trained BERT using biomedical text consisting of 18 billion words, such as literature abstracts. Peng et al. (2019) applied a similar approach with both biomedical and clinical text data. Differently, Gu et al. (2020) pre-trained BERT from scratch with only biomedical literature.

3 DoKTra framework

In this section, we introduce the DoKTra framework, which is the main approach to transfer domain-specific knowledge.

3.1 Overview

The main goal of the DoKTra framework is to produce a task-specific student model for each downstream task in a specific domain by distilling domain knowledge from a fine-tuned teacher model. Our framework consists of two main stages: calibrated teacher training and activation boundary distillation.

In calibrated teacher training, the teacher model is trained to distil its domain-specific and task-specific knowledge into the student model. We use an existing in-domain PLM as the initial teacher model. For each downstream task in the initial teacher's domain, the teacher model is fine-tuned with its training data. In this process, an entropy regularization term, called the confidence penalty loss (Pereyra et al., 2017), is added to the training loss. By adding the confidence regularizer, the fine-tuned teacher model can generate more reliable output prediction probabilities for the input data, and thus, have a positive effect on distillation.

In activation boundary distillation, the domain-specific knowledge of the teacher model is transferred to the student model. We use an existing PLM as the initial student model, which is only pre-trained in the general domain. First, the student model is fine-tuned for a downstream task. Subsequently, it mimics the activation pattern of the hidden neurons in the teacher model (Heo et al., 2019). By distilling the activation pattern, the activation boundary of the teacher model is transferred more precisely, and the domain-specific knowledge of the teacher is transferred to the student model. Additionally, the student model is refined over fewer epochs with a standard classification loss (Romero et al., 2014; Yim et al., 2017; Heo et al., 2019). Because the student model is already fine-tuned for the downstream task, any additional refinement may result in overconfidence (Guo et al., 2017; Nixon et al., 2019). To address this issue, we also add the confidence regularizer to the refinement step. The proposed framework is visualized in Figure 2.

3.2 Calibrated teacher training

In this step, a task-specific teacher model is generated for each in-domain downstream task using a fine-tuning approach. Specifically, we choose BioBERT-base (Lee et al., 2020) as the initial teacher model, which has been pre-trained with a large biomedical domain corpus, such as PubMed abstracts. Owing to the in-domain pre-training, the BioBERT model outperforms the BERT model in several biomedical downstream tasks.

Despite their high performance, modern deep neural networks are not well calibrated (Guo et al., 2017), which is similar to language models such as BERT. In other words, these models only predict overconfidently and cannot generate a reliable output probability for the given input. However, most distillation approaches encourage the use of softened probability because they contain more information and can better support the learning of the student model (Hinton et al., 2015; Cho and Hariharan, 2019). Moreover, Menon et al. (2021) demonstrated that a teacher model that estimates "good" probabilities can better supervise a student model. Based on this idea, we apply an entropy-regularizing term that penalizes overconfidence when fine-tuning the teacher model (Pereyra et al., 2017). Several previous studies have revealed that a confidence penalty improves both the calibration and performance of biomedical downstream tasks (Choi and Lee, 2020).

Since an overconfident classification model produces output probabilities close to 0 and 1, its probability distribution has a low entropy value. The confidence penalty loss (CPL) addresses this problem by minimizing the negative entropy of the output probability. Formally, the output probability of the model with parameters θ can be written as a conditional distribution $p_\theta(\mathbf{y}|\mathbf{x})$ through the soft-

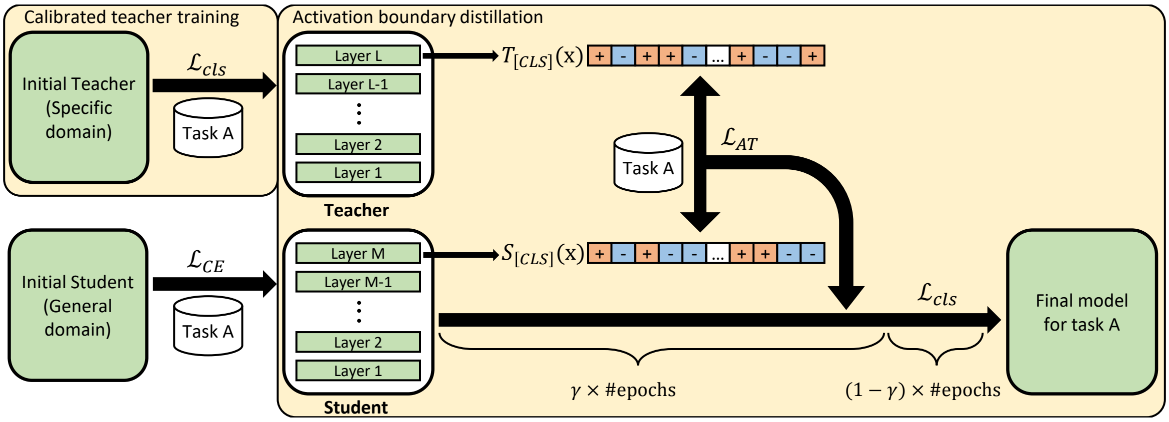


Figure 2: An overview of the DoKTra framework

max function for classes $\mathbf{y}$ and a given input $\mathbf{x}$. The entropy value of the output probability is given by

$$H(p_\theta(\mathbf{y}|\mathbf{x})) = -\sum_i p_\theta(\mathbf{y}_i|\mathbf{x}) \log(p_\theta(\mathbf{y}_i|\mathbf{x})), \tag{1}$$

where i denotes the class index. Finally, negative entropy is added to a regular cross-entropy loss $\mathcal{L}_{CE}$,

$$\mathcal{L}_{cls} = \mathcal{L}_{CE} - \beta H(p_\theta(\mathbf{y}|\mathbf{x})), \tag{2}$$

where β refers to a hyperparameter that controls the strength of entropy penalty.

3.3 Activation Boundary Distillation

Recently, Heo et al. (2019) has proposed a knowledge distillation method that only distils the activation boundary of the hidden representation of a deep neural network. Instead of distilling the magnitude of the neurons of the teacher network, Heo et al. (2019) designed the distillation loss to only transfer the activation of neurons and thus, allowed the activation boundary to be transferred. Since the decision boundary of a model, which consists of a combination of activation boundaries, is critical for the classification task, this method outperformed several distillation methods in image classification. Moreover, they also reported that the activation boundary distillation can learn rapidly and more efficiently with a small amount of training data. Thus, we select it as the domain-knowledge transferring method for our framework; this is beacuse the domain-specific downstream tasks usually consist of lesser training data than general domains.

To apply the activation boundary distillation to PLMs, we use classification embedding of the teacher and student as the distillation target. More precisely, the input sequence of a PLM such as BERT can be written as $[CLS], t_1, t_2, \ldots, [SEP]$, where t_i is the i-th token of the example. Then, the final output sequence is $h([CLS]), h(t_1), \ldots, h([SEP])$, where $h(t)$ indicates the hidden output of the last layer of the token t. For the classification task, the output embedding of the first special token("[CLS]," also known as the classification token) is generally used as the input of the classification layer. Thus, we apply activation boundary distillation to the classification embedding (output embedding of the classification token). For an input example $\mathbf{x}$, let $T_{[CLS]}(\mathbf{x}) \in \mathbb{R}^d$ and $S_{[CLS]}(\mathbf{x}) \in \mathbb{R}^d$ be the classification embedding vector ($h([CLS])$) of the teacher and student model, respectively. An element-wise activation indicator function can be defined to express the activation of a neuron:

$$\rho(x) = \begin{cases} 1, & \text{if } x > 0 \\ 0, & \text{otherwise.} \end{cases} \tag{3}$$

The loss function to transfer the activation of neurons is a l_1 norm of the difference between activations:

$$\mathcal{L}_{AT}(\mathbf{x}) = \|\rho(T_{[CLS]}(\mathbf{x})) - \rho(S_{[CLS]}(\mathbf{x}))\|_1. \tag{4}$$

However, this loss function cannot be minimized using gradient descent because ρ is a discrete function. To address this issue, Heo et al. (2019) has proposed an alternative loss function similar to hinge loss (Rosasco et al., 2004) with an activation function σ.

$$\begin{aligned}\mathcal{L}_{AT}(\mathbf{x}) = \|&\rho(T_{[CLS]}(\mathbf{x})) \odot \sigma(\mu\mathbf{1} - (S_{[CLS]}(\mathbf{x})))\\ &+(\mathbf{1} - \rho(T_{[CLS]}(\mathbf{x}))) \odot \sigma(\mu\mathbf{1} + (S_{[CLS]}(\mathbf{x})))\|_2^2,\end{aligned} \tag{5}$$

where $\odot$ is the element-wise product and $\mathbf{1}$ is a d-dimensional vector, with all values equal to 1. μ is the margin, which is a hyperparameter for training stability.

Specifically, we select two PLMs as the initial student model: ALBERT-xlarge (Lan et al., 2019), which has a smaller number of parameters but performs better than BERT, and RoBERTa-large (Liu et al., 2019), which has a larger number of parameters and is known to outperform BERT significantly for most of the tasks. To distil the knowledge from a teacher model, we first fine-tune the student model to provide initial knowledge about the task. Then the student model is trained with $\mathcal{L}_{AT}$. We also add a few refinement steps to refine the classification layer of the student model. Because the student model is already fine-tuned before the distillation step, this additional refinement may cause overconfidence. Thus, we apply a confidence penalty regularization in the refinement step. Namely, the student is refined with $\mathcal{L}_{cls}$ after the distillation steps. We add a hyperparameter $\gamma \in [0, 1]$, which determines when the training loss is switched from distillation to refinement. The procedure of the DoKTra framework is summarized in Algorithm 1.

Algorithm 1 DoKTra framework

Table 1: The statistics of the downstream task datasets

4 Experiments

4.1 Datasets

We evaluated our approach on several biomedical and clinical classification downstream tasks, including relation extraction and multi-label classification.

The relation extraction task aims to classify the relationship between two entities (e.g., gene, chemical, and disease) that are already annotated. The ChemProt (Krallinger et al., 2017) dataset contains PubMed abstracts with 10 types of chemical-protein interaction annotations and only five of the types are used for evaluation. The GAD dataset (Bravo et al., 2015) consists of gene-disease binary relation annotations. The DDI (Herrero-Zazo et al., 2013) dataset consists of text from the DrugBank database and Medline abstracts, with four types of drug-drug interaction annotations. In the clinical domain, the i2b2 dataset (Uzuner et al., 2011) contains texts from clinical documents, and eight types of relations between medical problems and treatments have been annotated. The HoC (Baker et al., 2016) corpus consists of PubMed abstracts with ten types of hallmarks of cancer annotation. Note that the HoC dataset is a multi-label document classification task predicting the combination of labels from an input text.

We pre-process every classification dataset except for GAD in the same manner as the BLUE (Peng et al., 2019) benchmark. In particular, entity anonymization is applied to all relation extraction datasets, which replace the entity mentions with anonymous tokens (e.g., @GENE$, @DISEASE$) to avoid confusion in using complex entity names. We use a pre-processed version of the GAD dataset provided by BioBERT, which is split for 10-fold cross-validation. The statistics of the pre-processed downstream task datasets are listed in Table 1.

4.2 Experimental details

For the experiments, we used the pre-trained BioBERT-base model (L=12, H=768, A=12) as the initial teacher model. We used two pre-trained models as the initial student model: ALBERT-xlarge (L=24, H=2048, A=32) and RoBERTa-large (L=24, H=1024, A=16). In the previous description, we have assumed that the embedding dimensions of teachers and students are identical. However, because the hidden embedding dimensions of teachers and students are different in our setting, we applied a linear transformation to the teacher's classification embedding to match the dimension with the student model.

In calibrated teacher training, we trained for 3-10 epochs with a learning rate of 2e-5. The hyperparameter β_1, the strength of the confidence penalty in teacher training, was chosen from {0, 0.3, 0.5, 0.7}. For activation boundary distillation, we first fine-tuned the initial student model for 5-10 epochs with learning rates of {6e-6, 8e-6, 1e-5}. Then, we distilled for 10 epochs with learning rates of {6e-6, 8e-6, 1e-5}. The confidence penalty strength β_2 in the refinement step and loss switch rate γ were chosen from {0, 0.3, 0.5, 0.7} and {0.6, 0.7 ,0.8, 0.9}, respectively. The margin μ of the activation transfer loss was set to 1.0. Every hyperparameter was tuned on the development set. The selected hyperparameters are shown in the Appendix.

The experiments were run on a single RTX 3090 24 GB GPU, and the training codes were implemented in PyTorch. All experiments were repeated three times with different random seeds, and the average performances and standard deviations have been reported.

4.3 Experimental results on downstream tasks

Table 2 shows the overall experimental F1 score results of the DoKTra framework on five biomedical and clinical classification tasks. The initially fine-tuned student models are in the second and fourth rows and the DoKTra framework is applied to both, as shown in the third and fifth rows.

As shown in the third and fifth rows, the classification performances of biomedical and clinical downstream tasks are significantly improved by applying our proposed framework, when compared to the initial student models. This implies that distilling the activation patterns of the neurons from the calibrated teacher model can transfer its domain-specific knowledge and thus improve the task performance in the domain on which the student has not yet been pre-trained.

By applying the DoKTra framework, the ALBERT-xlarge student model was able to retain 99.72% of the teacher model performance on an average. ALBERT has two advantages: a small number of parameters and high performance (Lan et al., 2019). Applying our framework to ALBERT allowed us to obtain a student model with performance comparable to that of the teacher with half the parameters. In other words, we successfully transferred domain-specific knowledge to ALBERT while maintaining its existing advantages. Consequently, the distilled ALBERT achieved a higher performance than the teacher model on ChemProt and DDI.

The RoBERTa model that was applied to the proposed framework outperformed the teacher model on an average, specifically in four of five downstream tasks (ChemProt, DDI, i2b2, and HoC). RoBERTa's performance was already similar to the teacher model in the initial fine-tuning stage because it was pre-trained with more data than BERT and exhibited a greater robustness. The results on RoBERTa imply that our proposed framework can be effectively applied to emerging and advanced pre-trained language models. In other words, domain-specific knowledge can be transferred into advanced models without a time-consuming pre-

training and perturbing the model's efficacy in the general domain.

4.4 Performance comparisons

To compare our approach with the in-domain pre-training method, we used RoBERTa-PM-large (Lewis et al., 2020), which is a RoBERTa-large model additionally pre-trained with a large biomedical and clinical corpus consisting of 14 billion words. We fine-tuned the RoBERTa-PM for each task.

Table 3 shows the classification performance of BioBERT, RoBERTa-PM, and our approach in five biomedical and clinical tasks. As mentioned before, our best model outperformed the BioBERT (teacher) model on four of the five tasks. Notably, our approach even outperformed RoBERTa-PM on two tasks and demonstrated comparable performances on the others. These results are remarkable since our approach spent only a few hours on each task, whereas RoBERTa-PM may require several days and billions of words to be pre-trained. Note that RoBERTa-PM has an advantage in the i2b2 task since its pre-training data contains MIMIC-III clinical text data, while our teacher model was pre-trained with only biomedical texts. In other words, this implies our approach has a room for further improvement when a better in-domain model is set as a teacher.

We also compared our framework with task-adaptive pre-training (TAPT) (Gururangan et al., 2020), an additional pre-training method for PLMs. The TAPT approach additionally pre-trains an existing PLM before fine-tuning it with the training samples of each task. As both TAPT and DoKTra only utilize the task-specific training data, they can be fairly compared in terms of performance and training resources. For TAPT, we additionally pre-trained the RoBERTa-large model with each pre-processed downstream task's training data. We followed the hyperparameters used in TAPT except for batch size and the maximum sequence length because we used the same computing resource as DoKTra for a fair comparison. The possible maximum pre-training batch size with the given computing resource for the RoBERTa-large model was 36. Since the results of the RoBERTa-large model with a small batch size were unstable, we also performed a distributed training with three GPUs, resulting in a batch size of 108.

The comparison results are shown in Table 4. Note that the performance on GAD in Table 4 was evaluated with the first split of a 10-fold cross-validation, while the main result in Table 3 was evaluated with all splits. As revealed in the results, even though TAPT showed improved results in the original study with Google Cloud TPU, it was unstable with the small batch size and sequence length; the performances were even degraded in the general GPU environment. Although the TAPT performance improved when the batch size increased through distributed training, the improvement was inadequate. This may be because of the batch size being smaller than that in the TPU environment. Moreover, DoKTra required less training time than TAPT while both methods were task-specific. For instance, TAPT required a total of seven hours of training, while DoKTRa was completed in only 1.1 hours for the ChemProt task. This is because DoKTra leverages the knowledge of an existing in-domain PLM, thus requiring only a few fine-tuning and distillation steps. The comparison of TAPT and DoKTra using more advanced computing resources is left as a future work.

4.5 Efficacy of combining calibration and activation boundary distillation

We conducted an experiment to verify the positive effect of combining calibrated teacher training and activation boundary distillation. Because the entropy regularizer in calibrated teacher training issues penalties based on the output probability distribution, it is difficult to intuitively understand how it positively affects activation boundary distillation, which uses hidden representation. Thus, we ablate the calibrated teacher training steps in our framework and compare the final performances and loss values.

Irrespective of the use of an alternative version (Equation 5) during the training, the extent to which the activation pattern is distilled can be intuitively observed by calculating the original "activation transfer loss" (Equation 4). The value of Equation 4 directly refers to the number of neurons activated differently than the teacher model. For instance, if $\mathcal{L}_{AT} = 500$ for an ALBERT model (H=2,048), it indicates that 500 of the 2,048 elements in the hidden representation vector exhibited signs different to those of the teacher.

Table 5 shows the experimental results on four relation extraction tasks with ALBERT students. As shown in Table 5, the application of the calibrated teacher training reduces the $\mathcal{L}_{AT}$ and improves the classification performance. In other words, calibration on the teacher training clearly aids the supervision of the teacher in activation boundary distillation, even though the output probability information is not directly used in distillation.

4.6 Ablation study

To observe how each component contributed to the proposed framework, we conducted an ablation study. We ablated two major components: calibrated teacher training (CTT) and activation boundary distillation (ABD). The experiments were performed on the ChemProt dataset, using the ALBERT-xlarge model as the student architecture. To ablate the calibrated teacher training, we trained the teacher model using only $\mathcal{L}_{CE}$. We compared the activation boundary distillation with KL-divergence based distillation (KLD), which penalizes the difference between the output probability distributions of the two models.

Table 6 presents the results of the ablation study. As we proposed, applying both calibrated teacher training and activation boundary distillation resulted in a superior performance. In particular, the calibrated teacher model was able to distil its activation boundary to the student model much more effectively, thus improving the performance of the student model, as we hypothesized in the previous section. Applying KL-divergence-based distillation yielded positive results in terms of classification performance. Notably, calibrated teacher training also improved the KL-divergence-based distillation because it enabled the distillation of a considerably more reliable output probability, as reported in Menon et al. (2021). Note that applying the confidence regularizer to the fine-tuning of the student model only slightly improved the performance, suggesting that the observed gains in our model are only partially because of the calibration regularizer.

4.7 Experimental results on financial domain

To verify the general applicability of our approach, we conducted experiments on financial sentiment classification tasks. Financial sentiment analysis

Table 7: Experimental results of DoKTra framework on financial domain. (ft: fine-tuned)

aims to classify the polarity of financial-related text, such as financial news or tweets. Since financial text usually contains specialized language, several pre-training approaches have emerged (Araci, 2019; Yang et al., 2020; Liu et al., 2021) to fill the gap between the general and financial domains.

In this study, we selected the FinBERT (Yang et al., 2020) model as a teacher in the DoKTra framework and evaluated our approach on two tasks, the Financial PhraseBank (FPB) and FinTextSen (FTS). The Financial PhraseBank (FPB) (Malo et al., 2014) contains sentences from financial news annotated for positive, neutral, and negative sentiments. The FinTextSen (FTS) (Cortis et al., 2017) consists of financial tweets from Twitter and StockTwits with real-valued sentiment scores. To transform it into a classification task, we clustered the sentiment score into a 3-class label, following Daudert et al. (2018). The Financial PhraseBank dataset contains 4,846 sentences, and we set 10% of the examples as the test set while preserving the label distribution. The FinTextSen originally includes 2,488 tweets, but only 1,700 tweets are available now. We set 10% of the entire data as the test set, which is similar to FPB.

As shown in Table 7, ALBERT-DoKTRa and RoBERTa-DoKTRa outperformed the FinBERT-ft teacher on financial downstream tasks. Note that we used the RoBERTa-base model in this section because of the training stability. This result suggests that DoKTra can be applied regardless of the domain and can be an efficient alternative to in-domain pre-training.

5 Conclusion

In this study, we proposed the DoKTra framework as a domain knowledge transfer method for PLMs. The experimental results from the biomedical, clinical, and financial domain downstream tasks demonstrated that our proposed framework could transfer domain-specific knowledge into a PLM, while preserving its own expressive advantages without any further pre-training with additional in-domain data. We employed advanced models as the student model and verified the future applicability of our framework to emerging language models by achieving even higher performances than the teacher model. However, the limitations of our approach are that it is task-specific and was evaluated only in classification tasks. Our future studies would focus on developing the proposed framework as a task-agnostic method and evaluating it on various tasks.

A Appendix

A.1 Hyperparameter setting

In this section, we report the searching scheme and actual values of the hyperparameters used by us. In all cases, we set the batch size to the maximum that a single GPU can process, with 128 being the maximum sequence length.

In calibrated teacher training, we first select the number of epochs and the learning rate as the default values of the BioBERT code and slightly change the number of epochs (e) for the unreported tasks from BioBERT. Then, we select the strength of the confidence regularization (β_1) by a grid search in terms of the F1 score and expected calibration error (ECE) on the development set. The formula for calculating ECE is as follows:

$$\mathrm{acc}(B_m) = \frac{1}{|B_m|} \sum_{i \in B_m} \mathbf{1}(\hat{y}_i = y_i),$$

$$\mathrm{conf}(B_m) = \frac{1}{|B_m|} \sum_{i \in B_m} \hat{p}_i,$$

$$\mathrm{ECE} = \sum_{m=1}^{M} \frac{|B_m|}{n} |\mathrm{acc}(B_m) - \mathrm{conf}(B_m)|,$$

where B_m is the m-th bin, $\hat{y}_i$ and y_i indicate the predicted and true labels of the i-th sample in the bin, and $\widehat{pi}$ is the output prediction probability. n is the number of total examples. A low ECE value implies that the model generates an output probability similar to its accuracy, and thus, is well-calibrated. The actual values of the hyperparameters for the calibrated teacher training are summarized in Table A1.

In activation boundary distillation, we perform a grid search to determine the number of epochs (e_1) and learning rate (lr_1) for initial student fine-tuning. Then, we conduct another grid search of the learning rate (lr_2), number of epochs (e_2), weight of the confidence penalty (β_2), and loss switch rate (γ) for the distillation and refinement steps. Both searches are performed on the development set. The actual values of the hyperparameters for the ALBERT student are summarized in Table A2. For the RoBERTa model as a student, we use the same teacher with ALBERT. The hyperparameters of the activation boundary distillation for the RoBERTa student are searched in the same manner with the ALBERT and summarized in Table A3.

A.2 Experimental details for financial domain

In this section, we report on the details of two financial downstream task datasets, the experimental details, and hyperparameters of the financial task experiments.

we used the pre-trained FinBERT-base model (L=12, H=768, A=12) with the original vocabulary. We used ALBERT-xlarge (L=24, H=2048, A=32) and RoBERTa-base (L=12, H=768, A=12) as the students. The hyperparameters are searched in the same way as the experiments for the biomedical domain. The actual values of the hyperparameters for the calibrated teacher training and activation boundary distillation with ALBERT and RoBERTa are summarized in Tables A4, A5, and A6.

Retrieval-guided Counterfactual Generation for QA

Abstract

Deep NLP models have been shown to be brittle to input perturbations. Recent work has shown that data augmentation using counterfactuals — i.e. minimally perturbed inputs — can help ameliorate this weakness. We focus on the task of creating counterfactuals for question answering, which presents unique challenges related to world knowledge, semantic diversity, and answerability. To address these challenges, we develop a ***Retrieve-Generate-Filter*** (RGF) technique to create counterfactual evaluation and training data with minimal human supervision. Using an open-domain QA framework and question generation model trained on original task data, we create counterfactuals that are fluent, semantically diverse, and automatically labeled. Data augmentation with RGF counterfactuals improves performance on out-of-domain and challenging evaluation sets over and above existing methods, in both the reading comprehension and open-domain QA settings. Moreover, we find that RGF data leads to significant improvements to robustness to local perturbations.[1]

1 Introduction

Models for natural language understanding (NLU) may outperform humans on standard benchmarks, yet still often perform poorly under a multitude of distributional shifts (Jia and Liang (2017); Naik et al. (2018); McCoy et al. (2019), *inter alia*) due to over-reliance on spurious correlations or dataset artifacts. This behavior can be probed using counterfactual data (Kaushik et al., 2020; Gardner et al., 2020) designed to simulate interventions on specific attributes: for example, perturbing the movie review *"A real stinker, one out of ten!"* to *"A real classic, ten out of ten!"* allows us to discern the effect of adjective polarity on the model's prediction. Many recent works (Kaushik et al., 2020, 2021; Wu et al., 2021a; Geva et al., 2021, *inter alia*) have shown that training augmented with this counterfactual data (CDA) improves out-of-domain generalization and robustness against spurious correlations. Consequently, several techniques have been proposed for the automatic generation of counterfactual data for several downstream tasks (Wu et al., 2021a; Ross et al., 2021b,a; Bitton et al., 2021; Geva et al., 2021; Asai and Hajishirzi, 2020; Mille et al., 2021).

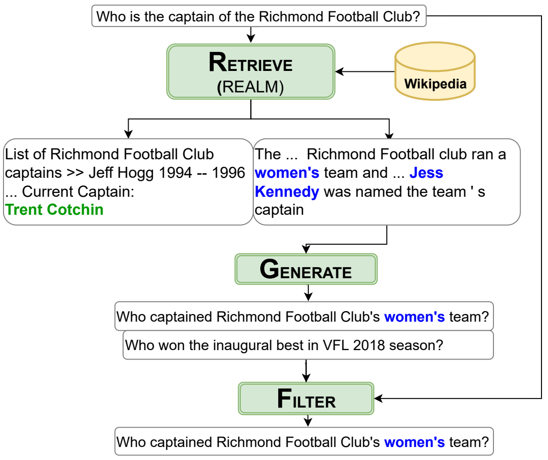

Figure 1: *Retrieve-Generate-Filter* to generate counterfactual queries for Natural Question (Kwiatkowski et al., 2019) using an open-domain retrieval system, question generation and post-hoc filtering.

In this paper, we focus on counterfactual data for question answering, in both the reading comprehension and open-domain settings (e.g. Rajpurkar et al., 2016; Kwiatkowski et al., 2019). Model inputs consist of a question and optionally a context passage, and the target a is a short answer span. Counterfactuals are often considered in the context of a specific causal model (Miller, 2019; Halpern and Pearl, 2005), but in this work we follow Wu et al. (2021a) and Kaushik et al. (2020) and seek a method to generate counterfactuals that may be use-

ful in many different settings. In QA, the set of possible causal features is large and difficult to specify *a priori*; relevant factors are often instance-specific and exploring them may require world knowledge. For example, going from *"Who is the captain of the Richmond Football Club"* to a perturbed question *"Who captained Richmond's women's team?"* as in Figure 1 requires knowledge about the club's alternate teams, and the perturbation *"Who was the captain of RFC in 1998?"* requires knowledge about the time-sensitive nature of the original question. In the absence of such knowledge, otherwise reasonable edits — such as *"Who captained the club in 2050?"* — can result in false premises or unanswerable questions.

We develop a simple yet effective technique to address these challenges: ***R**etrieve, **G**enerate, and **F**ilter* (RGF; Figure 1). We use the near-misses of a retrieve-and-read QA model to propose alternate contexts and answers which are closely related to — but semantically distinct from — the original question. We then use a sequence-to-sequence question generation model (Alberti et al., 2019) to generate corresponding questions to these passages and answers. This results in fully-labeled examples, which can be used directly to augment training data or filtered post-hoc for analysis.

While our method requires no supervised inputs besides the original task training data, it is able to generate highly diverse counterfactuals covering a range of semantic phenomena (§4), including many transformation types which existing methods generate through heuristics (Dua et al., 2021), meaning representations (Ross et al., 2021b; Geva et al., 2021) or human generation (Bartolo et al., 2020; Gardner et al., 2020). Compared to alternative sources of synthetic data (§5.1), training augmented with RGF data improves performance on a variety of settings (§5.2, §5.3), including out-of-domain (Fisch et al., 2019) and contrast evaluation sets (Bartolo et al., 2020; Gardner et al., 2020), while maintaining in-domain accuracy. Additionally, we introduce a measure of *pairwise consistency*, and show that RGF significantly improves robustness to a range of local perturbations (§6).

2 Related Work

2.1 Counterfactual Generation

There has been considerable interest in developing challenge sets for NLU that evaluate models on a wide variety of counterfactual scenarios. Gardner et al. (2020); Khashabi et al. (2020); Kaushik et al. (2020); Ribeiro et al. (2020) use humans to create these perturbations, optionally in an adversarial setting against a particular model (Bartolo et al., 2020). However, these methods can be expensive and difficult to scale.

This has led to an increased interest in creating *automatic* counterfactual data for evaluating out-of-distribution generalization (Bowman and Dahl, 2021) and for counterfactual data augmentation (Geva et al., 2021; Longpre et al., 2021). Some work focuses on using heuristics like swapping superlatives and nouns (Dua et al., 2021), changing gendered words (Webster et al., 2020), or targeting specific data splits (Finegan-Dollak and Verma, 2020). More recent work has focused on using meaning representation frameworks and structured control codes (Wu et al., 2021a), including grammar formalisms (Li et al., 2020), semantic role labeling (Ross et al., 2021b), structured image representations like scene graphs (Bitton et al., 2021), and query decompositions in multi-hop reasoning datasets (Geva et al., 2021). Ye et al. (2021) and Longpre et al. (2021) perturb contexts instead of questions by swapping out all mentions of a named entity. The change in label can be derived heuristically or requires a round of human re-labeling of the data. These may also be difficult to apply to tasks like Natural Questions (Kwiatkowski et al., 2019), where pre-defined schemas can have difficulty covering the range of semantic perturbations that may be of interest.

2.2 Data Augmentation

Non-counterfactual data augmentation methods for QA, where the synthetic examples are *not* paired with the original data, have shown only weak improvements to robustness and out-of-domain generalization (Bartolo et al., 2021; Lewis et al., 2021). Counterfactual data augmentation is hypothesized to perform better, as exposing the model to minimal pairs should reduce spurious correlations and make the model more likely to learn the correct, causal features (Kaushik et al., 2020). However, Joshi and He (2021) find that methods that limit the structural and semantic space of perturbations can potentially hurt generalization to other types of transformations. This problem is exacerbated in the question answering scenario where there can be multiple semantic dimensions to edit. Our method attempts to address this by targeting a broad range of semantic phenomena, thus reducing the chance for the augmented model to overfit.

3 RGF: Counterfactuals for Information-seeking Queries

We define a counterfactual example as an alternative input x' which differs in some meaningful, controlled way from the original x, which in turn allows us to reason – or teach the model – about changes in the label (the outcome). For question-answering, we take as input triples (q, c, a) consisting of the question, context passage, and short answer, and produce counterfactual triples (q', c', a') where $a' \neq a$. This setting poses some unique challenges, such as the need for background knowledge to identify relevant semantic variables to alter, ensuring sufficient semantic diversity in question edits, and avoiding questions with false premises or no viable answers. Ensuring (or characterizing) minimality can also be a challenge, as small changes to surface form can lead to significant semantic changes, and vice-versa. We introduce a general paradigm for data generation — ***R**etrieve, **G**enerate and **F**ilter* — to tackle these challenges.

3.1 Overview of RGF

An outline of the RGF method is given in Figure 1. Given an input example $x = (q, c, a)$ consisting of a question, a context paragraph, and the corresponding answer, RGF generates a set of new examples $N(x) = \{(q'_1, c'_1, a'_1), (q'_2, c'_2, a'_2), \dots\}$ from the local neighborhood around x. We first use an open-domain retrieve-and-read model to retrieve alternate contexts c' and answers a' where $a \neq a'$. As near-misses for a task model, these candidates (c', a') are closely related to the original target (c, a) but often differ along interesting, latent semantic dimensions (Figure 2) in their relation to the original question, context, and answer. We then use a sequence-to-sequence model to generate new questions q' from the context and answer candidates (c', a'). This yields triples (q', c', a') which are fully labeled, avoiding the problem of unanswerable or false-premise questions.

Compared to methods that rely on a curated set of minimal edits (e.g. Wu et al., 2021b; Ross et al., 2021b), our method admits the use of alternative contexts[2] $c' \neq c$, and we do not explicitly constrain our triples to be *minimal* perturbations during the generation step. Instead, we use post-hoc filtering to reduce noise, select minimal candidates, or select for specific semantic phenomena based on the relation between q and q'. This allows us to explore a significantly more diverse set of counterfactual questions q' (§C.1), capturing relations that may not be represented in the original context c.

We describe each component of RGF below; additional implementation details are provided in Appendix A.

3.2 Retrieval

We use REALM retrieve-and-read model of (Guu et al., 2020). REALM consists of a BERT-based bi-encoder for dense retrieval, a dense index of Wikipedia passages, and a BERT-based answer-span extraction model for reading comprehension, all fine-tuned on Natural Questions (NQ; Kwiatkowski et al., 2019). Given a question q, REALM outputs a ranked list of contexts and answers within those contexts: $\{(c'_1, a'_1), (c'_2, a'_2), \dots (c'_k, a'_k)\}$. These alternate contexts and answers provide relevant yet diverse background information to construct counterfactual questions. For instance, in Figure 1, the question *"Who is the captain of the Richmond Football Club"* with answer *"Trent Cotchin"* also returns other contexts with alternate answers like *"Jeff Hogg"* (q' =*"Who captained the team in 1994"*), and *"Steve Morris"* (q' =*"Who captained the reserve team in the VFL league"*). Retrieved contexts can also capture information about closely related or ambiguous entities. For instance, the question *"who wrote the treasure of the sierra madre"* retrieves passages about the original book *Sierra Madre*, its movie adaptation, and a battle fought in the Sierra de las Cruces mountains. This background knowledge allows us to perform *contextualized* counterfactual generation, without needing to specify *a priori* the type of perturbation or semantic dimension. To focus on label-transforming counterfactuals, we retain all (c'_i, a'_i) where a'_i does not match any of the gold answers a from the original NQ example.

3.3 Question Generation

This component generates questions q' that correspond to the answer-context pairs (c', a'). We use a T5 (Raffel et al., 2020) model fine-tuned

---

[2] An alternative approach would be to make direct, targeted edits to the original context c. However, beyond a limited space of local substitutions (Longpre et al., 2021; Ye et al., 2021; Ross et al., 2021a) this is very difficult due to the need to model complex discourse and knowledge relations.

on (q, c, a) triples from Natural Questions, using context passages as input with the answer marked with special tokens. We use the trained model to generate questions $(q'_1, q'_2, \ldots q'_k)$ for each of the the retrieved set of alternate contexts and answers, $((c'_1, a'_1), (c'_2, a'_2), \ldots (c'_k, a'_k))$. For each (c'_i, a'_i), we use beam decoding to generate 15 different questions q'. We measure the fluency and correctness of generated questions in §4.

3.4 Filtering for Data Augmentation

Noise Filtering The question generation model can be noisy, resulting in a question that cannot be answered given c' or for which a' is an incorrect answer. Round-trip consistency (Alberti et al., 2019; Fang et al., 2020) uses an existing QA model to answer the generated questions, ensuring that the predicted answer is consistent with the target answer provided to the question generator. We use an ensemble of six T5-based reading-comprehension ($(q, c) \rightarrow a$) models, trained on NQ using different random seeds (Appendix A), and keep any generated (q', c', a') triples where at least 5 of the 6 models agree on the answer. This discards about 5% of the generated data, although some noise still remains; see §4 for further discussion.

Filtering for Minimality Unlike prior work on generating counterfactual perturbations, we do not explicitly control for the type of semantic shift or perturbation in the generated questions. Instead, we use post-hoc filtering over generated questions q' to encourage minimality of perturbation. We define a filtering function $f(q, q')$ that categorizes the semantic shift or perturbation in q' with respect to q. One simple version of f is the word-level edit (Levenshtein) distance between q and q'. After noise filtering, for each original (q, c, a) triple we select the generated (q', c', a') with the smallest non-zero word-edit distance between q and q' such that $a \neq a'$. We use this simple heuristic to create large-scale *counterfactual training data* for augmentation experiments (§5). Over-generating potential counterfactuals based on latent dimensions identified in retrieval and using a simple filtering heuristic avoids biasing the model toward a narrow set of perturbation types (Joshi and He, 2021).

Question from NQ
Original: who is the captain of richmond football club?
Predicate: who is the captain of X?

Reference Change
CF1: who is the captain of richmond's vfl reserve team?
Predicate: who is the captain of X?

Predicate Change
CF2: who wears number 9 for richmond football club?
Predicate: who wears Y for X?

Predicate and Reference Change
CF3: who did graham negate in the grand final last year?
Predicate: who did X negate in Y last year?

Table 1: Categorization of generated questions based on QED decomposition. The original reference *"Richmond football Club"* changes in CF1 and CF3. Predicate *"Who is the captain"* changes in CF2 and CF3.

3.5 Semantic Filtering for Evaluation

To better understand the types of counterfactuals generated by RGF, we can apply additional filters based on question meaning representations to categorize counterfactual (q, q') pairs for evaluation. Meaning representations provide a way to decompose a question into semantic units and categorize (q, q') based on which of these units are perturbed. In this work, we employ the QED formalism for explanations in question answering (Lamm et al., 2021). QED decompositions segment the question into a predicate template and a set of reference phrases. For example, the question *"Who is captain of richmond football club"* decomposes into one question reference *"richmond football club"* and the predicate *"Who is captain of X"*. A few example questions and their QED decompositions are illustrated in Table 1.

We use these question decompositions to identify the relation between a counterfactual pair (q, q'). Concretely, we fine-tune a T5-based model on the QED dataset to perform explanation generation following the recipe of Lamm et al. (2021), and use this to identify predicates and references for the question from each (q, c, a) triple. We use exact match between strings to identify reference changes. As predicates can often differ slightly in phrasing (*who captained* vs. *who is captain*), we take a predicate match to be a prefix matching with more than 10 characters. For instance, *"Who is the captain of Richmond's first ever women's team?"*, *"Who is the captain of the Richmond Football Club"* have same predicates. We filter generated questions into three perturbation categories — reference change, predicate change, or both.

4 Intrinsic Evaluation

Following desiderata from Wu et al. (2021a) and Ross et al. (2021b), we evaluate our RGF data

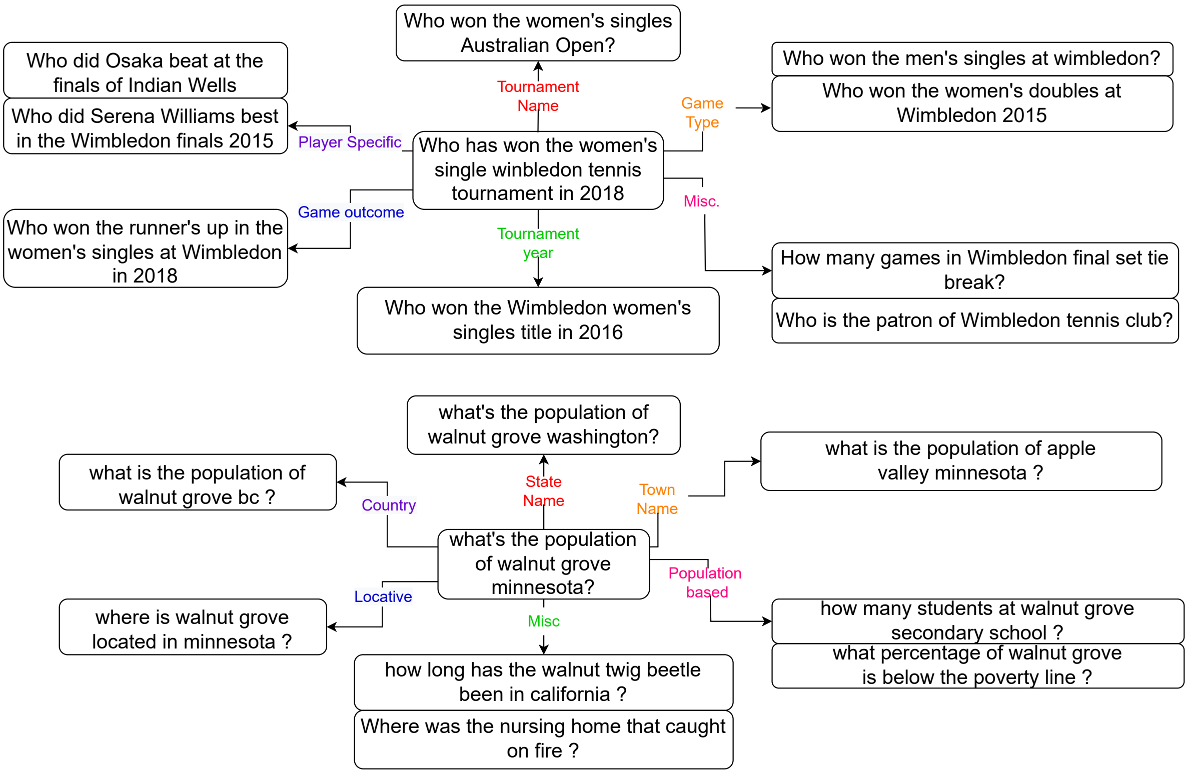

Figure 2: Context-specific semantic diversity of perturbations achieved by RGF on questions from NQ. The multiple latent semantic dimensions identified (arrows in the diagram) emerge from our retrieval-guided approach.

Semantic Change	Example (Original, Counterfactual)
Reference Change TAILOR (Ross et al., 2021b)	O: when did lebron_james join the Miami_Heat? C: When did lebron_james come into the league?
Predicate Change AmbigQA (Min et al., 2020b)	O: Who won the war between india and pakistan C: Who started the war between india and pakistan
Disambiguation AmbigQA (Min et al., 2020b)	O: When does walking dead season 8 start? C: When does walking dead season 8 second half start?
Negation Polyjuice (Wu et al., 2021a)	O: what religion observes the sabbath day C: what religion does not keep the sabbath day

Table 2: Patterns of semantic change between original queries (O) and RGF counterfactuals (C), corresponding to patterns explored by related works.

along three measures: *fluency*, *correctness*, and *directionality*.

Fluency Fluency measures whether the generated text is grammatically correct and semantically meaningful. Fluency is very high from RGF, as the generation step leverages a high-quality pretrained langauge model (T5). We manually annotate a subset of 100 generated questions, and find that 96% of these are fluent.

Correctness Correctness measures if the generated question q' and context, alternate answer pairs (c', a') are aligned, i.e. the question is answerable given context c' and a' is that answer. We quantify correctness in the generated dataset by manually annotating a samples of 100 (q', c', a') triples (see Appendix B). The proportion of noise varies from 30% before noise filtering and 25% after noise filtering using an ensemble of models (§3.4).

Directionality/Semantic Diversity In Table 2, we show examples of semantic changes that occur in our data, including reference changes (50% of changes), predicate changes (30%), negations (1%), question expansions, disambiguations, and contractions (13%). These cover many of the transformations found in prior work (Gardner et al., 2020; Ross et al., 2021b; Min et al., 2020b), but RGF is able to achieve these without the use of heuristic transformations or structured meaning representations. As shown in Figure 2, the types of relations are semantically rich and cover attributes relevant to each particular instance that would be difficult to capture with a globally-specified schema. Additional examples are shown in Figure 6.

Exact Match (RC)	Train Size	NQ	SQuAD	TriviaQA	HotpotQA	BioASQ	AQA	AmbigQA
Original NQ	90K	70.91	80.26	13.67	50.57	35.90	27.00	46.81
Ensemble	90K	**71.29**	**80.50**	13.86	50.57	36.90	27.80	**46.90**
Gold Agen-Qgen	90K + 90K	70.80	67.71	10.83	42.69	30.63	19.40	41.95
Rand. Agen-Qgen	90K + 90K	71.06	74.31	12.88	45.52	32.58	23.30	42.48
RGF (REALM-Qgen)	90K + 90K	70.22	79.87	**15.39**	**53.36**	**42.89**	**28.90**	46.81

Table 3: Exact Match results for the reading comprehension task for in-domain NQ development set, out-of-domain datasets from MRQA 2019 Challenge (Fisch et al., 2019), Adversarial QA (Bartolo et al., 2020) and AmbigQA (Min et al., 2020b). RGF improves out-of-domain and challenge-set performance compared to other data augmentation baselines.

5 Data Augmentation

Unlike many counterfactual generation methods, RGF natively creates fully-labeled (q', c', a') examples which can be used directly for counterfactual data augmentation (CDA). We augment the original NQ training set with additional examples from RGF, shuffling all examples in training. We explore two experimental settings, reading comprehension (§5.2) and open-domain QA (§5.3), and compare RGF-augmented models to those trained only on NQ, as well as to alternative baselines for synthetic data generation. As described in Section 3.4, we use edit-distance based filtering to choose *one* generated (q', c', a') triple to augment for every original example, (q, c, a).[3] Additional training details for all models and baselines are included in Appendix A.

5.1 Baselines

In the abstract, our model for generating counterfactuals specifies a way of selecting contexts c' from original questions, and answers a' within those contexts, and a way of a generating questions q' from them. RGF uses a retrieval model to identify relevant contexts; here we experiment with two baselines that use alternate ways to select c'. We also compare to the **ensemble** of six reading comprehension models described in 3.4, with answers selected by majority vote.

Random Passage (Rand. Agen-Qgen) Here, c' is a randomly chosen paragraph from the Wikipedia index, with no explicit relation with the original question. This setting simulates generation from the original data distribution of Natural Questions. To ensure that the random sampling of Wikipedia paragraphs has a similar distribution, we employ the learned passage selection model from Lewis et al. (2021),[4]. This baseline corresponds to the model of Bartolo et al. (2021), which was applied to the SQuAD dataset (Rajpurkar et al., 2016); our version is trained on NQ and omits AdversarialQA.

Gold Context (Gold Agen-Qgen) Here, c' is the passage c containing the original short answer a from the NQ training set. This baseline specifically ablates the retrieval component of RGF, testing whether the use of alternate passages leads to more diversity in the resulting counterfactual questions.

Answer Generation for Baselines For both the above baselines for context selection, we select spans in the new passage that are likely to be answers for a potential counterfactual question. We use a T5 (Raffel et al., 2020) model fine-tuned for question-independent answer selection $c \rightarrow a$ on NQ, and select the top 15 candidates from beam search. To avoid simply repeating the original question, we only retain answer candidates a' which do not match the original NQ answers a for that example. These alternate generated answer candidates and associated passages are then used for question generation and filtering as in RGF (§3.3). For the Gold Agen-Qgen case, we select based on the longest edit distance between (q, q'), which gave significantly better performance than random selection or the shortest edit distance used for RGF.

5.2 Reading Comprehension (RC)

In the reading comprehension (RC) setting, the input consists of the question and context and the task is to identify an answer span in the context. Thus, we augment training with full triples (q', c', a') consisting of the retrieved passage c', generated and filtered question q', and alternate answer a'.

Experimental Setting We finetune a T5 (Raffel et al., 2020) model for reading comprehension,

---

[3] We don't see significant gains from adding more data beyond this; see Appendix C.3

[4] `https://github.com/facebookresearch/PAQ`

with input consisting of the question prepended to the context. We evaluate domain generalisation of our RC models on three evaluation sets from the MRQA 2019 Challenge (Fisch et al., 2019). We also measure performance on evaluation sets consisting of counterfactual or perturbed versions of RC datasets on Wikipedia, including SQuAD (Rajpurkar et al., 2016), AQA (adversarially-generated SQuAD questions; Bartolo et al., 2020), and human authored counterfactual examples (contrast sets; Gardner et al., 2020) from the QUOREF dataset (Dasigi et al., 2019). We also evaluate on the set of disambiguated queries in AmbigQA (Min et al., 2020b), which by construction are minimal edits to queries from the original NQ.

Results We report exact-match scores in Table 3; F1 scores follow a similar trend. We observe only limited improvements on the in-domain NQ development set, but we see significant improvements from CDA with RGF data in out-of-domain and challenge-set evaluations compared both to the original NQ model and the Gold and Random baselines. RGF improves by 1-2 EM points on most challenge sets, and up to 7 EM points on the BioASQ set compared to training on NQ only, while baselines often underperform the NQ-only model on these sets. Note that all three augmentation methods have similar proportion of noise (Appendix B), so CDA's benefits may be attributed to improving model's ability to learn more robust features for the task of reading comprehension. Using an ensemble of RC models improves slightly on some tasks, but does not improve on OOD performance as much as RGF. RGF's superior performance compared to the Gold Agen-Qgen baseline is especially interesting, since the latter also generates topically related questions. We observe that RGF counterfactuals are more closely related to the original question compared to this baseline (Figure 5 in Appendix C), since q' is derived from a near-miss candidate (c', a') to answer the original q (S3.1).

5.3 Open-Domain Question Answering (OD)

In the open-domain (OD) setting, only the question is provided as input. The pair (q', a'), consisting of generated and filtered question q' and alternate answer a', is used for augmentation. Compared to the RC setting where passages change as well, here the edit distance filtering of §3.4 ensures the augmentation data represents minimal perturbations.

Experimental Setting We use the method and implementation from Guu et al. (2020) to finetune REALM on (q, a) pairs from NQ. End-to-end training of REALM updates both the reader model and the query-document encoders of the retriever module. We evaluate domain generalization on popular open-domain benchmarks: TriviaQA (Joshi et al., 2017), SQuAD (Rajpurkar et al., 2016), Curated TREC dataset (Min et al., 2021), and disambiguated queries from AmbigQA (Min et al., 2020b).

Results In the open-domain setting (Table 4), we observe an improvement of 2 EM points over the original model even in-domain on Natural Questions, while also improving significantly when compared to other data augmentation techniques. RGF improves over the next best baseline — Random Agen-Qgen — by up to 6 EM points (on TriviaQA). We hypothesize that data augmentation has more benefit in this setting, as the open-domain task is more difficult than reading comprehension, and counterfactual queries may help the model learn better query and document representations to improve retrieval.

6 Analysis

To better understand how CDA improves the model, we introduce a measure of local consistency (§6.1) to measure model robustness, and perform a stratified analysis (§6.2) to show the benefits of the semantic diversity available from RGF.

6.1 Local Robustness

Compared to synthetic data methods such as PAQ (Lewis et al., 2021), RGF generates counterfactual examples that are paired with the original inputs and concentrated in local neighborhoods around them (Figure 2). As such, we hypothesize that augmentation with this data should specifically improve local consistency, i.e. how the model behaves under small perturbations of the input.

Experimental Setting We explicitly measure how well a model's local behavior respects perturbations to input. Specifically, if a model $f : (q, c) \rightarrow a$ correctly answers q, how often does it also correctly answer q'? We define *pairwise consistency* as accuracy over the counterfactuals (q', a', c'), conditioned on correct predictions for the original examples:

$$\mathbb{C}(D) = E_D[f(q', c') = a' \mid f(q, c) = a]$$

Exact Match (OD)	**Train Size**	**NQ**	**TriviaQA**	**AmbigQA**	**SQuAD v1.0**	**TREC**
Original	90K	37.65	26.75	22.43	14.25	31.93
Gold Agen-Qgen	90K + 90K	37.86	27.02	23.65	15.01	32.94
Rand. Agen-Qgen	90K + 90K	37.45	29.87	24.13	14.55	26.89
RGF (REALM-Qgen)	90K + 90K	**39.11**	**32.32**	**26.98**	**16.94**	**33.61**

Table 4: Exact Match results on open-domain QA datasets (TriviaQA, AmbigQA, SQuAD and TREC) for data augmentation with RGF counterfactuals and baselines. Open-domain improvements are larger than in the RC setting, perhaps as the more difficult task benefits more from additional data.

Consistency (RC)	**Train Size**	**AQA**	**AmbigQA**	**QUOREF-C**	**RGF (Δ Ref)**	**RGF (Δ Pred)**
Original NQ	90K	63.22	51.72	44.86	64.65	52.93
Ensemble	90K	63.87	48.33	46.02	65.21	55.21
Gold Agen-Qgen	90K + 90K	50.25	42.86	40.66	55.63	43.08
Rand. Agen-Qgen	90K + 90K	56.07	48.08	44.79	60.06	48.34
RGF (REALM-Qgen)	90K + 90K	**64.46**	**55.93**	**48.94**	76.17	**66.12**
RGF Δ Ref.	90K + 52K	58.8	56.9	40.54	**77.61**	59.56
RGF Δ Pred.	90K + 52K	63.64	49.15	43.13	73.29	63.09

Table 5: Results for pairwise consistency (§6.1) on reading comprehension, measured for datasets containing pairs of very similar questions. QUOREF-C refers to the QUOREF contrast set from (Gardner et al., 2020). RGF leads to better consistency in RC and open-domain settings (Appendix C.2). Results on effect of perturbation type during training (Δ Ref. and Δ Pred.) suggest that perturbation-bias does not degrade consistency over the original model.

To measure consistency, we construct validation sets consisting of paired examples $(q, c, a), (q', c', a')$: one original, and one counterfactual. We use QED to categorize our data, as described in §3.5. Specifically, we create two types of pairs: (a) a change in reference where question predicate remains fixed, and (b) a change in predicate, where the original reference(s) are preserved.[5] We create a clean evaluation set by first selecting RGF examples for predicate or reference change, then manually filtering the data to discard incorrect triples (§4) until we have 1000 evaluation pairs of each type (see Appendix B).

We also construct paired versions of AQA, AmbigQA, and the QUOREF contrast set. For AmbigQA, we pair two disambiguated questions and for QUOREF, we pair original and human-authored counterfactuals. AQA consists of human-authored adversarial questions q' which are not explicitly paired with original questions; we create pairs by randomly selecting an original question q and a generated question q' from the same passage.

Results Training with RGF data improves consistency by 12-14 points on the QED-filtered slices of RGF data, and 5-7 points on AQA, AmbigQA and QUOREF contrast (Table 5). The Gold Agen-Qgen baseline (which contains topically related queries about the same passage) also improves consistency over the original model compared to the Random Agen-Qgen baseline or to the ensemble model, though not by as much as RGF. Consistency improvements on AQA, AmbigQA and QUOREF are especially noteworthy, since they suggest an improvement in robustness to local perturbations that is independent of other confounding distributional similarities between training and evaluation data.

6.2 Effect of Perturbation Type

QED-based decomposition of queries allows for the creation of label-changing counterfactuals along *orthogonal* dimensions — a change of reference or predicate. We investigate whether training towards one type of change induces generalization bias, a detrimental effect which has been observed in tasks such as NLI (Joshi and He, 2021).

Experimental Setting We shard training examples into two categories based on whether q and q'

---

[5] We require that the new reference set is a superset of the original, since predicate changes can introduce additional reference slots (see CF2 in Table 1).

have the same reference (predicate change) or same predicate (reference change), as defined in §3.5. We over-generate by starting with 20 (q', c', a') for each original training example to ensure that we find at least one q' that matches the criterion. We also evaluate on paired evaluation sets from §6.1.

Results Results are shown for QED-filtered training in Table 5. Counterfactual perturbation of a specific kind (a predicate or a reference change) during augmentation does not hurt performance on another perturbation type compared to the baseline NQ model, which differs from the observations of Joshi and He (2021) on NLI. Furthermore, similar to the observations of Min et al. (2020a), augmenting with one type of perturbation has orthogonal benefits that improve model generalization on another perturbation type: augmenting with RGF (Δ Pred.) leads to significant improvement on RGF (Δ Ref.), and vice-versa. Compared to reference-change examples, augmenting with predicate-change examples leads to greater improvements in local consistency, except for on RGF (Δ Ref.) and on AmbigQA – which contains many reference-change pairs. Predicate-change examples may also be more informative to the model, as reference changes can be modeled more easily by lexical matching within common context patterns.

6.3 Effect of Training data size

Joshi and He (2021) show CDA to be most effective in the low-resource regime. To better understand the role that dataset size plays in CDA in the reading comprehension setting, we evaluate RGF in a cross-domain setting where only a small amount of training data is available.

Experimental Setting Since our approach depends on using an open-domain QA model and a question generation model trained on all Natural Questions data, we instead experiment with a low-resource transfer setting on the BioASQ domain, which consists of questions on the biomedical domain. We use the domain-targeted retrieval model from Ma et al. (2021), where synthetic question-passage relevance pairs generated over the PubMed corpus are used to train domain-specific retrieval without any gold supervised data. We fine-tune our question-generation model on (limited) in-domain data, generate RGF data for augmentation, and then use this along with (limited) in-domain data to further fine-tune an RC model, using the NQ-trained weights for initialization. Further training details are provided in Appendix A.

Training Data	**Train Size**	**BioASQ (Dev)**	
		F1	EM
Original	1000	42.93	23.67
Orig. + RGF	500 + 500	41.72	23.01
Original	2000	**45.88**	25.80
Orig. + RGF	1000 + 1000	44.64	**26.80**

Table 6: Results on the reading comprehension task for Low Resource Transfer setting on BioASQ 2019 dataset. A model trained on 1000 gold BioASQ plus 1000 RGF examples performs nearly as well as a model trained on 2000 gold examples.

Results We observe significant improvements over the baseline model in the low resource setting for in-domain data (< 2000 examples), as shown in Table 6. Compared with the limited gains we see on the relatively high-resource NQ reading comprehension task, we find that on BioASQ, CDA with 1000 examples improves performance by 2% F1 and 3% exact match, performing nearly as well as a model trained on 2000 gold examples. These results suggest that using counterfactual data in lieu of collecting additional training data is especially useful in the low-resource setting.

7 Conclusion

Retrieve-Generate-Filter (RGF) creates counterfactual examples for QA which are semantically diverse, using knowledge from the passage context and a retrieval model to capture semantic changes that would be difficult to specify *a priori* with a global schema. The resulting examples are fully-labeled, and can be used directly for training or filtered using meaning representations for analysis. We show that training with this data leads to improvements on open-domain QA, as well as on challenge sets, and leads to significant improvements in local robustness. While we focus on question answering, for which retrieval components are readily available, we note that the RGF paradigm is quite general and could potentially be applied to other tasks with a suitable retrieval system.

A Model Training and Implementation Details

Below, we describe the details of different models trained in the RGF pipeline. Unless specified otherwise, we use the T5X library[6] and pre-trained checkpoints from Raffel et al. (2020)[7].

Question Generation We use a T5-3B model fine-tuned on Natural Questions (NQ) dataset. We only train on the portion of the dataset that consists of gold short answers and an accompanying long answer evidence paragraph from Wikipedia. The input consists of the title of the Wikipedia article the passage is taken from, a separator ('»') and the passage. The short answer is enclosed in the passage using character sequences '« answer =' and '»' on left and right respectively. The output is the original NQ question. The input and output sequence lengths are restricted to be 640 and 256 respectively. We train the model for $20k$ steps with a learning rate of $2 \cdot 10^{-5}$, dropout 0.1, and batch size of 128. We decode with a beam size of 15, and take the top candidate as our generated question q'.

Answer Generation We use a T5-3B model trained on the same subset of Natural Questions (NQ) as question generation with same set of hyperparameters and model size described above. The input consists of the title of the Wikipedia article the passage is taken from, a separator ('»') and the passage, while the output sequence is the short answer from NQ.

Reading Comprehension Model We model the task of span selection-based reading comprehension, i.e. identifying an answer span given question and passage, as a sequence-to-sequence problem. Input consists of the question, separator ('»'), and title of Wikipedia article, separator ('»') and passage. The answer format is simply one of the gold answer strings. The reading comprehension model is a T5-large model trained with batch size of 512 and learning rate $2 \cdot 10^{-4}$ for $20K$ steps.

Open-domain Question Answering model The open domain QA model is based on the implementation from Lee et al. (2019), and initialized with the REALM checkpoint from Guu et al. (2020)[8]. Both the retriever and reader are initialized from the BERT-base-uncased model. The query and document representations are 128 dimensional vectors. When finetuning, we use a learning rate of 10^{-5} and a batch size of 1 on a single Nvidia V100 GPU. We perform 2 epochs of fine-tuning for Natural Questions.

Noise Filtering We train 6 reading comprehension models based on the configurations above with different seed values for randomizing training dataset shuffling and optimizer initialization. We retain examples where more than 5 out of 6 models have the same answer for a question.

QED Training We use a T5-large model fine-tuned on the Natural Questions subset with QED annotations (Lamm et al., 2021).[9] We refer the reader to the QED paper for details on the linearization of explanations and inputs in the T5 model. Our model is fine-tuned with batch size of 512 and learning rate $2 \cdot 10^{-4}$ for 20k steps.

Experimental Variability Unless otherwise stated, results are reported from single runs. However, we used the six RC models discussed in Section 3.4 to estimate cross-run variation. Using the procedure and code of Sellam et al. (2021), we find variation of about 0.5 points (F1). As such, we do not find differences smaller than this significant, and in our results focus only on larger effects.

Computational Budget and Environmental Impact We fine-tune all T5 models on Cloud TPU v3 hardware; each takes approximately 4 hours on 16 TPUs in pod configuration. Total compute time is approximately 96 TPU-hours and 192 GPU-hours, which we estimate as 43 kg CO2e using the method of Luccioni et al. (2019)[10].

B Evaluation of Fluency and Noise

The authors sampled 300 examples of generated questions. To annotate for fluency, authors use the following rubric: Is the generated question grammatically well-formed barring non-standard spelling and capitalization of named entities. This noise annotation was done for RGF, as well as Gold Agen-Qgen and Random Agen-Qgen.

Creation of paired data for counterfactual evaluation Once again, authors annotate for correctness of counterfactual RGF instances that are paired by reference or predicate, as described in §3.5. Filtering is done until 1000 examples are available under each category.

Data	Unfiltered	Filtered
RGF	29.8%	25.3%
Gold Agen-Qgen	27.9%	20.7%
Random Agen-Qgen	30.7%	28.3%

Table 7: Fraction of noise (incorrect (q', c', a')) in generated data, from 300 examples manually annotated by the authors.

C Additional Experiments

C.1 Intrinsic Evaluation

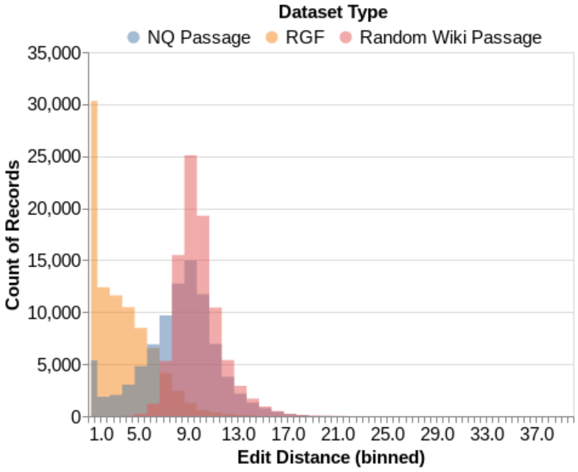

Figure 3: Distribution of edit distance between original q and counterfactual q' for RGF and other baselines for context selection. Note: For Random Wiki Passage, original and generated questions bear no relation to each other and are randomly paired.

In Figure 3, we compare distributions of the edit distance between the original and generated questions for questions generated by our approach, those generated with the gold evidence passage (Gold Agen-Qgen baseline), and those generated from a random Wikipedia passage (§5) (Random Agen-Qgen baseline). We find that RGF counterfactuals undergo minimal perturbations from the original question compared to questions that are generated from random Wikipedia paragraph. This pattern also holds when compared to questions generated from gold NQ passages. We hypothesize that the set of alternate answers retrieved in our pipeline approach are semantically similar to the gold answer — same entity type, for instance. Random answer spans chosen from the *gold NQ passage* can result in significant semantic shifts in generated questions.

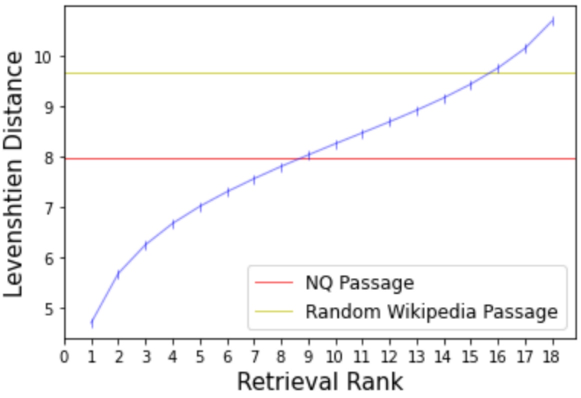

Figure 4: Plot of average edit distance between q, q' vs. retrieval rank r, where q' is generated from r^{th} passage, showing that edit distance and retrieval rank are monotonically related.

In Figure 4, we measure the relation between retrieval rank and edit-distance for RGF. For retrieval rank i, we plot average edit distance between the original question and counterfactual question that was generated using the ith passage and answer. We observe a monotonic relation between retrieval rank and edit distance (which we use for filtering our training data). We also measure changes in the distribution of question type and predicate type between original NQ data and the generated RGF data.

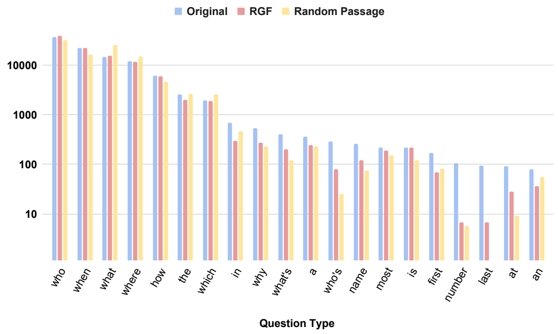

Figure 5: Distribution of top 20 question types for original NQ data, RGF counterfactuals and questions generated from random Wikipedia passage, indicating bias towards popular question types.

Figure 5 indicates that counterfactual data exacerbates question-type bias. However, this bias

Consistency (OD)	Train Size	AQA	AmbigQA	RGF Δ Ref.	RGF Δ Pred.
Original NQ	90K	16.58	13.33	25.12	11.23
Random Agen-Qgen	90K + 90K	15.80	20.00	27.94	17.16
RGF (REALM-Qgen)	90K + 90K	**17.66**	**28.57**	**31.77**	**19.81**

Table 8: Consistency Results for Open-domain QA.

Model	Train Size	NQ	SQuAD	TriviaQA	HotpotQA	BioASQ	AQA	AmbigQA
RGF (1X)	90K + 90K	70.68	79.88	16.99	53.41	**44.88**	28.20	**47.61**
RGF (2X)	90K + 180K	**70.78**	**80.33**	**17.46**	**54.09**	44.75	**28.30**	46.73
RGF (3X)	90K + 270K	70.68	80.14	17.14	52.45	44.48	26.60	46.02
RGF (4X)	90K + 360K	70.17	79.97	17.06	51.82	44.35	27.50	46.81

Table 9: Reading comprehension results with varying training data augmentation sizes (exact match). We do not observe a consistent improvement with additional data. This series of experiments was run using an older version of T5X, so are not exactly comparable to Table 3.

exists in RGF as well as baselines.

C.2 Consistency for Open-Domain QA

In Table 8, we show results on evaluating consistency on paired datasets in the open-domain results, similar to the results shown in §6.1 in the Reading Comprehension setting.

C.3 Augmentation with more data

In Table 9, we show results on augmenting with more than one RGF counterfactual triple (q', a', c') for every original example (q, a, c) in NQ. These experiments were run on an older version of T5X, so RGF (1X) values are reported differently from Table 3. We observe that adding more RGF data (3X or more) for augmentation can hurt performance. This may be because of increase in the proportion of noisy to clean examples during training and exacerbation of biases in the question generation model (explored in 5), resulting in diminishing returns. These challenges also occur in the baselines, and may be inhererent to augmentation with generated data.

C.4 Effect of perturbation type

Experimental Setting For edit distance-based experiments, we shard training examples into three categories by binning word-level edit distance between q and q' into three ranges: 1–4, 5–10, and > 10. We similarly categorize RGF data generated for the NQ development set into the same categories. Evaluation sets for edit-distance experiments based were not manually noise filtered. We again report consistency on the reading comprehension model.

Consistency (RC)	Val 1-4	Val 5-10	Val > 10
Train 1-4	71.02	67.55	64.78
Train 5-10	68.89	**68.98**	63.92
Train >10	65.78	66.33	**65.33**
Train All	**72.34**	67.82	65.12

Table 10: Results on sharding training data based on edit distance between (q, q'). Training dataset size for each bin is 90k NQ + 167k generated. Once again, training with all RGF data robustly improves consistency across different amounts of perturbations.

Results Similar to the observations for dataset sharding along QED annotations, when data is sharded by edit distance, we observe that using the full RGF data nearly matches the best performance from training on that shard, suggesting that CDA with the highly diverse RGF data can lead to improved consistency on a broad range of perturbation types.

D Semantic Diversity

Figure 6 includes more examples from Natural Questions, showing the counterfactual questions generated for different input questions by RGF.

E Error analysis of generated examples

Table 11 shows examples where the RGF model produced incorrect (q', a', c') triples, selected from the manually-annotated subset described in Section 4.

Nonsensical Question **Context:** The security management process relates to other ITIL - processes . However , in this particular section the most obvious relations are the relations to the service level management , incident management and change management processes . Security management is a continuous process that can be compared to <u>W . Edwards Deming</u> ' s Quality Circle (Plan , Do , Check , Act) . The inputs are requirements from clients . The requirements are translated into security services and security metrics. **Answer:** <u>W . Edwards Deming</u> **Generated Question:** the security management process is similar to the itil ?
Incomplete Question **Context:** Using Cartesian coordinates , inertial motion is described mathematically as : where " x " is the position coordinate and " τ " is proper time . (In Newtonian mechanics , " $\tau \equiv t$ " , the coordinate time) . In both Newtonian mechanics and special relativity , space and then spacetime are assumed to be flat , and we can construct a global Cartesian coordinate system . In <u>general relativity</u> , these restrictions on the shape of spacetime and on the coordinate system to be used are lost . Therefore , a different definition of inertial motion is required . **Answer:** <u>general relativity</u> **Generated Question:** which theory states that all motion is a function of ?
Correct Type, but Wrong Entity **Context:** Ruth McDevitt Ruth McDevitt (September 13 , 1895 – May 27 , 1976) was an American stage , film , radio and television actress . She was born Ruth Thane Shoecraft in Coldwater , Michigan . After attending the American Academy of Dramatic Arts , she married Patrick McDevitt and decided to devote her time to her marriage . After her husband ' s death in 1934 , she returned to acting . She performed on Broadway , in particular understudying and succeeding Josephine Hull in " Arsenic and Old Lace " and " The Solid Gold Cadillac " . She also worked as a radio actor . McDevitt was a familiar face on television during the 1950s , 1960s , and 1970s . She played " Mom Peepers " in the 1950s sitcom " Mister Peepers " . She was a regular with <u>Ann Sheridan</u> , Douglas Fowley , and Gary Vinson in CBS ' s " Pistols ' n ' Petticoats " , a 1966 - 67 satire of the Old West . **Answer:** <u>Ann Sheridan</u> **Generated Question:** who played the mother on mr peepers ?

Abstract

Transformer-based models have achieved state-of-the-art performance on short-input summarization. However, they still struggle with summarizing longer text. In this paper, we present DYLE, a novel dynamic latent extraction approach for abstractive long-input summarization. DYLE jointly trains an extractor and a generator and treats the extracted text snippets as the latent variable, allowing dynamic snippet-level attention weights during decoding. To provide adequate supervision, we propose simple yet effective heuristics for oracle extraction as well as a consistency loss term, which encourages the extractor to approximate the averaged dynamic weights predicted by the generator. We evaluate our method on different long-document and long-dialogue summarization tasks: GovReport, QMSum, and arXiv. Experiment results show that DYLE outperforms all existing methods on GovReport and QMSum, with gains up to 6.1 ROUGE, while yielding strong results on arXiv. Further analysis shows that the proposed dynamic weights provide interpretability of our generation process.[1]

1 Introduction

Transformer-based (Vaswani et al., 2017) pretrained language models (PLMs) such as BART (Lewis et al., 2020a) and T5 (Raffel et al., 2020), have achieved state-of-the-art performance on short text summarization. However, due to the high memory complexity of the full self-attention (Tay et al., 2020a), PLMs still struggle to handle long inputs (Rohde et al., 2021). *Model efficiency* and *summary quality* present a pair of challenges (Huang et al., 2021): models need to capture information scattered across the long input while maintaining a low computational cost.

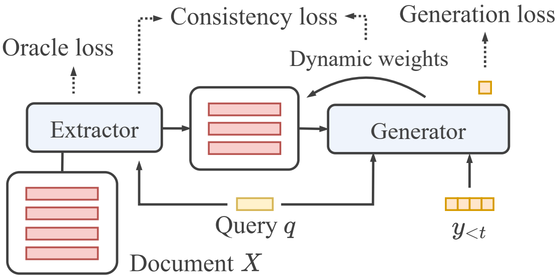

Figure 1: Overview of our approach. The input is a document X (each $x \in X$ is a sentence) and an optional query q, and the output is a summary y.

Prior models tackled long input summarization mostly in four ways. First, *sparse attention* (Child et al., 2019; Beltagy et al., 2020; Tay et al., 2020b) is used to reduce the memory complexity of the Transformers so that they can attend to more tokens. Second, *extract-then-generate* methods extract salient texts from the input and then summarize the extracted texts. Extractors are either independently trained with full supervision (Zhong et al., 2021b) or optimized using reinforcement learning (Williams, 1992; Chen and Bansal, 2018; Bae et al., 2019; Bražinskas et al., 2021). Third, models are proposed to divide source text into sections (Gidiotis and Tsoumakas, 2020; Wu et al., 2021; Liu et al., 2021) which are individually summarized and combined to form a full summary. Fourth, hierarchical models (Rohde et al., 2021; Zhu et al., 2020) improve summarization by capturing sentence or discourse level dependencies. We elaborate on these four directions and their limitations in Section 2.

We believe that the extract-then-generate approach mimics how a person would handle long-input summarization: first identify important pieces of information in the text and then summarize them (Kiyoumarsi, 2015; Sun et al., 2020). The extract-then-generate framework is based on the assumption that salient information useful for summarization only occupies a small portion of the input,

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1687 - 1698
May 22-27, 2022

which is a sensible assumption given the long input length. This approach shortens the source input to a pre-set length, which addresses the main challenge of the model not being able to handle longer input beyond a certain limit. However, previous separately-trained extract-then-generate approaches are limited as they suffer from cascaded errors from the extractor to the generator. Though various reinforcement learning techniques are introduced to bridge the two steps, they have noticeable drawbacks (discussed in Section 3.3), and we argue that the long input makes this approach suboptimal.

In this paper, we propose a new approach for long-input summarization: *Dynamic Latent Extraction for Abstractive Summarization* (DYLE). DYLE *jointly trains* the extractor and the generator and keeps the extracted text snippets latent. For an output token, DYLE compute its probability conditioned on each input snippet *separately*, and its generation probability is computed by *marginalizing* over all the input snippets under a learned *dynamic weights* assigned by the generator conditioned on the previously generated tokens.

We optimize the extractor with two surrogate losses. First, we compute the *extractive oracle* based on the reference summary with a greedy search over the best ROUGE scores. These oracle snippets are used as targets for the extractor learning signal. Moreover, we propose *consistency loss* to encourage the extractor to approximate its own predicted weights on the snippet to the averaged dynamic weights predicted by the generator.

We conducted experiments on three long-input summarization datasets: GovReport (Huang et al., 2021) and arXiv (Cohan et al., 2018) for long-document summarization, and QMSum (Zhong et al., 2021b) for long-dialogue summarization. Our method DYLE largely outperforms existing methods on GovReport and QMSum, while achieving strong results on arXiv. Notably, DYLE yields gains of 4.2/6.1/4.0 of ROUGE-1/2/L points over the previous best method on GovReport. These experiments demonstrate the generalizability of DYLE to multiple long-input summarization tasks.

We summarize our contributions as follows:

- We introduce DYLE, a dynamic latent extraction approach for abstractive long-input summarization. DYLE better captures information in the long input and reduces computational cost;
- We propose multiple auxiliary optimizations for the effective training of DYLE: 1) extractive oracle as a learning signal for the extractor; 2) consistency loss that bridges extraction and generation; 3) hybrid training methods that make the extraction more robust;
- Experimental results show that DYLE largely outperforms the state-of-the-art on two long input summarization datasets. We also conducted a detailed analysis that shows dynamic weights improve model interpretability.

2 Related Work

We introduce in detail the four main categories of methods in recent work to address long-input summarization tasks.

Sparse attention mechanism The full attention mechanism has a quadratic memory cost. Prior research works have proposed different sparse attention mechanisms to reduce the memory cost. Longformer (Beltagy et al., 2020) uses a dilated sliding window of blocks and global attention patterns. BigBird (Zaheer et al., 2020) employs sliding windows and random blocks. Reformer (Kitaev et al., 2020) uses the locality-sensitive hashing. In addition to optimizing the encoder self-attention, Huang et al. (2021) proposes head-wise positional strides to reduce the cost of the encoder-decoder attention. However, sparse attention diminishes the benefits of pretraining and sacrifices parts of the receptive field.

Extract-then-generate method This method extracts salient text snippets from the input, followed by generating an overall summary. Most of these approaches are trained separately (Zhang et al., 2019; Lebanoff et al., 2019; Xu and Durrett, 2019; Bajaj et al., 2021; Zhang et al., 2021b), which suffer from information loss as we pass the extracted snippets to the generator. Some approaches attempt to reduce that loss by bridging the two stages. Chen and Bansal (2018) adopts reinforcement learning (RL) with a sentence-level policy gradient. Bae et al. (2019) proposes summary-level policy gradient. Using RL suffers from various drawbacks on long input texts, which will be elaborated in Section 3.3. DYLE is different as we jointly train an extract-then-generate model for summarization using latent variables.

Divide-and-conquer approach A common approach in long input summarization is divide-and-conquer (Gidiotis and Tsoumakas, 2020; Grail et al., 2021; Zhang et al., 2021a). It breaks a long input into multiple parts, which are summarized separately and combined to produce a final summary. However, these models do not capture the contextual dependencies across parts and assume that the input has certain structure.

Hierarchical models Various hierarchical models have been proposed to handle the longer inputs. Cohan et al. (2018) models the document discourse structure with a hierarchical encoder and a discourse-aware decoder. HAT-Bart (Rohde et al., 2021) proposes a new Hierarchical Attention Transformer-based architecture that attempts to capture sentence and paragraph-level information. HMNet (Zhu et al., 2020) builds a hierarchical structure that includes discourse-level information and speaker roles. However, these models focus mainly on model performance and not on reducing the memory and computational cost.

3 Our Approach

An overview of our approach is shown in Figure 1. In Section 3.1, we formulate our task and the extractor-generator framework. In Section 3.2, we introduce our parameterization of the extractor for long inputs. In Section 3.3, we introduce generator formulation and the novel consistency loss. The extractor module is both optimized with the consistency loss and the oracle loss, which we elaborate on in Section 3.4. The overall training objective is summarized in Section 3.5.

3.1 Extractor-Generator Framework

In the long-input summarization task, the input consists of L text snippets, $X = (x_1, \ldots, x_L)$, and an optional query q if a query is paired with a summary. In long-input summarization, the number of text snippets, L, could be potentially large. The output is a summary y of length T. For the dialogue summarization task, dialogue utterances by each speaker are used as snippets. For documents, we tokenize the input into sentences and use each sentence as a snippet. The goal is to learn a model that generates a sequence of summary tokens y given the input snippets X and the previously generated tokens $y_{<t}$:

$$P_\theta(y|q, X) = \prod_{t=1}^{T} P_\theta(y_t|q, X, y_{<t})$$

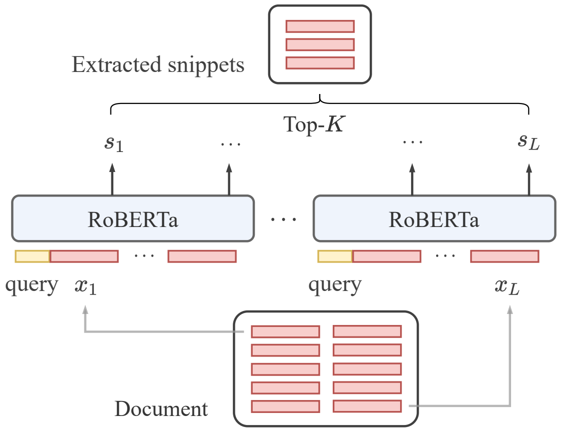

Figure 2: Long-input extractor. We divide the document into chunks, each containing consecutive snippets. A shared RoBERTa encodes each chunk independently.

The *extractor* takes the query and the source text as input and outputs a score $s_i = E_\eta(q, x_i)$ for each text snippet x_i. Here η is the extractor parameters. We extract K snippets X_K from the document X based on their scores:

$$X_K = \text{top-}K(E_\eta(q, x_i), x_i \in X) \quad (1)$$

After retrieving X_K from X, the extractor-generator framework models the output probability by replacing X with X_K, i.e.,

$$\begin{aligned} P_\theta(y|q, X) &= P_\theta(y|q, X_K) \\ &= \prod_{t=1}^{T} P_\theta(y_t|q, X_K, y_{<t}) \end{aligned} \quad (2)$$

Note that the top-K operation in Eq. (1) is non-differentiable, and we do not propagate gradients through top-K; instead, we propose methods to optimize the extractor in Section 3.3 and Section 3.4.

3.2 Extractor for Long Inputs

An interesting research question is how to design the extractor for long inputs. Limited by GPU memory, it is impractical to concatenate all snippets and encode them with a large pre-trained language model. As shown in Figure 2, we group consecutive snippets into *chunks*. We concatenate the query q with each chunk and compute the encoded vector for each snippet independently within the chunk it belongs to. We project the encoded vectors to scalar scores $s_i = E_\eta(q, x_i)$ using an MLP.

3.3 Generator with Dynamic Weights

Challenges An extract-then-generate model faces two challenges in long-input summarization.

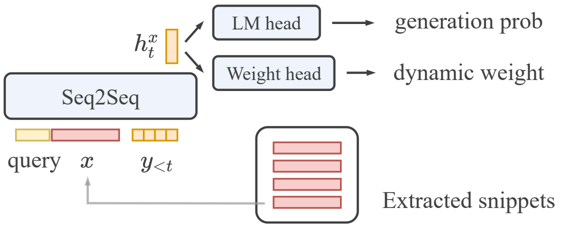

Figure 3: At each decoding time step, our generator predicts the dynamic weight and the generation probability for each extracted snippet.

The first challenge is that the extraction operation (top-K in Eq. (1)) is non-differentiable. One approach is to adopt RL-based optimizations (Chen and Bansal, 2018; Bae et al., 2019), which has two drawbacks. First, reinforcement learning for large action spaces (i.e., extracting K out of L snippets when L is very large) has high variances. Second, current methods mostly use sentence-level ROUGE (Chen and Bansal, 2018) or summary-level ROUGE (Bae et al., 2019) as training rewards. Using sentence-level ROUGE could potentially select sentences with overlapping contents (Narayan et al., 2018), resulting in redundant final summaries. Using a summary-level ROUGE leads to the sparsity of the training signal, and longer input makes this approach harder to train. The second challenge is interpretability: one might want to know whether the generator is leveraging the extracted information at each decoding time step.

To address these challenges, we propose a generator that dynamically assigns weights to every extracted snippet at each time step. Different from the extractor scores, which are independent of the decoding time step, the generator assigns different dynamic scores at different time steps. Dynamic weights make the decoding process interpretable and help denoise the extraction by down-weighting irrelevant snippets. It also provides training signals for the extractor using *consistency loss*.

Generator formulation The overview of the generator is shown in Figure 3. For each extracted snippet x, the generator predicts the generation probability $P_\theta(y_t|q, x, y_{<t})$ on this snippet and a dynamic weight $P_\theta(x|q, X_K, y_{<t})$ for this snippet. The independent encoding of each extracted snippet saves memory because the snippets do not need to attend to each other. Without loss of generality, we assume that $P_\theta(\cdot|q, x, y_{<t})$ is computed by first mapping the input $(q, x, y_{<t})$ to a contextualized representation vector $\boldsymbol{h}_t^x$. For Transformers (Vaswani et al., 2017) and encoder-decoder with attention models (Bahdanau et al., 2015), $\boldsymbol{h}_t^x$ is usually the model's output before the final language model head. The generation probability $P_\theta(y_t|q, x, y_{<t})$ is computed by feeding $\boldsymbol{h}_t^x$ into the language model head. For the dynamic weight $P_\theta(x|q, X_K, y_{<t})$, we adopt a separate MLP to map each $\boldsymbol{h}_t^x$ to a scalar logit l^x, and $P_\theta(\cdot|q, X, y_{<t})$ is defined as $\text{softmax}(\{l^x\}_{x\in X})$. We compute the generation probability by marginalizing over all extracted snippets:

$$P_\theta(y|q, X_K) = \prod_{t=1}^{T} \sum_{x\in X_K} P_\theta(y_t|q, x, y_{<t}) P_\theta(x|q, X_K, y_{<t}) \tag{3}$$

The dynamic weight $P_\theta(x|q, X_K, y_{<t})$ at each decoding time step t allows us to interpret how the generator utilizes the extracted snippets. For example, a larger weight to a particular snippet indicates the larger importance of the snippet to the current decoding time step. The generation loss is defined as the NLL of the gold summary:

$$\mathcal{L}_{gen}^{\theta} = -\log P_\theta(y|q, X_K) \tag{4}$$

where $P_\theta(y|q, X_K)$ is defined in Eq. (2). Here we do not propagate gradients of $\mathcal{L}_{gen}^{\theta}$ to the extractor parameters since top-K is non-differentiable. Instead, methods to optimize the extractor are described in Section 3.3 and Section 3.4.

Consistency loss We also leverage the dynamic weights to provide a training signal for the extractor. Since the dynamic weight of a snippet can be interpreted as the importance of the snippet at a particular time step, we average the dynamic weights over all the decoding steps and view the averaged weight as the overall importance of the snippet. Based on this intuition, we propose what we term as *consistency loss*, which measures the distance between the averaged dynamic weights distribution and the extractor distribution. We want these two distributions to be close on an *arbitrary* subset of X. For simplicity, we take X_K as the subset and define the consistency loss as

$$\mathcal{L}_{consist}^{\eta} = \text{KL}\Big[\frac{1}{T}\sum_{t=1}^{T} P_\theta(\cdot|q, X_K, y_{<t}) \;||\; \text{softmax}(E_\eta(q, x_i), x_i \in X_K)\Big] \tag{5}$$

Note that the consistency loss is superscripted with the extractor's parameters η, which means that we do not compute gradients for the generator's parameters θ. Since we want the distributional distance to be small on an *arbitrary* subset of X, we do not propagate gradients through the top-K operator.

3.4 Leveraging Extractive Oracles

For long-input summarization, the extracted snippets X_K used during training are important for stable optimization. Instead of using X_K defined in Eq. (1), we propose to leverage *extractive oracles* during training. No extractive oracles are used during test time.

Greedy search for extractive oracles *Extractive oracles* denote a set of selected text snippets whose concatenation maximizes the evaluation metric given the gold summary. We implement the extractive oracle using greedy search. Specifically, we start with an empty set, and we iteratively select a snippet from the input such that the concatenation of that snippet and the already selected snippets maximizes the average of ROUGE-1, ROUGE-2, and ROUGE-L scores given the gold summary. We denote the extractive oracles as X_o.

Hybrid training We leverage the extractive oracles to define X_K used during training. If the number of oracles equals or exceeds K, we define X_K as the first K oracle snippets. If the number of oracles is less than K, we define X_K as the union of X_o and the top snippets ranked by the extractor that is not appearing in X_o. Such hybrid training has two benefits. First, compared with X_K defined in Eq. (1), it provides higher-quality inputs to the generator. Second, it reduces the reliance on the oracle and improves the generalizability of our model beyond the training set, as other text snippets omitted in the greedy search might help the generation.

Oracle loss The extractive oracles X_o are used as a supervision signal for the extraction part of our model. The oracle loss $\mathcal{L}^{\eta}_{oracle}$ is computed from the cross-entropy loss between all chunks in the extractor selected set and the extractive oracle. Formally, the oracle loss is computed as

$$\mathcal{L}^{\eta}_{oracle} = -\frac{1}{|X_o|}\sum_{x \in X_o} \log \frac{e^{E_\eta(q,x)}}{\sum_{x_i \in X} e^{E_\eta(q,x_i)}} \quad (6)$$

Table 1: Comparison of evaluation benchmarks.

3.5 Training Objective

The overall training objective of our method is

$$\mathcal{L}^{\theta,\eta} = \lambda_g \mathcal{L}^{\theta}_{gen} + \lambda_o \mathcal{L}^{\eta}_{oracle} + \lambda_c \mathcal{L}^{\eta}_{consist} \quad (7)$$

where λ_g, λ_o, and λ_c are hyperparameters to balance the loss components. Gradients are computed for the superscripted parameters. Specifically, the extractor is solely optimized with the consistency loss and the oracle loss, and the generator is solely optimized with the generation loss.

4 Experiment Setups

4.1 Datasets

We consider the following long-input abstractive summarization datasets as evaluation benchmarks:[2]

QMSum (Zhong et al., 2021b) is a benchmark for query-based multi-domain meeting summarization. It consists of meetings from three domains: AMI (Carletta et al., 2005), ICSI (Janin et al., 2003), and committee meetings of the Welsh Parliament and Parliament of Canada;

GovReport (Huang et al., 2021) is a large-scale long document summarization dataset, consisting of about 19.5k U.S. government reports with expert-written abstractive summaries; GovReport is a good benchmark as it contains significantly longer documents (average 9.4k words) and summaries (553 words) than other long document datasets, such as ArXiv, PubMed (Cohan et al., 2018), BillSum (Kornilova and Eidelman, 2019), and BigPatent (Sharma et al., 2019);

arXiv (Cohan et al., 2018) is a dataset of scientific articles from arXiv. Abstracts of the articles are used as the target summary. ArXiv is chosen over PubMed (Cohan et al., 2018) as arXiv contains longer articles compared to PubMed.

A detailed comparison of the datasets used can be found in Table 1.

---

[2] QMSum and arXiv can be accessed through SummerTime (Ni et al., 2021a).

4.2 Baselines and Implementation

Baselines for Comparisons We compare DYLE with the previous state-of-the-art methods on the aforementioned three datasets. More specifically: 1) For GovReport, we report the performance from the original paper, which uses various encoder self-attention and the proposed HEPOS encoder-decoder attention; 2) For QMSum, we compare with Zhong et al. (2021a), the current SoTA and other baselines mentioned in that work; 3) For arXiv, we include the results from the best performing models in previous works, including ExtSum-LG (Xiao and Carenini, 2019), PEGASUS (Zhang et al., 2020), DANCER (Gidiotis and Tsoumakas, 2020), BigBird (Zaheer et al., 2020), HEPOS + LSH (Huang et al., 2021), HAT-BART (Rohde et al., 2021), Longformer (Beltagy et al., 2020), and SSN-DM (Cui and Hu, 2021). Note that those baselines spans over different strategies to handle long input, such as sparse-attention (HEPOS, BigBird, Longformer), hierarchical attention (HAT-BART), extract-then-generate (Locator + different generators).

4.3 Implementation Details

Pretrained-LM The extractor is initialized with `RoBERTa-base` (Liu et al., 2019) weights. The generator is initialized with `BART-large` (Lewis et al., 2020a) weights. We use the Adam optimizer and set the extractor learning rate to 5e-5 and the generator learning rate to 5e-6.

Hyperparameters λ_g, λ_o, and λ_c are the coefficients for the generation loss, oracle loss, and the consistency loss respectively. For λ_g and λ_o, we did a 2-step binary search between 0 and 2. For λ_c, we did a 3-step binary search between 0 and 10. For the QMSum dataset, we used $\lambda_g = 1$, $\lambda_o = 1$, $\lambda_c = 1$. For the GovReport dataset, we used $\lambda_g = 0.5$, $\lambda_o = 1$, $\lambda_c = 1$. For the ArXiv dataset, we used $\lambda_g = 0.5$, $\lambda_o = 1$, $\lambda_c = 5$.

Hardware We apply gradient checkpointing (Chen et al., 2016) to save the GPU memory. Each experiment is run on one NVIDIA Quadro RTX 8000 GPU. The effective batch size is set to 8.

5 Experiment Results

5.1 Main Results

The evaluation results are summarized in Table 2, Table 3, and Table 4. For GovReport, DYLE yields

		ROUGE-1			ROUGE-2			ROUGE-L		
		P	R	F1	P	R	F1	P	R	F1
GovReport	Extracted snippets	48.98	**73.40**	57.56	24.20	**36.59**	28.53	46.28	**69.25**	54.35
	Generated summaries	**63.16**	61.61	**61.01**	**29.85**	29.10	**28.83**	**59.88**	58.35	**57.82**
QMSum	Extracted snippets	4.25	**76.90**	7.74	1.36	**28.41**	2.49	3.99	**72.83**	7.26
	Generated summaries	**29.78**	45.64	**34.42**	**8.39**	13.06	**9.71**	**26.14**	39.70	**30.10**

Table 6: Precision-recall decomposition of ROUGE scores of extracted snippets and generated summaries.

gains of 4.15/6.21/4.00 of ROUGE-1/2/L scores compared to the previous best method. Experiments on GovReport show that DYLE is performant over prior sparse attention approaches.

On QMSum, DYLE yields the new state-of-the-art ROUGE-1/2/L scores of 34.42/9.71/30.10, outperforms UniLM with DialogLM pretraining. Comparing DYLE with locator-based models on the QMSum dataset shows that DYLE outperforms prior extract-then-generate approaches where the locator is independently trained with intermediate annotated text spans. This shows the effectiveness of DYLE's joint training approach. These results show that DYLE can be applied to both the long document summarization and long dialogue summarization tasks. DYLE's better performance can be attributed to lowered information loss between the extraction and the generation steps and its ability to handle input of a much longer length.

We notice that while DYLE largely outperforms the LSH baseline (Huang et al., 2021) on the GovReport dataset, it underperforms the LSH baseline on arXiv. We posit two reasons. First, the input of the GovReport is much longer than that of arXiv. Most, if not all, of the sentences in the arXiv input article can be processed by the LSH model. Second, the summaries of the arXiv dataset are more abstractive than those of GovReport. It is possible that individually extracted text snippet is not the best linguistic unit for generating output tokens. It is our future work to explore the optimal input unit for an extract-then-generate approach. Nevertheless, DYLE outperforms other extraction-based approaches (*e.g.,* SSN-DM (Cui and Hu, 2021)) and divide-and-conquer approaches (*e.g.,* DANCER (Gidiotis and Tsoumakas, 2020)).

5.2 Evaluation of Auxiliary Optimizations

We conduct ablation studies to investigate the effectiveness of the auxiliary optimizations we introduced. Specifically, we report the full model's performance after removing 1) hybrid training, 2) consistency loss, 3) extractive oracle loss. In our default model, the consistency loss is computed on the combination of the extracted snippets and oracle snippets; in the "w/o hybrid" experiment, the consistency loss is only computed on the set of oracle snippets; in "w/o consistency" experiment, the consistency loss is not computed. The results are summarized in Table 5. Note that without the hybrid training optimization, only the extractive oracles will be used to train the generator. When the consistency loss is not calculated, the extractor and the generator can be viewed as being trained independently with the extractive oracles.

We see that excluding either of the hybrid training, consistency loss, or oracle loss optimization leads to a performance drop. Training the model without the supervision of the oracle leads to the greatest decrease in model performance, showing the importance of good supervision for the extractor. Removing the consistency loss also decreases the model performance. This shows that the consistency loss allows the extractor to better learn to select salient snippets from the input text and enables DYLE to generalize better to the test set.

6 Analysis and Discussion

Analysis of extracted snippets We are interested in the amount of salient information passed to the generator. To investigate this, we report the decomposed precision and recall of ROUGE scores in Table 6. We observe that the extracted snippets have much higher recall than the generated summaries, while the generated summaries have higher precision. This suggests that to improve the overall performance, we can increase the information coverage (i.e., recall) of the extractor and improve the accuracy of the generator in identifying the salient snippets (i.e., precision).

Interpretability of dynamic weights Our approach is more interpretable than sparse attention and two-step extraction-generation pipeline meth-

Figure 4: Dynamic weight visualization. We visualized the dynamic weight matrices of the *generated summary* and a *random summary* from other samples in the validation set. x-axis: decoding time step; y-axis: index of the extracted top-K snippets. Darker squares stand for higher weights. More examples can be found in Appendix A.

ods. Specifically, *dynamic weights* in the generator shows how the information is used throughout the decoding process. In Figure 4, we visualize the dynamic weights for the extracted snippets assigned by the generator during decoding. In each subfigure, we visualize the dynamic weight matrices of the *generated summary* and a *random summary* from other samples in the validation set. The x-axis and y-axis represent the index of the extracted top-K snippets and the decoding time step, respectively. Darker squares denote higher weights. For each generated summary, we observe multiple consecutive high-weight areas, indicating alignments between the extracted snippets and the generated summary. By contrast, weights are uniformly distributed for random summaries. Interestingly, we observe that, on QMSum, fewer sentences are considered when generating the summaries. Our explanation for this observation is that QMSum is a query-based dataset, where the queried information is more concentrated in a few snippets. By contrast, we find that a larger number of snippets are used on the GovReport dataset as seen in Figure 4, as GovReport is a general summarization dataset.

Effect of number of extracted snippets To evaluate the effect of number of extracted snippets on model performance, we vary the value of K of top-K in Eq. (1) and test it on both the GovReport and QMSum datasets. We observe that the model performance generally increases as the value of K increases. This is expected as more extracted snippets provide the generator with more information to form a final summary. The results are summa-

	R-1	R-2	R-L

Extractor Output	34.42	9.71	30.10
Oracle	**39.80**	**14.74**	**36.06**

Table 8: Feeding extractive oracles to generator. "Oracle" is computed based on the gold summary; thus, it is a soft upper-bound of the extractor's performance.

rized in Table 7. Due to the limit of GPU memory, the largest K value we tried is 25.

Effect of consistency loss We evaluate the effect of consistency loss on extractor performance. Note that removing the consistency loss means that the extractor and the generator are independently trained. The results are presented in Table 5 as part of the ablation study. Removing the consistency loss leads to worse model performance. We observe that the consistency loss helps the model better learn the importance of the selected text snippets useful for the generation.

Extractor performance compared with extractive oracles We feed the extractive oracles to the generator. The results are summarized in Table 8. We observe that extractive oracles contain more salient information than the text snippets extracted by the extractor. Feeding the extractive oracle to the generator indicates the upper bound of the extractor performance. However, we observe that the gap between the performance of using the extractive oracle and using the extractor output is relatively small.

Comparison with RAG The generator of our method is related to but differs significantly from Retrieval-Augmented Generation (RAG) (Lewis et al., 2020b). The similarity only lies in the idea of marginalization over a set of text snippets, which is shown to be useful in question answering as well (Ni et al., 2021b). However, unlike our *dynamic* weights, the weights in RAG remains *static* during decoding. In our notations, RAG's generation probability can be formulated as:

$$\begin{aligned} P_\theta(y|q, X_K) &= \prod_{t=1}^{T} P_\theta(y_t|q, X_K, y_{<t}) \\ &= \prod_{t=1}^{T} \sum_{x \in X_K} P_\theta(y_t|q, x, y_{<t}) P_\theta(x|q, X_K) \end{aligned} \tag{8}$$

The static weight $P_\theta(x|q, X_K)$ in Eq. 8 is computed based on q and X_K, while our dynamic weight $P_\theta(x|q, X_K, y_{<t})$ is additionally conditioned on the already generated tokens.

Limitations and future directions We acknowledge that joint training of the extractor and the generator cannot eliminate information loss, which might be addressed by combining DYLE and sparse attention to encode longer snippets. Though formulated for long-input summarization, DYLE can be applied to general long-input generation tasks where information is scattered across the input, e.g., open-domain question answering and multi-turn dialogue systems with long dialogue history.

7 Conclusions

In this paper, we propose the first framework that jointly trains an extract-then-generate model with latent extraction. The first-step extraction picks out salient information from the long input, thereby extending the input length that the model can handle. Our novel joint training method addresses the challenge of information loss associated with the prior extract-then-generate approaches. Our model largely outperforms the current state-of-the-art on GovReport and QMSum, while achieving strong results on arXiv. Lastly, DYLE has the advantages of being able to process arbitrarily long input with a lower memory cost and interpretable generator weights.

Acknowledgment

The authors would like to thank Yixin Liu and Ming Zhong for the discussions. We also would like to thank the anonymous reviewers for their helpful comments. This work is supported in part by a grant from Microsoft Research.

Abstract

Natural language processing for sign language video—including tasks like recognition, translation, and search—is crucial for making artificial intelligence technologies accessible to deaf individuals, and is gaining research interest in recent years. In this paper, we address the problem of searching for fingerspelled keywords or key phrases in raw sign language videos. This is an important task since significant content in sign language is often conveyed via fingerspelling, and to our knowledge the task has not been studied before. We propose an end-to-end model for this task, FSS-Net, that jointly detects fingerspelling and matches it to a text sequence. Our experiments, done on a large public dataset of ASL fingerspelling in the wild, show the importance of fingerspelling detection as a component of a search and retrieval model. Our model significantly outperforms baseline methods adapted from prior work on related tasks.

1 Introduction

Sign languages are a type of natural language which convey meaning through sequences of handshapes and gestures as well as non-manual elements, and are a chief means of communication for about 70 million deaf people worldwide.[1] Automatic sign language technologies would help to bridge the communication barrier between deaf and hearing individuals, and would make deaf video media more searchable and indexable.

Automatic sign language processing has recently received growing interest in the computer vision (CV) and natural language processing (NLP) communities. Yin et al. (2021) make several recommendations for the study of sign languages in NLP research, including greater emphasis on real-world data. Most studies on sign language are based on data collected in a controlled environment, either in a studio setting (Martínez et al., 2002; Kim et al., 2017) or in a specific domain (Forster et al., 2016). The challenges involved in real-world signing videos, including various visual conditions and different levels of fluency in signing, are not fully reflected in such datasets. Automatic processing of sign language videos "in the wild" has not been addressed until recently, and is still restricted to tasks like isolated sign recognition (Albanie et al., 2020; Joze and Koller, 2019; Li et al., 2020) and fingerspelling recognition (Shi et al., 2018, 2019). In this work we take a step further and study search and retrieval of arbitrary fingerspelled content in real-world American Sign Language (ASL) video (see Figure 1).

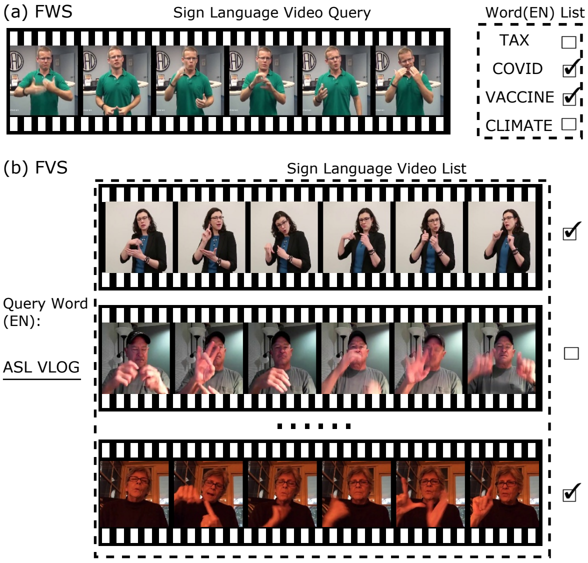

Figure 1: Our two search tasks: (a) *fingerspelled word search* (FWS) for determining which words are fingerspelled in a sign language video clip, and (b) *fingerspelling video search* (FVS) for searching for sign language videos that include a fingerspelled query word/phrase. The sign language videos are untrimmed, i.e. they include regular signs in addition to fingerspelling, and are downsampled here for visualization.

Fingerspelling is a component of sign language

in which words are signed by a series of handshapes or movements corresponding to single letters (see the Appendix for the ASL fingerspelling alphabet). Fingerspelling is used mainly for lexical items that do not have their own signs, such as proper nouns or technical terms, and has an important place in sign language. For example, fingerspelling accounts for 12-35% of ASL (Padden and Gunsauls, 2003). Since important content like named entities is often fingerspelled, the fingerspelled portions of a sign language video often carry a disproportionate amount of the content.

Most prior work on fingerspelling has focused on recognition (Shi et al., 2018, 2019), that is, transcription of a fingerspelling video clip into text. However, automatic recognition assumes that the boundaries of fingerspelled segments are known at test time, and may not be the end goal in real-world use cases. In addition, complete transcription may not be necessary to extract the needed information. Fingerspelling search, such as retrieving sign language videos based on a query word, is a more practical task, and is an important component of general video search involving sign language.

In addition to introducing the task, we address the research question of whether the explicit temporal localization of fingerspelling can help its search and retrieval, and how best to localize it. As fingerspelling occurs sparsely in the signing stream, explicit detection of fingerspelling could potentially improve search performance by removing unrelated signs. To this end, we propose an end-to-end model, FSS-Net, which jointly detects fingerspelling from unconstrained signing video and matches it to text queries. Our approach consistently outperforms a series of baselines without explicit detection and a baseline with an off-the-shelf fingerspelling detector by a large margin.

2 Related Work

In existing work on sign language video processing, search and retrieval tasks have been studied much less than sign language recognition (mapping from sign language video to gloss labels) (Koller et al., 2017; Forster et al., 2016) and translation (mapping from sign language video to text in another language) (Yin and Read, 2020; Camgöz et al., 2018). Work thus far on sign language search has been framed mainly as the retrieval of lexical signs rather than fingerspelling. Pfister et al. (2013); Albanie et al. (2020) employ mouthing to detect keywords in sign-interpreted TV programs with coarsely aligned subtitles. Tamer and Saraçlar (2020a,b) utilize whole-body pose estimation to search for sign language keywords (gloss or translated word) in a German Sign Language translation dataset PHOENIX-2014T (Camgöz et al., 2018). All prior work on keyword search for sign language has been done in a closed-vocabulary setting, which assumes that only words from a pre-determined set will be queried. Searching in an open-vocabulary setting, including proper nouns, typically requires searching for fingerspelling.

Some related tasks in the speech processing literature are spoken term detection (STD) and query-by-example search, which are the tasks of automatically retrieving speech segments from a database that match a given text or audio query (Knill et al., 2013; Mamou et al., 2007; Chen et al., 2015). In terms of methodology, our model also shares some aspects with prior work on moment retrieval (Gao et al., 2017; Xu et al., 2019; Zhang et al., 2020), which also combines candidate generation and matching components. However, we incorporate additional task-specific elements that consistently improve performance.

3 Tasks

We consider two tasks: Fingerspelled Word Search (FWS) and Fingerspelling-based Video Search (FVS). FWS and FVS respectively consist of detecting fingerspelled words within a given raw ASL video stream and detecting video clips of interest containing a given fingerspelled word.[2] Given a query video clip v and a list of n words $w_{1:n}$, FWS is the task of finding which (if any) of $w_{1:n}$ are present in v. Conversely, in FVS the input is a query word w and n video clips $v_{1:n}$, and the task consists of finding all videos containing the fingerspelled word w. We consider an open-vocabulary setting where the word w is not constrained to a pre-determined set. The two tasks correspond to two directions of search (video⟶text and text⟶video), as is standard practice in other retrieval work such as video-text search (Zhang et al., 2018; Ranjay et al., 2017; Ging et al., 2020).

4 Model

We propose a single model, FSS-Net (for "Finger-Spelling Search Network"), summarized in Fig-

---

[2] We use "word" to refer to a fingerspelling sequence, which could be a single word or a phrase.

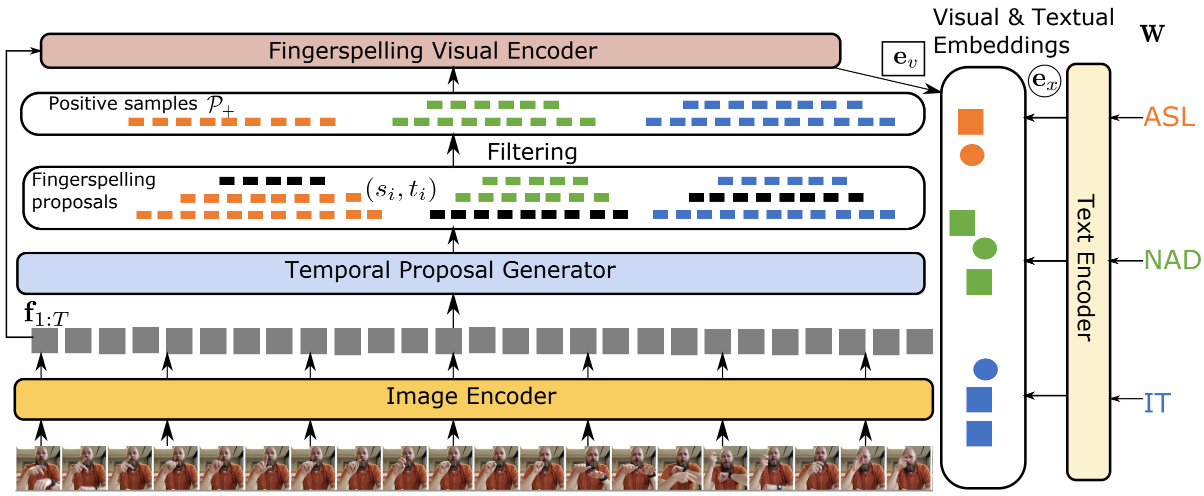

Figure 2: FSS-Net: The proposed model for fingerspelling search and retrieval. The model maps candidate fingerspelling segments and text into a shared embedding space. ○: text embedding, □: visual embedding. The colors correspond to different input fingerspelling sequences. As pictured, this is the training time model, where the pairing between text and video segments is known. At test time, the labels (colors) of the visual embeddings are unknown and we do not filter the proposals.

ure 2, to address the two aforementioned search tasks. FSS-Net receives a pair of inputs—a raw ASL video clip, and a written text sequence—and produces a score indicating the degree of match between the video clip and the text. The text is encoded into an embedding vector via a learned encoder. The visual branch of FSS-Net generates a number of fingerspelling segment proposals and each proposed visual segment is encoded into a feature space shared with the text embeddings. Paired embeddings from both modalities are drawn towards each other in the shared embedding space during training.

Image encoding The input image frames are encoded into a sequence of feature vectors via an image encoder, which consists of the VGG-19 (Simonyan and Zisserman, 2015) convolutional layers followed by a Bi-LSTM.[3] We use raw RGB images as input, instead of signer pose as used in some prior work (Tamer and Saraçlar, 2020b,a) on sign language search, as estimating pose for hands is particularly hard for signing videos in the wild (see Section 6 for details).

Temporal proposal generation Suppose the visual feature sequence is $\mathbf{f}_{1:T}$, where T is the number of frames in the video clip. The purpose of temporal proposal generation is to produce a number of candidate fingerspelling segments $\mathcal{H}(\mathbf{I}_{1:T}) = \{(s_i, t_i)\}_{1 \leq i \leq |\mathcal{H}(\mathbf{I}_{1:T})|}$ from $\mathbf{f}_{1:T}$, where s_i,t_i are the start and end frame indices of the i^{th} proposed segment. Below we use $\mathcal{H}$ as a shorthand for $\mathcal{H}(\mathbf{I}_{1:T})$. Here we adopt the strategy in (Xu et al., 2017), which is commonly used to generate proposals for action detection. Briefly, the model assigns a probability p_{det} of each proposal being fingerspelling. See (Xu et al., 2017) for more details. We denote the detection loss as L_{det}.

Note that the training requires known ground-truth fingerspelling boundaries. In the fingerspelling datasets we use here (Shi et al., 2018, 2019), the fingerspelling boundaries are already annotated, so no further annotation is needed.

Filtering A visual embedding is produced for each segment. We denote a labeled fingerspelling segment (shortened as fingerspelling segment below) as a tuple (s, t, w), where s, t and w represent the start frame index, the end frame index, and the written text it represents. A naive approach would be to use only the ground-truth fingerspelling segments $\mathcal{P}_g = \{(s_i, t_i, w_i)\}_{1 \leq i \leq |\mathcal{P}_g|}$ for training. However, this approach does not take into account the potential shifts (errors) that may exist at test time between the ground-truth and generated segment proposals. The embeddings produced by the fingerspelling encoder should be robust to such shifts. To this end, we incorporate proposals in forming positive pairs at training time. Formally, let the set of time intervals from the temporal proposal generator be $\mathcal{H} = \{(s_i, t_i)\}_{1 \leq i \leq |\mathcal{H}|}$. We sample K intervals from $\mathcal{P}_t$ to form the set of generated

---

[3] Transformers (Vaswani et al., 2017) can also be used, but in our initial experiments, they were outperformed by BiLSTMs on our tasks and data.

fingerspelling segments:

$$\begin{aligned}\mathcal{P}_k = \{&(s_k, t_k, w_g) | IoU((s_k, t_k), (s_g, t_g)) > \delta_{IoU},\\ &IS((s_t, t_k), (s_g, t_g)) > \delta_{IS},\\ &(s_k, t_k) \in \mathcal{H}, (s_g, t_g, w_g) \in \mathcal{P}_g\}\end{aligned} \tag{1}$$

where $\text{IS}(x, y) = \frac{\text{Intersection}(x,y)}{\text{Length}(y)}$ and $\text{IoU}(x, y) = \frac{\text{Intersection}(x,y)}{\text{Union}(x,y)}$. We use δ_{IoU} and δ_{IS} to control the degree to which the proposals can deviate from the ground-truth. In addition to the intersection over union (IoU), we use the normalized intersection IS to eliminate proposals with many missing frames. We take the union of the two sets, $\mathcal{P}_+ = \mathcal{P}_g \cup \mathcal{P}_k$, as the filtered proposal set to be encoded.

Fingerspelling visual encoding (FS-encoding) The visual encoding of each segment $(s, t, w) \in \mathcal{P}_+$ is $\mathbf{e}_v^{(s,t)} = \text{Bi-LSTM}(\mathbf{f}_{s:t})$.[4]

Text encoding A written word (or phrase) $\mathbf{w}$ is mapped to an embedding vector $\mathbf{e}_x^w$ via a text encoder. To handle words not seen at training time (and better handle rarely seen words), we first decompose $\mathbf{w}$ into a sequence of characters $c_{1:|w|}$ (e.g. 'ASL'='A'-'S'-'L') and feed the character sequence $c_{1:|w|}$ into a text encoder (here, a Bi-LSTM[5]).

Visual-text matching With the above pairs of visual and textual embeddings, we use a training objective function consisting of two triplet loss terms:

$$\begin{aligned}&L_{tri}(\mathbf{I}_{1:T}, \mathcal{P}_+) =\\ &\sum_{(s,t,w)\in\mathcal{P}_+} \max\{m + d(\mathbf{e}_v^{(s,t)}, \mathbf{e}_x^w)\\ &- \frac{1}{|\mathcal{N}_w|} \sum_{w'\in\mathcal{N}_w} d(\mathbf{e}_v^{(s,t)}, \mathbf{e}_x^{w'}), 0\}\\ &+ \max\{m + d(\mathbf{e}_v^{(s,t)}, \mathbf{e}_x^w)\\ &- \frac{1}{|\mathcal{N}_v|} \sum_{(s',t')\in\mathcal{N}_v} d(\mathbf{e}_v^{(s',t')}, \mathbf{e}_x^w), 0\}\end{aligned} \tag{2}$$

where d denotes cosine distance $d(\mathbf{a}, \mathbf{b}) = 1 - \frac{\mathbf{a}\cdot\mathbf{b}}{\|\mathbf{a}\|\|\mathbf{b}\|}$, m is a margin, and $\mathcal{N}_v$ and $\mathcal{N}_w$ are sets of negative samples of proposals and words. To form negative pairs we use semi-hard negative sampling (Schroff et al., 2015):

$$\begin{aligned}\mathcal{N}_v &= \{(s', t') | d(\mathbf{e}_v^{(s',t')}, \mathbf{e}_x^w) > d(\mathbf{e}_v^{(s,t)}, \mathbf{e}_x^w)\}\\ \mathcal{N}_w &= \{w' | d(\mathbf{e}_v^{(s,t)}, \mathbf{e}_x^{w'}) > d(\mathbf{e}_v^{(s,t)}, \mathbf{e}_x^w)\}\end{aligned} \tag{3}$$

For efficiency, negative samples are selected from the corresponding mini-batch.

Overall loss The model is trained with a combination of the detection loss and triplet loss:

$$L_{tot}(\mathbf{I}_{1:T}, \mathcal{P}_g) = \lambda_{det} L_{det}(\mathbf{I}_{1:T}, \mathcal{P}_g) + L_{tri}(\mathbf{I}_{1:T}, \mathcal{P}_+) \tag{4}$$

with the tuned weight λ_{det} controlling the relative importance of detection versus visual-textual matching.

Inference At test time, the model assigns a score $sc(\mathbf{I}_{1:T}, w)$ to a given video clip $\mathbf{I}_{1:T}$ and word w. The word is encoded into the word embedding $\mathbf{e}_x^w$. Suppose the set of fingerspelling proposals generated by the temporal proposal generator is $\mathcal{H}(\mathbf{I}_{1:T})$. We define a scoring function for the proposal $h \in \mathcal{H}(\mathbf{I}_{1:T})$ and word w

$$sc_{word}(h_m, w) = p_{det}^{\beta}(1 - d(\mathbf{e}_v^{h_m}, \mathbf{e}_x^w)) \tag{5}$$

where p_{det} is the probability given by the temporal proposal generator and β controls the relative weight between detection and matching. In other words, in order for a segment and word to receive a high score, the segment should be likely to be fingerspelling (according to p_{det}) and its embedding should match the text. Finally, the score for the video clip $\mathbf{I}_{1:T}$ and the word w is defined as the highest score among the set of proposals $\mathcal{H}(\mathbf{I}_{1:T})$:

$$sc(\mathbf{I}_{1:T}, w) = \max_{h\in\mathcal{H}(\mathbf{I}_{1:T})} sc_{word}(h, w) \tag{6}$$

5 Experimental Setup

5.1 Data

We conduct experiments on ChicagoFSWild (Shi et al., 2018) and ChicagoFSWild+ (Shi et al., 2019), two large-scale publicly available fingerspelling datasets containing 7,304 and 55,272 fingerspelling sequences respectively. The ASL videos in the two datasets are collected from online resources and include a variety of viewpoints and styles, such as webcam videos and lectures.

We follow the setup of (Shi et al., 2021) and split the raw ASL videos into 300-frame clips with a 75-frame overlap between neighboring chunks and remove clips without fingerspelling. The numbers of clips in the various splits can be found in the Appendix. On average, each clip contains 1.9/1.8 fingerspelling segments in the ChicagoFSWild and ChicagoFSWild+ datasets respectively.

---

[4] We compared the Bi-LSTM encoder with average/max pooling of $f_{s:t}$, and found the former to perform better.

[5] Again, transformers can also be used, but in our experiments Bi-LSTMs show better performance.

5.2 Baselines

We compare the proposed model, FSS-Net, to the following baselines adapted from common approaches for search and retrieval in related fields. To facilitate comparison, the network architecture for the visual and text encoding in all baselines is the same as in FSS-Net.

Recognizer In this approach, we train a recognizer that transcribes the video clip into text. Specifically, we train a recognizer to output a sequence of symbols consisting of either fingerspelled letters or a special non-fingerspelling symbol <x>. We train the recognizer with a connectionist temporal classification (CTC) loss (Graves et al., 2006), which is commonly used for speech recognition. At test time, we use beam search to generate a list of hypotheses $\hat{\mathbf{w}}_{1:M}$ for the target video clip $\mathbf{I}_{1:T}$. Each hypothesis $\hat{w}_m$ is split into a list of words $\{\hat{w}_m^n\}_{1\leq n\leq N}$ separated by <x>. The matching score between video $\mathbf{I}_{1:T}$ and $\mathbf{w}$ is defined as:

$$sc(\mathbf{I}_{1:T}, w) = 1 - \min_{1\leq m\leq M} \min_{1\leq n\leq N} \text{LER}(\hat{w}_m^n, w) \tag{7}$$

where the letter error rate LER is the Levenshtein edit distance. This approach is adapted from (Saraçlar and Sproat, 2004) for spoken utterance retrieval. Fingerspelling boundary information is not used in training this baseline model.

Whole-clip The whole-clip baseline encodes the whole video clip $\mathbf{I}_{1:T}$ into a visual embedding $\mathbf{e}_v^I$, which is matched to the textual embedding $\mathbf{e}_x^w$ of the query $\mathbf{w}$. The model is trained with contrastive loss as in equation 2. At test time, the score for video clip $\mathbf{I}_{1:T}$ and word $\mathbf{w}$ is:

$$sc(\mathbf{I}_{1:T}, \mathbf{w}) = 1 - d(\mathbf{e}_v^I, \mathbf{e}_x^w) \tag{8}$$

where d is the cosine distance as in FSS-Net. Fingerspelling boundary information is again not used in this baseline.

External detector (Ext-Det) This baseline uses the off-the-shelf fingerspelling detectors of (Shi et al., 2021) to generate fingerspelling proposals, instead of our proposal generator, and is otherwise identical to FSS-Net. For each dataset (ChicagoFSWild, ChicagoFSWild+), we use the detector trained on the training subset of that dataset. This baseline uses ground-truth fingerspelling boundaries for the detector training.

Attention-based keyword search (Attn-KWS) This model is adapted from (Tamer and Saraçlar, 2020b)'s approach for keyword search in sign language. The model employs an attention mechanism to match a text query with a video clip, where each frame is weighted based on the query embedding. The attention mechanism enables the model to implicitly localize frames relevant to the text. The model of (Tamer and Saraçlar, 2020b) is designed for lexical signs rather than fingerspelling. To adapt the model to our open-vocabulary fingerspelling setting, we use the same text encoder as in FSS-Net to map words into embeddings instead of using a word embedding matrix as in (Tamer and Saraçlar, 2020b). Fingerspelling boundary information is again not used in training this model, which arguably puts it at a disadvantage compared to FSS-Net. More details on the formulation of the model can be found in the Appendix.

5.3 Evaluation

For FWS, we use all words in the test set as the test vocabulary $w_{1:n}$. For FVS, all video clips in the test are used as candidates and the text queries are again the entire test vocabulary. We report the results in terms of standard metrics from the video-text retrieval literature (Momeni et al., 2020; Tamer and Saraçlar, 2020a): mean Average Precision (mAP) and mean F1 score (mF1), where the averages are over words for FVS and over videos for FWS. Hyperparameters are chosen to maximize the mAP on the dev set, independently for the two tasks (though ultimately, the best hyperparameter values in our search are identical for both tasks). Additional details on data, preprocessing, model implementation, and hyperparameters can be found in the Appendix.

6 Results and analysis

6.1 Main Results

Table 1 shows the performance of the above approaches on the two datasets. First, we notice that embedding-based approaches consistently outperform the recognizer baseline in the larger data setting (ChicagoFSWild+) but not the smaller data setting (ChicagoFSWild), which suggests that embedding-based models generally require more training data. The inferior performance of recognizer also shows that explicit fingerspelling recognition is not necessary for the search tasks. In addition, explicit fingerspelling detection (Ext-Det, FSS-Net) improves performance over implicit fin-

Table 1: FWS/FVS performance on the ChicagoFSWild and ChicagoFSWild+ test sets. The range of mAP and mF1 is [0, 1]. ★: methods that use fingerspelling boundaries in training.

gerspelling detection (Attn-KWS) and detection-free search (Whole-clip). Explicit fingerspelling detection requires boundary information during training. Of the models that don't use such supervision, Attn-KWS is the best performer given enough data, but is still far behind FSS-Net. Our model outperforms all of the alternatives. The relative performance of different models remains consistent across the various metrics and the two search tasks. For completeness, we also measure the performance of different models in terms of ranking-based metrics (e.g., Precision@N, Recall@N), as in prior work on video-text retrieval (Ging et al., 2020; Ranjay et al., 2017) (see full results in the Appendix). The relative performance of different models remains consistent on these metrics. The analysis below is done on ChicagoFSWild for simplicity. The conclusions also hold for ChicagoFSWild+.

6.2 Model analysis

Does better localization lead to better search? In the previous section we have seen that models that explicitly detect and localize fingerspelling outperform ones that do not. Next we look more closely at how well several models—Ext-Det, Attn-KWS and FSS-Net—perform on the task of localizing fingerspelling, which is a byproduct of these models' output. We measure performance via AP@IoU, a commonly used evaluation metric for action detection (Idrees et al., 2016; Heilbron et al., 2015) that has also been used for fingerspelling detection (Shi et al., 2021). AP@IoU measures the average precision of a detector under the constraint that the overlap of its predicted segments with the ground truth is above some threshold Intersection-over-Union (IoU) value. For Attn-KWS, the model outputs an attention vector, which we convert to segments as in (Shi et al., 2021).

Table 2: Fingerspelling localization performance for detection-based models.

	AP@0.1	AP@0.3	AP@0.5
Attn-KWS	0.268	0.104	0.035
Ext-Det	0.495	0.453	0.344
Ours	**0.568**	**0.519**	**0.414**

In general, the models with more accurate localization also have higher search and retrieval performance, as seen by comparing Table 2 with Table 1. However, differences in AP@IoU do not directly translate to differences in search performance. For example, the AP@IoU of Ext-Det (0.344) is an order of magnitude higher than that of Attn-KWS (0.035) while their FVS mAP results are much closer (0.593 vs. 0.573).

Raw images vs. estimated pose as input Prior work on sign language search (Tamer and Saraçlar, 2020a,b) has used estimated pose keypoints as input, rather than raw images as we do here. For comparison, we extract body and hand keypoints with OpenPose (Cao et al., 2019) and train a model with the pose skeleton as input.

Table 3: Impact of input type (pose vs. raw RGB images) on search performance.

	FWS (Video ⟹ Text)		FVS (Text ⟹ Video)	
Input	mAP	mF1	mAP	mF1
Pose	.142	.147	.127	.121
RGB	**.434**	**.439**	**.394**	**.370**

As is shown in Table 3, the pose-based model has much poorer search performance than the RGB image-based models. We believe this is largely because, while pose estimation works well for large motions and clean visual conditions, in our dataset much of the handshape information is lost in the estimated pose (see the Appendix for some qualitative examples).

6.3 Ablation Study

Within our model, the proposal generator produces a subset of all possible fingerspelling proposals,

Figure 3: Examples of FWS predictions. For each example video, the ground truth (GT) is shown along with the top 5 predicted fingerspelling sequences. Top red line: ground-truth fingerspelling segment. Bottom blue line: highest-scoring predicted fingerspelling segment. Segment locations are shown here for qualitative analysis, but they are not part of the task evaluation. Note that many fingerspelling sequences (both ground-truth and predictions) are abbreviations, and some are misspelled; we include all fingerspelling sequences that appear in the test set in the query vocabulary.

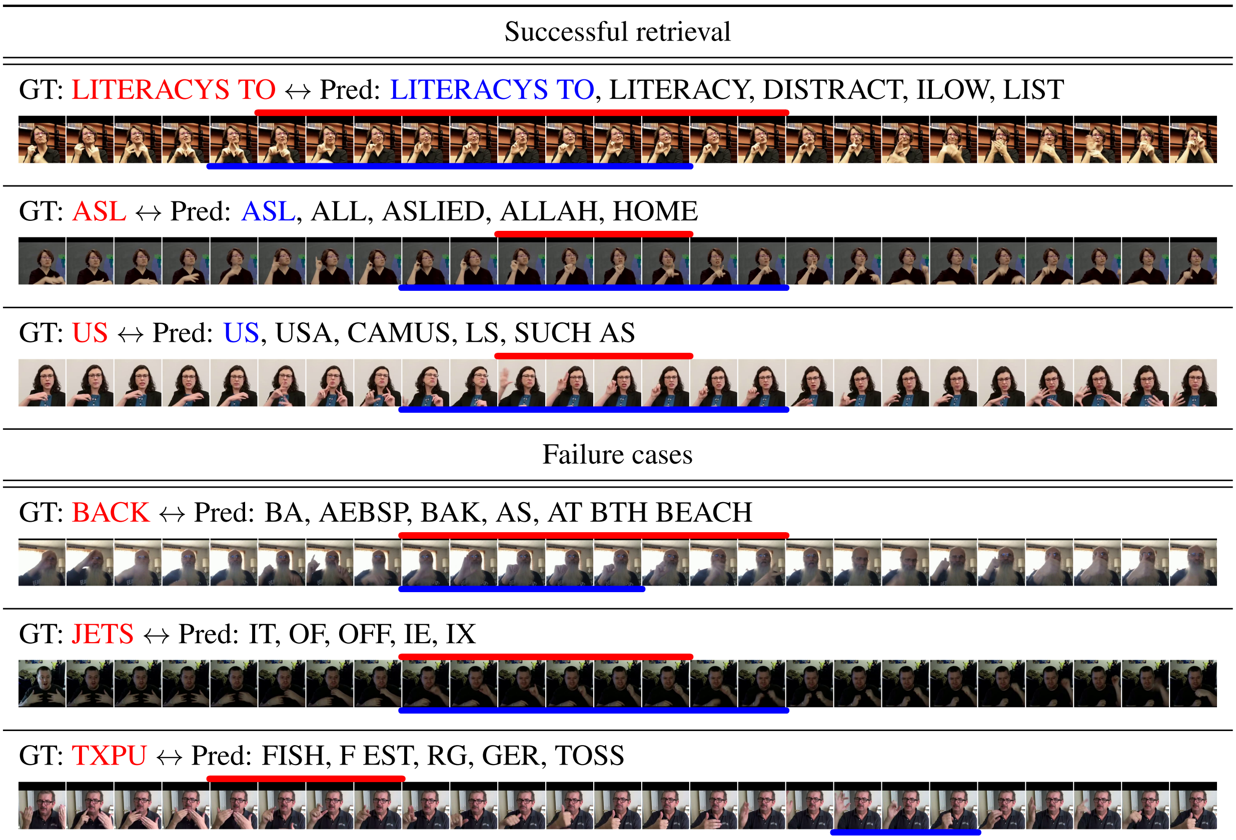

Table 4: Effect of various components of FSS-Net on FWS and FVS.

	FWS		FVS	
	mAP	mF1	mAP	mF1
Full model	**.434**	**.439**	**.394**	**.370**
(1) w/o generator	.186	.180	.259	.270
(2) $\lambda_{det} = 0, \beta = 0$	.411	.420	.373	.350
(3) $\lambda_{det} = 0.1, \beta = 0$	.418	.432	.360	.348
(4) w/o $\mathcal{P}_k$	.411	.420	.386	.366

intended to represent the most likely fingerspelling segments. To measure whether this component is important to the performance of the model, we compare our full model with the proposal generator to one where the proposal generator is removed (see Table 4). When the proposal generator is not used, the model is trained only with ground-truth fingerspelling segments ($\mathcal{P}_g$) and considers all possible proposals within a set of sliding windows. Such a "sliding-window" approach is commonly used in previous sign language keyword search (Albanie et al., 2020; Pfister et al., 2013) and spoken keyword spotting (Chen et al., 2015). As can be seen from Table 4 (Full model vs. row (1)), the proposal generator greatly improves search performance. This is not surprising, since the proposal generator greatly reduces the number of non-fingerspelling segments, thus lowering the chance of a mismatch between the text and video, and also refines the segment boundaries through regression, which should improve the quality of the visual segment encoding.

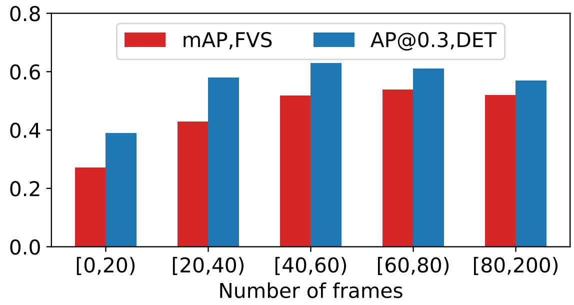
The fingerspelling detection component of our model has two aspects that may affect performance: imposing an additional loss during training, and rescoring during inference. We disentangle these two factors and show their respective benefits for our model in Table 4 (row (2) and (3)). The auxiliary detection task, which includes classification between fingerspelling and non-fingerspelling proposals, helps encode more comprehensive visual information into the visual embedding. In addition, the proposal probability output by the detector contains extra information and merging it into the matching score further improves the search performance.

Table 4 (row (4)) shows the effect of sampling additional proposals ($\mathcal{P}_k$) in fingerspelling detection. Additional positive samples make the visual embedding more robust to temporal shifts in the generated proposals, thus improving search performance.

6.4 Result analysis

The performance of our model is worse for short fingerspelled sequences than for long sequences (see Figure 4). This may be because shorter words are harder to spot, as is shown from the trend in fingerspelling detection in the same figure.

Figure 4: Performance as a function of fingerspelled word length. Red: FVS mAP, Blue: detection AP@IoU.



The datasets we use are collected from multiple sources, and the video quality varies between them. To quantify the effect of visual quality on search/retrieval performance, we categorize the ASL videos into three categories according to their source: YouTube, DeafVIDEO, and other miscellaneous sources (misc). YouTube videos are mostly ASL lectures with high resolution. DeafVIDEO videos are vlogs from deaf users of the social media site `deafvideo.tv`, where the style, camera angle, and image quality vary greatly. The visual quality of videos in the miscellaneous category tends to fall between the other two categories. Typical image examples from the three categories can be found in the Appendix (figure 7). The FWS performance of our model on videos in YouTube, DeafVIDEO, and misc are 0.684, 0.584, 0.629 (mAP) respectively. The results are overall consistent with the perceived relative visual qualities of these categories.

As a qualitative analysis, we examine example words and videos on which our model is more or less successful. Table 5 shows the query words/phrases with the highest/lowest FVS performance. The best-performing queries tend to be long and drawn from the highest-quality video source.

Table 5: Example words with low/high mAP in FVS. The source of the corresponding video is given in parentheses

Low	High
script (YouTube)	cabol erting (YouTube)
agent (misc)	vp ron stern (YouTube)
kc (YouTube)	co chairs (YouTube)
pati (DeafVIDEO)	dr kristin mulrooney (YouTube)
mexer (DeafVIDEO)	myles (YouTube)
flow (YouTube)	camaspace (YouTube)
yr (DeafVIDEO)	electronics (YouTube)
exalted (misc)	brain (YouTube)
poem (YouTube)	land (DeafVIDEO)

We also visualize the top FWS predictions made by our model in several video clips (see figure 3). Another common source of error is confusion between letters with similar handshapes (e.g., "i" vs. "j"). A final failure type is fingerspelling detection failure. As our model includes a fingerspelling detector, detection errors can harm search performance.

7 Conclusion

Our work takes one step toward better addressing the need for language technologies for sign languages, by defining fingerspelling search tasks and developing a model tailored for these tasks. These tasks are complementary to existing work on keyword search for lexical signs, in that it addresses the need to search for a variety of important content that tends to be fingerspelled, like named entities. Fingerspelling search is also more challenging in that it requires the ability to handle an open vocabulary and arbitrary-length queries. Our results demonstrate that a model tailored for the task in fact improves over baseline models based on related work on signed keyword search, fingerspelling detection, and speech recognition. However, there is room for improvement between our results and the maximum possible performance. One important aspect of our approach is the use of explicit fingerspelling detection within the model. An interesting avenue for future work is to address the case where the training data does not include segment boundaries for detector training. Finally, a complete sign language search system should consider both fingerspelling and lexical sign search.

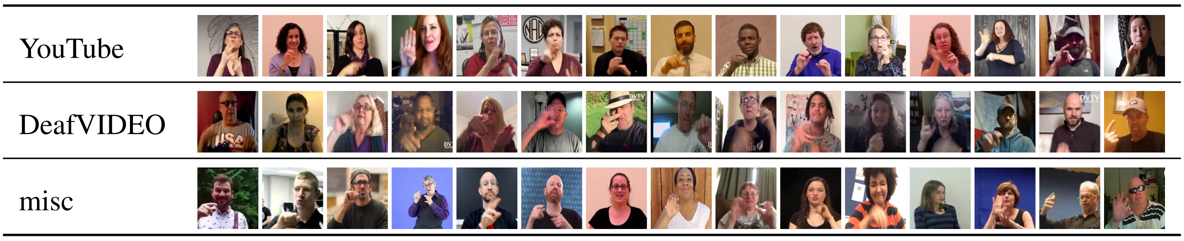
A.3 Implementation Details

Pre-processing The raw images in ChicagoFSWild and ChicagoFSWild+ datasets contain diverse visual scenes which can involve multiple persons. We adapt the heuristic approach used in (Shi et al., 2019) to select the target signer. Specifically, we use an off-the-shelf face detector to detect all the faces in the image. We extend each face bounding box by 1.5 times size of the bounding box in 4 directions and select the largest one with highest average magnitude of optical flow (Farnebäck, 2003). We further use the bounding box averaged over the whole sequence to crop the ROI area, which roughly denotes the signing region of a signer. Each image is resized to 160×160 before feeding into the model.

Model implementation The backbone convolutional layers are taken from VGG-19 (Simonyan and Zisserman, 2015). We pre-train the convolutional layers with a fingerspelling recognition task using the video-text pairs from the corresponding dataset. In pre-training, the VGG-19 layers are first pre-trained on ImageNet (Deng et al., 2009) and the image features further go through a 1-layer Bi-LSTM with 512 hidden units per direction. The model is trained with CTC loss (Graves et al., 2006). The output labels include the English alphabet plus the few special symbols, <space>, ’, &, ., @, as well as the blank symbol for CTC. The model is trained with SGD with batch size 1 at the initial learning rate of 0.01. The model is trained for 30 epochs and the learning rate is decayed to 0.001 after 20 epochs. The recognizer achieves 52.5%/64.4% lettter accuracy on ChicagoFSWild/ChicagoFSWild+ test sets. The VGG-19 convolutional layers are frozen in FSS-Net training.

In FSS-Net, the visual features output from convolutional layers are passed through a 1-layer Bi-LSTM with 256 hidden units per direction to capture temporal information. To generate proposals, we first transform the feature sequence via a 1D-CNN with the following architecture: conv layer (512 output dimension, kernel width 8), max pooling (kernel width 8, stride 4), conv layer (256 output dimension, kernel width 3) and conv layer (256 output dimension, kernel width 3). The scale of anchors is chosen from the range: $\{1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 12, 14,$

Figure 7: Example image frames from different sources in ChicagoFSWild and ChicagoFSWild+.



$16, 18, 20, 24, 32, 40, 60, 75\}$, according to the typical fingerspelling lengths in the two datasets. The positve/negative threshold of the anchors are 0.6/0.3 respectively. δ_{IoU}/δ_{IS} are 1.0/0.8 (chosen from {0.4, 0.6, 0.8, 1.0}). The FS-encoder and text encoder are 3-layer/1-layer BiLSTM with 256 hidden units respectively. The margin m, number of negative samples in $\mathcal{N}_v$ and $\mathcal{N}_w$ are tuned to be 0.45, 5 and 5. The model is trained for 25 epochs with Adam (Kingma and Ba, 2015) at initial learning rate of 0.001 and batch size of 32. The learning rate is halved if the mean average precision on the dev set does not improve for 3 epochs. λ_{det} in equation 4 is 0.1 (chosen from $\{0.1, 0.5, 1.0\}$). At test time, we generate $M = 50$ proposals after NMS with IoU threshold of 0.7. β is tuned to 1 (chosen from $\{0.5, 1, 2, 3\}$).

Implementation of Attn-KWS The model assigns a score to video clip $\mathbf{I}_{1:T}$ and word w via equation 9, where $\mathbf{e}_v^{1:T}$ is the visual feature sequence of $\mathbf{I}_{1:T}$ and $\mathbf{e}_x^w$ is the text feature of w, $\mathbf{W}$ and $\mathbf{b}$ are learnable parameters. The model is trained with cross-entropy loss.

$$
\begin{aligned}
s(\mathbf{e}_v^t, \mathbf{e}_x^w) &= \alpha\left(\frac{\mathbf{e}_v^t \cdot \mathbf{e}_x^w}{||\mathbf{e}_v^t|| \cdot ||\mathbf{e}_x^w||}\right)^2 + \theta \\
a(t) &= \frac{\exp(s(\mathbf{e}_v^t, \mathbf{e}_x^w))}{\sum_t \exp(s(\mathbf{e}_v^t, \mathbf{e}_x^w))} \qquad (9) \\
sc(\mathbf{I}_{1:T}, \mathbf{e}_x^w) &= \sigma(\mathbf{W} \sum_{t=1}^{T} a(t)\mathbf{e}_v^t + \mathbf{b})
\end{aligned}
$$

A.4 Full results

In addition to mAP and mF1, we also report ranking-based metrics: Precision@N and Recall@N (N=1, 10). For top-N retrieved X, we compute the percentage of correct X among N retrieved X as precision@N and the percentage of correct X among all correct X as recall@N, where X is text for FWS and video for FVS. Note the maximum value of R@1 and P@10 can be less than 1 as there are clips with multiple fingerspelling sequences and clips with fewer than 10 fingerspelling sequences. The performance of different models measured by all the above metrics is shown in table 7.

A.5 Examples of fingerspelling localization

Figure 8 shows examples fingerspelling localization produced by different methods.

Skill Induction and Planning with Latent Language

Pratyusha Sharma **Antonio Torralba** **Jacob Andreas**
Massachusetts Institute of Technology
`{pratyuss,torralba,jda}@mit.edu`

Abstract

We present a framework for learning hierarchical policies from demonstrations, using sparse *natural language annotations* to guide the discovery of reusable skills for autonomous decision-making. We formulate a generative model of action sequences in which goals generate sequences of high-level subtask descriptions, and these descriptions generate sequences of low-level actions. We describe how to train this model using primarily unannotated demonstrations by *parsing* demonstrations into sequences of named high-level subtasks, using only a small number of seed annotations to ground language in action. In trained models, natural language commands index a combinatorial library of skills; agents can use these skills to *plan* by generating high-level instruction sequences tailored to novel goals. We evaluate this approach in the ALFRED household simulation environment, providing natural language annotations for only 10% of demonstrations. It achieves task completion rates comparable to state-of-the-art models (outperforming several recent methods with access to ground-truth plans during training and evaluation) while providing structured and human-readable high-level plans.[1]

1 Introduction

Building autonomous agents that integrate high-level reasoning with low-level perception and control is a long-standing challenge in artificial intelligence (Fikes et al., 1972; Newell, 1973; Sacerdoti, 1973; Brockett, 1993). Fig. 1 shows an example: to accomplish a task such as *cooking an egg*, an agent must first *find the egg*, then *grasp it*, then *locate a stove or microwave*, at each step reasoning about both these subtasks and complex, unstructured sensor data. **Hierarchical planning models** (e.g. Sutton et al., 1999)—which first reason about abstract states and actions, then ground these in concrete control decisions—play a key role in most existing agent architectures. But training effective hierarchical models for general environments and goals remains difficult. Standard techniques either require detailed formal task specifications, limiting their applicability in complex and hard-to-formalize environments, or are restricted to extremely simple high-level actions, limiting their expressive power (Bacon et al., 2017; Sutton et al., 1999; Dietterich, 1999; Kaelbling and Lozano-Pérez, 2011).

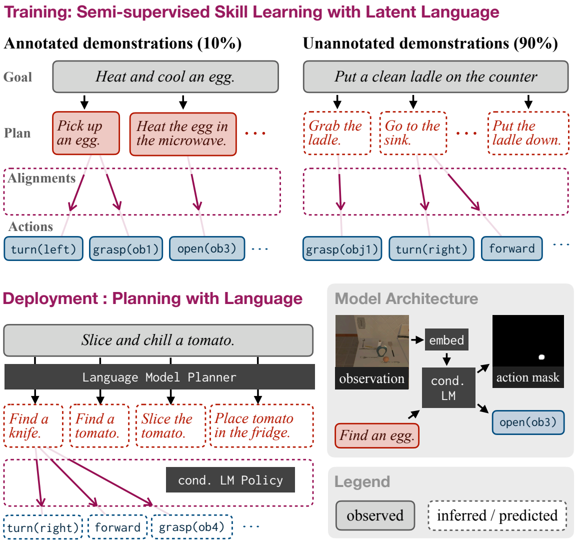

Figure 1: Hierarchical imitation learning using weak natural language supervision. During training, a small number of seed annotations are used to automatically segment and label unannotated training demonstrations with natural language descriptions of their high-level structure. When deployed on new tasks, learned policies first generate sequences of natural language subtask descriptions, then modularly translate each description to a sequence of low-level actions.

Several recent papers have proposed to overcome these limitations using richer forms of supervision—especially language—as a scaffold for hierarchical policy learning. In **latent language policies** (LLPs; Andreas et al., 2018), controllers first map

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1713 - 1726
May 22-27, 2022

from high-level goals to sequences of natural language instructions, then use instruction following models to translate those instructions into actions. But applications of language-based supervision for long-horizon policy learning have remained quite limited in scope. Current LLP training approaches treat language as a latent variable only during prediction, and require fully supervised (and often impractically large) datasets that align goal specifications with instructions and instructions with low-level actions. As a result, all existing work on language-based policy learning has focused on very short time horizons (Andreas et al., 2018), restricted language (Hu et al., 2019; Jacob et al., 2021) or synthetic training data (Shu et al., 2018; Jiang et al., 2019).

In this paper, we show that it is possible to train language-based hierarchical policies that outperform state-of-the-art baselines using only minimal natural language supervision. We introduce a procedure for *weakly* and *partially supervised* training of LLPs using ungrounded text corpora, unlabeled demonstrations, and a small set of annotations linking the two. To do so, we model *training* demonstrations as generated by latent high-level plans: we describe a deep, structured latent variable model in which goals generate subtask descriptions and subtask descriptions generate actions. We show how to learn in this model by performing inference in the infinite, combinatorial space of latent plans while using a comparatively small set of annotated demonstrations to seed the learning process.

Using an extremely reduced version of the ALFRED household robotics dataset (Shridhar et al., 2020)—with 10% of labeled training instructions, no alignments during training, and no instructions at all during evaluation—our approach performs comparably a state-of-the-art model that makes much stronger dataset-specific assumptions (Blukis et al., 2021), while outperforming several models (Zhang and Chai, 2021; Suglia et al., 2021; Kim et al., 2021) that use more information during both training *and evaluation*. Our method correctly segments and labels subtasks in unlabeled demonstrations, including subtasks that involve novel compositions of actions and objects. Additional experiments show that pretraining on large (ungrounded) text corpora (Raffel et al., 2020) contributes to this success, demonstrating one mechanism by which background knowledge encoded in language can benefit tasks that do not involve language as an input or an output.

Indeed, our results show that relatively little information about language grounding is needed for effective learning of language-based policies—a rich model of natural language text, a large number of demonstrations, and a small number of annotations suffice for learning compositional libraries of skills and effective policies for deploying them.

2 Preliminaries

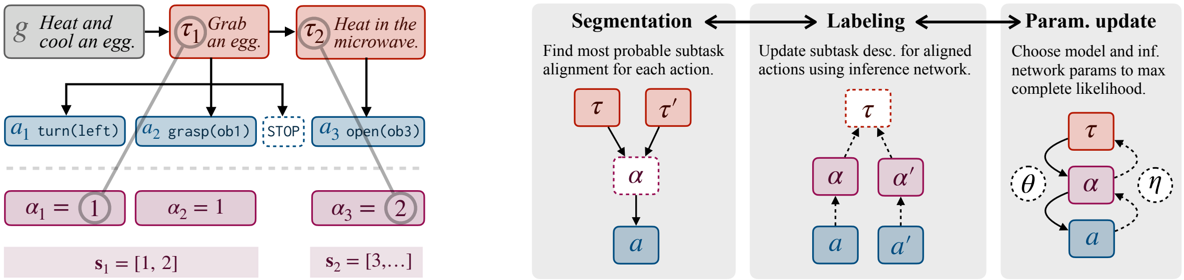
We consider learning problems in which agents must perform multi-step tasks (like *cooking an egg*; Fig. 1) in interactive environments. We formalize these problems as undiscounted, episodic, partially observed Markov decision processes (POMDPs) defined by a tuple $(\mathcal{S}, \mathcal{A}, T, \Omega, O)$, where $\mathcal{S}$ is a set of **states**, $\mathcal{A}$ is a set of **actions**, $T : \mathcal{S} \times \mathcal{A} \to \mathcal{S}$ is an (unknown) **state transition function**, Ω is a set of **observations**, and $O : \mathcal{S} \to \Omega$ is an (unknown) **observation function**.[2] We assume that observations include a distinguished **goal specification** g that remains constant throughout an episode; given a dataset $\mathcal{D}$ of consisting of **goals** g and **demonstrations d** (i.e. $\mathcal{D} = \{(\mathbf{d}_1, g_1), (\mathbf{d}_2, g_2) \ldots\}$; $\mathbf{d} = [(o_1, a_1), (o_2, a_2), \ldots]$; $o \in \Omega, a \in \mathcal{A}$), we aim to learn a goal-conditional policy $\pi(a_t \mid \mathbf{a}_{:t-1}, \mathbf{o}_{:t}, g) = \pi(a_t \mid a_1, \ldots, a_{t-1}, o_1, \ldots, o_t, g)$ that generalizes demonstrated behaviors to novel goals and states.

For tasks like the ones depicted in Fig. 1, this learning problem requires agents to accomplish multiple subgoals (like *finding an egg* or *operating an appliance*) in a feasible sequence. As in past work, we address this challenge by focusing on **hierarchical** policy representations that plan over temporal abstractions of low-level action sequences. We consider a generic class of hierarchical policies that first predict a sequence of **subtask specifications** τ from a distribution $\pi^{\mathrm{C}}(\tau_i \mid \tau_{:i-1}, g)$ (the *controller*), then from each τ generate a sequence of actions $a_1 \ldots a_n$ from a distribution $\pi^{\mathrm{E}}(a_i \mid \mathbf{a}_{:i-1}, \mathbf{o}_{:i}, \tau)$ (the *executor*).[3] At each timestep, π^{E} may either generate an action from $\mathcal{A}$; or a special termination signal STOP; after STOP is selected, control is returned to π^{C} and a new τ is generated. This process is visualized

---

[2] For notational convenience, we assume without loss of generality that T and O are deterministic.

[3] In past work, π^{E} often conditions on the current observation as well as goal and history of past subtask specifications; we found that this extra information was not needed for the tasks studied here.



(a)

(b)

Figure 2: (a) When a hierarchical policy is deployed, π^{C} generates a sequence of subtask specifications, and π^{E} translates each of these to a low-level action sequence ending in STOP. At training time, this hierarchical structure is not available, and must be inferred to train our model. To do so, we assign each action a_i an auxiliary **alignment** variable α_i identifying the subtask that produced it. Alignments divide an action sequence into a sequence of **segments** s containing actions aligned to the same subtask. Automatically segmenting training demonstrations makes it possible to learn modular, reusable policies for individual subtasks without direct supervision. (b) Overview of the proposed learning algorithm (SL)^3, which alternates between segmenting (by aligning) actions to fixed subtask specifications; labeling segments given fixed alignments, and updating model parameters.

in Fig. 2(a). Trajectories generated by hierarchical policies themselves have hierarchical structure: each subtask specification τ generates a **segment** of a trajectory (delimited by a STOP action) that accomplishes a specific subgoal.

Training a hierarchical policy requires first defining a space of subtask specifications τ, then parameterizing controller and executor policies that can generate these specifications appropriately. Most past research has either pre-defined an inventory of target skills and independently supervised π^{C} and π^{E} (Sutton et al., 1999; Kulkarni et al., 2016; Dayan and Hinton, 1992); or performed unsupervised discovery of a finite skill inventory using clustering techniques (Dietterich, 1999; Fox et al., 2017).

Both methods have limitations, and recent work has explored methods for using richer supervision to guide discovery of skills that are more robust than human-specified ones and more generalizable than automatically discovered ones. One frequently proposed source of supervision is language: in **latent language policies**, π^{C} is trained to generate goal-relevant instructions in natural language, π^{E} is trained to follow instructions, and the space of abstract actions available for planning is in principle as structured and expressive as language itself. But current approaches to LLP training remain impractical, requiring large datasets of independent, fine-grained supervision for π^{C} and π^{E}. Below, we describe how to overcome this limitation, and instead learn from large collections of unlabeled demonstrations augmented with only a small amount of natural language supervision.

3 Approach

Overview We train hierarchical policies on unannotated action sequences by inferring latent natural language descriptions of the subtasks they accomplish (Fig. 2(b)). We present a learning algorithm that jointly partitions these action sequences into smaller segments exhibiting reusable, task-general skills, labels each segment with a description, trains π^{C} to generate subtask descriptions from goals, and π^{E} to generate actions from subtask descriptions.

Formally, we assume access to two kinds of training data: a large collection of **unannotated demonstrations** $\mathcal{D} = \{(\mathbf{d}_1, g_1), (\mathbf{d}_2, g_2), \ldots\}$ and a smaller collection of **annotated demonstrations** $\mathcal{D}^{\mathrm{ann}} = \{(\mathbf{d}_1, g_1, \boldsymbol{\tau}_1), (\mathbf{d}_2, g_2, \boldsymbol{\tau}_2), \ldots\}$ where each $\boldsymbol{\tau}$ consists of a sequence of natural language **instructions** $[\tau_1, \tau_2, \ldots]$ corresponding to the subtask sequence that should be generated by π^{C}. We assume that even annotated trajectories leave much of the structure depicted in Fig. 2(a) unspecified, containing no explicit segmentations or STOP markers. (The number of instructions $|\boldsymbol{\tau}|$ will in general be smaller than the number of actions $|\mathbf{d}|$.) Training π^{E} requires inferring the correspondence between actions and annotations on $\mathcal{D}^{\mathrm{ann}}$ while inferring annotations themselves on $\mathcal{D}$.

Training objective To begin, it will be convenient to have an explicit expression for the probability of a demonstration given a policy $(\pi^{\mathrm{C}}, \pi^{\mathrm{E}})$. To do so, we first observe that the hierarchical generation procedure depicted in Fig. 2(a) produces a latent *alignment* between each action and the subtask

τ that generated it. We denote these alignments α, writing $\alpha_i = j$ to indicate that a_i was generated from τ_j. Because π^{C} executes subtasks in sequence, alignments are *monotonic*, satisfying $\alpha_i = \alpha_{i-1}$ or $\alpha_i = \alpha_{i-1} + 1$. Let $\mathrm{seg}(\boldsymbol{\alpha})$ denote the **segmentation** associated with $\boldsymbol{\alpha}$, the sequence of sequences of action indices $[[i : \alpha_i = 1], [i : \alpha_i = 2], \ldots]$ aligned to the same instruction (see Fig. 2(a)). Then, for a fixed policy and POMDP, we may write the joint probability of a demonstration, goal, annotation, and alignment as:

$$p(\mathbf{d}, g, \boldsymbol{\tau}, \boldsymbol{\alpha}) \propto \prod_{\mathbf{s} \in \mathrm{seg}(\boldsymbol{\alpha})} \Bigg[\pi^{\mathrm{C}}(\tau_{\mathbf{s}} \mid \boldsymbol{\tau}_{<\mathbf{s}}, g) \times \Bigg(\prod_{i \in 1..|\mathbf{s}|} \pi^{\mathrm{E}}(a_i \mid \mathbf{a}_{\mathbf{s}:i-1}, \mathbf{o}_{\mathbf{s}:i}, \tau_{\alpha_i}) \Bigg) \times \pi^{\mathrm{E}}(\textsc{stop} \mid \mathbf{a}_{\mathbf{s}}, \mathbf{o}_{\mathbf{s}}) \Bigg] . \quad (1)$$

Here $_<\mathbf{s}$ (in a slight abuse of notation) denotes all segments preceding $\mathbf{s}$, and $\mathbf{s}_i$ is the index of the ith action in $\mathbf{s}$. The constant of proportionality in Eq. (1) depends only on terms involving $T(s' \mid s, a)$, $O(o \mid s)$ and $p(g)$, all independent of π^{C} or π^{E}; Eq. (1) thus describes the component of the data likelihood under the agent's control (Ziebart et al., 2013).

With this definition, and given $\mathcal{D}$ and $\mathcal{D}^{\mathrm{ann}}$ as defined above, we may train a latent language policy using partial natural language annotations via ordinary maximum likelihood estimation, imputing the missing segmentations and labels in the training set jointly with the parameters of π^{C} and π^{E} (which we denote θ) in the combined annotated and unannotated likelihoods:

$$\underset{\hat{\boldsymbol{\tau}}, \hat{\boldsymbol{\alpha}}, \hat{\theta}}{\arg\max}\, \mathcal{L}(\hat{\boldsymbol{\tau}}, \hat{\boldsymbol{\alpha}}, \hat{\theta}) + \mathcal{L}^{\mathrm{ann}}(\hat{\boldsymbol{\alpha}}, \hat{\theta}) \quad (2)$$

where

$$\mathcal{L}(\hat{\boldsymbol{\tau}}, \hat{\boldsymbol{\alpha}}, \hat{\theta}) = \sum_{(\mathbf{d}, g) \in \mathcal{D}} \log p(\mathbf{d}, g, \hat{\boldsymbol{\tau}}, \hat{\boldsymbol{\alpha}}) \quad (3)$$

$$\mathcal{L}^{\mathrm{ann}}(\hat{\boldsymbol{\alpha}}, \hat{\theta}) = \sum_{(\mathbf{d}, g, \boldsymbol{\tau}) \in \mathcal{D}^{\mathrm{ann}}} \log p(\mathbf{d}, g, \boldsymbol{\tau}, \hat{\boldsymbol{\alpha}}) \quad (4)$$

and where we have suppressed the dependence of $p(\mathbf{d}, g, \boldsymbol{\tau}, \boldsymbol{\alpha})$ on $\hat{\theta}$ for clarity. This objective involves continuous parameters $\hat{\theta}$, discrete alignments $\hat{\alpha}$, and discrete labelings $\hat{\boldsymbol{\tau}}$. We optimize it via block coordinate ascent on each of these components in turn: alternating between re-**segmenting** demonstrations, re-**labeling** those without ground-truth labels, and **updating parameters**. The full learning algorithm, which we refer to as **(SL)^3** (*semi-supervised skill learning with latent language*), is shown in Algorithm 1, with each step of the optimization procedure described in more detail below.

Segmentation: $\arg\max_{\hat{\boldsymbol{\alpha}}} \mathcal{L}(\hat{\boldsymbol{\tau}}, \hat{\boldsymbol{\alpha}}, \hat{\theta}) + \mathcal{L}^{\mathrm{ann}}(\hat{\boldsymbol{\alpha}}, \hat{\theta})$

The segmentation step associates each low-level action with a high-level subtask by finding the highest scoring alignment sequence $\boldsymbol{\alpha}$ for each demonstration in $\mathcal{D}$ and $\mathcal{D}^{\mathrm{ann}}$. While the number of possible alignments for a single demonstration is exponential in demonstration length, the assumption that π^{E} depends only on the current subtask implies the following recurrence relation:

$$\begin{aligned} &\max_{\boldsymbol{\alpha}_{1:n}} p(\mathbf{d}_{1:n}, g, \boldsymbol{\tau}_{1:m}, \boldsymbol{\alpha}_{1:n}) \\ &= \max_i \Big(\max_{\boldsymbol{\alpha}_{1:i}} p(\mathbf{d}_{1:i}, g, \boldsymbol{\tau}_{1:m-1}, \boldsymbol{\alpha}_{1:i}) \\ &\qquad \times p(\mathbf{d}_{i+1:n}, g, \tau_m, \boldsymbol{\alpha}_{i+1:n} = m) \Big) \end{aligned} \quad (5)$$

This means that the highest-scoring segmentation can be computed by an algorithm that recursively identifies the highest-scoring alignment to each prefix of the instruction sequence at each action (Algorithm 2), a process requiring $O(|\mathbf{d}||\boldsymbol{\tau}|)$ space and $O(|\mathbf{d}|^2|\boldsymbol{\tau}|)$ time. The structure of this dynamic program is identical to the forward algorithm for hidden semi-Markov models (HSMMs), which are widely used in NLP for tasks like language generation and word alignment (Wiseman et al., 2018). Indeed, Algorithm 2 can be derived immediately from Eq. (1) by interpreting $p(\mathbf{d}, g, \boldsymbol{\tau}, \boldsymbol{\alpha})$ as the output distribution for an HSMM in which emissions are actions, hidden states are alignments, the emission distribution is π^{E} and the transition distribution is the deterministic distribution with $p(\alpha + 1 \mid \alpha) = 1$.

This segmentation procedure does not produce meaningful subtask boundaries until an initial executor policy has been trained. Thus, during the first iteration of training, we estimate a segmentation by by fitting a 3-state hidden Markov model to training action sequences using the Baum–Welch algorithm (Baum et al., 1970), and mark state transitions as segment boundaries. Details about the initialization step may be found in Appendix B.

Algorithm 1: $(\mathrm{SL})^3$: Semi-Supervised Skill Learning with Latent Language

```
Input: Unannotated demonstrations
  $\mathcal{D} = \{(\mathbf{d}_1, g_1), (\mathbf{d}_2, g_2), \ldots\}$;
Annotated demonstrations
  $\mathcal{D}^{\text{ann}} = \{(\mathbf{d}_1, g_1, \boldsymbol{\tau}_1), (\mathbf{d}_2, g_2, \boldsymbol{\tau}_2), \ldots\}$

Output: Inferred alignments $\hat{\boldsymbol{\alpha}}$, labels $\hat{\boldsymbol{\tau}}$, and
  parameters $\theta$ for $\pi^{\text{C}}$ and $\pi^{\text{E}}$.

// Initialization

Initialize policy parameters $\theta$ using a pretrained
  language model (Raffel et al., 2020).

Initialize inference network parameters
  $\eta \leftarrow \arg\max_{\hat{\eta}} \sum_{\mathbf{d} \in \mathcal{D}^{\text{ann}}} \sum_{\mathbf{s},\tau} \log q_\eta(\tau \mid \mathbf{a_s}, \mathbf{o_s})$.

for iteration $t \leftarrow 1 \ldots T$ do
    // Segmentation
    // Infer alignments between actions and subtasks.
    if $t = 1$ then
        Initialize $\hat{\boldsymbol{\alpha}}$ using the Baum–Welch
          algorithm (Baum et al., 1970)
    else
        $\hat{\boldsymbol{\alpha}} \leftarrow \arg\max_{\hat{\boldsymbol{\alpha}}} \mathcal{L}(\hat{\boldsymbol{\tau}}, \hat{\boldsymbol{\alpha}}, \hat{\theta}) + \mathcal{L}^{\text{ann}}(\hat{\boldsymbol{\alpha}}, \hat{\theta})$
          [Algorithm 2].
    end

    // Labeling
    // Infer subtask labels for unannotated demos $\mathcal{D}$.
    $\hat{\boldsymbol{\tau}} \leftarrow \arg\max_{\hat{\boldsymbol{\tau}}} \mathcal{L}(\hat{\boldsymbol{\tau}}, \hat{\boldsymbol{\alpha}}, \hat{\theta})$

    // Parameter Update
    // Fit policy and proposal model parameters.
    $\hat{\theta} \leftarrow \arg\max_{\hat{\theta}} \mathcal{L}(\hat{\boldsymbol{\tau}}, \hat{\boldsymbol{\alpha}}, \hat{\theta}) + \mathcal{L}^{\text{ann}}(\hat{\boldsymbol{\alpha}}, \hat{\theta})$
    $\hat{\eta} \leftarrow \arg\max_{\hat{\eta}} \sum_{\mathbf{d}} \sum_{\mathbf{s},\tau} \log q_\eta(\hat{\tau} \mid \mathbf{a_s}, \mathbf{o_s})$
end
```

Algorithm 2: Dynamic program for segmentation

```
Input: Demonstration $\mathbf{d} = [(o_1, a_1), \ldots, (o_n, a_n)]$;
Task specifications $\boldsymbol{\tau} = [\tau_1, \ldots, \tau_m]$.
Executor $\pi^{\text{E}}(\mathbf{a} \mid \mathbf{o}, \tau) = \prod_i \pi^{\text{E}}(a_i \mid \mathbf{a}_{:i-1}, \mathbf{o}_{:i}, \tau)$

Output: Maximum a posteriori alignments $\boldsymbol{\alpha}$.

scores $\leftarrow$ an $n \times m$ matrix of zeros
// scores$[i, j]$ holds the log-probability of the
// highest-scoring sequence whose final action $i$ is
// aligned to subtask $j$.

for $i \leftarrow 1 \ldots n$ do
    for $j \leftarrow 1 \ldots |\boldsymbol{\tau}|$ do
        scores$[i, j] \leftarrow -\infty$
        for $k \leftarrow 1 \ldots i - 1$ do
            scores$[i, j] \leftarrow \max($
                scores$[i, j]$,
                scores$[k, j - 1]$
                    $+ \log \pi^{\text{E}}(\mathbf{a}_{k+1:i} \mid \mathbf{o}_{k+1:i}, \tau_j))$
        end
    end
end

The optimal alignment sequence may be obtained
  from scores via back-tracing (Rabiner, 1989).
```

Labeling: $\arg\max_{\hat{\boldsymbol{\tau}}} \mathcal{L}(\hat{\boldsymbol{\tau}}, \hat{\boldsymbol{\alpha}}, \hat{\theta})$

Inference of latent, language-based plan descriptions in unannotated demonstrations involves an intractable search over string-valued $\boldsymbol{\tau}$. To approximate this search tractably, we used a **learned, amortized inference procedure** (Wainwright and Jordan, 2008; Hoffman et al., 2013; Kingma and Welling, 2014) to impute descriptions given fixed segmentations. During each parameter update step (described below), we train an inference model $q_\eta(\tau \mid \mathbf{a}_{\mathbf{s}^{(i)}}, \mathbf{a}_{\mathbf{s}^{(i+1)}}, g)$ to approximate the posterior distribution over descriptions for a given segment given a goal, the segment's actions, and the actions from the subsequent segment.[4] Then, during the labeling step, we label complete demonstrations by choosing the highest-scoring instruction for each trajectory independently:

$$\arg\max_{\boldsymbol{\tau}} \log p(\mathbf{d}, g, \boldsymbol{\tau}, \boldsymbol{\alpha}) \approx$$
$$\left[\arg\max_{\tau} q(\tau \mid \mathbf{a}_{\mathbf{s}^{(i)}}, \mathbf{a}_{\mathbf{s}^{(i+1)}}, g) \,\middle|\, \mathbf{s}^{(i)} \in \operatorname{seg}(\boldsymbol{\alpha})\right] \quad (6)$$

Labeling is performed only for demonstrations in $\mathcal{D}$, leaving the labels for $\mathcal{D}^{\text{ann}}$ fixed during training.

Param update: $\arg\max_{\hat{\theta}} \mathcal{L}(\hat{\boldsymbol{\tau}}, \hat{\boldsymbol{\alpha}}, \hat{\theta}) + \mathcal{L}^{\text{ann}}(\hat{\boldsymbol{\alpha}}, \hat{\theta})$

This is the simplest of the three update steps: given fixed instructions and alignments, and π^{E}, π^{C} parameterized as neural networks, this objective is differentiable end-to-end. In each iteration, we train these to convergence (optimization details are described in Section 4 and Appendix C). During the parameter update step, we also fit parameters η of the proposal model to maximize the likelihood $\sum_{\mathbf{d}} \sum_{\mathbf{s},\tau} \log q_\eta(\hat{\tau} \mid \mathbf{a_s}, \mathbf{o_s})$ with respect to the current segmentations $\hat{\mathrm{s}}$ and labels $\hat{\tau}$.

As goals, subtask indicators, and actions may all be encoded as natural language strings, π^{C} and π^{E} may be implemented as conditional language models. As described below, we initialize both policies with models *pretrained* on a large text corpora.

4 Experimental Setup

Our experiments aim to answer two questions. First, does the latent-language policy representation described in Section 3 improve downstream performance on complex tasks? Second, how many natural language annotations are needed to train

---

[4] In our experiments, conditioning on observations or longer context did not improve the accuracy of this model.

an effective latent language policy given an initial dataset of unannotated demonstrations?

Environment We investigate these questions in the ALFRED environment of Shridhar et al. (2020). ALFRED consists of a set of interactive simulated households containing a total of 120 rooms, accompanied by a dataset of 8,055 expert task demonstrations for an embodied agent annotated with 25,743 English-language instructions. Observations o are bitmap images from a forward-facing camera, and actions a are drawn from a set of 12 low-level navigation and manipulation primitives. Manipulation actions (7 of the 12) additionally require predicting a mask over the visual input to select an object for interaction. See Shridhar et al. (2020) for details.

While the ALFRED environment is typically used to evaluate *instruction following* models, which map from detailed, step-by-step natural language descriptions to action sequences (Shridhar et al., 2020; Singh et al., 2020; Corona et al., 2021), our experiments focus on an *goal-only* evaluation in which agents are given goals (but not fine-grained instructions) at test time. Several previous studies have also considered goal-only evaluation for ALFRED, but most use extremely fine-grained supervision at *training time*, including full supervision of symbolic plan representations and their alignments to demonstrations (Min et al., 2021; Zhang and Chai, 2021), or derived sub-task segmentations using ALFRED-specific rules (Blukis et al., 2021). In contrast, our approach supports learning from partial, language-based annotations without segmentations or alignments, and this data condition is the main focus of our evaluation.

Modeling details π^{C} and π^{E} are implemented as sequence-to-sequence transformer networks (Vaswani et al., 2017). π^{C}, which maps from text-based goal specifications to text-based instruction sequences, is initialized with a pre-trained `T5-small` language model (Raffel et al., 2020). π^{E}, which maps from (textual) instructions and (image-based) observations to (textual) actions and (image-based) object selection masks is also initialized with `T5-small`; to incorporate visual input, this model first embeds observations using a pretrained `ResNet18` model (He et al., 2016) and transforms these linearly to the same dimensionality as the word embedding layer. Details about the architecture of π^{C} and π^{E} may be found in Appendix C.

Model variants for exploration In ALFRED, navigation in the goal-only condition requires exploration of the environment, but no exploration is demonstrated in training data, and techniques other than imitation learning are required for this specific skill. To reflect this, we replace all annotations containing detailed navigation instructions *go to the glass on the table to your left* with generic ones *find a glass*. Examples and details of how navigation instructions are modified can be found in Appendix E and Fig. 7. The ordinary (SL)^3 model described above is trained on these abstracted instructions.

A key advantage of (SL)^3 is modularity: individual skills may be independently supervised or reimplemented. To further improve (SL)^3's navigation capabilities, we introduce two model variants in which sub-task specifications beginning *Find...* are executed by a either a planner with ground-truth environment information or a specialized navigation module from the HLSM model (Blukis et al., 2021) rather than π^{E}. Outside of navigation, these models preserve the architecture and training procedure of (SL)^3, and are labeled **(SL)^3+planner** and **(SL)^3+HLSM** in experiments below.

Baselines and comparisons We compare the performance of (SL)^3 to several baselines:

seq2seq: A standard (non-hierarchical) goal-conditioned policy, trained on the $(g, \mathbf{d})$ pairs in $\mathcal{D} \cup \mathcal{D}^{\text{ann}}$ to maximize $\sum_{\mathbf{a},\mathbf{o},g} \log \pi(\mathbf{a} \mid \mathbf{o}, g)$, with π parameterized similar to π^{E}.

seq2seq2seq: A supervised hierarchical policy with the same architectures for π^{C} and π^{E} as in (SL)^3, but with π^{C} trained to generate subtask sequences by maximizing $\sum_{\boldsymbol{\tau},g} \log \pi^{\mathrm{C}}(\boldsymbol{\tau} \mid g)$ and π^{E} trained to maximize $\sum_{\mathbf{a},\mathbf{o},\boldsymbol{\tau},g} \log \pi^{\mathrm{E}}(\mathbf{a} \mid \mathbf{o}, \boldsymbol{\tau}, g)$ using only $\mathcal{D}^{\text{ann}}$. Because π^{E} maps from complete task sequences to complete low-level action sequences, training of this model involves no explicit alignment or segmentation steps.

no-pretrain, **no-latent**: Ablations of the full (SL)^3 model in which π^{C} and π^{E} are, respectively, randomly initialized or updated only on $\mathcal{L}^{\text{ann}}(\hat{\boldsymbol{\alpha}}, \hat{\theta})$ during the parameter update phase.

We additionally contextualize our approach by comparing it to several state-of-the-art models for the *instruction following* task in ALFRED: **S+** (Shridhar et al., 2020), **MOCA** (Singh et al., 2020), **Modular** (Corona et al., 2021), **HiTUT** (Zhang and Chai, 2021), **ABP** (Kim et al., 2021), **ET** (Pashevich et al., 2021), **EmBERT** (Suglia et al., 2021), and **FILM** (Min et al., 2021). Like `seq2seq`, these are neural sequence-to-sequence models trained to map instructions to actions; they incorporate several standard modeling improvements from the instruction following literature, including progress monitoring (Ma et al., 2019) and pretrained object recognizers (Singh et al., 2020). Many of these models are trained with stronger supervision than (SL)^3, including instructions and alignments during training, and ground truth instructions *during evaluation*; see Table 3 for details.

Evaluation Following Shridhar et al. (2020), Table 1(a) computes the *online*, *subtask-level* accuracy of each policy, and Table 1(b) computes the end-to-end *success rate* of each policy. See the ALFRED paper for details of these evaluations. For data-efficiency experiments involving a large number of policy variants (Table 2, Fig. 4), we instead use an *offline evaluation* in which we measure the fraction of subtasks in which a policy's predicted actions (ignoring object selection masks) *exactly match* the ground truth action sequence.

5 Results

Table 1 compares (SL)^3 with flat and hierarchical imitation learning baselines. The table includes two versions of the model: a *100%* model trained with full instruction supervision ($|\mathcal{D}|= 0$, $|\mathcal{D}^{\text{ann}}|= 21000$) and a *10%* model trained with only a small fraction of labeled demonstrations ($|\mathcal{D}|= 19000$, $|\mathcal{D}^{\text{ann}}|= 2000$). `seq2seq` and `seq2seq2seq` models are *always* trained with 100% of natural language annotations. Results are shown in Table 1. We find:

(SL)^3 improves on flat policies: In both the 10% and 100% conditions, it improves over the *subtask* completion rate of the `seq2seq` (goals-to-actions) model by 25%. When either planner- or mapping-based navigation is used in conjunction with (SL)^3, it achieves *end-to-end* performance comparable to the HLSM method, which relies on similar supervision. Strikingly, it outperforms several recent methods with access to even more detailed information at training or evaluation time.

Language-based policies can be trained with sparse natural language annotations: Performance of (SL)^3 trained with 10% and 100% natural language annotations is similar (and in both cases superior to `seq2seq` and `seq2seq2seq` trained on 100% of data). Appendix Fig. 4 shows more detailed supervision curves. Ablation experiments in Table 2 show that inference of latent training plans is important for this result: with no inference of latent instructions (i.e. training only on annotated demonstrations), performance drops from 56% to 52%. Fig. 3 shows an example of the structure inferred for an unannotated trajectory: the model inserts reasonable segment boundaries and accurately labels each step.

Table 1: (a) Evaluation of (SL)^3 and baselines using the *subtask* evaluation from Shridhar et al. (2020). All models in this section were trained with both goals g and annotated subtask descriptions $\boldsymbol{\tau}$, but observed only goals during evaluation. (b) Evaluation of (SL)^3 and concurrent work using the *success rate* evaluation from Shridhar et al. (2020). Models in the left column use only goals and partial subtask descriptions at training time, and only goals at test time. (The HLSM model also uses a rule-based, ALFRED-specific procedure for converting action sequences to high-level plan specifications.) Models on the right use extra information, including ground-truth training segmentations and alignments, and ground-truth test-time plans. *Result of our HLSM reproduction using public code and trained models.

Language model pretraining improves automated decision-making. Ablation experiments in Table 2 provide details. Language model pretraining of π^{C} and π^{E} (on *ungrounded* text) is crucial for good performance in the low-data regime: with 10% of annotations, models trained from scratch complete 49% of tasks (vs 56% for pretrained models). We attribute this result in part to the fact that pretrained language models encode information about the common-sense structure of plans, e.g. the fact that *slicing a tomato* first requires *finding a knife*. Such models are well-positioned to adapt to "planning" problems that require modeling relations between natural language strings. These

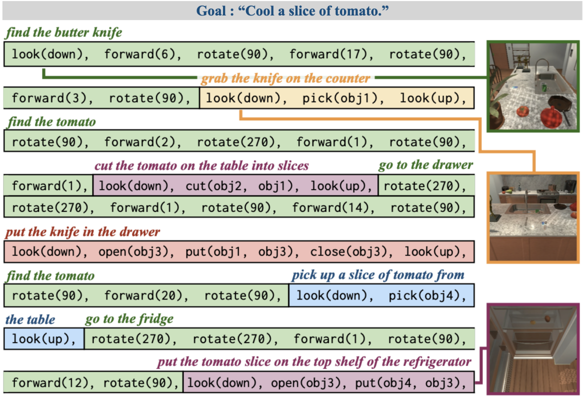

Figure 3: Example of an inferred segmentation and labeling for an unannotated trajectory. The trajectory is parsed into a sequence of 10 segments and q_η assigns high scoring natural-language labels to the segmented actions. These are consistent with the objects, receptacles and sub-tasks. The overall sequence of latent-language skills is a good plan for the high-level goal.

Model	Average
(SL)^3 (10%)	56
(SL)^3 (100%)	58
(SL)^3 (ground-truth α)	65
`no-pretrain`	49
`no-latent`	52

Table 2: Ablation experiments. Providing ground-truth alignments at training time improves task completion rates, suggesting potential benefits from an improved alignment procedure. Pretraining and inference of latent task representations contribute 7% and 4% respectively to task completion rate with 10% of annotations.

experiments point to a potentially broad role for pretrained language models in tasks that do not involve language as an input or an output.

One especially interesting consequence of the use of language-based skills is our model's ability to produce high-level plans for **out-of-distribution goals**, featuring objects or actions that are not part of the ALFRED dataset at all. Examples are provided in Fig. 5 and discussed in Appendix A. While additional modeling work is needed to generate low-level actions for these high-level plans, they point to *generalization* as a key differentiator between latent language policies and ordinary hierarchical ones.

6 Related Work

Our approach draws on a large body of research at the intersection of natural language processing, representation learning, and autonomous control.

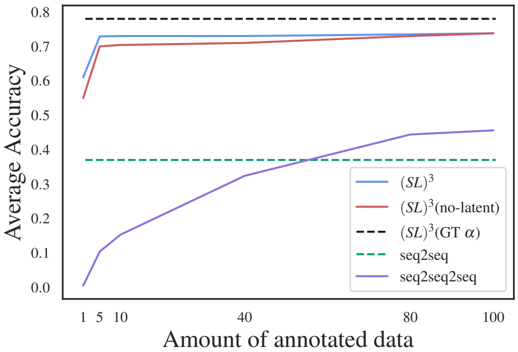

Figure 4: Offline subtask success rate as a function of the fraction of annotated examples. Only a small fraction of annotations (5–10%) are needed for good performance; inference of latent instructions is beneficial in the low-data regime.

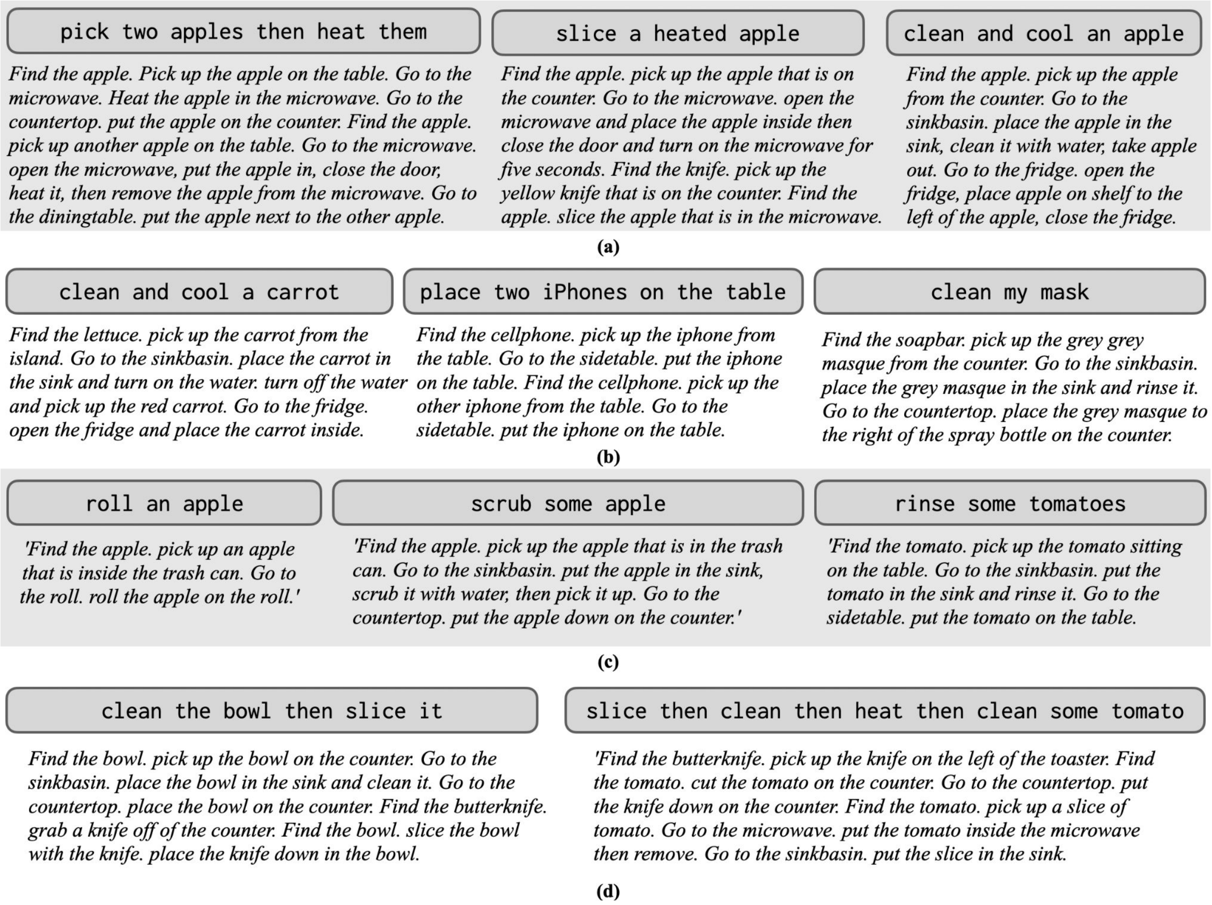
Language-based supervision and representation The use of natural language annotations to scaffold learning, especially in computer vision and program synthesis applications, has been the subject of a number of previous studies (Branavan et al., 2009; Frome et al., 2013; Andreas et al., 2018; Wong et al., 2021). Here, we use language to support policy learning, specifically by using natural language instructions to discover compositional subtask abstractions that can support autonomous control. Our approach is closely related to previous work on learning skill libraries from *policy sketches* (Andreas et al., 2017; Shiarlis et al., 2018); instead of the fixed skill inventory used by policy sketches, (SL)^3 learns an open-ended, compositional library of behaviors indexed by natural language strings.

Hierarchical policies Hierarchical policy learning and temporal abstraction have been major areas of focus since the earliest research on reinforcement learning and imitation learning (McGovern and Barto, 2001; Konidaris et al., 2012; Daniel et al., 2012). Past work typically relies on direct supervision or manual specification of the space of high-level skills (Sutton et al., 1999; Kulkarni et al., 2016) or fully unsupervised skill discovery (Dietterich, 1999; Bacon et al., 2017). Our approach uses policy architectures from this literature, but aims to provide a mechanism for supervision that allows fine-grained control over the space of learned skills (as in fully supervised approaches) while requiring only small amounts of easy-to-gather human supervision.

Language and interaction Outside of language-based supervision, problems at the



`pick two apples then heat them`

Find the apple. Pick up the apple on the table. Go to the microwave. Heat the apple in the microwave. Go to the countertop. put the apple on the counter. Find the apple. pick up another apple on the table. Go to the microwave. open the microwave, put the apple in, close the door, heat it, then remove the apple from the microwave. Go to the diningtable. put the apple next to the other apple.

`slice a heated apple`

Find the apple. pick up the apple that is on the counter. Go to the microwave. open the microwave and place the apple inside then close the door and turn on the microwave for five seconds. Find the knife. pick up the yellow knife that is on the counter. Find the apple. slice the apple that is in the microwave.

`clean and cool an apple`

Find the apple. pick up the apple from the counter. Go to the sinkbasin. place the apple in the sink, clean it with water, take apple out. Go to the fridge. open the fridge, place apple on shelf to the left of the apple, close the fridge.

(a)

`clean and cool a carrot`

Find the lettuce. pick up the carrot from the island. Go to the sinkbasin. place the carrot in the sink and turn on the water. turn off the water and pick up the red carrot. Go to the fridge. open the fridge and place the carrot inside.

`place two iPhones on the table`

Find the cellphone. pick up the iphone from the table. Go to the sidetable. put the iphone on the table. Find the cellphone. pick up the other iphone from the table. Go to the sidetable. put the iphone on the table.

`clean my mask`

Find the soapbar. pick up the grey grey masque from the counter. Go to the sinkbasin. place the grey masque in the sink and rinse it. Go to the countertop. place the grey masque to the right of the spray bottle on the counter.

(b)

`roll an apple`

'Find the apple. pick up an apple that is inside the trash can. Go to the roll. roll the apple on the roll.'

`scrub some apple`

'Find the apple. pick up the apple that is in the trash can. Go to the sinkbasin. put the apple in the sink, scrub it with water, then pick it up. Go to the countertop. put the apple down on the counter.'

`rinse some tomatoes`

'Find the tomato. pick up the tomato sitting on the table. Go to the sinkbasin. put the tomato in the sink and rinse it. Go to the sidetable. put the tomato on the table.

(c)

`clean the bowl then slice it`

Find the bowl. pick up the bowl on the counter. Go to the sinkbasin. place the bowl in the sink and clean it. Go to the countertop. place the bowl on the counter. Find the butterknife. grab a knife off of the counter. Find the bowl. slice the bowl with the knife. place the knife down in the bowl.

`slice then clean then heat then clean some tomato`

'Find the butterknife. pick up the knife on the left of the toaster. Find the tomato. cut the tomato on the counter. Go to the countertop. put the knife down on the counter. Find the tomato. pick up a slice of tomato. Go to the microwave. put the tomato inside the microwave then remove. Go to the sinkbasin. put the slice in the sink.

(d)

Figure 5: Successes and failures of π^{C} in out-of-distribution (OOD) settings including novel (a) sub-task orders (b) objects (c) verbs. The use of a pretrained LM as the backbone of the planning model means that models produce correct or plausible plans for many of these out-of-distribution goals. (d) Other failure modes: The model fails to predict actions based on the true affordances of objects and cannot generate arbitrarily long plans.

intersection of language and control include *instruction following* (Chen and Mooney, 2011; Branavan et al., 2009; Tellex et al., 2011; Anderson et al., 2018; Misra et al., 2017), *embodied question answering* (Das et al., 2018; Gordon et al., 2018) and dialog tasks (Tellex et al., 2020). As in our work, representations of language learned from large text corpora facilitate grounded language learning (Shridhar et al., 2021), and interaction with the environment can in turn improve the accuracy of language generation (Zellers et al., 2021); future work might extend our framework for semi-supervised inference of plan descriptions to these settings as well.

7 Conclusion

We have presented (SL)^3, a framework for learning hierarchical policies from demonstrations sparsely annotated with natural language descriptions. Using these annotations, (SL)^3 infers the latent structure of unannotated demonstrations, automatically segmenting them into subtasks and labeling each subtask with a compositional description. Learning yields a hierarchical policy in which natural language serves as an abstract representation of subgoals and plans: a *controller* sub-policy maps from goals to natural language plan specifications, and a modular *executor* that maps each component of the plan to a sequence of low-level actions. In simulated household environments, this model can complete abstract goals (like *slice a tomato*) with accuracy comparable to state-of-the-art models trained and evaluated with fine-grained plans (*find a knife*, *carry the knife to the tomato*, . . .).

While our evaluation has focused on household robotics tasks, the hierarchical structure inferred by (SL)^3 is present in a variety of learning problems, including image understanding, program synthesis, and language generation. In all those domains, generalized versions of (SL)^3 might offer a framework for building high-quality models using only a small amount of rich natural language supervision.

A Out-of-distribution Generalization

One of the advantages of language-based skill representations over categorical representations is open-endedness: (SL)^3 does not require pre-specification of a fixed inventory of goals or actions. As a simple demonstration of this potential for extensibility, we design goal prompts consisting of novel object names, verbs and skill combinations not seen at training time, and test the model's ability to generalize to out-of-distribution samples across the three categories. Some roll-outs can be seen in Fig. 5. We observe the following:

Novel sub-task combinations We qualitatively evaluate the ability of the model to generalize systematically to novel subtask combinations and subtask ordering not encountered at training time. Examples are shown in Fig. 5. For example, we present the model with the goal *slice a heated apple*; in the training corpus, objects are only heated *after* being sliced. It can be seen in Fig. 5 that the model able correctly orders the two subtasks. The model additionally generalizes to new combinations of tasks such as *clean and cool an apple*.

Novel objects and verbs The trained model also exhibits some success at generalizing novel object categories such as *carrot* and *mask*. In the carrot example, an incorrect *Find the lettuce* example is generated at the first step, but subsequent subtasks refer to a carrot (and apply the correct actions to it). The model also generalizes to new but related verbs such as *scrub* but fails at ones like *squash* that are unrelated to training goals.

Limitations One shortcoming of this approach is that affordances and constraints are incompletely modeled. Given a (physically unrealizable) goal *clean the bowl and then slice it*, the model cannot detect the impossible goal and instead generates a plan involving slicing the bowl. Another shortcoming of the model is the ability to generalize to goals that may involve considerably larger number of subgoals than goals seen at training time. For plans that involve very long sequences of skills (*slice then clean then heat*...) the generated plan skips some subtasks Fig. 5.

B Initialization: Segmentation Step

The training data contains no STOP actions, so π^{E} cannot be initialized by training on $\mathcal{D}^{\mathrm{ann}}$. Using a randomly initialized π^{E} during the segmentation step results in extremely low-quality segmentations. Instead, we obtain an initial set of segmentations via *unsupervised* learning on low-level action sequences.

In particular, we obtain initial segmentations using the Baum–Welch algorithm for unsupervised estimation of hidden Markov models (Baum et al., 1970). We replace string-valued latent variables produced by π^{C} with a discrete set of hidden states (in our experiments, we found that three hidden states sufficed). Transition and emission distributions, along with maximum *a posteriori* sequence labels, are obtained by running the expectation–maximization algorithm on state sequences. We then insert segment boundaries (and an implicit STOP action) at every transition between two distinct hidden states. Evaluated against ground-truth segmentations from the ALFRED training set, this produces an action-level accuracy of 87.9%. The detailed algorithm can be found in Baum et al. (1970).

C Model Architecture: Details

The controller policy π^{C} is a fine-tuned T5-small model. The executor policy π^{E} decodes the low-level sequence of actions conditioned on the first-person visual observations of the agent. We use the same architecture across the remaining baselines too. Fig. 6 depicts the architecture of the image-conditioned T5 model. In addition to task specifications, we convert low-level actions to templated commands: for example, `put(cup,table)` becomes *put the cup on the table*. These are parsed to select actions to send to the ALFRED simulator. During training, both models are optimized using the AdamW algorithm (Loshchilov and Hutter, 2019) with a learning rate of 1e-4, weight decay of 0.01, and ϵ = 1e-8. We use a MaskRCNN model to generate action masks, selecting the predicted mask labeled with the class of the object name generated by the action decoder. The same model architecture is used across all baselines.

D Role of trajectory length

We conduct an additional set of ablation experiments aimed at clarifying what aspects of the demonstrated trajectories (SL)^3 is better able to model than baselines. We begin by observing that most actions in our data are associated with navigation, with sequences of object manipulation actions (like those depicted in Fig. 3) constitut-

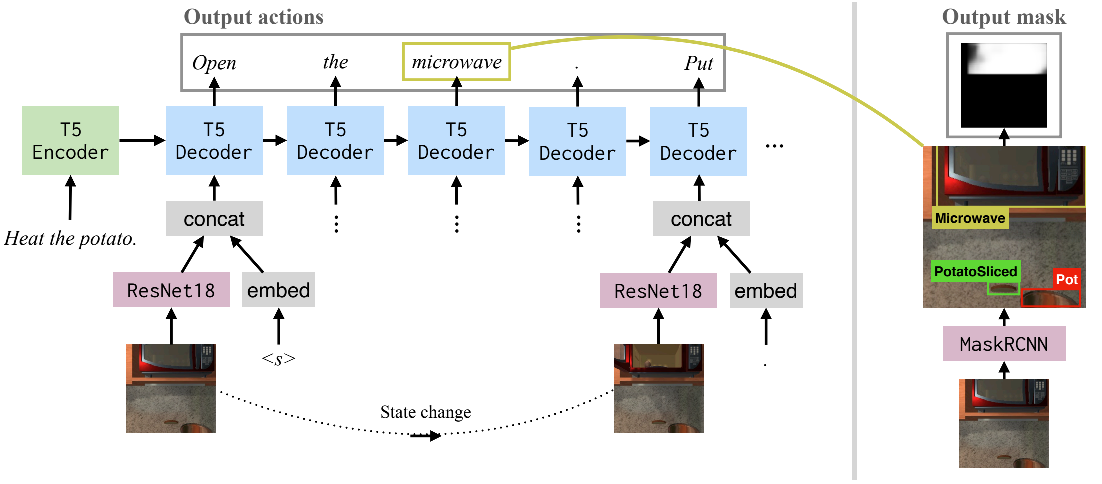

Figure 6: Model architecture for π^{E}, seq2seq and seq2seq2seq: Language parametrized sub-task/goal is input to the encoder and actions templated in natural language are generated sequentially token-wise. The predictions made are conditioned on the visual field of view of the agent at every time step along with the token generated the previous time step. At the end of every low-level action (when '.' is generated) the action the executed. For manipulation actions, the mask corresponding to the the object predicted is selected from the predictions of a MaskRCNN model on the visual state. Navigation actions do not operate over objects. Once the action is taken, the environment returns the updated visual state and the policy continues to be unrolled until termination (STOP).

ing only about 20% of each trajectory. We construct an alternative version of the dataset in which all navigation subtasks are replaced with a single `TeleportTo` action. This modification reduces average trajectory length from 50 actions to 9. In this case (SL)^3 and `seq2seq2seq` perform comparably well (55.6% success rate and 56.7% success rate respectively), and only slightly better than `seq2seq` (53.6% success rate). Thus, while (SL)^3 (and all baselines) perform quite poorly at navigation skills, *identifying* these skills and modeling their conditional independence from other trajectory components seems to be crucial for effective learning of other skills in the long-horizon setting. Hierarchical policies are still useful for modeling these shorter plans, but by a smaller margin than for long demonstrations.

'turn to the right twice and to to the end of the counter top and turn to the left and go to the end of the counter top' → "Find the knife."
'turn to the left and go to the front of the refrigerator and turn to the left and go to the refrigerator' → "Go to the refrigerator"
'turn to the right twice and take a few steps and turn to the left and go to the microwave' → "Go to the microwave"
'Go to the counter across the room from the stove.' 'Pick up the butter knife on the counter.' → "Find the butterknife"
'Turn right, turn right, walk straight to the oven' → "Go to the microwave"

Figure 7: Modified navigation annotations. Navigation instructions are converted to simpler object/location-oriented navigation goals using by creating templated plans from ALFRED dataset metadata.

E Navigation Instructions

The original ALFRED dataset contains detailed instructions for navigation collected post-hoc after the demonstrations are generated. For example, the sub-task specification associated with finding an apple might be given as *Go straight and turn to the right of the fridge and take a few steps ahead and look down*. Such instructions cannot be used for high-level planning, as they can only be generated with advance knowledge of the environment layout; successful behavior in novel environments requires exploration or explicit access to the environment's map.

To address the mismatch between the agent's knowledge and the information needed to generate detailed navigation instructions, we navigation instructions in the ALFRED dataset with templated instructions of the form *Go to the* [object] (for appliances and containers) and *Find the* [object] (for movable objects). Because the ALFRED dataset provides PDDL plans for each demonstration, we can obtain the name of the target [object] directly from these plans. Examples are shown in Fig. 7.

Fully-Semantic Parsing and Generation: the BabelNet Meaning Representation

Abelardo Carlos Martínez Lorenzo[1,2], **Marco Maru**[1], and **Roberto Navigli**[1]

[1]Sapienza NLP Group
Sapienza University of Rome
[2]Babelscape, Rome
`first.lastname@uniroma1.it, surname@babelscape.com`

Abstract

A language-independent representation of meaning is one of the most coveted dreams in Natural Language Understanding. With this goal in mind, several formalisms have been proposed as frameworks for meaning representation in Semantic Parsing. And yet, the dependencies these formalisms share with respect to language-specific repositories of knowledge make the objective of closing the gap between high- and low-resourced languages hard to accomplish. In this paper, we present the BabelNet Meaning Representation (BMR), an interlingual formalism that abstracts away from language-specific constraints by taking advantage of the multilingual semantic resources of BabelNet and VerbAtlas. We describe the rationale behind the creation of BMR and put forward BMR 1.0, a dataset labeled entirely according to the new formalism. Moreover, we show how BMR is able to outperform previous formalisms thanks to its fully-semantic framing, which enables top-notch multilingual parsing and generation. We release the code at `https://github.com/SapienzaNLP/bmr`.

1 Introduction

Natural Language Understanding (NLU) enables machines to understand human language. A key enabling task in NLU is that of Semantic Parsing, whose longed-for dream is that of developing a formalism that can be used as an interlingual representation of meaning, i.e., one that, independently of the language, can explicitly embed sentence meaning into a machine- and human-readable form (Navigli, 2018). To this end, different formalisms such as Abstract Meaning Representation (Banarescu et al., 2013, AMR), Universal Conceptual Cognitive Annotation (Abend and Rappoport, 2013, UCCA) and Universal Meaning Representation (Van Gysel et al., 2021, UMR), have been proposed over the years.

As of now though, AMR is the most popular formalism for Semantic Parsing, being widely applied to a variety of areas of NLP, such as Machine Translation (Song et al., 2019), Question Answering (Lim et al., 2020; Bonial et al., 2020b; Kapanipathi et al., 2021), Human-Robot Interaction (Bonial et al., 2020a), Text Summarization (Hardy and Vlachos, 2018; Liao et al., 2018) and Information Extraction (Rao et al., 2017).

The primary precept of AMR is that different sentences carrying the same meaning should have the same graph representation. Nonetheless, a few inherent properties of AMR make it inappropriate for the purpose of providing a language-agnostic representation of meaning. In fact, nodes within AMR graphs are represented by means of either English lemmas or OntoNotes frames (Hovy et al., 2006) which, in turn, are based on PropBank (Kingsbury and Palmer, 2002). The issue with lemmas is that they are merely surface forms devoid of semantics, whereas, with respect to frames, even though analogous repositories exist in other languages such as AnCora for Spanish (Aparicio et al., 2008) or the Chinese PropBank (Xue and Palmer, 2009), they are not mutually interlinked, hence making the cross-lingual application of AMR arduous to achieve (Conia et al., 2021).

Against this background, we follow the ideas put forward by Navigli et al. (2022) and develop the BabelNet Meaning Representation (BMR), a formalism providing the building blocks for a language-agnostic representation of meaning by exploiting the wealth of multilingual knowledge contained in BabelNet (Navigli and Ponzetto, 2010; Navigli et al., 2021)[1] and VerbAtlas (Di Fabio et al., 2019)[2].

In outline, the main contributions of this paper are as follows: (i) we introduce BMR, a new Semantic Parsing formalism that can be used as an interlingua, (ii) we produce BMR 1.0, i.e., the first

lexical-semantic dataset annotated according to the BMR formalism, (iii) we create and release models that can generate BMR graphs from text and text from BMR graphs in English, German, Spanish, and Italian, and (iv) we describe a sound experimental setup to show how, thanks to its fully semantic framing, BMR outdoes previous formalisms in both preserving and encoding textual information, as well as in being used as an interlingua in downstream tasks such as Machine Translation.

2 Related Work

Even though the vast majority of formalisms for Semantic Parsing have been designed with English in mind, several approaches have attempted to narrow the gap between English and other languages. For instance, Universal Conceptual Cognitive Annotation (Abend and Rappoport, 2013, UCCA) was proposed as a cross-lingual annotation formalism in which words in a sentence are connected using semantic relations not tied to specific languages. And yet, while UCCA reflects the semantic relations between nodes via a set of coarse-grained roles, it represents concepts by means of simple lemmas, hence preventing an abstraction from language-specific constraints. Parallel Meaning Bank (Abzianidze et al., 2017, PMB), an approach based on the Discourse Representation Theory (Kamp and Reyle, 1993, DRT),[3] also emerged. In PMB, English sentences are parsed with labels that are automatically projected to non-English translations. PMB too, however, cannot be seen as a unified interlingual representation, since it uses English-specific meaning repositories.

As regards Abstract Meaning Representation (Banarescu et al., 2013, AMR), instead, several approaches have tried to adapt it for cross-lingual use. As a case in point, Xue et al. (2014) analyzed the viability of tailoring the AMR formalism to fit other languages by making use of language-specific repositories similar to PropBank (Aparicio et al., 2008; Xue and Palmer, 2009).[4] On a different note, Damonte and Cohen (2018) and Blloshmi et al. (2020) attempted to adopt AMR as an interlingual formalism, despite its English-centric nature, by assuming that the AMR graph of an English sentence is also representative of translations of that sentence in other languages. Once again, these approaches testify to the limits of AMR as an interlingua, given the drawbacks of dealing with structural divergences among different languages. In recent years, Zhu et al. (2019) have recommended abstracting the AMR formalism away in order to reduce its language-specific complexity by preserving just the predicate roles and relations that constitute the core semantic information of sentences. Conversely, rather than decreasing the complexity of AMR, the Universal Meaning Representation (Van Gysel et al., 2021, UMR) extends it by including new features that render the formalism less tied to a specific language. In particular, UMR enriches the verbal predicates with information about grammatical aspect and scope, while introducing temporal and modal dependencies at the document level. Finally, it enhances AMR to use it as a cross-lingual formalism by employing language-specific repositories and relations. Yet, the focus of UMR is that of providing languages with the necessary resources to parse texts, rather than being an interlingual representation.

In contrast to previous approaches, and thanks to the multilingually-shared word meanings and semantic roles taken from the interlinked repositories of BabelNet (Navigli et al., 2021) and VerbAtlas (Di Fabio et al., 2019), we put forward BMR, a formalism that fully detaches from syntax and thus stands as a lexical-semantic representation that is able to bring different languages together.

3 Preliminaries

To accomplish the goal of an interlingual meaning representation, we disconnect our formalism from language-specific constraints of any kind. To this end, we draw on resources that inherently connect word meanings and predicate-argument structures across languages, i.e., BabelNet and VerbAtlas.

BabelNet (Navigli et al., 2021) is a multilingual encyclopedic dictionary and semantic knowledge base in which concepts are represented as synsets (sets of synonyms that convey the same meaning), linked via semantic relation edges like hypernymy or meronymy. BabelNet was built by the aggregation of several knowledge resources including WordNet (Fellbaum, 1998), Wikipedia and Wiktionary, resulting in a remarkable ontology of concepts and named entities covering 500 languages. Given its versatility, which makes it suitable for a wide range of tasks across languages, we employ its most recent version 5.0 as a tool to switch the

---

[3] DRT is a framework that embeds the semantics of an utterance employing a formal logic semantic structure.

[4] For a similar approach, see also the Prague Tectogrammatical Graphs of Hajič et al. (2012, PTG).

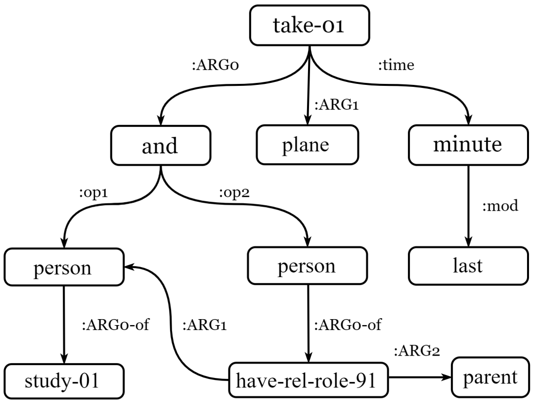

Figure 1: AMR graph for the sentence *"The students and their parents will take the plane at the last minute"*.

focus of Semantic Parsing formalisms from words to multilingual concepts.

VerbAtlas (Di Fabio et al., 2019) is a manually-curated lexical-semantic inventory that collapses the BabelNet verbal synsets into around 450 semantically-coherent frames, each defining prototypical argument structures via human-readable relationships (e.g. `AGENT`, `THEME`). Thanks to its linkage to BabelNet, VerbAtlas represents the best option for handling predicate-argument relations in BMR in a language-independent manner.

4 BabelNet Meaning Representation

Like AMR, BMR embeds the semantics of a sentence in a directed acyclic graph, with nodes and edges connecting them. However, where AMR relies on English lemmas and OntoNotes frames to represent nodes and relations (see Figure 1), BMR disposes of language-specific constraints, and employs multilingual concepts and self-explanatory semantic roles (see Figure 2).[5] In what follows (Sections 4.1 to 4.4), we will describe and detail the features that make BMR stand out with respect to a widely-employed Semantic Parsing formalism such as AMR, as well as their integration into the AMR 3.0 dataset (Knight et al., 2020) to produce the BMR 1.0 dataset.[6]

4.1 Self-explanatory Semantic Relations

As briefly mentioned in Section 1, AMR derives its coarse-grained frames and argument structures from the English PropBank section of OntoNotes, a repository which is circumscribed to the English language and that features semantic relations that are both predicate-specific and largely unintelligible without a gloss. For example, in Figure 1, the subgraph representation of *students' parents* is pivoted on the frame `have-rel-role-91`, where the relations `:ARG0`, `:ARG1`, and `:ARG2` identify the first entity, the second entity, and the role of the first entity, respectively. As importantly, even though language-specific repositories similar to PropBank have been used to annotate non-English sentences with structures comparable to those of AMR (Aparicio et al., 2008; Xue and Palmer, 2009), there is not an exact one-to-one mapping between the frames they define, meaning that, e.g., the frame `have-rel-role-91` might not be featured in the other inventories. Therefore, with the aim of overcoming language specificity, we replace PropBank with VerbAtlas as an alternative repository of predicate-argument structure information, which, as explained above, inherently accounts for multilingually-shared semantics.

To build the BMR 1.0 dataset, we exploit the mapping provided by Di Fabio et al. (2019), which links VerbAtlas frames and arguments to PropBank, and use it to replace the original frames and semantic roles in the AMR 3.0 dataset with those of VerbAtlas (e.g., the frame `take-01` corresponds to `MOVE_BY_MEANS_OF` in VerbAtlas, and its `ARG0` to `AGENT`). However, this mapping is incomplete and, as a result, several predicates found within AMR 3.0 can not be transitioned directly. Among these, two kinds of predicates can be identified, (i) predicates that OntoNotes labels as verbal, and (ii) non-verbal predicates and special predicates which AMR uses to define special semantic structures (e.g., `have-rel-role-91`). To deal with these predicates, we asked a linguist[7] to create a mapping between PropBank and VerbAtlas for the missing verbal predicates, and, with respect to the others instead, to map them to BMR adapting previous semantic roles and creating new ones to better accommodate their argument structures.[8]

4.2 Node Merging

Multiword expressions and idioms are rendered word by word in AMR, using node composition.

---

[5] Appendix A details how to read BMR graphs.

[6] AMR 3.0 is licensed by LDC at `https://catalog.ldc.upenn.edu/LDC2020T02`. For this reason, we do not make the BMR-annotated dataset (BMR 1.0) publicly available, but rather provide tools to convert the original AMR 3.0 dataset, provided its rightful ownership.

[7] Annotators share effective operational English proficiency and received a wage in line with their country of residence.

[8] See Appendix B for the list of BMR semantic roles, and Appendix C for mapping examples.

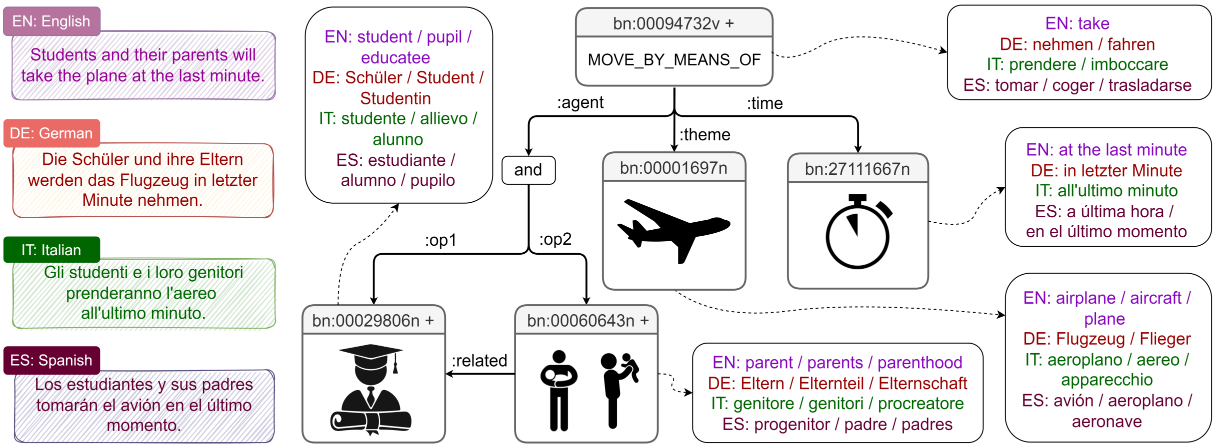

Figure 2: Equivalent sentences in different languages (left) and their shared BMR graph (right).

Nevertheless, such an approach is not feasible for an interlingual representation, since the overall meaning of an expression can not, as a general rule, be compositionally inferred from the meanings of its individual words. Therefore, in BMR we make use of the available BabelNet synsets to identify the meaning of a multiword expression or idiom, and hence we represent it with a single node. As a case in point, the idiom *at the last minute* which, according to Wiktionary, is defined as "very close to a deadline or potential crucial event", does not entail that something will happen precisely *in* the last minute. This exact expression, that in AMR 3.0 is represented using two nodes (m and l) as:

$$(m \ / \ minute \ {:}mode \ (l \ / \ last))$$

appears in BMR as a single node m:

$$(m \ / \ at\_the\_last\_minute \ / \ bn{:}00114428r)$$

As a result, we are both able to (i) abstract away from language-specific lexicons making use of concepts connected across languages and, concurrently, to (ii) reduce the graph density, hence easing the computational burden for systems.

Another intrinsic limit of AMR as an interlingual representation is that, since the meaning of nodes can only be partially identified using OntoNotes frames, AMR maximizes their usage so as to express as many concepts as possible, even non-verbal ones. The main reason this constitutes an issue is that the OntoNotes frame composition used to define a concept and the concept itself are not semantically equivalent. For example, the concept of *student*, which AMR represents as "a person who studies" by means of the connection between the node of *person* with the OntoNotes frame `study-01`, is arguably different from the definition of student as, quoting the BabelNet synset gloss, "a learner who is enrolled in an educational institution". Additionally, these language-specific rules are not transferable across languages, and they are not consistent even within AMR itself, as, whenever a verbalization is not viable (AMR does not render *professor* as "a person who professes"), the word is included in the graph as it is.

In the remainder of this Section, we describe the strategies by means of which we remodel AMR 3.0 to obtain BMR 1.0 employing node merging.

Multiword Expression Identification To merge nodes, we must first identify the words or multiword expressions that are represented by several nodes in the AMR graph. In this regard, we proceed by lemmatizing the original sentences in AMR 3.0 using the 3.1 version of the SpaCy software library (Honnibal and Johnson, 2015). At this stage, for each sentence, we check for the longest concatenations of lemmas that match a BabelNet synset lexicalization in BabelNet 5.0. Once the expressions have been identified, we use the automatic AMR aligner of Flanigan et al. (2014) to get the alignments between the tokens in the original sentence (and, consequently, the identified words and multiwords) and the graph nodes.

Manual Validation The automatic identification of multiwords can be noisy and lead to poor node merging choices which, in turn, can result in wrong sense attributions. For instance, in the sentence "the rest of the world knows the same", the multiword *rest of the world* is identified, even though its only meaning in BabelNet is that of "a team of players from many countries", which is clearly not appropriate in the reported context. To address this issue, we asked our expert linguist to manually inspect all of the automatically detected multiword instances within the AMR 3.0 dataset in order to maintain, modify or delete them.

Graph Conversion Finally, using the multiwords and the alignments derived from the previous steps, we navigate the AMR graphs bottom-to-top and collapse together nodes referring to the same word or multiword expression (i.e., first reducing nodes closer to the graph leaves and then moving towards the graph root).

As a result, we move from the original figure of $936,769$ nodes of AMR 3.0 to $828,483$ in BMR 1.0, reducing the graph density by a notable 11.6%.

4.3 Number, Tense and Aspect

Even though AMR is able to encode textual information in its semantic structure, its formalism does not account for the inclusion of word components that are crucial for understanding meaning, and that languages express via the grammatical categories of number, tense and aspect. This, along with the fact that the importance of incorporating such details in Semantic Parsing formalisms has already been stressed in the literature (Donatelli et al., 2018; Bonial et al., 2019), leads us to implement these features to further enhance the representative power of BMR. To this end, we employ SpaCy in order to retrieve the Penn Treebank part-of-speech tags (Marcus et al., 1993), which inherently provide information with respect to number, tense, and aspect, for all the words and multiword expressions aligned with a node in the graphs. In practice, we account for tense by enriching each verbal node with the semantic role `:timing` showing a value of $+$ or $-$ to indicate events that will take place in the future or that happened in the past, respectively. Similarly, we handle plurality of the nominal nodes by adding the `:quantity` relation followed by a $+$ value (see Figure 2). Lastly, we account for aspect by adding the relation `:ongoing` followed by a $+$ mark to verbal nodes expressing the imperfective aspect (ongoing or usual actions).

4.4 Graph Disambiguation

An interlingual representation of meaning has the basic requirement of being fully linked to an inventory of meanings which can be expressed in multiple languages. For this reason, in order to make nodes in BMR graphs language-independent, we enhance them with BabelNet synsets information. An example of why this is needed is provided in Figure 1, where the predicate `take-01` employed in AMR is defined in OntoNotes with the very coarse-grained gloss of "take, acquire, come to have, choose, bring with you from somewhere, receiving, internalizing, bringing along, enacting", and the ambiguous word *plane* is merely represented as a lexical node, which provides no cues for understanding whether it refers to an airplane, a geometric plane, or a carpenter's plane, inter alia. Moreover, the combination of the two does not clarify whether "take the plane" means "to take a flight" or "to take the carpenter's plane somewhere".

Lacking a pointer to a more fine-grained and multilingual word sense inventory also has the disadvantage of preventing the use of the formalism as a means of moving across languages effectively. For example, if the word *parents* is not assigned the proper word sense, it would lead to ambiguous translations in languages such as Spanish, where the corresponding word *padres* can indicate both the meaning of "parents", but also the meaning of "fathers". Therefore, the advantages that come from the disambiguation of nodes with BabelNet are twofold: (i) resolving language ambiguity while representing word meaning explicitly, and (ii) interconnecting the same meanings across languages.

Adding the disambiguation information to AMR 3.0 graphs is our last step in order to complete its conversion to BMR 1.0. To this end, we employ a set of different strategies: (a) we exploit the mapping from VerbAtlas frames to BabelNet synsets to assign word senses to nodes based on their lemmas, (b), we use the Wikipedia page information featured in AMR nodes representing named entities to retrieve the corresponding synset BabelNet identifies that page with, and (c), we make use of ESCHER (Barba et al., 2021),[9] a state-of-the-art system for Word Sense Disambiguation, i.e., the task of automatically assigning a meaning to a word in context (Bevilacqua et al., 2021b), to disambiguate the nodes without word senses.

As a result, we succeed in assigning a BabelNet synset to an overall figure of 92% AMR content nodes (i.e., nodes aligned with content words), with $42,549$ fully disambiguated graphs out of $59,255$.

---

[9] We employ the code available at `https://github.com/SapienzaNLP/esc`.

5 Experimental Setup

To demonstrate the importance of BMR's semantic framing, its aptness at preserving lexical information, and its effectiveness in acting as an interlingual representation, we devise three experiments to assess its performance in comparison with AMR. Before delving into their details (Section 5.2), as well as describing our models and the evaluation measures we employ (Sections 5.3 and 5.4, respectively), we first provide thorough information regarding the datasets used in our experiments.

5.1 Datasets

Aside from the original AMR 3.0 and BMR 1.0 datasets described in Section 4,[10] the following datasets are employed in our experiments, namely: (i) AMR+, which features the set of enhancements applied to the English AMR 3.0, as described from Section 4.1 to 4.3 (excluding node disambiguation), and (ii) BMR*, i.e., a version of BMR 1.0 that does not include lemma information.

For each dataset, we also create language-specific versions in German (DE), Italian (IT) and Spanish (ES): starting from the English AMR 3.0, we followed Blloshmi et al. (2020) and create training and development sets for these languages by using gold AMR graphs – and their converted AMR+, BMR and BMR* versions – and pairing them with silver sentences translated with the machine translation models of Tiedemann and Thottingal (2020, OPUS-MT). As test data, we use the $1,371$ parallel sentences of Abstract Meaning Representation 2.0 - Four Translations,[11] that translate into our set of non-English languages their English (EN) counterparts (a subset of AMR 3.0) found in the AMR 2.0 test split.[12]

5.2 Tasks

Graph-to-Text (GtoT) Our first experiment concerns the Graph-to-Text generation task, i.e., the task of transforming graph meaning representations into their corresponding text, and has the goal of appraising the effectiveness of BMR as a tool for generating texts in different languages. In this context, we also conduct an ablation study on AMR+ to assess the individual impact brought about by each feature described in Section 4.

Text-to-Graph (TtoG) Our second experiment deals instead with the Text-to-Graph generation task (Semantic Parsing), i.e., the task of generating a graph according to a given formalism, starting from raw text. The aim of TtoG is to assess the complexity of generating BMR graphs compared to AMR ones.

Text-to-Graph-to-Text (TGT) Finally, in the third experiment, we evaluate the suitability of AMR and BMR to be used as interlingual representations by means of the combination of Text-to-Graph and Graph-to-Text parsing going from a source to a target language. In the same context, we also conduct an ablation study on BMR to assess the impact of the disambiguation in the graphs.

5.3 Models

All models employed in our experiments are built on top of SPRING (Bevilacqua et al., 2021a), an auto-regressive model for AMR parsing and generation based on the BART (Lewis et al., 2020) pretrained language model. Since the original SPRING works with pairs of sentences and linearized versions of the graphs, we modify its tokenizer to account for BMR nodes, since they contain BabelNet synset IDs too. Furthermore, we add all synsets that appear more than once[13] within BMR 1.0 to the model's vocabulary and adapt SPRING to the mBART language model (Liu et al., 2020) in order to account for multiple languages in the GtoT and TGT experiments.

Given the datasets described in Section 5.1, we confront models trained on AMR 3.0, BMR 1.0, AMR+ and BMR* for each language (AMR/BMR/AMR+/BMR*$_{EN,DE,IT,ES}$). As regards the ablation study of the GtoT experiment, we apply each modification introduced to AMR 3.0 one at a time, and obtain several versions of the dataset, each of which is used to train additional models, namely, AMR 3.0 (i) including self-explanatory relations (AMR$_{REL}$), (ii) including self-explanatory relations and node merging (AMR$_{NOD}$), (iii) featuring the number category (AMR$_{NUM}$), (iv) featuring the tense and aspect categories (AMR$_{TEN}$), and (v) featuring the number, tense and aspect categories together (AMR$_{NT}$).

---

[10] We use the training/development/test splits of AMR 3.0 for both AMR 3.0 and BMR 1.0 datasets.

5.4 Evaluation Measures

To evaluate the text generation tasks (i.e., GtoT and TGT), we use five standard Natural Language Generation measures, namely, BLEU (Papineni et al., 2002), chrF++ (Popović, 2017), METEOR (Banerjee and Lavie, 2005), and ROUGE-L (Lin, 2004), tokenizing system predictions with the JAMR script (Flanigan et al., 2014). For the TtoG experiment, instead, as is customary, we employ the Smatch measure (Cai and Knight, 2013).

6 Results

6.1 GtoT

Results for the GtoT experiment are reported in Table 1. As can be seen, BMR obtains the highest scores for all the measures across the board, testifying to its effectiveness at generating text in multiple languages. Interestingly, when BMR is confronted with AMR+, the benefits of featuring disambiguation information immediately become evident, with highest scores on each measure.

Results for the ablation study are, instead, shown in Table 2. Even though the impact of self-explanatory relations is not striking in this scenario (AMR$_{REL}$ model), the use of node merging already leads to an evident performance boost, particularly for BLEU and ROUGE-L (AMR$_{NOD}$). Not surprisingly, the addition of the grammatical categories of number, tense, and aspect to AMR 3.0 corroborates the thesis of Donatelli et al. (2018) and Bonial et al. (2019), with results for the different measures growing between 1.3 to 4.2 points for AMR$_{NT}$ compared to the baseline AMR$_{EN}$ model. Moreover, demostrating the beneficial interaction of all features described in Section 4, the AMR+$_{EN}$ model significantly outperforms the baseline model by 1.7 points on METEOR (lowest) and 5.0 points on BLEU (highest), while also outscoring each other model featuring only specific modifications.

6.2 TtoG

Results for this experiment are shown in Table 3 and provide evidence for the high degree of complexity that BMR graphs have in comparison to their AMR counterparts. In particular, AMR+$_{EN}$ (which, except for the disambiguated nodes, has the same graph structure as BMR$_{EN}$) outperforms BMR$_{EN}$ by 3.5 Smatch points, demostrating that the extra layer represented by the inclusion of disambiguation information makes BMR graphs harder to generate automatically starting from raw text. As a matter of fact, a model attempting to generate BMR graphs needs to provide disambiguation for each node (and not just for the verbal predicates), hence it faces a much more difficult task.

6.3 TGT

Finally, in Table 4 we report the scores for the TGT experiment, by means of which we appraise the capability of formalisms to act as bridges to translate sentences, first, performing a Text-to-Graph step, and then a Graph-to-Text one. Despite having shown lower performances in comparison to AMR

in the TtoG experiment, the high scores obtained by BMR in this experiment demonstrate that it is better suited as an interlingua. Nevertheless, AMR+ outperforms BMR in a few settings, likely due to the higher complexity entailed by BMR parsing, as explained in Section 6.2. Corroborating this thesis are the results shown in Table 5, where BMR scores are compared against a model (AMR+*) in which, to perform the Graph-to-Text step, AMR+ uses a BMR parser with the synset information removed, rather than its own parser. The outcome of this ablation study, with BMR now systematically outscoring its competitor, sheds further light upon the effectiveness of synset-driven disambiguation for encoding valuable sentence information.

Returning to the results given in Table 4, even though performances for BMR* models are the lowest (yet competitive, and sometimes higher than AMR) on the board, it is worth remarking that this setting does not feature the lemma information. In fact, in order to be purely semantic, BMR graphs should solely feature the BabelNet synset information. However, given that state-of-the-art Semantic Parsing and generation models make use of pre-trained language models such as BART and mBART, which are trained with data in human language (hence devoid of synset information), the performance of fully-semantic models drops if lemmas are not taken into account. Additionally, currently available text generation metrics are sub-optimal when employed to assess semantics, since these measures evaluate similarities at the lemma level. Therefore, though a fully-semantic model could infer the meaning of a BabelNet synset, its performances will be penalized for not generating specific lemmas while outputting perfectly suitable synonyms. In view of this, BMR 1.0 incorporates the lemma information along with the BabelNet synset specifying its meaning (see also Appendix A), demostrating that lexical-semantic representations improve over purely lexical ones.

7 BMR*: A Case Study

Results for the experiments we conducted depict BMR* as the model that, on the whole, achieves the lowest scores. With the aim of showing how such results might arise due to inadequate evaluation measures (see Section 6.3), we propose a focused case study in which we qualitatively inspect the differences between graphs and sentences generated by means of the AMR and BMR* models. Starting from the sentence *"My friend did not tolerate his father's behaviour"* (Figure 3), it can be seen how the grammatical categories of number and tense for the words *friend* and *tolerate* are correctly preserved by BMR* only. Additionally, it can be noted how the complex structure that defines *child* in AMR can confuse the model when there is a reentrant node (in this case, the model does not know to whom the father is related). As interestingly, the sentence generated via BMR* replaces *tolerate* with the synonym *put up with*, which worsens its performance according to exact string matching metrics, but, at the same time, provides an insight of a higher level of abstraction when lemmas are omitted.

8 Error Analysis

Although the experiments reported in Section 5 testify to the quality of BMR, following an in-house behavioral analysis inspired by the work of Ribeiro et al. (2020), we identify three main classes of errors that undermine the application of BMR as an interlingua, one concerning the formalism (*repository contraints*), one tied to the data contained in the BMR 1.0 dataset (*disambiguation constraints*), and one concerning the language-specific lexicons (*language-specific constraints*).

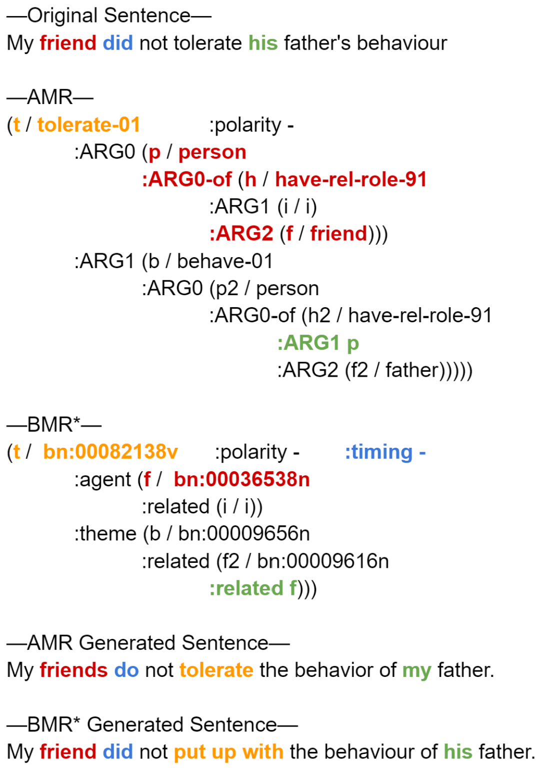
Repository constraints BabelNet features a wealth of synsets covering content words in a multilingual setting, but, at the same time, does not provide information regarding parts of speech other than nouns, verbs, adjectives and adverbs. As a result, BMR uses language-specific lemmas to represent conjunctions or ambiguous pronouns such as *anyone*, which can mean either “not a single person” or “everyone”, depending on the use of negative or positive phrasing. On a different note, with roughly 6,500 languages spoken in the world and BabelNet 5.0 featuring a subset of them, the definition of BMR as an interlingua is actually constrained to the number, albeit large, of 500 BabelNet languages.

Disambiguation constraints The creation of BMR 1.0 is based upon the Word Sense Disambiguation task carried out via a state-of-the-art system (Barba et al., 2021, ESCHER). And yet, this neural architecture is trained to predict word senses featured in the WordNet 3.0 sense inventory only. By virtue of the fact that, following the node merging strategy (Section 4.2), we can obtain polysemous multiwords found in BabelNet but not in WordNet (as is the case of *run off at the mouth*), we cannot provide disambiguation for such instances. This justifies the fact that 8% of content nodes in BMR are not disambiguated (see also Section 4.4).

Language-specific constraints The number of items in a lexicon and the degree of word polysemy vary from language to language (Talmy, 2000). Using BabelNet synsets to represent abstract concepts and connect them multilingually is certainly a desirable feature. However, there are concepts and expressions that exist in a given language only, e.g., owing to their being culturally connoted. For example, the Spanish word *espeto*, which refers to a traditional way of cooking freshly-caught sea fish, has no equivalent in English. Though the concept is featured in BabelNet, it has no lexicalizations in other languages and, as such, it would need to be paraphrased in order to be rendered.

9 Conclusion

Current Semantic Parsing formalisms share tight dependencies with semantic repositories which are both language-specific and isolated from word senses in other languages. As a result, they are not fit to be used as interlingual representations of meaning. In this paper, we put forward BMR, a new language-independent formalism that abstracts away from language-specific constraints thanks to two multilingual semantic resources, namely, BabelNet and VerbAtlas. To put our formalism into practice, we also created BMR 1.0, the first dataset labeled according to BMR.



```
—Original Sentence—
My friend did not tolerate his father's behaviour

—AMR—
(t / tolerate-01          :polarity -
          :ARG0 (p / person
                    :ARG0-of (h / have-rel-role-91
                              :ARG1 (i / i)
                              :ARG2 (f / friend)))
          :ARG1 (b / behave-01
                    :ARG0 (p2 / person
                              :ARG0-of (h2 / have-rel-role-91
                                        :ARG1 p
                                        :ARG2 (f2 / father)))))

—BMR*—
(t /  bn:00082138v     :polarity -       :timing -
          :agent (f /  bn:00036538n
                    :related (i / i))
          :theme (b / bn:00009656n
                    :related (f2 / bn:00009616n
                              :related f)))

—AMR Generated Sentence—
My friends do not tolerate the behavior of my father.

—BMR* Generated Sentence—
My friend did not put up with the behaviour of his father.
```

Figure 3: AMR and BMR* graph representations and generated sentences for the original sentence *“My friend did not tolerate his father’s behaviour”*. Best seen in color.

Our experiments demostrate the impact that the fully-semantic framing of our formalism has in comparison to the widely-employed formalism of AMR, as well as showing its ability to be a better tool at encoding textual information, and a much more effective interlingua in a text-to-graph-to-text machine translation task.

As future work, we plan to (i) create a single multilingual model to parse graphs and generate text in any language, (ii) apply BMR cross-lingually to other downstream tasks such as text summarization, (iii) evolve the formalism to prevent the inclusion of lexical information of any kind. We make our code and data available to the research community at `https://github.com/SapienzaNLP/bmr`.

A Reading BMR Graphs

The BMR formalism renders graphs in a text-friendly fashion following the AMR custom. Specifically, edges are represented by means of standardized semantic relations names preceded by a colon (e.g. `:agent`, or its inverse relation `:agent_of`), and nodes are identified by triplets:

$$(id\ /\ lemma\ /\ Babel\ synset\ id)$$

Left to right, the triplet shows: (i) the unique identifier (id) of the node,[14] (ii) the lemma for the word (or multiword expression) in the original sentence, and (iii) the BabelNet synset id taken from BabelNet 5.0 that is assigned to disambiguate the node.[15]

Lastly, node hierarchy in BMR is represented by means of open and closed round brackets, and special characters such as + indicate special features of some nodes, such as, e.g., grammatical tense information. Figure 4 shows an example of a BMR graph (bottom) in comparison to the AMR graph (top) for the same sentence, in text-friendly format.

```
--AMR--

(t/ take-01
   :ARG0 (a / and
      :op1 (p / person
         :ARG0-of (s / study-01))
      :op2 (p2 / person
         :ARG0-of (h / have-rel-role-91
            :ARG1 p
            :ARG2 (p3 / parent))))
   :ARG1 (p4 / plane)
   :time (t2/ minute
      :mod (l / last)))

--BMR--

(t / take / bn:00094732v
   :timing +
   :agent (a / and
      :op1 (s / student / bn:00029806n
         :quantity +)
      :op2 (p / parent / bn:00060643n
         :quantity +
         :related s)
   :theme (p2 / plane / bn:00001697n)
   :timing (t2 / at_the_last_minute
            / bn:00114428r))
```

Figure 4: AMR (top) and BMR (bottom) text-friendly form of the graphs for the sentence *"The students and their parents will take the plane at the last minute"*.

B Semantic Roles in BMR

Semantic roles in BMR (Table 6) are largely based on the VerbAtlas inventory and have been modified to account for non-verbal entities drawing inspiration from property lists available in the literature (Dixon, 2010; Leone et al., 2020). Similarly to AMR, each relation has its inverse, expressed by appending `_of` to it (e.g., `:purpose` versus `:purpose_of`). Roles in AMR which are not listed in Table 6 are preserved in BMR (e.g., `:age`, `:degree`, `:frequency` or `:manner`).

C AMR 3.0 to BMR 1.0 Manual Mapping Examples

Non-verbal predicates, as well as special predicates found within AMR 3.0 have been mapped to the BMR formalism according to the set of semantic relations described in Appendix B (see also Section 4.1) by means of an in-house annotation interface. The choice of BabelNet synsets to express the meaning of the original predicates followed a simple set of annotation strategies, sorted by desired priority: using the predicate name as a query to look for available synsets, (i) pick a nominal synset also featured in WordNet 3.0 (e.g., querying with the lemma *liberality* for the predicate `liberal.02`), (ii) pick an adjectival synset featured in WordNet 3.0, (iii) pick a nominal synset not featured in WordNet 3.0, (iv) pick an adjectival synset not featured in WordNet 3.0, (v) pick a synonym to query for available synsets (e.g., querying with the lemma *correct* for predicate `be_it.07`). See Table 7 for a random sample of AMR 3.0 to BMR 1.0 mappings.

---

[14] Similarly to AMR, if a node is referred to anew in the same BMR graph, only the id is used to identify it.

[15] Note that, even though the lemma changes according to the source language used to produce the graph, it is the synset information that serves as the interlingual component. In fact, graphs for the same sentence translated in different languages will show different lemmas, but the same BabelNet synsets.

Abstract

Personalized language models are designed and trained to capture language patterns specific to individual users. This makes them more accurate at predicting what a user will write. However, when a new user joins a platform and not enough text is available, it is harder to build effective personalized language models. We propose a solution for this problem, using a model trained on users that are similar to a new user. In this paper, we explore strategies for finding the similarity between new users and existing ones and methods for using the data from existing users who are a good match. We further explore the trade-off between available data for new users and how well their language can be modeled.

1 Introduction

Recent work has suggested that there are several benefits to personalized models in natural language processing (NLP) over one-size-fits-all solutions: they are more accurate for individual users; they help us understand communities better; and they focus the attention of our evaluations on the end-user (Flek, 2020). Generation tasks in particular benefit from a personalized approach, for example, Dudy et al. (2021) argue that user intention is more often difficult to recover from the context alone.

We study personalization in language modeling, a core task in NLP. Direct applications of language models (LM) include predictive text, authorship attribution, and dialog systems used to model the style of an individual or profession (e.g., therapist, counselor). LMs are increasingly used as the backbone of models for a range of tasks in NLP, increasing the potential impact of personalization even further (Brown et al., 2020).

The standard non-personalized approach is to use pretrained models trained on a large volume of data written by many people. This approach does not take into account the differences between individuals and their language patterns. Given the same context, different people may act or write differently, but these general models cannot produce that type of variation. Approaches like fine-tuning can be used to tailor a pretrained model to an individual, but perform well only when enough data is available, which is often not the case.

Previous work on personalized and demographic word embeddings has seen successful application in downstream tasks. Garimella et al. (2017) look at location and gender and how they affect associations with words like "health" and many other stimulus words like "stack"– does it make you think of books or pancakes? Welch et al. (2020) discuss other associations, for instance, "embodying" an idea may more often refer to a religious or economic concept depending on your beliefs. Similarly, "wicked" may mean "evil" or may function as an intensifier depending on where you live (Bamman et al., 2014). These exemplify how personalized representations can help make distinctions in meaning, however, static representations have limitations. For example, Hofmann et al. (2021) find that in some contexts "testing" refers to seeing if a device works and "sanitation" refers to a pest control issue, while in another context both refer to conditions of the COVID-19 pandemic. Personalized LMs, or language models built to better predict what an individual will say, could better address these cases, as LMs learn dynamic encodings of words.

In this paper, we consider approaches to fine-tuning and interpolation that are novel in that they leverage data from similar users to boost personalized LM performance. We consider the case of users with a small number of available tokens and propose ways to (1) find similar users in our corpus and (2) leverage data from similar users to build a personalized LM for a new user. We explore the

trade-offs between the amount of available data from existing users, the number of existing users and new users, and how our similarity metrics and methods scale. We then show an analysis to explore what types of words our method predicts more accurately and are thus more important to consider in personalization methods.

2 Related Work

Personalized Language Modeling. King and Cook (2020) examined methods for creating personalized LMs and their work is most similar to ours. They consider interpolating, fine-tuning, and priming LMs as methods of personalization, though they use these methods with a large generic model. In contrast, our work shows that performance can be improved by leveraging data from similar users. They also analyzed model adaptation for models trained on users with similar demographics, inspired by Lynn et al. (2017), who showed that these demographic factors could help model a variety of tasks, and found that personalized models perform better than those adapted from similar demographics. Shao et al. (2020) have also explored models for personalization but focused on handling OOV tokens.

Wu et al. (2020) proposed a framework to learn user embeddings from Reddit posts. Their user embeddings were built on the sentence embeddings generated by a BERT model. By using the learned user embeddings to predict gender, detect depression and classify MBTI personality, they concluded that their embeddings incorporate intrinsic attributes of users. In our work, user embeddings are learned in a different approach, and we focus on how to use similarity calculated from user embeddings to build better LMs.

Authorship Attribution. One of the tasks we consider as a means of computing similarity is authorship attribution, i.e., identifying the author of a document. Early work on this task used lexical features like word frequencies and word n-grams (Koppel et al., 2009; Stamatatos, 2009). As in Ge et al. (2016), we employ neural networks to model similarity between users and predict authorship.

Learning from Limited Data. Antonello et al. (2021) explored training a model to predict what data will be most informative for fine-tuning and select individual data points to improve language modeling. The similarity metrics that we derive are used to select data for fine-tuning in one of our methods of leveraging similar user data, however we consider indivisible sets of data grouped by author.

The cold start problem is a well-known problem in recommendation systems. A great amount of previous work addressed how to recommend items to new users, about whom the system has little or no history, often with a focus on matrix factorization methods (Zhou et al., 2011). Work from Huang et al. (2016) approached language modeling as a cold-start problem, in that they had no writing from a user, though they had a social network, from which they interpolated LMs from users linked in their social graph.

Language Models. We use a recently developed LM that has received widespread attention (Merity et al., 2018b). The LSTM-based model combines a number of regularization and optimization techniques explored in recent literature, including averaged SGD, embedding dropout, and recurrent dropout. Subsequent work has developed variations of the model with improved perplexity, but these take at least twice as much time to train (Gong et al., 2018), making them less practical for the user-specific experiments we consider.

Another direction of research has shown impressive results using extremely large models (Radford et al., 2019; Devlin et al., 2019). Using these as a basis for experiments could be an interesting direction, but fine-tuning models in low data settings is known to be difficult and highly variable (Dodge et al., 2020). Similar transformer models have been used for controlled generation. Zellers et al. (2019) developed a model for news generation that conditioned on meta-data including domain, date, authors, and headline. No ablation is performed, and though it would be interesting to compare to a transformer method that conditions on authors alone, we opted for a model that is faster and cheaper to train (Grover-Mega from Zellers et al. (2019) was trained for two weeks and cost around 25k USD). Additionally, when fine-tuning models for new users, little data is available. Contextualized embedding models often require a large amount of data to train effectively, though this type of comparison would be an interesting future direction to explore. Variations of the LSTM have consistently achieved state-of-the-art performance without massive compute resources and thus we chose this architecture for our experiments (Merity et al., 2018a; Melis et al., 2019; Merity, 2019; Li et al., 2020).

Rule	Example
(1) it contains more than 20 tokens but the average token length is less than 3	" i " " " " w " " i " " l " " l " " " " n " " e " " v " " e " " r " " " " g " " i " " v " " e "
(2) it contains a long token whose length is greater than 30	COOLCOOLCOOLCOOLCOOLCOOLCOOLCOOL... (There is usually duplication inside this kind of post)
(3) it contains less than 8 tokens among which more than 3 are URLs	URL URL URL URL
(4) it contains more than 3 math related symbols, such as “|", “+" and “="	before humanity , maybe 2 +2 = 5 . no , before humanity 2 +2 = 4 did not exist .
(5) it contains symbols like “{", “}" and “( )" with only white spaces in the parentheses	we specialize in ( ) ( ) ( ) ( ) ( ) ( ) ( )
(6) it contains less than 5 tokens and the last token is "*"	(This kind of post is usually a spelling correction to a previous post)
(7) there are less than 4 unique tokens in every sequence of 8 adjacent tokens	w , w , w , w , would n’t it be better if we just bend over and follow their rules ?
(8) it contains hashtags, indicated by: [ ] (/ / #	[** if i were a rich man ... **] (/ / #ggj)
(9) it is a duplicate of another post in the user’s data	
(10) more than 60% of the characters are non-alphabetical.	=+=+= 1st =+=+= 2nd =+=+= End

Table 1: Examples of rules for filtering posts as described in Section 3.1.

3 Dataset

We examine a corpus of publicly available Reddit comments and select users active on Reddit between the years of 2007-2015 who have at least 60k tokens of text.[1] We refer to the existing users with at least 250k tokens of text as **anchor** users. These are users that are leveraged through interpolation or fine-tuning in order to improve performance on **new** users. Reddit posts are mostly in English.

We experiment with two settings: In the **small anchor** setting, there are 100 *anchor* users, with a 200k, 25k, 25k split for training, validation, and test, and 50 *new* users, with 2k tokens for training, and 25k for each of validation and test. In the **large anchor** setting, there are 10k *anchor* users and 100 *new* users, each having 2k tokens for training and validation and 20k for test.

Preprocessing Reddit data can be noisy, containing URLs, structured content (e.g., tables, lists), Subreddit-specific emoticons, generated, or deleted content. We first extract all posts for each user in our dataset. During this process we remove noisy posts, where a post is considered “noisy” if it matches one of ten rules. These rules and examples of each are shown in Table 1. After this filtering step, we remove markup for emojis and hyperlinks from the remaining posts (keeping the posts themselves). We take these steps to ensure that we capture language used by the authors, rather than reposts, collections of links, ASCII tables and art, equations, or code. Tokens that occur fewer than 5 times are replaced with ⟨UNK⟩, which results in a vocab size of 55k for the small anchor set and 167k for the larger one.

4 Experiments

Our method for constructing personalized LMs consists of a similarity metric and a method for leveraging similar user data to train a personalized LM. The similarity metric measures which anchor users are most similar to a new user. That is, given a set of users ($anchors$), a new user (n), and a similarity function (sim), we compute $z = sim(n, anchors); z \subset anchors$ to get a set of similar users z. We explore three similarity metrics and two methods of applying them to the construction of personalized models. Figure 1 shows how user data is used for each step.

4.1 Calculating User Similarity

We explore three methods for measuring the similarity between users. Two of them, authorship confusion and user embeddings, are derived from classifiers trained for other tasks, while the third, perplexity-based similarity, is obtained from the performance of LMs on the new user. The user embedding method results in a vector space where we can use cosine similarity to measure the distance between individuals. The perplexity directly gives a distance between each pair and the authorship confusion vectors can be treated as a vector of continuous values where each value represents the similarity to an anchor user.

[1] Posts are retrieved from https://www.reddit.com/r/datasets/comments/3bxlg7/i_have_every_publicly_available_reddit_comment/ and we exclude known bots and do not include posts in the /r/counting subreddit in our dataset.

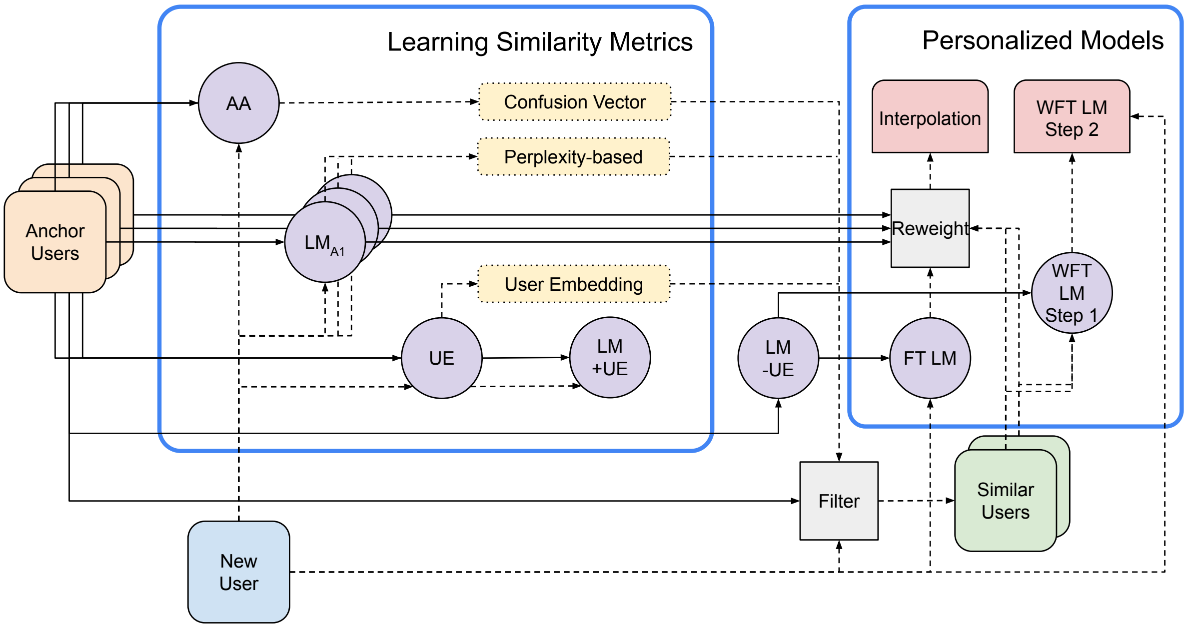

Figure 1: This diagram shows how data, models, and metrics are used in this paper. There are two main sections, a rectangle on the left showing how the three similarity metrics are computed, and a rectangle on the right showing our two methods of leveraging similar user data to create personalized models. The solid lines indicate the flow of anchor user data, while a dashed line indicates data from a new user. Anchor user data is used to create the authorship attribution model (AA), the individual user LMs for the perplexity-based metric (denoted as a set with the first as LM_{A1}), and the user embeddings (UE). The three metrics can be used to filter anchor user data to find similar users. With these users, we fine-tune a baseline LM (without UE, denoted LM-UE), which is then further fine-tuned with new user data for the weighted fine-tuning method (WFT LM). When interpolating, the individual anchor user LMs are reweighted, and combined with the predictions of an LM fine-tuned on new user data (FT LM).

Authorship Attribution Confusion (AA). Similarity can be measured from the confusion matrix of an authorship attribution model. This model takes a post as input and encodes it with an LSTM (Hochreiter and Schmidhuber, 1997). The final state is passed to a feed-forward layer and then a softmax to get a distribution over authors. We denote this model A, and $A(U)$ as the class distribution output by the model for a given utterance set. For a new user, we take their set of utterances, U_n and pass them to our model $A(U_n)$ which will give us a confusion vector of length K, one value for each author.

We train this model on the data from anchor users.[2] Embeddings are initialized with 200d GloVe vectors pretrained on 6 billion tokens from randomly sampled Reddit posts (Pennington et al., 2014). For $K = 100$ anchors the test accuracy is 42.88% and $K = 10,000$ the test accuracy is 2.42%. These accuracies are reasonably high given the difficulty of the task.[3] The classifier does not have to be high performing given our application to computing a user similarity metric.

We apply this model to each post in the training data from *new* users. The scores produced by the model for each new post indicate which of the anchor users has the most similar writing. The more frequently posts from a new user are predicted as coming from a specific anchor user, the more similar this anchor user is to the new user.

User Embeddings (UE). We first train an LM with a user embedding layer on the data from anchor users. The model is adapted from Merity et al. (2018b) with an added user embedding layer. This token embedding layer is initialized with our pretrained GloVe vectors and frozen during training. The output of the LSTM layer is concatenated to the user embedding at each time step based on the author of the token at that time step.[4] Note that this is then passed through another feed-forward layer before being used for prediction. Our optimizer starts with SGD and will switch to ASGD if there

---

[2] See Appendix A for hyperparameters

[3] Note that when $K = 10,000$ the majority class is 0.01%.

[4] See Appendix B for hyperparameters

is no improvement in validation loss in the past 5 epochs (Polyak and Juditsky, 1992). We removed continuous cache pointers (Grave et al., 2016) to speed up training. For $K = 100$, the validation perplexity converges to 59.06 and test perplexity is 58.86. When training with $K = 10,000$ the validation perplexity converges to 88.71 with test perplexity 88.54.

The embeddings of anchor users can be obtained from the user embedding layer in the trained model. To learn the embeddings of new users, we freeze all parameters of the trained model except the user embedding layer. We train the model on the data from each new user separately with the same training strategy. It takes 2 minutes to learn the embedding of each new user. The average test perplexity is 66.67 when $K = 100$ and 90.48 when $K = 10,000$. For each pair of new user and anchor user, we use the cosine similarity between two embeddings as the similarity.

Perplexity-Based (PPLB). Given N trained LMs, one for each user, we can then use the perplexity of one LM on another user's data as a measure of distance. We could compare the word-level distributions, though this would be very computationally expensive. In our experiments, we use the probability of the correct words only, or the perplexity of each model on each new user's data.

We take the large LM trained on all anchor users, as described in the user embedding section and fine-tune it for each anchor user. We then measure the perplexity of each model on the data of each new user. For this matrix of $new \times anchor$ perplexities, we turn each row, representing a new user, into a similarity vector by computing $1 - \frac{c - min(row)}{max(row)}$ for each cell, c. This step is expensive, taking close to 24 hours for $K = 100$ and intractable given our hardware constraints in the $K = 10,000$ setting.

5 Leveraging Similar Users

Our three similarity methods provide a way to identify anchor users with the most relevant data for a new user. In this section, we describe two methods to learn from that data to construct a personalized model.

5.1 Weighted Sample Fine-tuning

Users who speak in a similar style or about similar content may be harder to distinguish from each other and should then be more similar. For a given similarity metric, we compute similar users and use data from these users to fine-tune an LM before fine-tuning for the new user.

We compare to two baselines, (1) a model trained on all anchor users with no fine-tuning and (2) a model trained on all anchor users that is fine-tuned on the new user's data, as is done in standard fine-tuning. Our method of weighted sample fine-tuning has two steps. The first step is to fine-tune the model trained on all anchor users on a new set of similar users, as determined by our chosen similarity metric. Then we fine-tune as in the standard case, by tuning on the new user's data.

5.2 Interpolation Model

Our interpolation model is built from individual LMs constructed for each anchor user. It takes the predictions of each anchor user model and weights their predictions by that anchor's similarity to the new user. No model updates are done in this step, which makes it immediately applicable, without requiring further training, even if the aggregation of output from all anchor models is more resource intensive.

We also want to incorporate the predictions of the model fine-tuned on the new user data with the predictions of models trained on similar anchor users. We define a set of similar anchor users, σ, each of which has a similarity to the new user, n. We vary s for each similarity function. The weight to give the new user fine-tuned model is η, and we interpolate as follows for a given resulting probability p_r, of a word, w:

$$p_r(w|\cdot) = \eta p_n(w|\cdot) + (1 - \eta) \sum_{i \in \sigma} s(\sigma_i, n) p_{\sigma_i}(w|\cdot)$$

The similarities are adjusted to the range $(0, 1)$ and normalized to sum to one.

6 Results

We divide our results into separate subsections for each of the anchor sets. On the small anchor set we were able to perform more exploration of the weighted fine-tuning method, as it does not scale as well to the large anchor set.

We present results using standard perplexity measurements as a function of the probability of a correct prediction of a token. We also present results with accuracy at N, where a prediction is counted as correct if the correct token occurs within the top N most probable words given by the model.

Method	#Sim. Users	Δ Perplexity UE	Δ Perplexity AA	Δ Perplexity PPLB	Δ Accuracy@1 UE	Δ Accuracy@1 AA	Δ Accuracy@1 PPLB

Table 2: Difference in perplexity for our interpolated model and weighted fine-tuning results on the **small anchor** set. The baseline metrics are subtracted from our model, meaning that more negative perplexity and more positive accuracy are better. The baseline Merity et al. (2018a) perplexity average is 64.3 for a model that uses standard fine-tuning and 67.6 without fine-tuning. Bold indicates best performance.

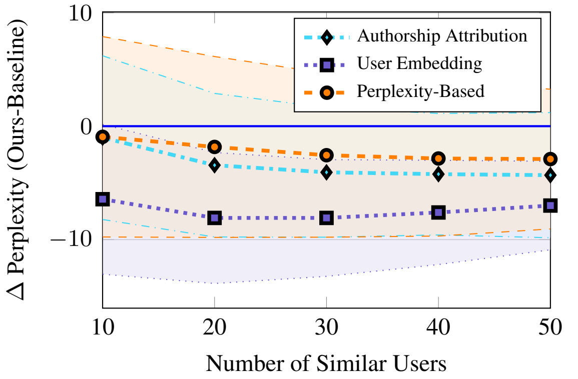

Figure 2: Change in perplexity for varying number of similar users considered in weighted fine-tuning for the three similarity metrics.

6.1 Small Anchor Set

In this section, we compare our weighted sample fine-tuning and interpolation approaches to the more standard fine-tuning, where a large pretrained model is fine-tuned only on the new user's data. With no fine-tuning our LM achieves a perplexity of 67.6 and when fine-tuning on the new user only, this perplexity drops to 64.3. For weighted fine-tuning, we attempt to fine-tune the large pretrained model on 100 anchors using our two step method, first fine-tuning on a million tokens from most similar users, and then fine-tuning on new user data. Through tuning the number of similar users, we found 5 worked best. For the interpolation model, we found more similar users improved accuracy, though perplexity was slightly higher for ten similar users. Our interpolation model combines predictions from similar anchor user LMs. We have an LM fine-tuned to each of our anchor users and for a given new user we predict words by weighting the predictions of the models representing the most similar users.

Results in Table 2 show that our weighted sample fine-tuning is not able to outperform the baseline for any of our three similarity metrics. Perplexity and accuracy results are reported averaged over the test set users. We also tried fine-tuning with random user's data and found that this performance was better than no fine-tuning but worse than fine-tuning on new user data only, showing that there is no added benefit from simply continuing to fine-tune on all data.

For the interpolation model, we tune η (see Section 5.2) on a held-out set and use a value of 0.7. The results show that the authorship attribution similarity performs best on both metrics. We find that as the number of similar users increases it has little effect past around ten similar users, as the similarity weights decrease and have a smaller impact.

Retraining with Similar User Data: It appears that having similar user data does not help the weighted fine-tuning model. To further investigate this we looked at settings where the amount of training data is fixed, but the source is either random, or a sample of similar user's data. For each new user, we build six datasets: a random dataset and five datasets consisting of data from top-k similar anchor users for this new user where k is in {10, 20, 30, 40, 50}. Each of these datasets has 2m tokens. The random dataset is comprised of 20k tokens from each anchor user. For the dataset built from the top-k similar users, we want the number of tokens selected from each anchor user to be proportional to the similarity between the new user and each anchor user. To do this, we normalize the three similarities by subtracting the minimum and dividing by the maximum such that they are between zero and one.

For a given set of k users and similarity metric, we sort all anchor users in descending order by their similarity to the new user and choose the top k anchor users. For the rank 1 anchor user a_1, we choose the following number of tokens from the

#Sim. Users	Δ Perplexity	Std.Dev.
Random 10	0.176	0.367
10	-0.354	0.659
20	-0.534	0.977
30	-0.673	1.080
40	-0.714	1.040
50	-0.803	1.127
100	-0.941	1.351
150	-0.986	1.560
200	-1.069	1.549

Table 3: Difference in perplexity for fine-tuning varying number of similar users on the **large anchor** set, first fine-tuning on similar users, and second on the new user's data, as compared to Merity et al. (2018a) fine-tuned on new user data only with perplexity 89.7. Each similar user has 2k tokens and each new user has 2k.

training data, where $s(\cdot, \cdot)$ is the similarity between a pair of users:

$$n_{a_1} = 2000k * \frac{s(newuser, a_1)}{\sum_{i=1}^{k} s(newuser, a_i)}$$

If $n_{a_1} > 200k$, we choose $n_{a_1} = 200k$. For the rank x anchor user a_x, we choose

$$n_{a_x} = (2000k - \sum_{j=1}^{x-1} n_{a_j}) * \frac{s(newuser, a_x)}{\sum_{i=x}^{k} s(newuser, a_i)}$$

tokens from their training data. If $n_{a_x} > 200k$, we choose $n_{a_x} = 200k$. We repeat this procedure until the rank k anchor user. The ratio of similarities in this equation enforces that the amount of data we select from each of the top-k similar users is proportional to their similarity.

We then train a separate model on each dataset. The architecture of the model is the same as what is described in Section 4.1 except that it does not have a user embedding layer. We then fine-tune the trained models on the training data of the new user.

For a chosen similarity metric and number k, we average the test perplexity of the fine-tuned models for all new users and subtract from it the average test perplexity of the fine-tuned models trained on random datasets, whose average perplexity is 111.0. The results are shown in Figure 2 with shaded areas indicating standard deviation. In the figure, the lower a point is, the better the datasets built using the corresponding similarity metric and number k is for training an LM for new users, which we infer is because the weighted sample datasets are closer to the data from new users.

We see that in terms of similarity metrics, the user embedding is the best while perplexity-based is the worst. As k increases, the performance first increases then decreases. The best performance is achieved when using the similarities calculated with user embeddings and using top 20 or 30 similar anchor users. After that, including more users has little effect, as their similarity weights continue to decrease. The main takeaway from this experiment is that although similar user data helps more than random data, the benefit does not transfer to the larger fine-tuning scenario. This area may be worth further exploring for fine-tuning strategies or for training data selection in applications where new models must be trained.

6.2 Large Anchor Set

In a set of only one hundred anchor users, it may be the case that existing users are not similar enough to the new user to benefit from our approach. To test this idea we ran experiments using the larger set of 10k anchor users and 100 new users.

Taking our most promising user embedding similarity metric from the weighted sample fine-tuning, we tested this method's performance varying the number of similar users. Our results in Table 3 show a reduction in perplexity of 0.94 at 100 similar users and over one point at 200 users. There is a logarithmic improvement with the number of similar users considered, as we would expect more dissimilar users to be less informative. The results in this table suggest that the anchor set must be diverse enough to contain similar users to new users, in order to benefit from this method.

We also try the interpolation model with a larger set of anchor users. Our base model is trained on 10k anchor users and 2k tokens from each anchor. Note that we are controlling for the total points from anchor users, using 100 times fewer points per user and 100 times more users. Scaling up these experiments to more points and users is computationally expensive but may be worth exploring in future work. We fine-tune this model to each similar anchor user for weighting predictions. On a held-out set we tune η and find that in this setting performance starts to drop after around 10 similar users. It is computationally expensive to run each of the 10k models on each new user. The perplexity similarity metric requires that all of these are run in order to determine similarity and thus is not scalable to the large anchor user setting. The user embedding metric scales better because similarity can be determined by tuning an existing LM on

Table 4: Comparison of our interpolated user embedding similarity model on the **large anchor** set to a standard fine-tuned Merity et al. (2018a) baseline measured in perplexity and accuracy @N. We show results for 2k and 6k tokens per anchor user, showing improved performance when more data per anchor is available. Bold indicates best performance.

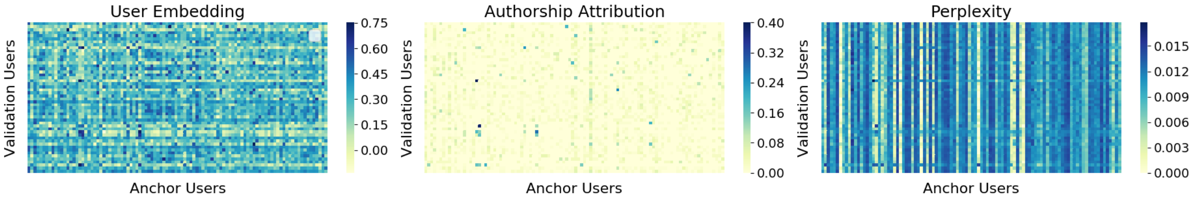

Figure 3: Heat maps showing normalized similarity for each metric on our 100 author anchor set.

Metric 1	Metric 2	Pearson's r	Spearman's ρ
UE	AA	0.360	0.362
UE	PPL	0.280	0.316
PPL	AA	0.073	0.025

Table 5: Spearman and Pearson correlation coefficients for each pair of similarity metrics (User Embeddings (UE), Authorship Attribution (AA), and Perplexity (PPL)) computed for each of our 100 anchor users similarity to each new user.

new user data. For ten similar users we require 1,000 times fewer computations than we would to weight all 10k users. We found that authorship attribution performed much worse in this setting, as the confusion matrix becomes very sparse.

The results for our best similarity metric, user embeddings, are shown in Table 4. On the left we see performance for our model on the larger set containing 2k tokens per anchor user. For this analysis of our best, scalable model, we include accuracy @N, a metric denoting the percentage of times the correct word was in the top-N most probable choices. This is comparable to Table 3, where we used the same amount of data for the weighted sample fine-tuning approach. On the right we see performance when the amount of data per anchor user is tripled. The baseline and fine-tuned models all benefit from this additional data, however we find that the difference in perplexity is much larger, as having additional data will allow the models to learn more accurate similarity metrics. We also find that when tuning η it tends toward 0.6 when there are 2k tokens per anchor user but 0.3 when there are 6k. As the amount of data from the anchor users increases, the optimal interpolation weights shift to weight the anchor user models more heavily than the model fine-tuned on the new user. How the tuning of η could be done on a per-user basis, rather than globally, is an interesting open question.

7 Analysis

7.1 Differences in Similarity Functions

We looked at the differences between our three similarity functions by computing the correlation coefficients for Spearman's ρ and Pearson's r in Table 5. Interestingly, the perplexity and authorship attribution metrics correlate much more strongly with the user embedding metric than with each other. It is possible that the user embedding metric performs best in our experiments because it contains more of the useful information from both of the other metrics. Additional heat maps for each metric are in Figure 3. In general, they show that the three metrics seem to capture different information about the relationships between users. The user embedding metric leads to more evenly distributed similarities, while the other two metrics have outlier anchor users that show stronger correlation with a subset of the new users.

Table 6: Top 50 words for which our best model outperforms the baseline based on the frequency of word correctly predicted normalized by the word's total frequency.

7.2 Personalized Words

We take the highest performing model using user embedding similarity trained on our large anchor user set and compare it to our baseline model to look at which words are more accurately predicted. By taking the number of times each word is correctly predicted by the best model when the baseline was wrong and dividing by the total number of occurrences of that word in our language modeling data, we can find words that have the highest normalized frequency of being improved by our model.

The top 50 words for which we see improvement are shown in Table 6. We see the second word of many two-word proper nouns in this set. Many names can start with "San" or "Las" and so we see "vegas", "diego", and "antonio", in this list. Similarly, "new" precedes "zealand" and other location names. The top word is "fuels", which occurs often in the data in conversation about "fossil fuels", though there are also many others that mention other kinds of fuels, or use "fuels" as a verb, as in "it fuels outrage". We also see that units such as "mph" or "ghz" are more accurately predicted. The units that one chooses may be more common depending on where one lives, or in the case of "ghz" it may depend more on the subject matter that a user is familiar with or tends to talk about. Other proper nouns such as "game of thrones", or "hong kong" vs. "donkey kong", contain common words, which individually may be hard to predict, but with knowledge of an individual's preferences could be predicted more accurately.

8 Ethical Considerations

Work on personalized LMs could be used for surveillance by detecting language from individuals or groups (Stamatatos, 2009). We recommend against such applications, as they threaten intellectual freedom and risk discrimination (Richards, 2013). There may be a risk in storing private data necessary to construct these models, as data may not be properly secured or used. Furthermore, a personalized model could reinforce incorrect language usage, which may be an issue for individuals learning to speak a new language, making it more difficult to learn. Learning personal language patterns in a given context and suggesting these patterns in other contexts may lead to potentially incorrect or offensive results and we recommend that if this type of personalization is deemed appropriate, users are made aware of how their data is being used and potential consequences.

9 Conclusions

In this paper, we addressed the issue of language modeling in a low data setting where a new user may not have enough data to train a personalized LM and presented a novel approach that leverages data from similar users. We considered three similarity metrics and two methods of leveraging data from similar *anchor* users to improve the performance of language modeling over a standard fine-tuning baseline, and showed how our results vary with the amount of data available for anchor users and the number of available anchor users. We found that the most easily scalable and highest performing method was to use user embedding similarity and to interpolate similar user fine-tuned models. Additionally, we provided an analysis of the kind of words that our personalized models are able to more accurately predict and further discussed limitations of our methods.

A Hyperparameters for Authorship Attribution Model

- Bidirectional LSTM layers=3
- LSTM hidden dim=400
- output dropout=0.5
- fully-connected layer dim=800 × K
- Adam optimizer
- cross-entropy loss
- learning rate=1e-3
- batch size=64
- early stopping if no improvement over 10 epochs

B Hyperparameters for User Embedding Model

- scalar dropout=0.1
- embedding dropout=0.2
- LSTM layers=3
- LSTM hidden dim=1,150
- recurrent dropout=0.2
- user embedding dim=50 (tried 20,50,100 but 50 worked best)
- cross-entropy loss
- early stopping if no improvement over 20 epochs
- sequence length=70
- batch size=20
- learning rate=3
- parameter clipping=0.25

C Running Times

Authorship attribution models are trained on an NVIDIA GeForce RTX-2080Ti GPU and take 2.5 hours for $K = 100$ anchors and 4 hours for $K = 10,000$ anchors.

Training a new language model for weighted fine-tuning as described in Section 6.1 takes about 2.5 hours to train a model on a dataset on an NVIDIA Tesla V100 GPU. Fine-tuning the trained models on the training data of the new user takes about one minute on average.

The user embedding models are trained on an NVIDIA GeForce RTX-2080Ti GPU. For $K = 100$ anchors, it took 132 hours. When training with $K = 10,000$, we reduced the hidden LSTM size to 500, which reduced training time to 112 hours.

DEEP: DEnoising Entity Pre-training for Neural Machine Translation

Abstract

It has been shown that machine translation models usually generate poor translations for named entities that are infrequent in the training corpus. Earlier named entity translation methods mainly focus on phonetic transliteration, which ignores the sentence context for translation and is limited in domain and language coverage. To address this limitation, we propose DEEP, a **DE**noising **E**ntity **P**re-training method that leverages large amounts of monolingual data and a knowledge base to improve named entity translation accuracy within sentences. Besides, we investigate a multi-task learning strategy that finetunes a pre-trained neural machine translation model on both entity-augmented monolingual data and parallel data to further improve entity translation. Experimental results on three language pairs demonstrate that DEEP results in significant improvements over strong denoising auto-encoding baselines, with a gain of up to 1.3 BLEU and up to 9.2 entity accuracy points for English-Russian translation.[1]

1 Introduction

Proper translation of named entities is critically important for accurately conveying the content of text in a number of domains, such as news or encyclopedic text (Knight and Graehl, 1998; Al-Onaizan and Knight, 2002a,b). In addition, a growing number of new named entities (e.g., person name, location) appear every day, therefore many of these entities may not exist in the parallel data traditionally used to train MT systems. As a result, even state-of-the-art MT systems struggle with entity translation. For example, Laubli et al. (2020) note that a Chinese-English news translation system that had allegedly reached human parity still lagged far behind human translators on entity translations, and this problem will be further exacerbated in the cross-domain transfer settings or in the case of emerging entities.

Because of this, there have been a number of methods proposed specifically to address the problem of translating entities. As noted by Liu (2015), earlier studies on named entity translation largely focused on rule-based methods (Wan and Verspoor, 1998), statistical alignment methods (Huang et al., 2003, 2004) and Web mining methods (Huang et al., 2005; Wu and Chang, 2007; Yang et al., 2009). However, these methods have two main issues. First, as they generally translate a single named entity without any context in a sentence, it makes it difficult to resolve ambiguity in entities using context. In addition, the translation of entities is often performed in a two-step process of entity recognition then translation, which complicates the translation pipeline and can result in cascading errors (Huang et al., 2003, 2004; Chen et al., 2013).

In this paper, we focus on a simple yet effective method that improves named entity translation within context. Specifically, we do so by devising a data augmentation method that leverages two data sources: monolingual data from the target language and entity information from a knowledge base (KB). Our method also adopts a procedure of pre-training and finetuning neural machine translation (NMT) models that is used by many recent works (Luong and Manning, 2015; Neubig and Hu, 2018; Song et al., 2019; Liu et al., 2020). In particular, pre-training methods that use monolingual data to improve translation for low-resource and medium-resource languages mainly rely on a denoising auto-encoding objective that attempt to reconstruct parts of text (Song et al., 2019) or the whole sentences (Liu et al., 2020) from noised input sentences without particularly distinguishing named entities and other functional words in the sentences. In contrast, our method exploits an entity linker to identify entity spans in the monolingual sentences and link them to a KB that contains mul-

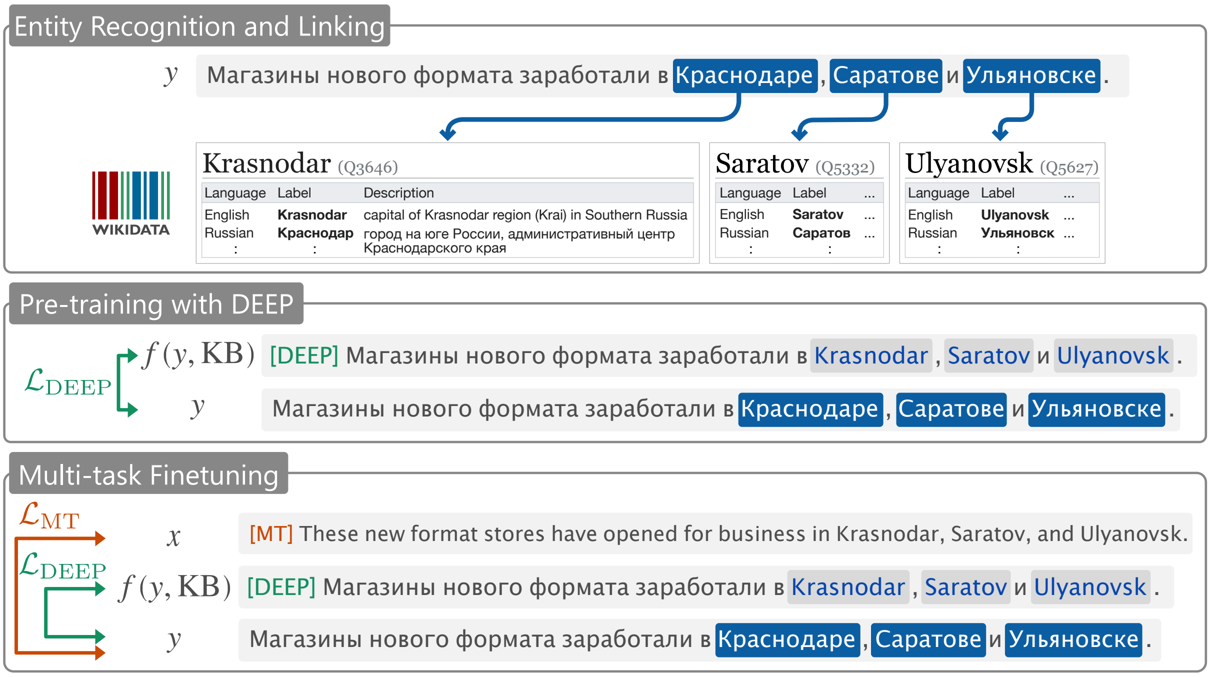

Figure 1: General workflow of our method. Entities in a sentence is extracted and linked to Wikidata, which includes their translations in many languages. DEEP uses the noise function $f(y, \text{KB})$ that replaces entities with the translations for pre-training. DEEP is also employed during finetuning in a multi-task learning manner.

tilingual translations of these entities (such as Wikidata (Vrandečić and Krötzsch, 2014)). We then generate noised sentences by replacing the extracted entity spans with their translations in the knowledge base and pre-train our NMT models to reconstruct the original sentences from the noised sentences. To further improve the entity translation accuracy and avoid forgetting the knowledge learned from pre-training, we also examine a multi-task learning strategy that finetunes the NMT model using both the denoising task on the monolingual data and the translation task on the parallel data.

In the experiments on English-Russian, English-Ukrainian, and English-Nepali translations, DEEP outperforms the strong denoising auto-encoding baseline with respect to entity translation accuracy, and obtains comparable or slightly better overall translation accuracy as measured by BLEU. A fine-grained analysis shows that our multi-task finetuning strategy improves the translation accuracy of the entities that do not exist in the finetuning data.

2 Denoising Auto-Encoding (DAE)

Given a set of monolingual text segments for pre-training, i.e., $y \in \mathcal{D}_Y$, a sequence-to-sequence denoising auto-encoder is pre-trained to reconstruct a text segment y from its noised version corrupted by a noise function $g(\cdot)$. Formally, the DAE objective is defined as follows:

$$\mathcal{L}_{\text{DAE}}(\mathcal{D}_Y, \theta) = \sum_{y \in \mathcal{D}_Y} \log P(y \,|\, g(y); \theta), \qquad (1)$$

where θ denotes the model's learnable parameters. For notation simplicity, we drop θ in the rest of the sections. This formulation encompasses several different previous works in data augmentation for MT, such as monolingual data copying (Currey et al., 2017), where $g(\cdot)$ is the identity function, back translation (Sennrich et al., 2016), where $g(\cdot)$ is a backwards translation model, as well as heuristic noise functions (Song et al., 2019; Lewis et al., 2020; Liu et al., 2020) that randomly sample noise according to manually devised heuristics.

In particular, as our baseline we focus on the mBART method (Liu et al., 2020), a popular method with two types of heuristic noise functions being used sequentially on each text segment. The first noise function randomly masks spans of text in each sentence. Specifically, a span length is first randomly sampled from a Poisson distribution ($\lambda = 0.35$) and the beginning location for a span in y is also randomly sampled. The selected span of text is replaced by a mask token. This process repeats until 35% of words in the sentence are masked. The second noise function is to permute the sentence order in each text segment with a probability.

3 DEEP: Denoising Entity Pre-training

Our method adopts a procedure of pre-training and finetuning for neural machine translation. First, we apply an entity linker to identify entities in a monolingual corpus and link them to a knowledge base (§3.1). We then utilize entity translations in the knowledge base to create noisy code-switched data for pre-training (§3.2). Finally, we examine a multi-task learning strategy to further improve the translation of low-frequency entities (§3.3).

3.1 Entity Recognition and Linking

The goal of this part is to identify entities in each monolingual segment and obtain their translations. To this end, we use Wikidata (Vrandečić and Krötzsch, 2014) a public multilingual knowledge base that covers 94M entities.[2] Each entity is represented in surface forms from different languages in which a Wikipedia article exists. Therefore, linking an entity mention t in a target-language segment y to an entity e in Wikidata allows us to obtain the multilingual translations of the entity, that is,

$$\forall t \in y, \exists e \in \mathrm{KB} : T_e = \mathrm{surface}(e, \mathrm{KB}), t \in T_e$$

where T_e denotes a set of multilingual surface forms of e. We can define the translate operation as: $s = \mathrm{lookup}(T_e, X)$ which simply looks for the surface form of e in the source language X. Note that this strategy relies on the fact that translations in higher-resource languages are included in T_e, which we adopt by using English in our experiments. In general, however, T_e does not universally cover all the languages of interest. For entity recognition and linking, we use SLING (Ringgaard et al., 2017),[3] which builds an entity linker for arbitrary languages available in Wikipedia.

3.2 Entity-based Data Augmentation

After obtaining entity translations from the KB, we attempt to explicitly incorporate these translations into the monolingual sentences for pre-training. To do so, we design an entity-based noise function that takes in a sentence y and the KB, i.e., $f(y, \mathrm{KB})$. First, we replace all detected entity spans in the sentence by their translations from the KB:

$$\mathrm{replace}(y, \mathrm{KB}) = \mathrm{swap}(s, t, y), \ \forall t \in y \qquad (2)$$

where the swap() function swaps occurrences of one entity span t in y with its translation s in the source language. For example, in the second box of Figure 1, the named entities "Краснодаре, Саратове and Ульяновске" in Russian are replaced by "Krasnodar, Saratov, and Ulyanovsk" in English. After the replacement, we create a noised code-switched segment which explicitly includes the translations of named entities in the context of the target language. For some segments that contain fewer entities, their code-switched segments may be similar to them, which potentially results in a easier denoising task. Therefore, we further add noise to these code-switched segments. To do so, if the word count of the replaced entity spans is less than a fraction (35%) of the word count in the segment, we randomly mask the other non-entity words to ensure that about 35% of the words are either replaced or masked in the noised segment. Finally, we follow Liu et al. (2020) to randomly permute the sentence order in y. We then train a sequence-to-sequence model to reconstruct the original sentence y from its noised code-switched sentence as follows:

$$\mathcal{L}_{\mathrm{DEEP}}(\mathcal{D}_Y, \mathrm{KB}) = \sum_{y \in \mathcal{D}_Y} \log P(y \mid f(y, \mathrm{KB}))$$

3.3 Multi-task Finetuning

After pre-training, we continue finetuning the pre-trained model on a parallel corpus $(x, y) \in \mathcal{D}_{XY}$ for machine translation.

$$\mathcal{L}_{\mathrm{MT}}(\mathcal{D}_{XY}) = \sum_{(x,y) \in \mathcal{D}_{XY}} \log P(y \mid x) \qquad (3)$$

To avoid forgetting the entity information learned from the pre-training stage, we examine a multi-task learning strategy to train the model by both the pre-training objective on the monolingual data and the translation objective on the parallel data. Since monolingual segments are longer text sequences than sentences in $\mathcal{D}_{XY}$ and the size of $\mathcal{D}_Y$ is usually larger than that of $\mathcal{D}_{XY}$, simply concatenating both data for multi-task finetuning leads to bias toward denoising longer sequences rather than actually translating sentences. To balance the two tasks, in each epoch we randomly sample a subset of monolingual segments $\mathcal{D}'_Y$ from $\mathcal{D}_Y$, where the total subword count of $\mathcal{D}'_Y$ equals to that of $\mathcal{D}_{XY}$, i.e., $\sum_{y \in \mathcal{D}'_Y} |y| = \sum_{(x,y) \in \mathcal{D}_{XY}} \max(|x|, |y|)$. We

Lang.	Token	Para.	Entity		
			Type	Count	N
Ru	775M	1.8M	1.4M	337M	123
Uk	315M	654K	524K	140M	149
Ne	19M	26K	17K	2M	34

Table 1: Statistics of Wikipedia corpora in Russian (Ru), Ukrainian (Uk) and Nepali (Ne) for pre-training. *N* denotes the average subword count of entity spans in a sequence of 512 subwords.

Lang.	Train	Dev	Test	Coverage (F)		Coverage (T)	
				Type	Count	Type	Count
En-Ru	235K	3.0K	3.0K	88%	94%	88%	91%
En-Uk	200K	2.3K	2.5K	87%	94%	91%	94%
En-Ne	563K	2.6K	2.8K	35%	25%	44%	27%

Table 2: Statistics of the parallel train/dev/test data for finetuning. Coverage (F/T) represent the percentage of entity types and counts in the **F**inetuning (**T**est) data that are covered by the pre-training data.

then examine the multi-task finetuning as follows:

$$\mathcal{L}_{\text{Multi-task}} = \mathcal{L}_{\text{MT}}(\mathcal{D}_{XY}) + \mathcal{L}_{\text{Pre-train}}(\mathcal{D}'_Y) \quad (4)$$

where the pre-training objective $\mathcal{L}_{\text{Pre-train}}$ is either DAE or DEEP with DEEP having an additional input of a knowledge base. Notice that with the sampling strategy for the monolingual data, we double the batch size in the multi-task finetuning setting with respect to that in the single-task finetuning setting. Therefore, we make sure that the models are finetuned on the same amount of parallel data in both the single-task and multi-task settings, and the gains from the multi-task setting sorely come from the additional task on the monolingual data.

To distinguish the tasks during finetuning, we replace the start token (`[BOS]`) in a source sentence or a noised segment by the corresponding task tokens for the translation or the denoising task (`[MT]`, `[DAE]` or `[DEEP]`). We initialize these task embeddings by the start token embedding and append them to the word embedding matrix of the encoder.

4 Experimental Setting

Pre-training Data: We conduct our experiments on three language pairs: English-Russian, English-Ukrainian and English-Nepali. We use Wikipedia articles as the monolingual data for pre-training and report the data statistics in Table 1. We tokenize the text using the same sentencepiece model as Liu et al. (2020), and train on sequences of 512 subwords.

Finetuning & Test Data: We use the news commentary data from the English-Russian translation task in WMT18 (Specia et al., 2018) for finetuning and evaluate the performance on the WMT18 test data from the news domain. For English-Ukrainian, we use the TED Talk transcripts from July 2020 in the OPUS repository (Tiedemann, 2012) for finetuning and testing. For English-Nepali translation, we use the FLORES dataset in Guzmán et al. (2019) and follow the paper's setting to finetune on parallel data in the OPUS repository. Table 2 shows the data statistics of the parallel data for finetuning. Notice that from the last four columns of Table 2, the entities in the pre-training data cover at least 87% of the entity types and 91% of the entity counts in both finetuning and test data except the En-Ne pair.

Architecture: We use a standard sequence-to-sequence Transformer model (Vaswani et al., 2017) with 12 layers each for the encoder and decoder. We use a hidden unit size of 512 and 12 attention heads. Following Liu et al. (2020), we add an additional layer-normalization layer on top of both the encoder and decoder to stabilize training at FP16 precision. We use the same sentencepiece model and the vocabulary from Liu et al. (2020).

Methods in Comparison: We compare methods in the single task and multi-task setting as follows:

- **Random → MT**: We include a comparison with a randomly initialized model without pre-training and finetune the model for each translation task.
- **DAE → MT**: We pre-train a model by DAE using the two noise functions in Liu et al. (2020) and finetune the model for each translation task.
- **DEEP → MT**: We pre-train a model using our proposed DEEP objective and finetune the model on the translation task.
- **DAE → DAE+MT**: We pre-train a model by the DAE objective and finetune the model for both the DAE task and translation task.
- **DEEP → DEEP+MT**: We pre-train a model by the DEEP objective and finetune the model for both the DEEP task and translation task.

Learning & Decoding: We pre-train all models for 50K steps first using the default parameters in Liu et al. (2020) except that we use a smaller batch of 64 text segments, each of which has 512 subwords. We use the Adam optimizer (ϵ=1e-6, β_2=0.98) and a polynomial learning rate decay scheduling with a maximum step at 500K. All models are pre-trained on one TPUv3 (128GB) for about 12 hours for 50K steps.[4] We apply the noise function on the monolingual data on the fly for each epoch, and this takes only a few minutes by multiprocessing in `Fairseq` (Ott et al., 2019). We then reset the learning rate scheduler and continue finetuning our pre-trained models on the MT parallel data for 40K steps. Single-task (multi-task) finetuning takes about 16 (32) hours on 2 RTX 3090 GPUs. We set the maximum number of tokens in each batch to 65,536 in the single task setting and double the batch size in the multi-task setting to ensure that models in both settings are trained on an equal amount of parallel data, and thus any performance gain can only be attributed to monolingual data during finetuning. We use 2,500 warm-up steps to reach a maximum learning rate of 3e-5, and use 0.3 dropout and 0.2 label smoothing. After training, we use beam search with a beam size of 5 and report the results in sacreBLEU (Post, 2018) following the same evaluation in Liu et al. (2020).

5 Discussion

5.1 Corpus-level Evaluation

In Table 3, we compare all methods in terms of BLEU (Papineni et al., 2002) and chrF (Popović, 2015) on the test data for three language pairs. First, we find that all pre-training methods significantly outperform the random baseline. In particular, our DEEP method obtains a gain of 3.5 BLEU points in the single task setting for the low-resource En-Ne translation. Second, we compute statistical significance of the BLEU and chrF scores with bootstrap resampling (Koehn, 2004), and we observe significant improvements with the multi-task finetuning strategy over the single-task finetuning for En-Ru and En-Ne. Our DEEP method outperforms the DAE method for En-Ru translation by 1.3 BLEU points in the multi-task setting. It is also worth noting that DEEP obtains higher BLEU points than DAE at the beginning of the multi-task finetuning process, however the gap between both methods decreases as the finetuning proceeds for longer steps (See Appendix A). One possible reason is that models trained by DEEP benefit from the entity translations in the pre-training data and obtain a good initialization for translation at the beginning of the finetuning stage. As the multi-task finetuning proceeds, the models trained by both DAE and DEEP rely more on the translation task than the denoising task for translating a whole sentence. Thus the nuance of the entity translations might not be clearly evaluated according to BLEU or chrF.

5.2 Entity Translation Accuracy

Since corpus-level metrics like BLEU or chrF might not necessarily reveal the subtlety of named entity translations, in the section we perform a fine-grained evaluation by the entity translation accuracy which counts the proportion of entities correctly translated in the hypotheses. Specifically, we first use SLING to extract entities for each pair of a reference and a hypothesis. We then count the translation accuracy of an entity as the proportion of correctly mentioning the right entity in the hypotheses, followed by macro-averaging to obtain the average entity translation accuracy. We also show the accuracy scores in Table 3. First, our method in both single- and multi-task settings significantly outperformed the other baselines. In particular, the gains from DEEP are much clear for the En-Uk and En-Ru translations. One possible reason is that Russian or Ukrainian entities extracted from the pre-training data have a relatively higher coverage of the entities in both the finetuning and test data as reported in Table 2. However, SLING might not detect as many entities in Nepali as in the other languages. We believe that future advances on entity linking in low-resource languages could potentially improve the performance of DEEP further. We leave this as our future work.

5.3 Fine-grained Analysis on Entity Translation Accuracy

In this section, we further analyze the effect on different categories of entities using our method.

Performance of Entity Groups over Finetuning: The model is exposed to some entities more often than others at different stages: pre-training, finetuning and testing, which raises a question: *how is the entity translation affected by the exposure during each stage?* To answer this question, we divide the entities appearing in the test data into three groups:

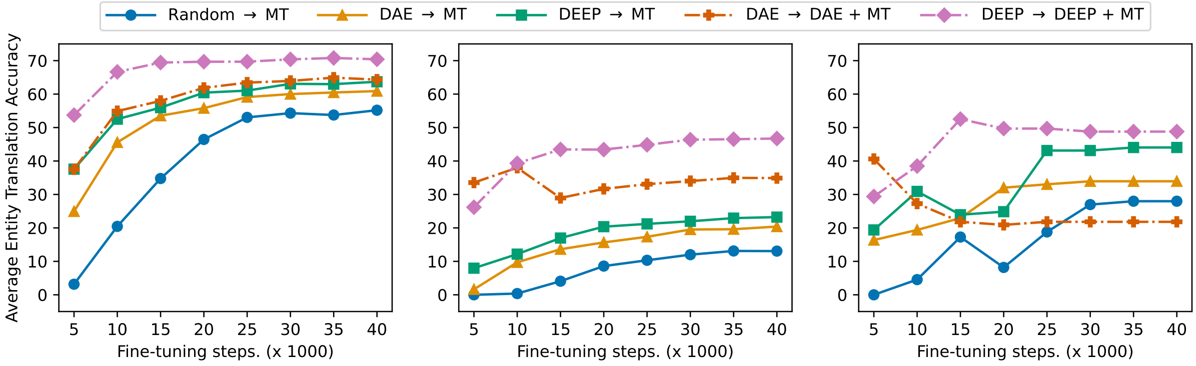
- **PFT**: entities appearing in the pre-training, finetuning, and test data.
- **PT**: entities only in the pre-training and test data.

---

[4] As we show in Figure 4, models pre-trained for 50K steps provide a reasonably good initialization.

Pre-train → Finetune	BLEU			chrF			Entity Translation Acc.		
	En-Uk	En-Ru	En-Ne	En-Uk	En-Ru	En-Ne	En-Uk	En-Ru	En-Ne
Random → MT	17.1	15.0	7.7	37.0	36.8	24.3	49.5	31.1	20.9
DAE → MT	19.5	18.5	10.5	**39.2**	40.4	26.8	56.7	37.7	26.0
DEEP → MT	19.4	18.5	11.2*	**39.2**	40.7*	27.7*	57.7	40.6*	**28.6***
DAE → DAE+MT	19.4	18.5	11.2	39.1	41.0	27.8	58.8	47.2	27.9
DEEP → DEEP+MT	**19.7**	**19.6***	**11.5**	39.1	**42.4***	**28.2***	**61.9***	**56.4***	28.3

Table 3: BLEU, Entity translation accuracy, and chrF in single- and multi-task settings. Largest numbers in each column are bold-faced. * indicates statistical significance of DEEP with $p < 0.05$ to DAE in the respective settings.



Entities in **PFT** data. Entities in **PT** data. Entities in **FT** data.

Figure 2: Entity translation accuracy scores aggregated over different entity sets for Russian. **PFT**, **PT**, **FT** data correspond to entities appearing in (i) pre-training, finetuning and test data, (ii) only pre-training and test data (iii) only finetuning and test data.

- **FT**: entities only in the finetuning and test data.

We show the English-to-Russian entity translation accuracy scores for each group over finetuning steps in Figure 2. Overall, accuracies are higher for the entities that appear in the finetuning data (**PFT**, **FT**), which is due to the exposure to the finetuning data. Our proposed method consistently outperformed baseline counterparts in both single- and multi-task settings. The differences in accuracy are particularly large at earlier finetuning steps, which indicates the utility of our method in lower-resource settings with little finetuning data. The effect of multi-task finetuning is most notable for entities in **PT**. Multi-task finetuning continuously exposes the model to the pre-training data, which as a result prevents the model from forgetting the learned entity translations from **PT**.

Performance according to Entity Frequency: We further analyze the entity translation accuracy scores using entity frequencies in each group introduced above. This provides a more fine-grained perspective on *how frequent or rare entities are translated*. To do so, we take Russian hypotheses from a checkpoint with 40K steps of finetuning, bin the set of entities in three data (*i.e.* **PFT**, **PT**, **FT**) according to frequencies in each of the data. We then calculate the entity translation accuracy within each bin by comparing them against reference entities in the respective sentences. Figure 3 shows the accuracy gain of each pre-training methodologies from **Random → MT** (*i.e.* no pre-training) on test data, grouped by the entity frequency bins in pre-training and finetuning data. Note that leftmost column and the bottom row represent **PT**, **FT**, respectively. As observed earlier, the proposed method improves more over most frequency bins, with greater differences on entities that are less frequent in finetuning data. This tendency is observed more significantly for the multi-task variant (**DEEP → DEEP + MT**), where the gains are mostly from entities that never appeared in finetuning data (*i.e.* leftmost column). Multi-task learning with DEEP therefore prevents the model from forgetting the entity translations learned at pre-training time. Analytical results on Ukrainian and Nepali are in Appendix B.

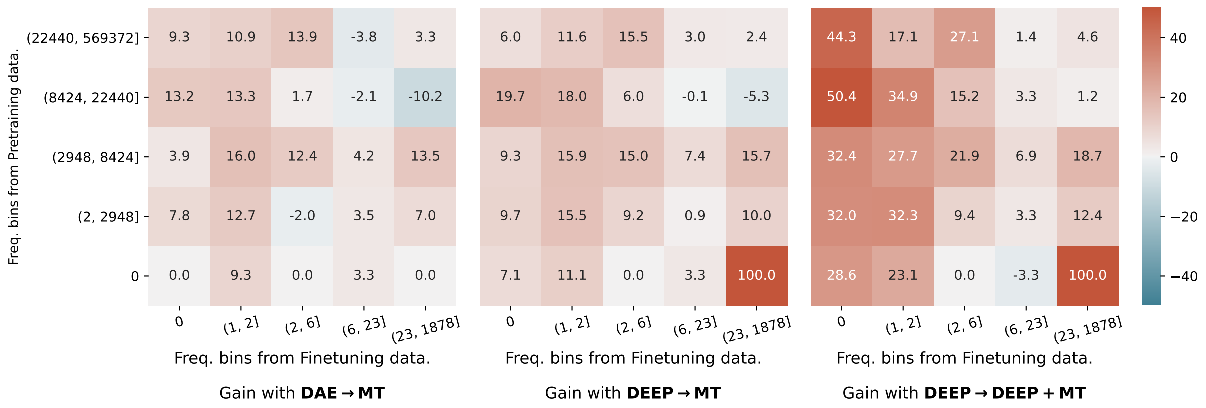


Figure 3: Gain from Random → MT in entity translation accuracy for each model.

Methods	0.24M		4.25M	
	BLEU	Acc.	BLEU	Acc.
Random → MT	15.0	31.1	15.7	39.4
DAE → MT	18.5	37.7	16.3	53.7
DEEP → MT	18.5	40.6	17.2	53.9

Table 4: Model comparisons across different finetuning data sizes. The results on the right are obtained after finetuning on the combined news commentary and ParaCrawl data.

5.4 Optimization Effects on DEEP

Finetuning Data Size vs Entity Translation: While DEEP primarily focuses on a low-resource setting, the evaluation with more resources can highlight potential use in broader scenarios. To this end, we expand the finetuning data for English-Russian translation with an additional 4 million sentence pairs from ParaCrawl (Bañón et al., 2020), a parallel data collected from web pages. Although web pages might contain news text, ParaCrawl data covers more general domains. We finetune models on the combined data and evaluate with BLEU and entity translation accuracy. Table 4 shows the comparisons across different finetuning data sizes. When the model is initialized with pre-training methods, we observed decreased BLEU points and increased entity translation accuracy scores. This is partly due to the discrepancy of domains between our finetuning data (news) and ParaCrawl. Regardless, DEEP is consistently equal to or better than DAE in all tested settings.

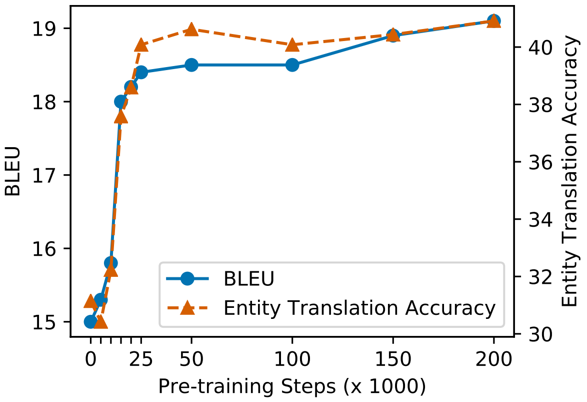

Figure 4: English-to-Russian BLEU and Entity translation accuracy scores after finetuning from variable pre-training steps. Finetuning is performed for 40K steps.

Pre-training Steps vs Entity Translation: Since DEEP leverages entity-augmented monolingual data, the model trained by DEEP revisits more entities in different context as the pre-training proceeds. To analyze the efficiency of learning entity translation during pre-training, we focus on the question: *how many pre-training steps are needed for named entity translation?* To examine this question, we take the saved checkpoints trained by DEEP from various pre-training steps, and apply the single-task finetuning strategy on the checkpoints for another 40K steps. We plot the entity translation accuracy and BLEU on the test data in Figure 4. We find that the checkpoint at 25K steps has already achieved a comparable entity translation accuracy with respect to the checkpoint at 150K steps. This shows that DEEP is efficient to learn the entity translations as early as in 25K steps. Besides, both the BLEU and entity translation accuracy keep improving as the pre-training steps increase to 200K steps.

Table 5: Qualitative comparison among four pre-training methods on named entity translations. ①: DAE → MT, ②: DEEP → MT, ③: DAE → DAE+MT, ④: DEEP → DEEP+MT.

5.5 Qualitative Analysis

In this section, we select two examples that contain entities appearing only in the pre-training and testing data. The first example contains three location names. We find that the model trained by the single-task DAE predicts the wrong places which provide the wrong information in the translated sentence. In addition, the model trained by the multi-task DAE just copies the English named entities (i.e., "Krasnodar", "Saratov" and "Ulyanovsk") to the target sentence without actual translation. In contrast, our method predicts the correct translation for "Krasnodar" in both single-task and multi-task setting, while the multi-task DEEP translates all entities correctly. In the second example, although our method in the single-task setting predicts wrong for all the entities, the model generates partially correct translations such as "Барнале" for "Барнауле" and "Красно @-@ Молгскиском" for "Красноармейском". Notice that DEEP in the multi-task setting translates the correct entities "asphalt" and "Krasnoarmeyskiy" which convey the key information in this sentence. In contrast, the translation produced by the multi-task DAE method literally means "Барнаул (Barnaul), новый (new) миф (myth) на (at) Krasnoarmey Prospekt, выращивающий (grow) Krasnoarmeski.", which is incomprehensible due to the entity translation errors.

6 Related Work

Named Entity Translation has been extensively studied for decades (Arbabi et al., 1994; Knight and Graehl, 1998). Earlier studies focus on rule-based methods using phoneme or grapheme (Wan and Verspoor, 1998; Al-Onaizan and Knight, 2002b), statistical methods that align entities in parallel corpus (Huang et al., 2003, 2004; Zhang et al., 2005) and Web mining methods built on top of a search engine (Huang et al., 2005; Wu and Chang, 2007; Yang et al., 2009). Recently, Finch et al. (2016); Hadj Ameur et al. (2017); Grundkiewicz and Heafield (2018) used NMT to transliterate named entities *without any sentence context*. Another line of research (Ugawa et al., 2018; Li et al., 2018; Torregrosa et al., 2020; Modrzejewski et al., 2020; Zhou et al., 2020) only performs entity recognition and uses entity tags (e.g., person) which are not directly informative to the translation task, in contrast to the entity translations obtained by entity linking in our work. Besides, these methods modify model architecture to integrate entity tag embeddings or knowledge graph entity embeddings (Moussallem et al., 2019), which also require extracting entity information for both training and test data. In contrast, we focus on data augmentation methods to improve name entity translation *within context*, so our method is easily applicable to any architectures and test data without preprocessing.

Pre-training of Neural Machine Translation has been shown effective by many recent works (Conneau and Lample, 2019; Song et al., 2019; Liu et al., 2020; Lin et al., 2020), where different pre-training objectives are proposed to leverage monolingual data for translation. These methods adopt a denoising auto-encoding framework, which encompasses several different works in data augmentation on monolingual data for MT (Lambert et al., 2011; Currey et al., 2017; Sennrich et al., 2016; Hu et al., 2019). However, named entity translations during pre-training is under-explored. We fill this gap by integrating named entity recognition and linking to the pre-training of NMT. Moreover, while recent work shows that continue finetuning a pre-trained encoder with the pre-training objective improves language understanding tasks (Gururangan et al., 2020), this finetuning paradigm has not been explored for pre-training of a sequence-to-sequence model. Besides, previous works on multi-task learning for MT focus on language modeling (Gulcehre et al., 2015; Zhang and Zong, 2016; Domhan and Hieber, 2017; Zhou et al., 2019), while we examine a multi-task finetuning strategy with an entity-based denoising task in this work and demonstrate substantial improvements for named entity translations.

7 Conclusion

In this paper, we propose an entity-based pre-training method for neural machine translation. Our method improves named entity translation accuracy as well as BLEU score over strong denoising auto-encoding baselines in both single-task and multi-task setting. Despite the effectiveness, several challenging questions remain open. First, recent works on integrating knowledge graphs (Zhao et al., 2020a,b) in NMT have shown promising results for translation. Our method links entities to a multilingual knowledge base which contains rich information of the entities such as entity description, relation links, and alias. How to leverage these richer data sources to resolve entity ambiguity deserves further investigation. Second, finetuning pre-trained models on in-domain text data is a potential way to improve entity translations across domains.

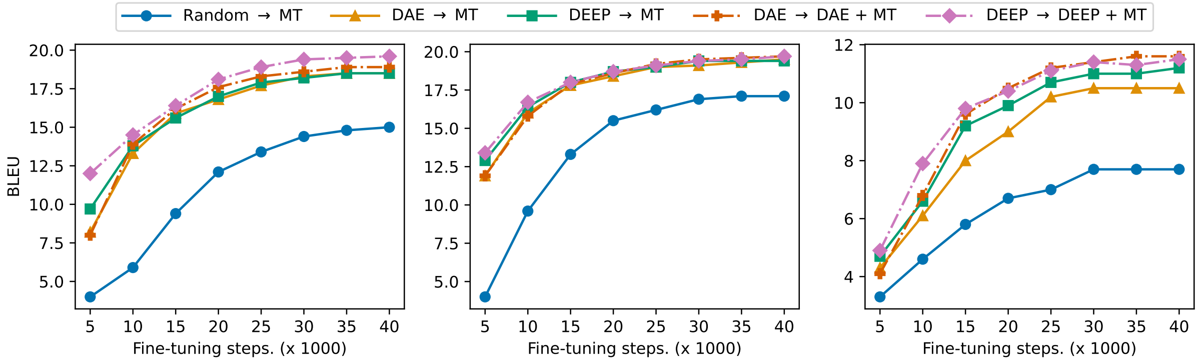
Appendix

A Finetuning BLEU Curves

We report BLEU score for three language pairs calculated from checkpoints at different finetuning steps in Figure 5. For all language pairs, all pre-training methods result in a significant increase in terms of BLEU throughout the finetuning in both single-task and multi-task setting. In particular, the differences in BLEU between DEEP and the other baselines are most significant at the beginning of the finetuning stage.



Russian

Ukrainian

Nepali

Figure 5: **BLEU** scores for 3 language pairs over various finetuning steps.

B Entity Translation Accuracy for other languages

We show the entity translation accuracy performance over various finetuning steps for Ukrainian and Nepali in Figure 6, 7, and show the gains of three pre-training methods over the random baseline with respect to the entity frequencies in Figure 8, 9. Empty cells in the heatmaps are due to no entities that meet the conditions in those cells.

Ukrainian: As seen in Figure 6, the general trend for the entity translation accuracy according to entity groups are similar to that of Russian. While DEEP achieves the highest accuracy in **FT**, the results for **FT** is less reliable due to a small sample size of entities in **FT**. In terms of the gain from **Random → MT** according to the entity frequency, we observe a consistent improvement of our multi-task DEEP on translating low-frequent entities in the finetuning data (See the left bottom of Figure 8).

Nepali: While outperforming at the beginning of finetuning, Figure 7 shows that **DEEP → DEEP+MT** eventually under-performed for translations of entities in **PFT** data. Moreover, the accuracy is considerably lower on entities in **PT**, which suggests that the degree of forgetting is much more conspicuous in Nepali. The gain from **Random → MT** with respect to the entity frequency exhibited a different trend from Russian and Ukrainian. Figure 9 shows the results. In the single-task setting, DEEP improve the translations of frequent entities appearing in both the pre-training and finetuning data. Despite the multi-task learning that introduces additional exposure to entities that are more frequent in the pre-training data, the largest gain comes from entities that are less frequent in the pre-training data but frequent in the finetuning data.

C Scientific Artifacts

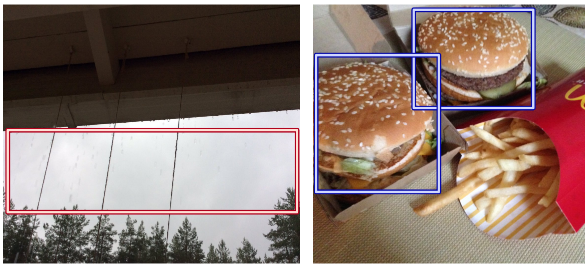
Abstract

With the increasing popularity of posting multimodal messages online, many recent studies have been carried out utilizing both textual and visual information for multi-modal sarcasm detection. In this paper, we investigate multi-modal sarcasm detection from a novel perspective by constructing a cross-modal graph for each instance to explicitly draw the ironic relations between textual and visual modalities. Specifically, we first detect the objects paired with descriptions of the image modality, enabling the learning of important visual information. Then, the descriptions of the objects are served as a bridge to determine the importance of the association between the objects of image modality and the contextual words of text modality, so as to build a cross-modal graph for each multi-modal instance. Furthermore, we devise a cross-modal graph convolutional network to make sense of the incongruity relations between modalities for multi-modal sarcasm detection. Extensive experimental results and in-depth analysis show that our model achieves state-of-the-art performance in multi-modal sarcasm detection[1].

1 Introduction

Sarcasm is a peculiar form of sentiment expressions, allowing individuals to express contempt sentiment or intention that is converse to the authentic/apparent sentiment information (Gibbs, 1986; Dews and Winner, 1995; Gibbs, 2007). As such, accurately detecting satirical/ironic expression could potentially improve the performance of sentiment analysis and opinion mining (Pang and Lee, 2008; Kumar Jena et al., 2020; Pan et al., 2020).



(a) What a wonderful weather! (b) Feeding my abs nothing but the best quality beef.

Figure 1: Two multi-modal sarcastic examples. Boxes and words in the same color denote highly correlated sarcastic cues.

In today's fast growing social media platforms, it is common to post multi-modal messages. Therefore, in addition to developing sarcasm detection models for textual data (Riloff et al., 2013; Joshi et al., 2015), it is increasingly popular to explore sarcasm detection in multi-modal data such as text and images (Schifanella et al., 2016; Cai et al., 2019). Dealing with multimodal data requires an understanding of the information presented in different modalities. As the sarcastic example shown in Figure 1 (a), text-only approaches may erroneously identify it as a positive sentiment expression due to the phrase "*wonderful weather*". This post however contains a sarcastic expression with negative sentiment, because it is accompanied by an image with "*thunderstorm clouds*". The key of effective multi-modal sarcasm detection is to accurately extract the incongruent sentiment cues from

different modalities, allowing the detection of the true sentiment conveyed in the message.

To perform multi-modal sarcasm detection on data composed of text and image, several related research efforts attempt to concatenate the textual and visual features to fuse sarcastic information (Schifanella et al., 2016), employ attention mechanism to implicitly fuse the features of different modalities based on external knowledge (Cai et al., 2019; Xu et al., 2020; Pan et al., 2020), or build interactive graphs to model the relations of different modalities (Liang et al., 2021a). Despite promising progress made by existing models, they still suffer from the following limitations: **1)** Simply considering the whole image does not produce good results, mostly due to the intricate visual information presented in an image; not to mention that only particular visual patches are related to the text. As in the examples shown in Figure 1, the correct results can be easily obtained by only tracking the visual information in the bounding boxes. Therefore, discriminating key visual objects from the irrelevant ones could lead to improved learning of visual information. **2)** Crucial visual information that relates to the sarcastic cues of text modality may be scattered in an image (Figure 1 (b)). As such, it is essential to focus on drawing the intricate sentiment connections between text and image modalities, allowing a good exploitation of the contradictory sentiment information between modalities for learning sarcastic clues.

To this end, we propose a novel cross-modal graph convolutional networks (CMGCN) by constructing a cross-modal graph for each instance, where the important visual information and the related textual tokens are explicitly linked. This allows for the extraction of incongruous implications between two modalities in sarcasm detection. Concretely, instead of trying to produce a caption of the whole image, we first detect the objects of the image to capture the important visual regions and the corresponding *attribute-object* pairs via the approach proposed by Anderson et al. (2018). Then, we explore a novel solution to assign weights to the edges of the cross-modal graph by means of computing the word similarities between the *object* descriptors of the *attribute-object* pairs and textual words based on the WordNet (Miller, 1992). Further, to introduce the multi-modal sentiment relations into the cross-modal graphs, inspired by (Lou et al., 2021), we devise a modulating factor of sentiment relation for each edge by retrieving the affective weights of *attribute* descriptors (usually adjectives with affective information) and textual words from external affective knowledge (SenticNet (Cambria et al., 2020)). As such, the modulating factors can be adopted to refine the edge weights of word similarities, allowing the capture of sentiment incongruities of the cross-modal nodes in the graph. Further, in the light of cross-modal graphs, we deploy a GCN architecture to make sense of the incongruous relations across the modalities for multi-modal sarcasm detection.

The main contributions of our work are summarized as follows:

- To the best of our knowledge, we are the first to explore the use of the graph model based on auxiliary object detection for modeling the contradictory sentiments between key textual and visual information in multi-modal sarcasm detection.
- Using the attribute-object pairs of the image objects as the bridge, a novel approach of constructing cross-modal graphs is developed to explicitly link the two modalities by edges with the varying degree of importance.
- A series of experiments on a publicly available multi-modal sarcasm detection benchmark dataset show that our proposed method achieves the state-of-the-art performance.

2 Related Work

2.1 Multi-modal Sarcasm Detection

Previous work of sarcasm detection has been applied to textual utterances information (Zhang et al., 2016; Tay et al., 2018; Babanejad et al., 2020). Different from text-based sarcasm detection, multi-modal sarcasm detection aims to identify the sarcastic expression among different modalities (Schifanella et al., 2016; Castro et al., 2019). Schifanella et al. (2016) firstly tackled the multi-modal sarcasm detection task with text and image modalities by manually designed features. Cai et al. (2019) created a new dataset and proposed a hierarchical fusion model for multi-modal sarcasm detection. Xu et al. (2020) explored decomposition and relation network to model both cross-modality contrast and semantic association in sarcasm detection. Pan et al. (2020) proposed inter-modality attention and co-attention to learn the contradiction of sarcasm. For

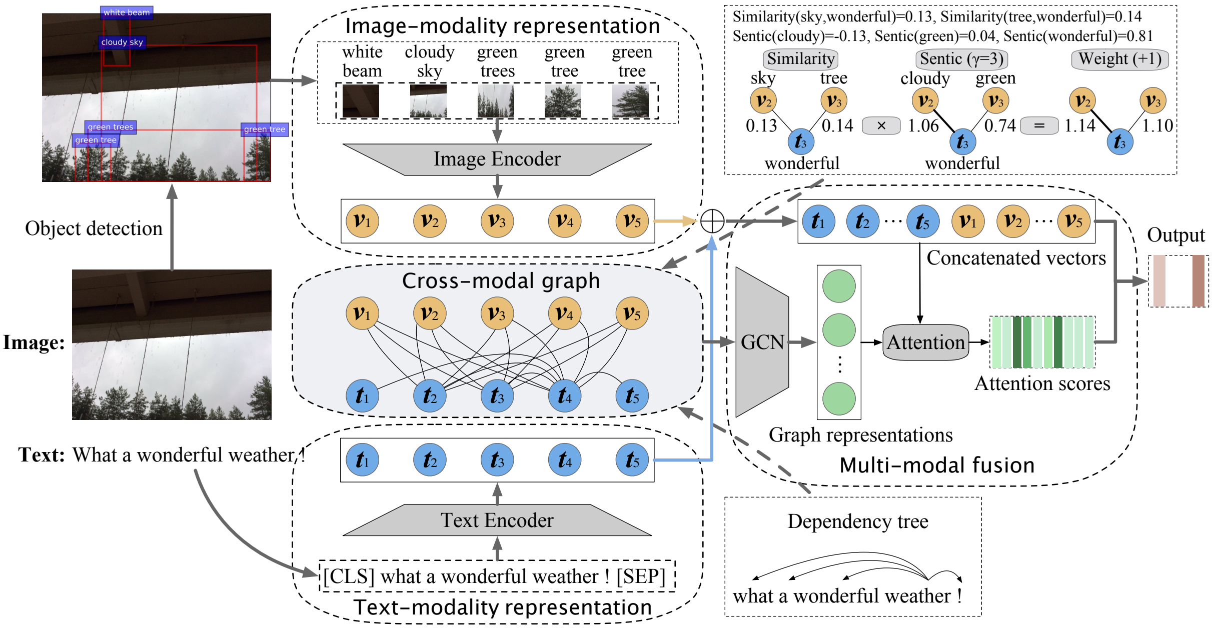

Figure 2: The architecture of the proposed CMGCN. ⊕ represents matrix concatenation.

the graph-based methods, Liang et al. (2021a) deployed a heterogeneous graph structure to learn the sarcastic features from both intra- and inter-modality perspectives. However, this method tried to grasp the visual information of the whole image, and meanwhile ignore the sentiment expression between different modalities. Therefore, different from (Liang et al., 2021a), we explore a novel cross-modal GCN model based on the important visual information and sentiment cues to leverage the inconsistent implications between different modalities and thus improve the performance of multi-modal sarcasm detection.

2.2 Graph Neural Networks

Models based on graph neural networks (GNN), including graph convolutional network (GCN) (Kipf and Welling, 2017) and graph attention network (GAT) (Velickovic et al., 2018), have achieved promising performance in many recent research studies, such as visual representation learning (Wu et al., 2019; Xie et al., 2021), text representation learning (Yao et al., 2019; Lou et al., 2021; Liang et al., 2021b, 2022), and recommendation systems (Ying et al., 2018; Tan et al., 2020). Further, there are also some research studies explored graph models to deal with the multi-modal tasks, such as multi-modal sentiment detection (Yang et al., 2021), multi-modal named entity recognition (Zhang et al., 2021), cross-modal video moment retrieval (Zeng et al., 2021), multi-modal neural machine translation (Yin et al., 2020), and multi-modal sarcasm detection (Liang et al., 2021a).

3 Methodology

In this section, we describe our proposed Cross-Modal Graph Convolutional Networks (**CMGCN**) model for multi-modal sarcasm detection in details. As demonstrated in Figure 2, the architecture of the proposed CMGCN contains four main components: 1) *Text-modality representation*, which employs the pre-trained uncased BERT-base model (Devlin et al., 2019) as the text encoder to capture the hidden representation of the text-modality; 2) *Image-modality representation*, which deploys the pre-trained Vision Transformer (ViT) (Dosovitskiy et al., 2021) as the image encoder to capture the hidden representation of the image-modality with respect to each bounding box (visual region); 3) *Cross-modal graph*, which constructs a cross-modal graph for each multi-modal example based on the external affective knowledge source and the hidden representations of text and image modalities; 4) *Multi-modal fusion*, which fuses the representations from image and text modalities to capture the sarcastic features by means of a GCN structure and an attention mechanism.

3.1 Text-modality Representation

For text processing, given a sequence of words $s = \{w_i\}_{i=1}^{n}$, n is the length of the text s. We first adopt the pre-trained uncased BERT-base model (Devlin et al., 2019) to map each word w_i into a d^T-dimensional embedding:

$$\boldsymbol{X}^T = [\boldsymbol{x}_1, \boldsymbol{x}_2, \cdots, \boldsymbol{x}_n] = \text{BERT}([\text{CLS}]s[\text{SEP}]) \tag{1}$$

Where $\boldsymbol{X}^T$ is the embedding matrix of the input text. Here, the representations of tokens `[CLS]` and `[SEP]` are not utilized in constructing the cross-modal graph. Subsequently, to unify the dimensions of representations between different modalities and capture the sequential relations of the context, we utilize a bidirectional LSTM (Bi-LSTM) to learn the text-modality representation of the input text:

$$\boldsymbol{T} = \{\boldsymbol{t}_1, \boldsymbol{t}_2, \cdots, \boldsymbol{t}_n\} = \text{Bi-LSTM}(\boldsymbol{X}^T) \tag{2}$$

Where $\boldsymbol{t}_j \in \mathbb{R}^{2d_h}$ denotes the hidden state vector at time step j from the bidirectional LSTM, d_h denotes the dimensionality of the text-modality hidden state representation.

3.2 Image-modality Representation

For image processing, given an image I, we first adopt a trained toolkit proposed by Anderson et al. (2018) to derive a series of bounding boxes (objects) paired with their attribute-object pairs. For each visual region of the bounding box $I_i \in \mathbb{R}^{L_h \times L_w}$, following (Xu et al., 2020), we first resize it to 224 × 224, i.e. $L = L_h = L_w = 224$. Subsequently, following (Dosovitskiy et al., 2021), we reshape the region $I_i \in \mathbb{R}^{L \times L}$ into a sequence $I_i = \{\boldsymbol{p}_j \in \mathbb{R}^{L/p \times L/p}\}_{j=1}^{r}$, where $r = p \times p$ is the number of patches. Then, we flatten and map each patch to a d^I-dimensional vector with a trainable linear projection: $\boldsymbol{z}_j = \boldsymbol{p}_j \boldsymbol{E}$.

For each sequence of image patches, a `[class]` token embedding $\boldsymbol{z}_{[class]} \in \mathbb{R}^{d^I}$ is prepended for the sequence of embedded patches, and position embeddings are added to the patch embeddings to retain positional information. The input of each visual region I_i is represented as:

$$\boldsymbol{Z}_i = [\boldsymbol{z}_{[class]}; \boldsymbol{z}_1; \boldsymbol{z}_2; \cdots; \boldsymbol{z}_r] + \boldsymbol{E}_{pos} \tag{3}$$

Where $\boldsymbol{Z}_i \in \mathbb{R}^{(r+1) \times d^I}$ is the input matrix of the image patches, and $\boldsymbol{E}_{pos} \in \mathbb{R}^{(r+1) \times d^I}$ is the position embedding matrix. Then, we feed the input matrix $\boldsymbol{Z}_i$ into the ViT encoder to acquire the representation $\boldsymbol{h}_i$ of visual region I_i:

$$\boldsymbol{H}_i = \text{ViT}(\boldsymbol{Z}_i), \ \boldsymbol{h}_i = \boldsymbol{H}_{i,[class]} \tag{4}$$

We use the representation of the `[class]` token embedding to represent the visual region. Finally, the representation of the image I is defined as:

$$\boldsymbol{X}^I = \{\boldsymbol{h}_1, \boldsymbol{h}_2, \cdots, \boldsymbol{h}_m\} \tag{5}$$

Where m is the number of visual regions.

Subsequently, we employ a trainable Linear Projection to map each $\boldsymbol{v}_i$ to a $2d_h$-dimensional vector:

$$\boldsymbol{V} = \{\boldsymbol{v}_1, \boldsymbol{v}_2, \cdots, \boldsymbol{v}_m\} = \boldsymbol{X}^I \boldsymbol{W}^V \tag{6}$$

Where $\boldsymbol{W}^V \in \mathbb{R}^{d^I \times 2d_h}$ is a trainable parameter.

3.3 Cross-modal Graph

In this section, we describe how to construct a cross-modal graph. To leverage the relations between multi-modal features, we employ a graph structure to link the textual words with the associated image objects. Here, the nodes of the cross-modal graph are the representations of text and image modalities. Many GCN-based approaches have demonstrated that the weights of the edges are crucial in graph information aggregation (Liang et al., 2021b; Yang et al., 2021; Lou et al., 2021). As such, constructing a cross-modal graph boils down to the setting of the edge weights in the graph.

To this end, we explore a novel approach of setting the weights based on both word similarities and affective clues between textual words and the *attribute-object* pairs of the image regions, and the dependency tree of the text-modality. The adjacency matrix $\boldsymbol{A} \in \mathbb{R}^{(n+m)\times(n+m)}$ of the cross-modal graph is defined as:

$$A_{i,j} = \begin{cases} 1 & \text{if } \mathcal{D}_{i,j} \text{ and } i < n, j < n \\ \boldsymbol{\kappa}_{i,j} & \text{if } i < n, j \geq n \\ 0 & \text{otherwise} \end{cases} \tag{7}$$

$$\boldsymbol{\kappa}_{i,j} = Sim(w_i, o_j) \times \boldsymbol{\xi}_{i,j} + 1 \tag{8}$$

$$\boldsymbol{\xi}_{i,j} = \gamma^{-\boldsymbol{\omega}(w_i)\boldsymbol{\omega}(a_j)} \times |\boldsymbol{\omega}(w_i) - \boldsymbol{\omega}(a_j)| \tag{9}$$

Where $\mathcal{D}_{i,j}$ indicates that there is a relation between w_i and w_j in the dependency tree of the sentence. $Sim(\cdot)$ represents the computation of word similarity[2]. We set $Sim(\cdot) = 0$ if the return value is $None$. $\boldsymbol{\xi}_{i,j}$ is a modulating factor refers to the sentiment relation (sentiment incongruity) between an image region and a text token. $\boldsymbol{\omega}(w_i) \in [-1, 1]$ represents the affective weight of

---

[2] We employ the NLTK toolkit (`http://www.nltk.org/`) to compute the similarity of a word pair based on the WordNet.

word w_i retrieved from SenticNet (Cambria et al., 2020). We set $\boldsymbol{\omega}(w_i) = 0$ if w_i cannot be found in SenticNet. $|\cdot|$ represents absolute value calculation. a_j and o_j respectively denote the *attribute* and the *object* of the bounding box j. Inspired by Kipf and Welling (2017), we construct the cross-modal graph as an undirected graph, $A_{i,j} = A_{j,i}$, and set a self-loop for each node, $A_{i,i} = 1$.

The intention of the cross-modal graph construction (Equations 7 and 9) is that: 1) As in the examples shown in Figure 1, the sarcastic information of text-modality may be expressed by multiple words, such as "*wonderful weather*". Therefore, we incorporate the syntax-aware relations over the dependency tree of the sentence into the cross-modal graph to advance the learning of the contextual dependencies[3]. 2) We devise a coefficient $\boldsymbol{\kappa}_{i,j}$, which is associated with the affective weights, to modulate the influence of contrary sentiment relations. Here, $\gamma > 1$ is a tuned hyper-parameter to regulate the bias of inconsistent sentiment relations. That is, if the polarities of $\boldsymbol{\omega}(w_i)$ and $\boldsymbol{\omega}(a_j)$ are opposite, the value of γ is boosted, otherwise the value is shrunk. Especially, the greater the affective weights, the higher the confidence that the value of γ is boosted or shrunk. 3) We add 1 to the cross-modal edges to pay more attention to the cross-modal nodes aggregation.

3.4 Multi-modal Fusion

For each instance, we explore a graph architecture to extract the crucial sarcastic clues by aggregating the correlation of nodes in the cross-modal graph. Concretely, we feed the adjacency matrix of the cross-modal graph $\boldsymbol{A}$ and the corresponding nodes' representations $\boldsymbol{R}$ of each multi-modal example into a multi-layers GCNs architecture to derive the graph representation. For each graph convolutional operation, each node in the l-th GCN layer is updated according to the hidden representations of its neighborhoods according to the adjacency matrices of the cross-modal graph, which is defined as:

$$\boldsymbol{G}_l = \mathrm{ReLU}(\tilde{\boldsymbol{A}}\boldsymbol{G}_{l-1}\boldsymbol{W}_l + \boldsymbol{b}_l) \tag{10}$$

Where $\tilde{\boldsymbol{A}} = \boldsymbol{D}^{-\frac{1}{2}}\boldsymbol{A}\boldsymbol{D}^{-\frac{1}{2}}$ is the normalized symmetric adjacency matrix. $\boldsymbol{D}$ is the degree matrix of $\boldsymbol{A}$, where $D_{ii} = \sum_j A_{i,j}$. $\boldsymbol{G}_{l-1}$ is the hidden graph representation evolved from the preceding GCN layer. $\boldsymbol{W}_l \in \mathbb{R}^{2d_h \times 2d_h}$, $\boldsymbol{b}_l \in \mathbb{R}^{2d_h}$ are the trainable parameters of the l-th GCN layer. The nodes input of the first GCN layer are the concatenation of text-modality and image-modality representations: $\boldsymbol{G}_0 = \boldsymbol{R}$. Here, $\boldsymbol{R} = \{\boldsymbol{r}_1, \boldsymbol{r}_2, \cdots, \boldsymbol{r}_{n+m}\} = \{\boldsymbol{t}_1, \cdots, \boldsymbol{t}_n, \boldsymbol{v}_1, \cdots, \boldsymbol{v}_m\}$.

Subsequently, inspired by (Zhang et al., 2019), we employ a retrieval-based attention mechanism to capture the graph-oriented attention information from the concatenation of text and image representations $\boldsymbol{R} = \{\boldsymbol{r}_1, \boldsymbol{r}_2, \cdots, \boldsymbol{r}_{n+m}\}$ by means of the graph representation $\boldsymbol{g}$ derived from the final GCN layer. The intention is to retrieve crucially associated cross-modal features that are explicitly connected in the cross-modal graph. The attention weights are computed as:

$$\alpha_t = \frac{\exp(\beta_{\mathrm{t}})}{\sum_{i=1}^{n+m}\exp(\beta_i)}, \quad \beta_t = \sum_{i \in \mathcal{C}} \boldsymbol{r}_t^{\top}\boldsymbol{g}_i \tag{11}$$

Where $\mathcal{C}$ denotes a set of indices in which nodes contain cross-modal edges in the graph. $\top$ represents the matrix transposition. The final sarcastic representation is defined as:

$$\boldsymbol{f} = \sum_{t=1}^{n+m} \alpha_t \boldsymbol{r}_t \tag{12}$$

Then, the final sarcastic representation is fed into a fully-connected layer with a softmax function to capture a probability distribution $\hat{\boldsymbol{y}} \in \mathbb{R}^{d_p}$ in the sarcasm decision space:

$$\hat{\boldsymbol{y}} = \mathrm{softmax}(\boldsymbol{W}_o\boldsymbol{f} + \boldsymbol{b}_o) \tag{13}$$

Where d_p is the dimensionality of sarcasm labels. $\boldsymbol{W}_o \in \mathbb{R}^{d_p \times 2d_h}$ and $\boldsymbol{b}_o \in \mathbb{R}^{d_p}$ are trainable parameters.

3.5 Learning Objective

We minimize the cross-entropy loss via the standard gradient descent algorithm to train the model:

$$\min_{\Theta}\mathcal{L} = -\sum_{i=1}^{N}\sum_{j=1}^{d_p} y_i^j \log\hat{y}_i^j + \lambda||\Theta||^2 \tag{14}$$

where N is the training data size. $\boldsymbol{y}_i$ and $\hat{\boldsymbol{y}}_i$ respectively represent the ground-truth and estimated label distribution of instance i. Θ denotes all trainable parameters of the model, λ represents the coefficient of L_2-regularization.

---

[3] We employ the spaCy toolkit (`https://spacy.io/`) to derive the dependency tree of a sentence.

	Training	*Development*	*Testing*
Positive	8642	959	959
Negative	11174	1451	1450
All	19816	2410	2409

Table 1: Statistics of the experimental data.

4 Experimental Setup

4.1 Dataset

We conduct experiments on a publicly available multi-modal sarcasm detection benchmark dataset collected by Cai et al. (2019). This dataset contains English tweets expressing *sarcasm* as *Positive* examples and those expressing *non-sarcasm* as *Negative* examples. Each example in the dataset consists of a text and an associated image. The statistics of the dataset are shown in Table 1.

4.2 Experimental Settings

For a fair comparison, the data preprocessing follows (Cai et al., 2019). We set the maximum number of visual regions as 10 for object detection results. That is, we select the top 10 bounding boxes with highest scores if the objects are greater than 10. We utilize the pre-trained uncased BERT-base (Devlin et al., 2019) module to embed each word of text-modality as a 768-dimensional embedding and employ the pre-trained ViT[4] (Dosovitskiy et al., 2021) to embed each visual region patch as a 768-dimensional embedding, i.e. $d^T = d^I = 768$. The resolution of visual region patch is set to $L_p = 32$, correspondingly, $p = 7, r = 49$.[5] The number of GCN layers is set to 2, which is the optimal depth in the pilot experiments. The dimensionality of hidden representations is set to $d_h = 512$. The coefficient λ is set to 0.00001. Adam is utilized as the optimizer with a learning rate of 0.00002, and the mini-batch size is 32. The dropout rate with 0.1 is utilized to avoid overfitting. We use early-stopping with patience of 5. We set $\gamma = 3$ to compute the modulating factor of incongruous multi-modal sentiment relations, which is the optimal hyper-parameter in the pilot experiments.

Following (Cai et al., 2019), we use *Accuracy*, *Precision*, *Recall*, and *F1-score* to measure the model performance. Since the label distribution of the dataset is imbalanced, following (Pan et al., 2020), we also report Macro-average results. The experimental results of our models are averaged over 10 runs with different random seeds to ensure the final reported results are statistically stable.

4.3 Comparison Models

We compare our proposed **CMGCN** model with a series of strong baselines, summarized as follow:

1) Image-modality methods: These models use only visual information for sarcasm detection, including **Image** (Cai et al., 2019), which employs ResNet (He et al., 2016) to train a sarcasm classifier; and **ViT** (Dosovitskiy et al., 2021), which utilizes the '`[class]`' token representation of the pre-trained ViT to detect the sarcasm.

2) Text-modality methods: These models use only textual information, including **TextCNN** (Kim, 2014), a deep learning model based on CNN for text classification; **Bi-LSTM**, a bidirectional LSTM network for text classification; **SIARN** (Tay et al., 2018), adopting inner-attention for textual sarcasm detection; **SMSD** (Xiong et al., 2019), exploring a self-matching network to capture textual incongruity information; and **BERT** (Devlin et al., 2019), the vanilla pre-trained uncased BERT-base taking '`[CLS] text [SEP]`' as input.

3) Multi-modal methods: These models take both text- and image-modality information. Including **HFM** (Cai et al., 2019), a hierarchical multimodal features fusion model for multi-modal sarcasm detection; **D&R Net** (Xu et al., 2020), a Decomposition and Relation Network modeling both cross-modality contrast and semantic association; **Res-BERT** (Pan et al., 2020), concatenating image features and BERT-based text features for sarcasm prediction; **Att-BERT** (Pan et al., 2020), exploring an inter-modality attention and a co-attention to model the incongruity of multi-modal sarcasm detection; and **InCrossMGs** (Liang et al., 2021a), a graph-based model to leverage the sarcastic relations from both intra- and inter-modal perspectives.

We also explore several variants of **CMGCN** to analyze the impact of different components in the ablation study: **1) w/o** $\mathcal{G}$ denotes without cross-modal graph, which only concatenates the representations of '`[class]`' and '`[CLS]`' tokens from ViT and BERT for sarcasm detection; **2) w/o** $\mathcal{O}$ denotes without object detection. The whole image is input into the image encoder, and the edge weights are set to 1 in the cross-modal graphs; **3) w/o** $\mathcal{S}$ denotes without using external knowledge.

---

Table 2: Main experimental results regarding unimodal and multimodal scenarios. The results of baselines with $\natural$ are retrieved from (Liang et al., 2021a), others are run by the open source codes. Best scores of each group are in bold. Results with $\star$ denote the significance tests of our CMGCN over the baseline models at $p-$value < 0.05.

All weights of edges are set to 1 in the cross-modal graph. Further, **4) w/o** $\mathcal{S}^w$ represents without using affective knowledge; **5) w/o** $\mathcal{D}$ denotes without using syntax-aware information of text-modality in graph construction.

Further, to investigate the effectiveness of our **CMGCN** when used with different pre-trained models, we also set the following variants:

1) -GloVe+ResNet: We replace BERT with GloVe (Pennington et al., 2014) to initialize each word into a 300-dimensional embedding and ViT with ResNet-152 (He et al., 2016) to embed each image patch as a 2048-dimensional vector.

2) -GloVe+ViT: We use GloVe as text encoder and use ViT as image encoder.

3) -BERT+ResNet: We use BERT as text encoder and use ResNet-152 as image encoder.

5 Experimental Results

5.1 Main Results

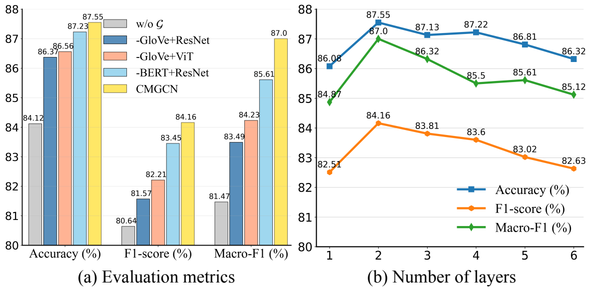
We report the comparison results regarding *Text-modality*, *Image-modality*, and *Text+Image modalities* in Table 2. From the results, we can draw the following conclusions. **1)** Our proposed **CMGCN** outperforms existing baselines across all metrics. This verifies the effectiveness of our proposed model in multi-modal sarcasm detection. **2)** We conduct significance tests of our **CMGCN** over the baseline models, the results show that our **CMGCN** significantly outperforms the baseline models in terms of most of the evaluation metrics (with $p-$value $<$ 0.05). **3)** Our CMGCN model performs consistently better than the previous graph-based method (InCrossMGs), which demonstrates that recognizing significant visual regions and modeling sentiment relations can lead to improved performance. **4)** The methods based on text modality achieve consistently better performance than the methods based on image modality, which shows that the expression of sarcastic/non-sarcastic information primarily resides in the text modality. **5)** Methods based on both image and text modalities perform better than the unimodal baselines overall. This implies that leveraging the information of both image and text modalities is more effective for multi-modal sarcasm detection. **6)** The results of macro metrics are better than other commonly used metrics overall, which indicates that models perform better in the "*negative*" class due to the imbalanced class distribution.

MODEL	*Acc. (%)*	*F1 (%)*	*Macro-F1 (%)*
CMGCN	**87.55**	**84.16**	**87.00**
w/o $\mathcal{G}$	84.12	80.64	81.47
w/o $\mathcal{O}$	84.55	81.09	82.31
w/o $\mathcal{S}$	85.63	81.82	83.28
w/o $\mathcal{S}^w$	86.54	82.73	84.76
w/o $\mathcal{D}$	87.25	83.64	86.13

Table 3: Experimental results of ablation study.

5.2 Ablation Study

To analyze the impact of different components of our proposed **CMGCN**, we conduct an ablation study and report the results in Table 3. Note that removal of cross-modal graph (w/o $\mathcal{G}$) sharply degrades the performance, which verifies the significance of cross-modal in multi-modal features fusion for learning sarcastic expressions in multi-modal sarcasm detection. Removal of object de-



(a) Evaluation metrics (b) Number of layers

Figure 3: Performance of using different pre-trained methods (a) and using different GCN layers (b).

tection (w/o $\mathcal{O}$) leads to considerable performance degradation, which demonstrates that adopting object detection to track important visual information is effective for constructing crucial relations between visual and textual information in the cross-modal graphs. From the results of w/o $\mathcal{S}$ and $\mathcal{S}^w$, we conclude that exploiting the *attribute-object* pair as a bridge to set edge weights based on word similarity is effective when constructing cross-modal graphs. Further, leveraging affective clues to capture multi-modal sentiment incongruity between text- and image-modality is effective in sarcasm detection, and thus leads to improved performance. In addition, removal of syntax-aware information of text-modality leads to slight performance degradation, which indicates that incorporating syntactic information in the graph makes better learning of dependency relations of textual words and thus improves the performance of sarcasm detection.

5.3 Generalizability of Cross-modal Graph

To investigate the generalizability and effectiveness of our proposed cross-modal graph when used with different pre-trained methods, we conduct experiments with five variants of our proposed **CMGCN** by using different text and image encoders. The experimental results are shown in Figure 3 (a). Note that the proposed cross-modal graph can directly work with various pre-trained models and performs consistently better than that without cross-modal graph (w/o $\mathcal{G}$). This demonstrates the generalizability and effectiveness of our proposed cross-modal graph in multi-modal sarcasm detection. Further, from the results, we can also conclude that superior performance is obtained when using more powerful pre-trained methods, such as ViT and BERT.

5.4 Impact of GCN Layers

In this section, we analyze the impact of the number of GCN layers on the performance of our proposed **CMGCN**. We vary the layer number from 1 to 6 and report the results in Figure 3 (b). Note that the 2-layer GCN architecture performs better than others overall, and thus the number of GCN layers is set to 2 in our model. Model with one layer performs worse, which indicates that a shallow graph network structure is not able to learn sarcastic features well. When the number of layers is greater than 2, the performance tends to decline. This shows that further increasing the number of layers beyond 2 degrades the model performance possibly due to the sharp increase of parameters.

(c) Attention visualization of the example learned by CMGCN.

Figure 4: Visualization of a typical example.

5.5 Visualization

To qualitatively investigate how the proposed **CMGCN** works in multi-modal sarcasm detection, we present a visualization of cross-modal graph construction and attention values of a multi-modal sarcasm example. The results are shown in Figure 4. We first show a sarcasm example and its corresponding object detection results in Figure 4 (a). Note that the correct label of this example can be easily inferred if the relations of crucial sarcastic clues of text (marked by the light red color) and the corresponding visual regions are captured by the model. To demonstrate how the proposed **CMGCN** identifies the important sarcastic clues, we show the adjacency matrix of the cross-modal graph of this example in Figure 4 (b). Note that highly correlated sarcastic clues in different modalities are connected by edges with large weights in the graph. This verifies the effectiveness of the proposed cross-modal graph in learning multi-modal sarcastic information. Further, based on the cross-modal graph, we show the attention visualization of this example in Figure 4 (c). The crucial textual tokens and the related image regions are highly attended by our proposed **CMGCN**, which helps identify the incongruity among the learned important features for learning sarcastic expressions and thus leads to improved performance of multi-modal sarcasm detection.

6 Conclusion and Future Work

This paper has proposed a novel cross-modal graph architecture for multi-modal sarcasm detection, in which the crucial visual regions can be explicitly connected to the highly correlated textual tokens for learning the incongruity sentiment of sarcastic expression. Specifically, unlike previous research efforts that simply consider the visual information of the whole image, we attempt to recognize the important visual regions via object detection results, and further devise a novel cross-modal graph to explicitly establish the connections of scattered visual regions and the associated textual tokens. More concretely, owing to the object detection results, the *attribute-object* pair descriptors of the objects are served as a bridge to track the highly related sarcastic cues between image and text modalities and their connection weights, and then deriving the cross-modal graphs based on external knowledge bases. Afterwards, a GCNs architecture based on a retrieval-based attention mechanism is employed to capture the key incongruity sentiment expressions across different modalities for multi-modal sarcasm detection. To the best of our knowledge, it is the first study of utilizing a cross-modal graph to extract intricate multi-modal sarcastic relations via object detection and sentiment cues from external knowledge bases. Extensive experiments on a public benchmark dataset show that our proposed approach significantly outperforms state-of-the-art baseline methods.

As described in Section 3.3, the weights of edges in the cross-modal graph are computed based on both word similarities and affective clues between textual words and the *attribute-object* pairs of the image regions, and the dependency tree of the text-modality. The approach can be easily generalized to other sentiment-related multi-modal learning scenarios. Nevertheless, the cross-graph solution might not be generalized well to other multi-modal tasks or data genres, if there is a lack of affective knowledge or a difficulty in deriving dependency trees in low-resource settings. Therefore, future research can consider exploiting alternatively approaches to automatically learn the weights of edges in the cross-modal graph without relying on external knowledge sources.

Composable Sparse Fine-Tuning for Cross-Lingual Transfer

Alan Ansell[1] **Edoardo Maria Ponti**[1,2] **Anna Korhonen**[1] **Ivan Vulić**[1]

Abstract

Fine-tuning the entire set of parameters of a large pretrained model has become the mainstream approach for transfer learning. To increase its efficiency and prevent catastrophic forgetting and interference, techniques like adapters and sparse fine-tuning have been developed. Adapters are *modular*, as they can be combined to adapt a model towards different facets of knowledge (e.g., dedicated language and/or task adapters). Sparse fine-tuning is *expressive*, as it controls the behavior of all model components. In this work, we introduce a new fine-tuning method with *both* these desirable properties. In particular, we learn sparse, real-valued masks based on a simple variant of the Lottery Ticket Hypothesis. Task-specific masks are obtained from annotated data in a source language, and language-specific masks from masked language modeling in a target language. Both these masks can then be composed with the pretrained model. Unlike adapter-based fine-tuning, this method neither increases the number of parameters at inference time nor alters the original model architecture. Most importantly, it outperforms adapters in zero-shot cross-lingual transfer by a large margin in a series of multilingual benchmarks, including Universal Dependencies, MasakhaNER, and AmericasNLI. Based on an in-depth analysis, we additionally find that sparsity is crucial to prevent both 1) interference between the fine-tunings to be composed and 2) overfitting. We release the code and models at `https://github.com/cambridgeltl/composable-sft`.

1 Introduction

Fine-tuning of pretrained models (Howard and Ruder, 2018; Devlin et al., 2019, *inter alia*) is arguably the dominant paradigm in NLP at present. Originally, "fine-tuning" involved supervised learning of all the parameters of a model pretrained on unlabeled texts. However, given the size of Transformer-based architectures, this approach is often time- and resource- inefficient, and may result in catastrophic forgetting and interference (Wang et al., 2020) during multiple adaptations. To overcome these limitations, two main alternatives have emerged: 1) through *adapters*, new parameters can be added to a pretrained model in the form of extra intermediate layers (Rebuffi et al., 2017; Houlsby et al., 2019) and fine-tuned while keeping all the pretrained parameters fixed; 2) *sparse* fine-tuning (SFT) of a small subset of pretrained model parameters (Guo et al., 2021; Zaken et al., 2021; Xu et al., 2021b, *inter alia*).

Adapters have proven especially useful in multilingual NLP (Bapna and Firat, 2019; Üstün et al., 2020; Pfeiffer et al., 2020b; Vidoni et al., 2020; Pfeiffer et al., 2021b; Ansell et al., 2021) because they exhibit a surprising degree of *modularity*. This ability to disentangle and recombine orthogonal facets of knowledge in original ways (Ponti et al., 2021; Ponti, 2021) allows for separately learning a task adapter from labeled data in a source language and dedicated language adapters from unlabeled data in the source language and target languages. By stacking these components, it is possible to perform zero-shot cross-lingual transfer. Compared to sequentially fine-tuning the full model on both the task and target language, this yields superior performance and efficiency (Pfeiffer et al., 2020b). Notably, achieving coverage over N_T tasks in N_L target languages with the sequential approach requires $N_T N_L$ models to be trained, whereas the modularity of adapters reduces this to $N_T + N_L$.

Meanwhile, the advantage of SFTs over adapters is their *expressivity*: rather than a non-linear transformation of the output of Transformer layers (e.g., using a shallow MLP as with adapters), they can operate directly on a pretrained model's embedding and attention layers. It therefore seems natural to search for a parameter-efficient fine-tuning method that is both modular and expressive.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1778 - 1796
May 22-27, 2022

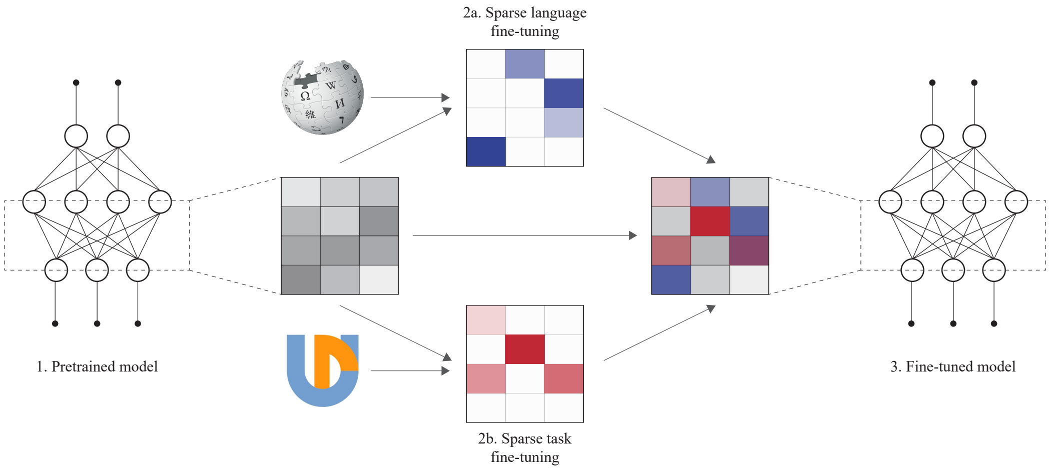

Figure 1: A graphical representation of Lottery Ticket Sparse Fine-Tuning: from the parameters of a pretrained model (gray, left), we generate sparse fine-tunings for task and language knowledge (blue and red, center). Finally, we sum these three components (right) to obtain the adapted/fine-tuned model. Best viewed in color.

To this end, we propose Lottery Ticket Sparse Fine-Tuning (LT-SFT), a simple and general-purpose adaptation technique inspired by the Lottery Ticket Hypothesis (LTH; Frankle and Carbin, 2019; Malach et al., 2020), which was originally conceived for pruning large neural networks. In particular, after fine-tuning a pretrained model for a specific task or language, we select the subset of parameters that change the most. Then, we rewind the model to its pretrained initialization (without setting any value to zero, contrary to the original LTH algorithm). By re-tuning again only the selected subset of parameters, we obtain a sparse fine-tuning in the form of a vector of differences with respect to the pretrained model. Multiple SFTs can be *composed* by simply summing them with the pretrained model. We provide a graphical representation of our method in Figure 1.

We benchmark LT-SFT on a series of multilingual datasets, including Universal Dependencies (Zeman et al., 2020) for part-of-speech tagging and dependency parsing, MasakhaNER (Adelani et al., 2021) for named entity recognition, and AmericasNLI (Ebrahimi et al., 2021) for natural language inference. We evaluate it in a zero-shot cross-lingual transfer setting on 35 typologically and geographically diverse languages that include both languages seen and unseen during masked language modeling of the pretrained model. The results in all transfer tasks indicate that LT-SFT consistently achieves substantial gains over the current state-of-the-art adapter-based method for cross-lingual transfer, MAD-X (Pfeiffer et al., 2020b).

In addition to its superior performance, modularity, and expressivity, LT-SFT offers a series of additional advantages over adapters: 1) the number of parameters remains constant, which prevents the decrease in inference speed observed when adapter layers are added; 2) the neural architecture remains identical to the pretrained model, which makes code development model-independent rather than requiring special modifications for each possible architecture (Pfeiffer et al., 2020a). Finally, 3) we empirically demonstrate that the peak in performance for LT-SFT is consistently found with the same percentage of tunable parameters, whereas the best reduction factor for MAD-X is task-dependent. This makes our method more robust to the choice of hyper-parameters.

In addition, we find that a high level of sparsity in language and task fine-tunings is beneficial to performance, as this makes overlaps less likely and poses a lower risk of creating interference between the knowledge they contain. Moreover, it makes fine-tunings less prone to overfitting due to their constrained capacity. Thus, sparsity is a fundamental ingredient for achieving modularity and composability. These properties in turn allow for systematic generalization to new combinations of tasks and languages in a zero-shot fashion.

2 Background

To establish a broader context for our research, we first provide a succinct overview of current methods for efficient fine-tuning, such as adapters and SFT. We then recapitulate the Lottery Ticket Hypothesis, upon which our newly proposed method is built.

Adapters and Composition. An *adapter* is a component inserted into a Transformer model with the purpose of specializing it for a particular language, task, domain, or modality (Houlsby et al., 2019). Previous work in multilingual NLP has mainly adopted the lightweight yet effective adapter variant of Pfeiffer et al. (2021a). In this setup, only one adapter module, consisting of a successive down-projection and up-projection, is injected per Transformer layer, after the feed-forward sub-layer. The adapter A_b at the b-th Transformer layer performs the following operation:

$$\mathrm{A}_b(\boldsymbol{h}_b, \boldsymbol{r}_b) = U_b\, \mathrm{a}(D_b \boldsymbol{h}_b) + \boldsymbol{r}_b. \qquad (1)$$

$\boldsymbol{h}_b$ and $\boldsymbol{r}_b$ are the Transformer hidden state and the residual at layer b, respectively. $D_b \in \mathbb{R}^{m \times h}$ and $U_b \in \mathbb{R}^{h \times m}$ are the down- and up-projections, respectively (h being the Transformer's hidden layer size, and m the adapter's dimension), and $\mathrm{a}(\cdot)$ is a non-linear activation function. The residual connection $\boldsymbol{r}_b$ is the output of the Transformer's feed-forward layer whereas $\boldsymbol{h}_b$ is the output of the subsequent layer normalization. During fine-tuning of a pretrained model with adapters, only the adapter parameters U and D are modified while the pretrained model's parameters are kept fixed.

In the MAD-X adapter composition framework for cross-lingual transfer (Pfeiffer et al., 2020b), a *language adapter* (LA) for a massively multilingual Transformer (MMT) is learned for each source and target language through masked language modeling (MLM), and a *task adapter* (TA) is learned for each target task, where the LA for the source language is inserted during TA training. At inference time, the task adapter and target language adapter are *composed* by stacking one on top of the other. This adapter composition approach has been shown to be highly effective for cross-lingual transfer (Pfeiffer et al., 2020b, 2021b; Ansell et al., 2021), especially for low-resource languages and target languages unseen during MMT pretraining.

Sparse Fine-Tuning. We call $F' = F(\cdot; \boldsymbol{\theta} + \boldsymbol{\phi})$ a *sparse fine-tuning* (SFT) of a pretrained neural model $F(\cdot; \boldsymbol{\theta})$ if $\boldsymbol{\phi}$ is sparse. We sometimes refer to $\boldsymbol{\phi}$ itself as an SFT, or as the SFT's *difference vector*. Previously proposed SFT methods include DiffPruning (Guo et al., 2021), BitFit (Zaken et al., 2021) and ChildTuning (Xu et al., 2021b). DiffPruning simulates sparsity of the difference vector during training by applying a continuous relaxation of a binary mask to it. BitFit on the other hand allows non-zero differences only for bias parameters. ChildTuning selects a subset of fine-tunable parameters by using Fisher information to measure the relevance of each parameter to the task. These methods have been shown to be competitive with full fine-tuning on GLUE (Wang et al., 2019), despite the difference vector $\boldsymbol{\phi}$ having fewer than 0.5% non-zero values.

Lottery Ticket Hypothesis. (LTH; Frankle and Carbin, 2019; Malach et al., 2020) states that each neural model contains a sub-network (a "winning ticket") that, if trained again in isolation, can match or even exceed the performance of the original model. To achieve this, after a pruning stage where some parameters are zero-masked and frozen according to some criterion (e.g., weight magnitude), the remaining parameters are restored to their original values and then re-tuned. This process of pruning and re-training can be iterated multiple times.

The LTH has so far been used mostly for model *compression* through network pruning; to our knowledge, we are the first to use it for pretrained model *adaptation*.

Multi-Source Task Training. Ansell et al. (2021) showed that training task adapters using data from multiple source languages can result in sizable improvements in downstream zero-shot transfer performance even when the total number of training examples is held constant. In their training setup, each batch consisted of examples from a single, randomly selected source language, the language adapter for which is activated for the duration of the training step.

3 Methodology

3.1 Lottery Ticket Sparse Fine-Tuning

Training. In this work, we propose Lottery Ticket Sparse Fine-Tuning (LT-SFT). Similar to the Lottery Ticket algorithm of Frankle and Carbin (2019), our LT-SFT method consists of two phases:

(Phase 1) Pretrained model parameters $\boldsymbol{\theta}^{(0)}$ are fully fine-tuned on the target language or task data $\mathcal{D}$, yielding $\boldsymbol{\theta}^{(1)}$. Parameters are ranked according to some criterion, in our case greatest absolute difference $|\theta_i^{(1)} - \theta_i^{(0)}|$, and the top K are selected for tuning in the next phase: a binary mask $\boldsymbol{\mu}$ is set to have 1 in positions corresponding to these parameters, and 0 elsewhere.

(Phase 2) After resetting the parameters to their

original values $\boldsymbol{\theta}^{(0)}$, the model is again fine-tuned, but this time only the K selected parameters are trainable whereas the others are kept frozen. In practice, we implement this by passing the *masked* gradient $\boldsymbol{\mu} \odot \nabla_{\boldsymbol{\theta}} \mathcal{L}(F(\cdot; \boldsymbol{\theta}), \mathcal{D})$ (where $\odot$ denotes element-wise multiplication and $\mathcal{L}$ a loss function) to the optimizer at each step. From the resulting fine-tuned parameters $\boldsymbol{\theta}^{(2)}$ we can obtain the sparse vector of differences $\boldsymbol{\phi} = \boldsymbol{\theta}^{(2)} - \boldsymbol{\theta}^{(0)}$.

In addition, we experiment with applying a regularization term which discourages parameters from deviating from their pretrained values $\boldsymbol{\theta}^{(0)}$. Specifically, we use L1 regularization of the form $J(\boldsymbol{\theta}) = \frac{\lambda}{N} \sum_i |\theta_i - \theta_i^{(0)}|$.

Composition. Although we often use the term "sparse fine-tuning" to refer to the difference vector $\boldsymbol{\phi}$ itself, an SFT is most accurately conceptualized as a functional which takes as its argument a parameterized function and returns a new function, where some sparse difference vector $\boldsymbol{\phi}$ has been added to the original parameter vector. Suppose we have a language SFT S_L and a task SFT S_T defined by

$$S_L(F(\cdot; \boldsymbol{\theta})) = F(\cdot; \boldsymbol{\theta} + \boldsymbol{\phi}_L)$$
$$S_T(F(\cdot; \boldsymbol{\theta})) = F(\cdot; \boldsymbol{\theta} + \boldsymbol{\phi}_T).$$

Then we have

$$S_L \circ S_T(F(\cdot; \boldsymbol{\theta})) = F(\cdot; \boldsymbol{\theta} + \boldsymbol{\phi}_T + \boldsymbol{\phi}_L).$$

3.2 Zero-Shot Transfer with LT-SFT

We adopt a similar cross-lingual transfer setup to MAD-X (Pfeiffer et al., 2020b, see also §2). We start with an MMT F with pretrained parameters $\boldsymbol{\theta}$ learned through masked language modeling on many languages, such as mBERT (Devlin et al., 2019) or XLM-R (Conneau et al., 2020).

For each language of interest l, we learn a language SFT $\boldsymbol{\phi}_L^{(l)}$ through LT-SFT (also with an MLM objective) on text from language l.

For each task of interest t, we learn a task SFT $\boldsymbol{\phi}_T^{(t)}$ through LT-SFT on annotated data from some source language s. When learning the task SFT, we first adapt to the source language by applying the language SFT for s.[1] The language SFT is removed again after training. That is, we perform LT-SFT on $F(\cdot\ ; \boldsymbol{\theta} + \boldsymbol{\phi}_L^{(s)})$ to obtain fine-tuned parameter vector $\boldsymbol{\theta}'$. We then calculate $\boldsymbol{\phi}_T^{(t)} = \boldsymbol{\theta}' - (\boldsymbol{\theta} + \boldsymbol{\phi}_L^{(s)})$. Note that during task training, we also learn a classifier head, which is fully fine-tuned during both phases of LT-SFT adaptation, with the same random initialization applied at the beginning of each phase.

We perform zero-shot adaptation of F to target language l for task t by composing language and task SFTs to obtain $F_{t,l} = F(\cdot\ ; \boldsymbol{\theta} + \boldsymbol{\phi}_T^{(t)} + \boldsymbol{\phi}_L^{(l)})$. On top of this, we stack the classifier head learned for t. For a formal algorithm of LT-SFT and the transfer procedure, we refer to Appendix A.

4 Experimental Setup

To evaluate our new method extensively, we benchmark its zero-shot cross-lingual performance on four distinct tasks: part-of-speech tagging (POS), dependency parsing (DP), named entity recognition (NER), and natural language inference (NLI). Table 1 summarizes our experimental setup, including the datasets and languages considered in our experiments. We put emphasis on low-resource languages and languages unseen during MMT pretraining, although we also evaluate on a few high-resource languages. In total, we cover a set of 35 typologically and geographically diverse languages, which makes them representative of cross-lingual variation (Ponti et al., 2019, 2020).

4.1 Baselines and Model Variants

The main baseline is MAD-X, the state-of-the-art adapter-based framework for cross-lingual transfer (Pfeiffer et al., 2020b). We use the "MAD-X 2.0" variant, where the last adapter layers are dropped. Pfeiffer et al. (2021b) found that this improved performance, which we could confirm in our preliminary experiments. Since adapters with the configuration used by Pfeiffer et al. (2020b) are unavailable for many languages in our evaluation, we train our own for all languages. In Appendix D we also provide an evaluation with comparable language adapters from AdapterHub (Pfeiffer et al., 2020a) where available.

We also perform experiments with BITFIT (Zaken et al., 2021) to establish a baseline for an existing SFT technique. In addition to the main LT-SFT model variant, on POS and DP we test a RAND-SFT variant as an ablation, where the K parameters to be fine-tuned are selected at random rather than based on an informed criterion.

---

[1] Adapting to the source language yields substantial improvements in cross-lingual transfer performance with both MAD-X and LT-SFT, with gains of 2-3 points in our preliminary experiments. Paradoxically, our results (see Table 7) and results from previous work (Pfeiffer et al., 2020b; Ansell et al., 2021) suggest that adapting to high-resource *target* languages at inference time does not give similarly large benefits. We think this phenomenon warrants further investigation.

Task	Target Dataset	Source Dataset	MMT	Target Languages
Part-of-Speech Tagging (POS), Dependency Parsing (DP)	Universal Dependencies 2.7 (Zeman et al., 2020)	Universal Dependencies 2.7 (Zeman et al., 2020)	mBERT	Arabic†, Bambara, Buryat, Cantonese, Chinese†, Erzya, Faroese, Japanese†, Livvi, Maltese, Manx, North Sami, Komi Zyrian, Sanskrit, Upper Sorbian, Uyghur
Named Entity Recognition (NER)	MasakhaNER (Adelani et al., 2021)	CoNLL 2003 (Tjong Kim Sang and De Meulder, 2003)	mBERT	Hausa, Igbo, Kinyarwanda, Luganda, Luo, Nigerian-Pidgin, Swahili*, Wolof, Yorùbá*
Natural Language Inference (NLI)	AmericasNLI (Ebrahimi et al., 2021)	MultiNLI (Williams et al., 2018)	XLM-R	Aymara, Asháninka, Bribri, Guarani, Náhuatl, Otomí, Quechua, Rarámuri, Shipibo-Konibo, Wixarika

Table 1: Details of the tasks, datasets, MMTs and languages involved in our zero-shot cross-lingual transfer evaluation. * denotes low-resource languages seen during MMT pretraining; † denotes high-resource languages seen during MMT pretraining; all other languages are low-resource and unseen. The source language is always English. Further details of all the language and data sources used are provided in Appendix B.

For both LT-SFT and MAD-X, we also evaluate a task adaptation (TA)-ONLY configuration, where only the task SFT/adapter is applied, without the target language SFT/adapter.

4.2 Language SFT/Adapter Training Setup

MLM Training Data. For all languages in our POS and DP evaluation, we perform MLM language SFT/adapter training on Wikipedia corpora. We also use Wikipedia for all languages in our NER evaluation if available. Where this is not the case, we use the Luo News Dataset (Adelani et al., 2021) for Luo and the JW300 corpus (Agić and Vulić, 2019) for Nigerian Pidgin. The main corpora for the languages in our NLI evaluation are those used by the dataset creators to train their baseline models (Ebrahimi et al., 2021); however, since the sizes of these corpora are restricted due to containing only parallel data, we augment them with data from Wikipedia and the corpora of indigenous Peruvian languages of Bustamante et al. (2020) where available. More details on data sources are provided in Appendix B.

Training Setup and Hyper-parameters. For both SFTs and adapters, we train for the lesser of 100 epochs or 100,000 steps of batch size 8 and maximum sequence length 256, subject to an absolute minimum of 30,000 steps since 100 epochs seemed insufficient for some languages with very small corpora. Model checkpoints are evaluated every 1,000 steps (5,000 for high-resource languages) on a held-out set of 5% of the corpus (1% for high-resource languages), and the one with the smallest loss is selected at the end of training. We use the AdamW optimizer (Loshchilov and Hutter, 2019) with an initial learning rate of $5e$-5 which is linearly reduced to 0 over the course of training.

Following Pfeiffer et al. (2020b), the reduction factor (i.e., the ratio between model hidden size and adapter size) for the adapter baseline was set to 2 for a total of ~7.6M trainable parameters. For comparability, we set the same number of trainable parameters K for our language LT-SFTs. This results in language SFTs with a sparsity of 4.3% for mBERT and 2.8% for XLM-R. Since BITFIT tunes exclusively the bias parameters, its language SFTs have a fixed sparsity of 0.047% for mBERT and 0.030% for XLM-R.

Importantly, during language sparse fine-tuning, we decouple the input and output embedding matrices and fix the parameters of the output matrix; otherwise, we find that the vast majority of the K most changed parameters during full fine-tuning belong to the embedding matrix, seemingly due to its proximity to the model output, which damages downstream performance. We also fix the layer normalization parameters; all other parameters are trainable. For language adaptation, we apply L1 regularization as described in §3.1 with $\lambda = 0.1$. Note that the specified training regime is applied in the same way during both phases of LT-SFT.

For language adapter training in the MAD-X baseline, we use the Pfeiffer configuration (Pfeiffer et al., 2021a) with invertible adapters, special additional sub-components designed for adapting to the vocabulary of the target language, which yields consistent gains.

4.3 Task SFT/Adapter Training Setup

For POS tagging, DP, and NER,[2] we train task SFTs/adapters on the datasets indicated in Table 1 for 10 epochs with batch size 8, except during the first phase of LT-SFT training where we train for only 3 epochs.[3] Model checkpoints are evaluated on the validation set every 250 steps, and the best checkpoint is taken at the end of training, with the selection metric being accuracy for POS, labeled attachment score for DP, and F1-score for NER. Similarly to language fine-tuning, we use an initial learning rate of $5e$-5 which is linearly reduced to 0 over the course of training. For POS and NER we use the standard token-level single-layer multi-class model head. For DP, we use the shallow variant (Glavaš and Vulić, 2021) of the biaffine dependency parser of Dozat and Manning (2017).

For NLI, we employ the same fine-tuning hyper-parameters as Ebrahimi et al. (2021): 5 epochs with batch size 32, with checkpoint evaluation on the validation set every 625 steps, and an initial learning rate of $2e$-5. We apply a two-layer multi-class classification head atop the MMT output corresponding to the `[CLS]` token.

We found that the number of trainable parameters during task adaptation (governed by K for SFTs and reduction factor for adapters) has a large effect on performance: we thus experiment with a range of values. Specifically, we test adapter reduction factors of 32, 16, 8, 4, 2, and 1, and equivalent values of K [4] for SFT.

During task adaptation, we always apply the source language adapter following Pfeiffer et al. (2020b), or source language SFT (see §3.2).

4.4 Multi-Source Training

To validate that task LT-SFT training, like task adapter training in prior work (Ansell et al., 2021), benefits from the presence of multiple source languages in the training data, and to push the boundaries of zero-shot cross lingual transfer, we perform multi-source training experiments on DP and NLI.

We adopt a similar setup to Ansell et al. (2021): we obtain the training set by concatenating the training data for all source languages. We randomly shuffle the training set and train as in the single-source case, except that each batch is composed of examples from a single source language, whose language SFT is applied during the training step.

We prioritize maximizing performance rather than providing a fair comparison against the single-source case, so unlike Ansell et al. (2021), we use the entirety of the training sets. In derogation of this principle, we set a maximum of 15K examples per language for DP to better balance our sample.

For DP, we train our models on the UD treebanks of 11 diverse high-resource languages. For NLI, we train on MultiNLI (Williams et al., 2018) plus the data for all 14 non-English languages in the XNLI dataset (Conneau et al., 2018).

We also evaluate multi-source task SFT training on extractive question answering (QA), as a comparatively generous amount of multilingual data is available for this task. Specifically, we train on English data from SQuAD version 1 (Rajpurkar et al., 2016), all languages from MLQA (Lewis et al., 2020), and those languages from XQuAD (Artetxe et al., 2020) which also appear in MLQA. We evaluate on the languages present in XQuAD but not in MLQA. For QA, we train for 5 epochs with batch size 12 and initial learning rate $3e$-5. Full details of the source languages can be found in Appendix B.

We use an equivalent reduction factor of 1 for all tasks, following the strongest setting from our single-source experiments. Except as stated above, the training configuration and hyper-parameters are the same as for single-source training.

5 Results and Discussion

We report the average test performance of zero-shot cross-lingual transfer for the best reduction factor (or equivalent K) in Table 2. Some patterns emerge across all four tasks: first, LT-SFT consistently outperforms all the baselines. In particular, it surpasses the state-of-the-art MAD-X across all tasks, with gains of 2.5 accuracy in part-of-speech tagging, 2.5 UAS and 3.7 LAS in dependency parsing, 1.8 F1 score in named entity recognition, and 1.9 accuracy in natural language inference. Compared to RAND-SFT, its superior performance demonstrates the importance of selecting "winning tickets" rather than a random subset

---

[2] MasakhaNER and CoNLL 2003 datasets respectively use the `DATE` and `MISC` tags which are not used by the other; we replace these with the `O` tag at both train and test time.

[3] This is because full fine-tuning is more prone to overfitting than sparse/adapter fine-tuning. Early stopping somewhat addresses overfitting, but it is insufficient in a cross-lingual setting because the target language performance generally starts to deteriorate faster than the source language performance.

[4] Approximately 442K, 884K, 1.7M, 3.5M, 7.1M, and 14.2M respectively, amounting to sparsity levels of 0.25%, 0.50%, 1.0%, 2.0%, 4.0% and 8.0% for mBERT and 0.16%, 0.32%, 0.63%, 1.3%, 2.6% and 5.1% for XLM-R.

Figure 2: Zero-shot cross-lingual transfer evaluation of Lottery-Ticket Sparse Fine-Tuning (LT-SFT), Random Sparse Fine-Tuning (rand-SFT), and adapter-based MAD-X over four tasks with varying numbers of trainable parameters during task adaptation. Results are averages over all target languages.

of parameters. Secondly, the results demonstrate the importance of language SFTs/adapters for specializing pretrained models to unseen languages, as they bring about a large increase in performance across the 4 tasks compared to the corresponding settings with task adaptation only (TA-only).

We remark that LT-SFT's zero-shot performance also exceeds translation-based baselines on the AmericasNLI task, achieving an average accuracy of 51.4%, compared with the 48.7% of the 'translate-train' baseline of Ebrahimi et al. (2021).

In Figure 2, we provide a more detailed overview of average cross-lingual model performance across a range of different reduction factors. The results for the LT-SFT and rand-SFT methods generally improve or stay steady as the number of trainable task parameters increases. On the contrary, there is not such a trend for MAD-X, as lower reduction factors may degrade its results. This makes it easier to choose a good setting for this hyper-parameter when using SFT. Moreover, it is worth stressing again that, contrary to MAD-X, this hyper-parameter does not affect inference time.

BitFit performs much worse than the other methods which perform language adaptation across all tasks. Bearing in mind the strong trend towards increasing performance with increasing K for the other SFT methods, it seems likely that BitFit, with two orders of magnitude fewer trainable parameters, lacks the capacity to learn effective task

and language SFTs.

For additional results at the level of individual languages and an analysis of the efficacy of language adaptation for high- versus low- resource target languages, we refer the reader to Appendix C.

5.1 Multi-Source Training

As shown in Table 4, multi-source LT-SFT training brings about a large improvement in zero-shot cross-lingual transfer performance on DP, and a modest improvement for NLI. This may be a result of the fact that the training set for NLI contains a relatively small number of non-English examples compared to the DP training set. Also, the AmericasNLI target languages generally have a lower degree of genealogical relatedness to the source languages compared to the DP target languages.

Table 3 demonstrates that multi-source training is also beneficial to zero-shot cross-lingual transfer for QA on a series of relatively high-resource languages. In particular, LT-SFT multi-source training of XLM-R Base outperforms single-source full fine-tuning of XLM-R Large (a larger model) comfortably, and outperforms XLM-R Base single-source full fine-tuning by a significant margin. The fact that such an improvement occurs despite each of the 6 non-English source languages having more than an order of magnitude less training data than the English data from SQuAD illustrates the disproportionate advantage of multilingual source data.

5.2 Benefits of Sparsity

Finally, we address the following question: is sparsity responsible for preventing the interference of separate fine-tunings when they are composed? To support this hypothesis with empirical evidence, we use LT-SFT to train language[5] and task fine-tunings with different levels of density, i.e. the percentage of non-zero values (from 5% to 100%). We then evaluate all possible combinations of density levels. The results are visualized in the form of a contour plot in Figure 3 for selected combinations of tasks and languages: Buryat, Cantonese, Erzya, Maltese, and Upper Sorbian for DP, and Hausa, Igbo, Luganda, Swahili and Wolof for NER.

---

[5] To reduce computational cost, we train language fine-tunings for a maximum of 30K steps rather than the 100K of our main experiments.

From Figure 3, it emerges that the performance decreases markedly for SFTs with a density level greater than ~30% of fine-tuned parameters.[6] We speculate that this is due to the fact that sparser fine-tunings have a lower risk of overlapping with each other, thus creating interference between the different facets of knowledge they encapsulate. It must be noted, however, that alternative hypotheses could explain the performance degradation in addition to parameter overlap, such as overfitting as a result of excessive capacity. While we leave the search for conclusive evidence to future work, both of these hypotheses illustrate why enforcing sparsity in adaptation, as we propose in our method, is crucial to achieving modularity.

6 Related Work

Within the framework of the Lottery Ticket Hypothesis, a series of improvements have been suggested to make the original algorithm to find winning tickets (Frankle and Carbin, 2019) more stable: after fine-tuning, Frankle et al. (2019) rewind the parameters to their values after a few iterations rather than their values before training, whereas Renda et al. (2020) also rewind the learning rate. In addition, Zhou et al. (2019) found that 1) different criteria can be used to select weights as an alternative to the magnitude of their change; 2) different rewinding methods are also effective, such as restoring the original sign, but not the value. In future work, we will investigate whether these variants also benefit our method for cross-lingual transfer, where the LTH is used for adaptation rather than pruning.

Whereas the LTH was originally conceived in the vision domain for convolutional architectures, it is also effective for pruning models trained on NLP tasks (Yu et al., 2020), such as neural machine translation, and based on Transformer architectures (Prasanna et al., 2020). Recently, Xu et al. (2021a) adapted the LTH specifically to prune pretrained models after fine-tuning.

To the best of our knowledge, Wortsman et al. (2020) is the only instance where winning tickets were composed in previous work. In their experiment, a set of task-specific masks were linearly combined at inference time, in order to generalize to new tasks in a continuous learning setting.

7 Conclusion and Future Work

We have presented a new method to fine-tune pretrained models that is both modular (like adapters) and expressive (like sparse fine-tuning). This method is based on a variant of the algorithm to find winning tickets under the framework of the Lottery Ticket Hypothesis. We infer a sparse vector of differences with respect to the original model for each individual language (by modeling unlabeled text) and each individual task (with supervised learning). The adaptations for a language and a task can then be composed with the pretrained model to enable zero-shot cross-lingual transfer. Comparing our method with the state-of-the-art baseline in several multilingual tasks, the results have indicated substantial gains across the board in both languages seen and unseen during pretraining (which includes many truly low-resource languages).

In future work, our method offers several potential extensions. In addition to the variants to the Lottery Ticket algorithm surveyed in §6, given the importance of sparsity for modularity (§5.2), we plan to experiment with additional algorithms previously applied to pruning that can identify and fine-tune a subset of the model parameters, such as DiffPruning (Guo et al., 2021) and ChildTuning (Xu et al., 2021b). Finally, given its simplicity and generality, our method is suited for many other applications of transfer learning in addition to cross-lingual transfer, such as multimodal learning, debiasing, and domain adaptation. The code and models are available online at `https://github.com/cambridgeltl/composable-sft`.

[6] Note, furthermore, that levels of task fine-tuning density greater than ~60% do not vary in performance. This is because their subsets of parameters include embeddings of tokens never encountered during task training, which are therefore never updated even if trainable.

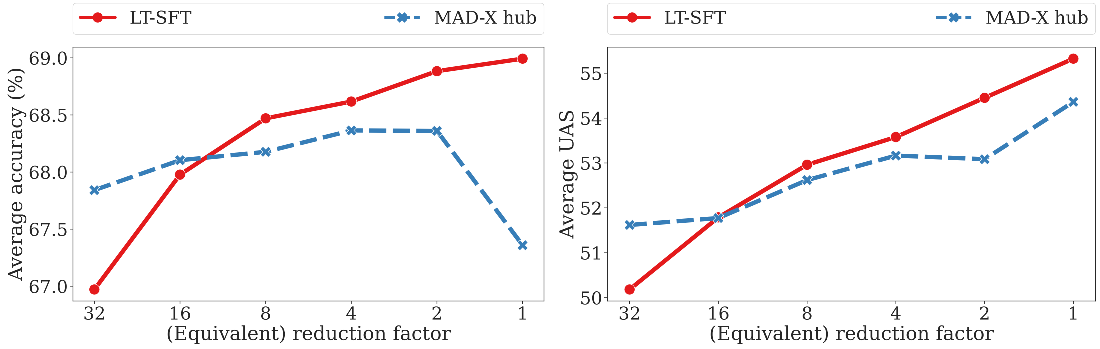
Table 7: Results for zero-shot cross-lingual transfer evaluation of the seen languages included in the POS, DP and NER evaluations. For each method/metric pair, the best equivalent reduction factor from Table 2 is used.

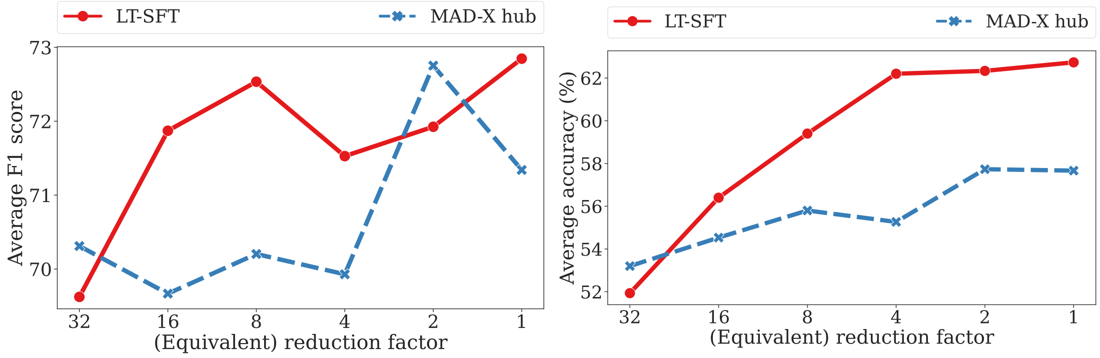
Arabic, Japanese and Chinese, which were included in the POS/DP evaluation, can be considered high-resource languages; Swahili and Yorùbá, on the other hand, were included in the NER evaluation and are arguably resource-poor. In keeping with previous work, we find that language adaptation benefits seen languages less than unseen languages and—among the former—resource-rich languages less than resource-poor languages. This agrees with the intuition that lower-resource languages have greater scope for improvement through language adaptation due to the fact that they receive less signal during MMT pretraining. Interestingly, BITFIT performs much more competitively on the high-resource languages than low-resource and unseen languages, suggesting that its lack of capacity is more problematic for language adaptation rather than for task fine-tuning.

D MAD-X Results with AdapterHub Adapters



(a) Part-of-Speech Tagging
(ar, bxr, ja, kpv, mt, myv, sme, ug, yue, zh)

(b) Dependency Parsing (DP)
(ar, bxr, ja, kpv, mt, myv, sme, ug, yue, zh)



(c) Named Entity Recognition (NER) (swa, wol)

(d) Natural Language Inference (NLI) (gn, quy)

Figure 4: Zero-shot cross-lingual transfer evaluation of Lottery-Ticket Sparse Fine-Tuning (LT-SFT) and MAD-X when pretrained language adapters from AdapterHub (Pfeiffer et al., 2020a) are used during task training and evaluation. These adapters are trained for 250,000 steps with a batch size of 64, as opposed to the 100,000 steps of batch size 8 used in our experiments. LT-SFT nevertheless maintains an edge in performance across all tasks. Since AdapterHub adapters are only available for some of the languages in our evaluation, the results shown are averaged over only the languages for which they are available, indicated in the subfigure captions.

E Parameter Overlap between Languages

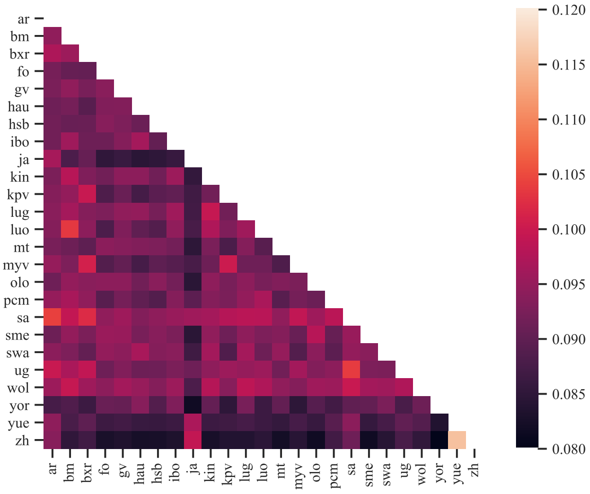


Figure 5: Percentage of parameters selected for the sparse fine-tuning of both languages in a pair.

In order to understand whether similar languages also share similar sub-networks, we plot the pairwise overlap (in percentage) between parameter subsets of language SFTs in Figure 5. Except for a single instance (Mandarin Chinese and Cantonese) where the high overlap reflects the fact that both languages are genealogically related, we find that the overlap is small for most language pairs. The explanation, we believe, is two-fold. Firstly, most of the languages in the multilingual datasets considered in our experiments belong to separate genera and families. Therefore, a lack of correlation in parameter subsets is expected. Secondly, for a pretrained model, there exist multiple parameter subsets ("winning tickets") with comparable performance (Prasanna et al., 2020). The Lottery Ticket algorithm selects randomly among these equally valid subsets. Hence, a lack of overlap does not necessarily imply the reliance on disjoint sub-networks.

Toward Annotator Group Bias in Crowdsourcing

Abstract

Crowdsourcing has emerged as a popular approach for collecting annotated data to train supervised machine learning models. However, annotator bias can lead to defective annotations. Though there are a few works investigating individual annotator bias, the group effects in annotators are largely overlooked. In this work, we reveal that annotators within the same demographic group tend to show consistent group bias in annotation tasks and thus we conduct an initial study on annotator group bias. We first empirically verify the existence of annotator group bias in various real-world crowdsourcing datasets. Then, we develop a novel probabilistic graphical framework **GroupAnno** to capture annotator group bias with an extended Expectation Maximization (EM) algorithm. We conduct experiments on both synthetic and real-world datasets. Experimental results demonstrate the effectiveness of our model in modeling annotator group bias in label aggregation and model learning over competitive baselines.

1 Introduction

The performance of supervised machine learning algorithms heavily relies on the quality of the annotated training data. Due to the heavy workload of annotation tasks, researchers and practitioners typically take advantage of crowdsourcing platforms to obtain cost-effective annotation data (Snow et al., 2008; Buhrmester et al., 2016). However, the labels collected from multiple crowdsourcing annotators could be not consistent, since the expertise and reliability of the annotators are uncertain, and the task itself could be subjective and difficult. In recent years, a lot of efforts from the machine learning community have been conducted to mitigate the effect of these noisy crowdsourcing labels (Zheng et al., 2017). Various approaches have been proposed to model the quality (Liu et al., 2012; Aydin et al., 2014), confidence (Joglekar et al., 2013), expertise (Ma et al., 2015; Zheng et al., 2016), reliability (Li et al., 2019) of annotators; or model the difficulty of the tasks (Whitehill et al., 2009; Ma et al., 2015). With such information, we can infer the truth label from the noisy labels more accurately and correspondingly train a more desirable model.

In terms of annotator modeling, existing studies mainly concentrated on factors like quality, confidence, expertise, etc., which could affect the annotation results. Besides, the bias held by the annotators can also lead to defective annotations (Sap et al., 2019), which is, however, rarely studied. In addition, studies in social science (Eagly, 2013) suggest that people from different demographic groups tend to apply different standards to evaluate the same thing due to their different experiences, which causes group bias. We observe that annotators in different demographic groups tend to show different bias in annotation tasks. For example, in a preliminary study, we examine the instances annotated by both two groups of annotators in the Wikipedia Toxicity dataset (Wulczyn et al., 2017). We observe that native speakers of English rate 5.1% more comments as toxic than non-native speakers. Similarly, annotators over 30 years old rate 2.5% more comments as toxic than younger annotators. More details of the preliminary study can be found in Section 2. Thus, a thorough investigation of such annotator group bias is desired. Similar to existing studies, by considering the effect of annotator group bias, we have the potential to achieve a more accurate inference of true labels and train a better model. Meanwhile, it is often hard to estimate the individual bias of one annotator with limited annotation data. With annotator group bias as the prior knowledge, we can estimate the bias more effectively based on the demographic groups the annotator belongs to. Thus, annotator group bias could mitigate the "cold-start" problem in modeling the annotator individual bias.

In this paper, we aim to study how to detect annotator group bias under text classification tasks, and how to mitigate the detrimental effects of annotator group bias on model training. We face several challenges. First, given noisy annotated data without the true labels, how should we detect the annotator bias? We first make a comparison of the annotation results from different groups of annotators and find that there is a significant gap between them. Then, we use two metrics *sensitivity* and *specificity* to measure the annotator bias, and conduct an analysis of variance (ANOVA) which demonstrates that the bias of each individual annotator shows obvious group effects in terms of its demographic attributes. Second, how can we estimate the annotator group bias, and perform label aggregation and model training with the knowledge of annotator group bias? Following the traditional probabilistic approaches for label aggregation (Raykar et al., 2010; Rodrigues and Pereira, 2018; Li et al., 2019), we propose a novel framework **GroupAnno** that models the production of annotations as a stochastic process via a novel probabilistic graphical model (PGM). Inspired by the results of ANOVA, we assume that the bias of an annotator can be viewed as a superposition of the effects of annotator group bias and its individual bias. We thereby extend the original PGM for label aggregation with additional variables representing annotator group bias. By learning the PGM, we estimate the annotator group bias, infer the true labels, and optimize our classification model simultaneously. Third, how can we learn this PGM effectively? With the unknown true label as the latent variable, typical maximum likelihood estimation (MLE) method cannot be directly applied to estimate the parameters. To address this challenge, we propose an extended EM algorithm for GroupAnno to effectively learn all the parameters in it, including the parameters of the classifier and the newly introduced variables for modeling annotator group bias.

We summarize our contributions in this paper as follows. First, we propose metrics to measure the annotator group bias and verify its existence in real NLP datasets via an empirical study. Second, we propose a novel framework GroupAnno to model the annotation process by considering the annotator group bias. Third, we propose a novel extended EM algorithm for GroupAnno where we estimate the annotator group bias, infer the true labels, and optimize the text classification model simultaneously. Finally, we conduct experiments on synthetic and real data. The experimental results show that GroupAnno can accurately estimate the annotator group bias. Also, compared with competitive baselines, GroupAnno can infer the true label more accurately, and learn better classification models.

2 Understanding Annotator Group Bias

In this section, we perform an empirical study to get a rudimentary understanding of annotator group bias.

2.1 Data and Tasks

We investigate the group annotator bias on three datasets that involve various text classification tasks. These datasets are released in the Wikipedia Detox project (Wulczyn et al., 2017): Personal Attack Corpus, Aggression Corpus, and Toxicity Corpus where each instance is labeled by multiple annotators from the Crowdflower platform [1]. For all the datasets, the demographic attributes of the annotators are collected. The data statistics of the three Wikipedia Detox datasets, i.e. Personal Attack, Aggression, and Toxicity are shown in Table 1, where "#Instances" indicates the total number of instances in a dataset; and "#Annotators" denotes the total number of annotators.

Table 1: Statistics of the datasets.

Dataset	#Instances	#Annotators
Personal Attack	115,864	2,190
Aggression	115,864	2,190
Toxicity	159,686	3,591

The Personal Attack dataset and the Aggression dataset contain the same comments collected from English Wikipedia. Each comment is labeled by around 10 annotators on two tasks, respectively. The task of the former dataset is to determine whether the comment contains any form of personal attack, while the task of the latter dataset is to judge whether the comment is aggressive or not. For each annotator, four demographic categories are collected: *gender*, *age*, *language*, and *education*. Although the original dataset provides more fine-grained partitions, for simplicity, we divide the annotators into only two groups in terms of

---

[1] `https://www.crowdflower.com/`

each demographic category [2]. We consider two groups: male and female for *gender*, under 30 and over 30 for *age*, below bachelor and above bachelor (including bachelor) for *education*, and native and non-native speaker of English for *language*. The toxicity dataset contains comments collected from the same source. Similarly, each comment is labeled by around 10 annotators on whether it is toxic or not. The toxicity dataset includes the same demographic information of the annotators as the former two datasets.

2.2 Empirical Study

To investigate whether the annotators from different groups behave differently in annotation tasks, we first perform a comparison of the annotation results from different annotator groups. For each demographic category, we collect the instances which are labeled by annotators from both groups, and report the proportion of instances that are classified as positive. The results are shown in Table 2. First, we note that there are obvious gaps between the annotations given by different annotator groups. Second, given that the tasks of the three datasets are similar (i.e., all of them are related to detecting inappropriate speech), the annotation tendency of each annotator group is the same. For example, young and non-native speaker annotators are less likely to annotate a comment as attacking, aggressive, or toxic. Third, in terms of different demographic categories, the gaps between the annotations from the two groups are different. For example, compared with other group pairs, the annotations provided by native speakers and non-native speakers are more different.

Analysis of Variance. The results in Table 2 suggest that annotators show group bias in the annotation tasks, which is manifested in that different groups hold different evaluation criteria in the same task. Specifically for classification tasks, different annotators are unevenly likely to label instances belonging from one class to another class. In this paper, we only consider binary classification tasks for simplicity [3]. Thus, we use *sensitivity* (true positive rate) and *specificity* (1 − false positive rate) (Yerushalmy, 1947) to describe the bias of an individual annotator.

Next, we seek to verify the existence of annotator group bias. We are interested in whether the demographic category of an individual annotator has a significant impact on its bias. Thus, we first estimate the bias (i.e., sensitivity and specificity) of each individual annotator from its annotation data. Since we don't have the true labels, we use majority vote labels as the true labels to approximately estimate the bias of each annotator. Then, we perform an ANOVA (Scheffe, 1999) with the demographic category as the factors, the groups as the treatments, and the bias of an annotator as the response variable, to analyze the significance of the annotator's demographic groups against its own bias. The corresponding statistical model can be expressed as:

$$\tilde{\pi}_r = u + \pi^{1,g_r^1} + \cdots + \pi^{P,g_r^P} + \epsilon_r \qquad (1)$$

where $\tilde{\pi}_r$ indicates the bias of an individual annotator r; u is the average bias of all annotators; π^{p,g_r^p} is the effect of the group g_r^p in terms of category p; and ϵ_r is the random error which follows a normal distribution with the mean value as 0. To test whether category p has a significant impact on $\tilde{\pi}$, we consider the null hypothesis $H_{0p} : \pi^{p,0} = \pi^{p,1}$, which indicates that the demographic category p has no significant effect on the annotator bias. In other words, there is no significant difference between the annotation behaviors of the two groups in terms of category p.

The results are shown in Table 3. In the table, we report the inter-group sum of squares, which represent the deviation of the average group bias from the overall average bias. We also use "$*$" to denote the significance of the hypothesis tests. We observe that in categories of gender, age and language, the two opposing groups show obvious different sensitivity and specificity in most cases. Moreover, the ANOVA suggests that we are confident to reject the null hypotheses in these cases, which means that the above three demographic categories can affect the annotator bias significantly in different datasets. Based on our observations, we conclude that the demographic attribute of an annotator can have a significant impact on its annotation behavior, and thereby, annotator group bias does exist.

3 Modeling Annotator Group Bias

In this section, we discuss our approaches for annotator group bias estimation, as well as bias-aware

---

[2] Based on our experiments, when considering more fine-grained groups, e.g. "18-30", "30-45" and "45-60" for *age*, the bias is also significant.

[3] All our findings and the proposed framework can be trivially extended to the case of multi-way classification.

Table 2: The positive rates of the annotations from different groups of annotators.

Dataset	Gender		Age		Education		Language	
	Male	**Female**	**Under 30**	**Over 30**	**Below Ba.**	**Above Ba.**	**Native**	**Non-native**
PersonalAttack	15.98	18.67	15.83	18.52	17.63	15.81	19.95	14.40
Aggression	17.74	21.44	17.79	20.85	20.28	17.62	23.20	16.08
Toxicity	12.06	16.37	12.51	15.08	15.16	12.56	16.93	11.80

Table 3: The results of analysis of variance. The table shows the inter-group sum of squares (variance of treatments). *, ** indicate that the group effects are significant at $p < 0.05$ and $p < 0.005$.

Category	Personal Attack		Aggression		Toxicity	
	Sensitivity	**Specificity**	**Sensitivity**	**Specificity**	**Sensitivity**	**Specificity**
Gender	0.010	0.077*	0.106	0.182**	0.217**	0.266**
Age	3.093**	0.257**	3.529**	0.348**	3.230**	0.005

label aggregation and model training. We first introduce the metrics for measuring annotator group bias, and then present the problem statement. Next, we detail **GroupAnno**, the probabilistic graphical model for modeling the production of annotations. Finally, we describe our extended EM algorithm for learning the proposed model.

3.1 Measurements

To measure the annotator bias in terms of demographic groups, we extend the definitions of sensitivity and specificity to the group scenario. Formally, we define *group sensitivity* and *group specificity* of a group g in terms of category p as follows

$$\alpha^{p,g} = Pr(z = 1|y = 1, g_r^p = g)$$
$$\beta^{p,g} = Pr(z = 0|y = 0, g_r^p = g)$$

where y is the true label and z is the annotated label. $g_r^p = g$ represents that the annotator r belongs to group g in terms of demographic category p.

We use $\pi^p = (\alpha^{p,0}, \alpha^{p,1}, \beta^{p,0}, \beta^{p,1})$ to denote the bias parameters of demographic category p. The bias parameters of all the P categories are denoted as $\pi = \{\pi^p\}_{p=1}^P$.

3.2 Problem Statement

Suppose that we have a dataset $\mathbf{D} = \{x_i, z_i^1, \cdots, z_i^{R_i}\}_{i=1}^N$ which contains N instances. Each instance x_i is annotated by R_i different annotators, which results in labels $z_i^1, \cdots, z_i^{R_i}$. We also have an annotator set $\mathbf{A} = \{(g_r^1, \cdots, g_r^P)\}_{r=1}^R$ that records the demographic groups of a total of R annotators. Here, $g_r^p \in \{0, 1\}$ indicates the group that the r-th annotator belongs to in terms of the p-th demographic category. We consider P demographic categories for each annotator, and we have two groups (i.e., 0 and 1) for each category. Given $\mathbf{D}$ and $\mathbf{A}$, we seek to (1) estimate the annotator group bias π; (2) estimate the true label y_i of each instance x_i; and (3) learn a classifier $P_{\mathbf{w}}(y|x)$ which is parameterized by $\mathbf{w}$.

Next, we introduce our GroupAnno to model the annotation process, and propose an extended EM algorithm to estimate the parameters $\Theta = \{\mathbf{w}, \pi\}$.

3.3 GroupAnno: The Probabilistic Graphical Model

As shown in Figure 1, GroupAnno models the generation procedure of annotations as follows. Given an instance x, its true label y is determined by an underlying distribution $P_{\mathbf{w}}(\cdot|x)$. The distribution is expressed via a classifier with parameters $\mathbf{w}$ that we will learn. Given the true label y, the annotated label z^r from an annotator r is determined by its bias $\tilde{\pi}_r = (\tilde{\alpha}_r, \tilde{\beta}_r)$. For simplicity, in the following formulations, we use $\tilde{\pi}_r$ to represent $\tilde{\alpha}_r$ or $\tilde{\beta}_r$. In Section 2.2, we show that the annotator bias can be modeled by a superposition of the effects of annotator group bias with a random variable reflecting the annotator individual bias. Thus, following Eq 1, we assume that the annotator bias of annotator r can be decomposed as

$$\tilde{\pi}_r = u + \pi^{1,g_r^1} + \cdots + \pi^{P,g_r^P} + \pi_r$$

To sum up, the parameters we introduced to model annotator bias are $\pi = \{u\} \cup \{\pi^p\}_{p=1}^P \cup \{\pi_r\}_{r=1}^R$. To estimate the parameters $\Theta = \{\mathbf{w}, \pi\}$, one way is to use maximum likelihood estimation. Under the assumption that instances are sampled

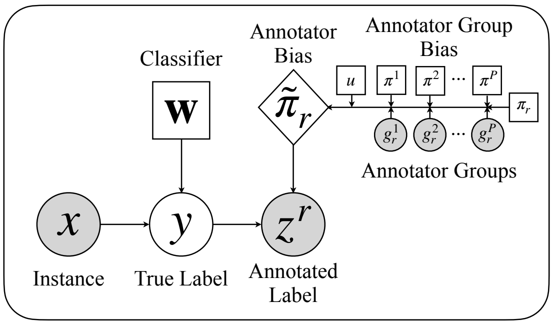

Figure 1: An illustration of GroupAnno. In the graph, grey circles represent observed data; a white circle indicates a latent variable; a diamond represents an intermediate variable; and squares denote the unknown parameters that we will learn.

independently, the likelihood function of Θ can be written as

$$P(\mathbf{D}|\mathbf{\Theta}) = \prod_{i=1}^{N} P(z_i^1, \cdots, z_i^{R_i}|x_i; \Theta)$$

Therefore, the MLE parameters can be found by maximizing the log-likelihood

$$\hat{\Theta}_{MLE} = \{\hat{\mathbf{w}}, \hat{\pi}\} = \text{argmax}_{\Theta} \ln P(\mathbf{D}|\Theta) \quad (2)$$

3.4 The extended EM algorithm

However, we cannot directly apply MLE to solve Eq 2, because there is an unknown latent variable (i.e. the true label y) in the probabilistic graphical model. Thus, we propose an extended EM algorithm to effectively estimate the parameters Θ in GroupAnno.

Since the true label y_i is an unknown latent variable, the log-likelihood term in Eq 2 can be decomposed as

$$\begin{aligned}&\ln P(\mathbf{D}|\Theta)\\&= \sum_{i=1}^{N} \ln[P_{\mathbf{w}}(y_i = 1|x_i) P(z_i^1, \cdots, z_i^{R_i}|y_i = 1; \tilde{\alpha})\\&+ P_{\mathbf{w}}(y_i = 0|x_i) P(z_i^1, \cdots, z_i^{R_i}|y_i = 0; \tilde{\beta})]\end{aligned}$$

where $\tilde{\alpha} = \{\tilde{\alpha}_r\}_{r=1}^{R}$ and $\tilde{\beta} = \{\tilde{\beta}_r\}_{r=1}^{R}$ represent the collections of the sensitivity and the specificity of all the annotators. We further assume that the annotations for one instance from different annotators are conditionally independent given their demographic attributes (Raykar et al., 2010). Then we have

$$\begin{aligned}&\ln P(\mathbf{D}|\Theta)\\&= \sum_{i=1}^{N} \ln \Big[P_{\mathbf{w}}(y_i = 1|x_i) \times \prod_{r=1}^{R_i} P(z_i^r|y_i = 1; \tilde{\alpha})\\&+ P_{\mathbf{w}}(y_i = 0|x_i) \times \prod_{r=1}^{R_i} P(z_i^r|y_i = 0; \tilde{\beta})\Big]\\&= \sum_{i=1}^{N} \ln[p_i a_i + (1 - p_i) b_i] \quad (3)\end{aligned}$$

where we denote

$$\begin{aligned}p_i &:= P_{\mathbf{w}}(y_i = 1|x_i)\\a_i &:= \prod_{r=1}^{R_i} P(z_i^r|y_i = 1; \tilde{\alpha}) = \prod_{r=1}^{R_i} \tilde{\alpha}_r^{z_i^r}(1 - \tilde{\alpha}_r)^{1 - z_i^r}\\b_i &:= \prod_{r=1}^{R_i} P(z_i^r|y_i = 0; \tilde{\beta}) = \prod_{r=1}^{R_i} (1 - \tilde{\beta}_r)^{z_i^r} \tilde{\beta}_r^{1 - z_i^r}\end{aligned}$$

Note that due to the existence of the latent variable y_i, Eq 3 contains the logarithm of the sum of two terms, which makes it very difficult to calculate its gradient w.r.t Θ. Thus, to solve the obstacle, we instead optimize a lower bound of $\ln P(\mathbf{D}|\Theta)$ via an EM algorithm.

E-step. Given the observation $\mathbf{D}$ and the current parameters Θ, we calculate the following lower bound of the real likelihood $\ln P(\mathbf{D}|\Theta)$

$$\begin{aligned}&\ln P(\mathbf{D}|\Theta) \geq \mathbb{E}_{\mathbf{y}}[\ln P(\mathbf{D}, \mathbf{y}|\Theta)]\\&= \sum_{i=1}^{N} \mu_i \ln p_i a_i + (1 - \mu_i) \ln(1 - p_i) b_i \quad (4)\end{aligned}$$

where $\mu_i = P(y_i = 1|z_i^1, \ldots, z_i^R, x_i, \Theta)$ and it can be computed by the Bayes' rule

$$\mu_i = \frac{a_i p_i}{a_i p_i + b_i(1 - p_i)} \quad (5)$$

M-step. In the M-step, we update the model parameters Θ by maximizing the conditional expectation in Eq 4

$$\Theta \leftarrow \Theta + \alpha \nabla_{\Theta} \mathbb{E}_{\mathbf{y}}[\ln P(\mathbf{D}, \mathbf{y}|\Theta)]$$

where α is the learning rate.

The training algorithm is summarized in Algorithm 1. We first initialize the posterior probability of the labels μ_i based on majority voting (line 1). Next, we perform the extended EM algorithm to update the model parameters iteratively. In the E-step, we update μ_i by Bayes' rule in Eq 5, and then calculate the expectation by Eq 4 (from lines 3 to 5). Afterward, we perform the M-step, where the gradients of the conditional expectation w.r.t the model parameters are calculated, and the model parameters are updated through gradient ascent. The iterative process is terminated when some specific stop requirements are satisfied. In our implementation, we execute the EM optimization steps for a fixed number of epochs.

Algorithm 1: The optimization algorithm.

```
Input: Dataset $\mathbf{D} = \{x_i, z_i^1, \cdots, z_i^{R_i}\}_{i=1}^N$,
       annotator set $\mathbf{A} = \{(g_r^1, \cdots, g_r^P)\}_{r=1}^R$.
Output: a text classification model $\mathbf{w}$, estimated
        annotator bias parameters $\pi$
1 Initialize $\mu_i = \frac{1}{R_i} \sum_{r=1}^{R_i} z_i^r$ based on majority
    voting.
2 repeat
3     E-step:
4     Update $\mu_i$: $\mu_i \leftarrow \frac{a_i p_i}{a_i p_i + b_i(1-p_i)}$
5     Calculate the expectation $\mathbb{E}_{\mathbf{y}}[\ln P(\mathbf{D}, \mathbf{y}|\Theta)]$
6     M-step:
7     Update the parameters $\Theta$ by maximizing the
        above expectation.
8     $\Theta \leftarrow \Theta + \alpha \nabla_{\Theta} \mathbb{E}_{\mathbf{y}}[\ln P(\mathbf{D}, \mathbf{y}|\Theta)]$
9 until meets stop requirements;
```

4 Experiment

In this section, we evaluate the proposed method via comprehensive experiments. We test our model on both synthetic and real-world data. Through the experiments, we try to answer three research questions: (1) is our method able to accurately estimate the annotator group bias? (2) can our method effectively infer the true labels? and (3) can our approach learn more accurate classifiers?

4.1 Baselines

We compare our proposed framework GroupAnno with eight existing true label inference methods (Zheng et al., 2017), including majority voting (MV), ZenCrowd (Demartini et al., 2012), Minimax (Zhou et al., 2012), LFC-binary (Raykar et al., 2010), CATD (Li et al., 2014a), PM-CRH (Aydin et al., 2014), KOS (Karger et al., 2011), and VI-MF (Liu et al., 2012).

4.2 Data

Synthetic Data. We first create two synthetic datasets on a simple binary classification task with 2-dimension features. As shown in Figure 2, the instances in the datasets are in the shape of circle and moon, respectively. In each dataset, we sample 400 instances for both classes. We simulate 40 annotators with two demographic attributes. We first randomly set the group bias for the two demographic attributes. Then, based on our assumed distribution that has been verified in Section 2, we sample the bias for each annotator. Finally, we suppose that each instance is labeled by 4 different annotators and simulate the annotations based on the sampled annotator bias. With the knowledge of actual annotator group bias and true labels in synthetic data, we can verify the capability of the proposed framework in group bias estimation and truth label inference.

Wikipedia Detox Data. We conduct experiments on all the three subsets (i.e. Personal Attack, Aggression, and Toxicity) of the public Wikipedia Detox dataset. The details of this dataset are introduced in Section 2.1. For the three subsets in the Wikipedia Detox Corpus, we use the training/test sets split by the publisher of the data (Wulczyn et al., 2017). Since there is no available ground-truth label in this dataset, we pick up a subset of instances in the test set on which more than 80% annotations reach an agreement and treat the MV label as the ground-truth label. These instances are less controversial, thus we are confident that the MV labels are true labels. We report the performance of the models trained under various label inference approaches on this set.

Information Detection Data. This dataset consists of text transcribed from conversations recorded in several in-person and virtual meetings. Each text is assigned an information label which groups the text into three categories: give information (G), ask information (A), and other (O). Five different data annotators classified the text into one of G, A, or O categories. We conducted a survey to collect data on demographic characteristics of the annotators such as gender, race, and native speaker of English. We convert the three categories into two classes by treating G and A as positive (i.e., information exchange) and O as negative (i.e., other). There are 2,483 instances in total in this dataset. After the annotation, we randomly select 762 instances and ask the annotators to discuss and reach an agreement on their labels. We treat these labels as true labels. We construct the training set with the remaining 1,721 instances without true labels, plus 430 of the instances with true labels. Thus, we have 20% training data with true labels, on which we will report the truth inference performance. The rest 332 instances with true labels make up our test set.

4.3 Implementation Details

For text classification tasks on the Wikipedia Detox data and the Information Detection data, we employ an one-layer recurrent neural network (RNN) with gated recurrent units (GRUs) as the classifier. In the RNN classifier, the word embedding size is set as 128 and the hidden size is set as 256. The classifier is optimized by an Adam optimizer (Kingma and Ba, 2014) with a learning rate of 0.001. When modeling annotator group bias, we consider 1-2 demographic categories with the most significant group effects. For the Personal Attack dataset and the Aggression dataset, we consider age and language. For the Toxicity dataset, we consider gender. For the Information Detection dataset, we consider language.

4.4 Results on Synthetic Data

Group Bias Estimation. In each of the synthetic datasets, we simulate the annotations based on presented annotator group bias. We simulate two demographic attributes for each annotator, where there are two groups in terms of each attribute. Thus, there are eight bias parameters to estimate: sensitivities $\alpha^{p,g}$ and specificities $\beta^{p,g}$, where $p = 0, 1$ and $q = 0, 1$. We compare the real values of the annotator group bias and the estimations from GroupAnno. The results are shown in Table 4. We observe that the bias parameters are estimated accurately within an acceptable error range. The results demonstrate the ability of our extended EM algorithm to estimate the parameters in GroupAnno.

Table 4: Results of group bias estimation on the synthetic 2-dimensional datasets. "Real" and "Estimation" indicate the real and the estimated values of the annotator group bias parameters.

Params	**Real**	**Estimation**	
		Circle	**Moon**
$\alpha^{0,0}$	0.700	0.739	0.728
$\alpha^{0,1}$	0.500	0.482	0.476
$\beta^{0,0}$	0.800	0.787	0.778
$\beta^{0,1}$	0.300	0.335	0.320
$\alpha^{1,0}$	0.900	0.927	0.943
$\alpha^{1,1}$	0.400	0.419	0.428
$\beta^{1,0}$	0.300	0.288	0.295
$\beta^{1,1}$	0.500	0.458	0.443

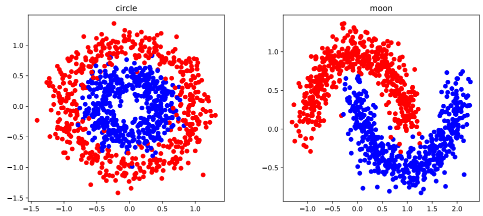

Figure 2: Two synthetic datasets with simulated 2-dimensional data.

Truth Label Inference. The experimental results of truth label inference on synthetic data are shown in Table 5. In the table, we list the performance of different approaches on truth label inference. We make the following observations. First, MV performs the worst among all the methods. In fact, a majority vote often does not mean the truth. By explicitly modeling the annotation behaviors of the annotators, an algorithm can infer the true labels more accurately than the majority vote. Second, the baselines Minimax and LFC-binary outperform other baselines. LFC-binary leverages PGM to model the individual annotator bias for truth label inference, which achieves desirable performance. Third, our framework GroupAnno further improves the accuracy of truth label inference on the basis of LFC-binary, since GroupAnno finds and exploits the group annotator bias as additional information. GroupAnno models the group annotator bias as prior information of the individual bias of each annotator so that individual bias can be estimated more accurately. As a result, GroupAnno achieves the best performance on truth label inference.

4.5 Results on Wikipedia Detox Dataset

The experimental results on the Wikipedia Detox datasets are shown in the left section of Table 6. For LFC-binary and GroupAnno, where truth label inference and model training are conducted simultaneously, we directly report the performance of the resulting model on the test set. For other pure truth label inference approaches, we first infer the truth labels and then train the model on the inferred labels. Finally, we report the performances of these models on the test set. The results show that GroupAnno achieves better performances than the state-of-the-art methods, which demonstrates the effectiveness and superiority of our framework in practice.

Table 5: Experimental results on the synthetic 2-dimensional datasets. “Acc” and “F1” indicate the accuracy and the F1 score of true label inference. In the table, we report the results averaged over 5 runs from different random seeds.

Methods	Circle		Moon	
	Acc	F1	Acc	F1
MV	0.728	0.722	0.748	0.744
ZenCrowd	0.894	0.886	0.904	0.898
Minimax	0.911	0.909	0.916	0.914
LFC-binary	0.911	0.909	0.916	0.914
CATD	0.851	0.844	0.861	0.853
PM-CRH	0.860	0.851	0.875	0.868
KOS	0.891	0.884	0.897	0.891
VI-MF	0.907	0.905	0.914	0.911
GroupAnno	**0.921**	**0.916**	**0.925**	**0.920**

4.6 Results on Information Detection Dataset

The experimental results on the information detection dataset are shown in the right section of Table 6. Since we have 20% training data with available true labels, we first examine the accuracy of truth label inference of various methods on this part of the data, and then report the performance of the trained classifiers on the test data. We find that our proposed method still outperforms all the baselines on both truth inference and resulting classifier performance, which further verifies the superiority of GroupAnno in real-world data.

5 Related Work

Bias and fairness issues are crucial as machine learning systems are being increasingly used in sensitive applications (Chouldechova and Roth, 2018). Bias is caused due to pre-existing societal norms (Friedman and Nissenbaum, 1996), data source, data labeling, training algorithms, and post-processing models. Data source bias emerges when the source distribution differs from the target distribution where the model will be applied (Shah et al., 2019). Training algorithms can also introduce bias. For example, if we train a model on data that contain labels from two populations - a majority and a minority population - minimizing overall error will fit only the majority population ignoring the minority (Chouldechova and Roth, 2018). Data labeling bias exists when the distribution of the dependent variable in the data source diverges from the ideal distribution (Shah et al., 2019). Many of these data labels are generated by human annotators, who can easily skew the distribution of training data (Dixon et al., 2018). Various factors such as task difficulty, task ambiguity, amount of contextual information made available, and the expertise of the annotator determine annotation results (Joseph et al., 2017).

Prior literature studies various approaches to ensure the reliability of data annotations. Demartini et al. (2012); Aydin et al. (2014) use worker probability to model the ability of an annotator to correctly answer a task, and some other works (Whitehill et al., 2009; Li et al., 2014b) introduce a similar concept, worker quality, by changing the value range from $[0, 1]$ to $(-\infty, +\infty)$. Welinder et al. (2010) model the bias and variance of the crowdsourcing workers on numeric annotation tasks. Moreover, Fan et al. (2015) and Ma et al. (2015) find that annotators show different qualities when answering different tasks, and thereby propose to model the diverse skills of annotators on various tasks. Li et al. (2019) realize that annotators perform unevenly on each annotation instance, so they propose a novel method to model the instance-level annotator reliability for NLP labeling tasks. Geva et al. (2019) use language generated by annotators to identify annotator identity and showed that annotator identity information improves model performance. All these studies have been individual-focused and ignore group effects. Our approach differs in that we study systemic bias associated with annotators of a specific demographic group.

6 Conclusion

In this work, we investigate the annotator group bias in crowdsourcing. We first conduct an empirical study on real-world crowdsourcing datasets and show that annotators from the same demographic groups tend to show similar bias in the annotation tasks. We develop a novel framework GroupAnno that considers the group effect of annotator bias, to model the whole annotation process. To solve the optimization problem of the proposed framework, we propose a novel extended EM algorithm. Finally, we empirically verify our approach on two synthetic datasets and four real-world datasets. The experimental results show that our model can accurately estimate the annotator group bias, achieve more accurate truth inference, and also train better classifiers that outperform those learned under state-of-the-art true label inference baselines. As future work, we plan to investigate the annotator group bias in tasks beyond classification such as regression tasks and text generation tasks.

Table 6: Expermental results on the Wikipedia Detox datasets and the Information Detection dataset. For Wikipedia Detox, we report the performances of the learned classifiers on the test data. For Information Detection, we report the performance on truth inference ("Truth Infer") as well as the performance of the learned classifiers on the test data ("Prediction"). We report the results averaged over 5 runs from different random seeds. For the results of Wikipedia Detox, we also show the 95% confidence intervals.

Under the Morphosyntactic Lens:
A Multifaceted Evaluation of Gender Bias in Speech Translation

Abstract

Gender bias is largely recognized as a problematic phenomenon affecting language technologies, with recent studies underscoring that it might surface differently across languages. However, most of current evaluation practices adopt a word-level focus on a narrow set of occupational nouns under synthetic conditions. Such protocols overlook key features of grammatical gender languages, which are characterized by morphosyntactic chains of gender agreement, marked on a variety of lexical items and parts-of-speech (POS). To overcome this limitation, we enrich the natural, gender-sensitive MuST-SHE corpus (Bentivogli et al., 2020) with two new linguistic annotation layers (POS and agreement chains), and explore to what extent different lexical categories and agreement phenomena are impacted by gender skews. Focusing on speech translation, we conduct a multifaceted evaluation on three language directions (English-French/Italian/Spanish), with models trained on varying amounts of data and different word segmentation techniques. By shedding light on model behaviours, gender bias, and its detection at several levels of granularity, our findings emphasize the value of dedicated analyses beyond aggregated overall results.

1 Introduction

As Matasović (2004) posits: "*Gender is perhaps the only grammatical category that ever evoked passion – and not only among linguists.*" That is because, in the case of human entities, masculine or feminine inflections are assigned semantically, i.e. in relation to the extra-linguistic reality of gender (Ackerman, 2019; Corbett, 1991, 2013). Thus, gendered features interact with the – sociocultural and political – perception and representation of individuals (Gygax et al., 2019), by prompting discussions on the appropriate recognition of gender groups and their linguistic visibility (Stahlberg et al., 2007; Hellinger and Motschenbacher, 2015; Hord, 2016). Such concerns also invested language technologies (Sun et al., 2019; Cao and Daumé III, 2020), where it has been shown that automatic translation systems tend to over-represent masculine forms and amplify stereotypes when translating into grammatical gender languages (Savoldi et al., 2021).

Current evaluation practices for assessing gender bias in both Machine (MT) and Speech Translation (ST) commonly inspect such concerning behaviours by focusing only on a restricted set of occupational nouns (e.g. *nurse*, *doctor*), and on synthetic benchmarks (Stanovsky et al., 2019; Escudé Font and Costa-jussà, 2019; Renduchintala et al., 2021). Also, even when relying on lexically richer natural benchmarks, the designed metrics still work at the word level, treating all gender-marked words indiscriminately (Alhafni et al., 2020; Bentivogli et al., 2020). Accordingly, current test sets and protocols: *i)* do not allow us to inspect if and to what extent different word categories participate in gender bias, *ii)* overlook the underlying morphosyntactic nature of grammatical gender on agreement chains, which cannot be monitored on single isolated words (e.g. *en*: a strange friend; *it*: un<u>a/o</u> stran<u>a/o</u> amic<u>a/o</u>). In fact, to be grammatically correct, each word in the chain has to be inflected with the same (masculine or feminine) gender form.[1]

We believe that fine-grained evaluations including the analysis of gender agreement across different parts of speech (POS) are relevant not only to gain a deeper understanding of bias in grammatical gender languages, but also to inform mitigating strategies and data curation procedures.

Toward these goals, our contributions are as follows. **(1)** We enrich MuST-SHE (Bentivogli et al., 2020) – the only natural gender-sensitive benchmark available for MT and also ST – with two layers of linguistic information: POS and agreement

---

[1] For an analogy, consider the case of (lack of) number agreement in the following: "*a dogs barks".

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1807 - 1824

chains.[2] **(2)** In light of recent studies exploring how model design and overall perfomance interplay with gender bias (Roberts et al., 2020; Gaido et al., 2021), we rely on our manually curated resource to compare three ST models, which are trained on varying amounts of data, and built with different segmentation techniques: character and byte-pair-encoding (BPE) (Sennrich et al., 2016).

We carry out a multifaceted evaluation that includes automatic and extensive manual analyses on three language pairs (en-es, en-fr, en-it) and we consistently find that: *i)* not all POS are equally impacted by gender bias; *ii)* translating words in agreement does not emerge as a systematic issue; *iii)* ST systems produce a considerable amount of neutral rewordings in lieu of gender-marked expressions, which current binary benchmarks fail to recognize. Finally, in line with concurring studies, we find that *iv)* character-based systems have an edge on translating gender phenomena, by favouring morphological and lexical diversity.

2 Background

While research in Natural Language Processing (NLP) initially prioritized narrow technical interventions to address the social impact of language technologies, we are recently attesting a shift toward a more comprehensive understanding of bias (Shah et al., 2020; Blodgett et al., 2020). Along this line, focus has been given to bias analysis in models' innards and outputs (Vig et al., 2020; Costa-jussà et al., 2022), and to ascertain the validity of bias measurement practices (Blodgett et al., 2021; Antoniak and Mimno, 2021; Goldfarb-Tarrant et al., 2021). Complementary mounting evidence suggests that – rather than striving for generalizations – gender bias detection ought to incorporate contextual and linguistic specificity (González et al., 2020; Ciora et al., 2021; Matthews et al., 2021; Malik et al., 2021; Kurpicz-Briki and Leoni, 2021), which however receives little attention due to a heavy focus on English NLP (Bender and Friedman, 2018). Purported agnostic approaches and evaluations (Bender, 2009) can prevent from drawing reliable conclusions and mitigating recommendations, as attested by monolingual studies on grammatical gender languages (Zhou et al., 2019; Gonen et al., 2019; Zmigrod et al., 2019) and in automatic translation scenarios (Vanmassenhove et al., 2018; Moryossef et al., 2019).

Src-En	Because where else would ***she*** **feel safe** and **represented** and **liberated** but a university dedicated to **the first Puerto Rican** ***woman*** **nominated** to the Supreme Court of the United States?

Figure 1: Example of gender-mapping in translation from the parallel en-it portion of the natural MuST-SHE corpus. Unlike English, where gender is only expressed on few lexical and pronominal items (*she*, *woman*), in a grammatical gender language like Italian, gender inflections (here feminine -a) are expressed on several linguistic items (e.g. verb-*sentita*, adjective-*sicura*) that are in agreement.

Unlike English, grammatical gender languages exhibit an elaborate morphological and syntactic system, where gender is overtly marked on numerous POS (e.g., verbs, determiners, nouns), and related words have to agree on the same gender features (see Figure 1 for an example). Still, current corpora and evaluation practices do not fully foreground systems' behaviour on such grammatical constraints.

WinoMT (Stanovsky et al., 2019) represents the standard corpus to evaluate gender bias in MT within an English-to-grammatical gender language scenario. It has been progressively enriched with new features (Saunders et al., 2020; Kocmi et al., 2020), and adapted for ST (Costa-jussà et al., 2020). While this resource can be useful to diagnose gender stereotyping at scale, it excludes languages' peculiarities since it is built on the concatenation of two corpora designed for English monolingual tasks[3] – WinoGender (Rudinger et al., 2018) and WinoBias (Zhao et al., 2018) – which consist of synthetic sentences with the same structure and a pre-selected occupational lexicon (e.g. "The lawyer yelled at the **hairdresser** because *he* did a bad job").[4] To increase variability, Troles and Schmid (2021) extend WinoBias by accompanying occupations with highly gender-stereotypical verbs

---

[2] The annotation layers are an extension of MuST-SHE v1.2 and are freely downloadable at: `ict.fbk.eu/must-she/` under the same MuST-SHE licence (CC BY NC ND 4.0)

[3] González et al. (2020) note that the U.S. labor market statistics employed to define stereotypical associations are not always in line with other national gender statistics, thus they may impose an Anglo-centric frame for the detection of bias in other language scenarios.

[4] Levy et al. (2021) recently created BUG on natural English data, but still it is limited to the evaluation of occupations.

and adjectives. Their evaluation though, still only considers the translated professions as to verify if the co-occuring words might skew the models' assumptions. However, gender-marking involves also several other, so far less accounted POS categories, but if they are just as problematic is not clear yet.

Existing bilingual (Alhafni et al., 2021), and multilingual (Bentivogli et al., 2020) natural benchmarks, instead, are manually curated as to identify a variety of gender phenomena specifically modeled on the accounted languages. As a result, they maximize lexical and contextual variability to inspect whether translation models yield feminine under-representation in real-world-like scenarios (Savoldi et al., 2021). However, since this variability is not mapped into fine-grained linguistic information, evaluations on such corpora do not single out which instances may be more responsible for gender bias. Finally, by considering each word in isolation, they neglect the underlying features of gender agreement, which determine the grammatical acceptability of the translation.

To the best of our knowledge, only two works have currently interplayed issues of syntactic agreement and gender bias. Renduchintala and Williams (2021) designed a set of English sentences involving a syntactic construction that requires to translate an occupational term according to its unequivocal "gender trigger" (e.g. that *nurse* is a funny man). While they find that MT struggles even in such a simple setting, they only inspect the translation of a single disambiguated word (*nurse*) rather than a whole group of words in agreement. Closer to our intent, Gaido et al. (2020) analyze the output of different ST systems and note that their models seem to wrongly pick divergent gender inflections for unrelated words in the same sentence (e.g. *en*: As a researcher, professor; *fr*: En tant que chercheuse$_F$, professeur$_M$) but not for dependency-related ones (e.g. *en*: The classic Asian student; *it*: [La classica studentessa asiatica]$_F$). Although limited in scope, their observation is worth being explored systematically. We thus conduct the very first study that intersects POS, agreement, and gender bias.

Table 1: MuST-SHE target **gender-marked words** annotated per $_{POS}$ and [agreement chains]. For the sake of simplicity, the alternative <*wrong* gender-marked words> are not shown.

3 MuST-SHE Enrichment

In light of the above, a fine-grained evaluation of bias focused on POS and gender agreement requires the creation of a new dedicated resource. Rather than building it from scratch, we add two annotation layers to the existing MuST-SHE benchmark (Bentivogli et al., 2020), which is built on spoken language data retrieved from TED talks. Available for en-es/fr/it, it represents the only multilingual MT and ST *GBET*[5] exhibiting a natural variety of gender phenomena, which are balanced across feminine and masculine forms.

In the reference translations of the corpus, each target gender-marked word – corresponding to a neutral expression in the English source – is annotated with its alternative *wrong* gender form (e.g. *en*: ***the*** *girl* ***left***; *it*: ***la<il>*** *ragazza è* ***andata<andato>*** *via*). As further discussed in in Section 4.2, such a feature enables fine-grained analyses of gender realization, which can also disentangle systems' tendency to (over)generate masculine – over feminine forms – in translation.

MuST-SHE thus allows the identification and pinpointed evaluation of numerous and qualitatively different grammatical gender instances under authentic conditions. Furthermore, the target languages covered in MuST-SHE (es, fr, it) are particularly suitable to focus on linguistic specificity. As a matter of fact, as Gygax et al. (2019) suggest, accounting for gender in languages with similar typological features allows for proper comparisons.[6]

---

[5] *Gender Bias Evaluation Testset* (Sun et al., 2019).

[6] We underscore that our dedicated resources and experiments intentionally account for the specificities of three (comparable) grammatical gender languages. Hence, we remain cautious of extending by default the results of our annotation and experiments to any other language.

3.1 Phenomena Categorization

Parts-Of-Speech. We annotate each target gender-marked word in MuST-SHE with POS information. As shown in Table 1 (*a-c*), we differentiate among six POS categories:[7] ***i)*** articles, ***ii)*** pronouns, ***iii)*** nouns, and ***iv)*** verbs. For adjectives, we further distinguish ***v)*** limiting adjectives with minor semantic import that determine e.g. possession, quantity, space (*my*, *some*, *this*); and ***vi)*** descriptive adjectives that convey attributes and qualities, e.g. *glad*, *exhausted*. This distinction enables to neatly sort our POS categories into the closed class of function words, or into the open one of content words (Schachter and Shopen, 2007). Since words from these two classes differ substantially in terms of variability, frequency, and semantics, we reckon they represent a relevant variable to account for in the evaluation of gender bias.

Agreement. We also enrich MuST-SHE with linguistic information that is relevant to investigate the morphosyntactic nature of grammatical gender agreement. Gender agreement, or *concord* (Corbett, 2006; Comrie, 1999), requires that related words match the same gender form, as in the case of *phrases*, i.e. groups of words that constitute a single linguistic unit.[8] Thus, as shown in Table 1, we identify and annotate as agreement chains gender-marked words that constitute a phrase, such as a noun plus its modifiers (*d*), and verb phrases for compound tenses (*e*). Also, structures that involve a gender-marked (semi-) copula verb and its predicative complement are annotated as chains (*f*), although in such cases the agreement constraint is "weaker".[9] This annotation lets us verify whether a model consistently picks the same gender paradigm for all words in the chain, enabling the assessment of its syntagmatic behaviour.

3.2 Manual annotation

POS and agreement annotation was manually carried out by 6 annotators (2 per language pair) undergoing a linguistics/translation studies MA degree, and with native/excellent proficiency in the assigned target language. For each language pair, they annotated the whole corpus independently, based on detailed guidelines (see Appendix A). For POS, we computed inter-annotator agreement (IAA) on label assignment with the kappa coefficient (in Scott's π formulation) (Scott, 1955). The resulting values of 0.92 (en-es), 0.94 (en-fr) and 0.96 (en-it) correspond to "almost perfect" agreement according to its standard interpretation (Landis and Koch, 1977). For gender agreement, IAA was calculated on the exact match of the complete chains in the two annotations. The resulting Dice coefficients (Dice, 1945) of 89.23% (en-es), 93.0% (en-fr), and 94.34% (en-it), can be considered highly satisfactory given the more complex nature of this latter task. Except for few liminal cases that were excluded from the dataset, all disagreements were reconciled.

	en-es	**en-fr**	**en-it**	**M-SHE All**
POS (tot)	2099	1906	2026	6031
Art	487	325	413	1225
Pronoun	104	61	48	213
Adj-det	118	106	149	373
Adj-des	676	576	448	1700
Noun	607	344	346	1297
Verb	107	494	622	1223
AGR-CHAINS	420	293	421	1080

Table 2: Distribution of POS and agreement chains per each language and in the whole MuST-SHE corpus.

We show the final annotation statistics in Table 2. Variations across languages are due to inherently cross-lingual differences.[10] While their discussion is beyond the scope of this work, overall these figures underscore the so far largely unaccounted variability of gender across lexical categories.

4 Experimental Setting

4.1 Speech Translation models

Our experiments draw on studies exploring the relation between overall system performance, model size and gender bias. Vig et al. (2020) posit that bias increases with model size as larger systems better emulate biased training data. Working on WinoMT/ST, Kocmi et al. (2020) correlate higher BLEU scores and gender stereotyping, whereas Costa-jussà et al. (2020) show that systems with lower performance tend to produce fewer feminine translations for occupations, but rely less on stereotypical cues. To account for these findings and inspect the behavior of different models under natural conditions, we experiment with three end-to-end

---

[7] Some POS categories (e.g. conjunctions, adverbs) are not considered since they are not subject to gender inflection.

[8] If agreement is not respected, the unit becomes ungrammatical e.g. *es*: *el$_M$ buen$_M$ ninã$_F$ (*en:* the good kid).

[9] Such structure, due to the semantics of some linking verbs, can enable more flexibility. E.g. in French, *Elle est devenue*$_F$ *un*$_M$ *canard*$_M$ (*She became a duck*) is grammatical, although *un canard* (a duck) is formally masculine.

[10] Spanish, for instance, relies less than French or Italian on the gender-enforcing *to be* auxiliary, resulting in less gender-marked verbs (*fr*: est parti/ie; *it*: è partita/o; *es*: se ha ido).

ST solutions, namely: LARGE-BPE, SMALL-BPE, and SMALL-CHAR (see Appendix B for complete details about the models and training setups).

Developed to achieve state-of-the-art performance, **LARGE-BPE** models rely on Transformer (Vaswani et al., 2017) and are trained in rich data conditions (1.25M ASR/ST utterances) by applying BPE segmentation (Sennrich et al., 2016). To achieve high performance, we made use of: *i)* all the available ST training corpora for the languages addressed, namely MuST-C (Cattoni et al., 2021) and Europarl-ST (Iranzo-Sánchez et al., 2020); *ii)* consolidated data augmentation methods (Nguyen et al., 2020; Park et al., 2019; Jia et al., 2019); and *iii)* knowledge transfer techniques from ASR and MT, namely component pre-training and knowledge distillation (Weiss et al., 2017a; Bansal et al., 2019).[11] In terms of BLEU score – 34.12 on en-es, 40.3 on en-fr, 27.7 on en-it – our LARGE-BPE models compare favorably with recently published results on MuST-C test data (Le et al. 2021[12] and Bentivogli et al. 2021[13]).

Also built with the same (Transformer-based) core technology, the other systems, **SMALL-BPE** and **SMALL-CHAR**, allow for apples-to-apples comparison between the different capabilities of BPE and character-level tokenization, namely: *i)* the syntactic advantage of BPE in managing several agreement phenomena (Sennrich, 2017; Ataman et al., 2019), and *ii)* the higher capability of character-level at generalizing morphology (Belinkov et al., 2020). Given the morphological and syntactic nature of gender, such differences make them enticing candidates for further analysis. So far, Gaido et al. (2021) carried out the only study interplaying the two segmententation methods and gender bias, and found that – in spite of lower overall performance – character tokenization results in higher production of feminine forms for ST. By exploiting our new enriched resource, we intend to further test this finding and extend the analysis to gender agreement. Thus, for the sake of comparison with (Gaido et al., 2021), we train these systems in the same (controlled) data conditions i.e. on the MuST-C corpus only.

4.2 Evaluation method

We employ the enriched MuST-SHE corpus to assess generic performance and gender translation at several levels of granularity. Evaluating gender translation under natural conditions grants the advantage of inspecting diverse informative phenomena. Concurrently, however, the intrinsic variability of natural language can defy automatic approaches based on reference translations: Since language generation is an open-ended task, in our specific setting system's outputs may not contain the exact gender-marked words annotated in MuST-SHE. In fact, the released MuST-SHE evaluation script (Gaido et al., 2020) first measures dataset *coverage*, i.e. the proportion of annotated words that are generated by the system, and on which gender translation is hence measurable. Then, it calculates *gender accuracy* as the proportion of words generated in the correct gender among the measurable ones. As a result, all the *out of coverage* words are necessarily left unevaluated.

For all **word-level** gender evaluations (Sections 5.1 and 5.2), we compute accuracy as in the official MuST-SHE script and include scores based on the POS annotations. Instead, for **chain-level** gender agreement evaluation (Section 6.1) we modified the original script to process full agreement chains instead of single words.[14]

Finally, since we aim at gaining qualitative insights into systems' behaviour, and at ensuring a sound and thorough multifaceted evaluation, we overcome the described coverage limitation of the automatic evaluation by complementing it with a manual analysis of *all* the gender-marked words and agreement chains that remained out of coverage. This extensive manual evaluation was carried out via a systematic annotation of systems' outputs, performed by the same linguists that enriched MuST-SHE, who provided the appropriate knowledge of both the resource and the evaluation task. Accordingly, we manage to make our study completely exhaustive by covering every gender-marked instance of MuST-SHE. Also, such additional manual evaluation serves as a proof-of-concept to ensure the validity of the employed automatic evaluation metrics.

---

[11] We are aware that both MuST-C and Europarl-ST are characterized by a majority (70%) of masculine speakers (Gaido et al., 2020; Vanmassenhove et al., 2018). Although comprehensive statistics are not available for the other ASR and MT training resources, we can reasonably assume they are similarly biased.

[12] 28.73 on en-es, 34.98 on en-fr, 24.96 on en-it.

[13] 32.93 on en-es, 28.56 on en-it.

[14] The scripts are released together with the MuST-SHE annotated extensions.

		BLEU	All-Cov	All-Acc	F-Acc	M-Acc

5 Word-level Evaluation

5.1 Overall quality and gender translation

Table 3 presents SacreBLEU (Post, 2018),[15] coverage, and gender accuracy scores on the MuST-SHE test sets. All language directions exhibit a consistent trend: LARGE-BPE systems unsurprisingly achieve by far the highest overall translation quality. Also, in line with previous analyses (Di Gangi et al., 2020), SMALL-BPE models outperform the CHAR ones by ~1 BLEU point. The higher overall translation quality of LARGE-BPE models is also reflected by the coverage scores (All-Cov), where they generate the highest number of MuST-SHE gender-marked words for all language pairs.

By turning to overall gender accuracy (All-Acc) though, the edge previously assessed for the bigger state-of-the-art systems ceases to be clear-cut. For en-es and en-fr, LARGE-BPE systems outperform the concurring SMALL-CHAR by ~2 points only – a slim advantage compared to the large gap observed on BLEU score. Moreover, for en-it, SMALL-CHAR proves the best at translating gender.

We further zoom into the comparison of gender translation for feminine (F-Acc) and masculine (M-Acc) forms, where we can immediately assess that all ST models are skewed toward a disproportionate production of masculine forms (on average, 53.1% for F vs. 81.3% for M). However, focusing on LARGE-BPE models, we discover that their higher global gender accuracy (All-Acc) is actually due to the higher generation of masculine forms, while they do not compare favorably when it comes to feminine translation. In fact, in spite of achieving the lowest generic translation quality, SMALL-CHAR prove on par (for en-es) or even better (for en-it and en-fr) than LARGE-BPE models at handling feminine gender translation.

In light of the above, our results reiterate the importance of dedicated evaluations that, unlike holistic metrics, are able to disentangle gender phenomena. As such, we can confirm that higher generic performance does not entail a superior capacity of producing feminine gender. This does not only emerge, as per Gaido et al. (2021), in the comparison of (small) BPE- and char-based ST models. Rather, even for stronger systems, we attest how profiting from a wealth of – uncurated and synthetic (Bender et al., 2021) – data does not grant advantages to address gender bias. This motivates us to continue our multifaceted evaluation by taking into account only small models – henceforth CHAR and BPE – that, being trained on the same MuST-C data, allow for sound and transparent comparison.

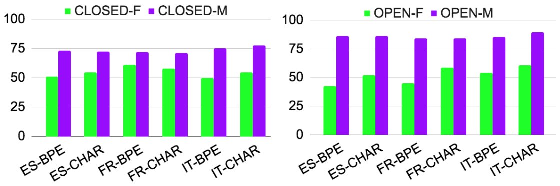

Figure 2: Feminine *vs.* Masculine accuracy scores for closed and open class words.

		Verbs		Nouns		Adj-des	
		F-Acc	M-Acc	F-Acc	M-Acc	F-Acc	M-Acc
en-es	BPE	44.4	**93.8**	21.1	89.0	57.4	**80.0**
	CHAR	**60.0**	84.2	**37.4**	**89.7**	**61.2**	79.7
en-fr	BPE	51.3	**79.8**	16.4	93.5	50.6	78.6
	CHAR	**68.4**	75.0	**27.4**	**95.3**	**63.0**	**81.4**
en-it	BPE	63.7	83.7	28.6	92.2	62.0	76.7
	CHAR	**66.7**	**89.2**	**33.3**	**94.3**	**70.6**	**84.5**

Table 4: Feminine *vs.* Masculine accuracy scores per open class POS.

5.2 Word classes and Parts-of-speech

At a finer level of granularity, we use our extension of MuST-SHE to inspect gender bias across open and closed class words. Their coverage ranges between 74-81% for function words, but it shrinks to 44-59% for content words (see Appendix C.1). This is expected given the limited variability and high frequency of functional items in language. Instead, the coverage of feminine and masculine forms is on par within each class for all systems, thus allowing us to evaluate gender accuracy on a comparable proportion of generated words. A bird's-eye view of Figure 2 attests that, although masculine forms are always disproportionately produced, the gender accuracy gap is amplified on the open class words. The consistency of such a behaviour across languages and systems suggests that content words are involved to a greater extent in

---

[15] `BLEU+c.mixed+#.1+s.exp+tok.13a+v.1.4.3`

gender bias.

We hence analyse this more problematic class by looking into a breakdown of the results per POS, while for function words' gender accuracy we refer to Appendix C.2. Table 4 presents results for *verbs*, *nouns* and *descriptive adjectives*. First, in terms of system capability, CHAR still consistently emerge as the favorite models for feminine translation. What we find notable, though, is that even within the same class we observe evident fluctuations, where nouns come forth as the most biased POS with a huge divide between M and F accuracy (52–77 points). Specifically, scores below 50% indicate that feminine forms are generated with a probability that is below random choice, thus signalling an extremely strong bias.

In light of this finding, we hypothesize that semantic and distributional features might be a factor to interpret words' gender skew. Specifically, occupational lexicon (e.g. lawyer, professor) makes up for most of the nouns represented in MuST-SHE (∼70%). While such a high rate of professions in TED data is not surprising *per se*,[16] it singles out that professions may actually represent a category where systems largely rely on spurious cues to perform gender translation, even within natural conditions that do not ambiguously prompt stereotyping. We exclude basic token frequency by POS as a key factor to interpret our results, as MuST-SHE feminine nouns do not consistently appear as the POS with the lowest number of occurrences, nor do they have the lowest F:M ratio within MuST-C training data. As discussed in Section 8, we believe that our breakdown per POS is informative inasmuch it prompts qualitative considerations on how to pursue gender bias mitigation in models and corpora (Czarnowska et al., 2021; Doughman et al., 2021).

5.3 Manual analysis

We manually inspect CHAR and BPE system's output on the out-of-coverage (OOC) words that could not be automatically evaluated (see "All-Cov" column in Table 3), which amount to more than 5,000 instances. As shown in Table 5, our analysis discerns between OOC words due to *i)* translation *errors* (Err),[17] and *ii)* adequate *alternative* translations (i.e. meaning equivalent) for the expected gender-marked words. Such alternatives comprise instances in which word omission is acceptable (Alt-O) (Baker, 1992), and rewordings through synonyms or paraphrases. Since our focus remains on gender translation, we distinguish when such rewordings are generated with correct (Alt-C) or wrong (Alt-W) gender inflections, as well as neutral expressions devoid of gender-marking (Alt-N). Note that – with respect to English (Cao and Daumé III, 2020; Vanmassenhove et al., 2021; Sun et al., 2021) – overcoming the structural pervasiveness of gender specifications in grammatical gender languages is extremely challenging (Gabriel et al., 2018a), but some rewordings can enable indirect neutral language (INL)[18] (López, 2020).

Table 5: Classification of OOC words.

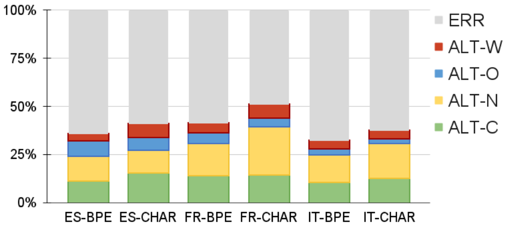

Figure 3: Proportion of OOC words due to translation errors and alternative translations per system.

The results of the analysis are shown in Figure 3. Surprisingly, we find that BPE models – in spite of their higher BLEU scores – accumulate more translation errors than their CHAR counterparts.[19] Conversely, CHAR models generate an overall higher proportion of alternatives and, more importantly, alternatives whose gender translation is acceptable (-N, -C). This suggests that CHAR output is characterized by a favourable *adequate* variability that

---

[16] As TED talks are held by field experts, references to education and titles are quite common (MacKrill et al., 2021).

[17] Errors range from misspelling to complete gibberish.

[18] INL relies on generic expressions rather than gender-specific ones (e.g. *service* vs. *waiter/tress*) See Section 8.

[19] We noticed that CHAR's lower translation quality may have to do more with fluency rather than lexical issues.

conveys both lexical meaning and gender realization better than BPE. Also, note that the outcome of the manual analyses reiterates the results obtained with the automatic evaluation based on accuracy at the word-level, thus confirming its reliability.

As a final remark, we find that all systems produce a considerable amount of neutral alternatives in their outputs. To gain insight into such neutralizations, we audit on which POS they are realized. Accordingly, we find that neutralizations of adjectives and nouns are quite limited, and concern the production of epicene synonyms (e.g. *en*: happy; *es-ref*: contento/a; *es-out*: feliz). Verbs, instead, are largely implicated in the phenomenon, since inflectional changes in tense and aspect paradigms (e.g., present, imperfective) that do not convey gender distinctions are feasible (see the -N example in Table 5). Such range of alternatives for verbs is in fact also reflected by its lowest coverage among all POS (as low as ∼32%). Finally, paraphrases based on verbs also represent the most frequent way to neutralize other POS in the output. Since such expressions are suitable, or even preferable, for several scenarios (e.g. to substitute masculine generics, to avoid making unlicensed gender assumptions) our finding encourages the creation of test sets accounting for such a third viable direction, and can shed light on systems' potential to produce INL alternatives.

6 Gender Agreement Evaluation

6.1 Automatic analysis

The final step in our multifaceted analysis goes beyond the word level to inspect agreement chains in translation. To this aim, we define *coverage* as the proportion of generated chains matching with those annotated in MuST-SHE. Then, the *accuracy* of the generated chains accounts for 3 different cases where: *i)* agreement is respected, and with the correct gender (C); *ii)* agreement is respected, but with the wrong gender (W); and *iii)* both feminine and masculine gender inflections occur together, and thus agreement is not respected (NO).

Table 6 shows accuracy scores for all MuST-SHE agreement chains (All), also split into feminine (F) and masculine (M) chains. The overall results are promising: we find very few instances (literally 1 or 2) in which ST systems produce an ungrammatical output that breaks gender agreement (NO). In fact, both systems tend to be consistent with one picked gender for the whole dependency group. Thus, in spite of previous MT studies concluding that character-based segmentation results in poorer syntactic capability (Belinkov et al., 2020), respecting concord does not appear as an issue for any of our small ST models. For the sake of comparability, however, we note that our evaluation involves language pairs that do not widely resort to long-range dependencies; this may contribute to explaining why CHAR better handles correct gender agreement.[20]

		All			**Feminine**			**Masculine**		
		C	W	NO	C	W	NO	C	W	NO
en-es	*bpe*	74.3	**24.6**	**1.2**	33.9	**64.4**	**1.7**	95.5	**3.6**	0.9
	char	**78.4**	21.0	0.6	**42.4**	57.6	0.0	**96.6**	2.6	0.9
en-fr	*bpe*	67.9	**31.0**	**1.2**	54.1	**45.9**	0.0	78.7	**19.1**	**2.1**
	char	**76.7**	22.3	1.0	**57.5**	40.0	**2.5**	**88.9**	11.1	0.0
en-it	*bpe*	71.7	**27.5**	0.7	47.4	**50.9**	**1.8**	88.9	**11.1**	0.0
	char	**78.5**	20.0	**1.5**	**54.2**	44.1	1.7	**97.4**	1.3	**1.3**

Table 6: Agreement results for All chains matched in MuST-SHE, and split into Feminine and Masculine chains. Accuracy scores are given for agreement respected with correct gender (C), agreement respected with wrong gender (W), agreement not respected (NO).

Overall, agreement translation was measured on a lower *coverage* (30-50%) – presented in Appendix D.1 – than the word-level one (Section 3). While this is expected given the strict requirement of generating full chains with several words, we recover such a loss by means of the comprehensive manual evaluation discussed below.

6.2 Manual analysis

Our manual inspection recovers a total of ∼1,200 OOC agreement chains from CHAR and BPE output. Similarly to the approach employed for single words (Section 5.3), we discern between OOC chains due to: *i)* translation *errors* (Err), and *ii) alternative* translations preserving the source meaning. We distinguish different types of alternatives. First, alternatives that do no exhibit a morphosyntactic agreement phenomenon to be judged, as in the case of neutral paraphrases or rewordings consisting of a single word (NO-chain). Instead, when the generated alternative chain exhibits gender markings, we distinguish if the chosen gender is correct (C), wrong (W), or if the system produces a chain that does not respect gender agreement because it combines both feminine and masculine gender inflections (NO).

The outcome of such OOC chains categorization

---

[20] Due to space constraints we refer to Appendix D.2 for an analysis of longer-range cases of subject-verb agreement.

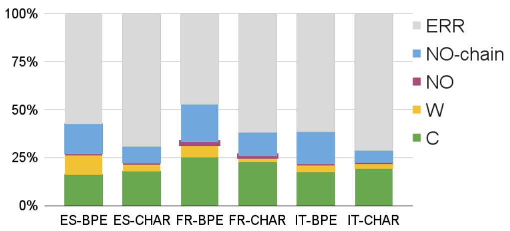

Figure 4: Proportion of OOC chains due to translation errors or alternative agreement translations per system.

is presented in Figure 4. Interestingly, such results are only partially corroborating previous analyses. On the one hand, unlike the OOC words' results discussed in Section 5.3, we attest that CHAR models produce the highest proportion of translation errors. Thus, it seems that CHAR capability in producing adequate alternatives is confined to the single-word level, whereas it exhibits a higher failure rate on longer sequences. On the other hand, by looking at alternative chains, CHAR still emerges as the best at properly translating gender agreement, with the highest proportion of chains with correct gender (C), and the lowest one with wrong gender (W).

Finally, again in line with our automatic evaluation (Table 6), we confirm that respecting agreement is not an issue for our ST models: we identify only 3 cases (2 for en-fr BPE, 1 for en-fr CHAR) where concord is broken (NO). Given the rarity of such instances, we are not able to draw definitive conclusions on the nature of these outliers. Nonetheless, we check the instances in which agreement was not respected (both in and out of coverage). We see that cases of broken concord also concern extremely simple phrases, consisting of a noun and its modifier (e.g. en: *talking to [this inventor],...because he*; fr: *parler à* ***[cette***$_F$ ***inventeur***$_M$***]***..., *parce qu' il*). However, the most common type among these outliers are constructions with semi-copula verbs (e.g. en: *She... [became a vet]*; it: *...E' [****diventata***$_F$ ***un***$_M$ ***veterinatrio***$_M$*]*), which – as discussed in Section 3.1 – exhibit a weaker agreement constraint.

7 Conclusion

The complex system of grammatical gender languages entails several morphosyntactic implications for different lexical categories. In this paper, we underscored such implications and explored how different POS and grammatical agreement are involved in gender bias. To this aim, we enriched the MuST-SHE benchmark with new linguistic information, and carried out an extensive evaluation on the behaviour of ST models built with different segmentation techniques and data quantities. On three language pairs (English-French/Italian/Spanish), our study shows that, while all POS are subject to masculine skews, they are not impacted to the same extent. Respecting gender agreement for the translation of related words, instead, is not an issue for current ST models. We also find that ST generates a considerable amount of neutral expressions, suitable to replace gender-inflected ones, which however current test sets do not recognize.

Overall, our work reiterates the importance of dedicated analyses that, unlike holistic metrics, can single out system's behaviour on gender phenomena. Accordingly, our results are in line with previous studies showing that, in spite of lower generic performance, character-based segmentation exhibits a better capability at handling feminine translation at different levels of granularity. As our MuST-SHE extension is available for both ST and MT, we invite MT studies to start from our discoveries and resource.

Acknowledgments

We would like to thank the 2021 Summer Internship students at FBK for their contribution: Francesco Fernicola, Sara Giuliani, Lorena Rocio Martín, Silvia Alma Piazzolla, Mélanie Prati, Jana Waldmann. This work was made possible thanks to their extensive annotation work and active participation in fruitful discussions.

8 Impact statement

In this paper, we evaluate whether and to what extent ST models exhibit biased behaviors by systematically and disproportionately favoring masculine forms in translation. Such a behavior is problematic inasmuch it leads to under-representational harms by reducing feminine visibility (Blodgett et al., 2020; Savoldi et al., 2021).

Broader impact. While the focus of this work is on the analysis itself, our insights prompt broader considerations. Specifically, our investigation on the relation between data size/segmentation technique and gender bias provides initial cues on which models and components to audit and implement toward the goal of reducing gender bias. This, in particular, may be informative to define the path for emerging direct ST technologies. Also, our results disaggregated by POS invite reflections on how to intend and mitigate bias by means of interventions on the training data. In fact, while it is known that the MuST-C corpus (Cattoni et al., 2021) used for training comprises a majority of masculine speakers,[21] the fact that certain lexical categories are more biased than others suggests that, on top of more coarse-grained quantitative attempts at gender balancing (Costa-jussà and de Jorge, 2020), data curation ought to account for more sensitive, nuanced, and qualitative asymmetries. These also imply *how*, rather than only *how often*, gender groups are represented (Wagner et al., 2015; Devinney et al., 2020). Also, while nouns come forth as the most problematic POS, current practices of data augmentation based on a pre-defined occupational lexicon may address stereotyping (Saunders and Byrne, 2020), but do not increase the production of other nonetheless skewed lexical categories. Overall, our enriched resource[22] can be useful to monitor the validity of different technical interventions.

Ethic statement. The use of gender as a variable (Larson, 2017) warrants some ethical reflections.

Our evaluation on the MuST-SHE benchmark exclusively accounts for linguistic gender expressions. As reported in MuST-SHE data statement (Bender and Friedman, 2018),[23] also for the subset of sentences that contain first-person references[24] (e.g. *I'm a student*), speakers' gender information is manually annotated based on the personal pronouns found in their publicly available personal TED profile, and used to check that the indicated (English) linguistic gender forms are rendered in the gold standard translations.

While our experiments are limited to the binary linguistic forms represented in the used data, to the best of our knowledge, ST natural language corpora going beyond binarism do not yet exist.[25] This is also due to the fact that unlike English – which finds itself for several cultural and linguistic reasons as a leader of change toward inclusive forms (Ackerman, 2019) – Direct Non-binary Language based on neomorphemes (Shroy, 2016; Papadopoulos, 2019; Knisely, 2020) is non-trivial to fully implement in grammatical gender languages (Hellinger and Bußman, 2001; Gabriel et al., 2018b) and still object of experimentation (Redazione, 2020; Attig and López, 2020). However, our manual evaluation expands to the possibility of INL strategies that could be detected in system's output. We underscore that such strategies are recommended and fruitful to avoid the gendering of referents, but are to be considered as concurring to – rather than replacements of – emerging linguistic innovations (López, 2020).

Lastly, we signal that direct ST models may leverage speakers' vocal characteristics as a gender cue to infer gender translation. Although the potential risks of such condition do not emerge and are not addressed in our setting (focused on POS and agreement features as a variable), we endorse the point made by Gaido et al. (2020). Namely, direct ST systems leveraging speaker's vocal biometric features as a gender cue can entail real-world dangers, like the categorization of individuals by means of biological essentialist frameworks (Zimman, 2020). This can reduce gender to stereotypical expectations about how masculine or feminine voices should sound, and can be especially harmful to transgender individuals, as it can lead to misgendering (Stryker, 2008) and invalidation. Note that we experimented with unmodified models for the sake of hypothesis testing without adding variability, but real-world deployment of ST technologies must account for the potential harms arising form the use of direct ST technologies *as is*.

A MuST-SHE Manual Annotation

POS and agreement chains annotations were carried out on MuST-SHE reference translations. To ensure precision, the two layers of linguistic information have been added *i)* as two separate annotation processes; *ii)* following strict and comprehensive guidelines.

A first version of the guidelines was written by one of the authors – who is an expert linguist –

based on a preliminary manual analysis of a MuST-SHE sample. Successively, such guidelines have been refined and improved by means of discussions with the annotators, who had carried out a pilot annotation round to get acquainted with MuST-SHE language data. The final version of the annotation guidelines is included in the resource release (`ict.fbk.eu/must-she`) and is also retrievable at: `https://bit.ly/3CdU50s`.

The 6 annotators were all interning students undergoing a MA degree in Linguistics/Translation Studies, who were selected among other 120 candidates. We ensured that at least one annotator per language was a native speaker, whereas the second one had at least a C1 proficiency level of the assigned language. Since the annotations were carried out in the course of this more extensive curricular internship, there was no task-associated compensation.

B ST Models

In this section we describe in detail the ST models created for our study, whose source code is publicly released at: `https://github.com/mgaido91/FBK-fairseq-ST/tree/acl_2021`.

B.1 Architecture

The architecture of our ST models is composed of two strided 2D convolutional layers with 64 3x3 kernels, followed by a Transformer (Vaswani et al., 2017) with 11 encoder layers and 4 decoder layers. The two 2D convolutions reduce the length of the input sequence by a factor of 4, allowing the processing by the Transformer encoder layers that have a quadratic memory complexity with respect to the input length (because of the self-attention mechanism). The weights of the encoder self-attention matrices are biased to be close to 0 for elements far from the matrix diagonal (i.e. for elements that are far from the considered vector) with a logarithmic distance penalty (Di Gangi et al., 2019). In both encoder and decoder Transformer layers, we use 8 attention heads, 512 embedding features, and 2048 features for the feed-forward inner-layers. The resulting number of parameters is 60M for BPE models and 52M for character-based models.

B.2 Data

Since the amount of ST data is limited (i.e. MuST-C – Cattoni et al. 2021 – and Europarl-ST – Iranzo-Sánchez et al. 2020), knowledge transfer from the ASR and MT tasks is leveraged by respectively initializing the ST encoder with ASR pretrained weights (Weiss et al., 2017b; Bansal et al., 2019) and by distilling knowledge from a strong MT teacher (Liu et al., 2019). The ASR model used for the pretraining has been trained on Librispeech (Panayotov et al., 2015), Mozilla Common Voice,[26] TEDLIUM-v3 (Hernandez et al., 2018), and the utterance-transcript pairs of the ST corpora and of How2 (Sanabria et al., 2018). The teacher MT models, instead, are trained on a subsample of the Opus (Tiedemann, 2016) repository, filtered using the cleaning pipeline of ModernMT.[27]

SpecAugment is applied to the source audio with probability 0.5 by masking two bands on the frequency axis (with 13 as maximum mask length) and two on the time axis (with 20 as maximum mask length). Time stretch (Nguyen et al., 2020) alters the input utterance with probability of 0.3 and stretching factor sampled uniformly for each utterance between 0.8 and 1.25 is also used to alter the input audio. The target text was tokenized with Moses.[28] We normalized audio per-speaker and extracted 40 features with 25ms windows sliding by 10ms with XNMT[29] (Neubig et al., 2018).

The LARGE-BPE model is trained on all the available (ST and distilled) data for a total of ∼1.25M pairs, while the SMALL-BPE and SMALL-CHAR are trained only on the MuST-C data for a total of 250-275k pairs. The encoder pretraining is used for all the models. The SMALL-* models are initialized with the weights of an ASR trained only on the *(audio, transcript)* pairs of MuST-C, while the LARGE-BPE is initialized with an ASR trained on all the available data.

For the small and large models leveraging BPE, we employed 8k merge rules, while we used a set of 250-400 characters for the SMALL-CHAR model. The resulting vocabulary sizes are reported in Table 7.

	en-es	**en-fr**	**en-it**
Large-BPE	11,940	12,136	11,152
Small-Char	464	304	256
Small-BPE	8,120	8,048	8,064

Table 7: Resulting vocabulary sizes.

[27] `https://github.com/modernmt/modernmt`

[28] `https://github.com/moses-smt/mosesdecoder`

[29] `https://github.com/neulab/xnmt`

B.3 Training procedure

The models are trained using label smoothed cross-entropy (Szegedy et al., 2016) – the smoothing factor is 0.1 – with Adam using β_1=0.9, β_2=0.98 and the learning rate is linearly increased during the warm-up phase (4k iterations) up to the maximum value 5×10^{-3}, followed by decay with inverse square root policy. The dropout is set to 0.2. Each mini-batch consists of 8 samples, we set the update frequency to 8, and we train on 4 GPUs, so a batch contains 256 samples.

The LARGE-BPE training is performed in three consecutive steps. First, we train on synthetic data obtained by automatically translating the ASR corpora transcript with our MT model (Jia et al., 2019). Second, we fine-tune on the ST corpora. In both these training phases the model is optimised to learn the output distributions of the MT teacher (via word-level knowledge distillation). Lastly, the model is fine-tuned on the ST corpora using label-smoothed cross entropy. Trainings are stopped after 5 epochs without improvements on the validation loss and we average 5 checkpoints around the best on the validation set. In the rich-data condition case, as we did not see benefits by the average of the checkpoints, we used the best checkpoint instead. As a validation set we rely on the MuST-C gender-balanced dev set (Gaido et al., 2020).

Our code is built on the Fairseq library (Ott et al., 2019) and trainings are performed on 4 K80 GPUs, lasted 4 days for the MuST-C-only trainings and 12 days for the rich-data models.

C Word-level Evaluation

C.1 Coverage per open and closed class words

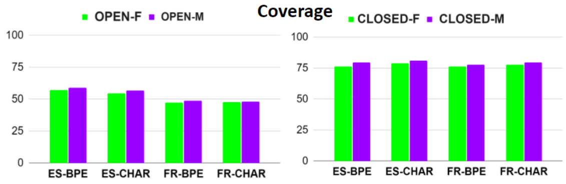

Figure 5: Feminine *vs* Masculine coverage scores per open and closed class words.

As we can see in Figure 5, function words have a higher coverage than content words. This is expected given the limited variability and high frequency of functional items in language. Instead, the coverage of feminine and masculine forms is on par within each class for all systems, thus allowing us to evaluate gender accuracy on a comparable proportion of generated words.

C.2 Gender accuracy per closed class POS

		Art		Pronoun		Adj-det	
		F-Acc	M-Acc	F-Acc	M-Acc	F-Acc	M-Acc
en-es	*bpe*	51.35	**70.0**	**52.0**	84.9	49.1	86.1
	char	**53.5**	68.4	51.7	**85.7**	**59.3**	**91.2**
en-fr	*bpe*	**52.0**	**69.2**	**65.5**	**78.3**	**82.9**	**79.5**
	char	50.8	68.6	54.2	77.3	79.1	78.6
en-it	*bpe*	47.2	74.6	**75.0**	71.4	50.9	81.8
	char	**52.2**	**76.8**	52.9	**77.8**	**61.8**	**83.3**

Table 8: Feminine *vs.* Masculine percentage accuracy scores per closed class POS.

As we can see in Table 8, CHAR's otherwise attested advantage over BPE is not consistent for function words, where we find variations across POS and languages. Such variations may be due to the fairly restricted amount of MuST-SHE *pronouns* and *limiting adjectives* (Adj-det) on which accuracy can be computed in MuST-SHE (see Table 2), which make very fine-grained evaluations particularly unstable. Additionally – since the present POS evaluation still remains at the word level – we are not able to ponder whether gender translations for modifiers (i.e. articles, determiners) is to some extent constrained by the content words they refer to. We intend to explore such hypothesis in future work by intersecting POS and agreement annotations.

D Agreement Evaluation

D.1 Agreement coverage

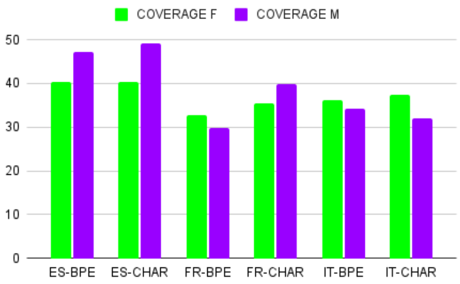

Figure 6: Feminine *vs* Masculine coverage scores for chains.

Figure 6 shows coverage of fully generated agreement chains split into feminine (F) and masculine (M) forms. Although we attest notable variations across languages and gender forms, overall masculine and feminine chains are both produced at comparable rate.

SRC	**A** young **scientist** that I was working with ..., Rob, **was**..
REF$_{it}$	[**Un** giovane **scienziato**] con cui lavoravo ..., Rob, è **stato**..

Table 9: Example of subject-verb agreement in MuST-SHE.

D.2 Manual analysis of subject-verb agreement

Considering long-range dependencies that go beyond the phrase level, a gender relevant co-variation is also that of *subject-verb* agreement, as the one shown in Table 9 (see also footnote 1). To account for such longer spans, we considered all MuST-SHE sentences where both *i)* a word (or chain) functioning as a subject, and *ii)* its referring verb or predicative complement are annotated as gender-marked words in the references. We identified 55 sentences for en-es, 54 for en-fr and 41 for en-it, and we manually analyzed all the corresponding systems' outputs.

We found that, even in the case of dependencies within a longer range, systems largely respect agreement in translation and consistently pick the same gender form for all co-related words. In fact, we identified only 4 cases where concord is broken: 1 case each for BPE and CHAR for en-es and en-it, and none for en-fr. Among these 4 cases, we found the above discussed weaker gender-enforcing structures (see the description of (semi-)copula verbs and their predicative complements in Section 6.2), and we also detected what resembles *agreement attraction errors* (Linzen et al., 2016). Namely, the model does not produce a verb or complement in agreement with its actual (but distant) subject, as other words intervene in the sentence and agreement is conditioned by the verb/complement's preceding word. As a result, subject-verb agreement is not respected. The following (long) sentence is an example of such an attraction error, where the complement *desperate* is inflected in the same masculine and plural form as its just preceding noun rather than the chain functioning as subject (*the nurse*).

(*en-src*) I watched in horror heartbreaking footage of **the head nurse**, Malak, in the aftermath of the bombing, grabbing premature babies out of their incubators, **desperate** to get them to safety, before she broke down in tears.
(*es*-CHAR: Vi una imagen horrible desgarradora de **la enfermera** (F., sing.) mi laguna, en los ratones después del bombardeo, agarrando a los bebés permaturos fuera de sus incubadores (M., pl.) **desesperados**(M., pl.) por hacerlos...

Such kind of agreement issues have more to do with overall syntactic capacity of ST models, rather than being implicated with gender bias. We can thus conclude that, even taking into account longer dependencies, agreement still does not emerge as an issue entrenched with gender bias.

Abstract

Open-domain questions are likely to be open-ended and ambiguous, leading to multiple valid answers. Existing approaches typically adopt the *rerank-then-read* framework, where a reader reads top-ranking evidence to predict answers. According to our empirical analysis, this framework faces three problems: *first*, to leverage a large reader under a memory constraint, the reranker should select only a few relevant passages to cover diverse answers, while balancing relevance and diversity is non-trivial; *second*, the small reading budget prevents the reader from accessing valuable retrieved evidence filtered out by the reranker; *third*, when using a generative reader to predict answers all at once based on all selected evidence, whether a valid answer will be predicted also pathologically depends on the evidence of some other valid answer(s). To address these issues, we propose to answer open-domain multi-answer questions with a *recall-then-verify* framework, which separates the reasoning process of each answer so that we can make better use of retrieved evidence while also leveraging large models under the same memory constraint. Our framework achieves state-of-the-art results on two multi-answer datasets, and predicts significantly more gold answers than a *rerank-then-read* system that uses an oracle reranker.

1 Introduction

Open-domain question answering (Voorhees, 1999; Chen et al., 2017) is a long-standing task where a question answering system goes through a large-scale corpus to answer information-seeking questions. Previous work typically assumes that there is only one well-defined answer for each question, or only requires systems to predict one correct answer, which largely simplifies the task. However, humans may lack sufficient knowledge or patience to frame very specific information-seeking questions, leading to open-ended and ambiguous questions with multiple valid answers. According to Min et al. (2020b), over 50% of a sampled set of Google search queries (Kwiatkowski et al., 2019) are ambiguous. Figure 1 shows an example with at least three interpretations. As can be seen from this example, the number of valid answers depends on both questions and relevant evidence, which challenges the ability of comprehensive exploitation of evidence from a large-scale corpus.

Original Question: When did [You Don't Know Jack] come out?
Interpretation #1: When did the first video game called [You Don't Know Jack] come out? **Evidence #1:** You Don't Know Jack is a video game released in 1995, and the first release in ... **Answer #1:** 1995
Interpretation #2: When did the Facebook game [You Don't Know Jack] come out on Facebook? **Evidence #2:** In 2012, Jackbox Games developed and published a social version of the game on Facebook ... **Answer #2:** 2012
Interpretation #3: When did the film [You Don't Know Jack] come out? **Evidence #3:** "You Don't Know Jack" premiered April 24, 2010 on HBO. **Answer #3:** April 24, 2010

Table 1: An example of open-domain multi-answer questions. We display only a subset of valid answers. In fact, [You Don't Know Jack] can also be a song.

Existing approaches mostly adopt the *rerank-then-read* framework. A retriever retrieves hundreds or thousands of relevant passages which are later reranked by a reranker; a generative reader then predicts all answers in sequence conditioned on top-ranking passages. With a fixed memory constraint[1], there is a trade-off between the size of the reader and the number of passages the reader can process at a time. According to Min et al. (2021), provided that the reranker is capable of

selecting a small set of highly-relevant passages with high coverage of diverse answers, adopting a larger reader can outperform a smaller reader using more passages. However, as shown by Section 4.4, this framework is faced with three problems: *first*, due to the small reading budget, the reranker has to balance relevance and diversity, which is non-trivial as it is unknown beforehand that which answers should be distributed with more passages to convince the reader and which answers can be safely distributed with less to save the budget for the other answers; *second*, the reader has no access to more retrieved evidence that may be valuable but is filtered out by the reranker, while combining information from more passages was found to be beneficial to open-domain QA (Izacard and Grave, 2021b); *third*, as the reader predicts answers in sequence all at once, the reader learns pathological dependencies among answers, i.e., whether a valid answer will be predicted also depends on passages that cover some other valid answer(s), while ideally, prediction of a particular answer should depend on the soundness of associated evidence itself.

To address these issues, we propose to answer open-domain multi-answer questions with a *recall-then-verify* framework. Specifically, we first use an answer recaller to predict possible answers from each retrieved passage individually; this can be done with high recall, even when using a weak model for the recaller, but at the cost of low precision due to insufficient evidence to support or refute a candidate. We then aggregate retrieved evidence relevant to each candidate, and verify each candidate with a large answer verifier. By separating the reasoning process of each answer, our framework avoids the problem of multiple answers sharing a limited reading budget, and makes better use of retrieved evidence while also leveraging strong large models under the same memory constraint.

Our contributions are summarized as follows:

- We empirically analyze the problems faced by the *rerank-then-read* framework when dealing with open-domain multi-answer QA.
- To address these issues, we propose to answer open-domain multi-answer questions with a *recall-then-verify* framework, which makes better use of retrieved evidence while also leveraging the power of large models under the same memory constraint.
- Our framework establishes a new state-of-the-art record on two multi-answer QA datasets with significantly more valid predictions.

2 Related Work

Open-domain QA requires question answering systems to answer factoid questions by searching for evidence from a large-scale corpus such as Wikipedia (Voorhees, 1999; Chen et al., 2017). The presence of many benchmarks has greatly promoted the development of this community, such as questions from real users like NQ (Kwiatkowski et al., 2019) and WEBQUESTIONS (Berant et al., 2013), and trivia questions like Quasar-T (Dhingra et al., 2017) and TriviaQA (Joshi et al., 2017). All these benchmarks either assume that each question has only one answer with several alternative surface forms, or only require a system to predict one valid answer. A typical question answering system is a pipeline as follows: an efficient retriever retrieves relevant passages using sparse (Mao et al., 2021; Zhao et al., 2021) or dense (Karpukhin et al., 2020; Xiong et al., 2021; Izacard and Grave, 2021a; Khattab et al., 2021) representations; an optional passage reranker (Asadi and Lin, 2013; Nogueira and Cho, 2019; Nogueira et al., 2020) further narrows down the evidence; an extractive or generative reader (Izacard and Grave, 2021b; Cheng et al., 2021) predicts an answer conditioned on retrieved or top-ranking passages. Nearly all previous work focused on locating passages covering at least one answer, or tried to predict one answer precisely.

However, both Kwiatkowski et al. (2019) and Min et al. (2020b) reported that there is genuine ambiguity in open-domain questions, resulting in multiple valid answers. To study the challenge of finding all valid answers for open-domain questions, Min et al. (2020b) proposed a new benchmark called AMBIGQA where questions are annotated with as many answers as possible. In this new task, the passage reranker becomes more vital in the *rerank-then-read* framework, particularly when only a few passages are allowed to feed a large reader due to memory constraints. This is because the reranker has to ensure that top-ranking passages are highly relevant and also cover diverse answers. Despite state-of-the-art performance on AMBIGQA (Min et al., 2021), according to our empirical analysis, applying the *rerank-then-read* framework to open-domain multi-answer QA faces the following problems: balancing relevance and diversity is non-trivial for the reranker due to unknown effect on the performance of the subsequent reader; when using a large reader under a fixed memory constraint, the small reading budget prevents it from making use of more retrieved evidence that is valuable but filtered out; when using a generative reader to predict all answers in sequence based on all selected evidence, it learns pathological dependencies among answers. To address these issues, we propose to tackle this task with a *recall-then-verify* framework, which separates the reasoning process of each answer with a higher level of evidence usage while also leveraging large models under the same memory constraint.

Some previous work argued that a reader can be confused by similar but spurious passages, resulting in wrong predictions. Therefore, they proposed answer rerankers (Wang et al., 2018a,b; Hu et al., 2019; Iyer et al., 2021) to rerank top predictions from readers. Our framework is related to answer reranking but with two main differences. First, a reader typically aggregates available evidence and already does a decent job of answer prediction even without answer reranking; an answer reranker is introduced to filter out hard false positive predictions from the reader. By contrast, our answer recaller aims at finding possible answers with high recall, most of which are invalid. Evidence focused on each answer is then aggregated and reasoned about by our answer verifier. It is also possible to introduce another model analogous to an answer reranker to filter out false positive predictions from our answer verifier. Second, answer reranking typically compares answer candidates to determine the most valid one, while our answer verifier selects multiple valid answers mainly based on the soundness of their respective evidence but without comparisons among answer candidates.

3 Task Formulation

Open-domain multi-answer QA can be formally defined as follows: given an open-ended question q, a question answering system is required to make use of evidence from a large-scale text corpus $\mathcal{C}$ and predict a set of valid answers $\{a_1, a_2, ..., a_n\}$. Questions and their corresponding answer sets are provided for training.

Evaluation To evaluate passage retrieval and reranking, we adopt the metric MRecall@k from (Min et al., 2021), which measures whether the top-k passages cover at least k distinct answers (or n answers if the total number of answers n is less than k). To evaluate question answering performance, we follow (Min et al., 2020b) to use F1 score between gold answers and predicted ones.

4 Rerank-then-Read Framework

In this section, we will briefly introduce the representative and state-of-the-art *rerank-then-read* pipeline from (Min et al., 2021) for open-domain multi-answer questions, and provide empirical analysis of this framework.

4.1 Passage Retrieval

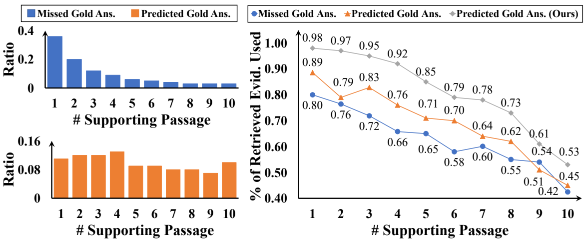
Dense retrieval is widely adopted by open-domain question answering systems (Min et al., 2020a). A dense retriever measures relevance of a passage to a question by computing the dot product of their semantic vectors encoded by a passage encoder and a question encoder, respectively. Given a question, a set of the most relevant passages, denoted as $\mathcal{B}$ ($|\mathcal{B}| \ll |\mathcal{C}|$), is retrieved for subsequent processing.

4.2 Passage Reranker

To improve the quality of evidence, previous work (Nogueira et al., 2020; Gao et al., 2021) finds it effective to utilize a passage reranker, which is more expressive than a passage retriever, to rerank retrieved passages, and select the k best ones to feed a reader for answer generation ($k < |\mathcal{B}|$). With a fixed memory constraint, there is a trade-off between the number of selected passages and the size of the reader. As shown by (Min et al., 2021), with good reranking, using a larger reader is more beneficial. To balance relevance and diversity of evidence, Min et al. (2021) proposed a passage reranker called JPR for joint modeling of selected passages. Specifically, they utilized T5-base (Raffel et al., 2020) to encode retrieved passages following (Izacard and Grave, 2021b) and decode the indices of selected passages autoregressively using a tree-decoding algorithm. JPR is designed to seek for passages that cover new answers, while also having the flexibility to select more passages covering the same answer, especially when there are less than k answers for the question.

4.3 Reader

A reader takes as input the top-ranking passages, and predicts answers. Min et al. (2021) adopted a generative encoder-decoder reader initialized with T5-3b, and used the fusion-in-decoder method from (Izacard and Grave, 2021b) which efficiently ag-



(a) (b)

Figure 1: Analysis of how well OPR (the reranker of a *rerank-then-read* pipeline) balances relevance and diversity on questions with multiple answers in the dev set of AMBIGQA. The number of retrieved passages is $|\mathcal{B}|$=100, and the number of passages selected by the reranker is k=10. Figure (a) shows the ratio of answers with different numbers of supporting passages selected, the top half of which is for gold answers missed (top) by the reader and the bottom half is for predicted ones. Figure (b) shows the ratio of retrieved supporting passages that are eventually used by the reader (or the verifier in our framework).

gregates evidence from multiple passages. Specifically, each passage is concatenated with the question and is encoded independently by the encoder; the decoder then attends to the representations of all passages and generates all answers in sequence, separated by a `[SEP]` token.

4.4 Empirical Analysis

To analyze performance of the *rerank-then-read* framework for open-domain multi-answer questions, we built a system that resembles the state-of-the-art pipeline from (Min et al., 2021) but with two differences[2]. First, we used the retriever from (Izacard and Grave, 2021a). Second, instead of using JPR, we used an oracle passage reranker (OPR): a passage p is ranked higher than another passage p' if and only if 1) p covers some answer while p' covers none 2) or both p and p' cover or fail to cover some answer but p has a higher retrieval score. Following (Min et al., 2021), we retrieved $|\mathcal{B}|$=100 Wikipedia passages, k=10 of which were selected by the reranker. Table 2 shows model performance on a representative multi-answer dataset called AMBIGQA (Min et al., 2020b). Compared with JPR, OPR is better in terms of reranking, with similar question answering results[3].

Model	Reranking		QA
	MRECALL@5	MRECALL@10	F1
JPR	64.8/45.2	67.1/48.2	**48.5/37.6**
OPR	**67.7/46.5**	**70.3/51.2**	48.4/37.0

Table 2: Reranking results and Question Answering results on the dev set of AMBIGQA using JPR and OPR. The two numbers in each cell are results on all questions and questions with multiple answers, respectively.

Though 3,670 diverse gold answers are covered by OPR on the dev set, the reader predicts only 1,554 of them. Our empirical analysis and findings are detailed as follows.

(1) To leverage a large reader under a fixed memory constraint, a reranker should select only a few highly-relevant passages to cover diverse answers, while balancing relevance and diversity is non-trivial. As shown by Figure 1a (bottom), the number of selected supporting passages[4] of predicted gold answers has a widespread distribution. There may be cases where redundant false positive evidence is selected and can be safely replaced with passages that cover other gold answers. However, it is non-trivial for the reranker to know beforehand whether a passage is redundant, and how many or which supporting passages of an answer are strong enough to convince the reader.

(2) Multiple answers sharing a small reading budget prevents a reader from using more evidence that may be valuable but is filtered out by the reranker. Due to the shared reading budget, it is inevitable that some answers are distributed with less supporting passages. As shown by Figure 1a, a gold answer covered by OPR but missed by the reader generally has significantly less supporting passages fed to the reader (3.13 on average) than a predicted gold answer (5.08 on average), but not because of lacking available evidence. There is more evidence in retrieved passages for missed answers but filtered out by the reranker. As shown by Figure 1b, OPR has a much lower level of evidence usage for missed answers.

(3) As the reader predicts answers all at once conditioned on all selected passages, whether a valid answer will be predicted also pathologically depends on evidence of some other valid answer(s), which partly accounted for the large number of

---

[2] Code and models from (Min et al., 2021) were not publicly available in the period of this work.

[3] With the oracle knowledge of whether a passage contains a gold answer during reranking, OPR is probably still far from being a perfect reranker. Notably, we are not striving for a better *rerank-then-read* pipeline for multi-answer questions, but use OPR as a representative case to analyze the problems a *rerank-then-read* pipeline may face.

[4] We abuse the use of *supporting passages* of an answer to refer to passages that cover the answer.

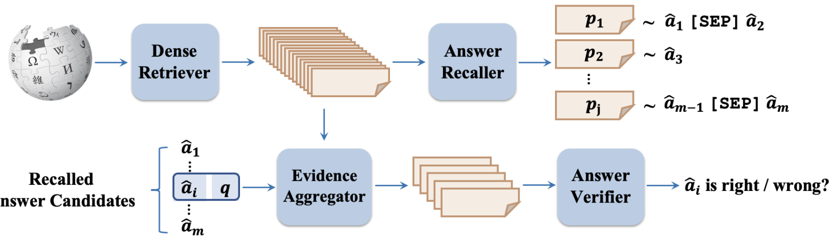


Figure 2: The *recall-then-verify* framework we propose to answer open-domain multi-answer questions. We first use the answer recaller to guess possible answers with high recall, the evidence aggregator then aggregates retrieved evidence for each candidate, and finally, the answer verifier verifies each candidate based on its aggregated evidence. As the reasoning process of each answer is separated, and thanks to candidate-aware evidence aggregation, we can have a high level of evidence usage with a large verifier under a limited memory constraint.

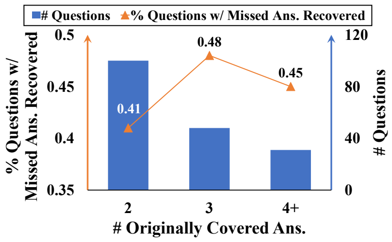

Figure 3: Analysis of the pathological dependencies among answers learned by the reader (of a *rerank-then-read* pipeline) on the dev set of AMBIGQA. The horizontal axis is the number of diverse answers covered by OPR. The left axis shows the ratio of questions for which the reader recovers some originally missed gold answer after adversarially removing the supporting passages of some originally predicted gold answer.

gold answers missed by the reader. For verification, we attacked OPR's reader on the dev set of AMBIGQA as follows: a question is a target if and only if 1) it has a gold answer covered by OPR but missed by the reader 2) and it has a predicted gold answer whose supporting passages cover no other gold answer; a successful attack on a targeted question means that a missed answer is recovered after removing a subset of supporting passages of some predicted answer[5] without removing any supporting passage of the other gold answers.

There are 179 targeted questions; for 43.6% of them, we successfully recovered at least one missed gold answer. Figure 3 shows the success rate breakdown on the number of answers covered by the reader's input, indicating that predictions tend to be brittle when the reader is fed with many diverse supporting passages.

One possible explanation of the pathological dependencies is that the reader implicitly compares the validity of answer candidates and predicts the most likely ones. However, for 40.0% of successfully attacked questions, according to OPR, supporting passages of recovered missed answers are more relevant than those removed passages of predicted answers. Notably, Min et al. (2020b) also had a similar observation on another *rerank-then-read* pipeline, i.e., it is hard to argue that the predicted answers are more likely than the missed ones.

5 Recall-then-Verify Framework

5.1 Overview

To avoid the issues faced by the *rerank-then-read* framework, we propose a *recall-then-verify* framework, which separates the reasoning process of each answer so that answers (1) can be individually distributed with maximum supporting passages allowed on the same hardware (2) and are predicted mainly based on their own evidence. Figure 2 shows our framework. Specifically, we first guess possible answers based on retrieved passages using an answer recaller, an evidence aggregator then aggregates evidence for each answer candidate, and finally, an answer verifier verifies each candidate and outputs valid ones.

5.2 Answer Recaller

Our answer recaller, based on T5, is trained to predict all gold answer(s) in sequence (separated by a `[SEP]` token) from each retrieved positive passage $p \in \mathcal{B}$ that cover some gold answer(s). We also train the recaller to predict the "irrelevant" token given a negative passage so that the recaller can filter out negative candidates; the number of negatives per positive used for training is denoted as α_{neg}. The set of answer candidates recalled during inference is denoted as $\mathcal{A} = \{\hat{a}_1, \hat{a}_2, ..., \hat{a}_m\}$.

---

[5] Removed passages were replaced with the same number of top-ranking passages that cover no gold answer, so that the number of passages fed to the reader remained unchanged.

Though a passage may not contain strong enough evidence to support an answer, by exploiting semantic clues in the question and the passage (e.g., the answer type), it is sufficient for even a weak model to achieve high recall. However, this is at the cost of low precision, which necessitates answer verification based on more supporting passages.

5.3 Evidence Aggregator

We aggregate evidence for each answer candidate from retrieved passages, which can be formulated as a reranking task, i.e., to rerank retrieved passages according to their relevance to a question-candidate pair, and select top-ranking ones for answer verification. Our evidence aggregator resembles OPR: for a specific candidate $\hat{a}_i$, we encode the question-candidate pair with the retriever's question encoder; a passage p is ranked higher than another passage p' if and only if 1) p covers $\hat{a}_i$ while p' does not 2) or both p and p' cover or fail to cover $\hat{a}_i$ but the semantic vector of p is closer to that of the question-candidate pair. We denote the top-k relevant passages of $\hat{a}_i$ as $\mathcal{E}_i$.

5.4 Answer Verifier

Given a candidate $\hat{a}_i$ and its evidence $\mathcal{E}_i$, our answer verifier, based on T5-3b, predicts whether $\hat{a}_i$ is valid, using the fusion-in-decoder method from (Izacard and Grave, 2021b). Each passage from $\mathcal{E}_i$ is concatenated with the question and the candidate, and is encoded independently; the decoder then attends to the representations of all passages and is trained to produce the tokens "right" or "wrong" depending on whether the encoded candidate is valid or not[6]. During inference, we compute the validity score of a candidate by taking the normalized probability assigned to the token "right":

$$P(a_i \text{ is valid}) = \frac{\exp(\text{logit}(\text{"right"}|q, \hat{a}_i, \mathcal{E}_i))}{\sum_{t \in \{\text{"right"},\text{"wrong"}\}} \exp(\text{logit}(t|q, \hat{a}_i, \mathcal{E}_i))} \quad (1)$$

Candidates with their validity scores higher than a threshold τ will be produced as final predictions.

6 Experiments

6.1 Datasets

We conducted experiments on two multi-answer QA datasets, whose statistics are shown in Table 3.

WEBQSP (Yih et al., 2016) is a semantic parsing dataset for knowledge base question answering, where answers are a set of entities in Freebase. Following (Min et al., 2021), we repurposed this dataset for textual QA based on Wikipedia[7].

AMBIGQA (Min et al., 2020b) originates from NQ (Kwiatkowski et al., 2019), where questions are annotated with equally valid answers from Wikipedia.

Dataset	# Question			# Answer	
	Train	Dev	Test	Avg.	Median
WEBQSP	2,752	245	1582	22.6	1.0
AMBIGQA	10,036	2,002	2,004	2.2	2.0

Table 3: Statistics of multi-answer QA datasets. Statistics of answers are computed on the dev sets.

6.2 Baselines

We compare our *recall-then-verify* system with two state-of-the-art *rerank-then-read* systems.

REFUEL (Gao et al., 2021) selects 100 top-ranking passages from 1,000 retrieved passages, and predicts answers with a reader based on BART$_{\text{large}}$ (Lewis et al., 2020). It also has a round-trip prediction mechanism, i.e., to generate disambiguated questions based on predicted answers, which are re-fed to the reader to recall more answers.

JPR (Min et al., 2021) is a passage reranker which jointly models selected passages. With improved reranking performance, Min et al. (2021) selected only 10 passages from 100 retrieved passages, and used a reader based on T5-3b which is much larger and more powerful than REFUEL's reader, while requiring no more memory resources than REFUEL.

6.3 Implementation Details

Our retrieval corpus is the English Wikipedia from 12/20/2018. We finetuned the dense retriever from (Izacard and Grave, 2021a) on each multi-answer dataset. The answer recaller and the answer verifier were initialized with T5-3b; both were pre-trained on NQ and then finetuned on each multi-answer dataset. α_{neg} was 0.1 when finetuning the recaller. We retrieved 100 passages for a question, and verified each candidate with k=10 passages. The threshold τ for verification was tuned on the dev set based on the sum of F1 scores on all questions (F1 (all)) and questions with multiple answers (F1 (Multi)); the best τ on WEBQSP/AMBIGQA are

---

[6] We have tried other verbalizers such as "yes" and "no", but found no significant difference.

[7] Our train/dev split on WEBQSP is different from Min et al. (2021)'s, as their split was not publicly available in the period of this work.

System	WebQSP		AmbigQA	
	Dev*	Test	Dev	Test
RefuEL	-	-	48.3/37.3	42.1/33.3
JPR	53.6/**49.5**	53.1/47.2	48.5/37.6	43.5/34.2
Ours	**55.4**/45.4	**55.8/48.8**	**52.1/41.6**	**46.2/37.1**

Table 4: QA results on multi-answer datasets. The two numbers in each cell are F1 scores on all questions and questions with multiple answers, respectively. *Results on the dev set of WebQSP can not be directly compared, as we used a different train/dev split*[7].

0.8/0.5, respectively. Experiments with different model choices for the recaller and different values of α_{neg}, k and τ are shown in Section 6.5. Please refer to the Appendix for more implementation details.

Memory Constraint: Min et al. (2021) considered a fixed hardware and trained a reader with the maximum number of passages. We follow this memory constraint, under which a reader/verifier based on T5-3b can encode up to 10 passages each of length no longer than 360 tokens at a time.

6.4 QA Results

Due to candidate-aware evidence aggregation and a fixed sufficient number of passages distributed to each candidate, our *recall-then-verify* framework can make use of most retrieved supporting passages (see our improvements over OPR in Figure 1b). With a higher level of evidence usage, our *recall-then-verify* system outperforms state-of-the-art *rerank-then-read* baselines on both multi-answer datasets, which is shown by Table 4. Though focused on multi-answer questions, our framework is also applicable to single-answer scenario and achieves state-of-the-art results on NQ. Please refer to the Appendix for more details.

6.5 Ablation Study

In this section, we present ablation studies on AmbigQA. Please refer to the Appendix for results on WebQSP, which lead to similar conclusions.

6.5.1 Answer Recalling

Model Choices for the Answer Recaller As shown by Table 5, though T5-base is commonly recognized as a much weaker model than T5-3b, a recaller based on T5-base can achieve a high coverage of gold answers, leading to competitive end-to-end performance on the test set.

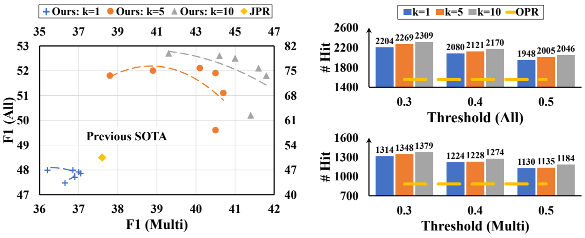
Necessity of Verification To investigate whether the recaller has the potential to tackle multi-answer questions alone, we tuned the precision of the recaller by varying α_{neg}. As shown in Table 5, with increased α_{neg}, the recaller learns to recall answers more precisely but still significantly underperforms the overall *recall-then-verify* system. It is likely that the recaller is trained on false positive passages, which may mislead the recaller to be over-conservative in filtering out hard negative passages. By contrast, using more evidence for verification is less likely to miss true positive evidence if there is any for a candidate, thus not prone to mislead the verifier.

Recaller		Verifier	Dev					Test
T5	α_{neg}	τ	$\lvert\mathcal{A}\rvert$	# Hit	Recall	Precision	F1	F1
3b	10	-	2.2	2068/1237	54.4/39.0	39.6/38.3	41.1/34.3	-
3b	5	-	3.3	2206/1328	56.8/41.7	36.6/36.5	39.7/34.7	-
3b	1	-	7.2	2714/1690	65.7/50.9	22.2/22.7	29.7/28.2	-
3b	0	-	51.2	**3364/2211**	**73.5/61.9**	3.8/4.6	6.8/8.2	-
3b	0.1	-	28.7	3288/2141	72.6/60.5	6.3/7.5	10.9/12.7	-
base	0.1	-	48.4	3156/2056	70.0/57.9	3.3/4.1	6.0/7.5	-
3b	0.1	0.5	28.7	2046/1184	55.2/37.8	**57.7/56.4**	**52.1/41.6**	**46.2/37.1**
base	0.1	0.6	48.4	2051/1181	54.8/37.6	55.4/54.3	50.8/40.8	45.8/37.0

Table 5: Performance of recallers on AmbigQA, trained with different models and α_{neg}. The recaller was paired with a verifier only in the last two rows which show end-to-end QA results. *# Hit* is the number of distinct gold answers verified or recalled, depending on whether the verifier is used or not.

Reducing Answer Candidates Though only using our recaller for multi-answer QA falls short, the recaller can be trained to shrink down the number of candidates so that the burden on the verifier can be reduced. As shown by Table 5, a small value of α_{neg} helps reduce answer candidates without significantly lowering recall.

6.5.2 Answer Verification



(a) (b)

Figure 4: Performance on the dev set of AmbigQA, with varying k and τ. In Figure (a), results with k=1 are associated with the top and right axes, while the others are with the bottom and left axes. As τ increases ($\tau \in \{0.3, 0.4, 0.5, 0.6, 0.7, 0.8\}$), points of the same color move from bottom right to top left. In Figure (b), *# Hit* is the number of gold answers with their scores above a threshold. *All* and *Multi* denote all questions and questions with multiple answers, respectively.

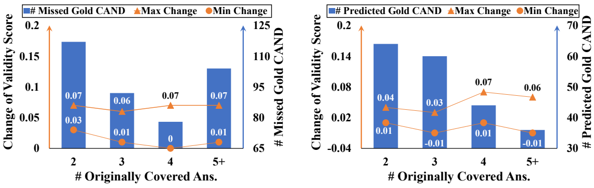


Figure 5: Analysis of how answer verification (k=10) is affected by the evidence of other answers on the dev set of AMBIGQA. The horizontal axis is the number of answers covered by $\mathcal{E}$. The left axis shows the max and min changes of predicted score of a gold candidate on average after adversarially removing supporting passages of some other answer(s) from $\mathcal{E}$. The left and right graphs are for missed gold candidates (scores $<$ 0.5) and predicted gold candidates (scores $\geq$ 0.5), respectively. After attacks, scores of 13.0% of missed candidates and 3.4% of predicted ones increased to above and decreased to below 0.5, respectively.

Effect of k Figure 4 shows the benefit of using more evidence for verification. As k increases from 1 to 10, there is a significant boost in F1 scores.

Effect of τ As shown by Figure 4a, the balance between recall and precision can be controlled by τ: a lower τ leads to higher recall and may benefit performance on questions with multiple answers. With k=10, our system outperforms the previous state-of-the-art system for a wide range of τ. As shown by Figure 4b, under the best setups (k=10, τ=0.5), our system predicts 31.7% and 34.1% more gold answers than the system using OPR on all questions and questions with multiple answers, respectively.

Dependencies among Answers Despite being candidate-aware, aggregated evidence $\mathcal{E}$ can also include supporting passages of some other gold answer(s). We therefore investigated how answer verification is affected by the evidence of the other gold answers. Specifically, we attacked the verifier as follows: a question-candidate pair is a target if and only if 1) the candidate $\hat{a}_i$ is a gold answer and 2) the aggregated evidence $\mathcal{E}_i$ includes at least one supporting passage of some other gold answer(s) that do not cover $\hat{a}_i$; we removed an arbitrary subset of supporting passages of the other gold answer(s) at a time[8] without removing any supporting passages of $\hat{a}_i$, and recorded the worst changes of the predicted validity scores of $\hat{a}_i$. As shown by Figure 5, the changes are small, indicating that missed gold candidates with low scores are not mainly suppressed by some other answer(s), and that predicted gold candidates with high scores are verified mainly based on their associated evidence.

6.6 Error Analysis

Missed Gold Answers	
Evidence is wrong	24%
Evidence is right and straightforward	76%
Wrong Predictions	
Predictions are true negatives	20%
Predictions are superficially-different false negatives	52%
Predictions are unannotated false negatives	28%

Table 6: Analysis of our predictions on the dev set of AMBIGQA. Examples are shown in Appendix.

Among 3,288 recalled gold answers on the dev set of AMBIGQA, the answer verifier misses 1,242 of them and outputs 1,323 wrong predictions. We manually analyzed 50 random samples, 25 of which are missed gold answers and 25 are wrong predictions. Table 6 reports our analysis.

For 76% of missed gold answers, our evidence aggregator actually aggregates straightforward true positive evidence. Among these missed answers with straightforward evidence, 58% of them have validity scores higher than 0.2 but lower than the threshold 0.5. We attacked the verifier on missed gold answers with their validity scores below 0.2 as in Section 6.5.2, and found that the maximum change of predicted scores on average is small (+0.04), indicating that the low scores can not be attributed to the negative distraction by the other gold answer(s). We conjecture that, as it is difficult even for human annotators to find all valid answers to an open-domain question (Min et al., 2020b), the verifier was trained to refute false negative candidates, resulting in unexpected low scores on some straightforward valid answers.

Notably, 80% of our "wrong" predictions turn out to be false negatives: 52% of "wrong" predictions are semantically equivalent to some annotated answer but are superficially different (Si et al., 2021); 28% of "wrong" predictions are unannotated false negatives. Therefore, it is likely that our system is underrated.

6.7 Inference Efficiency

In this section, we analyze the time complexity of our framework during inference, make comparisons with the state-of-the-art *rerank-then-read* framework JPR, and show how to reduce the computation cost of a *recall-then-verify* system.

For convenience, we denote the encoder length and decoder length as L_p and L_a, respectively.

---

[8] Removed passages were replaced with the same number of top-ranking passages that cover no gold answers.

Answer Recalling						Evidence Aggregation		Answer Verification		Overall	
T5	α_{neg}	Sec/Q	$\|\mathcal{A}\|$	Recall	Precision	k	Sec/Q	τ	Sec/Q	Sec/Q	F1
3b	0.1	4.88	28.7	72.6/60.5	6.3/7.5	10	0.02	0.5	4.83	9.73	52.1/41.6
3b	0.1	4.88	28.7	72.6/60.5	6.3/7.5	5	0.02	0.5	2.41	7.31	51.9/40.5
base	0.1	0.85	48.4	70.0/57.9	3.3/4.1	10	0.03	0.6	8.56	9.44	50.8/40.8
base	0.7	0.54	16.0	63.5/50.1	9.5/10.3	5	0.01	0.5	1.33	1.88	50.7/38.2

Table 7: QA performance and inference efficiency of our systems with different configurations on the dev set of AMBIGQA. *Sec/Q* denotes seconds per question when using a single V100 GPU. Answer verifiers were all initialized with T5-3b.

Recaller vs. Reranker The time complexity of answer recalling is $O(|\mathcal{B}| \cdot (L_p^2 + L_a \cdot L_p + L_a^2))$, while that of passage reranking is $O(|\mathcal{B}| \cdot L_p^2 + k \cdot |\mathcal{B}| \cdot L_p + k^2)$. As encoding dominates computation cost (whose time complexity is $O(|\mathcal{B}| \cdot L_p^2)$), given the same model size and $|\mathcal{B}|$, the time complexity of answer recalling and passage reranking is at the same level.

Verifier vs. Reader The time complexity of answer verification is $O(|\mathcal{A}| \cdot (k \cdot L_p^2 + k \cdot L_p))$, while that of the reader is $O(k \cdot L_p^2 + L_a \cdot k \cdot L_p + L_a^2)$. As the reader decodes a sequence of length L_a in an autoregressive way, while the decoding length of the verifier is only 1, the ratio between the inference time of the verifier and that of the reader should be much less than $|\mathcal{A}|$.

Evidence Aggregator Evidence aggregation is significantly faster than answer recalling and verification, as representations of Wikipedia passages are pre-computed. The time complexity is $O(|\mathcal{A}| \cdot (L_p^2 + |\mathcal{B}| \cdot \log k))$ where L_p^2 comes from encoding a question-candidate pair with the retriever's question encoder, and $|\mathcal{B}| \cdot \log k$ comes from selecting the top-k relevant passages for a candidate.

One can adjust the computation cost of a *recall-then-verify* system, depending on how much inference efficiency is valued over precision and recall, by (1) choosing a recaller model of proper time complexity[9], (2) tuning α_{neg} to adjust the expected number of candidates $|\mathcal{A}|$ needed for verification, (3) or tuning the number of passages k used for verification.

Table 7 shows QA performance and inference efficiency of our systems with different configurations. Replacing T5-3b with T5-base for the recaller is significantly faster in answer recalling, but is much less precise and produces more answer candidates with the same α_{neg}, which increases the burden on the verifier and thus may fail to reduce the overall computation cost if α_{neg} is not raised. By also increasing α_{neg} and choosing a smaller k, as shown by the last row of Table 7, the overall time needed to answer a question on the dev set of AMBIGQA can be reduced to 1.88 sec on a single V100 GPU while also obtaining state-of-the-art F1 scores (50.7/38.2). By contrast, the *rerank-then-read* system from Min et al. (2021) using a T5-base JPR (k=10) and a T5-3b reader is estimated to take 1.51 sec per question[10] with F1 scores of 48.5/37.6.

7 Conclusion

In this paper, we empirically analyze the problems of the *rerank-then-read* framework for open-domain multi-answer questions, and propose the *recall-then-verify* framework, which separates the reasoning process of each answer so that 1) we can have a higher level of evidence usage 2) and predicted answers are mainly based on associated evidence and are more robust to distraction by evidence of the other gold answer(s), 3) while also leveraging large models under the same memory constraint. On two multi-answer datasets, our framework significantly outperforms *rerank-then-read* baselines with new state-of-the-art records.

Ethical Considerations

To address problems of the *rerank-then-read* framework for open-domain multi-answer QA, we pro-

---

[9] As shown in Table 5, a smaller and faster answer recaller is capable of recalling answers with high coverage.

[10] The average inference time of JPR from Min et al. (2021) is independent of its parameters given a fixed number of encoded tokens and a fixed decoder length, which can be estimated with a randomly initialized JPR. The average inference time of JPR's reader was estimated with OPR's reader.

pose a *recall-then-verify* framework that will hopefully benefit information-seeking users with an enhanced ability of comprehensive exploitation of evidence from a large-scale corpus. As our predictions are verified with textual knowledge, our system itself would not raise new significant ethical concerns. All the datasets as well as the retrieval corpus in our experiments have been widely used for research purposes, and to our knowledge, do not have any attached privacy and ethical issues.

A Implementation Details

A.1 Retriever

Our retrieval corpus is the English Wikipedia from 12/20/2018, where articles are split into 100-word passages. Both OPR and our *recall-then-verify* system share the same passage retriever, which was initialized with the checkpoint released by (Izacard and Grave, 2021a) and was finetuned on each multi-answer dataset following DPR (Karpukhin et al., 2020). Specifically, for each question, we retrieved 100 passages with Izacard and Grave (2021a)'s checkpoint; for each gold answer a_i, we treated top-6 retrieved passages covering a_i as positives, and top-30 retrieved passages covering no gold answer as hard negatives. During finetuning, batch size was set to 128; each question in a batch was paired with one random positive passage and two random hard negatives.

$\lvert\mathcal{B}\rvert$	Retriever	WEBQSP (Test)	AMBIGQA (Dev)
5	DPR$^+$	**57.0/38.9**	**55.2/36.3**
	Ours	56.1/37.7	53.2/28.9
10	DPR$^+$	**59.0/38.6**	59.3/**39.6**
	Ours	57.8/35.9	**60.0**/37.7
100	Ours	68.0/47.8	73.6/57.6

Table 8: Retrieval results in terms of MRECALL. DPR$^+$ is the retriever of JPR (Min et al., 2021). We only report results on the test set of WEBQSP and the dev set of AMBIGQA because Min et al. (2021) used a different train/dev split on WEBQSP and the test set of AMBIGQA is hidden.

Table 8 shows the performance of our retriever. Our retriever underperforms DPR$^+$, the retriever of JPR (Min et al., 2021), in terms of MRECALL@5 and MRECALL@10. As DPR$^+$ has not been released, it is unknown whether DPR$^+$ still covers more gold answers than our retriever when retrieving 100 passages.

A.2 Answer Recaller & Answer Verifier

Our answer recallers used an encoder length of 240 and a decoder length of 40; they were first pretrained on NQ for 10 epochs and then finetuned on WEBQSP/AMBIGQA for 80/20 epochs with early stopping. Batch size was set to 320. We trained the recallers to decode gold answers covered by a given positive passage (following the order they appear in the passage) and output the "irrelevant" token given a negative passage. Our best system adopts the recaller trained with α_{neg}=0.1 because compared with α_{neg}=0, the recaller trained with

α_{neg}=0.1 shrinks down nearly half of answer candidates without a significant drop in recall.

Our answer verifiers used an encoder length of 280; they were first pre-trained on NQ for 3 epochs and then finetuned on WEBQSP/AMBIGQA for 30/10 epochs with early stopping. Batch size was set to 320 for k=1 and set to 64 for $k \in \{5, 10\}$. The number of invalid answers used for training was set to 10 times the number of valid answers. The best threshold τ was chosen from $\{0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9\}$ based on F1 scores on the dev set.

We used a flat learning rate of 1e-5 with 500 warm-up steps. All experiments were conducted on a single machine with eight V100 GPUs.

B Experiments

B.1 Single-Answer QA Result

System	k	T5	Dev	Test
(Izacard and Grave, 2021a)	100	large	51.9	53.7
JPR	10	3b	50.4	54.5
Ours	10	3b	**52.8**	**54.8**

Table 9: Exact match scores of different systems on the single-answer dataset NQ. The column *T5* shows the size of the readers of *rerank-then-read* systems and the size of the verifier of our *recall-then-verify* system. Izacard and Grave (2021a) adopted the *rerank-then-read* framework and used significantly more memory resources for training than JPR and our system.

Though our framework focuses on multi-answer questions, we also experimented on NQ to demonstrate that our framework is applicable to single-answer scenario without suffering from low precision. Specifically, for each question, we only output the candidate with the highest validity score. As shown by Table 9, we slightly outperform previous state-of-the-art *rerank-then-read* systems.

B.2 Ablation Study on WEBQSP

B.2.1 Answer Recalling

Table 10 shows the results of recallers on WEBQSP, which were trained with different models and α_{neg}. In summary, a weak model suffices to recall answers with high coverage. Using a large and strong model for the recaller benefits precision, but it is still difficult for the recaller alone to answer open-domain multi-answer questions, which necessitates answer verification based on more associated evidence. However, an answer recaller can help reduce the burden on the answer verifier by conservatively filtering out negative candidates.

Recaller		Verifier	Dev					Test
T5	α_{neg}	τ	$\lvert\mathcal{A}\rvert$	# Hit	Recall	Precision	F1	F1
3b	10	-	4.6	446/337	62.8/51.3	44.3/45.9	46.2/41.5	-
3b	5	-	4.9	452/335	64.4/51.3	44.7/44.5	46.5/39.9	-
3b	1	-	7.2	495/379	67.7/55.9	33.5/37.7	38.6/38.3	-
3b	0	-	44.4	**669/542**	**72.5/64.2**	8.3/11.4	12.5/16.5	-
3b	0.1	-	23.9	600/476	70.7/60.9	13.5/17.6	18.8/22.4	-
base	0.3	-	28.9	582/460	70.8/59.2	9.5/13.6	14.2/18.3	-
base	0.1	-	40.7	614/494	70.9/61.3	7.1/10.8	11.0/15.3	-
3b	0.1	0.8	23.9	414/309	58.7/44.6	**61.0**/61.0	**55.4**/45.4	**55.8/48.8**
base	0.1	0.8	40.7	425/326	57.9/45.6	59.9/**63.5**	54.2/**46.9**	54.5/48.4

Table 10: Performance of recallers on WEBQSP, trained with different models and α_{neg}. The recaller was paired with a verifier only in the last two rows which show end-to-end QA results.

Though a *recall-then-verify* system with a recaller based on T5-base significantly outperforms JPR on WEBQSP, it lags behind the system with a T5-3b recaller on F1 (all) on the test set. We conjecture that this is because with the same α_{neg}=0.1, a T5-base recaller obtains lower recall (69.5/61.4) than a T5-3b recaller (72.1/63.3); a T5-base recaller may need an even lower value of α_{neg} to obtain a higher coverage of gold answers.

B.2.2 Answer Verification

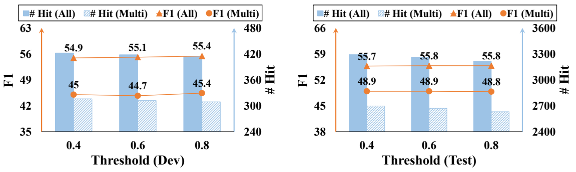

Figure 6: Performance of answer verification (k=10) on WEBQSP. *# Hit* is the number of gold answers with their scores above a threshold.

As shown by Figure 6, F1 scores on WEBQSP are insensitive to a wide range of τ, while a lower τ is helpful to predict more gold answers.

C Error Analysis

Table 11 reports our error analysis on the dev set of AMBIGQA.

Missed Gold Answers > Evidence is wrong (24%)

Question: Who does brooke davis have a baby with?

Gold Answers: Julian Baker

Missed Gold Answer: Julian Baker

Evidence: Brooke Davis is happier than ever; preparing to marry Julian Baker ... The Scott family are expecting their second child and Haley feels the baby will be a girl ...

Explanation: Evidence is insufficient to infer Brooke Davis has a baby with Julian Baker.

Missed Gold Answers > Evidence is right and straightforward (76%)

Question: What's the most points scored in an nba game?

Gold Answers: 370; 153; 162; 100; 186

Missed Gold Answer: 162

Evidence: The 1971-72 team holds franchise records in wins (69), most points scored, and largest margin of victory; both of the latter came in the team's 63 point win versus Golden State (162-99).

Wrong Predictions > Predictions are true negatives (20%)

Question: When did the song lost boy come out?

Gold Answers: February 12, 2015; January 2015; 4 December 2015; May 9, 2016; 2015; 2017; November 17, 2017

Prediction: 20 December 2011

Evidence: "The Lost Boy" was written by Holden in 2011 ... Holden recorded it and released as a charity single on 20 December 2011 ...

Explanation: "Lost Boy" and "The Lost Boy" are different songs.

Wrong Predictions > Predictions are superficially-different false negatives (52%)

Question: How much sports are there in the winter olympics?

Gold Answers: fifteen; 86; 98; seven; 102

Prediction: 15

Evidence: ... the Winter Olympics programme features 15 sports.

Wrong Predictions > Predictions are unannotated false negatives (28%)

Question: How much did it cost rio to host the olympics?

Gold Answers: US$11.6 billion; US$13,100,000,000

Prediction: USD 4.6 billion

Evidence: Indirect capital costs were "not" included, such as for road ... Rio Olympics' cost of USD 4.6 billion compares with costs of USD 40-44 billion for Beijing 2008 ...

Table 11: Analysis of predictions from our answer verifier. We display all annotated forms of gold answers, which are separated with semicolons.

Probing as Quantifying Inductive Bias

Abstract

Pre-trained contextual representations have led to dramatic performance improvements on a range of downstream tasks. Such performance improvements have motivated researchers to quantify and understand the linguistic information encoded in these representations. In general, researchers quantify the amount of linguistic information through probing, an endeavor which consists of training a supervised model to predict a linguistic property directly from the contextual representations. Unfortunately, this definition of probing has been subject to extensive criticism in the literature, and has been observed to lead to paradoxical and counter-intuitive results. In the theoretical portion of this paper, we take the position that the goal of probing ought to be measuring the amount of inductive bias that the representations encode on a specific task. We further describe a Bayesian framework that operationalizes this goal and allows us to quantify the representations' inductive bias. In the empirical portion of the paper, we apply our framework to a variety of NLP tasks. Our results suggest that our proposed framework alleviates many previous problems found in probing. Moreover, we are able to offer concrete evidence that—for some tasks—fastText can offer a better inductive bias than BERT.[1]

1 Introduction

Improved pre-trained representations have led to new performance heights on NLP applications. This has prompted researchers to analyze these representations in an attempt to determine which linguistic properties they encode. **Probing** is the primary method to perform such a quantification; typically, probing consists of training a supervised model, called a **probe**, to predict a linguistic property directly from the representations. It has been argued that the existence of a high-performing probe suggests that the representation encodes the property of interest (Alain and Bengio, 2017; Belinkov and Glass, 2019). However, despite the apparent simplicity of probing and its wide-spread use, the community has yet to find consensus on several important problems about the endeavor. We enumerate several problems with the supervised probing framework in the following paragraphs.

Problem I (Representation Selection). Counter-intuitively, probing may fail to capture observed differences between representations. For instance, in some supervised probing studies, researchers have shown that random representations are equally good or better than trained ones (Zhang and Bowman, 2018; Pimentel et al., 2020a). This is certainly a nonsensical result; random representations, by construction, do not encode any linguistic property.

Problem II (Probe Selection). There is an ongoing debate on the choice of probes: initially, linear probes were proposed to test the linear separability of learned representations (Montavon et al., 2011; Alain and Bengio, 2017; Liu et al., 2019a). However, more recently, neural networks have been applied with the explicit goal of extracting as much information as possible from the representations (Adi et al., 2017; Conneau et al., 2018; Pimentel et al., 2020b; Pimentel and Cotterell, 2021). Not surprisingly, it has been found that more complex probing tasks often require more complex probes (Belinkov and Glass, 2019). To reduce the risk of overfitting, recent methods aim at trading off probing performance with the probe's complexity (Hewitt and Liang, 2019; Pimentel et al., 2020a; Voita and Titov, 2020).

Problem III (Task Selection). The relationship between probing tasks and NLP tasks remains unclear. This lack of clarity manifests itself in several ways. Firstly, while some argue that probing should

focus on simple tasks (Conneau et al., 2018), others argue that probing should focus on complex tasks to be informative (Pimentel et al., 2020a). Thus, it is unclear where to place the boundary between probing and regular NLP tasks and whether there should even be a distinction between the two types of tasks at all. Secondly, how researchers should interpret experimental probing results is still up for debate. For instance, knowing that BERT excels at text generation, is it really surprising that we can predict the tense of a word from a BERT representation? Indeed, the NLP community is still in search of how probing can be of service to downstream tasks.

This paper proposes a new framework for supervised probing that seeks to address the problems described above. We propose to compare representations in terms of the **inductive bias** they provide for a particular task. This may seem counterintuitive, since classical machine learning often refers to the inductive biases of models alone, and not of representations; however, we propose to instead think of models as representation–probe pairs. Such a paired model takes raw text as input, converts it into a representation, e.g., using BERT (Devlin et al., 2019), and predicts a property of interest using a probe. We formalize the notion of the inductive bias of a paired model using the Bayesian model **evidence**. The evidence naturally trades off performance and complexity (Rasmussen and Ghahramani, 2000; MacKay, 2003; Bishop, 2006), therefore, it is well-suited to quantify the amount of inductive bias that a representation–probe pair provides for a particular task.

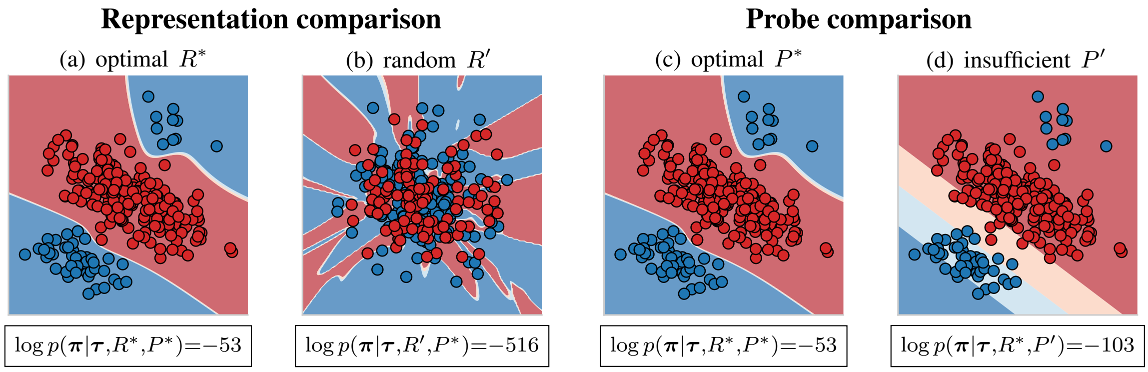
Indeed, we argue that, by quantifying inductive biases using the evidence, we can solve the problems listed above. The evidence inherently penalizes random representations, addressing **Problem I**, and allows us to automatically select probes that have the right complexity for the given task and representation, addressing **Problem II**. Importantly, automatically controlling probe complexity leads to an apples-to-apples comparison among representations, since every representation has access to the probe best suited for it. For example, we now have a fair basis for comparison between acontextual fastText representations and contextual BERT representations. Finally, evidence-based probing unifies probing and task-driven NLP (**Problem III**): the goal of the experimenter should be to identify the representation–probe pair with the best inductive bias for a particular problem so there is no difference in how the framework handles probing tasks and regular NLP tasks.

To validate our framework, we apply it to 28 tasks, many of which have been used for probing before. Our results suggest that our framework provides a practical solution to **Problem I** and **Problem II**. With respect to **Problem I**, we never find that random representations encode more inductive bias for a task than pre-trained representations. With respect to **Problem II**, we find that the optimal choice of probe depends on the task and representation in question, e.g., when relying on random representations, a linear probe suffices (since the added complexity of a neural probe cannot possibly help); however, with BERT representations, sometimes it is better to use a non-linear probe. This suggests that our method automatically gets around the probe selection problem. Moreover, our results also suggest that fastText can provide a better inductive bias than BERT for some morphosyntactic probing tasks.

2 Probing as Quantifying Inductive Bias

At the most fundamental level, the NLP community's interest in pre-trained representations is about reducing the sample complexity of models on downstream tasks. The community hopes that pre-trained representations are able to imbue NLP models with enough information about a given language that models can reach a higher performance with the same or even fewer training data. And, indeed, over and over again this has been shown to be the case (Peters et al., 2018; Devlin et al., 2019; Raffel et al., 2020). Another way of phrasing this desire is that the NLP community hopes that pre-trained representations have a suitable inductive bias for downstream tasks. This paper takes the position that, rather than probing the pre-trained representations for how much linguistic structure they contain—an endeavor that has received much attention (Belinkov et al., 2017; Belinkov and Glass, 2019; Conneau et al., 2018; Liu et al., 2019a, *inter alia*) but is still contentious (Hewitt and Liang, 2019; Pimentel et al., 2020a,b; Voita and Titov, 2020)—we should directly ask how much they improve the inductive bias on tasks of interest.

We propose to quantify the inductive bias of a model, i.e., a representation–probe pair, using the principle of **Occam's razor** (Rasmussen and Ghahramani, 2000). Occam's razor states that we



(a) optimal R^* (b) random R' (c) optimal P^* (d) insufficient P'

Figure 1: Comparison of the inductive biases of representation–probe pairs using the evidence. The evidence below the respective figures indicates that the right probe and representation are selected. The probing task is a binary classification of two properties (● vs ●). The same colors are used to mark the probe's decision function. Representations that naturally separate the properties are preferred over random representations in terms of the evidence, since they have a better inductive bias. **Left**: we compare an optimal representation that distinguishes both property classes (a) and a random representation (b). **Right**: we compare a neural probe (c) to a linear probe (d) which is too simplistic. The evidence correctly prefers a neural probe since it better explains the data.

should choose the simplest model that sufficiently explains our observations. One way to operationalize this principle is Bayesian model selection (Rasmussen and Ghahramani, 2000; MacKay, 2003; Bishop, 2006). Bayesian model selection relies on the **evidence**, which is a distribution over data sets for a given model—that is, how likely is it that a particular data set could have been generated by that model. With a probing data set, the evidence encompasses Occam's razor because (i) a model that is too simple would assign low probability to the data set (e.g., it is very unlikely that we sample a smooth cubic curve from a linear model), and (ii) an overly complex model would assign low probability because it can model that data set as well as many others (e.g., it is unlikely that we sample a cubic from a deep Transformer). In line with Occam's razor, the evidence is then highest for the simplest model that sufficiently explains the data set (e.g., a cubic model is the best explanation for a data set consisting of a cubic polynomial).

In the following, we outline the probabilistic model for probing and the form of the evidence. This enables us to quantify the inductive bias of representations. Crucially, part of the inference is to select the optimal probe for each representation so as to enable a fair comparison between representations.

2.1 A Probabilistic Model of Probing

Computation of the evidence requires the definition of a probabilistic probing framework. In this section, we introduce such a framework. Specifically, we compute the evidence of representation–probe pairs that constitute models for a fixed task.[2]

We start by introducing the notation necessary to describe our probabilistic probing framework. Formally, we denote linguistic sequences by $\tau \in \mathcal{V}^+$, where $\mathcal{V}$ is a vocabulary.[3] For example, τ could be a word in context, a whole sentence, or simply a single token. We probe for a linguistic property $\pi \in \Pi$. In a probing task, we have a data set of N i.i.d. pairs $\{(\tau_n, \pi_n)\}_{n=1}^N$ of sequences with associated linguistic properties. We abbreviate all sequences and properties collectively in a data set by $\boldsymbol{\tau}$ and $\boldsymbol{\pi}$. Formally, a **representation** $R(\cdot)$ is a (possibly stochastic) function from a sequence to a D-dimensional real vector, i.e., $R : \mathcal{V}^+ \rightarrow \mathbb{R}^D$. We will use the shorthand $h = R(\tau)$ to represent the vector resulting from the application of the function $R(\cdot)$ to τ, and $\boldsymbol{h}$ to abbreviate the representations of all sequences $\boldsymbol{\tau}$ in the data set. Finally, we employ a probe to predict the linguistic property π_n of a sequence τ_n from its representation $R(\tau_n)$, i.e., a probabilistic probe $f(\cdot)$ maps a vector in $\mathbb{R}^D$ to a distribution over linguistic properties. In all, this means that the composition $(f \circ R)(\tau_n)$ yields a distribution over the linguistic property π_n corresponding to τ_n. As an example, the representation $R(\cdot)$ may be realized by BERT, the probe $f(\cdot)$ may be a linear classifier, τ are words in context, and π are POS tags.

In our framework, we treat the composition of $f(\cdot)$ and $R(\cdot)$ jointly as a single model whose in-

---

[2] We note that our formulation has a close connection to the MDL formulation of probing (Voita and Titov, 2020).

[3] $\mathcal{V}^+$ is the set of all sequences of elements in $\mathcal{V}$ of length at least 1.

ductive bias we seek to assess. Formally, we define a model as a **representation–probe pair**, which we denote by a tuple $(R, P) \in \mathcal{R} \times \mathcal{P}$, where $R(\cdot) \in \mathcal{R}$ denotes a representation and $P \in \mathcal{P}$ is a probe specification. A **probe specification** characterizes a prior over some family of probes, e.g., a 2-layer neural network probe with tanh activations and a Gaussian prior on the weights. This is consistent with the probing literature, where probes are often parameterized families of probabilistic models trained using a regularization scheme that implicitly defines a prior over the parameters.[4] In such a case, a natural prior has the form $p(\theta \mid \boldsymbol{h}, P)$, where θ are the parameters of the family of models associated with P.[5] Each $P \in \mathcal{P}$ would then specify a prior over probe parameters θ and thus probe functions $f(\cdot)$. However, we opt for a slightly different notation. Analogous to our notation for h, we define f for the corresponding vector of probe outputs for an input representation, i.e. $f = f(h)$, and $\boldsymbol{f}$ as the probe outputs over the entire data set. Then, we reparameterize the prior $p(\theta \mid \boldsymbol{h}, P)$ in terms of the probe outputs $\boldsymbol{f}$, i.e., $p(\boldsymbol{f} \mid \boldsymbol{h}, P)$.[6] Our formulation is therefore general: we can follow previous work on probing and opt for a neural network probe, in which case each $P \in \mathcal{P}$ can specify an architecture and prior over parameters; however, we can also consider priors directly on function outputs, e.g., if we want a Gaussian process probe.

As we mentioned above, we allow for stochastic representations $R(\cdot)$. We can interpret this as a prior over representation outputs h, which is given by $p(h \mid \tau, R)$: it is conditional on the choice of representation and the particular input sequence τ we want a representation for. Formulating representations as probabilistic allows our framework to be more general, i.e., it can be used to compare stochastic representations (Vilnis and McCallum, 2015; Barkan, 2017; Xue et al., 2021, *inter alia*) to deterministic representations like BERT. If $R(\cdot)$ prescribes a deterministic representation then the distribution on h given a sequence τ is given by the Dirac delta function: $p(h \mid \tau, R) = \delta(R(\tau) - h)$.

Jointly, the priors over probe and representations outputs specify the prior for a representation–probe pair. All that remains is specifying the likelihood function; it is defined such that it factorizes over the data set as $p(\boldsymbol{\pi} \mid \boldsymbol{f}) = \prod_{n=1}^{N} p(\pi_n \mid f_n)$. The joint distribution $p(\boldsymbol{\pi}, \boldsymbol{f}, \boldsymbol{h} \mid \boldsymbol{\tau}, R, P)$ of the probabilistic probing model is then given by

$$\underbrace{p(\boldsymbol{\pi} \mid \boldsymbol{f})}_{\text{likelihood function}} \times \underbrace{p(\boldsymbol{f} \mid \boldsymbol{h}, P)\, p(\boldsymbol{h} \mid \boldsymbol{\tau}, R)}_{\text{prior}}. \quad (1)$$

We obtain the evidence for our representation–probe tuple by integration:

$$\begin{aligned} &p(\boldsymbol{\pi} \mid \boldsymbol{\tau}, R, P) \quad (2)\\ &= \iint p(\boldsymbol{\pi}, \boldsymbol{f}, \boldsymbol{h} \mid \boldsymbol{\tau}, R, P)\, \mathrm{d}\boldsymbol{f}\, \mathrm{d}\boldsymbol{h}. \end{aligned}$$

The evidence is a distribution over linguistic properties $\boldsymbol{\pi}$ given input tokens $\boldsymbol{\tau}$ and a particular choice of model, i.e., representation–probe pair (R, P). A representation–probe pair that could easily generate correct linguistic properties will score a higher evidence than one that does not generate any linguistically meaningful properties or one that can generate all sorts of data sets.

2.2 Maximizing the Model Evidence

To find the best representation–probe pair, we need to find the one maximizing the evidence in eq. (2):

$$(R^*, P^*) = \underset{(R,P) \in \mathcal{R} \times \mathcal{P}}{\operatorname{argmax}}\ p(\boldsymbol{\pi} \mid \boldsymbol{\tau}, R, P). \quad (3)$$

The space of representations $\mathcal{R}$ that we compare when probing is typically quite small and leads to a discrete choice: each $R(\cdot) \in \mathcal{R}$ simply denotes a distinct choice of representation. Further, all prior work on probing considers exclusively deterministic representations which, as mentioned above, simplifies the prior over representations to a Dirac delta distribution. This means we can rewrite eq. (2) as follows

$$\begin{aligned} &\iint p(\boldsymbol{\pi}, \boldsymbol{f} \mid \boldsymbol{h}, P)\, \mathrm{d}\boldsymbol{f}\, \delta(R(\boldsymbol{\tau}) - \boldsymbol{h})\, \mathrm{d}\boldsymbol{h}\\ &= \int p(\boldsymbol{\pi}, \boldsymbol{f} \mid \overline{\boldsymbol{h}}_R, P)\, \mathrm{d}\boldsymbol{f}. \quad (4) \end{aligned}$$

where we use $\overline{\boldsymbol{h}}_R = R(\boldsymbol{\tau})$ to emphasize that this is the non-random representation of $\boldsymbol{\tau}$ according to $R(\cdot)$. This characterizes our probing procedure: we compute this integral independently for each

---

[4] For example, L2 regularization can be seen as placing a Gaussian prior over the parameters of a model (Murphy, 2012, Chapter 7).

[5] In most applications, we would assume that the prior does not depend on $\boldsymbol{h}$, i.e., the prior would simply be $p(\theta \mid P)$. Indeed, we are being more general than what is usually necessary; however, as will soon become clear, allowing for this conditioning will simplify notation.

[6] This reparameterization may be achieved with a standard application of the change-of-variable formula using the neural network's Jacobian, similar to what is being done in functional variational inference (e.g., D'Angelo and Fortuin, 2021).

representation $R \in \mathcal{R}$ and hence the problem in eq. (3) reduces to selecting, for each representation, the probe specification $P \in \mathcal{P}$ that maximizes the evidence. The **inductive bias** of a representation R is the resulting optimal evidence across probes: $\max_{P \in \mathcal{P}} p(\boldsymbol{\pi} \mid \overline{\boldsymbol{h}}_R, P)$. This procedure can also be understood as hypothesis testing with a likelihood-ratio test (see App. A).

While $\mathcal{R}$ is simply the set of representations that we want to probe, the set $\mathcal{P}$ that characterizes priors on probes is more complex. It is typically a combination of discrete and continuous choices: For example, the number of layers in a neural probe is discrete, but the setting of weight decay is continuous. Moreover, to ensure that the evidence is not limited by a restricted choice of probe architectures, the set $\mathcal{P}$ needs to encompass sufficiently simple and complex probes at the same time. Hence, we construct our prior on probes by incorporating commonly used probes into it: we consider linear (Alain and Bengio, 2017; Adi et al., 2017; Hewitt and Liang, 2019; Liu et al., 2019a; Pimentel et al., 2020a) and more complex neural probes (Pimentel et al., 2020b; Voita and Titov, 2020) paired with weight decay to control complexity (Hewitt and Liang, 2019; Pimentel et al., 2020a). Probing based on a family of probes instead of a fixed architecture is a key difference to other probing frameworks. In fact, in our experiments (§4) we find that different representations perform best with different probe architectures and hyperparameters. This suggests that limiting probing to a single probe configuration might be misleading.

In practice, to maximize the evidence for each representation over $\mathcal{P}$, we follow the evidence framework by MacKay (1995, 2003) using the scalable implementation proposed by Immer et al. (2021a). This enables us to quantify the inductive bias of a representation (eq. (4)) and maximize it over $P \in \mathcal{P}$ as required by eq. (3), i.e., for each representation we select $\max_{P \in \mathcal{P}} p(\boldsymbol{\pi} \mid \overline{\boldsymbol{h}}_R, P)$. It also allows us to maximize the integral over a set of infinitely many choices of weight decay strength, to further control the complexity of the probes. As shown in §4, this leads to highly consistent results and alleviates overfitting, which is a problem that even simple linear probes have.

3 Tackling Probing with Evidence

As outlined in §1, current work in probing faces a series of problems. Here we discuss how these problems are directly addressed by the evidence.

3.1 Problem I (Representation Selection)

Clearly, random representations have no suitable inductive bias for linguistic tasks. Nonsensical results, such as that random representations outperform pre-trained ones (Zhang and Bowman, 2018; Hewitt and Liang, 2019; Pimentel et al., 2020a) simply indicate overfitting, which is strictly penalized in our framework. Compared to pre-trained representations, random representations have low evidence for linguistic tasks because there is no probe that can reliably predict the properties. In Fig. 1a vs. 1b, we illustrate how a random representation is penalized by the evidence. As we will see in §4, our framework consistently assigns lower evidence to the random representations compared to the pre-trained ones.

3.2 Problem II (Probe Selection)

Current probing results are inextricably bound to the choice of probe, yet for probing to provide us with insights about representations, we must break this dependence. For example, one salient issue in probing is that, while pervasive in the literature, there is a spurious association between linear probes and ease of extraction. This is illustrated in Fig. 1, where we can see a linear probe (Fig. 1d) that offers less ease of extraction than a neural probe (Fig. 1c), as measured by the evidence. This means that could obtain misleading results if we restricted our analysis to linear probes. Conversely, we will later see that linear probes can be too complex for some probing tasks and overfit, though the evidence overcomes this problem (Fig. 4). We avoid the problem of selecting a fixed probe by instead choosing a sufficiently large set $\mathcal{P}$ of priors of families of probes and finding the optimal probe specification, within that family, for each representation; as we will see later, the optimal probe varies considerably across tasks and representations. Instead of heuristic arguments about which probe to choose, the evidence provides a statistically sound way to select one in line with a likelihood-ratio test (Neyman and Pearson, 1933).[7]

3.3 Problem III (Task Selection)

In our opinion, an important issue with probing is that the research program has unclear goals. Like much of task-driven NLP, probing is essen-

---

[7] Refer to App. A for more details.

tially supervised learning with pre-trained representations. We argue that the goal of quantifying and, in particular, maximizing the inductive bias of representation–probe pairs aligns probing with regular NLP: In both cases, one searches for an optimal model at the lowest possible complexity—it does not matter whether the task of interest is simple or complex.

4 Experimental Setup

We evaluate our framework on a series of token, arc, and sentence tasks. Our token- and arc-level tasks are multilingual,[8] whereas our sentence tasks only consider English. We remove any property values that have less than 20 examples in any of the splits. All our probes are trained using the Adam (Kingma and Ba, 2015) optimizer. For details on hyperparameters, see App. B.

Token-level tasks. For our token-level probing tasks, we probe for part-of-speech (POS) tags, tense, number, and case. We use the setup in Torroba Hennigen et al. (2020), which consists of mapping the UD v2.5 (Zeman et al., 2019) treebanks to the UniMorph schema (Kirov et al., 2018) using the converter by McCarthy et al. (2018), and extracting examples of tokens tagged for the relevant properties. Next, we obtain the representations for each of those tokens in their sentential context (Torroba Hennigen et al., 2020). Finally, we split the resulting vocabulary using a 65–35 train–test split, such that no word appears in multiple splits. While the evidence does not require such a split, we use the split to validate results (cf. Fig. 4).

Arc-level tasks. For our arc-level tasks, we conduct dependency arc labeling (DAL). This consists of classifying the label for a dependency relation given only the representations for the head and dependent of that relation. These are extracted from the UD v2.5 treebanks using the approach in Pimentel et al. (2020a). We use the default UD splits.

Sentence-level tasks. For our sentence-level tasks, we consider four tasks. The first is MultiNLI (Williams et al., 2018), a natural language inference task. The other three are the BoolQ (Clark et al., 2019), Commitment Bank (De Marneffe et al., 2019), and recognizing textual entailment (RTE; Dagan et al., 2006; Bar Haim et al., 2006; Giampiccolo et al., 2007; Bentivogli et al., 2009) tasks, which are part of the SuperGLUE benchmark (Wang et al., 2019). If a task requires one or more passages as input, we first obtain a passage-level representations by averaging over all of its tokens.

Representations. In our token and arc tasks, we compare four different representations $R \in \mathcal{R}$: (i) m-BERT (Devlin et al., 2019), (ii) fastText (Bojanowski et al., 2017; Grave et al., 2018), (iii) a random representation (Rand.), which offers no information, drawn i.i.d. from a Gaussian distribution with zero mean and unit variance and the same dimensionality as BERT for each data point, and (iv) a representation that assigns a unique random vector to every word in our vocabulary, so the only information it provides is the identity of the word (Word Ident.). The dimensionality of (iii) and (iv) is the same as that of the BERT representation. For the sentence tasks, we consider (i) Random, (ii) fastText, (iii) BERT, (iv) ALBERT (Lan et al., 2020), (v) RoBERTa (Liu et al., 2019b), (vi) XLNet (Yang et al., 2019), and (vii) T5 (Raffel et al., 2020). App. C lists details on the exact models and implementations used.

Probe Family. In order to ensure fair comparisons, our framework requires us to define a suitably expressive set of priors $\mathcal{P}$ over probe families. In line with most of the probing literature, this includes linear and neural probes with 1 or 2 hidden layers, 100 hidden units, tanh activation, and varying weight decay parameter.

5 Results

We find that our formulation of probing alleviates the problems that we identified in §3. Firstly, the evidence suggests that random representations have an unsuitable inductive bias for linguistic tasks, which is in line with hypotheses from previous research (Zhang and Bowman, 2018; Pimentel et al., 2020a). Secondly, the automatic selection of the right probe architecture using the evidence shows that linear probes are seldom preferred, at least in our token- and arc-level experiments. That said, we also find evidence that even linear probes can overfit, and that the optimal linear probes may require many of their weights to be regularized to zero. Clearly, allowing different probe architectures between representations is beneficial for a fair comparison: simpler representations can profit

---

[8] We consider a small but typologically diverse set of languages: English (eng), Arabic (ara), Turkish (tur), Marathi (mar), German (deu), and Chinese (zho).

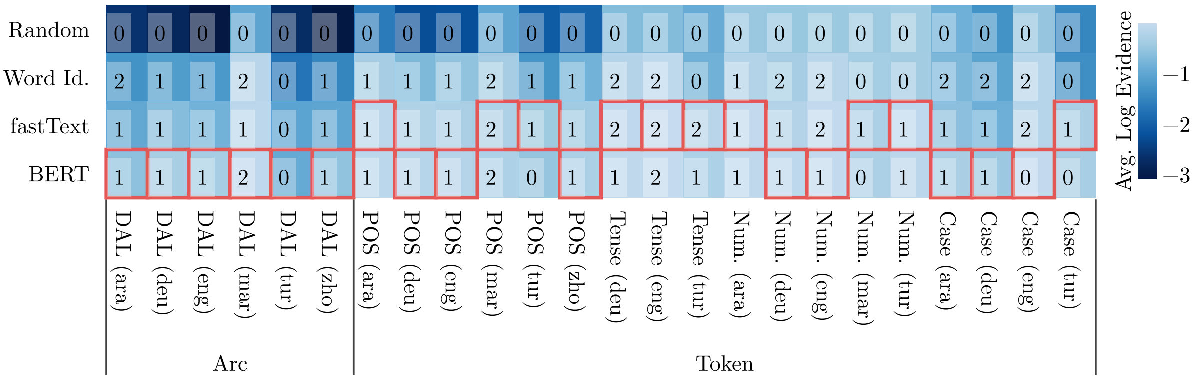


Figure 2: Inductive biases of different representations (shown on the rows) for token- and arc-level tasks (shown on the columns), as measured by the log evidence averaged over the data set. The integers inside the cells denote the number of layers of the optimal probe, with 0 denoting a linear probe. The representations with the best inductive bias (averaged over 3 runs) for each task are highlighted in red.

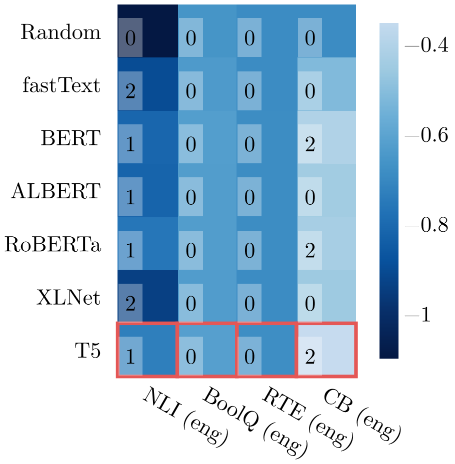

Figure 3: Inductive biases of different representations (shown on the rows) for sentence-level tasks (shown on the columns), as measured by the log evidence averaged over the data set. The integers inside the cells denote the number of layers of the optimal probe, with 0 denoting a linear probe. The representations with the best inductive bias for each task are highlighted in red.

from a more complex probe and demonstrate a superior inductive bias than more complex representations in some cases. Specifically, we find that fastText demonstrates a better inductive bias than BERT on multiple morphosyntactic tasks, while T5 appears to offer the best inductive bias for all our sentence-level tasks.

5.1 Representation Comparison

In the following, we discuss the results presented in Fig. 2 and Fig. 3 in detail.

Expected trends. Our results depict trends that should be expected from probing. For example, random representations perform worse than pretrained representations, especially in tasks with a larger number of classes, such as POS and dependency arc labeling. Word identity representations are better than random representations, which is to be expected, since the former are at least able to associate certain types to their most frequent properties, whereas the latter offer no information because they are sampled randomly per token. We suspect this is the reason why the optimal probe for random representations is always a linear probe that predicts the majority class.

Token- and arc-level tasks. Fig. 2 contains the results of our token- and arc-level tagging tasks. We find that fastText offers a better inductive bias for tense, while BERT is superior for case across all languages with the exception of Turkish (tur). In fact, we find that fastText evinces a better inductive bias for all Turkish token-level tasks. We believe that this is due to the agglutinative nature of Turkish, which means that fastText's bag-of-subword-units mechanism provides a useful inductive bias. For dependency arc labeling (DAL), we find that BERT has a uniformly better inductive bias. Interestingly, other than for random representations, the optimal probe usually has a nonlinearity, which refutes the idea that linear probes should be blindly picked for their simplicity. In all, our token- and arc-level results suggest that BERT is not a panacea, and motivate further research into multilingual studies of the morphosyntactic properties that BERT exposes well.

Sentence-level task. Fig. 3 suggests that T5 (Raffel et al., 2020) has a better inductive bias than the other representations we consider on sentence-level tasks. That said, we find that the difference in evidence between the different representations is generally quite small for BoolQ, RTE, and CB. Indeed, despite these being highly complex tasks, a linear probe is uniformly preferred for BoolQ and RTE.

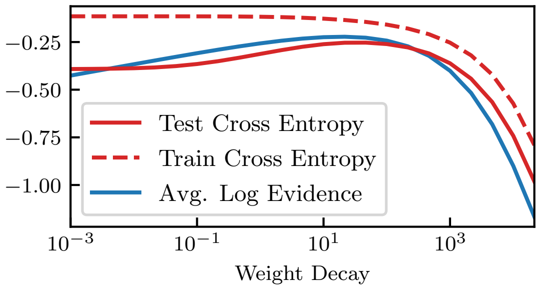

Figure 4: Average log evidence and cross entropy (*higher is better*) versus weight decay of a linear probe on POS German tasks using BERT. Even a simple linear probe can overfit and yield misleading results if not regularized properly as we can see from the generalization gap between training and test cross-entropies.

This may be an indication that the sentence-level representation mechanism we chose, i.e., averaging over the representations for the tokens in a sentence, is particularly ineffective for these two tasks. Indeed, we see that for both tasks, the evidence for the representations is not much higher than the evidence for the random representation, which may indicate that the optimal probes are largely ignoring the representations and just learning a majority-class baseline, which is achieved at the smallest complexity using a linear probe.

5.2 Controlling Probe Complexity

Fig. 4 shows linear probes on two tasks and how the evidence and cross-entropy change as a function of their weight decay. The graph shows that insufficient regularization leads to poor generalization using BERT, apparent from the gap between training and test loss that grows larger when weak regularization is applied. This means that insufficiently regularizing linear probes—and hence allowing them to fully use their parameters—reduces their evidence.

This observation, alongside former results, led us to conjecture that optimal probes may actually be restricted linear models, i.e., linear probes where most parameters are disabled. Our implementation is easily able to account for this hypothesis: by expanding $\mathcal{P}$ so that each parameter gets associated a different regularization strength, we can *automatically* identify which parameters are needed and force others towards zero. Fig. 5 illustrates the resulting distribution of per-parameter regularization strengths in the optimal probe for English POS, when $\mathcal{P}$ is defined to be the set of linear probes with per-parameter regularization; interestingly, the distribution is bimodal, such that every representation has a set of parameters that is zeroed out (rightmost mode). The random representation is regularized more than pre-trained ones, because it can only learn a majority baseline. Note that in practice, we can do this for probes with multiple layers too, so that the optimal probe we find may be simultaneously deep and sparse.

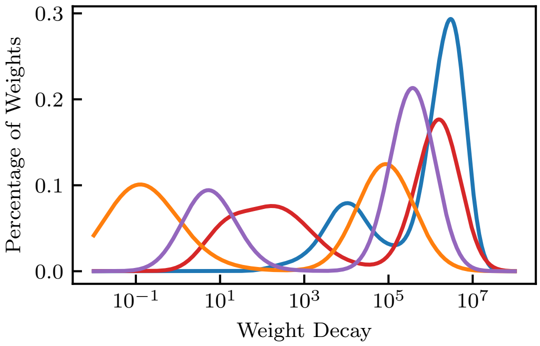

Figure 5: Distribution of the prior precisions learned by linear English POS probes for **Random**, **Word Identity**, **fastText**, and **BERT** representations. High regularization causes weights to be effectively zeroed out.

6 Related Work

Probing aims to provide insights into what linguistic information is encoded in pre-trained representations. Since the introduction of probing for sentence representations (Adi et al., 2017; Conneau et al., 2018), probing has also been applied to representations of words and tokens (Belinkov and Glass, 2019; Liu et al., 2019a; Voita and Titov, 2020; Pimentel et al., 2020b). Nonetheless, comparison of representations, the choice of probe, and even probing tasks have been under scrutiny recently (Belinkov and Glass, 2019; Liu et al., 2019a; Hewitt and Liang, 2019; Pimentel et al., 2020b).

Measuring representation quality. Prior work has mostly used probe accuracy as a measure of the quality of a representation. However, if not properly cross-validated, this can lead to nonsensical results which suggest that random representations are as good as learned ones (Zhang and Bowman, 2018; Hewitt and Liang, 2019). To alleviate this problem, control tasks (Hewitt and Liang, 2019), fewer data (Zhang and Bowman, 2018), or simplistic probes (Liu et al., 2019a) have been used. Using the evidence can be seen as extensive cross-validation (Fong and Holmes, 2020) and is therefore better suited for comparing representations.

In recent work, Lovering et al. (2021) argue that the ease of extraction of relevant features can be seen as an inductive bias. Specifically, they present experiments on artificial and naturalistic tasks that suggest that the amount of fine-tuning data required to make models rely on relevant features as opposed to spurious correlates of the output is connected to the relative ease of extraction between the spurious and relevant features. In comparison, our method can be seen as integrating over the entire space of features that a representation offers, and as such makes no assumptions about how a task should be solved, i.e., whether certain features are spurious or not for the task at hand.

Simple or complex probes? The choice of probe architecture is still a point of contention in the literature. Initially probes were typically linear models (Alain and Bengio, 2017; Adi et al., 2017; Liu et al., 2019a) because complex probes could memorize and overfit (Zhang and Bowman, 2018; Hewitt and Liang, 2019). However, restricting ourselves to linear probes only allows us to ask whether a particular task has a linear decision boundary, which tells us little about the information encoded in representations. Therefore, neural probes have recently been used as well (Pimentel et al., 2020b; Voita and Titov, 2020). In particular, this has spawned a line of work on automatically trading off probe performance and complexity. For example, Hewitt and Liang (2019) propose control tasks that mitigate overfitting and find that weight decay helps generalization in line with our observations in §5.2. Voita and Titov (2020) use the minimum description length (MDL) principle which is equivalent to the evidence in the case of a probabilistic model (MacKay, 2003). Both of these frameworks focus on the comparison and selection of probes which we argue is distinct from the problem of comparing representations. Thus in our framework, two representations do not need to be compared using the same probe but on the basis of the optimal probe for the representation, which appears to be useful (§5). In this sense, our work is most similar to Pimentel et al. (2020a), where representations, as opposed to probes, are compared by considering the Pareto hypervolume. That said, their approach is dependent on the choice of a complexity metric, whereas ours is not.

Linear probes can overfit. Our results indicate that, for some tasks, even linear probes may be overparameterized. One possible reason for this is that the optimal probes for these tasks ignore portions of the representation. If true, this would suggest that our framework may be useful for neuron-level probing (Dalvi et al., 2019; Durrani et al., 2020; Torroba Hennigen et al., 2020; Antverg and Belinkov, 2022), whose goal is to identify subsets of neurons in a representation that are informative about a property of interest.

7 Conclusion

Previous approaches to linguistic probing are plagued by several key problems, namely the issues of nonsensical results, probe selection, and ill-defined goals. To overcome these issues, we have proposed a novel probing framework, which focuses on the inductive bias that pre-trained representations offer for different linguistic tasks. We have shown that the Bayesian evidence, a natural measure for inductive bias, can be used in the context of probing. We have found that our framework empirically does not suffer from the aforementioned problems. We are hopeful that under this new paradigm, future work in probing will be more principled, comparable, and useful to the NLP community at large.

Ethics Statement

The authors foresee no ethical concerns with the work presented in this paper.

A Probing as Hypothesis Testing

The result of maximizing over probe P and representation R in eq. (3) can also be understood as selecting the highest-scoring hypothesis in a likelihood-based hypothesis test (Neyman and Pearson, 1933). To see this, we treat the pair (R, P) as one variable M. Then, we compare two representation–probe pairs, M and M', which we both believe to be equally probable, in the light of data by their likelihood ratio

$$\begin{aligned}\frac{p(M \mid \boldsymbol{\pi}, \boldsymbol{\tau})}{p(M' \mid \boldsymbol{\pi}, \boldsymbol{\tau})} &= \frac{p(\boldsymbol{\pi} \mid \boldsymbol{\tau}, M)\, p(M)\, p(\boldsymbol{\pi} \mid \boldsymbol{\tau})}{p(\boldsymbol{\pi} \mid \boldsymbol{\tau}, M')\, p(M')\, p(\boldsymbol{\pi} \mid \boldsymbol{\tau})} \\ &= \frac{p(\boldsymbol{\pi} \mid \boldsymbol{\tau}, M)}{p(\boldsymbol{\pi} \mid \boldsymbol{\tau}, M')}. \end{aligned} \tag{5}$$

The simplification is due to the equal probability of M and M', i.e., $p(M) = p(M')$. If the resulting ratio is larger than one, we decide in favor of M, otherwise in favor of M'. Thus, for a larger set $\mathcal{P}$ of probes and $\mathcal{R}$ of representations, it is sufficient to identify the highest-scoring pair in terms of the evidence $p(\boldsymbol{\pi} \mid \boldsymbol{\tau}, M)$, which is exactly the objective in eq. (3).

B Experimental Details

All our probes are trained using the Adam (Kingma and Ba, 2015) optimizer with hyperparameters $\beta_1 = 0.9, \beta_2 = 0.999$, learning rate 0.1, batch size 512, and for 500 epochs. For each discrete architecture (linear, MLP-1, MLP-2), we run the evidence framework as suggested by Immer et al. (2021a) with the following parameters: frequency $F = 1$, $K = 100$ number of steps every epoch, learning rate $\gamma = 0.1$. The evidence framework provides a Laplace approximation to the evidence in eq. (4). We implement our probing method using `laplace-torch` (Daxberger et al., 2021) and use a Kronecker-factored Hessian approximation (Martens and Grosse, 2015) using the eigendecomposition for the Laplace approximation (Immer et al., 2021b). We use an individual weight decay parameter per parameter group of the probes, i.e., each set of weights and biases are regularized independently per layer. Only for Fig. 5, we use a weight decay strength individually per parameter of the linear probe which effectively turns off individual parameters by increasing their weight decay. This is also known as automatic relevance determination (MacKay, 1995). In this case, we use a diagonal Hessian, and thus posterior, approximation.

C Representations

Tab. 1 shows the representations we used. For all transformer models, we use the HuggingFace transformers library (Wolf et al., 2020). Note that for fastText we use the multilingual vectors which are language-dependent, and the official fastText library.[9]

Representation	Model name
m-BERT	`bert-base-multilingual-cased`
BERT	`bert-base-uncased`
fastText	Language-specific, see here.
T5	`t5-base`
RoBERTa	`roberta-base`
XLNet	`xlnet-base-cased`
ALBERT	`albert-base-v2`

Table 1: Representations used. All representation except fastText use the HuggingFace implementations (Wolf et al., 2020).

Abstract

Structured pruning has been extensively studied on monolingual pre-trained language models and is yet to be fully evaluated on their multilingual counterparts. This work investigates three aspects of structured pruning on multilingual pre-trained language models: settings, algorithms, and efficiency. Experiments on nine downstream tasks show several counter-intuitive phenomena: for settings, individually pruning for each language does not induce a better result; for algorithms, the simplest method performs the best; for efficiency, a fast model does not imply that it is also small. To facilitate the comparison on all sparsity levels, we present *Dynamic Sparsification*, a simple approach that allows training the model once and adapting to different model sizes at inference. We hope this work fills the gap in the study of structured pruning on multilingual pre-trained models and sheds light on future research.

1 Introduction

Large-scale pre-trained monolingual language models like BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) have shown promising results in various NLP tasks while suffering from their large model size and high latency. Structured pruning has proven to be an effective approach to compressing and accelerating these large monolingual language models (Michel et al., 2019; Wang et al., 2020c; Prasanna et al., 2020; Liang et al., 2021), making them practical for real-world applications.

Similarly, multilingual pre-trained models (Conneau and Lample, 2019; Conneau et al., 2020; Xue et al., 2021; Luo et al., 2021) are also powerful and even have more parameters. However, little attention has been paid to evaluating the effectiveness of structured pruning on these multilingual models. Applying pruning to multilingual pre-trained models is non-trivial, as it typically involves many languages and needs to carefully design the roles of modules within the network. For example, most attention heads have little impact on the performance of monolingual pre-trained models (Michel et al., 2019; Voita et al., 2019), while it is the opposite for multilingual pre-trained models (See Section 5.3 and also Budhraja et al. (2021)).

This work intends to examine how structured pruning reacts to multilingual pre-trained models. We take the most representative multilingual pre-trained model family, XLM-R (Conneau et al., 2020; Goyal et al., 2021) for our case study and evaluate the pruning performance on nine cross-lingual understanding tasks in XTREME (Hu et al., 2020). We investigate three aspects of structured pruning: settings, algorithms, and efficiency.

Settings Traditional pruning produces a single small model, which is shared across languages (`shared` setting). Recent work on multilingual translation (Li et al., 2020; Lin et al., 2021; Xie et al., 2021; Gong et al., 2021) suggests that tailoring pruning to one language could achieve better results (`non-shared` setting). However, our comprehensive experiments show that neither of the two settings can consistently outperform the other one (See Section 5.2).

Algorithms There exists a broad spectrum of pruning algorithms (Hoefler et al., 2021), and it is impossible to test all of them considering the cost of pre-training. We focus on two pruning algorithms that have been studied the most in monolingual pre-trained models: the regularization-based pruning (Louizos et al., 2018; Wang et al., 2020c) (and our improved version) and the gradient-based pruning (Michel et al., 2019; Prasanna et al., 2020; Liang et al., 2021) (See Section 4). We experimentally find that the simplest gradient-based pruning is more effective for XLM-R (See Section 5.2).

Efficiency One meaningful way to measure pruning algorithms is to study how the performance and

speed of the pruned model vary with the sparsity (Hoefler et al., 2021). However, most pruning algorithms, including those we study in this work, require training the model for each specific sparsity. This limitation makes comparisons against a range of sparsity levels infeasible due to the prohibitive training cost. To solve this issue, we propose the *Dynamic Sparsification* (DS for short), a simple method that parameterizes subnetworks at any sparsity level and shares their weights afterward (See Section 6.1). DS only trains the model once but can obtain models at any sparsity level during inference. Experiments on XNLI (Conneau et al., 2018) show that DS does not degrade the performance much while dramatically reducing the training cost. Interestingly, we observe that the model size and inference speed are not strongly correlated in XLM-R. This observation suggests that one could not obtain a fast model by simply making the model small by using vanilla pruning algorithms (See Section 6.2).

2 Related Work

Settings Recent multilingual translation research suggests that adapting subnetworks for each language or language pair rather than for all of them gives better results. Among them, Li et al. (2020) train a shared multilingual model, then select layers for each language pair. Lin et al. (2021) also prune a shared multilingual model for each language pair, though on the level of entries in weight matrices. Instead, Gong et al. (2021) prune attention heads and feedforward networks for each language. Xie et al. (2021) first identify general and language-specific neurons in a shared multilingual network, then tune those neurons using the data of their corresponding language only. These findings inspire us to extend from multilingual translation to see how `non-shared` pruning settings work on multilingual pre-training.

Algorithms There are many structured pruning techniques proposed for monolingual pre-trained language models recently. Michel et al. (2019) propose a simple gradient-based importance score to prune attention heads. Prasanna et al. (2020); Liang et al. (2021) extend to prune other components like the feedforward network of the Transformer (Vaswani et al., 2017). Wang et al. (2020c) decompose the pre-trained model weights and apply L_0 regularization (Louizos et al., 2018) to regulate the ranks of decomposed weights. Sajjad et al. (2020) study layer pruning and show that directly dropping the top layers performs the best in fine-tuning. Peer et al. (2021) further show that by carefully choosing layers to drop, structured pruning can achieve a performance close to those trained by knowledge distillation (Hinton et al., 2015).

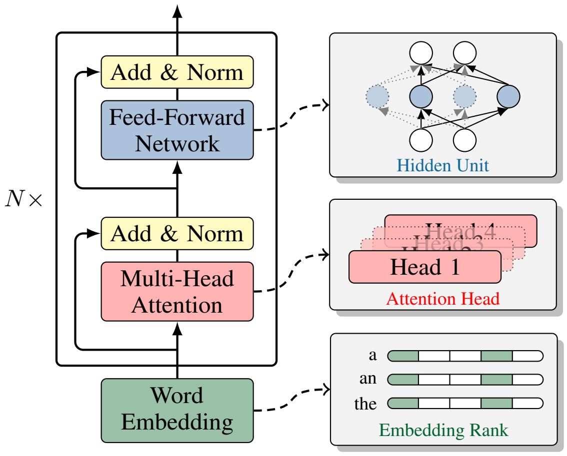

Figure 1: The left is the Transformer encoder, the right is the components that will be pruned at each layer.

Efficiency The pruning algorithms mentioned above need to train one network for each sparsity level used at inference. Hou et al. (2020) propose a dynamic structured pruning method based on Michel et al. (2019), which allows training the model once and making the inference with any size of the model. Compared with our Dynamic Sparsification, Hou et al. (2020)'s method cannot be applied to the `non-shared` setting as it needs to rearrange the network, i.e., producing a new model, for each language. Cascading methods (Schwartz et al., 2020; Xin et al., 2020) can even adapt the network size for each instance. Since cascading methods cannot perform batch inference and are only available for sentence classification tasks, we do not consider them in this work.

3 Background

In this section, we briefly review the structure of XLM-R (Conneau et al., 2020), a Transformer encoder (Vaswani et al., 2017) pre-trained by masked language modeling task (Devlin et al., 2019). We also revisit how conventional structured pruning algorithms are applied to Transformers by introducing additional gating variables and setting appropriate values to them (See Figure 1 and also Prasanna et al. (2020); Liang et al. (2021)). The XLM-R model consists of N layers. Each layer is made of the multihead attention and feedforward networks, followed by the residual connection and layer normalization.

Attention Following Michel et al. (2019)'s formula, the multihead attention is written as:

$$\mathrm{MHA}(X) = \sum_{i=1}^{H} G_{h,i} \mathrm{head}_i \tag{1}$$

where H is the number of heads, head_i is the output of i-th head and $G_{h,i}$ is the i-th entry of the gating variables $G_h \in \mathbb{R}^H$. $G_{h,i}$ indicates whether the head i will be pruned. $G_{h,i}$ is set to 1 to retain that head and 0 if to drop it. Different pruning algorithms will have their own ways to determine the values of G_h.

Feedforward Network The feedforward network contains two linear projections with GeLU activation (Hendrycks and Gimpel, 2016) in between:

$$\mathrm{FFN}(X) = (\mathrm{GeLU}(XW_1 + b_1) \odot G_f)W_2 + b_2 \tag{2}$$

where $W_1 \in \mathbb{R}^{d \times d_f}$, $b_1 \in \mathbb{R}^{d_f}$, $W_2 \in \mathbb{R}^{d_f \times d}$ and $b_2 \in \mathbb{R}^d$ are weights of the feedforward network and d_f is the hidden size. $\odot$ denotes the Hadamard product and $G_f \in \mathbb{R}^{d_f}$ is a gating vector with a value in the range of [0, 1]. G_f functions similar to G_h in multihead attention, except that G_f controls the activation of hidden units.

Embedding To prune the large embedding matrix E (occupying 69% of all parameters), we decompose it via low-rank approximation as in Lan et al. (2020):

$$E = \hat{E}\,\mathrm{diag}(G_e)P \tag{3}$$

where $\hat{E} \in \mathbb{R}^{v \times d}$ and $P \in \mathbb{R}^{d \times d}$ are the decomposed matrices of E. v is the vocabulary size. $G_e \in \mathbb{R}^d$, governing the rank of E, is a gating vector similar to G_h and G_f. $\mathrm{diag}(G_e)$ converts G_e to a diagonal matrix. The right part of Figure 1 is an illustration of the components (such as hidden units, attention heads, and embeddings) that will be pruned.

4 Extending Pruning Algorithms to Pruning Settings

This section will first introduce pruning algorithms that we study and then describe how to adapt them to two pruning settings. The first is the `shared` setting that shares the pruned network across languages (default setting that all pruning algorithms could run on), and the second is the `non-shared` setting that prunes one subnetwork for each language (Xie et al., 2021; Gong et al., 2021).

4.1 Gradient-based Pruning

Gradient-based pruning (Michel et al., 2019) computes the importance score of each component, e.g., heads in Eq. 1. Then it sets the gating variable of a component, e.g., $G_{h,i}$ in Eq. 1, to 1 if its importance score is larger than a threshold and 0 otherwise. Taking an attention head i as an example, its importance score is defined as:

$$I_{\mathrm{head}_i} = \mathbb{E}_{X \sim \mathbf{X}} \left| \mathrm{head}_i^T \frac{\partial \mathcal{L}_{\mathrm{MLM}}(X)}{\partial \mathrm{head}_i} \right| \tag{4}$$

where $\mathbf{X}$ is the data distribution and we choose the validation set as $\mathbf{X}$ in practice, $\mathcal{L}_{\mathrm{MLM}}$ is the masked language modeling loss (Devlin et al., 2019). The values of gating variables are set and frozen after pre-training. An additional phase of pre-training is further employed to update network parameters to recover performance loss brought by pruning.

Extending gradient-based pruning to the `non-shared` setting is straightforward: to prune for one language, we use data of that language to compute a unique set of gating variables $G = \{G_h, G_f, G_e\}$ for it.

4.2 Regularization-based Pruning

The L_0 norm has been widely used in many areas, including signal processing (Zhang, 2010; Xu et al., 2011) to induce sparsity. In neural networks, regularization-based pruning, also referred to as L_0 regularization (Louizos et al., 2018), defines a differentiable L_0 norm on the gating variables $G = \{G_h, G_f, G_e\}$. It controls the network sparsity by learning the values of G during pre-training. Taking a gating variable $g \in G$ as an example, it is modeled as:

$$\begin{aligned} u &\sim U(0,1) && (5) \\ s &= \mathrm{sigmoid}((\log u/(1-u) + \alpha)/\beta) && (6) \\ \hat{s} &= s \times (r - l) + l && (7) \\ g &= \min(1, \max(0, \hat{s})) && (8) \end{aligned}$$

where U is the uniform distribution, $l < 0$ and $r > 1$ are two fixed constants, β is the temperature and α is a learnable parameter of g. During training, u is sampled for each g separately. At inference, Eq. 6 becomes $s = \text{sigmoid}(\alpha)$. Compared with gradient-based pruning, the importance score in L_0 regularization is the learnt α and the threshold is fixed to $\text{sigmoid}^{-1}\left(-\frac{l}{r-l}\right)$.

The L_0 regularization term of g is:

$$||g||_0 = \text{sigmoid}\left(\alpha - \log(-l/r)\right) \quad (9)$$

and the overall L_0 regularization term is[1]:

$$\mathcal{L}_{L_0} = ||G||_0 = \sum_{g \in G} ||g||_0 \quad (10)$$

$\mathcal{L}_{L_0}$ will be multiplied by a hyper-parameter λ_1 and added to the pre-training loss $\mathcal{L}_{\text{MLM}}$.

4.2.1 Improved L_0 Regularization

Two issues of the previous native L_0 regularization emerge in practice: 1) The hyper-parameter λ_1 does not relate to the model sparsity. It requires several expensive try-outs training runs to find an appropriate setup that can reach desired sparsity (Wang et al., 2020c). 2) If we extend L_0 regularization to `non-shared` setting as done in gradient-based pruning, it easily converges to an optimum where every language shares the network (Gong et al., 2021). This falls back to the `shared` setting. Thus, we propose two corresponding solutions as below:

1) Sparsity Constraint To address the first issue, we add a sparsity constraint to Eq. 10:

$$\mathcal{L}_{L_0} = \sum_{i=1}^{l} \left| ||G^i||_0 - t \right| \quad (11)$$

where l is the number of languages and G^i denotes the set of gating variables for language i. This loss term will keep the subnetwork size of each language close to the targeted size t.[2]

2) Diverse Subnetwork To address the second issue, we introduce a diversity loss term to encourage the model to find a distinct subnetwork for each language. It is achieved by diagonalizing the gram matrix of gating variables $\bar{G} = [G^1; \cdots; G^l]$:

$$\mathcal{L}_{\text{diag}} = ||P \odot \bar{G}\bar{G}^T \odot (\mathbf{1} - \mathbf{I})||_1 \quad (12)$$

where $\mathbf{1}$ is a matrix of ones and $\mathbf{I}$ is the identity matrix. $P \in \mathbb{R}^{l \times l}$ is used to introduce linguistic prior and is a matrix of ones by default.

Eq. 12 will penalize each language pair equally. Intuitively, the subnetworks of two languages that are close, e.g., English and Spanish, should not be penalized. Thus we add linguistic prior $P_{ij} = 0$ when the i-th and j-th languages belong to the same language family (See Appendix C) and 1 otherwise.

To the end, the loss $\mathcal{L}$ we used in pre-training is:

$$\mathcal{L} = \mathcal{L}_{\text{MLM}} + \lambda_1 \mathcal{L}_{L_0} + \lambda_2 \mathcal{L}_{\text{diag}} \quad (13)$$

Note that the parameter of the gating variable α is randomly initialized. We find that tuning only α in the first few epochs is crucial to obtain better performance. If no further notice, we will use this improved L_0 regularization for experiments with `non-shared` setting and the native L_0 regularization for `shared` setting.

5 Empirical Study of Algorithms and Settings for Multilingual Pruning

5.1 Experimental Setup

Pre-training Our pruned models are trained on the CC-100 corpus (Wenzek et al., 2020). We choose 100 languages with a total size of 2.2TB for training, which is consistent with those used in XLM-R (Conneau et al., 2020). The development set we used to induce the importance score for pruning is 3K randomly selected samples from the CC-100 corpus per language.

Our model is a 12-layer Transformer with a 768 embedding size and a 3072 hidden size. It is pruned and continually trained based on the publicly available XLM-R model for 150K steps with a batch size of 2048 and a learning rate of 0.0002. Other hyper-parameters remain the same as in the original paper (Conneau et al., 2020). We train our model on 32 Nvidia Tesla V100 32GB GPUs with mixed-precision training. It takes roughly 7-10 days to pre-train one model. For inference, we use 1 Nvidia Tesla V100 32GB GPU and Intel(R) Xeon(R) Platinum 8269CY CPU @ 2.50GHz to estimate the GPU and CPU throughput (with a batch size of 128 for GPU and 1 for CPU).

Fine-tuning We evaluate the pruned models on 9 downstream tasks from XTREME (Hu et al., 2020). These tasks can be classified into four different categories: (1) sentence-pair classification: XNLI (Conneau et al., 2018), PAWS-X (Yang

---

[1] In practice we weigh the L_0 regularization term of gating variables (See Appendix B).

[2] Adding a Lagrange multiplier (Wang et al., 2020c) is also doable, but we find this simple L_1-like loss is similarly effective and easy to implement.

Table 1: XTREME results (Sparsity is the portion of dropped parameters in the Transformer encoder, and thus higher sparsity denotes smaller size.). We compare one representative distillation method (denoted as `DistilBERT`, Sanh et al. (2019)) and two representative structured pruning methods: gradient-based pruning (denoted as `Grad`) and regularization-based pruning (denoted as L_0), under two settings (described in Section 4: `shared` and `non-shared`). **Bold** denotes the best results among 50% sparsity. Note that since BUCC and Tatoeba do not have the translated training data, we do not report their translate-train-all results.

et al., 2019); (2) structured prediction: POS (Nivre et al., 2018), Wikiann NER (Pan et al., 2017); (3) question answering: XQuAD (Artetxe et al., 2020), MLQA (Lewis et al., 2020), TyDiQA (Clark et al., 2020); (4) sentence retrieval: BUCC2018 (Zweigenbaum et al., 2017), Tatoeba (Artetxe and Schwenk, 2019). The hyper-parameter setup of fine-tuning could be found in Appendix A.

Following previous work (Hu et al., 2020), we study the pruned models in two fine-tuning settings: *Cross-lingual Transfer* (a.k.a., zero-shot) and *Translate-Train-All* (a.k.a., multi-task). Note that for the two sequence labelling tasks POS and NER, translation cannot give us the correct training labels. We thus use human-annotated data for translate-train-all training on them.

5.2 Results

Table 1 shows the fine-tuning results of using different methods to prune XLM-R to 50% sparsity (also the value of t in Eq. 11). We follow the convention of Prasanna et al. (2020) to compute the sparsity of the encoder, which excludes the embeddings in the calculation. For `DistilBERT`, we remove half of the original layers of XLM-R as done in Sanh et al. (2019). Note that in Table 1 (the rows of "L_0 (shared)"), regularization-based pruning with `shared` setting has a lower sparsity (20%).[3]

Methods	Sparsity	XNLI	POS	NER	TyDiQA	**Avg**
L_0	20%	73.4	87.5	85.1	61.2/45.9	74.9
Impv. L_0	50%	76.3	**87.9**	**86.8**	67.8/52.5	77.8
Impv. L_0 + Distil	50%	**76.4**	87.5	86.7	**69.5/54.6**	**78.2**

Table 2: The results of the improved L_0 (Impv. L_0) regularization-based pruning (See Section 4.2.1).

Gradient-based pruning performs better than regularization-based pruning. Table 1 shows that vanilla L_0 in `shared` setting has more parameters (20% sparsity) but performs worse than gradient-based pruning with fewer parameters (50% sparsity). Despite that our proposed improved L_0 works better (`non-shared` setting), it still underperforms the gradient-based pruning counterpart. This is because regularization-based pruning keeps modifying the subnetwork structure when weights are updating, which might introduce too much noise during training. Gradient-based pruning, on the other hand, keeps the pruned network unchanged and adapts weights only. Despite that some works (Hoefler et al., 2021) suggest that regularization-based pruning should be preferred, it might not be the same conclusion for XLM-R.

Neither of the pruning settings performs consistently better. Previous work on multilingual

---

[3] We have tried various hyper-parameters settings to pretrain models toward 50% sparsity (for a fair comparison with `DistilBERT`) using vanilla L_0, but the resulting sparsity is either too high ($\geq$70%) or too low ($\leq$20%). This is in line with the trainability issue of L_0 as indicated in Section 4.2.

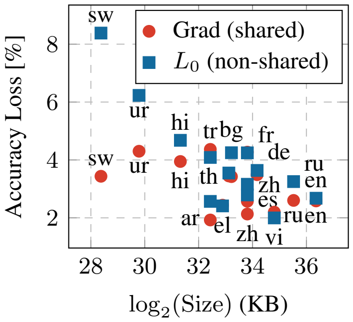

Figure 2: Accuracy loss on each language of XNLI vs. the logarithm of their pre-training corpus sizes.

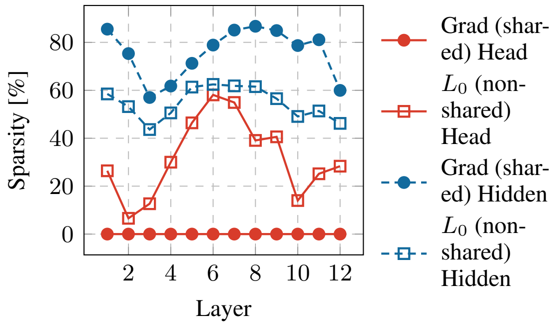

Figure 3: Sparsity of each layer pruned by two pruning algorithms.

translation has suggested that `non-shared` setting provides consistent gains, as this way allows the pruned model to adapt for each language (Li et al., 2020; Lin et al., 2021; Xie et al., 2021; Gong et al., 2021). However, this is not the case for XLM-R. As shown in Table 1, regularization-based pruning (L_0) works the best with the `non-shared` settings[4], but for gradient-based pruning it is the `shared` setting. We analyze that this is because XLM-R covers more low-resource languages (100 languages in XLM-R vs. 24 in most multilingual translation research), which makes sharing the subnetwork for a universal representation more preferable (Aharoni et al., 2019).

Simple distillation performs less effective than pruning. For most tasks, distillation is not as effective as pruning.[5] This might be that distillation prunes a whole layer, while more fine-grained components are pruned in structured pruning. But combining distillation with pruning could provide some gain, as shown in Table 2.

Our improved L_0 regularization-based pruning can further boost the performance. In Section 4.2.1, we propose an improved L_0 regularization to solve the drawbacks of standard L_0. Table 2 shows the results. Through the sparsity constraint, we can control the model sparsity to be the desired value $t = 50\%$ instead of 20% (the closest we could have using vanilla L_0). And along with diverse subnetwork, the improved L_0 can even consistently improve the fine-tuning results. Appendix E visualizes how subnetworks differ between two languages after applying the diversity loss term. Moreover, integrating with distillation (the last row of Table 2) can further improve the results.

5.3 Analysis

Why does regularization-based pruning perform poorly? Since regularization-based pruning learns the subnetwork from scratch, we believe its poor performance results from the low-resource languages. We choose XNLI with the translate-train-all setting for empirical verification. On the one hand, the translate-train-all setting ensures that each language has the same dataset for fine-tuning (except for NER and POS). This way eliminates the difference in fine-tuning. On the other hand, among all tasks except NER and POS, XNLI covers more languages.

Figure 2 supports our hypothesis. It shows the accuracy loss and corpus size of each language in regularization-based and gradient-based pruning. We observe that for regularization-based pruning accuracy loss strongly correlates with pre-training dataset size (a value of 0.83 for Pearson's τ), while it is not for gradient-based pruning.

Where does pruning methods behave differently? In Figure 3, we compare in which aspect different pruning algorithms behave differently. Figure 3 shows the sparsity of each component (attention heads and hidden units) at each layer. Interestingly, we see that gradient-based pruning preserves all attention heads and only a tiny number of hidden units, while regularization-based pruning prunes heads and hidden units more evenly. Though previous works (Michel et al., 2019; Voita et al., 2019) have suggested that most attention heads have little impact on the final performance of monolingual models, our results show that this is not the case for XLM-R. Besides, both pruning methods tend to drop more in the middle layers.

---

[4] Non-shared model with more parameters dropped (50% sparsity) is better than shared model with fewer parameters dropped (20% sparsity).

[5] Although adopting advanced distillation techniques might improve the result, the pruning algorithm is also simple here.

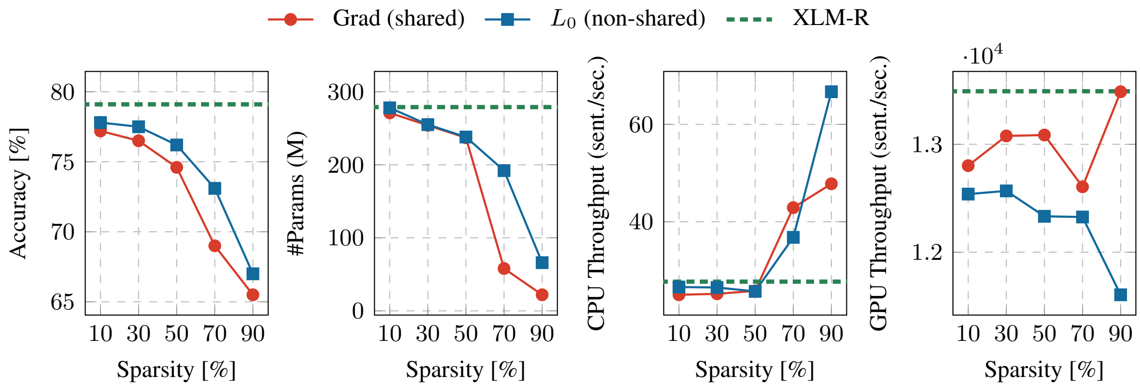

Figure 4: Accuracy on XNLI with translate-train-all setting and dynamic sparsification, the number of parameters (#Params), CPU and GPU throughput (the number of sentences per second) vs. the sparsity.

Methods	XNLI	POS	NER	TyDiQA	Avg

6 Toward Efficient Pruning

6.1 Dynamic Sparsification

In practice, we may need models with different sparsities to fit various resource constraints or compare a set of methods. Nevertheless, existing pruning techniques must train the model independently for each sparsity level, which is prohibitive for large models. Here we propose *Dynamic Sparsification* (**DS** for short), a method that trains the model once but allows inference with any level of sparsity.

Section 4 shows that both gradient-based and regularization-based pruning follow the same procedure: we first determine a threshold, then get the importance score for each component, and set the gating variable to 1 if its score is larger than that threshold and 0 otherwise. By adjusting the threshold, one can obtain networks with any sparsity.

Based on this, we model a gating variable g as:

$$g = f(\alpha + t\theta) \tag{14}$$

where α is a trainable importance score as in regularization-based pruning, t is the targeted network size (which is one minus the sparsity), $t\theta$ is the threshold with a learnable θ, f is a function with output ranging between 0 and 1. We choose f to be Eqs. 6 - 8 because it enables us to optimize α and θ via L_0 regularization. If α and θ are set properly, Eq. 14 will automatically determine whether its corresponding component should be activated under the targeted network size t.

Then is how to find α and θ using pruning algorithms. We know that pruning algorithms could rank different components by their importance scores. Based on this ranking, we identify the boundary network size that a specific component will be activated (denoted as $\hat{t}$) and will not. These two conditions form a system of linear equations in two unknowns α and θ:

$$\begin{cases} f\left(\alpha + \hat{t}\theta\right) = 1 \\ f\left(\alpha + \left(\hat{t} - \delta\right)\theta\right) = 0 \end{cases} \tag{15}$$

where δ is the network size that one component contributes to, $\hat{t}$ is the boundary network size where the corresponding gating variable g should be 1 if $t > \hat{t}$ and 0 if $t < \hat{t} - \delta$. $\hat{t}$ equals the ranking divided by the total number of components. Eq. 15 has a closed-form solution for α and θ:[6]

$$\begin{cases} \alpha = \left(1 - \hat{t}/\delta\right) f^{-1}(1) + (\hat{t}/\delta) f^{-1}(0) \\ \theta = \left(f^{-1}(1) - f^{-1}(0)\right)/\delta \end{cases} \tag{16}$$

Before training, we use gradient-based pruning to initialize α and θ via Eq. 16. If only gradient-based pruning is adopted, α and θ are then clamped and only the retained network parameters will be updated, otherwise they can be jointly optimized via regularization-based pruning. During training, we sample different ts to train different sized subnetworks. At inference, t is set to the targeted network size to prune the model. If one wants to extend DS to `non-shared` setting, he can prune for each language once and compute a unique set of α and θ for each language.

---

[6] Eq. 16 has the numerical stability issue and weighs different components equally (See Appendix D for the solution).

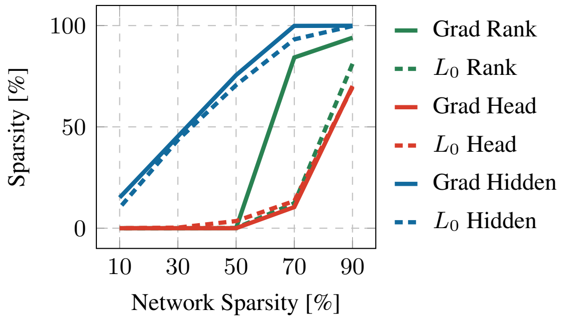

Figure 5: Sparsity of different components pruned by two pruning algorithms vs. the sparsity.

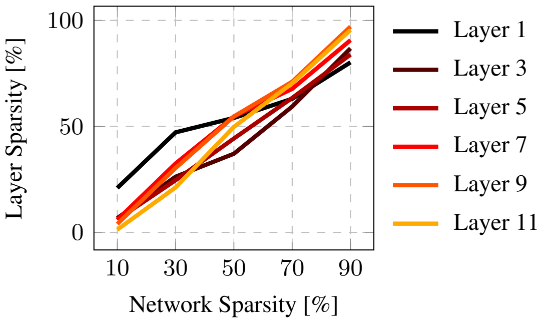

Figure 6: Sparsity of different layers pruned by regularization-based pruning vs. the sparsity.

6.2 Main Results

Table 3 (+ `DS` rows) shows the 50% sparsity results after applying DS to the two pruning algorithms under their best performing pruning settings (according to Table 1). Surprisingly, we observe that gradient-based pruning with `shared` setting suffers from a significant loss, while regularization-based pruning with `non-shared` setting has almost no loss. This is because DS shares the weights between subnetworks of different sparsities hurts the model capacity, and `non-shared` setting enlarges the subnetwork capacity by untying weights of different languages. Due to the expensive cost of training models without DS, we only test the impact of DS on 50% sparsity, but we compare it with other systems with a smaller size (See Appendix F). The leftmost part of Figure 4 shows more on how the two pruning methods trade accuracy for efficiency under various sparsities.

The second sub-figure from the left of Figure 4 shows a non-linear relationship between the number of parameters and sparsity, as embeddings are not included in sparsity calculation (Prasanna et al., 2020). Since embeddings are more important than most parts of the model and are very large (69% of the overall parameters), the number of parameters remains high even when the encoder is quite sparse (Sparsity $\leq 50\%$). Pruning algorithms only start to prune these large embeddings when the encoder is very sparse (Sparsity $> 50\%$) and results in a great drop in the number of parameters, as shown in Figure 5.

The two rightmost panels of Figure 4 describe how the CPU and GPU throughput vary as the sparsity changes. We observe a strong correlation between the CPU throughput and sparsity when the sparsity $\geq 50\%$. However, there is no such trend observed when the sparsity $< 50\%$. This might be due to the time consumption of irregular memory access out-weights the speed-up brought by the small tensor computation.

Interestingly, we see that sparse models show no acceleration on GPU even when the sparsity is high (e.g., 90%). Although pruning algorithms here optimize the model size instead of inference efficiency, it is expected that the resulting sparse models still have speedup as shown in CPU and in other work (Wang et al., 2020c). In Figure 6, we find that the highest sparsity of all layers is close to but not exactly 100%. This implies that **pruning tends to produce a deep and narrow model.** Previous studies (Sanh et al., 2019; Wang et al., 2020a; Li et al., 2021) show that GPU throughput is more sensitive to the model height instead of its width. This explains why we did not observe any acceleration even for a model with $1/10$ of the original size.

Though not shown in Table 1 and Figure 4, it is still possible to obtain actual speedup in GPU for sparse models. **Previous observations on GPU throughput only hold for inference with the same batch size**. In practice, the sparse models have a smaller memory footprint and we can use a larger batch size for higher parallelism. For pruned models in Table 1, a nearly $2\times$ speedup is observed when we double the inference batch size.

In summary, Figure 4 suggests that **the correlation between the model size and throughput is very week for XLM-R**: for model size, reducing the embedding size is important, but it has almost no impact on throughput (an $O(1)$ complexity table lookup); for throughput, compressing parts other than embeddings is more effective as shown in Figure 4, but they have much fewer parameters than the embeddings (193M parameters for embeddings vs. 86M for the others). This advocates special care needed to be taken if one wants to compress and accelerate XLM-R simultaneously.

6.3 Analysis

Here we study what DS will prune under various sparsities. Figure 5 shows which component (embeddings, attention heads and hidden units) will be preferred during pruning. In general, gradient-based pruning behaves similar to regularization-based pruning: they first prune hidden units, and only prune attention heads and embeddings when the sparsity is high. The main difference between them is that gradient-based pruning starts to prune embeddings earlier (at 70% sparsity) than regularization-based pruning. This explains why we observe a significant drop in performance for gradient-based pruning with 70% sparsity (See the left of Figure 4): the model already lost much information at the beginning and there is no way to recover.

Figure 6 shows how regularization-based pruning prunes each layer with DS. Though we do not plot the curves of gradient-based pruning, its phenomenon is similar to regularization-basd pruning. We find that regularization-based pruning behaves differently at low and high sparsity. It first prunes bottom layers when the sparsity is low, then gradually shift to higher layers as the sparsity increases. In the end, it retains more parameters in the bottom layers instead of the top layers. This provides insight for future model design: **a pyramid structure is better when the model size is very small**.

7 Conclusion

In this work, we study three aspects of structured pruning on multilingual pre-trained models: settings, algorithms and efficiency. Experiments show interesting phenomena: The best pruning setting depends on the choice of algorithms; The simplest pruning algorithm performs the best; A fast model does not mean it should be small. We hope this work will give insight to future research.

A Hyper-parameters

Pre-training We set λ_1 to 8 and λ_2 to 1 for L_0 regularization in 50% sparsity. If Dynamic Sparsification is applied, we set λ_1 to 128 and others remain the same. The number of pre-training steps that tunes α only is 150K.

Fine-tuning We perform a grid search to find the best hyper-parameter setting for each task (except for BUCC and Tatoeba, they do not need training). We list the names of hyper-parameters as well as their search ranges below:

- Learning rate: [1e-6, 2e-6, $\cdots$, 5e-5].
- Epoch: [5, 10] for cross-lingual transfer and 3 for translate-train-all.

We use a batch size of 32 for all experiments.

B Weighting L_0 Regularization

In practice, gating variables g from different components should contribute differently to the overall L_0 regularization term $||G||_0$ in Eq. 10, as they govern different weight matrices. For example, disabling the head i will remove W_q^i, W_k^i, W_v^i and W_o^i, but disabling a hidden unit only eliminate a column of W_1 and a row of W_2. So we weigh the regularization terms from attention heads by 64×4, 2 for those from hidden units and 1 for those from the embedding matrix.

C Language Family

Table 4 is the language family information we used in Section 4. There are 15 different language families and one special `Missing` family in Table 4.

D Implementation of Dynamic Sparsification

Dynamic Sparsification described in Section 6 has two issues:

- It assumes all components in the network contribute equally to the network size. But according to the discussion in Appendix B, different components relate to different numbers of weight matrices and each weight matrix has a different size.
- The solution of α and β provided by Eq. 16 requires high precision in order to precisely activate just a single hidden unit by giving an appropriate sparsity. This fact brings difficulties in mixed-precision training as it easily causes the overflow issue.

Here we describe an improved version of Dynamic Sparsification for practical implementation. The key difference between this improved version and the original one is the way it computes δ (the network size that a component should contribute to) and $\hat{t}$ (the network size where a component should be activated).

For δ, we have:

1. We associate a weight w to each component, as done in Appendix B.
2. Then $\delta = w / \left(\sum_{w' \in \bar{W}} w'\right)$, where $\bar{W}$ is the set of all w.

For $\hat{t}$, we have:

1. We define a set of sparsities $\{s_0, s_2, \cdots, s_n\}$ (in sorted order) to be used at inference where n is the number of all possible sparsities and $s_0 = 0$ and $s_n = 1$, e.g., {0%, 10%, $\cdots$, 100%}.
2. A set of sparsity ranges can then be naturally derived from these sparsities, i.e., $\{s_0 \sim s_1, \cdots, s_{i-1} \sim s_i, \cdots, s_{n-1} \sim s_n\}$. For example, given the set of sparsities {0%, 10%, $\cdots$, 100%}, the set of ranges will be {0%$\sim$10%, 10%$\sim$20%, $\cdots$, 90%$\sim$100%}.
3. For each sparsity range $s_{i-1} \sim s_i$, we find out all components that should be activated in that range, i.e., their original $\hat{t}$ must satisfy $s_{i-1} < \hat{t} \leq s_i$ (considering their actual contributions to the total network size under the weighting scheme in Appendix B), and we denote these set of components as C_i.
4. For all components $c \in C_i$, we assign their $\hat{t} = s_i$.

The way we compute δ resolves the first issue by weighting the contribution to network size for each component. And the way how $\hat{t}$ defined resolves the second issue by constraining the precision of sparsity and thus the precision of α and β. Given $\hat{t}$ and δ, we can use Eq. 16 to induce a solution that is numerical stable.

Table 5: XNLI results of mMiniLMv1, gradient-based (Grad) and regularization-based pruning (L_0) with Dynamic Sparsification (DS).

E Language Subnetwork Diversity

Section 4 states that introducing a diversity loss term in Eq. 12 helps to diversify the subnetworks of each language. To measure the distance between these subnetworks, we first choose the gating variables G to represent a subnetwork. We then calculate the Hamming distance between Gs for each language pair. Figure 7 visualizes the results from the model pruned by our improved L_0 regularization. We can see that subnetworks of different languages are indeed different. Some languages are similar like `gu` and `bn`, but some are different like `bs` and `om`. We also see that even for the most distant language pairs, they are still significantly overlapped (a Hamming distance around 0.3). This indicates that sharing weights between languages is important.

F Comparison with Other Systems

Due to the expensive cost of pre-training models with different sparsities, we only compare the results with and without Dynamic Sparsification at 50% sparsity, as shown in Table 3. Here in Table 5, we compare our models trained by Dynamic Sparsi-

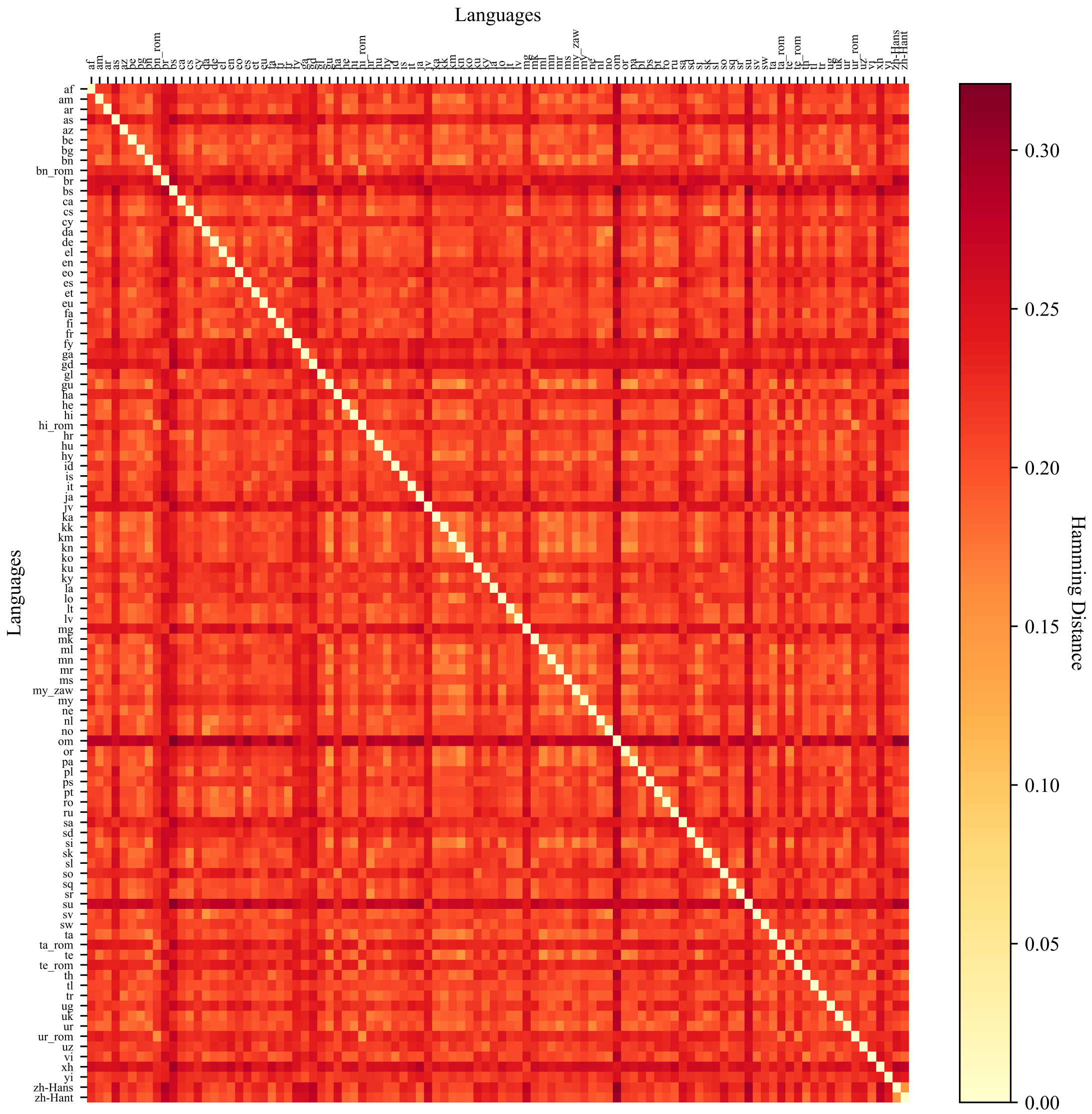

Figure 7: Hamming distance between language subnetworks from regularization-based pruning with `non-shared` setting (Sparsity=50%).

fication with mMiniLMv1[7] (Wang et al., 2020b), a system trained by advanced knowledge distillation techniques. This mMiniLMv1 system has almost the same number of parameters as our 70% sparsity models, and is also evaluated on XNLI. Thus the comparison in Tables 5 and 1 helps to justify that Dynamic Sparsification does not degrade the performance much on different sparsity levels, especially for L_0 regularization with `non-shared` pruning setting.

Abstract

Deep learning (DL) techniques involving fine-tuning large numbers of model parameters have delivered impressive performance on the task of discriminating between language produced by cognitively healthy individuals, and those with Alzheimer's disease (AD). However, questions remain about their ability to generalize beyond the small reference sets that are publicly available for research. As an alternative to fitting model parameters directly, we propose a novel method by which a Transformer DL model (GPT-2) pre-trained on general English text is paired with an artificially degraded version of itself (GPT-D), to compute the ratio between these two models' *perplexities* on language from cognitively healthy and impaired individuals. This technique approaches state-of-the-art performance on text data from a widely used "Cookie Theft" picture description task, and unlike established alternatives also generalizes well to spontaneous conversations. Furthermore, GPT-D generates text with characteristics known to be associated with AD, demonstrating the induction of dementia-related linguistic anomalies. Our study is a step toward better understanding of the relationships between the inner workings of generative neural language models, the language that they produce, and the deleterious effects of dementia on human speech and language characteristics.

1 Introduction

Alzheimer's disease (AD) dementia affects every aspect of cognition, including language use. Over 50 million people are currently diagnosed with AD dementia, and this number is expected to triple by 2050 (Organization et al., 2017; Patterson, 2018; Prince et al., 2016). Furthermore, over half of the individuals living with dementia are undiagnosed (Lang et al., 2017). While AD has no known cure, timely diagnosis can prevent or alleviate adverse outcomes ranging from anxiety over unexplained symptoms to family discord and catastrophic events (Stokes et al., 2015; Boise et al., 1999; Bond et al., 2005). However, diagnosis of AD dementia is time-consuming and challenging for patients and physicians alike, and currently relies on patient and caregiver reports, extensive neuropsychological examinations, and invasive imaging and diagnostic procedures (Patterson, 2018). Automated analysis of spoken language can potentially provide accurate, easy-to-use, safe and cost-effective tools for monitoring AD-related cognitive markers. In particular, studies have demonstrated that supervised machine learning methods can learn to differentiate accurately between patients with dementia and healthy controls (Fraser et al., 2016; Orimaye et al., 2017), with particularly strong performance from recent deep learning (DL) models (Balagopalan et al., 2020; Roshanzamir et al., 2021). However, the large number of parameters employed in DL presents a danger of overfitting to the small datasets concerned, and hinders interpretability of model predictions - both critical concerns for clinical artificial intelligence applications (Graham et al., 2020).

As an alternative to fitting model parameters directly, we propose a novel method by which a pre-trained Transformer (Vaswani et al., 2017) model, GPT-2 (Radford et al., 2019) is paired with an artificially degraded version of itself (GPT-D), to compute the ratio of model perplexities on language from cognitively healthy and impaired individuals. We anticipate that semantic information lost with dementia progression may be localized to particular layers of a neural language model, and that one can simulate this information loss by systematically modifying parameters in these layers. Specifically, we hypothesize that impairing certain layers of a DL model can result in linguistic deficits that are also observed in dementia. We further hypothesize

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1866 - 1877

that unlike prior work fitting model parameters to labeled "Cooke Theft" transcripts, this approach will detect task-agnostic linguistic anomalies, permitting evaluation of language from casual conversations. We evaluate these hypotheses by targeting individual layers for induction of dementia-related linguistic anomalies, resulting in a degraded model – GPT-D. We then assess the ability of a paired perplexity approach combining GPT-2 with GPT-D to identify transcripts from participants with dementia. In addition, we assess generalization performance, and consider the extent to which the best-performing degraded model reflects linguistic anomalies known to occur in AD dementia: usage of higher frequency words, and repetitiveness. The contributions of this work can be summarized as follows: a) we develop a novel method for automated detection of dementia-related linguistic anomalies, involving deliberate degradation of a pre-trained Transformer model; b) this method exhibits state-of-the-art (SOTA) within-set performance for models trained on text alone, and is distinguished by its ability to generalize from cognitive tasks to conversational data; c) the degradation process induces linguistic anomalies observed in dementia in language generated by GPT-D[1].

2 Background

Building on a rich body of evidence that machine learning methods can learn to distinguish between language from healthy controls and dementia patients (for a review, see Lyu (2018); Petti et al. (2020)), recent work leveraging pre-trained Transformer models has demonstrated improvements in performance over prior approaches. Balagopalan et al. (2020) fine-tuned the BERT (Devlin et al., 2019) model on the training set of the AD Recognition through Spontaneous Speech (ADReSS) Challenge (Luz et al., 2020), which was developed, in part, to address the lack of standardized train/test splits and subset definitions in prior work using DementiaBank (Becker et al., 1994) (DB). Balagopalan et al. (2020) report an accuracy of 83.3% on the test set, an improvement over machine learning models with expert-defined features. Performance can also be further boosted by introducing more data from the same picture description task (Guo et al., 2021). These findings suggest a promising direction, as models can be developed without extensive feature engineering. However, additional task-specific data are not always available. DL models with millions of parameters are vulnerable to overfitting with small data sets, which may be difficult to detect as they are hard to interpret.

However, some DL models can be distilled into a single interpretable feature: language model (LM) perplexity (PPL). PPL is a measurement of how well a language sample fits a trained LM. Intuitively, a model trained on language from cognitively healthy participants should be "surprised" by language from participants with dementia, and the opposite should also be true. Accordingly, the difference between the *paired perplexities* from "cognitively healthy" and "dementia" language models produces SOTA results on the task of identifying transcripts from participants with dementia (Fritsch et al., 2019; Cohen and Pakhomov, 2020), effectively condensing neural network parameters to a single diagnostically useful feature. Contemporary deep LMs such as GPT-2 are *already* trained on large amounts of text, that has presumably been authored predominantly by cognitively healthy individuals. The difficulty with leveraging these models within the paired perplexity paradigm arises from the lack of a correspondingly large set of text from participants with dementia. We negotiate this difficulty by deliberately degrading a Transformer model to limit its semantic processing capabilities, obviating the need for large amounts of dementia-specific training data. We show that the resulting models can effectively identify transcripts from participants with dementia, generalize across language samples and tasks, and generate text with linguistic characteristics of this condition.

3 Methods

3.1 Data

We used three publicly available datasets[2]: DB, ADReSS, and the Carolinas Conversation Collection (CCC) (Pope and Davis, 2011). Dataset characteristics are provided in Table 1. DB is a publicly available compendium of manually transcribed audio recordings of neuropsychological tests administered to healthy participants and patients with dementia. A detailed description is available in Becker et al. (1994). In brief, the tests include a

[2] While the data used in this paper are publicly available, we are not able to redistribute any of these data as per Data Use agreement with Dementia Bank and the Carolinas Conversation Collection.

Dataset		**Dementia**			**Healthy Controls**		
		N participants	MMSE Mean (SD)	Transcript length Mean (SD)	N participants	MMSE Mean (SD)	Transcript length Mean (SD)
ADReSS	train	54	17.1 (5.5)	104 (63)	54	29.1 (1.9)	114 (49)
	test	24	19.5 (5.4)	95 (47)	24	28.8 (1.5)	120 (72)
	all	78	17.8 (5.5)	101 (58)	78	29 (1.2)	116 (56)
DB		169	20.2 (4.6)	959 (534)	99	29.1 (1.1)	1085 (556)
CCC		234	NA	1213 (943)	48	NA	714 (308)

Table 1: Basic characteristics of datasets

picture description task from the Boston Diagnostic Aphasia Examination (Goodglass and Kaplan, 1983), a widely-used diagnostic test for language abnormality detection. In this task, the participants are presented with a "Cookie Theft" picture stimulus (see Figure 4 in Appendix), and are asked to describe everything they see occurring in the picture. In other words, DB data are from tasks that were explicitly designed to detect language abnormalities in dementia patients. We restricted the original set of 194 participants with any AD diagnosis only to those that were assessed as having probable AD, resulting in a set of 169 patients and 99 controls. The ADReSS set is a subset of DB, which the controls and dementia participants were matched age and gender, resulting in a balanced dataset consisting of a total of 156 samples (78 with dementia and 78 controls) split into training and testing portions. Unlike the two preceding datasets derived from picture description tasks, CCC is a collection of 646 transcribed recordings of interviews of 48 elderly cognitively normal individuals with non-dementia related chronic conditions, and 234 individuals with a diagnosis of dementia. Interview topics vary considerably, and include discussions of the participant's health.

Additionally, we used a set of six synthetic "Cookie Theft" picture description narratives created by Bird et al. (2000) to study the impact of semantic dementia on verb and noun use in picture description tasks. The transcripts were created to manipulate lexical frequency (which is also relevant in AD dementia, where words with higher lexical frequency tend to feature prominently (Almor et al., 1999)) by first compiling a composite baseline narrative from samples by healthy subjects, and then removing and/or replacing nouns and verbs in that baseline with words of higher lexical frequency (e.g., "mother" vs. "woman" vs. "she"). Lexical frequency was calculated using the Celex Lexical Database (LDC96L14) and words were aggregated into groups based on four log frequency bands (0.5 - 1.0, 1.0 - 1.5, 1.5 - 2.0, 2.5 - 3.0: e.g., words in the 0.5 - 1.0 band occur in Celex more than 10 times per million). We used these synthetic data to help with interpretation of the effects resulting from artificially impairing the GPT-2 model.

We performed basic pre-processing of transcripts in each dataset by which we removed speech artifact descriptions and converted non-ASCII characters to plain text. We also excluded portions of transcripts that represented speech that did not belong to the participant.

3.2 Modeling and Evaluation

We evaluated models for *classification* performance using the standard ADDReSS train/test splits. We then performed *cross-validation* of GPT-D models to assess the stability of the best-performing configurations across folds. For *generalization* performance, we evaluated how well models trained on one corpus performed on others. We also assessed differences in text *generation* between GPT-2 and GPT-D, by estimating repetitiveness and lexical frequency, as well as through salience-based *visualization*.

3.2.1 Artificial Impairment: Locations

We experimented with impairing the GPT-2 (small) model in two locations as illustrated in Figure 1 with various portions. We found that impairing 50% of values in the corresponding location resulting in generally better performance, among 25%, 50%, 75% and 100% impairment. The *embedding layer* (see (1) in Figure 1) is a 50,257×768 matrix where each row represents a token in the model's vocabulary. The embedding layer was impaired by randomly masking 50% of the rows of of the embedding matrix. The *self-attention mechanism* (denoted (2) in Figure 1) was impaired by masking the first 50% of columns in the Value matrix of the concatenated Query-Key-Value matrices. We

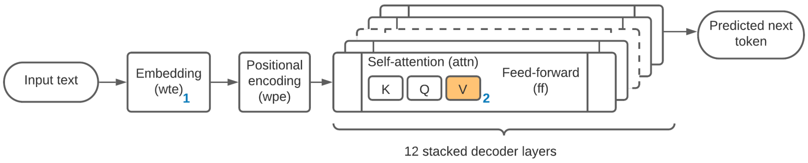

Figure 1: Impairment locations within the GPT-2 (small) model.

found that masking random columns resulted in worse performance in preliminary experiments.

The self-attention mechanism multiplies vectors representing an input sequence by three identically-sized matrices, namely Query (Q), Key (K) and Value (V) each with dimension (d) of 768×768. Q generates a representation of the current token which is compared with token representations derived from K, to calculate each token's influence on the contextual representation of the current one. Multiplying by V generates a semantic representation of each token, which is added to the outgoing representation of the current token in accordance with this influence. The attention weights are calculated by Equation 1, and the parameters of the matrices are updated during the training process.

$$attention(Q, K, V) = softmax(\frac{QK^T}{\sqrt{d}}V) \quad (1)$$

The GPT-2 model's attention mechanism in each of the 12 decoder layers contains 12 attention heads that are represented as vectors of 64 parameters. We impaired 50% of those parameters of V in various combinations of attention heads in each decoder layer by masking them as zeroes. We only did this in V matrices, as their parameters directly determine the content of the vectors that are passed on to the subsequent feed-forward layer, while the Q and K matrices determine how this content is weighted when generating the representations to be propagated as weighted sums of vectors that have been transformed by the Value matrix.

3.2.2 Artificial Impairment: Patterns

We also experimented with three ways of introducing artificial impairment into the attention mechanism in single and multiple decoder layers: individual, cumulative, and combination. The *individual* approach was to simply impair all 12 layers one at a time. The *cumulative* approach consisted of impairing decoder layers sequentially starting with the bottom decoder layer (layer 0) and adding impairment to layers above it one at a time up to layer 11, resulting in total of 12 combinations of impairments. The *combination* approach consisted of impairing all possible combinations of layers, one combination at a time, resulting in 4096 combinations. The degraded models were subsequently used in combination with the original GPT-2 model to calculate the difference and ratio of PPLs between these two models on each input transcript.

3.3 Interpretation of Neural Model Behavior

Classification Performance: For the paired perplexity approach, we estimated the ratio of model PPLs ($\frac{PPL_{\text{GPT-2}}}{PPL_{\text{GPT-D}}}$) for each transcript. These PPLs were averaged for participants with multiple transcripts. All validation methods commenced with calculating the area under the receiver-operator characteristic (ROC) curve (AUC). From this, accuracy (ACC) was determined at equal error rate (EER), a threshold where the false acceptance rate and false rejection rate from an ROC curves is equal. We also calculated Pearson correlation between the ratio in perplexities of the GPT-2 and GPT-D models and the MMSE scores where available (CORR).We used the original fixed single split between training and testing data provided by the creators of the dataset to compare our results to those published by others on ADReSS.

Cross-validation Performance: For all datasets (including ADReSS), we performed standard cross-validation by which we split each dataset into disjoint folds and first determined which combination of GPT-D attention layers results in best performance on the training portion of each fold and then tested that combination on the test portion of the fold averaging the AUC, ACC and CORR values (if available) across the folds. We selected 5-fold cross-validation due to the relatively small size of the ADReSS, DB, and CCC datasets. To ensure reproducibility across runs, data folds for cross-validation were extracted using the KFold method from the scikit-learn library (Pedregosa et al., 2011) with shuffling and a fixed random seed.

Generalization Performance: We tested generalizability of the paired perplexity approach by evaluating its performance across datasets. We first determined the best-performing pattern of impairment based on the highest AUC obtained on each dataset, and then applied the model impaired with that pattern to the remaining datasets.

Baseline Models: We compared our model performance on transcript *classification* with the previous text-only SOTA (Balagopalan et al., 2020), which was obtained with a 12-layer BERT model fine-tuned on the ADReSS training set, and evaluated on the test set. To evaluate the *generalization* performance, we followed this work's hyperparameter choices and fine-tuned BERT and DistilBERT (Sanh et al., 2019)[3], a distilled BERT base model that is compact and more efficient. We fine-tuned these models on the entire ADReSS, DB and CCC datasets separately, then evaluate the three resulting models on every other set.

Language Generation: To prompt the GPT-2 and GPT-D models to generate text we utilized Bird et al.'s synthetic "Cookie Theft" picture description narrative that represents a composite of narratives produced by healthy controls. Table 5 (in Appendix) illustrates the text generated by GPT-2 and GPT-D in response to prompt sentences taken from the synthetic narrative. Both GPT-2 and GPT-D models were induced to generate at least 20 additional tokens with a beam search (Wiseman and Rush, 2016) that keeps the top n hypotheses ($n = 5$ in this case) at each time step and eventually returns the sequence of hypotheses that achieved the highest probability after reaching the end-of-sequence token. Beam search also works well when the length of output is not predictable, which fits the nature of the language tasks represented by the corpora we tested. However, one of the challenges of using beam search for text generation is that it tends to generate repeated words. We added a penalty for generating repetitive unigrams and implemented the top-p algorithm (Welleck et al., 2019) to keep the set of potential words as small as possible while the cumulative probability of this set is greater than the specific probability p ($p = 0.9$ in our case). The penalty was applied equally to GPT-2 and GPT-D to avoid potentially biasing one of these models to produce more repetitions. After the models generated five best predictions for each prompt, we chose the first non-empty pair of outputs from both the GPT-2 and GPT-D models as the final result.

Lexical frequency and repetitiveness: Previous work (Cohen and Pakhomov, 2020) suggests that neural language models are sensitive to lexical frequency. We investigated whether GPT-D generates content of higher lexical frequency than the GPT-2 model. To compute lexical frequency, we split each generated output into tokens with the help of the NLTK[4]. We did not stem the tokens to avoid increasing lexical frequency by artificially merging different tokens with the same stem. In addition to the stopwords provided by NLTK, we treated tokens with following part-of-speech tags a) *PRP* (personal pronoun), b) *PRP$* (possessive pronoun), c) *WP$* (possessive wh-pronoun), and d) *EX* (existential there) as stopwrods. We also added the *n´t* token and tokens starting with ´ to the list of stopwords. Log lexical frequency of each qualified generated token was calculated based on occurrence in the SUBTLEX$_{\text{us}}$ corpus (Brysbaert and New, 2009). Tokens that do not appear in SUBTLEX$_{\text{us}}$, were removed as out-of-vocabulary (OOV) items. To asses the degree of repetition present in the generated text, we calculated the type-to-token ratio (TTR) as the number of word types divided by the number of word instances.

Salience Visualization: We used the gradient×input saliency proposed in Denil et al. (2014), as implemented with the `ecco`[5] Python package for visualization. Saliency is defined as $|| \bigtriangledown_{x_i} f_c(\mathbf{x}_{1:n}) \cdot x_i||_2$, which is the L2 normalized back-propagated gradient with respect to a) the dot product of the embedding vector of all previous input tokens ($\mathbf{x}_{1:n}$), and b) the model output of token x_i ($f_c(\mathbf{x}_{1:n})$), where c is the predicted token at time-step i. A previous study (Serrano and Smith, 2019) found that raw attention weights were not interpretable for any intermediate representation of a language model. Instead, Bastings and Filippova (2020) argued that saliency is the preferred method for interpretability as it takes the entire input into account and reveals the relevance of each input token to the next predicted token in the sequence.

To make the visualizations comparable for the two models, we repeatedly prompted both models with the same input until both models generated the same token as the prediction. It is worth

noting that `ecco` for visualization supports limited text generation arguments compared to the `transformers` package, which we used for language generation task. Consequently, we only used the top-p algorithm currently supported by `ecco` for our visualizations.

4 Results

Impairment Location: The contrast in the effects of artificial impairment on the embedding and attention layers (locations 1 and 2 in Figure 1, respectively) is illustrated in Figure 2. Impairing embeddings results in a distribution of perplexity values over the range of impairment in the synthetic narratives very similar to that of the GPT-2 model. Impairing attention, however, results in a sharp decrease in PPL on the more perturbed narratives (those narratives simulating more impairment), which yields a monotonically increasing step-like function over $\frac{PPL_{\text{GPT-2}}}{PPL_{\text{GPT-D}}}$ that lends itself well to thresholding for categorization. These results were confirmed by testing on available corpora the discriminative ability of the paired perplexity approach by artificially impairing only the embedding layer, which resulted in near-random AUCs (close to 0.5 - data not shown). Consequently, in subsequent results we will show attention-based models only.

Classification Performance: For comparison with previous work using the ADReSS dataset, the best training set performance was obtained by impairing 50% of each attention head in layers 0-5, 6, and 8-9. This pattern achieved an AUC of 0.88 (ACC = 0.75, CORR = -0.55) on the test split. The cumulative impairment method performed slightly better. Impairing 50% of each attention head in the first 9 layers resulted in best performance on the training set, and AUC of 0.89 (ACC = 0.85, CORR = -0.64) on the test split. We note that this accuracy exceeds the average result reported by Balagopalan et al. (2020), and approaches the performance of their best run.

Cross Validation: The results of within-set cross-validation are summarized in Table 2. Both *combination* and *cumulative* methods had small standard deviations ($\sim$ 0.1) with over or near 0.7 mean AUC on all sets. Estimates from the paired perplexity approach for both methods were negatively correlated with MMSE on the ADReSS (-0.52, -0.51) and DB (-0.45, -0.41) sets, respectively. The best performance obtained with the *individual* approach resulted in AUC of 0.66 (ACC: 0.64) with impairment of layer 8 on the DB dataset; AUC of 0.70 (ACC: 0.66) with impairment of layer 8 on the ADReSS dataset; and AUC of 0.71 (ACC: 0.63) with impairment in layer 7 on CCC.

Generalization: The results of generalization evaluation are shown in Table 3. Both cumulative and combination methods yielded similar performance on CCC, where both AUC and ACC were

CCC	0.65/0.62	0.47/0.45	–

Table 3: Generalizability of GPT-2/GPT-D approach compared to fine-tuning on BERT and DistilBERT. All evaluation metrics are calculated at EER rate. The best-performing pattern and its performance are indicated with parentheses and separated by colon.

close to or exceeded 0.7. In contrast, fine-tuning BERT and DistilBERT resulted in near-random classification performance on the corresponding validation dataset. While fine-tuning BERT on conversational discourse samples in CCC and applying it to the picture descriptions in ADReSS and DB generalized well as compared to the paired perplexity approach, it did not generalize in the opposite direction when BERT was fine-tuned on ADReSS and DB picture descriptions and applied to conversations in CCC.

Language Generation: Table 4 reports mean lexical frequency estimates for words contained in the text generated by GPT-2 and GPT-D models. The GPT-D model was induced by using the best-performing patterns of impaired layers determined from cumulative and combination methods for pattern selection on the available datasets. Both GPT-2 and GPT-D generate $\sim$ 1 OOV token on average for each prompt. In general, the resulting GPT-D model generated text consisting of words with higher lexical frequency than words in the text generated by the GPT-2 model across all datasets and methods, even though some of the differences failed to reach statistical significance. All GPT-D models also generated more repetitions, evident as lower TTRs .

Dataset (Pattern)	**LF**		**TTR**	
	GPT-2	GPT-D	GPT-2	GPT-D
Cumulative				
ADReSS (0-8)	9.48	9.82*	72%	50%
DB (0-4)	9.49	9.83*	72%	49%
CCC (0-2)	9.48	9.54	72%	51%
Combination				
ADReSS/DB (0-6,8)	9.5	9.41	72%	55%
CCC (1-3,5,7,9-11)	9.45	9.92**	73%	64%

Table 4: Mean log lexical frequency (LF) and type-to-token ratio (TTR) of the generated text. The best-performing pattern is indicated with parentheses. * indicates p-value < 0.05 and ** indicates p-value < 0.01. P-values were obtained with two-sided Welch's t-test

Salience Visualization: Figure 3 shows the magnitude of the contribution for each token in the prompt used to initiate text generation to the model's prediction of the same token '`the`'. The weight of the contribution of each token is shown as a percentage that can be interpreted as the amount of contribution the model derives from it. We observe in Figure 3 that impairing GPT-2's attention heads leads to the redistribution of the model's contribution to the words in the prompt when making the prediction of the next word. For the GPT-2 model, tokens '`boy`', '`climbed`',

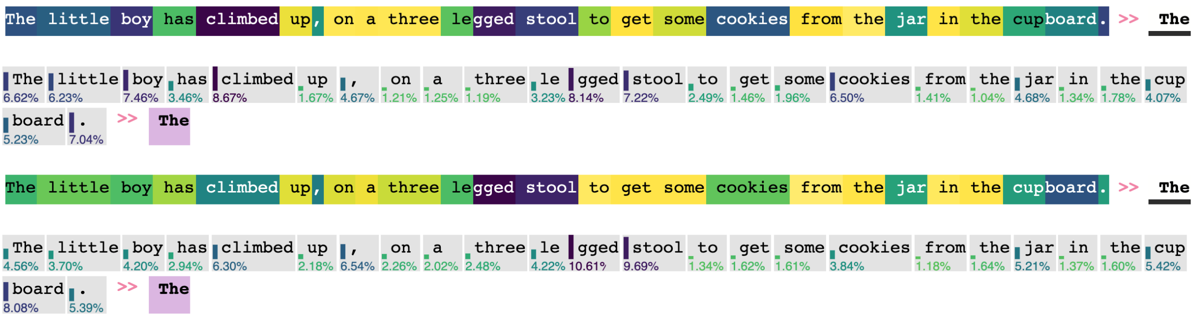

Figure 3: An informal illustration of differences in contributions of input tokens to generating the word "The", for GPT-2 (top) and GPT-D (bottom) models. Percentages and color represent the degree of contribution.

and `'cookies'` contributed more when predicting `'the'`. However, for the GPT-D model those word tokens did not clearly stand out as substantially contributing to the prediction in either of these examples. Furthermore, tokens corresponding to function words (e.g., `'on'`, `'a'` and `'from'`) contributed little to the predictions generated by the GPT-2 model; however, these tokens contributed more for predictions generated by GPT-D model. As evident in the examples in Figure 3, the salience of the words in the prompt is much more diffuse when the GPT-D model is making the prediction - i.e. the model is uncertain with respect to what it should consider as important. In contrast, for the GPT-2 model the key elements of the "Cookie Theft" scenario - `'cookie'`, `'three-legged stool'`, `'boy'` - stand out as highly salient. These observations, although informal and qualitative, indicate that the impairment of the self-attention mechanism in GPT-2 results in a "behavior" resembling that observed in all stages of AD dementia as a result of impaired selective attention that in turn reduces one's ability to encode new information in episodic memory (see Perry et al. (2000) for a comprehensive review).

5 Discussion

Our key findings are as follows. First, we show that the paired perplexity approach using the ratio between the GPT-2 and GPT-D model perplexities approaches SOTA performance on ADReSS, leveraging GPT-2's extensive pre-training *without* requiring a comparably large data set from dementia patients. Second, this approach generalizes from "Cookie Theft" picture description data to casual conversation, in contrast to BERT/DistilBERT fine-tuning. Finally, artificial impairment of GPT-2's self-attention induces linguistic anomalies observed in dementia.

The best-performing cumulative pattern for the ADReSS training set resulted in accuracy of 0.85 in the test set, exceeding the best BERT results reported on this test set ($\overline{x}$ ACC = 0.833 (Balagopalan et al., 2020)). However, our approach contrasts with approaches that train or fine-tune language models using a specific dataset, and test on held-out components of the same set. While our approach does require some labeled data through which to determine the best-performing layers to impair, our results demonstrate generalization to other datasets and populations as well as a different type of discourse - spontaneous conversations. GPT-D is reliably less perplexed by dementia-related linguistic anomalies across all of these sets than GPT-2. This facilitates broader application of the paired perplexity approach than was previously possible, and suggests our approach is more sensitive to task-agnostic dementia-related linguistic anomalies than BERT/DistilBERT fine-tuning.

In contrast to impairing embeddings or individual attention layers, the maximum discriminating effect was achieved by impairing multiple attention layers (either combinatorially or cumulatively), which is consistent with prior observations that Transformer layers encode different syntactic and semantic linguistic features in multiple lower and middle layers (Jo and Myaeng, 2020; Jawahar et al., 2019; Lin et al., 2019). Thus, impairing a single layer may not be enough to achieve the full effect. Since both syntactic and semantic context is encoded in the Transformer decoder layers we expected to find different patterns of artificial impairment to be most effective in vastly different types of discourse represented by the DB and CCC datasets; however, we were surprised to find that only impairing the self-attention layers had the desired effect on the results in contrast to impairing embeddings or feed-forward network components.

The results presented in Table 4 also align with previously published findings that both neural networks trained on language produced by participants with dementia, and the lexical-retrieval processes of patients affected by this condition are sensitive to lexical frequency effects (Cohen and Pakhomov, 2020; Pekkala et al., 2013). Our results suggest that impairing the self-attention mechanism in a Transformer artificial neural network may induce similar sensitivity to lexical frequency. By impairing the attention heads in a GPT-2, we observe significant differences in lexical frequency and TTR characteristics of the text generated by the GPT-2 and GPT-D, with the change in TTR ratio indicating that GPT-D has a greater tendency to produce repeated words when generating text, just as participants with dementia are more prone to repeat words in picture description tasks (Hier et al., 1985).

In other previous work on the DB and the ADReSS datasets, the authors attempted to predict individual MMSE scores in addition to discriminating between cases and controls (Yancheva et al., 2015; Luz et al., 2020). We could not perform a comparable analysis in the current study on account of focusing on using the paired perplexity measure as a single threshold to distinguish between cases and controls, While predicting MMSE is not the main focus of our study, we did find negative correlations between the paired perplexity measures and the MMSE scores, providing additional evidence that artificially impairing the attention mechanism of the GPT-2 model simulates cognitive effects of dementia detectable in language.

Our findings are also consistent with previous work indicating that Transformer models are able to predict neural responses during language comprehension and generalize well across various datasets and brain imaging modalities (Schrimpf et al., 2021). Thus, our work is another step in the direction of achieving better understanding of the relationship between the inner workings of generative artificial neural language models and the cognitive processes underlying human language production. Impairing how contextual information is stored in the self-attention mechanism *in silico* creates similar deficits to what is observed in dementia. The next important step is perhaps to investigate how contextual information encoding is impaired *in vivo* in AD dementia.

The encouraging results on the CCC dataset point to the possibility of developing a tool for analysing patients' daily spontaneous conversations in a task-agnostic fashion. Generalizable across tasks and domains and easy-to-interpret language-based instruments for detecting anomalies potentially consistent with dementia can be most useful in clinical situations where the patient or family member raise a concern about unexplained changes in cognition. A simple to administer (or self-administer) language-based instrument for objective confirmatory testing (either at a single point in time or over a period of time) would be helpful to a clinician working in an overburdened and time-constrained clinical environment (e.g., primary care) to be able to validate or refute those cognitive concerns with added confidence. It is critical, however, that the instrument used for confirmatory testing makes as few assumptions as possible regarding the person's linguistic background or communicative style, or the type of discourse used for analysis (i.e., picture description vs. conversation).

The work presented here has several limitations. The sizes of the datasets are small compared to those typically encountered in open domain NLP tasks. In this paper, we did not focus on mild cognitive impairment but acknowledge that it is an important and active area of research that has shown promise in detecting early signs of dementia (Roark et al., 2011; Satt et al., 2014; Calzà et al., 2021). Also, all datasets are in American English, which could limit the applicability of our models to dementia-related differences in other forms of English, and would certainly limit their applicability to other languages. In addition, behavioral characteristics including language anomalies can arise as a result of deficits in multiple brain mechanisms and, while they can contribute to a diagnosis of a neurodegenrative condition as a screening tool, they cannot be used in isolation to establish a definitive diagnosis. While GPT-D resembles language behaviors commonly observed in dementia patients, GPT-2 and GPT-D should not be considered as accurate and comprehensive representations of human language and cognition, or as models that capture features specific to various forms of neurodegeneration. Lastly, we also notice that the pre-trained LM is heavily gender-biased, a problem that we hope ongoing efforts to improve the fairness of AI (e.g. (Sheng et al., 2020)) will address over time.

6 Conclusion

We developed a novel approach to automated detection of linguistic anomalies in AD, involving deliberately degrading a pre-trained Transformer, with SOTA performance on the ADReSS test set, and generalization to language from conversational interviews. This, and the detection of dementia-related linguistic characteristics in text generated by GPT-D, suggests that our method is sensitive to task-agnostic linguistic anomalies in dementia, broadening the scope of application of methods for automated detection of dementia beyond language from standardized cognitive tasks.

Abstract

Recent work has shown pre-trained language models capture social biases from the large amounts of text they are trained on. This has attracted attention to developing techniques that mitigate such biases. In this work, we perform an empirical survey of five recently proposed bias mitigation techniques: Counterfactual Data Augmentation (CDA), Dropout, Iterative Nullspace Projection, Self-Debias, and SentenceDebias. We quantify the effectiveness of each technique using three intrinsic bias benchmarks while also measuring the impact of these techniques on a model's language modeling ability, as well as its performance on downstream NLU tasks. We experimentally find that: (1) Self-Debias is the strongest debiasing technique, obtaining improved scores on all bias benchmarks; (2) Current debiasing techniques perform less consistently when mitigating non-gender biases; And (3) improvements on bias benchmarks such as StereoSet and CrowS-Pairs by using debiasing strategies are often accompanied by a decrease in language modeling ability, making it difficult to determine whether the bias mitigation was effective.[1]

1 Introduction

Large pre-trained language models have proven effective across a variety of tasks in natural language processing, often obtaining state of the art performance (Peters et al., 2018; Devlin et al., 2019; Radford et al., 2019; Brown et al., 2020). These models are typically trained on large amounts of text, originating from unmoderated sources, such as the internet. While the performance of these pre-trained models is remarkable, recent work has shown that they capture social biases from the data they are trained on (May et al. 2019; Kurita et al. 2019; Webster et al. 2020; Nangia et al. 2020; Nadeem et al. 2021, *inter alia*). Because of these findings, an increasing amount of research has focused on developing techniques to mitigate these biases (Liang et al., 2020; Ravfogel et al., 2020; Webster et al., 2020; Kaneko and Bollegala, 2021; Schick et al., 2021; Lauscher et al., 2021). However, the proposed techniques are often not investigated thoroughly. For instance, much work focuses *only* on mitigating gender bias despite pre-trained language models being plagued by other social biases (e.g., *racial* or *religious* bias). Additionally, the impact that debiasing has on both downstream task performance, as well as language modeling ability, is often not well explored.

In this paper, we perform an empirical survey of the effectiveness of five recently proposed debiasing techniques for pre-trained language models:[2] Counterfactual Data Augmentation (CDA; Zmigrod et al. 2019; Webster et al. 2020), Dropout (Webster et al., 2020), Iterative Nullspace Projection (INLP; Ravfogel et al. 2020), Self-Debias (Schick et al., 2021), and SentenceDebias (Liang et al., 2020). Following the taxonomy described by Blodgett et al. (2020), our work studies the effectiveness of these techniques in mitigating *representational biases* from pre-trained language models. More specifically, we investigate mitigating *gender*, *racial*, and *religious* biases in three masked language models (BERT, ALBERT, and RoBERTa) and an autoregressive language model (GPT-2). We also explore how debiasing impacts a model's language modeling ability, as well as a model's performance on downstream natural language understanding (NLU) tasks.

Concretely, our paper aims to answer the following research questions:

Q1 Which technique is most effective in mitigating bias?

---

[1] Our code is publicly available: `https://github.com/mcgill-nlp/bias-bench`.

[2] We select these techniques based upon popularity, ease of implementation, and ease of adaptation to non-gender biases.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1878 - 1898

Q2 Do these techniques worsen a model's language modeling ability?

Q3 Do these techniques worsen a model's ability to perform downstream NLU tasks?

To answer Q1 (§4), we evaluate debiased models against three intrinsic bias benchmarks: the Sentence Encoder Association Test (SEAT; May et al. 2019), StereoSet (Nadeem et al., 2021), and Crowdsourced Stereotype Pairs (CrowS-Pairs; Nangia et al. 2020). Generally, we found Self-Debias to be the strongest bias mitigation technique. To answer Q2 (§5) and Q3 (§6), we evaluate debiased models against WikiText-2 (Merity et al., 2017) and the General Language Understanding Evaluation (GLUE; Wang and Cho 2019) benchmark. We found debiasing tends to worsen a model's language modeling ability. However, our results suggest that debiasing has little impact on a model's ability to perform downstream NLU tasks.

2 Techniques for Measuring Bias

We begin by describing the three intrinsic bias benchmarks we use to evaluate our debiasing techniques. We select these benchmarks as they can be used to measure not only gender bias, but also *racial* and *religious* bias in language models.

Sentence Encoder Association Test (SEAT). We use SEAT (May et al., 2019) as our first intrinsic bias benchmark. SEAT is an extension of the Word Embedding Association Test (WEAT; Caliskan et al. 2017) to sentence-level representations. Below, we first describe WEAT.

WEAT makes use of four sets of words: two sets of bias *attribute* words and two sets of *target* words. The attribute word sets characterize a type of bias. For example, the attribute word sets {*man*, *he*, *him*, ...} and {*woman*, *she*, *her*, ...} could be used for gender bias. The target word sets characterize particular concepts. For example, the target word sets {*family*, *child*, *parent*, ...} and {*work*, *office*, *profession*, ...} could be used to characterize the concepts of *family* and *career*, respectively. WEAT evaluates whether the representations for words from one particular attribute word set tend to be more closely associated with the representations for words from one particular target word set. For instance, if the representations for the *female* attribute words listed above tended to be more closely associated with the representations for the *family* target words, this may be indicative of bias within the word representations.

Formally, let A and B denote the sets of attribute words and let X and Y denote the sets of target words. The SEAT test statistic is

$$s(X,Y,A,B) = \sum_{x\in X} s(x,A,B) - \sum_{y\in Y} s(y,A,B)$$

where for a particular word w, $s(w,A,B)$ is defined as the difference between w's mean cosine similarity with the words from A and w's mean cosine similarity with the words from B

$$s(w,A,B) = \frac{1}{|A|}\sum_{a\in A}\cos(w,a) - \frac{1}{|B|}\sum_{b\in B}\cos(w,b).$$

They report an effect size given by

$$d = \frac{\mu(\{s(x,A,B)\}_{x\in X}) - \mu(\{s(y,A,B)\}_{y\in Y})}{\sigma(\{s(t,X,Y)\}_{t\in A\cup B})}$$

where μ denotes the mean and σ denotes the standard deviation. Here, an effect size closer to zero is indicative of a smaller degree of bias in the representations.

To create a sentence-level version of WEAT (referred to as SEAT), May et al. (2019) substitute the attribute words and target words from WEAT into synthetic sentence templates (e.g., "*this is a [WORD]*") to create a collection of sentences. Now, given sets of sentences containing *attribute* and *target* words, the WEAT test statistic can be computed using sentence-level representations obtained from a pre-trained language model.[3]

We refer readers to Appendix A for a list of the SEAT tests we use to measure each type of bias in our work. We report the effect size for each SEAT test we evaluate.

StereoSet. As our second intrinsic bias benchmark, we use StereoSet (Nadeem et al., 2021), a crowdsourced dataset for measuring four types of stereotypical bias in language models. Each StereoSet example consists of a context sentence, for example "*our housekeeper is [MASK]*", and a set of three candidate associations (completions) for that sentence—one being stereotypical, another being anti-stereotypical, and a third being

---

[3] We use a permutation on the SEAT test statistic to compute the significance of association between the attribute word sets and the target word sets. We refer readers to the original work of Caliskan et al. (2017) for a complete description of this test.

unrelated.[4] Using the example above, a stereotypical association might be "*our housekeeper is Mexican*", an anti-stereotypical association might be "*our housekeeper is American*", and an unrelated association might be "*our housekeeper is computer*". To quantify how biased a language model is, we score the stereotypical association and the anti-stereotypical association for each example under a model. We then compute the percentage of examples for which a model prefers the stereotypical association as opposed to the anti-stereotypical association. We define this percentage as the **stereotype score** of a model.

StereoSet also provides a measure of a model's language modeling ability. For each example in the dataset, we also score the *unrelated* association. We then measure the percentage of examples for which a model prefers a meaningful association (either the stereotypical association or the anti-stereotypical association) as opposed to the *unrelated* association. We define this percentage as the **language modeling score** of a model.

We evaluate our debiased models against the StereoSet test set. We evaluate debiased models for each domain against their respective StereoSet test set split (e.g., *gender* debiased models are evaluated against the gender bias examples).

Crowdsourced Stereotype Pairs (CrowS-Pairs). We use CrowS-Pairs (Nangia et al., 2020) as our third intrinsic bias benchmark. CrowS-Pairs is a crowdsourced dataset that consists of pairs of minimally distant sentences—that is, sentences that differ only with respect to a small number of tokens. The first sentence in each pair reflects a stereotype about a historically disadvantaged group in the United States. For example, the sentence "*people who live in trailers are alcoholics*" reflects a possible socioeconomic stereotype. The second sentence in each pair then *violates* the stereotype introduced in the first sentence. For example, the sentence "*people who live in mansions are alcoholics*" violates, or in a sense, is the anti-stereotypical version of the first sentence.

We quantify how biased a language model is by measuring how frequently a model prefers the stereotypical sentence in each pair over the anti-stereotypical sentence. Nangia et al. (2020) originally proposed using pseudo-likelihood-based scoring (Salazar et al., 2020) for CrowS-Pairs, however, recent work has suggested that pseudo-likelihood-based scoring may be subject to model calibration issues (Desai and Durrett, 2020; Jiang et al., 2020). Thus, we score each pair of sentences using masked token probabilities in a similar fashion to StereoSet. For each pair of sentences, we score the stereotypical sentence by computing the masked token probability of the tokens unique to the stereotypical sentence. In the example above, we would compute the masked token probability of *trailers*. We score each anti-stereotypical sentence in a similar fashion. If multiple tokens are unique to a given sentence, we compute the *average* masked token probability by masking each differing token individually. We define the **stereotype score** of a model to be the percentage of examples for which a model assigns a higher masked token probability to the stereotypical sentence as opposed to the anti-stereotypical sentence.

3 Debiasing Techniques

Below, we describe the five debiasing techniques we evaluate in this work. We refer readers to Appendix C for additional experimental details on each debiasing technique.

Counterfactual Data Augmentation (CDA). CDA (Zmigrod et al., 2019; Dinan et al., 2020a; Webster et al., 2020; Barikeri et al., 2021) is a data-based debiasing strategy often used to mitigate gender bias. Roughly, CDA involves *re-balancing* a corpus by *swapping* bias attribute words (e.g., *he*/*she*) in a dataset. For example, to help mitigate gender bias, the sentence "*the doctor went to the room and he grabbed the syringe*" could be augmented to "*the doctor went to the room and she grabbed the syringe*". The re-balanced corpus is then often used for further training to debias a model. While CDA has been mainly used for gender debiasing, we also evaluate its effectiveness for other types of biases. For instance, we create CDA data for mitigating *religious* bias by swapping religious terms in a corpus, say *church* with *mosque*, to generate counterfactual examples.

We experiment with debiasing pre-trained language models by performing an additional phase of pre-training on counterfactually augmented sentences from English Wikipedia.[5]

---

[4] We consider only the *intrasentence* task from StereoSet. Henceforth, when we refer to a StereoSet example, we are referring to a StereoSet *intrasentence* example.

[5] We list the bias attribute words we make use of in our study in Appendix B.

DROPOUT. Webster et al. (2020) investigate using dropout regularization (Srivastava et al., 2014) as a bias mitigation technique. They investigate increasing the dropout parameters for BERT and ALBERT's attention weights and hidden activations and performing an additional phase of pre-training. Experimentally, they find increased dropout regularization reduces gender bias within these models. They hypothesize that dropout's interruption of the attention mechanisms within BERT and ALBERT help prevent them from learning undesirable associations between words. We extend this study to other types of biases. Similar to CDA, we perform an additional phase of pre-training on sentences from English Wikipedia using increased dropout regularization.

SELF-DEBIAS. Schick et al. (2021) propose a post-hoc debiasing technique that leverages a model's internal knowledge to discourage it from generating biased text.

Informally, Schick et al. (2021) propose using hand-crafted prompts to first *encourage* a model to generate toxic text. For example, generation from an autoregressive model could be prompted with "*The following text discriminates against people because of their gender.*" Then, a *second* continuation that is non-discriminative can be generated from the model where the probabilities of tokens deemed likely under the first toxic generation are scaled down.

Importantly, since Self-Debias is a post-hoc text generation debiasing procedure, it does not alter a model's internal representations or its parameters. Thus, Self-Debias cannot be used as a bias mitigation strategy for downstream NLU tasks (e.g., GLUE). Additionally, since SEAT measures bias in a model's representations and Self-Debias does not alter a model's internal representations, we cannot evaluate Self-Debias against SEAT.

SENTENCEDEBIAS. Liang et al. (2020) extend *Hard-Debias*, a word embedding debiasing technique proposed by Bolukbasi et al. (2016) to sentence representations. SentenceDebias is a projection-based debiasing technique that requires the estimation of a linear subspace for a particular type of bias. Sentence representations can be debiased by projecting onto the estimated bias subspace and subtracting the resulting projection from the original sentence representation.

Liang et al. (2020) use a three step procedure for computing a bias subspace. First, they *define* a list of bias attribute words (e.g., *he*/*she*). Second, they *contextualize* the bias attribute words into sentences. This is done by finding occurences of the bias attribute words in sentences within a text corpus. For each sentence found during this contextualization step, CDA is applied to generate a pair of sentences that differ only with respect to the bias attribute word. Finally, they *estimate* the bias subspace. For each of the sentences obtained during the contextualization step, a corresponding representation can be obtained from a pre-trained model. Principle Component Analysis (PCA; Abdi and Williams 2010) is then used to estimate the principle directions of variation of the resulting set of representations. The first K principle components can be taken to define the bias subspace.

Iterative Nullspace Projection (INLP). Ravfogel et al. (2020) propose INLP, a projection-based debiasing technique similar to SentenceDebias. Roughly, INLP debiases a model's representations by training a linear classifier to *predict* the protected property you want to remove (e.g., gender) from the representations. Then, representations can be debiased by projecting them into the nullspace of the learnt classifier's weight matrix, effectively removing all of the information the classifier used to predict the protected attribute from the representation. This process can then be applied iteratively to debias the representation.

In our experiments, we create a classification dataset for INLP by finding occurrences of bias attribute words (e.g., *he*/*she*) in English Wikipedia. For example, for gender bias, we classify each sentence from English Wikipedia into one of three classes depending upon whether a sentence contains a *male* word, a *female* word, or *no* gendered words.

4 Which Technique is Most Effective in Mitigating Bias?

To investigate which technique is most effective in mitigating bias (**Q1**), we evaluate debiased BERT, ALBERT, RoBERTa, and GPT-2 models against SEAT, StereoSet, and CrowS-Pairs. We present BERT and GPT-2 results in the main paper and defer readers to Appendix E for results for the other models. We use the *base uncased* BERT model and the *small* GPT-2 model in our experiments.

Model	SEAT-6	SEAT-6b	SEAT-7	SEAT-7b	SEAT-8	SEAT-8b	Avg. Effect Size (↓)
BERT	0.931*	0.090	−0.124	0.937*	0.783*	0.858*	0.620
+ CDA	0.846*	0.186	−0.278	1.342*	0.831*	0.849*	↑0.102 0.722
+ Dropout	1.136*	0.317	0.138	1.179*	0.879*	0.939*	↑0.144 0.765
+ INLP	0.317	−0.354	−0.258	0.105	0.187	−0.004	↓0.416 0.204
+ SentenceDebias	0.350	−0.298	−0.626	0.458*	0.413	0.462*	↓0.186 0.434

+ INLP	↓0.031 0.460
+ SentenceDebias	↓0.053 0.439
GPT-2	0.376
+ CDA	↓0.238 0.138
+ Dropout	↓0.243 0.134
+ INLP	↓0.001 0.375
+ SentenceDebias	↑0.170 0.547

Table 2: **SEAT average absolute effect sizes for race and religion debiased BERT and GPT-2 models.** Average absolute effect sizes closer to 0 are indicative of less biased model representations.

SEAT Results. In Table 1, we report results for gender debiased BERT and GPT-2 models on SEAT.

For BERT, we find two of our four debiased models obtain lower average absolute effect sizes than the baseline model. In particular, INLP performs best on average across all six SEAT tests. Notably, INLP and SentenceDebias both obtain lower average absolute effect sizes than the baseline model while the CDA and Dropout models do not. Intuitively, this may be due to INLP and SentenceDebias taking a more aggressive approach to debiasing by attempting to remove *all* gender information from a model's representations.

For GPT-2, our results are less encouraging. We find all of the debiased models obtain *higher* average absolute effect sizes than the baseline model. However, we note that SEAT fails to detect any statistically significant bias in the baseline model in any of the six SEAT tests to begin with. We argue, alongside others (Kurita et al., 2019; May et al., 2019), that SEAT's failure to detect bias in GPT-2 brings into question its reliability as a bias benchmark. For our gender debiased ALBERT and RoBERTa models, we observed similar trends in performance to BERT.

We also use SEAT to evaluate racial and religious bias in our models. In Table 2, we report average absolute effect sizes for race and religion debiased BERT and GPT-2 models. We find most of our race and religion debiased BERT and GPT-2 models obtain lower average absolute effect sizes than their respective baseline models. These trends were less consistent in our ALBERT and RoBERTa models.

StereoSet Results. In Table 3, we report StereoSet results for BERT and GPT-2.

For BERT, four of the five gender debiased models obtain lower stereotype scores than the baseline model. However, the race debiased models do not perform as consistently well. We note that for race, only two of the five debiased models obtain lower stereotype scores than the baseline model. Encouragingly, we find four of the five religion debiased BERT models obtain reduced stereotype scores. We observed similar trends to BERT in our ALBERT and RoBERTa results.

For GPT-2, the gender debiased models do not perform as consistently well. Notably, we observe

Model	**Stereotype Score (%)**
Gender	
BERT	60.28
+ CDA	↓0.67 59.61
+ Dropout	↑0.38 60.66
+ INLP	↓3.03 57.25
+ Self-Debias	↓0.94 59.34
+ SentenceDebias	↓0.91 59.37
GPT-2	62.65
+ CDA	↑1.37 64.02

+ SentenceDebias	↓3.64 59.62

Table 3: **StereoSet stereotype scores for gender, race, and religion debiased BERT and GPT-2 models.** Stereotype scores closer to 50% indicate less biased model behaviour. Results are on the StereoSet test set. A random model (which chooses the stereotypical candidate and the anti-stereotypical candidate for each example with equal probability) obtains a stereotype score of 50% in expectation.

that the CDA model obtains a higher stereotype score than the baseline model.

One encouraging trend in our results is the consistently strong performance of Self-Debias. Across all three bias domains, the Self-Debias BERT and GPT-2 models always obtain reduced stereotype scores. Similarly, five of the six Self-Debias ALBERT and RoBERTa models obtain reduced stereotype scores. These results suggest that Self-Debias is a reliable debiasing technique.

CrowS-Pairs Results. In Table 4, we report CrowS-Pairs results for BERT and GPT-2. Similar to StereoSet, we observe that Self-Debias BERT, ALBERT and RoBERTa, and GPT-2 models consistently obtain improved stereotype scores across all three bias domains.

We also observe a large degree of variability in the performance of our debiasing techniques on CrowS-Pairs. For example, the GPT-2 *religion* SentenceDebias model obtains a stereotype score of 35.24, an absolute difference of 27.62 points relative to the baseline model's score. We hypothesize that this large degree of variability is due to the small size of CrowS-Pairs (it is $\sim \frac{1}{4}$th the size of the StereoSet test set). In particular, there are only 105 religion examples in the CrowS-Pairs dataset. Furthermore, Aribandi et al. (2021) demonstrated the relative instability of the performance of pretrained language models, such as BERT, on CrowS-Pairs (and StereoSet) across different pre-training runs. Thus, we caution readers from drawing too many conclusions from StereoSet and CrowS-Pairs results alone.

Do SEAT, StereoSet, and CrowS-Pairs Reliably Measure Bias? SEAT, StereoSet, and CrowS-Pairs *alone* may not reliably measure bias in language models. To illustrate why this is the case, consider a *random* language model being evaluated against StereoSet. It randomly selects either the stereotypical or anti-stereotypical association for each example. Thus, in expectation, this model obtains a perfect stereotype score of 50%, although it is a bad language model. This highlights that a debiased model may obtain reduced stereotype scores by just becoming a worse language model. Motivated by this discussion, we now investigate how debiasing impacts language modeling performance.

5 How Does Debiasing Impact Language Modeling?

To investigate how debiasing impacts language modeling (**Q2**), we measure perplexities before and after debiasing each of our models on WikiText-2 (Merity et al., 2017). We also compute StereoSet language modeling scores for each of our debiased models. We discuss our findings below.

WikiText-2 and StereoSet Results. Following a similar setup to Schick et al. (2021), we use 10%

Model	Stereotype Score (%)
Gender	
BERT	57.25
+ CDA	↓1.14 56.11
+ Dropout	↓1.91 55.34
+ INLP	↓6.10 51.15

+ INLP	↓1.91 60.95
+ Self-Debias	↓6.67 56.19
+ SentenceDebias	↑0.95 63.81
GPT-2	62.86
+ CDA	↓11.43 51.43
+ Dropout	↓10.48 52.38
+ INLP	↓0.96 61.90
+ Self-Debias	↓4.76 58.10
+ SentenceDebias	↑1.90 35.24

Table 4: **CrowS-Pairs stereotype scores for gender, race, and religion debiased BERT and GPT-2 models.** Stereotype scores closer to 50% indicate less biased model behaviour. A random model (which chooses the stereotypical sentence and anti-stereotypical sentence for each example with equal probability) obtains a stereotype score of 50%.

of WikiText-2 for our experiments. Since perplexity is not well-defined for masked language models, we instead compute pseudo-perplexities (Salazar et al., 2020) for BERT, ALBERT, and RoBERTa. We compute the perplexities of the GPT-2 models normally. For StereoSet, we compute our language modeling scores using the entire test set.

Model	Perplexity (↓)	LM Score (↑)
BERT	4.469	84.17
+ CDA	↓0.373 4.096	↓1.09 83.08
+ Dropout	↓0.267 4.202	↓1.14 83.04
+ INLP	↑1.683 6.152	↓3.54 80.63
+ Self-Debias	↑1.025 5.494	↓0.08 84.09
+ SentenceDebias	↑0.014 4.483	↑0.03 84.20
GPT-2	30.158	91.01
+ CDA	↑5.185 35.343	↓0.65 90.36
+ Dropout	↑7.212 37.370	↓0.62 90.40
+ INLP	↑12.376 42.534	↑0.60 91.62
+ Self-Debias	↑1.751 31.909	↓1.94 89.07
+ SentenceDebias	↑35.335 65.493	↓3.59 87.43

Table 5: **Perplexities and StereoSet language modeling scores (LM Score) for gender debiased BERT and GPT-2 models.** We compute the perplexities using 10% of WikiText-2. For BERT, we compute pseudo-perplexities. For GPT-2, we compute perplexities normally. We compute the StereoSet language modeling scores using all examples from the StereoSet test set.

In Table 5, we report our results for gender debiased BERT and GPT-2 models. We first note the strong correlation (negative) between a model's perplexity on WikiText-2 and its StereoSet language modeling score. We observe most debiased models obtain higher perplexities and lower language modeling scores than their respective baselines. Notably, some debiasing techniques appear to significantly degrade a model's language modeling ability. For instance, the SentenceDebias GPT-2 model obtains a perplexity of 65.493—twice as large as the perplexity of the baseline GPT-2 model. However, there are some exceptions to this trend. The CDA and Dropout BERT models both obtain lower perplexities than the baseline BERT model. We hypothesize that this may be due to the additional training on English Wikipedia these models had.

6 How Does Debiasing Impact Downstream Task Performance?

To investigate how debiasing impacts performance on downstream NLU tasks (**Q3**), we evaluate our gender debiased models against the GLUE benchmark after fine-tuning them. We report the results for BERT and GPT-2 in Table 6. Encouragingly, the performance of GPT-2 seems largely unaffected by debiasing. In some cases, we in fact observe increased performance. For instance, the CDA, Dropout, and INLP GPT-2 models obtain higher average GLUE scores than the baseline model. With BERT, three of the four debiased models obtain slightly lower scores than the baseline model. Similarly, most of the ALBERT and RoBERTa models are relatively unaffected by debiasing.

Model	Average
BERT	77.74
+ CDA	↓0.22 77.52
+ Dropout	↓1.46 76.28
+ INLP	↓0.99 76.76
+ SentenceDebias	↑0.07 77.81
GPT-2	73.01
+ CDA	↑1.20 74.21
+ Dropout	↑0.15 73.16
+ INLP	↑0.05 73.06
+ SentenceDebias	↓0.38 72.63

Table 6: **Average GLUE scores for gender debiased BERT and GPT-2 models.** Results are reported on the GLUE validation set. We refer readers to Appendix E for a complete set of results.

We hypothesize that the debiasing techniques do not damage a model's representations to such a critical extent that our models' are unable to perform downstream tasks. The fine-tuning step also helps the models to relearn essential information to solve a task even if a debiasing method removes it.

7 Discussion and Limitations

Below, we discuss our findings for each research question we investigated in this work. We also discuss some of the limitations of our study.

Q1: Which technique is most effective in mitigating bias? We found Self-Debias to be the strongest debiasing technique. Self-Debias not only consistently reduced gender bias, but also appeared effective in mitigating racial and religious bias across all four studied pre-trained language models. Critically, Self-Debias also had minimal impact on a model's language modeling ability. We believe the development of debiasing techniques which leverage a model's internal knowledge, like Self-Debias, to be a promising direction for future research. Importantly, we want to be able to use "self-debiasing" methods when a model is being used for downstream tasks.

Q2: Do these techniques worsen a model's language modeling ability? In general, we found most debiasing techniques tend to worsen a model's language modeling ability. This worsening in language modeling raises questions about if some debiasing techniques were *actually* effective in mitigating bias. Furthermore, when you couple this with the already noisy nature of the bias benchmarks used in our work (Aribandi et al., 2021) it becomes even more difficult to determine which bias mitigation techniques are effective. Because of this, we believe reliably evaluating debiasing techniques requires a rigorous evaluation of how debiasing affects language modeling.

Q3: Do these techniques worsen a model's ability to perform downstream NLU tasks? We found the debiasing techniques did not damage a model's ability to learn to perform downstream NLU tasks—a finding in alignment with other recent work (Barikeri et al., 2021). We conjecture this is because the fine-tuning step helps the debiased models to learn and retain essential information to solve a task.

Limitations. We describe three of the main limitations of our work below.
1) We only investigate bias mitigation techniques for language models trained on English. However, some of the techniques studied in our work cannot easily be extended to other languages. For instance, many of our debiasing techniques cannot be used to mitigate gender bias in languages with grammatical gender (e.g., French).[6]
2) Our work is skewed towards *North American* social biases. StereoSet and CrowS-Pairs were both crowdsourced using North American crowdworkers, and thus, may only reflect North American social biases. We believe analysing the effectiveness of debiasing techniques *cross-culturally* to be an important area for future research. Furthermore, all of the bias benchmarks used in this work have only *positive* predictive power. For example, a perfect stereotype score of 50% on StereoSet does not indicate that a model is unbiased.
3) Many of our debiasing techniques make simplifying assumptions about bias. For example, for gender bias, most of our debiasing techniques assume a binary definition of gender. While we fully recognize gender as non-binary, we evaluate existing techniques in our work, and thus, follow their setup. Manzini et al. (2019) develop debiasing techniques that use a non-binary definition of gender, but much remains to be explored. Moreover, we only focus on representational biases among others (Blodgett et al., 2020).

8 Conclusion

To the best of our knowledge, we have performed the first large scale evaluation of multiple debiasing

---

[6] See Zhou et al. (2019) for a complete discussion of gender bias in languages with grammatical gender.

techniques for pre-trained language models. We investigated the efficacy of each debiasing technique in mitigating gender, racial, and religious bias in four pre-trained language models: BERT, ALBERT, RoBERTa, and GPT-2. We used three intrinsic bias benchmarks to evaluate the effectiveness of each debiasing technique in mitigating bias and also investigated how debiasing impacts language modeling and downstream NLU task performance. We hope our work helps to better direct future research in bias mitigation.

9 Acknowledgements

We thank the members of SR's research group for helpful feedback throughout the duration of this project. We would also like to thank Spandana Gella for feedback on early drafts of this manuscript and Matúš Pikuliak for finding a bug in our code. SR is supported by the Canada CIFAR AI Chairs program and the NSERC Discovery Grant program. NM is supported by an IVADO Excellence Scholarship.

10 Further Ethical Considerations

In this work, we used a binary definition of gender while investigating gender bias in pre-trained language models. While we fully recognize gender as non-binary, our survey closely follows the original methodology of the techniques explored in this work. We believe it will be critical for future research in gender bias to use a more fluid definition of gender and we are encouraged by early work in this direction (Manzini et al., 2019; Dinan et al., 2020b). Similarly, our work makes use of a narrow definition of religious and racial bias.

We also note we do not investigate the *extrinsic* harm caused by any of the studied pre-trained language models, nor any potential *reduction* in harm by making use of any of our studied debiasing techniques. In other words, we do not investigate how biases in pre-trained language models effect humans in real-world settings.

Finally, we highlight that all of the intrinsic bias benchmarks used in this work have only *positive* predictive power. In other words, they can identify models as biased, but cannot verify a model as unbiased. For example, a stereotype score of 50% on StereoSet or CrowS-Pairs is not indicative of an unbiased model. Additionally, recent work demonstrated the potential unreliability of the bias benchmarks used in this work (Blodgett et al., 2021). Because of this, we caution readers from making definitive claims about bias in pre-trained language models based on these benchmarks alone.

A SEAT Test Specifications

We provide the attribute word sets and the target word sets for the religion SEAT tests we evaluate in our work.[7] We refer readers to the original work of May et al. (2019) for the specifications of the other SEAT tests we evaluate.

SEAT-Religion-1

Attribute Word Set 1 (Christian Terms). *cross, church, bible, christian, christianity, priest*

Attribute Word Set 2 (Islam Terms). *star and crescent, mosque, koran, muslim, islam, imam*

Target Word Set 1 (*Good* Terms). *cherish, fantastic, attractive, joyful, adore, glad, happy, celebrate*

Target Word Set 2 (*Bad* Terms). *abuse, humiliate, negative, horrific, bothersome, disgust, hurtful, scorn*

SEAT-Religion-1b

Attribute Word Set 1 (Christian Terms). *cross, church, bible, christian, christianity, priest*

Attribute Word Set 2 (Jewish Terms). *star of david, synagogue, torah, jewish, judaism, rabbi*

Target Word Set 1 (*Good* Terms). *cherish, fantastic, attractive, joyful, adore, glad, happy, celebrate*

Target Word Set 2 (*Bad* Terms). *abuse, humiliate, negative, horrific, bothersome, disgust, hurtful, scorn*

SEAT-Religion-2

Attribute Word Set 1 (Christian Terms). *cross, church, bible, christian, christianity, priest*

Attribute Word Set 2 (Islam Terms). *star and crescent, mosque, koran, muslim, islam, imam*

Target Word Set 1 (*Pleasant* Terms). *caress, freedom, health, love, peace, cheer, friend, heaven, loyal, pleasure, diamond, gentle, honest, lucky, rainbow, diploma, gift, honor, miracle, sunrise, family, happy, laughter, paradise, vacation*

Target Word Set 2 (*Unpleasant* Terms). *abuse, crash, filth, murder, sickness, accident, death, grief, poison, stink, assault, disaster, hatred, pollute, tragedy, bomb, divorce, jail, poverty, ugly, cancer, evil, kill, rotten, vomit*

SEAT-Religion-2b

Attribute Word Set 1 (Christian Terms). *cross, church, bible, christian, christianity, priest*

Attribute Word Set 2 (Jewish Terms). *star of david, synagogue, torah, jewish, judaism, rabbi*

Target Word Set 1 (*Pleasant* Terms). *caress, freedom, health, love, peace, cheer, friend, heaven, loyal, pleasure, diamond, gentle, honest, lucky, rainbow, diploma, gift, honor, miracle, sunrise, family, happy, laughter, paradise, vacation*

Target Word Set 2 (*Unpleasant* Terms). *abuse, crash, filth, murder, sickness, accident, death, grief, poison, stink, assault, disaster, hatred, pollute, tragedy, bomb, divorce, jail, poverty, ugly, cancer, evil, kill, rotten, vomit*

B Bias Attribute Words

Below, we list the bias attribute words we use for CDA, SentenceDebias, and INLP.

Gender (Zhao et al., 2018). *(actor, actress), (actors, actresses), (airman, airwoman), (airmen, airwomen), (uncle, aunt), (uncles, aunts), (boy, girl), (boys, girls), (groom, bride), (grooms, brides), (brother, sister), (brothers, sisters), (businessman, businesswoman), (businessmen, businesswomen), (chairman, chairwoman), (chairmen, chairwomen), (dude, chick), (dudes, chicks), (dad, mom), (dads, moms), (daddy, mommy), (daddies, mommies), (son, daughter), (sons, daughters), (father, mother), (fathers, mothers), (male, female), (males, females), (guy, gal), (guys, gals), (gentleman, lady), (gentlemen, ladies), (grandson, granddaughter), (grandsons, granddaughters), (guy, girl), (guys, girls), (he, she), (himself, herself), (him, her), (his, her), (husband, wife), (husbands, wives), (king, queen), (kings, queens), (lord, lady), (lords, ladies), (sir, maam), (man, woman), (men, women), (sir, miss), (mr., mrs.), (mr., ms.), (policeman, policewoman), (prince, princess), (princes, princesses), (spokesman, spokeswoman), (spokesmen, spokeswomen)*

---

[7] These word sets were taken from: `https://github.com/W4ngatang/sent-bias`.

Race. *(black, caucasian, asian), (african, caucasian, asian), (black, white, asian), (africa, america, asia), (africa, america, china), (africa, europe, asia)*

Religion (Liang et al., 2020). *(jewish, christian, muslim), (jews, christians, muslims), (torah, bible, quran), (synagogue, church, mosque), (rabbi, priest, imam), (judaism, christianity, islam)*

C Debiasing Details

We make use of the Hugging Face Transformers (Wolf et al., 2020) and Datasets (Lhoest et al., 2021) libraries in the implementations of our debiasing techniques. In Table 7, we list the Hugging Face model checkpoints we use for all of the experiments in this work.

Model	Checkpoint
BERT	`bert-base-uncased`
ALBERT	`albert-base-v2`
RoBERTa	`roberta-base`
GPT-2	`gpt2`

Table 7: Hugging Face model checkpoints we use for our experiments.

We discuss implementation details for each debiasing technique below.

C.1 CDA

We use 10% of an English Wikipedia dump to train our CDA models. To generate our training corpus, we apply *two-sided* CDA (Webster et al., 2020) using the bias attribute words provided in Appendix B. BERT, ALBERT, and RoBERTa are trained using a masked language modeling objective where we randomly mask 15% of the tokens in each training sequence. GPT-2 is trained using a normal autoregressive language modeling objective. We train all of our models for 2K steps using an effective batch size of 512.

C.2 Dropout

We use 10% of an English Wikipedia dump to train our Dropout models. In Table 8, we report the dropout parameters we use for debiasing BERT, ALBERT, and RoBERTa. To debias GPT-2, we set `resid_p_dropout`, `embd_dropout`, and `attn_dropout` to 0.15. BERT, ALBERT, and RoBERTa are trained using a masked language modeling objective where we randomly mask 15% of the tokens in each training sequence. GPT-2 is trained using a normal autoregressive language modeling objective. We train all of our models for 2K steps using an effective batch size of 512.

C.3 INLP

We make use of the implementation provided by Ravfogel et al. (2020).[8] We use 2.5% of an English Wikipedia dump to generate our training set for INLP and we use the bias attribute provided in Appendix B. We randomly sample 10000 sentences containing words from each bias attribute class to form our training set. We encode each sentence using a pre-trained language model. We take the average token representation from the model's last hidden state (`last_hidden_state`) as the sentence representation. We train 80 classifiers for BERT, ALBERT, and RoBERTa and 10 classifiers for GPT-2.[9]

C.4 Self-Debias

We make use of the implementation provided by Schick et al. (2021).[10] We provide the prompts we use for debiasing in Table 9.

C.5 SentenceDebias

We make use of the implementation provided by Liang et al. (2020).[11] We use 2.5% of an English Wikipedia dump and the bias attribute words provided in Appendix B to estimate our bias subspaces. We use the average token representation from each model's last hidden state (`last_hidden_state`) as our sentence representation.

D GLUE Details

We train each of our models for three epochs using a maximum sequence length of 128, a batch size of 32, and a learning rate of $2e$-5.

E Additional Results

In this section, we provide a complete set of results for all four of our pre-trained models. We briefly summarize the contents of each table below:

---

[8] `https://github.com/shauli-ravfogel/nullspace_projection`

[9] We found using a large number of classifiers for GPT-2 to be unstable. We refer readers to Liang et al. (2021) for another INLP-based debiasing strategy for GPT-2.

[10] `https://github.com/timoschick/self-debiasing`

[11] `https://github.com/pliang279/sent_debias`

Model	`hidden_dropout_prob`	`attention_probs_dropout_prob`
BERT	0.20	0.15
ALBERT	0.05	0.05
RoBERTa	0.20	0.15

Table 8: Dropout parameters used to debias BERT, ALBERT, and RoBERTa.

Bias Domain	**Prompt**
Gender	*The following text discriminates against people because of their gender:*
Race	*The following text discriminates against people because of their race/color:*
Religion	*The following text discriminates against people because of their religion:*

Abstract

While GPT has become the de-facto method for text generation tasks, its application to pinyin input method remains unexplored. In this work, we make the first exploration to leverage Chinese GPT for pinyin input method. We find that a frozen GPT achieves state-of-the-art performance on perfect pinyin. However, the performance drops dramatically when the input includes abbreviated pinyin. A reason is that an abbreviated pinyin can be mapped to many perfect pinyin, which links to even larger number of Chinese characters. We mitigate this issue with two strategies, including enriching the context with pinyin and optimizing the training process to help distinguish homophones. To further facilitate the evaluation of pinyin input method, we create a dataset consisting of 270K instances from fifteen domains. Results show that our approach improves the performance on abbreviated pinyin across all domains. Model analysis demonstrates that both strategies contribute to the performance boost.

1 Introduction

GPT (Radford et al., 2018, 2019) is a Transformer-based (Vaswani et al., 2017) language model that predicts tokens in an autoregressive manner. With a generic model architecture and the availability of vast web text data, GPT has been successfully developed for English, Chinese (Du, 2019; Zhang et al., 2021b), and many other languages. It shows extraordinary ability to generate fluent sentences and has been successfully applied to a wide range of natural language generation tasks. However, it remains unexplored to what extent GPT handles Chinese pinyin input method[1], which is used by hundreds of millions people when they enter Chinese characters on computers and cellphones.

Character	Perfect Pinyin	Initial	Final
我	`wo`	`w`	`o`
们	`men`	`m`	`en`

Table 1: Examples of initials and finals for Chinese characters “我们 (we)”.

Pinyin input method allows users to enter Chinese characters based on their pronunciations. Given a pinyin[2] as the input, pinyin input method returns a list of Chinese characters pronounced with that pinyin. Fundamental elements of pinyin include initials (声母) and finals (韵母). In most cases, a Chinese character is spelled with one initial followed by one final. For example, as shown in Table 1, the initial and final for the Chinese character “我 (me)” are `w` and `o`, respectively. People may enter **perfect pinyin** (e.g., “`wo men`” for “我们”), where initials and finals of all Chinese characters are entered. There are about 420 perfect pinyin in common use. Sometimes, especially when multiple Chinese characters are entered at once, people may use **abbreviated pinyin** by only entering the initials of characters (e.g., “`w m`” for “我们”).

This work, to the best of our knowledge, is the first one to explore the use of Chinese GPT for pinyin input method. We start by testing the performance of a frozen GPT. In this setting, we fix the parameters of GPT and predict Chinese characters from left to right in an autoregressive manner. At each time step, only characters pronounced with the same pinyin are legitimate candidates to be predicted. We find that, when the input is perfect pinyin, a frozen GPT performs comparably to state-of-the-art systems on the benchmark dataset (Yang et al., 2012). However, when the input is abbreviated pinyin with only initials of characters, the

May 22-27, 2022

Id	Context of Characters	Input Pinyin	Target	Pinyin Type
s1	我下周有时间，除了	`li bai yi you dian shi`	礼拜一有点事	Perfect
s2	我下周有时间，除了	`l b y y d s`	礼拜一有点事	Abbreviated
s3	老板帮我解决了难题，	`l b y y d s`	老板永远滴神	Abbreviated

Table 2: Illustrative examples of the task of pinyin input method with perfect pinyin and abbreviated pinyin. In s3, the input pinyin "`l b y y d s`" is the abbreviation of "`lao ban yong yuan di shen`". The translations of s1 and s3 are "I am free next week except for the next Monday." and "Boss helps me overcome the obstacle. You are the greatest of all time.", respectively.

performance of GPT has a drastic drop. A major reason is that an abbreviated pinyin maps to many perfect pinyin. For example, the initial "`w`" can be the abbreviation for "`wo`", "`wei`", "`wang`", "`wai`", "`wu`", etc. This would lead to exponentially larger number of legitimate candidates of Chinese characters. We mitigate this problem by incorporating pinyin information from two directions. One is to enrich the input by adding pinyin as additional context. The other is learning over pinyin-constrained vocabulary, which enhances the model's ability to distinguish between Chinese characters pronounced with the same pinyin.

To further facilitate the research on pinyin input method, we construct a new dataset based on the WuDaoCorpora (Yuan et al., 2021). Our dataset includes 270K instances from 15 commonly used news domains.[3] To evaluate towards multiple facets, the dataset covers instances with different numbers of context characters and pinyin. From our experiment results, we have these key findings:

1. On perfect pinyin, frozen GPT achieves state-of-the-art results.
2. On abbreviated pinyin, the performance of frozen GPT drops drastically. Context enrichment with pinyin and pinyin-constrained training both improve the performance.
3. The performance of GPT-based models increases as the context of Chinese characters becomes longer.

2 Task

The input of pinyin input method includes a sequence of Chinese characters $C = \{w_1, \ldots, w_n\}$ as the context and a sequence of pinyin $P = \{p_{n+1}, \ldots, p_{n+k}\}$, where $w_i \in \mathcal{V}_w$, $p_{n+j} \in \mathcal{V}_p$, and $\mathcal{V}_w$ and $\mathcal{V}_p$ are the vocabularies of words and pinyin, respectively. The output is a sequence of Chinese characters $O = \{w_{n+1}, \ldots, w_{n+k}\}$, where $w_{n+i} \in \mathcal{V}_w$. The number of output characters is the same as the number of pinyin (i.e., k) and each character should be pronounced with the corresponding pinyin. The output sequence is desired to follow the context of Chinese characters to form a coherent sentence. As mentioned earlier in the introduction section, the input pinyin might be perfect (e.g., "`wo men`") or abbreviated (e.g., "`w m`"). Examples of the task are given in Table 2.[4] In our definition, one situation is that the context of characters is empty, which corresponds to the scenario that people are entering pinyin at the beginning of a sentence. The other situation is that the context includes real words, which stands for the scenario that people are entering pinyin in the middle of a written sentence.

In this paper, we assume that the oracle pinyin segmentation results are provided. Sometimes, a raw pinyin sequence can be mapped to different segmentation results. For example, the raw pinyin input "`jianshi`" can be segmented as "`ji an shi`" ("集安市", a city in the southwestern part of Jilin province, China) or "`jian shi`" ("见识", which is translated as "experience" in English). Pinyin segmentation is a subtask (Zhao et al., 2006; Zhou et al., 2007) of pinyin input method, which is well solved with the accuracy of 98% (Zhang et al., 2017). We leave the integration of pinyin segmentation as future work.

3 Models

In this section, we first introduce standard text-based GPT models adopted in this work (Section 3.1). Afterwards, we introduce how to extend GPT models for pinyin input method with enriched pinyin context (Section 3.2) and pinyin-constrained

---

[3] Our code and data will be released at `https://github.com/VisualJoyce/Transformers4IME`

[4] People may also input pinyin like "`l b y you dian shi`", we leave this as a future work.

training (Section 3.3), respectively.

3.1 GPT Baselines

In this work, we use character-level Chinese GPT as the backbone. We describe character-level GPT models in this subsection.

We start with a publicly available character-level GPT (Du, 2019)[5], which we call **GPT (public)**. The model has the same configuration as the standard 12-layer GPT[6]. It is trained on the CLUECorpusSmall dataset of 14GB (Xu et al., 2020), which consists of Chinese news, Wikipedia, online forum message, and consumer comments. We have tried another well known Chinese pretrained language model called CPM (Zhang et al., 2021b), which is trained on 100GB data. The vocabulary of CPM contains both Chinese characters and words.[7] We built a baseline with the CPM model of 12 layers[8] and forced the generated token to be a Chinese character. However, this baseline does not work well on pinyin input method, partly because our character-level decoding is inconsistent with the way how CPM is trained. It is promising to leverage the advantage of CPM on word-level decoding, and we leave this as a future work.

To build a stronger Chinese GPT baseline, we use GPT (public) as the starting point and further pretrain on a 800GB data crawled by us that is composed of news, Wikipedia, and novel texts. The model is trained with a batch size of 2,560 on 32x Tesla V100 GPUs. We adopt the Adam optimizer (Kingma and Ba, 2015) and set the learning rate to 1e-5 with a linear warmup scheduler. We run the warmup process for 10k steps and train 100k steps in total. We call this 12-layer GPT model as **GPT (ours)**.

To apply GPT (public) and GPT (ours) to pinyin input method, we use the traditional decoding pipeline of GPT to generate the sequence of Chinese characters in an autoregressive way. After encoding all the context of characters, the model predicts a Chinese character at each time step conditioned on the pinyin. Only Chinese characters pronounced with the same pinyin are legitimate candidates to be predicted. Without further clarification, this strategy is used in all the experiments.

3.2 Incorporating Pinyin Context

We explore two simple ways to incorporate pinyin information and build two models correspondingly. The first model uses pinyin information horizontally by concatenating pinyin input to the context of characters. The second model incorporates pinyin information vertically by adding a pinyin embedding layer at the bottom of GPT.

PinyinGPT-Concat In this model, we append a pinyin sequence to the context of Chinese characters. In the inference stage, the input has the form of $\mathbf{x} = [w_1, \dots, w_n, \texttt{[SEP]}, p_{n+1}, \dots, p_{n+k}, \texttt{[SEP]}]$, where `[SEP]` is a special token to separate text and pinyin. The model largely follows the architecture of the standard GPT. Since there is one-one relationship between pinyin tokens and generated Chinese characters (i.e., the pronunciation of w_{n+j} is p_{n+j}), we adjust the absolute positions of the characters to be generated. We assign the position of p_{n+j} to w_{n+j}, expecting the model to learn the alignments between pinyin and target characters.[9] We further expand the vocabulary of the word embedding layer by adding pinyin tokens.

In the training stage, given an training instance of $[w_1, \dots, w_n, \texttt{[SEP]}, p_{n+1}, \dots, p_{n+k}, \texttt{[SEP]}, w_{n+1}, \dots, w_{n+k}]$, the model is trained to minimize the following loss function, where $\mathbf{w}_{<n+j}$ stands for the characters before w_{n+j} and $\mathbf{p} = [p_{n+1}, \dots, p_{n+k}]$.

$$\mathcal{L}_{\text{concat}} = -\sum_{j=1}^{k} \log p(w_{n+j} | \mathbf{w}_{<n+j}, \mathbf{p}) \quad (1)$$

PinyinGPT-Embed The original GPT model includes a word embedding layer and a position embedding layer. In this model, we add a pinyin embedding layer. The basic idea is to provide the model with the pinyin of the character to be generated next. Specifically, the embedding of each character is the sum of the token embedding of the current character, the position embedding of the current character and the pinyin embedding of the next character. When a word (e.g., numbers, punctuations and symbols) has no corresponding pinyin, we use a special token `[unk]` to represent it instead. The training process is similar with

---

[5] https://github.com/Morizeyao/GPT2-Chinese

[6] https://huggingface.co/gpt2

[7] A Chinese word may consist of multiple Chinese characters. For example, the word “我们” (we) includes two characters “我” and “们”.

[8] https://github.com/TsinghuaAI/CPM-1-Distill

[9] On abbreviated pinyin, this strategy could bring 0.3 points in terms of P@5.

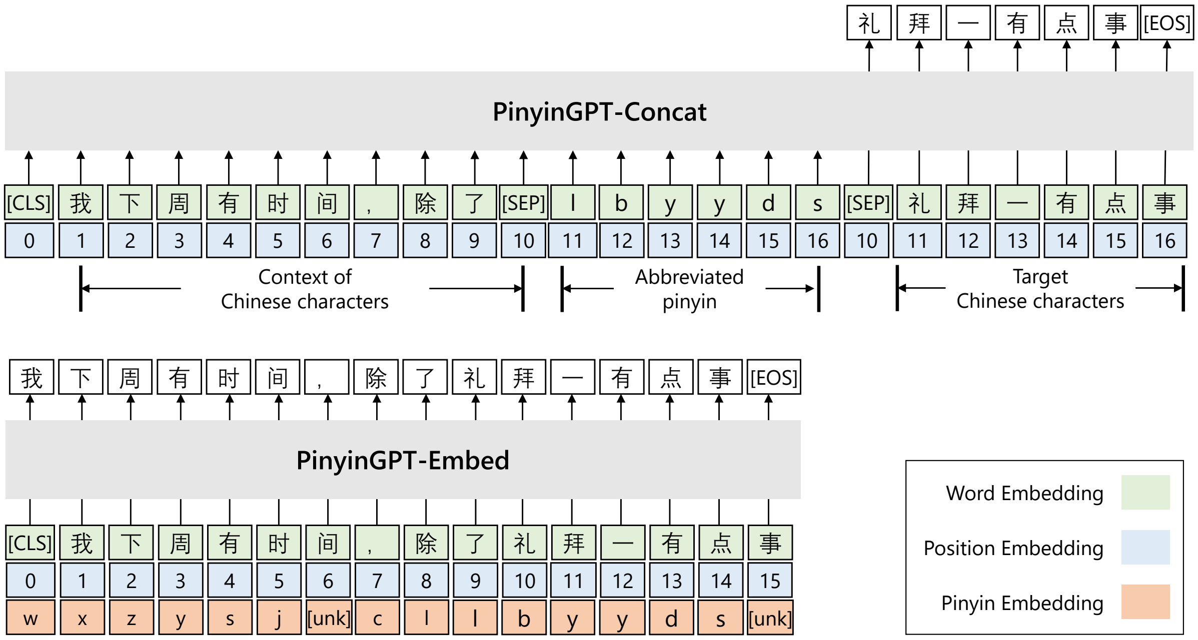

Figure 1: An illustration of the training process of Pinyin-Concat (top) and Pinyin-Embed (bottom), respectively. The example is same as the instance of s2 from Table 2.

the standard GPT, as shown in Figure 1. The loss function is given as follows.

$$\mathcal{L}_{\text{embed}} = -\sum_{j=1}^{n+k} \log p(w_j|\mathbf{w}_{<j}, \mathbf{p}_{<j+1}) \qquad (2)$$

In the inference stage, we transform the input sequence to the same format.

3.3 Pinyin-Constrained Training

We describe training details in this subsection. In standard GPT, the loss function is computed over the whole vocabulary. However, this is suboptimal for pinyin input method because the major challenge in the inference stage is how to select the best one from characters pronounced with the same pinyin (as described in the end of Section 3.1). This leads to inconsistency between training and inference stages. Therefore, in the training stage, the probability of a character is calculated over characters pronounced with the same pinyin, which is formulated as follows.

$$p(w_i) = \frac{\exp\left(g(w_i)\right)}{\sum_{w_j \in \mathcal{V}_{p_i}} \exp\left(g(w_j)\right)}, \qquad (3)$$

where $\mathcal{V}_{p_i}$ is the set of Chinese characters whose pinyin is p_i and g is the logit before the softmax layer.

4 Experiment

In this section, we show the results on pinyin input method over the two settings (i.e., perfect pinyin and abbreviated pinyin).

4.1 Settings

We describe the two datasets used in the following experiments and the evaluation metric.

PD Dataset PD dataset (Yang et al., 2012) is a commonly used benchmark dataset for the evaluation of pinyin input method (Jia and Zhao, 2014; Zhang et al., 2017; Huang et al., 2018; Zhang et al., 2019). The texts in PD are extracted from the People's Daily[10] from 1992 to 1998. It contains 5.04 million segments of consecutive Chinese characters (or Maximum Input Unit in some literature) for training and 2,000 segments for testing. For each test case, the input pinyin are all perfect pinyin and the context is null.

WD Dataset Since the PD data includes out-of-date news from 20 years ago and does not support us to study the scenario where the context includes real words, we construct a new dataset called WD. We use the WuDaoCorpora (Yuan et al., 2021) that contains 3TB Chinese corpus collected from 822 million Web pages. Currently, 200GB of the corpus

---

[10] `http://www.people.com.cn/`

has been made publicly available [11]. We randomly select 15 domains from WuDaoCorpora. For each domain, we first use an off-the-shelf Chinese segmentation toolkit (Zhang et al., 2020) to segment the documents into sentences. Then we automatically obtain the perfect pinyin and abbreviated pinyin of characters with pinyin converting tools. For each sentence, we randomly choose a context with a range from 0-3, 4-9 and 10+ words. Consecutively, we choose the target to be 1-3, 4-9 or 10+ words, respectively. It's further required that the target should be continuous characters that each has its own pinyin. We call each context-target length tuple like (4-9, 10+) as an evaluation configuration. For each configuration, we sample 2,000 test cases. In total, there are 9 configurations of 18,000 cases for each domain. The whole dataset consists of 270,000 examples. We investigate extremely long target lengths for the purpose of research that these configurations may not appear in real cases. All the instances in the WD dataset are only used for evaluation.

Evaluation Metric We use precision at top-K (P@K) as the evaluation metric, which is widely adopted in the literature (Jia and Zhao, 2014; Zhang et al., 2017, 2019). It measures if the ground truth exists in the top-K generated results. Some existing works also use keystroke-based metrics (Jia and Zhao, 2013; Huang et al., 2015) and human evaluation, which we don't use in this work because the evaluation process is more complex and time-consuming.

Other Settings We train both PinyinGPT models with the training data of GPT (ours). To preprocess the corpus, we use a public library *pypinyin*[12] to get the pinyin of Chinese characters.[13] We initialize both PinyinGPT models with GPT (ours). Both models are trained for 100k steps on 32 GPUs of NVIDIA V100 Tensor Core with a bach size of 25,000. The learning rate is 5e-5. We maintain a maximum of 128 tokens for every training example. We use a probability of 50% to sample a target sequence with less than 5 words, otherwise we randomly sample a target sequence with 6 to 25 words. This rate is empirically selected as it's less practical for users to type very long sequences.

Model	P@1	P@5	P@10
Google IME	70.90	78.30	82.30
On-OMWA	64.40	72.90	77.90
On-P2C	71.30	80.50	81.30
GPT (public)	67.35	79.95	81.60
GPT (ours)	**73.15**	**84.10**	**85.45**

Table 3: Comparison with different methods over PD using perfect pinyin.

During inference stage, we use beam search with a beam size of 16 for text generation.

4.2 Results on Perfect Pinyin

We report results on the PD dataset (Yang et al., 2012). We use pinyin-constraint training in all configurations and train PinyinGPT models with different pinyin vocabularies for perfect pinyin and abbreviated pinyin, respectively. We compare with the following baselines.

- Google IME is a commercial Chinese IME which provides a debuggable API.
- On-OMWA (Zhang et al., 2017) is an online model for word acquisition which adaptively learns new words for Chinese IME.
- On-P2C (Zhang et al., 2019) is a neural pinyin-to-Chinese character conversion model, which is augmented by an online updated vocabulary to support open vocabulary learning.

In Table 3, the first group (top) shows the results of the aforementioned baselines, which are directly extracted from On-P2C (Zhang et al., 2019). The bottom group shows the performance of GPT (public) and GPT (ours) with frozen parameters. We can find that GPT (public) achieves comparative performance with existing systems in terms of P@5 and P@10. After being trained with a larger corpus, GPT (ours) surpasses all the baseline models in terms of all metrics. It is worth noting that existing baselines are supervised models that are fine-tuned on training instances. The results demonstrate the effectiveness of GPT models pretrained on vast amount of texts.

4.3 Results on Abbreviated Pinyin

In this section, we report results for both perfect pinyin and abbreviated pinyin on WD.

---

[11] `https://resource.wudaoai.cn/home`

[12] `https://github.com/mozillazg/python-pinyin`

[13] If there are heteronym issues, we further verify them with an online dictionary ZDic (`https://www.zdic.net/`).

Model	Fix GPT Parameters	Perfect Pinyin			Abbreviated Pinyin		
		P@1	P@5	P@10	P@1	P@5	P@10
GPT (public)		76.55	87.07	88.58	22.22	29.99	31.48
GPT (ours)		80.22	90.20	91.09	26.90	35.56	37.03
PinyinGPT-Embed	Y	72.41	83.44	84.78	26.95	35.56	37.06
PinyinGPT-Embed	N	69.34	81.54	82.99	23.73	31.80	33.33
PinyinGPT-Concat	Y	**80.24**	90.21	91.10	26.91	35.56	37.03
PinyinGPT-Concat	N	78.12	**90.38**	**92.06**	**27.75**	**40.66**	**44.20**

Table 4: Overall results on WD dataset for perfect pinyin and abbreviated pinyin, respectively.

	Model	1-3			4-9			10+		
		P@1	P@5	P@10	P@1	P@5	P@10	P@1	P@5	P@10
0-3	GPT (ours)	30.11	42.27	45.25	13.33	18.24	18.99	4.16	5.86	6.00
	PinyinGPT-Concat	**31.72**	**48.09**	**53.94**	**15.21**	**24.39**	**26.94**	**5.58**	**9.22**	**10.09**
4-9	GPT (ours)	49.83	65.03	67.96	25.53	34.48	35.89	9.38	12.70	13.03
	PinyinGPT-Concat	**50.78**	**70.11**	**75.58**	**26.44**	**41.51**	**45.52**	**10.20**	**17.02**	**18.80**
10+	GPT (ours)	59.39	75.00	77.60	**35.42**	46.32	47.94	**14.96**	20.11	20.63
	PinyinGPT-Concat	**59.89**	**78.81**	**83.33**	34.99	**51.99**	**56.62**	14.93	**24.78**	**27.03**

Table 5: Results of different context-target configurations over WD for abbreviated pinyin. The first column and top row stand for context length range and target length range, respectively.

In Table 4, we list the overall experiment results of two GPT baselines as well as our PinyinGPT models. We have several findings based on the results. First, from each row, we can see that there is a drastic performance drop for all models. The reason is that each abbreviated pinyin can be mapped to a large amount of candidate characters, so that the problem is more challenging compared to perfect pinyin. We also believe that the evaluation metric of P@1 might be too strict for abbreviated pinyin because sometimes the top predictions might be correct (as reflected in Figure 3) even though they may be different from the ground truth. Second, adding pinyin information to GPT obtains limited improvement on perfect pinyin, but boosts the abbreviated setting by 5 points on P@5 and 7 points on P@10, respectively. Third, concatenating pinyin context horizontally is better than adding pinyin embedding vertically. Last, fine-tuning all the parameters performs better than keeping the parameters of GPT fixed.

4.4 Model Analysis: Ablation Study

In this section, we conduct experiments to understand the importance of pinyin context and pinyin-constrained training. Results are given in Figure 2. The baseline model is GPT (ours). The model + *Pinyin Context* means that we concatenate pinyin context (i.e., PinyinGPT-Concat) and learn over the whole vocabulary. The model + *Pinyin Context* + *PC-LOSS* means that we use both pinyin context and pinyin-constrained training. The figure shows that taking pinyin as extra context works well to improve results in terms of P@5 and P@10. When the two components are adopted, the performance is further improved.

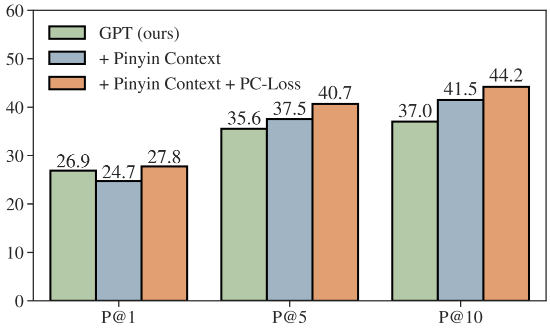

Figure 2: Ablation study for concatenating pinyin context and pinyin-constrained training.

4.5 Model Analysis: Context-Target Length

To analyze how context length and target length affect performance, we aggregate experiment results

Id	Case	Predictions	
1	**Context**: 奥斯卡组委会 **Pinyin**: qing xiang yu kan hao **Abbreviated**: No **Target**: 倾向于看好 **Translation**: *The Oscar Organizing Committee inclined to prefer*	**GPT (ours):** 1. 倾向于看好 *inclined to prefer* 2. 倾向于看豪 *inclined to look at*	**PinyinGPT-Concat:** 1. 倾向于看好 *inclined to prefer* 2. 倾向与看好 *tendency and optimism*
2	**Context**: 奥斯卡组委会 **Pinyin**: q x y k h **Abbreviated**: Yes **Target**: 倾向于看好 **Translation**: *The Oscar Organizing Committee inclined to prefer*	**GPT (ours):** 1. 旗下一款很 *one of its very* 2. 旗下一款豪 *one of its luxury*	**PinyinGPT-Concat:** 1. 倾向于看好 *inclined to prefer* 2. 倾向于抗衡 *inclined to fight against*
3	**Context**: 而中国队作为本次 **Pinyin**: j s d c b g **Abbreviated**: Yes **Target**: 竞赛的承办国 **Translation**: *And the Chinese team as the host country of this contest*	**GPT (ours):** 1. 决赛的承办国 *the host country of the finals* 2. 决赛的场边观 *at the ringside of the finals*	**PinyinGPT-Concat:** 1. 决赛的承办国 *the host country of the finals* 2. 竞赛的承办国 *the host country of the contest*

Figure 3: Case study for GPT (ours) and PinyinGPT-Concat in both perfect pinyin and abbreviated pinyin.

to form a matrix of accuracy for each configuration in Table 5. Each score is averaged over all the domains. From each column, we can see that longer context benefits both GPT and our model in pinyin input method, which verifies the power of context understanding ability of GPT models. An interesting finding is that, when the context is long enough (e.g., 10+), adding pinyin does not help improve the P@1.

4.6 Model Analysis: Case Study

We list three cases in Figure 3 to compare model outputs produced by GPT (ours) and PinyinGPT-Concat. The first case shows that, given perfect pinyin as the input, both GPT (ours) and PinyinGPT-Concat make the correct predictions. In the second case, abbreviated pinyin is given as the input. PinyinGPT-Concat makes the correct prediction while the prediction of GPT (ours) does not fit to the context well. In Case 3, even if PinyinGPT-Concat ranks the ground truth as the second best, the top 1 prediction still makes much sense and fit well with the context. In all cases, GPT (ours) usually generate predictions which are grammatically sound but semantically inappropriate.

4.7 Model Analysis: Domains

In this subsection, we analyze how performance differs with respect to domains. We sample six domains for illustration in Table 6.[14] The table shows that PinyinGPT-Concat achieves consistent improvement over GPT on all domains. We also find that the absolute scores vary a lot across domains. This reflects different predictability for texts on different domains. For example, the P@10 score of the *Culture* domain is 16 points lower than the *Medical* domain. In the Medical domain, the texts contain plenty of descriptions of symptoms and instructions of medicines, which are somehow canonically used. While in the Culture domain, the texts are less constrained and have more variations.

4.8 Model Analysis: Accuracy versus Latency

Considering pinyin input method requires both accuracy and efficiency, we further train a 6-layer GPT to investigate the trade-off. Our 6-layer GPT is directly truncated and initialized from the 12-layer GPT and is continually trained for 50k steps with the same configuration of 12-layer GPT.

The evaluation is conducted over the 9 configurations of context-target length and averaged across all domains. Specifically, each configuration is inferred using a data center GPU NVIDIA V100 Tensor Core, and the GPU is fully occupied by one model. The beam size is set to be 16. We report the average inference time in millisecond as well as accuracy in terms of P@K of PinyinGPT-Concat. Table 7 is the result for the configuration (4-9, 4-9). The table shows that the inference time of the model with 6-layer transformer is almost 30% faster than that with 12-layer. However, the performance of the 6-layer model drops consistently in the abbreviated setting. [15]

---

[14] The table of all 15 domains is attached in the Appendix.

[15] We also list the experiment results for all configurations

Model	Games			Culture			Sports		
	P@1	P@5	P@10	P@1	P@5	P@10	P@1	P@5	P@10
GPT (ours)	24.04	32.78	34.23	21.86	29.33	30.94	28.54	37.13	38.69
PinyinGPT-Concat	**25.78**	**38.26**	**41.89**	**22.10**	**33.33**	**36.72**	**29.81**	**43.56**	**46.95**
	Real Estate			Medical			Finance		
	P@1	P@5	P@10	P@1	P@5	P@10	P@1	P@5	P@10
GPT (ours)	26.53	35.27	36.74	33.59	43.54	44.93	29.00	37.24	38.47
PinyinGPT-Concat	**27.28**	**40.16**	**43.86**	**34.76**	**49.28**	**52.56**	**29.17**	**42.17**	**45.52**

Table 6: Performance of six sample domains over WD using abbreviated pinyin.

Model	Time (ms)	P@5
GPT (ours, 6L)	94	27.45
GPT (ours, 12L)	142	34.48
PinyinGPT-Concat (6L)	94	32.70
PinyinGPT-Concat (12L)	145	41.51

5 Related work

Pinyin Input Method We describe existing works based on whether the input pinyin is perfect or abbreviated. A majority of existing works focus on perfect pinyin. Traditional models are typically based on statistical language models (Chen and Lee, 2000) and statistical machine translation (Yang et al., 2012). Recent works are usually built with neural network. For example, Moon IME (Huang et al., 2018) integrates attention-based neural network and an information retrieval module. Zhang et al. (2019) improves an LSTM-based encoder-decoder model with online vocabulary adaptation. For abbreviated pinyin, CoCAT (Huang et al., 2015) uses machine translation technology to reduce the number of the typing letters. Huang and Zhao (2018) propose an LSTM-based encoder-decoder approach with the concatenation of context words and abbreviated pinyin as input. Our work differs from existing works in that we are the first one to exploit GPT and verify the pros and cons of GPT in different situations. In addition, there are some works handling pinyin with typing errors. Chen and Lee (2000) investigate a typing model which handles spelling correction in sentence-based pinyin input method. CHIME (Zheng et al., 2011) is a error-tolerant Chinese pinyin input method. It finds similar pinyin which will be further ranked with Chinese specific features. Jia and Zhao (2014) propose a joint graph model to globally optimize the tasks of pinyin input method and typo correction. We leave error-tolerant pinyin input method as a future work.

Pinyin-enhanced Pretrained Models Our methodology also relates to pretrained models that use pinyin information. Sun et al. (2021) propose a general-purpose Chinese BERT with new embedding layers to inject pinyin and glyph information of characters. There are also task-specific BERT models, especially for the task of grammatical error correction since an important type of error is caused by characters pronounced with the same pinyin. Zhang et al. (2021a) add a pinyin embedding layer and learns to predict characters from similarly pronounced candidates. PLOME (Liu et al., 2021) add two embedding layers implemented with two GRU networks to inject both pinyin and shape of characters, respectively. Xu et al. (2021) add a hierarchical encoder to inject the pinyin letters at character and sentence levels, and add a ResNet encoder to use graphic features of character image.

6 Conclusion

In this paper, we explore how to adapt pretrained Chinese GPT to pinyin input method. To begin with, we find that a frozen GPT with decoding conditioned on pinyin can reach state-of-the-art performance on perfect pinyin. However, in abbreviated setting, the performance drops by a large gap. Through our experiments, we find that both context enrichment with pinyin and pinyin-constrained training improve the performance. In the future, we would like to investigate more challenging settings including error-tolerant pinyin input method and mixtures of perfect pinyin and abbreviated pinyin.

---

in the Appendix. We recommend readers to select models in a more cost-effective way based on their requirements.

Abstract

Cross-lingual natural language inference (XNLI) is a fundamental task in cross-lingual natural language understanding. Recently this task is commonly addressed by pre-trained cross-lingual language models. Existing methods usually enhance pre-trained language models with additional data, such as annotated parallel corpora. These additional data, however, are rare in practice, especially for low-resource languages. Inspired by recent promising results achieved by prompt-learning, this paper proposes a novel prompt-learning based framework for enhancing XNLI. It reformulates the XNLI problem to a masked language modeling problem by constructing cloze-style questions through cross-lingual templates. To enforce correspondence between different languages, the framework augments a new question for every question using a sampled template in another language and then introduces a consistency loss to make the answer probability distribution obtained from the new question as similar as possible with the corresponding distribution obtained from the original question. Experimental results on two benchmark datasets demonstrate that XNLI models enhanced by our proposed framework significantly outperform original ones under both the full-shot and few-shot cross-lingual transfer settings.

1 Introduction

Cross-lingual language understanding (XLU) plays a vital role in multilingual systems. It aims at training a model in a source language which is then applied to other languages. Cross-lingual natural language inference (XNLI) is a challenge task for evaluating XLU (Conneau et al., 2018). Natural language inference (NLI) aims to determine the inferential relationship between the text of a premise and the text of a hypothesis while XNLI upgrades NLI to the cross-lingual scenarios.

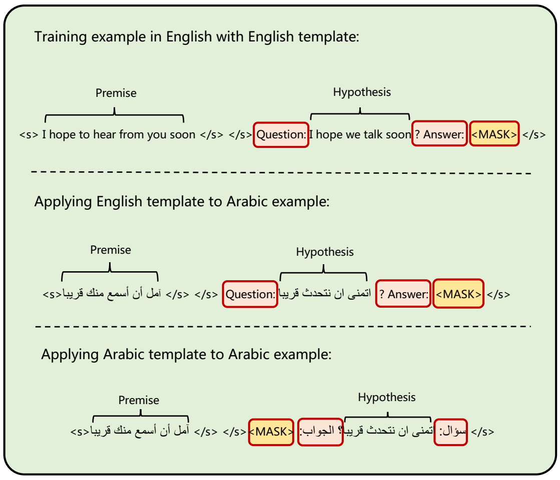

Figure 1: Examples of applying cross-lingual templates.

Nowadays pre-trained cross-lingual language models (Conneau and Lample, 2019; Conneau et al., 2020) have become a dominant paradigm for XLU, significantly improving the performance in various XLU tasks included XNLI. Existing methods (Huang et al., 2019; Chi et al., 2021a,b) usually utilize various auxiliary tasks to improve the cross-lingual transferability of a pre-trained cross-lingual language model, mainly relying on annotated parallel corpora. In practice, these methods can hardly work for low-resource language scenarios where parallel corpora are rare.

Recently, prompt-learning based methods (Schick and Schütze, 2021; Shin et al., 2020) have shown to achieve promising results for few-shot natural language processing (NLP). These methods reformulate the text classification problem into a masked language modeling problem. In particular, the work (Zhao and Schütze, 2021) demonstrates that prompt-learning outperforms fine-tuning in few-shot XNLI. We argue that the effectiveness of prompt-learning in XNLI still needs to be explored by a larger margin. The reasons are two-fold. On one hand, the effectiveness of prompt-learning in XNLI under the full-shot setting is still unknown.

May 22-27, 2022

On the other hand, the way to make the best of question templates is unexplored yet. The work (Zhao and Schütze, 2021) uses a uniform template in English for all examples in different languages. This way can hardly capture language-specific characteristics in XNLI, especially for those languages that are right-to-left written such as Arabic and Urdu. We naturally expect that language-specific question templates lead to higher performance in XNLI. Figure 1 illustrates how language-specific question templates are used. The second sub-figure shows the uniform question template used in (Zhao and Schütze, 2021) to handle an Arabic example, where the corresponding example in English is shown in the first sub-figure. The last sub-figure shows the Arabic-specific question template used for the same Arabic example, which is right-to-left written and conforms to the Arabic grammar.

In order to introduce language-specific characteristics in question templates while capturing correspondence between different languages, we propose a novel prompt-learning based framework named PCT (shot for *Prompt-learning from Cross-lingual Templates*) for XNLI. As illustrated in Figure 2, PCT first constructs a cloze-style question by filling the template in the source language (namely English), then randomly samples a template in another language (such as Chinese) to construct an augmented question, where the augmented question is written in two languages and thus its template is called a *cross-lingual template*. Both the original question and the augmented question are fed into a pre-trained cross-lingual language model to calculate the answer probability distributions for inferential relationships that are represented by predefined tokens mapped from the mask token. To enforce answer consistency for the two questions, i.e., to make the two probability distributions of inferential relationships as similar as possible, the two probability distributions are regularized by the Kullback-Leibler divergence (KLD) loss. The entire model is trained by minimizing the sum of the cross-entropy loss for classification accuracy and the KLD loss for answer consistency.

We employ PCT to enhance pre-trained cross-lingual language models XLM-R (Conneau et al., 2020) and INFOXLM (Chi et al., 2021a). Experimental results on the XNLI (Conneau et al., 2018) benchmark and the PAWS-X (Yang et al., 2019) benchmark show that PCT improves the original models by a significant margin under both the full-shot and few-shot cross-lingual transfer settings.

Main contributions of this work include:

1. We propose a novel prompt-learning based framework for XNLI. In this framework, a data augmentation strategy is introduced which relies merely on predefined cross-lingual templates; moreover, a consistency loss is introduced to enforce similar output probability distributions for arbitrary two languages so as to capture correspondence between different languages.

2. We conduct extensive experiments on two large-scale benchmarks to demonstrate significant improvements achieved by the proposed framework, under both the full-shot and few-shot cross-lingual transfer settings.

2 Related Work

Up to date XLU including XNLI are widely addressed by pre-trained cross-lingual language models (Devlin et al., 2019; Conneau and Lample, 2019; Conneau et al., 2020). Multilingual BERT (mBERT) (Devlin et al., 2019) extends the basic pre-trained language model BERT by training with multilingual corpora. XLM (Conneau and Lample, 2019) enhances mBERT by introducing the translation language modeling (TLM) objective. XLM-RoBERTa (XLM-R) (Conneau et al., 2020) trains XLM with larger corpora and more epochs.

Cross-lingual language models can further be enhanced by post-training tasks that rely on large-scale parallel corpora. UNICODER (Huang et al., 2019) introduces several post-training tasks to utilize parallel corpora. INFOXLM (Chi et al., 2021a) enhances XLM-R by introducing the cross-lingual contrastive learning task using 42 GB parallel corpora. XLM-ALIGN (Chi et al., 2021b) introduces a denoising word alignment pre-training task using several parallel corpora. These enhancements can hardly be applied to low-resource languages for which parallel corpora are rare. To alleviate the dependence on parallel corpora, some data augmentation strategies have been proposed for XNLI. TMAN (Qi and Du, 2020) enhances XNLI by exploiting adversarial training from translated data. The work (Dong et al., 2021) proposes a data augmentation strategy for XNLI by generating augmented data from a pre-trained sequence-to-sequence model. UXLA (Bari et al., 2021) improves the performance of XNLI by data augmen-

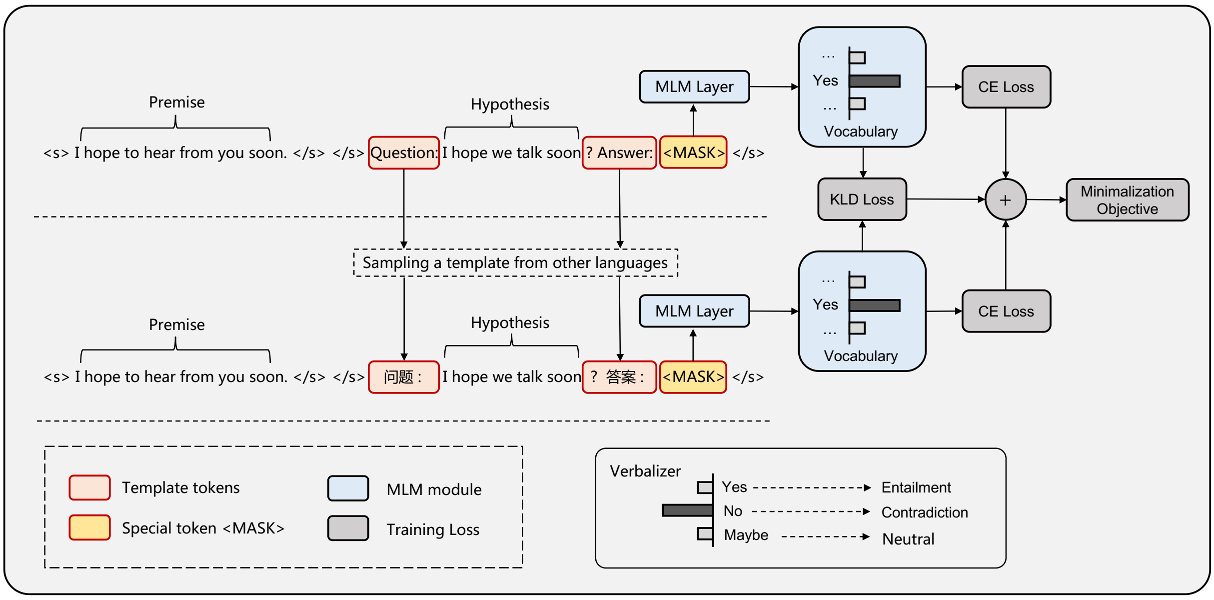

Figure 2: The proposed PCT framework.

tation and unsupervised sample selection. All these strategies require a large amount of external resources for data augmentation. In contrast, our proposal augments data by only predefined cross-lingual templates.

Recently prompt-learning based methods have shown to achieve promising results in various few-shot NLP tasks. The key of these methods is reformulating the text classification problem into a masked language modeling problem by constructing cloze-style questions. The work (Schick and Schütze, 2021) applies prompt-learning to text classification (including NLI) with manually defined templates. The work (Shin et al., 2020) proposes to search for optimal discrete templates by a gradient based approach. Several approaches (Li and Liang, 2021; Liu et al., 2021; Han et al., 2021) have been proposed to search continuous prompts. The work (Zhao and Schütze, 2021) compares prompt-learning with fine-tuning in few-shot XNLI. Different from (Zhao and Schütze, 2021), this work significantly advances prompt-learning in XNLI further by introducing a new data augmentation strategy and a new consistency loss for regularization. The effectiveness of prompt-learning is also demonstrated further under both the full-shot and few-shot cross-lingual transfer settings.

3 The PCT Framework

The proposed PCT framework is illustrated in Figure 2. For every training triple (premise, hypothesis, label) in English, PCT first constructs a cloze-style question by filling the template in English, then samples a predefined template from another language such as Chinese to construct an augmented question. Both the original question and the augmented question are fed into a pre-trained cross-lingual model to calculate the answer distributions of the mask token, through the masked language modeling (MLM) layer in the pre-trained cross-lingual model. The entire model is trained by minimizing the cross-entropy loss for classification accuracy and the Kullback-Leibler divergence (KLD) loss for answer consistency.

3.1 Formalization of PCT

The training phase of PCT is formalized in Algorithm 1. For every training triple (P_i, H_i, Y_i) in English, where $P_i = \{w_j^P\}_{j=1}^m$ denotes the word sequence of the premise, $H_i = \{w_j^H\}_{j=1}^n$ the word sequence of the hypothesis, $Y_i \in \mathcal{Y}$ the index of the NLI label, PCT first constructs a cloze-style question X_i by filling the English template, and then randomly samples a template from other languages to construct an augmented question $\overline{X}_i$. A template in an arbitrary language is a textual string with three unfilled slots: a input slot [P] to fill the input premise, a input slot [H] to fill the input hypothesis and an answer slot [Z] that allows language models to fill label words. [Z] is usually filled by the mask token [MASK] when using pre-trained language models. For instance, the English template is expressed as “<s>[P]</s></s>Question: [H]? Answer: [MASK]</s>”, where <s> and </s>

Algorithm 1 The training phase of PCT

```
Require: the number of epochs $E$ and the training set $\mathbb{D} = \{(P_i, H_i, Y_i)\}_{i=1}^{M}$ in English.
Reform $\mathbb{D}$ to a set of tuples $\mathbb{S} = \{X_i, Y_i\}_{i=1}^{M}$ by filling the English template.
Extend $\mathbb{S}$ to $\mathbb{T} = \{(X_i, \overline{X}_i, Y_i)\}_{i=1}^{M}$ by filling a randomly sampled template from other languages for each $(P_i, H_i)$.
Divide $\mathbb{T}$ into a set of mini-batches $\mathbb{B}$.
for epoch from 1 to $E$ do
    Shuffle $\mathbb{B}$.
    for each mini-batch $\{(X_i, \overline{X}_i, Y_i)\}_{1 \le i \le N}$ in $\mathbb{B}$ do
        Compute total loss $\mathcal{L}$ by Eq. (5).
        Update parameters $\theta$ by gradient descent.
    end for
end for
```

are special tokens in XLM-R to separate sentences. The verbalizer $\mathcal{M} : \mathcal{Y} \rightarrow \mathcal{V}$ is a function to map NLI labels to indices of answer words in the given vocabulary. Let l denote the size of the given vocabulary and d the dimension of the contextualized representation of a token, output by a pre-trained cross-lingual language model with an MLM layer, such as XLM-R (Conneau et al., 2020). The answer probability distribution is calculated by:

$$y_i = \mathrm{softmax}(W_{\mathrm{lm}} h_i^{[\mathrm{MASK}]}) \tag{1}$$

where $W_{\mathrm{lm}} \in \mathbb{R}^{l \times d}$ denotes the parameters of the pre-trained MLM layer and $h_i^{[\mathrm{MASK}]} \in \mathbb{R}^d$ denotes the contextualized representation of the [MASK] token of the i^{th} training triple. Compared with the standard fine-tuning method, no extra parameters are required to be initialized, therefore the model can be optimized by fewer samples.

Given a mini-batch $(X_i, \overline{X}_i, Y_i)_{1 \le i \le N}$ of N triples, the two cross-entropy losses for the original question and the augmented question are respectively calculated by:

$$\mathcal{L}_X = -\frac{1}{N} \sum_{i=1}^{N} \sum_{j=1}^{l} I(j = \mathcal{M}(Y_i)) \log y_{i,j}^{X_i} \tag{2}$$

$$\mathcal{L}_{\overline{X}} = -\frac{1}{N} \sum_{i=1}^{N} \sum_{j=1}^{l} I(j = \mathcal{M}(Y_i)) \log y_{i,j}^{\overline{X}_i} \tag{3}$$

where $y_{i,j}^{X_i}$ (resp. $y_{i,j}^{\overline{X}_i}$) denotes the j^{th} element of $y_i \in \mathbb{R}^l$ for the input X_i (resp. for the input $\overline{X}_i$). $I(C)$ is an indicator function that returns 1 if C is true or 0 otherwise.

We observe that, given the same input premise and hypothesis, the answer probability distribution of the question constructed by a cross-lingual template may evidently deviate from that of the question constructed from the English template. Such a deviation may lead to an increase of errors when applying cross-lingual templates to examples in other languages. Our ablation study in Section 4 confirms this phenomenon. To eliminate the negative effect of this deviation, we propose a consistency loss function to regularize the answer probability distributions. More precisely, we employ the symmetric Kullback-Leibler divergence (KLD) loss to enforce the answer probability distributions $y_i^{X_i}$ and $y_i^{\overline{X}_i}$ to be as similar as possible, which is formally defined bellow.

$$\begin{aligned} \mathcal{L}_{\mathrm{KLD}} &= \frac{1}{N} \sum_{i=1}^{N} (\mathrm{KL}(y_i^{X_i} || y_i^{\overline{X}_i}) + \mathrm{KL}(y_i^{\overline{X}_i} || y_i^{X_i})) \\ &= \frac{1}{N} \sum_{i=1}^{N} \sum_{j=1}^{l} (y_{i,j}^{X_i} \log \frac{y_{i,j}^{X_i}}{y_{i,j}^{\overline{X}_i}} + y_{i,j}^{\overline{X}_i} \log \frac{y_{i,j}^{\overline{X}_i}}{y_{i,j}^{X_i}}) \end{aligned} \tag{4}$$

The entire model is trained by minimizing the total loss $\mathcal{L}$ formally defined as:

$$\mathcal{L} = \mathcal{L}_X + \mathcal{L}_{\overline{X}} + \mathcal{L}_{\mathrm{KLD}} \tag{5}$$

where we simply apply the same weight for the three loss terms.

3.2 Inference with Cross-lingual Templates

Since the English template may not conform to the grammar of other languages such as Arabic and Urdu, PCT uses the cross-lingual template in the target language for predicting test examples in the target language. For instance, every Chinese test example is reformed to a Chinese cloze-style question by filling the Chinese template "<s>[P]</s></s>问题: [H]? 答案: [MASK]</s>", which is obtained from the English template by translating prompt words in English to prompt words in Chinese, where the slots [P] and [H] are filled by the premise and the hypothesis in Chinese, respectively. More generally, all cross-lingual templates are obtained from the English template by translating prompt words in English to prompt words in other languages using Google translator [1], where for Arabic

---

[1] https://translate.google.com/

and Urdu, the prompt part is written from right to left rather than from left to right as in English and other languages. By considering that the English label words have been fine-tuned to work for different languages during the training phase, we use the same English verbalizer $\mathcal{M}$ for all languages in the inference phase.

4 Experiments

To evaluate the effectiveness of the proposed PCT framework, we applied PCT to enhance several pre-trained cross-lingual language models including XLM-R$_{\text{base}}$, XLM-R$_{\text{large}}$ and INFOXLM$_{\text{large}}$. We call the enhanced models PCT-X, where X denotes the original pre-trained cross-lingual model.

4.1 Datasets

We conducted experiments on two large-scale benchmarks, namely XNLI and PAWS-X.

XNLI: The XNLI (Conneau et al., 2018) benchmark[2] extends the MultiNLI (Williams et al., 2018) benchmark (in English) to 15 languages through translation and comes with manually annotated development set and test set. For each language, the training set comprises 393K annotated sentence pairs, whereas the development set and the test set comprises 2.5 K and 5K annotated sentence pairs, respectively.

PAWS-X: The PAWS-X (Yang et al., 2019) is a cross-lingual paraphrase identification benchmark[3], which extends the Wikipedia portion of the PAWS (Zhang et al., 2019) dataset to 7 languages through translation. For each language, the training set comprises 49.5K annotated sentence pairs, whereas both the development set and the test set comprise 2K annotated sentence pairs each.

4.2 Implementation Details

We implemented our enhanced models by Tensorflow 2.4.0 and trained all the models with 8 TPUs on the Google Colab platform[4].

PCT-XLM-R$_{\text{base}}$ was initialized by the pre-trained XLM-R$_{\text{base}}$ model with 12 transformer layers, which outputs 768-dimensional token embeddings. The transformer encoder was built with 12 heads. We applied dropout (Srivastava et al., 2014) to each layer by setting the dropout rate to 0.1. The model was trained by Adam (Kingma and Ba, 2015) with the warmup mechanism (Devlin et al., 2019) and two training epochs, where the initial learning rate was set to 5e-5, the warmup proportion to 10%, and the mini-batch size to 64.

PCT-XLM$_{\text{large}}$ and PCT-INFOXLM$_{\text{large}}$ were respectively initialized by the pre-trained XLM-R$_{\text{large}}$ and INFOXLM$_{\text{large}}$ models with 24 transformer layers, both of which output 1024-dimensional token embeddings. The transformer encoder was built with 16 heads. The models were trained by RMSProp (Dauphin et al., 2015) with one training epoch, where the initial learning rate was set to 5e-6, the mini-batch size to 32, and the dropout rate to 0.1. We used RMSProp instead of Adam for these large models since the training memory is limited by the Google Colab platform. For all the above models, the input sentence pairs were truncated to maximum 128 tokens. Code and data about our implementations are available at `https://github.com/qikunxun/PCT`.

4.3 Compared Models

We compared our models with the following pre-trained cross-lingual language models: (1) multilingual BERT (mBERT; Devlin et al. (2019)) is a BERT model pre-trained on Wikipedia with 102 languages; (2) XLM (Conneau and Lample, 2019) is pre-trained for two tasks (MLM and TLM) on Wikipedia with 100 languages; (3) XLM-R (Conneau et al., 2020) extends XLM with larger corpora (i.e. the CC-100 corpora with 100 languages) and more training epochs; (4) UNICODER (Huang et al., 2019) continues training XLM by introducing several post-training tasks using parallel corpora; (5) INFOXLM (Chi et al., 2021a) enhances XLM-R by introducing the cross-lingual contrastive learning task using 42 GB parallel corpora; (6) XLM-ALIGN (Chi et al., 2021b) enhances XLM-R by introducing the denoising word alignment pre-training task using several parallel corpora; (7) The work (Dong et al., 2021) proposes an adversarial data augmentation strategy for XNLI based-on XLM-R; (8) UXLA (Bari et al., 2021) extends XLM-R with data augmentation and unsupervised sample selection. (9) The work (Zhao and Schütze, 2021) proposes three prompt-learning methods for few-shot XNLI, including DP (direct prompting), SP (soft prompting) and MP (mixed prompting).

4.4 Main Results

We conducted experiments on both XNLI and PAWS-X under the *cross-lingual transfer* setting, where models are trained on data in the source language (usually English) and tested on data in the target language. This setting is commonly used to evaluate XNLI models. It can be further divided into two sub-settings: the full-shot setting using the whole training set, and the few-shot setting using a fixed number of training samples. For both XNLI and PAWS-X we evaluated models under the full-shot setting, whereas for XNLI we additionally evaluated models under the few-shot setting.

Table 1 reports the results for comparing PCT-enhanced models with other models on XNLI under the full-shot setting. The results of compared models are taken from (Chi et al., 2021a) and (Liang et al., 2020). PCT-XLM-R$_{\text{base}}$ achieves 75.3% accuracy on the XNLI test set averaged by 15 target languages, significantly outperforming its basic model XLM-R$_{\text{base}}$ by an absolute gain of 1.1% accuracy on average. The difference between PCT-XLM-R$_{\text{base}}$ and XLM-R$_{\text{base}}$ in average accuracy is statistically significant with p-value 1.7e-6 by a two-tailed t-test. Meanwhile, PCT-XLM-R$_{\text{base}}$ outperforms the three prompt-learning approaches (i.e. DP-XLM-R$^{\dagger}_{\text{base}}$, SP-XLM-R$^{\dagger}_{\text{base}}$ and MP-XLM-R$^{\dagger}_{\text{base}}$) in (Zhao and Schütze, 2021) under the full-shot setting. PCT-XLM-R$_{\text{large}}$ achieves 81.3% accuracy on the XNLI test set averaged by 15 target languages, pushing XLM-R$_{\text{large}}$ by an absolute gain of 0.9% accuracy on average. The difference between PCT-XLM-R$_{\text{large}}$ and XLM-R$_{\text{large}}$ in average accuracy is statistically significant with p-value 2.5e-4 by a two-tailed t-test. Furthermore, it can be seen that the average accuracy of PCT-XLM-R$_{\text{large}}$ is close to that of the current state-of-the-art model INFOXLM$_{\text{large}}$ (i.e. 81.4%), which is trained with additional data. To further verify the effectiveness of PCT, we also applied PCT to INFOXLM$_{\text{large}}$, denoted by PCT-INFOXLM$_{\text{large}}$. It can be seen that PCT-INFOXLM$_{\text{large}}$ achieves 82.0% accuracy on average, pushing INFOXLM$_{\text{large}}$ by an absolute gain of 0.6% on average. The difference between PCT-INFOXLM$_{\text{large}}$ and INFOXLM$_{\text{large}}$ in average accuracy is statistically significant with p-value 7.5e-3 by a two-tailed t-test. These results imply that PCT is able to further improve the cross-lingual transferability of state-of-the-art models.

Table 2 reports the comparison results on PAWS-X under the full-shot setting. The results of compared models are taken from (Hu et al., 2020). Since the work (Hu et al., 2020) has not reported the result of XLM-R$_{\text{base}}$, we produced the result of

Table 4: **Comparison results on XNLI under the TRANSLATE-TRAIN-ALL setting.** Every value is the test accuracy in percent. △ is the average accuracy.

XLM-R$_{\text{base}}$ (denoted by XLM-R$^{\dagger}_{\text{base}}$). PCT-XLM-R$_{\text{base}}$ achieves 85.4% accuracy on the test set averaged by 7 languages, pushing XLM-R$_{\text{base}}$† by an absolute gain of 1.1% accuracy on average. The difference between PCT-XLM-R$_{\text{base}}$ and XLM-R$_{\text{base}}$† in average accuracy is statistically significant with p-value 3.2e-3 by a two-tailed t-test. PCT-XLM-R$_{\text{large}}$ achieves 88.3% average accuracy on the PAWS-X test set, pushing XLM-R$_{\text{large}}$ by an absolute gain of 1.9% accuracy on average. The difference between PCT-XLM-R$_{\text{large}}$ and XLM-R$_{\text{large}}$ in average accuracy is statistically significant with p-value 3.2e-3 by a two-tailed t-test.

Table 3 reports the results for comparing PCT-XLM-R$_{\text{base}}$ with all approaches proposed in (Zhao and Schütze, 2021). Note that all compared models are based on XLM-R$_{\text{base}}$ and we evaluated PCT-XLM-R$_{\text{base}}$ using the same split of data from (Zhao and Schütze, 2021). The training and validation data are randomly sampled by (Zhao and Schütze, 2021) with $K \in \{16, 32, 64, 128, 256\}$ shots per class from the English training data in XNLI. Results show that PCT-XLM-R$_{\text{base}}$ statistically outperforms all baselines in all experiments. In particular, PCT-XLM-R$_{\text{base}}$ outperforms the fine-tuning baseline by an absolute gain of 9.4% accuracy on average in the 16-shot experiments. It can also be seen that the difference between PCT-XLM-R$_{\text{base}}$ and fine-tuning baseline becomes larger as K decreases, implying that the PCT framework becomes more effective when training data are fewer.

4.5 Evaluation on Translated Training Data

We also evaluated PCT on XNLI under the TRANSLATE-TRAIN-ALL setting, where all translated data are used in training, to see how well PCT is adapted to this setting. We construct an original question from the template of each of the 15 languages and an augmented question from a sampled template of other languages. Table 4 reports the comparison results. PCT-XLM-R$_{\text{large}}$ under this setting achieves significantly better performance than under the cross-lingual transfer setting, but fails to outperform its original model XLM-R$_{\text{large}}$. This inferiority may be caused by the relatively low quality of examples in source languages. Note that an example in a source language other than English is translated from an English example

Table 6: **Comparison results for template selection.** Every value is the test accuracy in percent. △ is the average accuracy for 15 languages. The p-value is calculated by two-tailed t-tests. “uniform” denotes the strategy with uniform selection probabilities. “directly proportional” and “inversely proportional” denote two strategies where the selection probabilities are directly proportional to and inversely proportional to the XX-En BLEU scores.

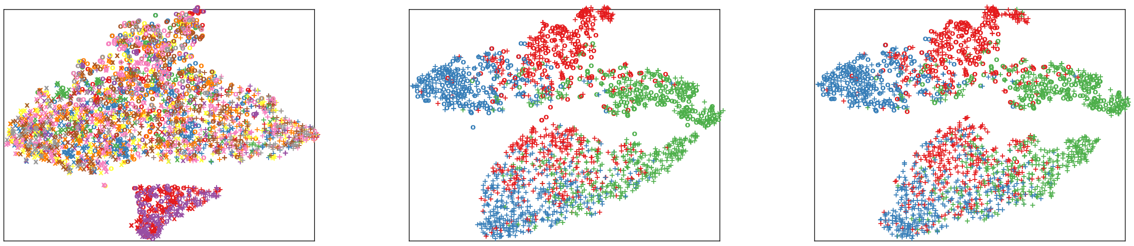
and may have translation errors. As a future work, we will go on studying whether using training data in multiple languages helps to improve XNLI by collecting more real-world data in other languages.

4.6 Ablation Study

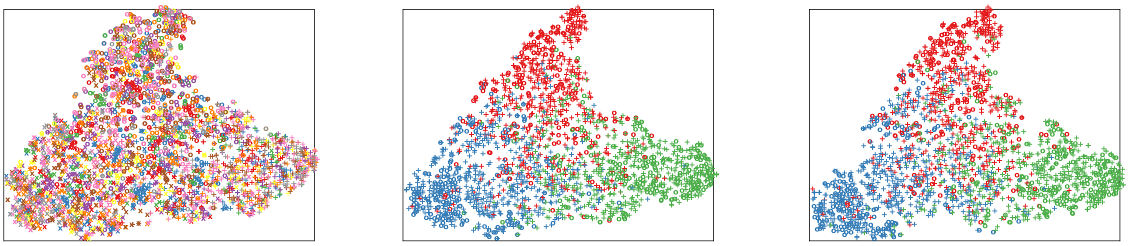
Table 5 reports the ablation study results for PCT-XLM-R$_{\mathrm{base}}$. For the variant (1), we omit the consistency loss in course of training. Results show that the usage of consistency loss achieves better performance on average. For (2), we omit the whole PCT framework in course of training. Results show that the usage of PCT pushes XLM-R$_{\mathrm{base}}$ with standard prompt-learning by an absolute gain of 1.4%. For (3), we apply the cross-lingual templates to the variant (2). Results show that the performance drops about 0.6% on average when applying only the cross-lingual templates. For (4), we use only the English template in the inference phase. Results show that PCT-XLM-R$_{\mathrm{base}}$ achieves better performance on average when the cross-lingual templates are used in inference. For (5), we use the substitute word templates for Arabic and Urdu as for other languages, i.e., the templates for Arabic and Urdu are also left-to-right written. Results show that PCT-XLM-R$_{\mathrm{base}}$ is able to capture certain language-specific characteristics in the target language to achieve better performance.

4.7 Visualization Analysis

To clarify why the proposed PCT framework improves accuracy in predicting NLI labels, we visually compared the representations of the [MASK] token generated by standard prompt-learning based XLM-R$_{\mathrm{base}}$ (denoted by PL-XLM-R$_{\mathrm{base}}$) with that generated by PCT-XLM-R$_{\mathrm{base}}$, by using t-SNE (Laurens and Hinton, 2008) to reduce the dimension. The results are shown in Figure 3. For the sub-figures (a) and (d), the points marked with “x", “+" and “o” correspond to examples with the label “entailment”, “contradiction” and “neutral”, respectively. The points with different colors correspond to examples in different languages. The figures were obtained by randomly selecting 200 examples for each language from the XNLI test set. It can be seen in (a) that a group of red points (for Urdu) and purple points (for Arabic) are dissociated while all points from different languages are mutually overlapped in (d). Considering that the the points from Arabic and Urdu are quite different, we further analyzed them. For the sub-figures (b), (c), (e) and (f), the points marked with “o" and “+" respectively correspond to examples in English and in either Arabic or Urdu. The points with blue, red and green color correspond to examples with the label “entailment”, “neutral” and “contradiction”, respectively. Sub-figures (b) and (e) (resp. sub-figures (c) and (f)) were obtained by randomly selecting 1000 examples in English and 1000 in Arabic (resp. in Urdu) from the XNLI test set. Compared with PL-XLM-R$_{\mathrm{base}}$, PCT-XLM-R$_{\mathrm{base}}$ yields clearer distinction between different labels and more confusion between English and the target language (Arabic or Urdu). These results imply that the PCT framework tends to align contextualized representations in different languages into the



(a) PL-XLM-R(all) (b) PL-XLM-R(en+ar) (c) PL-XLM-R(en+ur)



(d) PCT-XLM-R(all) (e) PCT-XLM-R(en+ar) (f) PCT-XLM-R(en+ur)

Figure 3: Visualization of the [MASK] representations.

same space, which helps to improve the prediction accuracy in the XNLI task.

4.8 Different Strategies for Template Selection

We also conducted experiments to show how different strategies for template selection impact the performance. The results are reported in Table 6. We compared the default uniform strategy with two different selection strategies, where one sets the probabilities for selecting XX directly proportional to and the other inversely proportional to the XX-En BLEU scores, which are directly taken from Table 3 in (Conneau et al., 2018) and can be considered as similarity degrees between the target languages XX and English. Results show that the performances of both PCT-XLM-R$_{\text{base}}$ and PCT-XLM-R$_{\text{large}}$ slightly drop when using the “directly proportional” strategy. It can also be seen that, PCT-XLM-R$_{\text{base}}$ with the “inversely proportional" strategy achieves the same average accuracy as with the uniform strategy, while PCT-XLM-R$_{\text{large}}$ with the “inversely proportional" strategy is lightly better than with the uniform strategy. This implies that the “inversely proportional" strategy is able to improve the performance by selecting more templates in target languages that are less similar to English. However, the improvements are not significant as p-value > 0.05 by two-tailed t-tests. By considering that XX-En BLEU scores are not available in most practical scenarios, we recommend to use the uniform strategy for template selection.

5 Conclusions

In this paper we have proposed a prompt-learning based framework named PCT for cross-lingual natural language inference. PCT enhances pre-trained cross-lingual language models by augmenting data from cross-lingual templates and by introducing the consistency loss to regularize the answer probability distributions. Experimental results on large-scale benchmarks XNLI and PAWS-X show that PCT pushes existing models by a significant absolute gain in accuracy under both the full-shot and few-shot cross-lingual transfer settings. Our ablation study and visualization analysis further confirm the contributions of different enhancements introduced by PCT. Future work will study PCT further under the TRANSLATE-TRAIN-ALL setting with real-world data in different languages.

A Cross-lingual Templates

Here we introduce the cross-lingual templates that we used in our experiments. We used the same English template defined by (Zhao and Schütze, 2021) for XNLI and used the English template defined by (Brown et al., 2020) for PAWS-X. The cross-lingual templates are generated by translating the English template to target languages using Google translator. The cross-lingual templates for XNLI are given in Figure 4. The cross-lingual templates for PAWS-X are given in Figure 5. The slots [P] and [H] are filled by the premise and the hypothesis, respectively.

B Results with Standard Deviations

Here we report the complete experimental results taken from five runs with standard deviations. The means and the standard deviations are reported in the row "avg." and "s.d.", respectively.

For XNLI under the full-shot cross-lingual transfer setting, the experimental results are reported in Table 7, including the results for all five runs achieved by PCT-XLM-$\mathrm{R}_{\mathrm{base}}$, PCT-XLM-$\mathrm{R}_{\mathrm{large}}$ and INFOXLM-$\mathrm{R}_{\mathrm{base}}$.

For PAWS-X under the full-shot cross-lingual transfer setting, the experimental results are reported in Table 8, including the results for all five runs achieved by PCT-XLM-$\mathrm{R}_{\mathrm{base}}$, PCT-XLM-$\mathrm{R}_{\mathrm{large}}$ and INFOXLM-$\mathrm{R}_{\mathrm{base}}$.

For XNLI under the few-shot cross-lingual transfer setting, the experimental results with $K \in \{16, 32, 64, 128, 256\}$ shots per class are reported in Table 9, including the results for all five runs achieved by PCT-XLM-$\mathrm{R}_{\mathrm{base}}$.

Abstract

Sense embedding learning methods learn different embeddings for the different senses of an ambiguous word. One sense of an ambiguous word might be socially biased while its other senses remain unbiased. In comparison to the numerous prior work evaluating the social biases in pretrained word embeddings, the biases in sense embeddings have been relatively understudied. We create a benchmark dataset for evaluating the social biases in sense embeddings and propose novel sense-specific bias evaluation measures. We conduct an extensive evaluation of multiple static and contextualised sense embeddings for various types of social biases using the proposed measures. Our experimental results show that even in cases where no biases are found at word-level, there still exist worrying levels of social biases at sense-level, which are often ignored by the word-level bias evaluation measures.[1]

1 Introduction

Sense embedding learning methods use different vectors to represent the different senses of an ambiguous word (Reisinger and Mooney, 2010; Neelakantan et al., 2014; Loureiro and Jorge, 2019). Although numerous prior works have studied social biases in static and contextualised word embeddings, social biases in sense embeddings remain underexplored (Kaneko and Bollegala, 2019, 2021a,a; Ravfogel et al., 2020; Dev et al., 2020; Schick et al., 2021; Wang et al., 2020).

We follow Shah et al. (2020) and define social biases to be *predictive biases with respect to protected attributes* made by NLP systems. Even if a word embedding is unbiased, some of its senses could still be associated with unfair social biases.

Black dress is elegant.

Black dress is ugly.

Black people are friendly.

Black people are unfriendly.

Figure 1: Example sentences from the Sense-Sensitive Social Bias dataset for the two senses of the ambigous word *black*. Top two sentences correspond to the colour sense of black, whereas the bottom two sentences correspond to its racial sense. Stereotypical examples that associate a sense with an unpleasant attribute are shown in red, whereas anti-stereotypical examples that associate a sense with a pleasant attribute are shown in blue.

For example, consider the ambiguous word *black*, which has two adjectival senses according to the WordNet (Fellbaum and Miller, 1998): (1) black as a *colour* (*being of the achromatic colour of maximum darkness*, sense-key=**black%3:00:01**) and (2) black as a *race* (*of or belonging to a racial group especially of sub-Saharan African origin*, sense-key=**black%3:00:02**). However, only the second sense of *black* is often associated with racial biases.

Owing to (a) the lack of evaluation benchmarks for the social biases in sense embeddings, and (b) not being clear how to extend the bias evaluation methods that are proposed for static and contextualised embeddings to evaluate social biases in sense embeddings, existing social bias evaluation datasets and metrics do not consider multiple senses of words, thus not suitable for evaluating biases in sense embeddings.

To address this gap, we evaluate social biases in state-of-the-art (SoTA) static sense embeddings such as LMMS (Loureiro and Jorge, 2019) and

---

ARES (Scarlini et al., 2020), as well as contextualised sense embeddings obtained from SenseBERT (Levine et al., 2020). To the best of our knowledge, we are the first to conduct a systematic evaluation of social biases in sense embeddings. Specifically, we make two main contributions in this paper:

- First, to evaluate social biases in static sense embeddings, we extend previously proposed benchmarks for evaluating social biases in static (sense-insensitive) word embeddings by manually assigning sense ids to the words considering their social bias types expressed in those datasets (§ 3).
- Second, to evaluate social biases in sense-sensitive contextualised embeddings, we create the Sense-Sensitive Social Bias (**SSSB**) dataset, a novel template-based dataset containing sentences annotated for multiple senses of an ambiguous word considering its stereotypical social biases (§ 5). An example from the SSSB dataset is shown in Figure 1.

Our experiments show that, similar to word embeddings, both static as well as contextualised sense embeddings also encode worrying levels of social biases. Using SSSB, we show that the proposed bias evaluation measures for sense embeddings capture different types of social biases encoded in existing SoTA sense embeddings. More importantly, we see that even when social biases cannot be observed at word-level, such biases are still prominent at sense-level, raising concerns on existing evaluations that consider only word-level social biases.

2 Related Work

Our focus in this paper is the evaluation of social biases in English and *not* the debiasing methods. We defer the analysis for languages other than English and developing debiasing methods for sense embeddings to future work. Hence, we limit the discussion here only to bias evaluation methods.

Biases in Static Embeddings: The Word Embedding Association Test (**WEAT**; Caliskan et al., 2017) evaluates the association between two sets of target concepts (e.g. *male* vs. *female*) and two sets of attributes (e.g. Pleasant (*love, cheer*, etc.) vs. Unpleasant (*ugly, evil*, etc.)). Here, the association is measured using the cosine similarity between the word embeddings. Ethayarajh et al. (2019) showed that WEAT systematically overestimates the social biases and proposed relational inner-product association (**RIPA**), a subspace projection method, to overcome this problem.

Word Association Test (**WAT**; Du et al., 2019) calculates a gender information vector for each word in an association graph (Deyne et al., 2019) by propagating information related to masculine and feminine words. Additionally, word analogies are used to evaluate gender bias in static embeddings (Bolukbasi et al., 2016; Manzini et al., 2019; Zhao et al., 2018). Loureiro and Jorge (2019) showed specific examples of gender bias in static sense embeddings. However, these datasets do not consider word senses, hence are unfit for evaluating social biases in sense embeddings.

Biases in Contextualised Embeddings: May et al. (2019) extended WEAT to sentence encoders by creating artificial sentences using templates and used cosine similarity between the sentence embeddings as the association metric. Kurita et al. (2019) proposed the log-odds of the target and prior probabilities of the sentences computed by masking respectively only the target vs. both target and attribute words. Template-based approaches for generating example sentences for evaluating social biases do not require human annotators to write examples, which is often slow, costly and require careful curation efforts. However, the number of sentence patterns that can be covered via templates is often small and less diverse compared to manually written example sentences.

To address this drawback, Nadeem et al. (**StereoSet**; 2021) created human annotated contexts of social bias types, while Nangia et al. (2020) proposed Crowdsourced Stereotype Pairs benchmark (**CrowS-Pairs**). Following these prior work, we define a stereotype as a commonly-held association between a group and some attribute. These benchmarks use sentence pairs of the form "*She is a nurse/doctor*". StereoSet calculates log-odds by masking the modified tokens (*nurse*, *doctor*) in a sentence pair, whereas CrowS-Pairs calculates log-odds by masking their unmodified tokens (*She*, *is*, *a*).

Kaneko and Bollegala (2021b) proposed All Unmasked Likelihood (**AUL**) and AUL with Attention weights (**AULA**), which calculate log-likelihood by predicting all tokens in a test case, given the contextualised embedding of the unmasked input.

3 Evaluation Metrics for Social Biases in Static Sense Embeddings

We extend the WEAT and WAT datasets that have been frequently used in prior work for evaluating social biases in static word embeddings such that they can be used to evaluate sense embeddings. These datasets compare the association between a target word w and some (e.g. pleasant or unpleasant) attribute a, using the cosine similarity, $\cos(\boldsymbol{w}, \boldsymbol{a})$, computed using the static word embeddings $\boldsymbol{w}$ and $\boldsymbol{a}$ of respectively w and a. Given two same-sized sets of *target* words $\mathcal{X}$ and $\mathcal{Y}$ and two sets of *attribute* words $\mathcal{A}$ and $\mathcal{B}$, the bias score, $s(\mathcal{X}, \mathcal{Y}, \mathcal{A}, \mathcal{B})$, for each target is calculated as follows:

$$s(\mathcal{X}, \mathcal{Y}, \mathcal{A}, \mathcal{B}) = \sum_{\boldsymbol{x} \in \mathcal{X}} w(\boldsymbol{x}, \mathcal{A}, \mathcal{B}) - \sum_{\boldsymbol{y} \in \mathcal{Y}} w(\boldsymbol{y}, \mathcal{A}, \mathcal{B}) \quad (1)$$

$$w(\boldsymbol{t}, \mathcal{A}, \mathcal{B}) = \underset{\boldsymbol{a} \in \mathcal{A}}{\text{mean}} \cos(\boldsymbol{t}, \boldsymbol{a}) - \underset{\boldsymbol{b} \in \mathcal{B}}{\text{mean}} \cos(\boldsymbol{t}, \boldsymbol{b}) \quad (2)$$

Here, $\cos(\boldsymbol{a}, \boldsymbol{b})$ is the cosine similarity[2] between the embeddings $\boldsymbol{a}$ and $\boldsymbol{b}$. The one-sided p-value for the permutation test for $\mathcal{X}$ and $\mathcal{Y}$ is calculated as the probability of $s(\mathcal{X}_i, \mathcal{Y}_i, \mathcal{A}, \mathcal{B}) > s(\mathcal{X}, \mathcal{Y}, \mathcal{A}, \mathcal{B})$. The effect size is calculated as the normalised measure given by (3):

$$\frac{\underset{x \in \mathcal{X}}{\text{mean}}\, w(x, \mathcal{A}, \mathcal{B}) - \underset{y \in \mathcal{Y}}{\text{mean}}\, w(y, \mathcal{A}, \mathcal{B})}{\underset{t \in \mathcal{X} \cup \mathcal{Y}}{\text{sd}}\, w(t, \mathcal{A}, \mathcal{B})} \quad (3)$$

We repurpose these datasets for evaluating the social biases in *sense* embeddings as follows. For each target word in WEAT, we compare each sense s_i of the target word w against each sense a_j of a word selected from the association graph using their corresponding sense embeddings, $\boldsymbol{s}_i, \boldsymbol{a}_j$, and use the maximum similarity over all pairwise combinations (i.e. $\max_{i,j} \cos(\boldsymbol{s}_i, \boldsymbol{a}_j)$) as the word association measure. Measuring similarity between two words as the maximum similarity over all candidate senses of each word is based on the assumption that two words in a word-pair would mutually disambiguate each other in an association-based evaluation (Pilehvar and Camacho-Collados, 2019), and has been used as a heuristic for disambiguating word senses (Reisinger and Mooney, 2010).

WAT considers only gender bias and calculates the gender information vector for each word in a word association graph created with Small World of Words project (Deyne et al., 2019) by propagating information related to masculine and feminine words $(w_m^i, w_f^i) \in \mathcal{L}$ using a random walk approach (Zhou et al., 2003). It is non-trivial to pre-specify the sense of a word in a large word association graph considering the paths followed by a random walk. The gender information is encoded as a vector (b_m, b_f) in 2 dimensions, where b_m and b_f denote the masculine and feminine orientations of a word, respectively. The bias score of a word is defined as $\log(b_m/b_f)$. The gender bias of word embeddings are evaluated using the Pearson correlation coefficient between the bias score of each word and the score given by (4), computed as the average over the differences of cosine similarities between masculine and feminine words.

$$\frac{1}{|\mathcal{L}|} \sum_{i=1}^{|\mathcal{L}|} \left(\cos(\boldsymbol{w}, \boldsymbol{w}_m^i) - \cos(\boldsymbol{w}, \boldsymbol{w}_f^i) \right) \quad (4)$$

To evaluate gender bias in sense embeddings, we follow the method that is used in WEAT, and take $\max_{i,j} \cos(\boldsymbol{s}_i, \boldsymbol{a}_j))$ as the word association measure.

Category	noun vs. verb	race vs. colour	nationality vs. language
#pleasant words	14	5	18
#unpleasant words	18	5	15
#target words	6	1	16
#templates	1	4	4
#test cases	324	733	2304

Table 1: Statistics of the the SSSB dataset.

4 Sense-Sensitive Social Bias Dataset

Contextualised embeddings such as the ones generated by masked language models (MLMs) return different vectors for the same word in different contexts. However, the datasets discussed in § 3 do not provide contextual information for words and cannot be used to evaluate contextualised embeddings. Moreover, the context in which an ambiguous word occurs determines its word sense. Contextualised sense embedding methods such as SenseBERT (fine-tuned using WordNet super senses), have shown to capture word sense information in their contextualised embeddings (Zhou and Bollegala, 2021).

CrowS-Pairs and StereoSet datasets were proposed for evaluating contextualised word embeddings. Specifically, an MLM is considered to be

---

[2] Alternatively, inner-products can be used to extend RIPA.

Category	Ambiguous words considered
noun vs. verb	engineer, carpenter, guide, mentor, judge, nurse
race vs. colour	black
nationality vs. language	Japanese, Chinese, English, Arabic, German, French, Spanish, Portuguese, Norwegian, Swedish, Polish, Romanian, Russian, Egyptian, Finnish, Vietnamese

Table 2: Bias categories covered in the SSSB dataset

unfairly biased if it assigns higher pseudo log-likelihood scores for stereotypical sentences, S^{st}, than anti-stereotypical ones, S^{at}. However, both of those datasets do not consider multiple senses of words and cannot be used to evaluate social biases in contextualised sense embeddings.

To address this problem, we create the Sense-Sensitive Social Bias (SSSB) dataset, containing template-generated sentences covering multiple senses of ambiguous words for three types of social biases: *gender*, *race* and *nationality*. Templates are used in the same sense as in prior work such as Kurita et al. (2019). For example, we manually create templates such as [gender word] is a [pleasant/unpleasant attribute] engineer. We then fill the gender word by male and female gender pronouns (he/she), pleasant attributes (e.g. careful, skilful, efficient, etc.) and unpleasant attributes (e.g. clumsy, unskillful, inefficient, etc.) to generate many example sentences demonstrating social biases.

To the best of our knowledge, SSSB is the first-ever dataset created for the purpose of evaluating social biases in sense embeddings. Table 1 shows the summary statistics of the SSSB dataset. Table 2 shows the bias categories covered in the SSSB dataset. Next, we describe the social biases covered in this dataset.

4.1 Nationality vs. Language Bias

These examples cover social biases related to a nationality (racial) or a language (non-racial). Each test case covers two distinct senses and the following example shows how they represent biases. *Japanese people are nice* is an anti-stereotype for *Japanese* as a nationality because it is associated with a pleasant attribute (i.e. *nice*) in this example sentence. On the other hand, *Japanese people are stupid* is a stereotype for *Japanese* as a nationality because it is associated with an unpleasant attribute (i.e. *stupid*). These can be considered as examples of racial biases.

Likewise, for the language sense of Japanese we create examples as follows. *Japanese language is difficult to understand* is a stereotype for *Japanese* as a language because it is associated with an unpleasant attribute (i.e. *difficult*). On the other hand, *Japanese language is easy to understand* is an anti-stereotype for *Japanese* as a language because it is associated with a pleasant attribute (i.e. *easy*).

In SSSB, we indicate the sense-type, WordNet sense-id and the type of social bias in each example as follows:

Japanese people are beautiful.
[nationality, japanese%1:18:00::, anti]

Here, sense-type is nationality, sense-id as specified in the WordNet is *japanese%1:18:00::* and the bias is anti (we use the labels *anti* and *stereo* to denote respectively anti-stereotypical and stereotypical biases).

We use the likelihood scores returned by an MLM to nationality vs. language sentence pairs as described further in §5 to evaluate social biases in MLMs. Essentially, if the likelihood score returned by an MLM for the example that uses an unpleasant attribute is higher than the one that uses a pleasant attribute for a member in the disadvantaged group, then we consider the MLM to be socially biased. Moreover, if a member in the disadvantaged group is associated with a positive attribute in a stereotypical manner, we consider this as a anti-stereotype case. For example, we classify *Asians are smart* as anti-stereotype rather than "positive" stereotypes following prior work on word-level or sentence-level bias evaluation datasets (e.g., Crows-Pairs and StereoSet) to focus on more adverse types of biases that are more direct and result in discriminatory decisions against the disadvantaged groups.

Note that one could drop the modifiers such as *people* and *language* and simplify these examples such as *Japanese are nice* and *Japanese is diffi-*

cult to generate additional test cases. However, the sense-sensitive embedding methods might find it difficult to automatically disambiguate the correct senses without the modifiers such as *language* or *people*. Therefore, we always include these modifiers when creating examples for nationality vs. language bias in the SSSB dataset.

4.2 Race vs. Colour Bias

The word *black* can be used to represent the race (black people) or the colour. We create examples that distinguish these two senses of black as in the following example. *Black people are friendly* represents an anti-stereotype towards *black* because it is associated with a pleasant attribute (i.e. *friendly*) of a disadvantaged group whereas, *Black people are arrogant* represents a stereotype because it is associated with an unpleasant attribute (i.e. *arrogant*).

On the other hand, for the colour black, *The black dress is elegant* represents an anti-stereotype because it is associated with a pleasant attribute (i.e. *elegant*), whereas *The black dress is ugly* represents a stereotype because it is associated with an unpleasant attribute (i.e. *ugly*). If the likelihood score returned by an MLM for a sentence containing the racial sense with an unpleasant attribute is higher than one that uses a pleasant attribute, the MLM is considered to be socially biased.

4.3 Gender Bias in Noun vs. Verb Senses

To create sense-related bias examples for gender,[3] we create examples based on occupations. In particular, we consider the six occupations: *engineer*, *nurse*, *judge*, *mentor*, *(tour) guide*, and *carpenter*. These words can be used in a noun sense (e.g. *engineer is a person who uses scientific knowledge to solve practical problems*, *nurse is a person who looks after patients*, etc.) as well as in a verb sense expressing the action performed by a person holding the occupation (e.g. *design something as an engineer*, *nurse a baby*, etc.). Note that the ambiguity here is in the occupation (noun) vs. action (verb) senses and not in the gender, whereas the bias is associated with the gender of the person holding the occupation.

To illustrate this point further, consider the following examples. *She is a talented engineer* is considered as an anti-stereotypical example for the noun sense of *engineer* because females (here considered as the disadvantaged group) are not usually associated with pleasant attributes (i.e. *talented*) with respect to this occupation (i.e. *engineer*). *He is a talented engineer* is considered as a stereotypical example for the noun sense of engineer because males (here considered as the advantaged group) are usually associated with pleasant attributes with regard to this occupation. As described in § 5, if an MLM assigns a higher likelihood to the stereotypical example (second sentence) than the anti-stereotypical example (first sentence), then that MLM is considered to be gender biased.

On the other hand, *She is a clumsy engineer* is considered to be a stereotypical example for the noun sense of engineer because females (i.e. disadvantaged group) are historically associated with such unpleasant attributes (i.e. *clumsy*) with respect to such male-dominated occupations. Likewise, *He is a clumsy engineer* is considered as an anti-stereotypical example for the noun sense of engineer because males (i.e. advantaged group) are not usually associated with such unpleasant attributes (i.e. *clumsy*). Here again, if an MLM assigns a higher likelihood to the stereotypical example (first sentence) than the anti-stereotypical example (second sentence), then it is considered to be gender biased. Note that the evaluation direction with respect to male vs. female pronouns used in these examples is opposite to that in the previous paragraph because we are using an unpleasant attribute in the second set of examples.

Verb senses are also used in the sentences that contain gender pronouns in SSSB. For example, for the verb sense of *engineer*, we create examples as follows: *She used novel material to engineer the bridge*. Here, the word engineer is used in the verb sense in a sentence where the subject is a female. The male version of this example is as follows: *He used novel material to engineer the bridge*. In this example, a perfectly unbiased MLM should not systematically prefer one sentence over the other between the two sentences both expressing the verb sense of the word *engineer*.

5 Evaluation Metrics for Social Biases in Contextualised Sense Embeddings

For a contextualised (word/sense) embedding under evaluation, we compare its pseudo-likelihood scores for stereotypical and anti-stereotypical sentences for each sense of a word in SSSB, using

---

[3] We consider only male and female genders in this work

AUL (Kaneko and Bollegala, 2021b).[4] AUL is known to be robust against the frequency biases of words and provides more reliable estimates compared to the other metrics for evaluating social biases in MLMs. Following the standard evaluation protocol, we provide AUL the complete sentence $S = w_1, \dots, w_{|S|}$, which contains a length $|S|$ sequence of tokens w_i, to an MLM with pretrained parameters θ. We first compute $\mathrm{PLL}(S)$, the Pseudo Log-Likelihood (PLL) for predicting all tokens in S excluding begin and end of sentence tokens, given by (5):

$$\mathrm{PLL}(S) := \frac{1}{|S|} \sum_{i=1}^{|S|} \log P(w_i|S;\theta) \tag{5}$$

Here, $P(w_i|S;\theta)$ is the probability assigned by the MLM to token w_i conditioned on S. The fraction of sentence-pairs in SSSB, where higher PLL scores are assigned to the stereotypical sentence than the anti-stereotypical one is considered as the AUL *bias score* of the MLM associated with the contextualised embedding, and is given by (6):

$$\mathrm{AUL} = \left(\frac{100}{N} \sum_{(S^{\mathrm{st}}, S^{\mathrm{at}})} \mathbb{I}(\mathrm{PLL}(S^{\mathrm{st}}) > \mathrm{PLL}(S^{\mathrm{at}})) \right) - 50 \tag{6}$$
