
(a) Plots illustrating changes of each MRC capability during training.

(b) A 5-dimensional map of MRC model capabilities on step 50, 1k, 2k, 20k.

Figure 6: Illustration of MRC model capabilities on different training stages.

Finally, our full model achieves significantly higher EM, F_1 and $Acc.$ compared to all other baselines, demonstrating the necessity of the decorrelation between capability-specific scores. Its superior performance roots from constructing a decorrelated value representation of each dimension for our CBBC learning strategy. Overall, compared to M_1, our full model achieves tremendous improvement of EM / F_1 up to 11.22% / 8.71% on the average of three answer extraction style datasets.

Qualitative Results. Figure 5 shows the performance of baselines on the HotpotQA dev set. There are two observations worth noting here. First, the performance of our full model lies consistently on top of the other baseline models during the whole training stage. This result shows that CBBC can make the model more prepared for complex samples by enlarging its capability boundary step by step. Second, the performance plot of the baseline model with v_4 sits on top of other baselines with v_1, v_2, and v_3 from the beginning of training to the end. This result highlights the main contribution of v_4 (understanding sentences) to the final performance.

Furthermore, the capability map after max-min normalization of the model is shown in Fig-

Value	SQuADv1	SQuADv2	HotpotQA	RACE
v_1	0.602	0.536	0.630	0.589
	0.625	0.559	0.653	0.612
v_2	0.696	0.683	0.755	0.620
	0.714	0.701	0.773	0.638
v_3	0.730	0.573	0.550	0.797
	0.674	0.517	0.494	0.741
v_4	0.553	0.674	0.672	0.819
	0.488	0.609	0.607	0.754
	0.468	0.589	0.587	0.734
	0.472	0.593	0.591	0.738
	0.547	0.668	0.666	0.813
	0.503	0.612	0.609	0.761

Table 4: Pearson's correlation coefficients between human judgments and data properties for four capabilities and their subclasses.

ure 6. First, among 4-dimensional capability, the c_3 (*i.e.* understanding words) has the largest initial value. A possible explanation is that pre-trained BERT has a fair amount of prior knowledge obtained from unlabeled corpus, which concentrates more on semantic understanding of words. Second, the capability c_1 increases at the fastest speed as the training progresses. Interestingly, the model M_4 based on v_1 does not seem improving accordingly as the capability c_1 increases. The possible reason could be that the superficial structure is easy to learn from samples but makes a limited contribution to the final performance. *Please refer to Appendix D for the results of other MRC models.*

4.2 Human Annotation

Annotation specification. we ask three annotators to answer ($100 \times 4 = 400$) questions randomly sampled from four datasets, consisting of SQuADv1, SQuADv2, HotpotQA, and RACE. Using only our proposed four capabilities, they first read the context, question, and gold standard answer (the correct candidate answer under multiple-choice situation), and then choose the evidence sentences in context. After that, they respectively label the subclasses of four major capabilities as 1 (required) or 0 (not required). *Please refer to Appendix A for more details about human annotation.*

Annotation results. In the annotation of required capabilities, the inter-annotator agreement is 75.33% for all 400 samples. We use the average of three corresponding annotator labels as the final human judgments for a specific sub-capability required by the question. Finally, a sample will be annotated ($2 + 2 + 2 + 6 = 12$) human ratings. Table 4 summarizes the correlations between human judgments and capability-specific scores of samples. The relatively strong correlations on all four dimensions indicate that our employed heuristic metrics can reasonably approximate the learning value contained in the samples.

5 Related Work

Analytic approaches to MRC capability. Some works performed skill-based analyses for the MRC model. In the scientific question domain, Clark et al. (2018) constituted the ARC benchmark, which requires far more powerful knowledge and reasoning than previous benchmarks. In a generalizable definition, Sugawara et al. (2017) proposed a set of 10 skills for MCTest (Richardson et al., 2013). The others focused more on the analysis of the MRC dataset itself. For example, Sugawara et al. (2020) proposed a semi-automated, ablation-based methodology to assess the capacities of datasets. Rajpurkar et al. (2016) analyzed their proposed datasets using several types of reasoning, *e.g.* lexical and syntactic variation, and multiple sentence reasoning. Nevertheless, they require too costly human efforts and ignore that the model capability changes as training progresses.

Data selection for debiased representations. Some works proposed different criteria to score instances according to the model response to input. Swayamdipta et al. (2020) built data maps using training dynamics measures for scoring data samples. Toneva et al. (2018) also employed the number of "forgotten" events to measure a sample, which was misclassified during a later epoch of training, despite being classified correctly earlier. The others (Le Bras et al., 2020) used adversarial filtering algorithms to rank instances based on their "predictability". However, these approaches require training a model once in advance on the dataset to obtain the corresponding training dynamics, which is computationally expensive, especially when using a large model.

6 Conclusion

We design a competency assessment framework for MRC capabilities, which describes model skills in an explainable and multi-dimensional manner. By leveraging the framework, we further uncover and disentangle the connections between various data properties and model performance on a specific task, as well as propose a capability boundary breakthrough curriculum (CBBC) strategy to maximize the data value and improve training efficiency. The experiments performed on four benchmark datasets verified that our approach can significantly improve the performance of existing MRC models. Our work shows a deep understanding of model capabilities and data properties helps monitor the model skills during training and improves learning efficiency. Our framework and learning strategy are also generally applicable to other NLP tasks.

A Annotation Details

We ask three annotators to answer ($100 \times 4 = 400$) questions randomly sampled from four datasets, consisting of SQuADv1, SQuADv2, HotpotQA, and RACE. They are graduate students majoring in Computer Science or Electronic Engineering and competent in English. They voluntarily offer to help without being compensated in any form. Before annotation, they are informed of the detailed annotation instruction with the following three steps.

- **Step 1.** Make a hypothesis using a question statement and gold standard answer or the correct candidate answer under the multiple-choice situation.

  Example 1:

  Q: Why did Tom look angry? A: His sister ate his cake.

  → *Hypothesis*: Tom looked angry because his sister ate his cake.

  Example 2:

  Q: When did French Revolution occur? A: In 1789

  → *Hypothesis*: French Revolution occurred in 1789.

- **Step 2.** Select sentences (from the context) required to provide the hypothesis.

  Example 1:

  Context: (C1) Tom is a student. (C2) Tom looks annoyed because his sister ate his cake. (C3) His sister's name is Sylvia.

  Hypothesis: Tom looks angry because his sister ate his cake.

  → *Select*: C2

- **Step 3.** Select capabilities required for understanding an entailment from selected context sentences to hypothesis and label the corresponding capability as 1 (required).

  Example 1:

  C2: Tom looks annoyed because his sister ate his cake.

  Hypothesis: Tom looks angry because his sister ate his cake.

  → *Capability*: causal relation ("because"), semantic overlap (lexical knowledge of "annoyed = angry")

Then, we describe our annotation schema in greater detail. We present the respective phenomenon, give a short description, and present an example illustrating the corresponding feature.

- **Reading words**

  Recognize vocabulary. We annotate this as "1" if repetition of some word rarely occurs in a sentence (less than two times in every ten words).

  Question with label 0: The creek of which Paradise Creek is a tributary of what river?

  Context: Paradise Creek is a 9.6 mi tributary of Brodhead Creek in the Poconos of eastern Pennsylvania in the United States. Brodhead Creek is a 21.9 mi tributary of the Delaware River in the Poconos of eastern Pennsylvania in the United States.

  Question with label 1: Of these two publications–Báiki and Sick–what type of publication is the one that was published most frequently?

  Context: Báiki: The International Sámi Journal ("Báiki" means a place in Sami) is a biannual English-language publication that covers Sami culture, history, and current affairs. The coverage also includes the community affairs of the Sami in North America, estimated at some 30,000 people. Sick was a satirical-humor magazine published from 1960 to 1980, lasting 134 issues.

  Recognize function words. We annotate this as "1" if a sentence consists of lots of the structural relationships between words signaled by function words (more than five times in every ten words).

  Question: What drug is among the list of illegal drugs in the Philippines and can be taken by mouth or by injection?

  Context: [. . .] Ephedrine and methylenedioxy methamphetamine are also among the list of illegal drugs that are of great concern to the authorities. Ephedrine is a medication and stimulant. [. . .]

- **Reading sentences**

  Recognize grammaticality. We annotate this as "1" the sentence pattern and grammar involved are relatively complex, such as multiple nested subordinate clause structures.

Question: Sudha Kheterpal, who is a musician best known as the percussionist in Faithless, has played with what singer who is recognized as the highest-selling Australian artist of all time by the Australian Recording Industry Association?

Readability. We annotate this as"1" if there are a lot of obscure words in the question or context (more than five times in every ten words).

Question: The creature HNoMS Draug is named after comes from what kind of mythology?

Context: Two ships of the Royal Norwegian Navy have borne the name HNoMS "Draug", after the sea revenant Draugr: The draugr or draug (Old Norse: "draugr", plural draugar ; modern Icelandic: "draugur", Faroese: "dreygur" and Danish, Swedish, and Norwegian: "draug"), also called aptrganga or aptrgangr , literally "again-walker" (Icelandic: "afturganga") is an undead creature from Norse mythology.

- **Understanding words**

  Arithmetic operation. We annotate this as "1" if an arithmetic operation needs to be performed to answer the question, such as addition, subtraction, ordering, and counting.

  Question: How many points were the Giants behind the Dolphins at the start of the 4th quarter?

  Context: New York was down 17-10 behind two rushing touchdowns.

  Logical operation. We annotate this as "1" if it is required to understand the concept of quantification (existential and universal) in order to determine the correct answer.

  Question: How many presents did Susan receive?

  Context: On the day of the party, all five friends showed up. Each friend Quantification had a present for Susan.

- **Understanding sentences**

  Syntactic and semantic overlap. We annotate this as "1" if some part of the context and the question overlap semantically.

  Question: Is it freezing today?

  Context: The weather is cold today.

  Coreference resolution. We annotate this as "1" if inter-sentence coreference and anaphora need to be resolved in order to retrieve the expected answer.

  Question: What is the name of the psychologist who is known as the originator of social learning theory?

  Context: Albert Bandura OC (born December 4, 1925) is a psychologist who is the David Starr Jordan Professor Emeritus of Social Science in Psychology at Stanford University. [...] He is known as the originator of social learning theory and the theoretical construct of self-efficacy and is also responsible for the influential 1961 Bobo doll experiment.

  Con/Dis-junction, negation. We annotate this as "1" if logical conjunction, disjunction, or negation needs to be resolved in order to conclude the answer.

  Question: Is dad in the living room?

  Context: Dad is either in the kitchen or the living room.

  Question: How many percent are not Marriage couples living together?

  Context: [...] 46.28% were Marriage living together. [...]

  Causality. We annotate this as "1" if causal (*i.e.* cause-effect) reasoning between events, entities, or concepts is required to answer a question correctly.

  Question: Why did Sam stop Mom from making four sandwiches?

  Context: [...] There are three of us, so we need three sandwiches. [...]

  Spatial/Temporal relationship. We annotate this as "1" understanding about directions, environment, spatiality, and succession is required in order to derive an answer.

  Question: What is the 2010 population of the city 2.1 miles southwest of Marietta Air Force Station?

  Context: Marietta Air Force Station is located 2.1 mi northeast of Smyrna, Georgia.

  Multi-hop reasoning. We annotate this as "1" if information to answer the question needs to be gathered from multiple supporting facts, "Multi-hop" by commonly mentioned entities, concepts, or events. This phenomenon is also known as "Bridging" in literature.

Question: What show does the host of The 2011 Teen Choice Awards ceremony currently star on?

Context: [. . .] The 2011 Teen Choice Awards ceremony, hosted by Kaley Cuoco, aired live on August 7, 2011, at 8/7c on Fox. [. . .] Kaley Christine Cuoco is an American actress. Since 2007, she has starred as Penny on the CBS sitcom "The Big Bang Theory", for which she has received Satellite, Critics' Choice, and People's Choice Awards. [. . .]

B Examples of Our Employed Metrics

We first present a brief overview of employed metrics, especially those that are adapted from other studies. In the following descriptions, the question Q and corresponding context C are denoted as the sequence of n-grams $Q^n = \{q_i^n\}$ and $C^n = \{c_j^n\}$, respectively.

Intra-n and Ent-n. *Intra-n* (Gu et al., 2018) and *Ent-n* (Serban et al., 2017) are originally designed to evaluate the diversity of neural dialogue responses. The former calculates the ratio of distinct unigrams (Intra-1) and bigrams (Intra-2) in generated responses, while the latter measures the information entropy of n-grams. Specifically, in our work, they are formulated as:

$$\text{Intra-n} = \frac{Unique(Q^n)}{|Q^n|} \tag{2}$$

$$\text{Ent-n} = \sum_{i=1} -\frac{Count(q_i^n)}{|Q^n|} \log \frac{Count(q_i^n)}{|Q^n|} \tag{3}$$

Tree statistics. Empirically, most of the complicated sentences have a relatively high and wide constituency parsing tree. In this paper, we calculate the height and width of the constituency parsing tree by Standford CoreNLP API (Manning et al., 2014).

Readability metrics. Readability is the ease with which a reader can understand a written text. Readability metrics produce an approximate representation of the US grade level needed to comprehend the text and are widely used in the field of education to assess the English proficiency of non-native English speakers. We employ the py-readability package (`https://pypi.org/project/py-readability-metrics/`) to calculate the readability of a question based on two metrics, including *Flesch Kincaid Grade Level* and *Automated Readability Index (ARI)*.

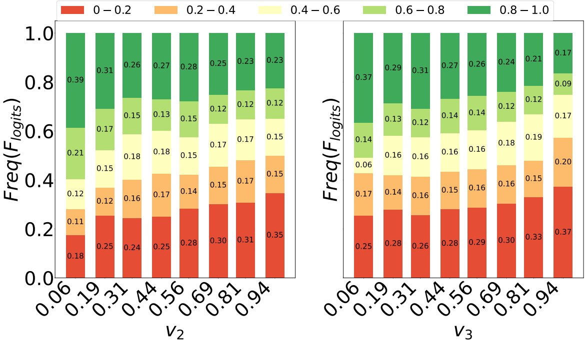

Figure 7: Bar diagram illustrating the relationship between the distribution of model performance and different ranges of v_i. Horizontal axes represent the different score ranges of v_i of samples, and the vertical axis means the performance distribution by the frequency of F_{logits} on five levels (plotted in five colors).

BERTScore and MoverScore. To measure the semantic overlap between the question and corresponding context, we slightly modify the contextualized embedding-based similarity metrics of text generation task, comprising *BERTScore* (Zhang* et al., 2020) and *MoverScore* (Zhao et al., 2019). Unlike the original implementation, the question and the context rather than the gold standard reference are fed into the metrics computation.

We exemplify two samples from HotpotQA dev set to show the difference of specific metrics in Table 5 and Table 6.

C Additional Diagrams of Samples' Capability-specific Value

The distribution diagrams of v_2 and v_3 are shown in Figure 7. They present a conclusion consistent with v_1 and v_4 discussed in Section 2.2. That is, among all the bins of v_i, the frequency of prediction results within the intermediate range ($0.4 \sim 0.6$) are similar ($\approx 50\%$). Furthermore, as the v_i increases, the frequency of prediction results within a low range ($0.0 \sim 0.2$) also increases, while the one of a high range ($0.8 \sim 1.0$) decreases.

In addition to the distribution of model performance over different ranges of v_i, the mean value and standard deviation of model performance (in F_{logits}) over them and their subclasses are illustrated in Figure 8. As shown in the figure, it qualitatively shows the relatively strong correlation be-

ID	Q1(5a7322a25542991f9a20c634)	Q2(5a72bd0b5542992359bc318f)
Context	The Metropolitan Life Insurance Company Tower, colloquially known as the Met Life Tower, is a landmark skyscraper located on Madison Avenue near the intersection with East 23rd Street, across from Madison Square Park in Manhattan, New York City. Designed by the architectural firm of Napoleon LeBrun & Sons and built by the Hedden Construction Company, the tower is modeled after the Campanile in Venice, Italy. The hotel located in the clock tower portion of the building has the address 5 Madison Avenue, while the office building covering the rest of the block, occupied primarily by Credit Suisse, is referred to as 1 Madison Avenue. 15 Hudson Yards is a residential building currently under construction on Manhattan's West Side. Located in Chelsea near Hell's Kitchen Penn Station area, the building is a part of the Hudson Yards project, a plan to redevelop the Metropolitan Transportation Authority's West Side Yards. The tower started construction on December 4, 2014.	Andrea Louise Martin (born January 15, 1947) is an American actress, singer, author, and comedian, best known for her work in the television series "SCTV". She has appeared in films such as "Black Christmas" (1974), "Wag the Dog" (1997), "Hedwig and the Angry Inch" (2001), "My Big Fat Greek Wedding" (2002), and "My Big Fat Greek Wedding 2" (2016), and lent her voice to the animated films "Anastasia" (1997), "The Rugrats Movie" (1998) and " (2001).Mark S. Hoplamazian is an American businessman who is the President and CEO of Hyatt Hotels Corporation. He received his A.B. in economics from Harvard College and his M.B.A. from the University of Chicago Booth School of Business.
Question	Was the Metropolitan Life Insurance Company Tower [Met Life Tower] or the 15 Hudson Yards building designed by the firm of Napoleon LeBrun & Sons?	Who achieved more academically, Andrea Martin or Mark Hoplamazian?

tween the model performance and each capability-specific score.

D Additional Experiments Using Other Models

In addition to the Transformer-based MRC model, we also perform ablation analysis using the following systems to further verify the effectiveness of our proposed assessment framework, whose training setting is consistent with that of our BERT-based MRC model.

- R-Net (Wang et al., 2017) matches the question and passage with gated recurrent neural networks (RNNs) to obtain the question-aware passage representation and employs the pointer networks to locate the positions of answer span from the passages.
- QANet (Yu et al., 2018) encodes the local and global interactions with the convolution and self-attention, respectively. It achieves higher training efficiency while obtaining the equivalent accuracy to the recurrent models.

The quantitative results of R-Net and QANet are summarized in Table 7 and Table 8, respectively. Our assessment framework also provides a significant performance improvement to these weaker backbones than BERT, such as RNN-based R-Net and convolution-based QANet.

E Additional Experiments Using Other Pipelines

To further verify the effectiveness of our proposed MRC competency assessment framework and reveal more available application scenarios for it, we embed it into the active learning pipeline besides curriculum learning.

CBBC in active learning. Given the training state of a model, active learning aims to select the most valuable samples from the unlabeled dataset and hand it over to the oracle (*e.g.* human annotator) for labeling so as to reduce the cost of labeling as much as possible while still maintaining performance. Take the most common pool-based active learning (Lewis and Gale, 1994; Gal and Ghahramani, 2016) as an example, which queries the best sample based on the confidence evaluation and ranking of the entire dataset. This query strategy is usually implemented by the uncertainty-based sampling (Ebrahimi et al., 2019; Gal et al., 2017; Houlsby et al., 2011; Kirsch et al., 2019) and distribution-based sampling (Pinsler et al., 2019; Wei et al., 2015). Compared to the original pool-based active learning (shown in Figure 9a), CBBC-guided active learning (shown in Figure 9b) pro-

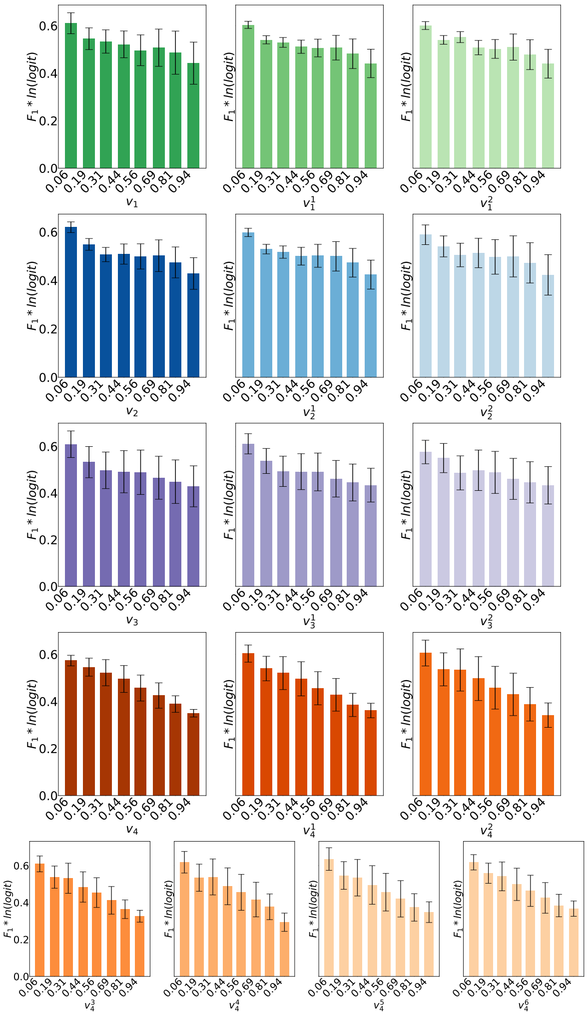

Figure 8: Bar diagram illustrating the relationship between the mean value and standard deviation of model performance and different ranges of v_i and its subclasses. The height of each bar and its error line represent the mean value and standard deviation of model performance, respectively.

vides a novel and interpretable query strategy by assessing the model in a 4-dimensional capability. In addition to the pool-based baseline, we employ a more recent active learning pipeline ICAL (Gao et al., 2020) as a comparison, which selects samples with the high inconsistency of predictions over a set of data augmentations.

We employ BERT as our MRC backbone. In each active learning cycle, we continue to train the MRC model by adding 5% labeled data points by simulating the oracle annotating process. The initial training set is randomly sampled from the HotpotQA train split and follows Gao et al. (2020) for the setting of initial training set size and active learning budget.

Figure 10 illustrates the results of different methods at each active learning cycle qualitatively. Our CBBC-guided active learning (denoted as “CBBC-AL”) achieve a higher MRC performance than the pool-based active learning (denoted as “Pool-AL”) and ICAL from the start of training, demonstrating that the assessment of MRC model capability derived by our CBBC is reasonable and can also make a substantial difference to active learning beside curriculum learning. When using only 35% labeled samples, our CBBC-guided active learning outperforms the baseline model normally trained on the entire dataset by a considerable margin.

Abstract

Simile interpretation (SI) and simile generation (SG) are challenging tasks for NLP because models require adequate world knowledge to produce predictions. Previous works have employed many hand-crafted resources to bring knowledge-related into models, which is time-consuming and labor-intensive. In recent years, pre-trained language models (PLMs) based approaches have become the de-facto standard in NLP since they learn generic knowledge from a large corpus. The knowledge embedded in PLMs may be useful for SI and SG tasks. Nevertheless, there are few works to explore it. In this paper, we probe simile knowledge from PLMs to solve the SI and SG tasks in the unified framework of simile triple completion for the first time. The backbone of our framework is to construct masked sentences with manual patterns and then predict the candidate words in the masked position. In this framework, we adopt a secondary training process (Adjective-Noun mask Training) with the masked language model (MLM) loss to enhance the prediction diversity of candidate words in the masked position. Moreover, pattern ensemble (PE) and pattern search (PS) are applied to improve the quality of predicted words. Finally, automatic and human evaluations demonstrate the effectiveness of our framework in both SI and SG tasks.

1 Introduction

The simile, which is a special type of metaphor, is defined as a figurative expression in which two fundamentally different things are explicitly compared, usually using “like” or “as” (Israel et al., 2004; Zeng et al., 2020). It is widely used in literature because it can inspire the reader’s imagination (Paul, 1970) by giving a vivid and unexpected analogy between two objects with similar attributes.

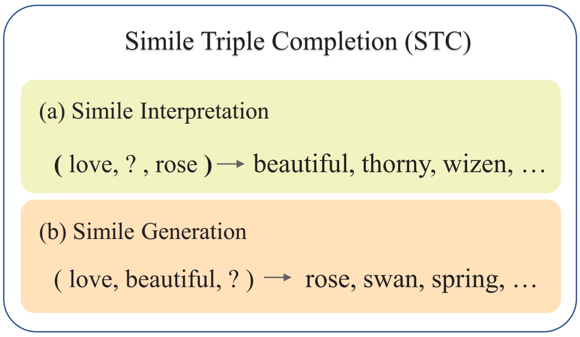

Figure 1: In the form of triple, the tasks of Simile Interpretation and Simile Generation can be unified into Simile Triple Completion.

A simile sentence usually contains three key elements: the **tenor**, the **attribute** and the **vehicle**,[1] which can be defined in the form of a triple (*tenor*, *attribute*, *vehicle*) (Song et al., 2021). For example, the simile sentence “Love is as thorny as rose” can be extracted as the triple (love, thorny, rose), where the tenor is “love”, the vehicle is “rose”, and the attribute is “thorny”. Note that a simile triple can produce different simile sentences with different templates. For the example triple above, the simile sentences can be also constructed as “*love is thorny like rose*" with the pattern “*tenor* is *attribute* like *vehicle*".

The study of simile is benefit to many downstream tasks, like sentiment analysis (Rentoumi et al., 2012), question answering (Zheng et al., 2020), writing polishment (Zhang et al., 2021) and creative writing (Gero and Chilton, 2019). **Simile interpretation** (SI) (Qadir et al., 2016; Su et al., 2016) and **simile generation** (SG) (Yu and Wan, 2019) are the two important tasks in the study of simile (Tong et al., 2021). The SI task is to find suitable attributes as a mediator between the tenor

Volume 1: Long Papers, pages 5875 - 5887
May 22-27, 2022 ©2022 Association for Computational Linguistics

and vehicle. Likewise, the SG task is to select a proper vehicle for the tenor with the given attribution. And these two tasks can be unified into the form of **simile triple completion** (STC) (Song et al., 2021) as shown in Figure 1.

Previous works on the SI and SG tasks relied on a limited training corpus or labor-intensive knowledge base, which leads to an upper limit on the diversity of results. (Song et al., 2021) collected sentences containing comparator words from a Chinese essays corpus and manually annotated them to obtain the simile triple. Some works (Stowe et al., 2021; Gero and Chilton, 2019; Veale et al., 2016) relied on a knowledge base such as ConceptNet[2], FrameNet[3], which are scarce to other languages because it is time-consuming and labor-intensive to construct such a knowledge base. It is notable that pre-trained language models (PLMs) (Devlin et al., 2019; Radford et al., 2019) have made significant progress recently in many NLP tasks since it learns generic knowledge such as grammar, common sense from a large corpus (Davison et al., 2019; Liu et al., 2021a,b). Considering the sufficient existence of simile in the large corpus, it's reasonable to assume that PLMs are equipped with rich knowledge of similes during the pre-training stage. However, few works have explored directly probing the knowledge of simile from the PLMs.

In this paper, we propose a unified framework to solve the SI and SG tasks by mining the knowledge in PLMs, which does not require fine-labeled training data or knowledge graphs. The backbone of our method is to construct masked sentences with manual patterns from an incomplete simile triple, and then use language models with MLM heads to predict the masked words over the task-specific vocabulary. We take the K words with the highest probability as the result words. However, there are problems with this crude approach. Firstly, the predicted words should be creative and surprised for the simile sentence. On the contrary, the PLMs tend to predict common words (e.g., good, bad) with a higher probability. To address this issue, we introduce a secondary pre-training stage - Adjective-Noun mask Training (ANT), where only the noun or adjective contained in the *amod* dependencies (Nivre et al., 2017) could be masked in the MLM training process and the number of words masked times are limited. Secondly, the words predicted by MLM have a preference for different patterns. For this reason, we employ a pattern ensemble to obtain high-quality and robust results. Finally, we also introduce a prompt-search method to improve the quality of the simile component predictions.

Our main contributions are as follows:

- We propose a unified framework to solve both the simile interpretation (SI) and simile generation (SG) tasks based on pre-trained models. To the best of our knowledge, it is the first work to introduce pre-trained language models to unify these tasks.

- We propose a secondary pre-training stage that effectively improves the prediction diversity. Further, we employ the pattern-ensemble and pattern-search approaches to obtain better results.

- We compare our models on both automated metrics and manual measures, and the results show that our approach outperforms the baselines in terms of diversity and correctness.

2 Related Work

2.1 Simile Interpretation and Generation

Simile interpretation and simile generation are the two main directions of the simile study (Yu and Wan, 2019). The SI task (Shutova, 2010; Su et al., 2017) aims at finding a suitable attribute when given the tenor and vehicle, while the SG task (Yu and Wan, 2019) is to find a proper vehicle when given the tenor and its attribute. For simile interpretation, some works (Zheng et al., 2020; Bar et al., 2018; Xiao et al., 2016; Gagliano et al., 2016; Qadir et al., 2016) applied word vectors to decide which attribute words can fit into the tenor and vehicle domains and some other works (Gero and Chilton, 2019; Stowe et al., 2021) introduced knowledge base (Baker et al., 1998; Speer et al., 2017) to help find intermediate attributes. For simile generation, some works focused on constructing limited training corpus to finetune a sequence-to-sequence model (Lewis et al., 2020) by pattern-based (Zhang et al., 2021; Bollegala and Shutova, 2013) or knowledge-based approaches (Chakrabarty et al., 2020, 2021; Stowe et al., 2021). There are also some works (Abe et al., 2006; Hervás et al., 2007; Zheng et al., 2020) that focused more on the relationships between concepts (i.e.,

---

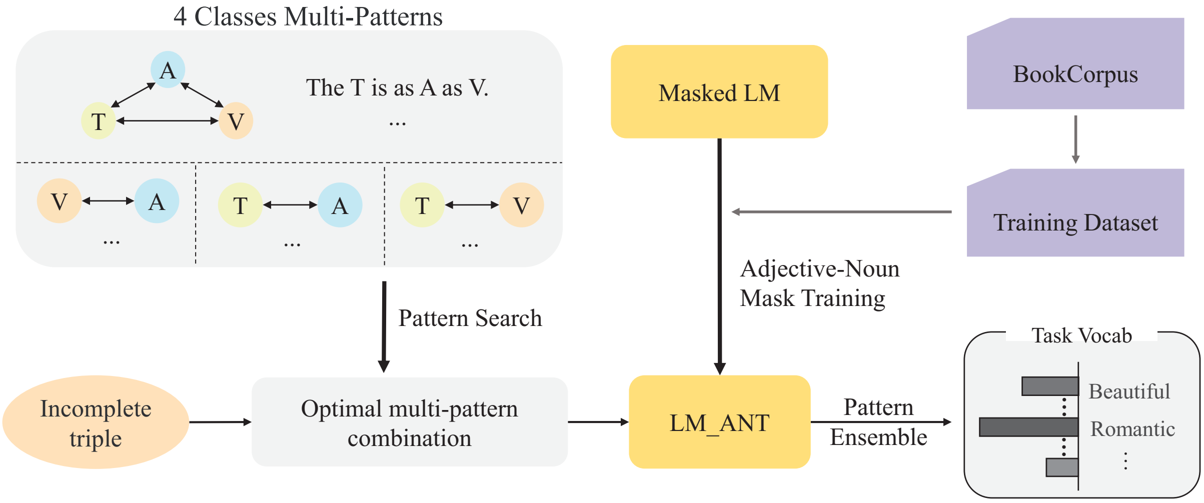

Figure 2: The unified framework for STC. The incomplete triple will be transfer to masked sentences by a multi-pattern combination, which is searched from four classes well-designed patterns. And LM_ANT (obtained by using unlabeled corpus to perform Adjective-Noun Mask Training) predicts the missing simile element over the task-specific vocabulary based on the masked sentences.

tenor and vehicle) and attribute. However, our paper carries out the task of simile interpretation and generation uniformly in the form of simile triples. And instead of extracting the simile triples from the limited corpus using designed templates or a hand-crafted knowledge base, we probe simile-related knowledge from PLMs.

2.2 Explore knowledge from PLMs

Pre-trained language models such as Bert and GPT (Devlin et al., 2019; Radford et al., 2019) are trained on the large-scale unlabeled corpus. Many recent works (Manning et al., 2020; Ettinger, 2020; Petroni et al., 2019; Shin et al., 2020; Haviv et al., 2021; Jiang et al., 2020; Zhong et al., 2021; Wang et al., 2022a,b; Li and Liang, 2021) focused on exploring the rich knowledge embedded in these PLMs. Manning et al. (2020) and Ettinger (2020) learned the syntactic and semantic knowledge from PLMs. Among these works, one branch of works(Petroni et al., 2019; Shin et al., 2020; Haviv et al., 2021; Jiang et al., 2020) designed discrete patterns to explore the common sense and world knowledge embedded in PLMs. In addition, some works (Zhong et al., 2021; Li and Liang, 2021) probed knowledge by searching the best-performing continuous patterns in the space of embedding. Inspired by the above works, in this paper, we probe the knowledge of simile in these pre-trained models and further apply pattern ensemble and pattern search to improve the results.

3 Backbone

3.1 Simile Triple Completion

As shown in Figure 1, the simile triple complete consists of two tasks: simile interpretation (SI) and simile generation (SG). Each simile sentence can be abstracted into the form of a triple. Therefore, we define a triple: $(\mathcal{T}, \mathcal{A}, \mathcal{V})$, where $\mathcal{T}$, $\mathcal{V}$ are mainly nouns or noun phrases and represent the tenor and vehicle in the simile sentence, respectively. $\mathcal{A}$ is the attribute in simile sentences, which is an adjective. If the $\mathcal{A}$ is None in the triple, i.e. $(\mathcal{T}, None, \mathcal{V})$, we define it as the simile interpretation task. Similarly, if the $\mathcal{V}$ is None, i.e. $(\mathcal{T}, \mathcal{A}, None)$, this will be the task of simile generation.

3.2 Masked Language Model

The masked language model (MLM) (Devlin et al., 2019; Taylor, 1953) randomly masks the words in the input sentence and feeds the masked sentence into the pre-trained models to make predictions by other visible words. For example, given a sentence $s = [w_1, w_2, \ldots, w_i, \ldots, w_m]$, where the w_i means the i-th word in the sentence. We can randomly mask s and feed the masked sequence $\widetilde{s}$ into the PLMs e.g. BERT (Devlin et al., 2019) to obtain the masked words by Equation:

$$\widetilde{s} = f_{mask}(s, i, v) \tag{1}$$

$$P = f_\theta(\widetilde{s}) \tag{2}$$

where the v means the Vocabulary for pre-trained models, and the i denotes the position of the masked word in Equation 1. The θ is the parameters of PLMs in Equation 2. We can select the word corresponding to the maximum probability in P as the output of the model.

3.3 Probe Simile Knowledge with MLM

To probe the simile knowledge in pre-trained masked language models, the intuitive solution is: (1) Construct a sentence that contains the simile triple in Section 3.1 with the given pattern. (2) Mask the attribute $\mathcal{A}$ or vehicle $\mathcal{V}$ in this simile sentence. (3) Predict the words in the masked position with MLM. For example, when given a pattern *The* $\mathcal{T}$ *is as* $\mathcal{A}$ *as* $\mathcal{V}$, the input sentence of MLM is *The* $\mathcal{T}$ *is as [MASK] as* $\mathcal{V}$ for the SI task while *The* $\mathcal{T}$ *is as* $\mathcal{V}$ *as [MASK]* for the SG task.

To formulate this problem, we define the pattern function as $p(\tau)$, where $\tau \in \{SG, SI\}$. The pre-trained MLM is denoted as $\mathcal{M}$ and the predicted distribution Q over vocabulary V can be formulated as:

$$Q(w|p(\tau)) = \frac{exp(\mathcal{M}(w|p(\tau)))}{\sum_{w' \in V} exp(\mathcal{M}(w'|p(\tau)))} \quad (3)$$

4 Method

In this section, we will introduce our proposed method of probing simile knowledge from pre-trained models. Our method first introduces a secondary pre-training stage - Adjective-Noun mask Training (ANT) based on pre-trained language models to acquire diverse lexical-specific words. Then two modules of pattern ensemble and pattern search are used to obtain the high-quality predictions. The framework of our method is shown in Figure 2 in detail[4].

4.1 Adjective-Noun Mask Training (ANT)

For the MLM task, pre-trained models prefer to output high-frequency words as candidate words since the objective of the training is to minimize the cross-entropy loss (Gehrmann et al., 2019). However, the components of simile triples are usually nouns or adjectives and the simile sentences are appealing due to their creativity and unexpectedness. Therefore, to predict more diverse and specific words of simile component, we introduce a secondary pre-training stage - Adjective-Noun mask Training (ANT) that fine-tune the pre-trained model with specially designed datasets. First, we utilize *trankit* (Nguyen et al., 2021) to construct the training set by selecting sentences from BookCorpus (Zhu et al., 2015) that contains *amod*[5] dependencies (Nivre et al., 2017). Second, we mask a word at the end of *amod* relation, instead of randomly masking, and all words are masked no more than 5 times. Finally, the pre-trained model is fine-tuned on the constructed dataset with MLM loss. In this way, the pre-trained model will avoid the bias to high-frequency words and have a higher probability of generating diverse and novel words.

4.2 Pattern Ensemble (PE)

Since words predicted by MLM have a preference for different patterns and only using one pattern is insufficient, we apply the pattern ensemble to obtain better performance where different types of patterns are designed as shown in Table 1. Specifically, the class I describes the relationship between the three-element $\mathcal{T}$, $\mathcal{V}$ and $\mathcal{A}$. However, the similes tend to highlight an obvious attribute between tenor and vehicle (Israel et al., 2004). We further design the class II and class III to find the attribute corresponding to the tenor and vehicle, respectively. Finally, the attributes of simile sentences are sometimes omitted and thus the class IV is designed to deal with this case. Additionally, we also design three patterns for each class to obtain high-quality and robust results.

The output distribution Q_{PE} of pattern ensemble can be formulated as

$$Q_{PE}(w|P) = \frac{1}{|P|} \sum_{p(\tau) \in P} log(Q(w|p(\tau))) \quad (4)$$

where P is the set of patterns $p(\tau)$ for specific task τ. Note that though we design four classes of patterns in Table 1, some classes of patterns are not required for the SI or SG task. Specifically, The patterns of Class IV are not used for the SI task because the attribute $\mathcal{A}$ is missed in Class IV. Likewise, the patterns of Class III are not used for the SG task due to the lack of vehicle $\mathcal{V}$.

[4] we released our code at https://github.com/nairoj/Probing-Simile-from-PLM.

[5] An adjectival modifier of a noun (or pronoun) is any adjectival phrase that serves to modify the noun (or pronoun). The relation applies whether the meaning of the noun is modified in a compositional way (e.g., large house) or an idiomatic way (hot dogs).

Class	Relationship	Pattern	
I		The {tenor} is as {attribute} as {vehicle}.	p_1
		{vehicle} is very {attribute}, so as {tenor}.	p_2
		{tenor} is like {vehicle}, because they are both {attribute}.	p_3
II		The {attribute} {vehicle}.	p_4
		{vehicle} is very {attribute}.	p_5
		{vehicle} is {attribute}.	p_6
III		The {attribute} {tenor}.	p_7
		{tenor} is very {attribute}.	p_8
		{tenor} is {attribute}.	p_9
IV		{tenor} is similar to {vehicle}.	p_{10}
		{tenor} is like {vehicle}.	p_{11}
		{tenor} and {vehicle} are alike.	p_{12}

Table 1: All patterns and corresponding classes. Class I models the relationship between three elements, and other classes model relationships between two elements. Every pattern is denoted as the right side symbol p_i.

4.3 Pattern Search (PS)

The prediction of pattern ensemble in Section 4.2 is averaged by adding up the output distributions of all the patterns. Conversely, the hand-designed patterns are heuristic, which may lead to suboptimal results. Therefore, it is worth studying how these patterns can be combined to obtain better performance. To solve this problem, we introduce an approach of pattern search (PS) to find the best combination of different patterns. Specifically, given a simile dataset $\mathcal{D}_{PS}$, we calculate Equation 4 on $\mathcal{D}_{PS}$ by iterating all subsets of the patterns. Finally, we select the optimal subset p_{best} as the input of MLM to predict simile components.

5 Experiments

5.1 Dataset

Dataset for ANT: We constructed our train set of ANT from BookCorpus. We first extracted the sentences with length less than 64 and then masked nouns or adjectives in them based on *amod* dependencies (Nivre et al., 2017). Meanwhile, we limited the frequency of masked words to less than 5. Finally, we got 98k sentences as the dataset of ANT, which contains 68k noun-masked sentences and 30k adjective-masked sentences.

Dataset for PE and PS: We evaluate our method on the dataset proposed in (Roncero and de Almeida, 2015). As the samples in Table 2, there are multiple attributes for each ($\mathcal{T}$, $\mathcal{V}$) pair. For example, the pair of (anger, fire) has the attributes of dangerous, hot, and red. In addition, we followed the previous work (Xiao et al., 2016) to filter the dataset by reversing simile triples with attribute frequencies greater than 4. Eventually, we obtain the train set with 533 samples and the test set with 145 samples. Notice that the train set is the $\mathcal{D}_{PS}$ in Section 4.3 used for the pattern search and the test set is used for evaluating all the approaches in this paper.

Triple	Frequency
(Anger, Dangerous, Fire)	8
(Anger, Hot, Fire)	8
(Anger, Red, Fire)	5
(Love, Beautiful, Rainbow)	10
(Love, Beautiful, Melody)	2
(Love, Beautiful, Rose)	9

Table 2: Some samples from the dataset. Frequency represents the number of annotators who consider the attribute is suitable for the Tenor-Vehicle pair.

5.2 Implementation Details

Details for ANT: In adjective-nouns mask training, we utilized Adam as our optimizer and the learning rate is 5e-5. The batch size is set to 32 and the max sequence length is set to 64, respectively. Further, we utilize the Bert-Large[6] with 340M parameters as the basic model to perform adjective-nouns mask training and the number of training epoch is 3.

Vehicle Filtering: For simile generation, we filter the predicted vehicles that are similar to the tensor by calculating the semantic similarity with Glove embedding. For instance, given the sentence “The child is as tall as [MASK]", we will filter out the word “father" as its vehicle due to not meeting the simile definition[7]. To solve this problem, we compute the similarity score of the tenor and vehicle and filter the predicted vehicle whose score is above the threshold 0.48[8].

[7] Using something with similar characteristics to give an analogy to another thing

[8] The threshold is the maximum similarity score of tenor and vehicle in the train set

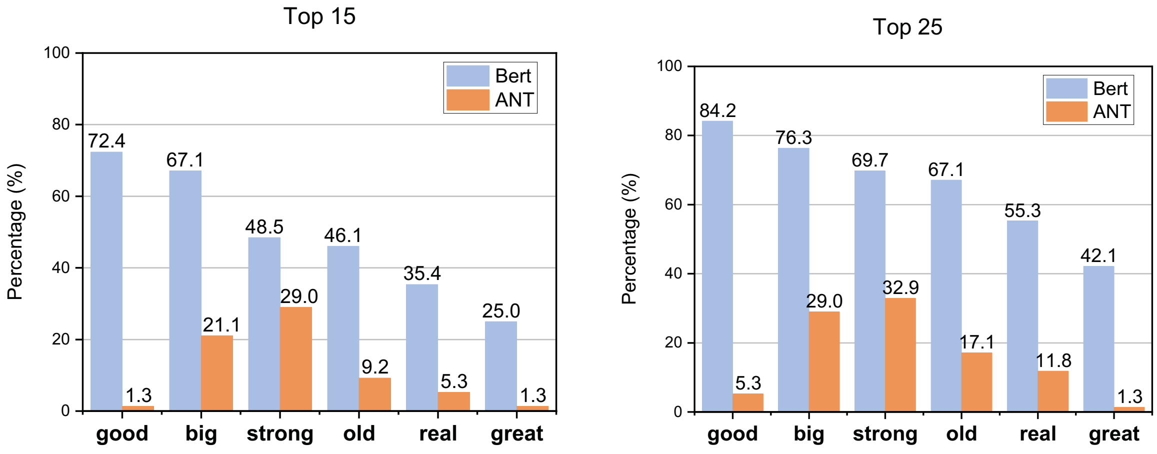

Figure 3: Percentage of samples whose top K predicted words contain a given common word. The horizontal coordinates are some common adjectives.

5.3 Evaluating the effectiveness of ANT

In this section, we will demonstrate that ANT could improve the diversity of predicted words for both the SI and SG tasks. We compare the predicted results of MLM (i.e., Bert) before and after ANT, which use the patterns "The $\mathcal{T}$ is as [MASK] as $\mathcal{V}$" for the SI task and "The $\mathcal{T}$ is as $\mathcal{A}$ as [MASK]" for the SG task.

Metric: We evaluate the diversity of the MLM predictions by calculating the proportion of unique words in the predicted Top K results on the test set. It can be formulated as

$$p@K = \frac{Num(Unique\_words)}{K * N} \quad (5)$$

where the $Num(Unique\_words)$ means the number of unique words, and the N represents size of the test set.

Result: To illustrate the effectiveness of ANT, We evaluate the results on the test set based on Equation 5. As shown in Table 3, the diversity of predicted words significantly improves after ANT for different $p@K$, specifically about 100% improvement for the SI task and about 50% for the SG task. Additionally, Figure 3 plots the percentage of samples on the test set, where a given common word (e.g., good, big, strong) appears in the list of the top $k = 15, 25$ predicted words. We can observe that the frequency of common words decreases significantly after ANT. For example, the frequency of the common word *good* decreases from 72.37% to 1.32% when $k = 15$.

	Method	p@5	p@10	p@15	p@25
SI	Bert	0.263	0.216	0.189	0.163
	ANT	0.492	0.412	0.382	0.312
SG	Bert	0.232	0.201	0.182	0.158
	ANT	0.370	0.299	0.256	0.216

Table 3: The results of diversity on both the SI and SG tasks. The method *Bert* and *ANT* separately represent the results before and after the Adjective-Noun mask training.

5.4 Evaluating the effectiveness of PE and PS

5.4.1 Baselines

We compare the proposed approaches with the following baseline:

(1) **Meta4meaning (Xiao et al., 2016)**: It uses the trained LSA vector representation according to the degree of abstraction and salience imbalance to select appropriate attributes. (2) **GEM (Bar et al., 2018)**: A method calculates the cosine similarity and normalized PMI between each attribute and tensor/vehicle based on Glove representing to obtain the best attribute with ranking. (3) **Bert (Devlin et al., 2019)**: Directly use pre-trained MLM to predict the simile component with a single pattern as Section 3.3. In this paper, we utilize the *bert-large-uncased* as the basic pre-trained MLM. (4) **ConScore (Zheng et al., 2020)**: A connecting score is proposed to select an attribute word $\mathcal{A}$ for $\mathcal{T}$ and $\mathcal{V}$.

Our proposed approaches are denoted as:

(1) **ANT**: Perform Adjective-Noun mask Training based on a pre-trained MLM with the datasets mentioned in Section 5.1. (2) **ANT+PE**: Based on ANT, the output distribution over vocabulary is pre-

Task	Method	MRR	R@5	R@10	R@15	R@25	R@50
SI	Meta4meaning	N/A	0.221	0.303	0.339	0.397	0.454
	GEM	**0.312**	0.198	0.254	0.278	0.405	0.562
	ConScore	0.078	0.076	0.138	0.172	0.269	0.386
	Bert	0.266	0.338	0.428	0.448	0.538	0.641
	ANT	0.245	0.310	0.407	0.455	0.510	0.614

	Bert	0.597†	0.667†	0.629†
	ANT	0.867†	0.868†	0.808†
	ANT+PE	0.887†	0.805†	0.751†
	ANT+PS+PE	**1.123**	**1.052**	**0.973**

Table 5: The average score of human evaluation for STC. The best results are in bold, and the second best results are underlined. † denotes significant difference with the best result (t-test, p-value<0.05).

dicted by average on all the corresponding patterns in Table 1. (3) **ANT+PS+PE**: Based on ANT, first the pattern search is to decide which patterns in Table 1 are applied, and then the pattern ensemble is used over these selected patterns.

5.4.2 Metrics

We use both automatic evaluation and human evaluation to compare our approaches with baselines.

Automatic Evaluation:

(1) Mean Reciprocal Rank (MRR): average on the reciprocal of the ranking r_i of label words in the predicted candidates, denoted as

$$MRR = \frac{1}{N} \sum_{i=1}^{N} \frac{1}{r_i} \tag{6}$$

(2) $R@K$: the percentage of the label words appear in the top K predictions. Note that, following previous works (Xiao et al., 2016; Bar et al., 2018), we consider a predicted word as the correct answer if it is a synonym of label word n in WordNet (Miller, 1992). It can be formulated as

$$cor(w) = \begin{cases} 1 & w \in Synonyms(L_i) \\ 0 & w \notin Synonyms(L_i) \end{cases} \tag{7}$$

$$R@K = \frac{1}{N} \sum_{i=1}^{N} \frac{\sum_{w \in K_i} cor(w)}{K} \tag{8}$$

where K_i denotes the list of predicted words, L_i denotes the list of label words and $Synonyms(L_i)$ represents the synonyms of a word.

Human Evaluation: To further prove our approaches are better than baselines, human evaluation is used to evaluate the quality of predicted simile triples from three levels (0, 1, 2). 0 - The triple is unacceptable. 1 - The triple is acceptable. 2 - The triple is acceptable and creative. Given a simile triple, annotators need to score it according to their subjective judgment and each triple is annotated by three annotators independently. We use the average score of three annotators as the quality of a simile triple.

5.4.3 Results

Automatic and Human Evaluation: The results of both automatic and human evaluation are shown in Table 4 and Table 5. The agreement between annotators is measured using Fleiss's kappa κ (Randolph, 2005). The κ value is 0.68 (substantial agreement) for the SI task and 0.48 (moderate agreement) for the SG task.

From the results, we can conclude

Task	Subset of Patterns	MRR	R@5	R@10	R@15	R@25
SI	$\{p_1, p_5\}$	**0.100**	**0.126**	**0.184**	**0.233**	**0.281**
	$\{p_1, p_2, p_3, p_4, p_5, p_9\}$	0.095	0.107	0.171	0.203	0.268
	$\{p_1, p_2, p_3, p_4, p_5, p_7, p_8\}$	0.095	0.099	0.163	0.206	0.274
	$\{p_1, p_4, p_5\}$	0.094	0.094	0.163	0.203	0.261
SG	$\{p_3, p_4\}$	**0.056**	0.068	**0.105**	**0.135**	**0.159**
	$\{p_1, p_4\}$	0.056	**0.071**	0.092	0.120	0.154
	$\{p_1, p_3, p_4\}$	0.052	0.06	0.105	0.128	0.163
	$\{p_1, p_2, p_4\}$	0.052	0.058	0.096	0.116	0.137

Table 6: The top 4 best performing pattern subsets for SI and SG tasks (see Table 1 for which class the pattern p_i belongs to). The best results are in bold. More results of pattern search are shown in the Appendix A

.

(1) For both SI and SG tasks, our proposed approaches (i.e., ANT, ANT+PE, ANT+PS+PE) significantly outperform the baselines on both automatic and human evaluations. It proves that our methods not only enhance the diversity of predicted simile components in Section 5.3 but also their quality.

(2) Pre-trained MLM-based methods (i.e., Bert, ANT, ANT+PE and ANT+PS+PE) perform better than the traditional methods (i.e., GEM, Meta4meaning, ConScore). It shows the potential of pre-trained models in probing simile knowledge.

(3) Compared ANT with Bert, we found that though ANT improves the diversity of predicted words in Table 3, the average scores on automatic and human evaluations decrease because the simile knowledge is not involved in the ANT training process. However, our proposed PE and PS compensate for the performance.

(4) The scores of automatic evaluation metrics on the SI task are remarkably higher than the SG task. Yet, the scores of human evaluation metrics are significantly lower than on the SG task. We conjecture that this may be because the list of candidate words of attribute predicted by SI are smaller than that of the vehicle for the SG task. For example, given the SI sample "(Cloud, $None$, Cotton)", the attribute words are almost restricted to the physical properties of the vehicle, such as "Soft", while the choices of vehicle words are more varied and unexpected given the SG sample "(Cloud, soft, $None$)" such as "cotton, silk, towel".

Discussion for PS: Compared ANT+PS+PE to ANT+PE, it can be included that pattern search brings a great improvement to the results on both automatic and human evaluations. To have a deeper insight into PS, the pattern subsets with high performance are listed in Table 6. For the SI task, the optimal multi-pattern combination is $\{p_1, p_5\}$, which support the hypothesis proposed by (Ortony, 1979) considers that the highlighted attribute of a simile triple is more salient in the vehicle domain despite it is commonly shared by both tenor and vehicle domains. Specifically, pattern p_1 belonging to the Class I, models the relationship of all three simile components while the pattern p_5 belonging to Class II requires the candidate words to be the salient attribute of the vehicle. Similarly, for SG task, optimal multi-pattern combination is $\{p_3, p_4\}$, which is also a combination of the Class I pattern and the Class II pattern.

6 Conclusion and Future work

In this paper, from the perspective of simile triple completion, we propose a unified framework to solve the SI and SG tasks by probing the knowledge of the pre-trained masked language model. The backbone of our method is to construct masked sentences with manual patterns from an incomplete simile triple, and then use language models with MLM heads to predict the masked words. Moreover, a secondary pre-training stage (the adjective-noun mask training) is applied to improve the diversity of predicted words. Pattern ensemble (PE) and pattern search (PS) are further used to improve the quality of predicted words. Finally, automatic and human evaluations demonstrate the effectiveness of our framework in both SI and SG tasks. In future work, we will continue to study how to mine broader or complex knowledge from pre-trained models, such as metaphor, common sense and we expect more researchers to perform related research.

Abstract

Entity alignment (EA) aims to find the equivalent entity pairs between KGs, which is a crucial step for integrating multi-source KGs. For a long time, most researchers have regarded EA as a pure graph representation learning task and focused on improving graph encoders while paying little attention to the decoding process. In this paper, we propose an effective and efficient EA **D**ecoding **A**lgorithm via **T**hird-order **T**ensor **I**somorphism (DATTI). Specifically, we derive two sets of isomorphism equations: (1) Adjacency tensor isomorphism equations and (2) Gramian tensor isomorphism equations. By combining these equations, DATTI could effectively utilize the adjacency and inner correlation isomorphisms of KGs to enhance the decoding process of EA. Extensive experiments on public datasets indicate that our decoding algorithm can deliver significant performance improvements even on the most advanced EA methods, while the extra required time is less than 3 seconds.

1 Introduction

Knowledge graphs (KGs) illustrate the relations between real-world entities—e.g., objects, situations, or concepts—and usually are stored in the form of triples $(subject, relation, object)$. Over recent years, a large number of KGs have been constructed to provide structural knowledge to facilitate downstream applications, such as recommendation systems (Cao et al., 2019) and question-answering systems (Zhao et al., 2020).

Most KGs are independently extracted from different languages or domains. Thus, these KGs usually hold unique information individually but also have some shared parts. Integrating these cross-lingual / domain KGs could provide a broader view for users, especially for the minority language users who usually suffer from lacking language resources. As shown in Figure 1, entity alignment (EA) aims to find the equivalent entity pairs between KGs, which is a crucial step for integrating KGs.

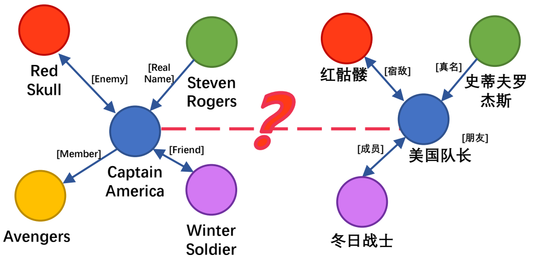

Figure 1: An example of cross-lingual entity alignment.

Existing EA methods are built on the same core premise: equivalent entity pairs between KGs have similar neighborhood structures (i.e., isomorphism). Therefore, most existing EA methods (Wang et al., 2018; Sun et al., 2020b; Mao et al., 2020) could be abstracted into the same architecture (as shown in Figure 2): encoding the structural information of KGs into a low-dimensional vector space by Siamese graph encoders and then mapping equivalent entity pairs into the proximate space by alignment loss functions.

For a long time, most researchers have regarded EA as a graph representation learning task and focused on improving graph encoders. Starting from the simplest graph encoder TransE (Bordes et al., 2013), the newest graph encoding methods are successively introduced into EA and achieve decent improvements. For example, GCN-align (Wang et al., 2018) first proposed to use graph convolutional networks (GCN) (Kipf and Welling, 2017) to encode KGs. RSN (Guo et al., 2019) introduces recurrent neural networks (RNN) (Graves et al., 2008) and biased random walk to exploit the long-term relational dependencies existing in KGs. Dual-AMN (Mao et al., 2021a) proposes the proxy-matching layer and normalized hard samples mining loss to speed up the training process.

In stark contrast to the efforts on graph encoders, few researchers focus on improving EA decoding

algorithms (Sun et al., 2020c), which have been proved to significantly improve performance and reliability in other fields, such as dependency parsing (Zmigrod et al., 2020) and machine translation (He et al., 2021). Earlier EA studies (Wang et al., 2018; Sun et al., 2017) simply calculate the similarities of each pair of entities and select the closest one as the alignment result. This naive strategy results in one entity may be aligned to multiple entities simultaneously, which violates the one-to-one constraint of EA [1]. Thus, some recent studies (Xu et al., 2020; Zhu et al., 2021) propose the global alignment strategy, i.e., regarding the decoding process as a one-to-one assignment problem that could be solved by the Hungarian algorithm (Kuhn, 1955). Overall, these studies just use existing decoding algorithms without further exploration of KGs' characteristics. Similar to graph encoders, we argue that a good EA decoding algorithm should also be capable of exploiting the structural information of KGs.

In this paper, we propose an effective and efficient EA **D**ecoding **A**lgorithm via **T**hird-order **T**ensor **I**somorphism (DATTI). Different from recent studies (Fey et al., 2020; Mao et al., 2021b) that regard EA as a matrix (second-order tensor) isomorphism problem, we express the isomorphism of KGs in the form of third-order tensors, which could completely describe the structural information of KGs. Specifically, we derive two sets of tensor isomorphism equations: (1) Adjacency tensor isomorphism equations and (2) Gramian tensor isomorphism equations. By combining these equations, DATTI could effectively utilize the adjacency and inner correlation isomorphisms of KGs to enhance the decoding process of EA, thus significantly improving the performance. Besides, the introduction of third-order tensors will inevitably lead to a quadratic increase in space-time complexity. Therefore, we adopt the randomized truncated singular value decomposition algorithm (RTSVD) (Sarlós, 2006) and Sinkhorn operator (Sinkhorn, 1964) to improve efficiency.

To comprehensively evaluate our proposed method, we apply DATTI to three advanced EA methods with different kinds of graph encoders. Experimental results on two widely used public datasets show that DATTI can deliver significant performance improvements (3.9% on *Hits@1* and 3.2% on *MRR*) even on the most advanced EA methods. Furthermore, our decoding algorithm is highly efficient. The decoding time is less than 3 seconds, which is almost negligible compared to the time consumption of the training process. The main contributions are summarized as follows:

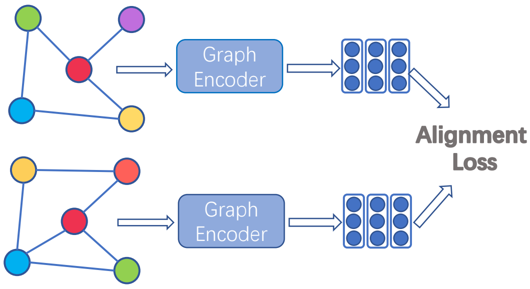

Figure 2: The architecture of existing EA methods.

- We propose an effective and efficient EA Decoding Algorithm via Third-order Tensor Isomorphism (DATTI), which consists of two sets of tensor isomorphism equations: (1) Adjacency tensor isomorphism equations and (2) Gramian tensor isomorphism equations.
- Extensive experiments on public datasets indicate that our decoding algorithm can deliver significant performance improvements even applied to the SOTA method, while the extra required time is less than 3 seconds.

2 Task Definition

A KG could be defined as $G = (E, R, T)$, where E,R, and T represent the entity set, relation set, and triple set, respectively. Given a source graph $G_s = (E_s, R_s, T_s)$ and a target graph $G_t = (E_t, R_t, T_t)$, the goal of EA is to explore the one-to-one entity correspondences $\boldsymbol{P}_e$ between KGs.

3 Related Work

3.1 Encoders and Enhancement

The core premise of EA methods is that equivalent entity pairs between KGs have similar neighborhood structures. As shown in Figure 2, most of them could be summarized into two steps: (1) Using KG embedding methods (e.g., TransE, GCN, and GAT (Velickovic et al., 2018)) to encode entities and relations into low-dimensional embeddings. (2) Mapping these embeddings into a unified vector space through pre-aligned entity pairs and alignment loss functions. To organize existing EA methods clearly, we categorize them based on the encoders and enhancement strategies in Table 1.

---

[1] Most KGs usually have removed the duplicated entities within the same KG.

Encoders and Losses. There are mainly two kinds of Encoders: *Trans* represents TransE (Bordes et al., 2013) and subsequent derivative algorithms. These methods assume that entity and relation embeddings follow the equation $h + r \approx t$. Because of the easy implementation, the *Trans* encoders are widely used in early EA methods. More recently, Graph Neural Networks (GNN) gradually became the mainstream encoder because of their powerful modeling capability on graph structures. Inspired by language models, RSN proposes a biased random walk sampling strategy and uses RNN to encode the sampled sequences. As for alignment losses, the vast majority of EA methods (Wang et al., 2018; Wu et al., 2019; Mao et al., 2020) adopt contrastive losses, e.g., Triplet loss (Schroff et al., 2015). These loss functions share one core idea, attracting positive entity pairs and repulsing negative entity pairs.

Enhancement. Due to the lack of labeled data, several methods (Sun et al., 2018; Mao et al., 2020) adopt iterative strategies to produce semi-supervised aligned entity pairs. Despite significant performance improvements, the time consumption of these methods increases several times more. Some methods (Xu et al., 2019; Yang et al., 2019) introduce textual information (e.g., entity name embeddings) as the initial features of GNN to provide a multi-aspect view. However, literal information is not always available in real applications. For example, there will be privacy risks when using user-generated content. Therefore, we will separately discuss these textual-based methods in the experiment section.

As mentioned in Section 1, some studies (Xu et al., 2020; Wu et al., 2019) regard the decoding process as a one-to-one assignment problem. The assignment problem is a fundamental combinatorial optimization problem. An intuitive instance is to assign N jobs for N workers. The assignment problem is to find a one-to-one assignment plan so that the total profit is maximum. Formally, it is equivalent to maximizing the following equation:

$$\underset{\boldsymbol{P}\in\mathbb{P}_N}{arg\ max}\ \langle \boldsymbol{P}, \boldsymbol{X} \rangle_F \tag{1}$$

$\boldsymbol{X} \in \mathbb{R}^{N\times N}$ is the profit matrix. $\boldsymbol{P}$ is a permutation matrix denoting the assignment plan. There are exactly one entry of 1 in each row and each column in $\boldsymbol{P}$ while 0s elsewhere. $\mathbb{P}_N$ represents the set of all N-dimensional permutation matrices. Here, $\langle\cdot\rangle_F$ represents the Frobenius inner product.

4 The Proposed Method

In the following, we describe our proposed decoding algorithm (DATTI), which consists of two sets of tensor isomorphism equations: (1) Adjacency tensor isomorphism equations and (2) Gramian tensor isomorphism equations. Furthermore, we adopt the randomized truncated singular value decomposition (RTSVD) algorithm and the Sinkhorn operator to speed up the decoding process.

4.1 Adjacency Isomorphism

Some recent studies (Fey et al., 2020; Mao et al., 2021b) regard EA as a matrix isomorphism problem. These methods assume that the adjacency matrices $\boldsymbol{A}_s \in \mathbb{R}^{|E_s|\times|E_s|}$ of source graph G_s and $\boldsymbol{A}_t \in \mathbb{R}^{|E_t|\times|E_t|}$ of target graph G_t are isomorphic, i.e., $\boldsymbol{A}_s$ could be transformed into $\boldsymbol{A}_t$ according to the entity correspondence matrix $\boldsymbol{P}_e$:

$$\boldsymbol{P}_e \boldsymbol{A}_s \boldsymbol{P}_e^\top = \boldsymbol{A}_t \tag{2}$$

$\boldsymbol{P}_{e_{[i,j]}} = 1$ indicates that e_i and e_j are equivalent. However, matrices (second-order tensors) cannot fully describe the adjacency information of KGs, which is stored in the form of triples. Therefore, we use third-order tensors to express KGs to avoid the information missing from using matrices. Let $\boldsymbol{\mathcal{A}_s} \in \mathbb{R}^{|E_s|\times|R_s|\times|E_s|}$ and $\boldsymbol{\mathcal{A}_t} \in \mathbb{R}^{|E_t|\times|R_t|\times|E_t|}$ be the adjacency tensors of G_s and G_t. $\boldsymbol{\mathcal{A}}_{[h,r,t]} = 1$ indicates that the triple (h, r, t) is in the KG. The matrix isomorphism Equation (2) could be generalized into the third-order form as follows:

$$\boldsymbol{\mathcal{A}_s} \times_1 \mathbf{P_e} \times_2 \mathbf{P_r} \times_3 \mathbf{P_e} = \boldsymbol{\mathcal{A}_t} \tag{3}$$

where $\boldsymbol{P}_r$ represents the one-to-one relation correspondence matrix between G_s and G_t and $\times_k$ represents the k-mode tensor-matrix product.

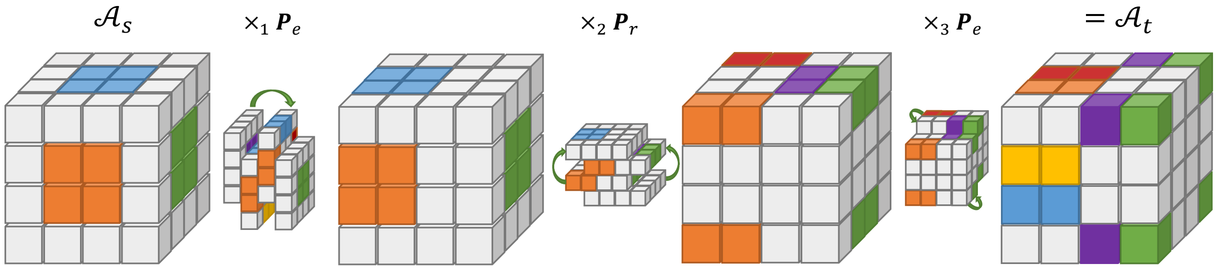

Figure 3: The illustration of tensor-matrix product and isomorphic adjacency tensors.

As illustrated in Figure 3, Equation (3) can be interpreted as successively reordering the tensor along three axes. Since the number of triples $|T|$ is usually much less than $|E| \times |R| \times |E|$, $\boldsymbol{\mathcal{A}_s}$ and $\boldsymbol{\mathcal{A}_t}$ are extremely sparse. Unfortunately, existing tensor computing frameworks (e.g., Numpy (Harris et al., 2020) and Tensorflow (Abadi et al., 2015)) can only provide few and limited operators for third-order sparse tensors. Therefore, we have to re-transform Equation (3) into the matrix form:

$$\begin{aligned} & \boldsymbol{\mathcal{A}_s} \times_1 \mathbf{P_e} \times_2 \mathbf{P_r} \times_3 \mathbf{P_e} = \boldsymbol{\mathcal{A}_t} \\ \iff \quad & \boldsymbol{P}_e \boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{1})} (\boldsymbol{P}_e \otimes \boldsymbol{P}_r)^\top = \boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{1})} \\ & \boldsymbol{P}_r \boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{2})} (\boldsymbol{P}_e \otimes \boldsymbol{P}_e)^\top = \boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{2})} \\ & \boldsymbol{P}_e \boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{3})} (\boldsymbol{P}_r \otimes \boldsymbol{P}_e)^\top = \boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{3})} \end{aligned} \tag{4}$$

here $\otimes$ represents the Kronecker product, $\boldsymbol{P}_e \otimes \boldsymbol{P}_r \in \mathbb{P}^{(|E|\cdot|R|)\times(|E|\cdot|R|)}$. $\boldsymbol{\mathcal{A}}^{(\boldsymbol{k})}$ represents the mode-k unfolding matrix of the tensor $\boldsymbol{\mathcal{A}}$, e.g., $\boldsymbol{\mathcal{A}}^{(\mathbf{1})} = [\boldsymbol{\mathcal{A}}_{[:,:,0]} \| \boldsymbol{\mathcal{A}}_{[:,:,1]} \| ... \| \boldsymbol{\mathcal{A}}_{[:,:,|E|]}] \in \mathbb{R}^{|E|\times(|E|\cdot|R|)}$, where $\|$ is the concatenate operation. When $\boldsymbol{\mathcal{A}_s}$ and $\boldsymbol{\mathcal{A}_t}$ are second-order adjacency tensors, the above equations degrade to Equation (2):

$$\begin{aligned} & \boldsymbol{\mathcal{A}_s} \times_1 \mathbf{P_e} \times_2 \mathbf{P_e} = \boldsymbol{\mathcal{A}_t} \\ \iff \quad & \boldsymbol{P}_e \boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{1})} \boldsymbol{P}_e^\top = \boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{1})} \end{aligned} \tag{5}$$

4.2 Gramian Isomorphism

Gramian matrix $G(\boldsymbol{A}) = \boldsymbol{A}\boldsymbol{A}^\top$ reflects the inner correlations between each vector of matrix $\boldsymbol{A}$. If we regard $\boldsymbol{A}$ as random variables, $G(\boldsymbol{A})$ is equivalent to the uncentered covariance matrix. When $\boldsymbol{A}_s$ and $\boldsymbol{A}_t$ are isomorphic, their Gramian matrices $\boldsymbol{A}_s\boldsymbol{A}_s^\top$ and $\boldsymbol{A}_t\boldsymbol{A}_t^\top$ are isomorphic too:

$$\boldsymbol{A}_t\boldsymbol{A}_t^\top = (\boldsymbol{P}_e\boldsymbol{A}_s\boldsymbol{P}_e^\top)(\boldsymbol{P}_e\boldsymbol{A}_s\boldsymbol{P}_e^\top)^\top = \boldsymbol{P}_e\boldsymbol{A}_s\boldsymbol{A}_s^\top\boldsymbol{P}_e^\top \tag{6}$$

Similar to adjacency matrices, the Gramian matrix isomorphism equation could also be generalized into the third-order form:

$$\begin{aligned} \boldsymbol{P}_e G(\boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{1})}) \boldsymbol{P}_e^\top &= G(\boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{1})}) \\ \boldsymbol{P}_r G(\boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{2})}) \boldsymbol{P}_r^\top &= G(\boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{2})}) \\ \boldsymbol{P}_e G(\boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{3})}) \boldsymbol{P}_e^\top &= G(\boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{3})}) \end{aligned} \tag{7}$$

Furthermore, it is easy to prove that the following equations hold for arbitrary depth $l \in \mathbb{N}$:

$$\begin{aligned} \boldsymbol{P}_e G(\boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{1})})^l \boldsymbol{P}_e^\top &= G(\boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{1})})^l \\ \boldsymbol{P}_r G(\boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{2})})^l \boldsymbol{P}_r^\top &= G(\boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{2})})^l \\ \boldsymbol{P}_e G(\boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{3})})^l \boldsymbol{P}_e^\top &= G(\boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{3})})^l \end{aligned} \tag{8}$$

4.3 Decoding via Isomorphism

Although we have derived two sets of isomorphic equations, neither of them could be solved directly. These equations are equivalent to the quadratic or cubic assignment problem (Yan et al., 2016), which has been proved to be NP-hard (Lawler, 1963). Fortunately, these isomorphic equations could be used to enhance the decoding process.

Let $\boldsymbol{H}_s^e \in \mathbb{R}^{|E_s|\times d^e}$ and $\boldsymbol{H}_s^r \in \mathbb{R}^{|R_s|\times d^r}$ represent the entity and relation embeddings of G_s. $\boldsymbol{H}_t^e \in \mathbb{R}^{|E_t|\times d^e}$ and $\boldsymbol{H}_t^r \in \mathbb{R}^{|R_t|\times d^r}$ represent the embeddings of G_t. Assume that these embeddings have been approximately aligned by EA methods:

$$\begin{aligned} \boldsymbol{P}_e\boldsymbol{H}_s^e &\approx \boldsymbol{H}_t^e \\ \boldsymbol{P}_r\boldsymbol{H}_s^r &\approx \boldsymbol{H}_t^r \end{aligned} \tag{9}$$

As mentioned in Section 1, some recent studies (Xu et al., 2020; Sun et al., 2020c) regard the decoding process of $\boldsymbol{P}_e$ as an assignment problem:

$$\begin{aligned} & \underset{\boldsymbol{P}_e\in\mathbb{P}_{|E|}}{arg\ min} \|\boldsymbol{P}_e\boldsymbol{H}_s^e - \boldsymbol{H}_t^{e^\top}\|_F^2 \\ \iff \quad & \underset{\boldsymbol{P}_e\in\mathbb{P}_{|E|}}{arg\ max} \left\langle \boldsymbol{P}_e, \boldsymbol{H}_s^e\boldsymbol{H}_t^{e^\top} \right\rangle_F \end{aligned} \tag{10}$$

Since this simple decoding strategy does not utilize the structural information of KGs, we propose to introduce the adjacency and Gramian isomorphism equations into the decoding process. By combining Equations (4), (8), and (9), the connection between the 8-tuple $\{\boldsymbol{\mathcal{A}_s}, \boldsymbol{\mathcal{A}_t}, \boldsymbol{H}_s^e, \boldsymbol{H}_t^e, \boldsymbol{H}_s^r, \boldsymbol{H}_t^r, \boldsymbol{P}_e, \boldsymbol{P}_r\}$ could be described as follows, for arbitrary depth $l \in \mathbb{N}$:

$$\boldsymbol{P}_e G(\boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{1})})^l \boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{1})} (\boldsymbol{H}_s^e \otimes \boldsymbol{H}_s^r) \approx G(\boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{1})})^l \boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{1})} (\boldsymbol{H}_t^e \otimes \boldsymbol{H}_t^r) \tag{11}$$

$$\boldsymbol{P}_r G(\boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{2})})^l \boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{2})} (\boldsymbol{H}_s^e \otimes \boldsymbol{H}_s^e) \approx G(\boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{2})})^l \boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{2})} (\boldsymbol{H}_t^e \otimes \boldsymbol{H}_t^e) \tag{12}$$

$$\boldsymbol{P}_e G(\boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{3})})^l \boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{3})} (\boldsymbol{H}_s^r \otimes \boldsymbol{H}_s^e) \approx G(\boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{3})})^l \boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{3})} (\boldsymbol{H}_t^r \otimes \boldsymbol{H}_t^e) \tag{13}$$

Detailed proof is listed in Appendix A. Although it looks complex, the above equations essentially have the same form as Equation (9). Take Equation (11) as an example, let $\hat{\boldsymbol{H}}_s^l = G(\boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{1})})^l \boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{1})} (\boldsymbol{H}_s^e \otimes \boldsymbol{H}_s^r)$ and $\hat{\boldsymbol{H}}_t^l = G(\boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{1})})^l \boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{1})} (\boldsymbol{H}_t^e \otimes \boldsymbol{H}_t^r)$, Equation (11) can be simplified into as follows:

$$\boldsymbol{P}_e \hat{\boldsymbol{H}}_s^l \approx \hat{\boldsymbol{H}}_t^l \tag{14}$$

Therefore, $\boldsymbol{P}_e$ could also be solved by maximizing the equation $\underset{\boldsymbol{P}_e \in \mathbb{P}_{|E|}}{arg\ max} \left\langle \boldsymbol{P}_e, \hat{\boldsymbol{H}}_s^l \hat{\boldsymbol{H}}_t^{l\top} \right\rangle_F$. Theoretically, for arbitrarily depth $l \in \mathbb{N}$, the result of $\boldsymbol{P}_e$ should be the same. However, the above equations are based on the ideal isomorphic situation. In practice, $\boldsymbol{\mathcal{A}}_{\boldsymbol{s}}$ and $\boldsymbol{\mathcal{A}}_{\boldsymbol{t}}$ can not always be strictly isomorphic. In order to reduce the impact of noise existing in practice, $\boldsymbol{P}_e$ should be fit for various l:

$$\begin{aligned} &\sum_{l=0}^{L} \underset{\boldsymbol{P}_e \in \mathbb{P}_{|E|}}{arg\ max} \left\langle \boldsymbol{P}_e, \hat{\boldsymbol{H}}_s^l \hat{\boldsymbol{H}}_t^{l\top} \right\rangle_F \\ \Longleftrightarrow\ &\underset{\boldsymbol{P}_e \in \mathbb{P}_{|E|}}{arg\ max} \left\langle \boldsymbol{P}_e, \sum_{l=0}^{L} \hat{\boldsymbol{H}}_s^l \hat{\boldsymbol{H}}_t^{l\top} \right\rangle_F \end{aligned} \tag{15}$$

By Equation (15), we successfully integrate the adjacency and Gramian isomorphism equations into the decoding process of EA. Similar to the above, Equation (12) could obtain the relation alignment result $\boldsymbol{P}_r$. Because Equation (13) is equivalent to Equation (11), it only needs to solve either of them to obtain the entity alignment result $\boldsymbol{P}_e$. It is noted that entity scales $|E_s|$ and $|E_t|$ are usually inconsistent in practice, which is called the unbalanced assignment problem. Assuming that $|E_s| > |E_t|$, a naive solution is to pad the profit matrix with zeros such that its shape becomes $\mathbb{R}^{|E_s| \times |E_s|}$.

4.4 Reducing the Complexity

Randomized truncated SVD. The introduction of third-order tensors enables DATTI to fully describe the structural information of KGs. However, there is no such thing as a free lunch. The space-time complexity also increases quadratically. The main bottleneck is to compute $\hat{\boldsymbol{H}}_s^l \in \mathbb{R}^{|E_s| \times (d^e \cdot d^r)}$ and $\hat{\boldsymbol{H}}_t^l \in \mathbb{R}^{|E_t| \times (d^e \cdot d^r)}$. Even with the sparse optimization trick, the complexity is still up to $O(l d^r d^e |T|)$, which is much worse than most GNN encoders $O(l(d^e + d^r)|T|)$ (Mao et al., 2020).

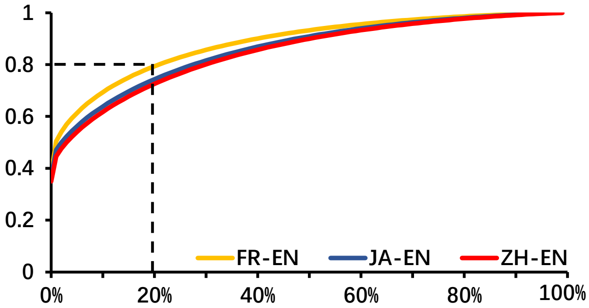

Figure 4: The singular value distribution of $\hat{\boldsymbol{H}}_s^l$ obtained by TransEdge on DBP15K.The abscissa represents the top $k\%$ singular values, and the ordinate represents the proportion of these singular values in total.

In Figure 4, we list the singular value distribution of $\hat{\boldsymbol{H}}_s^l$ obtained by TransEdge (Sun et al., 2020a) on DBP15K. Interestingly, the distribution is highly concentrated in the top 20%, which means the contained information of $\hat{\boldsymbol{H}}_s^l$ is sparse and compressible. By dropping the smaller singular values of $\hat{\boldsymbol{H}}_s^l$ and $\hat{\boldsymbol{H}}_t^l$, the space-time complexity could be significantly reduced. This paper adopts randomized truncated SVD (Sarlós, 2006) to decompose matrices approximately and only retains the top $\phi\%$ of the singular values of $\hat{\boldsymbol{H}}_s^l$ and $\hat{\boldsymbol{H}}_t^l$.

Sinkhorn operator. The first and most well-known solving algorithm for the assignment problem is the Hungarian algorithm (Kuhn, 1955), which is based on improving a matching along the augmenting paths. The time complexity of the original Hungarian algorithm is $O(n^4)$. Then, Jonker and Volgenant (1987) improve the algorithm to achieve an $O(n^3)$ running time.

Besides the Hungarian algorithm, the assignment problem could also be regarded as a special case of the optimal transport (OT) problem. Based on the Sinkhorn operator (Sinkhorn, 1964), Cuturi (2013) proposes a fast and completely parallelizable algorithm for OT problem:

$$\begin{aligned} S^0(\boldsymbol{X}) &= exp(\boldsymbol{X}), \\ S^k(\boldsymbol{X}) &= \mathcal{N}_c(\mathcal{N}_r(S^{k-1}(\boldsymbol{X}))), \\ \text{Sinkhorn}(\boldsymbol{X}) &= \lim_{k \to \infty} S^k(\boldsymbol{X}). \end{aligned} \tag{16}$$

where $\mathcal{N}_r(\boldsymbol{X}) {=} \boldsymbol{X} \oslash (\boldsymbol{X} \mathbf{1}_N \mathbf{1}_N^T)$ and $\mathcal{N}_c {=} \boldsymbol{X} \oslash (\mathbf{1}_N \mathbf{1}_N^T \boldsymbol{X})$ are the row and column-wise normalization operators of a matrix, $\oslash$ represents the element-wise division, and $\mathbf{1}_N$ is a column vector of ones.

Datasets		$\|E\|$	$\|R\|$	$\|T\|$
$\text{DBP}_{\text{ZH-EN}}$	Chinese	19,388	1,701	70,414
	English	19,572	1,323	95,142
$\text{DBP}_{\text{JA-EN}}$	Japanese	19,814	1,299	77,214
	English	19,780	1,153	93,484
$\text{DBP}_{\text{FR-EN}}$	French	19,661	903	105,998
	English	19,993	1,208	115,722
$\text{SRPRS}_{\text{FR-EN}}$	French	15,000	177	33,532
	English	15,000	221	36,508
$\text{SRPRS}_{\text{DE-EN}}$	German	15,000	120	37,377
	English	15,000	222	38,363

Table 2: Statistical data of DBP15K and SRPRS.

Then, Mena et al. (2018) further prove that the Sinkhorn operation could also solve the assignment problem as a special case of OT problem:

$$\begin{aligned} &\underset{\boldsymbol{P}\in\mathbb{P}_N}{arg\ max}\ \langle \boldsymbol{P}, \boldsymbol{X}\rangle_F \\ =\ &\lim_{\tau\to 0^+} \text{Sinkhorn}(\boldsymbol{X}/\tau) \end{aligned} \tag{17}$$

The time complexity of the Sinkhorn operator is $O(kn^2)$. According to our experimental results, a small k is enough to achieve decent performance. Compared with the Hungarian algorithm, the Sinkhorn operation is much more efficient. Therefore, this paper adopts the Sinkhorn operator to solve Equation (15).

5 Experiments

Our experiments are conducted on a PC with a GeForce GTX 3090 GPU and a Ryzen ThreadRipper 3970X CPU. The code and datasets are available in Github [2].

5.1 Datasets

To comprehensively evaluate the proposed decoding algorithm, we experiment with two widely used public datasets: (1) **DBP15K** (Sun et al., 2017) consists of three cross-lingual subsets from multilingual DBpedia. Each subset contains $15,000$ entity pairs. (2) **SRPRS** (Guo et al., 2019). Each subset also contains $15,000$ entity pairs but with much fewer triples compared to DBP15K. The statistics of these datasets are summarized in Table 2. To be consistent with previous studies (Wang et al., 2018; Sun et al., 2018), we randomly split 30% of the pre-aligned entity pairs for training and development while using the remaining 70% for testing. All the results are the average of five independent runs.

5.2 Baselines

To ensure the universality, we evaluate DATTI on three advanced EA methods with different types of graph encoders: Dual-AMN (Mao et al., 2021a) is the SOTA of GNN-based methods; TransEdge (Sun et al., 2020a) is the SOTA of Trans-based methods; RSN (Guo et al., 2019) is the only EA method using RNN as the encoder. Furthermore, we choose the Hungarian algorithm (*Hun.*) as the decoding baseline, proven to be effective by recent EA methods (Xu et al., 2020; Zhu et al., 2021).

5.3 Settings

Metrics. Following convention, we use *Hits@k* and *Mean Reciprocal Rank* (MRR) as the evaluation metrics. The $Hits@k$ score is calculated by measuring the proportion of correct pairs in the top-k. In particular, *Hits@1* equals accuracy.

Hyper-parameter. For TransEdge, we retain the top ϕ=20% of the singular values of $\hat{\boldsymbol{H}}_s^l$ and $\hat{\boldsymbol{H}}_t^l$. Since the output dimensions of Dual-AMN (d^e=768, d^r=128) and RSN (d^e=d^r=256) are much larger than TransEdge (d^e=d^r=75), we only set the retaining ratio ϕ=2%. Other hyper-parameters keep the same for all datasets and methods: iterations k=15; temperature τ=0.02; max depth L=3.

5.4 Main Experiments

We list the main experimental results in Table 3. Among these three EA methods, Dual-AMN beats other baselines by more than 5.5% on *Hits@1* and 4.2% on *MRR*, which indicates the advantages of GNN encoders. On RSN and TransEdge, the Hungarian algorithm shows decent performance improvements on *Hits@1* by at least 3.2%. In contrast, the Hungarian does not positively affect Dual-AMN, probably due to the bi-directional nearest iterative strategy of Dual-AMN that has included the core idea of the Hungarian algorithm.

Our proposed DATTI consistently achieves the best performances on all datasets and baselines. On DBP15K, DATTI delivers performance gains by at least 2.8% on *Hits@1* and 3.2% on *MRR*. Especially for the SOTA method Dual-AMN, DATTI further raises the performance ceiling of EA by more than 3.9% on *Hits@1*. On SRPRS, DATTI could significantly improve the performances of RSN and TransEdge. But for Dual-AMN, the improvements are much less. One possible explanation is that SRPRS removes too many triples, resulting in a lower performance ceiling.

Table 4: Time costs (second) on DBP15K and SRPRS.

5.5 Auxiliary Experiments

To explore the behavior of our proposed decoding algorithm in different situations, we design the following experiments:

Time Efficiency. By adopting RTSVD and the Sinkhorn operator, our proposed decoding algorithm acquires high efficiency. Table 4 lists the time costs of the training and decoding process (DATTI) of three EA methods on DBP15K and SRPRS. DATTI only requires 3 seconds to obtain the result at most, which is negligible even compared to the training process of the fastest method Dual-AMN.

Adjacency and Gramian Isomorphism. The core contribution of DATTI is to introduce the adjacency and Gramian isomorphism equations into the EA decoding process. To demonstrate their effectiveness, we independently add each of them on Dual-AMN. As shown in Table 5, both could slightly improve the performance (less than 1.6% on *Hits@1*). Interestingly, the performance gain brought by their combination is greater than the sum of their independent gains, which means these two kinds of isomorphism equations could capture non-overlapping information.

Method	$\text{DBP}_{\text{ZH-EN}}$		$\text{DBP}_{\text{JA-EN}}$		$\text{DBP}_{\text{FR-EN}}$	
	Hits@1	MRR	Hits@1	MRR	Hits@1	MRR
Dual-AMN	0.804	0.853	0.803	0.856	0.834	0.881
+Adj.	0.820	0.866	0.818	0.868	0.859	0.902
+Gram.	0.809	0.857	0.812	0.863	0.848	0.895
+DATTI	0.835	0.880	0.836	0.884	0.873	0.913

Table 5: Ablation studies on DBP15K.

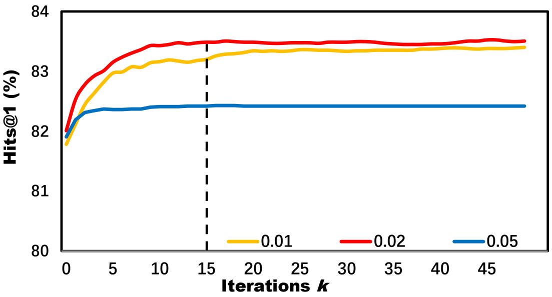

Figure 5: *Hits@1* on $\text{DBP}_{\text{ZH-EN}}$ with different τ.

Iterations k and Temperature τ. The τ in the Sinkhorn operator is used to make distribution closer to one-hot, which is similar to the τ in the softmax operator. We set τ from 0.01 to 0.05 and report the corresponding performance curves of DATTI (Dual-AMN) on $\text{DBP}_{\text{ZH-EN}}$ in Figure 5. If we choose an appropriate value, the Sinkhorn operator will converge quickly to the optimal solution. Although τ theoretically needs to be close to zero, an over small τ will make the algorithm unstable because of the error of big floating-point numbers. In contrast, an over large τ will lead the algorithm to fail to converge.

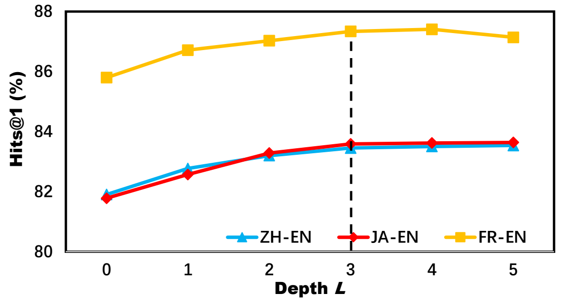

Figure 6: *Hits@1* on DBP15K with different depths L.

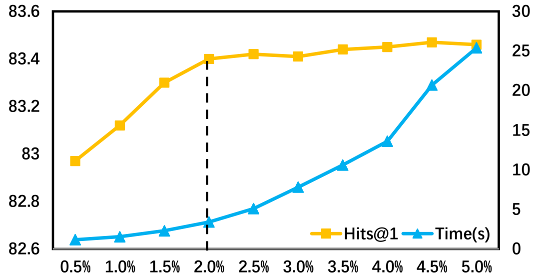

Figure 7: *Hits@1* and time cost (second) on $\mathrm{DBP}_{\mathrm{ZH-EN}}$ with different retaining ratios ϕ.

Depth L. Figure 6 lists the performances of DATTI (Dual-AMN) with different max depths L. In particular, $L = 0$ is equivalent to only using adjacency isomorphism equations to decode $\boldsymbol{P}_e$. When the depth L is less than 3, each additional layer could deliver significant performance improvements on all subsets of DBP15K. When stacking more layers, the performance gains become negligible or even degrade, which indicates that over-smoothing (Kipf and Welling, 2017) also exists in DATTI.

Retaining ratio ϕ. To reduce the space-time complexity of DATTI, we only retain the top ϕ% of the singular values of $\hat{\boldsymbol{H}}_s^l$ and $\hat{\boldsymbol{H}}_t^l$. In Figure 7, we report the *Hits@1* and time cost of DATTI (Dual-AMN) on $\mathrm{DBP}_{\mathrm{ZH-EN}}$ with different retaining ratios ϕ. From the observation, when the retaining ratio exceeds 2%, the growth of *Hits@1* becomes very slow, while the time cost still keeps quadratic growing. Therefore, ϕ=2% is the sweet spot between performance and efficiency in this situation. In practice, the retaining ratio ϕ could be adjusted according to computing resources and data scales.

5.6 Unsupervised Entity Alignment

So far, all the experiments are based on pure structural-based EA methods. As mentioned in Section 3.1, some methods (Xu et al., 2020; Wu et al., 2019) introduce textual information (e.g., entity name) to provide a multi-aspect view. Specifically, these methods first use machine translation systems or cross-lingual word embeddings to map entity and relation names into a unified semantic space and then average the pre-trained word embeddings to construct the initial features for entities and relations. In our opinion, since the initial features of entity $\boldsymbol{H}^e$ and relation $\boldsymbol{H}^r$ have been pre-mapped, these textual-based EA methods are more like decoding algorithms to eliminate the translation noise. In this situation, DATTI could also play a similar role even without any pre-aligned entity pairs.

Method	$\mathrm{DBP}_{\mathrm{ZH-EN}}$		$\mathrm{DBP}_{\mathrm{JA-EN}}$		$\mathrm{DBP}_{\mathrm{FR-EN}}$	
	Hits@1	Hits@10	Hits@1	Hits@10	Hits@1	Hits@10

RDGCN	0.697	0.842	0.763	0.763	0.873	0.957
DGMC	0.801	0.875	0.848	0.897	0.933	0.960
AtrrGNN	0.796	0.929	0.783	0.920	0.919	0.979
CREA	0.736	-	0.792	-	0.924	-
RAGA	0.873	-	0.909	-	0.966	-
Init-Emb	0.625	0.756	0.680	0.807	0.848	0.919
+Hun.	0.667	-	0.728	-	0.893	-
+DATTI	**0.890**	**0.958**	**0.921**	**0.971**	**0.979**	**0.995**
(Imp.%)	1.9%	3.1%	1.3%	5.5%	1.3%	1.6%

Table 6: Performances of textual-based EA methods. The results of baselines are collected from the origin papers. Init-Emb represents only using the cosine similarity between the averaged name embeddings.

To make fair comparisons with these textural-based EA methods, we use the same entity name translations and pre-trained word embeddings provided by Xu et al. (2019). For DATTI, we retain the top 10% of the singular values of $\hat{\boldsymbol{H}}_s^l$ and $\hat{\boldsymbol{H}}_t^l$, while keeping other hyper-parameters the same. Table 6 lists the performances of DATTI and six baselines on DBP15K. Surprisingly, unsupervised DATTI outperforms all the supervised competitors, improves the performance on *Hits@1* by more than 1.3%. Besides showing the powerful competitiveness of DATTI, this result also indicates that existing textural-based EA methods have considerable redundancy. When the initial features have been pre-mapped, complex neural networks and pre-aligned entity pairs may not be necessary.

6 Conclusion

In this paper, we propose an effective and efficient EA decoding algorithm via third-order tensor isomorphism (DATTI). Extensive experiments on public datasets indicate that our decoding algorithm can deliver significant performance improvements even on the most advanced EA methods, while the extra required time is less than 3 seconds.

A Appendix

Proof: To prove Equation (11), we combine the first sub-equations of Equation (4) and (8):

$$\begin{cases} \boldsymbol{P}_e G(\boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{1})})^l \boldsymbol{P}_e^\top = G(\boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{1})})^l \\ \boldsymbol{P}_e \boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{1})} (\boldsymbol{P}_e \otimes \boldsymbol{P}_r)^\top = \boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{1})} \end{cases}$$

Because $\boldsymbol{P}_e^\top \boldsymbol{P}_e = \boldsymbol{E}$, thus:

$$\boldsymbol{P}_e G(\boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{1})})^l \boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{1})} (\boldsymbol{P}_e \otimes \boldsymbol{P}_r)^\top = G(\boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{1})})^l \boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{1})}$$

According to Equation (9), we could obtain:

$$\boldsymbol{P}_e \boldsymbol{H}_s^e \otimes \boldsymbol{P}_r \boldsymbol{H}_s^r \approx \boldsymbol{H}_t^e \otimes \boldsymbol{H}_t^r \tag{18}$$

Finally, because of $(\boldsymbol{P}_e \otimes \boldsymbol{P}_r)^\top (\boldsymbol{P}_e \boldsymbol{H}_s^e \otimes \boldsymbol{P}_r \boldsymbol{H}_s^r) = \boldsymbol{P}_e^\top \boldsymbol{P}_e \boldsymbol{H}_s^e \otimes \boldsymbol{P}_r^\top \boldsymbol{P}_r \boldsymbol{H}_s^r = \boldsymbol{H}_s^e \otimes \boldsymbol{H}_s^r$, Equation (11) is proved as follows:

$$\begin{aligned} &\boldsymbol{P}_e G(\boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{1})})^l \boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{1})} (\boldsymbol{P}_e \otimes \boldsymbol{P}_r)^\top (\boldsymbol{P}_e \boldsymbol{H}_s^e \otimes \boldsymbol{P}_r \boldsymbol{H}_s^r) \\ &\qquad = \boldsymbol{P}_e G(\boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{1})})^l \boldsymbol{\mathcal{A}}_{\boldsymbol{s}}^{(\mathbf{1})} (\boldsymbol{H}_s^e \otimes \boldsymbol{H}_s^r) \\ &\qquad \approx G(\boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{1})})^l \boldsymbol{\mathcal{A}}_{\boldsymbol{t}}^{(\mathbf{1})} (\boldsymbol{H}_t^e \otimes \boldsymbol{H}_t^r) \end{aligned}$$

Furthermore, Equations (12) and (13) could also be proved in similar way. □

Entailment Graph Learning with Textual Entailment and Soft Transitivity

Abstract

Typed entailment graphs try to learn the entailment relations between predicates from text and model them as edges between predicate nodes. The construction of entailment graphs usually suffers from severe sparsity and unreliability of distributional similarity. We propose a two-stage method, Entailment Graph with Textual Entailment and Transitivity (EGT2). EGT2 learns local entailment relations by recognizing possible textual entailment between template sentences formed by typed CCG-parsed predicates. Based on the generated local graph, EGT2 then uses three novel soft transitivity constraints to consider the logical transitivity in entailment structures. Experiments on benchmark datasets show that EGT2 can well model the transitivity in entailment graph to alleviate the sparsity issue, and lead to significant improvement over current state-of-the-art methods[1].

1 Introduction

Entailment, as an important relation in natural language processing (NLP), is critical to semantic understanding and natural language inference (NLI). Entailment relation has been widely applied in different NLP tasks such as Question Answering (Pathak et al., 2021; Khot et al., 2018), Machine Translation (Padó et al., 2009) and Knowledge Graph Completion (Yoshikawa et al., 2019). When coming across a question that *"Which medicine cures the infection?"*, one can recognize the information *"Griseofulvin is preferred for the infection,"* in the corpus and appropriately write down the answer with the knowledge that *"is preferred for"* entails *"cures"* when their arguments are *medicines* and *diseases*, although the surface form of predicate *"cures"* does not exactly appear in the corpus. There are many ways to present one question, and it is impossible to handle them without understanding the entailment relations behind the predicates. Previous works on analyzing entailment mainly focus on Recognizing Textual Entailment (RTE) between pairs of sentences, and many recent attempts have achieved quite promising performance in detecting entailment relations using transformer-based language models (He et al., 2020; Raffel et al., 2020; Schmitt and Schütze, 2021b).

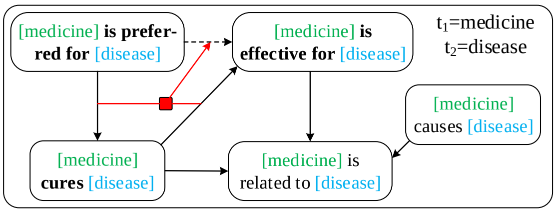

Figure 1: A simple example of entailment graph with types *medicine* and *disease*. The dashed line represents a missing entailment recovered by considering the transitivity constraint (red) based on the two premise entailment between three **boldfaced** predicates.

By modeling typed predicates as nodes and entailment relations as directed edges, the **Entailment Graph** (**EG**) is a powerful and well-established form to represent the context-independent entailment relations between predicates and reflect the global features of entailment inference, such as paraphrasing and transitivity. As EGs are able to help reasoning without additional context or resource, they can be seen as a special type of structural knowledge in natural language. Figure 1 shows an excerpt entailment graph about two types of arguments, *Medicine* and *Disease*. Generally speaking, an entailment graphs can be built based on a three-step process: **extracting** predicate pairs from a corpus, building **local** graphs with locally computed entailment scores, and modifying the graphs with **global** methods.

However, existing EG construction methods still face challenges in both local and global stages. The Distributional Inclusion Hypothesis (DIH) about entailment assumes that given a predicate (rela-

Volume 1: Long Papers, pages 5899 - 5910

tion) p, it can be replaced in any context by another predicate (relation) q if and only if p entails q (Geffet and Dagan, 2005). Most local methods in previous works are guided by DIH, thus rely on the distributional co-occurrences from corpora, including named entities, entity pairs and context, as features to compute the *local* entailment scores. Since different predicate pairs are processed independently, the locally built graphs suffer from severe **data sparsity**. That is, there are many entailment relations missing (as edges) in the graphs if the predicate pairs do not co-occur in the corpus. Furthermore, predictions from local models may not be coherent with each other, for example, a local model may output three predictions like, a *entails* b, b *entails* c and c *entails* a at the same time, which actually indicate possible errors among the local predictions.

To overcome the challenges faced by local models, different global approaches are used to take the interactions and dependencies between entailment relations into consideration. The first discussed global dependency is the logical *transitivity* among different predicates, that is, predicate a entails predicate c if there is another predicate b making both "a entails b" and "b entails c" hold simultaneously. Berant et al. (2011) uses the Integer Linear Programming (ILP) to ensure the transitivity constraints on the entailment graphs, which is , unfortunately, not scalable on large graphs with thousands of nodes. Hosseini et al. (2018) models the structural similarity across graphs and paraphrasing relations within graphs to learn the global consistency, but does not gain further improvement due to the lack of **high-quality local graphs** and proper **transitivity** modeling.

In order to deal with the problems in the local and global stages, we propose a novel entailment graph learning approach, **E**ntailment **G**raph with **T**extual Entailment and **T**ransitivity (**EGT2**). EGT2 builds high-quality local entailment graphs by inputting predicates as sentences into a transformer-based language model fine-tuned on an RTE task to avoid the unreliability of distributional scores, and models the global transitivity on these scores through carefully designed soft constraint losses, which alleviate the data sparsity and are feasible on large-scale local graphs. Our key insight is that the entailment relation $a \rightarrow c$ correctly implied by the transitivity constraint is based on two conditions: (1) the appropriate constraint scalable on large graphs containing rich information, and (2) the reliability of local graphs offering the premise $a \rightarrow b$ and $b \rightarrow c$, which is impractical for previous distributional approaches, but may be available for the models well-behaved on RTE tasks. Specifically, the input sentences fed to transformer-based language models are formed without context, which makes our method accessible to those predicates not appearing in the corpus. The transitivity implication is confined to entailment relations with high confidence, which improves the quality of implied edges and cuts down the computational overheads. In a word, this paper makes the following contributions:

- we present a novel approach based on textual entailment to scoring predicate pairs on local entailment graphs, which is reliable without distributional features and valid for arbitrary predicate pairs.
- we present three carefully designed global soft constraint loss functions to model the transitivity among entailment relations on large entailment graphs, thus alleviate the data sparsity issue of previous local approaches.
- we evaluate our method on benchmark datasets, and show that our EGT2 significantly outperforms previous entailment graphs construction approaches. The further analysis proves that our local and global approaches are both useful for learning entailment graphs.

2 Related Work

Based on DIH, previous works extract feature vectors for typed predicates to compute the local distributional similarity. The set of entity argument pair strings, like *"Griseofulvin-infection"* in the example of Section 1, are used as the features weighted by Pointwise Mutual Information (Berant et al., 2015; Hosseini et al., 2018). Given the feature vectors for a predicate pair, different similarity scores, like cosine similarity, Lin (Lin, 1998), DIRT (Lin and Pantel, 2001), Weeds (Weeds and Weir, 2003) and Balanced Inclusion (Szpektor and Dagan, 2008), are calculated as the local similarities. Hosseini et al. (2019) and Hosseini et al. (2021) use Markov Chain on an entity-predicate bipartite graph weighted by link prediction scores to calculate the transition probability between two predicates as the local score. They rely on the link predication model to generate the features in fact. Guillou et al. (2020) adds temporal information into entailment graphs by extracting entity pairs within a limited temporal window as predicate features. McKenna et al. (2021) extends the graphs to include entailment relations between predicates with different numbers of arguments by splitting the features from argument pairs into independent entity slots, which impairs the representation ability of features when unary predicates are involved.

As mentioned in Section 1, entailment graphs are generally learned by imposing global constraints on the local entailment relations about extracted predicates. The transitivity in entailment graphs is modeled by the Integer Linear Programming (ILP) in Berant et al. (2011), which selects a transitive sub-graph of a local weighted graph to maximize the summation over the weights of its edges. Their work is limited to a few hundreds of predicates due to the computational complexity of ILP. For better scalability, Berant et al. (2012) and Berant et al. (2015) make a strong FRG-assumption that *if predicate* a *entails predicates b and c, b and c entail each other*, and an approximation method, called Tree-Node-Fix (TNF). Obviously, the assumption is too strong to be satisfied by real cases.

Since the hard constraints are difficult to work well on large-scale entailment graphs, Hosseini et al. (2018) propose two global soft constraints that maintain the similarity between paraphrasing predicates within typed graphs and between predicates with the same names in graphs with different argument types. Their soft constraints are also used in Hosseini et al. (2019) and Hosseini et al. (2021). The similarity between paraphrasing predicates, which ensures $(a \rightarrow c) \odot (b \rightarrow c)$ and $(c \rightarrow a) \odot (c \rightarrow b)$ when $a \leftrightarrow b$, implicitly takes the transitivity between paraphrasing predicates and third predicate into consideration. But it ignores the transitivity in more common cases, and leads to a limited improvement on performance.

Meanwhile, the transformer-based Language Model (LM), although proved to be effective in RTE tasks (He et al., 2020; Raffel et al., 2020; Schmitt and Schütze, 2021b), has received less attention in entailment graph learning. Schmitt and Schütze (2021a) uses pretrained LM on the Lexical Inference in Context (LIiC) task, which is closely related to entailment graph learning. Hosseini et al. (2021) uses pretrained BERT to initialize the contextualized embeddings in their contextualized link prediction and entailment score calculation. Higher scores are assigned to the entailed predicates in the context of their premises, which is one implicit expression form of DIH and different from our direct utilization of LM on textual entailment.

3 Our Method: EGT2

3.1 Definition and Notations

The goal of entailment graph learning is to extract predicates, learn the entailment relations and build entailment graphs from raw text corpora. Following previous works (Hosseini et al., 2018, 2019), we use the binary relations from neo-Davisonian semantics as predicates, which is a type of first-order logic with event identifiers. For instance, with the semantic parser (here, GraphParser (Reddy et al., 2014)), the sentence:

"Griseofulvin is preferred for the infection."

can be transformed into the logical form

$$\exists e.prefer_2(e, Griseofulvin) \cap prefer_{for}(e, infection)$$

where e denotes an event. By considering a relation for each pair of extracted arguments, this sentence refers to one predicate, $p =$ *(prefer.2,prefer.for.2,medicine,disease)* [2]. Likely, the sentence *"Griseofulvin cures the infection."* contains $q =$ *(cure.1,cure.2,medicine,disease)*. Formally, a predicate with argument types t_1 and t_2 is represented as $p = (w_{p,1}.i_{p,1}, w_{p,2}.i_{p,2}, t_1, t_2)$. The event-based predicate form is strong enough to describe most of the relations in real cases (Parsons, 1990).

With T as the set of types and P as the set of all typed predicates, $V(t_1, t_2)$ contains typed predicates p with unordered argument types t_1 and t_2, where $p \in P$ and $t_1, t_2 \in T$. For predicate $p = (w_{p,1}.i_{p,1}, w_{p,2}.i_{p,2}, t_1, t_2)$, we denote that $\tau_1(p) = t_1$, $\tau_2(p) = t_2$ and $\pi(p) = (w_{p,1}.i_{p,1}, w_{p,2}.i_{p,2})$. In other words, $V(t_1, t_2) = \{p | (\tau_1(p) = t_1 \wedge \tau_2(p) = t_2) \vee (\tau_1(p) = t_2 \wedge \tau_2(p) = t_1)\}$.

A typed entailment graph $G(t_1, t_2) =< V(t_1, t_2), E(t_1, t_2) >$ is composed of the nodes of typed predicates $V(t_1, t_2)$ and the weighted edges $E(t_1, t_2)$. The edges can be also represented as sparse score matrix $W(t_1, t_2) \in [0, 1]^{|V(t_1,t_2)| \times |V(t_1,t_2)|}$, containing the entailment scores between predicates with type t_1 and t_2. As

---

[2] The numbers after the predicate words are corresponding argument positions of entity *"Griseofulvin"* (second argument of *prefer*) and *"infection"* (second argument of the preposition *for*), and the later two items are the types of arguments.

Table 1: Examples of sentence generator S.

Predicates	Sentences
(be.1,be.capital.of.2,location$_1$,location$_2$)	Location A is capital of Location B.
(contain.1,contain.2,location$_2$,location$_1$)	Location B contains Location A.
(prefer.2,prefer.for.2,medicine,disease)	Medicine A is preferred for Disease B.
(give.2,give.3,person,thing)	Person A is given Thing B.
(aggrieved.by.2,aggrieved.felt.1,thing,person)	Person B feels aggrieved by Thing A.

the different argument types can naturally determine whether two predicates have the same order of arguments, the order of argument type is not important while $t_1 \neq t_2$, and therefore we can ensure that $G(t_1, t_2) = G(t_2, t_1)$. For those predicates p with $\tau_1(p) = \tau_2(p)$, the two argument types are labeled with orders, which allows the graph to contain the entailment relations with different argument orders, like *(be.1,be.capital.of.2,location$_1$,location$_2$)* $\rightarrow$ *(contain.1,contain.2,location$_2$,location$_1$)*.

3.2 Local Entailment based on Textual Entailment

Inspired by the outstanding performance of pretrained and fine-tuned LMs on RTE task, which is closely related to the entailment graphs, EGT2 uses fine-tuned transformer-based LM to calculate the local entailment scores of typed predicated pairs.

In order to utilize the knowledge about entailment relations in pretrained and fine-tuned LM, EGT2 firstly transfers the predicate pair (p, q) into corresponding sentence pair $(S(p), S(q))$ by sentence generator S, as the complicated predicates cannot be directly input into the LM. For typed predicate $p = (w_{p,1}.i_{p,1}, w_{p,2}.i_{p,2}, t_1, t_2)$, the generator deduces the positions of arguments about the predicate based on $i_{p,1}$ and $i_{p,2}$, generates the surface form of p based on $w_{p,1}$ and $w_{p,2}$, and finally concatenates the surface form with capitalized types as its arguments. Some generated examples are shown in Table 1, and the detailed algorithm of S is described in Appendix A.

After generating sentence pair $(S(p), S(q))$ for predicate pair (p, q), EGT2 inputs $(S(p), S(q))$ into a transformer-based LM to calculate the probability of the entailment relation $p \rightarrow q$ as the local entailment score in $G(t_1, t_2)$. In our experiments, the LM is implemented as DeBERTa (He et al., 2020). Generally, an entailment-oriented LM will output three scores for a sentence pair, representing the probability of relationship *entail*, *contradict* and *neutral* respectively. Formally, we denote the weighted matrix of local entailment graph with type t_1 and t_2 as W^{local}, and the weight of the edge between p and q in W^{local} is calculated as:

$$\begin{gathered} W^{local}_{p,q} = P(p \rightarrow q) \in [0, 1], \\ P(p \rightarrow q) = \frac{e^{LM(entail|p,q)}}{\sum_{r \in \{entail, contradict, neutral\}} e^{LM(r|p,q)}}, \end{gathered} \tag{1}$$

where $LM(r|p, q)$ is the output score of corresponding relationship by the LM. As the local entailment is based on the LM fine-tuned to perform textual entailment, the local graph can be built for any predicates in the parsed semantic form, or in any other forms by changing sentence generator S.

3.3 Global Entailment with Soft Transitivity Constraint

Existing approaches use global learning to find correct entailment relations which are missing or underestimated in local entailment graphs to overcome the data sparsity. Following Hosseini et al. (2018), the evidence from existing local edges with high confidence is used by EGT2 to predict missing edges in the entailment graphs.

The *transitivity* in entailment relation inference implies $a \rightarrow c$ while both $a \rightarrow b$ and $b \rightarrow c$ hold. For instance, in the example of Figure 1, the entailment *"is preferred for"* $\rightarrow$ *"is effective for"* is discovered because *"is preferred for"* $\rightarrow$ *"cures"* and *"cures"* $\rightarrow$ *"is effective for"* have been learned. The key challenge to incorporate the transitivity constraint into weighted graphs is discreteness of logical rules. Discreteness makes the rules impossible to be directly used in gradient-based learning methods without NP-hard complexity, as different predicate pairs are jointly involved in the calculation. To unify the discrete logical rules with gradient-based learning, inspired by Li et al. (2019), EGT2 uses the logical constraints in the form of differentiable triangular norms (Gupta and Qi, 1991; Klement et al., 2013), or called t-norms, as the

$$\begin{aligned}
L_1 &= -log \prod_{\substack{a,b,c\in V(t_1,t_2),\\ W_{a,b},W_{b,c}>1-\epsilon}} \min(1,\frac{W_{a,c}}{W_{a,b}W_{b,c}}) \\
&= \sum_{a,b,c\in V(t_1,t_2)} I_{1-\epsilon}(W_{a,b})I_{1-\epsilon}(W_{b,c})ReLU(logW_{a,b}+logW_{b,c}-logW_{a,c}) \\
L_2 &= \sum_{a,b,c\in V(t_1,t_2)} -I_{1-\epsilon}(W_{a,b})I_{1-\epsilon}(W_{b,c})I_0(W_{a,b}W_{b,c}-W_{a,c})logW_{a,c} \\
L_3 &= \sum_{a,b,c\in V(t_1,t_2)} -I_{1-\epsilon}(W_{a,b})I_{1-\epsilon}(W_{b,c})I_0(W_{a,b}W_{b,c}-W_{a,c})W_{a,b}W_{b,c}logW_{a,c}
\end{aligned} \tag{2}$$

soft constraints so that the gradient-based learning methods can be applied.

Different t-norm methods transfer the discrete rules into different continuous loss functions. Traditional product t-norm maps $P(A \wedge B)$ into $P(A)P(B)$, $P(A \vee B)$ into $P(A) + P(B) - P(A)P(B)$, and $P(A \rightarrow B)$ into $\min(1, \frac{P(B)}{P(A)})$. For the entailment relations, the probability of transitivity to be satisfied is:

$$\begin{aligned}
&P[(a \rightarrow b \wedge b \rightarrow c) \rightarrow (a \rightarrow c)] \\
&= \min(1, \frac{W_{a,c}}{W_{a,b}W_{b,c}}),
\end{aligned} \tag{3}$$

where the probability of the entailment relation $a \rightarrow b$ is represented by the local entailment scores $W_{a,b}$. To alleviate the noise from those edges assigned low confidence by local LM, EGT2 only takes the local edges whose scores are higher than $1-\epsilon$ into account (as $a \rightarrow b$ and $b \rightarrow c$), where ϵ is a small hyper-parameter because the local probability scores tend to be close to 0 or 1 in practice. Therefore, to maximize the probability of transitivity constraint satisfied over all predicates in the entailment graph $G(t_1, t_2)$, EGT2 tries to minimize the following minus-log-likelihood loss function L_1 in Eq. 2, where $I_y(x) = 1$ if $x > y$, or 0 otherwise.

Another important t-norm, called the Gödel t-norm, maps $P(A \rightarrow B)$ into 1 if $P(B) \geq P(A)$ or $P(B)$ otherwise. Therefore, the Gödel probability of transitivity to be satisfied is:

$$\begin{aligned}
&P[(a \rightarrow b \wedge b \rightarrow c) \rightarrow (a \rightarrow c)] \\
&= \begin{cases} W_{a,c} & W_{a,b}W_{b,c} > W_{a,c} \\ 1 & otherwise \end{cases},
\end{aligned} \tag{4}$$

and EGT2 similarly tries to minimize the loss function L_2 in Eq. 2. It should be noted that transitivity constraints will be disobeyed not only by the missing edges, but also by the spurious edges in the local graphs. Therefore, we expect the soft constraints to take reducing the weights of premise edges into consideration. L_1 achieves this by the loss item $W_{a,b}$ and $W_{b,c}$, and we modify L_2 to L_3 in Eq. 2 so that the low confidence of $W_{a,c}$ will help to detect whether $W_{a,b}$ and $W_{b,c}$ are spurious. Our t-norm soft constraints, although do not guarantee the obedience of transitivity, are effective approximations for the transitivity property.

Given the local entailment graph $G(t_1, t_2)$ with weighted edges W^{local}, in order to ensure that the global entailment graph W is not too far from W^{local}, EGT2 finally minimizes the following loss function L to trade off the distance from local graphs and the soft transitivity constraint:

$$L = \sum_{a,b\in V} (W_{a,b} - W_{a,b}^{local})^2 + \lambda L_i,\ i = 1,2,3 \tag{5}$$

where L_i is the specified implementation of soft transitivity constraint in Eq. 2, and λ is a non-negative hyper-parameter that controls the influence of two loss terms.

4 Experimental Setup

4.1 Predicate Extraction

Following Hosseini et al. (2018) and Hosseini et al. (2019), we use the multiple-source NewsSpike corpus (Zhang and Weld, 2013), which contains 550K news articles, to extract binary relations as generated predicates in EGT2. We make use of the triples released and filtered in Hosseini et al. (2019), which applies GraphParser (Reddy et al., 2014) based on Combinatorial Categorial Grammar (CCG) syntactic derivations to extracting binary relations between predicates and arguments. The argument entities are linked to Freebase (Bollacker et al., 2008) and mapped to the first level of FIGER types (Ling and Weld, 2012) hierarchy. The type of a predicate is determined by its two corresponding argument entities. The triples are filtered by two rules to remove the noisy binary relations and arguments: (1) we only keep those argument-pairs appearing in at least 3 relations; (2) we only keep those relations with at least 3 different argument-pairs. The number of relations in the corpus is reduced from 26M to 3.9M, covering 304K typed predicates in 355 typed entailment graphs. Only those predicate pairs co-occurring with at least one same entity-pair (e.g., *Griseofulvin-infection*) will be linked to calculate the local scores, and as a result, our local predicate pairs are identical with Hosseini et al. (2019). As we focus on using global models to alleviate the sparsity of local edges, more potential methods to extracting denser local edges will be studied in our future research.

4.2 Evaluation Datasets and Metrics

We use Levy/Holt Dataset (Levy and Dagan, 2016; Holt, 2018) and Berant Dataset (Berant et al., 2011) to evaluate the performance of entailment graph models.

In Levy's dataset, each example contains a pair of triples with the same entities but different predicates. Some questions with one predicate were shown to the annotating workers, like *"Which medicine cures the infection?"*. The label for each example are either *True* or *False*, indicating whether the first typed predicate entails the second one, by asking the workers whether the first predicates can answer the question with the second one. For example, if *"Griseofulvin is preferred for the infection"* is a correct answer of the above question, the dataset labels *"is preferred for"* → *"cures"*. Holt (2018) re-annotates Levy's dataset and forms a new dataset with 18,407 examples (3,916 positive and 14,491 negative), referred as Levy/Holt Dataset. The dataset is split into validation set (30%) and test set (70%) as Hosseini et al. (2018) in our experiments.

Berant et al. (2011) annotates all the entailment relations in their corpus, which generates 3,427 positive and 35,585 negative examples, referred as Berant Dataset. Their entity types do not exactly match with the first level of FIGER types hierarchy, and therefore a simple hand-mapping by Hosseini et al. (2018) is used to unify the predicate types.

To be comparable with previous works, we evaluate our methods on the test set of Levy/Holt Dataset and the whole Berant Dataset by calculating the area under the curves (AUC) with changing the classification threshold of global entailment scores. Hosseini et al. (2018) argues that the AUC of Precision-Recall Curve (PRC) for precisions in the range $[0.5, 1]$, as predictions with higher precision than *random* are more important for the downstream applications. Therefore, we report both the AUC of PRC for precisions in the range $[0.5, 1]$ and the traditional AUC of ROC, which is more widely used in evaluation of other tasks.

4.3 Comparison Methods

We compare our model with existing entailment graph construction methods (Berant et al., 2011; Hosseini et al., 2018, 2019, 2021) and the best local distributional method, Balanced Inclusion (Szpektor and Dagan, 2008) , referred as BInc. We also include ablation variants of our EGT2, including local models with or without fine-tuning.

4.4 Implementation Details

For local transformer-based LM, EGT2 uses DeBERTa (He et al., 2020) implemented by the Hugging Face transformers library (Wolf et al., 2019)[3], which has been fine-tuned on MNLI (Williams et al., 2018) dataset. In order to adapt it to the special type-oriented sentence pattern generated by S, we expand the validation set by extracting all of the predicates, generating sentence pairs by generator S for every two predicates, and checking whether they are labeled as paraphrase or entailment in the Paraphrase Database collection (PPDB) (Pavlick et al., 2015). We split 80% of the generated corpus to fine-tune the DeBERTa with Cross-Entropy Loss, and the rest as the validation set of fine-tuning process. The fine-tuning learning rate $\alpha_f = 10^{-5}$, and the process is terminated while the F_1 score of *entail* on validation set does not increase in 10 epochs or training after 100 epochs.

For global soft transitivity constrains, we use SGD (Cun et al., 1998) to optimize the scores W in entailment graphs with loss function L in Eq. 5 for $e = 5$ epochs. The SGD learning rate $\alpha = 0.05$, the coefficient $\lambda = 1$, and the confidence threshold $\epsilon = 0.02$. The hyper-parameters are selected based on Levy/Holt validation dataset. More implementation details are given in Appendix B.

For testing, if one or both predicates of the example do not appear in the corresponding typed entailment graph, we handle the example as un-

---

typed one by resorting to its average score among all typed entailment graphs. This setting is also used for all local and global methods in the experiments for fair comparison.

5 Experiment Results and Discussion

5.1 Main Results

We summarize the model performances on both Levy/Holt and Berant datasets in Table 2. All global methods, including Hosseini et al. (2018), Hosseini et al. (2019) and EGT2, perform better than their corresponding local methods, which demonstrates the effect of global constraints in alleviating the data sparsity. Although using the same extracted entailment relations with Hosseini et al. (2019), our EGT2-Local significantly outperforms previous local methods because of the high-quality entailment scores generated by reliable fine-tuned textual entailment LM. On the whole, EGT2 with transitivity constraint L_3 outperforms all the other models on both Levy/Holt Dataset and Berant Dataset with AUC of PRC, while EGT2-L_1 performs best with AUC of ROC. All of three soft transitivity constraints boost the performance of local model on all evaluation metrics, which shows that making use of transitivity rule between entailment relations improves the local entailment graph. EGT2-L_1 or EGT2-L_3 performs better than EGT2-L_2, which indicates that involving the premises $a \rightarrow b$ and $b \rightarrow c$ into loss function is also important for using transitivity constraints.

The Precision-Recall Curves of different methods and the Precision-Recall Point of Berant et al. (2011) on the two evaluation datasets are shown in Figure 2(a) and 2(b) respectively. The local and global models of EGT2 consistently outperform previous state-of-the-art methods on all levels of precision and recall, which indicates the effect of our local model based on textual entailment and global soft constraints based on transitivity. The EGT2-Local achieves slightly higher precision than global models in the range $recall < 0.5$, but its precision drops quickly if we require higher recall and therefore leads to worse performance than global models. The result indicates that global models with transitivity constraints gain significant improvement on recall with far less expense on precision than EGT2-Local.

5.2 How the local model fine-tuning works?

As described in Section 4.4, a new corpus is generated for fine-tuning the local model. We claim that the fine-tuning corpus helps to improve the performance of EGT2-Local by adapting it to the special sentence pattern by S, rather than offering additional data to fit the distribution of target datasets as traditional training datasets do. To prove this, we also test a simple supervised method, labelled as Local-Sup, which fits a 2-layers feedforward neural network on the fine-tuning corpus with cosine similarity, Weed, Lin and BInc scores as features. If the corpus acts as training dataset, the performance of Local-Sup should be obviously better than its unsupervised features.

As shown in Table 2, Local-Sup does not perform significantly better on Levy/Holt Dataset, and even worse on Berant Dataset than BInc, which is one of the inputting features of Local-Sup. The result illustrates the difference between the fine-tuning corpus and the evaluation datasets, and shows that the corpus plays a role as pattern adapting corpus rather than training dataset.

5.3 Why are global constraints helpful?

In Section 1, we expect that the improvement of soft transitivity constraints is attributed to the alleviation of data sparsity in corpus. To examine the sparsity before and after the applying of transitivity constraints, we count how many the positive and negative entailment relations in the Levy/Holt test set exactly appear in the local and global entailment graph respectively, and show the counting results in Table 3. All three soft transitivity constraints help to find more entailment relations than

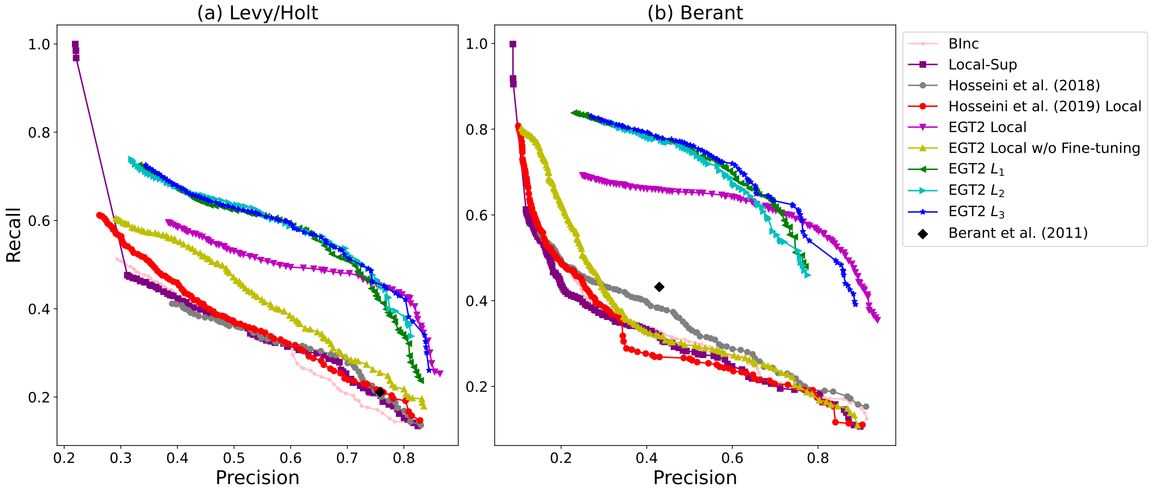

Figure 2: The Precision-Recall Curves of different methods on (a) Levy/Holt Dataset and (b) Berant Dataset. The result of Berant et al. (2011) is shown as a point, as they generate entailment graphs without weight.

Table 3: The number of testing examples appearing in entailment graphs learnt by corresponding models.

Methods	Positive #	Negative #
EGT2-Local	378	75
EGT2-L_1	642	174
EGT2-L_2	783	277
EGT2-L_3	685	190

Table 4: Model performance on the directional section of Levy/Holt Dataset.

Methods	PRC	ROC
BInc	.038	.567
Hosseini18	.038	.564
Hosseini19-Local	.040	.579
EGT2-Local	.176	.654
EGT2-L_3	.171	.696

local entailment graph and therefore achieve better performance on the evaluation datasets. Although EGT2-L_2 finds the most entailment relations in the dataset in global stage, it finds more negative examples concurrently and thus performs worse than L_1 and L_3 as shown in Table 2. On the other hand, EGT2-L_1 and EGT2-L_3 obtain more proportions of positive examples by considering premise relations during the gradient calculation. The low confidence of hypothesis relationship $W_{a,c}$ should be helpful to detect spurious premises $W_{a,b}$ and $W_{b,c}$. Therefore, EGT2-L_3 slightly outperforms EGT2-L_1 as the gradients of $W_{a,b}$ and $W_{b,c}$ in L_3 are related to the hypothesis relationship $W_{a,c}$.

We have also applied the soft transitivity constraints on the local graph with BInc and Hosseini et al. (2019), but observed only slightly improvement of performance, as .155 → .157 and .167 → .170 for EGT2-L_3 on PRC of Levy/Holt Dataset respectively. Comparing it with the significant improvement based on EGT2-Local, we claim that the high-quality local entailment graphs are the basis of effective soft transitivity constraints.

The previous cross-graph soft constraint and paraphrase resolution soft constraint proposed in Hosseini et al. (2018) have shown improvement of performance based on their local graphs. However, due to the distinct distribution and scales of local scores, their constraints are computationally unavailable on our local graphs , partially due to the high overhead for cross-graph calculation.

5.4 Does EGT2 learn directional entailment?

Generally, the logical entailment should be directional which makes it different from *paraphrase*. Although EGT2 significantly improves the performance on two datasets, it is unclear whether the improvement comes from the directional entailment cases, or only paraphrasing ones, as the local LM might be strong in recognizing paraphrases but weak in recognizing directional entailment (Cabezudo et al., 2020). To examine how EGT2 works under directional cases, we eliminate those paraphrase predicate pairs $a \rightarrow b$ with label $l \in \{True, False\}$ from Levy/Holt test dataset, if the corresponding $b \rightarrow a$ is also appearing and labelled as l in the test dataset. The rest directional section of Levy/Holt Dataset contains 8,140 examples (753 positive and 7,387 negative). We expect that this section should be more challenging as undirectional paraphrase becomes unavailable.

We report the model performance on the directional section of Levy/Hold Dataset in Table 4. We can see that previous baselines do not perform well on AUC of PRC, which indicate that it is difficult for them to reach $precision > 0.5$. Meanwhile, EGT2-Local and EGT2-L_3 outperform all baselines on the directional section of Levy/Holt Dataset. Unsurprisingly, all models' AUC scores on the directional section become lower compared on the original Levy/Holt Dataset, showing the challenges of directional entailment inference. Two EGT2 variants maintain high performance, which proves that our local model can learn to capture directional predicate entailment better than distributional baselines, and the global soft constraint also helps to make directional entailment inference.

5.5 Error Analysis

We randomly sample and analyze 100 false positive (FP) examples and 100 false negative (FN) examples from Levy/Holt test set according to predictions by EGT2-L_3. We manually setup the decision threshold as 0.574 to make the precision level close to 0.76, which is the same as Berant et al. (2011). The major error types are shown in Table 5. Although the global constraint is used, about half of FN errors are due to the data sparsity where the entailment relations are not found in the entailment graph. When compared with the results in Hosseini et al. (2018), EGT2-L_3 reduces the ratio of *Sparsity* in FN errors from 93% to 46% with stronger alleviation ability of data sparsity. About a quarter of FN are caused by the *Under-weighted Relations* in the graph, where EGT2 finds the entailment relations but gives them scores lower than the threshold. The rest of FN are related to *Dataset Wrong Labels* which happens when the predicates are indeed entailed by others but labelled as negative, or the predicate pairs are incomplete.

Most of FP errors are caused by the *Spurious Correlation* as these relations are too fraudulent for EGT2 to see through their spurious relationships and consequently given high scores. A few FP errors are caused by *Lemma-based Processing* in LM inevitably, but the ratio still reduces from 12% in Hosseini et al. (2018) to 5%. The result indicates that our fine-tuned LM can handle the predicates even with similar surface forms and contexts better than parsing-based distributional local features.

Table 5: The major error types of false positive and false negative predictions by EGT2-L_3 in Levy/Holt test set, with predicted scores in the parentheses.

Error Types	**Examples**
False Negative	
Sparsity (46%)	Pain relieves by application of Chloroform. → Chloroform reduces pain. (0.0)
Under-weighted Relations (23%)	The Druids build the Stonehenge. → The Druids construct the Stonehenge. (0.558)
Dataset Wrong Labels (31%)	Salicylates reduces pain. → Salicylates is given for pain. (0.034)
False Positive	
Spurious Correlation (68%)	The cat sleeps on a fur. → The cat has a fur. (0.683)
Lemma-based Process (5%)	Lincoln comes to New York. → Lincoln comes from New York. (0.867)
Dataset Wrong Labels (27%)	The lamps are made of metal. → The lamps are made of metal. (1.0)

6 Conclusions

In this paper, we propose a novel typed entailment graph learning framework, EGT2, which uses language models fine-tuned on textual entailment tasks to calculate local entailment scores and applies soft transitivity constraints to learn global entailment graphs in gradient-based method. The transitivity constraints are achieved by carefully designed loss functions, and effectively boost the quality of local entailment graphs. By using the fine-tuned local LM and global soft constraints, EGT2 does not rely on distributional features, and can be easily applied to large-scale graphs. Experiments on standard benchmark datasets show that EGT2 achieves significantly better performance than existing state-of-the-art entailment graph methods.

```

B Additional Implementation Details

We select the SGD learning rate α from $\{0.02, 0.05, 0.1\}$, the number of training epochs from $\{2, 3, 5, 7\}$, the coefficient λ from $\{0.5, 1, 2\}$, and the confidence threshold ϵ from $\{0.005, 0.01, 0.02\}$. We manually tune the hyper-parameters based on the AUC of PRC on Levy/Holt validation dataset, which is .327 corresponding to our settings.

Under our experiment settings, one training epoch costs about 4 hours on an NVIDIA A40 GPU.

Logic Traps in Evaluating Attribution Scores

Abstract

Modern deep learning models are notoriously opaque, which has motivated the development of methods for interpreting how deep models predict. This goal is usually approached with attribution method, which assesses the influence of features on model predictions. As an explanation method, the evaluation criteria of attribution methods is how accurately it reflects the actual reasoning process of the model (faithfulness). Meanwhile, since the reasoning process of deep models is inaccessible, researchers design various evaluation methods to demonstrate their arguments. However, some crucial logic traps in these evaluation methods are ignored in most works, causing inaccurate evaluation and unfair comparison. This paper systematically reviews existing methods for evaluating attribution scores and summarizes the logic traps in these methods. We further conduct experiments to demonstrate the existence of each logic trap. Through both theoretical and experimental analysis, we hope to increase attention on the inaccurate evaluation of attribution scores. Moreover, with this paper, we suggest stopping focusing on improving performance under unreliable evaluation systems and starting efforts on reducing the impact of proposed logic traps.

1 Introduction

The opaqueness of deep models has grown in tandem with their power (Doshi-Velez and Kim, 2017), which has motivated efforts to interpret how these black-box models work (Sundararajan et al., 2017; Belinkov and Glass, 2019). Post-hoc explanation aims to explain a trained model and reveal how the model arrives at a decision (Jacovi and Goldberg, 2020; Molnar, 2020). This goal is usually approached with attribution method, which assesses the influence of features on model predictions as shown in Figure 1. Recent years have witnessed an increasing number of attribution methods being developed. For example, Erasure-based method calculate attribution scores by measuring the change of output after removing target features (Li et al., 2016; Feng et al., 2018; Chen et al., 2020); Gradient-based method uses gradients to study the influence of features on model predictions (Sundararajan et al., 2017; Wallace et al., 2019; Hao et al., 2020); Meanwhile, these methods also received much scrutiny, arguing that the generated attribution scores are fragile or unreliable (Alvarez-Melis and Jaakkola, 2018; Pruthi et al., 2020; Wang et al., 2020; Slack et al., 2020).

Figure 1: An example of attribution explanations, which assesses the influence of each token on the predictions of a binary sentiment classification task. The saturation of the colors signifies the magnitude of the influence.

As an explanation method, the evaluation criteria of attribution methods should be how accurately it reflects the true reasoning process of the model (faithfulness), not how convincing it is to humans (plausibility) Jacovi and Goldberg (2020). Meanwhile, since the reasoning process of deep models is inaccessible, researchers design various evaluation methods to support their arguments, some of which appear valid and are widely used in the research field. For example, *meaningful perturbation* is used for making comparison in many works (Samek et al., 2016; Chen et al., 2019; DeYoung et al., 2020; Chen et al., 2020; Kim et al., 2020). The philosophy of *meaningful perturbation* is simple, i.e., modifications to the input instances, which are in accordance with the generated attribution scores, can bring about significant differences to model predictions if the attribution scores are faithful to the target system.

However, some crucial logic traps existing in these evaluation methods are ignored in most

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 5911 - 5922
May 22-27, 2022

works, causing inaccurate evaluation and unfair comparison. For example, we found that we can manipulate the evaluation results when using *meaningful perturbation* to make comparisons: by choosing the modification strategy, we can assign any of the three candidate attribution methods as the best method. The neglect of these traps has damaged the community in many aspects: First, the existence of logic traps will lead to an inaccurate evaluation and unfair comparison, making the conclusions unreliable; Second, the wide use of evaluation metrics with logic traps brings pressure to newly proposed works, requiring them to compare with other works using the same metrics; Last, the over-belief in existing evaluation metrics encourages efforts to propose more accurate attribution methods, notwithstanding the evaluation system is unreliable.

In this paper, we systematically review existing methods for evaluating attribution scores and categorize them into classes. We summarize the logic traps in these methods and further conduct experiments to demonstrate the existence of each logical trap. Though strictly accurate evaluation metrics for attribution methods might be a “unicorn” which will likely never be found, we should not just ignore logic traps in existing evaluation methods and draw conclusions recklessly. Through both theoretical and experimental analysis, we hope to increase attention on the inaccurate evaluation of attribution scores. Moreover, with this paper, we suggest stopping focusing on improving performance under unreliable evaluation systems and starting efforts on reducing the impact of proposed logic traps.

2 Evaluation Methods and Corresponding Logic Traps

2.1 Part I

Evaluation 1: Using Human Annotated Explanations As the Ground Truth

Evaluation 1 verifies the validity of the attribution scores by comparing them with the human problem-solving process. In this evaluation, works (e.g., Murdoch et al. (2018); Kim et al. (2020); Sundararajan et al. (2017)) often give examples consistent with human understandings to demonstrate the superiority of their proposed method. For example, as shown in Table 1, Murdoch et al. (2018) shows heat maps for a yelp review generated by different attribution techniques. They argue that the proposed method: Contextual decomposition, is better than others because only it can identify *‘favorite’* as positive and *‘used to be’* as negative, which is consistent with human understandings.

Method	Heat Map
Leave One Out	*used to be my favorite*
Integrated gradients	*used to be my favorite*
Contextual decomposition	*used to be my favorite*

Legend: Very Negative Negative Neutral Positive Very Positive

Table 1: Heat maps for a portion of a yelp review generated by different attribution techniques. The example and results are taken from Murdoch et al. (2018).

Furthermore, resorting to human-annotated explanations, works can also evaluate attribution methods quantitatively in evaluation 1. For example, the SST-2 (Socher et al., 2013) corpus provides not only sentence-level labels, but also five-class word-level sentiment tags ranging from very negative to very positive. Thus, many works (Lei et al., 2016; Li et al., 2016; Tsang et al., 2020; Kim et al., 2020) perform quantitative evaluation of attribution scores by comparing them with the word-level tags in SST-2.

Logic Trap 1: The decision-making process of neural networks is not equal to the decision-making process of humans.

First, we cannot completely deny the rationality of evaluation 1. Since many attribution methods work without any human-annotated information, such as erasure-based and gradient-based methods, the similarity between human-annotated explanations and generated attribution scores can be seen as drawing from the reasoning process of target models. However, since the deep model often rely on unreasonable correlations, even when producing correct predictions, attribution scores preposterous to humans may reflect the reasoning process of the deep model faithfully. Thus we cannot deny the validity of an attribution score through its inconsistency to human-annotated explanations and cannot use human-annotated explanations to conduct a quantitative evaluation.

Experiment 1:

In experiment 1, we give an example to demonstrate that the model might rely on correlations inconsistent with human understandings to get the prediction: though trained with questions, a question-answering model could maintain the same prediction for a large ratio of samples when the question information is missing, which is obviously different from humans.

We experiment on RACE (Lai et al., 2017), a large-scale question-answering dataset. As shown in Table 2, RACE requires the model to choose the right answer from candidate options according to the given question and document.

Document: *"...Many people optimistically thought industry awards for better equipment would stimulate the production of quieter appliances. It was even suggested that noise from building sites could be alleviated ..."*

Question: *What was the author's attitude towards the industry awards for quieter?*

Options:	A. suspicious	B. positive
	C. enthusiastic	D. indifferent

Table 2: An sample taken from RACE dataset.

We first train a model with BERT$_{base}$ (Devlin et al., 2019) as encoder[1] with questions, and achieve 65.7% accuracy on the development set. Then, we replace the development set questions with empty strings and feed them into the trained model. Surprisingly, the trained MRC model maintained the original prediction on 64.0% of the test set samples (68.4% on correctly answered samples and 55.4% on wrongly answered samples). Moreover, we analyze the model confidence change in these unchanged samples, where the probability on the predicted label is used as the confidence score. As shown in Figure 2, most of the samples have confidence decrease smaller than 0.1, demonstrating question information are not essential for the model to get predictions in these samples.

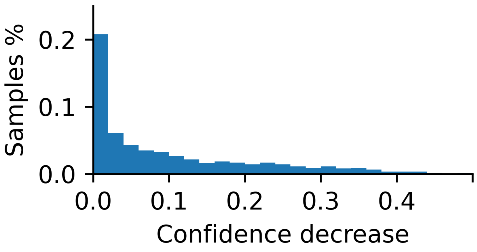

Figure 2: Confidence decrease in unchanged samples.

Since question information is usually crucial for humans to answer the question, attribution scores faithfully reflect the reasoning process of this model may be inconsistent with human annotations. Thus, it is improper to use human-annotation explanations as the ground truth to evaluate attribution methods.

2.2 Part II

Evaluation 2: Evaluation Based on Meaningful Perturbation

Most existing methods for quantitatively evaluating attribution scores can be summarized as evaluations based on *meaningful perturbation*. The philosophy of *meaningful perturbation* is simple, i.e., modifications to the input instances, which are in accordance with the generated attribution scores, can bring about significant differences to the target model's predictions if the attribution scores are faithful to the target model.

For example, Samek et al. (2016); Nguyen (2018); Chen and Ji (2020) use the area over the perturbation curve (AOPC) (Samek et al., 2016) as evaluation metrics. Specifically, given the attribution scores of a set of features, AOPC(k) modifies the top k% features and calculates the average change in the prediction probability as follows,

$$AOPC(K) = \frac{1}{N}\sum_{i=1}^{N}\left\{p(\hat{y}|x_i) - p(\hat{y}|\tilde{x}_i^{(k)})\right\}$$

where $\hat{y}$ is the predicted label, N is the number of examples, $p(\hat{y}|)$ is the probability on the predicted class, and $\tilde{x}_i^{(k)}$ is modified sample. Higher AOPCs is better, which means that the features chosen by attribution scores are more important; Feng et al. (2018); Petsiuk et al. (2018); Kim et al. (2020) use area under the curve (AUC) to evaluate attribution scores. As shown in Figure 3, AUC plots a prediction probability curve about modified feature numbers where features are modified in order of attribution scores. The argument is if attribution scores are faithful, then the curve will drop rapidly, resulting in a small area under a curve.

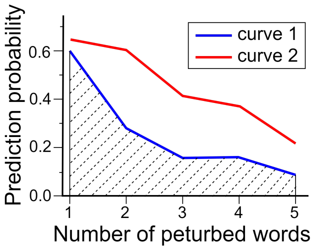

Figure 3: AUC evaluation metric. The smaller area under the curve, the better the result.

---

[1] Our implementations of experiment 1 and experiment 2 are based on the Huggingface's transformer model hub (`https://github.com/huggingface/transformers`), and we use its default model architectures without change for corresponding tasks.

Besides these works, a lot of works (Shrikumar et al., 2017; Chen et al., 2019; Nguyen, 2018; DeYoung et al., 2020; Chen et al., 2020; Hao et al., 2020; Jiang et al., 2021) use similar metrics to perform evaluation and comparisons. The main difference between evaluation metrics in these works is the difference in the modification strategy. For example, to evaluate word-level attribution scores for SST-2, Chen et al. (2020) uses deleting tokens as modification while Kim et al. (2020) uses replacing tokens with tokens sampled from the distribution inferred by BERT.

Logic Trap 2: Using an attribution method as the ground truth to evaluate the target attribution method.

Evaluation methods based on *meaningful perturbation* can be seen as an attribution method too. For example, AOPC(k), which assesses the importance of k% features, can be seen as an attribution method calculating an attribution score for k% features. Specifically, when using deleting tokens as modification and narrowing the k% to one token, AOPC(k) degenerates into the basic attribution method: **leave-one-out** (Li et al., 2016). Thus, evaluation 2 uses an attribution method as the ground truth to evaluate the target attribution method, which measures the similarity between two attribution methods instead of faithfulness.

Since *meaningful perturbation* assesses the importance of features by calculating output change after modifications, its results are mainly depend on how to conduct the modifications, which means different modification strategies might lead to different evaluation results. Evaluation 2 is widely used to compare attribution methods in the research field. Accordingly, the neglect of logic trap 2 has led to a high risk of unfair comparisons and unreliable conclusions.

Experiment 2:

In experiment 2, we give an example of unfair comparisons in evaluation 2: the more similar the target attribution method to the modification strategy, the better the evaluation results. Specifically, by modifying the modification strategies in APOC and AUC, we can assign any of the three candidate attribution methods as the best method. We conduct experiments on on widely used SST-2 task of the GLUE benchmark (Wang et al., 2019)), and use BERT$_{base}$ as encoder to build the target model[1] (achieve 86.4% accuracy).

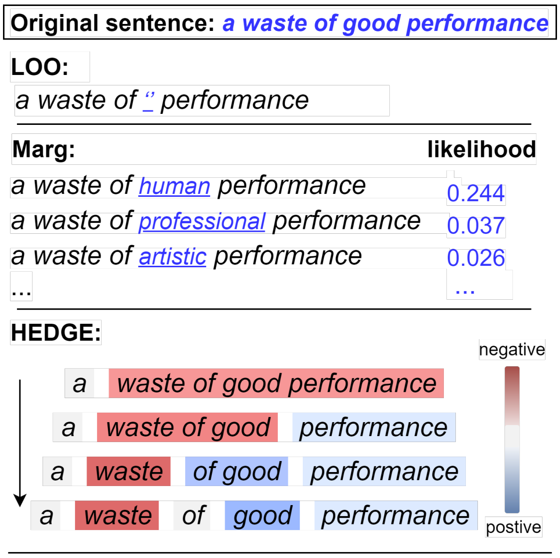

Figure 4: The overview of LOO, Marg and HEDGE.

Attribution Methods We experiment with three attribution methods: leave-one-out (LOO) (Li et al., 2016), HEDGE (Chen et al., 2020) and Marg (Kim et al., 2020). The schemes of these attribution methods are shown in Figure 4, LOO assign attribution scores to the target word *‘good’* by deleting it from the sentence and observing change in the model predictions; Marg marginalizes the target word *‘good’* out considering the likelihoods of all candidate words, which uses BERT to measure the likelihoods of candidate words to replace the target word; HEDGE builds hierarchical explanations by recursively detecting the weakest interactions and then dividing large text spans into smaller ones. HEDGE assign attribution scores to spans by using ’[PAD]’ token to replace other words in a sentence and measuring how far the prediction is to the prediction boundary.

Evaluation metrics and Results We first evaluate three attribution methods with metrics drawn from Marg and HEDGE papers. Marg uses AUC as evaluation metrics and modifies words by gradually replacing them with a token sampled from the distribution inferred by BERT, denoted as AUC$_{rep}$; HEDGE uses AOPC as evaluation metrics and modifies words by deleting them directly, denoted as AOPC$_{del}$. Both papers modify 20% of words in the sentence. The results are shown in Table 3. As shown in Table 3, Marg performs best in AUC$_{rep}$ while LOO performs best in AOPC$_{del}$. Since the

Method/Metric	AOPC$_{del}$ ↑	AUC$_{rep}$ ↓	AOPC$_{rep}$ ↑	AUC$_{del}$ ↓	AOPC$_{pad}$ ↑	AUC$_{pad}$ ↑
LOO	**0.541**	0.666	0.378	**0.526**	0.935	0.896
HEDGE	0.466	0.702	0.324	0.638	**0.978**	**0.984**
Marg	0.477	**0.617**	**0.391**	0.588	0.928	0.874

Table 3: Evaluation results of three attribution methods. ↑ / ↓ refers to higher / lower scores are better. del, rep, and pad refer to different modification strategies in the evaluation metrics.

modification strategy of AOPC$_{del}$ is consistent with LOO, and that of AUC$_{rep}$ is most similar to Marg, the evaluation results are consistent with the inference in logic trap 2: *the more similar the target evaluated method to the modification strategy, the better the evaluation results.*

Manipulate Evaluation Results We further conduct ablation experiments by changing the modification strategies in AOPC$_{del}$ and AUC$_{rep}$. Concretely, we switched perturbing strategy in AOPC$_{del}$ and AUC$_{rep}$ and get new evaluation metrics: AOPC$_{rep}$ and AUC$_{del}$. As shown in Table 3, different from the initial results, Marg performs best in APOC metric while LOO performs best in AUC metric. The opposite results demonstrate that evaluation results mainly depend on the modification strategies, and we can manipulate evaluation results by changing them. Moreover, we note that HEDGE performs worst in all four evaluation metrics. Thus, we further customize the modification strategy to HEDGE's advantage: padding unimportant features according to the attribution scores, denoted as AOPC$_{pad}$ and AUC$_{pad}$. Not surprisingly, results in Table 3 show that HEDGE perform best in customized metrics.

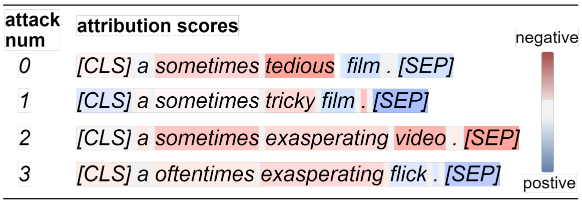
Summarization Because of the existence of logic trap 2, we can manipulate the evaluation results in evaluation 2 by changing the modification strategies, assigning any of the three candidate attribution methods as the best method. In fact, because we cannot simply assign a modification strategy as faithful, we should not use evaluation 2 to quantitatively evaluate attribution scores and make comparisons. Since the wide use of evaluation 2, the neglect of logic trap 2 has negatively impacted the research field for a long time. First, it brings a risk of unfair comparisons: works can customize evaluation metrics to their advantage and thus achieve the best performance. Second, the wide use of evaluation 2 also brings pressure to new proposed works, forcing them to make comparisons to others in such evaluation.

2.3 Part III

Evaluation 3: Disprove Attribution Methods by Examining the Consistency of Attribution Scores

In this evaluation, works evaluate attribution methods by examining the consistency of attribution scores for similar inputs. The philosophy of Evaluation 3 is that semantically similar inputs which share the same model predictions should have similar attribution scores if the attribution method is reliable. Evaluation 3 is often used to disprove the effectiveness of attribution methods by searching for counterexamples.

For example, ExplainFooler (Sinha et al., 2021) attacks Integrated Gradients and (Sundararajan et al., 2017) and LIME (Sundararajan et al., 2017), which are two popular attribution methods in NLP, by searching adversarial sentences with different attribution scores. As shown in Figure 5, these adversarial sentences are semantically similar to the original sentence and share the same model predictions. However, the attribution scores of these sentences are very different from that of the original sentence. Sinha et al. (2021) observes the rank order correlation drops by over 20% when less than 10% of words are changed on average and thus draws the conclusion that Integrated Gradients and LIME are fragile.



attack num	attribution scores
0	[CLS] a sometimes tedious film . [SEP]
1	[CLS] a sometimes tricky film . [SEP]
2	[CLS] a sometimes exasperating video . [SEP]
3	[CLS] a oftentimes exasperating flick . [SEP]

Figure 5: Examples taken from ExplainFooler (Sinha et al., 2021), which attacks attribution methods by searching adversarial sentences with different attribution scores. *attack num* refers to the number of replaced words.

A lot of works (Alvarez-Melis and Jaakkola, 2018; Kindermans et al., 2019; Ghorbani et al., 2019; Ding and Koehn, 2021; Sinha et al., 2021) use evaluation 3 to examine the validity of existing attribution methods. For example, Ghorbani et al. (2019) argues that interpretations of neural networks are fragile by showing that systematic perturbations can lead to different interpretations without changing the label; Alvarez-Melis and Jaakkola (2018) argues that a crucial property that attribution methods should satisfy is robustness to local perturbations of the input.

Logic Trap 3: The change in attribution scores maybe because the model reasoning process is really changed rather than the attribution method is unreliable.

When solving similar samples like those shown in Figure 5, humans tend to use similar reasoning methods. However, deep models are not as robust enough as humans and often rely on unreasonable correlations. Semantically similar texts often cause different reasoning processes in deep models. For example, it is well known that deep models are vulnerable to adversarial samples (Goodfellow et al., 2015; Papernot et al., 2016). By deliberately adding some subtle interference that people cannot detect to the input sample, the target model will give a different prediction with high confidence. The success in adversarial attacks on deep models demonstrates similar inputs for humans can share very different reasoning processes in deep models.

The main difference between attribution-attacking methods and model-attacking is that attribution-attacking methods require the model to give the same prediction for adversarial samples. However, giving the same prediction is very weak to constraint model reasoning because deep models have compressed the complicated calculation process into limited classes in the prediction. For example, there is always half probability of giving the same prediction for a binary classification task even with totally random reasoning. Thus, it is no surprise that attribution-attacking methods can find adversarial samples which share the same prediction label to the original sample yet have different attribution scores.

The logic trap in evaluation 3 is that the change in attribution scores may be because the model reasoning process is really changed rather than the attribution method is unreliable. As shown in Figure 6. (b), an attribution method should generate different attribution scores for the original and adversarial samples if it faithfully reflects the model reasoning. However, it will be regarded as fragile or unreliable in evaluation 3. Unfortunately, existing works ignore this logic trap and propose various methods to attack attribution methods. Since the high susceptibility of deep models to adversarial samples, not surprisingly, all of these works get the same conclusion: existing attribution methods are fragile or unreliable.

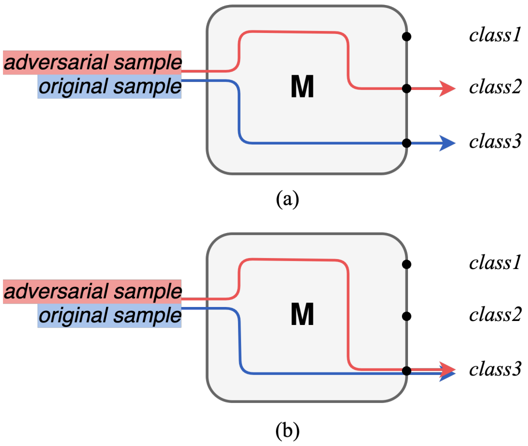


Figure 6: We use lines connecting inputs and outputs to represent the model reasoning process. (a) is a successful attack on the target model while (b) might be regarded as a successful attack on attribution methods, falling into the logic trap 3.

Experiment 3:

In experiment 3, we demonstrate that deep models can assign the same label to semantically similar samples yet use different reasoning. We experiment on widely used SST-2 and MNLI tasks of the GLUE benchmark (Wang et al., 2019)). MNLI requires the model to predict whether the premise entails the hypothesis, contradicts it, or is neutral.

Model Since the attribution methods are defaulted as unreliable in evaluation 3, we cannot use existing attribution methods to judge whether the model reasoning is different. To solve the problem, we use a two-stage model framework, where the model first extracts a subset of inputs and gives prediction based only on the subset information. This way, we can observe whether the model reasoning is changed from the chosen subset, i.e., different subsets means the model chooses to use different

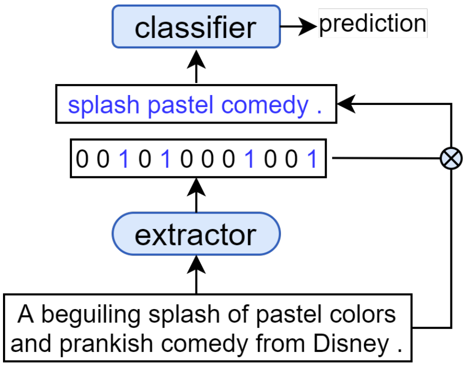

Figure 7: The overview of the model scheme, which consists of two components: extractor and classifier. Only the information of the selected subset can pass to the classifier.

information to make the final decision[2].

The overview of our model is shown in Figure 7. To guarantee that only the subset information is included in the classifier, we discretely select the words and pass words instead of the hidden states of the extractor to the classifier. Since gradients do not flow through discrete samples, we resort to HardKuma (Bastings et al., 2019) to jointly train the model, which gives support to binary outcomes. HardKuma allows for setting the percentage of selected words and is proved more effective and stable than REINFORCE (Williams, 1992) in such scenarios. We set the selection ratio as 20% for SST-2 and 40% for MNLI because larger ratios will not cause further performance improvement. Finally, We get 85.6% accuracy on SST-2 and 66.2/65.5 % accuracy on MNLI-m/mm.

Adversarial Attack Method We use TextFooler (Jin et al., 2020) to generate adversarial samples. We use the same settings to Jin et al. (2020) to guarantee the semantical similarity of adversarial samples. The only difference is that we search for samples with minimal similarity in the selected subset instead of the model prediction. We guarantee that the model makes the same predictions, which is often used as the constraint for model reasoning in evaluation 3. We generate adversarial samples with 10% and 20% perturbation ratios.

Results We use F1-score to compute the similarity score between subsets and report the Macro-averaging F1-score of the whole development set.

Dataset/Ratio	10%	20%
SST-2	0.32	0.18
MNLI-m/mm	0.43 / 0.52	0.37 / 0.43

Table 4: The similarity scores between selected subsets. *Rato* refers to the perturbation ratio used to generate adversarial samples.

A lower score is better, reflecting a larger difference in selected subsets. Note that since some words in original samples are replaced with their synonyms in adversarial samples, synonyms are seen as identical to their original words when evaluating. We evaluate all samples in the SST-2 development set and the first 1000 samples in MNLI-m/mm development sets. The results are shown in Table 4

As shown in Table 4, though semantically similar to the original samples and share the same model predictions, the adversarial samples can have subsets with low similarity to the original subset. Moreover, with a 10% perturbation ratio, **31.8%** of samples in SST-2 have an adversarial subset with none word overlap with the original subset. This result increases to **50.5%** with a 20% perturbation ratio. With no overlap between the two subsets, there is no way we can hypothesis the adversarial samples share similar model reasoning to the original samples.

Summarization Though evaluation 3 seems reasonable, sharing similar semantics and the same model predictions is a weak constraint for similar model reasoning. Thus the change in attribution scores may come from different model reasoning instead of the instability of attribution methods. Because of deep models' high sensitivity to adversarial samples, works resorting to evaluation 3 all get the same conclusion that existing attribution methods are fragile or unreliable. We argue we should find a more strict constraint for model reasoning first instead of ignoring logic trap 3 and disproving attribution methods recklessly.

3 Discussion

3.1 Attacking attribution methods by replacing the target model.

Besides resorting to methods in evaluation 3, there are works (Jain and Wallace, 2019; Wang et al., 2020; Slack et al., 2020) disprove the reliability of attribution methods by replacing the target model which attribution methods should work on.

---

[2] Note that similar subsets are regarded as a necessary condition rather than a sufficient condition for the similar model reasoning process.

For example, Slack et al. (2020) trains an adversarial classifier $e(x)$ to distinguish whether the inputs have been perturbed or not and then uses a different sub-model to process perturbed instances. Specifically, if we want to attack the LOO method, we can build a loo set from the original dataset and train $e(x)$ in the following form:

$$e(x) = \begin{cases} f(x), & if\ x \in original\ set \\ \psi(x), & if\ x \in loo\ set \end{cases}$$

This way, $\psi(x)$, a model irrelevant to model predictions, is used when using LOO to calculate attribution scores, making generated attribution scores meaningless. Slack et al. (2020) assert that results of perturbation-based attribution methods such as LIME and SHAP (Lundberg and Lee, 2017) are easily attacked by their method. Similarly, Wang et al. (2020) add an extra model to the original model, which has uniform outputs but large gradients for some particular tokens such as 'CLS' in BERT. Since the extra model generates uniform outputs, it will not affect predictions of the original model. However, the extra model's gradients will add to the original model and thus can confuse gradient-based attribution methods.

3.2 Should We Use Attribution Methods in a Black-Box Way?

The attack methods in Section 3.1 fool the attribution methods through designing a special structure and require attribution methods to be used in a black-box way. In this setting, the attribution methods are easily attacked and generate meaningless results. However, the question is: as a tool to help humans understand how deep models work, is it necessary to use attribution methods in a black-box way? Take the linear model as an example. The linear model is regarded as a white-box model, and humans don't need attribution methods to understand how it works. However, the understanding of a linear model is based on the analysis of its calculation process. Meanwhile, the deep model is regarded as a black-box model because its calculation process is too complicated to understand for humans, not because its calculation process is inaccessible. Thus, we believe there are no compelling reasons to require attribution methods to be used in a black-box way. The attacks in Wang et al. (2020); Slack et al. (2020) will fail when humans use attribution methods with knowing the model structures.

3.3 Reducing the impact of proposed logic traps.

Since logic traps in existing evaluation methods can cause an inaccurate evaluation, we believe reducing the impact of these traps is the next question in the research field of post-hoc interpretations. In this section, we provide some thoughts for reducing the impact of logic trap 3:

The change in attribution scores may be because the model reasoning process is changed rather than the attribution method is unreliable.

To reduce the impact of this logic trap, we should try to guarantee the similarity in model reasoning when processing semantically similar inputs. In other words, we hope the target model used to test attribution methods more robustness to adversarial samples, which can be conducted through the following ways:

1 **Enhancing the target model.** The success of adversarial attacks on deep models motivates efforts to defend against such attacks. Thus, we can use these defense techniques, such as adversarial training (Tramèr et al., 2018) and randomization (Xie et al., 2018), to enhance the target model and make it more robustness to adversarial samples.

2 **Excluding predictions with low confidence.** The deep model will give a prediction for a sample regardless of whether knowing how to deal with it. The randomness of reasoning increases with the uncertainty in model decisions (Bella et al., 2010). Thus, we can guarantee the stability of model reasoning by excluding low-confident predictions. For example, we can resorting to **Confidence Calibration techniques** (Guo et al., 2017; Seo et al., 2019), which calculate confidence interval for a predicted response.

3.4 Conclusions

The proposed logic traps in existing evaluation methods have been ignored for a long time and negatively affected the research field. Though strictly accurate evaluation metrics for evaluating attribution methods might be a "unicorn" which will likely never be found, we should not just ignore these logic traps and draw conclusions recklessly. With a clear statement and awareness of these logic traps, we should reduce the focus on improving performance under such unreliable evaluation systems and shift it to reducing the impact of proposed logic traps. Moreover, other aspects of the research field should give rise to more attention, such as the applications of attribution scores (denoising data, improving the model performance, etc.) and proposing new explanation forms.

A Experimental Details

In this section, we provide the experimental details of our experiments. Moreover, we will release our code and model within two months.

A.1 Experiment 1

We merged dev-high and dev-middle sets as the development set. As shown in Figure 8, the document D, question Q, and one of the choices C are concatenated together as the input of model, and we replace the development set questions with empty strings in our experiment.

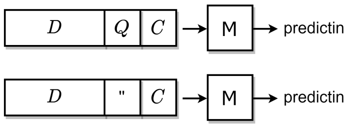

Figure 8: The overview of experiment 1.

A.2 Experiment 2

We use the tokenizer of BERT to split the sentence into words in experiment 2. We modify 20% of words in the sentences in experiment 2. Since the word number in a sentence is not necessarily a multiple of five, we need to choose between rounding up or down. We use the same setting in code of HEDGE, i.e., rounding down. Specifically, we modify one word when word number is smaller than five.

A.3 Experiment 3

Since HardKuma allows for setting the percentage of selected words, we first experiment with settings ranging from 10% to 100%. The results are shown in Figure 9. Under the premise of maintaining model performance, we choose the smallest setting (20% setting for SST-2 and 40% setting for MNLI). We use beam search to find adversarial samples and set the maximum reserved sample number to 100.

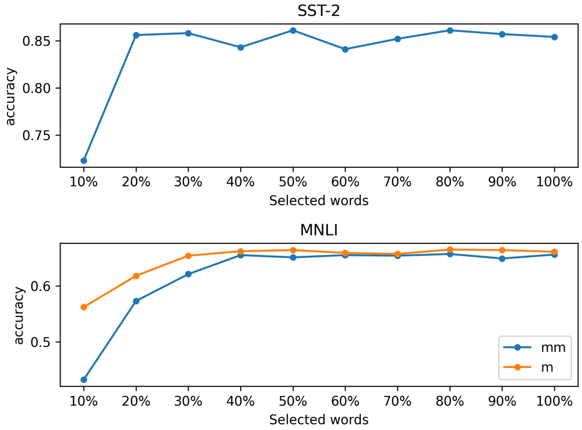

Figure 9: Model performance trained in different settings.

Continual Pre-training of Language Models for Math Problem Understanding with Syntax-Aware Memory Network

Abstract

In this paper, we study how to continually pre-train language models for improving the understanding of math problems. Specifically, we focus on solving a fundamental challenge in modeling math problems, *i.e.,* how to fuse the semantics of textual description and formulas, which are highly different in essence. To address this issue, we propose a new approach called **COMUS** to <u>co</u>ntinually pre-train language models for <u>m</u>ath problem <u>u</u>nderstanding with <u>s</u>yntax-aware memory network. In this approach, we first construct the math syntax graph to model the structural semantic information, by combining the parsing trees of the text and formulas, and then design the syntax-aware memory networks to deeply fuse the features from the graph and text. With the help of syntax relations, we can model the interaction between the token from the text and its semantic-related nodes within the formulas, which is helpful to capture fine-grained semantic correlations between texts and formulas. Besides, we devise three continual pre-training tasks to further align and fuse the representations of the text and math syntax graph. Experimental results on four tasks in the math domain demonstrate the effectiveness of our approach. Our code and data are publicly available at the link: `https://github.com/RUCAIBox/COMUS`.

1 Introduction

Understanding math problems via automated methods is a desired machine capacity for artificial intelligence assisted learning. Such a capacity is the key to the success of a variety of educational applications, including math problem retrieval (Reusch et al., 2021), problem recommendation (Liu et al., 2018), and problem solving (Huang et al., 2020).

To automatically understand math problems, it is feasible to learn computational representations from problem statement texts with pre-trained language models (PLMs) (Shen et al., 2021; Peng et al., 2021). Pre-trained on the large-scale general corpus, PLMs (Devlin et al., 2019) can be effectively transferred into new domains or tasks by continual pre-training on task-specific datasets. Different from traditional text comprehension tasks, as shown in Figure 1, math problems usually involve a complex mixture of mathematical symbols, logic and formulas, which becomes a barrier to the accurate understanding of math problems.

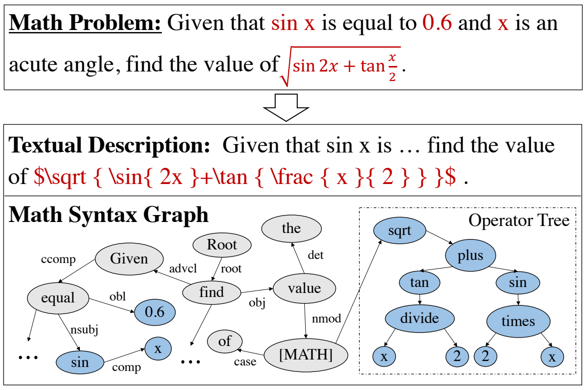

Figure 1: Illustration of a math problem with its textual description and math syntax graph.

However, previous works (Reusch et al., 2021; Shen et al., 2021) mostly oversimplify the issues of math problem understanding. They directly concatenate the formulas with the textual description as an entire sentence, and then perform continual pre-training and encoding without special considerations. Therefore, two major shortcomings are likely to affect the understanding of math problems. First, formulas (the most important elements of the problem) contain complex mathematical logic, and modeling them as plain text may incur the loss of important information. Second, the textual description contains essential explanations or hints about the symbols and logic within the formulas. Hence, it is necessary to accurately capture fine-grained

correlations between words from the description text and symbols from math formulas.

To better model the computational logic of formulas, operator trees are introduced to represent the math formulas (Zanibbi and Blostein, 2012), which are subsequently encoded by graph neural network (GNN). Although these methods can improve the comprehension capacity of math problems to some extent, there still exists a semantic gap between graph encoding and text encoding due to the heterogeneity of formulas and texts. With simple concatenation or self-attention mechanisms (Peng et al., 2021), it is still hard to capture the fine-grained associations among tokens and symbols, *e.g.,* the dependency relation between math symbols and corresponding explanation tokens.

In order to better fuse the information from formulas and texts, our solution is twofold. First, we construct a syntax-aware memory network based on a structure called *math syntax graph* (Figure 1), which integrates operator trees from formulas and syntax trees from texts. The key point lies in that we store the node embeddings from the GNN and dependency relation embeddings as entries of memory networks, and then design the corresponding read and write mechanism, using token embeddings from the PLM as queries. Such a way can effectively associate the representation spaces of the text and formulas. Second, we devise specific continual pre-training tasks to further enhance and fuse the text and graph representations, including the masked language model and dependency triplet completion tasks to improve the understanding of math symbols in the text and formulas logic in the syntax graph, respectively, and the text-graph contrastive learning task to align and unify the representations of the text and graph.

To this end, we propose **COMUS**, to **co**ntinually pre-train language models for **m**ath problem **u**nderstanding with **s**yntax-aware memory network. In our approach, we first encode the textual description and math syntax graph via PLM and GAT, respectively. Then, we add syntax-aware memory networks between the last k layers of PLM and GAT. In each of the last k layers, we first conduct the multi-view read and write operation to fuse the token and node representations, respectively, and then adopt the next layer of PLM and GAT to encode the fused representations. All parameters of our model are initialized from PLMs and will be continually pre-trained by our devised three tasks, namely masked language model, dependency triplet completion and text-graph contrastive learning. Experimental results on four tasks in the math domain have demonstrated the effectiveness of our approach, especially with limited training data.

Our contributions can be summarized as follows:

(1) We construct a novel syntax-aware memory network to capture the fine-grained interactions between the text and formulas.

(2) We design three continual pre-training tasks to further align and fuse the representations of the text and graph data.

(3) Experiments on four tasks in the math domain demonstrate the effectiveness of our model.

2 Preliminaries

In this section, we formulate the problem statement and then introduce the math syntax graph.

Problem Statement. Generally, a math problem consists of a textual description d and several formulas $\{f_1, f_2, \cdots, f_m\}$. The textual description provides necessary background information for the math problem. It is formally denoted as a sequence of tokens $d = \{t_1, t_2, \cdots, t_l\}$, where t_i is either a word token or a mathematical symbol (*e.g.,* a number or an operator). The formulas describe the relationship among mathematical symbols, which is the key to understand and solve the math problem. Each formula consists of a sequence of mathematical symbols, denoted as $f_i = \{s_1, \cdots, s_n\}$.

Based on the above notations, this work focuses on continually pre-training a PLM on unsupervised math problem corpus for domain adaptation. After that, the PLM can be fine-tuned on various tasks in the math domain (*e.g.,* knowledge point classification), and improve the task performance.

Math Syntax Graph. In order to understand the mathematical text and formulas, it needs to capture the complex correlations within words, symbols and operators. Inspired by previous works (Mansouri et al., 2019; Peng et al., 2021), we construct a *syntax graph*, where the textual description is represented as a syntax dependency tree and the formulas are represented as operator trees (OPT).

Specifically, given a math problem consisting of a textual description d and several formulas $\{f_1, f_2, \cdots, f_m\}$, we first utilize the open-source toolkit TangentS[1] to convert each formula into an

---

[1] https://github.com/BehroozMansouri/TangentCFT

OPT, and Stanza[2] to convert the textual description into a syntax dependency tree. Then, we combine the syntax dependency tree and the OPTs to compose an entire graph, where a special token "[MATH]" is applied to link them. We call such a composite graph as the math syntax graph $\mathcal{G}$ of the math problem. Let $\mathcal{N}$ and $\mathcal{R}$ denote the set of nodes and relations on $\mathcal{G}$, respectively. We can extract dependency triplets from $\mathcal{G}$, where a dependency triplet (h, r, t) denotes that there exists an edge with the relation $r \in \mathcal{R}$ to link the head node $h \in \mathcal{N}$ to the tail node $t \in \mathcal{N}$.

3 Methodology

As shown in Figure 2, our approach aims to effectively encode the textual description and formulas, and fuse these two kinds of information for understanding math problems. In what follows, we first present the base models for encoding math problems, and then introduce the devised syntax-aware memory network and continual pre-training tasks.

3.1 Base Models

Encoding Math Text. We use BERT (Devlin et al., 2019) as the PLM to encode the math text, *i.e.,* the textual description d. Given $d = \{t_1, t_2, \cdots, t_L\}$ of a math problem, the PLM first projects these tokens into corresponding embeddings. Then, a stack of Transformer layers will gradually encode the embeddings to generate the l-th layer representations $\{\mathbf{h}_1^{(l)}, \mathbf{h}_2^{(l)}, \cdots, \mathbf{h}_L^{(l)}\}$. Since the textual description d may contain specific math symbols that were not seen during pre-training, we add them into the vocabulary of the PLM and randomly initialize their token embeddings. These new embeddings will be learned during continual pre-training.

Encoding Math Syntax Graph. We incorporate a graph attention network (GAT) (Veličković et al., 2018) to encode the math syntax graph, which is composed of an embedding layer and a stack of graph attention layers. Given a math syntax graph $\mathcal{G}$ with N nodes, the GAT first maps the nodes into a set of embeddings $\{\mathbf{n}_1, \mathbf{n}_2, \cdots, \mathbf{n}_N\}$. Then each graph attention layer aggregates the neighbors' hidden states using multi-head attentions to update the node representations as:

$$\mathbf{n}_i^{(l+1)} = \Big\Vert_{k=1}^{K} \sigma\Big(\sum_{j \in \mathcal{N}_i} \alpha_{ij}^{k} \mathbf{W}_k^{(l)} \mathbf{n}_j^{(l)}\Big). \qquad (1)$$

where $\mathbf{n}_i^{(l+1)}$ is the representation of the i-th node in the $l+1$ layer, $\Vert$ denotes the concatenation operation, σ denotes the sigmoid function, K is the number of attention heads, $\mathcal{N}_i$ is the set of neighbors of node i in the graph, $\mathbf{W}_k^{(l)}$ is a learnable matrix, and α_{ij}^{k} is the attention value of the node i to its neighbor j in attention head k.

3.2 Syntax-Aware Memory Network

To improve the semantic interaction and fusion of the representations of math text and the syntax graph, we add k syntax-aware memory networks between the last k layers of PLM and GAT. In the memory network, node embeddings (from the math syntax graph) with dependency relations are considered as slot entries, and we design multi-view read/write operations to allow token embeddings (*e.g.,* explanation tokens or hints) to attend to highly related node embeddings (*e.g.,* math symbols).

Memory Initialization. We construct the memory network based on the dependency triplets and node representations of the math syntax graph. Given the dependency triplets $\{(h, r, t)\}$, we treat the head and relation (h, r) as the key and the tail t as the value, to construct a syntax-aware key-value memory. The representations of the heads and tails are the corresponding node representations from GAT, while the relation representations are randomly initialized and will be optimized by continual pre-training. Finally, we concatenate the representations of heads and relations to compose the representation matrix of *Keys* as $\mathbf{K}^{(l)} = \{[\mathbf{n}_{h_1}^{(l)}; \mathbf{r}_1], [\mathbf{n}_{h_2}^{(l)}; \mathbf{r}_2], \cdots, [\mathbf{n}_{h_N}^{(l)}; \mathbf{r}_N]\}$, and obtain the representation matrix of *Values* as $\mathbf{V}^{(l)} = \{\mathbf{n}_{t_1}^{(l)}, \mathbf{n}_{t_2}^{(l)}, \cdots, \mathbf{n}_{t_N}^{(l)}\}$.

Multi-view Read Operation. We read important semantics within the syntax-aware memory to update the token representations from PLM. Since a token can be related to several nodes within the math syntax graph, we design a multi-view read operation to capture these complex semantic associations. Concretely, via different bilinear transformation matrices $\{\mathbf{W}_1^S, \mathbf{W}_2^S, \cdots, \mathbf{W}_n^S\}$, we first generate multiple similarity matrices $\{\mathbf{S}_1, \mathbf{S}_2, \cdots, \mathbf{S}_n\}$ between tokens and keys (head and relation) within the memory, and then aggregate the values (tail) to update the token representations. Given the token representations from the l-th layer of PLM $\mathbf{H}^{(l)} = \{\mathbf{h}_1^{(l)}, \mathbf{h}_2^{(l)}, \cdots, \mathbf{h}_L^{(l)}\}$,

---

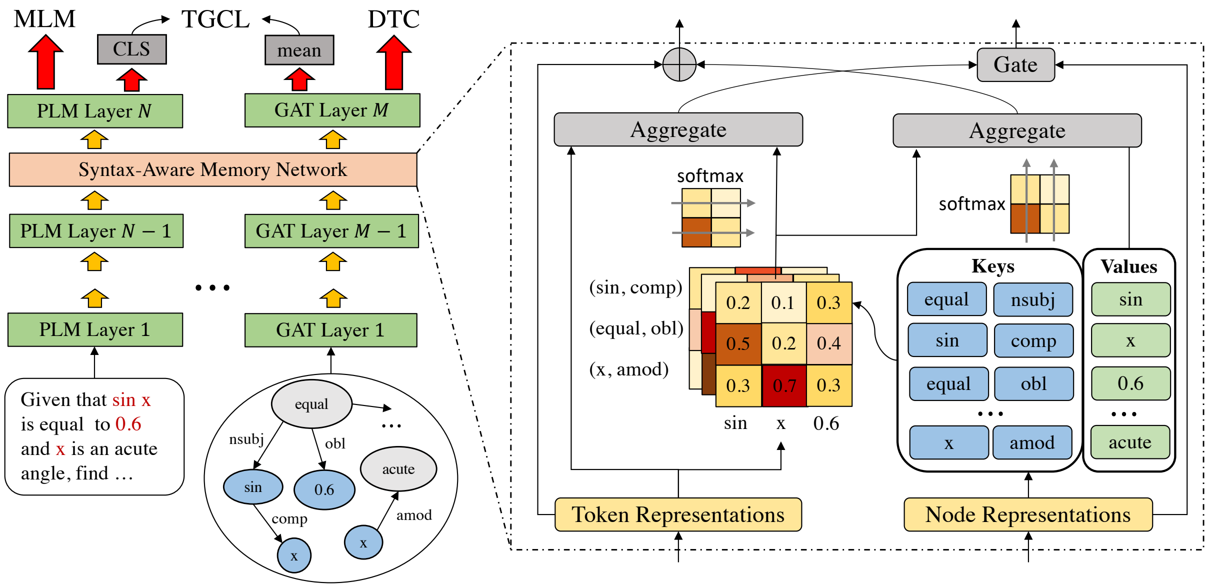

Figure 2: Illustration of our COMUS. We encode the textual description and the math syntax graph using PLM and GAT, respectively, and insert the syntax-aware memory networks in the last k layers to fuse their representations. In the syntax-aware memory network, we utilize the token representations and the node representations as the queries and values, respectively, and implement the *read* and *write* operations to update them.

the similarity matrix $\mathbf{S}_i$ is computed as

$$\mathbf{S}_i = \mathbf{H}^{(l)} \mathbf{W}_i^S {\mathbf{K}^{(l)}}^\top \tag{2}$$

where $\mathbf{W}_i^S$ is a learnable matrix, and an entry $\mathbf{S}_i[j,k]$ denotes the similarity between the j-th token and the k-th key in the i-th view. Based on these similarity matrices, we update the token representations by aggregating the value representations as

$$\hat{\mathbf{H}}^{(l)} = \mathbf{H}^{(l)} + [\alpha_1 \mathbf{V}; \alpha_2 \mathbf{V}; \cdots; \alpha_h \mathbf{V}]\mathbf{W}^O \tag{3}$$

$$\alpha_i = \texttt{softmax}(\mathbf{S}_i) \tag{4}$$

where $\mathbf{W}^O$ is a learnable matrix and α_i is the attention score distribution along the key dimension. In this way, we can capture the multi-view correlations between tokens and nodes, and the token representations can be enriched by the representations of multiple semantic-related nodes. After that, the updated token representations $\hat{\mathbf{H}}^{(l)}$ are fed into the next layer of PLM, where the Transformer layer can capture the interaction among token representations to fully utilize the fused knowledge from the syntax graph.

Multi-View Write Operation. After updating the token representations, we update the representations of nodes from GAT via memory writing. We still utilize the multi-view similarity matrices $\{\mathbf{S}_1, \mathbf{S}_2, \cdots, \mathbf{S}_h\}$. Concretely, we compute the attention score distribution β using softmax function along the token dimension of the similarity matrices, and then aggregate the token representations as

$$\mathbf{V}_{new}^{(l)} = [\beta_1 \mathbf{H}^{(l)}; \beta_2 \mathbf{H}^{(l)}; \cdots; \beta_h \mathbf{H}^{(l)}]\mathbf{W}^R \tag{5}$$

$$\beta_i = \texttt{softmax}(\mathbf{S}_i^\top) \tag{6}$$

where $\mathbf{W}^R$ is a learnable matrix. Based on the aggregated token representations, we incorporate a gate to update the representations of the values as

$$z = \sigma(\mathbf{V}_{new}^{(l)} \mathbf{W}^A + \mathbf{V}^{(l)} \mathbf{W}^B) \tag{7}$$

$$\hat{\mathbf{V}}^{(l)} = z \cdot \mathbf{V}_{new}^{(l)} + (1 - z) \cdot \mathbf{V}^{(l)} \tag{8}$$

where $\mathbf{W}^A$ and $\mathbf{W}^B$ are learnable matrices. The updated node representations $\hat{\mathbf{V}}^{(l)}$ are also fed into the next layer of GAT, where the graph attention mechanism can further utilize the fused knowledge from the text to aggregate more effective node representations.

3.3 Continual Pre-training

Continual pre-training aims to further enhance and fuse the math text and math syntax graph. To achieve it, we utilize the masked language model and dependency triplet completion tasks to improve the understanding of math text and math syntax graph, respectively, and the text-graph contrastive learning task to align and fuse their representations.

Masked Language Model (MLM). Since the math text contains a number of special math symbols, we utilize the MLM task to learn it for better understanding the math text. Concretely, we randomly select 15% tokens of the input sequence to be masked. Of the selected tokens, 80% are replaced with a special token [MASK], 10% remain unchanged, and 10% are replaced by a token randomly selected from the vocabulary. The objective is to predict the original tokens of the masked ones as:

$$L_{MLM} = \sum_{t_i \in \mathcal{V}_{mask}} -\log p(t_i) \tag{9}$$

where $\mathcal{V}_{mask}$ is the set of masked tokens, and $p(t_i)$ denotes the probability of predicting the original token in the position of t_i.

Dependency Triplet Completion (DTC). In the math syntax graph, the correlation within the dependency triplet (h, r, t) is essential to understand the complex math logic of the math problem. Thus, inspired by TransE (Bordes et al., 2013), we design the dependency triplet completion task to capture the semantic correlation within a triplet. Specifically, for each triplet (h, r, t) within the math syntax graph, we minimize the DTC loss by

$$L_{DTC} = \max\left(\gamma + d(\mathbf{n}_h + \mathbf{r}, \mathbf{n}_t) - d(\mathbf{n}_h + \mathbf{r}^{'}, \mathbf{n}_t), 0\right) \tag{10}$$

where $\gamma > 0$ is a margin hyper-parameter, $d(\cdot)$ is the euclidean distance, and $\mathbf{r}^{'}$ is the randomly sampled negative relation embedding. In this way, the head and relation embeddings can learn to match the semantics of the tail embeddings, which enhances the node and relation representations by capturing the graph structural information.

Text-Graph Contrastive Learning (TGCL). After enhancing the representations of the math text and math syntax graph via MLM and DTC tasks respectively, we further align and unify the two types of representations. The basic idea is to adopt contrastive learning to pull the representations of the text and graph of the same math problem together, and push apart the negative examples. Concretely, given a text-graph pair of a math problem $(d_i, \mathcal{G}_i)$, we utilize the representation of the [CLS] token $\mathbf{h}_i^d$ as the sentence representation of d_i, and the mean pooling of the node representations $\mathbf{n}_i^{\mathcal{G}}$ as the graph representation of $\mathcal{G}_i$. Then, we adopt the cross-entropy contrastive learning objective with in-batch negatives to align the two representations

$$L_{TGCL} = -\log \frac{\exp(f(\mathbf{h}_i^d, \mathbf{n}_i^{\mathcal{G}})/\tau)}{\sum_{i \neq j} \exp(f(\mathbf{h}_i^d, \mathbf{n}_j^{\mathcal{G}})/\tau)} \tag{11}$$

where $f(\cdot)$ is a dot product function and τ denotes a temperature parameter. In this way, the representations of the text and graph can be aligned, and the data representations from one side will be further enhanced by another side.

3.4 Overview and Discussion

Overview. Our approach focuses on continually pre-training PLMs to improve the understanding of math problems. Given the math text and math syntax graph of the math problem, we adopt PLM and GAT to encode them, respectively, and utilize syntax-aware memory networks in the last k layers to fuse the representations of the text and graph. In each of the last k layers, we first initialize the queries and values of the memory network using the representations of tokens and nodes, respectively, then perform the read and write operations to update them using Eq. 3 and Eq. 8. After that, we feed the updated representations into the next layers of PLM and GAT to consolidate the fused knowledge from each other. Based on such an architecture, we adopt MLM, DTC and TGCL tasks to continually pre-train the model parameters using Eq. 9, Eq. 10 and Eq. 11. Finally, for downstream tasks, we fine-tune our model with specific data and objectives, and concatenate the representations of text $\mathbf{h}^d$ and graph $\mathbf{n}^{\mathcal{G}}$ from the last layer for prediction.

Discussion. The key of our approach is to deeply fuse the math text and formula information of the math problem via syntax-aware memory networks and continual pre-training tasks. Recently, MathBERT (Peng et al., 2021) is proposed to continually pre-train BERT in math domain corpus, which applies the self-attention mechanism for the feature interaction of formulas and texts, and learns similar tasks as BERT. As a comparison, we construct the math syntax graph to enrich the formula information and design the syntax-aware memory network to fuse the text and graph information. Via the syntax-aware memory network, the token from math text can trace its related nodes along the relations in the math syntax graph, which can capture the fine-grained correlations between tokens and nodes. Besides, we model the math syntax graph

Task	Train	Dev	Test
KPC	8,721	991	1,985
QRC	10,000	2,000	4,000
QAM	14,000	2,000	4,000
SQR	250,000	11,463	56,349

Table 1: Statistics of the datasets.

via GAT, and devise the DTC task to improve the associations within triplets from the graph, and the TGCL task to align the representations of the graph and text. In this way, we can better capture graph structural information and fuse it with textual information. It is beneficial for understanding logical semantics from formulas of math problems .

4 Experiment

4.1 Experimental Setup

We conduct experiments on four tasks in the math domain to verify the effectiveness of our approach.

Pre-training Corpus. Our pre-training corpus is collected from a Chinese educational website Zhixue [3], which consists of 1,030,429 problems of high school math exams and tests. Each math problem contains the information of problem statement, answer and solution analysis. For data preprocessing, we first transform these collected problems from the HTML format into plain text format, then extract and convert the formulas and mathematical symbols into a unified LaTex mathematical format.

Evaluation Tasks. We construct four tasks based on the collected math problems for high school students, which cover math problem classification and recommendation. The statistics of these tasks are summarized in Table 1.

- **Knowledge Point Classification** (KPC) is a multi-class classification task. Given a math question, the goal is to classify what knowledge point (KP) this question is associated with. The knowledge points are defined and annotated by professionals, and we finally have 387 KPs in this task.
- **Question-Answer Matching** (QAM) is a binary classification task to predict whether an answer is matched with a question. For each question, we randomly sample an answer from other problems as the negative example.
- **Question Relation Classification** (QRC) is a 6-class classification task. Given a pair of math questions, this task aims to predict their relation (*e.g.,* equivalent, similar, problem variant, conditional variant, situation variant, irrelevant).
- **Similar Question Recommendation** (SQR) is a ranking task. Given a question, this task aims to rank retrieved candidate questions by the similarity.

Evaluation Metrics. For classification tasks (KPC, QRC, QAM), we adopt Accuracy and F1-macro as the evaluation metrics. For the recommendation task (SQR), we employ top-k Hit Ratio (HR@k) and top-k Normalized Discounted Cumulative Gain (NDCG@k) for evaluation. Since the length of candidate list is usually between 6 and 15, we report results on HR@3 and NDCG@3.

Baseline Methods. We compare our proposed approach with the following nine baseline methods:

- **TextCNN** (Kim, 2014) is a classic text classification model using CNN on top of word vectors.
- **TextRCNN** (Lai et al., 2015) combines both RNN and CNN for text classification tasks.
- **GAT** (Veličković et al., 2018) utilizes the attention mechanism to aggregate neighbors' representations to produce representation for each node.
- **R-GCN** (Schlichtkrull et al., 2018) extended Graph Convolutional Network with multi-edge encoding to aggregate neighbors' representations.
- **BERT-Base** (Devlin et al., 2019) is a popular pre-trained model. We use the bert-base-chinese, and add some new tokens into the original vocab to represent specific symbols in math problem dataset.
- **DAPT-BERT** (Gururangan et al., 2020) continually pre-trains BERT on the domain-related corpus. We use our collected math problem dataset with the masked language model task for implementation.
- **BERT+GAT** concatenates the [CLS] embedding from BERT and mean node embedding from GAT as the representation of a math question.
- **DAPT-BERT+GAT** replaces BERT in BERT+GAT with the DAPT-BERT.
- **MathBert** (Peng et al., 2021) continually pre-train BERT on the math corpus with similar pre-training tasks, and revises the self-attention layers for encoding the OPT of formulas.

Implementation Details. For baseline models, all hyper-parameters are set following the suggestions from the original papers. For all PLM-related models, we implement them based on HuggingFace Transformers [4] (Wolf et al., 2020). For the models

Table 3: Performance comparison *w.r.t.* different amount of training data on KPC and QRC tasks.

combining PLM and GAT, we set GAT's number of layer, attention head and hidden states as 6, 12 and 64, respectively. And we set the number of syntax-aware memory network layers k as 2 for our proposed COMUS.

In the continual pre-training stage, we initialize the weights of all models with bert-base-chinese [5] and pre-train them on our pre-training corpus with the same hyper-parameter setting as follows. We continually pre-train the parameters with a total of 128 batch size for 100,000 steps. And the max length of input sequences is set as 512. We use AdamW (Loshchilov and Hutter, 2019) optimization with $\beta_1 = 0.9$, $\beta_2 = 0.999$, and apply learning rate warmup over the first 5% steps, and linear decay of the learning rate. The learning rate is set as $1e^{-4}$. We set τ as 0.07 for our TGCL tasks. It costs about 40 hours to perform the continual pre-training on 4 Tesla-V100-PCIE-32G GPUs.

During fine-tuning on downstream tasks, we use AdamW with the same setting as pre-training. And batch size for all experiments is set as 32. The learning rate is set to $3e^{-5}$ for pre-training based methods, and $1e^{-3}$ for other methods.

4.2 Main Results

The results of all the comparison methods on four tasks are shown in Table 2. Based on these results, we can find:

As for non-pre-training methods, text-based methods (*i.e.,* TextCNN and TextRCNN) outperform GNN-based methods (*i.e.,* GAT and R-GCN). It indicates that text representations are more capable of understanding math problems than graph representations in our dataset. Overall, non-pre-training methods perform worse than pre-training based methods, since pre-training based models have learned sufficient general knowledge during the pre-training on large-scale corpus.

Among the five pre-training methods, we can have two major findings. First, combining PLMs with GNN yields performance improvement in most cases. The reason is that GNN can capture the structural semantics from formulas as the auxiliary information to help PLMs understand the math problem, but the improvement is unstable, since these methods simply concatenate the representations of the text and graph without deeply fusing them. Second, continual pre-training brings a significant improvement on all the evaluation

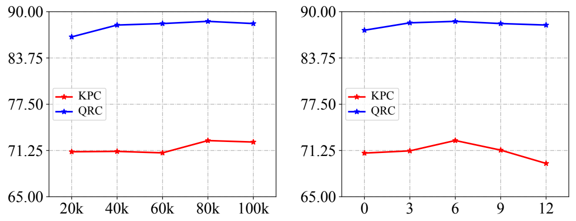
Table 4: Ablation study of our approach on the KPC and QRC tasks.



(a) Pre-training Steps (b) GAT Layers

Figure 3: Performance comparison *w.r.t.* the number of pre-training steps and GAT layers

tasks. General-purpose PLMs can't effectively understand mathematical semantics, and it is the key to adapt them to the math domain via continual pre-training.

Finally, by comparing our approach with all the baselines, it is clear to see that our model performs consistently better than them on four tasks. We utilize the syntax-aware memory network to fuse and interact the representations of textual descriptions and formulas, and adopt three continual pre-training tasks to further align and enhance these representations. Among these results, we can see that our model achieves a large improvement on the KPC task. A possible reason is that it requires a deeper semantic fusion of formulas and text for identifying the correct knowledge points.

4.3 Few-shot Learning

To validate the reliability of our method under the data scarcity scenarios, we conduct few-shot experiments on KPC and QRC tasks by using different proportions of the training data, *i.e.,* 5%, 10%, 20% and 40%. We compare our model with DAPT-BERT, DAPT-BERT+GAT and MathBERT.

Table 3 shows the evaluation results with different ratios of training data. We can see that the performance substantially drops when the size of training set is reduced. However, our model performs consistently better than the others across different tasks and metrics. It demonstrates that our model is capable of leveraging the data more effectively with the help of the syntax-aware memory networks and continual pre-training tasks. With 5% training data, our model exceeds the best baseline by a large margin. It further indicates that our model is more robust to the data scarcity problem.

4.4 Ablation Study

Our proposed approach contains several complementary modules and pre-training tasks. Thus, we conduct experiments on KPC and QRC tasks to verify the contribution of these modules and tasks. Concretely, we remove the module GAT, BERT, Syntax-Aware Memory Network, or the task MLM, DTC and TGCL, respectively.

In Table 4, we can see that the performance drops by removing any modules or pre-training tasks. It shows the effectiveness of these modules or pre-training tasks in our proposed model. Especially, the model performance significantly decreases when we removing the textual encoder BERT, which implies that the text representations are more important for math problem understanding. Besides, we can see that removing MLM also results in a large performance drop, since it is the key pre-training task for our text encoder.

4.5 Hyper-Parameters Analysis

Our proposed model contains a few parameters to tune. In this part, we tune two parameters and examine their robustness on model performance, *i.e.,* the number of GAT Layer and the continual pre-training steps. We conduct experiments on KPC and QRC tasks and show the change curves of Accuracy in Figure 3.

We can observe that our model achieves the best performance in 80k steps. It indicates that our model can be improved by continual pre-training gradually and may overfit after 80k steps. Besides, our model achieves the best performance with 6 GAT layers, which shows that 6 GAT layers are sufficient to capture the information in syntax graph.

5 Related Work

In this section, we review the related work from the following two aspects, namely math problem understanding and continual pre-training of language models.

Math Problem Understanding. Math problem understanding tasks focus on understanding the texts, formulas and symbols in math domain. A surge of works aim to understand the math formulas for problem solving or mathematical information retrieval. In a typical way, the formula is usually transformed as a tree or graph (*e.g.,* Operator Tree (Zanibbi and Blostein, 2012)), then network embedding method (Mansouri et al., 2019) and graph neural network (Song and Chen, 2021) are utilized to encode it. Besides, a number of works focus on understanding math problem based on the textual information. Among them, Math Word Problem (MWP) Solving is a popular task that generates executable mathematical expression for the math word problem to produce the final answer. Numerous deep learning based methods have been proposed to tackle the MWP task, including Seq2Seq (Chiang and Chen, 2019; Li et al., 2019), Seq2Tree (Wang et al., 2019; Qin et al., 2020), and Pre-trained Language Models (Kim et al., 2020; Liang et al., 2021). More recently, several studies attempt to model more complex math problems (Huang et al., 2020; Hendrycks et al., 2021) that require a deep understanding of both textual and formula semantics.

Continual Pre-training of Language Models. Continually pre-training can effectively improve pre-trained model's performance on new domains or downstream tasks (Gururangan et al., 2020). To achieve it, most of previous works either continually optimize the model parameters with BERT-like tasks on domain or task related corpus (*e.g.,* scientific (Beltagy et al., 2019) and bio-media (Lee et al., 2020)), or design new pre-training objectives for task adaption (*e.g.,* commonsense reasoning (Zhou et al., 2021) and dialogue adaption (Li et al., 2020)). Besides, several works (Wang et al., 2020; Xiang et al., 2020) utilize both domain-related corpus and new pre-training objectives for continual pre-training, or revise the Transformer structure of PLMs for better adaption (Ghosal et al., 2020). For math problem understanding, the recently proposed MathBERT (Peng et al., 2021) adopts math domain corpus and formula-related pre-training tasks for continual pre-training.

6 Conclusion and Future Work

In this paper, we proposed COMUS, a continual pre-training approach for math problem understanding. By integrating the formulas with the syntax tree of mathematical text, we constructed the math syntax graph and designed the syntax-aware memory network to fuse the semantic information from the text and formulas. In the memory network, we treated tokens from the text and triplets from the graph as the queries and slot entries, respectively, and modeled the semantic interaction between tokens and their semantic-related nodes via multi-view read and write operations. Besides, we devised three continual pre-training tasks to further enhance and align the representations of the textual description and math syntax graph of the math problem. Experimental results have shown that our approach outperforms several competitive baselines on four tasks in the math domain.

In future work, we will consider applying our method to solve more difficult math-related tasks, *e.g.,* automatic math problem solving and analysis generation. Besides, we will also consider incorporating external math domain knowledge into our model to improve the understanding of mathematical logic and numerical reasoning.

Ethical Consideration

In this part, we discuss the main ethical consideration of this work: (1) Privacy. The data adopted in this work (*i.e.,* pre-training corpus and fine-tuning data) is created by human annotation for research purposes, and should not cause privacy issues. (2) Potential Problems. PLMs have been shown to capture certain biases from their pre-trained data (Bender et al., 2021). There are increasing efforts to address this problem in the community (Ross et al., 2021).

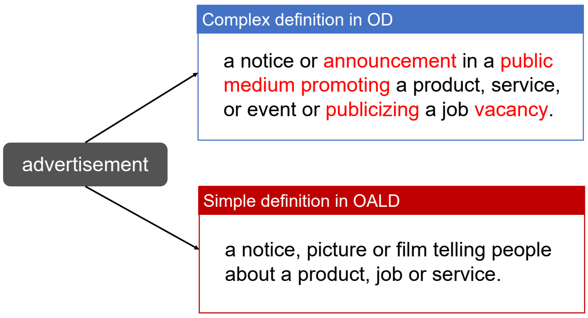
Abstract

The definition generation task can help language learners by providing explanations for unfamiliar words. This task has attracted much attention in recent years. We propose a novel task of Simple Definition Generation (SDG) to help language learners and low literacy readers. A significant challenge of this task is the lack of learner's dictionaries in many languages, and therefore the lack of data for supervised training. We explore this task and propose a multitasking framework **SimpDefiner** that only requires a standard dictionary with complex definitions and a corpus containing arbitrary simple texts. We disentangle the complexity factors from the text by carefully designing a parameter sharing scheme between two decoders. By jointly training these components, the framework can generate both complex and simple definitions simultaneously. We demonstrate that the framework can generate relevant, simple definitions for the target words through automatic and manual evaluations on English and Chinese datasets. Our method outperforms the baseline model by a 1.77 SARI score on the English dataset, and raises the proportion of the low level (HSK level 1-3) words in Chinese definitions by 3.87% [1].

1 Introduction

Helping language learners understand words in doubt is an important topic in the field of Intelligent Computer-Assisted Language Learning (ICALL) (Segler et al., 2002; Enayati and Gilakjani, 2020; Lolita et al., 2020). In recent years, researchers attempted to automatically generate definitions for words rather than formulating predefined word-definition inventories (Ishiwatari et al., 2019; Yang et al., 2020; Huang et al., 2021). There are two reasons for this. Firstly, it can be difficult for users to distinguish which sense is appropriate in the current context because of the cognitively inaccurate nature of discrete sense boundaries (Rosch and Mervis, 1975; Kilgarriff, 1997; Tyler and Evans, 2001). Secondly, the predefined inventories need to be updated manually by lexicographers, which is time-consuming and causes dictionaries to lag behind the ever-changing language usage.



a notice or announcement in a public medium promoting a product, service, or event or publicizing a job vacancy.

a notice, picture or film telling people about a product, job or service.

Figure 1: Different definitions for *advertisement* in the Oxford Dictionary (OD) and Oxford Advanced Learner's Dictionary (OALD).

Different from previous work (Noraset et al., 2017; Gadetsky et al., 2018; Mickus et al., 2019; Kong et al., 2020) that focused only on how to generate definitions, we further propose a novel task of **S**imple **D**efinition **G**eneration (SDG). Making the definitions easier to read and understand could benefit the language learners, low literacy readers, as well as helping people with aphasia or dyslexia. For example, compared with the Oxford Dictionary (OD), the Oxford Advanced Learner's Dictionary (OALD) has simpler definitions, which are specifically designed for language learners. As shown in Figure 1, the definition of the word *advertisement* in OALD does not contain difficult words or phrases such as *announcement* and *public medium*.

The goal of SDG task is to generate simple definitions for languages that lack learner's dictionary. For example, Chinese as Second Language (CSL) learners do not have suitable dictionaries. As Zhang (2011) pointed out, since the difficulty of

definitions is not considered, the existing dictionary cannot meet CSL learner's needs.

The SDG task is challenging because it requires a model to learn from a standard dictionary containing complex definitions and then generate simple ones, and hence fully unsupervised. A seemingly feasible solution is to generate definitions first and then simplify them, i.e., the generation-simplification pipeline. However, the simplification task requires dataset with complex-simple sentence pairs, and such data is also difficult to find in languages other than English (Martin et al., 2020). Besides, the pipeline methods do not perform well due to accumulated errors (Section 6.1).

To solve this dilemma and bridge the gap between practical needs for simple definitions and current trivial definition generation systems, we present a novel method for the SDG task. As illustrated in Figure 2, our method leverages a multitasking framework **SimpDefiner** to generate simple definitions by performing three sub-tasks at the same time, which are definition generation, text reconstruction, and language modeling tasks. The framework consists of a fully shared encoder and two partially shared decoders. We disentangle the complexity factors from the text by designing a parameter sharing scheme. Particularly, we share parameters in Complexity-Dependent Layer Normalization and Complexity-Dependent Query Projection of the transformer architecture (Vaswani et al., 2017) to control the complexity (Section 3.3). Through joint learning and sharing parameters between the decoders, the SimpDefiner is able to generate complex and simple definitions simultaneously.

Main contributions of our paper are listed below:

- For the first time, we propose the task of SDG to generate simple definitions without supervised training data.
- We propose a multitasking framework SimpDefiner to tackle this task. Through joint training three sub-tasks, the framework can generate complex and simple definitions simultaneously.
- Both automatic and manual evaluations demonstrate the effectiveness of SimpDefiner. The framework outperforms the baseline model by 1.77 SARI score on the English test set. And the proportion of low level words (HSK level 1-3) in generated definitions raised by 3.87% on the Chinese test set.

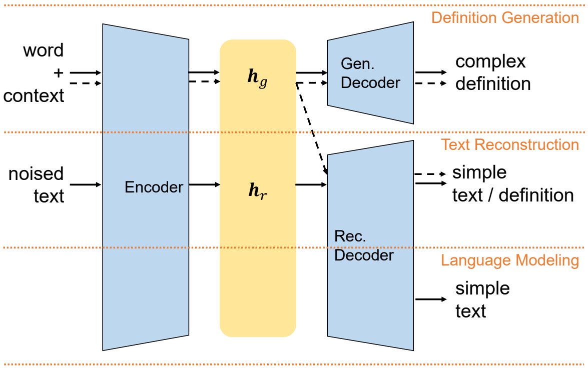

Figure 2: The SimpDefiner consists of three sub-tasks. Gen. means generation and Rec. means reconstruction. The solid black lines indicate the data-flow during training, and the dashed black lines indicate the data-flow during inference.

2 Related Work

2.1 Definition Generation

The definition generation task is first introduced by Noraset et al. (2017). Although this task is proposed as a potentially useful tool for explainable AI, many subsequent works believe that it can assist language learning by giving definitions for words in the text (Ishiwatari et al., 2019; Mickus et al., 2019; Yang et al., 2020).

Various studies attempted to generate multiple different definitions for polysemous words. Gadetsky et al. (2018) tackled this problem by computing the AdaGram vectors (Bartunov et al., 2016) of input words, which are capable of learning different representations at desired semantic resolutions. However, generating different definitions based on contexts, i.e., example sentences, became the mainstream method (Chang et al., 2018; Reid et al., 2020; Li et al., 2020; Bevilacqua et al., 2020). Among them, some studies used pre-trained language models to obtain contextualized embeddings. Reid et al. (2020) initialized encoders with BERT (Devlin et al., 2019) and employed variational inference for estimation and leveraged contextualized word embeddings for improved performance. Bevilacqua et al. (2020) employed a novel span-based encoding scheme to fine-tune a pre-trained English encoder-decoder system to generate definitions. Huang et al. (2021) leveraged the T5 (Raffel et al., 2019) model for this task and introduced a re-ranking mechanism to model specificity in definitions.

Our proposed SimpDefiner also takes the given word and context as input. Differently, our main focus is to generate definitions with appropriate complexity to better help language learners. Besides, our model is based on MASS (Song et al., 2019), which is a pre-trained encoder-decoder model and is suitable for generation tasks.

2.2 Sentence Simplification

Researchers usually regard the sentence simplification task as a monolingual variant of machine translation (MT) (Wubben et al., 2012). Benefiting from the advancement of neural machine translation, this task has also made great progress in recent years.

Lately, many works built upon the Seq2Seq MT model (Sutskever et al., 2014) performed well. First attempted by Nisioi et al. (2017), the Seq2Seq models for this task are able to perform lexical simplification and content reduction simultaneously by training on complex-simple sentence pairs. This method was inherited and improved by many subsequent works, such as combining with the reinforcement learning method by setting a simplification reward (Zhang and Lapata, 2017), augmenting memory capacities (Vu et al., 2018) or training with multitasking on entailment and paraphrase generation (Guo et al., 2018). Martin et al. (2019) proposed to prepend additional prompt tokens to source sentences at train time, which enables the end-users to condition the simplifications returned by the model on attributes like length, lexical complexity, and syntactic complexity. This controllable simplification system (called ACCESS) and its improved version MUSS (Martin et al., 2020) achieved SOTA results on the Turk corpus in terms of the SARI metric (Xu et al., 2016).

The generation-simplification pipeline methods are used as baselines of the SDG task, and we use both ACCESS and MUSS models for the simplification. Unlike the baseline, the SimpDefiner can generate simple definitions directly, alleviating the accumulated errors.

2.3 Unsupervised Style Transfer

Style transfer aims to change the style attributes while preserving the content. Our work is related to unsupervised style transfer by regarding the text complexity as one of the style attributes (Kawashima and Takagi, 2019).

Dumoulin et al. (2017) demonstrated that the neural networks can capture the artistic style of a diversity of paintings. The authors discovered that adjusting parameters in the layer normalization mechanism leads to different artistic styles. This method permits users to transform images to arbitrary styles learned from individual paintings. Jin et al. (2020) successfully applied this method to the task of headline generation, allowing the model to generate headlines of a specific style, such as humorous, romantic or click-baity, in an unsupervised manner.

By treating the task of simplification as a variant of style transfer, we borrow the insight of learning complexity-dependent parameters in the Layer Normalization mechanism. Additionally, we introduce the language modeling task into SimpDefiner, which is to enhance the decoder and make it more sensitive to text complexity.

3 Method

We integrate three sub-tasks of definition generation, text reconstruction, and language modeling into the SimpDefiner. This section first gives a formal definition of the SDG task, then introduces each sub-task, and finally the parameter sharing scheme.

3.1 Task Formulation

The SDG task is to generate a simple definition $\boldsymbol{d}^{sim}$ for a given word and context $(w^*, \boldsymbol{c})$, where $\boldsymbol{c} = [w_1, \ldots, w^*, \ldots, w_n]$ is a sentence containing w^*. This task is challenging because there is no corpus like $\{(w_i^*, \boldsymbol{c}_i, \boldsymbol{d}_i^{sim})\}_{i=1}^N$ and hence it is fully unsupervised.

The only data available in this work include a standard dictionary dataset $G = \{(w_i^*, \boldsymbol{c}_i, \boldsymbol{d}_i^{com})\}_{i=1}^N$ and a simple text corpus $Y = \{\boldsymbol{y}_i\}_{i=1}^M$. Note that we use $\boldsymbol{d}^{com}$ for complex definitions and $\boldsymbol{d}^{sim}$ for simple ones.

3.2 Multitasking Framework

We design the three sub-tasks in the SimpDefiner to learn different abilities. Cooperating with each other, the entire framework obtains the ability to compute the conditional probability $P(\boldsymbol{d}^{sim}|w^*, \boldsymbol{c})$ of simple definitions in a zero-shot manner.

Specifically, the definition generation task aims to model the probability of a complex definition given the word and context $P(\boldsymbol{d}^{com}|w^*, \boldsymbol{c})$ (Section 3.2.1). And the text reconstruction task aims to model the probability of a simple sentence given the corrupted version $P(\boldsymbol{y}|\tilde{\boldsymbol{y}})$ (Section 3.2.2). As we can see, neither task can directly get the $P(\boldsymbol{d}^{sim}|w^{*}, \boldsymbol{c})$. To solve the problem, we assume that complexity and semantic information are controlled by different parameters in the decoders, and we attempt to disentangle the complexity factors from the text through a carefully designed parameter sharing scheme. In the inference stage, we obtain a simple definition by feeding the encoded hidden state into the reconstruction decoder as in Figure 2. The detailed parameter sharing scheme is in Section 3.3.

Nevertheless, the complexity information may still be kept in some shared parameters, resulting in the reconstruction decoder fail to generate simple definitions occasionally. Eliminating the complexity information in all shared parameters is obviously technically impossible. Instead, we introduce the language modeling task (Section 3.2.3) to enhance the reconstruction decoder and make it more *focused* on simple text generation. The experiment results in Section 6 confirm our assumption.

3.2.1 Definition Generation Task

We follow the mainstream method (Yang et al., 2020; Kong et al., 2020; Reid et al., 2020) to concatenate the word and context together with a special token [SEP] as $\mathbf{x} = (w^{*}; \text{[SEP]}; \boldsymbol{c})$. The entire sequence is then fed into SimpDefiner, and the definition is obtained by the following language model:

$$P(\boldsymbol{d}^{com}|\mathbf{x};\boldsymbol{\theta}_g) = \prod_t P\left(\boldsymbol{d}_t^{com}|\boldsymbol{d}_{<t}^{com}, \mathbf{x}; \boldsymbol{\theta}_g\right), \quad (1)$$

where $\boldsymbol{d}_t^{com}$ is the t-th token of the definition, and $\boldsymbol{\theta}_g$ is the set of parameters. The model is optimized using the following loss function.

$$\mathcal{L}_{gen}(\boldsymbol{\theta}_g) = -\sum_{(\mathbf{x},\boldsymbol{d}^{com})\in G} \log P(\boldsymbol{d}^{com}|\mathbf{x};\boldsymbol{\theta}_g) \quad (2)$$

3.2.2 Text Reconstruction Task

We corrupt each sentence in the corpus Y by randomly deleting or blanking some words and shuffling the word orders. And then we obtain a new corpus $\tilde{Y} = \{(\tilde{\boldsymbol{y}}_i, \boldsymbol{y}_i)\}_{i=1}^{M}$, and $\tilde{\boldsymbol{y}}$ is a corrupted version of $\boldsymbol{y}$. We input $\tilde{\boldsymbol{y}}$ into SimpDefiner and obtain $\boldsymbol{y}$ by solving a self-supervised task of

$$P(\boldsymbol{y}|\tilde{\boldsymbol{y}};\boldsymbol{\theta}_r) = \prod_t P\left(\boldsymbol{y}_t|\boldsymbol{y}_{<t}, \tilde{\boldsymbol{y}}; \boldsymbol{\theta}_r\right), \quad (3)$$

where $\boldsymbol{y}_t$ is the t-th token of the sentence, and $\boldsymbol{\theta}_r$ is a set of parameters. The loss function of this task is as follows:

$$\mathcal{L}_{rec}(\boldsymbol{\theta}_r) = -\sum_{(\boldsymbol{y},\tilde{\boldsymbol{y}})\in\tilde{Y}} \log P(\boldsymbol{y}|\tilde{\boldsymbol{y}};\boldsymbol{\theta}_r). \quad (4)$$

3.2.3 Language Modeling Task

This task facilitates zero-shot generation of $P(\boldsymbol{d}^{sim}|\mathbf{x})$ by jointly training the reconstruction decoder as a language model. Once the model captures correct complexity that guides the model to generate the desired simple texts, it's more likely for the model to ignore the wrongly shared complexity information. Similar to Eq. 3, we have:

$$P(\boldsymbol{y}|\boldsymbol{\theta}_l) = \prod_t P\left(\boldsymbol{y}_t|\boldsymbol{y}_{<t}; \boldsymbol{\theta}_l\right). \quad (5)$$

It is equivalent to masking the encoder out and ignoring the attention modules between the encoder and reconstruction decoder. The model is optimized by the following loss function:

$$\mathcal{L}_{lm}(\boldsymbol{\theta}_l) = -\sum_{\boldsymbol{y}\in Y} \log P(\boldsymbol{y}|\boldsymbol{\theta}_l). \quad (6)$$

Finally, we train the entire SimpDefiner by jointly minimizing the weighted sum of all above mentioned loss functions. And the overall loss function is calculated as:

$$\mathcal{L} = \lambda_\alpha \mathcal{L}_{gen} + \lambda_\beta \mathcal{L}_{rec} + \lambda_\gamma \mathcal{L}_{lm}, \quad (7)$$

where λ_α, λ_β, λ_γ are hyper-parameters.

3.3 Parameter-Sharing Scheme

For parameters in the decoders, we divided them into two parts, which are complexity-independent and complexity-dependent parameters. The former ones are shared between decoders, and the latter ones are not, as illustrated in Figure 3.

We now introduce the complexity-dependent layers, namely Complexity-Dependent Layer Normalization and Complexity-Dependent Query Projection.

Complexity-Dependent Layer Normalization Previous works (Dumoulin et al., 2017; Jin et al., 2020) demonstrated that the layer normalization is related to the style of the target texts. We further argue that as an attribute of style, the complexity can be retained by independent layer normalization. Thus, we make the scaling and shifting parameters

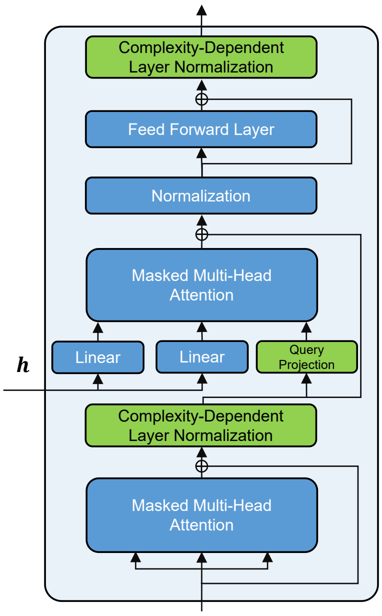

Figure 3: The parameter-sharing scheme between decoders. Parameters in blue layers are shared, and those in green are not.

for layer normalization not shared in both decoders. This approach is to transform a layer activation $\boldsymbol{x}$ into a complexity-specific normalized activation $\boldsymbol{z}$ as:

$$\boldsymbol{z} = \gamma_c(\frac{\boldsymbol{x} - \mu}{\sigma}) - \beta_c, \tag{8}$$

where μ, σ are the mean and standard deviation of the batch of $\boldsymbol{x}$, and γ_c, β_c are learnable parameters specific to complexity c. Note that c is a binary variable indicating different decoders. This mechanism is used in all decoder layers.

Complexity-Dependent Query Projection The decoder layers extract information from encoded hidden states through cross-attention mechanism. We believe that the required information may vary for different complexity. Therefore, the parameters of the linear mapping used for the query transformation in the cross-attention are not shared among decoders. This calculation is as follows:

$$\boldsymbol{Q} = \hat{\boldsymbol{Q}} \cdot \boldsymbol{W}_c^q, \tag{9}$$

where $\boldsymbol{W}_c^q$ is the query transformation matrix specific to complexity c. The obtained query vector $\boldsymbol{Q}$ is then fed into the cross-attention mechanism. By using this approach, the model can obtain different information from the encoded hidden states for different complexities.

4 Datasets

We evaluate the proposed multitasking framework on both English and Chinese datasets. Each language has a definition generation dataset and a simple text corpus.

4.1 English Dataset

The English datasets are constructed from the Oxford Dictionary (OD) and Oxford Advanced Learner's Dictionary (OALD). Since the OALD is for language learners, it has much simpler definitions than OD. Therefore, we use the OD for the definition generation training, and use the OALD for validation of simple definition generation. Note that the words used for testing are excluded from the training and validation sets.

For the definition generation dataset, we directly use the OD dataset published by Gadetsky et al. (2018). The training set has 33,128 words and 97,855 entries. Each entry consists of a triplet of $(w^*, \boldsymbol{c}, \boldsymbol{d}^{com})$. For testing, we align the words and context in OD with the definitions in OALD through manual annotation. The annotated test set includes 3,881 words and 5,111 entries, which is used for automatic evaluation in experiments. Each entry in the test set has both golden complex and simple definitions from OD and OALD, respectively. Detailed statistics are listed in Table 1.

We extract the OALD definitions that are not in the test set for constructing the simple text corpus. This corpus has 32,395 sentences with an average length of 12.12. We list more statistics in Table 2.

During training, the definition generation dataset and the simple text corpus are randomly sampled as mini-batches respectively. And there is no alignment between the two mini-batches at each step.

4.2 Chinese Dataset

For the definition generation dataset, we use the Chinese WordNet (CWN) (Huang et al., 2010), which is a semantic lexicon aiming to provide a knowledge base of sense distinction.[2] We use the corresponding words, contexts, and definitions in CWN for the definition generation task. We split the entire dataset into training, validation, and test sets roughly according to the ratio of 8:1:1. The training set contains 6,574 words and 67,861 entries. Statistics are listed in Table 1.

---

[2] Chinese WordNet: `http://lope.linguistics.ntu.edu.tw/cwn2`

	OD			OALD	CWN		
	Train	Valid	Test	Test	Train	Valid	Test
Words	33,128	8,867	3,881	3,881	6,574	823	823
Entries	97,855	12,232	5,111	5,111	67,861	8,082	8,599
Context Length	17.74	17.80	16.24	16.24	34.49	34.73	34.06
Def. Length	11.02	10.99	10.03	12.74	14.76	14.60	14.72

Table 1: Statistics of the OD (English) dataset, OALD (English) test set, and CWN (Chinese) dataset. The rows are number of words and entries, and the average length of contexts and definitions.

	Sents	Tokens	Avg. Len
English	32,395	392,625	12.12
Chinese	58,867	860,761	14.62

Table 2: Statistics of simple text corpora. The columns are number of sentences and tokens, and the average length of sentences.

For the simple text corpus, we extract 58,867 sentences from a number of primary level Chinese as Second Language textbooks, with an average sentence length of 14.62.

Since no suitable dictionary can be used for evaluation, there are no golden simple definitions in Chinese Dataset. In the experiments, we count the difficulty level of words in definitions to estimate if they are simple. We also organize a manual evaluation to score the accuracy and simplicity of definitions.

5 Experiments

This section presents the experimental settings and evaluation methods.

5.1 Settings

Baselines We compare the SimpDefiner with generation-simplification pipelines. We first employ LOG-CaD (Ishiwatari et al., 2019) and MASS (Song et al., 2019) models to generate definitions, and then employ ACCESS (Martin et al., 2019) and MUSS (Martin et al., 2020) models to simplify them. Thus, we have four different pipeline baselines. Since these models are not available in Chinese, we only apply these pipelines to English datasets. For the Chinese SDG task, we specially pretrained a MASS-ZH model from scratch using the *Chinese Gigaword Fifth Edition*[3] corpus. Note that we set the learning rate to 3e-4, warmup steps to 500 when fine-tuning both MASS and MASS-ZH.

SimpDefiner We use the parameters in the MASS model to initialize the encoder and two decoders in SimpDefiner. For the sentence corruption in the text reconstruction task, we randomly delete or blank words with a uniform probability of 0.2, and randomly shuffle the order of words within 5 tokens. For the language modeling task, we set the input representations to **0** and use the simplified text as the target output. We tune the λ parameters in Eq. 7 on the validation set and adopt the same hyper-parameters as the baseline for comparison. We set 5 different random seeds as and report the average result of multiple runs. Each run takes 7.68 GPU hours on 4 GeFource RTX 2080 Ti GPUs.

5.2 Evaluation

Evaluation of the generated definitions mainly focuses on two aspects, i.e., accuracy and simplicity. We perform both automatic and manual evaluations for each aspect.

We first introduce these automatic metrics, and then the manual evaluation method.

BLEU Previous definition generation studies (Noraset et al., 2017; Yang et al., 2020; Kong et al., 2020) used the BLEU (Papineni et al., 2002) score to measure the closeness of generated results to the standard answers, and to evaluate the accuracy of results. Since the English test set is manually annotated, we calculate the BLEU score of both complex and simple definitions, respectively.

Semantic Similarity In addition to the BLEU score, we use the sentence-transformers toolkit (Reimers and Gurevych, 2020) to convert the generated definitions and references into sentence vectors, and calculate cosine similarity between them.

SARI SARI (Xu et al., 2016) is a lexical simplicity metric that measures how good are the words added, deleted and kept by a simplification model. This metric compares the model output to simplification references and the original sentence. We use

	L1-3 (%)	L7+ (%)
MASS	44.16	37.05
SimpDefiner	**48.03**	**36.59**

Table 4: Main results on the Chinese test set.

the SARI implementation in the EASSE toolkit[4].

HSK Level HSK, namely Chinese Proficiency Test, is set up to test the proficiency of non-native speakers[5]. It has nine levels, from easy to hard, and each level corresponds to a vocabulary. We count the proportion of words at levels 1-3 and 7+ in the generated definitions. The higher the proportion of words in levels 1-3 (7+), the easier (more challenging) the definitions are understood.

Manual Evaluation We randomly select 200 words and contexts from the Chinese test set and let the MASS and SimpDefiner generate definitions for them one by one. We mix the two generated definitions and the golden complex definition and then ask three native-speaker annotators to score them. Specifically, each annotator evaluates the definitions on two criteria of accuracy and simplicity. Both criteria have a range of 1-3. For accuracy, the annotators are asked to evaluate how semantically relevant the definitions are to the word. For simplicity, the annotators are asked to evaluate how simple the definitions are. After collecting evaluation results, we average the scores as final score.

6 Results and Analysis

6.1 Main Results

Table 3 and Table 4 present the experiment results on the English and Chinese test sets respectively. Results show that our proposed SimpDefiner significantly outperforms baseline methods of generation-simplification pipelines on both English and Chinese datasets.

		#1	#2	#3	Avg.
Acc.	Golden	3.00	2.93	2.98	2.97
	MASS	1.26	1.30	1.38	1.31
	SimpDefiner	1.48	1.47	1.59	**1.51**
Sim.	Golden	2.04	2.06	2.11	2.07
	MASS	1.92	2.03	1.89	1.95
	SimpDefiner	2.14	2.04	2.21	**2.13**

Table 5: Manual evaluation results on the Chinese test set. Accuracy and simplicity scores are listed in the table. The last column are averaged scores among all three annotators.

For English results, the performance of simple definition generation improves 2.1 and 8.46 on the BLEU and SemSim metrics respectively, and improves 1.77 on the SARI metric. This indicates that both accuracy and simplicity are effectively improved comparing with the baseline. We also observe that complex definition generation also improves by 0.17 on BLEU and 1.09 on SemSim. This shows that SimpDefiner improves the ability to generate both complex and simple definitions.

For Chinese results, we compute the HSK Level metric on generated simple definitions. We can see that the proportion of low-level (HSK level 1-3) words increases by 3.87%, and that of high-level (HSK level 7+) words decreases by 0.46%. The lexical complexity of the SimpDefiner generated definitions are significantly reduced.

Besides, we also conduct a manual evaluation on the Chinese test set, and the results are listed in Table 5. From the averaged scores, we observe that SimpDefiner outperforms MASS by 0.2 in terms of accuracy (more accurate) and 0.18 in terms of simplicity (more straightforward). On the accuracy score, all three annotators agree that SimpDefiner has higher accuracy than MASS, which shows the superiority of our framework. As expected, the golden definitions have the highest accuracy in the table, far exceeding the definitions generated by the two models. We believe this is caused by insufficient knowledge in the model, and this can be solved by using larger pretrained models, such as BART (Lewis et al., 2019). On the simplicity score, three annotators agree that SimpDefiner generates simpler definitions than MASS, and two of three annotators think SimpDefiner generates simpler definitions than the golden ones.

6.2 Ablation Study

We conduct ablation experiment to demonstrate the effectiveness of SimpDefiner components and

Word	commander
Context	Military commanders have warned coalition troops in the south.
Golden	A person who is in charge of sth, especially an officer in charge of a particular group of soldiers or a military operation.
Baseline	An officer of the highest rank is a country in a country.
SimpDefiner	The head of a military force.
Word	督促 (supervise and urge)
Context	我很感谢他的支持、鼓励与督促。 I appreciate his support, encouragement and supervision.
Golden	监督他人并促使后述事件发生。 Supervise others and promote the occurrence of the following events.
Baseline	以后述对象为凭借进行特定事件。 Sb. is used as a reference for specific events.
SimpDefiner	要求后述对象赶快行动。 Ask sb. to act quickly.

Table 8: Cases of generated simple definitions.

the parameter sharing scheme. For the language modeling (LM) and text reconstruction (TR) tasks, we ablate them by setting their weights to 0. For the layer normalization (LN) and query projection (QP) as parameter-shared layers, we ablate them by sharing their parameters between models. We illustrate the experiment results in Table 6.

In general, ablating any of the components or parameter-shared layers reduces the performance in terms of simple definitions, which indicates that the SimpDefiner benefits from both components and parameter sharing scheme. We also observe that the performance of ablation experiments have slight disturbance on complex definitions. But since we pay more attention to the performance on simple definitions, we argue that the benefits of SimpDefiner far outweigh the losses.

6.3 Analysis on Hyper-Parameters

Furthermore, we conduct additional experiments on the English dataset to study how hyper-parameters affect the performance. By setting different λ to each model, we observe the relationship between the performance and these weights.

The experiment results are listed in Table 7. From the table, we observe the inconsistency between metrics. As the definition generation task weight declines, the BLEU and SemSim metrics are generally declining, but the SARI metric is increasing. Since the BLEU and SemSim measure the accuracy and the SARI measures simplicity, we consider this phenomenon as a seesaw between the two attributes of accuracy and simplicity. The balance between them can be achieved by conditioning the hyper-parameters.

6.4 Case Study

Table 8 shows two generation cases from English and Chinese test set respectively. In both cases, the golden definition is a long sentence with quite complicated syntax. The baseline generated definitions contains difficult words and often wrongly defines the given word. In the English case, the word *commander* is defined by the baseline as *an officer of the highest rank in a country*, which is incorrect in most cases. In the Chinese case, the baseline generated definition contains difficult words like 凭借 *(reference)* and 特定事件 *(specific events)*. On the other hand, the SimpDefiner generates simple and accurate definitions in both cases.

7 Conclusion

In this work, we propose the SDG task, a novel task of generating simplified definitions in a zero-shot manner. To this end, we leverage a multitasking framework SimpDefiner to tackle this task. We introduce a text reconstruction task to the framework to control the text complexity, and a language modeling task to enhance the decoder. For evaluation, we construct a novel test set in English by manually aligning the two dictionaries of OD and OALD. The automatic and manual evaluations indicate that the our proposed framework can generate more accurate and more straightforward definitions than other models and the generation-simplification pipelines. In the future, we will try to combine the current method with prompt learning methods, aiming to let users condition the complexity of generated definitions.

Abstract

Solving math word problems requires deductive reasoning over the quantities in the text. Various recent research efforts mostly relied on sequence-to-sequence or sequence-to-tree models to generate mathematical expressions without explicitly performing relational reasoning between quantities in the given context. While empirically effective, such approaches typically do not provide explanations for the generated expressions. In this work, we view the task as a *complex relation extraction* problem, proposing a novel approach that presents explainable deductive reasoning steps to iteratively construct target expressions, where each step involves a primitive operation over two quantities defining their relation. Through extensive experiments on four benchmark datasets, we show that the proposed model significantly outperforms existing strong baselines. We further demonstrate that the deductive procedure not only presents more explainable steps but also enables us to make more accurate predictions on questions that require more complex reasoning.[1]

1 Introduction

Math word problem (MWP) solving (Bobrow, 1964) is a task of answering a mathematical question that is described in natural language. Solving MWP requires logical reasoning over the quantities presented in the context (Mukherjee and Garain, 2008) to compute the numerical answer. Various recent research efforts regarded the problem as a generation problem – typically, such models focus on generating the complete target mathematical expression, often represented in the form of a linear sequence or a tree structure (Xie and Sun, 2019).

Question: *In a division sum , the remainder is **8** and the divisor is **6** times the quotient and is obt--ained by adding **3** to the thrice of the remainder. What is the divident?*

Answer: 129.5 **Expr**: $((8 \times 3 + 3) \times (8 \times 3 + 3) \div 6) + 8$

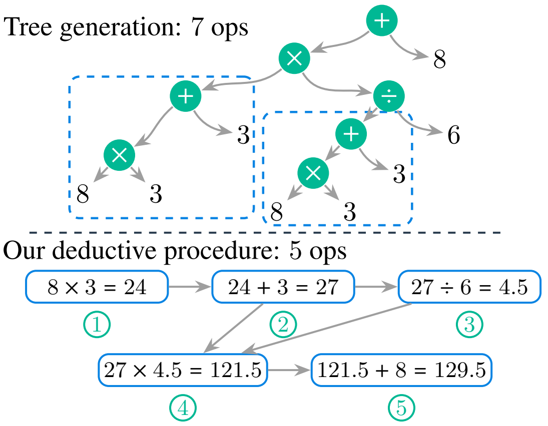

Figure 1: A MWP example taken from MathQA. Top: tree generation. Bottom: deductive procedure.

Figure 1 (top) depicts a typical approach that attempts to generate the target expression in the form of a tree structure, which is adopted in recent research efforts (Xie and Sun, 2019; Zhang et al., 2020; Patel et al., 2021; Wu et al., 2021). Specifically, the output is an expression that can be obtained from such a generated structure. We note that, however, there are several limitations with such a structure generation approach. First, such a process typically involves a particular order when generating the structure. In the example, given the complexity of the problem, the decision of generating the addition ("+") operation as the very first step could be counter-intuitive and does not provide adequate explanations that show the reasoning process when being presented to a human learner. Furthermore, the resulting tree contains identical sub-trees ("8 × 3 + 3") as highlighted in blue dashed boxes. Unless a certain specifically designed mechanism is introduced for reusing the already generated intermediate expression, the approach would need to repeat the same effort in its process for generating the same sub-expression.

---

May 22-27, 2022 ©2022 Association for Computational Linguistics

Solving math problems generally requires deductive reasoning, which is also regarded as one of the important abilities in children's cognitive development (Piaget, 1952). In this work, we propose a novel approach that explicitly presents deductive reasoning steps. We make a key observation that MWP solving fundamentally can be viewed as a *complex relation extraction* problem – the task of identifying the complex relations among the quantities that appear in the given problem text. Each primitive arithmetic operation (such as *addition*, *subtraction*) essentially defines a different type of relation. Drawing on the success of some recent models for relation extraction in the literature (Zhong and Chen, 2021), our proposed approach involves a process that repeatedly performs relation extraction between two chosen quantities (including newly generated quantities).

As shown in Figure 1, our approach directly extracts the relation ("*multiplication*", or "×") between 8 and 3, which come from the contexts "*remainder is 8*" and "*thrice of the remainder*". In addition, it allows us to reuse the results from the intermediate expression in the fourth step. This process naturally yields a deductive reasoning procedure that iteratively derives new knowledge from existing ones. Designing such a complex relation extraction system presents several practical challenges. For example, some quantities may be irrelevant to the question while some others may need to be used multiple times. The model also needs to learn how to properly handle the new quantities that emerge from the intermediate expressions. Learning how to effectively search for the optimal sequence of operations (relations) and when to stop the deductive process is also important.

In this work, we tackle the above challenges and make the following major contributions:

- We formulate MWP solving as a complex relation extraction task, where we aim to repeatedly identify the basic relations between different quantities. To the best of our knowledge, this is the first effort that successfully tackles MWP solving from such a new perspective.
- Our model is able to automatically produce explainable steps that lead to the final answer, presenting a deductive reasoning process.
- Our experimental results on four standard datasets across two languages show that our model significantly outperforms existing strong baselines. We further show that the model performs better on problems with more complex equations than previous approaches.

2 Related Work

Early efforts focused on solving MWP using probabilistic models with handcrafted features (Liguda and Pfeiffer, 2012). Kushman et al. (2014) and Roy and Roth (2018) designed templates to find the alignments between the declarative language and equations. Most recent works solve the problem by using sequence or tree generation models. Wang et al. (2017) proposed the Math23k dataset and presented a sequence-to-sequence (seq2seq) approach to generate the mathematical expression (Chiang and Chen, 2019). Other approaches improve the seq2seq model with reinforcement learning (Huang et al., 2018), template-based methods (Wang et al., 2019), and group attention mechanism (Li et al., 2019). Xie and Sun (2019) proposed a goal-driven tree-structured (GTS) model to generate the expression tree. This sequence-to-tree approach significantly improved the performance over the traditional seq2seq approaches. Some follow-up works incorporated external knowledge such as syntactic dependency (Shen and Jin, 2020; Lin et al., 2021) or commonsense knowledge (Wu et al., 2020). Cao et al. (2021) modeled the equations as a directed acyclic graph to obtain the expression. Zhang et al. (2020) and Li et al. (2020) adopted a graph-to-tree approach to model the quantity relations using the graph convolutional networks (GCN) (Kipf and Welling, 2017). Applying pre-trained language models such as BERT (Devlin et al., 2019) was shown to significantly benefit the tree expression generation (Lan et al., 2021; Tan et al., 2021; Liang et al., 2021; Li et al., 2021; Shen et al., 2021).

Different from the tree-based generation models, our work is related to deductive systems (Shieber et al., 1995; Nederhof, 2003) where we aim to obtain step-by-step expressions. Recent efforts have also been working towards this direction. Ling et al. (2017) constructed a dataset to provide explanations for expressions at each step. Amini et al. (2019) created the MathQA dataset annotated with step-by-step operations. The annotations present the expression at each intermediate step during problem-solving. Our deductive process (Figure 1) attempts to automatically obtain the expression in an incremental, step-by-step manner.

Our approach is also related to relation extraction (RE) (Zelenko et al., 2003), a fundamental task in

$$\begin{array}{ll} \textbf{input:} & q \text{ in } \mathcal{Q}^{(0)} \\ \textbf{axiom:} & 0 : \langle q_1, \cdots, q_{|\mathcal{Q}^{(0)}|} \rangle \end{array}$$

$$q_i \xrightarrow{op} q_j : \frac{t : \langle q_1, \cdots, q_{|\mathcal{Q}^{(t-1)}|} \rangle}{t+1 : \langle q_1, \cdots, q_{|\mathcal{Q}^{(t-1)}|} \mid q_{|\mathcal{Q}^{(t)}|} := e^{(t)}_{i,j,op} \rangle}$$

Figure 2: Our deductive system. t is the current step. $\langle \cdot \rangle$ denotes the quantity list.

the field of information extraction that is focused on identifying the relationships between a pair of entities. Recently, Zhong and Chen (2021) designed a simple and effective approach to directly model the relations on the span pair representations. In this work, we treat the operation between a pair of quantities as the relation at each step in our deductive reasoning process. Traditional methods (Liang et al., 2018) applied rule-based approaches to extract the mathematical relations.

MWP solving is typically regarded as one of the *system 2* tasks (Kahneman, 2011; Bengio et al., 2021), and our current approach to this problem is related to neural symbolic reasoning (Besold et al., 2017). We design differentiable modules (Andreas et al., 2016; Gupta et al., 2020) in our model (§3.2) to perform reasoning among the quantities.

3 Approach

The math word problem solving task can be defined as follows. Given a problem description $\mathcal{S} = \{w_1, w_2, \cdots, w_n\}$ that consists of a list of n words and $\mathcal{Q}_\mathcal{S} = \{q_1, q_2, \cdots, q_m\}$, a list of m quantities that appear in $\mathcal{S}$, our task is to solve the problem and return the numerical answer. Ideally, the answer shall be computed through a mathematical reasoning process over a series of primitive mathematical operations (Amini et al., 2019) as shown in Figure 1. Such operations may include "+" (*addition*), "−" (*subtraction*), "×" (*multiplication*), "÷" (*division*), and "∗∗" (*exponentiation*).[2]

In our view, each of the primitive mathematical operations above can essentially be used for describing a specific *relation* between quantities. Fundamentally, solving a math word problem is a problem of *complex relation extraction*, which requires us to repeatedly identify the relations between quantities (including those appearing in the text and those intermediate ones created by relations). The overall solving procedure requires invoking a relation classification module at each step, yielding a deductive reasoning process.

In practice, some questions cannot be answered without relying on certain predefined constants (such as π and 1) that may not have appeared in the given problem description. We therefore also consider a set of constants $\mathcal{C} = \{c_1, c_2, \cdots, c_{|\mathcal{C}|}\}$. Such constants are also regarded as quantities (i.e., they would be regarded as $\{q_{m+1}, q_{m+2}, \ldots, q_{m+|\mathcal{C}|}\}$) which may play useful roles when forming the final answer expression.

3.1 A Deductive System

As shown in Figure 1, applying the mathematical relation (e.g., "+") between two quantities yields an intermediate expression e. In general, at step t, the resulting expression $e^{(t)}$ (after evaluation) becomes a *newly created quantity* that is added to the list of candidate quantities and is ready for participating in the remaining deductive reasoning process from step $t+1$ onward. This process can be mathematically denoted as follows:

- Initialization:

$$\mathcal{Q}^{(0)} = \mathcal{Q}_\mathcal{S} \cup \mathcal{C}$$

- At step t:

$$\begin{aligned} e^{(t)}_{i,j,op} &= q_i \xrightarrow{op} q_j \quad q_i, q_j \in \mathcal{Q}^{(t-1)} \\ \mathcal{Q}^{(t)} &= \mathcal{Q}^{(t-1)} \cup \{e^{(t)}_{i,j,op}\} \\ q_{|\mathcal{Q}^{(t)}|} &:= e^{(t)}_{i,j,op} \end{aligned}$$

where $e^{(t)}_{i,j,op}$ represents the expression after applying the relation *op* to the ordered pair (q_i, q_j). Following the standard deduction systems (Shieber et al., 1995; Nederhof, 2003), the reasoning process can be formulated in Figure 2. We start with an axiom with the list of quantities in $\mathcal{Q}^{(0)}$. The inference rule is $q_i \xrightarrow{op} q_j$ as described above to obtain the expression as a new quantity at step t.

3.2 Model Components

Reasoner Figure 3 shows the deductive reasoning procedure in our model for an example that involves 3 quantities. We first convert the quantities (e.g., $2,088$) into a general quantity token "<*quant*>". We next adopt a pre-trained language model such as BERT (Devlin et al., 2019) or Roberta (Cui et al., 2019; Liu et al., 2019) to obtain the quantity representation $\boldsymbol{q}$ for each quantity q.

---

[2] While we consider binary operators, extending our approach to support unary or ternary operators is possible (§4.3).

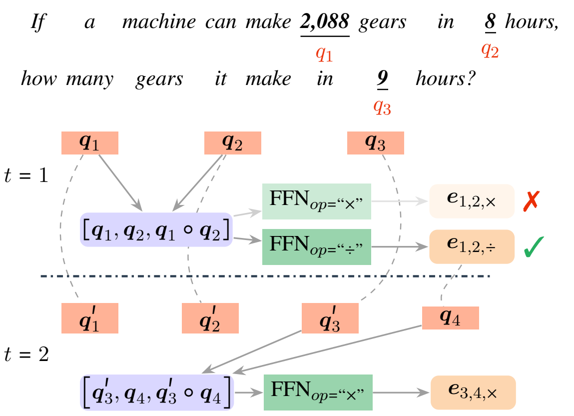

Figure 3: Model architecture for the deductive reasoner. We show the inference procedure to obtain the expression "$q_1 \div q_2 \times q_3$" for the example question.

Given the quantity representations, we consider all the possible quantity pairs, (q_i, q_j). Similar to Lee et al. (2017), we can obtain the representation of each pair by concatenating the two quantity representations and the element-wise product between them. As shown in Figure 3, we apply a non-linear feed-forward network (FFN) on top of the pair representation to get the representation of the newly created expression. The above procedure can be mathematically written as:

$$\boldsymbol{e}_{i,j,op} = \text{FFN}_{op}([\boldsymbol{q}_i, \boldsymbol{q}_j, \boldsymbol{q}_i \circ \boldsymbol{q}_j]), \quad i \le j \qquad (1)$$

where $\boldsymbol{e}_{i,j,op}$ is the representation of the intermediate expression e and op is the operation (e.g., "+", "−") applied to the ordered pair (q_i, q_j). FFN$_{op}$ is an operation-specific network that gives the expression representation under the particular operation op. Note that we have the constraint $i \le j$. As a result we also consider the "*reverse operation*" for division and subtraction (Roy and Roth, 2015).

As shown in Figure 3, the expression $\boldsymbol{e}_{1,2,\div}$ will be regarded as a new quantity with representation $\boldsymbol{q}_4$ at $t = 1$. In general, we can assign a score to a single reasoning step that yields the expression $e^{(t)}_{i,j,op}$ from q_i and q_j with operation op. Such a score can be calculated by summing over the scores defined over the representations of the two quantities and the score defined over the expression:

$$s(e^{(t)}_{i,j,op}) = s_q(\boldsymbol{q}_i) + s_q(\boldsymbol{q}_j) + s_e(\boldsymbol{e}_{i,j,op}) \qquad (2)$$

where we have:

$$\begin{aligned} s_q(\boldsymbol{q}_i) &= \mathbf{w}_q \cdot \text{FFN}(\boldsymbol{q}_i) \\ s_e(\boldsymbol{e}_{i,j,op}) &= \mathbf{w}_e \cdot \boldsymbol{e}_{i,j,op} \end{aligned} \qquad (3)$$

Rationalizer	**Mechanism**
Multi-head Self-Attention	Attention($Q = [\boldsymbol{q}_i, \boldsymbol{e}], K = [\boldsymbol{q}_i, \boldsymbol{e}], V = [\boldsymbol{q}_i, \boldsymbol{e}]$)
GRU cell	GRU_Cell(input = $\boldsymbol{q}_i$, previous hidden = $\boldsymbol{e}$)

Table 1: The mechanism in different rationalizers.

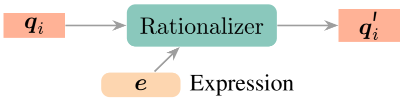

Figure 4: Rationalizing quantity representation.

where $s_q(\cdot)$ and $s_e(\cdot)$ are the scores assigned to the quantity and the expression, respectively, and $\mathbf{w}_q$ and $\mathbf{w}_e$ are the corresponding learnable parameters. Our goal is to find the optimal expression sequence $[e^{(1)}, e^{(2)}, \cdots, e^{(T)}]$ that enables us to compute the final numerical answer, where T is the total number of steps required for this deductive process.

Terminator Our model also has a mechanism that decides whether the deductive procedure is ready to terminate at any given time. We introduce a binary label τ, where 1 means the procedure stops here, and 0 otherwise. The final score of the expression e at time step t can be calculated as:

$$S(e^{(t)}_{i,j,op}, \tau) = s(e^{(t)}_{i,j,op}) + \mathbf{w}_\tau \cdot \text{FFN}(\boldsymbol{e}_{i,j,op}) \qquad (4)$$

where $\mathbf{w}_\tau$ is the parameter vector for scoring the τ.

Rationalizer Once we obtain a new intermediate expression at step t, it is crucial to update the representations for the existing quantities. We call this step *rationalization* because it could potentially give us the rationale that explains an outcome (Lei et al., 2016). As shown in Figure 4, the intermediate expression $\boldsymbol{e}$ serves as the rationale that explains how the quantity changes from $\boldsymbol{q}$ to $\boldsymbol{q}'$. Without this step, there is a potential shortcoming for the model. That is, because if the quantity representations do not get updated as we continue the deductive reasoning process, those expressions that were initially highly ranked (say, at the first step) would always be preferred over those lowly ranked ones throughout the process.[3] We rationalize the quantity representation using the current intermediate expression $e^{(t)}$, so that the quantity is aware of the generated expressions when its representation gets updated. This procedure can be mathematically formulated as follows:

$$\boldsymbol{q}_i' = \text{Rationalizer}(\boldsymbol{q}_i, \boldsymbol{e}^{(t)}) \quad \forall\ 1 \le i \le |\mathcal{Q}| \qquad (5)$$

---

[3] See the supplementary material for more details on this.

Dataset	#Train	#Valid	#Test	Avg. Sent Len	#Const.	Lang.

MathQA†	16,191	2,411	1,605	39.6	24	English
SVAMP	3,138	-	1,000	34.7	17	English

Table 2: Dataset statistics. †: we follow Tan et al. (2021) to do preprocessing and obtain the subset.

Two well-known techniques we can adopt as rationalizers are *multi-head self-attention* (Vaswani et al., 2017) and a *gated recurrent unit* (GRU) (Cho et al., 2014) cell, which allow us to update the quantity representation, given the intermediate expression representation. Table 1 shows the mechanism in two different rationalizers. For the first approach, we essentially construct a sentence with two token representations – quantity $\boldsymbol{q}_i$ and the previous expression $\boldsymbol{e}$ – to perform self-attention. In the second approach, we use $\boldsymbol{q}_i$ as the input state and $\boldsymbol{e}$ as the previous hidden state in a GRU cell.

3.3 Training and Inference

Similar to training sequence-to-sequence models (Luong et al., 2015), we adopt the teacher-forcing strategy (Williams and Zipser, 1989) to guide the model with gold expressions during training. The loss[4] can be written as:

$$\mathcal{L}(\boldsymbol{\theta}) = \sum_{t=1}^{T} \Big(\max_{(i,j,op)\in\mathcal{H}^{(t)},\tau} \Big[\mathcal{S}_{\boldsymbol{\theta}}(e^{(t)}_{i,j,op},\tau) \Big] - \mathcal{S}_{\boldsymbol{\theta}}(e^{(t)}_{i^*,j^*,op^*},\tau^*) \Big) + \lambda||\boldsymbol{\theta}||^2 \qquad (6)$$

where $\boldsymbol{\theta}$ includes all parameters in the deductive reasoner and $\mathcal{H}^{(t)}$ contains all the possible choices of quantity pairs and relations available at time step t. λ is the hyperparameter for the L_2 regularization term. The set $\mathcal{H}^{(t)}$ grows as new expressions are constructed and become new quantities during the deductive reasoning process. The overall loss is computed by summing over the loss at each time step (assuming totally T steps).

During inference, we set a maximum time step T_{max} and find the best expression e^* that has the highest score at each time step. Once we see $\tau = 1$ is chosen, we stop constructing new expressions and terminate the process. The overall expression (formed by the resulting expression sequence) will be used for computing the final numerical answer.

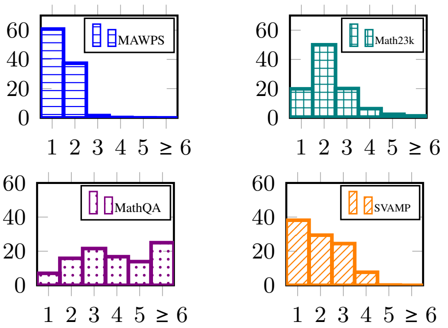

Figure 5: Percentage of questions with different operation count.

Declarative Constraints Our model repeatedly relies on existing quantities to construct new quantities, which results in a structure showing the deductive reasoning process. One advantage of such an approach is that it allows certain declarative knowledge to be conveniently incorporated. For example, as we can see in Equation 6, the default approach considers all the possible combinations among the quantities during the maximization step. We can easily impose constraints to avoid considering certain combinations. In practice, we found in certain datasets such as SVAMP, there does not exist any expression that involve operations applied to the same quantity (such as $9 + 9$ or 9×9, where 9 is from the same quantity in the text). Besides, we also observe that the intermediate results would not be negative. We can simply exclude such cases in the maximization process, effectively reducing the search space during both training and inference. We show that adding such declarative constraints can help improve the performance.

4 Experiments

Datasets We conduct experiments on four datasets across two different languages: MAWPS (Koncel-Kedziorski et al., 2016), Math23k (Wang et al., 2017), MathQA (Amini et al., 2019), and SVAMP (Patel et al., 2021). The dataset statistics can be found in Table 2. For MathQA[5], we follow Tan et al. (2021)[6] to

---

[4] Actually, one might have noticed that this loss comes with a trivial solution at $\boldsymbol{\theta} = \mathbf{0}$. In practice, however, our model and training process would prevent us from reaching such a degenerate solution with proper initialization (Goodfellow et al., 2016). This is similar to the training of a structured perceptron (Collins, 2002), where a similar situation is also involved.

[5] The original MathQA (Amini et al., 2019) dataset contains a certain number of instances that have annotated equations which cannot lead to the correct numerical answer.

[6] Our dataset size is not exactly the same as Tan et al. (2021) as they included some instances that are wrongly annotated. We only kept the part that has correct annotations. We con-

	Model	Val Acc.
S2S	GroupAttn (Li et al., 2019)	76.1
	Transformer (Vaswani et al., 2017)	85.6
	BERT-BERT (Lan et al., 2021)	86.9
	Roberta-Roberta (Lan et al., 2021)	88.4
S2T/G2T	GTS (Xie and Sun, 2019)	82.6
	Graph2Tree (Zhang et al., 2020)	85.6
	Roberta-GTS (Patel et al., 2021)	88.5
	Roberta-Graph2Tree (Patel et al., 2021)	88.7

	Roberta-DeductReasoner	**92.0** (± 0.20)
	mBERT-DeductReasoner	91.6 (± 0.13)
	XLM-R-DeductReasoner	91.6 (± 0.11)

Table 3: 5-fold cross-validation results on MAWPS.

adapt the dataset to filter out some questions that are unsolvable. We consider the operations "*addition*", "*subtraction*", "*multiplication*", and "*division*" for MAWPS and SVAMP, and an extra "*exponentiation*" for MathQA and Math23k.

The number of operations involved in each question can be one of the indicators to help us gauge the difficulty of a dataset. Figure 5 shows the percentage distribution of the number of operations involved in each question. The MathQA dataset generally contains larger portions of questions that involve more operations, while 97% of the questions in MAWPS can be answered with only one or two operations. More than 60% of the instances in MathQA have three or more operations, which likely makes their problems harder to solve. Furthermore, MathQA (Amini et al., 2019) contains GRE questions in many domains including physics, geometry, probability, etc., while Math23k questions are from primary school. Different from other datasets, SVAMP (Patel et al., 2021)[7] is a challenging set that is manually created to evaluate a model's robustness. They applied variations over the instances sampled from MAWPS. Such variations could be: adding extra quantities, swapping the positions between noun phrases, etc.

Baselines The baseline approaches can be broadly categorized into sequence-to-sequence (S2S), sequence-to-tree (S2T) and graph-to-tree (G2T) models. **GroupAttn** (Li et al., 2019) designed several types of attention mechanisms such as question or quantity related attentions in the seq2seq model. Tan et al. (2021) uses multilingual BERT with an LSTM decoder (**mBERT-LSTM**). Lan et al. (2021) presented two seq2seq models that use BERT/Roberta as both encoder and decoder, namely, **BERT-BERT** and **Roberta-Roberta**. Sequence-to-tree models mainly use a tree-based decoder with GRU (**GTS**) (Xie and Sun, 2019) or BERT as the encoder (**BERT-Tree**) (Liang et al., 2021; Li et al., 2021). **NUMS2T** (Wu et al., 2020) and **NeuralSymbolic** (Qin et al., 2021) solver incorporate external knowledge in the S2T architectures. **Graph2Tree** (Zhang et al., 2020) models the quantity relations using GCN.

Table 4: Results on Math23k. †: they used their own splits (so their results may not be directly comparable).

Training Details We adopt BERT (Devlin et al., 2019) and Roberta (Liu et al., 2019) for the English datasets. Chinese BERT and Chinese Roberta (Cui et al., 2019) are used for Math23k. We use the GRU cell as the rationalizer. We also conduct experiments with multilingual BERT and XLM-Roberta (Conneau et al., 2020). The pre-trained models are initialized from HuggingFace's Transformers (Wolf et al., 2020). We optimize the loss with the Adam optimizer (Kingma and Ba, 2014; Loshchilov and Hutter, 2019). We use a learning rate of $2e$-5 and a batch size of 30. The regularization coefficient λ is set to 0.01. We run our models with 5 random seeds and report the average results (with standard deviation). Following most previous works, we mainly report the value accuracy (percentage) in our experiments. In other words, a prediction is considered correct if the predicted expression leads to the same value as the gold expression. Following previous practice (Zhang et al., 2020; Tan et al., 2021; Patel et al., 2021), we report

---

firmed such information with the authors of Tan et al. (2021), and make our version of this dataset publicly available.

[7] There is no test split for this dataset. We strictly follow the experiment setting in Patel et al. (2021).

Table 6: Test accuracy comparison on SVAMP.

5-fold cross-validation results on both MAWPS[8] and Math23k, and also report the test set performance for Math23k, MathQA and SVAMP.

4.1 Results

MAWPS and Math23k We first discuss the results on MAWPS and Math23k, two datasets that are commonly used in previous research. Table 3 and 4 show the main results of the proposed models with different pre-trained language models. We compare with previous works that have reported results on these datasets. Among all the encoders for our model DeductReasoner, the Roberta encoder achieves the best performance. In addition, DeductReasoner significantly outperforms all the baselines regardless of the choice of encoder. The performance on the best S2S model (Roberta-Roberta) is on par with the best S2T model (Roberta-Graph2Tree) on MAWPS. Overall, the accuracy of Roberta-based DeductReasoner is more than 3 points higher than Roberta-Graph2Tree ($p < 0.001$)[9] on MAWPS, and more than 2 points higher than BERT-Tree ($p < 0.005$) on Math23k. The comparisons show that our deductive reasoner is robust across different languages and datasets of different sizes.

MathQA and SVAMP As mentioned before, MathQA and SVAMP are more challenging – the former consists of more complex questions and the latter consists of specifically designed challenging questions. Table 5 and 6 show the performance comparisons. We are able to outperform the best baseline mBERT-LSTM[10] by 1.5 points in accuracy on MathQA. Different from other three datasets, the performance between different language models shows larger gaps on SVAMP. As we can see from baselines and our models, the choice of encoder appear to be important for solving questions in SVAMP – the results on using Roberta as the encoder are particularly striking. Our best variant Roberta-DeductReasoner achieves an accuracy score of 47.3 and is able to outperfrom the best baseline (Roberta-Graph2Tree) by 3.5 points ($p < 0.01$). By incorporating the constraints from our prior knowledge (as discussed in §3.3), we observe significant improvements for all variants – up to 7.0 points for our BERT-DeductReasoner.

Overall, these results show that our model is more robust as compared to previous approaches on such challenging datasets.

Fine-grained Analysis We further perform fine-grained performance analysis based on questions with different numbers of operations. Table 7 shows the accuracy scores for questions that involve different numbers of operations. It also shows the equation accuracy on all datasets[11]. We compared our Roberta-DeductReasoner with the best performing baselines in Table 3 (Roberta-Graph2Tree), 4 (BERT-Tree), 5 (mBERT+LSTM) and 6 (Roberta-Graph2Tree). On MAWPS and Math23k, our Roberta-DeductReasoner model consistently yields higher results than baselines. On MathQA, our model also performs better on questions that involve 2, 3, and 4 operations. For the other more challenging dataset SVAMP, our model

---

[8] All previous efforts combine training/dev/test sets and perform 5-fold cross validation, which we follow.

[9] We conduct bootstrapping t-test to compare the results.

[10] We ran the their code on our adapted MathQA dataset.

[11] Equ Acc: we regard an equation as correct if and only if it matches with the reference equation (up to reordering of sub-expressions due to commutative operations, namley "+" and "×").

Question: *Xiaoli and Xiaoqiang typed a manuscript together. Their typing speed ratio was **5:3**. Xiaoli typed **1,400** more words than Xiaoqiang. How many words are there in this manuscript?*

Gold Expr: $\frac{1400}{5\div(5+3)-3\div(5+3)}$ **Answer**: 5600

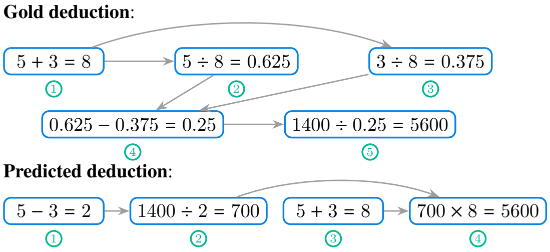

Figure 6: Deductive steps by our reasoner.

has comparable performance with the baseline on 1-step questions, but achieves significantly better results (+14.3 points) on questions that involve 2 steps. Such comparisons on MathQA and SVAMP show that our model has a robust reasoning capability on more complex questions.

We observe that all models (including ours and existing models) are achieving much lower accuracy scores on SVAMP, as compared to other datasets. We further investigate the reason for this. Patel et al. (2021) added irrelevant information such as extra quantities in the question to confuse the models. We quantify the effect by counting the percentage of instances which have quantities unused in the equations. As we can see in Table 8, SVAMP has the largest proportion (i.e., 44.5%) of instances whose gold equations do not fully utilize all the quantities in the problem text. The performance also significantly drops on those questions with more than one unused quantity on all datasets. The analysis suggests that our model still suffer from extra irrelevant information in the question and the performance is severely affected when such irrelevant information appears more frequently.

Effect of Rationalizer Table 9 shows the performance comparison with different rationalizers. As described in §3.2, the rationalizer is used to update the quantity representations at each step, so as to better "prepare them" for the subsequent reasoning process given the new context. We believe this step is crucial for achieving good performance, especially for complex MWP solving. As shown in Table 9, the performance drops by 7.3 points in value accuracy for Math23k without rationalization, confirming the importance of rationalization in solving more complex problems that involve more steps. As most of the questions in MAWPS involve only 1-step questions, the significance of using rationalizer is not fully revealed on this dataset.

It can be seen that using self-attention achieves worse performance than the GRU unit. We believe the lower performance by using multi-head attention as rationalizer may be attributed to two reasons. First, GRU comes with sophisticated internal gating mechanisms, which may allow richer representations for the quantities. Second, attention, often interpreted as a mechanism for measuring similarities (Katharopoulos et al., 2020), may be inherently biased when being used for updating quantity representations. This is because when measuring the similarity between quantities and a specific expression (Figure 4), those quantities that have just participated in the construction of the expression may receive a higher degree of similarity.

4.2 Case Studies

Explainability of Output Figure 6 presents an example prediction from Math23k. In this question, the gold deductive process first obtains the speed difference by "$5 \div (5+3) - 3 \div (5+3)$" and the final answer is 1400 divided by this difference. On the other hand, the predicted deductive process offers a slightly different understanding in speed difference. Assuming speed can be measured by some abstract "units", the predicted deductive

Question: *There are **255** apple trees in the orchard. Planting another **35** pear trees makes the number exactly the same as the apple trees. If every **20** pear trees are planted in a row, how many rows can be planted in total?*
Gold Expr: $(255 - 35) \div 20$ **Answer**: 11
Predicted Expr: $(255 + 35) \div 20$ **Predicted**: 14.5
Deductive Scores:

$\boxed{255 + 35 = 260}$ Prob.: 0.068 > $\boxed{255 - 35 = 220}$ Prob.: 0.062

Perturbed Question: *There are **255** apple trees in the orchard. **The number of pear trees are 35 fewer than the apple trees.** If every **20** pear trees are planted in a row, how many rows can be planted in total?*
$\boxed{255 + 35 = 260}$ **Prob.:** 0.061 < $\boxed{255 - 35 = 220}$ **Prob.:** 0.067

Figure 7: Question perturbation in deductive reasoning.

process first performs subtraction between 5 and 3, which gives us "2 units" of speed difference. Next, we can obtain the number of words associated with each speed unit ($1400 \div 2$). Finally, we can arrive at the total number of words by multiplying the number of words per unit (700) and the total number of units (8).[12] Through such an example we can see that our deductive reasoner is able to produce explainable steps to understand the answers.

Question Perturbation The model predictions also give us guidance to understand the errors. Figure 7 shows how we can perturb a question given the error prediction (taken from Math23k). As we can see, the first step is incorrectly predicted with the "+" relation between 255 and 35. Because the first step involves the two quantities in the first two sentences, where we can locate the possible cause for the error. The gold step has a probability of 0.062 which is somewhat lower than the incorrect prediction. We believe that the second sentence (marked in red) may convey semantics that can be challenging for the model to digest, resulting in the incorrect prediction. Thus, we perturb the second sentence to make it semantically more straightforward (marked below in blue). The probability for the sub-expression $225 - 35$ becomes higher after the purtubation, leading to a correct prediction (the "−" relation). Such an analysis demonstrates the strong interpretability of our deductive reasoner, and highlights the important connection between math word problem solving and reading comprehension, a topic that has been studied in educational psychology (Vilenius-Tuohimaa et al., 2008).

4.3 Practical Issues

We discuss some practical issues with the current model in this section. Similar to most previous research efforts (Li et al., 2019; Xie and Sun, 2019), our work needs to maintain a list of constants (e.g., 1 and π) as additional candidate quantities. However, a large number of quantities could lead to a large search space of expressions (i.e., $\mathcal{H}$). In practice, we could select some top-scoring quantities and build expressions on top of them (Lee et al., 2018). Another assumption of our model, as shown in Figure 3, is that only binary operators are considered. Actually, extending it to support unary or ternary operators can be straightforward. Handling unary operators would require the introduction of some unary rules, and a ternary operator can be defined as a composition of two binary operators.

Our current model performs the greedy search in the training and inference process, which could be improved with a beam search process. One challenge with designing the beam search algorithm is that the search space $\mathcal{H}^{(t)}$ is expanding at each step t (Equation 6). We empirically found the model tends to favor outputs that involve fewer reasoning steps. In fact, better understanding the behavior and effect of beam search in seq2seq models remains an active research topic (Cohen and Beck, 2019; Koehn and Knowles, 2017; Hokamp and Liu, 2017), and we believe how to perform effective beam search in our setup could be an interesting research question that is worth exploring further.

5 Conclusion and Future Work

We provide a new perspective to the task of MWP solving and argue that it can be fundamentally regarded as a complex relation extraction problem. Based on this observation, and motivated by the deductive reasoning process, we propose an end-to-end deductive reasoner to obtain the answer expression in a step-by-step manner. At each step, our model performs iterative mathematical relation extraction between quantities. Thorough experiments on four standard datasets demonstrate that our deductive reasoner is robust and able to yield new state-of-the-art performance. The model achieves particularly better performance for complex questions that involve a larger number of operations. It offers us the flexibility in interpreting the results, thanks to the deductive nature of our model.

Future directions that we would like to explore include how to effectively incorporate commonsense knowledge into the deductive reasoning process, and how to facilitate counterfactual reasoning (Richards and Sanderson, 1999).

---

[12] Interestingly, when we presented this question to 3 human solvers, 2 of them used the first approach and 1 of them arrived at the second approach.

A Importance of Rationalizer

We further elaborate on the importance of the rationalizer module in this section. As mentioned in §3.2, it is crucial for us to properly update the quantity representations, especially for questions that require more than 3 operations to solve (i.e., $t \geq 3$). Because if the quantity representations do not get updated as we continue the deductive reasoning process, those expressions that were initially highly ranked (say, at the first step) would always be preferred over those lowly ranked ones throughout the process.

We provide an example here to illustrate the scenario. Suppose our target expression is $(1 + 2) * (3 + 4)$, the first step is to predict:

$$e^{(1)} = 1 + 2 \tag{7}$$

In order to obtain the correct intermediate expression $1 + 2$ as $e^{(1)}$, the model has to give the highest score to this expression. Note that, the score of the expression $e_{1,2,+}$ also has to be larger than the score of $e_{3,4,+}$.

$$s(e^{(1)}_{1,2,+}) > s(e^{(1)}_{3,4,+}) \tag{8}$$

However, in order to reach the final target expression, in the next step, the model needs to construct the intermediate expression $3 + 4$. Without the rationalizer, the representations for the quantities are unchanged, so we would have:

$$s(e^{(2)}_{1,2,+}) = s(e^{(1)}_{1,2,+}) > s(e^{(1)}_{3,4,+}) = s(e^{(2)}_{3,4,+}) \tag{9}$$

From here we could see that the model would not be able to produce the intermediate expression $3 + 4$ in the second step (but would still prefer to generate another $1 + 2$). With the rationalizer in place, the above two equations in Equation 9 in general may not hold, which effectively prevents such an issue from happening.

B Additional Implementation Details

We implement our model with PyTorch and run all experiments using Tesla V100 GPU. The feed-forward network in our model is simply linear transformation followed by the ReLU activation. We also apply layer normalization and dropout in the feed-forward network. The hidden size in the feed-forward network is 768, which the is same as the hidden size used in BERT/Roberta.

When did you become so smart, oh wise one?! Sarcasm Explanation in Multi-modal Multi-party Dialogues

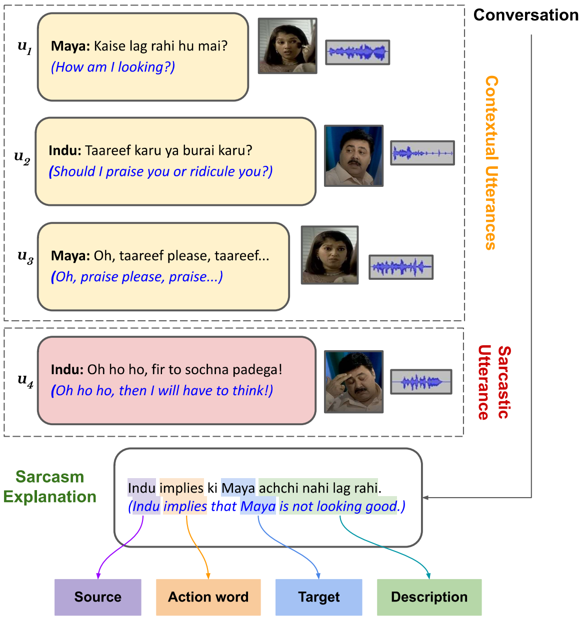
Abstract

Indirect speech such as sarcasm achieves a constellation of discourse goals in human communication. While the indirectness of figurative language warrants speakers to achieve certain pragmatic goals, it is challenging for AI agents to comprehend such idiosyncrasies of human communication. Though sarcasm identification has been a well-explored topic in dialogue analysis, for conversational systems to truly grasp a conversation's innate meaning and generate appropriate responses, simply detecting sarcasm is not enough; it is vital to explain its underlying sarcastic connotation to capture its true essence. In this work, we study the discourse structure of sarcastic conversations and propose a novel task – ***Sarcasm Explanation in Dialogue*** (**SED**). Set in a multimodal and code-mixed setting, the task aims to generate natural language explanations of satirical conversations. To this end, we curate **WITS**, a new dataset to support our task. We propose **MAF** (Modality Aware Fusion), a multimodal context-aware attention and global information fusion module to capture multimodality and use it to benchmark WITS. The proposed attention module surpasses the traditional multimodal fusion baselines and reports the best performance on almost all metrics. Lastly, we carry out detailed analyses both quantitatively and qualitatively.

1 Introduction

The use of figurative language serves many communicative purposes and is a regular feature of both oral and written communication (Roberts and Kreuz, 1994). Predominantly used to induce humour, criticism, or mockery (Colston, 1997), paradoxical language is also used in concurrence with hyperbole to show surprise (Colston and Keller, 1998) as well as highlight the disparity between expectations and reality (Ivanko and Pexman, 2003). While the use and comprehension of sarcasm is a cognitively taxing process (Olkoniemi et al., 2016), psychological evidence advocate that it positively correlates with the receiver's theory of mind (ToM) (Wellman, 2014), i.e., the capability to interpret and understand another person's state of mind. Thus, for NLP systems to emulate such anthropomorphic intelligent behavior, they must not only be potent enough to identify sarcasm but also possess the ability to comprehend it in its entirety. To this end, moving forward from sarcasm identification, we propose the novel task of ***Sarcasm Explanation in Dialogue*** (**SED**).



Maya: Kaise lag rahi hu mai?
(How am I looking?)

Indu: Taareef karu ya burai karu?
(Should I praise you or ridicule you?)

Maya: Oh, taareef please, taareef...
(Oh, praise please, praise...)

Indu: Oh ho ho, fir to sochna padega!
(Oh ho ho, then I will have to think!)

Indu implies ki Maya achchi nahi lag rahi.
(Indu implies that Maya is not looking good.)

Figure 1: Sarcasm Explanation in Dialogues (SED). Given a sarcastic dialogue, the aim is to generate a natural language explanation for the sarcasm in it. *Blue text represents the English translation for the text.*

For dialogue agents, understanding sarcasm is even more crucial as there is a need to normalize its sarcastic undertone and deliver appropriate responses. Conversations interspersed with sarcastic statements often use contrastive language to convey the opposite of what is being said. In a real-world setting, understanding sarcasm goes beyond negat-

---

Volume 1: Long Papers, pages 5956 - 5968
May 22-27, 2022

ing a dialogue's language and involves the acute comprehension of audio-visual cues. Additionally, due to the presence of essential temporal, contextual, and speaker-dependent information, sarcasm understanding in conversation manifests as a challenging problem. Consequently, many studies in the domain of dialogue systems have investigated sarcasm from textual, multimodal, and conversational standpoints (Ghosh et al., 2018; Castro et al., 2019; Oraby et al., 2017; Bedi et al., 2021). However, baring some exceptions (Mishra et al., 2019; Dubey et al., 2019; Chakrabarty et al., 2020), research on figurative language has focused predominantly on its identification rather than its comprehension and normalization. This paper addresses this gap by attempting to generate natural language explanations of satirical dialogues.

To illustrate the proposed problem statement, we show an example in Figure 1. It contains a dyadic conversation of four utterances $\langle u_1, u_2, u_3, u_4\rangle$, where the last utterance (u_4) is a sarcastic remark. Note that in this example, although the opposite of what is being said is, *"I don't have to think about it,"* it is not what the speaker means; thus, it enforces our hypothesis that sarcasm explanation goes beyond simply negating the dialogue's language. The discourse is also accompanied by ancillary audio-visual markers of satire such as an ironical intonation of the pitch, a blank face, or roll of the eyes. Thus, conglomerating the conversation history, multimodal signals, and speaker information, SED aims to generate a coherent and cohesive natural language explanation associated with sarcastic dialogues.

For the task at hand, we extend MASAC (Bedi et al., 2021) – a sarcasm detection dataset for code-mixed conversations – by augmenting it with natural language explanations for each sarcastic dialogue. We name the dataset WITS[1]. The dataset is a compilation of sarcastic dialogues from a popular Indian TV show. Along with the textual transcripts of the conversations, the dataset also contains multimodal signals of audio and video.

We experiment with unimodal as well as multimodal models to benchmark WITS. Text, being the driving force of the explanations, is given the primary importance, and thus, we compare a number of established text-based sequence-to-sequence systems on WITS. To incorporate multimodal information, we propose a unique fusion scheme of *Multimodal Context-Aware Attention* (MCA2). Inspired by Yang et al. (2019), this attention variant facilitates deep semantic interaction between the multimodal signals and textual representations by conditioning the key and value vectors with audio-visual information and then performing dot product attention with these modified vectors. The generated audio and video information-informed textual representations are then combined using the *Global Information Fusion Mechanism* (GIF). The gating mechanism of GIF allows for the selective inclusion of information relevant to the satirical language and also prohibits any multimodal noise from seeping into the model. We further propose MAF (*Modality Aware Fusion*) module where the aforementioned mechanisms are introduced in the Generative Pretrained Models (GPLMs) as adapter modules. Our fusion strategy outperforms the text-based baselines and the traditional multimodal fusion schemes in terms of multiple text-generation metrics. Finally, we conduct a comprehensive quantitative and qualitative analysis of the generated explanations.

In a nutshell, our contributions are four fold:

- We propose Sarcasm Explanation in Dialogue (SED), **a novel task** aimed at generating a natural language explanation for a given sarcastic dialogue, elucidating the intended irony.
- We extend an existing sarcastic dialogue dataset, to curate WITS, **a novel dataset** containing human annotated gold standard explanations.
- We **benchmark our dataset** using MAF-TAV$_\mathrm{B}$ and MAF-TAV$_\mathrm{M}$ variants of BART and mBART, respectively, that incorporate the audio-visual cues using a unique context-aware attention mechanism.
- We carry out **extensive quantitative and qualitative analysis** along with human evaluation to assess the quality of the generated explanations.

Reproducibility: The source codes and the dataset can be found here: https://github.com/LCS2-IIITD/MAF.git.

2 Related Work

Sarcasm and Text: Joshi et al. (2017) presented a well-compiled survey on computational sarcasm where the authors expanded on the relevant datasets, trends, and issues for automatic sarcasm identification. Early work in sarcasm detection dealt with standalone text inputs like tweets and reviews (Kreuz and Caucci, 2007; Tsur et al., 2010;

---

[1] WITS: "Why Is This Sarcastic"

Joshi et al., 2015; Peled and Reichart, 2017). These initial works mostly focused on the use of linguistic and lexical features to spot the markers of sarcasm (Kreuz and Caucci, 2007; Tsur et al., 2010). More recently, attention-based architectures are proposed to harness the inter- and intra-sentence relationships in texts for efficient sarcasm identification (Tay et al., 2018; Xiong et al., 2019; Srivastava et al., 2020). Analysis of figurative language has also been extensively explored in conversational AI setting. Ghosh et al. (2017) utilised attention-based RNNs to identify sarcasm in the presence of context. Two separate LSTMs-with-attention were trained for the two inputs (sentence and context) and their hidden representations were combined during the prediction.

The study of sarcasm identification has also expanded beyond the English language. Bharti et al. (2017) collected a Hindi corpus of 2000 sarcastic tweets and employed rule-based approaches to detect sarcasm. Swami et al. (2018) curated a dataset of 5000 satirical Hindi-English code-mixed tweets and used n-gram feature vectors with various ML models for sarcasm detection. Other notable studies include Arabic (Abu Farha and Magdy, 2020), Spanish (Ortega-Bueno et al., 2019), and Italian (Cignarella et al., 2018) languages.

Sarcasm and Multimodality: In the conversational setting, MUStARD, a multimodal, multi-speaker dataset compiled by Castro et al. (2019) is considered the benchmark for multimodal sarcasm identification. Chauhan et al. (2020) leveraged the intrinsic interdependency between emotions and sarcasm and devised a multi-task framework for multimodal sarcasm detection. Currently, Hasan et al. (2021) performed the best on this dataset with their humour knowledge enriched transformer model. Recently, Bedi et al. (2021) proposed a code-mixed multi-party dialogue dataset, MASAC, for sarcasm and humor detection. In the bimodal setting, sarcasm identification with tweets containing images has also been well explored (Cai et al., 2019; Xu et al., 2020; Pan et al., 2020) .

Beyond Sarcasm Identification: While studies in computational sarcasm have predominantly focused on sarcasm identification, some forays have been made into other domains of figurative language analysis. Dubey et al. (2019) initiated the work of converting sarcastic utterances into their non-sarcastic interpretations using deep learning. In another direction, Mishra et al. (2019) devised a modular unsupervised technique for sarcasm generation by introducing context incongruity through fact removal and incongruous phrase insertion. Following this, Chakrabarty et al. (2020) proposed a retrieve-and-edit-based unsupervised framework for sarcasm generation. Their proposed model leverages the valence reversal and semantic incongruity to generate sarcastic sentences from their non-sarcastic counterparts.

Table 1: Statistics of dialogs present in WITS.

In summary, much work has been done in sarcasm detection, but little, if any, effort has been placed into *explaining the irony behind sarcasm*. This paper attempts to fill this gap by proposing a new problem definition and a supporting dataset.

3 Dataset

Situational comedies, or *'Sitcoms'*, vividly depict human behaviour and mannerism in everyday real-life settings. Consequently, the NLP research community has successfully used such data for sarcasm identification (Castro et al., 2019; Bedi et al., 2021). However, as there is no current dataset tailored for the proposed task, we curate a new dataset named WITS, where we augment the already existing MASAC dataset (Bedi et al., 2021) with explanations for our task. MASAC is a multimodal, multi-party, Hindi-English code-mixed dialogue dataset compiled from the popular Indian TV show, 'Sarabhai v/s Sarabhai'[2]. We manually analyze the data and clean it for our task. While the original dataset contained 45 episodes of the TV series, we add 10 more episodes along with their transcription and audio-visual boundaries. Subsequently, we select the sarcastic utterances from this augmented dataset and manually define the utterances to be included in the dialogue context for each of them. Finally, we are left with 2240 sarcastic dialogues with the number of contextual utterances ranging from 2 to 27. Each of these instances is manually

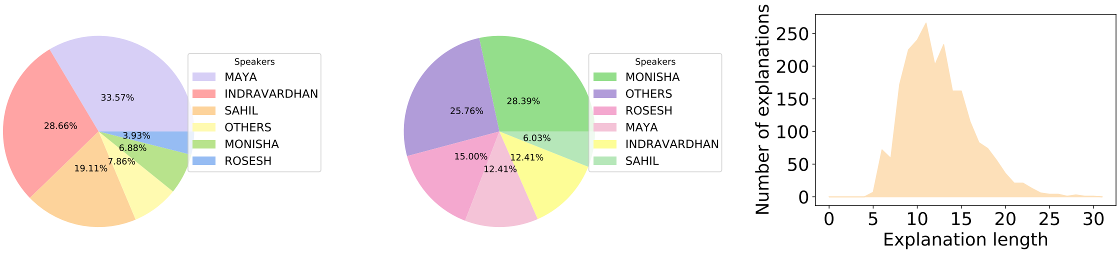
(b) Speaker distribution

(c) Source-target pair distribution



(d) Sarcasm source distribution

(e) Sarcasm target distribution

(f) Explanation length distribution

Figure 2: Distribution of attributes in WITS. The number of utterances in a dialog lies between 2 and 27. Maximum number of speakers in a dialogue are 6. The speaker ‘Maya’ is the most common common sarcasm source while the speaker ‘Monisha’ is the most prominent sarcasm target.

annotated with a corresponding natural language explanation interpreting its sarcasm. Each explanation contains four primary attributes – source and target of sarcasm, action word for sarcasm, and an optional description for the satire as illustrated in Figure 1. In the explanation “Indu implies that Maya is not looking good.", ‘Indu’ is the sarcasm source, ‘Maya’ is the target, ‘implies’ is the action word, while ‘is not looking good’ forms the description part of the explanation. We collect explanations in code-mixed format to keep consistency with the dialogue language. We split the data into train/val/test sets in an 80:10:10 ratio for our experiments, resulting in 1792 dialogues in the train set and 224 dialogues each in the validation and test sets. The next section illustrates the annotation process in more detail. Table 1 and Figure 2 show detailed statistics of WITS.

3.1 Annotation Guidelines

Each of the instance in WITS is associated with a corresponding video, audio, and textual transcript such that the last utterance is sarcastic in nature. We first manually define the number of contextual utterances required to understand the sarcasm present in the last utterance of each dialogue. Further, we provide each of these sarcastic statements, along with their context, to the annotators who are asked to generate an explanation for these instances based on the audio, video, and text cues. Two annotators were asked to annotate the entire dataset. The target explanation is selected by calculating the cosine similarity between the two explanations. If the cosine similarity is greater than 90% then the shorter length explanation is selected as the target explanation. Otherwise, a third annotator goes through the dialogue along with the explanations and resolves the conflict. The average cosine similarity after the first pass is 87.67%. All the final selected explanations contain the following attributes:

- **Sarcasm source:** The speaker in the dialog who is being sarcastic.
- **Sarcasm target:** The person/ thing towards whom the sarcasm is directed.
- **Action word:** Verb/ action used to describe how the sarcasm is taking place. For e.g. mocks, insults, taunts, etc.
- **Description:** A description about the scene which helps in understanding the sarcasm.

Figure 1 represents an example annotation from WITS with its attributes.

4 Proposed Methodology

In this section, we present our model and its nuances. The primary goal is to smoothly integrate multimodal knowledge into the BART architecture. To this end, we introduce *Multimodal Aware Fusion* (MAF), an adapter-based module that comprises of *Multimodal Context-Aware Attention (MCA2)* and *Global Information Fusion (GIF)* mechanisms.

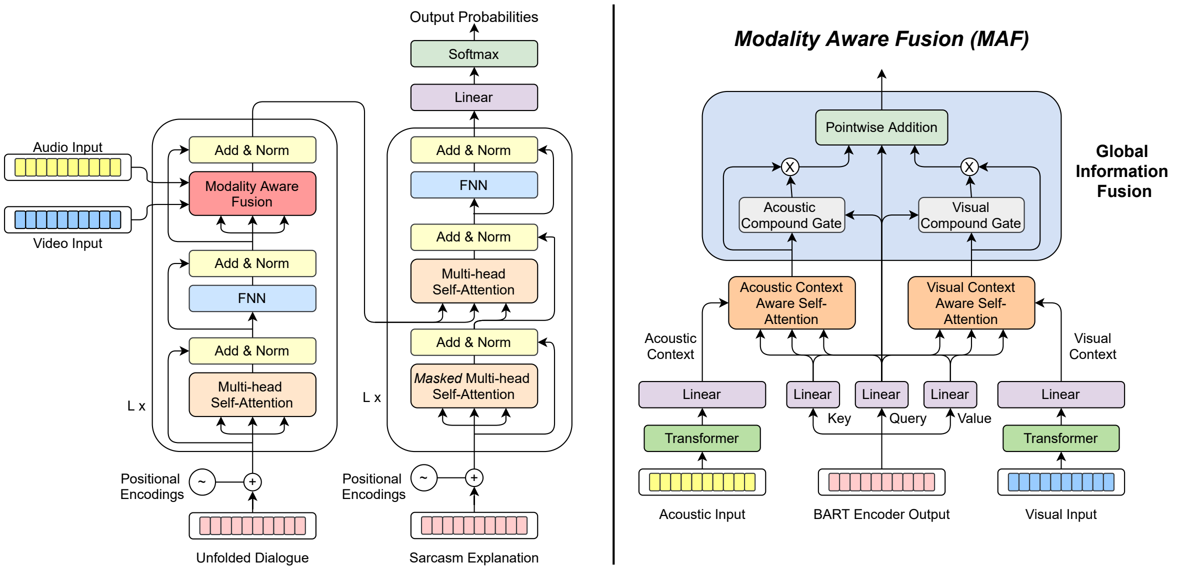


Figure 3: Model architecture for MAF-TAV$_B$. The proposed Multimodal Fusion Block captures audio-visual cues using Multimodal Context Aware Attention (MCA2) which are further fused with textual representations using Global Information Fusion (GIF) block.

Given the textual input sarcastic dialogue along with the audio-video cues, the former aptly introduces multimodal information in the textual representations, while the latter conglomerates the audio-visual information infused textual representations. This adapter module can be readily incorporated at multiple layers of BART/mBART to facilitate various levels of multimodal interaction. Figure 3 illustrates our model architecture.

4.1 Multimodal Context Aware Attention

The traditional dot-product-based cross-modal attention scheme leads to the direct interaction of textual representations with other modalities. Here the text representations act as the query against the multimodal representations, which serve as the key and value. As each modality comes from a different embedding subspace, a direct fusion of multimodal information might not retain maximum contextual information and can also leak substantial noise in the final representations. Thus, based on the findings of Yang et al. (2019), we propose multimodal fusion through *Context Aware Attention*. We first generate multimodal information conditioned key and value vectors and then perform the traditional scaled dot-product attention. We elaborate on the process below.

Given the intermediate representation H generated by the GPLMs at a specific layer, we calculate the query, key, and value vectors Q, K, and $V \in \mathbb{R}^{n \times d}$, respectively, as given in Equation 1, where W_Q, W_K, and $W_V \in \mathbb{R}^{d \times d}$ are learnable parameters. Here, n denotes the maximum sequence length of the text, and d denotes the dimensionality of the GPLM generated vector.

$$[QKV] = H\,[W_Q W_K W_V] \tag{1}$$

Let $C \in \mathbb{R}^{n \times d_c}$ denote the vector obtained from audio or visual representation. We generate multimodal information informed key and value vectors $\hat{K}$ and $\hat{V}$, respectively, as given by Yang et al. (2019). To decide how much information to integrate from the multimodal source and how much information to retain from the textual modality, we learn matrix $\lambda \in \mathbb{R}^{n \times 1}$ (Equation 3). Note that U_k and $U_v \in \mathbb{R}^{d_c \times d}$ are learnable matrices.

$$\begin{bmatrix}\hat{K}\\ \hat{V}\end{bmatrix} = (1 - \begin{bmatrix}\lambda_k\\ \lambda_v\end{bmatrix})\begin{bmatrix}K\\ V\end{bmatrix} + \begin{bmatrix}\lambda_k\\ \lambda_v\end{bmatrix}(C\begin{bmatrix}U_k\\ U_v\end{bmatrix}) \tag{2}$$

Instead of making λ_k and λ_v as hyperparameters, we let the model decide their values using a gating mechanism as computed in Equation 3. The matrices of $W_{k_1}, W_{k_2}, W_{v_1}$, and $W_{v_2} \in \mathbb{R}^{d \times 1}$ are trained along with the model.

$$\begin{bmatrix}\lambda_k\\ \lambda_v\end{bmatrix} = \sigma(\begin{bmatrix}K\\ V\end{bmatrix}\begin{bmatrix}W_{k_1}\\ W_{v_1}\end{bmatrix} + C\begin{bmatrix}U_k\\ U_v\end{bmatrix}\begin{bmatrix}W_{k_2}\\ W_{v_2}\end{bmatrix}) \tag{3}$$

Finally, the multimodal information infused vectors $\hat{K}$ and $\hat{V}$ are used to compute the traditional scaled dot-product attention. For our case, we have two modalities – audio and video. Using the *context-aware attention mechanism*, we obtain the acoustic-information-infused and visual-information infused vectors H_A and H_V, respectively (c.f. Equations 4 and 5).

$$H_a = Softmax(\frac{Q\hat{K}_a^T}{\sqrt{d_k}})\hat{V}_a \quad (4)$$

$$H_v = Softmax(\frac{Q\hat{K}_v^T}{\sqrt{d_k}})\hat{V}_v \quad (5)$$

4.2 Global Information Fusion

In order to combine the information from both the acoustic and visual modalities, we design the GIF block. We propose two gates, namely the *acoustic gate* (g_a) and the *visual gate* (g_v) to control the amount of information transmitted by each modality. They are as follows:

$$g_a = [H \oplus H_a]W_a + b_a \quad (6)$$

$$g_v = [H \oplus H_v]W_v + b_v \quad (7)$$

Here, $W_a, W_v \in \mathbb{R}^{2d \times d}$ and $b_a, b_v \in \mathbb{R}^{d \times 1}$ are trainable parameters, and $\oplus$ denotes concatenation. The final multimodal information fused representation $\hat{H}$ is given by Equation 8.

$$\hat{H} = H + g_a \odot H_a + g_v \odot H_v \quad (8)$$

This vector $\hat{H}$ is inserted back into GPLM for further processing.

5 Experiments, Results and Analysis

In this section, we illustrate our feature extraction strategy, the comparative systems, followed by the results and its analysis. For a quantitative analysis of the generated explanations, we use the standard metrics for generative tasks – ROUGE-1/2/L (Lin, 2004), BLEU-1/2/3/4 (Papineni et al., 2002), and METEOR (Denkowski and Lavie, 2014). To capture the semantic similarity, we use the multilingual version of the BERTScore (Zhang et al., 2019).

5.1 Feature Extraction

Audio: Acoustic representations for each instance are obtained using the openSMILE python library[3]. We use a window size of 25 ms and a window shift of 10 ms to get the non-overlapping frames. Further, we employ the eGeMAPS model (Eyben et al., 2016) and extract 154 dimensional functional features such as Mel Frequency Cepstral Coefficients (MFCCs) and loudness for each frame of the instance. These features are then fed to a Transformer encoder (Vaswani et al., 2017) for further processing.

Video: We use a pre-trained action recognition model, ResNext-101 (Hara et al., 2018), trained on the Kinetics dataset (Kay et al., 2017) which can recognise 101 different actions. We use a frame rate of 1.5, a resolution of 720 pixels, and a window length of 16 to extract the 2048 dimensional visual features. Similar to audio feature extraction, we employ a Transformer encoder (Vaswani et al., 2017) to capture the sequential dialogue context in the representations.

5.2 Comparative Systems

To get the best textual representations for the dialogues, we experiment with various sequence-to-sequence (seq2seq) architectures. **RNN:** We use the openNMT[4] implementation of the RNN seq-to-seq architecture. **Transformer** (Vaswani et al., 2017): The standard Transformer encoder and decoder are used to generate explanations in this case. **Pointer Generator Network** (See et al., 2017): A seq-to-seq architecture that allows the generation of new words as well as copying words from the input text for generating accurate summaries. **BART** (Lewis et al., 2020): It is a denoising auto-encoder model with standard machine translation architecture with a bidirectional encoder and an auto-regressive left-to-right decoder. We use its base version. **mBART** (Liu et al., 2020): Following the same architecture and objective as BART, mBART is trained on large-scale monolingual corpora in different languages [5].

5.3 Results

Text Based: As evident from Table 2, BART performs the best across all the metrics for the textual modality, showing an improvement of almost 2-3% on the METEOR and ROUGE scores when compared with the next best baseline. PGN, RNN, and Transformers demonstrate admissible performance considering that they have been trained from scratch. However, it is surprising to see mBART not performing better than BART as it is trained on multilingual data. We elaborate more on this in Appendix A.1.

Table 2: Experimental results. (Abbreviation: R1/2/L: ROUGE1/2/L; B1/2/3/4: BLEU1/2/3/4; M: METEOR; BS: BERT Score; PGN: Pointer Generator Network).

Multimodality: Psychological and linguistic literature suggests that there exist distinct paralinguistic cues that aid in comprehending sarcasm and humour (Attardo et al., 2003; Tabacaru and Lemmens, 2014). Thus, we gradually merge auditory and visual modalities using MAF module and obtain MAF-TAV$_{\text{B}}$ and MAF-TAV$_{\text{M}}$ for BART and mBART, respectively. We observe that the inclusion of acoustic signals leads to noticeable gains of 2-3% across the ROUGE, BLEU, and METEOR scores. The rise in BERTScore also suggests that the multimodal variant generates a tad more coherent explanations. As ironical intonations such as mimicry, monotone, flat contour, extremes of pitch, long pauses, and exaggerated pitch (Rockwell, 2007) form a significant component in sarcasm understanding, we surmise that our model, to some extent, is able to spot such markers and identify the intended sarcasm behind them.

We notice that visual information also contributes to our cause. Significant performance gains are observed for MAF-TV$_{\text{B}}$ and MAF-TV$_{\text{M}}$, as all the metrics show a rise of about 3-4%. While MAF-TA$_{\text{B}}$ gives marginally better performance over MAF-TV$_{\text{B}}$ in terms of R1, RL, and B1, we see that MAF-TV$_{\text{B}}$ performs better in terms of the rest of the metrics. Often, sarcasm is depicted through gestural cues such as raised eyebrows, a straight face, or an eye roll (Attardo et al., 2003). Moreover, when satire is conveyed by mocking someone's looks or physical appearances, it becomes essential to incorporate information expressed through visual media. Thus, we can say that, to some extent, our model is able to capture these nuances of non-verbal cues and use them well to normalize the sarcasm in a dialogue. In summary, we conjecture that whether independent or together, audio-visual signals bring essential information to the table for understanding sarcasm.

Model	R1	R2	RL	B1	B2	B3	B4	M	BS
MAF-TAV$_{\text{M}}$	**38.52**	14.13	36.60	30.50	15.20	9.78	5.74	27.42	76.70

Table 3: Ablation results on MAF-TAV$_{\text{M}}$ and MAF-TAV$_{\text{B}}$ (DPA: Dot Product Attention).

5.4 Ablation Study

Table 3 reports the ablation study. CONCAT1 represents the case where we perform bimodal concatenation $((T \oplus A), (T \oplus V))$ instead of the *MCA2* mechanism, followed by the GIF module, whereas, CONCAT2 represents the simple trimodal concatenation $(T \oplus A \oplus V)$ of acoustic, visual, and textual representations followed by a linear layer for dimensionality reduction. In comparison with *MCA2*, CONCAT2 reports a below-average performance with a significant drop of more than 14% for MAF-TAV$_{\text{B}}$ and MAF-TAV$_{\text{M}}$. This highlights the need to have deftly crafted multimodal fusion mechanisms. CONCAT1, on the other hand, gives good performance and is competitive with DPA and MAF-TAV$_{\text{B}}$. We speculate that treating the audio and video modalities separately and then merging them to retain the complimentary and differential features lead to this performance gain. Our proposed MAF outperforms DPA with gains of 1-3%. This underlines that our unique multimodal fusion strategy is aptly able to capture the contextual information provided by the audio and video signals. Replacing the *GIF* module with simple addition, we observe a noticeable decline in the performance across almost all metrics by about 2-3%. This attests to the inclusion of *GIF* module over simple addition. We also experiment with fusing multimodal information using MAF before different layers of the BART encoder. The best performance was obtained when the fusion was done before the sixth layer of the architecture (c.f. Appendix A.2).

5.5 Result Analysis

We evaluate the generated explanations based on their ability to correctly identify the source and target of a sarcastic comment in a conversation. We report such results for mBART, BART, MAF-TA$_{\text{B}}$, MAF-TV$_{\text{B}}$, and MAF-TAV$_{\text{B}}$. BART performs better than mBART for the source as well as target identification. We observe that the inclusion of audio (↑ 10%) and video (↑ 8%) information dras-

INDRAVARDHAN: Accha suno Monisha tumhaare ghar mein been ya aisa kuuch hain? *Listen Monisha, do you have a flute or something similar?*
MAYA: Kaise hogi? Monisha aapne ghar pe dustbin mushkil se rakhti hain to snake charmer waali been kaha se rakhegi? *How will it be there? Monisha hardly keeps a dustbin in her home so how will she has a snake charmer's flute?*

Gold	Maya Monisha ko tana marti hai safai ka dhyan na rakhne ke liye *Maya taunts Monisha for not keeping a check of cleanliness*
BART	Maya Monisha ko tumaari burayi nahi karta. *Maya doesn't blame you for Monisha*
MAF-TAV$_{\text{B}}$	Maya implies ki Monisha bohot ghar mein bahar nahi kar sakati. *Maya implies that Monisha very in home cannot do outside.*

(a) Incoherent explanation

SAHIL: Ab tumne ghar ki itni saaf safai ki hai and secondly us Karan Verma ke liye pasta, lasagne, caramel custard banaya. *Now you have cleaned the house so much and secondly made pasta, lasagne, caramel custard for that Karan Verma.*
MONISHA: Walnut brownie bhi. *And walnut brownie too.*
SAHIL: Walnut brownie, matlab wo khane wali? *You mean edible walnut brownie?*

Gold	Sahil monisha ki cooking ka mazak udata hai *Sahil makes fun of Monisha's cooking.*
BART	Monisha sahil ko walnut brownie ki matlab wo khane wali. *Walnut Brownie to Monisha Sahil means she eats*
MAF-TAV$_{\text{B}}$	Sahil monisha ki cooking ka mazak udata hai *Sahil makes fun of Monisha's cooking.*

(b) Explanation related to dialogue

MONISHA: Ladki ka naam Ajanta Kyon Rakha? *Why did they named the girl Ajanta?*
INDRAVARDHAN: Kyunki uski maa ajanta caves dekh rahi thi Jab vo Paida Hui haha. *Because her mother must be watching the Ajanta caves when she was born haha.*

Gold	Indravadan Ajanta ke naam ka mazak udata hai *Indravardhan makes fun of Ajanta's name*
BART	Indravardhan Monisha ko taunt maarta hai ki uski maa ajanta caves dekh rahi thi Jab vo Paida Hui *Indravardhan taunts Monisha as her mother was watching Ajanta Caves when she was born.*
MAF-TAV$_{\text{B}}$	Indravadan ajanta ke naam ka mazak udata hai *Indravardhan makes fun of Ajanta's name*

(c) Explanation related to sarcasm

Table 4: Actual and generated explanations for sample dialogues from test set. The last utterance is the sarcastic utterance for each dialogue.

	mBART	**BART**	**MAF-TA$_{\text{B}}$**	**MAF-TV$_{\text{B}}$**	**MAF-TAV$_{\text{B}}$**
Source	75.00	77.23	87.94	85.71	**91.07**
Target	45.53	**52.67**	43.75	43.75	46.42

Table 5: Source-target accuracy of the generated explanations for BART-based systems.

tically improves the source identification capability of the model. The combination of both these nonverbal cues leads to a whopping improvement of more than 13% for the same. As a result, we infer that multimodal fusion enables the model to incorporate audio-visual peculiarities unique to each speaker, resulting in improved source identification. The performance for target identification, however, drops slightly on the inclusion of multimodality. We encourage future work in this direction.

Qualitative Analysis. We analyze the best performing model, MAF-TAV$_{\text{B}}$, and its corresponding unimodal model, BART, and present some examples in Table 4. In Table 4a, we show one instance where the explanations generated by the BART as well as MAF-TAV$_{\text{B}}$ are neither coherent nor comply with the dialogue context and contain much scope of improvement. On the other hand, Table 4b illustrates an instance where the explanation generated by MAF-TAV$_{\text{B}}$ adheres to the topic of the dialogue, unlike the one generated by its unimodal counterpart. Table 4c depicts a dialogue where MAF-TAV$_{\text{B}}$'s explanation better captures the satire than BART. We further dissect the models based on different modalities in Appendix A.3.

Human Evaluation. Since the proposed SED task is a generative task, it is imperative to manually inspect the generated results. Consequently, we perform a human evaluation for a sample of 30 instances from our test set with the help of 25 evaluators[6]. We ask the evaluators to judge the generated explanation, given the transcripts of the sarcastic dialogues along with a small video clip with audio as well. Each evaluator has to see the video clips and then rate the generated explanations on a scale of 0 to 5 based on the following factors[7]:

- **Coherence:** Measures how well the explanations are organized and structured.
- **Related to dialogue:** Measures whether the generated explanation adheres to the topic of the dialogue.
- **Related to sarcasm:** Measures whether the explanation is talking about something related to the sarcasm present in the dialogue.

Table 6 presents the human evaluation analysis with average scores for each of the aforementioned categories. Our scrutiny suggests that MAF-TAV$_{\text{B}}$ generates more syntactically coherent explanations when compared with its textual and bimodal counterparts. Also, MAF-TAV$_{\text{B}}$ and MAF-TV$_{\text{B}}$ generate explanations that are more focused on the conversation's topic, as we see an increase of 0.55 points in the *related to the dialogue* category. Thus, we reestablish that these models are able to incorporate information that is explicitly absent from the dialogue, such as scene description, facial fea-

---

[6] Evaluators are the experts in linguistics and NLP and their age ranges in 20-28 years.

[7] 0 denoting poor performance while 5 signifies perfect performance.

	Coherency	Related to dialogue	Related to sarcasm
mBART	2.57	2.66	2.15
BART	2.73	2.56	2.18
MAF-TA$_B$	2.95	2.91	2.51
MAF-TV$_B$	3.01	**3.11**	2.66
MAF-TAV$_B$	**3.03**	**3.11**	**2.77**

Table 6: Human evaluation statistics – comparing different models. Multimodal models are BART based.

tures, and looks of the characters. Furthermore, we establish that MAF-TAV$_B$ is better able to grasp sarcasm and its normalization, as it shows about 0.6 points improvement over BART in the *related to sarcasm* category. Lastly, as none of the metrics in Table 6 exhibit high scores (3.5+), we feel there is still much scope for improvement in terms of the generation performance and human evaluation. The research community can further explore the task with our proposed dataset, WITS.

6 Conclusion

In this work, we proposed the new task of ***Sarcasm Explanation in Dialogue*** *(***SED***)*, which aims to generate a natural language explanation for sarcastic conversations. We curated WITS, a novel multimodal, multiparty, code-mixed, dialogue dataset to support the SED task. We experimented with multiple text and multimodal baselines, which give promising results on the task at hand. Furthermore, we designed a unique multimodal fusion scheme to merge the textual, acoustic, and visual features via Multimodal Context-Aware Attention (MCA2) and Global Information Fusion (GIF) mechanisms. As hypothesized, the results show that acoustic and visual features support our task and thus, generate better explanations. We show extensive qualitative analysis of the explanations obtained from different models and highlight their advantages as well as pitfalls. We also perform a thorough human evaluation to compare the performance of the models with that of human understanding. Though the models augmented with the proposed fusion strategy perform better than the rest, the human evaluation suggested there is still room for improvement which can be further explored in future studies.

A Appendix

A.1 Embedding Space for BART and mBART

We compared various text based unimodal methods for our task. Although BART is performing the best for SED, it is important to note that BART is pre-trained on English datasets (GLUE (Wang et al., 2018) and SQUAD (Rajpurkar et al., 2016)). In order to explore how the representation learning is being transferred to a code-mixed setting, we analyse the embedding space learnt by the model before and after fine-tuning it for our task. We considered three random utterances from WITS and created three copies of them- one in English, one in Hindi (romanised), and one without modification i.e. code-mixed. Figure 4 illustrates the PCA plot for the embeddings obtained for these nine utterance representations obtained by BART before and after fine-tuning on our task. It is interesting to note that even before any fine-tuning the Hindi, English, and code-mixed representations lie closer to each other and they shift further closer when we fine-tune our model. This phenomenon can be justified as out input is of romanised code-mixed format and thus we can assume that representations are already being captured by the pre-trained model. Fine-tuning helps us understand the Hindi part of the input. Table 7 shows the cosine distance between the representations obtained for English-Hindi, English-Code mixed, and Code mixed-Hindi utterances for the sample utterances. It can be clearly seen that the distance is decreasing after fine-tuning.

Example	English-Hindi		English-Code mixed		Code mixed-Hindi	
	PT	FT	PT	FT	PT	FT
1	0.183	**0.067**	0.014	**0.006**	0.118	**0.056**
2	0.282	**0.093**	0.017	**0.007**	0.197	**0.066**
3	0.321	**0.113**	0.065	**0.020**	0.132	**0.057**

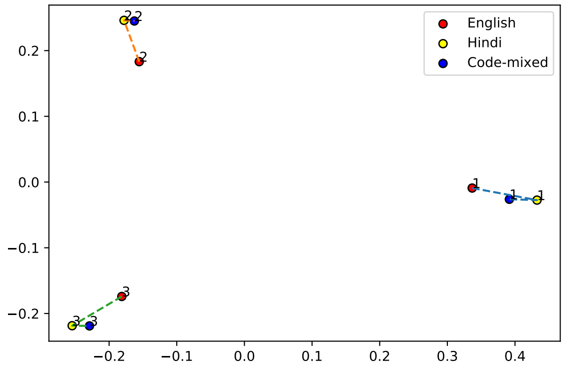
(a) Pre-trained



(b) Fine-tuned

Figure 4: Embedding space for BART before and after fine-tuning on sarcasm explanation in dialogues.

A.2 Fusion at Different Layers

We fuse the multimodal information of audio and video in the BART encoder using the proposed fusion mechanism before different layers of the BART encoder. Table 8 shows the results we obtain when the fusion happens at different layers. We obtain the best results when the fusion happens before layer 6 i.e. the last layer of the encoder. This can be attributed to the fact that since there is only one layer of encoder after the fusion, the multimodal information is being retained efficiently and thus being decoded more accurately.

Fusion before layer #	R1	R2	RL
1	37.27	13.95	35.24
2	37.63	14.32	35.57
3	36.73	13.15	34.63
4	37.61	14.98	36.04
5	37.34	13.67	35.48
6	**39.69**	**17.10**	**37.37**

Table 8: ROUGE scores for fusion before different layers (R1/2/L: ROUGE1/2/L).

A.3 More Qualitative Analysis

Table 9 highlights one of many cases where BART is able to capture the essence of sarcasm in a better way when compared to mBART. While mBART gives us an incorrect and incoherent explanation, BART generates an explanation which essentially means the same as the ground truth explanation. The inclusion of audio modality in the unimodal system often helps in generating preferable explanations, as shown in Table 10. AVII-TA is able to capture the essense of sarcasm in the dialogue while the unimodal systems were not able to do so. Furthermore, video modality facilitates even better understanding of sarcasm as illustrated in Table 11. AVII-TV is able to generate the best results while audio may act as noise in this particular example.

MAYA: Sahil, beta tum bhi soche ho ki maine Monisha ki speech churai? *Sahil, do you also think that I stole Monisha's speech?* INDRAVARDHAN: Haan.*Yes.* MAYA: Are darling maine to speech ko chua bhi nahin. chhoti to germs nahin lag jaate? Kyunki Monisha ne mithaai box ki wrapper per likhi thi apni speech hath mein uthati to makkhiya bhanbhana ne lagti. *Darling, I didn't even touch the speech. Would I not have got germs by touching it? Monisha used sweets wrapper to write her speech, if I would have picked it up, there would've been flies buzzing around me.*	
Gold	Maya ne Monisha ke speech ka mazak udaya. *Maya makes fun of Monisha's speech.*

Abstract

Recently, finetuning a pretrained language model to capture the similarity between sentence embeddings has shown the state-of-the-art performance on the semantic textual similarity (STS) task. However, the absence of an interpretation method for the sentence similarity makes it difficult to explain the model output. In this work, we explicitly describe the sentence distance as the weighted sum of contextualized token distances on the basis of a transportation problem, and then present the optimal transport-based distance measure, named RCMD; it identifies and leverages semantically-aligned token pairs. In the end, we propose CLRCMD, a contrastive learning framework that optimizes RCMD of sentence pairs, which enhances the quality of sentence similarity and their interpretation. Extensive experiments demonstrate that our learning framework outperforms other baselines on both STS and interpretable-STS benchmarks, indicating that it computes effective sentence similarity and also provides interpretation consistent with human judgement. The code and checkpoint are publicly available at `https://github.com/sh0416/clrcmd`.

1 Introduction

Predicting the semantic similarity between two sentences has been extensively studied in the literature (Gomaa et al., 2013; Agirre et al., 2015; Majumder et al., 2016; Cer et al., 2017). Several recent studies successfully utilized a pretrained language model such as BERT (Devlin et al., 2019) by finetuning it to capture sentence similarity (Reimers and Gurevych, 2019). To be specific, they define a similarity score between sentence embeddings, which are obtained by aggregating contextualized token embeddings (e.g., avg pooling) or using a special token (e.g., `[CLS]`), then optimize the score for natural language inference (NLI) or semantic textual similarity (STS) tasks (Gao et al., 2021).

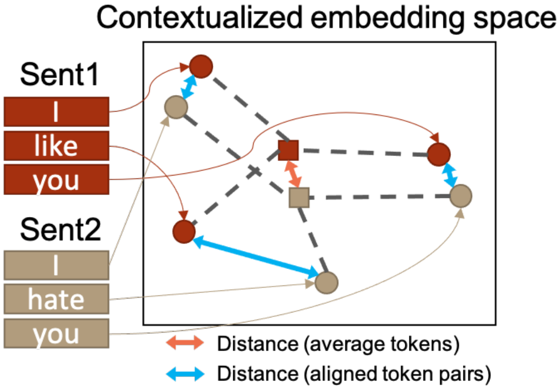

Figure 1: An illustrative example of a transportation problem in contextualized embedding space. The existing distance measure between average-pooled sentence embeddings (orange) cannot clearly capture the distances of semantically-aligned token pairs (blue).

Along with the quality of sentence similarity, interpreting the predicted sentence similarity is also important for end-users to better understand the results (Agirre et al., 2016; Gilpin et al., 2018; Rogers et al., 2020). In general, finding out the cross-sentence alignment and the importance of each aligned part is useful for analyzing sentence similarity (Sultan et al., 2015). For example, there were several attempts to use explicit features (e.g., TF-IDF) for easily analyzing the interaction among the shared terms (Salton and Buckley, 1988) or to adopt sophisticated metrics (e.g., word mover's distance) for explicitly describing it by the importance and similarity of word pairs across two sentences (Kusner et al., 2015). However, for recent approaches that leverage sentence embeddings from a pretrained model, it has not been studied how the cross-sentence interaction of each part contributes to the final sentence similarity.

In this work, we propose an analytical method based on optimal transport to analyze existing ap-

May 22-27, 2022

proaches that leverage a pretrained model. We consider a sentence similarity measure a solution to a transportation problem, which aims to transport a collection of contextualized tokens in a sentence to the ones in another sentence. As byproducts of the problem, we obtain a cost matrix and a transportation matrix, which encode the similarities of all token pairs across sentences and their contributions to the sentence similarity, respectively. Using this analytical method, we point out that the existing approaches suffer from the rank-1 constraint in the transportation matrix; this eventually keeps the model from effectively capturing the similarities of semantically-aligned token pairs into sentence similarity. For example, considering transportation in a contextualized embedding space (Figure 1), the distance between averaged token embeddings (orange arrows) cannot clearly represent the distance of semantically-aligned token pairs (blue arrows).

To resolve the above limitation and enhance the interpretability of a model, we present a novel distance measure and a contrastive learning framework that optimizes the distance between sentences. First, we apply optimal transport in a contextualized embedding space and leverage the optimal solution for a relaxed transportation problem as our distance measure. This sentence distance is composed of the distances of semantically-aligned token pairs; this makes the result easily interpretable. Furthermore, we present a contrastive learning framework that adopts the proposed distance to finetune the model with token-level supervision. It optimizes the model to learn the relevance of semantically-aligned token pairs from that of sentence pairs, which further enhances interpretability.

We extensively evaluate our approach and validate the effectiveness of its sentence similarity and interpretation. The comparison on 7 STS benchmarks supports the superiority of sentence similarity predicted by the model trained by our framework. In particular, the evaluation on 2 interpretable-STS datasets demonstrates that the proposed distance measure finds out semantically relevant token pairs that are more consistent with human judgement compared to other baseline methods. Our qualitative analysis shows that both the token alignment and their similarity scores from our model serve as useful resources for end-users to better understand the sentence similarity.

2 Related work

2.1 Semantic textual similarity

Most recent studies tried to leverage a pretrained language model with various model architectures and training objectives for STS tasks, achieving the state-of-the-art performance. In terms of model architecture, Devlin et al. (2019) focus on exhaustive cross-correlation between sentences by taking a concatenated text of two sentences as an input, while Reimers and Gurevych (2019) improve scalability based on a Siamese network and Humeau et al. (2020) adopt a hybrid approach. Along with the progress of model architectures, many advanced objectives for STS tasks were proposed as well. Specifically, Reimers and Gurevych (2019) mainly use the classification objective for an NLI dataset, and Wu et al. (2020) adopt contrastive learning to utilize self-supervision from a large corpus. Yan et al. (2021); Gao et al. (2021) incorporate a parallel corpus such as NLI datasets into their contrastive learning framework.

Despite their effectiveness, the interpretability of the above models for STS tasks was not fully explored (Belinkov and Glass, 2019). One related task is interpretable STS, which aims to predict chunk alignment between two sentences (Agirre et al., 2016). For this task, a variety of supervised approaches were proposed based on neural networks (Konopík et al., 2016; Lopez-Gazpio et al., 2016), linear programming (Tekumalla and Jat, 2016), and pretrained models (Maji et al., 2020). However, these methods cannot predict the similarity between sentences because they focus on finding chunk alignment only. To the best of our knowledge, no previous approaches based on a pretrained model have taken into account both sentence similarity and interpretation.

2.2 Optimal transport

Optimal transport (Monge, 1781) has been successfully applied to many applications in natural language processing (Li et al., 2020; Xu et al., 2021), by the help of its ability to find a plausible correspondence between two objects (Lee et al., 2021a,b). For example, Kusner et al. (2015) adopt optimal transport to measure the distance between two documents with pretrained word vectors. Zhao et al. (2019) adopt optimal transport for evaluating text generation and Zhang et al. (2020) take a greedy approach leveraging pretrained language model. In addition, Swanson et al. (2020) discover the rationale in text-matching via optimal transport, thereby improving model interpretability.

One well-known limitation of optimal transport is that finding the optimal solution is computationally intensive, and thus approximation schemes for this problem have been extensively researched (Grauman and Darrell, 2004; Shirdhonkar and Jacobs, 2008). To get the solution efficiently, Cuturi (2013) provides a regularizer inspired by a probabilistic theory and then uses Sinkhorn's algorithm. Kusner et al. (2015) relax the problem to get the quadratic-time solution by removing one of the constraints, and Wu et al. (2018) introduce a kernel method to approximate the optimal transport.

3 Method

We first analyze the similarity measure used by existing models from the perspective of a transportation problem. Considering the above analysis, we present a novel distance measure and a contrastive sentence learning framework to enhance the interpretability of a sentence similarity model.

3.1 Distance as a transportation problem

We briefly explain the transportation problem and how to interpret the total transportation cost as a distance measure. A transportation problem consists of three components: states before and after transportation, and a cost matrix. In general, the two states are represented in high-dimensional simplex, i.e., $\mathbf{d}^1 \in \Sigma^{d_1}$ and $\mathbf{d}^2 \in \Sigma^{d_2}$, where each dimension implies a specific location with a non-negative quantity. The cost matrix $\mathbf{M} \in \mathbb{R}^{d_1 \times d_2}$ encodes the unit transportation cost from location i to j into $\mathbf{M}_{i,j}$. In this situation, we search the transportation plan to transport from $\mathbf{d}^1$ to $\mathbf{d}^2$ with the minimum cost. Using the above notations, the optimization problem is written as follows:

$$\underset{\mathbf{T}\in\mathbb{R}_{\geq 0}^{d_1\times d_2}}{\text{minimize}} \sum_{i,j} \mathbf{T}_{i,j}\mathbf{M}_{i,j} \quad (1)$$
$$\text{subject to } \mathbf{T}^\top \vec{\mathbf{1}} = \mathbf{d}^2, \mathbf{T}\vec{\mathbf{1}} = \mathbf{d}^1,$$

where each entry of the transportation matrix $\mathbf{T}_{i,j}$ indicates how much quantity is transferred from location i to j. The optimal solution to this problem is called optimal transport, which is also known as earth mover's distance (EMD):

$$d_{\mathbf{M}}^{\text{EMD}} := \sum_{i,j} \mathbf{T}_{i,j}^{*}\mathbf{M}_{i,j}. \quad (2)$$

In Equation (2), the distance is computed by the sum of element-wise multiplications of the optimal transportation matrix $\mathbf{T}^*$ and the cost matrix $\mathbf{M}$. In this sense, EMD considers the optimality of distance when combining unit costs in $\mathbf{M}$. That is, the priority of each unit cost when being fused to the distance is encoded in the transportation matrix, which serves as a useful resource for analyzing the distance.

3.1.1 Example: Average pooling

We express cosine similarity with average pooling as a transportation problem and analyze its properties in terms of the transportation matrix. Note that this similarity measure is widely adopted in most of the previous studies (Reimers and Gurevych, 2019; Wu et al., 2020; Gao et al., 2021). Formally, for a sentence of length L, the sentence embedding is generated by applying average pooling to L contextualized token embeddings, i.e., $\mathbf{s} = \frac{1}{L}\sum_{i=1}^{L}\mathbf{x}_i$, where $\mathbf{x}_i$ is the i-th token embedding obtained from a pretrained model. Using the sentence embeddings, the sentence similarity is defined by

$$s^{\text{AVG}} = \cos(\mathbf{s}^1, \mathbf{s}^2) = \frac{\mathbf{s}^{1\top}\mathbf{s}^2}{\|\mathbf{s}^1\|\|\mathbf{s}^2\|}.$$

This average pooling-based sentence similarity can be converted into the distance, $d^{\text{AVG}} = 1 - s^{\text{AVG}}$, described by the token embeddings as follows:

$$d^{\text{AVG}} = 1 - \sum_{i=1}^{L_1}\sum_{j=1}^{L_2} \frac{1}{L_1 L_2} \frac{\|\mathbf{x}_i^1\|\|\mathbf{x}_j^2\|}{\|\mathbf{s}^1\|\,\|\mathbf{s}^2\|} \frac{\mathbf{x}_i^{1\top}\mathbf{x}_j^2}{\|\mathbf{x}_i^1\|\|\mathbf{x}_j^2\|}.$$

From the perspective of Equation (1), this distance is interpreted as a naive solution of a special transportation problem, where the cost matrix and the transportation matrix are

$$\mathbf{M}_{i,j}^{\text{AVG}} = \frac{\|\mathbf{s}^1\|\|\mathbf{s}^2\|}{\|\mathbf{x}_i^1\|\|\mathbf{x}_j^2\|} - \cos(\mathbf{x}_i^1, \mathbf{x}_j^2),$$
$$\mathbf{T}_{i,j}^{\text{AVG}} = \frac{1}{L_1 L_2} \frac{\|\mathbf{x}_i^1\|\|\mathbf{x}_j^2\|}{\|\mathbf{s}^1\|\,\|\mathbf{s}^2\|}. \quad (3)$$

Each entry of the cost matrix includes negative cosine similarities between token embeddings, and the contribution of each token pair to the sentence distance (i.e., the transportation matrix) is determined by the norms of the token embeddings. In theory, the rank of the transportation matrix is constrained to be one, which prevents effective integration of the token distances into the sentence distance. In practice, it is impossible to involve only semantically-aligned token pairs across sentences because all possible token pairs are considered by the products of their norms. From this analysis, we point out that the average pooling-based similarity is not effective enough to capture the token correspondence between sentences.

3.2 Relaxed optimal transport distance for contextualized token embeddings

To resolve the ineffectiveness of the existing measure, we introduce a novel distance measure based on optimal transport. We first define a transportation problem that considers semantic relevance in a contextualized embedding space. Given the token embeddings of two sentences from a pretrained language model, we construct a cost matrix $\mathbf{M}^{\mathrm{CMD}} \in \mathbb{R}^{L_1 \times L_2}$ that encodes token similarities using cosine distance, and define the state vectors for the two sentences as one vectors normalized by their sentence lengths $\mathbf{d}^1 := \frac{1}{L_1}\vec{\mathbf{1}}$ and $\mathbf{d}^2 := \frac{1}{L_2}\vec{\mathbf{1}}$. As discussed in Section 3.1, we consider the optimal solution to this problem as a distance measure named contextualized token mover's distance (CMD):

$$\mathbf{M}^{\mathrm{CMD}}_{i,j} := 1 - \cos\left(\mathbf{x}^1_i, \mathbf{x}^2_j\right),$$
$$d^{\mathrm{CMD}}_{\mathbf{M}} := \sum_{i,j} \mathbf{T}^*_{i,j}\mathbf{M}^{\mathrm{CMD}}_{i,j}.$$

However, finding $\mathbf{T}^*$ incurs huge computational complexity of $O(L^3 \log L)$ where $L = \max(L_1, L_2)$ (Villani, 2008). For this reason, we relax the optimization problem by removing the first constraint, $\mathbf{T}^\top\vec{\mathbf{1}} = \mathbf{d}'$, similar to Kusner et al. (2015). The optimal solution for this relaxed transportation problem is found in $O(L^2)$, keeping the rank of the transportation matrix larger than one. In the end, the optimal transportation matrix and the corresponding distance named relaxed CMD (RCMD) are derived as follows:

$$\mathbf{T}^{\mathrm{RCMD}_1}_{i,j} = \begin{cases} \frac{1}{L_1} & \text{if } j = \operatorname{argmin}_{j'} \mathbf{M}^{\mathrm{CMD}}_{i,j'} \\ 0 & \text{otherwise,} \end{cases}$$
$$d^{\mathrm{RCMD}_1}_{\mathbf{M}} := \frac{1}{L_1}\sum_i \min_j \mathbf{M}^{\mathrm{CMD}}_{i,j}. \qquad (4)$$

Similarly, the elimination of the second constraint, $\mathbf{T}\vec{\mathbf{1}} = \mathbf{d}$, results in $\mathbf{T}^{\mathrm{RCMD}_2}$ and $d^{\mathrm{RCMD}_2}_{\mathbf{M}}$, where the solutions for the two relaxed problems use min operation on the cost matrix in a row-wise and a column-wise manner, respectively. Note that $\mathbf{T}^{\mathrm{RCMD}_1}$ represents the token-level binary alignment from the first sentence to the second sentence and accordingly the final distance is computed by averaging all the distances of the aligned token pairs. Also, it is obvious that $\mathbf{T}^{\mathrm{RCMD}_1}$ has a much higher rank than $\mathbf{T}^{\mathrm{AVG}}$, which implies that it can express more complex token-level semantic relationship between two sentences.

We remark that our solution provides better interpretability of semantic textual similarity compared to the case of average pooling. For the sentence distance in Equation (3), $\mathbf{T}^{\mathrm{AVG}}$ assigns non-zero values to all token pairs that include irrelevant pairs; this makes it difficult to interpret the result. On the contrary, $\mathbf{T}^{\mathrm{RCMD}_1}$ in Equation (4) is designed to explicitly involve the most relevant token pairs across sentences for the sentence distance, which allows us to interpret the result easily.

3.3 Contrastive sentence similarity learning with semantically-aligned token pairs

We present a contrastive learning framework for RCMD (CLRCMD) that incorporates RCMD into the state-of-the-art contrastive learning framework. To this end, we convert RCMD to the corresponding similarity by $s^{\mathrm{RCMD}_1}_{\mathbf{M}} = 1 - d^{\mathrm{RCMD}_1}_{\mathbf{M}}$:

$$s^{\mathrm{RCMD}_1}_{\mathbf{M}}(\mathbf{s}^1, \mathbf{s}^2) = \frac{1}{L_1}\sum_{i=1}^{L_1} \max_j \cos(\mathbf{x}^1_i, \mathbf{x}^2_j).$$

$s^{\mathrm{RCMD}_2}_{\mathbf{M}}$ is computed in the same manner as well, and we average them to consider bidirectional semantic alignment between two sentences; this provides diverse gradient signals during optimization. The final similarity is described by

$$s^{\mathrm{RCMD}}_{\mathbf{M}}(\mathbf{s}^1, \mathbf{s}^2) := \frac{1}{2}\left(s^{\mathrm{RCMD}_1}_{\mathbf{M}}(\mathbf{s}^1, \mathbf{s}^2) + s^{\mathrm{RCMD}_2}_{\mathbf{M}}(\mathbf{s}^1, \mathbf{s}^2)\right).$$

Adopting this similarity measure, the contrastive learning objective for the i-th sentence pair in a training batch is defined as follows:

$$-\log \frac{\exp(s^{\mathrm{RCMD}}_{\mathbf{M}}(\mathbf{s}^i, \mathbf{s}^i_+)/\tau)}{\sum_{j=1}^{B}(\exp(s^{\mathrm{RCMD}}_{\mathbf{M}}(\mathbf{s}^i, \mathbf{s}^j_+)/\tau) + \exp(s^{\mathrm{RCMD}}_{\mathbf{M}}(\mathbf{s}^i, \mathbf{s}^j_-)/\tau))},$$

where τ is the temperature parameter and B is the batch size. Following (Gao et al., 2021), CLRCMD uses the other sentences in the batch to generate negative pairs.

We argue that CLRCMD enhances both the sentence similarity and its interpretability in the following aspects. First, CLRCMD alleviates the catastrophic forgetting of pretrained semantics during

Model	STS12	STS13	STS14	STS15	STS16	STS-B	SICK-R	Avg

Table 1: The results on 7 STS benchmarks. We measure Spearman correlation on all the examples (Gao et al., 2021). † indicates the baseline results reported in their original papers.

the finetuning process. Its token-level supervision is produced by leveraging the textual semantics encoded in a pretrained checkpoint, because token pairs are semantically aligned according to their similarities in the contextualized embedding space. Namely, CLRCMD updates the parameters to improve the quality of sentence similarity while less breaking token-level semantics in the pretrained checkpoint. Furthermore, CLRCMD directly distills the relevance of a sentence pair into the relevance of semantically-aligned token pairs. In this sense, our contextualized embedding space effectively captures the token-level semantic relevance from training sentence pairs, which provides better interpretation for its sentence similarity.

4 Experiments

To analyze our approach in various viewpoints, we design and conduct experiments that focus on the following three research questions:

- **RQ1** Does CLRCMD effectively measure sentence similarities using a pretrained language model?
- **RQ2** Does CLRCMD provide the interpretation of sentence similarity which is well aligned with human judgements?
- **RQ3** Does CLRCMD efficiently compute its sentence similarity for training and inference?

4.1 Training details

We finetune a pretrained model using CLRCMD in the following settings. Following previous work (Gao et al., 2021), we use NLI datasets with hard negatives: SNLI (Bowman et al., 2015) and MNLI (Williams et al., 2018). We use a pretrained backbone attached with a single head, which is the same with (Gao et al., 2021). As the initial checkpoint of the pretrained models, we employ `bert-base-uncased` and `roberta-base` provided by huggingface (Devlin et al., 2019; Liu et al., 2019). Adam optimizer is used with the initial learning rate $5e-5$ and linear decay schedule. Fp16 training is enabled where the maximum batch size is 128 on a single V100 GPU, and the softmax temperature is set to $\tau = 0.05$ (Gao et al., 2021). The training is proceeded with 4 different random seeds and the best model is chosen using the best Spearman correlation on STSb validation set which is evaluated every 250 steps during training.

4.2 Semantic textual similarity

We evaluate the similarity model finetuned by CLRCMD for STS task to quantitatively measure the quality of sentence similarity (**RQ1**).

Metric We measure Spearman correlation for each of seven STS benchmarks and calculate their average to compare the capability of representing sentences in general (Conneau and Kiela, 2018).

Baselines We select the baselines that leverage a pretrained model, and they turn out to outperform other traditional baselines. We only list the baseline names for BERT$_{\text{base}}$ below; the names for RoBERTa$_{\text{base}}$ are obtained by replacing BERT$_{\text{base}}$

with RoBERTa$_{\text{base}}$.

- **BERT$_{\text{base}}$-avg** generates sentence embeddings by averaging the token embeddings from BERT$_{\text{base}}$ without finetuning. It indicates zero-shot performance of a checkpoint.
- **SBERT$_{\text{base}}$** (Reimers and Gurevych, 2019) is a pioneering work to finetune a pretrained model for sentence embeddings. It trains a Siamese network using NLI datasets.
- **SimCSE$_{\text{cls}}$-BERT$_{\text{base}}$** (Gao et al., 2021) adopts a contrastive learning framework (Chen et al., 2020) using SNLI and MNLI datasets. The contextualized embedding of `[CLS]` is used as a sentence embedding.
- **SimCSE$_{\text{avg}}$-BERT$_{\text{base}}$** (Gao et al., 2021) is the same with SimCSE$_{\text{cls}}$-BERT$_{\text{base}}$ except that it performs average pooling on token embeddings to obtain a sentence embedding.

Result Table 1 reports Spearman correlation for each dataset and their average. For most of the datasets, CLRCMD shows higher correlation compared to the state-of-the-art baselines. In particular, for STS14, STS15, SICK-R datasets, CLRCMD-BERT$_{\text{base}}$ achieves comparable performance to SimCSE$_{\text{cls}}$-RoBERTa$_{\text{base}}$ whose backbone language model is pretrained with 10 times larger data compared to BERT$_{\text{base}}$. This implies that finetuning with token-level supervision from CLRCMD achieves the performance as good as using an expensively pretrained checkpoint.

4.3 Interpretable semantic textual similarity

Next, we measure the performance of our approach on interpretable STS (iSTS) tasks in order to validate that CLRCMD embeds a sufficient level of interpretability even without any supervision (i.e., labeled training data) about semantically-aligned chunk pairs (**RQ2**).

Experimental setup We utilize the "images" and "headlines" data sources included in SemEval2016 Task 2: iSTS (Agirre et al., 2016). We measure the agreement between human judgement (gold semantic alignment across sentences) and the contributions of all token pairs to sentence similarity (element-wise multiplication of $(1-\mathbf{M})$ and $\mathbf{T}$). One challenge to use our similarity model for this task is to convert token pair contributions into chunk-level alignment. First, we summarize token pair contributions into chunk pair contributions by applying simple average pooling based on the chunk mapping represented by $c(i)=\{k|\text{is\_overlap}(c_i,t_k)\}$, where c_i is the i-th chunk and t_k is the k-th token in a sentence.[1] Then, to obtain the alignment based on the pairwise chunk contributions, we design a criterion for selecting confident chunk pairs (i,j) as follows:

Model	images	headlines
BERT$_{\text{base}}$-avg	82.45	85.98
BERT$_{\text{base}}$-RCMD	**83.00**	**88.25**
SimCSE$_{\text{avg}}$-BERT$_{\text{base}}$	82.98	85.80
CLRCMD-BERT$_{\text{base}}$	**87.25**	**90.55**
RoBERTa$_{\text{base}}$-avg	61.68	52.01
RoBERTa$_{\text{base}}$-RCMD	**82.44**	**88.92**
SimCSE$_{\text{avg}}$-RoBERTa$_{\text{base}}$	73.66	77.30
CLRCMD-RoBERTa$_{\text{base}}$	**84.93**	**88.45**

Table 2: The results on SemEval2016 task 2: iSTS.

$$\mathbf{C}_{i,j}=\frac{1}{|c_1(i)||c_2(j)|}\sum_{k}^{c_1(i)}\sum_{l}^{c_2(j)}\mathbf{T}_{k,l}\mathbf{M}_{k,l},$$
$$a(i,j)=\mathbb{I}[j=\underset{j'}{\text{argmax}}\,\mathbf{C}_{i,j'}]\cdot\mathbb{I}[i=\underset{i'}{\text{argmax}}\,\mathbf{C}_{i',j}].$$

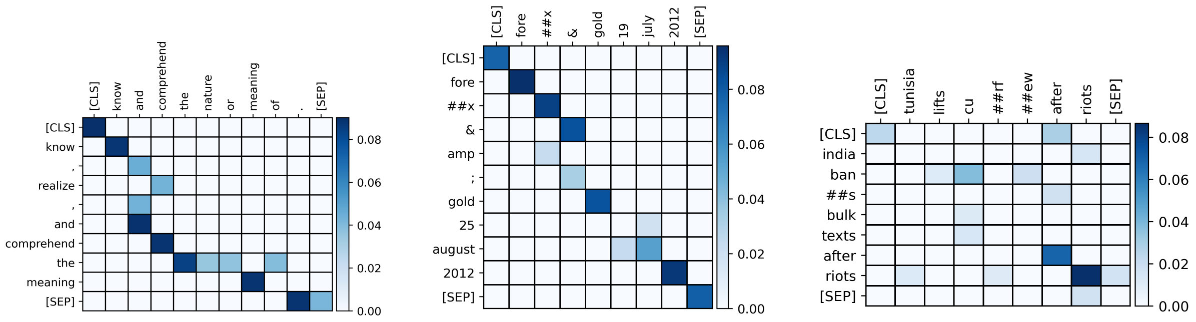
Using the aligned chunk pairs obtained by each method, we compute the alignment F1 score as the evaluation metric, which indicates the agreement between human judgement and chunk contribution.[2] We consider eight different configurations to investigate the effectiveness of the following components: 1) sentence similarity, 2) contrastive learning, and 3) pretrained checkpoints.

Result Table 2 shows the clear tendency of iSTS performance with respect to each of the above components. First of all, the token pair contribution from RCMD is more consistent with human judgement than that from average pooling. RCMD improves alignment F1 scores even without finetuning (BERT$_{\text{base}}$-RCMD and RoBERTa$_{\text{base}}$-RCMD), indicating that RCMD effectively discovers the token-level relevance encoded inside a pretrained checkpoint. In addition, the alignment F1 score increases when we finetune a model using CLRCMD. Notably, CLRCMD-BERT$_{\text{base}}$ successfully improves the alignment F1 score whereas

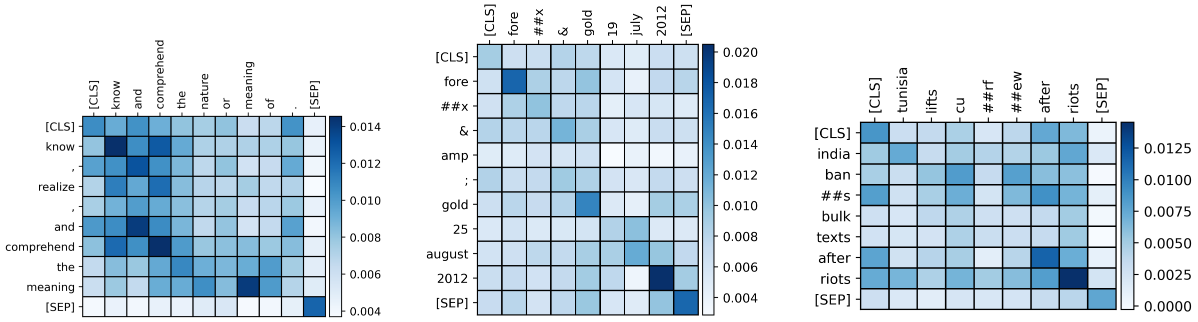
---

[1] We use gold standard chunking information to focus on alignment only, which is the second subtrack in iSTS.

[2] We employ alignment F1 score implemented in the evaluation script provided by the task organizer.



(a) Positive, CLRCMD (b) Neutral, CLRCMD (c) Negative, CLRCMD



(d) Positive, SimCSE$_{\text{avg}}$ (e) Neutral, SimCSE$_{\text{avg}}$ (f) Negative, SimCSE$_{\text{avg}}$

Figure 2: Token pair contribution heatmaps. We use the model finetuned from BERT$_{\text{base}}$ for this experiment.

SimCSE$_{\text{avg}}$-BERT$_{\text{base}}$ does not. This result shows that finetuning a model using the similarity measure based on semantically-aligned token pairs (i.e., fine-grained supervision induced by RCMD) further enhances the interpretability of a model.

4.4 Qualitative analysis

We qualitatively analyze the sentence similarity from the perspective of the transportation problem in order to demonstrate that a model trained by CLRCMD provides clear and accurate explanation (**RQ2**). To this end, we visualize the contribution of token pairs obtained from CLRCMD-BERT$_{\text{base}}$ and that from SimCSE$_{\text{avg}}$-BERT$_{\text{base}}$, and then clarify how their sentence similarity is computed differently from each other. Three sentence pairs are randomly selected from STS13 dataset. Figure 2 illustrates the token pair contribution heatmap for positive, neutral, and negative sentence pairs.

CLRCMD vs. SimCSE$_{\text{avg}}$ Overall, CLRCMD aligns two sentences better than the baseline. To be specific, CLRCMD effectively highlights the contributions of semantically-relevant token pairs and excludes the other contributions (Figure 2 upper). On the contrary, SimCSE$_{\text{avg}}$ fails to represent meaningful token-level relevance for sentence similarity (Figure 2 lower). The rank-1 constraint of SimCSE$_{\text{avg}}$ prevents the model from getting any plausible alignment between two sentences, while it simply tunes the contributions of all possible token pairs at once. We emphasize that the superfluous correlation in the heatmap not only inhibits the capability to capture sentence similarity, but also makes it difficult for humans to understand how sentence similarity is computed.

Case study on positive, neutral, and negative sentence pairs For the positive pair (Figure 2 left), CLRCMD clearly matches all semantically-aligned token pairs including the linking words ({“,”, “and”}–{“and”}), synonyms ({“realize”, “comprehend”}–{“comprehend”}), and omitted contexts ({“the”}–{“the nature of”, “of”}). For the neutral pair (Figure 2 middle), the two sentences have the same lexical structure except for the date. In this case, CLRCMD assigns low contributions to the token pairs about day and month ({“25”, “august”}–{“19”, “july”}), while keeping the contributions high for all the other pairs of identical tokens. Therefore, end-users can clearly figure out which part is semantically different based on their contributions as well as alignment. In case of the negative pair (Figure 2 right), both the models are not able to find any plausible alignment; CLRCMD lowers contributions for most of the token pairs ex-

Batch size	16	32	64	128
$\text{RCMD}_{\text{dense}}$	7.5	22.2	OOM	OOM
$\text{RCMD}_{\text{sparse}}$	4.6	6.1	10.6	25.8

Table 3: GPU memory usage (GB) of CLRCMD with various batch sizes. OOM: out-of-memory.

cept the token pair with identical contents ("after riots"). That is, end-users also can interpret the negative pair based on the heatmap where semantic correspondence between two sentences does not clearly exist but few overlapped tokens highly contribute to the sentence similarity.

4.5 Resource evaluation

We measure GPU memory usage and inference time of CLRCMD-$\text{BERT}_{\text{base}}$ to demonstrate that CLRCMD can be executed on a single GPU and an inference of our model takes almost the same cost to that of the baseline (**RQ3**).

4.5.1 GPU memory usage analysis

Implementation of RCMD We implement two variants of RCMD, $\text{RCMD}_{\text{dense}}$ and $\text{RCMD}_{\text{sparse}}$, to investigate the effect of exploiting the sparseness in RCMD. Both of them calculate sentence distance by the sum of element-wise multiplications of the cost matrix and the transportation matrix. For an input sentence pair, $\text{RCMD}_{\text{dense}}$ maintains the full pairwise token distances ($\mathbf{M}^{\text{CMD}}$), whereas $\text{RCMD}_{\text{sparse}}$ only keeps the token distances at which the transportation matrix has nonzero values ($\{\mathbf{M}^{\text{CMD}}_{i,j} | \mathbf{T}^{\text{CMD}}_{i,j} \neq 0\}$). Note that the number of nonzero entries in the transportation matrix of RCMD is at most $2L$, which is an order of magnitude smaller than the number of all entries, L^2.

Result Table 3 reports the GPU memory usage during the finetuning process. For batch-wise contrastive learning, GPU memory requirement becomes $O(B^2)$ in terms of the batch size B, because all pairwise sentence similarities within a batch need to be computed. In this situation, $\text{RCMD}_{\text{dense}}$ using a dense matrix drastically increases GPU memory usage by $O(B^2L^2)$, and as a result, the batch size cannot grow larger than 32. In contrast, $\text{RCMD}_{\text{sparse}}$ successfully enlarges the batch size up to 128 by exploiting sparseness in the transportation matrix of RCMD, which eventually reduces the space complexity to $O(B^2L)$.

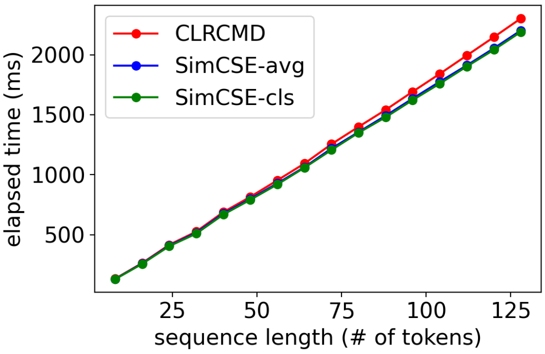


Figure 3: Elapsed time (ms) for the inference of 512 sentence pairs. The result of $\text{SimCSE}_{\text{avg}}$ and $\text{SimCSE}_{\text{cls}}$ are overlapped.

4.5.2 Inference time analysis

Experimental setup We measure the time for predicting the similarities of 512 sentence pairs on a single V100 GPU while increasing the sequence length from 8 to 128, which is the most influential factor for inference time. We repeat this process 10 times and report the average values.

Result Figure 3 shows the average elapsed time for inference. The model with RCMD takes almost the same inference time as the model with the simple average pooling-based similarity. We highlight that 98% of the sentences in STS13 dataset consist of at most 48 tokens and particularly, the time difference is negligible in case of predicting the sentence pairs whose sentences have less than 48 tokens. This result shows that significant increment of inference time does not occur within the range of the sequence length owing to parallel GPU computations, even though RCMD has the quadratic time complexity with respect to the sentence length.

5 Conclusion

In this work, we present CLRCMD, a learning framework for an interpretable sentence similarity model based on optimal transport. First, we view each sentence similarity measure as a transportation problem, pointing out the unexpressiveness of the existing pooling-based similarity. Integrating the concept of optimal transport into a pretrained language model, CLRCMD defines the distance measure by using the semantically-aligned token pairs between two sentences and furthermore, it finetunes a model with this distance based on contrastive learning for better interpretability. We empirically show that CLRCMD accurately predicts sentence similarity while providing interpretable token pair contributions consistent with human judgements. With the belief that the ability to interpret model behavior is critical for future AI models, we focus on enhancing this virtue targeted on STS task throughout this research.

Abstract

Recent years have witnessed growing interests in incorporating external knowledge such as pre-trained word embeddings (PWEs) or pre-trained language models (PLMs) into neural topic modeling. However, we found that employing PWEs and PLMs for topic modeling only achieved limited performance improvements but with huge computational overhead. In this paper, we propose a novel strategy to incorporate external knowledge into neural topic modeling where the neural topic model is pre-trained on a large corpus and then fine-tuned on the target dataset. Experiments have been conducted on three datasets and results show that the proposed approach significantly outperforms both current state-of-the-art neural topic models and some topic modeling approaches enhanced with PWEs or PLMs. Moreover, further study shows that the proposed approach greatly reduces the need for the huge size of training data.

1 Introduction

Topic models have been widely used for discovering hidden themes from a large collection of documents in an unsupervised manner. Recently, to avoid the complex and specific inference process of graph model-based method such as LDA (Blei et al., 2003), neural topic modeling that utilizes neural-network-based black-box inference has been the main research direction in this field (Blei, 2012; Miao et al., 2016; Srivastava and Sutton, 2017). Typically, neural topic models infer topics of a document by utilizing its bag-of-words (BoWs) representation to capture word co-occurrence patterns. The BoWs representation, however, fails to encode rich word semantics, leading to relatively inferior quality of topics generated by the topic models. Therefore, approaches have been proposed to address the limitation of BoWs representation by incorporating the external knowledge, such as pre-trained word embeddings (PWEs) (Das et al., 2015; Wang et al., 2020; Dieng et al., 2020).

In recent years, pre-trained language models (PLMs) (Peters et al., 2018; Devlin et al., 2019; Brown et al., 2020) have achieved state-of-the-art performance on a wide range of natural language processing tasks. Different from PWEs[1] in which a word is mapped to a static word emebdding, PLMs generate a specific word embedding for each occurrence of a word depending on the context. It is appealing to incorporate PLMs into topic models since contextualized embeddings generated by PLMs encode richer semantics and naturally deal with word polysemy (Pasini et al., 2020). One straightforward way is to replace BoWs representation with the outputs of PLM (Bianchi et al., 2020b) in existing topic models or take PLM outputs as additional inputs to topic modeling (Bianchi et al., 2020a). A more sophisticated approach is to distill the knowledge of a PLM into a topic model. For example, (Hoyle et al., 2020) employed the probability estimates of a teacher PLM over a text sequence to guide the training of a student topic model.

However, the approaches mentioned above still have limitations. Firstly, using PLMs for topic model training in such ways leads to huge computational overhead. Most neural topic models are based on shallow multi-layer perceptions with few hidden units. However, most popular PLMs are based on deep Transformers (Vaswani et al., 2017) where at each layer expensive self-attention operations are performed, which have a time complexity quadratic in document length. Therefore, the overall training time is dominated by PLM, and it will be worse if PLM is further fine-tuned, as shown in (Hoyle et al., 2020). Secondly, there is the gap of training objectives between PLMs and topic models, where PLMs are trained to learn the semantic

May 22-27, 2022

and syntactic knowledge within a sentence while topic models focus on extracting main themes over whole corpus. As shown in Table 4, a model based on GloVe embeddings (Pennington et al., 2014) performs better than PLMs-based models such as those proposed in (Bianchi et al., 2020a) and (Bianchi et al., 2020b).

To overcome these challenges, we propose a simple yet effective strategy, namely Pre-trained Neural Topic Model (PT-NTM), to utilize extensive knowledge from large corpora for neural topic modeling with low computational complexity. Instead of pre-training the embeddings and acquiring knowledge indirectly, PT-NTM directly pre-trains the topic model itself on the knowledge source corpora. In specific, a neural topic model is firstly trained on a large corpus only once, which is called *pre-training*. Afterward, it is fine-tuned on any other dataset, which is called *fine-tuning*. As the architecture of the neural topic model used in *pre-training* and *fine-tuning* is the same, it incurs little computational overhead to any subsequent training. Experiments have been conducted on three datasets and the results show that the proposed approach significantly outperforms not only some state-of-the-art neural topic models but also the topic modeling approaches using PWEs and PLMs. Moreover, it is observed that on the NYTimes dataset, the neural topic model trained on 1% of the whole dataset using the proposed approach achieves superior performance than other baseline models that are trained on the whole dataset. It further shows that the proposed approach greatly reduces the need for the huge size of training data.

The main contributions are:

- We proposed a simple yet effective strategy for training neural topic models in which the models are pre-trained on a large corpus and then fine-tuned on a specific dataset.
- We conducted extensive experiments and the results show that the pre-trained neural topic models significantly outperform baselines in terms of topic coherence and topic diversity.
- The proposed approach greatly reduces the amount of training data needed. In our experiments on the NYTimes dataset, a pre-trained model fine-tuned with 1% of documents achieves superior performance than baselines that are trained on the whole dataset.

2 Related Work

2.1 Neural Topic Modeling

Due to the flexible modeling choices and high representation capacity, neural networks have been widely used for topic modeling in recent years. Some approaches (Kingma and Welling, 2013; Miao et al., 2016) model topics with variational autoencoders (VAEs) and view the latent variables of VAEs as document topics. However, topic models typically use Dirichlet distribution as the prior of multinomial topic distributions, while the reparameterization trick required by VAEs hinders the usage of a Dirichlet prior. Therefore, some follow-up works (Srivastava and Sutton, 2017; Card et al., 2018) used logistic normal to approximate Dirichlet. Another family of neural topic models (Nan et al., 2019; Wang et al., 2020; Hu et al., 2020) overcome the problem with adversarial training (Goodfellow et al., 2014) by encouraging the model to generate topic distributions that are similar to samples randomly drawn from a Dirichlet prior.

2.2 Topic Modeling with External Knowledge

There are mainly two ways to incorporate external knowledge into topic modeling, namely by PWEs and PLMs.

Some attempts incorporate pre-trained word representations into neural topic models. For example, (Card et al., 2018; Dieng et al., 2020) used PWEs to initialize word embeddings of topic models. (Wang et al., 2020) built a generative process that models word embeddings with per-topic Gaussian distributions.

Beyond static word embeddings, researchers also tried to utilize PLMs. (Bianchi et al., 2020b,a) treated PLM outputs as an additional knowledge source to enhance or replace BoW-based inputs. (Hoyle et al., 2020) employed knowledge distillation to guide the training of a student topic model with a PLM teacher network. Recently, (Song et al., 2020) proposed TopicOcean to train LDA-based topic models on large corpora and then transfer the knowledge of accumulated topics to new corpora which can also be considered a way of pre-training.

It should be pointed out that the proposed PT-NTM differs from the previous PLMs-based topic models or TopicOcean in that the architecture of neural topic models during pre-training and fine-tuning are the same in PT-NTM while other methods combine the large PLM with the topic models, the two different model architectures.

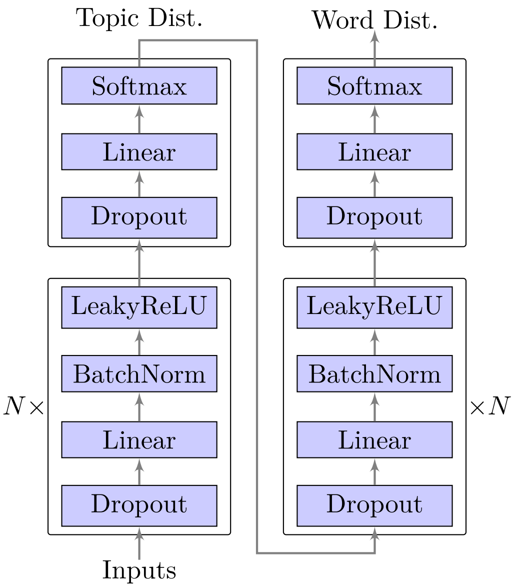

Figure 1: The architecture of neural topic model employed in PT-NTM. Both the encoder on the left and the decoder on the right have $N+1$ layers.

3 Methodology

In this section, we describe the detailed processes of PT-NTM. First, we will introduce the architecture of neural topic model, which we call NTM in the following, employed in PT-NTM. Then, we will introduce how to pre-train the neural topic model on a large-scale dataset. Finally, we will introduce how to fine-tune the pre-trained neural topic model on the target dataset.

3.1 Neural Topic Model Architecture

For the architecture of NTM, we follow the encoder-decoder architecture, as employed by many neural topic models (Srivastava and Sutton, 2017; Miao et al., 2017; Nan et al., 2019). The encoder takes a document's BoW $\boldsymbol{x} \in \mathbb{R}^V$ as input and infers its topic distribution $\hat{\boldsymbol{z}} \in \mathbb{R}^K$, where V is the vocabulary size and K the topic number. The decoder then reconstructs the original document from $\hat{\boldsymbol{z}}$, denoted as $\hat{\boldsymbol{x}}$.

The whole architecture of NTM is shown in Figure 1. In specific, the encoder is a stack of $N+1$ MLP layers. From the bottom to the top, the first N layers have an identical structure. Each layer has four sub-layers: Dropout (Srivastava et al., 2014), Linear, BatchNorm (Ioffe and Szegedy, 2015), and LeakyReLU (Maas et al., 2013). The final layer is a Dropout sub-layer and a Linear transformation followed by a Softmax. The decoder shares the same architecture as the encoder, though they may vary in input/output dimensions. In our experiments, we set a Dropout probability of 0.5 in the first encoder layer and 0.2 in the remaining encoder and decoder layers. All LeakyReLU sub-layers have a negative slope of 0.01.

Combining the encoder and the decoder, we now have the reconstruction loss:

$$\mathcal{L}_{\text{rec}}(X, \hat{X}) = -\mathbb{E}(\boldsymbol{x} \log \hat{\boldsymbol{x}}), \qquad (1)$$

which encourages the decoder outputs $\hat{X} = \{\hat{\boldsymbol{x}}^{(i)}\}_{i=1}^m$ to be as similar as the corresponding encoder inputs $X = \{\boldsymbol{x}^{(i)}\}_{i=1}^m$ for each training batch, where m is the batch size.

For topic distribution $\hat{\boldsymbol{z}}$, what we have done above is insufficient to generate reasonable topics since $\hat{\boldsymbol{z}}$'s distribution Q is not well defined. To this end, we follow a similar approach proposed in (Nan et al., 2019) and further impose on $\hat{\boldsymbol{z}}$ a Dirichlet prior P by minimizing the Maximum Mean Discrepancy (MMD) (Gretton et al., 2012) between the two distributions P and Q:

$$\mathcal{L}_{\text{MMD}}(Z, \hat{Z}) = -\frac{2}{m^2}\sum_{i,j} k(\boldsymbol{z}^{(i)}, \hat{\boldsymbol{z}}^{(j)}) + \frac{1}{m(m-1)}\sum_{i \neq j}(k(\boldsymbol{z}^{(i)}, \boldsymbol{z}^{(j)}) + k(\hat{\boldsymbol{z}}^{(i)}, \hat{\boldsymbol{z}}^{(j)})), \qquad (2)$$

where $Z = \{\boldsymbol{z}^{(i)}\}_{i=1}^m$ are topic distributions randomly drawn from the prior P, $\hat{Z} = \{\hat{\boldsymbol{z}}^{(i)}\}_{i=1}^m$ are encoder outputs, and k is the kernel function that is information diffusion kernel (Lebanon and Lafferty, 2003) in our experiments following (Nan et al., 2019).

The overall training objective is:

$$\mathcal{L} = \mathcal{L}_{\text{rec}}(X, \hat{X}) + \lambda r \mathcal{L}_{\text{MMD}}(Z, \hat{Z}), \qquad (3)$$

where we balance $\mathcal{L}_{\text{rec}}$ and $\mathcal{L}_{\text{MMD}}$ with a hyperparameter λ and another factor

$$r = \frac{\|\nabla_{\boldsymbol{b}^{(N+1)}} \mathcal{L}_{\text{rec}}(X, \hat{X})\|_2}{\|\nabla_{\boldsymbol{b}^{(N+1)}} \mathcal{L}_{\text{MMD}}(Z, \hat{Z})\|_2}, \qquad (4)$$

where $\|\cdot\|_2$ denotes L2 normalization and $\boldsymbol{b}^{(N+1)}$ is the bias term of the last Linear sub-layer of the encoder, i.e., the one just before the Softmax sub-layer. Equation (4) shows that the two losses are balanced with their relative gradient norm with respect to $\boldsymbol{b}^{(N+1)}$. We found in our experiments that r greatly reduces the effort of tuning λ and generally produces better results.

3.2 Pre-training

By pre-training the topic model on a large and topically diverse corpus, we expect the model would learn topic-related knowledge that is general enough to be reused on other corpora. For the proposed approach, the knowledge may include word semantics, common senses, and document encoding and decoding patterns at each layer.

The details of the pre-training procedure are presented in Algorithm 1. The pre-training corpus $\mathcal{D}$ is the subset00 of the OpenWebText dataset (Gokaslan and Cohen, 2019), an open-source recreation of the WebText dataset as detailed in (Radford et al., 2019). We preprocess data by tokenization, lemmatization, stopword removal, and only keeping words occurred in at least 50 documents. After preprocessing, there are about 392K documents, consisting of 45K unique words, in the resulting dataset. At each training mini-batch, we update model parameters according to Equation (3) using the Adam optimizer (Kingma and Ba, 2014).

Algorithm 1 Pre-training.

```
Require: $\mathcal{D}$, the pre-training corpus; $E$, the encoder; $D$, the decoder; $\boldsymbol{\theta}$, parameters of $E$ and $D$; $\boldsymbol{\theta}_0$, initial parameters; $m$, the batch size; $n$, the number of training epochs; $P(\boldsymbol{z})$, the Dirichlet prior.
$\boldsymbol{\theta} \leftarrow \boldsymbol{\theta}_0$
for $i = 1, \cdots, n$ do
    Shuffle $\mathcal{D}$.
    for each $X = \{\boldsymbol{x}^{(j)}\}_{j=1}^{m}$ from $\mathcal{D}$ do
        $\hat{Z} \leftarrow E(X)$; $\hat{X} \leftarrow D(\hat{Z})$
        Sample $Z = \{\boldsymbol{z}^{(j)}\}_{j=1}^{m} \sim P(\boldsymbol{z})$.
        Compute $\mathcal{L}$ by Equation (3).
        $\boldsymbol{\theta} \leftarrow \text{Adam}(\nabla_{\boldsymbol{\theta}} \frac{1}{m} \sum_{j=1}^{m} \mathcal{L}^{(j)}, \boldsymbol{\theta})$
    end for
end for
```

3.3 Fine-tuning

Fine-tuning is the process of adapting the pre-trained topic model to a specific dataset. However, directly fine-tuning the pre-trained model on a new dataset does not always work and may introduce severe bias to subsequent tuning steps since the ideal number of topics might change and the corpus-wide topic distributions might be different. Therefore, our fine-tuning begins with the pre-trained model but randomly re-initializes parameters in the last encoder layer and the first decoder layer. If we fine-tune the model without any re-initialization, we find that in our experiments the corpus-wide topic distributions discovered by the fine-tuned model would be biased towards the topic distribution of the pre-training corpus, which is unexpected. The proposed fine-tuning strategy with re-initialization solves this issue. Algorithm 2 shows the fine-tuning steps. We keep the pre-trained parameters fixed for the first n_1 epochs and use a small learning rate in the remaining training epochs since they have already been well trained before fine-tuning.

Algorithm 2 Fine-tuning.

```
Require: $\mathcal{D}'$, the target corpus; $E$, the encoder; $D$, the decoder; $\boldsymbol{\theta}_r$, randomly initialized parameters; $\boldsymbol{\theta}_p$, pre-trained parameters; $m$, the batch size; $n$, the number of training epochs; $n_1$, $n_1 \in \mathbb{N}$ and $0 \leq n_1 \leq n$; $P(\boldsymbol{z})$, the Dirichlet prior.
for $i = 1, \cdots, n$ do
    Shuffle $\mathcal{D}'$.
    for each $X = \{\boldsymbol{x}^{(j)}\}_{j=1}^{m}$ from $\mathcal{D}'$ do
        $\hat{Z} \leftarrow E(X)$; $\hat{X} \leftarrow D(\hat{Z})$
        Sample $Z = \{\boldsymbol{z}^{(j)}\}_{j=1}^{m} \sim P(\boldsymbol{z})$.
        Compute $\mathcal{L}$ by Equation (3).
        $\boldsymbol{\theta}_r \leftarrow \text{Adam}(\nabla_{\boldsymbol{\theta}_r} \frac{1}{m} \sum_{j=1}^{m} \mathcal{L}^{(j)}, \boldsymbol{\theta}_r)$
        if $i > n_1$ then
            $\boldsymbol{\theta}_p \leftarrow \text{Adam}(\nabla_{\boldsymbol{\theta}_p} \frac{1}{m} \sum_{j=1}^{m} \mathcal{L}^{(j)}, \boldsymbol{\theta}_p)$
        end if
    end for
end for
```

By comparing Algorithm 1 with Algorithm 2, it can be observed that the fine-tuning process adds little overhead to the training stage. More importantly, the proposed method does not introduce any additional computations or parameters during inference.

4 Experiments

We used three datasets in (Hu et al., 2020): NYTimes[2], Grolier[3], and 20Newsgroups[4]. We did not include the DBPedia dataset as it is based on Wikipedia and potentially overlaps with the dataset used for our pre-training. The dataset statistics are shown in Table 1.

The proposed basic model, NTM, is the one described in Section 3 without pre-training. Both the

---

[3] `https://cs.nyu.edu/~roweis/data`

[4] `http://qwone.com/~jason/20Newsgroups`

Dataset	#Documents	Vocabulary Size
NYTimes	99,992	12,604
Grolier	29,762	15,276
20Newsgroups	11,258	2,000

Table 1: Dataset statistics.

encoder and the decoder have three layers ($N = 2$) and 300 neurons at each hidden layer. We have four variants:

- NTM-w2v, we initialize weights $\boldsymbol{w}_{e1} \in \mathbb{R}^{V\times 300}$ of the first encoder Linear sub-layer and $\boldsymbol{w}_{d3} \in \mathbb{R}^{300\times V}$ of the the last decoder Linear sub-layer with the corresponding 300-dim Word2Vec embeddings trained on Google News.

- NTM-glv, same as NTM-w2v but utilizing 300-dim GloVe embeddings trained on Wikipedia and Gigaword 5.

- PT-NTM-w2v, pre-training from NTM-w2v initialization and then fine-tuning.

- PT-NTM-glv, pre-training from NTM-glv initialization and then fine-tuning.

The number of training epochs is 200 for pre-training, fine-tuning (PT-* models) and fresh training (NTM). We used the Dirichlet prior distribution whose parameters are all $\frac{1}{K}$, where K is the topic number. MMD loss weight λ is 1 for all models expect the fine-tuning of *-pre models in which λ is 0.3. We will analyze the effect of λ in our experiments. During pre-training, the batch size is 1,024, the learning rate is 2e-2, and the topic number is 200. For fine-tuning, n_1 is 100, and the learning rates for reinitialized and pre-trained parameters are 2e-2 and 1e-5, respectively (Algorithm 2), showing that the pre-trained parameters are only slightly tuned. The batch size of fine-tuning and fresh training varies on different datasets depending on their sizes. Specifically, it is set to 128 for 20Newsgroups, 256 for Grolier and 512 for NYTimes. Finally, it should be noted that fine-tuning on each datasets shares the same pre-trained model checkpoint for each model variant.

We compare our models with following baselines:

- LDA (Blei et al., 2003), we used the implementation of GibbsLDA++[5].

- ProdLDA (Srivastava and Sutton, 2017), a VAE-based model that employs logistic normal prior for topic distributions.

- W-LDA (Nan et al., 2019). Our model follows W-LDA loss but differs in training and implementation.

- BAT (Wang et al., 2020), an adversarially trained neural topic model.

- ToMCAT (Hu et al., 2020), an adversarial neural topic model with cycle-consistency objective.

- ZeroShotTM (Bianchi et al., 2020b), taking Sentence-BERT (Reimers and Gurevych, 2019) embeddings as input.

- CombinedTM (Bianchi et al., 2020a), same as ZeroShotTM but combining the input with BoWs.

- G-BAT (Wang et al., 2020), extending BAT to incorporate pre-trained word embeddings.

- TopicOcean (Song et al., 2020), integrating well-trained LDAs and transferring the knowledge of accumulated topics to new corpora, which is re-implemented by ourselves.

We evaluate the model performance with three topic coherence measures and one topic diversity measure. Topic coherence measures first calculate the coherence scores of pairs of top words ranked by their topic-associated probabilities for each topic and then aggregate all topic scores as the final topic coherence. The used topic coherence measures are C_A (Aletras and Stevenson, 2013), C_P (Röder et al., 2015), and NPMI (Aletras and Stevenson, 2013) of top-10 topic words, implemented in Palmetto (Röder et al., 2015) [6]. Topic coherence measures are highly correlated with human evaluation but have no penalizing mechanism for repetitive or similar topics. We remedy the problem by also evaluating topic diversity. Our topic diversity measure is calculate by $\mathrm{TD} = 1 - \frac{N_{\text{rep}}}{N_{\text{total}}}$, where $N_{\text{total}} = 10 \times K$ is the total number of topic words and N_{rep} counts the number of repetitions in all topic words. For example, 5 identical words would add 4 to N_{rep}.

Table 2: Average topic coherence (C_A, C_P, and NPMI) and topic diversity (TD) scores of 5 topic number settings (20, 30, 50, 75, 100) on 3 datasets (NYTimes, Grolier, and 20Newsgroups). Bold values indicate best-performing models under corresponding settings. NYTimes and Grolier only have BoW data so we cannot evaluate ZeroShotTM and CombinedTM, which require word order information, on them.

4.1 Topic Modeling Results

The topic modeling results are presented in Table 2. We report results averaged over five runs with topic number set to 20, 30, 50, 75, and 100 respectively in all our experiments unless otherwise specified.

From Table 2, we can observe that: 1) Among all models, PT-NTM and its variants outperform other methods by a large margin. Since PT-NTM and NTM share the identical model architecture, we attribute the improvements of PT-NTM over NTM to the pre-training strategy. 2) For PLMs-based methods, both ZeroShotTM and CombinedTM performs badly, for some metric even worse than regular methods. We think the reason maybe the gap between the learning objectives of PLMs (word order-based) and topic models (word-cooccurrence based). 3) For PWEs-based methods, non-pretrained methods (NTM, BAT) benefits a lot from the PWEs. We think the reason maybe the PWEs are also trained based on word-cooccurrence, so the gap between PWEs and topic models is relatively small. Another interesting thing is that the benefit of using PWEs in topic modeling seems diminishing with our proposed topic model pre-training strategy. For example, PT-NTM gives similar results compared to PT-NTM-w2v and PT-NTM-glv. This shows that word semantic knowledge has somehow been captured to a certain degree by pre-training the topic model on a large corpus. 4) For pre-training-based models, PT-NTM outperforms TopicOcean, consider the performance gap between their base models (NTM for PT-NTM and LDA for TopicOcean), the improvement of PT-NTM is even larager. What's more, our method is based on neural network, which is easier to incorporated with PWEs or other information than TopicOcean, which is based on graphical models.

One concern about PT-NTM may be that the whether the $fine - tuning$ stage works. To get a sense of the topics extracted by our model, we list in Table 3 top 4 topics extracted by PT-NTM on the $pre - training$ and $fine - tuning$ dataset. The topic labels are assigned manually. The whole topics are presented in the attachment.

4.2 Contextualized vs. Static word embeddings

Contextualized word embeddings like those produced by BERT (Devlin et al., 2019) provide richer semantic than static ones like Word2Vec (Mikolov et al., 2013) or GloVe (Pennington et al., 2014). Thus we also conducted experiments to test their performance on topic modeling. The baseline models are ZeroShotTM (Bianchi et al., 2020b) and CombinedTM (Bianchi et al., 2020a). ZeroShotTM and CombinedTM both take Sentence-BERT (Reimers and Gurevych, 2019) embeddings as inputs but CombinedTM additionally uses BoW. We also implement three NTM-based models, namely BERT-NTM, Word2Vec-NTM, and GloVe-NTM, according to the input embeddings they used. BERT-NTM follows the idea of ZeroShotTM, aim-

ing at providing a fair comparison between BERT-based topic models. Word2Vec-NTM only uses pre-trained embeddings in the encoder, which is different from NTM-w2v as the latter use the the pre-trained Word2Vec embeddings in both the first encoder layer and the last decoder layer. The same setup applies to GloVe-NTM.

The experimental results on 20Newsgroups[7] are shown in Table 4. All the models have similar topic diversity. Our NTM variants outperform both ZeroShotTM and CombinedTM on all three topic coherence measures. The possible reasons could be: 1) Topic modeling does not quite rely on word order information, at least for our experimented dataset; and 2) Training of GloVe utilizes global word-word co-occurrence statistics that are also helpful for topic modeling. As topic modeling can be viewed as a form of word clustering, our results are somewhat inline with previous findings reported in Meng et al. (2019) that using BERT leads to poor performance on text clustering.

4.3 Ablation Study and Further Analysis

Number of model layers We vary the number of encoder and decoder layers of pre-training and fine-tuning models, and show the results in Table 5. It can be observed that the four-layer and the three-layer models achieve the highest topic coherence and topic diversity respectively. Further increasing the layer number resulted in slight declines in all four metrics.

MMD loss weight λ We present the impact of λ on our model in Figure 2. With λ increasing from 0.03 to 30, the NPMI of PT-NTM-glv first gradually increases, peaking at about 0.14 when $\lambda = 1$, and then gradually decreases. For Topic Diversity (TD), however, we observe a steady decline for

---

[7] The other two datasets only contain word counts, making it impossible to extract BERT embeddings since no word context information is present.

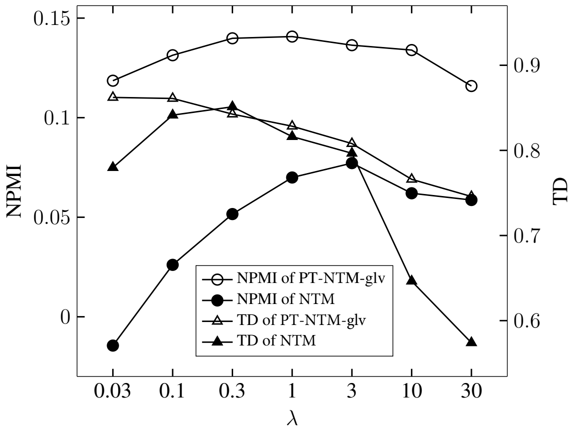

Figure 2: NPMI and TD results on 20Newsgroups of PT-NTM-glv and NTM w.r.t. MMD loss weight λ.

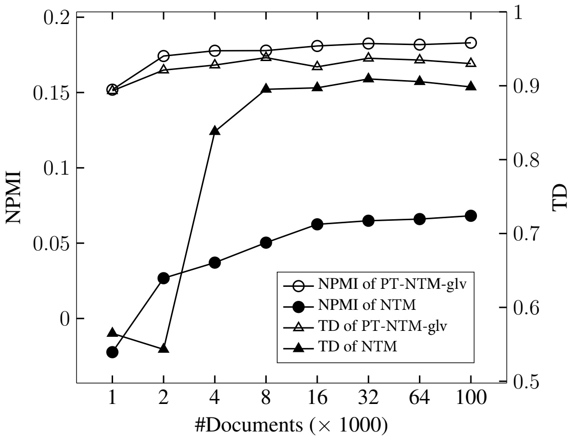

Figure 3: NPMI and TD results on NYTimes of PT-NTM-glv and NTM w.r.t. the training dataset sizes.

PT-NTM-glv. PT-NTM also has a similar trend but with more drastic changes. Given these findings, it seems that there is a trade-off towards generating more coherent or diverse topics.

Nevertheless, it is worth noting that in comparison to NTM, the PT-NTM-glv is very robust to the choices of λ. The NPMI values of PT-NTM-glv only fluctuate in the range of $[0.11, 0.14]$ while its TD values vary between 0.74 and 0.86. This is in contrast to NTM in which it has poor topic coherence for $\lambda \leq 0.1$ and low topic diversity for $\lambda \geq 10$. We attribute the advantage of the pre-trained model to our proposed fine-tuning strategy. During fine-tuning, we mainly update a small set of parameters that are directly related to topics while only slightly tune others, which consequently enables more controllable data/gradient flows and thus produces more stable results.

Data efficiency With pre-training, a topic model indeed captures extensive knowledge from an external corpus. As have been shown in our experiments, the acquired knowledge can improve the performance of subsequent fine-tuning on other datasets, It would be interesting to see to what extent such knowledge can increase data efficiency. To this end, we conducted experiments that take subsets of NYTimes dataset of varying sizes as training datasets. Specifically, we used dataset sizes including 1K, 2K, 4K, $\cdots$, 64K, and 100K. For each size, we averaged the results over five runs whose training datasets are randomly sampled from the whole dataset with different random seeds.

The results are shown in Figure 3. PT-NTM-glv has a very high starting point when the document number is 1000: the NPMI and TD is about 0.15 and 0.89 respectively. While at the same time, NTM has extremely poor performance with negative NPMI and low TD. Only when the document number increases to 8000, the topics generated by NTM has comparable topic diversity to topics from PT-NTM-glv. But even when the whole dataset is used by PT-NTM, i.e., the document number is 100K, NTM's NPMI is still about 0.08 lower than the 1000-document PT-NTM-glv, which indeed represents a significant difference in topic quality. In summary, pre-training the topic model greatly reduces the need for training data and helps the model achieve superior performance with only 1% of documents on the NYTimes dataset.

5 Conclusion

In this paper, we proposed a simple yet effective strategy to incorporating external knowledge into neural topic modeling by pre-training topic models on a large corpus before fine-tuning them on specific datasets. By experiments, we have presented the effectiveness of the method of pre-trained neural topic model in terms of topic coherence, topic diversity, and data efficiency over other methods such as by incorporating PWEs and PLMs. Another advantage of this approach is that it introduces little overhead to the training and none to the inference. Limited by computing resources, we did not experiment pre-trainings on larger datasets, though we believe there is still room for improvement given more pre-training data. For future research, we encourage further explorations in model architectures, pre-training objectives, and fine-tuning procedures.

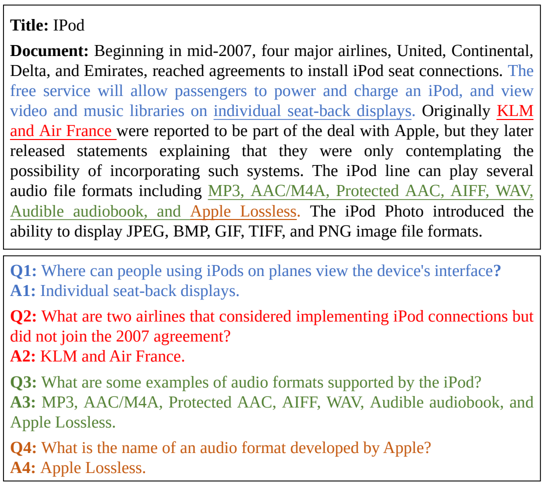
Abstract

Dense retrieval has achieved impressive advances in first-stage retrieval from a large-scale document collection, which is built on bi-encoder architecture to produce single vector representation of query and document. However, a document can usually answer multiple potential queries from different views. So the single vector representation of a document is hard to match with multi-view queries, and faces a semantic mismatch problem. This paper proposes a multi-view document representation learning framework, aiming to produce multi-view embeddings to represent documents and enforce them to align with different queries. First, we propose a simple yet effective method of generating multiple embeddings through viewers. Second, to prevent multi-view embeddings from collapsing to the same one, we further propose a global-local loss with annealed temperature to encourage the multiple viewers to better align with different potential queries. Experiments show our method outperforms recent works and achieves state-of-the-art results.



Title: IPod

Document: Beginning in mid-2007, four major airlines, United, Continental, Delta, and Emirates, reached agreements to install iPod seat connections. The free service will allow passengers to power and charge an iPod, and view video and music libraries on individual seat-back displays. Originally KLM and Air France were reported to be part of the deal with Apple, but they later released statements explaining that they were only contemplating the possibility of incorporating such systems. The iPod line can play several audio file formats including MP3, AAC/M4A, Protected AAC, AIFF, WAV, Audible audiobook, and Apple Lossless. The iPod Photo introduced the ability to display JPEG, BMP, GIF, TIFF, and PNG image file formats.

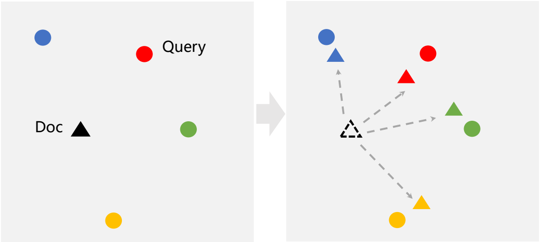
Q1: Where can people using iPods on planes view the device's interface?
A1: Individual seat-back displays.

Q2: What are two airlines that considered implementing iPod connections but did not join the 2007 agreement?
A2: KLM and Air France.

Q3: What are some examples of audio formats supported by the iPod?
A3: MP3, AAC/M4A, Protected AAC, AIFF, WAV, Audible audiobook, and Apple Lossless.

Q4: What is the name of an audio format developed by Apple?
A4: Apple Lossless.

(a) An example from SQuAD Open Dataset.



(b) Our proposed MVR method.

Figure 1: The illustration of our multi-view document representation learning framework. The triangles and circles mean document and query vectors separately. Usually, one document can be asked to different potential queries from multiple views. Our method comes from this observation and generates multi-view representations for documents to better align with different potential queries.

1 Introduction

Over the past few years, with the advancements in pre-trained language models (Devlin et al., 2019; Liu et al., 2019), dense retrieval has become an important and effective approach in open-domain text retrieval (Karpukhin et al., 2020; Lee et al., 2019; Qu et al., 2021; Xiong et al., 2020). A typical dense retriever usually adopts a bi-encoder (Huang et al., 2013; Reimers and Gurevych, 2019) architecture to encode input query and document into a single low-dimensional vector (usually CLS token), and computes the relevance scores between their representations. In real-world applications, the embedding vectors of all the documents are pre-computed in advance, and the retrieval process can be efficiently boosted by the approximate nearest neighbor (ANN) technique (Johnson et al., 2019). To enhance bi-encoder's capacity, recent studies carefully design sophisticated methods to train it effectively, including constructing more challenging hard negatives (Zhan et al., 2021; Xiong et al., 2020; Qu et al., 2021) and continually pre-train the

language models (Gao and Callan, 2021a; Oğuz et al., 2021) for a better transfer.

However, being limited to the single vector representation, bi-encoder faces the upper boundary of representation capacity according to theoretical analysis in Luan et al. (2021). In the real example from SQuAD dev dataset, we also find that a single vector representation can't match well to multi-view queries, as shown in Figure.1. The document corresponds to four different questions from different views, and each of them matches to different sentences and answers. In the traditional bi-encoder, the document is represented to a single vector while it should be recalled by multiple diverse queries, which limits the capacity of the bi-encode.

As for the multi-vector models, cross-encoder architectures perform better by computing deeply-contextualized representations of query-document pairs, but are computationally expensive and impractical for first-stage large-scale retrieval (Reimers and Gurevych, 2019; Humeau et al., 2020). Some recent studies try to borrow from cross-encoder and extend bi-encoder by employing more delicate structures, which allow the multiple vector representations and dense interaction between query and document embeddings. including late interaction (Khattab and Zaharia, 2020) and attention-based aggregator (Humeau et al., 2020; Tang et al., 2021). However, most of them contain softmax or sum operators that can't be decomposed into max over inner products, and so fast ANN retrieval can't be directly applied.

Based on these observations, we propose ***Multi-View document Representations learning*** framework, ***MVR*** in short. MVR originates from our observation that a document commonly has several semantic units, and can answer multiple potential queries which contain individual semantic content. It is just like given a specified document, different askers raise different questions from diverse views. Therefore, we propose a simple yet effective method to generate multi-view representations through **viewers**, optimized by a global-local loss with annealed temperature to improve the representation space.

Prior work has found *[CLS]* token tends to aggregate the overall meaning of the whole input segment (Kovaleva et al., 2019; Clark et al., 2019), which is inconsistent with our goal of generating multi-view embeddings. So we first modify the bi-encoder architecture, abandon *[CLS]* token and add multiple *[Viewer]* tokens to the document input. The representation of the viewers in the last layer is then used as the multi-view representations.

To encourage the multiple viewers to better align with different potential queries, we propose a global-local loss equipped with an annealed temperature. In the previous work, the contrastive loss between positive and negative samples is widely applied (Karpukhin et al., 2020). Apart from global contrastive loss, we formulate a local uniformity loss between multi-view document embeddings, to better keep the uniformity among multiple viewers and prevent them from collapsing into the same one. In addition, we adopt an annealed temperature which gradually sharpens the distribution of viewers, to help multiple viewers better match to different potential queries, which is also validated in our experiment.

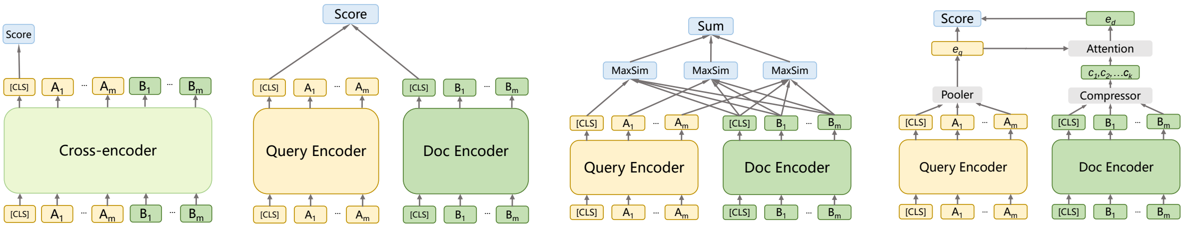
The contributions of this paper are as follows:

- We propose a simple yet effective method to generate multi-view document representations through multiple viewers.
- To optimize the training of multiple viewers, we propose a global-local loss with annealed temperature to make multiple viewers to better align to different semantic views.
- Experimental results on open-domain retrieval datasets show that our approach achieves state-of-the-art retrieval performance. Further analysis proves the effectiveness of our method.

2 Background and Related Work

2.1 Retriever and Ranker Architecture

With the development of deep language model (Devlin et al., 2019), fine-tuned deep pre-trained BERT achieve advanced re-ranking performance (Dai and Callan, 2019; Nogueira and Cho, 2019). The initial approach is the cross-encoder based re-ranker, as shown in Figure.2(a). It feeds the concatenation of query and document text to BERT and outputs the *[CLS]* token's embeddings to produce a relevance score. Benefiting from deeply-contextualized representations of query–document pairs, the deep LM helps bridge both vocabulary mismatch and semantic mismatch. However, cross-encoder based rankers need computationally expensive cross-attention operations (Khattab and Zaharia, 2020; Gao and Callan, 2021a), so it is



(a) Cross-encoder(e.g., BERT) (b) Bi-encoder (e.g., DPR) (c) Late Interaction (e.g., ColBERT) (d) Attention-based Aggregator (e.g., PolyEncoder)

Figure 2: The comparison of different model architectures designed for retrieval/re-ranking.

impractical for large-scale first-stage retrieval and is usually deployed in second-stage re-ranking.

As for first-stage retrieval, bi-encoder is the most adopted architecture (Karpukhin et al., 2020) for it can be easily and efficiently employed with support from approximate nearest neighbor (ANN) (Johnson et al., 2019). As illustrated in Figure.2(b), it feeds the query and document to the individual encoders to generate single vector representations, and the relevance score is measured by the similarity of their embeddings. Equipped with deep LM, bi-encoder based retriever has achieved promising performance (Karpukhin et al., 2020). And later studies have further improved its performance through different carefully designed methods, which will be introduced in Sec.2.2

Beside the typical bi-encoder, there are some variants(Gao et al., 2020; Chen et al., 2020; Mehri and Eric, 2021) proposing to employ dense interactions based on Bi-encoder. As shown in Fig.2(c), ColBERT (Khattab and Zaharia, 2020) adopts the late interaction paradigm, which computes token-wise dot scores between all the terms' vectors, sequentially followed by max-pooler and sum-pooler to produce a relevance score. Later on, Gao et al. (2021) improve it by scoring only on overlapping token vectors with inverted lists. Another variant is the attention-based aggregator, as shown in Fig.2(d). It utilizes the attention mechanism to compress the document embeddings to interact with the query vector for a final relevance score. There are several works (Humeau et al., 2020; Luan et al., 2021; Tang et al., 2021) built on this paradigm. Specifically, Poly-Encoder(learnt-k) (Humeau et al., 2020) sets k learnable codes to attend them over the document embeddings. DRPQ (Tang et al., 2021) achieve better results by iterative K-means clustering on the document vectors to generate multiple embeddings, followed by attention-based interaction with query. However, the dense interaction methods can't be directly deployed with ANN, because both the sum-pooler and attention operator can't be decomposed into max over inner products, and the fast ANN search cannot be applied. So they usually first approximately recall a set of candidates then refine them by exhaustively re-ranking, While MVR can be directly applied in first-stage retrieval.

Another related method is ME-BERT(Luan et al., 2021), which adopts the first k document token embeddings as the document representation. However, only adopting the first-k embeddings may lose beneficial information in the latter part of the document, while our viewer tokens can extract from the whole document. In Sec.5.2, we also find the multiple embeddings in MEBERT will collapse to the same *[CLS]*, while our global-local loss can address this problem.

2.2 Effective Dense Retrieval

In addition to the aforementioned work focusing on the architecture design, there exist loads of work that proposes to improve the effectiveness of dense retrieval. Existing approaches of learning dense passage retriever can be divided into two categories: (1) pre-training for retrieval (Chang et al., 2020; Lee et al., 2019; Guu et al., 2020) and (2) fine-tuning pre-trained language models (PLMs) on labeled data (Karpukhin et al., 2020; Xiong et al., 2020; Qu et al., 2021).

In the first category, Lee et al. (2019) and Chang et al. (2020) propose different pre-training task and demonstrate the effectiveness of pre-training in dense retrievers. Recently, DPR-PAQ (Oğuz et al., 2021) proposes domain matched pre-training, while Condenser (Gao and Callan, 2021a,b) enforces the model to produce an information-rich CLS representation with continual pre-training.

As for the second class, recent work (Karpukhin et al., 2020; Xiong et al., 2020; Qu et al., 2021; Zhan et al., 2021) shows the key of fine-tuning an effective dense retriever revolves around hard negatives. DPR (Karpukhin et al., 2020) adopts in-batch negatives and BM25 hard negatives. ANCE (Xiong et al., 2020) proposes to construct hard negatives dynamically during training. RocketQA (Qu et al., 2021; Ren et al., 2021b) shows the cross-encoder can filter and mine higher-quality hard negatives. Li et al. (2021) and Ren et al. (2021a) demonstrate that passage-centric and query-centric negatives can make the training more robust. It is worth mentioning that distilling the knowledge from cross-encoder-based re-ranker into bi-encoder-based retriever (Sachan et al., 2021; Izacard and Grave, 2021; Ren et al., 2021a,b; Zhang et al., 2021) can improve the bi-encoder's performance. Most of these works are built upon bi-encoder and naturally inherit its limit of a single vector representation, while our work modified the bi-encoder to produce multi-view embeddings, and is also orthogonal to these strategies.

3 Methodology

3.1 Preliminary

We start with a bi-encoder using BERT as its backbone neural network, as shown in Figure 2(b). A typical Bi-encoder adopts dual encoder architecture which maps the query and document to single dimensional real-valued vectors separately.

Given a query q and a document collection $D = \{d_1, \ldots, d_j, \ldots, d_n\}$, dense retrievers leverage the same BERT encoder to get the representations of queries and documents. Then the similarity score $f(q, d)$ of query q and document d can be calculated with their dense representations:

$$f(q, d) = sim(E_Q(q), E_D(d)) \tag{1}$$

Where $sim(\cdot)$ is the similarity function to estimate the relevance between two embeddings, e.g., cosine distance, euclidean distance, etc. And the inner-product on the *[CLS]* representations is a widely adopted setting (Karpukhin et al., 2020; Xiong et al., 2020).

A conventional contrastive-learning loss is widely applied for training query and passage encoders supervised by the target task's training set. For a given query q, it computed negative log likelihood of a positive document d^+ against a set of negatives $\{d_1^-, d_2^-, ..d_l^-\}$.

$$\mathcal{L} = -\log \frac{e^{f(q,d^+)/\tau}}{e^{f(q,d^+)/\tau} + \sum\limits_{l} e^{f(q,d_l^-)/\tau}} \tag{2}$$

Where τ is hyper-parameter of temperature-scaled factor, and an appropriate temperature can help in better optimization (Sachan et al., 2021; Li et al., 2021).

3.2 Multi-Viewer Based Architecture

Limited to single vector representation, the typical bi-encoder faces a challenge that a document contains multiple semantics and can be asked by different potential queries from multi-view. Though some previous studies incorporate dense interaction to allow multiple representations and somehow improve the effectiveness, they usually lead to more additional expensive computation and complicated structure. Therefore, we propose a simple yet effective method to produce multi-view representations by multiple viewers and we will describe it in detail.

As pre-trained BERT has benefited a wide scale of the downstream tasks including sentence-level ones, some work has found *[CLS]* tend to aggregate the overall meaning of the whole sentence (Kovaleva et al., 2019; Clark et al., 2019). However, our model tends to capture more fine-grained semantic units in a document, so we introduce **multiple viewers**. Rather than use the latent representation of the *[CLS]* token, we adopt newly added multiple viewer tokens *[VIE]* to replace *[CLS]*, which are randomly initialized. For documents input, we add different $[VIE_i]$(i=1,2,..., n) at the beginning of sentence tokens. To avoid effect on the positional encoding of the original input sentences, we set all the position ids of $[VIE_i]$ to 0, and the document sentence tokens start from 1 as the original. Then We leverage the dual encoder to get the representations of queries and documents:

$$\begin{aligned} E(q) &= Enc_q([VIE] \circ q \circ [SEP]) \\ E(d) &= Enc_d([VIE_1] \cdots [VIE_n] \circ d \circ [SEP]) \end{aligned} \tag{3}$$

Where $\circ$ is the concatenation operation. *[VIE]* and *[SEP]* are special tokens in BERT. Enc_q and Enc_d mean query and document encoder. We use the last layer hidden states as the query and document embeddings.

The representations of the *[VIE]* tokens are used as representations of query q and document d, which are denoted as $E_0(q)$ and $E_i(d)(i = 0, 1, ..., k-1)$, respectively. As the query is much shorter than the document and usually represents one concrete meaning, we retain the typical setting to produce only one embedding for the query.

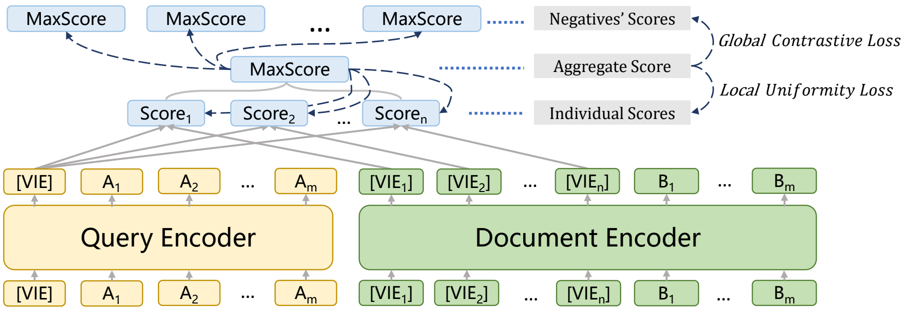


Figure 3: The general framework of multi-view representation learning with global-local loss. The gray blocks indicates the categories of scores in different layers.

Then the similarity score $f(q,d)$ of query q and document d can be calculated with their dense representations. As shown in Figure.3, we first compute the *Individual Scores* between the single query embedding and document's multi-view embeddings, in which we adopt the inner-product. The resulted score corresponding to $[VIE_i]$ is denoted as $f_i(q,d)(i=0,1,...,k-1)$. The we adopt a max-pooler to aggregate individual score to the *Aggregate Score* $f(q,d)$ as the similarity score for the given query and document pairs:

$$\begin{aligned} f(q,d) &= \underset{i}{Max}\{f_i(q,d)\} \\ &= \underset{i}{Max}\{sim(E_0(q),E_i(d))\} \end{aligned} \tag{4}$$

3.3 Global-Local Loss

In order to encourage the multiple viewers to better align to different potential queries, we introduce a *Global-Local Loss* to optimize the training of multi-view architecture. It combines the global contrastive loss and the local uniformity loss.

$$\mathcal{L} = \mathcal{L}_{global} + \lambda \mathcal{L}_{local} \tag{5}$$

The global contrastive loss is inherited from the traditional bi-encoder. Given the query and a positive document d^+ against a set of negatives $\{d_1^-, d_2^-, ..d_l^-\}$, It is computed as follows:

$$\mathcal{L}_{global} = -\log \frac{e^{f(q,d^+)/\tau}}{e^{f(q,d^+)/\tau} + \sum_l e^{f(q,d_l^-)/\tau}} \tag{6}$$

To improve the uniformity of multi-view embedding space, we propose applying *Local Uniformity Loss* among the different viewers in Eq.7. For a specific query, one of the multi-view document representations will be matched by max-score in Eq.4. The local uniformity loss enforces the selected viewer to more closely align with the query and distinguish from other viewers.

$$\mathcal{L}_{local} = -\log \frac{e^{f(q,d^+)/\tau}}{\sum_k e^{fi(q,d^+)/\tau}} \tag{7}$$

To further encourage more different viewers to be activated, we adopt an annealed temperature in Eq.8, to gradually tune the sharpness of viewers' softmax distribution. In the start stage of training with a high temperature, the softmax values tend to have a uniform distribution over the viewers, to make every viewer fair to be selected and get back gradient from train data. As the training process goes, the temperature decreases to make optimization more stable.

$$\tau = max\{0.3, exp(-\alpha t)\} \tag{8}$$

Where α is a hyper-parameter to control the annealing speed, t denotes the training epochs, and the temperature updates every epoch. To simplify the settings, we use the same annealed temperature in $\mathcal{L}_{local}$ and $\mathcal{L}_{global}$ and our experiments validate the annealed temperature works mainly in conjunction with $\mathcal{L}_{local}$ through multiple viewers.

During inference, we build the index of all the reviewer embeddings of documents, and then our model directly retrieves from the built index leveraging approximate nearest neighbor (ANN) technique. However, both Poly-Encoder (Humeau et al., 2020) and DRPQ (Tang et al., 2021) adopt attention-based aggregator containing softmax or sum operator so that the fast ANN can't be directly applied. Though DRPQ proposes to approximate softmax to max operation, it still needs to first recall a set of candidates then rerank them using the complex aggregator, leading to expensive computation and complicated procedure. In contrast, MVR

can be directly applied in first-stage retrieval without post-computing process as them. Though the size of the index will grow by viewer number k, the time complexity can be sublinear in index size (Andoni et al., 2018) due to the efficiency of ANN technique(Johnson et al., 2019).

4 Experiments

4.1 Datasets

Natural Questions (Kwiatkowski et al., 2019) is a popular open-domain retrieval dataset, in which the questions are real Google search queries and answers were manually annotated from Wikipedia. **TriviaQA** (Joshi et al., 2017) contains a set of trivia questions with answers that were originally scraped from the Web. **SQuAD Open**(Rajpurkar et al., 2016) contains the questions and answers originating from a reading comprehension dataset, and it has been used widely used for open-domain retrieval research.

We follow the same procedure in (Karpukhin et al., 2020) to preprocess and extract the passage candidate set from the English Wikipedia dump, resulting to about two million passages that are non-overlapping chunks of 100 words. Both NQ and TQA have about 60K training data after processing and SQuAd has 70k. Currently, the authors release all the datasets of NQ and TQ. For SQuAD, only the development set is available. So we conduct experiments on these three datasets, and evaluate the top5/20/100 accuracy on the SQuAD dev set and test set of NQ and TQ. We have counted how many queries correspond to one same document and the average number of queries of SQuAD, Natural Questions and Trivia QA are 2.7, 1.5 and 1.2, which indicates the multi-view problem is common in open-domain retrieval.

4.2 Implementation Details

We train MVR model following the hyper-parameter setting of DPR (Karpukhin et al., 2020). All models are trained for 40 epochs on 8 Tesla V100 32GB GPUs. We tune different viewer numbers on the SQuAD dataset and find the best is 8, then we adopt it on all the datasets. To make a fair comparison, we follow coCondenser (Gao and Callan, 2021b) to adopt mined hard negatives and warm-up pre-training strategies, which are also adopted in recent works (Oğuz et al., 2021; Gao and Callan, 2021a) and show promotion. Note that we only adopt these strategies when compared to them, while in the ablation studies our models are built only with the raw DPR model. During inference, we apply the passage encoder to encode all the passages and index them using the Faiss IndexFlatIP index (Johnson et al., 2019).

4.3 Retrieval Performance

We compare our MVR model with previous state-of-the-art methods. Among these methods, DRPQ (Tang et al., 2021) achieved the best results in multiple embeddings methods, which is the main compared baseline for our model. In addition, we also compare to the recent strong dense retriever, including ANCE (Xiong et al., 2020), RocketeQA (Qu et al., 2021), Condenser (Gao and Callan, 2021a), DPR-PAQ (Oğuz et al., 2021) and coCondenser (Gao and Callan, 2021b). For coCondenser, we reproduced its results and find it a little lower than his reported one, maybe due to its private repo and tricks. Overall, these methods mainly focus on mining hard negative samples, knowledge distillation or pre-training strategies to

Table 3: Ablation study on Global-local Loss on SQuAD dev set.

improve dense retrieval. And our MVR framework is orthogonal to them and can be combined with them for better promotion.

As shown in Table 1, we can see that our proposed MVR performs better than other models. Compared to DRPQ which performs best in the previous multi-vector models, MVR can outperform it by a large margin, further confirming the superiority of our multi-view representation. It's worth noting that our model improves more on the SQuAD dataset, maybe due to the dataset containing more documents that correspond to multiple queries as we state in Sec.4.1. It indicates that MVR can address the multi-view problem better than other models.

4.4 Ablation Study

Impact of Viewers' Number: We conduct ablation studies on the development set of SQuAD open. For fair comparison, we build all the models mentioned in the following based on DPR toolkit, including MEBERT and MVR. The results are shown in Table 2, and the first block shows the results of DPR and MEBERT which adopt the first k token embeddings. Compared to DPR and MEBERT, our model shows strong performance, which indicates the multi-view representation is effective and useful. Then, we analyze how the different numbers of viewers ($k = 4, 6, 8, 12$) affect performance in MVR. We find that the model achieves the best performance when $k = 8$. When k increase to $k = 12$ or larger, it leads little decrease in the performance, maybe due to there being not so many individual views in a document.

Method	Doc Encoding	Retrieval
DPR	2.5ms	10ms
ColBERT	2.5ms	320ms
MEBERT	2.5ms	25ms
DRPQ	5.3ms	45ms
MVR	2.5ms	25ms

Table 4: Time cost of online and offline computing in SQuAD retrieval task.

Analysis on Global-local Loss: In this part, we conduct more detailed ablation study and analysis of our proposed Global-local Loss. As shown in Table 3, we gradually reduce the strategies adopted in our model. We find not having either local uniformity loss (LC loss in table) or annealed temperature damages performance, and it decreases more without both of them. We also provide more experimental results to show the effectiveness of the annealed temperature. We first tune the fixed temperature, find it between 0.3 to 1 is beneficial. We adopt the annealed temperature annealed from 1 to 0.3 gradually as in Eq.8, finding a suitable speed($\alpha = 0.1$) can better help with optimization during training. Note that the model w/o Multiple Viewers can be seen as DPR with annealed τ, just little higher than raw DPR in Table 2, while annealed τ improves more when using multi-viewer. It indicates our annealed strategy plays a more important role in multi-view learning.

Efficiency Analysis: We test the efficiency of our model on 4 Nvidia Tesla V100 GPU for the SQuAD dev set, as shown in Table 4. We record the encoding time per document and retrieval time per query, and don't include the query encoding time for it is equal for all the models. To compare our approach with other different models, we also record the retrieval time of other related models. We can see that our model spends the same encoding time as DPR, while DRPQ needs additional time to run K-means clustering. With the support of Faiss, the retrieval time MVR cost is near to DPR and less than ColBERT (Khattab and Zaharia, 2020) and DRPQ (Tang et al., 2021) which need additional post-computing as we state in Sec.2.1.

Models	R@5	R@20	R@100
DPR	66.2	76.8	85.2

5 Further Analysis

5.1 Comparison to Sentence-level Retrieval

To analyze the difference between MVR and sentence-level retrieval which is another way to produce multiple embeddings, we design several models as shown in Table 5. Sentence-level means that we split all the passages into individual sentences with NLTK toolkit[1], resulting to an average of 5.5 sentences per passage. The new positives are the sentences containing answers in the original positives, and new negatives are all the split sentences of original negatives. K-equal-splits means the DPR's original 100-words-long passages are split into k equal long sequences and training positives and negatives as Sentence-level's methods. Compared to MVR, Sentence-level drops a lot even lower than DPR maybe for they lose contextual information in passages. It also indicates that the multi-view embeddings of MVR do not just correspond to sentence embeddings, but capture semantic meanings from different views. For even a single sentence may contain diverse information that can answer different potential queries (as in Fig.1). The k-equal-split methods perform worse much for it further lose the sentence structure and may contain more noise.

5.2 Analysis of Multi-View Embeddings

To further show the effectiveness of our proposed MVR framework, we evaluate the distribution of multi-view document representations. We conduct evaluations on the randomly sampled subset of SQuAD development set, which contains 1.5k query-doc pairs and each document has an average of 4.8 corresponding questions. We adopt two metrics *Local Variation* and *Perplexity* (Brown et al., 1992)(denoted as *LV* and *PPL*) to illustrate the effect of different methods. We first compute the normalized scores between the document's multi-view embeddings and query embedding as in Eq.4, and record the scores $f_i(q,d)$ of all the viewers. Then Local Variation of a query-doc pair can be computed as follows, and then we average it on all the pairs.

$$LV = Max(f_i(q,d)) - \frac{\sum_k f_i(q,d) - Max(f_i(q,d))}{k-1} \quad (9)$$

The Local Variation measures the distance of the max scores to the average of the others, which can curve the uniformity of different viewers. The higher it is, the more diversely the multi-view embeddings are distributed.

Then we collect the index of the viewer having the max score, and group the indexes of different queries corresponding to the same documents. Next, we can get the distributions of different indexes denoted as p_i. The Perplexity can be computed as follows:

$$PPL = exp(-\sum_m p_i \log p_i) \quad (10)$$

If different viewers are matched to totally different queries, the p_i tends to be a uniform distribution and PPL goes up. The comparison results are shown in Table 6. When evaluating MEBERT, we find its multiple embeddings collapse into the same [CLS] embeddings rather than using the different token embeddings. So its PPL is near to one and Local Variation is too high. For MVR model, we find that without local uniformity loss (LC loss in short), the Local Variation drops rapidly, indicating our proposed LC loss can improve the uniformity of different viewers. In addition, MVR w/o annealed τ will damage the PPL, which also confirms it does help activate more viewers and align them better with different queries.

5.3 Qualitative Analysis

As shown in Table 7, there are two examples retrieved by DPR and MVR for qualitative analysis. The top scoring passages retrieved by DPR can't give a clear answer for the queries, though they

Table 7: Examples of passages returned from DPR and MVR. Correct answers are written in **bold**.

seem to have a similar topic to the queries. In contrast, our MVR is able to return the correct answers when the passages contain rich information and diverse semantics. Take the second sample as an example, the passage retrieved by DPR is around *Ordovician* in the question but there are no more details answering the question. In comparison, MVR mines more fine-grained information in the passage and return the correct answer *485.4 ± 1.9 Ma* (Ma means million years ago). It indicates that DPR can only capture the rough meaning of a passage from a general view, while our MVR is able to dive into the passage and capture more fine-grained semantic information from multiple views.

6 Conclusions

In this paper, we propose a novel Multi-View Representation Learning framework. Specifically, we present a simple yet effective method to generate multi-view document representations through multiple viewers. To optimize the training of multiple viewers, we propose a global-local loss with annealed temperature to enable multiple viewers to better align with different semantic views. We conduct experiments on three open-domain retrieval datasets, and achieve state-of-the-art retrieval performance. Our further analysis proves the effectiveness of different components in our method.

A Scale Factor of Global-Local Loss

We have tuned the scale factor λ of the Global-local loss in Eq.5. The performances on SQuAD dev set are shown in Table 8. We find that a suitable scaling factor (λ=0.01) can improve more than others. Analysing other results, we infer that a large factor of local uniformity loss may lead to much impact on optimization of global loss, while a smaller one will degenerate into the form without local uniformity loss.

λ	R@5	R@20	R@100
0.5	72.4	80.4	85.9
0.05	74.7	82.5	87.3
0.01	75.5	83.2	87.9
0.001	72.9	82.2	85.7

Table 8: Performance on SQuAD dev set under different setting of scale factor.

Graph Pre-training for AMR Parsing and Generation

Abstract

Abstract meaning representation (AMR) highlights the core semantic information of text in a graph structure. Recently, pre-trained language models (PLMs) have advanced tasks of AMR parsing and AMR-to-text generation, respectively. However, PLMs are typically pre-trained on textual data, thus are sub-optimal for modeling structural knowledge. To this end, we investigate graph self-supervised training to improve the structure awareness of PLMs over AMR graphs. In particular, we introduce two graph auto-encoding strategies for graph-to-graph pre-training and four tasks to integrate text and graph information during pre-training. We further design a unified framework to bridge the gap between pre-training and fine-tuning tasks. Experiments on both AMR parsing and AMR-to-text generation show the superiority of our model. To our knowledge, we are the first to consider pre-training on semantic graphs.

1 Introduction

Abstract meaning representation (AMR; Banarescu et al. (2013)) is a semantic structure formalism. It represents the meaning of a text in a rooted directed graph, where nodes represent basic semantic units such as entities and predicates, and edges represent their semantic relations, respectively. One example is shown in Figure 1(a), with the corresponding sentence in Figure 1(b). Serving as a structural representation, AMR has been shown useful for NLP tasks such as text summarization (Liu et al., 2015; Liao et al., 2018; Chen et al., 2021), machine translation (Song et al., 2019), information extraction (Huang et al., 2016; Zhang and Ji, 2021) and dialogue systems (Bai et al., 2021).

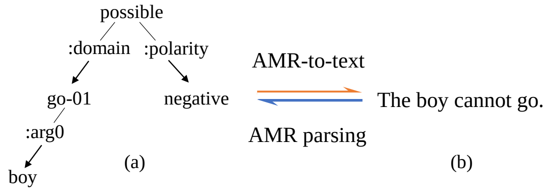

Figure 1: Illustration of AMR tasks: (a) an AMR graph; (b) a corresponding sentence.

There are two fundamental NLP tasks concerning AMR, namely AMR parsing (Flanigan et al., 2014; Konstas et al., 2017; Lyu and Titov, 2018; Guo and Lu, 2018; Zhang et al., 2019a; Cai and Lam, 2020; Bevilacqua et al., 2021) and AMR-to-text generation (Konstas et al., 2017; Song et al., 2018; Zhu et al., 2019; Zhao et al., 2020; Bai et al., 2020; Ribeiro et al., 2021a). As shown in Figure 1, the former transforms a textual input (*e.g.*, a sentence) into a corresponding AMR structure, and the latter transforms an AMR input into a fluent and grammatical sentence that conveys the same meaning. A common challenge to both tasks is that AMR exists in the form of a graph structure, which is difficult for neural models to learn with limited human-curated data.

Recently, large-scale pre-trained sequence-to-sequence (seq2seq) language models (Lewis et al., 2020; Raffel et al., 2020) have been shown useful for both tasks above. The basic idea is to linearize AMR structures into a sequence form, so that both AMR parsing and AMR-to-text generation can be solved as standard seq2seq tasks, using a pre-trained language model fine-tuned on task-specific data. In this way, semantic knowledge learned in self-supervised text-to-text (`t2t`) pre-training can benefit both text-to-graph (`t2g`) and graph-to-text (`g2t`) transformation.

Intuitively, structural knowledge from AMR can be a useful complement to semantic knowledge from text. A natural question is whether similar self-supervision strategy can be useful for AMR graphs, so that graph-to-graph (`g2g`) denoise auto-encoder training can serve as effective addition to `t2t` pre-training, before a model is fine-tuned on `t2g` and `g2t` tasks. We investigate this problem in this paper. In particular, there are three questions of interest. *First, as mentioned before, is* `g2g`

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 6001 - 6015

pre-training complementary to `t2t` *pre-training? Second, what is the most effective way to combine* `t2t` *and* `g2g` *training? Third, is silver data useful for AMR self-supervision training, and what is the most effective way of making use of such data?*

Taking BART (Lewis et al., 2020) as the seq-to-seq model, we introduce two strategies for `g2g` pre-training and propose four tasks to combine `t2t` and `g2g` training. To reduce the gap among different pre-training tasks and between pre-training and fine-tuing, we unify all pre-training tasks and fine-tuning tasks in a general framework. Experimental results on standard benchmarks show that: 1) graph pre-training achieves significant improvements over the state-of-the-art systems; 2) silver data are useful for our pre-training framework; 3) our pre-training framework is a better way than fine-tuning to make use of silver data and; 4) our model is more robust than existing systems in unseen domains. Our final models give the best reported results on both AMR parsing and AMR-to-text generation tasks, with a large margin of improvement over the previous best results. To our knowledge, we are the first to consider graph-to-graph self-supervised training on semantic graphs. We release code at `https://github.com/muyeby/AMRBART`.

2 Related Work

AMR Parsing. Early AMR parsing systems use statistical methods (Flanigan et al., 2014, 2016; Wang et al., 2015a,b). With the advance in deep learning, various neural models are developed for AMR parsing. Those models can be categorized into: 1) neural transition-based parsers (Ballesteros and Al-Onaizan, 2017; Liu et al., 2018; Fernandez Astudillo et al., 2020; Zhou et al., 2021); 2) sequence-to-graph parsers (Zhang et al., 2019a; Lyu et al., 2020; Cai and Lam, 2020) and; 3) sequence-to-sequence parsers (Konstas et al., 2017; Peng et al., 2017, 2018; Zhang et al., 2019b; Xu et al., 2020; Bevilacqua et al., 2021). Recently, pre-training techniques have significantly boosted the performance of AMR parsing. For example, Lyu and Titov (2018), Zhang et al. (2019a,b) and Cai and Lam (2020) use BERT (Devlin et al., 2019) for sentence encoding; Bevilacqua et al. (2021) fine-tune BART for sequence-to-AMR generation. Xu et al. (2020) pre-train a model on relevant seq2seq learning tasks (e.g., machine translation (Bahdanau et al., 2015), syntactic parsing (Zhu et al., 2013)) before fine-tuning on AMR parsing. Similar to those methods, we consider using pre-trained models to improve the model capacity. However, previous studies focus on fine-tuning language models trained on text data for AMR parsing task, in contract, we focus on integrating structural information into the pre-training. In addition, our method does not require information from auxiliary tasks.

AMR-to-Text Generation. On a coarse-grained level, we categorize existing AMR-to-text generation approaches into two main classes: Graph-to-sequence models that adopt a graph encoder to process an AMR graph and use a sequence decoder for generation (Beck et al., 2018; Damonte and Cohen, 2019; Zhu et al., 2019), and sequence-to-sequence models that linearize an AMR graph into a sequence and solve it as a seq2seq problem using randomly initialized (Konstas et al., 2017) or pre-trained models (Mager et al., 2020; Ribeiro et al., 2021a; Bevilacqua et al., 2021). This work follows a seq2seq manner, but we use an encoder that integrates AMR and text information. The closest to our work, Ribeiro et al. (2021b) integrate AMR structures into pre-trained T5 (Raffel et al., 2020) using adapters (Houlsby et al., 2019) for AMR-to-text generation. However, they do not pre-train on AMR graphs, and their method cannot solve both AMR parsing and AMR-to-text generation tasks as they require the full AMR structure as the input.

Graph Self-supervised Learning. Kipf and Welling (2016) introduce a variational graph auto-encoder to allow self-supervised learning on graph data. Hu et al. (2020a,b) propose local and global learning strategies to pre-train a graph neural network on large-scale protein ego-networks, academic graphs and recommendation data. Lu et al. (2021) enhance the graph learning strategies of Hu et al. (2020b) with dual adaptations. While existing work considers graph neural networks, we pre-train a seq2seq model on AMR graphs. In addition, we jointly pre-train on graphs and text for graph-text correlation modeling. In contrast, existing work pre-trains models on graphs and in isolation with text pre-training. To our knowledge, we are the first to consider AMR as a graph pre-training target.

3 Method

We take BART (Lewis et al., 2020) as the basic seq2seq model (Section 3.1), and introduce graph pre-training strategies (Section 3.2) and an unified pre-training framework (Section 3.3) for both AMR parsing and AMR-to-text generation.

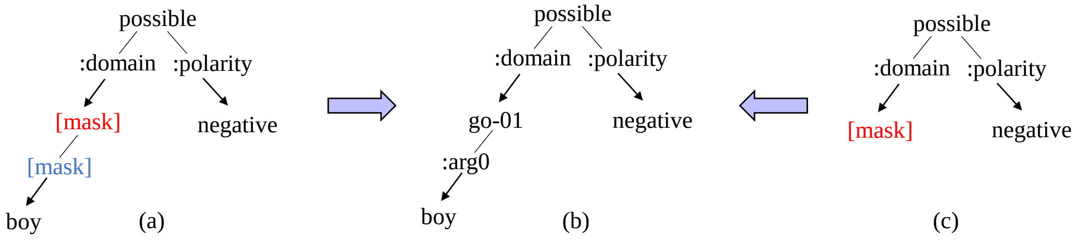

Figure 2: Illustration of two graph pre-training strategies: 1) node/edge level denoising (a→ b); 2) sub-graph level denoising (c→ b). Two transformations can be composed.

3.1 BART

BART (Lewis et al., 2020) is a pre-trained denoising auto-encoder, which is implemented as a seq2seq model based on standard Transformer (Vaswani et al., 2017) architecture. Typically, BART is trained to reconstruct original text based on a corrupted text generated by 5 noising functions: 1) Token Masking. Tokens are randomly replaced by `[mask]` elements; 2) Token Deletion. Tokens are randomly deleted from the input; 3) Text Infilling. Text spans are randomly replaced by a single `[mask]` token; 4) Sentence Permutation. Text is divided into segments and then shuffled; 5) Document Rotation. A document is rotated to start with a random token. In the fine-tuning, BART takes a complete text as input and maps it into a task-specific output sequence.

We linearize an AMR graph into a sequence, so that both AMR parsing and AMR-to-text generation can be performed using a seq2seq model. In addition, it allows pre-training on AMR structures using BART. Following Konstas et al. (2017), we adopt the depth-first search (DFS) algorithm, which is closely related to the linearized natural language syntactic trees (Bevilacqua et al., 2021). For instance, the AMR graph in Figure 1 is linearized into: `( <Z0> possible :domain ( <Z1> go :arg0 ( <Z2> boy ) ) :polarity ( <Z3> negative ) )`, where `<Z0>`, `<Z1>` and `<Z2>` are special tokens to handle co-referring nodes. To deal with such AMR symbols, we follow previous work (Bevilacqua et al., 2021) and expand the vocabulary by adding all relations and frames. In addition, to distinguish between texts and AMR graphs, we add two special tokens, `<g>` and `</g>`, to mark the beginning and end of AMR graphs, respectively.

3.2 Pre-training on AMR graphs

We introduce two self-supervised training strategies to further pre-train a BART model on AMR graphs. As shown in Figure 2(a), the node/edge level denoising strategy encourages the model to capture local knowledge about nodes and edges. The graph level denoising strategy (Figure 2(c)) enforces the model to predict a sub-graph, thus facilitating the graph-level learning.

1) Node/edge level denoising. We apply a noise function on AMR nodes/edges to construct a noisy input graph. In particular, the noise function is implemented by masking 15% nodes and 15% edges in each graph. As shown in Figure 2(a), the node `[go-01]` and edge `[:arg0]` are replaced with two `[mask]` tokens.

2) Sub-graph level denoising. This task aims to recover the complete graph when given part of the graph. We randomly remove a sub-graph[1] from the graph and replace it with a `[mask]` token (*cf.* Figure 2(c)). The masking probability is 0.35.

3.3 Unified Pre-training Framework

The above standard pre-training and fine-tuning strategies are shown in Table 1(a), by using `<s>` and `<g>` for differentiating text and graphic information, respectively. However, the model does not fully learn the interaction between textual and AMR information during pre-training. To further address this issue, we consider a unified pre-training framework, which combines text and AMR sequences as input to the denoise auto-encoder. In this way, dynamic masking can be carried out on the text, AMR or both ends, so that the model can learn to make use of one source of information for inferring the other. This can benefit both a parser and a generation model by enforcing the learning of correspondence between text and AMR structures.

In addition, as shown in Table 1, there is a gap between standard pre-training and fine-tuning for AMR from/to text transduction. Specifically, the input and output formats are same in the pre-training (*i.e.*, $\hat{\mathtt{t}}\mathtt{2t}$ and $\hat{\mathtt{g}}\mathtt{2g}$) but different in the fine-tuning

---

[1] We define a sub-graph has at least one edge and one node.

Phase		Task	Input	Output
(a)	**Std. P.T.**	$\hat{\mathtt{t}}\mathtt{2t}$	<s> $x_1, ..$[mask]$.., x_n$ </s>	<s> $x_1, x_2, ..., x_n$ </s>
		$\hat{\mathtt{g}}\mathtt{2g}$	<g> $g_1, ..$[mask]$.., g_m$ </g>	<g> $g_1, g_2, ..., g_m$ </g>
	Std. F.T.	$\mathtt{g2t}$	<g> $g_1, g_2, ..., g_m$ </g>	<s> $x_1, x_2, ..., x_n$ </s>
		$\mathtt{t2g}$	<s> $x_1, x_2, ..., x_n$ </s>	<g> $g_1, g_2, ..., g_m$ </g>
(b)	**Unified P.T.**	$\hat{\mathtt{t}}\overline{\mathtt{g}}\mathtt{2t}$	<s> $x_1, ..$[mask]$.., x_n$ </s> <g> [mask] </g>	<s> $x_1, x_2, ..., x_n$ </s>
		$\overline{\mathtt{t}}\hat{\mathtt{g}}\mathtt{2g}$	<s> [mask] </s><g> $g_1, ..$[mask]$.., g_m$ </g>	<g> $g_1, g_2, ..., g_m$ </g>
		$\hat{\mathtt{t}}\mathtt{g2t}$	<s> $x_1, ..$[mask]$.., x_n$ </s> <g> $g_1, g_2, ..., g_m$ </g>	<s> $x_1, x_2, ..., x_n$ </s>
		$\mathtt{t}\hat{\mathtt{g}}\mathtt{2g}$	<s> $x_1, x_2, ..., x_n$ </s> <g> $g_1, ..$[mask]$.., g_m$ </g>	<g> $g_1, g_2, ..., g_m$ </g>
		$\hat{\mathtt{t}}\hat{\mathtt{g}}\mathtt{2t}$	<s> $x_1, ..$[mask]$.., x_n$ </s> <g> $g_1, ..$[mask]$.., g_m$ </g>	<s> $x_1, x_2, ..., x_n$ </s>
		$\hat{\mathtt{t}}\hat{\mathtt{g}}\mathtt{2g}$	<s> $x_1, ..$[mask]$.., x_n$ </s> <g> $g_1, ..$[mask]$.., g_m$ </g>	<g> $g_1, g_2, ..., g_m$ </g>
	Unified F.T.	$\overline{\mathtt{t}}\mathtt{g2t}$	<s> [mask] </s> <g> $g_1, g_2, ..., g_m$ </g>	<s> $x_1, x_2, ..., x_n$ </s>
		$\mathtt{t}\overline{\mathtt{g}}\mathtt{2g}$	<s> $x_1, x_2, ..., x_n$ </s> <g> [mask] </g>	<g> $g_1, g_2, ..., g_m$ </g>

Table 1: Different pre-training and fine-tuning strategies. P.T. = pre-training, F.T. = fine-tuning. $\mathtt{t}/\mathtt{g}$ denotes the *original* text/graph. $\hat{\mathtt{t}}/\hat{\mathtt{g}}$ represents a *noisy* text/graph. $\overline{\mathtt{t}}/\overline{\mathtt{g}}$ means an *empty* text/graph.

(*i.e.*, $\mathtt{t2g}$ and $\mathtt{g2t}$). This gap restrains models to make the best use of *pre-trained knowledge* in the fine-tuning phase. The unified pre-training framework can also benefit task-specific fine-tuning by eliminating the difference of input and output formats between pre-training and fine-tuning.

Formally, denoting the text and linearized graph sequence as $\mathtt{t}$ and $\mathtt{g}$, where $\mathtt{t} = \{x_1, x_2, ..., x_n\}$ and $\mathtt{g} = \{g_1, g_2, ..., g_n\}$. $\hat{\mathtt{t}}$ and $\hat{\mathtt{g}}$ represent the *noisy* text and graph, respectively, and $\overline{\mathtt{t}}$ and $\overline{\mathtt{g}}$ refer to the *empty* text and graph, respectively. As shown in Table 1(b), we unify the input format for both pre-training and fine-tuning to $\mathtt{tg}$. For consistency, all input sequences start with a text sequence and end with a graph sequence.

Joint Text and Graph Pre-training. We introduce 4 auxiliary pre-training tasks to encourage information exchanging between graphs and text. As shown in Table 1(b), the auxiliary tasks are:

1) Graph augmented text denoising ($\hat{\mathtt{t}}\mathtt{g2t}$), where an AMR graph is taken as additional input to help masked text reconstruction;

2) Text augmented graph denoising ($\mathtt{t}\hat{\mathtt{g}}\mathtt{2g}$), where text helps masked graph reconstruction;

3) Noisy graph augmented text denoising ($\hat{\mathtt{t}}\hat{\mathtt{g}}\mathtt{2t}$), where the target text is generated based on a pair of masked text and masked graph;

4) Noisy text augmented graph denoising ($\hat{\mathtt{t}}\hat{\mathtt{g}}\mathtt{2g}$), where a target graph is generated based on a pair of masked text and masked graph.

Dynamic masking rate. Different from standard masking (Devlin et al., 2019) that uses a static masking rate, we adopt a dynamic masking rate p for task $\hat{\mathtt{t}}\mathtt{g2t}$ and $\mathtt{t}\hat{\mathtt{g}}\mathtt{2g}$. Formally, at step t, we calculate the masking probability p as:

$$p = 0.1 + 0.75 * t/T, \tag{1}$$

where 0.1 is the initial masking rate, T denotes the total training step. p increases as t grows, as t approaches to T, the pre-training tasks $\hat{\mathtt{t}}\mathtt{g2t}$ and $\mathtt{t}\hat{\mathtt{g}}\mathtt{2g}$ are closer to fine-tuning tasks.

Unified Pre-training and Fine-tuning. In our unified framework, fine-tuning tasks can be viewed as having an *empty* text/graph in the original input, resulting in an input format of $\overline{\mathtt{t}}\mathtt{g2t}$ for AMR-to-text generation and $\mathtt{t}\overline{\mathtt{g}}\mathtt{2g}$ for AMR parsing. In this way, pre-training and fine-tuning tasks share the same input format, thus facilitating knowledge transfer from pre-training to fine-tuning.

3.4 Training

To pre-train our model, we optimize the total loss ($\mathcal{L}_{total}$) which is calculated as:

$$\begin{aligned}
\mathcal{L}_{\hat{\mathtt{t}}\mathtt{2t}} &= -\log P(\mathtt{t}|\hat{\mathtt{t}}, \overline{\mathtt{g}}), \\
\mathcal{L}_{\hat{\mathtt{g}}\mathtt{2g}} &= -\log P(\mathtt{g}|\overline{\mathtt{t}}, \hat{\mathtt{g}}), \\
\mathcal{L}_{\hat{\mathtt{t}}\mathtt{g2t}} &= -\log P(\mathtt{t}|\hat{\mathtt{t}}, \mathtt{g}), \\
\mathcal{L}_{\mathtt{t}\hat{\mathtt{g}}\mathtt{2g}} &= -\log P(\mathtt{g}|\mathtt{t}, \hat{\mathtt{g}}), \\
\mathcal{L}_{\hat{\mathtt{t}}\hat{\mathtt{g}}\mathtt{2t}} &= -\log P(\mathtt{t}|\hat{\mathtt{t}}, \hat{\mathtt{g}}), \\
\mathcal{L}_{\hat{\mathtt{t}}\hat{\mathtt{g}}\mathtt{2g}} &= -\log P(\mathtt{g}|\hat{\mathtt{t}}, \hat{\mathtt{g}}), \\
\mathcal{L}_{total} &= \mathcal{L}_{\hat{\mathtt{t}}\mathtt{2t}} + \mathcal{L}_{\hat{\mathtt{g}}\mathtt{2g}} + \mathcal{L}_{\hat{\mathtt{t}}\mathtt{g2t}} \\
&\quad + \mathcal{L}_{\mathtt{t}\hat{\mathtt{g}}\mathtt{2g}} + \mathcal{L}_{\hat{\mathtt{t}}\hat{\mathtt{g}}\mathtt{2t}} + \mathcal{L}_{\hat{\mathtt{t}}\hat{\mathtt{g}}\mathtt{2g}},
\end{aligned} \tag{2}$$

where $\mathcal{L}_{\hat{\mathtt{t}}\mathtt{2t}}$ and $\mathcal{L}_{\hat{\mathtt{g}}\mathtt{2g}}$ are standard pre-training loss on text (Section 3.1) and graph (Section 3.2), respectively. $\mathcal{L}_{\hat{\mathtt{t}}\mathtt{g2t}}, \mathcal{L}_{\mathtt{t}\hat{\mathtt{g}}\mathtt{2g}}, \mathcal{L}_{\hat{\mathtt{t}}\hat{\mathtt{g}}\mathtt{2t}}$ and $\mathcal{L}_{\hat{\mathtt{t}}\hat{\mathtt{g}}\mathtt{2g}}$ denote joint pre-training losses (Section 3.3), respectively.

For fine-tuning, the training objectives are:

$$\begin{aligned}
\mathcal{L}_{\mathtt{amr2text}} &= -\log P(\mathtt{t}|\overline{\mathtt{t}}, \mathtt{g}), \\
\mathcal{L}_{\mathtt{text2amr}} &= -\log P(\mathtt{g}|\mathtt{t}, \overline{\mathtt{g}}),
\end{aligned} \tag{3}$$

where $\mathcal{L}_{\mathtt{amr2text}}$ and $\mathcal{L}_{\mathtt{text2amr}}$ are training loss of AMR-to-text generation and AMR parsing, respectively.

Table 2: Benchmark AMR datasets.

4 Experiments

We evaluate the effectiveness of our model on five benchmarks and compare the results with state-of-the-art models on AMR parsing and AMR-to-text generation, respectively. In addition to standard supervised training settings, we evaluate the robustness of our model in a zero-shot domain adaptation setting.

4.1 Datasets

Table 2 shows the statistics of datasets. Following Bevilacqua et al. (2021), we use the **AMR2.0** (LDC2017T10) and **AMR3.0** (LDC2020T02). We also evaluate the model performance on **New3**, *The Little Prince* (**TLP**) and *Bio AMR* (**Bio**) corpora. For pre-training, we additionally use 200k silver data parsed by SPRING (Bevilacqua et al., 2021). These data are randomly selected from Gigaword (LDC2011T07) corpus, which shares the same textual source with AMR data.[2]

4.2 Settings

We follow Bevilacqua et al. (2021) in pre-processing and post-processing AMR graphs, except for omitting the recategorization step which does not consistently improve model performance in our preliminary experiments. Our model is built based on a vanilla BART[3]. The best model and hyper-parameters are selected by performance on the validation set. The detailed hyper-parameters are given in Appendix A.

Metrics. Following Bevilacqua et al. (2021), we evaluate on the AMR parsing benchmarks by using Smatch (Cai and Knight, 2013) and other fine-grained metrics.[4] Regarding AMR-to-text, we use three common Natural Language Generation measures, including BLEU (Papineni et al., 2002), CHRF++ (Popović, 2017) and METEOR (Banerjee and Lavie, 2005), tokenizing with the script provided with JAMR (Flanigan et al., 2014).

Setting	Smatch	BLEU	Avg
BART-base	82.7	42.5	62.6
+ $\hat{\texttt{t}}\overline{\texttt{g}}\texttt{2t}$	82.9	42.9	62.9
+ $\overline{\texttt{t}}\hat{\texttt{g}}\texttt{2g}$	83.1	42.6	62.9
+ $\hat{\texttt{t}}\overline{\texttt{g}}\texttt{2t}, \overline{\texttt{t}}\hat{\texttt{g}}\texttt{2g}$	83.1	42.8	63.0
+ $\hat{\texttt{t}}\overline{\texttt{g}}\texttt{2t}, \overline{\texttt{t}}\hat{\texttt{g}}\texttt{2g}, \texttt{t}\hat{\texttt{g}}\texttt{2g}$	83.4	42.8	63.1
+ $\hat{\texttt{t}}\overline{\texttt{g}}\texttt{2t}, \overline{\texttt{t}}\hat{\texttt{g}}\texttt{2g}, \hat{\texttt{t}}\texttt{g2t}$	83.1	45.3	63.2
+ $\hat{\texttt{t}}\overline{\texttt{g}}\texttt{2t}, \overline{\texttt{t}}\hat{\texttt{g}}\texttt{2g}, \texttt{t}\hat{\texttt{g}}\texttt{2g}, \hat{\texttt{t}}\texttt{g2t}$	83.3	45.0	63.2
+ $\hat{\texttt{t}}\overline{\texttt{g}}\texttt{2t}, \overline{\texttt{t}}\hat{\texttt{g}}\texttt{2g}, \hat{\texttt{t}}\hat{\texttt{g}}\texttt{2g}$	83.2	43.0	63.1
+ $\hat{\texttt{t}}\overline{\texttt{g}}\texttt{2t}, \overline{\texttt{t}}\hat{\texttt{g}}\texttt{2g}, \hat{\texttt{t}}\hat{\texttt{g}}\texttt{2t}$	83.1	44.2	63.7
+ $\hat{\texttt{t}}\overline{\texttt{g}}\texttt{2t}, \overline{\texttt{t}}\hat{\texttt{g}}\texttt{2g}, \hat{\texttt{t}}\hat{\texttt{g}}\texttt{2g}, \hat{\texttt{t}}\hat{\texttt{g}}\texttt{2t}$	83.2	44.0	63.6
+ `ALL`	83.6	45.6	64.1

Table 3: AMP parsing (Smatch) and AMR-to-text generation (BLEU) performance on valid set of AMR2.0.

4.3 Compared Models

For **AMR parsing**, we consider following systems for comparison: 1) Lyu and Titov (2018; LyuT), a neural parser trained by jointly modeling alignments, concepts and relations; 2) Zhang et al. (2019b; Zhang+), a seq2seq approach that incrementally builds up an AMR via predicting semantic relations; 3) Zhou et al. (2020; Zhou+), an aligner-free parser enhanced by explicit dependency and latent structures; 4) Cai and Lam (2020a; CaiL), a graph-based parser that enhances incremental sequence-to-graph model with a graph-sequence iterative inference mechanism; 5) Bevilacqua et al. (2021; Bevilacqua+), a fine-tuned BART model that predicts a linearized AMR graph.

For **AMR-to-text generation**, the compared models are: 1) Zhu et al. (2019; Zhu+), a Transformer-based model that enhances self-attention with graph relations; 2) Zhang et al. (2020; Zhang+), a graph-to-sequence model which uses a dynamic graph convolutional networks for better graph modeling. 3) Bai et al. (2020; Bai+), a graph encoder (Zhu et al., 2019) with a structural decoder that jointly predicts the target text and the input structure; 4) Mager et al. (2020; Mager+), a fine-tuned GPT that predicts text based on a PENMAN linearized AMR graph; 5) Bevilacqua et al. (2021; Bevilacqua+), a fine-tuned BART that predicts text based on a DFS linearized AMR graph; 6) Ribeiro et al. (2021; Ribeiro+), a fine-tuned BART based on a PENMAN linearized AMR graph. For a fair comparison, we leave out models based on T5 (Ribeiro et al., 2021a,b), which has about two times more parameters than BART.

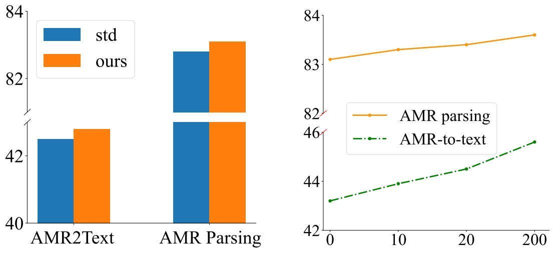
4.4 Development Experiments

Table 3 shows results on the validation set of AMR2.0 under different model settings, where we take a fine-tuned BART-based model (Bevilacqua et al., 2021) as our baseline.

We first study the effectiveness of pre-training only on text and graphs. As shown in Table 3, both pre-training on the text ($\hat{\mathtt{t}}\bar{\mathtt{g}}\mathtt{2t}$) and graph ($\bar{\mathtt{t}}\hat{\mathtt{g}}\mathtt{2g}$) leads to better results, and combining them can give better results on both tasks. Also, adding joint pre-training tasks improves the performance. In particular, $\mathtt{t}\hat{\mathtt{g}}\mathtt{2g}$ gives a Smatch improvement of 0.7 for AMR paring, and $\hat{\mathtt{t}}\mathtt{g2t}$ reaches a BLEU of 45.3 for AMR-to-text generation, which is 2.8 points higher than baseline. Adding $\hat{\mathtt{t}}\hat{\mathtt{g}}\mathtt{2g}$ gives a Smatch of 83.2 for AMR parsing, and $\hat{\mathtt{t}}\hat{\mathtt{g}}\mathtt{2t}$ improves the baseline by 1.7 BLEU points for generation. By combining $\mathtt{t}\hat{\mathtt{g}}\mathtt{2g}$ and $\hat{\mathtt{t}}\mathtt{g2t}$, the performance increase by 0.6 and 2.5 points on AMR parsing and AMR-to-text generation, respectively. Similar trend can be observed by combining $\hat{\mathtt{t}}\hat{\mathtt{g}}\mathtt{2g}$ and $\hat{\mathtt{t}}\hat{\mathtt{g}}\mathtt{2t}$. Finally, using all 6 pre-training tasks, our model reach a result of 83.6 Smatch and 45.6 BLEU, respectively.

We also study the impact of two graph self-supervised training strategies. In particular, we evaluate the performance after removing the node/edge or the sub-graph masking task independently. As shown in Table 4, the performance decreases on both AMR parsing and AMR-to-text generation tasks without the node/edge level masking strategy. The performance drop is larger when removing the sub-graph masking task, with a margin of 0.5 Smatch and 0.9 BLEU, respectively.

Figure 3(a) compares the performance of standard pre-training ($\hat{\mathtt{t}}\mathtt{2t}$, $\hat{\mathtt{g}}\mathtt{2g}$) and fine-tuning ($\mathtt{t2g}$, $\mathtt{g2t}$) with our unified framework. The unified framework gives better results than standard versions on both tasks. This confirms our assumption that our unified framework is helpful for reducing the gap between pre-training and fine-tuning. Besides, we find that by unifying pre-training and fine-tuning formats, our model converges faster than the baseline during fine-tuning (*cf.* Appendix C.1).



(a) (b)

Figure 3: Development results: (a) comparison of standard pre-training and fine-tuning phase (std) and our unified frameworks; (b) impact of silver data.

Figure 3(b) shows the model performance regarding different scales of silver data. Even without silver data, the performance of our model is better than the baseline, indicating that graph pre-training is beneficial for downstream tasks when using various auxiliary tasks. When silver data are available, the performance of both AMR parsing and AMR-to-text generation tasks increases as the scale of silver data increases, with a margin of 2 BLEU score. We also *fine-tune* a BART model on silver data under our unified framework (i.e., $\bar{\mathtt{t}}\mathtt{g2t}$ and $\mathtt{t}\bar{\mathtt{g}}\mathtt{2g}$), and find that our dual graph and text denoising tasks are more useful (*cf.* Appendix C.2 for more analysis and discussion).

4.5 Main Results

AMR parsing. Table 5 lists the result of different models on AMR2.0 and AMR3.0. Among previous works, Bevilacqua+ (2021, large) achieves the best results, consistently outperforming other systems. Compared with the system of Bevilacqua et al. (2021), our model obtains significantly (p<0.01) better Smatch scores in both *base* and *large* settings on both datasets. In particular, our *base* model outperforms the Bevilacqua+ (2021, base) by 0.9 Smatch point on AMR2.0, and our *large* model obtains a Smatch of 85.4 and 84.2 on AMR2.0 and AMR3.0, respectively. To our knowledge, these are the best-reported results, showing the effectiveness of our method.

Besides, Bevilacqua+ (2021, large)^s uses silver data for fine-tuning, yet does not lead to consistent improvement over Bevilacqua+ (2021, large). In contrast, our large model gives 1.1 and 1.2 higher Smatch than Bevilacqua+ (2021, large)^s on AMR2.0 and AMR3.0, respectively. This indicates that our pre-training framework is a better way than fine-tuning to make use of silver data. The main

Table 5: AMR parsing results on AMR2.0 and AMR3.0. * means the model uses 200k silver data for fine-tuning. † means the model is based on pre-trained models. The best result within each row block is shown in bold.

reason is that our models are pre-trained using a denoising auto-encoding manner, which is less sensitive to silver (or noisy) data than fine-tuning. We also find that further fine-tuning our models on silver data (same with pre-training) cannot bring improvement (*cf.* Appendix C.3).

AMR-to-text generation. We report the results of different systems on AMR2.0 and AMR3.0 in Table 6, respectively. With the help of BART, Ribeiro+ (2021) and Bevilacqua+ (2021, large) obtain significantly better results than previous graph-to-sequence and GPT-based models. Compared with Bevilacqua+ (2021), our models (*base* and *large*) give significantly (p<0.001) better results in terms of all evaluation metrics. In particular, our *base* model achieves comparable or better performance than Bevilacqua+ (2021, large). Compared with Bevilacqua+ (2021, large)^s, our large model improves the performance by 3.9 and 2.7 points on AMR2.0 and AMR3.0, respectively. Similar with AMR parsing, we observe that when fine-tuning our models on silver data cannot bring improvement for AMR-to-text generation task (Table 6 and Appendix C.3).

Zero-shot Domain Adaption. We use the model trained on AMR2.0 to get predictions on out-of-domain test sets. Table 7 shows the results on AMR parsing and AMR-to-text generation tasks. Similar to in-domain experiments, our models achieve better results than existing methods. In particular, our *base* model can give comparable performance than Bevilacqua+ (2021, large), and our *large* model obtains the best-reported results. This indicates that our model is more robust to new domains, thanks to joint graph and text pre-training. Regarding different domains, our method achieves bigger improvements on New3 than the other two domains. This is intuitive, as pre-training strengthens the model representation power on the domain of graph pre-training data, and New3 is closer to it than other two datasets.

In addition, Bevilacqua+ (2021, large)^s gives lower results than Bevilacqua+ (2021, large) in

Model	New3	TLP	Bio
AMR Parsing			
Bevilacqua+ (2021, large)	73.7	77.3	59.7

Ours (base)	74.4	77.8	58.8
Ours (large)	**76.9**	**79.8**	**63.2**
AMR-to-Text			
Bevilacqua+ (2021, large)	38.8	25.4	18.7
Bevilacqua+ (2021, large)^s	38.2	25.1	19.4
Ours (base)	41.0	26.4	16.9
Ours (large)	**44.8**	**29.1**	**20.7**

Table 7: Out of distribution performance on AMR parsing (Smatch) and AMR-to-text (BLEU).

New3 (both tasks) and TLP (only AMR-to-text generation). In contrast, our model gives consistent improvements on all 3 domains. This can be because fine-tuning leads to catastrophic forgetting of distributional knowledge (Kirkpatrick et al., 2017).

4.6 Impact of Graph

Table 8 shows the effects of the graph size, graph diameter and reentrancies on the performance. We split the test set of AMR2.0 into different groups and report the performance improvement over the baseline model (Bevilacqua et al., 2021). All models are trained on AMR2.0. We first consider graph size, which records the number of nodes in an AMR graph. Our model consistently outperforms the baseline model on both tasks, with the performance gap growing on larger graphs. This indicates that our system is more powerful in dealing with larger graphs. The main reason is that our joint text and graph pre-training mechanism enhances the model with the ability to capture word or span level correlation between text and graph, which is helpful for dealing with long sequence and large graphs.

The graph depth is defined as the longest distance between the AMR node and root node. A graph with deeper depth has more long-range dependencies. For AMR parsing, our model gives a better Smatch than the baseline model on the first two groups of graphs, and a comparable score on graphs with a depth bigger than 6. For AMR-to-text generation, our model consistently improves over the baseline model on all graphs, and the improvements are bigger on deeper graphs. This shows that our model is better for learning more complex graphs. It can be that our graph masking strategies train the model to learn the relationships between a sub-graph and the remaining graph context, making it easier to understand deep graphs.

Graph Size	1-10 (522)	11-20 (556)	>20 (293)
AMR parsing	+0.3	+1.0	+0.8
AMR-to-text	+0.9	+3.2	+2.1
Graph Depth	1-3 (422)	4-6 (667)	>6 (282)
AMR parsing	+0.8	+0.9	0.0
AMR-to-text	+1.2	+2.3	+2.8
Reentrancies	0 (622)	1-3 (712)	>4 (37)
AMR parsing	+1.1	+0.6	0.0
AMR-to-text	+2.0	+2.7	+0.4

Table 8: Performance improvements on AMR parsing (Smatch) and AMR-to-text (BLEU).

Reentrancy is the number of nodes that has multiple parents. Reentrancies pose difficulties to both AMR parsing and AMR-to-text tasks (Damonte and Cohen, 2019; Szubert et al., 2020). The more reentrancies, the harder the graph is to be understood. Our method gives significantly (p<0.01) better results on both tasks when the input graphs have less than 4 reentrancies. For graphs with more than 4 reentrancies, the proposed model is 0.4 better on AMR-to-text generation task and comparable than the baseline model on AMR parsing task. This means that our system has an overall better ability on learning reentrancies.

4.7 Case study

Table 9 presents two cases of AMR parsing, with the model outputs generated by our model and the baseline model, and the gold output given the same input sentence. As shown in the first case, the baseline model omits the semantic unit "*hard*", thus generates an incomplete AMR graph of a different meaning compared with the input sentence. In contrast, our system preserves the concept "*hard*" and transfers the semantic relations correctly, thanks to the modeling of correspondence between text and graph during pre-training. In the second case, the baseline output includes a **cyclic** sub-graph (*i.e.*, `( z1 harm-01 :ARG1 z1 )`), which is contrary to the grammar that *AMRs should be acyclic*. Our system gives a valid AMR graph which is semantically similar with gold graph.

Table 10 lists two AMR graphs and model outputs of our AMR-to-text model and the baseline model. In the first case, although the baseline generates a fluent sentence, it ignores the concept "*have-purpose-91*", resulting in that the generated sentence is of a different meaning compared with the input graph. In the second AMR graph, "*before*" modifies the phrase "*won many championships*". However, in the baseline output, "*before*" is used to

   :ARG1 (c / championship-02
      :ARG0 p2
      :quant (m / many))
   :time (b / before)
   :part-of (c2 / compete-01
      :mod (i / international)))
```

Gold: Fengzhu Xu has won many championships in international competitions before.

Baseline: Fengzhu Xu won many championships before participating in international competitions.

Ours: Fengzhu Xu has won many championships in international competitions before.

Table 10: Two AMR-to-text generation cases. Given an AMR graph, we present the gold text and two generated outputs, given by baseline and our model, respectively.

modify the phrase "*participating in international competitions*". Compared with the baseline, our system recovers all concepts and maps the modification relationship from the AMR graph to text correctly. This indicates that our model generates more faithful sentences than the baseline.

5 Conclusion

We investigated graph pre-training as a complement to text pre-training for AMR parsing and AMR-to-text generation tasks, using a novel unified framework with dual graph and text denoising. We find that graph pre-training is highly effective for both AMR parsing and AMR -to-text generation, and is a more effective way of making use of silver data compared with fine-tuning. Our methods give the best results on multiple benchmarks for both tasks.

A Model Hyper-Parameters

Table 11 lists all model hyper-parameters used for our experiments. We implement our model based on *Pytorch* and *Huggingface Transformers*. The pre-processed data, source code and pre-trained models are released at `https://github.com/muyeby/AMRBART`.

B Fine-grained Evaluation Metric for AMR Parsing

The Smatch score (Cai and Knight, 2013) measures the degree of overlap between the gold and the prediction AMR graphs. It can be further broken into different sub-metrics, including:

- Unlabeled (Unlab.): Smatch score after removing edge-labels
- NoWSD: Smatch score after ignoring Propbank senses (*e.g.*, go-01 vs go-02)
- Concepts (Con.): F-score on the concept identification task
- Wikification (Wiki.): F-score on the wikification (`:wiki` roles)
- Named Entity Recognition (NER): F-score on the named entities (`:name` roles).
- Reentrancy (Reen.): Smatch score on reentrant edges.
- Negation (Neg.): F-score on the negation detection (`:polarity` roles).
- Semantic Role Labeling (SRL): Smatch score computed on `:ARG-i` roles.

C More Experimental Results

C.1 Effect of Unified Framework

Figure 4 compares the learning curve between our system (fine-tuning from our pre-trained model) and baseline (fine-tuning from vanilla BART, i.e., Bevilacqua+) on AMR2.0 validation set[5]. It can be observed that our system has a initial BLEU score of 26.0, which is significantly (p< 0.001) better than the baseline. This confirm that our unified

---

[5] We use the same learning rate and optimizer.

Setting	AMR parsing	AMR-to-text
AMR2.0		
Ours (large)	85.4	49.8
+ silver	85.1	49.6
AMR3.0		
Ours (large)	84.2	49.2
+ silver	83.8	48.9

Table 13: Model performance on AMR2.0 and 3.0 datasets for AMR parsing and AMR-to-text. For AMR parsing, we report Smatch score here, and for AMR-to-text, we report BLEU-4 score here. +silver denotes to that further fine-tuning the model on silver data.

framework can reduce the gap between pre-training and fine-tuning. In addition, the training curve of the proposed model converges faster while the BLEU score is better than the baseline. This indicates that our model has a larger capacity than baseline.

C.2 Impact of denoising Tasks

To distinguish the contribution of de-nosing tasks and silver data, an ablation study is present where we 1) "fine-tune" a vanilla BART on silver data following our unified framework (i.e., $\overline{\texttt{t}}\texttt{g2t}$ and $\texttt{t}\overline{\texttt{g}}\texttt{2g}$); 2) continue pre-train a BART on silver data according to proposed de-nosing tasks (in Table 1). As shown in Table 12, we observe that using sliver data for fine-tuning leads to a 0.1 Smatch decrease in AMR parsing and 2.4 BLEU increase in AMR-to-text. This observation is consistent with previous works (Konstas et al., 2017; Song et al., 2018; Bevilacqua et al., 2021). In addition, using silver data for pre-training gives further improvements on both tasks, with 1.0 Smatch for AMR pasring and 0.7 BLEU for AMR-to-text generation. This indicates that our de-nosing tasks can help model to better understand silver data.

C.3 Are Silver Data Still Helpful for Fine-tuning after Being Used for Pre-training?

As discussed in Section 4.5, we find that graph pre-training is a better way to make use of silver data compared with fine-tuning. We further investigate whether fine-tuning our model on silver data can still bring improvement. As shown in Table 13, our models achieve the best performance on all tasks and datasets, indicating that further fine-tuning our models on silver data decreases the performance. This can be that silver data are already presented in the pre-training phase and thus further fine-tuning can bring no improvement. In addition, fine-tuning can be more sensitive to data quality than pre-training. When training data contain noise (silver data), fine-tuning on such data can in turn damage the model performance.

Turning Tables: Generating Examples from Semi-structured Tables for Endowing Language Models with Reasoning Skills

Ori Yoran[†] **Alon Talmor** **Jonathan Berant**
Tel-Aviv University
{ori.yoran, alon.talmor, joberant}@cs.tau.ac.il

Abstract

Models pre-trained with a language modeling objective possess ample world knowledge and language skills, but are known to struggle in tasks that require reasoning. In this work, we propose to leverage semi-structured tables, and automatically generate at scale question-paragraph pairs, where answering the question requires reasoning over multiple facts in the paragraph. We add a pre-training step over this synthetic data, which includes examples that require 16 different reasoning skills such as number comparison, conjunction, and fact composition. To improve data efficiency, we sample examples from reasoning skills where the model currently errs. We evaluate our approach on three reasoning-focused reading comprehension datasets, and show that our model, PReasM, substantially outperforms T5, a popular pre-trained encoder-decoder model. Moreover, sampling examples based on model errors leads to faster training and higher performance.

Figure 1: An example table and question-context-answer triplets generated from the table as synthetic data. Each color corresponds to a different reasoning skill and colored cells are necessary to answer the question. The contexts shown are partial, such that the actual context contains the necessary information to answer the question and additional distractors. Answers are not necessarily extractive (e.g., date difference).

1 Introduction

Large pre-trained language models (LMs) (Devlin et al., 2019; Liu et al., 2019; Brown et al., 2020) have become the backbone of natural language processing in recent years. However, recent work has shown that they struggle in performing symbolic reasoning operations, such as composition or conjunction of facts (Talmor et al., 2019, 2020), numerical operations (Wallace et al., 2019; Hidey et al., 2020), and quantification (Warstadt et al., 2019), without substantial amounts of additional data.

Past work on improving reasoning in pre-trained models has taken two flavors: (a) adding specialized components for specific skills, like numerical and temporal reasoning (Ran et al., 2019; Gupta et al., 2020a; Khot et al., 2021; Chen et al., 2020a), or (b) generating synthetic examples at scale, for example, by using grammars or templates (Rozen et al., 2019; Zhao et al., 2019; Andreas, 2020; Asai and Hajishirzi, 2020; Campagna et al., 2020), and question generation models (Alberti et al., 2019; Puri et al., 2020; Bartolo et al., 2021).

In this work, we take the latter approach and argue that semi-structured tables are a valuable resource for automatic generation of training data that can endow LMs with reasoning skills. Tables can be crawled from the web at scale, and cover a wide range of domains and topics. Moreover, their structured nature makes them amenable to automatic processes of data generation. Specifically, given a table, we use templates to generate reading comprehension (RC) examples, that is, question-context-answer triplets, where answering the question requires diverse types of reasoning over facts mentioned in the context. Fig. 1 shows an example table, and three generated question-context-answer examples, which require fact composition, number comparison, and computing a date difference.

q: How old was the Russian battleship Tsesarevich when Aksel Berg served on it?

c: The ship was laid down on 8 July 1899 and launched on 23 February 1901. Berg joined the Imperial Russian Navy in 1914 and served as junior navigating officer...

Figure 2: Approach overview. First, we use tables to generate large amounts of data from 16 different example generators (EGs), each corresponding to a different reasoning skill. Then, a pre-trained LM is trained over this data to obtain our model, PReasM, where we sample examples based on current model errors (arrow width corresponds to number of examples). Last, our model is fine-tuned and evaluated on target tasks that require reasoning.

Unlike prior work where semi-structured data was used for reasoning over tables or knowledge-bases (Eisenschlos et al., 2020; Yin et al., 2020; Herzig et al., 2020; Yu et al., 2021), here we harness tables to allow LMs to reason over *text* directly.

Fig. 2 provides an overview of our approach. We generate data by crawling tables from Wikipedia, and applying 16 different example generators (EGs) on each table. Each EG corresponds to a particular reasoning skill (composition, numerical comparison, see Table 1 for full list), and comprises a small set of question templates. Variables in the templates are filled with content from the table, and the structure of the table allows to compute the answer automatically. The context is a list of facts generated from the table that contain facts required for answering the question as well as distractor facts.

We add a pre-training step over this generated data, where we perform multi-task training over the 16 task corresponding to the EGs. Since each EG can generate vast numbers of examples, it is important to focus training on reasoning skills that the model lacks. Thus, we use *error-driven sampling* (Gottumukkala et al., 2020) to construct training batches, where most examples are sampled from EGs that the model currently struggles with.

We fine tune our **P**re-traind for **Reas**oning **M**odel, PReasM, on three RC datasets that require reasoning: DROP (Dua et al., 2019), IIRC (Ferguson et al., 2020), and MMQA (Talmor et al., 2021). PReasM outperforms the original pre-trained T5 (Raffel et al., 2020) model by significant margins: 7.6, 4.1, and 1.2 F_1 points, respectively. Our results set a new state-of-the-art on MMQA and are the best results on IIRC for models where the retriever and reader are trained separately. Our analysis shows that PReasM leads to improvements of up to 40 F_1 points on specific question types, such as computing the difference between two dates, without causing a drop in other question types.

In conclusion, our results suggest that tables are a viable and untapped source of information for automatically generating large amounts of data that can be used to endow LMs with skills that are not captured using current pre-training approaches. Our code, data, and models are publicly available and can be downloaded from `https://github.com/oriyor/turning_tables`.

2 Data Generation

Our goal is to train a RC model that given a question q and textual context c returns an answer a, given a training set $D = \{(q_i, c_i, a_i)\}_{i=1}^{N}$. We focus on questions that require reasoning over the context, e.g., composing two facts. To endow LMs with reasoning skills, we want to generate a large synthetic training set $D_{syn} = \{(q_j, c_j, a_j)\}_{j=1}^{M}$ ($M \gg N$) from semi-structured tables, before fine-tuning on a target dataset.

2.1 Generating Examples from Tables

We use tables from English Wikipedia[1] to generate D_{syn}. English Wikipedia includes millions of tables with high lexical and domain diversity (Fetahu et al., 2019; Chen et al., 2020b; Gupta et al., 2020b; Talmor et al., 2021; Nan et al., 2021; Neeraja et al., 2021a). We extract from Wikipedia all tables $\mathcal{T}$ that have at least two columns and 10-25 rows, resulting in more than 700K tables. Then, we annotate all table columns with their semantic type (`STRING`, `NUMBER`, or `DATE`), which allows us to generate questions that involve manipulating numbers and dates. Details on the process of column annotation are in §A.1.

---

[1] We use the 01-01-2020 Wikipedia dump.

EG	*Template*	*Question*
2/3-hop Composition	What was the `col:1`(s) when the `col:2` was `val:2` in `table-title` of `page-title`?	“What was the **Play(s)** when the **Author** was **William Shakespeare** in **Notable works** of **Lidia Zamkow**?”
Conjunction	What was the `col:1` when the `col:2` was `val:2` and the `col:3` was `val:3` in `table-title` of `page-title`?	“What was the **Common name** when the **Family** was **Picidae** and the **Distribution** was **Okinawa** in **List of species** of **List of endemic birds of Japan**?”
Quantifiers Only	Is `val:1` the only `col:1` that has `col:2` `val:2` in `table-title` of `page-title`?	“Is **Jean Philippe** the only **Artist** that has **Language French** in **Results** of **Eurovision Song Contest 1959**?”
Quantifiers Every/Most	In `table-title` of `page-title`, does [OPERATOR] `col:1` have `col:2` `val:2`?	“In **Coal** of **List of Mines in South Africa**, does **every Mine** have **Owner Exxaro**?”
Num. Comparison	In `table-title` of `page-title`, which `col:1` had [OPERATOR] `col:2`: `val:1` or `val:1`?	“In **Administration** of **Mueang Nonthaburi District**, which **Name** had **a higher population**: **Suan Yai** or **Bang Khen**?”
Temp. Comparison	In `table-title` of `page-title`, what happened [OPERATOR]: the `col:1` was `val:1` or the `col:2` was `val:2`?	“In **Awards and nominations** of **Alexandre Pires**, what happened **earlier**: the **Category** was **Pop New Artist** or the **Category** was **Album of the Year**?”
Num. Yes/No Comparison	In `table-title` of `page-title` did `val:1` have [OPERATOR] `col:2` than `val:1`?	“In **Top employers** of **Chula Vista, California**, did **Walmart** have **more Employees** than **Target**?”
Temp. Yes/No Comparison	The `col:1` was `val:1` [OPERATOR] the `col:2` was `val:2` in `table-title` of `page-title`?	“The **Referee** was **Salim Oussassi more recently than when** the **Referee** was **Rachid Medjiba** in **1980 to 1999** of **Algerian Cup Final referees**?”
Temp./Num. Superlatives	In `table-title` of `page-title`, which `col:1` has the [OPERATOR] `col:2`?	“In **List of graphic novels** of **Minx (comics)**, which **Title** has the **earliest Release date**?”
Arithmetic Superlatives	In `table-title` of `page-title`, what was the [OPERATOR] `col:1` when the `col:2` was `val:2`?	“In **By rocket** of **1961 in spaceflight**, what was the **highest Successes** when the **Remarks** was **Maiden flight**?”
Counting	How many `col:1` have `col:2` `val:2` in `table-title` of `page-title`?	“How many **Elections** have **Candidate John Kufuor** in **Presidential elections** of **New Patriotic Party**?”
Arithmetic Addition	In `table-title` of `page-title`, what was the total number of `col:1` when the `col:2` was `val2`?	“In **Assists table** of **2010-11 La Liga**, what was the total number of **Assists** when the **Club** was **Villarreal**?”
Date Difference	In `table-title` of `page-title`, how much time had passed between when the `col:1` was `val:1` and when the `col:2` was `val:2`?	“In **Notable events | Concerts** of **Candlestick Park**, how much time had passed between when the **Artist** was **Paul McCartney** and when the **Artist** was **The Beatles**?”

Table 1: Question templates with examples for all EGs. Variable names specify permissible instantiations, where `col` is a column name, `val` is a value, and indices denote that a value must originate from a particular column. 2/3-hop composition examples are generated by generating 2/3-long fact chains between the answer and the value in the question. For example, above, the chain will include the facts *“The Role when the Author was Shakespeare was Lady Macbeth. The Play when the Role was Lady Macbeth was Macbeth”*. ‘[OPERATOR]’ corresponds to EG-specific operators that we instantiate, e.g., in the EG ‘Temp. comparison’ [OPERATOR] is replaced with the operators *‘earlier’* or *‘later’*. Some EGs are collapsed into a single row (e.g., Quantifiers Every/Most).

The core of the generation process are the example generators (EGs), each corresponding to a reasoning skill (Table 1). Each example generator $g \in \mathcal{G}$ is a function that takes a table $t \in \mathcal{T}$ and randomly samples at most ten (q, c, a) triplets from the set of all possible triplets, where (i) q is a question is pseudo-language, (ii) c is the context, i.e., a list of facts extracted from t that includes the *gold facts* necessary for answering q and *distractor facts*, all phrased in pseudo-language, and (iii) a is the answer. Overall, the synthetic training set is $D_{syn} = \bigcup_{t \in \mathcal{T}} \bigcup_{g \in \mathcal{G}} g(t)$.

EGs generate examples in the following way. Each EG is associated with one or more question templates, which differ in their surface phrasing.[2] Templates contain typed variables that are instantiated with content from the table (see all variables in Table 1). Column and value variables are indexed to specify that the variable `val:i` must be instantiated by a value from the column `col:i`. Instantiating all variables results in the question q and the template allows us to programmatically compute the answer a. E.g., in the question from Fig. 1: *“In League Cup of 1990–91 Chelsea F.C. season, Which Round had a higher Attendance: QF or QFR?”* the answer a can be found by finding the rows with the values *“QF”* and *“QFR”* in the column *“Round”*, and returning the value that has a higher number in the column *“Attendance”*.

The context c is generated from the content necessary for answering the question, which can be identified using the instantiated question template. Facts generally have the form “The `col:1` when the `col:2` was `val:2` was `val:1`”. E.g., to answer the question above, we generate the gold facts *“The Attendance when the Round was QF was 34,178”*, and *“The Attendance when the Round was QFR was 33,861”*. We also generate distractors by generating facts from rows or columns that are not relevant for the question, e.g., *“The Attendance when the Round was R4 was 9,789”*.

Overall, our process results in a large set D_{syn}, which includes examples from 16 EGs (all shown in Table 1).

---

[2] We also experimented with using just one question template per EG and observed very similar downstream results.

EG	*Question*	*Context*	*Answer*
3-hop Composition	What was the Result(s) when the Round was R4 in League Cup of 1990-91 Chelsea F.C. season?	In League Cup of 1990-91 Chelsea F.C. season: The attendance when the round was R2 1st Leg was 5,666. The result when the date was 6 November 1990 was 3-2. The date when the attendance was 34,669 was 27 February 1991. The attendance when the round was QF was 34,178. The date when the attendance was 34,074 was 24 February 1991. The date when the attendance was 16,085 was 6 November 1990. The attendance when the round was R3 was 16,699. **The date when the attendance was 9,789 was 28 November 1990. The result when the date was 28 November 1990 was 2-1.** The result when the date was 31 October 1990 was 0-0. The attendance when the round was QFR was 33,861. The result when the date was 16 January 1991 was 0-0. **The attendance when the round was R4 was 9,789.** The result when the date was 10 October 1990 was 4-1 (won 9-1 on agg). The date when the attendance was 5,666 was 26 September 1990.	2-1
Counting	In Presidential elections of New Patriotic Party, how many Elections have Candidate John Kufuor?	In Presidential elections of New Patriotic Party: The candidate when the election was 1992 was Albert Adu Boahen. The candidate when the election was 2008 (1) was Nana Akufo-Addo. **The candidate when the election was 2000 (2nd) was John Kufuor. The candidate when the election was 2000 (1st) was John Kufuor**. The candidate when the election was 1992 was Albert Adu Boahen. **The candidate when the election was 2004 was John Kufuor. The candidate when the election was 1996 was John Kufuor.** The candidate when the election was 2008 (2) was Nana Akufo-Addo.	4
Date Difference	In Notable concerts of Comiskey Park, how much time had passed between when the Artist was The Beatles and when the Artist was The Police?	In Notable concerts of Comiskey Park: The artist was Rush in August 19, 1979. **The artist was The Police in July 23, 1983.** The dates when the artist was The Jacksons were October 12, 1984, October 13, 1984, and October 14, 1984. The artist was Simon and Garfunkel in July 24, 1983. **The artist was The Beatles in August 20, 1965.** The date when the artist was Aerosmith was July 10, 1976.	17 years, 11 months, and 3 days

Table 3: Number of examples generated by each EG. During data generation, we randomly generate at most 10 examples from each EG and table.

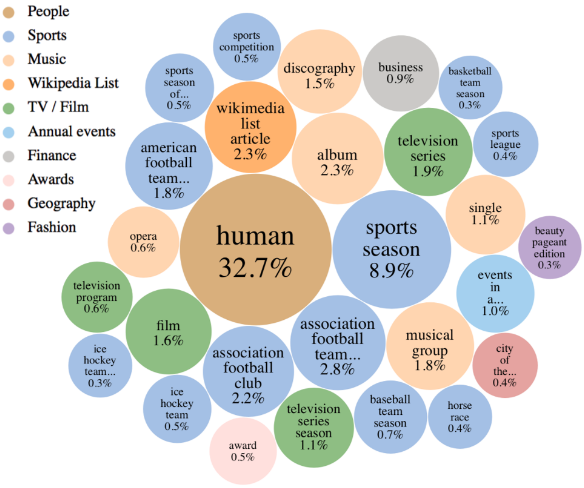

Figure 3: The most frequent categories of our Wikipedia pages and their frequency. Colors represent domains.

2.2 Data Analysis

Data generation yields 4.8M questions from over 176K tables and 130K pages. Table 2 contains examples for generated (q, c, a) triplets, including the full context c. Table 3 shows the number of generated examples for each EG. The number of distinct words is large (850K), illustrating the wide coverage and high lexical diversity of our approach. Moreover, generated examples have diverse answer types, which include text spans (43.2%), yes/no questions (31.6%), numeric (15.8%), and date answers (9.4%). In addition, our questions cover a wide range of domains including popular culture, politics and science. Tables cover more than 2,500 different Wikipedia categories, with 150 categories covering 80% of the data. Fig. 3 presents the most common categories of the Wikipedia pages from which we scraped our tables.

3 Training

Since our EGs generate large quantities of examples, one can think of each EG as providing an infinite stream of examples. In this setup, a natural question is how to construct training batches such that the model learns the required skills as quickly as possible. After briefly describing our model, we will detail our training framework, where we sample examples from EGs in an error-driven manner.

Model We use a standard encoder-decoder architecture (Raffel et al., 2020; Lewis et al., 2020). Given a training example (q, c, a), the model takes as input the sequence of tokens 'q [SEP] c', and the task is to autoregressively decode the answer a token-by-token. We train to maximize the maximum likelihood objective $\log P(a \mid q, c)$.

3.1 Multi-task Training over EGs

Given a pre-trained LM, we add another pre-training step, where we multi-task over a set of tasks $\mathcal{S}$, each task corresponding to examples generated from one EG. Similar to past work (Yogatama et al., 2019; Geva et al., 2020), to avoid "catastrophic forgetting" (Kirkpatrick et al., 2016) of the language skills, we sample batches from the original pre-training task with probability $\lambda = 0.5$.

Past work (Gottumukkala et al., 2020) has shown that *heterogeneous batching*, i.e., having examples from all tasks in each batch, leads to better performance compared to having entire batches from a single task. We follow this practice, and in every batch sample examples from every task according to a probability distribution $P_{\mathit{tasks}} \in \mathbb{R}^{|\mathcal{S}|}$. The main question is how to determine the distribution P_{tasks}, which we turn to next.

3.2 Sampling Strategies

We describe strategies for computing P_{tasks}, starting with the commonly-used *uniform sampling* approach, and then turn to error-driven approaches.

Uniform sampling Past work (Khashabi et al., 2020; Raffel et al., 2020; Wang et al., 2020) used uniform sampling, where the probability to sample from a task s is $P_{\mathit{tasks}}(s) = \frac{1}{|\mathcal{S}|}$, as a-priori all tasks are equally important. Some approaches also sample examples in proportion to the size of the training set (Raffel et al., 2020; Wang et al., 2020). This is not applicable in our case, where we assume an infinite stream of examples for every task, and make no assumptions on the distribution over reasoning skills in the downstream test set.

Error sampling Recent work (Sharma et al., 2018; Gottumukkala et al., 2020) proposed to construct P_{tasks} based on model errors, where one over-samples tasks with higher errors. More formally, let $\mathit{Ceil}(s)$ be an estimate of the maximum accuracy achievable on a task s, and $\mathit{Acc}(s)$ be the current model accuracy for task s on an held-out set. We define $\Delta(s) = \mathit{Ceil}(s) - \mathit{Acc}(s)$ and $P_{\mathit{tasks}}(s) = \frac{\Delta(s)}{\sum_{s' \in \mathcal{S}} \Delta(s')}$. The distribution P_{tasks} of a task is updated every time we evaluate the current model on the held-out data. In our setup, since the data is synthetic and abundant, we assume that the ceiling accuracy for all tasks is 1.0, and hence: $\Delta(s) = 1.0 - \mathit{Acc}(s)$. Similar to Gottumukkala et al. (2020), we use accuracy over a held-out set rather than the training loss, as this corresponds directly to our target metric.

Momentum sampling A potential issue with error sampling, is that if the error rate on a task is high, the model will spend most of its time on that task at the expense of other tasks, which may lead to low data efficiency. To remedy this, we introduce *momentum sampling*, a sampling strategy that samples from a task in proportion to its *rate of improvement*, putting most probability mass on skills that are improving rapidly.

Algorithm 1 Momentum Sampling(w, t, ϵ, k)

Input: windows size w, training time t, minimum share of examples per task ϵ, smoothing factor k.

```
for $s \in \mathcal{S}$ do
    if $t \geq w$ then
        $Acc_{\text{head}} \leftarrow \frac{1}{k} \sum_{i=t-k}^{t} Acc_s(i)$
        $Acc_{\text{tail}} \leftarrow \frac{1}{k} \sum_{i=t-w}^{t-w+k} Acc_s(i)$
        $P_{\mathit{tasks}}[s] \leftarrow \max(|Acc_{\text{head}} - Acc_{\text{tail}}|, \epsilon)$
    else
        $P_{\mathit{tasks}}[s] \leftarrow 1/|\mathcal{S}|$
$P_{\mathit{tasks}} \leftarrow P_{\mathit{tasks}} / \|P_{\mathit{tasks}}\|_1$
```

Alg. 1 provides the details of momentum sampling. Let t denote the index of a checkpoint evaluated on the held-out set, let w be a window size, and $Acc_s(i)$ be the held-out accuracy of checkpoint i on task s. We estimate model accuracy on a task s at the beginning and end of the window, and sample examples in proportion to the difference[3] in accuracy during that window. To smooth out accuracy fluctuations in adjacent checkpoints, we estimate accuracy as an average of k model checkpoints. During the first w checkpoint evaluations, we simply use uniform sampling.

Momentum sampling has several theoretical benefits over error sampling. First, it does not assume anything on the ceiling accuracy of a task. Second, when all tasks converge to their ceiling accuracy, momentum sampling converges to uniform sampling, unlike error sampling, which will over-sample from tasks for which $\mathit{Ceil}(s)$ is low. This is useful in cases where the variance of $\mathit{Ceil}(s)$ is high across tasks. On the other hand, momentum sampling requires a warm-up of w steps, and might under-sample from tasks that train slowly. In §A.2., we describe two synthetic experiments where momentum sampling clearly outperforms error sampling. However, we do *not* observe an advantage for momentum sampling in our experiments in §5, and leave further investigation of momentum sampling to future work.

4 Experimental Setup

4.1 Models

Baselines Our main baseline is T5 (Raffel et al., 2020), a popular pre-trained encoder-decoder model, which we fine-tune on the downstream

---

[3] We use the difference in performance and not the gain to account for cases of sudden drops in performance.

datasets. We experiment with *Base* and *Large* size models. For each dataset, we compare to the relevant state-of-the-art model.

Our pre-trained for reasoning model, PReasM, is a T5 model with another pre-training step on D_{syn}. We experiment with uniform sampling (*PReasM-Uni*), error sampling (*PReasM-Err*), and momentum sampling (*PReasM-Moment*) strategies.

4.2 Datasets

DROP (Dua et al., 2019) is a RC dataset with questions that require numeric reasoning. As an additional baseline, we also compare to GenBERT (Geva et al., 2020), which similar to our approach injects numerical skills by automatically generating synthetic data from a grammar.

IIRC (Ferguson et al., 2020) is a QA dataset, where annotators were given a single Wikipedia paragraph, and were asked to author questions that depend on that paragraph, but also on other paragraphs linked from the input paragraph. This resulted in questions that require discrete temporal (28%) or numeric (11%) reasoning. In addition, 30% of the questions are unanswerable.

We experiment with IIRC in two settings: (a) *Oracle*, where the model is given the gold context, reducing the problem to RC, where we can apply our models. (b) *Retrieval*, where we use the "improved pipeline"introduced by Ni et al. (2021) to retrieve the context, and replace the NumNet+ (Base) reader (Ran et al., 2019) used by the authors (which has specialized architecture) with T5/PReasM.

MMQA (Talmor et al., 2021) is a QA dataset, where the input is a question and a context that consists of a table, multiple text paragraphs, and multiple images, and the model must reason over a subset of the input modalities to answer the question.[4] We chose to use MMQA as it has many questions that involve a conjunction of facts, an operation that is largely missing from other datasets. Moreover, a large fractions of the questions can be answered by reasoning over the text and table only.

Since T5/PReasM cannot handle images or very long contexts, we construct a pipeline that automatically directs some MMQA questions to T5/PReasM, and uses the original *Implicit-Decomp* baseline from Talmor et al. (2021) elsewhere. Our pipeline includes two classifiers, the first determines whether a question requires reasoning over an image, and the second classifies whether a text paragraph is necessary to answer a question. Again, we experiment with an *oracle* and *retrieval* setting, such that in the oracle setting our model is presented with the gold paragraphs. We provide the full description of this pipeline in §A.4.

Evaluation metrics For all datasets, we use the official scripts for computing F_1 and EM, which compare the gold and predicted list of answers.

5 Experimental Results

We present results on the downstream RC datasets (§5.1) and on the synthetic data (§5.2).

5.1 Performance on RC Datasets

Table 4 presents the results of our large models over all datasets, also in comparison to current state-of-the-art. We observe that PReasM substantially improves performance compared to T5 in all conditions, improving on the test set by 7.6, 7.9, 4.1, and 1.2 F_1 points on DROP, $\mathrm{IIRC}_{\mathrm{oracle}}$, IIRC, and MMQA respectively.[5] We obtain new state-of-the-art results on MMQA and $\mathrm{IIRC}_{\mathrm{oracle}}$. On IIRC, we improve performance when using the same retriever (Pipeline) and replacing the NumNet+ reader with PReasM.[6] On DROP, specialized architectures for handling numbers still substantially outperform both T5 and PReasM.

Table 5 shows the effect of different sampling strategies. Error sampling and momentum sampling generally outperform uniform sampling, but there is no clear advantage to momentum sampling compared to error sampling. We further analyze the effect of sampling methods in §5.2.

We now look at performance on different answer types across datasets, where PReasM leads to dramatic improvements on some types, while maintaining similar performance on other types.

DROP Table 6 breaks down performance based on answer types: PReasM outperforms T5 across

---

[4] We removed tables that appear in the MMQA development and test sets from D_{syn}.

[5] To verify that the gains of PReasM over T5 are not due to knowledge memorized from D_{syn}, we trained T5 and PReasM to generate the answer given the question only (without context). We found that the performance of T5 and PReasM is nearly identical in this setup.

[6] We report the numbers from Ni et al. (2021) (45.8/44.3 F_1 on the development/test sets). To fairly compare with the NumNet+ reader, we got the retrieved paragraphs for the Pipeline model through personal communication. However, results on these paragraphs was lower than reported in the paper: 45.5/42.8 F_1. The reported results of our models are with this slightly worse retriever, but still outperform the performance of NumNet+ (Pipeline) from the original paper.

Dataset	*Model*	*Development*	*Test*

	NumNet+ (Joint)	**50.6/46.9**	**50.5/47.4**
MMQA	T5-Large	64.3/57.9	63.4/57.0
	PReasM-Large	**65.5/59.0**	**64.6/58.3**
	Implicit-Decomp	55.5/48.8	55.9/49.3

Table 4: Development and test results. The two values in each cell indicate F_1/EM. Improvement over T5 is statistically significant in all cases ($p < 0.05$) according to the paired bootstrap test (Efron and Tibshirani, 1993).

Model	*DROP*	*$\text{IIRC}_{\text{oracle}}$*	*IIRC*	*MMQA*
T5-Large	64.6±0.1	69.6±0.3	46.7±0.5	64.2±0.2
PReasM-Uni-Large	71.4±0.1	75.1±0.2	48.9±0.3	64.9±0.4
PReasM-Moment-Large	71.7±0.1	**76.8**±0.4	**49.7**±0.1	64.9±0.2
PReasM-Err-Large	**72.2**±0.1	76.5±0.5	49.3±0.4	**65.3**±0.1

Table 5: F_1 on the development set with different sampling strategies. Results show the average and standard deviation over 3 seeds for DROP and MMQA, and 5 seeds for IIRC and $\text{IIRC}_{\text{oracle}}$.

the board for all model sizes and answer types. PReasM-Base outperforms GenBERT on 3 of 4 answer types. The high performance of GenBERT on *Number* questions can be explained by: (a) GenBERT uses digit tokenization which improves arithmetic reasoning (Thawani et al., 2021), and (b) training on multiple numerical reasoning templates.

IIRC Table 7 breaks down performance based on answer types. PReasM outperforms T5 in the oracle setup by roughly 8 points for both Base and Large models, and by 2.6-4 points in the retrieval setup. Improvements are mostly due to cases when the answer is a numerical *Value*, where PReasM outperforms T5 by 39.1 and 40.3 F_1 points in Base and Large models (oracle setup).

Comparing PReasM-Base to NumNet+, PReasM outperforms NumNet+ on *None*, *Span* and *Binary* questions, but lags behind on *Value* questions, where NumNet+ uses specialized architecture.

Overall, PReasM-Large improves state-of-the-art in the oracle setup by 4.7 F_1 points. In the retrieval setting, PReasM outperforms NumNet+ (Pipeline) by 4.2 and 0.8 F_1 points on the development and test sets, respectively (see Table 4).

Model	*Span*	*Spans*	*Date*	*Number*	*Total*
T5-Base	77.5	65.8	57.1	43.7	55.8
PReasM-Base	**81.1**	**69.4**	**64.6**	**61.5**	**68.1**
T5-Large	86.1	**78.4**	75.7	52.2	64.6
PReasM-Large	**86.6**	**78.4**	**77.7**	64.4	**72.3**
GenBERT	74.5	24.2	56.4	**75.2**	**72.3**

Table 6: Drop development F_1 across answer types.

Model	*Oracle*	*None*	*Span*	*Binary*	*Value*	*Total*
T5-Base	✓	91.4	72.0	76.6	8.7	66.3
PReasM-Base	✓	92.5	74.9	71.9	47.8	**74.5**
T5-Large	✓	92.2	77.7	81.3	10.9	69.9
PReasM-Large	✓	92.2	78.4	80.5	51.2	**77.4**
T5-Base	✗	57.1	47.6	54.7	6.7	43.5
PReasM-Base	✗	53.9	49.1	64.8	24.3	**47.5**
T5-Large	✗	56.2	49.9	77.3	11.5	47.4
PReasM-Large	✗	55.9	50.8	69.5	28.6	**50.0**
NumNet+ (Pipeline)	✗	49.6	48.4	52.3	30.0	45.8

Table 7: IIRC Development F_1 across answer types.

MMQA Table 8 breaks down performance based on reasoning skills (annotated per example in MMQA). PReasM outperforms T5 in both the oracle and retrieval setting, and for both model sizes.

The main cause for improvement are comparison questions, where PReasM outperforms T5 by 19 and 11.7 F_1 points on Base and Large models. PReasM outperforms T5 on conjunction questions in Base models, and yes/no questions in all settings. Interestingly, T5 is equipped with decent composition skills, *without* any specialized pre-training.

Compared to *Implicit-Decomp*, although *Implicit-Decomp* outperforms our models on questions that require hopping between two table columns and aggregations, PReasM outperforms *Implicit-Decomp* in all other cases. When considering only questions that require reasoning over text and tables, PReasM-Large improves F_1 by 16.1 points, from 62.3 to 78.4.

5.2 Performance on D_{syn}

Fig. 4 shows statistics on the performance of PReasM on different tasks in D_{syn} during training. The average accuracy across all tasks at the end of training is high – almost 98.0 F_1. PReasM reaches high performance on all tasks, where the lowest-performing tasks are 'arithmetic addition' (91.1) and 'date difference' (94.7). On those tasks, the advantage of error-driven sampling is evident, and it outperforms uniform sampling by as much as 4 points.

Zooming-in on the learning curve, momentum

Model	*Oracle*	*ColumnHop*	*Text*	*Composition*	*Comparison*	*Conjunction*	*Yes/No*	*Aggregate*	*Total*

PReasM-Base	✓	86.9	80.0	75.4	84.1	82.6	89.2	36.4	79.9
T5-Large	✓	88.2	85.9	79.4	74.1	83.2	83.1	36.4	82.7
PReasM-Large	✓	87.8	85.6	79.8	83.6	82.3	90.8	45.5	83.8
Implicit-Decomp	✓	96.6	57.1	53.2	78.4	68.1	76.9	59.1	62.3

Table 8: Development F_1 on MMQA with reasoning type breakdown on the development set. The column 'Total' refers to all questions that do not require reasoning over the image modality.

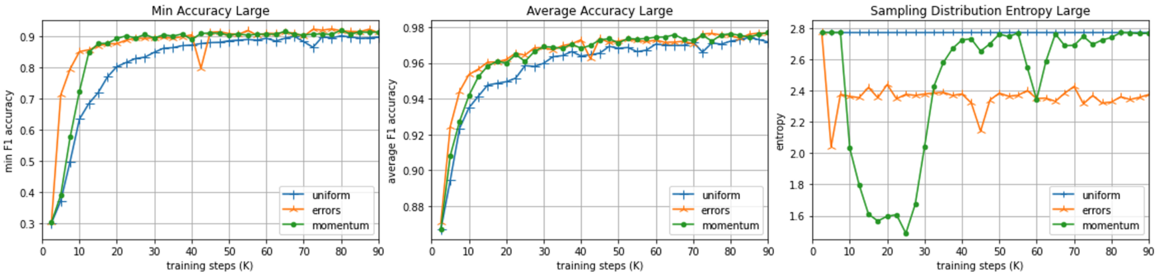

Figure 4: Minimum (left) and average (center) task accuracy on 1,000 held-out examples per task from D_{syn}, and the entropy of P_{tasks} (right) as a function of the number of training steps for all sampling strategies (Large models).

and error sampling learn reasoning skills a lot faster than uniform sampling. Looking at the entropy of P_{tasks} sheds light on the difference between error sampling and momentum sampling. Error sampling puts most probability mass on the lowest-performing task (arithmetic addition), and thus its entropy over tasks is roughly constant from a certain point. Conversely, momentum sampling puts a lot of probability mass on tasks that are improving quickly at the beginning, but as improvements plateau, it converges towards uniform sampling.

Fig. 5 and Table 11 (in the Appendix) show the results for T5 and PReasM on D_{syn}. The results for T5 were obtained by training in a few-shot manner on 32 examples for 200 steps, as suggested in Ram et al. (2021). T5-Large outperforms T5-Base on most tasks, suggesting that larger models are able to learn reasoning skills faster. On tasks such as date difference and arithmetic addition, the results for T5-Large are low, at around 10 F_1. Our PReasM models significantly outperform T5 on all tasks.

6 Analysis

Reasoning skills in DROP To check which reasoning skills PReasM has, we use a proposed split of a subset of DROP to reasoning skills (Gupta et al., 2020a). Table 9 presents the F_1 for our best PReasM and T5 models, as well as the F_1 from the neural module network (NMN) used in Gupta et al. (2020a). NMN was trained only on a subset of the original DROP dataset. When comparing to T5, PReasM dramatically improves performance on Date-Difference, and also leads to sizable gains in Number-Compare, Extract-Number and Count.

Question Type	*NMN*	T5-*Base*	PReasM-*Base*	T5-*Large*	PReasM-*Large*
Date-Compare	82.6	86.4	87.5	87.6	**89.9**
Date-Difference	75.4	19.6	78.9	45.4	**80.4**
Number-Compare	92.7	91.3	95.2	97.3	**98.5**
Extract-Number	86.1	91.8	94.9	92.1	**95.1**
Count	55.7	80.1	86.7	86.7	**89.2**
Extract-Argument	69.7	87.6	86.2	90.5	**92.1**

Table 9: F_1 on a previously-proposed split of a subset of the development set of DROP to reasoning skills.

Accuracy vs. training cost trade-off We evaluate PReasM-Base models on DROP and $\text{IIRC}_{\text{oracle}}$ as we vary the number of pre-training steps on D_{syn} (Fig. 6). Most of the improvement happens in the first 100K steps, and error-driven sampling outperforms uniform sampling throughout training. Error sampling outperforms momentum sampling in the latter part of training. A possible reason is that the reasoning skills in the downstream tasks are correlated with the harder tasks during pre-training (arithmetic addition and date difference). This provides an advantage for error

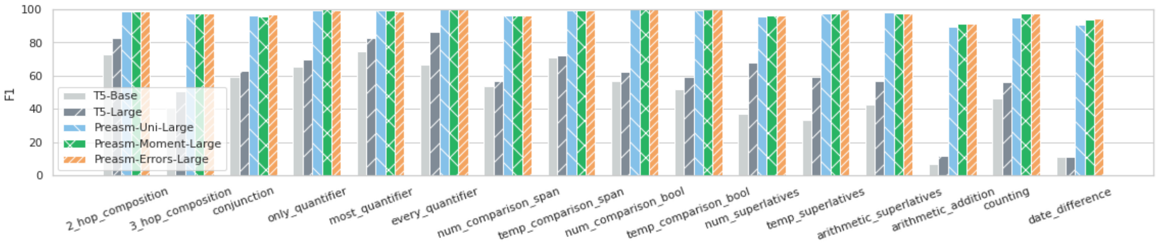

Figure 5: F_1 for each task in D_{syn}, for T5 and PReasM on the held-out evaluation set.

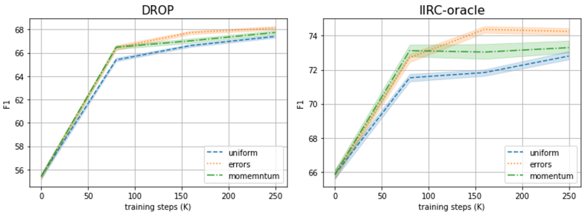

Figure 6: Development F_1 on DROP and $\text{IIRC}_{\text{oracle}}$ as a function of the number of training steps (Base models). The light lines mark confidence intervals over 5 seeds. The first point shows the performance of T5-Base.

sampling, since it will focus on these tasks even if the improvement during pre-training is small.

7 Related Work

Template-based data generation has been previously used for data augmentation, for example to inject numerical skills (Geva et al., 2020), and to improve consistency (Asai and Hajishirzi, 2020), and zero-shot accuracy (Zhao et al., 2019). In addition, templates were used for dataset construction (Talmor and Berant, 2018; Clark et al., 2020; Thorne et al., 2021), and to analyse model generalization (Rozen et al., 2019). In this work, we automatically generate examples by instantiating templates using structured data. Since our method relies solely on tables as input, it is highly scalable, has rich lexical diversity, and can be easily extended to new skills and domains.

Recently, Thorne et al. (2021) introduced the WIKINLDB dataset, which includes queries that require reasoning over a set of textual facts. Queries are instantiated with values from a knowledge graph (KG), and facts are generated by a LM. Unlike this work, WIKINLDB is focused on *evaluating* reasoning skills. We, on the other hand, show that generated examples can be used to endow a pre-trained LM with new reasoning skills. Moreover, tables are much easier to collect at scale compared to KGs, which tend to have limited coverage.

Data augmentation techniques have been extensively explored in RC, QA, and dialogue (Feng et al., 2021; Talmor and Berant, 2019; Khashabi et al., 2020; Alberti et al., 2019; Puri et al., 2020; Bartolo et al., 2021). Here, we focus on tables as a valuable source for data generation.

Pre-training over tables has focused in the past on reasoning over tables and knowledge-bases (Eisenschlos et al., 2020; Yin et al., 2020; Herzig et al., 2020; Müller et al., 2021; Yu et al., 2021; Neeraja et al., 2021b). Here, we use pre-training over tables to improve reasoning over *text*. We leave evaluation on tasks beyond RC to future work.

Error-driven sampling has been considered in the past in the context of active learning (Sharma et al., 2018), reinforcement learning (Graves et al., 2017; Glover and Hokamp, 2019; Xu et al., 2019), transfer learning (Zhang et al., 2020; Pilault et al., 2021), and distributionally robust optimization (Oren et al., 2019; Sagawa et al., 2020), where the goal is to perform well over a family of distributions. Similar to Gottumukkala et al. (2020), we compute heterogeneous batches based on error rates, and show that this improves efficiency and performance.

8 Conclusion

We propose semi-structured tables as a valuable resource for generating examples that can endow pre-trained language models with reasoning skills. We generate 5M examples that correspond to 16 reasoning skills from Wikipedia tables and add a pre-training step over this data. To improve data efficiency we use error-driven sampling, which focuses training on reasoning skills that the model currently lacks. We evaluate our model, PReasM, on three reasoning-focused RC datasets and show that it leads to substantial improvements in all cases.

Acknowledgments

A Supplemental Material

A.1 Data Generation

In this section, we provide details about how we classify table columns.

Classifying table columns When annotating the semantic types of columns, a column will be of type `NUMBER` or `DATE` if all values in the column can be parsed with standard tools for parsing numbers and dates,[7] accordingly. Otherwise, we annotate the column as type `STRING`.

Information in tables is usually aggregated such that certain columns serve as the *semantic index* of the table. For example, the table in Fig. 1 provides information about each round in a tournament. In order for our examples to be semantically meaningful, we generate questions about columns that serve as the semantic index of their table.

---

[7] `https://pypi.org/project/python-dateutil/`

Since the semantic index is not provided, we use a linear decision rule to find such columns. The features to our classifier include the column's distance from the leftmost column, the percentage of unique cells in the column, the percentage of cells whose values are links to Wikipedia articles, the percentage of cells with short text (at most 2 characters), the percentage of cells with numbers, and the column's header. We allow more than one semantic index per table, such that both the *Round* and *Opponent* columns can serve as a semantic index in the table in Fig. 1.

A.2 Advantages of Momentum Sampling

To highlight the theoretical benefits of momentum sampling, we construct synthetic experiments where there is high variance in the ceiling accuracy between different tasks. As we show in §5.2, our models are able to achieve near perfect accuracy on our tasks when provided with enough training examples. Hence, we create settings where the ceiling accuracy for a task is lower than 1.0, either by adding noise or by down-sampling the number of training examples. More specifically, we train on two tasks: an *arithmetic addition* task that trains slowly and has a high ceiling accuracy, and a second task that trains quickly, and evaluate the performance on a held-out set of arithmetic addition examples.

First, we train on *arithmetic addition* and *2-hop composition*, which is faster to train. We conduct two experiments, in which we add noise to the 2-hop composition task by randomly sampling the label from the vocabulary in order to force the ceiling accuracy to be lower than 1.0. To check the performance of sampling strategies in varying levels of noise, we conduct two experiments where we add noise to 30% or 100% of the examples (in the latter case the label of 2-hop composition is random). We expect that this will lead to slower learning of arithmetic addition for error sampling, since more probability mass will be allocated to the noisy task (since its ceiling accuracy is low), despite the fact that it is easier.

Next, we train on *arithmetic addition* and *date difference*, both of which train slowly. To force the ceiling accuracy of the date difference task to be lower than 1.0, our training set contains only 1,000 examples. This emulates settings where the data is not generated automatically and the cost of generating examples is higher. Again, we expect error sampling to over-sample from the date difference task even when this would not lead to gains in performance, due to the small training set.

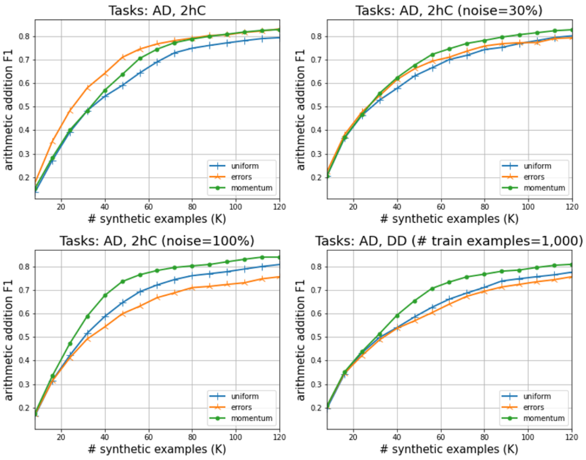

Figure 7: Motivation for momentum sampling. AD=Arithmetic Addition, 2hC=2-hop Composition, DD=Date Difference. When one task has high ceiling accuracy and trains slowly, and the other task has a lower ceiling accuracy and trains fast, momentum sampling outperforms error sampling.

Fig. 7 illustrates the advantage of momentum sampling in these settings. Without noise (top left), both momentum sampling and error sampling learn faster than uniform sampling. Momentum sampling learns more slowly than error sampling, due to the warm-start period in the first w evaluation checkpoints. As we add noise to 30% of the examples (top right), error sampling focuses on the noisy task once accuracy approaches a certain level (0.7 F_1). When we add noise to all of the 2-hop composition examples (bottom left), uniform sampling outperforms error sampling, while momentum sampling still performs well. This phenomenon repeats when we switch the 2-hop composition task with the date difference task and down-sample the number of training examples (bottom right).

A.3 Implementation Details

The following section includes implementation details for our experiments, including: hyperparameters for the momentum sampling algorithm, the original pre-training task, and technical details.

Experiment	*Size*	*LR*	*Batch Size*	*GAS*	*Epochs*
PReasM	Base	1e-4	64	1	50
PReasM	Large	1e-4	18	4	36
DROP	Base	1e-4	20	1	20
IIRC	Base	1e-4	20	1	60
$\text{IIRC}_{\text{oracle}}$	Base	1e-4	20	1	60
MMQA	Base	1e-4	6	3	20
DROP	Large	5e-5	16	2	20
IIRC	Large	5e-5	16	2	60
$\text{IIRC}_{\text{oracle}}$	Large	5e-5	16	2	60
MMQA	Large	1e-4	2	16	10

Table 10: Hyper-parameters used in all experiments, LR and GAS refer to learning-rate and gradient accumulation steps. In our PReasM experiments, epochs refer to the number of steps between evaluations, which is set to $5,000$ and $2,500$ for our base and large experiments, which leads to $250,000$ and $90,000$ optimization steps, respectively.

Momentum sampling For momentum sampling we use a window size of $w = 4$, a smoothing factor of $k = 2$, and sample at least $\epsilon = 0.002$ examples from every task in D_{syn}.

Original pre-training task In order to avoid catastrophic forgetting (Kirkpatrick et al., 2016), we continue training with the span-corruption objective introduced in (Raffel et al., 2020), over sequences of length 256 from the English Wikipedia.

Technical details We train all our experiments on one RTX8000 (48GB) or RTX3090 (24GB) GPUs. Our PReasM-Base and PReasM-Large models training time was 5-6 and 8-9 days on one RTX8000 GPU, respectively. We use the T5 model from `https://huggingface.co/transformers/model_doc/t5.html` (Wolf et al., 2020). Table 10 contains the hyper-parameters used in our experiments.

A.4 MMQA Pipeline

The first classifier in our pipeline is a T5-large model fine-tuned on the MMQA training set to determine if a question is likely to require an image or not. When the classifier determines a question requires an image, the example is directed to *Implicit-Decomp*. The accuracy of this classifier on the MMQA development set is 99.2%.

The second classifier in the pipeline is a T5-3B model, fine-tuned on the MMQA training set to determine given a question and one of the textual paragraphs if that paragraph is required for answering the question. Then, for every question that does not require an image, we classify each of the textual paragraphs and only use the ones classified as relevant. This process identifies all gold paragraphs in 95.8% of the examples.

Last, we convert the table into text by linearizing the table as described in Talmor et al. (2021). The model is presented with multiple paragraphs and the linearized table, and can answer questions that require any reasoning across them. Since the context is long, we present the model with contexts of size 1,536 word-pieces (without any change to the original T5 model).

Abstract

Existing KBQA approaches, despite achieving strong performance on i.i.d. test data, often struggle in generalizing to questions involving unseen KB schema items. Prior ranking-based approaches have shown some success in generalization, but suffer from the coverage issue. We present RnG-KBQA, a **R**ank-a**n**d-**G**enerate approach for KBQA, which remedies the coverage issue with a generation model while preserving a strong generalization capability. Our approach first uses a contrastive ranker to rank a set of candidate logical forms obtained by searching over the knowledge graph. It then introduces a tailored generation model conditioned on the question and the top-ranked candidates to compose the final logical form. We achieve new state-of-the-art results on GrailQA and WebQSP datasets. In particular, our method surpasses the prior state-of-the-art by a large margin on the GrailQA leaderboard. In addition, RnG-KBQA outperforms all prior approaches on the popular WebQSP benchmark, even including the ones that use the oracle entity linking. The experimental results demonstrate the effectiveness of the interplay between ranking and generation, which leads to the superior performance of our proposed approach across all settings with especially strong improvements in zero-shot generalization.[1]

Figure 1: Overview of our rank-and-generate approach. Given a question, we first rank logical form candidates obtained by searching over the KB based on predefined rules. Here, the ground truth logical form is not in the top-ranked candidates as it is not covered by the rules. We solve this problem using another generation step that produces the correct logical form based on top-ranked candidates. The final logical form is executed over the KB to yield the answer.

1 Introduction

Modern knowledge bases (KB) are reliable sources of a huge amount of world knowledge but can be difficult to interact with since they are extremely large in scale and require specific query languages (e.g., Sparql) to access. Question Answering over Knowledge Base (KBQA) serves as a user-friendly way to query over KBs and has garnered increasing attention (Berant et al., 2013; Cai and Yates, 2013). Recent research has attempted to build systems achieving strong results on several public benchmarks that contain i.i.d. train and test distribution such as SimpleQ (Bordes et al., 2015) and WebQSP (Yih et al., 2016). However, users often want to ask questions involving unseen compositions or KB schema items (see Figure 5 for examples), which still remains a challenge. Generation-based approaches (e.g., a seq-to-seq parser) are not effective enough to handle such practical generalization scenarios due to the difficulty of generating unseen KB schema items. Ranking-based approaches, which first generate a set of candidate logical forms using predefined rules and then select

the best-scored one according to the question, have shown some success (Gu et al., 2021). However, it suffers from the coverage problem, because it is often impractical to exhaust all the rules to cover the desired logical form due to the scale of the KB.

We propose RnG-KBQA, a new framework targeted at generalization problems in the task of KBQA. Our approach combines a ranker with a generator, which addresses the coverage issue in ranking-only based approaches while still benefiting from their generalization power. As shown in Figure 1, we first employ a ranker to select a set of related logical forms from a pool of candidate logical forms obtained by searching over the graph. The selected logical forms are not required to cover the correct one, but are semantically coherent and aligned with the underlying intents in the question. Next, we introduce a generator that consumes both the question and the top-k ranked candidates to compose the final logical form. The core idea of our approach is the interplay between the ranker and the generator: the ranker provides essential ingredients of KB schema items to the generator, which then further refines the top-candidates by complementing missing constructions or constraints, and hence allows covering a broader range of logical form space.

We base both our ranker and generator on pretrained language models for better generalization capability. Unlike prior systems which rank candidates using a grammar-based parser (Berant et al., 2013) or a seq-to-seq parser (Gu et al., 2021), our ranker is a BERT-based (Devlin et al., 2019) bi-encoder (taking as input question-candidate pair) trained to maximize the scores of ground truth logical forms while minimizing the scores of incorrect candidates. Such training schema allows learning from the contrast between the candidates in the entire territory, whereas prior parsing-based ranker (Berant et al., 2013; Gu et al., 2021) only learns to encourage the likelihood of the ground truth logical forms. We further develop an iterative-bootstrap-based training curriculum for efficiently training the ranker to distinguish spurious candidates (Section 2.2). In addition, we extend the proposed logical form ranker, keeping the architecture and logic the same, for the task of entity disambiguation, and show its effectiveness as a second-stage entity ranker. Our generator is a T5-based (Raffel et al., 2020) seq-to-seq model that fuses semantic and structural ingredients found in top-k candidates to compose the final logical form. To achieve this, we feed the generator with the question followed by a linearized sequence of the top-k candidates, which allows it to distill a refined logical form that will fully reflect the question intent by complementing the missing pieces or discarding the irrelevant parts without having to learn the low-level dynamics.

We test RnG-KBQA on two datasets, GrailQA and WebQSP, and compare against an array of strong baselines. On GrailQA, a challenging dataset focused on generalization in KBQA, our approach sets the new state-of-the-art performance of 68.8 exact match 74.4 F1 score, surpassing prior SOTA (58.1 exact match and 65.3 F1 score) by a large margin. On the popular WebQSP dataset, RnG-KBQA also outperforms the best prior approach (QGG (Lan and Jiang, 2020)) and achieves a new SOTA performance of 75.7 F1 score. The results demonstrate the effectiveness of our approach across all settings and especially in compositional generalization and zero-shot generalization.

2 Generation Augmented KBQA

2.1 Preliminaries

A knowledge base collects knowledge data stored in the form of subject-relation-object triple (s, r, o), where s is an entity, r is a binary relation, and o can be entities or literals (e.g., date time, integer values, etc.). Let the question be x, our task is to obtain a logical form y that can be executed over the knowledge base to yield the final answer. Following Gu et al. (2021), we use *s-expressions* to represent queries over knowledge base. S-expression (examples in Figure 1) uses functions (e.g., JOIN) operating on set-based semantics and eliminates variable usages as in lambda DCS (Liang, 2013). This makes s-expression a suitable representation for the task of KBQA because it balances readability and compactness (Gu et al., 2021).

Enumeration of Candidates Recall that our approach first uses a ranker model to score a list of candidate logical forms $C = \{c_i\}_{i=1}^{m}$ obtained via enumeration. We'll first introduce how to enumerate the candidates before delving into the details of our ranking and generation models.

We start from every entity detected in the question and query the knowledge base for paths reachable within two hops. Next, we write down an s-expression corresponding to each of the paths,

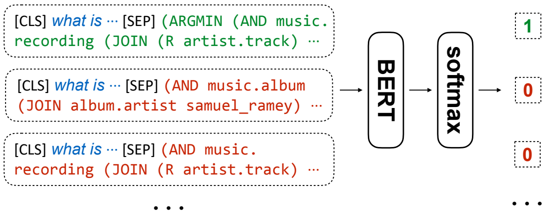

Figure 2: The ranker that learns from the contrast between the ground truth and negative candidates.

which constitutes a set of candidates. We note that we do not exhaust all the possible compositions when enumerating (e.g., we do not include comparative operations and argmin/max operations), and hence does not guarantee to cover the target s-expression. A more comprehensive enumeration method is possible but will introduce a prohibitively large number (greater than 2,000,000 for some queries) of candidates. Therefore, it's impractical to cover every possible logical form when enumerating, and we seek to tackle this issue via our tailored generation model.

2.2 Logical Form Ranking

Our ranker model learns to score each candidate logical form by maximizing the similarity between question and ground truth logical form while minimizing the similarities between the question and the negative logical forms (Figure 2). Specifically, given the question x and a logical form candidate c, we use a BERT-based encoder that takes as input the concatenation of the question and the logical form and outputs a logit representing the similarity between them formulated as follows:

$$s(x, y) = \textsc{Linear}(\textsc{BertCls}([x; y]))$$

where \textsc{BertCls} denotes the [CLS] representation of the concatenated input; \textsc{Linear} is a projection layer reducing the representation to a scalar similarity score. The ranker is then optimized to minimize the following loss function:

$$\mathcal{L}_{\text{ranker}} = -\frac{e^{s(x,y)}}{e^{s(x,y)} + \sum_{c \in C \wedge c \neq y} e^{s(x,c)}} \qquad (1)$$

where the idea is to promote the ground truth logical form while penalizing the negative ones via a contrastive objective. In contrast, the ranker employed in past work (Gu et al., 2021), a seq-to-seq model, aims to directly map the question to target logical form, only leveraging supervision from the ground truth. Consequently, our ranker is more effective in distinguishing the correct logical forms from *spurious ones* (similar but not equal to the ground truth ones).

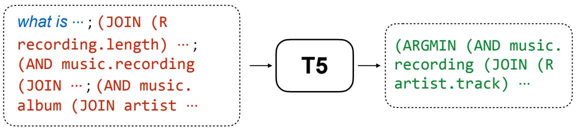

Figure 3: The generation model conditioned on question and top-ranked candidates returned by the ranker.

Bootstrapping Negative Samples in Training Due to the large number of candidates and limited GPU memory, it is impractical to feed all the candidates $c \in C$ as in Eq (1) when training the ranker. Therefore, we need to sample a subset of negatives logical forms $C' \subset C$ at each batch. A naive way for sampling negative logical forms is to draw random samples. However, because the number of candidates is often large compared to the allowed size of negative samples in each batch, it may not be possible to cover spurious logical forms within the randomly selected samples.

We propose to sample negative logical forms by bootstrapping, inspired by the negative sampling methods used in Karpukhin et al. (2020). That is, we first train the ranker using random samples for several epochs to warm start it, and then choose the spurious logical forms that are confusing to the model as the negative samples for further training the model. We find the ranker can benefit from this advanced negative sampling strategy and perform better compared to using random negative samples.

2.3 Target Logical Form Generation

Having a ranked list of candidates, we introduce a generation model to compose the final logical form conditioned on the question and the top-k logical forms. Our generator is a transformer-based seq-to-seq model (Vaswani et al., 2017) instantiated from T5 ((Raffel et al., 2020)), as it demonstrates strong performance in generation-related tasks. As shown in Figure 3, we construct the inputs by concatenating the question and the top-k candidates returned by the ranker separated by semi-colon (i.e., $[x; c_{t_1}; ...; c_{t_k}]$). We train the model to generate the ground truth logical form autoregressively with cross-entropy objective using teacher forcing. In the inference, we use beam-search to decode top-k target logical forms. To construct the top-k

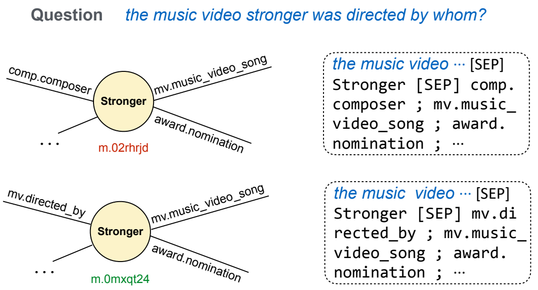

Figure 4: Illustrative example of running entity disambiguation as ranking. A confusing entity (red) and the correct entity (green) both match the surface form in the question. To distinguish them, we train an entity disambiguation model following the same architecture as in logical form ranking but construct inputs by concatenating the question and relations.

logical form candidates needed for training the generator, we first train the ranker, and then use the rankings it produces on the training data.

Since the generation model can now leverage both the question and KB schema information (contained in the candidates), the context is much more specified as compared to only conditioning on the question. This enables our generator to leverage the training data more efficiently by focusing only on correcting or supplementing existing logical forms instead of learning both the generation rule and correctness of logical forms.

Execution-Augmented Inference We use a vanilla T5 generation model without syntactic constraints, which does not guarantee the syntactic correctness nor executability of the produced logical forms. Therefore, we use an execution-augmented inference procedure, which is commonly used in prior semantic parsing related work (Devlin et al., 2017; Ye et al., 2020b). We first decode top-k logical forms using beam search and then execute each logical form until we find one that yields a valid (non-empty) answer. In case that none of the top-k logical forms is valid, we return the top-ranked candidate obtained using the ranker as the final logical form, which is guaranteed to be executable. This inference schema can ensure finding one valid logical form for each problem. It is possible to incorporate a more complex mechanism to control the syntactic correctness in decoding (e.g., using grammar-based decoder (Rabinovich et al., 2017) or dynamical beam pruning techniques (Ye et al., 2020a)). We leave such extension aside since we find that executability of produced logical forms is not the bottleneck (see Section 3.3 in experiments).

2.4 Extension: Entity Disambiguation as Ranking

Our ranking model is mainly proposed for the task of ranking candidate logical forms. Here, we introduce a simple way to adapt our ranking model for the task of entity disambiguation. A common paradigm of finding KB entities referred in a question is to first detect the entity mentions with an NER system and then run fuzzy matching based on the surface forms. This paradigm has been employed in various methods (Yih et al., 2015; Sun et al., 2019; Chen et al., 2021; Gu et al., 2021). One problem with this paradigm lies in entity disambiguation: a mention usually matches surface forms of more than one entities in the KB.

A common way to disambiguate the matched entities is to choose the most popular one according to the popularity score provided by FACC1 project (Chen et al., 2021; Gu et al., 2021), which can be imprecise in some cases. We show an example in Figure 4. Consider the question "the music video stronger was directed by whom?" taken from GRAILQA, where the most popular matched entity is "Stronger" (`m.02rhrjd`, song by Kanye West)" and the second is also "Stronger" (`m.0mxqqt24`, music video by Britney Spears). The surface form matching and popularity scores do not provide sufficient information needed for disambiguation.

However, it is possible to leverage the relation information linked with an entity to further help assess if it matches a mention in the question. By querying relations over KB, we see there is a relation about mv director `mv.directed_by` linking to `m.0mxqqt24`, but there are no such kind of relations connected with `m.02rhrjd`. We therefore cast the disambiguation problem to an entity ranking problem, and adapt the ranking model used before to tackle this problem. Given a mention, we concatenate the question with the relations for each entity candidate matching the mention. We reuse the same model architecture and loss function as in Section 2.2 to train another entity disambiguation model to further improve the ranking of the target entity. We apply our entity disambiguation model on GRAILQA, and achieve substantial improvements in terms of entity linking.

3 Experiments

We mainly test our approach on GRAILQA (Gu et al., 2021), a challenging dataset focused on evaluating the generalization capabilities. We also ex-

Figure 5: Examples of compositional generalization to new composition of KB schema items and zero-shot generalization to unseen schema items (red).

periment on WEBQSP and compare against a number of prior approaches to demonstrate the general applicability of our approach.

3.1 Experiment: GRAILQA

GRAILQA is the first dataset that evaluates the zero-shot generalization. Specifically, GRAILQA contains 64,331 questions in total and carefully splits the data so as to evaluate three levels of generalization in the task of KBQA, including *i.i.d.* setting, *compositional* generalization to unseen composition, and *zero-shot* generalization to unseen KB schema (examples in Figure 5). The fraction of each setting in the test set is 25%, 25%, and 50% , respectively. Aside from the generalization challenge, GRAILQA also presents additional difficulty in terms of the large number of involved entities/relations, complex compositionality in the logical forms (up to 4 hops), and noisiness of the entities mentioned in questions (Gu et al., 2021).

Implementation Detail We link an entity mention to an entity node in KB using our approach described in Section 2.4. We first use a BERT-NER systems provided by the authors of GRAILQA to detect mention spans in the question. For each mention span, we match the span with surface forms in FACC1 project (Gabrilovich et al., 2013), rank the matched entities using popularity score, and retain the top-5 entity candidates. Lastly, we use the disambiguation model trained on GRAILQA to select only one entity for each mention. Our entity ambulation model is initiated from BERT-base-uncased model provided by huggingface library (Wolf et al., 2020), and finetuned for 3 epochs with a learning rate of 1e-5 and a batch size of 8.

When training the ranker, we sample 96 negative candidates using the strategy described in Section 2.2. Our ranker is finetuned from BERT-base-uncased for 3 epochs using a learning rate of 1e-5 and a batch size of 8. We do bootstrapping after every epoch. It is also noteworthy that we perform teacher-forcing when training the ranker, i.e., we use ground truth entity linking for training.

We base our generation model on T5-base (Raffel et al., 2020). We use top-5 candidates returned by the ranker and finetune for 10 epochs using a learning rate of 3e-5 and a batch size of 8.

Metrics For GRAILQA, we use exact match (EX) and F1 score (F1) as the metrics, all of which are computed using official evaluation script.

Results Table 1 summarizes the results on GRAILQA. The results of other approaches are directly taken from the leaderboard.[2] Overall, our

---

[2] Accessed on 03/10/2022.

approach sets the new state-of-the-art performance on GRAILQA dataset, achieving 68.8 EM and 74.4 F1. This exhibits a large margin over the other approaches: our approach outperforms ReTrack (Chen et al., 2021) by 10.7 EM and 8.2 F1.

Furthermore, RNG-KBQA performs generally well for all three levels of generalization and is particularly strong in zero-shot setting. Our approach is slightly better than ReTrack and substantially better than all the other approaches in i.i.d. setting and compositional setting. However, ReTrack fails in generalizing to unseen KB Schema items and only achieves poor performance in zero-shot setting, whereas our approach is generalizable and beats ReTrack with a margin of 16.1 F1.

To directly compare the effectiveness of our rank-and-generate framework against rank-only baseline (BERT Ranking), we also provide the performance of a variant of RNG-KBQA without the entity-disambiguation model. In this variant, we directly use the entity linking results provided by the authors of Gu et al. (2021). Under the same entity linking performance, our ranking-and-generation framework is able to improve the performance by 11.4 EM and 8.2 F1. Furthermore, the variant of our model without the entity-disambiguation module (RnG-KBQA w/o Entity Disambiguation) still substantially outperforms all other approaches. In particular, this variant beats ReTrack by 3.3 EM and 2.1 F1 even if ReTrack includes an entity disambiguation model that yields better entity linking performance. Please refer to Appendix A for more discussion on entity linking performance.

3.2 Experiment: WEBQSP

WEBQSP is a popular dataset which evaluates KBQA approaches in i.i.d. setting. It contains 4,937 question in total and requires reasoning chains with up to 2 hops. Since there is no official development split, we randomly sample 200 examples from the training set for validation.

Implementation Detail For experiments on WEBQSP, we use ELQ (Li et al., 2020) as the entity linker, which is trained on WEBQSP dataset to perform entity detection and entity linking, since it produces more precise entity linking results and hence leads to less number of candidate logical forms for each question. Because ELQ always links a mention to only one entity, we do not need an entity-disambiguation step for WEBQSP dataset. Similarly, we initiate the logical form ranker using BERT-base-uncased, and the generator using T5-base. We also sample 96 negative candidates for each question, and feed the top-5 candidates to the generation model. The ranker is trained for 10 epochs and we run bootstrapping every 2 epochs; the generator is trained for 20 epochs.

	F1	EM	Hits$^{@1}$
PullNet* (Sun et al., 2019)	62.8	–	67.8
GraftNet* (Sun et al., 2018)	–	–	68.1
Bert Ranking* (Gu et al., 2021)	67.0	–	–
EmbedQA* (Saxena et al., 2020)	–	–	72.5
ReTrack* (Chen et al., 2021)	74.7	–	74.6
Topic Units (Lan et al., 2019)	67.9	–	68.2
UHop (Chen et al., 2019)	68.5	–	–
NSM (Liang et al., 2017)	69.0	–	–
ReTrack (Chen et al., 2021)	71.0	–	71.6
STAGG (Yih et al., 2015)	71.7	63.9	–
CBR (Das et al., 2021)	72.8	70.0	–
QGG (Lan and Jiang, 2020)	74.0	–	–
RNG-KBQA **(Ours)**	**75.6**	**71.1**	–

Table 2: Results of RNG-KBQA and baselines on WEBQSP. * (approach in the top section) denotes using oracle entity linking annotations provided by the dataset. Our approach achieves the new state-of-the-art performance (75.6 F1) with a discernible margin over the performance of best prior method (74.0 F1 obtained by QGG). Our approach even outperforms a number of prior work using oracle entity linking annotations.

Metrics F1 is used as the main evaluation metric. In addition, for approaches that are able to select entity sets as answers, we report the exact match (EM) used in the official evaluation. For information-retrieval based approaches that can only predict a single entity, we report Hits$^{@1}$ (if the predicted entity is in the ground truth entity set), which is considered as a loose approximation of EM.

Results For baseline approaches, we directly take the results reported in corresponding original paper. As shown in Table 1, RNG-KBQA achieves 75.6 F1, surpassing the prior state-of-the-art (QGG) by 1.6. Our approach also achieves the best EM score of 71.1, surpassing CBR (Das et al., 2021). The performance of our approach obtained using ELQ-predicted entity linking outperforms all the prior methods, even if they are allowed to use oracle entity linking annotations (denoted as * in the top section). It is also noteworthy that both CBR and QGG, the two methods achieving strong performance closest to ours, use an entity linker with equal or better performance compared to ours. In particular, CBR also uses ELQ for entity linking.

	GrailQA	WebQSP
Full Model	75.1	75.6
Gen Only (Rand Rank)	47.6	69.9
Rank Only	69.8	72.7
Rank Only (w/o Bootstrap)	68.6	71.3

Table 3: F1 scores on GrailQA (dev set) and WebQSP of three ablations, including a generation-only variant (Gen Only, which uses randomly selected logical form candidates), a ranking-only variant (Rank Only), and a ranking-only variant without using bootstrap training strategy (w/o Bootstrap). Removing either component leads to performance deterioration.

QGG uses an entity linker achieving 85.2 entity linking F1 (calculated using public available code) which is slightly better than ours achieving 84.8 entity linking F1. To summarize, the results on WebQSP suggest that, in addition to outstanding generalization capability, our approach is also as strong in solving simpler questions in i.i.d. setting.

3.3 Analysis

Ablation Study We first compare the performance of our full model against incomplete ablations in Table 3. We derive a generation-only (Gen Only) model from our base model by replacing the trained ranker with a random ranker, which leads to a performance drop of 27.5 and 5.7 on GrailQA and WebQSP, respectively. The performance deterioration is especially sharp on GrailQA as it requires generalizing to unseen KB schema items, for which the generator typically needs to be based on a good set of candidates to be effective.

To test the effects of our generation step, we compare the performance of a ranking-only variant (directly using the top-ranked candidate) against the performance of the full model. As shown in Table 3, the generation model is able to remedy some cases not addressable by the ranking model alone, which boosts the performance by 5.3 on GrailQA and 2.9 on WebQSP.

We additionally evaluate the performance of a ranking model trained without bootstrapping strategy introduced in Section 2.2. The performance of this variant lags its counterpart by 1.2 and 1.4 on GrailQA and WebQSP, respectively. The bootstrapping strategy is indeed helpful for training the ranker to better distinguish spurious candidates.

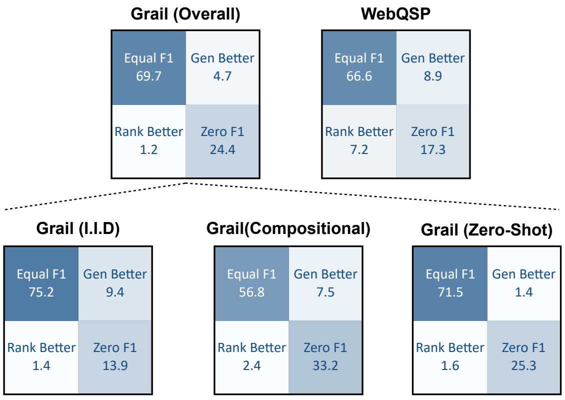

Figure 6: Comparison between the ranker's top predictions and the generator's top predictions. Generation model mostly keeps or improves the prediction while occasionally introducing errors.

Comparing Outputs of Ranking Model and Generation Model We have demonstrated the benefit of adding a generation stage on top of the ranking step on previous result sections. Here, we present a more detailed comparison between the outputs of ranking model and generation model. Figure 6 presents the "comparison matrices" showing the fractions of questions where

○ top left: the top ranking prediction and top generation prediction achieves a equal nonzero F1,

○ top right: the top generation prediction is better,

○ bottom left: the top ranking prediction is better,

○ bottom right: they both fail (achieving a 0 F1).

The generator retains the ranking predictions without any modifications for most of the time. For 4.7% and 8.9% of the questions from GrailQA and WebQSP, respectively, the generator is able to fix the top-ranked candidates and improves the performance. Although generator can make mistakes in non-negligible fraction of examples on WebQSP, it is mostly caused by introducing false constraints (e.g., Figure 7 (d)). Thanks to our execution-guided inference procedure, we can still turn back to ranker-predicted results when the generator makes mistakes, which allows tolerating generation errors to some extent.

We also show the break down by types of generalization on GrailQA (bottom row in Figure 6). Generation stage is more helpful in i.i.d. and compositional setting, but less effective in zero-shot setting, as it involves unseen relations that are usually hard to generate.

Executability We use executability to further measure the quality of generated outputs. Table 4 shows executable rate (producing an executable

Generation Better Than Ranking

(a) Q *what is the shortest recording by samuel ramey?*
R `(AND music.recording (JOIN recording.artist ramey))`
G `(ARGMIN (AND music.recording (JOIN recording.artist ramey)) recording.length)`

(b) Q *where did kevin love go to college?*
R `(JOIN education.institution (JOIN person.education love))`
G `(AND (JOIN topic.notable_types college) (JOIN edu.institution (JOIN person.education love)))`

Ranking Better Than Generation

(c) Q what song for tv or television did benny davis compose?
R `(AND tv.tv_song (JOIN composition.lyricist davis))`
G `(AND tv.tv_song (JOIN composition.song (JOIN composition.composer davis)))`

(d) Q what team does heskey play for?
R `(JOIN sports_team_roster.team (JOIN pro_athlete.teams heskey))`
G `(JOIN sports_team_roster.team (AND (JOIN sports_team_roster.from 2015) (JOIN pro_athlete.teams heskey)))`

Figure 7: Examples of outputs from the generator (G) and ranker (R). A generation step is able to compensate some missing operators not supported in the enumeration (a), or patch some implicit clue (b). However, generator does introduce errors if it produces another prediction when there is inherent ambiguity in the question and the top-ranked one is indeed correct (c). Generator also adds unnecessary constraint sometimes (d).

	GRAILQA		WEBQSP	
	EXEC	VALID	EXEC	VALID
Top-1	99.7	88.1	98.7	91.1
Top-3	99.7	89.4	99.5	94.5
Top-5	99.7	89.8	99.5	94.6
Top-10	99.7	90.4	99.5	95.4

Table 4: The chances of finding an executable (EXEC) and a valid (VALID) logical form among the top-k generated. logical forms.

logical forms) and valid rate (producing a logical form that yields non-empty answer) among the top-k decoded list. Nearly all the top-1 logical forms are executable. This suggests that the generation model can indeed produce high-quality predictions in terms of syntactic correctness and consistency with KB. As the beam size increases, more valid logical forms can be found in the top-k list, which our inference procedure can benefit from.

Output Examples of Ranking Model and Generation Model For more intuitive understanding of how the generator works, we attach several concrete examples (Figure 7). As suggested by example (a), the generation model can remedy some missing operations (*ARGMIN*) not supported when enumerating. It can also patch the top-ranked candidate with implicit constraints: the `(JOIN topic.notable_types college)` in (b) is not explicitly stated, and our NER system fails to recognize *college* as an entity.

As in example (c), the generation model makes a worse prediction sometimes because it prefers another prediction in the top-ranked list due to inherent ambiguity in the question. It can also fail when falsely adding a constraint which results in empty answer (d).

4 Related Work

KBQA is a promising technique for users to efficiently query over large KB, which has been extensively studied over the last decade. Past work has collected a series of datasets (Yih et al., 2016; Bordes et al., 2015; Zhang et al., 2018; Su et al., 2016; Gu et al., 2021) as well as proposed a diversity of approaches for this task.

One line of KBQA approaches first constructs a query-specific subgraph with information retrieved from the KB and then rank entity nodes to select top entities as the answer (Sun et al., 2018, 2019; Saxena et al., 2020; Cohen et al., 2020; Shi et al., 2021). The subgraph can either be retrieved in one-shot using heuristic rules (Sun et al., 2018), or iteratively built using learned models (Sun et al., 2019; Shi et al., 2021; Cohen et al., 2020; Saxena et al., 2020). Later, a neural model operating over subgraph is employed to determine the answer nodes (Sun et al., 2018, 2019; Shi et al., 2021). Such information retrieval based approaches are usually less interpretable as they do not produce the inference path reaching the answer, whereas our approach is more transparent since we are able to produce logical forms.

More closely related to our approach, another line answers a question by parsing it into an executable logical form in various representations, including lambda-DCS (Liang, 2013; Berant et al., 2013), sparql query (Das et al., 2021), graph query (Yih et al., 2015; Su et al., 2016; Lan and Jiang, 2020), and s-expression (Gu et al., 2021). Past work has attempted to generate logical forms using grammar-based parsera (Berant et al., 2013) or seq-to-seq parsers (Zhang et al., 2019). There has also been an alternative way that first enumerates a list of logical form candidates and then choose one that best matches the intents in the question (Lan and Jiang, 2020; Luo et al., 2018; Yih et al., 2015; Yavuz et al., 2016, 2017; Reddy et al., 2017; Sun et al., 2020). Our approach differs in that we employ a generation stage to remedy the coverage issue which these approaches often suffer from.

5 Conclusion

We have presented RNG-KBQA for question answering over knowledge base. RNG-KBQA consists of a ranking step and a generation step. Our ranker trained with iterative bootstrapping strategy can better distinguish correct logical forms from spurious ones than prior seq-to-seq ranker. Our generator can further remedy uncovered operations or implicitly mentioned constraints in the top-ranked logical forms. The experimental results on two datasets, GRAILQA and WEBQSP, suggest the strong performance of our approach: RNG-KBQA achieves new state-of-the-art performance on both datasets, and particularly outperforms prior methods in generalization setting by a large margin.

	Linking F1	KBQA F1
Bert Ranking (Gu et al., 2021)	72.2	58.0
ReTrack (Chen et al., 2021)	77.4	65.3
RnG-KBQA (Ours)	79.6	74.4
w/o Entity Disambiguation	72.2	67.4

Table 5: The entity linking F1 (on dev set) and the corresponding final F1 scores (on leaderboard) on GRAILQA of various methods.

A Details of Entity Linking Performance

Table 5 shows the entity linking performance and KBQA performance on GRAILQA of various methods. Compared to the popularity-based baseline (Bert Ranking), Our entity disambiguation model is effective and successfully improves the entity linking F1 by 7.4, which boosts the final KBQA F1 score by 7.0. Our entity linking model is also better than the Bootleg approach (Orr et al., 2021) used in ReTrack (Chen et al., 2021).

Furthermore, our method without the entity disambiguation modules outperforms Bert Ranking with a substantially large margin (11.4 F1 score). Our method even beats ReTrack when it is built upon a much better entity linking model. The results suggest the strong effectiveness of our rank-and-generate framework.

Rethinking Self-Supervision Objectives for Generalizable Coherence Modeling

Abstract

Given the claims of improved text generation quality across various pre-trained neural models, we consider the coherence evaluation of machine generated text to be one of the principal applications of coherence models that needs to be investigated. Prior work in neural coherence modeling has primarily focused on devising new architectures for solving the permuted document task. We instead use a basic model architecture and show significant improvements over state of the art within the same training regime. We then design a harder self-supervision objective by increasing the ratio of negative samples within a contrastive learning setup, and enhance the model further through automatic hard negative mining coupled with a large global negative queue encoded by a momentum encoder. We show empirically that increasing the density of negative samples improves the basic model, and using a global negative queue further improves and stabilizes the model while training with hard negative samples. We evaluate the coherence model on task-independent test sets that resemble real-world applications and show significant improvements in coherence evaluations of downstream tasks.[1]

1 Introduction

Coherence is a property of a well-written text that makes it different from a random set of sentences: sentences in a coherent text are connected in systematic ways such that each sentence follows naturally from previous ones and leads into the following ones (Halliday and Hasan, 1976; Grosz and Sidner, 1986). **Coherence models** (Barzilay and Lapata, 2005) that can distinguish a coherent text from incoherent ones have a wide range of applications in language generation, summarization, and coherence assessment tasks such as essay scoring and sentence ordering.

With recent advancements in neural methods, claims of fluency in summarization (Liu et al., 2017; Celikyilmaz et al., 2018), language modeling (Radford et al., 2019; Brown et al., 2020), response generation (Zhang et al., 2020; Hosseini-Asl et al., 2020) and human parity in machine translation (Hassan et al., 2018) have led to calls for finer-grained discourse-level evaluations (Läubli et al., 2018; Sharma et al., 2019; Popel et al., 2020), since traditional metrics such as BLEU and ROUGE are unable to measure text quality and readability (Paulus et al., 2018; Reiter, 2018). Coherence models that can evaluate machine-generated text have become the need of the hour.

A majority of coherence models proposed optimize their learning objectives on the permuted document task using the Penn Treebank (WSJ) corpus. An original article is considered a 'positive' sample of a coherent document, while a permutation of its sentences is considered a 'negative' or incoherent sample (see Appendix A.1 for an example). Models are usually trained in a *pairwise ranking* fashion to distinguish the two.

The basic entity-grid model proposed by Barzilay and Lapata (2005, 2008) was extended to incorporate entity-specific features (Elsner and Charniak, 2011), multiple ranks (Feng and Hirst, 2012), and coherence relations (Lin et al., 2011; Feng et al., 2014). Their neural extensions have also been proposed (Nguyen and Joty, 2017; Mohiuddin et al., 2018). More recent state-of-the-art models like the Transferable Neural model (Xu et al., 2019) consider coherence at a local level by training a forward and backward model only on adjacent sentences, in addition to generative pre-training of the sentence encoders. The Unified Coherence model (Moon et al., 2019) uses bi-linear layer and lightweight convolution-pooling in a Siamese framework to capture discourse relations and topic structures, along with an explicit language model loss to capture syntactic patterns.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 6044 - 6059
May 22-27, 2022

Mohiuddin et al. (2021) recently tested these state-of-the-art models by conducting coherence evaluations on the WSJ permuted document task, machine translation, summarization and next utterance ranking tasks. They found that while models performed well on the permuted document task, when tested off-the-shelf, models generalized poorly to downstream evaluation tasks. They call for more comprehensive evaluations of coherence models. Pishdad et al. (2020) also reached a similar conclusion. They retrained several neural coherence models for tasks analogous to coherence modeling such as detecting connective substitution and topic switching. They found that performance on the permuted document task is only partially indicative of coherence modeling capabilities.

In light of these recent findings, our aim is to propose a coherence model that generalizes well to downstream tasks. We train our model purely through *self-supervision*, without tailoring the model architecture specifically to the permuted document task or any other form of supervision.

Li and Jurafsky (2017) point out that coherence models are exposed to a limited number of incoherent samples in the *pairwise* setup, since only a small sample of all possible incoherent permutations of a document are used to train models. Learning with more negatives can better maximize the mutual information between their representations (van den Oord et al., 2018). By using a *contrastive learning* (Gutmann and Hyvärinen, 2010) setup, where each 'positive' document is compared with multiple 'negative' documents, we increase the proportion of negative samples that the model is exposed to, and show that the coherence model shows significant improvements in performance.

Wu et al. (2020) show that the difficulty of the negative samples used for contrastive training can strongly influence model success for visual representation learning. Guided by this principle, we train the model with automatically mined hard negatives, coupled with a large global negative queue encoded by a momentum encoder (He et al., 2019).

In summary, our contributions are:

- A neural coherence model trained purely through well-designed self-supervision tasks that generalizes well to downstream applications.
- Evaluation on multiple independent test sets that are more indicative of real-world performance of the coherence model.
- Empirical results demonstrating that increase in the density and quality of negative samples leads to better generalization for coherence models.

2 Datasets

To ensure that our coherence model is useful for evaluation in downstream applications, we use a selection of task-independent test sets that cover a variety of domains and genres, including machine generated text from summarization systems and language models. Following Pishdad et al. (2020), we also evaluate the models on a commonsense reasoning narrative dataset. We train (and validate) the coherence models on standard WSJ data, while using the rest as "independent" test sets to indicate the generalizability of the trained models. All evaluations on downstream tasks are conducted in a pairwise setting to enable a fair comparison.

2.1 Training Data

• **WSJ** The Wall Street Journal (WSJ) corpus consists of news articles divided into 1240/138/1053 documents for training/development/testing in the standard setup. We exclude documents with <4 sentences and truncate them to a maximum length of 600 tokens. To maximally utilize documents which are otherwise truncated due to GPU memory constraints, we partition documents with 20+ sentences into blocks of 10 sentences and consider each block as a separate positive document. This increases the number of coherent 'documents' that we can use to generate a larger training set. Moon et al. (2019) use 20 permutations of a document for training; since their setup is pairwise, it means the original positive document is repeated 20x. We regenerate the permuted documents similarly, sampling a larger set of permutations for our contrastive learning setup.[2] This gives us $46,522$ instances of positive and corresponding negative documents for training and $4,522$ instances for development. We use the original pairwise test set used by Moon et al. (2019) with $20,411$ pairs for testing.

2.2 Machine Generated Texts

• **SUMMEVAL** Fabbri et al. (2020) conduct a manual coherence evaluation of the summaries generated by 16 different summarization systems for

---

[2] We ensure that the generated permuted documents are not repeated. For example, our contrastive learning setup requires 5 negative samples per instance; because each positive document appears 20 times in the original dataset, 100 unique permutations would be generated and divided accordingly.

100 source articles based on the CNN/DailyMail (Hermann et al., 2015) dataset. Likert-style coherence ratings from 3 expert annotators are available for each summarized text. We adapt this to the pairwise setting by creating pairs of summaries from every system for each unique source article. The summary with the higher average coherence rating is designated as the positive document, while the summary with the lower rating is the negative document for that pair. This results in $\binom{16}{2} \times 100 = 12,000$ pairs for evaluation.

• **LMvLM** To cover a wider variety of machine generated text, we generated texts from various language models using prompts taken from the validation and test sets of the WritingPrompts dataset (Fan et al., 2018). Four language models were chosen for this purpose: GPT2-Small, GPT2-XL, CTRL and GPT3. The continuations produced by these models for each prompt were truncated at approximately 150 tokens and paired together. Using these texts, we conducted a user study on Amazon Mechanical Turk. Workers were instructed about the concept of coherence and shown examples of coherent and incoherent texts. Given the prompt, they were asked to choose the more coherent text out of two given language model outputs; they were also given an option to choose neither in case the texts were equally coherent/incoherent (see Appendix A.3 for more details such as the study interface). After removing the samples with low agreements and ties, a total of $1,046$ pairs with judgments from 3 annotators each were collected. The Krippendorff's alpha coefficient (Krippendorff, 2011) between the annotators was **0.84**. We calculate the agreements of the coherence model ranking with these judgments, designated LMvLM.

2.3 Curated Test Sets

• **INSTED** Shen et al. (2021) propose a sentence intrusion detection task in order to test the coherence modeling capabilities of pre-trained language models. Incoherent documents are created by substituting a sentence from a document with another sentence from a different document, ensuring that the replacement sentence is similar to the original document to make the task sufficiently hard. We adapt their task to the pairwise setting by pairing the original coherent and the corrupted incoherent document, giving us $7,168$ instances from their CNN test set (INSTED-CNN) and $3,666$ instances from their Wikipedia test set (INSTED-WIKI) for evaluation. Shen et al. (2021) also create a hand-crafted linguistic probe test set, where incoherence is manually inserted based on a range of linguistic phenomena; we use this test set for analysis (§4).

• **STORYCLOZE** The STORYCLOZE dataset (created from ROCSTORIES (Sharma et al., 2018)) consists of a short narrative-style text with two possible endings, one of which is implausible. The test set labels are not public so we use the validation set. We designate the text with the correct ending as the positive document and the text with the incorrect ending as the negative document, resulting in a total of $1,571$ pairs for evaluation.

3 Methodology

3.1 Model Architecture

Previous work on coherence modeling proposed elaborate architectures to capture various aspects of coherence (see §1). However, our key hypothesis is that large-scale pre-trained models are expressive enough to model coherence given the right self-supervision. Effective bi-directional encoding through large Transformer networks (Vaswani et al., 2017) can consider longer language context, while language modeling objectives enforce syntactic and local coherence patterns in the model.

In our work, we adopt XLNet (Yang et al., 2019) as the backbone model. It is trained using a permuted language modeling objective, in which the expected log-likelihood of a sequence with respect to all permutations of the factorization order is maximized. This allows the modeling of bi-directional context, while maintaining the auto-regressive property and avoiding the pretrain-finetune discrepancy. In addition, XLNet also incorporates segment recurrence (or memory) and the relative encoding scheme of Transformer-XL (Dai et al., 2019), which makes it effective in modeling longer text sequences. This makes it suitable for our purpose of coherence modeling.

Given a document $\mathcal{D}$ with n sentences $(s_1, s_2, \ldots, s_n)$ as input, our model uses the representations obtained through XLNet (parameterized by ϕ) to assign a coherence score to the model. Specifically, for each sentence s_i with k tokens $(w_1, w_2 \ldots w_k)$, XLNet maps each token w_t to its vector representation $v_t \in \mathbb{R}^d$ where d is the dimension of the embedding. In addition, the complete input $\mathcal{D}$ is also mapped to a document representation $\mathbf{z} \in \mathbb{R}^d$ (*i.e.*, the representation of the [CLS] token). We simply add a linear layer to convert document representation $\mathbf{z}$ to obtain the final coherence score: $f_\theta(\mathcal{D}) = \mathbf{w}^\top \mathbf{z} + b$, where $\mathbf{w}$ and b are the weight and bias of the linear layer with $\theta = \{\phi, \mathbf{w}, b\}$ being the entire parameter set of the model (see the upper part of Figure 1).

3.2 Margin-based Pairwise Ranking

Setup. Traditionally, coherence model training has been done in a pairwise ranking setup. In this setup, the model is trained to score the coherent or positive document higher than the incoherent or negative document, using a pairwise ranking loss (Collobert et al., 2011) defined as follows:

$$\mathcal{L}_\theta = \max\left(0, \tau - f_\theta(\mathcal{D}^+) + f_\theta(\mathcal{D}^-)\right) \qquad (1)$$

where $f_\theta(\mathcal{D}^+)$ is the coherence score of the positive document, $f_\theta(\mathcal{D}^-)$ is the coherence score of the negative document and τ is the margin.

Baselines. We compare our models against all three versions of the **L**ocal **C**oherence **D**iscriminator or LCD model (Xu et al., 2019)[3]: (*i*) LCD-G, that uses GloVe (Pennington et al., 2014) representations, (*ii*) LCD-I, that uses InferSent (Conneau et al., 2017) representations, and (*iii*) LCD-L, that uses representations from an RNN-based language model trained on the training data. We also compare against the **Uni**fied **C**oherence model or UNC (Moon et al., 2019)[4], which is the previous SOTA on the WSJ permuted document task. Results from evaluation of existing coherence models by Pishdad et al. (2020) and Mohiuddin et al. (2021) indicate that UNC and LCD are the best-performing models (see Appendix A.4 for a full comparison). We retrain their models with our training data for comparison. In addition, to ascertain the contribution of the pre-trained XLNet embeddings, we train our pairwise model without fine-tuning the representations, *i.e.,* only the score-producing linear layer weights $\mathbf{w}$ and b are trained on the pairwise ranking task.

Results. The results for the baseline models are given in Table 1 (see top five rows). We see that despite accuracies of more than 90% on the WSJ permuted document task, the LCD models perform only a little above a random baseline of 50% on most of the independent test sets, with LCD-G being the best generalizing model out of the three. Similarly, despite a relatively high performance on the WSJ test set (94.11%), UNC's performance on the independent test sets is quite poor, even failing to do better than the random baseline of 50% in two out of five cases. Both the LCD and UNC models have slightly better success on the INSteD-CNN dataset, which is the same domain (news) as the training data, with the UNC model reaching 67.21% accuracy. Our XLNet-Pairwise model trained without fine-tuning the representations (No FT) performs no better than the baseline models. This shows that both the LCD-G and the UNC models are in fact strong baselines despite using GloVe and ELMo (Peters et al., 2018) pre-trained representations respectively.

Our fully-trained XLNet-Pairwise model not only outperforms the UNC model on the standard WSJ permuted document task, but also significantly outperforms all baseline models on the independent test sets, showing an absolute improvement of 15-20% on the SUMMEVAL, INSTED-CNN, INSTED-WIKI and the STORYCLOZE datasets. On LMVLM, the UNC model has a better performance; we suspect that its explicit conditional language modeling loss might provide an additional advantage for this particular task. Overall, our results are consistent with observations from Mohiuddin et al. (2021) that show poor generalizability in the previous SOTA model.

3.3 Contrastive Learning

Setup. In pairwise ranking, each positive sample is only compared to one negative at a time. Contrastive learning (Gutmann and Hyvärinen, 2010) makes it general, where a single positive sample can be compared to multiple negatives, which can be particularly useful in the permuted document task where the number of possible incoherent samples per coherent document can be very large. The number of negatives considered and their quality can affect model performance (Arora et al., 2019). Wu et al. (2020) show that contrastive loss maximizes a lower bound on the mutual information between representations. A larger number of negatives increases the tightness of the bound; learning with more negatives can better maximise the mutual information. We train our model with a margin-based contrastive loss defined as:

$$\mathcal{L}_\theta = -\log\left(\frac{e^{f_\theta(\mathcal{D}^+)}}{e^{f_\theta(\mathcal{D}^+)} + \sum_{j=1}^{N} e^{(f_\theta(\mathcal{D}_j^-) - \tau)}}\right) \qquad (2)$$

Table 1: Results on the WSJ permuted document test set and the various independent test sets of LCD GloVe (LCD-G), LCD Infersent (LCD-I), LCD Language Model (LCD-L), UNC, and our XLNet based models. The XLNet representations are not fine-tuned during training for our Pairwise (No FT) model. Except for the LMvLM results which are reported in terms of Krippendorff's alpha agreement with human annotators, all other results are reported in terms of accuracy of the models in scoring the positive document higher than the negative document. All results are averaged over 5 runs with different seeds.

where $f_\theta(\mathcal{D}^+)$ is the coherence score of the positive document, $f_\theta(\mathcal{D}_1^-), \cdots, f_\theta(\mathcal{D}_N^-)$ are the scores of the N negative documents, and τ is the margin.

Training. We use the same training data as the baseline models to train our contrastive model; the positive documents remain the same, while we use 5 negative documents per instance (instead of only 1 in the pairwise setup). Effectively, the model sees the same number of positive or coherent documents, but five times as many negative samples during training compared to the pairwise setting. Appendix A.5 gives the full set of hyperparameters.

Results. From the results in Table 1, we see that the contrastive model (second to last row) further improves the results across all the independent test sets; the results on the LMvLM dataset also improve, surpassing the UNC model performance. Although the improvement on the WSJ permuted document task is small, the improvement in the generalizability of the model is more significant.

3.4 Hard Negative Mining

It has been shown that the difficulty of the negative samples used for contrastive training can strongly influence model success (Wu et al., 2020; Huang et al., 2020). We therefore automatically mine hard negatives during training. For the permuted document task, we can take advantage of the fact that the negative sample space can be huge; for a document with n sentences, the candidate pool of permutations has $n! - 1$ incoherent documents from which we can mine hard negatives. For the problem of dense text retrieval, Xiong et al. (2020) find *global* hard negatives by computing document encodings using a recent checkpoint to build an asynchronous index of the entire corpus, and sampling negative documents from the index. However, the huge candidate pool for permuted documents also makes it infeasible to mine global negatives in our case.

Instead, we perform *local* negative sample ranking. For each positive instance in the training data, we sample a larger number of permuted documents (h) per instance than we need for training (*i.e.,* $h > N$). We score these negative documents using the model updated thus far and use the highest ranking negatives for training. Specifically, the model is first trained with x instances (x is a hyperparameter) of data, by using 5 negative samples randomly chosen out of h. The updated model is then used to score all the h negative samples each for another set of x instances from the training data. The scores of the h negative samples are ranked and the top scoring 5 negative samples for each instance are used to train the model for the next x gradient steps. This process is repeated throughout training; the model therefore iteratively mines harder and harder negative samples as it improves. See Algorithm 1 in Appendix A.2 for the pseudocode.

In practice however, we find that using hard negative samples directly leads to instability in model training (see §4.1). We therefore use hard negative training in combination with a momentum encoder, which we describe in the next subsection.

3.5 Hard Negatives with Momentum Encoder

While increasing the number of negative samples per instance has been shown to be effective for constrastive learning, resource constraints can limit the number of negatives that can be considered per instance. One solution is to consider other positive instances in the same training batch as nega-

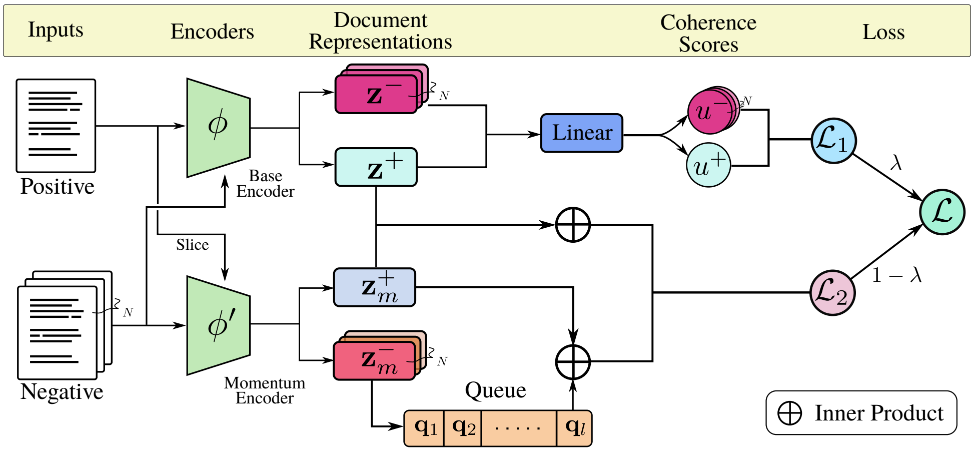

Figure 1: Our coherence model with the auxiliary momentum encoder. ϕ is our base encoder similar to our setup in §3.3, while ϕ' is our momentum encoder. $u^+ = f_\theta(\mathcal{D}^+)$ and $u^- = f_\theta(\mathcal{D}^-)$ are the coherence scores of the positive and negative documents respectively. Note that only the parameters of ϕ and the linear layer are updated through backpropagation.

tives (Karpukhin et al., 2020; Chen et al., 2020). However, it is not suitable for the permuted document task since the negatives are instance-specific. While a permuted document is still independently incoherent, training with permutations of other documents will not provide the same cues for coherence modeling as the original self-supervision.

Another solution is to maintain a large global queue of negative samples that are independent of the current training instance. During training, negative samples (specifically, their representations) from the latest batch are enqueued to build a queue upto some size l. As training continues, the negative samples from the oldest batch are dequeued to accommodate newer samples. However, representations of the documents will evolve through training as the model parameters get updated; this will make the negative samples in the queue inconsistent with each other and the training instances in the current batch. Moreover, the issue of mismatched self-supervision with negatives that are permuted versions of other documents still remains.

Momentum Encoder. To address these issues, we add an auxiliary momentum encoder (He et al., 2019), which is also XLNet (Yang et al., 2019). Figure 1 shows the overall architecture. Keeping the base contrastive setup the same (the upper part), we add an additional contrastive objective based on representations from the momentum encoder. Specifically, we re-encode the positive and negative samples through the momentum encoder; the negative samples thus encoded are used to build the queue. We train the model to promote the similarity between the positive representations from the momentum encoder and the positive representations from our base encoder over the similarity with the negative samples from the queue, $\boldsymbol{Q}$. Specifically, we define a momentum loss $\mathcal{L}_\theta^{\text{mom}}$ as:

$$c^+ = \frac{(\mathbf{z}^+)^\top(\mathbf{z}_m^+)}{||\mathbf{z}^+||\;||\mathbf{z}_m^+||};\quad c_j^- = \frac{(\mathbf{z}_m^+)^\top \mathbf{q}_j}{||\mathbf{z}_m^+||\;||\mathbf{q}_j||};$$
$$\mathcal{L}_\theta^{\text{mom}} = -\log\left(\frac{e^{c^+}}{e^{c^+} + \sum_{j=1}^{l} e^{(c_j^- - \tau)}}\right) \tag{3}$$

where $\mathbf{z}^+$ and $\mathbf{z}_m^+$ are the positive representations from the base encoder (ϕ) and the momentum encoder (ϕ') respectively, $\mathbf{q}_1, \ldots, \mathbf{q}_l$ indexed by j are the negative representations from ϕ' in the queue, and τ is the margin. The momentum encoder ϕ' is updated based on the base encoder ϕ as:

$$\phi' \leftarrow \mu * \phi' + (1-\mu) * \phi \tag{4}$$

where $\mu \in [0, 1)$ is the momentum coefficient; only ϕ is updated through backpropagation. Our full model is trained with a combination of the original contrastive objective (Eq. 2) and the momentum encoded contrastive similarity objective (Eq. 3):

$$\mathcal{L}_\theta = \lambda\mathcal{L}_\theta + (1-\lambda)\mathcal{L}_\theta^{\text{mom}} \tag{5}$$

where λ is a weighting hyperparameter. Note that the momentum encoder can be considered as a *temporal ensemble* model consisting of exponential-moving-average versions of the base model. Due to this, the gradients from the momentum loss (Eq. 3) also help in stabilising the overall training (§4).

Length Invariance. In the permuted document task, both the positive and the negative samples have the same number of sentences. This is not necessarily the case for downstream applications. To incorporate length invariance into our model, we encode a random contiguous slice of the positive document through the momentum encoder ϕ'.[5]

The global negatives queue $\boldsymbol{Q}$ is constructed from the mined hard negative samples used for training. Our model is therefore trained to rely not only on comparative coherence cues from the traditional permuted document setup, but also to recognize more independent cues for coherence through the global queue, which is additionally enhanced by incorporating length invariance and automatically mined hard negative samples.

Training. We train the model with the same training data, this time sampling $h = 50$ negatives[6] per instance for hard negative ranking, and setting the training steps (or instances) $x = 200$. We use a queue size of $l = 1000$ and set our momentum coefficient $\mu = 0.9999999$, with loss weighting parameter $\lambda = 0.85$. Due to GPU memory constraints (24GB, Quadro RTX 6000), we train our model with a batch size of 1. See Appendix A.5 for the full set of hyperparameters.

Results. The results in Table 1 (last row) show that our momentum encoder model with hard negative mining outperforms all previous models across the independent testsets. This improvement comes despite a very similar performance on the WSJ test set; we believe that our model truly improves in generalizability without overfitting to the permuted document task. The improvements on the out-of-domain test sets, particularly on LMvLM and StoryCloze, support this conclusion.

4 Analysis

4.1 Hard Negative Training

We only train our complete model (*i.e.,* base contrastive plus momentum model) by mining hard negative samples (§3.5), because we find that training the base contrastive model directly with hard negatives leads to instability during training. Figure 2a plots development set accuracies of our base model trained with and without hard negative mining, and our complete model trained with hard negative mining (evaluated every 1000 steps). As seen in the figure, the contrastive model displays significant volatility when trained with hard negatives only, while the complete model is quite stable. This is inline with the finding of Xuan et al. (2020) who show that training with the hardest negative samples leads to bad local minima. This can be explained with the gradient analysis of such negatives which have a larger gradient norm (Xiong et al., 2020), resulting in abrupt gradient steps. The momentum encoder being a temporal ensemble of the base models has a regularizing effect, addressing this issue and leading to stable and improved results (see §3.5).

4.2 Effects of Hyperparameters

Number of Ranked Negatives. Figure 2b shows the results across the test sets for different numbers of negative samples considered for ranking (h) during hard negative mining. We see that increasing the number of negatives considered improves results across the board, with results on out-of-domain test sets LMvLM and StoryCloze showing particular improvement.

Momentum Coefficient. Figure 2c shows the variation in the model performance across the test sets for different values of the momentum coefficient μ. We see that apart from a slight drop on the INSteD-Wiki dataset at $\mu = 0.9999999$, overall an increasing μ value leads to better generalization on the independent test sets, presumably due to a more consistent global negative queue.

Queue Size. Figure 2d shows the variation in model performance across different test sets for various sizes of the global negative queue $\boldsymbol{Q}$. We see that while increasing the queue size generally leads to an improvement in scores, at high queue sizes the improvement is limited to test sets from the same domain (WSJ, SummEval and INSteD-CNN), and the model's generalizability is affected.

4.3 Effects of Varying Task & Dataset

So far, we have reported the results of training our model on the permuted document task using documents from the WSJ corpus as was done by

---

[5] Minimum is 4 and maximum is full document.

[6] As previously described in §2, we ensure the sampled negative documents are unique even when the positive documents are repeated. This ensures that a much larger sample of the overall candidate pool is considered during training. Since we sample and rank 50 negative documents per positive instance, accounting for 20 repetitions of the positive documents, $20 * 50 = 1000$ total negative documents are considered for hard negative mining. This is 10 times larger than the contrastive setup (100 unique negatives) and 50 times larger than the pairwise setup (only 20 unique negatives).

(a)

(b)

(c)

(d)

Figure 2: (a) A plot of the development accuracy during training our contrastive model with and without hard negative mining, and our complete model with hard negative mining. The accuracies are evaluated after every 1000 gradient steps. (b) Results on the various test sets for our model trained with hard negative mining by sampling different number of negatives (h) for ranking. (c) Results on the various test sets for our complete model trained with different momentum coefficient (μ) values. (d) Results on the various test sets for our model trained with different global queue $\boldsymbol{Q}$ sizes. Please note that the agreement values for LMvLM test set have been scaled by a factor of 100 to facilitate visualization in figures (b), (c) and (d).

most prior work (Elsner and Charniak, 2011; Moon et al., 2019). We now test the effectiveness of other datasets, by varying the task itself and by using a different dataset for the permuted document task.

Sentence Intrusion. As described in §2.3, Shen et al. (2021) propose a sentence intrusion task to test coherence modeling capabilities of pre-trained language models. We adapt their dataset to the pairwise setting by pairing the original coherent document (positive) with the corrupted (negative) document; setting aside 10% of the data for development gives us 25,852 positive-negative training pairs for INSTED-CNN and 41,135 pairs for INSTED-WIKI. We train our pairwise (§3.2) model on this task. From the results in Table 2 (first two rows), we see that the performance on the same domain/task (as the training) and the performance on the LMVLM dataset is high, but the models trained on this task generalize poorly to the other independent test sets.

Permuted Document Task with INSTED. We train our model on the permuted document task using the INSTED datasets. We generate 52,607 and 66,679 positive-negative pairs for INSTED-CNN and INSTED-WIKI respectively by sampling permutations, similar to our training data (see §2.1), and train our pairwise model with this data. Specifically for machine generated texts, results in Table 2 show that the sentence intrusion task training does better on the LMVLM dataset. On the other hand, the permuted document task training does better on SUMMEVAL. This could be because the documents in SUMMEVAL are summaries of the same source article and therefore similar in content (detecting incoherence through permutations might help here), while the text generated by language models even for the same prompt tends to differ in content more significantly (detecting intruder sentences might help here). Additionally, the performance of our WSJ model on the INSTED-CNN

Train Dataset	Neg. Type	Model	WSJ	SUMMEVAL	LMVLM	INSTED-CNN	INSTED-WIKI	STORYCLOZE
INSTED-WIKI	Intrusion	Pairwise	$95.24_{\pm 0.37}$	$53.03_{\pm 1.49}$	$0.490_{\pm 0.01}$	$94.07_{\pm 0.29}$	$82.01_{\pm 0.24}$	$64.21_{\pm 1.98}$
INSTED-CNN	Intrusion	Pairwise	$95.48_{\pm 0.47}$	$57.85_{\pm 2.47}$	$0.502_{\pm 0.01}$	$97.83_{\pm 0.15}$	$73.52_{\pm 1.17}$	$71.75_{\pm 1.81}$
INSTED-WIKI	Permuted	Pairwise	$96.89_{\pm 0.23}$	$64.53_{\pm 0.82}$	$0.491_{\pm 0.01}$	$84.17_{\pm 1.50}$	$71.35_{\pm 0.88}$	$69.09_{\pm 2.29}$
INSTED-CNN	Permuted	Pairwise	$97.03_{\pm 0.12}$	$66.63_{\pm 0.97}$	$0.483_{\pm 0.01}$	$92.61_{\pm 0.62}$	$69.88_{\pm 0.64}$	$68.95_{\pm 1.02}$
WSJ	Permuted	Pairwise	$98.23_{\pm 0.20}$	$64.83_{\pm 1.03}$	$0.458_{\pm 0.02}$	$91.96_{\pm 1.09}$	$70.85_{\pm 1.85}$	$71.84_{\pm 2.33}$

Table 2: Results on the WSJ permuted document test set and other independent test sets of the pairwise model trained on different datasets. All results are averaged over 5 runs with different seeds.

Linguistic Probe	LCD	UNC	Our		Example
Pronoun Animacy Downgrade	87.0	76.0	100.0	✔	She→It was the mother of twins Lakshmana and Shatrughna.
Pronoun Animacy Upgrade	46.0	63.0	100.0	✔	It→She has been collected in two tankōbon volumes.
Pronoun Gender Flip	49.0	55.0	100.0	✔	She→He is also well known for her→his role as Mary, the mother of Jesus.
Past to Future Flip	68.0	86.0	96.0	✘	The Danes finished→will finish first in the 2014 World Junior Hockey Championship.
Single Determiner Flip	57.9	62.1	83.2	✘	In 1969, he was again sold, this→these time to the Milwaukee Bucks.
Number	56.0	58.0	80.0	✘	He had a career record of 67→6.7 wins and 62→-6.2 losses.
Conjunction Flip	54.0	55.0	78.0	✘	The school was founded in 1908, and→but has been a non-profit organization since 1956.
Negation	46.0	60.0	78.0	✘	He was not named as the Australian squad captain and was not captain of the Wallabies.

Table 3: Accuracies of the best performing LCD-G, UNC and our full model on the hand-crafted linguistic probe dataset constructed by Shen et al. (2021). Examples (abridged for brevity) shown indicate the manual changes made to make the text incoherent; the original words are shown in blue while the modified/added words are shown in red. Checks (✔) indicate our model correctly scored the coherent text higher for that example, while crosses (✘) indicate that our model failed to do so.

and INSTED-WIKI datasets is comparable to the performance of the respective in-domain pairwise models, while outperforming both the other models on the STORYCLOZE dataset. Overall, the model trained on the WSJ permuted document task generalizes well.

4.4 Linguistic Probe Analysis

Shen et al. (2021) create 8 hand-crafted linguistic probe test sets by manually modifying words in coherent texts based on various linguistic phenomena, ensuring the incoherent text produced as a result remains syntactically correct. Except for the words targeted by the probe, the rest of the text remains identical. Each test set has 100 samples each.[7]

We evaluate the best performing LCD-G, UNC and our full models on these test sets. The results are shown in Table 3 along with some examples from the dataset. The LCD-G model has mixed success across the test sets. The UNC model has the most success with the tense agreement test set and is moderately successful on the pronoun test sets. We see that our model has perfect accuracy on all pronoun-related test sets and near-perfect accuracy on the tense agreement test set. This shows that our model is indeed capturing the discourse-level phenomena that constitute coherence. Where our model falters is in cases which may require commonsense knowledge, such as identifying that *6.7 wins* is not possible. Overall, our model is quite successful in detecting several kinds of incoherence.

5 Conclusion

We show empirically that increasing the ratio and quality of negative samples improves the generalizability of the coherence model. We also test our model on a wide-ranging collection of independent test sets that resemble downstream applications, including machine generated text, on which our model significantly outperforms the previous SOTA model. Our work thus also sets a new evaluation standard for future research in coherence modeling. We open source our code base to encourage research in a new paradigm of coherence modeling.

Acknowledgements

We would like to thank the Senior Area Chairs of ACL 2022 for evaluating our paper on its merits, and the reviewers and meta-reviewer of ARR for their reviews. We would also like to thank our colleagues Mathieu Ravaut and Han Cheol Moon for their valuable inputs.

[7] Except for Single Determiner Flip, which has 95.

Ethics Statement

Data

A description of the data pre-processing is provided in §2.1. Datasets that we created will be open-sourced. In the case of the WSJ dataset, the data is licensed for use only to members by the Linguistic Data Consortium. Consequently, we only release scripts to generate the data we use and not the data itself. We highlight however that the permuted document self-supervision task that we train on is independent of the dataset used and the task can be reproduced on any other corpus; see also §4.3. All other datasets we use are licensed freely for academic use.

Annotation of LMvLM Dataset

We conduct a user study to collect pairwise coherence judgments on our language model output dataset. As part of our crowd-sourced user study on Amazon Mechanical Turk to collect these coherence judgements, we do not collect any personal information from the participants. Based on the average time spent to perform the tasks, participants were paid the equivalent of 16 USD per hour for their work. The annotation instructions and interface provided to the participants are included in Appendix A.3.

One potential issue is that the language model output that we generate from prompts may lead to malicious text generation by the models. We flagged the task to warn the workers that there may be potentially offensive content, and manually checked the final dataset post curation.

Applicability Across Languages

All our experiments are conducted using data for the English language. However, as coherence and discourse relations in text are a universal concept, and our training data is automatically generated, we expect the permuted document task to be easily extensible to other languages.

A Appendix

A.1 WSJ Permuted Document Task

The examples for the permuted document task on the WSJ data are shown in Table 5.

A.2 Hard Negative Ranking Pseudocode

The pseudocode for our hard negative mining through local sample ranking is given in Algorithm 1.

A.3 LMvLM User Study

The instructions and the interface provided to the workers in the user study comparing pairs of language model outputs is given in Figure 3. Workers were restricted to the native English speaking regions of Canada, United Kingdom and the United States and could only participate in our task if they had completed $> 10,000$ HITs with a $> 98\%$ acceptance rate. Each task was estimated to take 2 minutes, and workers were paid the equivalent of 16 USD per hour.

A.4 Comparison of Existing State-of-The-Art Coherence Models

We report the results obtained by Pishdad et al. (2020) and Mohiuddin et al. (2021) on their evaluation tasks for SOTA neural coherence models in Table 6.

A.5 Hyperparameters

The hyperparameters used in our experiments are given in Table 4.

Parameters	Values
Margin-based Pairwise Ranking (without XLnet fine-tuning)	
- margin	0.1
- optimizer	AdamW
- scheduler	SWALR
- learning rate	5e-6
- annealed to	1e-6
- anneal rate	5000 steps
- batch-size	1
- XLNet model	base
- dimension size	768

Original Document

(S1) Judy and I were in our back yard when the lawn started rolling like ocean waves.
(S2) We ran into the house to get Mame, but the next tremor threw me in the air and bounced me as I tried to get to my feet.
(S3) We are all fine here, although Mame was extremely freaked.
(S4) Books and tapes all over my room.
(S5) Not one thing in the house is where it is supposed to be, but the structure is fine.

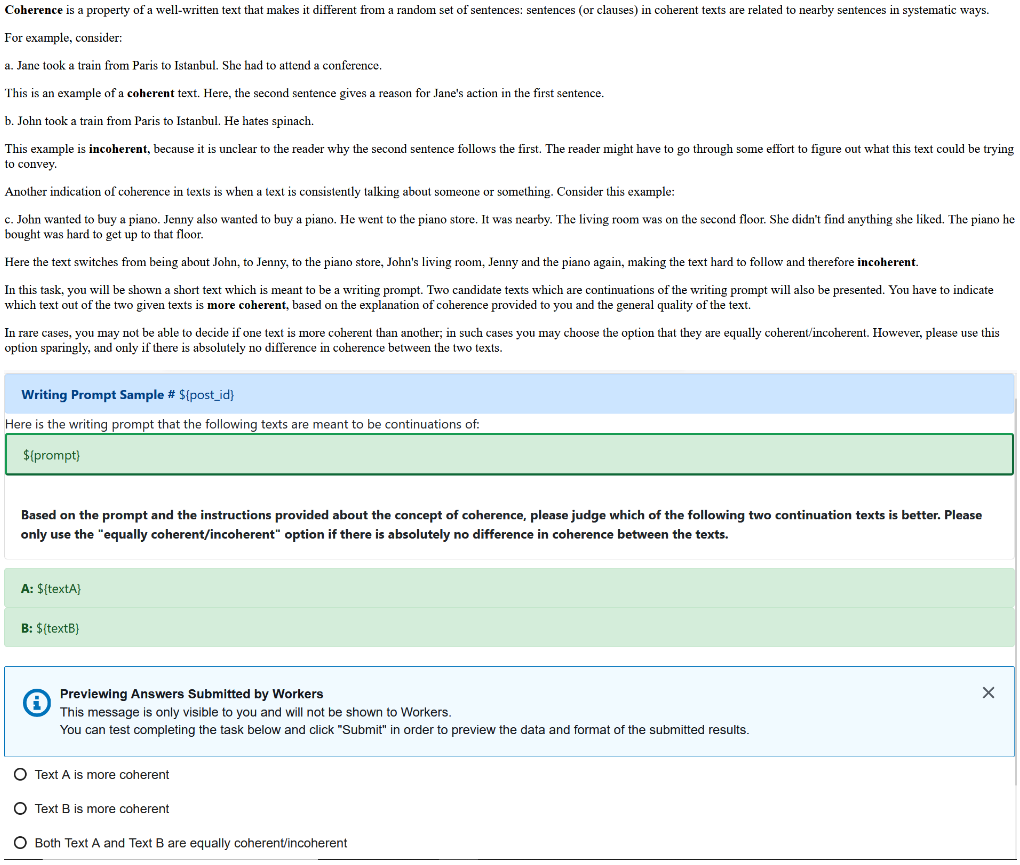
Permuted Document

(S4) Books and tapes all over my room.
(S3) We are all fine here, although Mame was extremely freaked.
(S2) We ran into the house to get Mame, but the next tremor threw me in the air and bounced me as I tried to get to my feet.
(S5) Not one thing in the house is where it is supposed to be, but the structure is fine.
(S1) Judy and I were in our back yard when the lawn started rolling like ocean waves.

Table 5: Examples showing the original coherent document and the incoherent document created by permuting the sentences of the original. Text taken from WSJ-1778.

Algorithm 1 Local Negative Sample Ranking

```
Require: Training data $D$ in which each instance consists of a positive document and $h$ negative
    documents, model $\theta$
Initialize empty hard negative array $\hat{D}^-$ for each instance $\in D$
procedure HARDNEGATIVERANKING($\theta, D$)
    Partition the dataset into sets of $x$ instances $D_1 \dots D_r$
    for $i = 1 \dots r$ do
        if i==0 then                                        ▷ No hard negatives for first iteration
            for $j = 1 \dots x$ do
                Randomly sample $N$ negatives from $D^-_{(i,j)}$ and store in $\hat{D}^-_{(i,j)}$
        Train $\theta$ with $(D^+_i, \hat{D}^-_i)$
        for $j = 1 \dots x$ do
            Score all the $h$ negative documents in $D^-_{(i+1,j)}$
            Sort $D^-_{(i+1,j)}$ in descending order of scores
            Get $N$ top scoring negative documents and store in $\hat{D}^-_{(i+1,j)}$
                                                            ▷ Store hard negatives for the next iteration
```



Coherence is a property of a well-written text that makes it different from a random set of sentences: sentences (or clauses) in coherent texts are related to nearby sentences in systematic ways.

For example, consider:

a. Jane took a train from Paris to Istanbul. She had to attend a conference.

This is an example of a **coherent** text. Here, the second sentence gives a reason for Jane's action in the first sentence.

b. John took a train from Paris to Istanbul. He hates spinach.

This example is **incoherent**, because it is unclear to the reader why the second sentence follows the first. The reader might have to go through some effort to figure out what this text could be trying to convey.

Another indication of coherence in texts is when a text is consistently talking about someone or something. Consider this example:

c. John wanted to buy a piano. Jenny also wanted to buy a piano. He went to the piano store. It was nearby. The living room was on the second floor. She didn't find anything she liked. The piano he bought was hard to get up to that floor.

Here the text switches from being about John, to Jenny, to the piano store, John's living room, Jenny and the piano again, making the text hard to follow and therefore **incoherent**.

In this task, you will be shown a short text which is meant to be a writing prompt. Two candidate texts which are continuations of the writing prompt will also be presented. You have to indicate which text out of the two given texts is **more coherent**, based on the explanation of coherence provided to you and the general quality of the text.

In rare cases, you may not be able to decide if one text is more coherent than another; in such cases you may choose the option that they are equally coherent/incoherent. However, please use this option sparingly, and only if there is absolutely no difference in coherence between the two texts.

Writing Prompt Sample # ${post_id}

Here is the writing prompt that the following texts are meant to be continuations of:

${prompt}

Based on the prompt and the instructions provided about the concept of coherence, please judge which of the following two continuation texts is better. Please only use the "equally coherent/incoherent" option if there is absolutely no difference in coherence between the texts.

A: ${textA}

B: ${textB}

Previewing Answers Submitted by Workers
This message is only visible to you and will not be shown to Workers.
You can test completing the task below and click "Submit" in order to preview the data and format of the submitted results.

○ Text A is more coherent

○ Text B is more coherent

○ Both Text A and Text B are equally coherent/incoherent

Abstract

Word and sentence embeddings are useful feature representations in natural language processing. However, intrinsic evaluation for embeddings lags far behind, and there has been no significant update since the past decade. Word and sentence similarity tasks have become the *de facto* evaluation method. It leads models to overfit to such evaluations, negatively impacting embedding models' development. This paper first points out the problems using semantic similarity as the gold standard for word and sentence embedding evaluations. Further, we propose a new intrinsic evaluation method called *EvalRank*, which shows a much stronger correlation with downstream tasks. Extensive experiments are conducted based on 60+ models and popular datasets to certify our judgments. Finally, the practical evaluation toolkit is released for future benchmarking purposes.[1]

1 Introduction

Distributed representation of words (Bengio et al., 2003; Mikolov et al., 2013a; Pennington et al., 2014; Bojanowski et al., 2017) and sentences (Kiros et al., 2015; Conneau et al., 2017; Reimers and Gurevych, 2019; Gao et al., 2021) have shown to be extremely useful in transfer learning to many NLP tasks. Therefore, it plays an essential role in how we evaluate the quality of embedding models. Among many evaluation methods, the word and sentence similarity task gradually becomes the de facto intrinsic evaluation method.

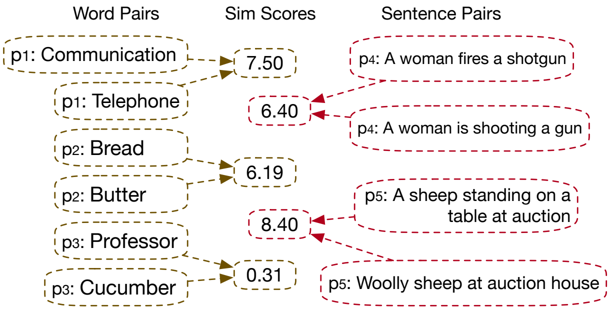

Figure 1: Word and sentence pairs with human-annotated similarity scores from WS-353 and STS-B datasets (scaled to range 0 (lowest) to 10 (highest)).

Figure 1 shows examples from word and sentence similarity datasets. In general, the datasets consist of pairs of words (w_1, w_2) (or sentences) and human-annotated similarity scores S_h. To evaluate an embedding model $\phi(\cdot)$, we first extract embeddings for (w_1, w_2): $(\mathbf{e}_1, \mathbf{e}_2) = (\phi(w_1), \phi(w_2))$. Then, a similarity measure is applied to compute an predicted score $S_p = sim(\mathbf{e}_1, \mathbf{e}_2)$, where cosine similarity is adopted as sim unquestionably in the majority of cases. Finally, the correlation between S_h and S_p is computed, and a higher correlation suggests good alignment with human annotations and a better embedding model.

Many studies, especially those targeting on information retrieval via semantic search and clustering (Reimers and Gurevych, 2019; Su et al., 2021), have used the similarity task as the only or main evaluate method (Tissier et al., 2017; Mu et al., 2018; Arora et al., 2017; Li et al., 2020; Gao et al., 2021). We observe a number of issues in word or sentence similarity tasks ranging from dataset collection to the evaluation paradigm, and consider that focusing too much on similarity tasks would negatively impact the development of future embedding models.

The significant concerns are summarized as follows, which generally apply to both word and sentence similarity tasks. First, the definition of similarity is too vague. There exist complicated relationships between sampled data pairs, and almost all relations contribute to the similarity score, which is challenging to non-expert annotators. Second, the similarity evaluation tasks are not directly

relevant to the downstream tasks. We believe it is because of the data discrepancy between them, and the properties evaluated by similarity tasks are not the ones important to downstream applications. Third, the evaluation paradigm can be tricked with simple post-processing methods, making it unfair to benchmark different models.

Inspired by Spreading-Activation Theory (Collins and Loftus, 1975), we propose to evaluate embedding models as a retrieval task, and name it as *EvalRank* to address the above issues. While similarity tasks measure the distance between similarity pairs from all similarity levels, *EvalRank* only considers highly similar pairs from a local perspective.

Our main contributions can be summarized as follows:

1 We point out three significant problems for using word and sentence similarity tasks as the de facto evaluation method through analysis or experimental verification. The study provides valuable insights into embeddings evaluation methods.

2 We propose a new intrinsic evaluation method, *EvalRank*, that aligns better with the properties required by various downstream tasks.

3 We conduct extensive experiments with 60+ models and 10 downstream tasks to certify the effectiveness of our evaluation method. The practical evaluation toolkit is released for future benchmarking purposes.

2 Related Work

Word embedding has been studied extensively, and popular work (Mikolov et al., 2013a; Pennington et al., 2014; Bojanowski et al., 2017) are mainly built on the distributional hypothesis (Harris, 1954), where words that appear in the same context tend to share similar meanings. The early work on sentence embedding are either built upon word embedding (Arora et al., 2017; Rücklé et al., 2018; Almarwani et al., 2019) or follow the distributional hypothesis on a sentence level (Kiros et al., 2015; Hill et al., 2016; Logeswaran and Lee, 2018). Recent development of sentence embedding are incorporating quite different techniques including multi-task learning (Cer et al., 2018), supervised inference data (Conneau et al., 2017; Reimers and Gurevych, 2019), contrastive learning (Zhang et al., 2020; Carlsson et al., 2020; Yan et al., 2021; Gao et al., 2021) and pre-trained language models (Li et al., 2020; Wang and Kuo, 2020; Su et al., 2021). Nonetheless, even though different methods choose different evaluation tasks, similarity task is usually the shared task for benchmarking purposes.

Similarity task is originally proposed to mimic human's perception about the similarity level between word or sentence pairs. The first word similarity dataset was collected in 1965 (Rubenstein and Goodenough, 1965), which consists of 65 word pairs with human annotations. It has been a standard evaluation paradigm to use cosine similarity between vectors for computing the correlation with human judges (Agirre et al., 2009). Many studies raise concerns about such evaluation paradigm. Faruqui et al. (2016) and Wang et al. (2019b) points out some problems with word similarity tasks, including low correlation with downstream tasks and lack of task-specific similarity. Reimers et al. (2016), Eger et al. (2019) and Zhelezniak et al. (2019) states current evaluation paradigm for Semantic Textual Similarity (STS) tasks are not ideal. One most recent work (Abdalla et al., 2021) questions about the data collection process of STS datasets and creates a new semantic relatedness dataset (STR) by comparative annotations (Louviere and Woodworth, 1991).

There are also other intrinsic evaluation methods for word and sentence embedding evaluation, but eventually did not gain much popularity. Word analogy task is first proposed in (Mikolov et al., 2013a,c) to detect linguistic relations between pairs of word vectors. Zhu and de Melo (2020) recently expanded the analogy concept to sentence level. However, the analogy task is more heuristic and fragile as an evaluation method (Gladkova et al., 2016; Rogers et al., 2017). Recently, probing tasks have been proposed to measure intriguing properties of sentence embedding models without worrying much about practical applications (Zhu et al., 2018; Conneau et al., 2018; Barancíková and Bojar, 2019). Because of the lack of effective intrinsic evaluation methods, Reimers and Gurevych (2019) and Wang et al. (2021) seeks to include more domain-specific tasks for evaluation.

3 Problems with Similarity Tasks

In this work, we discuss the problems of similarity tasks both on word and sentence levels. They are highly similar from data collection to evaluation paradigm and are troubled by the same problems.

3.1 Multifaceted Relationships

First, the concept of similarity and relatedness are not well-defined. Similar pairs are related but not vise versa. Taking synonym, hypernym, and antonym relations as examples, the similarity rank should be “synonym > hypernym > antonym” while the relatedness rank should be “synonym > hypernym ≈ antonym”. This was not taken into consideration when constructing datasets. Agirre et al. (2009) intentionally split one word similarity dataset into similarity and relatedness subsets. However, we find that obtained subsets are erroneous towards polysemy, and the relatedness between pair (‘stock’, ‘egg’, 1.81) is much lower than pair (‘stock’, ‘oil’, 6.34). It is because only the ‘financial stock market’ is compared but not the ‘stock of supermarkets‘. Furthermore, relationships between samples are far more complicated than currently considered, which is a challenge to all current datasets.

Second, the annotation process is not intuitive to humans. The initial goal of the similarity task is to let the model mimic human perception. However, we found that the instructions on similarity levels are not well defined. For example, on STS 13∼16 datasets, annotators must label sentences that ‘share some details’ with a score of 2 and ‘on the same topic’ with a score of 1. According to priming effect theory, (Meyer and Schvaneveldt, 1971; Weingarten et al., 2016), humans are more familiar with ranking several candidate samples based on one pivot sample (priming stimulus). Therefore, a more ideal way of annotation is to give one pivot sample (e.g. ‘cup’) and rank candidates with different similarity levels (e.g. ‘trophy’, ‘tableware’, ‘food’, ‘article’, ‘cucumber’). In other words, it is more intuitive for human to compare (a,b) > (a,c) than (a,b) > (c,d) as far as similarity is concerned. However, in practice, it is hard to collect a set of candidates for each pivot sample, especially for sentences.

3.2 Weak Correlation with Downstream Tasks

In previous studies, it was found that the performance of similarity tasks shows little or negative correlation with the performance of downstream tasks (Faruqui et al., 2016; Wang et al., 2019b, 2021). An illustration is shown in Table 1a. We think there are two reasons behind 1) low testing corpus overlap and 2) mismatch of tested properties.

Score (rank)	STS-B	SST2	MR
GloVe	47.95 (4)	79.52 (6↓)	77.54 (5↓)
InferSent	70.94 (3)	83.91 (3)	77.61 (4↓)

BERT-avg	47.29 (5)	85.17 (2↑)	80.05 (2↑)
BERT-flow	71.76 (2)	80.67 (4↓)	77.01 (6↓)
BERT-whitening	71.79 (1)	80.23 (5↓)	77.96 (3↓)

(a)

Rank	cos	l_2
SBERT	1	2↓
SimCSE	2	1↑
BERT-avg	5	3↑
BERT-flow	4	4
BERT-whitening	3	5↓

(b)

Table 1: (a) Performance scores and rank of embedding models on STS-B, SST2, and MR tasks. (b) Performance rank of models on STS-B testset with *cos* and l_2 similarity metrics.

First, similarity datasets have their data source and are not necessarily close to the corpus of downstream tasks. For example, Baker et al. (2014) collect word pairs for verbs only while Luong et al. (2013) intentionally test on rare words. Also, for STS datasets, (Agirre et al., 2012) annotates on sentence pairs from paraphrases, video captions, and machine translations, which has limited overlap on downstream tasks like sentiment classification.

Second, the original goal for the similarity task is to mimic human perceptions. For example, STS datasets are originally proposed as a competition to find the most effective STS systems instead of a gold standard for generic sentence embedding evaluation. Some properties evaluated by similarity tasks are trivial to downstream tasks, and it is more important to test on mutually important ones. As examples in Figure 1, the similarity tasks inherently require the model to predict sim(p_1)>sim(p_2) and sim(p_5)>sim(p_4), which we believe are unnecessary for most downstream applications. Instead, similar pairs are more important than less similar pairs for downstream applications (Kekäläinen, 2005; Reimers et al., 2016). Therefore, it is enough for good embedding models to focus on gathering similar pairs together while keeping dissimilar ones far away to a certain threshold.

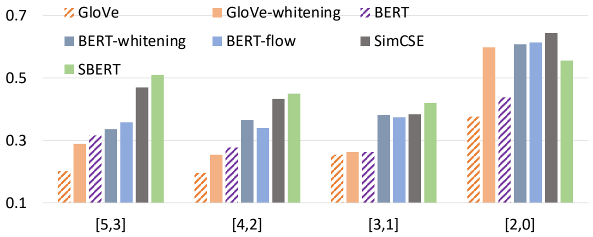

Figure 2: Performance of embedding models on the whole STS-Benchmark dataset w.r.t different similarity levels.

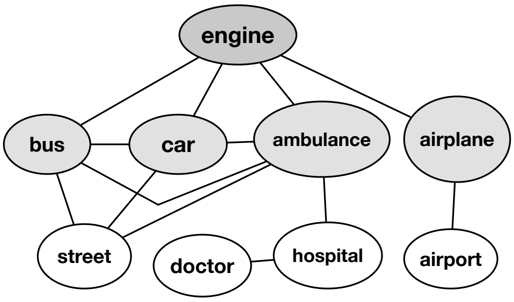

Figure 3: Example of Concept Network in SAT

3.3 Overfitting

As similarity tasks become one de facto evaluation method for embedding models, recent work tend to overfit the current evaluation paradigm, including the choice of similarity measure and the post-processing step.

Similarity Metrics. Cosine similarity is the default choice for similarity tasks. However, simply changing the similarity metric to other commonly used ones can lead to contradictory results.

In Table 1b, we compare recent five BERT-based sentence embedding models including BERT (Devlin et al., 2019), BERT-whitening (Su et al., 2021), BERT-flow (Li et al., 2020), SBERT (Reimers and Gurevych, 2019) and SimCSE (Gao et al., 2021).[2] The results on standard STS-Benchmark testset are reported under both cosine and l_2 similarity. As we can see, the performance rank differs under different similarity metrics. This is especially true for BERT-flow and BERT-whitening, which do not even outperform their baseline models when evaluating with l_2 metric. Therefore, we can infer that some models overfit to the default cosine metric for similarity tasks.

Whitening Tricks. A number of studies attempted the post-processing of word embeddings (Mu et al., 2018; Wang et al., 2019a; Liu et al., 2019b) and sentence embeddings (Arora et al., 2017; Liu et al., 2019a; Li et al., 2020; Su et al., 2021). The shared concept is to obtain a more isotropic embedding space (samples evenly distributed across directions) and can be summarized as a space whitening process. Even though the whitening tricks help a lot with similarity tasks, we found it is usually not applicable to downstream tasks or even hurt the model performance.[3] We think the whitening methods are overfitted to similarity tasks and would like to find the reasons behind.

First, we take the whole STS-Benchmark dataset and create subsets of sentence pairs from certain similarity levels. We test on two baseline sentence embedding models: GloVe, BERT; three whitening tricks: ABTT on GloVe (Mu et al., 2018), BERT-whitening, BERT-flow; two strong sentence embedding models that perform well on both STS and downstream tasks: SBERT, SimCSE. Figure 2 shows the result, and we can see that the whitening-based methods are boosting the baseline performance mainly for less similar pairs (e.g., pairs with a similarity score within [2,0]). In contrast, the models that perform well on downstream tasks show consistent improvement on all subsets with different similarity scores. As discussed in Section 3.2, highly similar pairs are more critical than less similar pairs for downstream tasks. Since the post-processing methods mainly help with less similar pairs, they do not help much on downstream tasks.

4 Evaluation by Ranking

4.1 Theory and Motivations

In cognitive psychology, Spreading-Activation Theory (SAT) (Collins and Loftus, 1975; Anderson, 1983) is to explain how concepts store and interact within the human brain. Figure 3 shows one example about the concept network. In the network, only highly related concepts are connected. To find the relatedness between concepts like *engine* and *street*, the activation is spreading through mediating concepts like *car* and *ambulance* with decaying factors. Under this theory, the similarity task is measuring the association between any two concepts in the network, which requires complicated long-distance activation propagation. Instead, to test the soundness of the concept network, it is enough to ensure the local connectivity between concepts. Moreover, the long-distance relationships can be inferred thereby with various spreading activation

Table 2: Statistics of *EvalRank* Datasets

algorithms (Cohen and Kjeldsen, 1987).

Therefore, we propose *EvalRank* to test only on highly related pairs and make sure they are topologically close in the embedding space. It also alleviates the problems of similarity tasks. First, instead of distinguishing multifaceted relationships, we only focus on highly related pairs, which are intuitive to human annotators. Second, it shows a much stronger correlation with downstream tasks as desired properties are measured. Third, as we treat the embedding space from a local perspective, it is less affected by the whitening methods.

4.2 Methodology

We frame the evaluation of embeddings as a retrieval task. To this purpose, the dataset of *EvalRank* contains two sets: 1) the positive pair set $P = \{p_1, p_2, ..., p_m\}$ and 2) the background sample set $C = \{c_1, c_2, ..., c_n\}$. Each positive pair $p_i = (c_x, c_y)$ in P consists of two samples in C that are semantically similar.

For each sample (c_x) and its positive correspondence (c_y), a good embedding model should has their embeddings ($\mathbf{e_x}$, $\mathbf{e_y}$) close in the embedding space. Meantime, the other background samples should locate farther away from the sample c_x. Some samples in the background may also be positive samples. We assume it barely happens and is negligible if good datasets are constructed.

Formally, given an embedding model $\phi(\cdot)$, the embeddings for all samples in C are computed as $\{\mathbf{e_1}, \mathbf{e_2}, ..., \mathbf{e_n}\} = \{\phi(c_1), \phi(c_2), ..., \phi(c_n)\}$. The *cos* similarity and l_2 similarity between two samples (c_x, c_y) are defined as:

$$S_{cos}(c_x, c_y) = \frac{\mathbf{e}_x^T \mathbf{e}_y}{||\mathbf{e}_x|| \cdot ||\mathbf{e}_y||}$$

$$S_{l_2}(c_x, c_y) = \frac{1}{1 + ||\mathbf{e}_x - \mathbf{e}_y||}$$

Further, the similarity score is used to sort all background samples in descending order and the performance at each positive pair p_i is measured by the rank of c_x's positive correspondence c_y w.r.t all background samples:

$$rank_i = rank(S(c_x, c_y), [||_{j=1, j \neq x}^{n} S(c_x, c_j)])$$

where || refers to the concatenation operation. To measure the overall performance of model $\phi(\cdot)$ on all positive pairs in P, the mean reciprocal rank (MRR) and Hits@k scores are reported and a higher score indicates a better embedding model:

$$MRR = \frac{1}{m} \sum_{i=1}^{m} \frac{1}{rank_i}$$

$$Hits@k = \frac{1}{m} \sum_{i=1}^{m} \mathbb{1}[rank_i \leq k]$$

Note that there are two similarity metrics, and we found that S_{cos} shows a better correlation with downstream tasks while S_{l_2} is more robust to whitening methods. We use S_{cos} in the experiments unless otherwise specified.

4.3 Dataset Collection

Word-Level. We collect the positive pairs from 13 word similarity datasets (Wang et al., 2019b). For each dataset, the pairs with the highest 25% similarity score are gathered as positive pairs. Background word samples contain all words that appear in the similarity datasets. Further, we augment the background word samples using the most frequent 20,000 words from Wikipedia corpus.

Sentence-Level. Similarly, the pairs with top 25% similarity/relatedness score from STS-Benchmark dataset (Cer et al., 2017) and STR dataset (Abdalla et al., 2021) are collected as positive pairs. All sentences that appear at least once are used as the background sentence samples.

In both cases, if positive pair (c_x, c_y) exists, the reversed pair (c_y, c_x) is also added as positive pairs. Detailed statistics of *EvalRank* datasets are listed in Table 2.

4.4 Alignment and Uniformity

Recently, Wang and Isola (2020) identifies the alignment and uniformity properties as an explanation to the success of contrastive loss. It shares many similarities with our method and can also shed light on why *EvalRank* works. First, the alignment property requires similar samples to have similar features, which aligns with the objective of

Table 3: Spearman's rank correlation ($\rho \times 100$) between performance scores of word-level intrinsic evaluation and downstream tasks, where the best is marked with **bold** and second best with underline.

EvalRank. Second, the uniformity property is measured by the average Gaussian distance between any two samples. In contrast, *EvalRank* focuses on the distance between points from a local perspective and would require the pivot sample to have longer distances to any background samples than its positive candidate. Measuring the distance from a local perspective has unique advantages because the learned embedding space will likely form a manifold and can only approximates euclidean space locally. Therefore, simple similarity metrics like cos or l_2 are not suitable to model long-distance relationships.

4.5 Good Intrinsic Evaluator

A good intrinsic evaluator can test the properties that semantically similar samples are close in vector space (Reimers and Gurevych, 2019; Gao et al., 2021) and serve as prompt information to real-world applications. As *EvalRank* directly test on the first property, we design experiments to show the correlation with various downstream tasks as a comparison of intrinsic evaluators. To be comprehensive, we first collect as many embedding models as possible and test them on the intrinsic evaluator and downstream task. The Spearman's rank correlation is computed between the results, and a higher score indicates better correlation with downstream tasks and better intrinsic evaluator.

Meantime, we do not think similarity evaluations should be discarded, even though it fails to correlate well with downstream applications. It has its advantages as aiming to mimic human perception about semantic-related pairs.

5 Word-Level Experiments

5.1 Experimental Setup

Word Embedding Models. We collect 19 word embedding models from GloVe (Pennington et al., 2014), word2vec (Mikolov et al., 2013b), fastText (Bojanowski et al., 2017), Dict2vec (Tissier et al., 2017) and PSL (Wieting et al., 2015). Meantime, we apply ABTT (Mu et al., 2018) post-processing to all models to double the total number of embedding models. When testing on downstream tasks, the simplest bag-of-words feature is used as sentence representations in order to focus on measuring the quality of word embeddings.

Word Similarity Tasks. 9 word similarity datasets are compared as the baseline methods including WS-353-All (Finkelstein et al., 2001), WS-353-Rel (Agirre et al., 2009), WS-353-Sim (Agirre et al., 2009), RW-STANFORD (Luong et al., 2013), MEN-TR-3K (Bruni et al., 2014), MTURK-287 (Radinsky et al., 2011), MTURK-771 (Halawi et al., 2012), SIMLEX-999 (Hill et al., 2015), SIMVERB-3500 (Gerz et al., 2016). The word similarity datasets with less than 200 pairs are not selected to avoid evaluation occasionality. Cosine similarity and Spearman's rank correlation are deployed for all similarity tasks.

Downstream Tasks. SentEval (Conneau and Kiela, 2018) is a popular toolkit in evaluating sentence embeddings. We use 9 downstream tasks from SentEval including MR (Pang and Lee, 2005), CR (Hu and Liu, 2004), MPQA (Wiebe et al., 2005), SUBJ (Pang and Lee, 2004), SST2 (Socher et al., 2013), SST5 (Socher et al., 2013), TREC (Li and Roth, 2002), MRPC (Dolan et al., 2004), SICK-E (Marelli et al., 2014). (b) Sentence-Level

Table 5: Benchmarking results on *EvalRank*. Performance is reported as % (×100).

that SentEval tasks are biased towards sentiment analysis (Wang et al., 2018). Therefore, we add one extra domain-specific classification task SCICITE (Cohan et al., 2019) which assigns intent labels (background information, method, result comparison) to sentences collected from scientific papers that cite other papers. For all tasks, a logistic regression classifier is used with cross-validation to predict the class labels.

5.2 Results and Analysis

Table 3 shows the word-level results. In short, *EvalRank* outperforms all word similarity datasets with a clear margin. For evaluation metrics, we can see that Hits@3 score shows a higher correlation than MRR and Hits@1 scores. However, the gap between the evaluation metrics is not big, which makes them all good measures. Among all 10 downstream tasks, *EvalRank* shows a strong correlation (ρ>0.6) with 7 tasks and a very strong correlation (ρ>0.8) with 5 tasks. While, among all word similarity datasets, only one dataset (RW-STANFORD) shows a strong correlation with one downstream task (SST2).

For word similarity datasets, RW-STANFORD dataset shows the best correlation with downstream tasks. It confirms the finding in Wang et al. (2019b) that this dataset contains more high-quality and low-frequency word pairs.

Ablation Study. We experiment with several variants of our *EvalRank* method and the result is shown in Table 4. First, if we do not augment the background word samples with the most frequent 20,000 words from the Wikipedia corpus, it leads to certain performance downgrading. Without sufficient background samples, positive pairs are not challenging enough to test each model's capability. Second, we tried to add more positive samples (e.g. 5k samples) using synonym relations from WordNet (WN) database (Miller, 1998). However, no obvious improvement is witnessed because the synonym pairs in WN contain too many noisy pairs. Last, for similarity measures, we notice that *cos* similarity is consistently better than l_2 similarity while both outperform word similarity baselines.

Benchmarking Results. In Table 5a, we compared four popular word embedding models, including GloVe, word2vec, fastText, and Dict2vec, where fastText achieves the best performance.

6 Sentence-Level Experiments

6.1 Experimental Setup

Sentence Embedding Models. We collect 67 embedding models, where 38 of them are built upon word embeddings with bag-of-words features and 29 of them are neural-network-based models. For neural-network-based models, we collect variants from InferSent (Conneau et al., 2017), BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2020), BERT-flow (Li et al., 2020), BERT-whitening (Su et al., 2021), SBERT (Reimers and Gurevych, 2019) and SimCSE (Gao et al., 2021).

Sentence Similarity Tasks. We evaluate on 7 standard semantic textual similarity datasets including STS12∼16 (Agirre et al., 2012, 2013, 2014, 2015, 2016), STS-Benchmark (Cer et al., 2017) and SICK-Relatedness (Marelli et al., 2014). Recently, Abdalla et al. (2021) questioned the labeling process of STS datasets and released a new semantic textual relatedness (STR) dataset, which is also included in our experiments.

Downstream Tasks. We use 7 classification tasks

		SCICITE	MR	CR	MPQA	SUBJ	SST2	SST5	TREC
STS12		32.96	38.62	44.77	31.52	21.76	33.79	35.68	30.79
STS13		22.04	32.62	41.23	12.39	7.64	26.45	22.98	12.16
STS14		25.91	34.77	41.89	19.23	10.13	29.20	26.82	17.70
STS15		31.84	40.64	48.11	25.12	16.48	35.50	33.30	24.70
STS16		29.56	40.14	51.66	14.35	16.53	33.61	29.44	21.43
STS-Benchmark		32.99	46.03	52.78	21.09	26.47	40.41	36.75	34.64
SICK-Relatedness		40.38	38.51	50.68	29.87	18.87	34.54	36.73	25.25
STR		-14.48	-8.38	-7.79	-29.57	-23.91	-16.33	-22.77	-14.30
EvalRank	MRR	<u>65.95</u>	83.43	<u>87.08</u>	<u>43.93</u>	<u>72.72</u>	<u>80.97</u>	<u>74.16</u>	<u>76.74</u>
	Hits@1	**69.01**	**85.39**	**89.36**	**45.81**	**74.93**	**82.65**	**76.65**	**78.72**
	Hits@3	63.35	<u>83.92</u>	85.43	41.24	70.98	80.36	72.05	74.70

Table 6: Spearman's rank correlation ($\rho \times 100$) between performance scores of sentence-level intrinsic evaluation and downstream tasks, where the best is marked with **bold** and second best with <u>underline</u>.

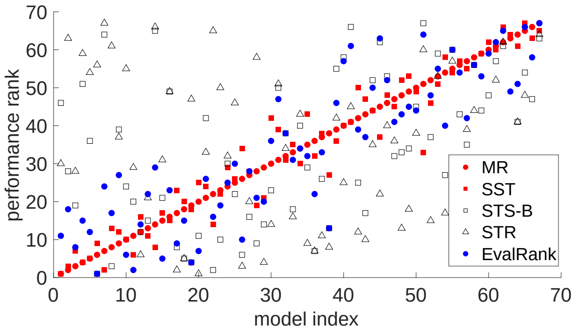

Figure 4: Visualization of models' performance rank on 2 downstream tasks and 3 intrinsic evaluation methods.

		SCICITE	MR	SST2
EvalRank (STS-B + STR)	MRR	65.95	83.43	80.97
	Hits@1	69.01	85.39	82.65
	Hits@3	63.35	83.92	80.36
EvalRank (STS-B)	MRR	63.05	75.85	72.87
	Hits@1	66.22	77.94	75.20
	Hits@3	61.23	75.49	72.92
EvalRank (STR)	MRR	63.51	83.28	80.20
	Hits@1	66.59	84.53	82.14
	Hits@3	60.68	82.55	79.42

Table 7: Performance under different data sources. Spearman's rank correlation ($\rho \times 100$) is reported.

from SentEval evaluation toolkit, including MR, CR, MPQA, SUBJ, SST2, SST5, TREC, as well as the domain-specific classification task SCICITE. We exclude the MRPC and SICK-E because they are highly similar with STS tasks (Conneau and Kiela, 2018).

6.2 Results and Analysis

Table 6 shows the sentence-level results. *EvalRank* outperform all sentence similarity datasets with a clear margin. For evaluation metric, Hits@1 shows a higher correlation comparing with MRR and Hits@3. Among all 7 downstream tasks, *EvalRank* shows strong correlation ($\rho > 0.6$) with 6 tasks.

For sentence similarity datasets, no one clearly outperforms others. Additionally, we found that STR dataset shows the worst correlation with downstream tasks. Even though STR adopts a better data annotation schema than STS datasets, it still follows the previous standard evaluation paradigm and is exposed to the same problems. It further verifies our discussion about problems with sentence similarity evaluation.

Correlation Visualization. Figure 4 shows the performance rank of 67 sentence embedding models on five tasks, including 2 downstream tasks (MR, SST2) and 3 intrinsic evaluations (STS-B, STR, *EvalRank*). The models' performance rank on the MR task is used as the pivot.

As MR and SST2 datasets are both related to sentiment analysis, they correlate well with each other. Among the three intrinsic evaluation tasks, *EvalRank* shows a higher correlation with downstream tasks as the blue dots roughly follow the trend of red dots. In contrast, the dots of STS-B and STR are dispersed in different regions. This shows that the performance of STS-B and STR is not a good indicator of the performance on downstream tasks.

Ablation Study. In Table 7, we show the performance of *EvalRank* with different data sources. By combining the positive pairs collected from both STS-B and STR datasets, *EvalRank* leads to the best performance. Interestingly, according to our results, even though STR evaluation does not correlate well with downstream tasks, the positive pairs collected from STR have better quality than STS-B. It also confirms the argument that STR improves the dataset collection process (Abdalla et al., 2021).

Benchmarking Results. Table 5b benchmarked seven popular sentence embedding models. As the widely accepted SOTA model, SimCSE outperforms others with a clear margin.

7 Conclusion

In this work, we first discuss the problems with current word and sentence similarity evaluations and proposed *EvalRank*, an effective intrinsic evaluation method for word and sentence embedding models. It shows a higher correlation with downstream tasks. We believe that our evaluation method can have a broader impact in developing future embedding evaluation methods, including but not limited to its multilingual and task-specific extensions.

A Embedding Models

A good intrinsic evaluator should be a good indicator for downstream tasks. We want to compute the correlation between the results from intrinsic evaluators and downstream tasks to measure the quality of intrinsic evaluators. For this purpose, we collect as many models as possible and finally involved 38 word embedding models and 67 sentence embedding models in our experiments. We give a detailed introduction to the collected embedding models in this section.

A complete set of selected word embedding models is shown in Table 8. We collect pre-trained word embeddings with different dimensions and training corpus from GloVe, word2vec, fastText, Dict2vec, and PSL. ABTT (Mu et al., 2018) post-processing is further applied to each model to double the total number of word embedding models.

A complete set of selected sentence embedding models is shown in Table 9. Besides the models obtained using bag-of-words features from word embeddings, we also include popular neural-network-based models including InferSent, BERT, RoBERTa, SBERT, BERT-whitening, BERT-flow, and SimCSE. Different variants of these models are considered in order to be more comprehensive.

B More Experimental Details

In Section 3, we conduct several experiments to certify our judgments, and we would like to elaborate on the detailed experiment settings here.

In Table 1b, the performance rank of five BERT-based sentence embedding models are shown under both cos and l_2 distance measure. Detailed model settings are shown below:

- **SBERT**: BERT-base model trained on Natural Language Inference data with mean token embeddings. `https://huggingface.co/sentence-transformers/bert-base-nli-mean-tokens`

- **SimCSE**: Unsupervised SimCSE trained upon BERT-based-uncased. `https://huggingface.co/princeton-nlp/unsup-simcse-bert-base-uncased`

- **BERT**: BERT-based uncased model `https://huggingface.co/bert-base-uncased`

- **BERT-flow**: We use the BERT-base-uncased and average the word representations from the first and last layers as the sentence representation. The Gaussian mapping is trained on the target corpus, which is the STS-B testset in our case.

- **BERT-whitening**: Similar to BERT-flow, the averaging of word representation from first and last layers are used as sentence representations, and the BERT-base-uncased model is used. The whitening objective is computed using the target corpus.

In Table 1a, 6 models are selected, and their performance on one similarity task: STS-B and two downstream tasks: MR and SST2 are reported. The setting of the models follows the experiments in Table 1b. For GloVe and InferSent, the following settings are used:

- **GloVe**: 300-dimensional vector trained on Common Crawl corpus (840B tokens).

- **InferSent**: Version 1 of InferSent is used where the GloVe model is served as input.

Figure 2 shows a detailed analysis on different similarity levels. For the experiment, we first collect all sentence pairs from STS-B dataset. Then, we split the pairs into four subsets based on their similarity levels ([5,3],[4,2],[3,1],[2,0]). Further, we randomly sampled 3,000 samples for each subset as the final dataset splits to keep the number of samples even.

C More Discussions

C.1 Effect of Whitening on Downstream Tasks

A lot whitening methods been proposed targeting on improving the quality of word embeddings (Mu et al., 2018; Wang et al., 2019a; Liu et al., 2019b) and sentence embeddings (Arora et al., 2017; Liu et al., 2019a; Li et al., 2020; Su et al., 2021). However, in previous studies, the whitening methods are only proven to be effective with similarity tasks. The performance comparison on downstream tasks is either missing or limited.

Therefore, we conduct extensive experiments on two popular post-processing methods. For word embedding, the ABTT (Mu et al., 2018) post-processing technique is examined. For sentence embedding, the Principal Component Removal (Arora et al., 2017) method is applied for word-embedding-based models and BERT-whitening (Su et al., 2021) or BERT-flow (Li et al., 2020) is applied to BERT-based models. Arora et al. (2017) propose a weighting schema and post-processing step for sentence embeddings. Here, we solely test the effectiveness of the post-processing step.

Table 10 shows the performance comparison between the original model and the post-processed model. From both word-level and sentence-level experiments, we conclude that the post-processing methods play no obvious role or even hurt the performance in downstream tasks. In contrast, the results on similarity tasks improve a lot.

C.2 Alignment and Uniformity

Wang and Isola (2020) discussed alignment and uniformity property as an explanation to the success of contrastive learning. *EvalRank* can be viewed as a variant of these two measures and focus more on the local perspective. Therefore, the success of *EvalRank* also can be explained under the same umbrella. Meantime, measuring from a local perspective is more suitable for word and sentence embedding models because they are likely to form a manifold and can only approximate euclidean space locally.

Alignment: In Wang and Isola (2020), the alignment loss is defined with the average distance between positive samples:

$$L_{align}(f;\alpha) = \mathbb{E}_{(x,y)\sim p_{pos}}[||f(x) - f(y)||_2^{\alpha}]$$

It measures the total distance between positive pairs, and the smaller, the better. The alignment measure does not consider the local properties of the embedding space. In contrast, *EvalRank* requires the positive pairs to be close in the embedding space while considering the density of the local embedding regions. If the density of embedding space around positive pairs is high, *EvalRank* method requires the embeddings of positive pairs to be more tightly closed. If the density of embedding space around positive pairs is low, *EvalRank* has a looser distance requirement for the positive pairs.

Uniformity: In Wang and Isola (2020), the uniformity loss is designed as the logarithm of the average pairwise Gaussian potential:

$$L_{uniform}(f;t) = \log \ \mathbb{E}_{(x,y\tilde{p}_{data})}[e^{-t||f(x)-f(y)||_2^2}]$$

Intuitive, the uniformity loss asks features to be far away from each other. In contrast, *EvalRank* score focus on a local perspective. It requires the negative samples to have larger embedding distances than positive samples concerning the pivot sample. For the negative samples that are far away from the pivot sample in the embedding space, they are less likely to be confusing with positive samples and, therefore, not considered as important.

C.3 Correlation Results without Post-Processing Models

In previous experiments, we select as many models as possible in order to be more comprehensive. However, the side effect is that a reasonable portion of the models is built with post-processing techniques. It may lead to some concern that our selected embedding models might be biased on post-processed models. Therefore, we re-do the experiments on sentence embedding evaluations without considering post-processed models.

We filter out all models related to post-processing techniques, and as a result, 34 sentence embedding models are kept. We further conduct correlation analysis between the performance on intrinsic evaluation methods and downstream tasks.

The result is shown in Table 11. As we can see, *EvalRank* still outperforms sentence similarity tasks in 7 of the tasks. And we can witness a higher correlation between *EvalRank* and the downstream tasks comparing with the results in Table 6. *EvalRank* shows strong correlation ($\rho > 0.6$) on all 8 tasks and very strong correlation ($\rho > 0.8$) on 7 of the tasks. The result again proves the effectiveness of *EvalRank*.

MarkupLM: Pre-training of Text and Markup Language for Visually Rich Document Understanding

Abstract

Multimodal pre-training with text, layout, and image has made significant progress for Visually Rich Document Understanding (VRDU), especially the fixed-layout documents such as scanned document images. While, there are still a large number of digital documents where the layout information is not fixed and needs to be interactively and dynamically rendered for visualization, making existing layout-based pre-training approaches not easy to apply. In this paper, we propose **MarkupLM** for document understanding tasks with markup languages as the backbone, such as HTML/XML-based documents, where text and markup information is jointly pre-trained. Experiment results show that the pre-trained MarkupLM significantly outperforms the existing strong baseline models on several document understanding tasks. The pre-trained model and code will be publicly available at `https://aka.ms/markuplm`.

1 Introduction

Multimodal pre-training with text, layout, and visual information has recently become the de facto approach (Xu et al., 2020, 2021a,b; Pramanik et al., 2020; Garncarek et al., 2021; Hong et al., 2021; Powalski et al., 2021; Wu et al., 2021; Li et al., 2021a,b; Appalaraju et al., 2021) in Visually-rich Document Understanding (VRDU) tasks. These multimodal models are usually pre-trained with the Transformer architecture (Vaswani et al., 2017) using large-scale unlabeled scanned document images (Lewis et al., 2006) or digital-born PDF files, followed by task-specific fine-tuning with relatively small-scale labeled training samples to achieve the state-of-the-art performance on a variety of document understanding tasks, including form understanding (Jaume et al., 2019; Xu et al., 2021b), receipt understanding (Huang et al., 2019; Park et al., 2019), complex document understanding (Graliński et al., 2020), document type classification (Harley et al., 2015), and document visual question answering (Mathew et al., 2021), etc. Significant progress has been witnessed not only in research tasks within academia, but also in different real-world business applications such as finance, insurance, and many others.

Visually rich documents can be generally divided into two categories. The first one is the fixed-layout documents such as scanned document images and digital-born PDF files, where the layout and style information is pre-rendered and independent of software, hardware, or operating system. This property makes existing layout-based pre-training approaches easily applicable to document understanding tasks. While, the second category is the markup-language-based documents such as HTML/XML, where the layout and style information needs to be interactively and dynamically rendered for visualization depending on the software, hardware, or operating system, which is shown in Figure 1. For markup-language-based documents, the 2D layout information does not exist in an explicit format but usually needs to be dynamically rendered for different devices, e.g., mobile/tablet/desktop, which makes current layout-based pre-trained models hard to apply. Therefore, it is indispensable to leverage the markup structure into document-level pre-training for downstream VRDU tasks.

To this end, we propose **MarkupLM** to jointly pre-train text and markup language in a single framework for markup-based VRDU tasks. Distinct from fixed-layout documents, markup-based documents provide another viewpoint for the document representation learning through markup structures because the 2D position information and document image information cannot be used straightforwardly during the pre-training. Instead, MarkupLM takes advantage of the tree-based markup

Figure 1: HTML-based webpages rendered by different platforms, such as mobile, tablet and desktop. (https://amzn.to/2ZZoi5R)

structures to model the relationship among different units within the document. Similar to other multimodal pre-trained layout-based models, MarkupLM has four input embedding layers: (1) a text embedding that represents the token sequence information; (2) an XPath embedding that represents the markup tag sequence information from the root node to the current node; (3) a 1D position embedding that represents the sequence order information; (4) a segment embedding for downstream tasks. The overall architecture of MarkupLM is shown in Figure 2. The XPath embedding layer can be considered as the replacement of 2D position embeddings compared with the LayoutLM model family (Xu et al., 2020, 2021a,b). To effectively pre-train the MarkupLM, we use three pre-training strategies. The first is the Masked Markup Language Modeling (MMLM), which is used to jointly learn the contextual information of text and markups. The second is the Node Relationship Prediction (NRP), where the relationships are defined according to the hierarchy from the markup trees. The third is the Title-Page Matching (TPM), where the content within "<title> ... </title>" is randomly replaced by a title from another page to make the model learn whether they are correlated. In this way, MarkupLM can better understand the contextual information through both the language and markup hierarchy perspectives. We evaluate the MarkupLM models on the Web-based Structural Reading Comprehension (WebSRC) dataset (Chen et al., 2021) and the Structured Web Data Extraction (SWDE) dataset (Hao et al., 2011). Experiment results show that the pre-trained MarkupLM significantly outperforms the several strong baseline models in these tasks.

The contributions of this paper are summarized as follows:

- We propose MarkupLM to address the document representation learning where the layout information is not fixed and needs to be dynamically rendered. For the first time, the text and markup information is pre-trained in a single framework for the VRDU tasks.

- MarkupLM integrates new input embedding layers and pre-training strategies, which have been confirmed effective on HTML-based downstream tasks.

- The pre-trained MarkupLM models and codes for fine-tuning will be publicly available at https://aka.ms/markuplm.

2 MarkupLM

MarkupLM utilizes the DOM tree in markup language and the XPath query language to obtain the markup streams along with natural texts in markup-language-based documents (Section 2.1). We propose this Transformer-based model with a new XPath embedding layer to accept the markup sequence inputs (Section 2.2) and pre-train it with three different-level objectives, including Masked Markup Language Modeling (MMLM), Node Relation Prediction (NRP), and Title-Page Matching (TPM) (Section 2.3).

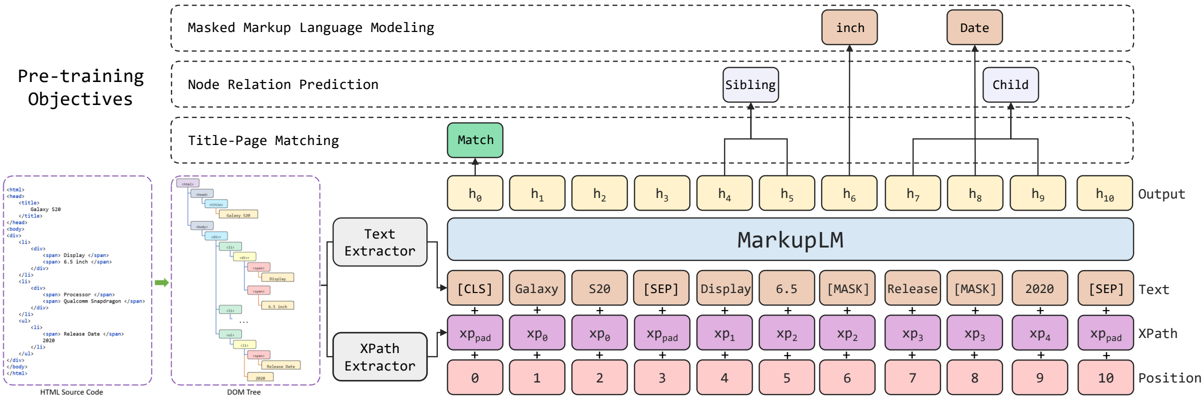

Figure 2: The architecture of MarkupLM, where the pre-training tasks are also included.

2.1 DOM Tree and XPath

A DOM[1] tree is the tree structure object of a markup-language-based document (*e.g.,* HTML or XML) in the view of DOM (Document Object Model) wherein each node is an object representing a part of the document.

XPath[2] (XML Path Language) is a query language for selecting nodes from a markup-language-based document, which is based on the DOM tree and can be used to easily locate a node in the document. In a typical XPath expression, like `/html/body/div/li[1]/div/span[2]`, the texts stand for the tag name of the nodes while the subscripts are the ordinals of a node when multiple nodes have the same tag name under a common parent node.

We show an example of DOM tree and XPath along with the corresponding source code in Figure 3, from which we can clearly identify the genealogy of all nodes within the document, as well as their XPath expressions.

2.2 Model Architecture

To take advantage of existing pre-trained models and adapt to markup-language-based tasks (*e.g.*, webpage tasks), we use the BERT (Devlin et al., 2019) architecture as the encoder backbone and add a new input embedding named **XPath embedding** to the original embedding layer. The overview structures of MarkupLM and the newly-proposed XPath Embedding are shown in Figure 2 and 4.

Figure 3: An example of DOM tree and XPath with the source HTML code.

XPath Embedding For the i-th input token x_i, we take its corresponding XPath expression and split it by "/" to get the node information at each level of the XPath as a list, $xp_i = [(t^i_0, s^i_0), (t^i_1, s^i_1), \cdots, (t^i_d, s^i_d)]$, where d is the depth of this XPath and (t^i_j, s^i_j) denotes the tag name and the subscript of the XPath unit on level j for x_i. Note that for units with no subscripts, we assign 0 to s^i_j. To facilitate further processing, we do truncation and padding on xp_i to unify their lengths as L.

The process of converting XPath expression into XPath embedding is shown in Figure 4. For (t^i_j, s^i_j), we input this pair into the j-th tag unit embedding table and j-th subscript unit embedding table respectively, and they are added up to get the j-th unit embedding ue^i_j. We set the dimensions of these two embeddings as d_u.

$$ue^i_j = \texttt{TagUnitEmb}_j(t^i_j) + \texttt{SubsUnitEmb}_j(s^i_j)$$

We concatenate all the unit embeddings to get the intermediate representation r_i of the complete XPath for x_i.

$$r_i = [ue^i_0; ue^i_1; \cdots; ue^i_L]$$

---

[1] https://en.wikipedia.org/wiki/Document_Object_Model

[2] https://en.wikipedia.org/wiki/XPath

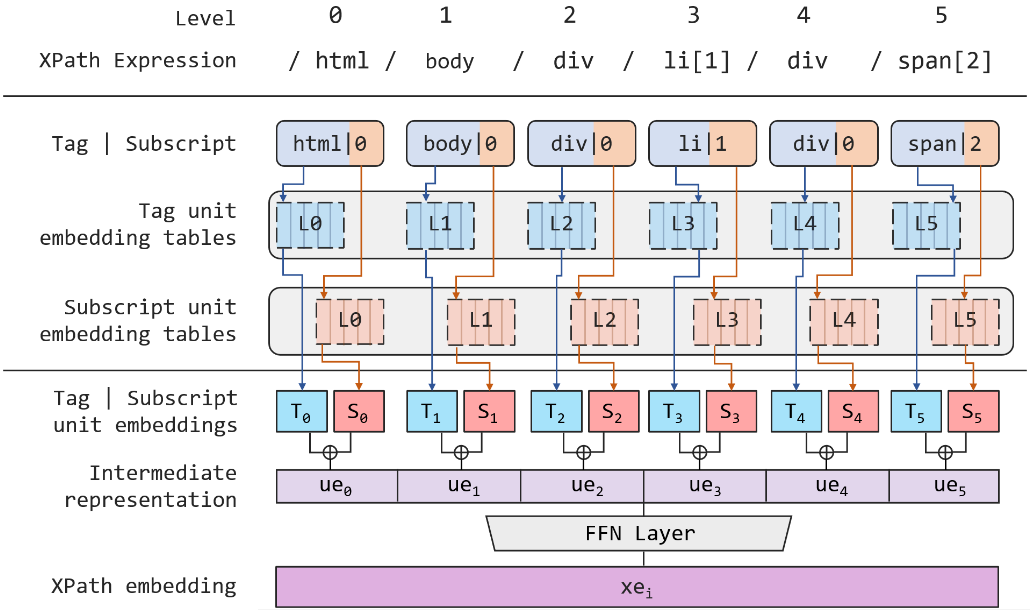

Figure 4: Overview of the XPath embedding from an XPath expression.

Finally, to match the dimension of other embeddings, we feed the intermediate representation r_i into an FFN layer to get the final XPath embedding xe_i.

$$
\begin{gathered}
xe_i = W_2[\mathrm{ReLU}(W_1 r_i + b_1)] + b_2, \\
W_1 \in \mathbb{R}^{4d_h \times L d_u}, b_1 \in \mathbb{R}^{4d_h}, \\
W_2 \in \mathbb{R}^{d_h \times 4d_h}, b_2 \in \mathbb{R}^{d_h}
\end{gathered}
$$

where d_h is the hidden size of MarkupLM. To simplify the converting process, we have also tried replacing the FFN layer with a single linear transformation. However, this tiny modification makes the training process much more unstable and slightly hurts the performance so we keep the original design.

2.3 Pre-training Objectives

To efficiently capture the complex structures of markup-language-based documents, we propose pre-training objectives on three different levels, including token-level (MMLM), node-level (NRP), and page-level (TPM).

Masked Markup Language Modeling Inspired by the previous works (Devlin et al., 2019; Xu et al., 2020, 2021a), we propose a token-level pre-training objective Masked Markup Language Modeling (MMLM), which is designed to enhance the language modeling ability with the markup clues. Basically, with the text and markup input sequences, we randomly select and replace some tokens with `[MASK]`, and this task requires the model to recover the masked tokens with all markup clues.

Node Relation Prediction Although the MMLM task can help the model improve the markup language modeling ability, the model is still not aware of the semantics of XPath information provided by the XPath embedding. With the naturally structural DOM tree, we propose a node-level pre-training objective Node Relation Prediction (NRP) to explicitly model the relationship between a pair of nodes. We firstly define a set of directed node relationships $R \in$ {`self`, `parent`, `child`, `sibling`, `ancestor`, `descendent`, `others`}. Then we combine each node to obtain the node pairs. For each pair of nodes, we assign the corresponding label according to the node relationship set, and the model is required to predict the assigned relationship labels with the features from the first token of each node.

Title-Page Matching Besides the fine-grained information provided by markups, the sentence-level or topic-level information can also be leveraged in markup-language-based documents. For HTML-based documents, the element `<title>` can be excellent summaries of the `<body>`, which provides a supervision for high-level semantics. To efficiently utilize this self-supervised information, we propose a page-level pre-training objective Title-Page Matching (TPM). Given the element `<body>` of a markup-based document, we randomly replace the text of element `<title>` and ask the model to predict if the title is replaced by using the representation of token `[CLS]` for binary classification.

2.4 Fine-tuning

We follow the scheme of common pre-trained language models (Devlin et al., 2019; Liu et al., 2019) and introduce the fine-tuning recipes on two downstream tasks including reading comprehension and information extraction.

For the reading comprehension task, we model it as an extractive QA task. The question and context are concatenated together as the input sequence, and slicing is required when its length exceeds a threshold. For tokens of questions, the corresponding XPath embeddings are the same as `[PAD]` token. We input the last hidden state of each token to a binary linear classification layer to get two scores for start and end positions, and make span predictions with these scores following the common practice in SQuAD (Rajpurkar et al., 2016).

For the information extraction task, we model it as a token classification task. We input the last hidden state of each token to a linear classification layer, which has $n + 1$ categories, where n is the number of attributes we need to extract and the extra category is for tokens that belong to none of these attributes.

3 Experiments

In this work, we apply our MarkupLM framework to HTML-based webpages, which is one of the most common markup language scenarios. Equipped with the existing webpage datasets Common Crawl (CC)[3], we pre-train MarkupLM with large-scale unlabeled HTML data and evaluate the pre-trained models on web-based structural reading comprehension and information extraction tasks.

3.1 Data

Common Crawl The Common Crawl (CC) dataset contains petabytes of webpages in the form of raw web page data, metadata extracts, and text extracts. We choose one of its snapshots[4], and use the pre-trained language detection model from `fasttext` (Joulin et al., 2017) to filter out non-English pages. Specifically, we only take the page when the model predicts it as English with the classifier score > 0.6 and discard all the others. Besides, we only keep the tags that may contain texts (*e.g.* `<div>`, `<span>`, `<li>`, `<a>`, etc.) and delete those with no texts (*e.g.,* `<script>`, `<style>`, etc.) in these pages to save storage space. After pre-processing, a subset of CC with 24M English webpages is extracted as our pre-training data for MarkupLM.

WebSRC The Web-based Structural Reading Comprehension (WebSRC) dataset (Chen et al., 2021) consists of 440K question-answer pairs, which are collected from 6.5K web pages with corresponding HTML source code, screenshots, and metadata. Each question in WebSRC requires a certain structural understanding of a webpage to answer, and the answer is either a text span on the web page or yes/no. After adding the additional yes/no tokens to the text input, WebSRC can be modeled as a typical extractive reading comprehension task. Following the original paper (Chen et al., 2021), we choose evaluation metrics for this dataset as **Exact match (EM)**, **F1 score (F1)**, and **Path overlap score (POS)**. We use the official split to get the training and development set. Note that the authors of WebSRC did not release their testing set, so all our results are obtained from the development set.

SWDE The Structured Web Data Extraction (SWDE) dataset (Hao et al., 2011) is a real-world webpage collection for automatic extraction of structured data from the Web. It involves 8 verticals, 80 websites (10 per vertical), and 124,291 webpages (200 - 2,000 per website) in total. The task is to extract the values corresponding to a set of given attributes (depending on which vertical the webpage belongs to) from a webpage, like value for *author* in *book* pages. Following previous works (Hao et al., 2011; Lin et al., 2020; Zhou et al., 2021), we choose **page-level F1 scores** as our evaluation metrics for this dataset.

Since there is no official train-test split, we follow previous works (Hao et al., 2011; Lin et al., 2020; Zhou et al., 2021) to do training and evaluation on each vertical (*i.e.*, category of websites) independently. In each vertical, we select k consecutive seed websites as the training data and use the remaining $10 - k$ websites as the testing set. Note that in this few-shot extraction task, none of the pages in the $10 - k$ websites have been visited in the training phase. This setting is abstracted from the real application scenario where only a small

Table 2: Comparing the extraction performance (F1 score) of five baseline models to our method MarkupLM using different numbers of seed sites $k = \{1, 2, 3, 4, 5\}$ on the SWDE dataset, the results are from (Zhou et al., 2021). Each value in the table is computed from the average over 8 verticals and 10 permutations of seed websites per vertical (80 experiments in total).

set of labeled data is provided for specific websites and we aim to infer the attributes on a much larger unseen website set. The final results are obtained by taking the average of all 8 verticals and all 10 permutations of seed websites per vertical, leading to 80 individual experiments for each k. For the pre- and post-processing of data, we follow Zhou et al. (2021) to make a fair comparison.

3.2 Settings

Pre-training The size of the selected tags and subscripts in XPath embedding are 216 and 1,001 respectively, the max depth of XPath expression (L) is 50, and the dimension for the tag-unit and subscript-unit embedding (d_u) is 32. The token-masked probability in MMLM and title-replaced probability in TPM are both 15%, and we do not mask the tokens in the input sequence corresponding to the webpage titles. The max number of selected node pairs is 1,000 in NRP for each sample, and we limit the ratio of pairs with `non-others` (*i.e.*, `self`, `parent`, $\cdots$) labels as 80% to make a balance. We initialize MarkupLM from RoBERTa and train it for 300K steps on 8 NVIDIA A100 GPUs. We set the total batch size as 256, the learning rate as 5e-5, and the warmup ratio as 0.06. The selected optimizer is AdamW (Loshchilov and Hutter, 2019), with $\epsilon = 1e-6$, $\beta_1 = 0.9$, $\beta_2 = 0.98$, `weight decay` $= 0.01$, and a linear decay learning rate scheduler with 6% warmup steps. We also apply `FP16`, `gradient-checkpointing` (Chen et al., 2016), and `deepspeed` (Rasley et al., 2020) to reduce GPU memory consumption and accelerate training.

Table 3: Evaluation results of MarkupLM (BASE on left and LARGE on right) on the SWDE dataset with different numbers of seed sites $k = \{1, 2, 3, 4, 5\}$ for training, Ver. stands for vertical while #Seed is the number of seed sites.

Fine-tuning For WebSRC, we fine-tune MarkupLM for 5 epochs with the total batch size of 64, the learning rate of 1e-5, and the warmup ratio of 0.1. For SWDE, we fine-tune MarkupLM with 10 epochs, the total batch size of 64, the learning rate of 2e-5, and the warmup ratio of 0.1. The max sequence length is set as 384 in both tasks, and we keep other hyper-parameters as default.

3.3 Results

The results for WebSRC are shown in Table 1. Selected baselines are T-PLM, H-PLM, and V-PLM in Chen et al. (2021), referring to the paper for more details. To make a fair comparison, we re-run the released baseline experiments with RoBERTa. We observe MarkupLM significantly surpass H-PLM which uses the same modality of information. This strongly indicates that MarkupLM makes better use of the XPath features with the specially designed embedding layer and pre-training objectives compared with merely adding more tag tokens into the input sequence as in H-PLM. Besides, MarkupLM also achieves a higher score than the previous state-of-the-art V-PLM model that requires a huge amount of external resources to render the HTML source codes and uses additional vision features from Faster R-CNN (Ren et al., 2015), showing that our render-free MarkupLM is more lightweight and can learn the structural information better even without any visual information. It is also worth noting that adding HTML tags as input tokens in H-PLM and V-PLM drastically increases the length of input strings, so more slicing operations are required to fit the length limitation of language models, which results in more training samples (∼860k) and longer training time, while MarkupLM does not suffer from this (only ∼470k training samples) and can greatly reduce training time.

The results for SWDE are in Table 2 and 3. It is observed that our MarkupLM also substantially outperforms the strong baselines. Different from the previous state-of-the-art model SimpDOM which explicitly sends the relationship between DOM tree nodes into their model and adds huge amounts of extra discrete features (*e.g.*, whether a node contains numbers or dates), MarkupLM is much simpler and is free from time-consuming additional webpage annotations. We also report detailed statistics with regard to different verticals in Table 3. With the growth of k, MarkupLM gets more webpages as the training set, so there is a clear ascending trend reflected by the scores. We also see the variance among different verticals since the number and type of pages are not the same.

3.4 Ablation Study

To investigate how each pre-training objective contributes to MarkupLM, we conduct an ablation study on WebSRC with a smaller training set containing 1M webpages. The model we initialized from is BERT-base-uncased in this sub-section with all the other settings unchanged. The results are in Table 4. According to the four results in #1, we see both of the newly-proposed training objectives improve the model performance substantially, and the proposed TPM (+4.6%EM) benefits the model more than NRP (+2.4%EM). Using both objectives together is more effective than using either one alone, leading to an increase of 5.3% on EM. We can also see a performance improvement (+1.9%EM) from #1d to #2a when replacing BERT with a stronger initial model RoBERTa. Finally, we get the best model with all three objectives and better initialization on larger data, as the comparison between #2a and #2b.

		Pre-training Data	Objectives			Metrics		
#	Initialization	Samples	MMLM	NRP	TPM	EM	F1	POS
1a	$\text{BERT}_{\text{BASE}}$	1M	✓			54.29	61.47	82.03
1b	$\text{BERT}_{\text{BASE}}$	1M	✓	✓		56.72	65.07	83.02
1c	$\text{BERT}_{\text{BASE}}$	1M	✓		✓	58.87	66.74	83.85

2a	$\text{RoBERTa}_{\text{BASE}}$	1M	✓	✓	✓	61.48	69.15	84.32
2b	$\text{RoBERTa}_{\text{BASE}}$	24M	✓	✓	✓	68.39	74.47	87.93

Table 4: Ablation study on the WebSRC dataset, where EM, F1 and POS scores on the development set are reported. "MMLM", "NRP" and "TPM“ stand for Masked Markup Language Model, Node Relation Prediction and Title Page Matching respectively. All these models, except #2b, are pre-trained with 200k steps and the same hyper-parameter settings described in Section 3.2.

4 Related Work

Multimodal pre-training with text, layout, and image information has significantly advanced the research of document AI, and it has been the de facto approach in a variety of VRDU tasks. Although great progress has been achieved for the fixed-layout document understanding tasks, the existing multimodal pre-training approaches cannot be easily applied to markup-based document understanding in a straightforward way, because the layout information of markup-based documents needs to be rendered dynamically and may be different depending on software and hardware. Therefore, the markup information is vital for the document understanding. Ashby and Weir (2020) compared the Text+Tags approach with their Text-Only equivalents over five web-based NER datasets, which indicates the necessity of markup enrichment of deep language models. Lin et al. (2020) presented a novel two-stage neural approach named FreeDOM. The first stage learns a representation for each DOM node in the page by combining both the text and markup information. The second stage captures longer range distance and semantic relatedness using a relational neural network. Experiments show that FreeDOM beats the previous SOTA results without requiring features over rendered pages or expensive hand-crafted features. Zhou et al. (2021) proposed a novel transferable method SimpDOM to tackle the problem by efficiently retrieving useful context for each node by leveraging the tree structure. Xie et al. (2021) introduced a framework called WebKE that extracts knowledge triples from semi-structured webpages by extending pre-trained language models to markup language and encoding layout semantics.

However, these methods did not fully leverage the large-scale unlabeled data and self-supervised pre-training techniques to enrich the document representation learning. To the best of our knowledge, MarkupLM is the first large-scale pre-trained model that jointly learns the text and markup language in a single framework for VRDU tasks.

5 Conclusion and Future Work

In this paper, we present MarkupLM, a simple yet effective pre-training approach for text and markup language. With the Transformer architecture, MarkupLM integrates different input embeddings including text embeddings, positional embeddings, and XPath embeddings. Furthermore, we also propose new pre-training objectives that are specially designed for understanding the markup language. We evaluate the pre-trained MarkupLM model on the WebSRC and SWDE datasets. Experiments show that MarkupLM significantly outperforms several SOTA baselines in these tasks.

For future research, we will investigate the MarkupLM pre-training with more data and more computation resources, as well as the language expansion. Furthermore, we will also pre-train MarkupLM models for digital-born PDFs and Office documents that use XML DOM as the backbones. In addition, we will also explore the relationship between MarkupLM and layout-based models (like LayoutLM) to deeply understand whether these two kinds of models can be pre-trained under a unified multi-view and multi-task setting and whether the knowledge from these two kinds of models can be transferred to each other to better understand the structural information.

CLIP Models are Few-shot Learners:
Empirical Studies on VQA and Visual Entailment

Abstract

CLIP has shown a remarkable zero-shot capability on a wide range of vision tasks. Previously, CLIP is only regarded as a powerful visual encoder. However, after being pre-trained by language supervision from a large amount of image-caption pairs, CLIP itself should also have acquired some few-shot abilities for vision-language tasks. In this work, we empirically show that CLIP can be a strong vision-language few-shot learner by leveraging the power of language. We first evaluate CLIP's zero-shot performance on a typical visual question answering task and demonstrate a zero-shot cross-modality transfer capability of CLIP on the visual entailment task. Then we propose a parameter-efficient fine-tuning strategy to boost the few-shot performance on the vqa task. We achieve competitive zero/few-shot results on the visual question answering and visual entailment tasks without introducing any additional pre-training procedure.

1 Introduction

Vision-language understanding (VLU) tasks, such as visual question answering (Antol et al., 2015) and visual entailment (Xie et al., 2019), test a system's ability to comprehensively understand the semantics of both visual world and natural language. To capture the alignment between vision and language, various efforts have been made to build the vision-language pre-trained models (Lu et al., 2019; Chen et al., 2020; Su et al., 2020; Zhang et al., 2021; Wang et al., 2021). Despite their superior performances, these methods have extensively utilized human-annotated training data that are expensive or require expert knowledge, such as object detection datasets (Lin et al., 2014; Kuznetsova et al., 2020) and aligned image-text pairs (Deng et al., 2009; Sharma et al., 2018). Collecting such datasets requires heavy work on data gathering and human annotation, and thus their scales are only in the realm of tens of millions, which are much smaller than the Internet text corpora for NLP pre-training (Devlin et al., 2019; Brown et al., 2020).

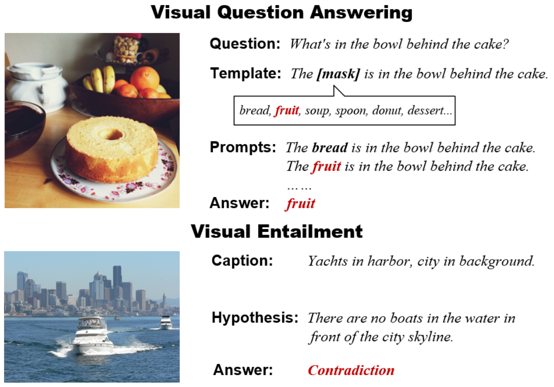

Figure 1: Examples of the two vision-language understanding tasks. For VQA, language prompts are used. For visual entailment, caption and hypothesis, i.e., text-text pairs, are used in training, while image and hypothesis, i.e., image-text pairs, are used at inference.

Recently, CLIP (Radford et al., 2021) has been proposed to learn visual concepts with natural language supervision, where its 400 million image-text pairs are crawled from the Internet. CLIP consists of a visual encoder and a text encoder, and it learns visual representations by aligning images and texts through contrastive loss. In this way, CLIP achieves strong zero-shot performances on vision benchmarks such as ImageNet. Besides, Shen et al. (2022) prove that CLIP could be leveraged as a strong visual encoder to benefit downstream vision-language tasks. However, there are two major differences between CLIP and previous visual encoders: 1) it is trained on much larger yet noisy web data, and 2) it has a shallow interaction between vision and language. The first feature promises the generalization ability of CLIP, and the second one equips alignment ability across modalities. Could the strong zero-shot ability of CLIP be transferred to vision-language understanding tasks?

Volume 1: Long Papers, pages 6088 - 6100
May 22-27, 2022

To answer the above question, in this work, we empirically study how to transfer CLIP's zero-shot ability into VLU tasks and further turn CLIP into a few-shot learner. We carried out experiments on two VLU tasks: 1) visual question answering, where the model needs to give an answer according to the details of an image and a natural sentence question, and 2) visual entailment, where the model needs to determine the entailment relation between an image and a natural sentence. Figure 1 demonstrates the basic forms of the two studied tasks.

For the zero-shot visual question answering task, the key to a successful zero-shot capability transfer is to mitigate the gap between the pre-training task of CLIP and the task form of question answering. Inspired by the recent advancements of few-shot learning in NLP (Schick and Schütze, 2021b; Gao et al., 2021), we address this issue by introducing a two-step prompt generation strategy, including automatic conversions from question to statement to get masked templates, and a span-infilling with generative pre-trained T5 model (Raffel et al., 2020) to get candidate answers.

We explore a zero-shot cross-modality (language and vision) transfer capability through the visual entailment task. Specifically, we replace the image with its captions during training and only update a small classification layer. Then at inference, as usual, we still use image-text pairs for testing. This allows us to investigate how well the language and vision representations are aligned in CLIP models.

We further leverage few-shot learning to improve CLIP's visual question answering performance based on the zero-shot transferring methods. We find that optimizing only bias and normalization (BiNor) parameters would make better use of limited examples and yield better results than the latest few-shot model *Frozen* (Tsimpoukelli et al., 2021). Experiments confirm that CLIP models can be good vision-language few-shot learners.

Our contributions are summarized as follows:

- To the best of our knowledge, this is the first work that studies how to transfer CLIP's zero-shot capabilities into VLU tasks and confirms CLIP models can be good few-shot learners.
- A zero-shot cross-modality transfer capability in CLIP is demonstrated.
- A parameter-efficient fine-tuning strategy, BiNor, is proposed to boost CLIP's few-shot visual question answering performance.

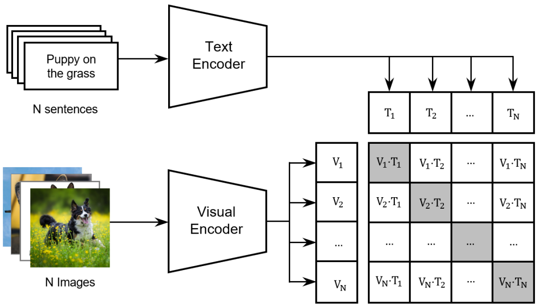

Figure 2: CLIP consists of a visual encoder $\mathbb{V}$, a text encoder $\mathbb{T}$, and a dot product between their outputs. It is trained to align images and texts with a contrastive loss. The dot product is used as an alignment score.

2 Preliminaries

2.1 CLIP

CLIP, short for Contrastive Language-Image Pretraining (Radford et al., 2021), learns visual representations from natural language supervision. Figure 2 shows its key components and the way it works. It consists of a visual encoder $\mathbb{V}$, e.g. ResNet (He et al., 2016) and ViT (Dosovitskiy et al., 2020), and a text encoder $\mathbb{T}$, e.g. transformer (Vaswani et al., 2017), where they encode images and texts independently. Followed up is a dot-product between the two encoders' outputs, i.e. $\mathbb{T}(\text{text}) \cdot \mathbb{V}(\text{image})$, which is used as an alignment score between the input image and text. It is pretrained to distinguish aligned image-text pairs from randomly combined ones by a contrastive loss. Instead of training on vision benchmarks, CLIP leverages abundant language supervisions from 400 million web-crawled image-text pairs and can conduct a variety of image classification tasks without specific optimizing. However, directly applying CLIP as a vision-language understanding model is still difficult (Kim et al., 2021; Shen et al., 2022).

2.2 Vision-Language Understanding Tasks

Visual question answering. The task of VQA requires the model to answer questions about the details of input images. Following previous work, we experiment on the VQAv2 (Goyal et al., 2017) dataset and formulate the task as a classification problem over 3,129 pre-defined most frequent answers. The images in VQAv2 come from Microsoft COCO (Lin et al., 2014), and there are 65 types of questions in the dataset, such as *how many* and *what color is*. For answers, there are three types, including *yes/no*, *number*, and *other*.

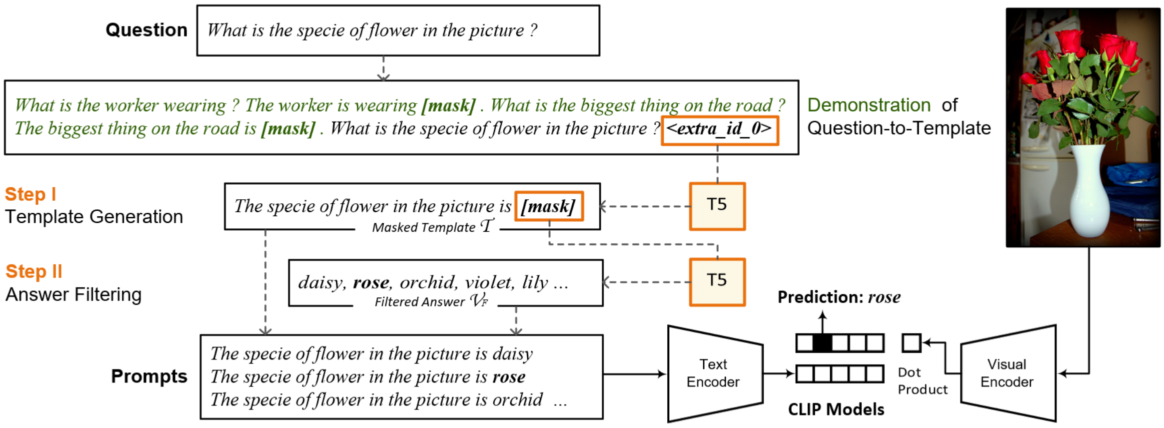

Figure 3: The overall framework of the proposed TAP-C method for zero-shot VQA. TAP-C first generates a masked template from the question by demonstrating examples to T5 and then filters out impossible answers according to the language model. Infilling the masked template with selected answers results in prompts, which could be paired with images to calculate image-text alignment scores by the CLIP. The dashed line denotes the process of prompts generation (§ 3.1), and the solid line denotes prompting CLIP to conduct zero-shot VQA (§ 3.2).

Visual entailment. Similar to the natural language inference (NLI), the task of visual entailment predicts the entailment relations, including *entailment*, *neutral*, and *contradiction*, between a premise and a hypothesis. Under the VL setting, the premise in visual entailment is based on the details of an image rather than textual descriptions in NLI. The SNLI-VE dataset (Xie et al., 2019) is adapted from SNLI (Bowman et al., 2015) and replaces SNLI's premises with the images in the Flickr30k dataset (Young et al., 2014). Considering the above characteristics, here we leverage the SNLI-VE dataset to verify the zero-shot cross-modality (language and vision) transfer capabilities of the CLIP models. This zero-shot setting investigates how well the vision and language representations are aligned in CLIP models.

3 Zero-shot VQA

3.1 A Two-Step Prompt Generation Method

Previous works (Kim et al., 2021; Shen et al., 2022) have found that directly applying CLIP models for zero-shot VL tasks are infeasible. For example, nearly random-chance level zero-shot performances are observed on the VQAv2 dataset by directly applying a "question: [*question text*] answer: [*answer text*]" prompt template (Shen et al., 2022). After rethinking the essence of prompt engineering in CLIP, we can find that the key to a successful zero-shot capability transfer for the VQA task is to mitigate the gap between natural language description and the form of question answering.

Motivated by the above observations, we propose a two-step automatic prompt generation method to enable the zero-shot VQA capabilities in CLIP models, with the assistant of a pre-trained generative T5 model (Raffel et al., 2020). The key ideas of the two-step prompt generation method is illustrated in Figure 3: the first step is to convert the question into a masked template $\mathcal{T}$, and the second step is to filter out impossible answers by language model and get a candidate answer set $\mathcal{V}_F$. The infilled template connects both the question and answers in a natural description way and thus could be an ideal form of prompt for the VQA task.

Step I: Automatic Template Generation

This step is designed to convert the question into a template, which is a statement with a mask token. To tackle the conversion challenge, we explore two ways, including an in-context demonstration method and a dependency parsing based method.

Demonstration to T5. The idea of this conversion method is relatively simple: by demonstrating question-to-template (with [mask] token) examples to the language model, the model could implicitly capture the conversion pattern. We define a few examples for each question type and convert the questions according to their types. Figure 3 shows a conversion example. More cases could be found at appendix D. Specifically, we use T5 (Raffel et al., 2020), a large pre-trained text-to-text Transformer, for the question to template conversion. T5 is pre-trained to infill the missing spans (replaced by T5 special tokens, e.g. <*extra_id_0*>) of a sentence.

We present a concatenation of examples, question, and the <*extra_id_0*> token to T5 for conditional generation to restore it, and the generated span is our masked template, named as $\mathcal{T}_{\text{demo}}$.

Dependency parsing. Although the T5 conversion method works well in most situations, it still faces some out-of-coverage problems. To compensate for this shortcoming, we turn to a traditional dependency parsing based way. This method converts a question to a statement by its part-of-speech tagging and parsing results, where the wh-word, root word, auxiliary, or copula, as well as prepositions and particles that are dependents of the wh-word or the root, are identified, and transformations are performed according to grammar rules. We use the Stanza (Qi et al., 2020) to POS tag and parse the question and leave the answer as a mask token. Then the rules[1] in Demszky et al. (2018) are leveraged to perform the conversion. We name the template obtained in this way as $\mathcal{T}_{\text{parsing}}$.

Step II: Answer Filtering

As common sense, "*the specie of a flower*" can never be a vase. Therefore, leveraging pre-trained language models, which have well learned such concepts during pre-training, to filter out less likely answers would have a positive influence on the final question answering performance. Given a masked template $\mathcal{T}$, a language model $\mathcal{L}$, and the answer vocabulary $\mathcal{V}$, we get the filtered answers $\mathcal{V}_F$ as:

$$\underset{v \in \mathcal{V}}{\text{Top-}k} \left\{ \log P_{\mathcal{L}} \left([\text{mask}] = v | \mathcal{T} \right) \right\}, \tag{1}$$

where the [mask] is the answer span in template $\mathcal{T}$, and $P_{\mathcal{L}}$ is the output distribution of the language model. Here we also apply the T5 to infill answers because it makes no assumption about the length and position of the span. Once we get the template $\mathcal{T}$ and the filtered answers $\mathcal{V}_F$, we replace the [mask] token in template $\mathcal{T}$ with every selected answer in $\mathcal{V}_F$ to get the prompts $\mathcal{P}$.

3.2 TAP-C Method for VQA

The proposed method follows a Template-Answer-Prompt then CLIP discrimination pipeline, and thus we name it as **TAP-C**. To make better use of template $\mathcal{T}_{\text{parsing}}$ and $\mathcal{T}_{\text{demo}}$, we use an ensemble of both templates by simply setting a threshold for the T5's generation confidence. We prefer to use $\mathcal{T}_{\text{demo}}$ but use $\mathcal{T}_{\text{parsing}}$ if the generation confidence is low. Finally, given an image i and the generated prompts $\mathcal{P}$, the TAP-C method can get a zero-shot VQA prediction by:

$$\max_{v \in \mathcal{V}_F,\, p_v \in \mathcal{P}} \left\{ \mathbb{V}(i) \cdot \mathbb{T}(p_v) \right\}, \tag{2}$$

where $\mathbb{V}$ and $\mathbb{T}$ are the visual and text encoders in CLIP models. The p_v is a prompt generated by the TAP-C method, where the masked template is infilled with answer v from the filtered answer vocabulary $\mathcal{V}_F$.

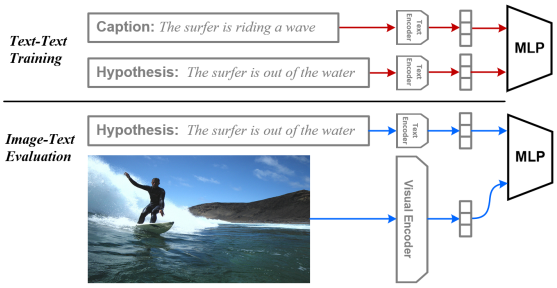

Figure 4: Zero-shot cross-modality transfer on visual entailment task. The red line denotes the text-only training process, and the blue line denotes the image-text, i.e., cross-modality, evaluation process. The MLP is shared between training and evaluation, while both encoders in CLIP models are not updated.

4 Zero-shot Cross-modality Transfer

Recent pre-trained multilingual language models (Wu and Dredze, 2019; Liu et al., 2020; Xue et al., 2021) have been shown to be successful in transferring representations across different languages. For example, they can be only fine-tuned on a source language and evaluated on various target languages without specific training, yet still achieving good performance. On the other hand, the CLIP models achieve strong zero-shot performances on both image-to-text and text-to-image retrieval tasks (Radford et al., 2021) only through a dot product between vision and language representations, which gives us an intuition that the two modalities are well aligned in the CLIP models. Is there a cross-modality capability between language and vision in the CLIP models, just like the multilingual ones across languages?

To answer the above question, we utilize the visual entailment task (§ 2.2) to explore the zero-shot cross-modality performance. Figure 4 briefs the key idea. Specifically, we train an MLP classifier over the fused representations of premise and hy-

---

[1] https://github.com/kelvinguu/qanli

pothesis, and the fusion function is:

$$\text{fuse}\left(v_1, v_2\right) = \left[v_1, v_2, v_1 + v_2, v_1 - v_2, v_1 \cdot v_2\right],$$

where v_1 and v_2 are two input vectors. During training, text-only premise and hypothesis are used as the input of CLIP text encoder:

$$\text{MLP}\left\{\text{fuse}\left(\mathbb{T}(\text{pre}_t),\ \mathbb{T}(\text{hyp}_t)\right)\right\}, \tag{3}$$

where $\mathbb{T}$ is the CLIP text encoder and is not updated during training. And pre_t and hyp_t are the text premise and hypothesis. Then at inference, the premise is in image and is fed into the CLIP visual encoder. The trained MLP is leveraged for prediction:

$$\max\left\{\text{MLP}\left\{\text{fuse}\left(\mathbb{V}(\text{pre}_i),\ \mathbb{T}(\text{hyp}_t)\right)\right\}\right\}, \tag{4}$$

where the pre_i is the image premise and $\mathbb{V}$ is the CLIP visual encoder.

5 Few-shot Learning for VQA

In this section, We aim to investigate whether the CLIP models could benefit from *few-shot* learning, where we work on the visual question answering task to study it.

5.1 Setup of Few-shot VQA

Here we briefly define the terminology used in our few-shot visual question answering settings:

- **Number of ways.** Originally, it is defined as the distinct classes in a task. However, rather than defining a 3,129-way task according to the answer vocabulary, we define the number of ways as question type times answer type (§ 2.2), i.e., 65×3=195 ways, to ensure the model's generalization ability where it can answer a type of questions.
- **Number of shots.** The number of distinct examples in each way. Here a shot is an image along with the question and the answer.
- **Support set and query set.** Before training, we will sample a 195-way K-shot subset from the VQAv2 training set, and thus there are 195×K distinct examples available during few-shot learning. In each training epoch, we select C ways out of 195 ways for parameter optimizing and divide *k* shots in each way into support set and query set with a fixed proportion. The support set is used for model training, and the query set is used for performance evaluation (similar to a typical dev set).

5.2 Parameter-efficient Fine-tuning

Under the few-shot setting, our goal is to make the CLIP models learn from N-way K-shot examples and improve the zero-shot VQA performance. Specifically, we identify only a very small set of parameters in CLIP models (about 0.3 million out of over 100 million, details in appendix B.3), including the *bias* term and *normalization* term, to be optimized. For either the BatchNorm in ResNet or the LayerNorm in Transformer, the normalization could be uniformly denoted as:

$$y = \frac{x - \text{E}(x)}{\sqrt{\text{Var}(x) + \epsilon}} \cdot \gamma + \beta, \tag{5}$$

where x and y are the mini-batched input and output, and the γ and β are learned parameters. And for all the linear layers and projection layers in CLIP models, they could be denoted as:

$$o = w \cdot h + bias, \tag{6}$$

where h and o are the input and output vectors. We define the learnable parameter set as:

$$\text{P}_{learn} = \{bias, \gamma, \beta\}. \tag{7}$$

We optimize the **Bi**as and **Nor**malization (BiNor) parameters on the few-shot examples with a standard cross-entropy loss over the dot products from each image-prompt pair (Eq.2).

Besides, when there are a few examples available, we could also leverage an in-context demonstration manner to improve the performance of the *answer filtering* process in TAP-C (§ 3.1) by:

$$\underset{v \in \mathcal{V}}{\text{Top-}k}\left\{\log P_{\mathcal{L}}\left([\text{mask}] = v \mid [\mathcal{D}, \mathcal{T}]\right)\right\}, \tag{8}$$

where the $\mathcal{D}$ denotes the demonstrations. $\mathcal{D}$ is similar to template $\mathcal{T}$ but has been infilled with the answers, and it is sampled from the same type of question in the available few-shot examples. The resulting filtered vocabulary is noted as $\mathcal{V}_{\text{demo}}$. We report the few-shot training procedure in appendix C.

6 Experiments

6.1 Experimental Settings

Datasets. For visual question answering and visual entailment, we carry out experiments on the VQAv2 (Goyal et al., 2017) and the SNLI-VE (Xie et al., 2019) datasets, respectively. We report the statistics of the two datasets in appendix A. For the VQA task's evaluation, we follow the *Frozen* model (Tsimpoukelli et al., 2021) to calculate the *vqa scores* on the VQAv2 validation set. For visual entailment, we calculate the *accuracy* on both validation and test sets through the *sklearn* toolkit.

CLIP models. According to the types of visual encoders, e.g. ResNet or ViT, CLIP models have different variants, resulting in a significant difference in the number of learnable *bias* and *normalization* parameters. We report the number of learnable parameters of CLIP variants in appendix B.3. We select two best performing (and publicly available) variants from two kinds of visual encoders, including the CLIP Res50x16 and the CLIP ViT-B/16, to empirically study their zero-shot and few-shot vision-language understanding performances by applying our transferring methods (§§ 3–5).

6.2 Results of Zero-shot VQA

As previous VL models heavily rely on object detection sub-modules, it is not feasible to directly apply them under the zero-shot setting. Here we setup zero-shot VL baselines from two latest works:

- **Frozen.** *Frozen* (Tsimpoukelli et al., 2021) prompts a seven-billion-parameter 32-layer language model with image representations. It is trained on aligned image-caption data and is also the first model that shows promising zero-shot and few-shot VQA performances.
- **Question irrelevant prompt.** Shen et al. (2022) explored directly prompting the CLIP models for the VQA task. They used a "question: [*question text*] answer: [*answer text*]" template, together with the prompt engineering of image classification, to prepare prompts. The resulting prompts are irrelevant to questions, and thus we note this method as QIP.

We report the zero-shot VQA results in Table 1. The experimental results verify our hypothesis (§ 3.1) that the prompts of CLIP should be used to describe the labels rather than the tasks. As we can see, the question irrelevant prompting methods simply present the task description and answers to the CLIP models and only get barely better than random guess results. In contrast, by converting questions into templates and filtering answers with pre-trained language models, our TAP-C method enables CLIP models a strong zero-shot capability on the VQA task, even compared with the seven-billion-parameter *Frozen* zero-shot model.

Zero-shot Methods	Yes/No	Number	Other	All
Frozen (Tsimpoukelli et al., 2021)	-	-	-	29.50
QIP (Shen et al., 2022)

Table 2: Zero-shot cross-modality transfer results on the SNLI-VE valid and test set (*valid acc / test acc*).

6.3 Zero-shot Cross-modality Transfer

We report the zero-shot cross-modality transfer results in Table 2. We first investigate the language to vision transfer capability. As introduced in § 4, we train a classifier on the text-only SNLI-VE dataset where the image is replaced by its caption. At inference, the trained classifier is evaluated by taking the image and text as inputs. As shown in the first group of results, after solely trained on text-text (caption as the premise) entailment data, different CLIP variants could successfully gain a similar discriminative ability under the image-text setting. To ensure that the above results are indeed transferring from language to vision, we made a double check by masking out the images at inference time, and the results are reported at *Image Masked*. As we can see, the results are similar to a random guess of three relations, indicating the images are of importance in the cross-modality evaluation.

Now that we have observed the language to vision transferring capability in CLIP models, we further investigate whether there is also a vision to language transfer capability. We conduct a similar experiment but train the classifier on the original SNLI-VE dataset, i.e., image premise and text hypothesis. At inference, we evaluate the classifier with the text-only valid and test data. The results are reported in Table 2, which confirms the vision to language capability. Since text data are usually much cheaper than visual data, the first kind of transferring tends to be more promising in practice.

TAP-C$_{\text{Res50x16}}$	38.36	45.87	50.18
w/o a.filt.	32.43 (16%)	34.56 (25%)	40.97 (18%)
w/o t.gen. + a.filt.	23.07 (40%)	23.98 (48%)	24.86 (51%)

Table 5: Ablation results of TAP-C. In brackets is the percentage of VQA performance degradation. When both steps are all removed, the few-shot learning is performed on CLIP with question irrelevant prompts.

6.4 Results of Few-shot VQA

We report the few-shot VQA results in Table 3. We take the *Frozen* model and the image blacked out *Frozen*$_{\text{blind}}$ as baselines. Under different k, our methods could always learn from limited training examples and improve over the zero-shot results, which confirms that CLIP models could be VL few-shot learners. With the increase of the number of shots, significant performance gains are observed in *other* category, which concurs with our intuition: as we sample examples from each question type, most answers in *other* category are not revealed to the model. As a result, the model could always learn to improve. Similarly, presenting examples to the T5 could also improve the answer filtering process, leading to significant performance gains over the *other* category. In contrast, the score of *number* category improves significantly when the model just begins to see some training examples while slowing down as k continues to increase.

6.5 Analyses and Discussion

The effects of template generation methods. Our TAP-C method uses an ensemble of dependency parsing template $\mathcal{T}_{\text{parsing}}$ and T5 demonstration template $\mathcal{T}_{\text{demo}}$. Here we investigate whether it is necessary to use such an ensemble. We report the ablation results of two templates in Table 4. The results show that the two templates have different effects over different questions, and the ensemble could make the best use of their advantages.

The effects of two steps in TAP-C. The TAP-C method generates prompts through template generation (**t.gen.**) and answer filtering (**a.filt.**). Here we quantify how much each step contributes to the final zero/few-shot VQA performances. We report the ablation results in Table 5. When we remove the *answer filtering* step (w/o a.filt.), both the zero-shot and few-shot performances generally fall by about 20%, but the models still retain some few-shot learning capabilities. We further remove the *template generation* step and only use question irrelevant templates: all results are nearly cut in half, indicating the importance of considering questions in both zero-shot and few-shot scenarios.

Few-shot Mehtods	K=1			K=4			K=16			K=32		
	Full-FT	BitFit	BiNor	Full-FT	BitFit	BiNor	Full-FT	BitFit	BiNor	Full-FT	BitFit	BiNor
TAP-C$_{\text{ViT-B/16}}$	37.78*	42.96	**43.27**	38.30*	44.77	**44.98**	39.99	46.80	**47.42**	40.35	47.78	**49.19**
TAP-C$_{\text{Res101}}$	36.63*	42.21	**42.98**	37.92*	43.02	**44.72**	39.42	44.83	**47.43**	39.58	45.59	**48.86**
TAP-C$_{\text{Res50x16}}$	35.96*	**43.38**	43.24	38.03*	44.30	**45.87**	39.84	46.57	**48.89**	40.42	47.74	**50.18**

Table 6: The performance comparisons of different fine-tuning strategies on the few-shot VQA task. Results marked with "$*$" are lower than the zero-shot performance. Full-FT is short for full fine-tuning. Besides BiNor's good performance, it improves ResNet CLIPs more significantly due to the number of normalization parameters.

Comparisons of fine-tuning methods. We only update the bias and normalization parameters during few-shot learning (§ 5.2). To investigate whether our BiNor fine-tuning strategy works well, we compare BiNor with two fine-tuning methods: 1) **Full-FT** (Full fine-tuning), which updates all parameters in the model. 2) **BitFit** (Ben Zaken et al., 2021), which only updates the bias-terms in all model layers. We report the comparison results in Table 6. Both BiNor and BitFit significantly outperform the full fine-tuning way: millions of parameters are very easy to overfit to a few training examples. When *k* is small, the performance differences between BiNor and BitFit are very small. When *k* becomes larger, BiNor begins to outperform BitFit with a noticeable margin. Our BiNor fine-tuning strategy is similar to the BitFit but differs in that it also updates the normalization parameters, which would grant the ResNet CLIP models better flexibility to adapt to new examples due to their larger number of batch normalization parameters. For the specific number of different parameters in each CLIP variant, please refer to the appendix B.3.

Limitations of TAP-C. The proposed TAP-C method explores CLIP models' potential to conduct zero/few-shot VQA tasks. However, we also found several limitations that hinder further improving the few-shot performance, which could be rooted in the CLIP models. First, CLIP models struggle with counting the number of fine-grained objects in an image, especially counting from a small area of the image. This shortcoming can hardly be improved by any kind of language knowledge. Besides, the CLIP models perform poorly in distinguishing subtle semantic differences. For example, when asked "what is the man in the background doing?", all the experimented CLIP models give predictions of the man "in the foreground". Under such cases, even if the TAP-C method perfectly converts the question into a prompt, the final results would still be wrong. Nevertheless, We believe this issue could be well addressed by enhancing CLIP models with a stronger text encoder, and we will make explorations in future work.

7 Related Work

Vision-language few-shot learning. Leveraging aligned caption data, vision-language models pre-trained by an image-text discriminative loss have recently enabled strong zero-shot generalization on image classification and cross-modality retrieval tasks (Jia et al., 2021; Radford et al., 2021). Different from the discriminative manner, Tsimpoukelli et al. (2021) prompt a large frozen language model with vision prefix in a generative way, which is the first vision-language few-shot model.

Language model prompting. This work is also inspired by the line of research in language model prompting (Liu et al., 2021). Initialized by the GPT series (Radford et al., 2018, 2019; Brown et al., 2020), prompting has become a popular manner to mining knowledge from pre-trained language models (Petroni et al., 2019) in a zero-shot or few-shot way (Shin et al., 2020; Gao et al., 2021; Qin and Eisner, 2021). Besides mining knowledge from the language model, PET work (Schick and Schütze, 2021a,b) presents a semi-supervised prompting method for improving few-shot language understanding performance.

8 Conclusions

In this work, we empirically studied how to transfer CLIP models into vision-language understanding tasks. We first explored the CLIP models' zero-shot VQA capability by leveraging language prompts and further proposed a parameter-efficient fine-tuning method to boost the few-shot performance. We also demonstrate a zero-shot cross-modality transfer capability of CLIP models on the visual entailment task. Experiments and analyses on VQAv2 and SNLI-VE confirm that the CLIP models can be good VL few-shot learners.

Table 7: Basic statistics of the two datasets. The upper is the number of examples, and the lower is the number of distinct images. And *# Vocab* is the vocabulary size.

B Details of Implementation

B.1 Zero-shot Model Briefs

In our experiments, we leverage two kinds of pre-trained models: the CLIP variants and the T5. We brief these models as follows.

For the CLIP models, the text encoder is always a transformer, but its hidden size varies according to the size of visual encoders. And there are two architectures of visual encoders, including the vision transformer (ViT) and ResNet.

- **CLIP ViT-B/16**: both the text and visual encoders are 12-layer, 512-hidden transformers.
- **CLIP RN101**: the text encoder is a 12-layer transformer, and the visual encoder is ResNet101, both with a hidden size of 512.
- **CLIP RN50x16**: the text encoder is a 12-layer transformer, and the visual encoder is ResNet50x16, both with a hidden size of 768.

All CLIP models we used are from the official CLIP repository[2]. For the language model T5, we use a publicly available T5_{large} checkpoint from the Huggingface repository[3]. The T5_{large} has 24 hidden layers, 16 self-attention heads, 1024 hidden size, and a total of 770M parameters. It is trained on Colossal Clean Crawled Corpus (C4). Note that the T5 model had not been trained or finetuned under both few-shot and zero-shot settings.

B.2 Hyperparameters

We report the hyperparameter settings of few-shot CLIP training in Table 8. We apply the same set of hyperparameters to fine-tune both ResNet CLIP and ViT CLIP.

Hyperparameters	Value
Training epochs	30
Batch size	8
Initial temperature	0.07
Maximum temperature	100.0
Adam ϵ	1e-8
Adam β	(0.9, 0.999)
Learning rate	2e-5
Gradient clipping	2.0
Weight decay	0.001
Number of filtered answers	200

Table 8: Hyperparameters used for CLIP models in few-shot learning.

Hyperparameters	Value
Layers	3
Layer Dimension	1024-128-3
Training epochs	20
Adam ϵ	1e-8
Adam β	(0.9, 0.999)
Gradient clipping	2.0
Learning rate	{1e-6, 3e-6, 5e-6}
Batch size	{32, 64, 128}
Dropout	{0, 0.1, 0.4}

Table 9: Hyperparameters of the MLP classifier in zero-shot language to vision transfer.

The hyperparameters used for the MLP classifier in the visual entailment task are reported in Table 9. We performed grid searches on the combination of the learning rate, batch size, and dropout. The CLIP variants reached the best performances under different parameter combinations.

Template Generation Hyperparameters	Value
Number of beams	20
Number of returned sequences	10
Max returned span length	30
Answer Filtering Hyperparameters	Values
Batch size	128
Number of beams	200
Number of returned sequences	200
Max returned span length	6
Max number of demonstration	16

Table 10: Hyperparameters used for T5 in template generation and answer filtering.

Table 10 shows the hyperparameter configurations for T5's conditional generation, which is leveraged to generate the masked template and filter answers.

CLIP	*# Bias*	*# Normalize*	*# BiNor*	*# All*
CLIP$_{\text{RN101}}$	127,488	123,392	189,184	100M
CLIP$_{\text{RN50x16}}$	209,088	132,160	319,488	229M
CLIP$_{\text{ViT-B/16}}$	171,008	65,536	203,776	149M

Table 11: Statistics of different type of parameters in CLIP models.

B.3 The Number of Learnable Parameters

Table 11 shows the number of different type of learnable parameter in CLIP models. The counting of Bias and Normalization share the β in Eq.7. The numbers of BiNor parameters are about 0.2M to 0.3M, accounting for less than 0.3% of all parameters.

C Few-shot Training Procedure

Algorithm 1 CLIP models few-shot training.

```
Input: $\mathbb{V}$: visual encoder, ResNet or ViT; $\mathbb{T}$: text encoder,
    Transformer; $I$: few-shot images; $P$: few-shot prompts;
    $A$: few-shot answers; $\tau$: learned temperature parameter;
    $N$: max iterations; Adam: optimizer;
Output: Few-shot CLIP model.
initial $epoch = 0$, freeze parameters in $\mathbb{V}$ and $\mathbb{T}$ except
    bias and normalization;
repeat
    Sample C-way K-shot $E$ from ($I$,$P$,$A$);
    Split $E$ into support set and query set;
    for all minibatch (i,p,a) in support set do
        I$_f$ = $\mathbb{V}$(i), T$_f$ = $\mathbb{T}$(p);
        I$_e$ = norm(I$_f$), T$_e$ = norm(T$_f$);
        logits = $\tau$ * dot($I_e$, $T_e$);
        labels = map(a, p);
        loss = cross_entropy(logits, labels);
        Adam.step();
    end for;
    $epoch = epoch + 1$;
    Evaluate on query set;
until ($epoch \geq N$).
```

D Examples of Template Generation

In this section, we showcase several template generation examples to illustrate how the proposed method works. Since we have introduced how to convert a question into a masked template by demonstrating examples to the T5 (§ 3.1), here we directly present several examples in Table 12. These examples are sampled from five different question types and also cover the three answer types. As shown in Table 12, a single demo in the demonstration consists of a question and an answer with the [mask] token. Notice that the [mask] token is only a placeholder rather than a real mask in the pre-trained language models. Different from the <*extra_id_0*> in T5 that represents a corrupted span, the [mask] is used to inform the T5 where the answer words should be placed. After seeing several examples in the demonstration, the powerful T5$_{\text{large}}$ model could capture the conversion pattern in each type of question and perfectly complete most conversions without ignoring the subtle grammars. Once the masked template is generated, we could infill the [mask] place with answer words and then carry out further processing. The processing for the *yes/no* type is a little different: as it is a binary task, we directly generate a positive prompt and a negative prompt, rather than masked templates, for the *yes* and *no*, respectively.

Question Type	what color is
Demonstration	What color is the floor of this area? The color of floor of this area is [mask]. What color is the pillow the cat is on? The color of the pillow the cat on is [mask]. What color is the child's shorts? The color of the child's shorts is [mask]. What color is the lettering on the business sign? The color of the lettering on the business sign is [mask].
Question	What color is the fence behind the man?
Generated Template	The color of the fence behind the man is [mask].
Question	What color is the statue near the building?
Generated Template	The color of the statue near the building is [mask].

Question Type	why is the
Demonstration	Why is the ground surface near the train a different color? The ground surface near the train is in a different color because of [mask]. Why is the cat under an umbrella? The cat under an umbrella is because of [mask]. Why is the laptop sitting above a larger keyboard? The laptop is sitting above a larger keyboard because of [mask]. Why is the car being towed? The car is being towed because of [mask].
Question	Why is the little boy having fun?
Generated Template	The little boy is having fun because of [mask].
Question	Why is the elephant's trunk two color's?
Generated Template	The elephant's trunk is two colors because of [mask].

Question Type	which
Demonstration	Which utensil is on the table in the foreground? The [mask] utensil is on the table in the foreground. Which way is the train going? The [mask] way is the train going. Which hand holds the racket? The [mask] hand holds the racket. Which foot is lifted in the air? The [mask] foot is lifted in the air.
Question	Which hot dog has a larger variety of toppings?
Generated Template	The [mask] hot dog has a larger variety of toppings.
Question	Which operating system is being used on this computer?
Generated Template	The [mask] operating system is being used on this computer.
Question	Which side of the room is the television probably on?
Generated Template	The [mask] side of the room is the television probably on.

Question Type	how many
Demonstration	How many unopened rolls of paper are in the picture? There are [mask] unopened rolls of paper in the picture. How many engines does the closest airplane have? The closest airplane has [mask] engines. How many different types of doors are visible? There are [mask] different types of doors visible. How many people are wearing plaid shirts? There are [mask] people wearing plaid shirts.
Question	How many people are participating in the eating contest?
Generated Template	There are [mask] people participating in the eating contest.
Question	How many cabinets have been installed?
Generated Template	There are [mask] cabinets installed.
Question	How many people in this picture are wearing glasses?
Generated Template	There are [mask] people wearing glasses.

Question Type	does this
Demonstration	Positive: Does this food look burnt? This food looks burnt. Does this appear to be a noisy environment? This appears to be a noisy environment. Negative: Does this boat have an engine? This boat has no engine. Does this type of fruit change color? This type of fruit does not change color. Does this animal produce dairy products? This animal does not produce dairy products. Does this pizza look hot? This pizza does not look hot.
Question	Does this look like a happy occasion?
Generated Prompts	Yes→ This looks like a happy occasion No → This does not look like a happy occasion
Question	Does this man have both of his skis on?
Generated Prompts	Yes→ This man has both of his skis on No → This man does not have both of his skis on
Question	Does this transportation run on gasoline?
Generated Prompts	Yes→ This transportation runs on gasoline No → This transportation does not run on gasoline

Table 12: Examples of generating masked templates. The demonstrations are defined for each type of question and are demonstrated to the T5. For the binary *yes/no* type, we directly generate positive prompt for *yes* and negative prompt for *no*. Full question types are available at https://github.com/GT-Vision-Lab/VQA/tree/master/QuestionTypes.

KQA Pro: A Dataset with Explicit Compositional Programs for Complex Question Answering over Knowledge Base

Abstract

Complex question answering over knowledge base (Complex KBQA) is challenging because it requires various compositional reasoning capabilities, such as multi-hop inference, attribute comparison, set operation. Existing benchmarks have some shortcomings that limit the development of Complex KBQA: 1) they only provide QA pairs without explicit reasoning processes; 2) questions are poor in diversity or scale. To this end, we introduce KQA Pro, a dataset for Complex KBQA including ~120K diverse natural language questions. We introduce a compositional and interpretable programming language KoPL to represent the reasoning process of complex questions. For each question, we provide the corresponding KoPL program and SPARQL query, so that KQA Pro serves for both KBQA and semantic parsing tasks. Experimental results show that SOTA KBQA methods cannot achieve promising results on KQA Pro as on current datasets, which suggests that KQA Pro is challenging and Complex KBQA requires further research efforts. We also treat KQA Pro as a diagnostic dataset for testing multiple reasoning skills, conduct a thorough evaluation of existing models and discuss further directions for Complex KBQA. Our codes and datasets can be obtained from `https://github.com/shijx12/KQAPro_Baselines`.

1 Introduction

Thanks to the recent advances in deep models, especially large-scale unsupervised representation learning (Devlin et al., 2019), question answering of simple questions over knowledge base (Simple KBQA), i.e., single-relation factoid questions (Bordes et al., 2015), begins to saturate (Petrochuk and Zettlemoyer, 2018; Wu et al., 2019; Huang et al., 2019). However, tackling complex questions (Complex KBQA) is still an ongoing challenge, due to the unsatisfied capability of compositional reasoning. As shown in Table 1, to promote the community development, several benchmarks are proposed for Complex KBQA, including LC-QuAD2.0 (Dubey et al., 2019), ComplexWebQuestions (Talmor and Berant, 2018), MetaQA (Zhang et al., 2018), CSQA (Saha et al., 2018), CFQ (Keysers et al., 2020), and so on. However, they suffer from the following problems:

1) Most of them only provide QA pairs without explicit reasoning processes, making it challenging for models to learn compositional reasoning. Some researchers try to learn the reasoning processes with reinforcement learning (Liang et al., 2017; Saha et al., 2019; Ansari et al., 2019) and searching (Guo et al., 2018). However, the prohibitively huge search space hinders both the performance and speed, especially when the question complexity increases. For example, Saha et al. (2019) achieved a 96.52% F1 score on simple questions in CSQA, whereas only 0.33% on complex questions that require comparative count. We think that intermediate supervision is needed for learning the compositional reasoning, mimicking the learning process of human beings (Holt, 2017).

2) Questions are not satisfactory in diversity and scale. For example, MetaQA (Zhang et al., 2018) questions are generated using just 36 templates, and they only consider relations between entities, ignoring literal attributes; LC-QuAD2.0 (Dubey et al., 2019) and ComplexWebQuestions (Talmor and Berant, 2018) have fluent and diverse human-written questions, but their scale is less than 40K.

To address these problems, we create **KQA Pro**, a large-scale benchmark for Complex KBQA. In KQA Pro, we define a Knowledge-oriented Programming Language (**KoPL**) to explicitly describe

Question 1: When did Cleveland Cavaliers pick up LeBron James

SPARQL:

```
SELECT DISTINCT ?qpv WHERE { ?e_1 <pred:name> “LeBron James” . ?e_2 <pred:name> “Cleveland Cavaliers“ . ?e_1 <drafted by> ?e_2 . [ <pred:fact_h> ?e_1 ; <pred:fact_r> <winner> ; <pred:fact_t> ?e_2 ] <point_in_time> ?qpv .  }
```

Question 2: Who is taller, LeBron James Jr. or his father?

SPARQL:

```
SELECT ?e WHERE { { ?e <name> “LeBron James Jr.” .  } UNION { ?e_1 <name> “LeBron James Jr.” . ?e_1 <father> ?e .  } ?e <height> ?v .  } ORDER BY DESC(?v) LIMIT 1
```

Figure 1: Example of our KB and questions. Our KB is a dense subset of Wikidata (Vrandečić and Krötzsch, 2014), including multiple types of knowledge. Our questions are paired with executable KoPL programs and SPARQL queries.

the reasoning process for solving complex questions (see Fig. 1). A program is composed of symbolic **functions**, which define the basic, atomic operations on KBs. The composition of functions well captures the language compositionality (Baroni, 2019). Besides KoPL, following previous works (Yih et al., 2016; Su et al., 2016), we also provide the corresponding SPARQL for each question, which solves a complex question by parsing it into a query graph. Compared with SPARQL, KoPL 1) provides a more explicit reasoning process. It divides the question into multiple steps, making human understanding easier and the intermediate results more transparent; 2) allows humans to control the model behavior better, potentially supporting human-in-the-loop. When the system gives a wrong answer, users can quickly locate the error by checking the outputs of intermediate functions. We believe the compositionality of KoPL and the graph structure of SPARQL are two complementary directions for Complex KBQA.

To ensure the diversity and scale of KQA Pro, we follow the synthesizing and paraphrasing pipeline in the literature (Wang et al., 2015a; Cao et al., 2020), first synthesize large-scale (canonical question, KoPL, SPARQL) triples, and then paraphrase the canonical questions to natural language questions (NLQs) via crowdsourcing. We combine the following two factors to achieve diversity in questions: (1) To increase structural variety, we leverage a varied set of templates to cover all the possible queries through random sampling and recursive composing; (2) To increase linguistic variety, we filter the paraphases based on their edit distance with the canonical utterance. Finally, KQA Pro consists of 117,970 diverse questions that involve varied reasoning skills (*e.g.*, multi-hop reasoning, value comparisons, set operations, *etc.*). Besides a QA dataset, it also serves as a semantic parsing dataset. To the best of our knowledge, KQA Pro is currently the largest corpus for NLQ-to-SPARQL and NLQ-to-Program tasks.

We reproduce the state-of-the-art KBQA models and thoroughly evaluate them on KQA Pro. From the experimental results, we observe significant performance drops of these models compared with on existing KBQA benchmarks. It indicates that Complex KBQA is still challenging, and KQA Pro could support further explorations. We also treat KQA Pro as a diagnostic dataset for analyzing a model's capability of multiple reasoning skills, and discover weaknesses that are not widely known, *e.g.*, current models struggle on comparisonal reasoning for lacking of literal knowledge (*i.e.*, *(LeBron James, height, 206 centimetre)*), or perform poorly on questions whose answers are not obverseved in the training set. We hope all contents of KQA Pro could encourage the community to make further breakthroughs.

2 Related Work

Complex KBQA aims at answering complex questions over KBs, which requires multiple reasoning capabilities such as multi-hop inference, quantitative comparison, and set operation (Lan et al., 2021). Current methods for Complex KBQA can be grouped into two categories: 1) semantic parsing based methods (Liang et al., 2017; Guo et al., 2018; Saha et al., 2019; Ansari et al., 2019), which parses a question to a symbolic logic form (*e.g.*, λ-calculus (Artzi et al., 2013), λ-DCS (Liang, 2013; Pasupat and Liang, 2015; Wang et al., 2015b; Pasupat and Liang, 2016), SQL (Zhong et al., 2017), AMR (Banarescu et al., 2013), SPARQL (Sun et al., 2020), and *etc.*) and then executes it against the KB and obtains the final answers; 2) information retrieval based methods (Miller et al., 2016; Saxena

Table 1: Comparison with existing datasets of Complex KBQA. The column *multiple kinds of knowledge* means whether the dataset considers multiple types of knowledge or just relational knowledge (introduced in Sec.3.1). The column *natural language* means whether the questions are in natural language or written by templates.

et al., 2020; Schlichtkrull et al., 2018; Zhang et al., 2018; Zhou et al., 2018; Qiu et al., 2020; Shi et al., 2021), which constructs a question-specific graph extracted from the KB and ranks all the entities in the extracted graph based on their relevance to the question.

Compared with information retrieval based methods, semantic parsing based methods provides better interpretability by generating expressive logic forms, which represents the intermediate reasoning process. However, manually annotating logic forms is expensive and labor-intensive, and it is challenging to train a semantic parsing model with weak supervision signals (*i.e.*, question-answer pairs). Lacking logic form annotations turns out to be one of the main bottlenecks of semantic parsing.

Table 1 lists the widely-used datasets in Complex KBQA community and their features. MetaQA and CSQA have a large number of questions, but they ignore literal knowledge, lack logic form annotations, and their questions are written by templates. Query graphs (*e.g.*, SPARQLs) are provided in some datasets to help solve complex questions. However, SPARQL is weak in describing the intermediate procedure of the solution, and the scale of existing question-to-SPARQL datasets is small.

In this paper, we introduce a novel logic form KoPL, which models the procedure of Complex KBQA as a multi-step program, and provides a more explicit reasoning process compared with query graphs. Furthermore, we propose KQA Pro, a large-scale semantic parsing dataset for Complex KBQA, which contains ~120k diverse natural language questions with both KoPL and SPARQL annotations. It is the largest NLQ-to-SPARQL dataset as far as we know. Compared with these existing datasets, KQA Pro serves as a more well-rounded benchmark.

3 Background

3.1 KB Definition

Typically, a **KB** (*e.g.*, Wikidata (Vrandečić and Krötzsch, 2014)) consists of:

Entity, the most basic item in KB.

Concept, the abstraction of a set of entities, *e.g.*, *basketball player*.

Relation, the link between entities or concepts. Entities are linked to concepts via the relation *instance of*. Concepts are organized into a tree structure via relation *subclass of*.

Attribute, the literal information of an entity. An attribute has a key and a value, which is one of four types[1]: string, number, date, and year. The number value has an extra unit, *e.g.*, 206 centimetre.

Relational knowledge, the triple with form (entity, relation, entity), *e.g.*, *(LeBron James Jr., father, LeBron James)*.

Literal knowledge, the triple with form (entity, attribute key, attribute value), *e.g.*, *(LeBron James, height, 206 centimetre)*.

Qualifier knowledge, the triple whose head is a relational or literal triple, *e.g.*, *((LeBron James, drafted by, Cleveland Cavaliers), point in time, 2003)*. A qualifier also has a key and a value.

3.2 KoPL Design

We design KoPL, a compositional and interpretable programming language to represent the reasoning process of complex questions. It models the complex procedure of question answering with a program of intermediate steps. Each step involves a function with a fixed number of arguments. Every program can be denoted as a binary tree. As shown in Fig. 1, a directed edge between two nodes represents the dependency relationship between two

---

[1] Wikidata also has other types like geographical and time. We omit them for simplicity and leave them for future work.

functions. That is, the destination function takes the output of the source function as its argument. The tree-structured program can also be serialized by post-order traversal, and formalized as a sequence with n functions. The general form is shown below. Each function f_i takes in a list of textual arguments $\mathbf{a}_i$, which need to be inferred according to the question, and a list of functional arguments $\mathbf{b}_i$, which come from the output of previous functions.

$$f_1(\mathbf{a}_1, \mathbf{b}_1) f_2(\mathbf{a}_2, \mathbf{b}_2) ... f_n(\mathbf{a}_n, \mathbf{b}_n) \tag{1}$$

Take function *Relate* as an example, it has two textual inputs: relation and direction (i.e., *forward* or *backward*, meaning the output is object or subject). It has one functional input: a unique entity. Its output is a set of entities that hold the specific relation with the input entity. For example, in Question 2 of Fig. 1, the function *Relate*([*father, forward*], [*LeBron James Jr.*]) returns LeBron James, the father of LeBron James Jr. (the direction is omitted in the figure for simplicity).

We analyze the generic, basic operations for Complex KBQA, and design 27 functions[2] in KoPL. They support KB item manipulation (*e.g.*, *Find*, *Relate*, *FilterConcept*, *QueryRelationQualifier*, *etc.*), various reasoning skills (*e.g.*, *And*, *Or*, *etc.*), and multiple question types (*e.g.*, *QueryName*, *SelectBetween*, *etc.*). By composing the finite functions into a KoPL program[3], we can model the reasoning process of infinite complex questions.

Note that qualifiers play an essential role in disambiguating or restricting the validity of a fact (Galkin et al., 2020; Liu et al., 2021). However, they have not been adequately modeled in current KBQA models or datasets. As far as we know, we are the first to explicitly model qualifiers in Complex KBQA.

4 KQA Pro Construction

To build KQA Pro dataset, first, we extract a knowledge base with multiple kinds of knowledge (Section 4.1). Then, we generate canonical questions, corresponding KoPL programs and SPARQL queries with novel compositional strategies (Section 4.2). In this stage, we aim to cover all the possible queries through random sampling and recursive composing. Finally, we rewrite canonical questions into natural language via crowdsourcing (Section 4.3). To further increase linguistic variety, we reject the paraphrases whose edit distance with the canonical question is small.

4.1 Knowledge Base Extraction

We took the entities of FB15k-237 (Toutanova et al., 2015) as seeds, and aligned them with Wikidata via Freebase IDs[4]. The reasons are as follows: 1) The vast amount of knowledge in the full knowledge base (*e.g.*, full Freebase (Bollacker et al., 2008) or Wikidata contains millions of entities) may cause both time and space issues, while most of the entities may never be used in questions. 2) FB15k-237 is a high-quality, dense subset of Freebase, whose alignment to Wikidata produces a knowledge base with rich literal and qualifier knowledge. We added 3,000 other entities with the same name as one of FB15k-237 entities to increase the disambiguation difficulty. The statistics of our final knowledge base are listed in Table 2.

# Con.	# Ent.	# Name	# Pred.	# Attr.
794	16,960	14,471	363	846

# Relational facts	# Literal facts	# High-level facts
415,334	174,539	309,407

Table 2: Statistics of our knowledge base. The top lists the numbers of concepts, entities, unique entity names, predicates, and attributes. The bottom lists the numbers of different types of knowledge.

4.2 Question Generation Strategies

To generate diverse complex questions in a scalable manner, we propose to divide the generation into two stages: **locating** and **asking**. In locating stage we describe a single entity or an entity set with various restrictions, while in asking stage we query specific information about the target entity or entity set. We define several strategies for each stage. By sampling from them and composing the two stages, we can generate large-scale and diverse questions with a small number of templates. Fig. 2 gives an example of our generation process.

For locating stage, we propose 7 strategies and show part of them in the top section of Table 3. We can fill the placeholders of templates by sampling from KB to describe a target entity. We support quantitative comparisons of 4 operations: equal, not equal, less than, and greater than, indicated by "`<OP>`" of the template. We support optional qualifier restrictions, indicated by "(`<QK>` is `<QV>`)",

---

[2] The complete function instructions are in Appendix A.

[3] The grammar rules of KoPL are in Appendix B.

[4] The detailed extracting process is in Appendix C.

Strategy	Template	Example
Locating Stage		
Entity Name	-	LeBron James
Concept + Literal	the `<C>` whose `<K>` is `<OP>` `<V>` (`<QK>` is `<QV>`)	the basketball team whose social media followers is greater than 3,000,000 (point in time is 2021)
Concept + Relational	the `<C>` that `<P>` `<E>` (`<QK>` is `<QV>`)	the basketball player that was drafted by Cleveland Cavaliers
Recursive Multi-Hop	unfold `<E>` in a *Concept + Relational* description	the basketball player that was drafted by the basketball team whose social media followers is greater than 3,000,000 (point in time is 2021)
Intersection	Condition 1 *and* Condition 2	the basketball players whose height is greater than 190 centimetres and less than 220 centimetres
Asking Stage		
QueryName	What/Who is `<E>`	Who is the basketball player whose height is equal to 206 centimetres?
Count	How many `<E>`	How many basketball players that were drafted by Cleveland Cavaliers?
SelectAmong	Among `<E>`, which one has the largest/smallest `<K>`	Among basketball players, which one has the largest mass?
Verify	For `<E>`, is his/her/its `<K>` `<OP>` `<V>` (`<QK>` is `<QV>`)	For the human that is the father of LeBron James Jr., is his/her height greater than 180 centimetres?
QualifierRelational	`<E>` `<P>` `<E>`, what is the `<QK>`	LeBron James was drafted by Cleveland Cavaliers, what is the point in time?

Table 3: Representative templates and examples of our locating and asking stage. Placeholders in template have specific implication: `<E>`-description of an entity or entity set; `<C>`-concept; `<K>`-attribute key; `<OP>`-operator, selected from {=, !=, <, >}; `<V>`-attribute value; `<QK>`-qualifier key; `<QV>`-qualifier value; `<P>`-relation description, *e.g.*, *was drafted by*. The complete instruction is in Appendix D.

which can narrow the located entity set. In *Recursive Multi-Hop*, we replace the entity of a relational condition with a more detailed description, so that we can easily increase the hop of questions. For asking stage, we propose 9 strategies and show some of them in the bottom section of Table 3. Our *SelectAmong* is similar to *argmax* and *argmin* operations in λ-DCS. The complete generation strategies are shown in Appendix D due to space limit.

Our generated instance consists of five elements: question, SPARQL query, KoPL program, 10 answer choices, and a golden answer. Choices are selected by executing an abridged SPARQL[5], which randomly drops one clause from the complete SPARQL. With these choices, KQA Pro supports both multiple-choice setting and open-ended setting. We randomly generate lots of questions, and only preserve those with a unique answer. For example, since *Akron* has different populations in different years, we will drop questions like *What is the population of Akron*, unless the time constraint (*e.g.*, *in 2010*) is specified.

4.3 Question Paraphrasing and Evaluation

After large-scale generation, we release the generated questions on Amazon Mechanical Turk (AMT) and ask the workers to paraphrase them without changing the original meaning. For the convenience of paraphrasing, we visualize the KoPL flowcharts like Fig. 1 to help workers understand complex questions. We allow workers to mark a question as confusing if they cannot understand it or find logical errors. These instances will be removed from our dataset.

After paraphrasing, we evaluate the quality by 5 other workers. They are asked to check whether the paraphrase keeps the original meaning and give a fluency rating from 1 to 5. We reject those paraphrases which fall into one of the following cases: (1) marked as different from the original canonical question by more than 2 workers; (2) whose average fluency rating is lower than 3; (3) having a very small edit distance with the canonical question.

4.4 Dataset Analysis

Our KQA Pro dataset consists of 117,970 instances with 24,724 unique answers. Fig. 3(a) shows the question type distribution of KQA Pro. Within the 9 types, *SelectAmong* accounts for the least fraction (4.6%), while others account for more or less than 10%. Fig. 3(b) shows that multi-hop questions cover 73.7% of KQA Pro, and 4.7% questions even require at least 5 hops. We compare the question length distribution of different Complex KBQA

---

[5] The SPARQL implementation details are shown in Appendix E.

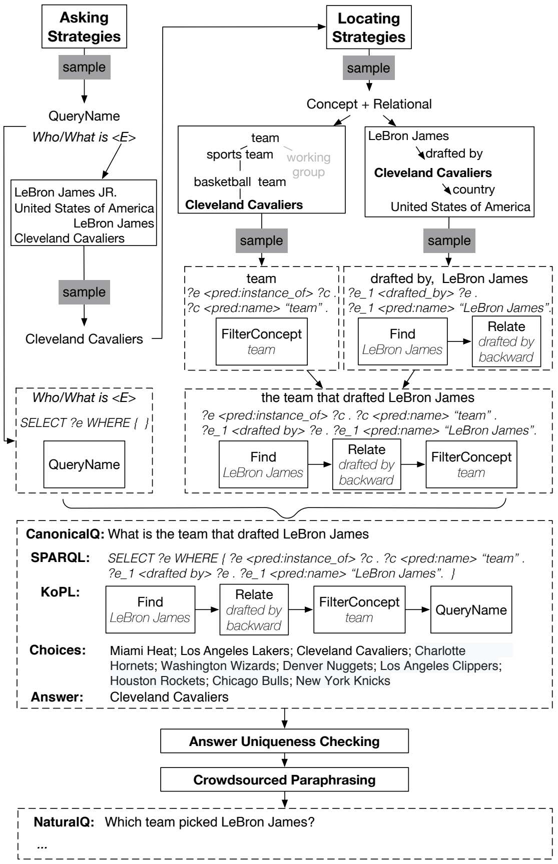

Figure 2: Process of our question generation. First, we sample a question type from asking strategies and sample a target entity from KB. Next, we sample a locating strategy and detailed conditions to describe the target entity. Finally, we combine intermediate snippets into the complete question and check whether the answer is unique. **Note that the snippets of canonical question, SPARQL, and KoPL are operated simultaneously.**. A more detailed explanation of this example is in Appendix F.

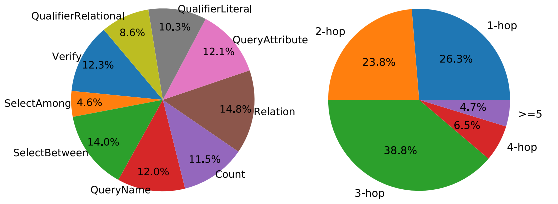
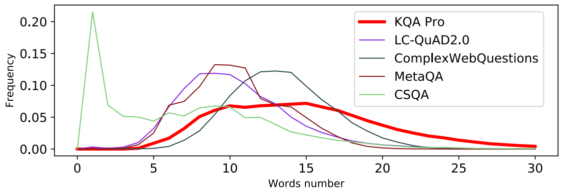


(a) Distribution of 9 different types of questions.

(b) Distribution of question hops. 73.7% of our questions require multiple-hops.



(c) Question length distribution of Complex KBQA datasets. We can see that KQA Pro questions have a wide range of lengths and are longer on average than all others.

Figure 3: Question statistics of KQA Pro.

datasets in Fig. 3(c). We observe that our KQA Pro has longer questions than others on average. In KQA Pro, the average length of questions/programs/SPARQLs is 14.95/4.79/35.52 respectively. More analysis is included in Appendix G.

5 Experiments

The primary goal of our experiments is to show the challenges of KQA Pro and promising Complex KBQA directions. First, we compare the performance of state-of-the-art KBQA models on current datasets and KQA Pro, to show whether KQA Pro is challenging. Then, we treat KQA Pro as a diagnostic dataset to investigate fine-grained reasoning abilities of models, discuss current weakness and promising directions. We further conduct an experiment to explore the generation ability of our proposed model. Last, we provide a case study to show the interpretablity of KoPL.

5.1 Experimental Settings

Benchmark Settings. We randomly split KQA Pro to train/valid/test set by 8/1/1, resulting in three sets with 94,376/11,797/11,797 instances. About 30% answers of the test set are not seen in training.

Representative Models. KBQA models typically follow a retrieve-and-rank paradigm, by constructing a question-specific graph extracted from the KB and ranks all the entities in the graph based on their relevance to the question (Miller et al., 2016; Saxena et al., 2020; Schlichtkrull et al., 2018; Zhang et al., 2018; Zhou et al., 2018; Qiu et al., 2020); or follow a parse-then-execute paradigm, by parsing a question to a query graph (Berant et al., 2013; Yih et al., 2015) or program (Liang et al., 2017; Guo et al., 2018; Saha et al., 2019; Ansari et al., 2019) through learning from question-answer pairs.

Experimenting with all methods is logistically challenging, so we reproduce a representative subset of mothods: **KVMemNet** (Miller et al., 2016), a well-known model which organizes the knowledge into a memory of key-value pairs, and iteratively reads memory to update its query vector. **EmbedKGQA** (Saxena et al., 2020), a state-of-the art model on MetaQA, which incorporates knowledge embeddings to improve the reasoning performance. **SRN** (Qiu et al., 2020), a typical path search model to start from a topic entity and predict a sequential relation path to find the target entity. **RGCN** (Schlichtkrull et al., 2018), a variant of graph convolutional networks, tackling Complex KBQA through the natural graph structure of knowledge base.

Our models. Since KQA Pro provides the annotations of SPARQL and KoPL, we directly learn our parsers using supervised learning by regarding the semantic parsing as a sequence-to-sequence task. We explore the widely-used sequence-to-sequence model—**RNN** with attention mechanism (Dong and Lapata, 2016), and the pretrained generative language model—**BART** (Lewis et al., 2020), as our SPARQL and KoPL parsers.

For KoPL learning, we design a serializer to translate the tree-structured KoPL to a sequence. For example, the KoPL program in Fig. 2 is serialized as: *Find* $\langle arg \rangle$ *LeBron James* $\langle func \rangle$ *Relate* $\langle arg \rangle$ *drafted by* $\langle arg \rangle$ *backward* $\langle func \rangle$ *FilterConcept* $\langle arg \rangle$ *team* $\langle func \rangle$ *QueryName*. Here, $\langle arg \rangle$ and $\langle func \rangle$ are special tokens we designed to indicate the structure of KoPL.

To compare machine with **Human**, we sample 200 instances from the test set, and ask experts to answer them by searching our knowledge base.

Implementation Details. For our BART model, we used the bart-base model of HuggingFace[6]. We used the optimizer Adam (Kingma and Ba, 2015) for all models. We searched the learning rate for BART paramters in {1e-4, 3e-5, 1e-5}, the learning rate for other parameters in {1e-3, 1e-4, 1e-5}, and the weight decay in {1e-4, 1e-5, 1e-6}. According to the performance on validation set, we finally used learning rate 3e-5 for BART parameters, 1e-3 for other parameters, and weight decay 1e-5.

5.2 Difficulty of KQA Pro

We compare the performance of KBQA models on KQA Pro with MetaQA and WebQSP (short for WebQuestionSP), two commonly used benchmarks in Complex KBQA. The experimental results are in Table 4, from which we observe that:

Although the models perform well on MetaQA and WebQSP, their performances are significantly lower and not satisfying on KQA Pro. It indicates that our KQA Pro is challenging and the Complex KBQA still needs more research efforts. Actually, 1) Both MetaQA and WebQSP mainly focus on relational knowledge, *i.e.*, multi-hop questions. Therefore, previous models on these datasets are designed to handle only entities and relations. In comparison, KQA Pro includes three types of knowledge, *i.e.*, relations, attributes, and qualifiers, thus is much more challenging. 2) Compared with MetaQA which contains template questions, KQA Pro contains diverse natural language questions and can evaluate models' language understanding abilities. 3) Compared with WebQSP which contains 4,737 fluent and natural questions, KQA Pro covers more question types (*e.g.*, verification, counting) and reasoning operations (*e.g.*, intersect, union).

Model	**MetaQA**			**WebQSP**	**KQAPro**
	1-hop	2-hop	3-hop		
KVMemNet	96.2	82.7	48.9	46.7	16.61
SRN	97.0	95.1	75.2	-	12.33
EmbedKGQA	97.5	98.8	94.8	66.6	28.36
RGCN	-	-	-	37.2	35.07
BART	-	-	99.9	67.5	88.55

Table 4: SOTA models of Complex KBQA and their performance on different datasets. SRN's result on KQA Pro, 12.33%, is obtained on questions about only relational knowledge. The RGCN results on WebQSP is from (Sun et al., 2018). The BART results on MetaQA 3-hop WebQSP results are from (Huang et al., 2021).

5.3 Analyses on Reasoning Skills

KQA Pro can serve as a diagnostic dataset for in-depth analyses of reasoning abilities (*e.g.*, counting, comparision, logical reasoning, *etc.*) for Complex KBQA, since KoPL programs underlying the questions provide tight control over the dataset.

We categorize the test questions to measure fine-grained ability of models. Specifically, *Multi-hop* means multi-hop questions, *Qualifier* means questions containing qualifier knowledge, *Comparison* means quantitative or temporal comparison between two or more entities, *Logical* means logical union or intersection, *Count* means questions that ask the number of target entities, *Verify* means questions that take "yes" or "no" as the answer, *Zero-shot* means questions whose answer is not seen in the training set. The results are shown in Table 5, from which we have the following observations:

(1) Benefits of intermediate reasoning supervision. Our RNN and BART models outperform current models significantly on all reasoning skills. This is because KoPL program and SPARQL query provide intermediate supervision which benefits the learning process a lot. As (Dua et al., 2020) suggests, future dataset collection efforts should set aside a fraction of budget for intermediate annotations, particularly as the reasoning required

---

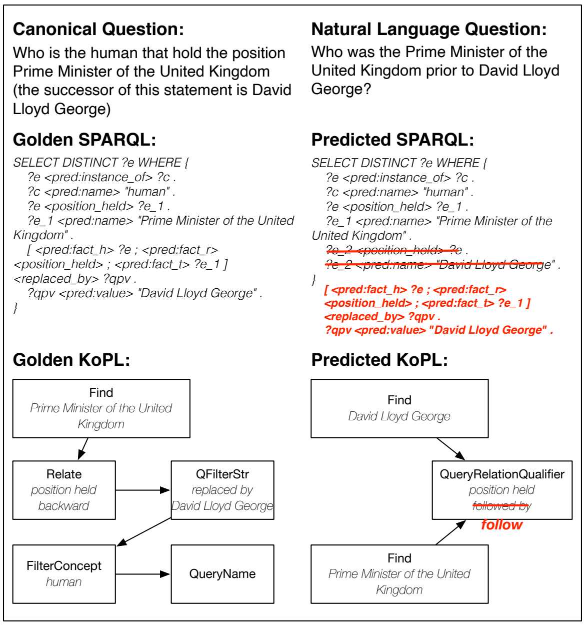
BART KoPL$^{\mathrm{CG}}$	77.86	77.86	61.46	93.61	77.88	79.17	89.01	76.04
Human	97.50	97.24	95.65	100.00	98.18	83.33	95.24	100.00

Table 5: Accuracy of different models on KQA Pro test set. BART KoPL$^{\mathrm{CG}}$ denotes the BART based KoPL parser on the compositional generalization experiment (see Section 5.4)

becomes more complex. We hope our dataset KQA Pro with KoPL and SPARQL annotations will help guide further research in Complex KBQA. (2) More attention to literal and qualifier knowledge. Existing models perform poorly in situations requiring comparison capability. This is because they only focus the relational knowledge, while ignoring the literal and qualifier knowledge. We hope our dataset will encourage the community to pay more attention to multiple kinds of knowledge in Complex KBQA. (3) Generalization to novel questions and answers. For zero-shot questions, current models all have a close to zero performance. This indicates the models solve the questions by simply memorizing their training data, and perform poorly on generalizing to novel questions and answers.

5.4 Compositional Generalization

We further use KQA Pro to test the ability of KBQA models to generalize to questions that contain novel combinations of the elements observed during training. Following previous works, we conduct the "productivity" experiment (Lake and Baroni, 2018; Shaw et al., 2021), which focuses on generalization to longer sequences or to greater compositional depths than have been seen in training (for example, from a length 4 program to a length 5 program). Specifically, we take the instances with short programs as training examples, and those with long programs as test and valid examples, resulting in three sets including 106,182/5,899/5,899 examples. The performance of BART KoPL drops from 90.55% to 77.86%, which indicates learning to generalize compositionally for pretrained language models requires more research efforts. Our KQA Pro provides an environment for further experimentation on compositional generalization.



Canonical Question:
Who is the human that hold the position Prime Minister of the United Kingdom (the successor of this statement is David Lloyd George)

Natural Language Question:
Who was the Prime Minister of the United Kingdom prior to David Lloyd George?

Golden SPARQL:

```
SELECT DISTINCT ?e WHERE {
   ?e <pred:instance_of> ?c .
   ?c <pred:name> "human" .
   ?e <position_held> ?e_1 .
   ?e_1 <pred:name> "Prime Minister of the United
Kingdom" .
   [ <pred:fact_h> ?e ; <pred:fact_r>
<position_held> ; <pred:fact_t> ?e_1 ]
<replaced_by> ?qpv .
   ?qpv <pred:value> "David Lloyd George" .
}
```

Predicted SPARQL:

```
SELECT DISTINCT ?e WHERE {
   ?e <pred:instance_of> ?c .
   ?c <pred:name> "human" .
   ?e <position_held> ?e_1 .
   ?e_1 <pred:name> "Prime Minister of the
United Kingdom" .
   ~~?e_2 <position_held> ?e~~ .
   ~~?e_2 <pred:name> "David Lloyd George~~" .
}
   [ <pred:fact_h> ?e ; <pred:fact_r>
   <position_held> ; <pred:fact_t> ?e_1 ]
   <replaced_by> ?qpv .
   ?qpv <pred:value> "David Lloyd George" .
```

Golden KoPL:

Predicted KoPL:

Figure 4: Predicted SPARQL and KoPL by BART. We show the natural language question and canonical question before human rewriting. We mark the error corrections of the wrong predictions in red.

5.5 Case Study

To further understand the quality of logical forms predicted by the BART parser, we show a case in Fig. 4, for which the SPARQL and KoPL parsers both give wrong predictions. The SPARQL parser fails to understand *prior to David Lloyd George* and gives a totally wrong prediction for this part. The KoPL parser gives a function prediction which is semantically correct but very different from our generated golden one. It is a surprising result, revealing that the KoPL parser can understand the semantics and learn multiple solutions for each question, similar to the learning process of humans. We manually correct the errors of predicted SPARQL and KoPL and mark them in red. Compared to SPARQLs, KoPL programs are easier to be understood and more friendly to be modified.

6 Conclusion and Future Work

In this work, we introduce a large-scale dataset with explicit compositional programs for Complex KBQA. For each question, we provide the corresponding KoPL program and SPARQL query so that KQA Pro can serve for both KBQA and semantic parsing tasks. We conduct a thorough evaluation of various models, discover weaknesses of current models and discuss future directions. Among these models, the KoPL parser shows great interpretability. As shown in Fig. 4, when the model predicts the answer, it will also give a reasoning process and a confidence score (which is ommited in the figure for simplicity). When the parser makes mistakes, humans can easily locate the error through reading the human-like reasoning process or checking the outputs of intermediate functions. In addition, using human correction data, the parser can be incrementally trained to improve the performance continuously. We will leave this as our future work.

A Function Library of KoPL

Table 6 shows our 27 functions and their explanations. Note that we define specific functions for different attribute types (i.e., string, number, date, and year), because the comparison of these types are quite different. Following we explain some necessary items in our functions.

Entities/Entity: *Entities* denotes an entity set, which can be the output or functional input of a function. When the set has a unique element, we get an *Entity*.

Name: A string that denotes the name of an entity or a concept.

Key/Value: The key and value of an attribute.

Op: The comparative operation. It is one of $\{=, \neq, <, >\}$ when comparing two values, one of $\{greater, less\}$ in *SelectBetween*, and one of $\{largest, smallest\}$ in *SelectAmong*.

Pred/Dir: The relation and direction of a relation.

Fact: A literal fact, *e.g.*, (*LeBron James*, *height*, *206 centimetre*), or a relational fact, *e.g.*, (*LeBron James*, *drafted by*, *Cleveland Cavaliers*).

QKey/QValue: The key and value of a qualifier.

B Grammar Rules of KoPL

As shown in Table 7, the supported program space of KoPL can be defined by a synchrounous context-free grammar (SCFG), which is widely used to generate logical forms paired with canonical questions (Wang et al., 2015a; Jia and Liang, 2016; Wu et al., 2021). The programs are meant to cover the desired set of compositional functions, and the canonical questions are meant to capture the meaning of the programs.

C Knowledge Base Extraction

Specifically, we took the entities of FB15k-237 (Toutanova et al., 2015), a popular subset of Freebase, as seeds, and then aligned them with Wikidata via Freebase IDs[7], so that we could extract their rich literal and qualifier knowledge from Wikidata. Besides, we added 3,000 other entities with the same name as one of FB15k-237 entities, to further increase the difficulty of disambiguation. For the relational knowledge, we manually merged the relations of FB15k-237 (*e.g.*, */people/person-/spouse_s./people/marriage/spouse*) and Wikidata (*e.g.*, *spouse*), obtaining 363 relations totally. Finally, we manually filtered out useless attributes (*e.g.*, about images and Wikidata pages) and entities (*i.e.*, never used in triples).

D Generation Strategies

Table 8 list the complete generation strategies, including 7 locating and 9 asking strategies. In locating stage we describe a single entity or an entity set with various restrictions, while in asking stage we query specific information about the target entity or entity set.

E SPARQL Implementation Details

We build a SPARQL engine with Virtuoso [8] to execute generated SPARQLs. To denote qualifiers, we create a virtual node for those literal and relational triples. For example, to denote the point in time of *(LeBron James, drafted by, Cleveland Cavaliers)*, we create a node *_BN* which connects to the subject, the relation, and the object with three special edges, and then add *(_BN, point in time, 2003)* into the graph. Similarly, we use virtual node to represent the attribute value of number type, which has an extra unit. For example, to represent the height of *LeBron James*, we need *(LeBron James, height, _BN), (_BN, value, 206), (_BN, unit, centimetre)*.

F Generation Examples

Consider the example of Fig. 2 in Section 4.2 in the main text, following is a detailed explanation. At the first, the asking stage samples the strategy *QueryName* and samples *Cleveland Cavaliers* from the whole entity set as the target entity. The corresponding textual description, SPARQL, and KoPL of this stage is "*Who is <E>*", "*SELECT ?e WHERE { }*", and "*QueryName*", respectively. Then we switch to the locating stage to describe the target entity *Cleveland Cavaliers*. We sample the strategy, *Concept + Relational*, to locate it. For the concept part, we sample *team* from all concepts of *Cleveland Cavaliers*. The corresponding textual description, SPARQL, and KoPL is "*team*", "*?e <pred:instance_of> ?c . ?c <pred:name> "team" .*", and "*FilterConcept(team)*", respectively. For the relation part, we sample *(LeBron James, drafted by)* from all triples of *Cleveland Cavaliers*. The corresponding textual description, SPARQL, and KoPL is "*drafted LeBron James*", "*?e_1 <drafted*

---

[7] Wikidata provides the Freebase ID for most of its entities, but the relations are not aligned.

[8] https://github.com/openlink/virtuoso-opensource

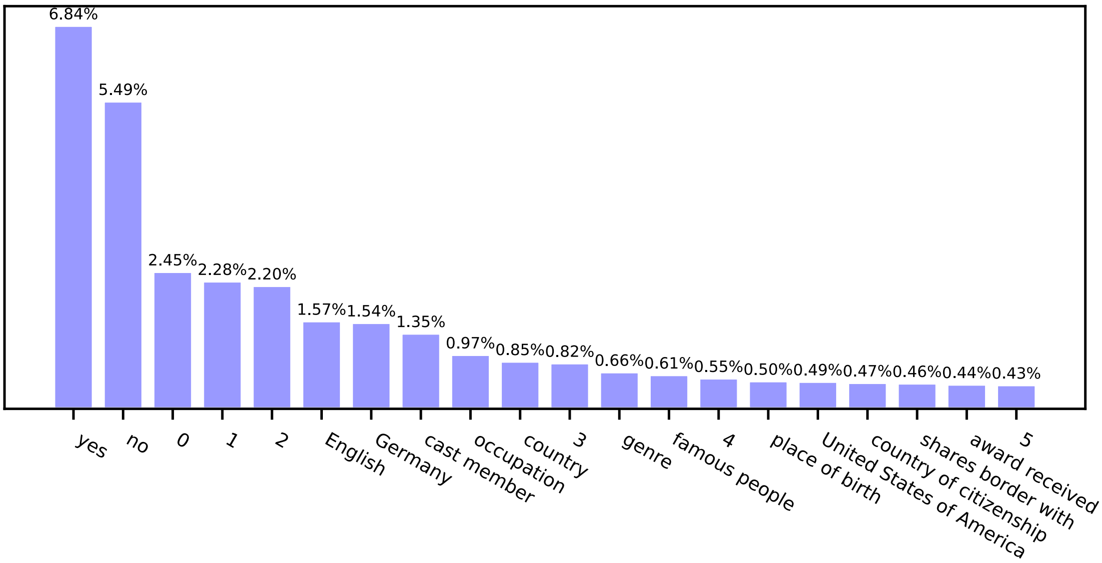

Figure 5: Top 20 most occurring answers in KQA Pro. The most frequent one is ”yes“, which is the answer of about half of type *Verify*.

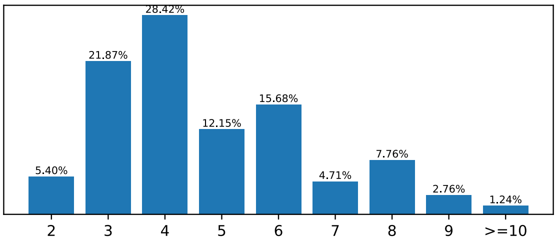

Figure 6: Distribution of program lengths.

by> ?e . ?e_1 <pred:name> ’LeBron James’ .”, “*Find(LeBron James) → Relate(drafted by, backward)*”, respectively. The locating stage combines the concept and the relation, obtaining the entity description “*the team that drafted LeBron James*” and the corresponding SPARQL and KoPL. Finally, we combine the results of the two stages and output the complete question. Figure 8 and 9 show more examples of KQA Pro.

G Data Analysis

There are 24,724 unique answers in KQA Pro. We show the top 20 most frequent answers and their fractions in Fig. 5. “yes” and “no” are the most frequent answers, because they cover all questions of type *Verify*. “0”, “1”, “2”, “3”, and other quantity answers are for questions of type *Count*, which accounts for 11.5%.

Fig. 6 shows the Program length distribution. Most of our problems (28.42%) can be solved by 4 functional steps. Some extreme complicated ones (1.24%) need more than 10 steps.

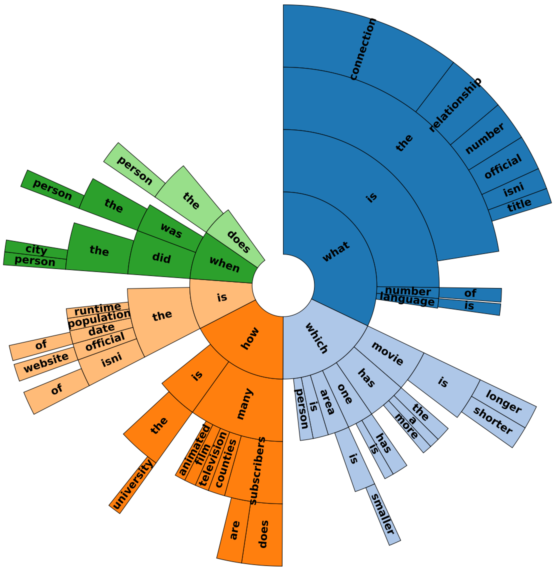

Figure 7: Distribution of first 4 question words.

Fig. 7 shows sunburst for first 4 words in questions. We can see that questions usually start with “what”, “which”, “how many”, “when”, “is” and “does”. Frequent topics include “person”, “movie”, “country”, “university”, and etc.

H Baseline Implementation Details

KVMemNet. For literal and relational knowledge, we concatenated the subject and the attribute/relation as the memory key, *e.g.*, “LeBron James drafted by”, leaving the object as the memory value.

Function	**Functional Inputs × Textual Inputs → Outputs**	**Description**	**Example** (only show textual inputs)
FindAll	() × () → (*Entities*)	Return all entities in KB	-
Find	() × (*Name*) → (*Entities*)	Return all entities with the given name	*Find(LeBron James)*
FilterConcept	(*Entities*) × (*Name*) → (*Entities*)	Find those belonging to the given concept	*FilterConcept(athlete)*
FilterStr	(*Entities*) × (*Key*, *Value*) → (*Entities*, *Facts*)	Filter entities with an attribute condition of string type, return entities and corresponding facts	*FilterStr(gender, male)*
FilterNum	(*Entities*) × (*Key*, *Value*, *Op*) → (*Entities*, *Facts*)	Similar to *FilterStr*, except that the attribute type is number	*FilterNum(height, 200 centimetres, >)*
FilterYear	(*Entities*) × (*Key*, *Value*, *Op*) → (*Entities*, *Facts*)	Similar to *FilterStr*, except that the attribute type is year	*FilterYear(birthday, 1980, =)*
FilterDate	(*Entities*) × (*Key*, *Value*, *Op*) → (*Entities*, *Facts*)	Similar to *FilterStr*, except that the attribute type is date	*FilterDate(birthday, 1980-06-01, <)*
QFilterStr	(*Entities*, *Facts*) × (*QKey*, *QValue*) → (*Entities*, *Facts*)	Filter entities and corresponding facts with a qualifier condition of string type	*QFilterStr(language, English)*
QFilterNum	(*Entities*, *Facts*) × (*QKey*, *QValue*, *Op*) → (*Entities*, *Facts*)	Similar to *QFilterStr*, except that the qualifier type is number	*QFilterNum(bonus, 20000 dollars, >)*
QFilterYear	(*Entities*, *Facts*) × (*QKey*, *QValue*, *Op*) → (*Entities*, *Facts*)	Similar to *QFilterStr*, except that the qualifier type is year	*QFilterYear(start time, 1980, =)*
QFilterDate	(*Entities*, *Facts*) × (*QKey*, *QValue*, *Op*) → (*Entities*, *Facts*)	Similar to *QFilterStr*, except that the qualifier type is date	*QFilterDate(start time, 1980-06-01, <)*
Relate	(*Entity*) × (*Pred*, *Dir*) → (*Entities*, *Facts*)	Find entities that have a specific relation with the given entity	*Relate(capital, forward)*
And	(*Entities*, *Entities*) × () → (*Entities*)	Return the intersection of two entity sets	-
Or	(*Entities*, *Entities*) × () → (*Entities*)	Return the union of two entity sets	-
QueryName	(*Entity*) × () → (string)	Return the entity name	-
Count	(*Entities*) × () → (number)	Return the number of entities	-
QueryAttr	(*Entity*) × (*Key*) → (*Value*)	Return the attribute value of the entity	*QueryAttr(height)*
QueryAttrUnderCondition	(*Entity*) × (*Key*, *QKey*, *QValue*) → (*Value*)	Return the attribute value, whose corresponding fact should satisfy the qualifier condition	*QueryAttrUnderCondition(population, point in time, 2019)*
QueryRelation	(*Entity*, *Entity*) × () → (*Pred*)	Return the relation between two entities	*QueryRelation(LeBron James, Cleveland Cavaliers)*
SelectBetween	(*Entity*, *Entity*) × (*Key*, *Op*) → (string)	From the two entities, find the one whose attribute value is greater or less and return its name	*SelectBetween(height, greater)*
SelectAmong	(*Entities*) × (*Key*, *Op*) → (string)	From the entity set, find the one whose attribute value is the largest or smallest	*SelectAmong(height, largest)*
VerifyStr	(*Value*) × (*Value*) → (boolean)	Return whether the output of *QueryAttr* or *QueryAttrUnderCondition* and the given value are equal as string	*VerifyStr(male)*
VerifyNum	(*Value*) × (*Value*, *Op*) → (boolean)	Return whether the two numbers satisfy the condition	*VerifyNum(20000 dollars, >)*
VerifyYear	(*Value*) × (*Value*, *Op*) → (boolean)	Return whether the two years satisfy the condition	*VerifyYear(1980, >)*
VerifyDate	(*Value*) × (*Value*, *Op*) → (boolean)	Return whether the two dates satisfy the condition	*VerifyDate(1980-06-01, >)*
QueryAttrQualifier	(*Entity*) × (*Key*, *Value*, *QKey*) → (*QValue*)	Return the qualifier value of the fact (*Entity*, *Key*, *Value*)	*QueryAttrQualifier(population, 199,110, point in time)*
QueryRelationQualifier	(*Entity*, *Entity*) × (*Pred*, *QKey*) → (*QValue*)	Return the qualifier value of the fact (*Entity*, *Pred*, *Entity*)	*QueryRelationQualifier(drafted by, point in time)*

Table 6: Details of our 27 functions. Each function has 2 kinds of inputs: the functional inputs come from the output of previous functions, while the textual inputs come from the question.

For high-level knowledge, we concatenated the fact and the qualifier key as the memory key, *e.g.*, "LeBron James drafted by Cleveland Cavaliers point in time". For each question, we pre-selected a small subset of the KB as its relavant memory. Following (Miller et al., 2016), we retrieved 1,000 key-value pairs where the key shares at least one word with the question with frequency < 1000 (to ignore stop words). KVMemNet iteratively updates a query vector by reading the memory attentively. In our experiment we set the update steps to 3.

SRN. SRN can only handle relational knowledge. It must start from a topic entity and terminate with a predicted entity. So we filtered out questions that contain literal knowledge or qualifier knowledge, retaining 5,004 and 649 questions as its training set and test set. Specifically, we retained the questions with *Find* as the first function and *QueryName* as the last function. The textual input of the first *Find* was regarded as the topic entity and was fed into the model during both training and testing phase.

EmbedKGQA. EmbedKGQA utilizes knowledge graph embedding to improve multi-hop reasoning. To adapt to existing knowledge embedding techniques, we added virtual nodes to represent the qualifier knowledge of KQA Pro. Different from SRN, we applied EmbedKGQA on the entire KQA Pro dataset, because its classification layer is more flexible than SRN and can predict answers outside the entity set. The topic entity of each question was

Table 7: SCFG rules for producing KoPL program and canonical question pairs. "|" matches either expression in a group. "?" denotes the expression preceding it is optional. *Key_Text*, *QKey_Text*, and *Pred_Text* denote the annotated template for attribute keys, qualifier keys, and relations. For example, for *Pred place of birth*, the *Pred_Text* is "was born in".

extracted from the golden program and then fed into the model during both training and testing.

RGCN. To build the graph, we took entities as nodes, connections between them as edges, and relations as edge labels. We concatenated the literal attributes of an entity into a sequence as the node description. For simplicity, we ignored the qualifier knowledge. Given a question, we first initialized node vectors by fusing the information of node descriptions and the question, then conducted RGCN to update the node features, and finally aggregated features of nodes and the question to predict the answer via a classification layer. Our RGCN implementation is based on DGL,[9] a high performance Python package for deep learning on graphs. Due to the memory limit, we set the graph layer to 1 and set the hidden dimension of nodes and edges to 32.

RNN-based KoPL and SPARQL Parsers. For KoPL prediction, we first parsed the question to the sequence of functions, and then predicted textual inputs for each function. We used Gated Recurrent Unit (GRU) (Cho et al., 2014; Chung et al., 2014), a well-known variant of RNNs, as our encoder of questions and decoder of functions. At-

Strategy	Template	Example
Locating Stage		
Entity Name	-	LeBron James
Concept Name	`<C>`	basketball players
Concept + Literal	the (<C>) whose `<K>` is `<OP>` `<V>` (`<QK>` is `<QV>`)	the basketball team whose social media followers is greater than 3,000,000 (point in time is 2021)
Concept + Relational	the (<C>) that `<P>` `<E>` (`<QK>` is `<QV>`)	the basketball player that was drafted by Cleveland Cavaliers
Recursive Multi-Hop	unfold `<E>` in a *Concept + Relational* description	the basketball player that was drafted by the basketball team whose social media followers is greater than 3,000,000 (point in time is 2021)
Intersection	Condition 1 *and* Condition 2	the basketball players whose height is greater than 190 centimetres and less than 220 centimetres
Union	Condition 1 *or* Condition 2	the basketball players that were born in Akron or Cleveland
Asking Stage		
QueryName	What/Who is `<E>`	Who is the basketball player whose height is equal to 206 centimetres?
Count	How many `<E>`	How many basketball players that were drafted by Cleveland Cavaliers?
QueryAttribute	For `<E>`, what is his/her/its `<K>` (`<QK>` is `<QV>`)	For Cleveland Cavaliers, what is its social media follower number (point in time is January 2021)?
Relation	What is the relation from `<E>` to `<E>`	What is the relation from LeBron James Jr. to LeBron James?
SelectAmong	Among `<E>`, which one has the largest/smallest `<K>`	Among basketball players, which one has the largest mass?
SelectBetween	Which one has the larger/smaller `<K>`, `<E>` or `<E>`	Which one has the larger mass, LeBron James Jr. or LeBron James?
Verify	For `<E>`, is his/her/its `<K>` `<OP>` `<V>` (`<QK>` is `<QV>`)	For the human that is the father of LeBron James Jr., is his/her height greater than 180 centimetres?
QualifierLiteral	For `<E>`, his/her/its `<K>` is `<V>`, what is the `<QK>`	For Akron, its population is 199,110, what is the point in time?
QualifierRelational	`<E>` `<P>` `<E>`, what is the `<QK>`	LeBron James was drafted by Cleveland Cavaliers, what is the point in time?

Table 8: Templates and examples of our locating and asking stage. Placeholders in template have specific implication: `<E>`-description of an entity or entity set; `<C>`-concept; `<K>`-attribute key; `<OP>`-operator, selected from {=, !=, <, >}; `<V>`-attribute value; `<QK>`-qualifier key; `<QV>`-qualifier value; `<P>`-relation description, *e.g.*, *was drafted by*.

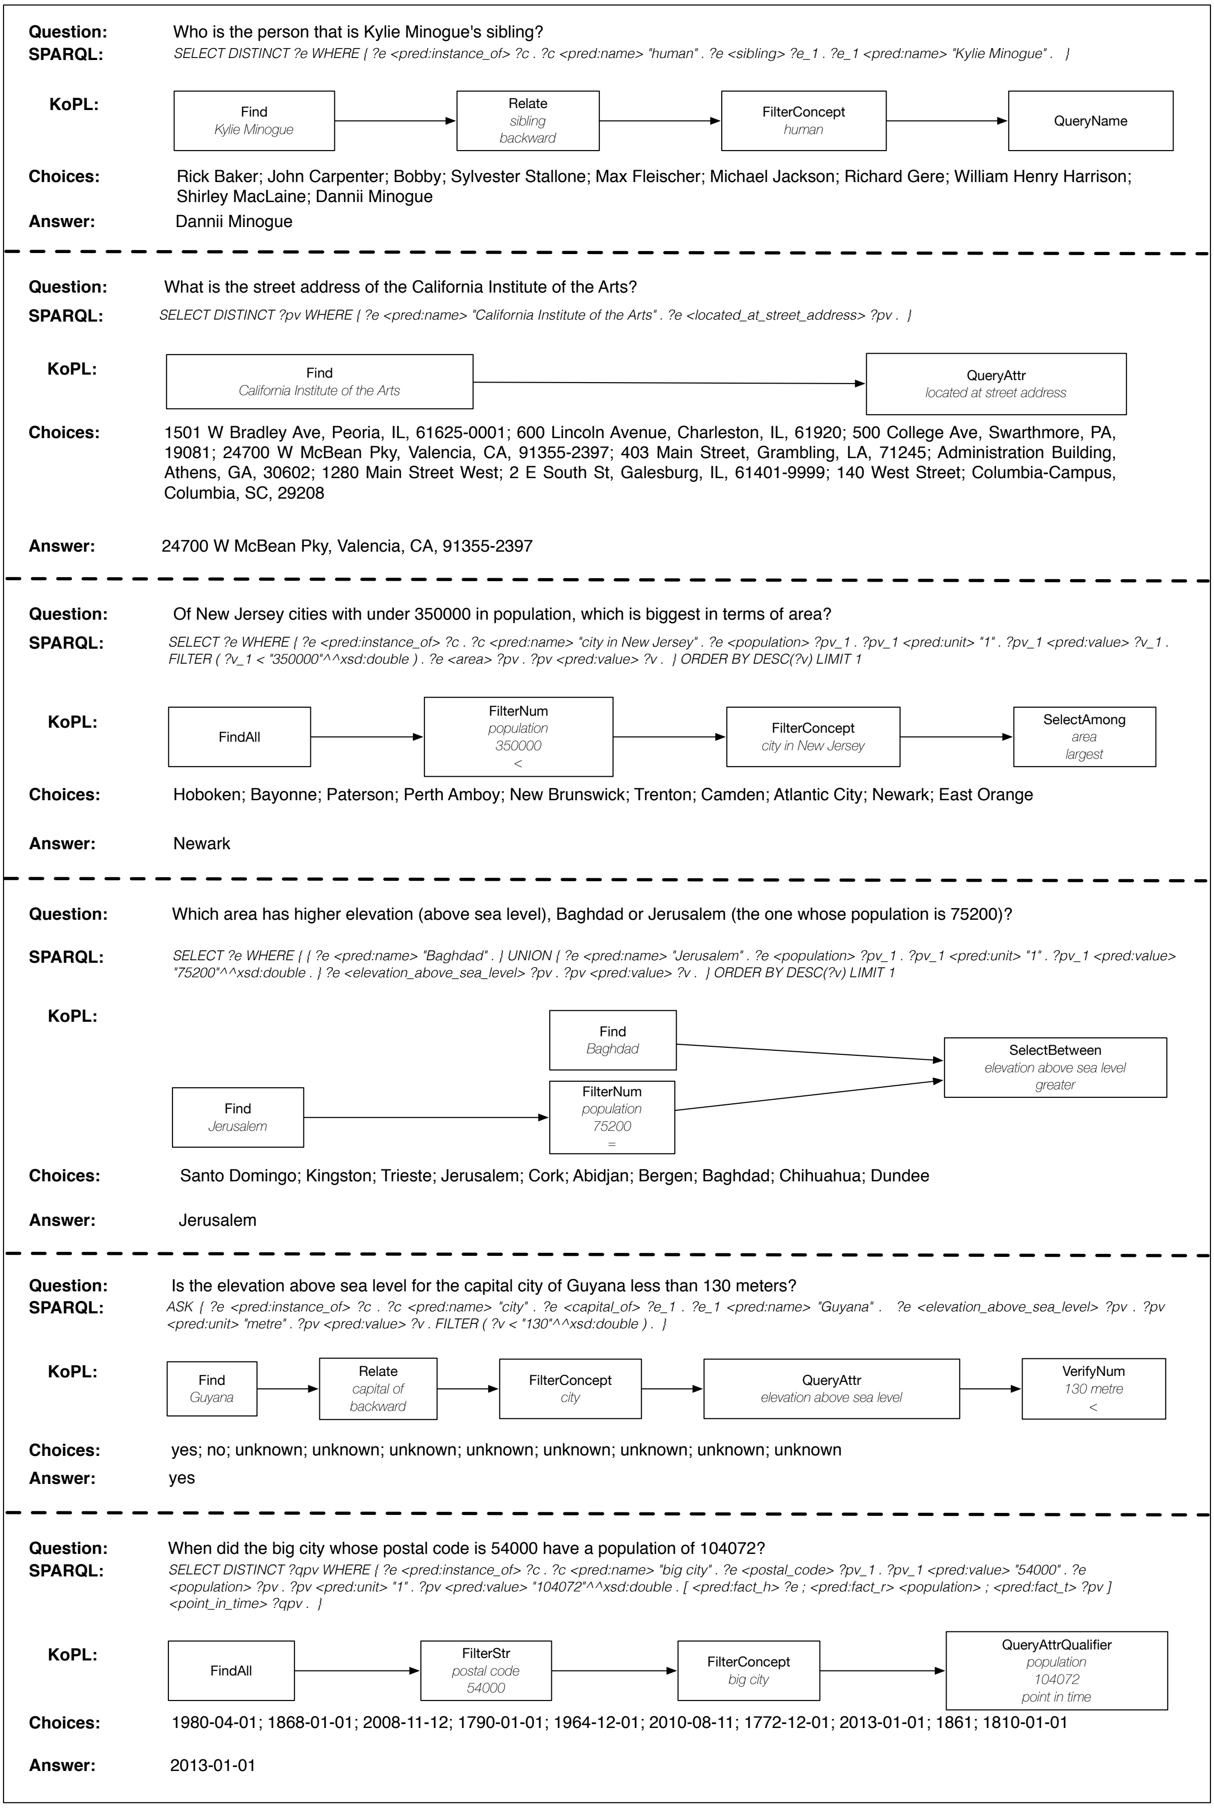
tention mechanism (Dong and Lapata, 2016) was applied by focusing on the most relavant question words when predicting each function and each textual input. The SPARQL parser used the same encoder-decoder structure to produce SPARQL token sequences. We tokenized the SPARQL query by delimiting spaces and some special punctuation symbols.

I BART KoPL Accuracy of different #hops

In Table 9, we presents the BART KoPL accuracy of different #hops. Note that KQA Pro not only consider multi-hop relations, but also consider attributes and qualifiers. We count all of them into the hop number. So in KQA Pro, given a question with “4-hops”, it does not mean 4 relations, but may be 1 relations + 2 attributes + 1 comparison. *E.g.*, “Who is taller, LeBron James Jr. or his father?”.

2-3 Hop	4-5 Hop	6-7 Hop	8-9 Hop
92.4	87.71	86.41	86.51

Table 9: BART KoPL Accuracy of different #hops.



Question: Who is the person that is Kylie Minogue's sibling?

SPARQL: *SELECT DISTINCT ?e WHERE { ?e <pred:instance_of> ?c . ?c <pred:name> "human" . ?e <sibling> ?e_1 . ?e_1 <pred:name> "Kylie Minogue" .   }*

KoPL:

Choices: Rick Baker; John Carpenter; Bobby; Sylvester Stallone; Max Fleischer; Michael Jackson; Richard Gere; William Henry Harrison; Shirley MacLaine; Dannii Minogue

Answer: Dannii Minogue

Question: What is the street address of the California Institute of the Arts?

SPARQL: *SELECT DISTINCT ?pv WHERE { ?e <pred:name> "California Institute of the Arts" . ?e <located_at_street_address> ?pv . }*

KoPL:

Choices: 1501 W Bradley Ave, Peoria, IL, 61625-0001; 600 Lincoln Avenue, Charleston, IL, 61920; 500 College Ave, Swarthmore, PA, 19081; 24700 W McBean Pky, Valencia, CA, 91355-2397; 403 Main Street, Grambling, LA, 71245; Administration Building, Athens, GA, 30602; 1280 Main Street West; 2 E South St, Galesburg, IL, 61401-9999; 140 West Street; Columbia-Campus, Columbia, SC, 29208

Answer: 24700 W McBean Pky, Valencia, CA, 91355-2397

Question: Of New Jersey cities with under 350000 in population, which is biggest in terms of area?

SPARQL: *SELECT ?e WHERE { ?e <pred:instance_of> ?c . ?c <pred:name> "city in New Jersey" . ?e <population> ?pv_1 . ?pv_1 <pred:unit> "1" . ?pv_1 <pred:value> ?v_1 . FILTER (?v_1 < "350000"^^xsd:double) . ?e <area> ?pv . ?pv <pred:value> ?v . } ORDER BY DESC(?v) LIMIT 1*

KoPL:

Choices: Hoboken; Bayonne; Paterson; Perth Amboy; New Brunswick; Trenton; Camden; Atlantic City; Newark; East Orange

Answer: Newark

Question: Which area has higher elevation (above sea level), Baghdad or Jerusalem (the one whose population is 75200)?

SPARQL: *SELECT ?e WHERE { { ?e <pred:name> "Baghdad" . } UNION { ?e <pred:name> "Jerusalem" . ?e <population> ?pv_1 . ?pv_1 <pred:unit> "1" . ?pv_1 <pred:value> "75200"^^xsd:double . } ?e <elevation_above_sea_level> ?pv . ?pv <pred:value> ?v . } ORDER BY DESC(?v) LIMIT 1*

KoPL:

Choices: Santo Domingo; Kingston; Trieste; Jerusalem; Cork; Abidjan; Bergen; Baghdad; Chihuahua; Dundee

Answer: Jerusalem

Question: Is the elevation above sea level for the capital city of Guyana less than 130 meters?

SPARQL: *ASK { ?e <pred:instance_of> ?c . ?c <pred:name> "city" . ?e <capital_of> ?e_1 . ?e_1 <pred:name> "Guyana" . ?e <elevation_above_sea_level> ?pv . ?pv <pred:unit> "metre" . ?pv <pred:value> ?v . FILTER (?v < "130"^^xsd:double) . }*

KoPL:

Choices: yes; no; unknown; unknown; unknown; unknown; unknown; unknown; unknown; unknown

Answer: yes

Question: When did the big city whose postal code is 54000 have a population of 104072?

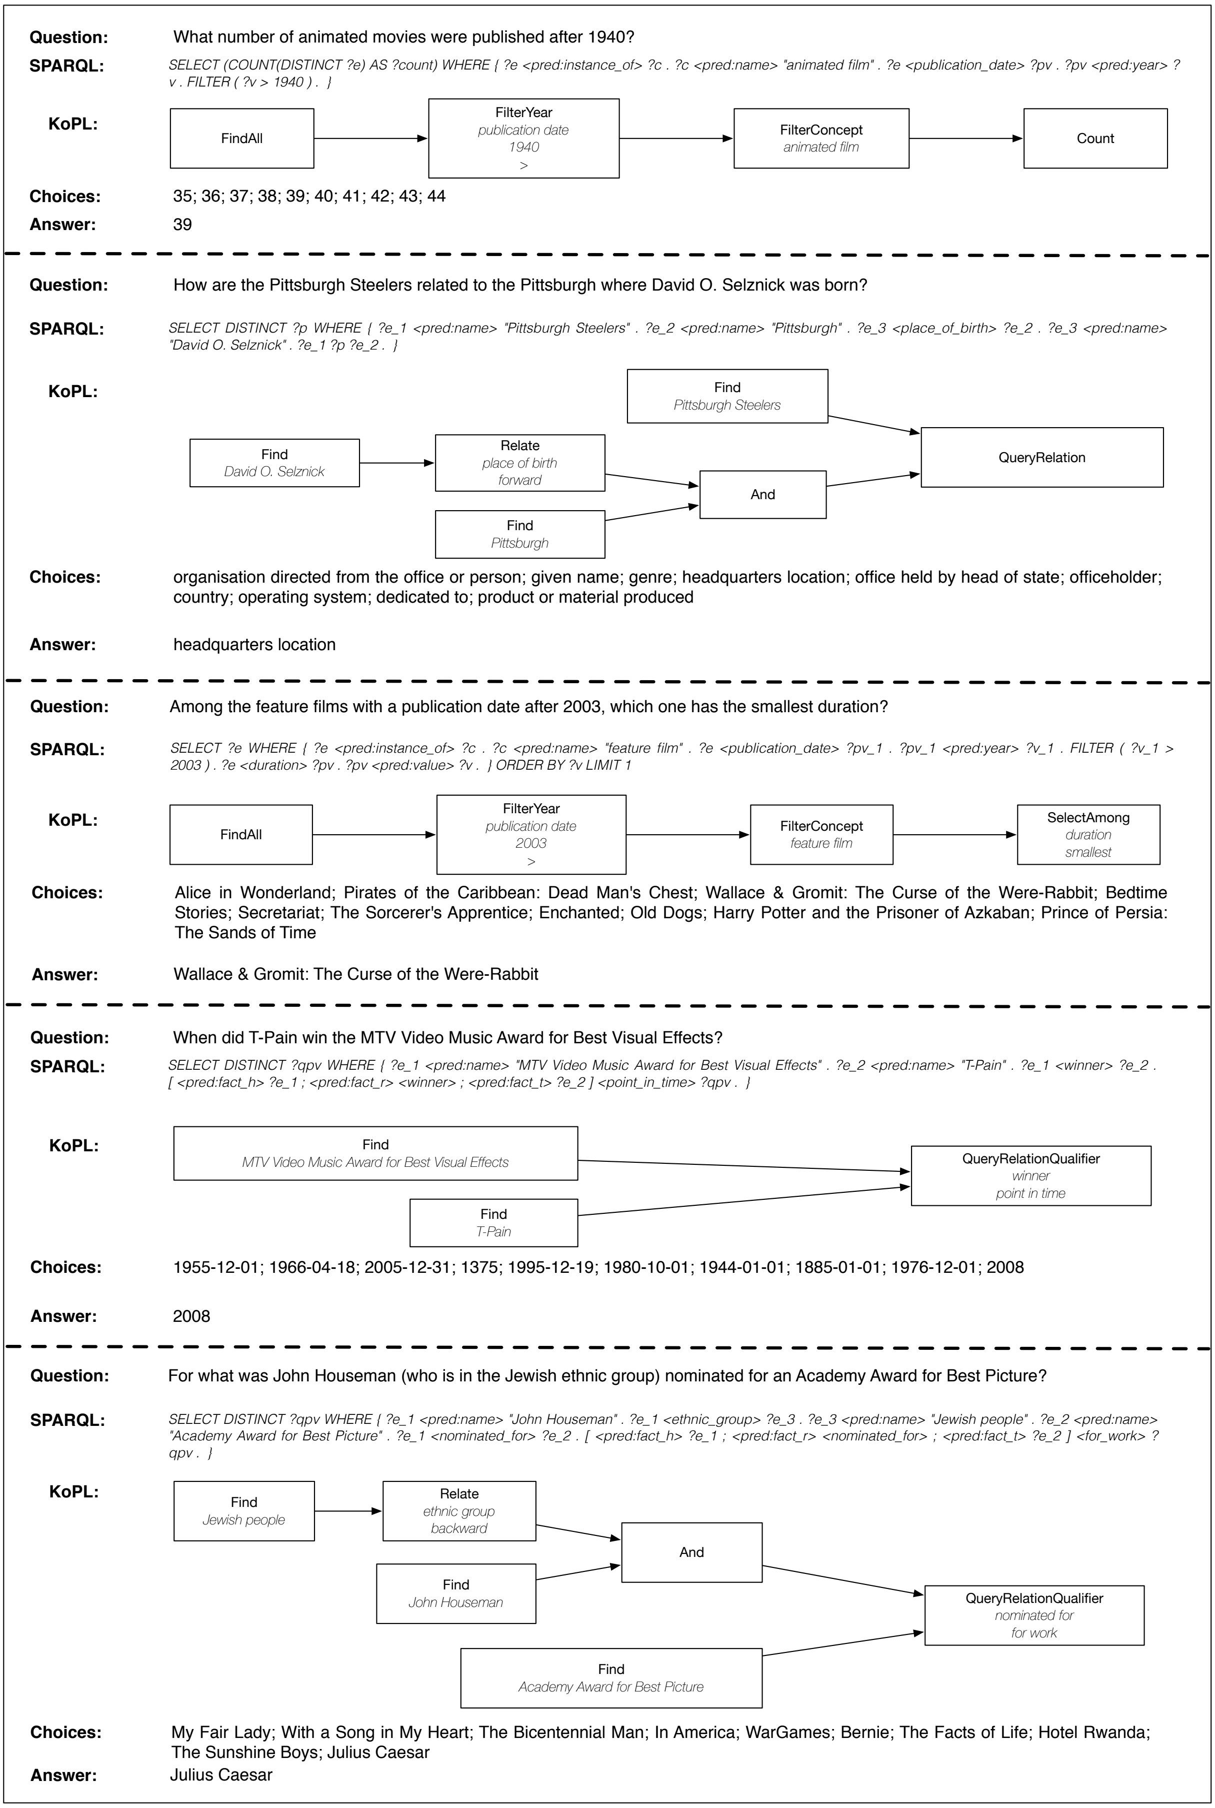
SPARQL: *SELECT DISTINCT ?qpv WHERE { ?e <pred:instance_of> ?c . ?c <pred:name> "big city" . ?e <postal_code> ?pv_1 . ?pv_1 <pred:value> "54000" . ?e <population> ?pv . ?pv <pred:unit> "1" . ?pv <pred:value> "104072"^^xsd:double . [<pred:fact_h> ?e ; <pred:fact_r> <population> ; <pred:fact_t> ?pv] <point_in_time> ?qpv . }*

KoPL:

Choices: 1980-04-01; 1868-01-01; 2008-11-12; 1790-01-01; 1964-12-01; 2010-08-11; 1772-12-01; 2013-01-01; 1861; 1810-01-01

Answer: 2013-01-01

Figure 8: Examples of KQA Pro. In KQA Pro, each instance consists of 5 components: the textual question, the corresponding SPARQL, the corresponding KoPL, 10 candidate choices, and the golden answer. Choices are separated by semicolons in this figure. For questions of *Verify* type, the choices are composed of "yes", "no", and 8 special token "unknown" for padding.



Question: What number of animated movies were published after 1940?

SPARQL:

```
SELECT (COUNT(DISTINCT ?e) AS ?count) WHERE { ?e <pred:instance_of> ?c . ?c <pred:name> "animated film" . ?e <publication_date> ?pv . ?pv <pred:year> ?v . FILTER ( ?v > 1940 ) .  }
```

KoPL:

Choices: 35; 36; 37; 38; 39; 40; 41; 42; 43; 44

Answer: 39

Question: How are the Pittsburgh Steelers related to the Pittsburgh where David O. Selznick was born?

SPARQL:

```
SELECT DISTINCT ?p WHERE { ?e_1 <pred:name> "Pittsburgh Steelers" . ?e_2 <pred:name> "Pittsburgh" . ?e_3 <place_of_birth> ?e_2 . ?e_3 <pred:name> "David O. Selznick" . ?e_1 ?p ?e_2 .  }
```

KoPL:

Choices: organisation directed from the office or person; given name; genre; headquarters location; office held by head of state; officeholder; country; operating system; dedicated to; product or material produced

Answer: headquarters location

Question: Among the feature films with a publication date after 2003, which one has the smallest duration?

SPARQL:

```
SELECT ?e WHERE { ?e <pred:instance_of> ?c . ?c <pred:name> "feature film" . ?e <publication_date> ?pv_1 . ?pv_1 <pred:year> ?v_1 . FILTER ( ?v_1 > 2003 ) . ?e <duration> ?pv . ?pv <pred:value> ?v .  } ORDER BY ?v LIMIT 1
```

KoPL:

Choices: Alice in Wonderland; Pirates of the Caribbean: Dead Man's Chest; Wallace & Gromit: The Curse of the Were-Rabbit; Bedtime Stories; Secretariat; The Sorcerer's Apprentice; Enchanted; Old Dogs; Harry Potter and the Prisoner of Azkaban; Prince of Persia: The Sands of Time

Answer: Wallace & Gromit: The Curse of the Were-Rabbit

Question: When did T-Pain win the MTV Video Music Award for Best Visual Effects?

SPARQL:

```
SELECT DISTINCT ?qpv WHERE { ?e_1 <pred:name> "MTV Video Music Award for Best Visual Effects" . ?e_2 <pred:name> "T-Pain" . ?e_1 <winner> ?e_2 . [ <pred:fact_h> ?e_1 ; <pred:fact_r> <winner> ; <pred:fact_t> ?e_2 ] <point_in_time> ?qpv .  }
```

KoPL:

Choices: 1955-12-01; 1966-04-18; 2005-12-31; 1375; 1995-12-19; 1980-10-01; 1944-01-01; 1885-01-01; 1976-12-01; 2008

Answer: 2008

Question: For what was John Houseman (who is in the Jewish ethnic group) nominated for an Academy Award for Best Picture?

SPARQL:

```
SELECT DISTINCT ?qpv WHERE { ?e_1 <pred:name> "John Houseman" . ?e_1 <ethnic_group> ?e_3 . ?e_3 <pred:name> "Jewish people" . ?e_2 <pred:name> "Academy Award for Best Picture" . ?e_1 <nominated_for> ?e_2 . [ <pred:fact_h> ?e_1 ; <pred:fact_r> <nominated_for> ; <pred:fact_t> ?e_2 ] <for_work> ?qpv .  }
```

KoPL:

Choices: My Fair Lady; With a Song in My Heart; The Bicentennial Man; In America; WarGames; Bernie; The Facts of Life; Hotel Rwanda; The Sunshine Boys; Julius Caesar

Answer: Julius Caesar

Abstract

Recently, contrastive learning has been shown to be effective in improving pre-trained language models (PLM) to derive high-quality sentence representations. It aims to pull close positive examples to enhance the alignment while push apart irrelevant negatives for the uniformity of the whole representation space. However, previous works mostly adopt in-batch negatives or sample from training data at random. Such a way may cause the sampling bias that improper negatives (*e.g.,* false negatives and anisotropy representations) are used to learn sentence representations, which will hurt the uniformity of the representation space. To address it, we present a new framework **DCLR** (Debiased Contrastive Learning of unsupervised sentence Representations) to alleviate the influence of these improper negatives. In DCLR, we design an instance weighting method to punish false negatives and generate noise-based negatives to guarantee the uniformity of the representation space. Experiments on seven semantic textual similarity tasks show that our approach is more effective than competitive baselines. Our code and data are publicly available at the link: `https://github.com/RUCAIBox/DCLR`.

1 Introduction

As a fundamental task in the natural language processing (NLP) field, unsupervised sentence representation learning (Kiros et al., 2015; Hill et al., 2016) aims to derive high-quality sentence representations that can benefit various downstream tasks, especially for low-resourced domains or computationally expensive tasks, *e.g.,* zero-shot text semantic matching (Qiao et al., 2016), large-scale semantic similarity comparison (Agirre et al., 2015), and document retrieval (Le and Mikolov, 2014).

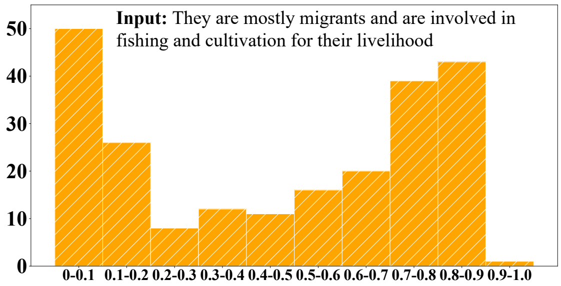

Figure 1: The distribution of cosine similarity between an input sentence and 255 in-batch negatives from the commonly-used Wikipedia Corpus. It is evaluated by the SimCSE model (Gao et al., 2021). Almost half of the negatives have high similarities with the input.

Recently, pre-trained language models (PLMs) (Devlin et al., 2019) have become a widely-used semantic representation approach, achieving remarkable performance on various NLP tasks. However, several studies have found that the native sentence representations derived by PLMs are not uniformly distributed with respect to directions, but instead occupy a *narrow cone* in the vector space (Ethayarajh, 2019), which largely limits their expressiveness. To address this issue, contrastive learning (Chen et al., 2020) has been adopted to refine PLM-derived sentence representations. It pulls semantically-close neighbors together to improve the alignment, while pushes apart non-neighbors for the uniformity of the whole representation space. In the learning process, both positive and negative examples are involved in contrast with the original sentence. For positive examples, previous works apply data augmentation strategies (Yan et al., 2021) on the original sentence to generate highly similar variations. While, negative examples are commonly sampled from the batch or training data (*e.g.,* in-batch negatives (Gao et al., 2021)) at random, due to the lack of ground-truth annotations for negatives.

Although such a negative sampling way is simple and convenient, it may cause *sampling bias* and affect the sentence representation learning. First, the sampled negatives are likely to be *false negatives* that are indeed semantically close to the

original sentence. As shown in Figure 1, given an input sentence, about half of in-batch negatives have a cosine similarity above 0.7 with the original sentence based on the SimCSE model (Gao et al., 2021). It is likely to hurt the semantics of the sentence representations by simply pushing apart these sampled negatives. Second, due to the anisotropy problem (Ethayarajh, 2019), the representations of sampled negatives are from the narrow representation cone spanned by PLMs, which cannot fully reflect the overall semantics of the representation space. Hence, it is sub-optimal to only rely on these representations for learning the uniformity objective of sentence representations.

To address the above issues, we aim to develop a better contrastive learning approach with debiased negative sampling strategies.The core idea is to improve the random negative sampling strategy for alleviating the sampling bias problem. First, in our framework, we design an instance weighting method to punish the sampled false negatives during training. We incorporate a complementary model to evaluate the similarity between each negative and the original sentence, then assign lower weights for negatives with higher similarity scores. In this way, we can detect semantically-close false negatives and further reduce their influence. Second, we randomly initialize new negatives based on random Gaussian noises to simulate sampling within the whole semantic space, and devise a gradient-based algorithm to optimize the noise-based negatives towards the most nonuniform points. By learning to contrast with the nonuniform noise-based negatives, we can extend the occupied space of sentence representations and improve the uniformity of the representation space.

To this end, we propose **DCLR**, a general framework towards Debiased Contrastive Learning of unsupervised sentence Representations. In our approach, we first initialize the noise-based negatives from a Gaussian distribution, and leverage a gradient-based algorithm to update the new negatives by considering the uniformity of the representation space. Then, we adopt the complementary model to produce the weights for these noise-based negatives and randomly sampled negatives, where the false negatives will be punished. Finally, we augment the positive examples via dropout (Gao et al., 2021) and combine them with the above weighted negatives for contrastive learning. We demonstrate that our DCLR outperforms a number of competitive baselines on seven semantic textual similarity (STS) tasks using BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019).

Our contributions are summarized as follows:

(1) To our knowledge, our approach is the first attempt to reduce the sampling bias in contrastive learning of unsupervised sentence representations.

(2) We propose DCLR, a debiased contrastive learning framework that incorporates an instance weighting method to punish false negatives and generates noise-based negatives to guarantee the uniformity of the representation space.

(3) Experimental results on seven semantic textual similarity tasks show the effectiveness of our framework.

2 Related Work

In this section, we review the related work from the following three aspects.

Sentence Representation Learning. Learning universal sentence representations (Kiros et al., 2015; Hill et al., 2016) is the key to the success of various downstream tasks. Previous works can be roughly categorized into supervised (Conneau et al., 2017; Cer et al., 2018) and unsupervised approaches (Hill et al., 2016; Li et al., 2020). Supervised approaches rely on annotated datasets (*e.g.,* NLI (Bowman et al., 2015; Williams et al., 2018)) to train the sentence encoder (Cer et al., 2018; Reimers and Gurevych, 2019). Unsupervised approaches consider deriving sentence representations without labeled datasets, *e.g.,* pooling word2vec embeddings (Mikolov et al., 2013). Recently, to leverage the strong potential of PLMs (Devlin et al., 2019), several works propose to alleviate the anisotropy problem (Ethayarajh, 2019; Li et al., 2020) of PLMs via special strategies, *e.g.,* flow-based approach (Li et al., 2020) and whitening method (Huang et al., 2021). Besides, contrastive learning (Wu et al., 2020; Gao et al., 2021) has been used to refine the representations of PLMs.

Contrastive Learning. Contrastive learning has been originated in the computer vision (Hadsell et al., 2006; He et al., 2020) and information retrieval (Bian et al., 2021; Zhou et al., 2022) field with significant performance improvement. Usually, it relies on data augmentation strategies such as random cropping and image rotation (Chen et al., 2020; Yan et al., 2021) to produce a set of semantically related positive examples for learning, and randomly samples negatives from the batch or whole dataset. For sentence representation learning, contrastive learning can achieve a better balance between alignment and uniformity in semantic representation space. Several works further adopt back translation (Fang and Xie, 2020), token shuffling (Yan et al., 2021) and dropout (Gao et al., 2021) to augment positive examples for sentence representation learning. However, the quality of the randomly sampled negatives is seldom studied.

Virtual Adversarial Training. Virtual adversarial training (VAT) (Miyato et al., 2019; Kurakin et al., 2017) perturbs a given input with learnable noises to maximize the divergence of the model's prediction with the original label, then utilizes the perturbed examples to improve the generalization (Miyato et al., 2017; Madry et al., 2018). A class of VAT methods can be formulated into solving a min-max problem, which can be achieved by multiple projected gradient ascent steps (Qin et al., 2019). In the NLP field, several studies incorporate adversarial perturbations in the embedding layer, and show its effectiveness on text classification (Miyato et al., 2017), machine translation (Sun et al., 2020), and natural language understanding (Jiang et al., 2020) tasks.

3 Preliminary

This work aims to make use of unlabeled corpus for learning effective sentence representations that can be directly utilized for downstream tasks, *e.g.,* semantic textual similarity task (Agirre et al., 2015). Given a set of input sentences $\mathcal{X} = \{x_1, x_2, \ldots, x_n\}$, our goal is to learn a representation $h_i \in \mathcal{R}^d$ for each sentence x_i in an unsupervised manner. For simplicity, we denote this process with a parameterized function $h_i = f(x_i)$.

In this work, we mainly focus on using BERT-based PLMs (Devlin et al., 2019; Liu et al., 2019) to generate sentence representations. Following existing works (Li et al., 2020; Yan et al., 2021), we fine-tune PLMs on the unlabeled corpus via our proposed unsupervised learning approach. After that, for each sentence x_i, we encode it by the fine-tuned PLMs and take the representation of the `[CLS]` token from the last layer as its sentence representation h_i.

4 Approach

Our proposed framework DCLR focuses on reducing the influence of sampling bias in the contrastive learning of sentence representations. In this framework, we devise a noise-based negatives generation strategy to reduce the bias caused by the anisotropy PLM-derived representations, and an instance weighting method to reduce the bias caused by false negatives. Concretely, we initialize the noise-based negatives based on a Gaussian distribution and iteratively update these negatives towards non-uniformity maximization. Then, we utilize a complementary model to produce weights for all negatives (*i.e.,* randomly sampled and the noise-based ones). Finally, we combine the weighted negatives and augmented positive examples for contrastive learning. The overview of our DCLR is presented in Figure 2.

4.1 Generating Noise-based Negatives

We aim to generate new negatives beyond the sentence representation space of PLMs during the training process, to alleviate the sampling bias derived from the anisotropy problem of PLMs (Ethayarajh, 2019). For each input sentence x_i, we first initialize k noise vectors from a Gaussian distribution as the negative representations:

$$\{\hat{h}_1, \hat{h}_2, \cdots, \hat{h}_k\} \sim \mathcal{N}(0, \sigma^2), \tag{1}$$

where σ is the standard variance. Since these vectors are randomly initialized from such a Gaussian distribution, they are uniformly distributed within the whole semantic space. By learning to contrast with these new negatives, it is beneficial for the uniformity of sentence representations.

To further improve the quality of the new negatives, we consider iteratively updating the negatives to capture the non-uniformity points within the whole semantic space. Inspired by VAT (Miyato et al., 2017; Zhu et al., 2020), we design a non-uniformity loss maximization objective to produce gradients for improving these negatives. The non-uniformity loss is denoted as the contrastive loss between the noise-based negatives $\{\hat{h}_j\}$ and the positive representations of the original sentence (h_i, h_i^+) as:

$$L_U(h_i, h_i^+, \{\hat{h}\}) = -\log \frac{e^{\text{sim}(h_i, h_i^+)/\tau_u}}{\sum_{\hat{h}_j \in \{\hat{h}_j\}} e^{\text{sim}(h_i, \hat{h}_i)/\tau_u}}, \tag{2}$$

where τ_u is a temperature hyper-parameter and $\text{sim}(h_i, h_i^+)$ is the cosine similarity $\frac{h_i^\top h_i^+}{||h_i|| \cdot ||h_i^+||}$. Based on it, for each negative $\hat{h}_j \in \{\hat{h}\}$, we opti-

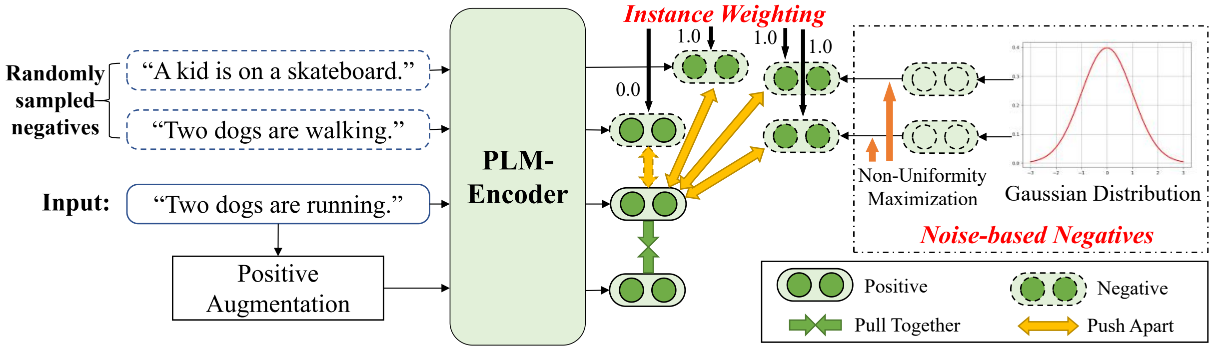

Figure 2: The overview of our DCLR framework with noise-based negatives and the instance weighting strategy. We show the case that a false negative is punished by assigning the weight 0.

mize it by t steps gradient ascent as

$$\hat{h}_j = \hat{h}_j + \beta g(\hat{h}_j)/||g(\hat{h}_j)||_2, \tag{3}$$

$$g(\hat{h}_j) = \nabla_{\hat{h}_j} L_U(h_i, h_i^+, \{\hat{h}\}), \tag{4}$$

where β is the learning rate, $||\cdot||_2$ is the L_2-norm. $g(\hat{h}_j)$ denotes the gradient of $\hat{h}_j$ by maximizing the non-uniformity loss between the positive representations and the noise-based negatives. In this way, the noise-based negatives will be optimized towards the non-uniform points of the sentence representation space. By learning to contrast with these negatives, the uniformity of the representation space can be further improved, which is essential for effective sentence representations.

4.2 Contrastive Learning with Instance Weighting

In addition to the above noise-based negatives, we also follow existing works (Yan et al., 2021; Gao et al., 2021) that adopt other in-batch representations as negatives $\{\tilde{h}^-\}$. However, as discussed before, the sampled negatives may contain examples that have similar semantics with the positive example (*i.e.,* false negatives).

To alleviate this problem, we propose an instance weighting method to punish the false negatives. Since we cannot obtain the true labels or semantic similarities, we utilize a complementary model to produce the weights for each negative. In this paper, we adopt the state-of-the-art SimCSE (Gao et al., 2021) as the complementary model. [1] Given a negative representation h^- from $\{\tilde{h}^-\}$ or $\{\hat{h}\}$ and the representation of the original sentence h_i, we utilize the complementary model to produce the weight as

$$\alpha_{h^-} = \begin{cases} 0, \mathrm{sim}_C(h_i, h^-) \geq \phi \\ 1, \mathrm{sim}_C(h_i, h^-) < \phi \end{cases} \tag{5}$$

where ϕ is a hyper-parameter of the instance weighting threshold, and $\mathrm{sim}_C(h_i, h^-)$ is the cosine similarity score evaluated by the complementary model. In this way, the negative that has a higher semantic similarity with the representation of the original sentence will be regarded as a false negative and will be punished by assigning the weight 0. Based on the weights, we optimize the sentence representations with a debiased cross-entropy contrastive learning loss function as

$$L = -\log \frac{e^{\mathrm{sim}(h_i, h_i^+)/\tau}}{\sum_{h^- \in \{\hat{h}\} \cup \{\tilde{h}^-\}} \alpha_{h^-} \times e^{\mathrm{sim}(h_i, h^-)/\tau}}, \tag{6}$$

where τ is a temperature hyper-parameter. In our framework, we follow SimCSE (Gao et al., 2021) that utilizes dropout to augment positive examples h_i^+. Actually, we can utilize various positive augmentation strategies, and will investigate it in Section 6.1.

4.3 Overview and Discussion

In this part, we present the overview and discussion of our DCLR approach.

4.3.1 Overview of DCLR

Our framework DCLR contains three major steps. In the first step, we generate noise-based negatives to extend in-batch negatives. Concretely, we first initialize a set of new negatives via random Gaussian noises using Eq. 1. Then, we incorporate a gradient-based algorithm to adjust the noise-based negatives by maximizing the non-uniform objective using Eq. 3. After several iterations, we can

---

[1] For convenience, we utilize SimCSE on BERT-base or RoBERTa-base model as the complementary model.

obtain the noise-based negatives that correspond to the nonuniform points within the whole semantic space, and we mix up them with in-batch negatives to compose the negative set. In the second step, we adopt a complementary model (*i.e.,* SimCSE) to compute the semantic similarity between the original sentence and each example from the negative set, and produce the weights using Eq. 5. Finally, we augment the positive examples via dropout and utilize the negatives with corresponding weights for contrastive learning using Eq. 6.

4.3.2 Discussion

As mentioned above, our approach aims to reduce the influence of the *sampling bias* about the negatives, and is agnostic to various positive data augmentation methods (*e.g.,* token cutoff and dropout). Compared with traditional contrastive learning methods (Yan et al., 2021; Gao et al., 2021), our proposed DCLR expands the negative set by introducing noise-based negatives $\{\hat{h}\}$, and adds a weight term α_{h^-} to punish false negatives. Since the noise-based negatives are initialized from a Gaussian distribution and do not correspond to real sentences, they are highly confident negatives to broaden the representation space. By learning to contrast with them, the learning of the contrastive objective will not be limited by the anisotropy representations derived from PLMs. As a result, the sentence representations can span a broader semantic space, and the uniformity of the representation semantic space can be improved.

Besides, our instance weighting method also alleviates the false negative problem caused by the randomly sampling strategy. With the help of a complementary model, the false negatives with similar semantics as the original sentence will be detected and punished.

5 Experiment - Main Results

5.1 Experiment Setup

Following previous works (Kim et al., 2021; Gao et al., 2021), we conduct experiments on seven standard STS tasks. For all these tasks, we use the SentEval toolkit (Conneau and Kiela, 2018) for evaluation.

Semantic Textual Similarity Task. We evaluate our approach on 7 STS tasks: STS 2012–2016 (Agirre et al., 2012, 2013, 2014, 2015, 2016), STS Benchmark (Cer et al., 2017) and SICK-Relatedness (Marelli et al., 2014). These datasets contain pairs of two sentences, whose similarity scores are labeled from 0 to 5. The relevance between gold annotations and the scores predicted by sentence representations is measured by the Spearman correlation. Following the suggestions from previous works (Gao et al., 2021; Reimers and Gurevych, 2019), we directly compute the cosine similarity between sentence embeddings for all STS tasks.

Baseline Methods. We compare DCLR with competitive unsupervised sentence representation learning methods, consisting of non-BERT and BERT-based methods:

(1) **GloVe** (Pennington et al., 2014) averages GloVe embeddings of words as the sentence representation.

(2) **USE** (Cer et al., 2018) utilizes a Transformer model that learns the objective of reconstructing the surrounding sentences within a passage.

(3) **CLS**, **Mean** and **First-Last AVG** (Devlin et al., 2019) adopt the `[CLS]` embedding, mean pooling of token representations, average representations of the first and last layers as sentence representations, respectively.

(4) **Flow** (Li et al., 2020) applies mean pooling on the layer representations and maps the outputs to the Gaussian space as sentence representations.

(5) **Whitening** (Su et al., 2021) uses the whitening operation to refine representations and reduce dimensionality.

(6) **Contrastive (BT)** (Fang and Xie, 2020) uses contrastive learning with back-translation for data augmentation to enhance sentence representations.

(7) **ConSERT** (Yan et al., 2021) explores various text augmentation strategies for contrastive learning of sentence representations.

(8) **SG-OPT** (Kim et al., 2021) proposes a contrastive learning method with a self-guidance mechanism for improving the sentence embeddings of PLMs.

(9) **SimCSE** (Gao et al., 2021) proposes a simple contrastive learning framework that utilizes dropout for data augmentation.

Implementation Details. We implement our model based on Huggingface's transformers (Wolf et al., 2020). For BERT-base and RoBERTa-base, we start from the pre-trained checkpoints of their original papers. For BERT-large and RoBERTa-large, we utilize the checkpoints of SimCSE for stabilizing the convergence process. Following Sim-

Table 1: Sentence embedding performance on STS tasks (Spearman's correlation). The best performance and the second-best performance methods are denoted in bold and underlined fonts respectively. †: results from Kim et al. (2021); ‡: results from Gao et al. (2021); all other results are reproduced or reevaluated by ourselves.

CSE (Gao et al., 2021), we use 1,000,000 sentences randomly sampled from Wikipedia as the training corpus. During training, we train our models for 3 epoch with temperature $\tau = 0.05$ using an Adam optimizer (Kingma and Ba, 2015). For BERT-base and RoBERTa-base, the batch size is 128, the learning rate is 3e-5. For BERT-large and RoBERTa-large, the batch size is 256, the learning rate is 3e-5 and 1e-5, respectively. For the four backbone models, we set the instance weighting threshold ϕ as 0.9, 0.85, 0.9 and 0.85, respectively. For each batch, we generate $k \times batch\_size$ noise-based negatives as the shared negatives of all instance within it, and k is 1, 2.5, 4 and 5 for BERT-base, RoBERTa-base, BERT-large and RoBERTa-large, respectively. The standard variance of the noise-based negatives is 1, and we update the noise-based negatives four times with the learning rate of 1e-3. We evaluate the model every 150 steps on the development set of STS-B and SICK-R and keep the best checkpoint for evaluation on test sets.

5.2 Main Results

To verify the effectiveness of our framework on PLMs, we select BERT-base and RoBERTa-base as the base model. Table 1 shows the results of different methods on seven STS tasks.

Based on the results, we can find that the non-BERT methods (*i.e.,* GloVe and USE) mostly outperform native PLM representation based baselines (*i.e.,* CLS, Mean and First-Last AVG). The reason is that directly utilizing the PLM native representations is prone to be influenced by the anisotropy issue. Among non-BERT methods, USE outperforms Glove. A potential reason is that USE encodes the sentence using the Transformer model, which is more effective than simply averaging GloVe embeddings.

For other PLM-based approaches, first, we can see that flow and whitening achieve similar results and outperform the native representations based methods by a margin. These two methods adopt specific improvement strategies to refine the representations of PLMs. Second, approaches based on contrastive learning outperform the other baselines in most cases. Contrastive learning can enhance both the alignment between semantically related positive pairs and the uniformity of the representation space using negative samples, resulting in better sentence representations. Furthermore, SimCSE performs the best among all the baselines. It indicates that dropout is a more effective positive augmentation method than others since it rarely hurts the semantics of the sentence.

Finally, DCLR performs better than all the baselines in most settings, including the approaches based on contrastive learning. Since these methods mostly utilize randomly sampled negatives (*e.g.,* in-batch negatives) to learn the uniformity of all sentence representations, it may lead to sampling bias, such as false negatives and anisotropy representations. Different from these methods, our framework adopts an instance weighting method to punish false negatives and a gradient-based algorithm to generate noise-based negatives towards the nonuniform points. In this way, the sampling bias problem can be alleviated, and our model can better learn the uniformity to improve the quality of the sentence representations.

6 Experiment - Analysis and Extension

In this section, we continue to study the effectiveness of our proposed DCLR.

6.1 Debiased Contrastive Learning on Other Methods

Since our proposed DCLR is a general framework that mainly focuses on negative sampling for contrastive learning of unsupervised sentence representations, it can be applied to other methods that rely on different positive data augmentation strategies. Thus, in this part, we conduct experiments to examine whether our framework can bring improvements with the following positive data augmentation strategies: (1) *Token Shuffling* that randomly shuffles the order of the tokens in the input sequences; (2) *Feature/Token/Span Cutoff* (Yan et al., 2021) that randomly erases features/tokens/token spans in the input; (3) *Dropout* that is similar to SimCSE (Gao et al., 2021). Note that we only revise the negative sampling strategies to implement these variants of our DCLR.

Model	**STS-Avg.**
BERT-base+Ours	**77.22**
w/o Noise-based Negatives	76.17
w/o Instance Weighting	76.31
BERT-base+Random Noise	75.22
BERT-base+Knowledge Distillation	75.05
BERT-base+Self Instance Weighting	73.93

Table 2: Ablation and variation studies of our approach on the test set of seven STS tasks.

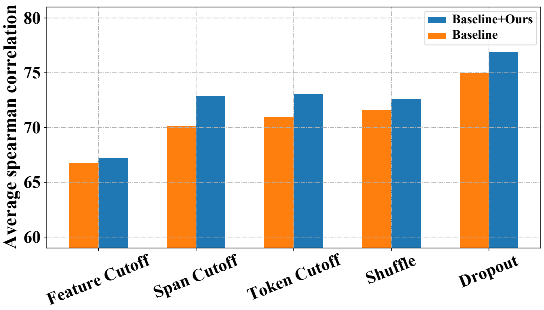

Figure 3: Performance comparison using different positive augmentation strategies on the test set of seven STS tasks.

As shown in Figure 3, our DCLR can boost the performance of all these augmentation strategies, it demonstrates the effectiveness of our framework with various augmentation strategies. Furthermore, the Dropout strategy leads to the best performance among all the variants. It indicates that dropout is a more effective approach to augment high-quality positives, and is also more appropriate for our approach.

6.2 Ablation Study

Our proposed DCLR incorporates an instance weighting method to punish false negatives and also utilizes noise-based negatives to improve the uniformity of the whole sentence representation space. To verify their effectiveness, we conduct an ablation study for each of the two components on seven STS tasks and report the average value

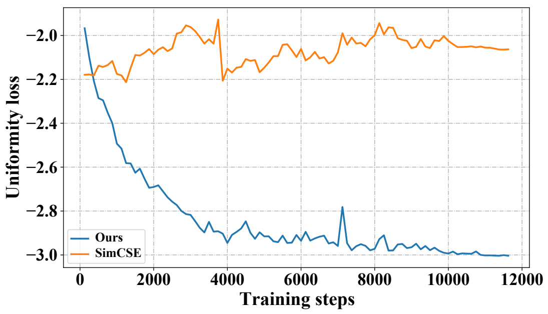

Figure 4: The uniformity loss of DCLR and SimCSE using BERT-base on the validation set of STS-B during training.

of the Spearman's correlation metric. As shown in Table 2, removing each component would lead to the performance degradation. It indicates that the instance weighting method and the noise-based negatives are both important in our framework. Besides, removing the instance weighting method results in a larger performance drop. The reason may be that the false negatives have a larger effect on sentence representation learning.

Besides, we prepare three variants for further comparison: (1) *Random Noise* directly generates noise-based negatives without the gradient-based optimization; (2) *Knowledge Distillation* (Hinton et al., 2015) utilizes SimCSE as the teacher model to distill knowledge into the student model during training; (3) *Self Instance Weighting* adopts the model itself as the complementary model to generate the weights. From Table 2, we can see that these variations don't perform as well as the original DCLR. These results indicate the proposed designs in Section 4 are more suitable for our DCLR framework.

6.3 Uniformity Analysis

Uniformity is a desirable characteristic for sentence representations, describing how well the representations are uniformly distributed. To validate the improvement of the uniformity of our framework, we compare the uniformity loss curves of DCLR and SimCSE using BERT-base during training.

Following SimCSE (Gao et al., 2021), we utilize the following function to evaluate the uniformity:

$$\ell_{uniform} \triangleq \log \underset{x_i,x_j \overset{i.i.d.}{\sim} p_{data}}{\mathbb{E}} e^{-2\|f(x_i)-f(x_j)\|^2},$$

where p_{data} is the distribution of all sentence representations, and a smaller value of this loss indicates a better uniformity. As shown in Figure 4, the uniformity loss of DCLR is much lower than that of SimCSE in almost the whole training process. Furthermore, we can see that the uniformity loss of DCLR decreases faster as training goes, while the one of SimCSE shows no significant decreasing trend. It might be because our DCLR samples noise-based negatives beyond the representation space, which can better improve the uniformity of sentence representations.

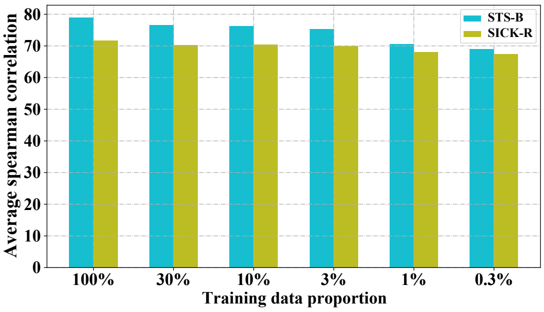

Figure 5: Performance tuning of our DCLR *w.r.t.* different amounts of training data.

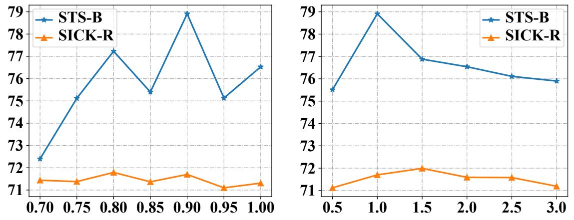

(a) Weighting Threshold ϕ (b) Negative Proportion k

Figure 6: Performance tuning *w.r.t.* ϕ and k.

6.4 Performance under Few-shot Settings

To validate the reliability and the robustness of DCLR under the data scarcity scenarios, we conduct few-shot experiments using BERT-base as the backbone model. We train our model via different amounts of available training data from 100% to the extremely small size (*i.e.,* 0.3%). We report the results evaluated on STS-B and SICK-R tasks.

As shown in Figure 5, our approach achieves stable results under different proportions of the training data. Under the most extreme setting with 0.3% data proportion, the performance of our model drops by only 9 and 4 percent on STS-B and SICK-R, respectively. The results reveal the robustness and effectiveness of our approach under the data scarcity scenarios. Such characteristics are important in real-world application.

6.5 Hyper-parameters Analysis

For hyper-parameters analysis, we study the impact of instance weighting threshold ϕ and the proportion of noise-based negatives k. The ϕ is the threshold to punish false negatives, and k is the ratio of the noise-based negatives to the batch size. Both hyper-parameters are important in our framework. Concretely, we evaluate our model with varying values of ϕ and k on the STS-B and SICK-R tasks using the BERT-base model.

Weighting threshold. Figure 6(a) shows the influence of the instance weighting threshold ϕ. For the STS-B tasks, ϕ has a significant effect on the model performance. Too large or too small ϕ may lead to a performance drop. The reason is that a larger threshold cannot achieve effective punishment and a smaller one may cause misjudgment of true negatives. In contrast, the SICK-R is insensitive to the changes of ϕ. The reason may be that the problem of false negatives is not serious in this task.

Negative proportion. As shown in Figure 6(b), our DCLR performs better when the number of noise-based negatives is close to the batch size. Under these circumstances, the noise-based negatives are more capable to enhance the uniformity of the whole semantic space without hurting the alignment, which is key why DCLR works well.

7 Conclusion

In this paper, we proposed DCLR, a debiased contrastive learning framework for unsupervised sentence representation learning. Our core idea is to alleviate the sampling bias caused by the random negative sampling strategy. To achieve it, in our framework, we incorporated an instance weighting method to punish false negatives during training and generated noise-based negatives to alleviate the influence of anisotropy PLM-derived representation. Experimental results on seven STS tasks have shown that our approach outperforms several competitive baselines.

In the future, we will explore other approaches to reducing the bias in contrastive learning of sentence representations (*e.g.,* debiased pre-training). Besides, we will also consider to apply our method for multilingual or multimodal representation learning.

Ethical Consideration

In this section, we discuss the ethical considerations of this work from the following two aspects. First, for intellectual property protection, the code, data and pre-trained models adopted from previous works are granted for research-purpose usage. Second, since PLMs have been shown to capture certain biases from the data they have been pretrained on (Bender et al., 2021), there is a potential problem about biases that are from the use of PLMs in our approach. There are increasing efforts to address this problem in the community (Ross et al., 2020).

Abstract

Prompting has recently been shown as a promising approach for applying pre-trained language models to perform downstream tasks. We present Multi-Stage Prompting, a simple and automatic approach for leveraging pre-trained language models to translation tasks. To better mitigate the discrepancy between pre-training and translation, MSP divides the translation process via pre-trained language models into multiple separate stages: the encoding stage, the re-encoding stage, and the decoding stage. During each stage, we independently apply different continuous prompts for allowing pre-trained language models better shift to translation tasks. We conduct extensive experiments on three translation tasks. Experiments show that our method can significantly improve the translation performance of pre-trained language models. [1]

1 Introduction

Prompting (Brown et al., 2020; Lester et al., 2021), which refers to the approach of generating task-specific outputs from language models (LMs) by conditioning on extra information (known as *prompts*), has emerged as a new way of using LMs to perform natural language processing (NLP) tasks (Gao et al., 2020; Liu et al., 2021). While being efficient in parameters (Lester et al., 2021), prompting can enable mixed-task inference, which is not possible for other related approaches like finetuning or adapter-based tuning (Li and Liang, 2021; Lester et al., 2021). Prompting also opens the possibility of using a single pre-trained LM to perform all NLP tasks (Liu et al., 2021).

Machine translation (MT), which involves transformations between two languages, is considered one of the most challenging tasks in NLP (Koehn and Knowles, 2017). While neural machine translation (NMT) (Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017) is the current *de facto* approach for machine translation, using pre-trained LMs as translators via prompting is appealing in several aspects. For example, for the method described in this paper, supporting a new translation direction with a pre-trained LM occupies disk spaces below 20M, which is much smaller than training a separate neural machine translation model, where the model size is typically larger than 60M per language pair for the Transformer architecture. [2] Furthermore, the pre-trained LM also retains the ability to perform other downstream tasks, which is an important characteristic that has not been validated available on neural machine translation models.

However, it is challenging to leverage pre-trained LMs to translation tasks via prompting. First, finding an appropriate prompt for a translation task is not trivial and requires specific designs (Brown et al., 2020; Gao et al., 2020; Li and Liang, 2021; Lester et al., 2021). Second, the prompting method with a single prompt may be sub-optimal for steering pre-trained LMs to translation tasks, as there is a clear discrepancy between the objectives of translation and pre-training. Translation imposes strict *semantic equivalence* and *language space* constraint, in which a source sentence must translate to a semantically equivalent sentence in the target language space. As the objective of pre-training is usually to reconstruct parts of the input sentence (Radford et al., 2018; Devlin et al., 2019), the generation of a pre-trained LM conditioned on a source sentence will likely be in the source language space with non-equivalent semantics. Therefore, using a single prompt to guide the LM for mitigating both the semantic and language gap is likely to be sub-optimal. Third, prevalent

(a) Basic (single-stage) prompting for MT.

(b) Multi-stage prompting.

Figure 1: Overview of using prompts for steering a multilingual GPT (mGPT) model to machine translation tasks. Note that we reset the position ids during each stage in multi-stage prompting for ease of implementation. All stages use the same mGPT model.

generative LMs such as GPTs use a decoder-only architecture (Radford et al., 2018), which is unidirectional and may be sub-optimal for encoding source sentences (Devlin et al., 2019). While recent works in prompting like prefix-tuning (Li and Liang, 2021) or prompt tuning (Lester et al., 2021) alleviate the first challenge by introducing differentiable continuous prompts, the last two challenges remain to be addressed.

In this paper, we present Multi-Stage Prompting (MSP) for addressing the challenges of steering pre-trained language models to translation tasks. MSP encapsulates the idea of breaking translation tasks into simpler consecutive stages, allowing the pre-trained LM to learn "smoother transitions" to translation tasks by providing different prompts at different stages. For GPT-style pre-trained LMs, we design a three-stage prompting scheme for modeling the translation process, which consists of an *encoding stage*, a *re-encoding stage*, and a *decoding stage*. Specifically, the pre-trained LM focuses on learning source representations at the encoding stage and learns refined bidirectional representations by re-encoding source sentences at the re-encoding stage. Therefore, the LM can produce better translations with refined source representations at the decoding stage. Following prefix-tuning (Li and Liang, 2021) and prompt tuning (Lester et al., 2021), we use independent trainable continuous prompts at different stages, which are learned through back-propagation. The difference between basic (single-stage) prompting and multi-stage prompting is illustrated in Figure 1.

We demonstrate the effectiveness of our method with a multilingual GPT (mGPT) model on Romanian-English, English-German, and English-Chinese translation tasks. Experiments verify that compared with prompt tuning or prefix-tuning, MSP can significantly improve the translation performance of pre-trained LMs. Our method improves the translation performance of pre-trained language models via prompt tuning and prefix-tuning by 18.6 and 4.1 BLEU points on average over the three translation tasks, respectively, suggesting that MSP is a more effective prompting method for translation tasks.

2 Background

2.1 Prompting

Prompting is an approach of using an LM to perform downstream tasks by adding extra information for the LM to condition during its generation (Lester et al., 2021). This extra information, also known as a *prompt*, plays an important role in prompting methods and is often prepended to LM's input for better control of its generation. Depending on the form of prompts, prompting methods can be divided into two categories: using textual prompts or using continuous prompts.

Textual prompts are typically composed of natural language tokens. As a representative approach of textual prompts, Brown et al. (2020) use manually designed prompts to steer GPT-3's generation. A typical prompt used in GPT-3 consists of a task description and a few task-specific examples. Gao et al. (2020) and Shin et al. (2020) propose different automatic methods to generate textual prompts. Textual prompts are typically understandable by humans. However, Shin et al. (2020) indicate that automatically generated textual prompts may lack interpretability.

Continuous prompts, which consist of a sequence of continuous vectors, have gained increasing popularity recently. For example, in (Li and Liang, 2021), the continuous prompts consist of a sequence of key-value pairs (also called prefixes). Lester et al. (2021) propose a simplified version of continuous prompts, which consists of virtual tokens that are only added to the embedding layer. Compared with textual prompts, using continuous prompts is generally more powerful but less interpretable (Lester et al., 2021).

2.2 mGPT

In this paper, we use GPT (Radford et al., 2018, 2019; Brown et al., 2020) as the backbone LM for machine translation tasks. GPTs are a series of causal language models based on the Transformer architecture (Vaswani et al., 2017). To be more suitable for translation tasks that involve multiple languages, we introduce a *multilingual GPT* (mGPT) model instead of using a standard GPT-2 model. [3] The main difference between mGPT and GPT-2 is the training data. mGPT is trained on the mC4 dataset (Xue et al., 2021), which is a multilingual dataset covering over 101 languages. For further details about mGPT, please refer to Appendix A.1.

Let $\mathbf{z} = [z_1, \ldots, z_n]$ be a sequence of tokens, mGPT uses an autoregressive Transformer network to model the conditional probability $P(z_t|\mathbf{z}_{<t})$, where $t \in [1, n]$ and $\mathbf{z}_{<t} = [z_1, \ldots, z_{t-1}]$. We use $f_{\mathrm{LM}}(\boldsymbol{z}, \boldsymbol{H}; \boldsymbol{\theta})$ to denote the Transformer network, where $\boldsymbol{z}$ is a word embedding, $\boldsymbol{H}$ is a sequence of past activations, and $\boldsymbol{\theta}$ denotes the parameters of the Transformer network.

Initially, the inputs to the Transformer network are z_1 and $\boldsymbol{H}_0$, where $\boldsymbol{H}_0$ is an empty sequence. The Transformer network produces two outputs: the final output $\boldsymbol{g}_1 \in \mathbb{R}^d$ and the activation $\boldsymbol{h}_1 \in \mathbb{R}^{2N \times d}$, [4] where d denotes the hidden size of the Transformer network and N is the number of layers of the Transformer network.

For subsequent inputs z_t and $\boldsymbol{H}_{t-1}$, where $\boldsymbol{H}_{t-1} = [\boldsymbol{h}_1, \ldots, \boldsymbol{h}_{t-1}]$, the computation is formally described as

$$\boldsymbol{g}_t, \boldsymbol{h}_t = f_{\mathrm{LM}}(\boldsymbol{e}_{z_t}, \boldsymbol{H}_{t-1}), \tag{1}$$

where $\boldsymbol{e}_{z_t}$ denotes the word embedding of z_t. To make the notation simpler, we use the following equation to denote the repeated application of f_{LM} over a sequence $\mathbf{z}^{i:j} = [z_i, \ldots, z_j]$ given past activations $\boldsymbol{A}$:

$$\boldsymbol{G}^{i:j}, \boldsymbol{H}^{i:j} = f_{\mathrm{LM}}(\boldsymbol{Z}^{i:j}, \boldsymbol{A}), \tag{2}$$

where $\boldsymbol{Z}^{i:j} = [\boldsymbol{e}_{z_i}, \ldots, \boldsymbol{e}_{z_j}]$, $\boldsymbol{G}^{i:j} = [\boldsymbol{g}_i, \ldots, \boldsymbol{g}_j]$, and $\boldsymbol{H}^{i:j} = [\boldsymbol{h}_i, \ldots, \boldsymbol{h}_j]$.

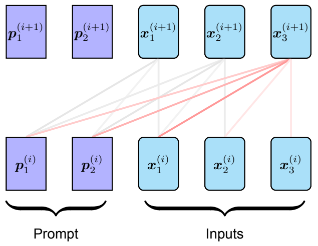

Figure 2: A deep continuous prompt is prepended to the inputs in all attention layers, which affects the computation of all attention layers. We do not distinguish keys and values here for simplicity.

Finally, the conditional probability $P(z_t|\mathbf{z}_{<t})$ is modeled as follows:

$$P(z_t|\mathbf{z}_{<t}) = \frac{\exp\left(\boldsymbol{e}_{z_t}^{\mathsf{T}} \cdot \boldsymbol{g}_t\right)}{\sum_{i=1}^{|V|} \exp\left(\boldsymbol{e}_{z_i}^{\mathsf{T}} \cdot \boldsymbol{g}_t\right)}, \tag{3}$$

where $|V|$ is the vocabulary size, and "$\cdot$" denotes matrix production.

3 Multi-Stage Prompting

We propose multi-stage prompting (MSP), a simple and lightweight method for steering pre-trained LMs to translation tasks. We first describe the concept of deep continuous prompts in Section 3.1. Then we detail the stages and training objective in Section 3.2 and Section 3.3, respectively. Finally, we describe the reparameterization of deep continuous prompts in Section 3.4.

3.1 Deep Continuous Prompts

We adopt "continuous prompts" (Li and Liang, 2021; Lester et al., 2021) instead of using textual prompts in our method. Using continuous prompts allows learning through differentiable methods like back-propagation (Lester et al., 2021). To be specific, we use deep continuous prompts which are in the same form as in (Li and Liang, 2021). Formally, a prompt $\boldsymbol{P}$ is a sequence of L continuous vectors $[\boldsymbol{p}_1, \ldots, \boldsymbol{p}_L]$. Each vector $\boldsymbol{p}_i$ $(1 \leq i \leq L)$ is a concatenation of key-value pairs in all N Transformer layers, which directly affect the computation of every attention layer. Therefore, the dimension of $\boldsymbol{p}_i$ is $2N \times d$. We give an illustration of conditioning on a deep continuous prompt in Figure 2.

3.2 Stages

To effectively mitigate the semantic and language gap between the pre-training and translation, we

---

[3] We release our checkpoint at `https://huggingface.co/THUMT/mGPT`.

[4] $\boldsymbol{h}$ is a concatenation of a set of key-value pairs $\{\langle \boldsymbol{k}^{(i)}, \boldsymbol{v}^{(i)} \rangle | i = 1 \ldots N\}$ in the Transformer network.

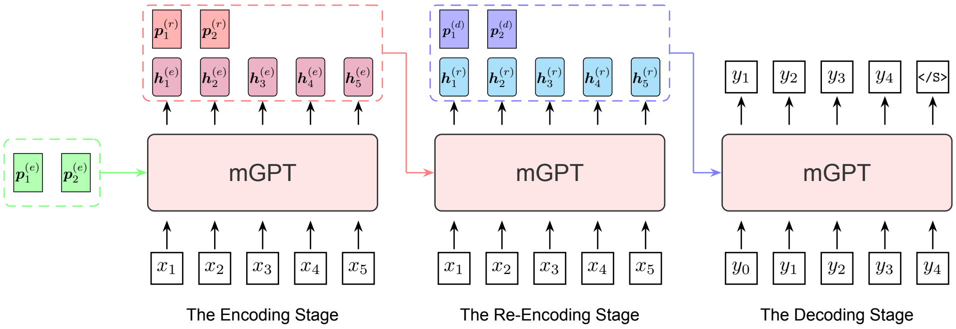

Figure 3: Detailed computations involved in the multi-stage prompting for machine translation tasks. We use rectangles to denote prompt vectors and rounded rectangles to denote activations.

propose multi-stage prompting which divides the procedure of using pre-trained LMs as translators into three separate stages: the encoding, the re-encoding, and the decoding stages. Given different prompts at different stages, the pre-trained LM is expected to behave differently during each stage and is more capable of generating translations.

Given a source sentence $\mathbf{x} = [x_1, \dots, x_S]$ and a target sentence $\mathbf{y} = [y_1, \dots, y_T]$, the details of the three stages are described as follows:

The Encoding Stage. At the encoding stage, the pre-trained LM encodes the source sentence $\mathbf{x}$ into a sequence of activations $\boldsymbol{H}_e^{1:S}$ by using an encoding stage prompt $\boldsymbol{P}_e$. This procedure is the same as basic prompting. Formally, it can be described as follows:

$$\boldsymbol{G}_e^{1:S}, \boldsymbol{H}_e^{1:S} = f_{\text{LM}}(\boldsymbol{X}^{1:S}, \boldsymbol{P}_e). \tag{4}$$

The Re-encoding Stage. At the re-encoding stage, the pre-trained LM produces fine-grained representations of the source sentence by re-encoding $\mathbf{x}$ given past activations $\boldsymbol{H}_e^{1:S}$ and a re-encoding stage prompt $\boldsymbol{P}_r$, which allows each representation to condition on all words in $\mathbf{x}$. This procedure can be described as

$$\boldsymbol{G}_r^{1:S}, \boldsymbol{H}_r^{1:S} = f_{\text{LM}}(\boldsymbol{X}^{1:S}, [\![\boldsymbol{P}_r; \boldsymbol{H}_e^{1:S}]\!]), \tag{5}$$

where $[\![\boldsymbol{P}_r; \boldsymbol{H}_e^{1:S}]\!]$ denotes the concatenation of two sequences $\boldsymbol{P}_r$ and $\boldsymbol{H}_e^{1:S}$. It is also possible to employ more than one re-encoding stage, allowing the pre-trained LM to obtain further refined representations of the source sentence.

The Decoding Stage. Finally, we obtain the hidden vectors $\boldsymbol{G}_d^{1:T}$ for predicting the probability of the target sentence $\mathbf{y}$ at the decoding stage, given the refined source representations $\boldsymbol{H}_r^{1:S}$ and a decoding stage prompt $\boldsymbol{P}_d$:

$$\boldsymbol{G}_d^{1:T}, \boldsymbol{H}_d^{1:T} = f_{\text{LM}}(\boldsymbol{Y}^{1:T}, [\![\boldsymbol{P}_d; \boldsymbol{H}_r^{1:S}]\!]). \tag{6}$$

Figure 3 gives a detailed illustration of MSP. By dividing the translation process into multiple stages and applying different prompts, we expect the pre-trained LM model can generate better translations.

3.3 Training Objective

We use the cross-entropy loss for learning prompts. Given $\boldsymbol{G}_d^{1:T} = [\boldsymbol{g}_1^{(d)}, \dots, \boldsymbol{g}_T^{(d)}]$ in Eq. (6), the training objective is formally described as follows:

$$\begin{aligned}\mathcal{L} &= -\frac{1}{T}\sum_{t=1}^{T} \log P(y_t|\mathbf{y}_{<t}, \mathbf{x}) \\ &= -\frac{1}{T}\sum_{t=1}^{T} \log \frac{\exp\left(\boldsymbol{e}_{z_t}^{\mathsf{T}} \cdot \boldsymbol{g}_t^{(d)}\right)}{\sum_{i=1}^{|V|} \exp\left(\boldsymbol{e}_{z_i}^{\mathsf{T}} \cdot \boldsymbol{g}_t^{(d)}\right)}.\end{aligned} \tag{7}$$

Note that the parameters $\boldsymbol{\theta}$ of the pre-trained LM are fixed during training.

3.4 Reparameterization

Li and Liang (2021) suggest that using a neural network to reparameterize continuous prompts is more robust to different choices of hyperparameters. In contrast to their approach which uses an MLP network to reparameterize continuous prompts, we introduce a much simpler *scaled reparameterization* method, in which a continuous prompt is reparameterized as a product of a learnable scalar and an embedding. More precisely, the reparameterization of the three prompts are as follows:

$$\boldsymbol{P}_e = \max(\alpha_e, 1.0) \times \boldsymbol{\phi}_e, \tag{8}$$

$$\boldsymbol{P}_r = \max(\alpha_r, 1.0) \times \boldsymbol{\phi}_r, \tag{9}$$

$$\boldsymbol{P}_d = \max(\alpha_d, 1.0) \times \boldsymbol{\phi}_d, \tag{10}$$

where $\phi_e \in \mathbb{R}^{2N\times d}$, $\phi_r \in \mathbb{R}^{2N\times d}$, and $\phi_d \in \mathbb{R}^{2N\times d}$. α_e, α_r, and α_d are initialized to 1.0 at the beginning of training. Therefore, the set of trainable parameters ϕ in our method is $\phi = \{\alpha_e, \alpha_r, \alpha_d, \phi_e, \phi_r, \phi_d\}$, which contains much less tunable parameters than an MLP network.

Scaled reparameterization enables directly adjusting the value of prompts by a tunable scaling factor, leading to a much faster convergence without loss of performance. Further analysis is presented in Section 4.7.

4 Experiments

4.1 Setup

Datasets We conduct experiments on Romanian-English (Ro-En), English-German (En-De), and English-Chinese (En-Zh) translation tasks to verify our proposed method. For the Ro-En translation task, we used the WMT16 Romanian-English dataset, which consists of 0.6M bilingual sentence pairs and 2M back-translated sentence pairs.[5] We used *newsdev2016* as the development set and *newstest2016* as the test set. For the En-De translation task, we used the WMT14 English-German dataset, which consists of 4.5M sentence pairs. The development set is *newstest2013* and the test set is *newstest2014*. For the En-Zh translation task, we used the WMT20 English-Chinese dataset as the training corpus, which consists of 28M sentence pairs. The development set is *newstest2019* and the test set is *newstest2020*. The details of preprocessing and postprocessing are given in Appendix A.2.

Metric. We used case-sensitive BLEU (Papineni et al., 2002) as the evaluation metric. The BLEU score is calculated using the SACREBLEU toolkit (Post, 2018).[6]

Baselines. We used the mGPT model as the backbone LM in all our experiments, which contains 560M parameters. We compare our method with the following prompting methods: [7]

- Prompt tuning (Lester et al., 2021). A prompting method that only prepends virtual tokens to the embedding layer of pre-trained LMs.
- Prefix-tuning (Li and Liang, 2021). A prompting method that uses deep continuous prompts, which prepend virtual tokens to all key-value pairs in attention layers of pre-trained LMs. We use an MLP network to reparameterize a continuous prompt during training as suggested in (Li and Liang, 2021).

Implementations. All our models are trained on a machine with 8 RTX 3090Ti GPUs. For all prompting methods, we set the prompt length to 128. For the training, we use the Glorot uniform initilizer (Glorot and Bengio, 2010) to initialize tunable parameters unless otherwise noted. We use Adam (Kingma and Ba, 2015) ($\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\epsilon = 1\times 10^{-9}$) as the optimizer with a batch size of roughly 32K tokens. We use the same learning rate schedule as described in (Vaswani et al., 2017). The number of warmup steps is set to 4K. We set the maximum learning rate to 0.02 for prompt tuning and MSP, and 7e-4 for prefix-tuning.[8] We train prompts for a total of 80K steps for prompt tuning and prefix-tuning, and 40K steps for MSP. For the inference, we use the beam search algorithm to obtain translation from the mGPT model, and the beam size is set to 4. The length penalty is determined by the results evaluated on the development set. We set the length penalty to 1.0 for the En-Zh translation task and 0.0 for other translation tasks. We implement our models on top of the THUMT (Tan et al., 2020) toolkit and the Transformers library (Wolf et al., 2020).

4.2 Main Results

Table 1 shows the results for the Ro-En, En-De, and En-Zh translation tasks.

As the most parameter-efficient among the three prompting methods, prompt tuning introduces only 131K parameters during training for each translation task. However, it only achieves 9.4 BLEU points on average over the three translation tasks. Lester et al. (2021) indicate that language model capacity is a key ingredient for prompt tuning to succeed. As mGPT is a pre-trained LM with only 560M parameters, the results coincide with the conclusion of Lester et al. (2021).

Prefix-tuning, which uses deep continuous prompts, achieves an average of 23.9 BLEU points over the three translation tasks. The results indicate that using deep continuous prompts is beneficial

[6] Signature: nrefs:1|case:mixed|eff:no|tok:{13a,zh}|smooth:exp|version:2.0.0

[7] In our preliminary experiments, we also experimented with the few-shot approach as described in (Brown et al., 2020). However, we found mGPT often failed to generate meaningful translations.

[8] We found using a large learning rate for prefix-tuning would result in unstable training.

Method	**#Params.**	**Ro-En**	**En-De**	**En-Zh**	**Average**
Prompt Tuning	131K	17.7	5.9	4.5	9.4
Prefix-Tuning	26M	32.5	17.5	21.9	23.9
MSP (*Ours*)	19M	**34.7**	**21.2**	**28.1**	**28.0**

Table 1: BLEU score on three different translation tasks for different prompting methods. All prompting methods use the same pre-trained language model "mGPT". "#Params." denotes the number of tunable parameters during training.

LM	**Architecture**	**#M-Params.**	**Method**	**BLEU**
mT5-XXL (Zhang et al., 2021)	Encoder-Decoder	13B	Finetuning	24.0
CPM-2 (Zhang et al., 2021)	Encoder-Decoder	11B	Prompt Tuning	24.1
CPM-2 (Zhang et al., 2021)	Encoder-Decoder	11B	Finetuning	26.2
Ernie 3.0 (Sun et al., 2021a)	Encoder-Decoder	10B	Finetuning	26.8
mGPT (*Ours*)	Decoder	560M	MSP	**28.1**

Table 2: Comparisons with previous studies on the WMT20 En-Zh translation task. "#M-Params." indicates the number of parameters of pre-trained LMs.

for steering mGPT to translation tasks. However, introducing deep continuous prompts inevitably requires more free parameters. The MLP network used in prefix-tuning introduces about 26M parameters for each translation task during training in our experiments.

Finally, MSP achieves 28.0 BLEU points on average over the three translation directions and outperforms prompt tuning and prefix-tuning by 18.6 and 4.1 BLEU points, respectively. MSP introduces 19M parameters for each translation task during training, which is more than prompt tuning but less than prefix-tuning. MSP explicitly divides the translation process using mGPT into separate stages, which are not present in prompt tuning and prefix-tuning. The results suggest that MSP is more effective in instructing pre-trained LMs to perform translation than prompt tuning and prefix-tuning.

4.3 Comparison with Other LMs

Table 2 gives the results of mT5-XXL (Zhang et al., 2021), CPM-2 (Zhang et al., 2021), Ernie 3.0 (Sun et al., 2021a), and mGPT on the WMT20 En-Zh translation task. Except for mGPT, other LMs are based on the encoder-decoder architecture. Despite using a much smaller pre-trained LM with about 5% parameters of mT5-XXL, CPM-2, and Ernie 3.0, MSP achieves the best performance on the En-Zh translation task. Therefore, we show that MSP is an efficient and effective approach to steering pre-trained LMs to translation tasks.

4.4 Comparison with Transformer

We compare our method with the state-of-the-art Transformer NMT model (Vaswani et al., 2017) [9] on the TedTalks dataset (Blackwood et al., 2018) and the WMT14 English-German dataset. TedTalks dataset is an English-centric multilingual corpus including 59 languages with around 3K to 200K sentence pairs per language pair. For the sake of simplicity, we only report results for 5 selected languages that contain more than 150K sentence pairs. However, the Transformer model is trained on all available parallel sentences covering 59 languages, serving as a strong NMT baseline. For mGPT with MSP, we individually train the model on each language pair following the same procedure described in this paper.

The results of "X→En" and "En→X" directions are shown in Table 3. Although mGPT with MSP is independently trained on each language pair, the model still outperforms the strong multilingual NMT baseline by 3.4 and 3.9 BLEU points on "X-En" and "En-X" directions, respectively. The results demonstrate that using pre-trained LMs as translators with an appropriate prompting method has the potential to excel a strong Transformer NMT model.

Table 4 shows the comparison between Transformer and our mGPT model with MSP on the En-

---

[9] We used the *transformer-big* setting. Tokenizations and vocabularies are the same with mGPT for fair comparisons.

Model	**#Params.**	**Bg**	**Es**	**It**	**Ru**	**Tr**	**Avg.**
				X→En			
Transformer	437M	35.2	38.0	34.2	22.6	21.0	30.2
mGPT (MSP)	19M	**38.9**	**42.1**	**37.8**	**24.4**	**24.9**	**33.6**
				En→X			
Transformer	437M	29.2	34.0	29.2	16.7	11.6	24.1
mGPT (MSP)	19M	**34.1**	**38.4**	**32.8**	**19.2**	**15.6**	**28.0**

Table 3: Results on the TedTalks "X→En" and "En→X" translation directions. For MSP, each translation direction introduces 19M parameters.

Model	**#Params.**	**BLEU**
Transformer (big)	450M	27.9
mGPT (MSP)	19M	21.2

Table 4: Results on the WMT14 En-De dataset. "#Params." denotes the number of tunable parameters during training.

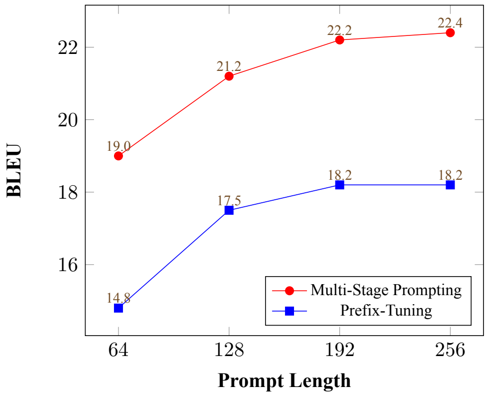

Figure 4: Comparison between MSP and prefix-tuning on the WMT14 En-De translation task with different prompt lengths.

De translation task. While there is still a noticeable performance gap between Transformer and mGPT with MSP, using mGPT as a translator with MSP is much more parameter-efficient than training a separate NMT model. Supporting En-De translation with mGPT only introduces 19M parameters with MSP method. In comparison, the model size of the Transformer model for En-De translation is 450M. While mGPT model can perform other downstream tasks by providing different prompts, such abilities have not been validated on the Transformer NMT model. Besides being efficient in disk spaces, learning prompts for the En-De translation task are also faster than training a separate NMT model. It takes 21 hours to train prompts for MSP, whereas 72 hours for training a Transformer model.

4.5 Effect of Prompt Length

Figure 4 shows the effect of prompt length for prefix-tuning and MSP. We omit the comparison to prompt tuning because of its inferior performance. We found that using longer prompts generally leads to better performance for both prefix-tuning and MSP, but with diminishing returns. This finding is consistent with previous studies (Li and Liang, 2021; Lester et al., 2021). Furthermore, MSP consistently outperforms prefix-tuning when using the same prompt length. Even MSP with a prompt length of 64 performs better than prefix-tuning with a prompt length of 256 (19.0 vs. 18.2). The results further confirm that MSP is a better prompting method than prefix-tuning for steering pre-trained LMs to translation tasks. For the inference time, we found longer prompts do not significantly affect the decoding speed on GPUs as the computation of attention layers are highly parallel, which is also consistent with the findings of Li and Liang (2021).

4.6 Effect of Stages

Table 5 shows the comparison of using different stage settings on the WMT14 En-De and the WMT20 En-Zh translation tasks. For single-stage prompting, we also adopt scaled reparameterization instead of MLP reparameterization for a fair comparison. On the WMT14 En-De translation task, using single-stage prompting achieves 17.9 BLEU points. By comparison, explicitly separating encoding and decoding stages improve the translation performance over single-stage prompting by 2.3 BLEU points, which indicates the importance of differentiating stages. Adding a re-encoding stage further improves the translation performance by 1.0 BLEU point, suggesting that the re-encoding stage is effective. Adding a second re-encoding stage further improves the translation performance

Method	**#Params.**	**Training**	**Inference**	**En-De**	**En-Zh**
Single-stage	6.3M	14h	0.10 s/sent.	17.9	22.8
Two-stage (encoding/decoding)	12.6M	14h	0.10 s/sent.	20.2	25.2
+ Re-encoding (*default*)	19.0M	21h	0.11 s/sent.	21.2	28.1
+ 2nd Re-encoding	25.1M	29h	0.11 s/sent.	21.8	28.4
+ Prompt sharing	6.3M	21h	0.11 s/sent.	19.8	24.5

Table 5: Comparison of using different stage settings on the WMT14 En-De translation task and WMT20 Zh-En translation task. "#Params." denotes the number of trainable parameters. "Training" denotes the total training time. "Inference" denotes the inference speed measured on the test set using 8 GPUs. "s/sent." denotes seconds per sentence. All experiments use *scaled reparameterization* for fair comparison.

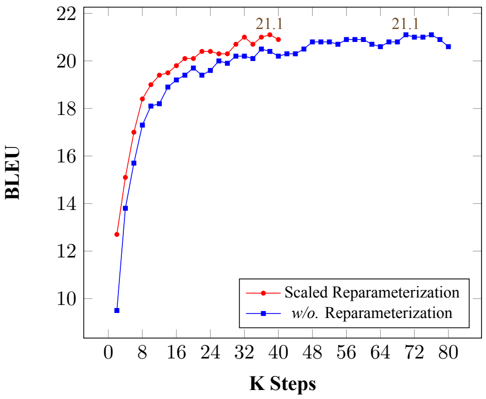

Figure 5: Comparison between using scaled reparameterization and without using reparameterization on the WMT14 translation task. The BLEU score is evaluated on *newstest2013*.

by 0.6 BLEU points. Although adding stages introduces more trainable parameters, it should be noted that sharing a single prompt for the encoding/re-encoding/decoding stages also improves over the single-stage prompting by 1.9 BLEU points. The results suggest that most improvements are attributed to the explicit separation of stages rather than increased parameters. Adding more stages generally slows the training speed. However, we do not observe notable inference speed drop as re-encoding stages are computed one time in parallel during inference. On the En-Zh translation task, the results are consistent with the results on the En-De translation task. Therefore, we conclude that using more stages helps improve the translation quality.

4.7 Effect of Reparameterization

Figure 5 shows the comparison between MSP using scaled reparameterization and without using reparameterization. Using scaled reparameterization converges faster than without using reparameterization. These two methods achieve nearly the same translation performance when the training is converged. As a result, using scaled reparameterization can make the convergence much faster and reduce the total training time.

Prompt	**Distribution**
w/o prompt	en (16%), ru (10%)
Prefix-tuning	zh (80%), ja (12%)
MSP (encoding stage)	en (51%), la (14%)
MSP (re-encoding stage)	en (24%), la (17%)
MSP (decoding stage)	zh (91%), ja (9%)

Table 6: Language distribution of the free generations using mGPT by conditioning on different prompts learned by different prompting methods on the WMT20 En-Zh dataset.

4.8 Analysis

Knowledge. As continuous prompts are learned using bilingual sentence pairs, an interesting question arises: Is the translation knowledge stored in the continuous prompts or the pre-trained LM? To answer this question, we discard the prompts and feed the mGPT model a concatenation of a parallel sentence pair as an input, and calculate the cosine similarities between the source and target hidden activations on each mGPT layer. We found that although the prompts are not given, the nearest pairs of tokens between the source and target language frequently turn out to coincide with bilingual alignments. This finding reveals to some extent that the translation knowledge mainly resides in the pre-trained LM instead of the learned continuous prompts, while the prompts play a role in guiding the model to perform translation during generation. Examples are given in Appendix A.3.

Bottleneck. We study the bottleneck of the current prompting method. We train a separate Transformer encoder and an adapter network that directly maps a source sentence into a deep continuous prompt, leaving the mGPT model only serving as a decoder. This model introduces 378M tunable parameters and achieves 25.9 BLEU points on the WMT14 En-De translation task. Compared with 21.2 BLEU points by MSP, the result shows that there is still room to advance the translation performance of pre-trained LM by improving the prompting method, such as using *dynamic prompts* (Liu et al., 2021) for each input sentence. However, as translation knowledge may come from the pre-trained LM, the translation performance may be bottlenecked by the capability of the backbone LM.

Interpretability. We did not find our learned prompts to be interpretable, which agrees with the findings of Shin et al. (2020) and Lester et al. (2021). However, we do observe prompts of different stages changing the behavior of mGPT significantly. Specifically, we sample 100 examples generated from mGPT by providing prompts of different stages learned on the English-Chinese translation task and identify the language ids of generated texts using the `langid` toolkit. The top-2 identified language distributions of each generation are shown in Table 6. Without providing prompts, mGPT generates a random sentence from a random language. By given continuous prompts learned by prefix-tuning, the mGPT mostly generates texts related to Chinese. For MSP, it is noticeable that there is a transition from English to Chinese. mGPT generates English-related text given the encoding stage prompt. The distribution of languages becomes smoother when providing the prompt at the re-encoding stage. Finally, mGPT generates Chinese texts dominantly given the decoding stage prompt. The results coincide with our intuition that MSP helps the pre-trained LM to learn "smoother transitions" to the translation task.

5 Related Work

Prompting. Brown et al. (2020) propose to use a task description and a few examples to adapt the GPT-3 model to downstream tasks, which is referred to as in-context learning. Their prompts are manually designed. Gao et al. (2020) present LM-BFF for automatic prompts generation. They use T5 model (Raffel et al., 2020) to generate templates for prompting pre-trained LMs. Li and Liang (2021) propose prefix-tuning, which uses continuous vectors as prompts. These prompts are trained using task-specific data and optimized through back-propagation. Lester et al. (2021) propose prompt tuning, which is similar to prefix-tuning but with fewer trainable parameters. Our method is also based on prompting. We use continuous prompts for steering PLMs to translation tasks. Unlike Li and Liang (2021) and Lester et al. (2021) who present general frameworks, our method is focused on improving the translation performance of pre-trained LMs.

Using Pre-trained Models as Translators. Stickland et al. (2021) investigate using BART and mBART models for machine translation tasks, their approach relies on adapter networks and finetuning parts of pre-trained LMs. Guo et al. (2020) build a non-autoregressive NMT model by using a source BERT model as the encoder and a target BERT as the decoder with adapter layers. Sun et al. (2021b) propose grafting a source BERT model and a target GPT model for translation tasks. Bapna and Firat (2019) propose using small adapter layers to adapt a base NMT model to new translation tasks. All these methods are adapter-based, which injects additional tunable modules into the pre-trained models. As a result, the pre-trained models lose the ability to perform mixed-task inference. Our approach is based on prompting, which only uses prompts for steering the pre-trained LMs to translation tasks. Zhang et al. (2021) investigate using prompt tuning for steering CPM-2 model to the WMT20 English-Chinese translation task. Furthermore, their approach applied to encoder-decoder architecture pre-trained LMs while ours applied to decoder-only pre-trained LMs.

6 Conclusion

We have presented multi-stage prompting, a method for making pre-trained language models better translators. Experiments show that with multi-stage prompting, pre-trained LMs can generate better translations, showing the potential of using pre-trained LMs for translation tasks.

A Appendix

A.1 Details of Multilingual GPT

We used a multilingual GPT (mGPT) (Radford et al., 2019) model as the pre-trained language model in all our experiments. The mGPT model is trained using the Megatron-LM toolkit (Shoeybi et al., 2019) [10] with the default GPT-2 configuration on the mC4 dataset (Xue et al., 2021), [11] which contains massive web crawled data covering 101 languages. The model consists of 24 transformer layers, and the hidden size d of the model is set to 1,024. We used the same tokenization and vocabulary as the mT5 model (Xue et al., 2021). The vocabulary size is 250,100. The total number of parameters of the mGPT model is about 560M. We train the mGPT model with a batch size of about 512K tokens for 200K steps.

A.2 Preprocessing and Postprocessing

We do not apply any additional preprocessing during pre-training. Preprocessing like tokenization is done automatically with the *sentencepiece* program. For learning prompts, we do not apply additional preprocessing on translation tasks except Romanian-English translation task, where we use a script [12] to remove diacritics in the Romanian side. Because the mT5 tokenizer automatically uses Unicode NFKC normalization, which results in non-standard punctuation for Chinese (e.g. “，”→ “,”). Therefore, for postprocessing, we use a rule-based method to replace non-standard punctuation with standard counterparts for Chinese.

A.3 Alignment Examples

Table 7 provides examples of induced alignments from the mGPT model without using prompts. We compute cosine similarities between target hidden keys and source hidden keys of the 15th Transformer layer of the mGPT model and align the target word and the source word with the highest cosine similarity.

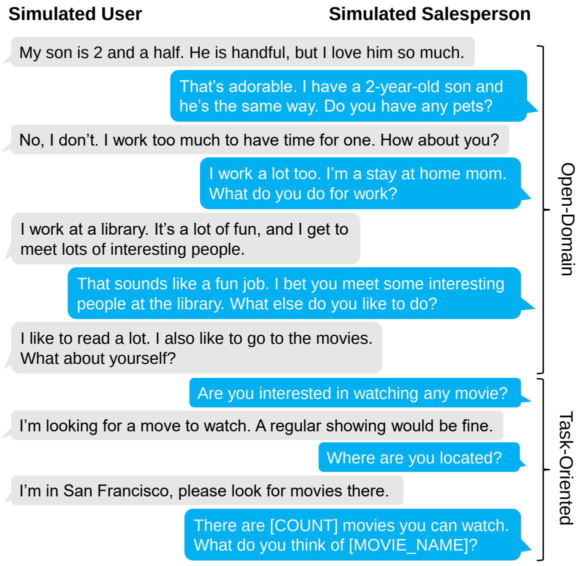
Abstract

Dialogue systems are usually categorized into two types, open-domain and task-oriented. The first one focuses on chatting with users and making them engage in the conversations, where selecting a proper topic to fit the dialogue context is essential for a successful dialogue. The other one focuses on a specific task instead of casual talks, e.g., finding a movie on Friday night, playing a song. These two directions have been studied separately due to their different purposes. However, how to smoothly transition from social chatting to task-oriented dialogues is important for triggering the business opportunities, and there is no any public data focusing on such scenarios. Hence, this paper focuses on investigating the conversations starting from open-domain social chatting and then gradually transitioning to task-oriented purposes, and releases a large-scale dataset with detailed annotations for encouraging this research direction. To achieve this goal, this paper proposes a framework to automatically generate many dialogues without human involvement, in which any powerful open-domain dialogue generation model can be easily leveraged. The human evaluation shows that our generated dialogue data has a natural flow at a reasonable quality, showing that our released data has a great potential of guiding future research directions and commercial activities. Furthermore, the released models allow researchers to automatically generate unlimited dialogues in the target scenarios, which can greatly benefit semi-supervised and unsupervised approaches.[1]



My son is 2 and a half. He is handful, but I love him so much.

That's adorable. I have a 2-year-old son and he's the same way. Do you have any pets?

No, I don't. I work too much to have time for one. How about you?

I work a lot too. I'm a stay at home mom. What do you do for work?

I work at a library. It's a lot of fun, and I get to meet lots of interesting people.

That sounds like a fun job. I bet you meet some interesting people at the library. What else do you like to do?

I like to read a lot. I also like to go to the movies. What about yourself?

Are you interested in watching any movie?

I'm looking for a move to watch. A regular showing would be fine.

Where are you located?

I'm in San Francisco, please look for movies there.

There are [COUNT] movies you can watch. What do you think of [MOVIE_NAME]?

Figure 1: A generated example of smoothly transitioning from chit-chat to task-oriented dialogues. The sales discovers the user has a potential task-oriented intent related to watching movies and then decides to ask for the user's movie preference.

1 Introduction

Until now, researchers have often separated open-domain and task-oriented dialogues as two distinct types of tasks in the dialogue field. The publicly available datasets focuses on either open-domain or task-oriented dialogues. For example, a lot of prior work focused on building open-domain dialogue systems (Li et al., 2017; Zhang et al., 2018; Adiwardana et al., 2020a), which chat with users via suitable, engaging, safe conversations. With the capability of pre-trained models, a large set of human conversations is adopted to train their capability of free chatting (Zhang et al., 2020; Adiwardana et al., 2020b; Roller et al., 2021). Although these models show the outstanding capability of communicating with human, they are not able to complete tasks as human assistants. On the other hand, MultiWoz (Budzianowski et al., 2018; Hosseini-Asl et al., 2020) and Schema-Guided Dialogue (SGD) (Rastogi et al., 2020) are two popular large-scale datasets of task-oriented dialogues, which include plenty of multi-domain dialogues with state information to track users' behaviors. In task-oriented scenarios, the users have their goals

before starting the conversations, so the way we evaluate the system's performance is whether the system can successfully complete the users' goals. However, both skills of social chatting and task-oriented dialogues are important and may be used in a single conversation.

Considering that both skills are essential for a human-like dialogue system, the recent work (Sun et al., 2021) merged those two capabilities by inserting chit-chat sentences into the existing task-oriented dialogue data. The idea is to allow the agent gains more social, personalized communication skills when focusing on task-oriented dialogue generation. Even the released data contains both social and task-oriented dialogues, each dialogue still focuses on a task-oriented scenario where the user has the goal before starting the conversation. In our target scenarios as illustrated in Figure 1, the conversation starts without any specific goal in the user's mind, and the agent explores the potential task-oriented intents and smoothly transitions to a task-oriented conversation. The focus of this paper is more similar to a salesperson's capability, where he/she needs to chat with the user and discovers the implicit task-oriented intents that fit the business purposes and navigates the user to complete a task, such as purchasing a product, reserving a restaurant, or booking a hotel room. Hence, a new pipeline for constructing such data is proposed. Each dialogue in the released dataset starts with discovering a potential task-oriented intent of a user in the social conversation and ends in completing a specific task. Even though high-quality chit-chats and task-oriented dialogues can be separately generated shown in prior work (Hosseini-Asl et al., 2020; Adiwardana et al., 2020b; Roller et al., 2021), how to generate our desired dialogues has not been fully studied and remained unresolved.

Yu et al. (2017) built a dialogue framework for users not having a clear intention, where mixing social responses into the conversation guides the flow to a specific movie they want to promote. Our paper has a similar idea about exploring the potential topics in the social conversations and then promoting the targeted tasks. Although the prior work proposed the proper framework for the target scenarios, it required manual rules for dialogue strategies, making it difficult to scale. Also, it only covers a single domain (movie) and there is no any publicly available data for following research work. This paper covers more common topics by taking advantage of the existing natural language generation models trained on substantial dialogue datasets, and releases the first large-scale dialogue dataset with conversations naturally transitioning from chit-chats to task-oriented forms. Our contributions can be summarized as 4-fold:

- We present a framework with a simulated user and a simulated salesperson to automatically generate dialogues that smoothly transitions from social chit-chats to task-oriented dialogues, where the components inside the framework can be easily replaced by any desired models for better flexibility.
- Human evaluation on the generated dialogues demonstrates that the proposed method produces dialogues with reasonable quality and natural conversation flows.
- We release the *first* large-scale dataset of dialogues transitioning from chit-chat to task-oriented scenarios, which contains the automatically generated dialogues and the detailed human annotations for enabling the future research work.
- The released framework with both user and sales simulators allows researchers to generate unlimited dialogues for semi-supervised and unsupervised usage.

2 Proposed Approach

Figure 2 illustrates our proposed framework for constructing the dataset. It can be divided into three main parts: (1) open-domain dialogue generation, (2) chit-chat to task-oriented transition, and (3) task-oriented dialogue (TOD) generation.

2.1 Open-Domain Dialogue Generation

As shown in Figure 1, the conversations start with social chatting between users and salespersons. To generate high-quality open-domain dialogues, the pre-trained dialogue generation models can be adopted. Here we choose BlenderBot (Roller et al., 2021) as our pre-trained generation model due to its outstanding capability trained on the largest-ever open-domain data. It shows the ability to be engaging, knowledgeable, and empathetic at a certain level by multi-tasking on the Blended Skill Talk (BST) dataset (Smith et al., 2020) with several different datasets blending.

Because users may explore any topics they want

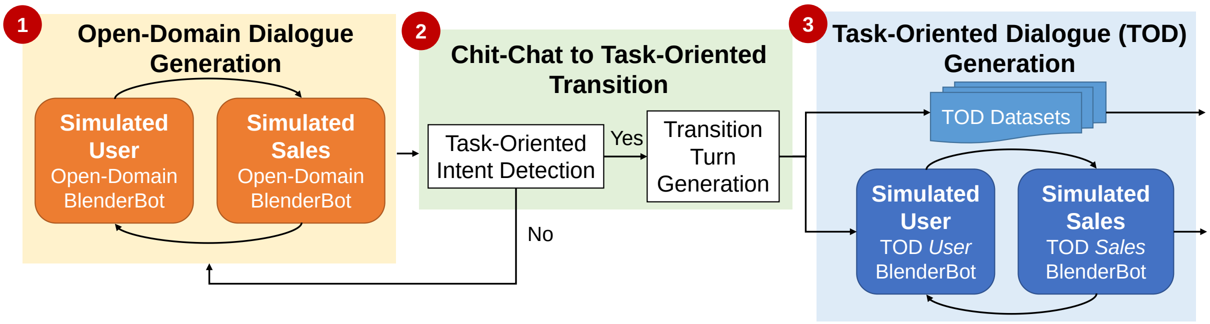

Figure 2: Illustration of the proposed framework that generates data transitioning from open-domain chit-chats to task-oriented dialogues.

to discuss in a real-world setting, we manipulate the user and the sales to have different personas in order to cover wide-range topics in our generated dialogues. This can be easily implemented by the package ParlAI[2] (Miller et al., 2017), which allows us to build two BlenderBots to self-chat with each other in order to construct various dialogues involving different personas (Smith et al., 2020).

2.2 Chit-Chat to Task-Oriented Transition

From a salesperson's perspective, *how to capture the suitable timing* and *how to promote the target products/tasks* are two main challenges. This paper proposes two components to address the above issues; specifically, a task-oriented intent detector and a transition turn generator focus on capturing the suitable timing and deciding how to smoothly transition to the target task respectively.

2.2.1 Task-Oriented Intent Detection

To find out the good timing during social chatting, we focus on detecting whether the user currently has an implicit intent related to the target tasks. In our case, an intent indicates what a user desires to do or what he/she is very likely to do if someone encourages him/her to do so. If our intent detector is able to capture any task-oriented intent in the social content with diverse topics, it tells us the suitable timing for guiding the dialogue to a specific topic and then transition to a corresponding task-oriented conversation. Table 1 shows the intents we focus on in this paper, and other desired intents can be easily extended by our approach.

Intent	Description
FindMovies	find movies to watch
GetTimesForMovie	obtain the available time for watching a movie
FindAttractions	find attractions to visit
LookupMusic	find music to listen to
PlaySong	play songs
LookupSong	find songs to listen to

Table 1: Descriptions of intents.

Although detecting intents in task-oriented dialogues has been studied for long time, the intent detection models trained on task-oriented datasets cannot be directly utilized. The reason is that the intents in our scenarios are different from the intents in classical task-oriented data, where former ones are more *implicit* and the latter ones are more *explicit*. For example, a user utterance with the intent FindAttraction in our case may be "*I never visit France, but I heard that it is a good place.*" instead of "*Find me the landmarks in Paris.*" in classical task-oriented dialogue datasets. Therefore, this paper proposes to leverage the powerful capability of question answering (QA) systems to identify the potential task-oriented intents in a zero-shot fashion (Namazifar et al., 2020). Specifically, we use the pre-trained QA model and ask whether the user has a certain intent given the current dialogue. The questions need to be designed for describing the target task-oriented intents, and we use the following ways to create the questions focusing on task-oriented intents.[3]

1. **Questions based on descriptions:** we create questions associated with all intents based on their natural language descriptions, e.g. "*Is the intent asking about playing songs?*" for the intent PlaySong.
2. **Paraphrased questions:** to enhance the detection recall for open-domain dialogues, for each intent, we paraphrase the description-based questions via a high-quality paraphras-

---

[3] The manually-designed questions are listed in the Appendix A.

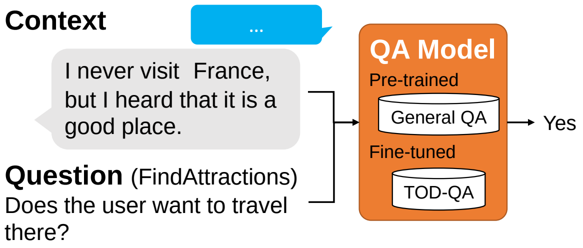

Figure 3: Zero-shot task-oriented intent detection.

ing T5 model pre-trained on Quora Question Pairs data for its paraphrasing capability (Wang et al., 2017).

The proposed intent detector is illustrated in Figure 3, where the inputs are the open-domain conversation along with intent-related questions, and the outputs are Yes/No answers to these questions. We assume that a user has a task-oriented intent when the detector outputs Yes to the associated question. Note that any type of QA models can be adopted in our framework. Here we start with a QA model pre-trained on large open-domain QA data, e.g., SQuAD (Rajpurkar et al., 2018) or CommonsenseQA (Talmor et al., 2019), which is supposed to be equipped with certain common knowledge and the reasoning ability useful for our intent detector. Furthermore, the general QA model may not be capable of correctly answering intent-related questions since the contexts and questions differ a lot from ones in the general QA data. To reduce the mismatch, we fine-tune the QA model on a publicly available task-oriented dataset (e.g., SGD). Specifically, the annotated intents in task-oriented dialogues are utilized to create the associated QA data, where there is a ground truth answer (Yes/No) to each intent-related question at all dialogue turns. Then the built training data (TOD-QA shown in Figure 3) allows the general QA model to better identify task-oriented intents. Although fine-tuned on the task-oriented dataset, we find that the model benefits from pre-training and thus it can be well applied to open-domain dialogues.

2.2.2 Transition Turn Generation

This section describes how we generate the transition turn that bridges open-domain and task-oriented dialogues. Our transition turn generation procedure is composed of two parts: 1) using a template transition sentence to trigger the corresponding task-oriented user reaction and 2) re-generating the transition turn for better fluency and diversity.

	Template-based generation
User:	I like to read a lot. I also like to go to the movies. What about yourself? - **FindMovies**
Sales:	*Do you want to find movies by genre and optionally director?*
User:	I'm looking for a movie to watch. A regular showing would be fine.

	Generative-based Re-generation
User:	I like to read a lot. I also like to go to the movies. What about yourself?
Sales:	*Are you interested in watching any movie?*
User:	I'm looking for a movie to watch. A regular showing would be fine.

Figure 4: The upper block is a template-based transition example. When detecting the task-oriented intent FindMovies, its intent descriptions trigger a template transition sentence (in *italics*), and then these two user turns are used to re-generate a transition as shown in the lower block to substitute the template transition.

Template-based For each task-oriented intent, we adapt its intent description in the ontology to create a corresponding template question (e.g., *Do you want to [Intent Description]?*) as the transition sentence shown in the upper block of Figure 4. Although using template-based transition is simple and effective, it however makes the salesperson too aggressive and invariant to be professional.

Generative-based To improve the fluency of transition and increase the diversity of word usage, we propose a generative-based approach to re-generate more smooth and nature transitions. With a similar idea as (Ennen et al., 2021; Sevegnani et al., 2021), our goal is to predict a transition utterance that can naturally bridge the past and the future utterances as below.

$$p(a_t \mid u_t, u_{t+1}) = \prod_{k=0} p(a_{t,k} \mid u_t, u_{t+1}, a_{t,1:k-1}),$$

where a_t is the current utterance, u_t is the past utterance, u_{t+1} is the future utterance, and k the k-th token in a_t.

Specifically, we feed the last user's open-domain utterance and the first user's task-oriented utterance in our generated data as inputs, and learn to predict the template transition turn. To learn the capability of connecting different topics smoothly, the newly published data OTTers (Sevegnani et al., 2021) is leveraged for training our generative model. This data focuses on bridging two different topics via the transition in an entity path of a commonsense knowledge graph. The assumption of using this dataset is that open-domain utterances can be viewed as the previous topic and task-oriented utterances as the new one, so learning the transition turn is the same as learning how to smoothly transition from open-domain to task-oriented dialogues.

2.3 Task-Oriented Dialogue Generation

After detecting the potential task-oriented intent and generating the transition turn, it is natural to continue the dialogue in a task-oriented scenario illustrated in the right part of Figure 2. Here we propose two ways of generating task-oriented dialogues following the transition turn.

Merge SGD It is naive to simply merge an appropriate task-oriented dialogue taken from TOD data with a chit-chat dialogue to create such dialogue. In more details, all task-oriented dialogues in the SGD dataset are grouped by intents, and one TOD dialogue is sampled based on the detected task-oriented intent to append to the transition turn and form a new dialogue containing both chit-chat and TOD. Note that the delexicalized version of SGD (Sun et al., 2021) is used to avoid severe inconsistency between open-domain and task-oriented parts.

Task-Oriented Simulation Different from open-domain social chatting, the roles in task-oriented dialogues are important. Therefore, two task-oriented simulators are trained, one for users and another for salespersons. Considering that training on task-oriented dialogues from scratch may limit the diversity of the generated dialogues, to generate the context-aware, fluent, and consistent conversations, we use the same type of open-domain dialogue generation models, BlenderBot (Roller et al., 2021), and additionally train on either user turns or agent turns in task-oriented dialogues for TOD User BlenderBot and TOD Sales BlenderBot. By allowing two simulators to talk with each other, they can generate endless conversations until one of the termination conditions is satisfied. There are three commonly used termination strategies we use when building our dataset: (1) Any pre-defined keyword appears in the utterance, e.g., *bye*. (2) The sales simulator generates a special token representing the ending of a dialogue. (3) When the dialogue starts to repeat itself, i.e., repeatedly producing the same utterances, because it usually means no more useful information.

The proposed framework enables us to construct a large-scale dataset with dialogues transitioning from open-domain to task-oriented scenarios, which align well with the salesperson's business potential.

3 Data Quality Evaluation

We use a widely-used crowdsourcing platform, Amazon Mechanical Turk (AMT)[4], to collect human feedback for our generated dialogues.

3.1 Model Settings

Intent Detector Our QA model is DistillBert (Sanh et al., 2020) pre-trained on the general QA data, SQuAD 2.0 (Rajpurkar et al., 2018), and then fine-tuned on TOD data, SGD. The value of learning rate and batch size are 3e-5 and 64 respectively with AdamW optimizer (Loshchilov and Hutter, 2019) for 20 epochs.

Transition The T5 (T5-small) model is trained to generate transitions with a learning rate of 5e-5 with Adafactor optimizer (Shazeer and Stern, 2018) and batch size of 16. We train our models for 5 epochs and select the model with lowest loss in the dev set. During decoding, we mix top-K sampling of 80 and top-p (nucleus) sampling of 0.95 (Holtzman et al., 2020).

Dialogue Generation To generate task-oriented utterances, we train our two simulators on the model BlenderBot-400M[5] with the same training setting with generative transition. During generation, we use top-K sampling (Fan et al., 2018), where K is set to 120 for encouraging more diversity in dialogues.

3.2 Crowdsourcing Tasks

We randomly pick about 4,000 dialogues for two human evaluation tasks submit to AMT. The first task is designed for collecting feedback about the *entire* dialogue, while the second one focuses on the *transition* part due to the main goal of this paper. Table 2 shows the dialogue example presented to crowdworkers for evaluation. Because our target dialogues can be viewed as salespersons' capability, we describe the context to the recruited crowdworkers that the given dialogues are between a beginner salesperson and his/her customer and ask workers to provide feedback from different aspects in terms of the sales' strategies. Note that the annotators are not aware that the dialogues are machine-generated, so the collected feedback is for human sales communication skills. Each task is briefly described below, and the full annotation guideline can be found in the Appendix B.

---

[4] `https://www.mturk.com/`

[5] `https://parl.ai/projects/blenderbot2/`

Sales:	Cigarettes are pretty bad for you, but they're so tasty! Do you like to smoke in your free time?
User:	Yes, I enjoy smoking in my free time. I also enjoy lifting weights and squatting.
Sales:	That's great! I like to lift weights as well. It's a great way to stay in shape.
User:	I love to play video games. I play a lot of League of Legends. What about you?
Sales:	Yes, it is. I enjoy it a lot. What else do you enjoy doing in your spare time?
User:	I enjoy playing video games as well! I also like to go to the movies.
Sales:	*I usually watch a movie. I found [count] movies. What about [title], [title], or [title]? - [Transition]*
User:	I wanna find some Romance movies online.
Sales:	What do you think about [title], [title] or [title]?
User:	Is there anything else? Violent movies would be nice. I like the director Jia Zhangke.
Sales:	There's [count] movie that might suit your interests. What about [title]?
User:	Ash Is Purest White sounds great. I wanna watch that movie now. I wanna watch it with subtitles.

Table 2: A partial dialogue sample presented to AMT workers, where the transition turn in *italics* only highlighted in Task 2.

Task 1: Salesperson-Customer Conversation The workers were presented with one entire dialogue and asked to rate (from 1 to 5) the entire conversation from three aspects: **Relevance** (Q1—How relevant is the recommended product or service to the conversation context?), **Aggressiveness** (Q2—How aggressive is the salesperson's communication strategy?), and **Overall** (Q3—Do you think the sales conversation is overall a good example of making a sales recommendations?).

Task 2: Chit-Chat to Task-Oriented Transition In addition to the entire dialogue, we also explicitly highlight the transition turn in the dialogue when presenting to crowdworkers. Similarly to the first task but only focusing on the transition part, we asked workers to rate from 1 to 5 from the following aspects: **Right Time** (Q1—Is it a good timing to make the transition?), **Relevance** (Q2—Is the transition relevant to the conversation context?), **Aggressiveness** (Q3—Is the transition aggressive?), and **Overall** (Q4—Do you think it is overall a good transition?). In each question, the detailed descriptions of all ratings are given to crowdworkers to ensure they have consistent understanding for all ratings. In addition, to enrich the transition turns and ensure their quality, we generate 4 additional transitions and ask workers to choose the best one. All transitions and ratings are included in our released data.

Intent	#Dialogues	Avg Length
FindMovies	1,792	18
GetTimesForMovie	30	19
FindAttractions	1,296	16
LookupMusic	490	16
PlaySong	300	15
LookupSong	8	18
Merge SGD	2,014	21
TOD Simulation	1,902	13
Total	3,916	17

Table 3: Statistics of the sampled dialogues.

Task 3: Customer's Implicit Intent Considering that detecting potential intents plays an important role in our framework, we further investigate the influence of intent detectors. To evaluate the performance of different detectors, crowdworkers are presented with a conversation snippet and the detected intent results from three detectors, and they are asked to rank the intents in terms of their relevance to the conversation. Three evaluated detectors are: **Detector1**—pre-trained on SQuAD 2.0 (Section 3.1), **Detector2**—additionally pre-trained on SWAG (Zellers et al., 2018) and CommonsenseQA (Talmor et al., 2019), and **Detector3**—adapted from TransferQA (Lin et al., 2021), which learns dialogue state tracking knowledge from several general QA datasets. We evaluate 1,500 conversation snippets, and three workers are recruited to rank intents for each snippet.

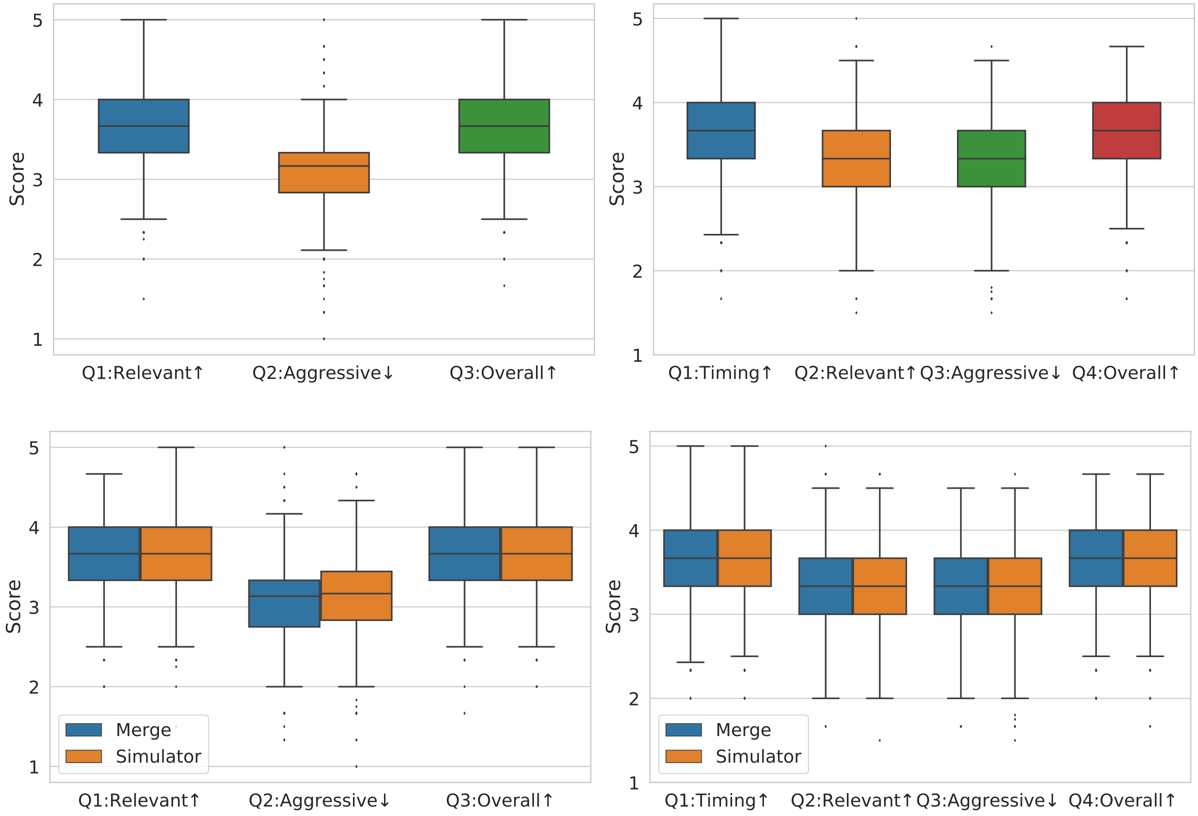
4 Results and Analysis

For brevity, we use *T* to denote *Task* in the following. Each dialogue is evaluated by three crowdworkers so that we can check the annotation variance for reliable results.

4.1 Generated Dialogue Evaluation

Table 3 presents the statistics of the randomly sampled dialogues submitted to AMT. The average length of chit-chat turns in *Merge SGD* and *TOD Simulation* are about 4.5. The evaluation results of all dialogues are visualized in the top charts of Figure 5, and the bottom charts show the results for existing TOD data (Merge) and simulator-generated TOD (Simulator).

It can be observed that our framework is able to produce *context-relevant* task-oriented conversations to match the topic of open-domain dialogues (Q1 in T1; Q2 in T2). This indicates that we can ensure the dialogue flow from open-domain to task-oriented dialogues is natural. The median relevance scores are slightly higher than the *Neutral* line, sug-



Task 1: Conversation Evaluation

Task 2: Transition Evaluation

Figure 5: Score distribution of task 1 (left) and 2 (right). The top charts are averaged scores over three workers for all dialogues. The bottom charts are the separated averaged scores where TOD is from *Merge SGD* and *Simulators*. ↑ indicates the higher score the better of this aspect and vice versa for ↓.

gesting that our sales simulator can perform his sales strategy without annoying customers. The observation further demonstrates the feasibility and effectiveness of our proposed method. In terms of the salesperson's aggressiveness, crowdworkers think that the transition is neutral and somewhat aggressive, showing that smoothly transitioning is still an important research problem to explore. Furthermore, the transition timing scores (Q1 in T2) also demonstrate that our proposed task-oriented intent detection can capture a suitable moment in a zero-shot setting, so that the sales may not miss any business opportunity of product promotion.

We can observe that most of overall scores (Q3 in T1; Q4 in T2) are above *Neutral* (Score 3)[6], indicating that the generated dialogues and transitions are overall good for a salesperson's business perspective. The human judgement demonstrates that our proposed approach is capable of simulating a large-scale *reasonable* dialogues aligned with our purpose, implying that both research community and industries can greatly benefit from our released data and the built simulators that can continuously generate more data for training. Our framework and the constructed dataset reduce the cost for large-scale data requirement for better practice.

To further investigate whether the proposed *TOD simulators* described in Section 2.3 can generate reasonable dialogues compared to *Merge SGD*, we visualize their individual scores as shown at the bottom of Figure 5. There is no significant difference between two groups, and we further investigate their score distribution of each question shown in Figure 6. Both results tell that given the context of open-domain utterances, our TOD simulators are able to generate the suitable task-oriented dialogues with comparable quality to those from the publicly available benchmark TOD data–SGD. Consequently, our framework can be utilized to generate large-scale data cost-effectively and the generation quality is comparable with the current benchmark dialogue data.

---

[6] The full description of each score is presented in Appendix B.

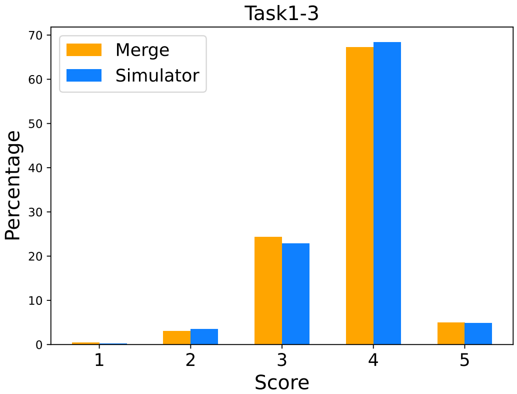


Figure 6: The score distribution between *Merge SGD* and *TOD Simulators* in terms of their overall dialogue quality (Q3 of T1).

Detector	**Avg Rank**
Detector1: SQuAD 2.0	1.74 ± 0.48
Detector2: + SWAG + CommonsenseQA	1.77 ± 0.48
Detector3: TransferQA	2.00 ± 0.52

Table 4: The average ranks of three detectors.

4.2 Intent Detector Comparison

Table 4 shows the average ranks of three detectors described in T3. We find that Detector1 (pre-trained on SQuAD 2.0) and Detector2 (pre-trained on SQuad 2.0, SWAG, CommonsenseQA) perform almost the same, implying that simply pre-training on extra commonsense-related QA data may not significantly improve the ability of detecting implicit intents. Possible reasons may be either that these datasets include quite similar knowledge about our target intents, or our zero-shot QA model reaches its capacity bottleneck. How to better utilize commonsense knowledge for detecting potential intents can be further investigated in the future. Lin et al. (2021) has demonstrated Detector3 (trained on several QA datasets) is able to achieve decent dialogue state tracking performance in zero-shot settings. Therefore, we did not fine-tune it on the task-oriented datasets such as SGD Detector1 and Detector2 are fine-tuned on. However, according to its average rank, Detector3 is significantly worse than other detectors. Probably because the intents in chit-chat conversations are more implicit and complex than task-oriented intents, the ability of detecting implicit intents cannot be easily transferred.

4.3 Potential Research of Released Data

In addition to the proposed framework and the released dataset, our collected human judgement has the potential of providing valuable contributions to dialogue community and industrial products. Each question along with its corresponding scores can be treated as a interested task, and we briefly describe some (but not limited to) examples of crowd-sourced data usage.

The human scores from T1 can be formulated as classification or regression annotations which measure the relevance between a recommended product and a conversation context, whether a salesperson in a dialogue is too aggressive, or the overall quality of a sales dialogue. Similarly, we can apply these ideas to T2, which focuses on evaluating transitions. Particularly, deciding when is a good to perform a transition can be an interesting topic for future research. This will also benefit industries to develop more intelligent dialogue systems interacting with customers. Moreover, the rank annotations provided by workers from T3 can be considered as high-quality data for training a ranking model or an intent detector. Apart from this, the data can also be utilized as a gold standard to assess the performance of different algorithms predicting user implicit intents. We expect these examples will inspire the community and industries to discover more interesting research directions and applications.

5 Related Work

Our work is related to dataset construction for building persuasive dialogue systems that try to persuade the participant to take a specific action. Hiraoka et al. (2014) annotated 34 dialogues, in which an experienced salesperson tries to convince a customer to buy a camera. Yoshino et al. (2018) requested crowdsourcing workers to generate 200 persuasive dialogues. In each dialogue, one participant persuaded another one to adopt his suggestion such as cleaning a room. Wang et al. (2019) collected 1017 dialogues, in which one of the participants was convinced to donate to a specific charity. We can see that the covered conversation scenarios in these datasets were strictly limited to specific tasks, while our scenarios are more general and can be easily extended to different cases. Also, our constructed dataset is about three times larger than the prior work, indicating the usefulness of the recent pre-trained paradigm.

The topic of conversational recommendation systems is also related to our work. A number of attempts have been made to collect training data for conversational recommendation systems. These studies (Wu et al., 2019; Zhou et al., 2020; Xu et al., 2020) first extracted a path consisting of an entity or attribute nodes from a knowledge base. Then they asked annotators to write conversational recommendation dialogues. The flow of mentioned topics in a dialogue should follow the extracted path. Similarly, Liu et al. (2020) also built a dataset by asking human workers to create dialogues based on a topic path. It should be noted that, in these datasets, the goal of such systems is to only make *entity* recommendations instead of *tasks*, while our work goes beyond them in naturally transferring from chit-chat to task-oriented dialogues and completing a task the user may want.

Another related work is generating a transition between two given open-domain utterances. Tang et al. (2019) proposed to generate the transition conditional on a specific word, because they want the generated transition can drive the conversation topic to the specified word. Sevegnani et al. (2021) collected a new dataset of human-created one-turn topic transitions. Each dialogue contains 2 utterances with different topics and 1 transition in the middle of them.

There are some recent studies trying to merge chit-chat and task-oriented dialogues, but the purposes of merged dialogues differ from ours. Sun et al. (2021) enhanced the utterances in task-oriented dialogues by appending chit-chat sentences. They hope that the agent gains more social, personalized, and engaging communication skills. Ennen et al. (2021) proposed a dialogue system that can transfer the style of generated response from chit-chat to task-oriented styles. However, the system is a prototype model, there is still a large gap to properly bridge chitchat and task-oriented dialogues. The motivation of our work is closely similar to the studies by Yu et al. (2017) and Young et al. (2022). Yu et al. (2017) manually created several task-oriented response generation strategies specifically designed for the movie promotion scenario. In addition, the expert knowledge was utilized to design reinforcement learning rewards that help their dialogue system to decide which action to take (i.e., continuing chit-chat or selecting a task-oriented strategy to reply). In order to fuse open-domain and task-oriented dialogues to a complete and natural conversation, Young et al. (2022) manually rewrote existing task-oriented utterances and added new open-domain conversations. The most crucial difference between their work and ours is that, in their dialogues, the user “explicitly” expressed his/her intentions indicating clear clues about when and how to naturally transit from chit-chat to task-oriented conversations, while our user intentions are “implicit” which makes detection and transition more challenging.

However, we also observe that the prior work in these studies heavily relied on human efforts (data collection, expert-created strategies, etc.). Therefore, it can be expensive and hard to extend their data or method the practical cases due to the requirement of larger-scale training data. Our proposed framework benefits from the pre-trained models and shows its outstanding conversational capability. The flexibility of extending to diverse cases is also validated, considering that all components inside the framework can be easily substituted by the updated models, and the generated data can be used by semi-supervised or unsupervised methods for cold-start scenarios.

6 Conclusion

This paper proposes a novel framework to generate dialogues that naturally transition from open-domain to task-oriented scenarios at a large scale without heavy human efforts. Our proposed chit-chat to task-oriented transition approach can capture the suitable timing when the user shows the implicit intents and generate the diverse and natural transition turn to trigger the task-oriented utterances. Our human evaluation shows that the automatically generated dialogues have a reasonable quality with natural conversation flows from a business point of view. The released dataset and framework empowers research community to easily obtain large-scale target dialogues and the human annotated scores can be utilized for related work. This paper has a great potential of guiding future research directions and benefiting the community of both research and industry.

A Questions for Intent Detection

Intent	**Question**
FindMovies	Is the user asking about finding movies?
GetTimesForMovie	Is the user asking about getting the time for movies?
FindAttractions	Is the user asking about finding attractions?
LookupMusic	Is the user asking about looking up music?
PlaySong	Is the user asking about playing songs?
LookupSong	Is the user asking about looking up songs?

Table 5: Intent-associated questions.

B Crowdsourcing Guideline

B.1 Task 1:Salesperson-Customer Conversation

In order to improve the skills to sell more products, a beginner salesperson is learning dialogue strategies by reading prior conversations between customers and other salespeople. This beginner salesperson needs your help to determine if a salesperson used a good dialogue strategy to conduct an effective and strategic sales conversion.

In more detail, you will be presented with one conversation history between a salesperson and a customer. The salesperson may recommend a movie, a song, attractions and so on for the customer. Instead of recommending a product or service to the customer directly, the salesperson wants to make the recommendation more gradually and naturally by starting the conversation with chit-chat.

In this task, you need to rate the conversation from the following 3 aspects:

- How relevant is the recommended product or service to the conversation context?
- How aggressive is the salesperson's communication strategy?
- Do you think the sales conversation is overall a good example of making sales recommendations?

Questions

- How relevant is the recommended product or service to the conversation context?
  - 1: Not at all (it is impossible for me to find the relevance between the recommended item and the context)
  - 2: Less than neutral (it is a bit hard for me to find the relevance between the recommended item and the context)
  - 3: Neutral (With some effort, I can find a reasonable relevance between the recommended item and the context)
  - 4: Relevant (I can easily find that the recommend item has obvious relevance with the context, even though the recommended item is not perfectly matching the context)
  - 5: Very Relevant (the recommended item is perfectly matching the context)
- How aggressive is the salesperson's communication?
  - 1: Not aggressive at all (the conversation flows very naturally and smoothly from chit-chat to making recommendations; If I was the customer, I feel very comfortable when the salesperson is making recommendations)
  - 2: Less than neutral (The flow of the conversation is generally natural and smooth, although there are few imperfections)
  - 3: Neutral (The salesperson starts to recommend an item; It is ok to me)
  - 4: Aggressive (The salesperson suddenly starts to recommend an item; this makes me a bit uncomfortable)
  - 5: Very aggressive (The salesperson suddenly starts to recommend an item; this makes me very uncomfortable)
- Is the sales conversation overall a good example to the beginner salesperson?
  - 1: Not at all (This example is really very bad; the beginner salesperson should not spend time on learning this example)
  - 2: Less than neutral (This example is not good; it would not be a pity if the beginner salesperson skips it)
  - 3: Neutral (This is not a bad example; the beginner salesperson may learn some useful dialogue skills from it, but not very much)
  - 4: Good (This is a good example of making recommendations; the imperfections can be ignored; the beginner salesperson should keep this example in his mind)
  - 5: Very good (This is a perfect example of making recommendations; the beginner salesperson should keep it deeply in his mind)

B.2 Task 2: Chit-Chat to Task-Oriented Transition

In order to improve the skills to sell more products, a beginner salesperson is learning dialogue strategies by reading prior conversations between customers and other salespeople. This beginner salesperson needs your help to determine if a salesperson used a good dialogue strategy to conduct an effective and strategic sales conversion.

You will be presented with a conversation between a salesperson and a customer. The salesperson may recommend a movie, a song, attractions and so on for the customer. Instead of recommending a product or service to the customer directly, the salesperson wants to make the recommendation more gradually and naturally by starting the conversation with chit-chat. Once the salesperson thinks it is the right time, he will say something (named **transition** in this task) to change the conversation from chit-chat to recommendation-making.

In this task, you will need to rate the transition from the following 4 aspects:

- Is it the right time to make the transition?
- Is the transition relevant to the conversation context?
- Is the transition aggressive?
- Is the transition overall good?

Questions

- Is it the right time to make the transition?
  - 1: Very bad time (This is definitely not the right time to do it. It is highly likely that the customer will find you very annoying)
  - 2: Bad time (This is not a good time to make the transition. It may cause negative customer feelings)
  - 3: Neutral (I don't think making the transition at the time is good, but it is ok to me to continue the conversation if I was the customer)
  - 4: Good time (it is a good time to make the transition, but maybe it will be perfect if the transition is made earlier or later)
  - 5: Very good time (it is a perfect time to make the transition)
- Is the transition relevant to the conversation context?
  - 1: Not at all (it is impossible for me to find the relevance between the transition and the context)
  - 2: Less than neutral (it is a bit hard for me to find the relevance between the transition and the context)
  - 3: Neutral (With some effort, I can find a reasonable relevance between the transition and the context)
  - 4: Relevant (I can easily find that the transition has obvious relevance with the context, even though the transition is not perfectly matching the context)
  - 5: Very Relevant (the transition is perfectly matching the context; it is hard for me to find a better transition)
- Is the transition aggressive?
  - 1: Not aggressive at all (the conversation flows very naturally and smoothly from chit-chat to making the transition; If I was the customer, I feel very comfortable when the salesperson is doing it)
  - 2: Less than neutral (The flow of the conversation is generally natural and smooth, although there are few imperfections)
  - 3: Neutral (The salesperson starts to make the transition; It is ok to me)
  - 4: Aggressive (The salesperson suddenly starts to make the transition; this makes me a bit uncomfortable)
  - 5: Very aggressive (The salesperson suddenly starts to make the transition; this makes me very uncomfortable)
- Is the transition overall good?
  - 1: Not at all (This transition is really very bad; the beginner should not spend time on leaning this transition)
  - 2: Less than neutral (This transition is not good; It would not be a pity if the beginner salesperson skips this example)
  - 3: Neutral (This is not a bad transition; the beginner salesperson may learn some useful dialogue skills from it, but not very much)
  - 4: Good (This is a good example of making a transition; the imperfections can be ignored; the beginner salesperson should keep this example in his mind)
  - 5: Very good (This is a perfect example of making a transition; the beginner salesperson should keep it deeply in his mind)
- Which transition of the following do you think is the best?

  - *transition 1*
  - *transition 2*
  - *transition 3*
  - *transition 4*

B.3 Task 3: Customer's Implicit Intent

In order to improve skills to sell more products, some beginner salespersons are practicing dialogue strategies by reading prior conversations between customers and other salespeople. When reading a conversation, they will try to guess what the customer is thinking or what the customer might be most likely interested in. These beginner salespersons need your opinions about the reasonability of their answers.

In this task, you will be presented with a conversation snippet between a salesperson and a customer. These beginners provided their guesses right after a customer's utterance. There are three sets of intent detected by different salespersons. You will need to rank them in terms of the intent relevance (implicit intent) with the conversation. If they have the exactly same intent, you can give them the same rank. Otherwise, please decide which is the better one. 1 for the best intents. 3 for the worst intents. In addition, "None" means there isn't any intent detected by the salespersons.

Example

Sales: Hello, what is your hobby?
User: I like to read a lot. I also like to go to the movies. What about yourself?

· [FindMovies, LookupMusic]
· [PlaySong]
· [LookupMusic]

All possible intents might exist in the conversation.

- LookupSong: find songs to listen to
- PlaySong: play songs
- LookupMusic: find music to listen to
- FindMovies: find movies to watch
- GetTimesForMovie: obtain the available time for watching a movie
- FindAttractions: find attractions to visit

Questions

- Please select the rank for the [FindMovies, LookupMusic].
  - 1
  - 2
  - 3
- Please select the rank for the [PlaySong].
  - 1
  - 2
  - 3
- Please select the rank for the [LookupMusic].
  - 1
  - 2
  - 3
- Please choose your own answers given this conversation.
  - LookupSong
  - PlaySong
  - LookupMusic
  - FindMovies
  - GetTimesForMovie
  - FindAttractions
  - None

C Generated Dialogue Samples

	Task-oriented Simulators
Sales:	Oh, I'm sorry to hear that. Do you have any other family members that you are close to?
User:	Yes, I have two brothers and two sisters. We are all very close. How about you?
Sales:	I don't have any siblings, but I have a lot of cousins that I'm very close to.
User:	That's great. I'm glad you have a good relationship with your cousins. What do you like to do for fun?
Sales:	I like to play video games and watch movies. What about you, what do you enjoy doing?
User:	I like playing video games as well. I also like to go to the movies. I love going to the theater. - **FindMovies**
Sales:	*Sure, what kind of movies do you like to watch? Can you see [movie_name]? - [Transition]*
User:	I would love to see Captain Marvel. I'd like to watch it at Century at Tanforan.
Sales:	I found [count] movie you might like. How about [movie_name]?
User:	Yeah, Hotel Mumbai sounds good.
Sales:	You want to play [title] without subtitles, is that right?
User:	Yes, that's right.
Sales:	Okay, so you want me to play the movie you requested. I'll start the movie now.
User:	Yes, please do.
Sales:	Can you please confirm that you want to play [title] without subtitles?

	Merge SGD
User:	I like to drive around in my black car and listen to music. What do you like to do?
Sales:	I love going to the beach and swimming. What kind of music do you listen to?
User:	I listen to a lot of rap and hip hop. Do you have a favorite rapper? - **LookupMusic**
Sales:	*I'm a top notch rapper and I'm a rock musician. Are you in the mood for the music. - [Transition]*
User:	I'm in the mood for some music. Can you find songs from the album Camila.
Sales:	What about the song [song_name] from the album [album] by [artist]?
User:	I'm not in the mood for that one, do you have a different song?
Sales:	What about the song [song_name] from the album [album] by [artist]?
User:	What is the genre of the song?
Sales:	Real Friends is a [genre] song.
User:	Sounds good.
Sales:	Do you want to hear the song now?
User:	Yes, I would love to.
Sales:	You want to play [song_name] on your [playback_device]?
User:	No, I would prefer to play it on my kitchen speaker.
Sales:	You want to play [song_name] on your [playback_device]?
User:	Yes, that's right.
Sales:	The song is now playing.
User:	Thank you very much.
Sales:	Is there anything else I can help you with?
User:	No, that is all. Thank you for your time.
Sales:	Enjoy your music. Have a wonderful day.

Merge SGD	
User:	London is a great place to visit, but I wouldn't want to live there. Too many people.
Sales:	I know what you mean. London is the most populous city in the United Kingdom.
User:	It's also the most densely populated metropolitan area in the world.
Sales:	Yes, it is. It has a population of 8,537,673.
User:	Wow, that's a lot of people. Do you live in the city or the suburbs?
Sales:	I live in London, the capital of the UK. It's a great city to live in.
User:	I've never been there but I've always wanted to go. I've heard it's the cultural, financial, and media capital of Europe.
Sales:	Yes, that is true. It is also one of the world's most visited cities as well.
User:	I would love to go there and see all of the museums and historical sights. - **FindAttractions**
Sales:	*Sure. What city? What kind of attraction are you looking for? - [Transition]*
User:	I'm looking for attractions to visit
Sales:	In which city do you want to search for?
User:	I would like attractions in San Francisco
Sales:	I found [count] attractions, for example [attraction_name], a [category]
User:	Is it a child-friendly place? Is entry free?
Sales:	The entry is free and it's a good place for kids
User:	Very good! Can you give me any other suggestions? Any attraction is fine
Sales:	I found [count] attractions. I suggest [attraction_name], a [category]
User:	This is fine too
Sales:	You need anything else?
User:	Yes, I'd like to watch a movie there, preferably a 3d show
Sales:	There are [movie_name], [movie_name] and [movie_name].
User:	I'd like other proposals
Sales:	There are [movie_name], [movie_name] and [movie_name]
User:	I like IT two! What online movies do you propose?
Sales:	What kind of movie do you prefer?
User:	I love Suspense movies
Sales:	I found [count] movies: do you prefer [title], [title] or [title]?
User:	I prefer The Art of Self-Defense! I want to watch it now with English subtitles
Sales:	Playing [title] with [subtitle_language] subtitles: do you confirm?
User:	No, I prefer with French subtitles, thanks!
Sales:	Playing [title] with [subtitle_language] subtitles: do you confirm?
User:	Now it's correct, I confirm.
Sales:	The movie is starting!
User:	Who is the main actor?
Sales:	The mai actor is [starring].
User:	Thank you! It's all for now!

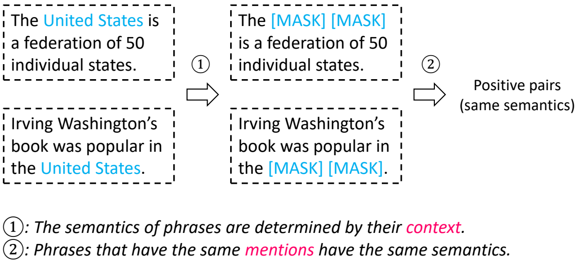
Table 6: These are more examples generated by different strategies in our framework. The text has the underline is the detected intent. The sentence in *italics* is the transition.

UCTopic: Unsupervised Contrastive Learning for Phrase Representations and Topic Mining

Jiacheng Li, Jingbo Shang, Julian McAuley
University of California, San Diego
`{j9li,jshang,jmcauley}@eng.ucsd.edu`

Abstract

High-quality phrase representations are essential to finding topics and related terms in documents (a.k.a. topic mining). Existing phrase representation learning methods either simply combine unigram representations in a context-free manner or rely on extensive annotations to learn context-aware knowledge. In this paper, we propose UCTopic, a novel unsupervised contrastive learning framework for context-aware phrase representations and topic mining. UCTopic is pretrained in a large scale to distinguish if the contexts of two phrase mentions have the same semantics. The key to pretraining is positive pair construction from our phrase-oriented assumptions. However, we find traditional in-batch negatives cause performance decay when finetuning on a dataset with small topic numbers. Hence, we propose cluster-assisted contrastive learning (CCL) which largely reduces noisy negatives by selecting negatives from clusters and further improves phrase representations for topics accordingly. UCTopic outperforms the state-of-the-art phrase representation model by 38.2% NMI in average on four entity clustering tasks. Comprehensive evaluation on topic mining shows that UCTopic can extract coherent and diverse topical phrases.



①: *The semantics of phrases are determined by their context.*
②: *Phrases that have the same mentions have the same semantics.*

Figure 1: Two assumptions used in UCTopic to produce positive pairs for contrastive learning.

1 Introduction

Topic modeling discovers abstract 'topics' in a collection of documents. A topic is typically modeled as a distribution over terms. High-quality phrase representations help topic models understand phrase semantics in order to find well-separated topics and extract coherent phrases. Some phrase representation methods (Wang et al., 2021; Yu and Dredze, 2015; Zhou et al., 2017) learn context-free representations by unigram embedding combination. Context-free representations tend to extract similar phrases mentions (e.g. "great food" and "good food", see Section 4.3). Context-aware methods such as DensePhrase (Lee et al., 2021) and LUKE (Yamada et al., 2020) need supervision from task-specific datasets or distant annotations with knowledge bases. Manual or distant supervision limits the ability to represent out-of-vocabulary phrases especially for domain-specific datasets. Recently, contrastive learning has shown effectiveness for unsupervised representation learning in visual (Chen et al., 2020) and textual (Gao et al., 2021) domains.

In this work, we seek to advance state-of-the-art phrase representation methods and demonstrate that a contrastive objective can be extremely effective at learning phrase semantics in sentences. We present UCTopic, an Unsupervised Contrastive learning framework for phrase representations and TOPIC mining, which can produce superior phrase embeddings and have topic-specific finetuning for topic mining. To conduct contrastive learning for phrase representations, we first seek to produce contrastive pairs. Existing data augmentation methods for natural language processing (NLP) such as back translation (Xie et al., 2020), synonym replacement (Zhang et al., 2015) and text mix up (Zhang et al., 2018) are not designed for phrase-oriented noise, and thus cannot produce training pairs for phrase representation learning. In UCTopic, we propose two assumptions about phrase semantics to obtain contrastive pairs:

1. The phrase semantics are determined by their

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 6159 - 6169
May 22-27, 2022 ©2022 Association for Computational Linguistics

context.

2. Phrases that have the same mentions have the same semantics.

As shown in Figure 1, given two sentences that contain the same phrase mentions (e.g., United States), we can mask the phrase mentions and the phrase semantics should stay the same based on assumption (1). Then, the phrase semantics from the two sentences are same as each other given assumption (2). Therefore, we can use the two masked sentences as positive pairs in contrastive learning. The intuition behind the two assumptions is that we expect the phrase representations from different sentences describing the same phrase should group together in the latent space. Masking the phrase mentions forces the model to learn representations from context which prevents overfitting and representation collapse (Gao et al., 2021). Based on the two assumptions, our context-aware phrase representations can be pre-trained on a large corpus via a contrastive objective without supervision.

For large-scale pre-training, we follow previous works (Chen et al., 2017; Henderson et al., 2017; Gao et al., 2021) and adopt in-batch negatives for training. However, we find in-batch negatives undermine the representation performance as finetuning (see Table 1). Because the number of topics is usually small in the finetuning dataset, examples in the same batch are likely to have the same topic. Hence, we cannot use in-batch negatives for data-specific finetuning. To solve this problem, we propose cluster-assisted contrastive learning (CCL) which leverages clustering results as pseudo-labels and sample negatives from highly confident examples in clusters. Cluster-assisted negative sampling has two advantages: (1) reducing potential positives from negative sampling compared to in-batch negatives; (2) the clusters are viewed as topics in documents, thus, cluster-assisted contrastive learning is a topic-specific finetuning process which pushes away instances from different topics in the latent space.

Based on the two assumptions and cluster-assisted negative sampling introduced in this paper, we pre-train phrase representations on a large-scale dataset and then finetune on a specific dataset for topic mining in an unsupervised way. In our experiments, we select LUKE (Yamada et al., 2020) as our backbone phrase representation model and pre-train it on Wikipedia [1] English corpus. To evaluate the quality of phrase representations, we conduct entity clustering on four datasets and find that pre-trained UCTopic achieves 53.1% (NMI) improvement compared to LUKE. After learning data-specific features with CCL, UCTopic outperforms LUKE by 73.2% (NMI) in average. We perform topical phrase mining on three datasets and comprehensive evaluation indicates UCTopic extracts coherent and diverse topical phrases. Overall, our contributions are three-fold:

- We propose UCTopic which produces superior phrase representations by unsupervised contrastive learning based on positive pairs from our phrase-oriented assumptions.
- To finetune on topic mining datasets, we propose a cluster-assisted negative sampling method for contrastive learning. This method reduces false negative instances caused by in-batch negatives and further improves phrase representations for topics accordingly.
- We conduct extensive experiments on entity type clustering and topic mining. Objective metrics and a user study show that UCTopic can largely improve the phrase representations, then extracts more coherent and diverse topical phrases than existing topic mining methods.

2 Background

In this section, we introduce background knowledge about contrastive learning and our phrase encoder LUKE (Yamada et al., 2020).

2.1 Contrastive Learning

Contrastive learning aims to learn effective representations by pulling semantically close neighbors together and pushing apart non-neighbors in the latent space (Hadsell et al., 2006). Assume that we have a contrastive instance $\{x, x^+, x_1^-, \dots, x_{N-1}^-\}$ including one positive and $N-1$ negative instances and their representations $\{\mathbf{h}, \mathbf{h}^+, \mathbf{h}_1^-, \dots, \mathbf{h}_{N-1}^-\}$ from the encoder, we follow the contrastive learning framework (Sohn, 2016; Chen et al., 2020; Gao et al., 2021) and take cross-entropy as our objective function:

$$l = -\log \frac{e^{\mathrm{sim}(\mathbf{h},\mathbf{h}^+)/\tau}}{e^{\mathrm{sim}(\mathbf{h},\mathbf{h}^+)/\tau} + \sum_{i=1}^{N-1} e^{\mathrm{sim}(\mathbf{h},\mathbf{h}_i^-)/\tau}} \tag{1}$$

where τ is a temperature hyperparameter and $\mathrm{sim}(\mathbf{h}_1, \mathbf{h}_2)$ is the cosine similarity $\frac{\mathbf{h}_1^\top \mathbf{h}_2}{\|\mathbf{h}_1\| \cdot \|\mathbf{h}_2\|}$.

---

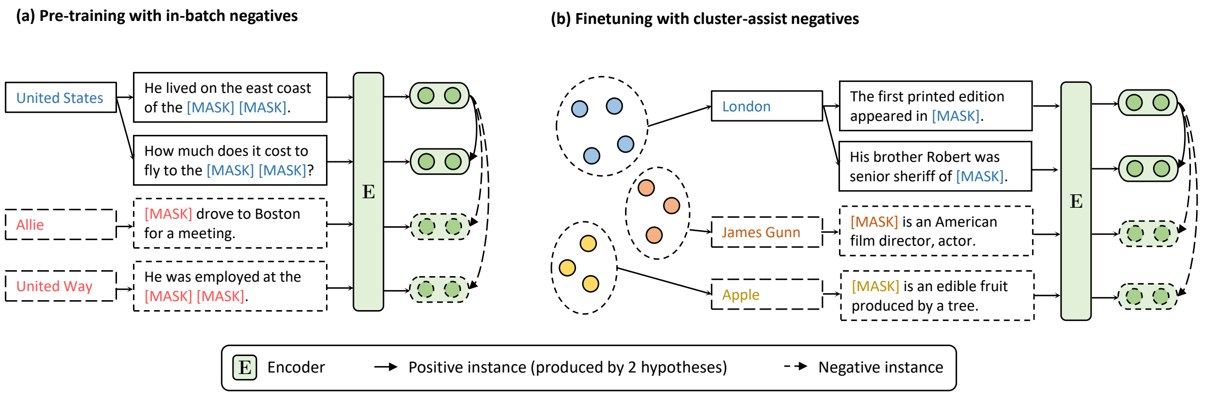

Figure 2: (a) Pre-training UCTopic on a large-scale dataset with positive instances from our two assumptions and in-batch negatives. (b) Finetuning UCTopic on a topic mining dataset with positive instances from our two assumptions and negatives from clustering.

2.2 Phrase Encoder

In this paper, our phrase encoder **E** is transformer-based model LUKE (Yamada et al., 2020). LUKE is a pre-trained language model that can directly output the representations of tokens and spans in sentences. Our phrase instance $x = (s, [l, r])$ includes a sentence s and a character-level span $[l, r]$ (l and r are left and right boundaries of a phrase). **E** encodes the phrase x and output the phrase representation $\mathbf{h} = \mathbf{E}(x) = \mathbf{E}(s, [l, r])$. Although LUKE can output span representations directly, we will show that span representations from LUKE are not able to represent phrases well (see Section 4.2). Different from LUKE, which is trained by predicting entities, UCTopic is trained by contrastive learning on phrase contexts. Hence, the phrase presentations from UCTopic are context-aware and robust to different domains.

3 UCTopic

UCTopic is an unsupervised contrastive learning method for phrase representations and topic mining. Our goal is to learn a phrase encoder as well as topic representations, so we can represent phrases effectively for general settings and find topics from documents in an unsupervised way. In this section, we introduce UCTopic from two aspects: (1) constructing positive pairs for phrases; (2) cluster-assisted contrastive learning.

3.1 Positive Instances

One critical problem in constrastive learning is to how to construct positive pairs (x, x^+). Previous works (Wu et al., 2020; Meng et al., 2021) apply augmentation techniques such as word deletion, reordering, and paraphrasing. However, these methods are not suitable for phrase representation learning. In this paper, we utilize the proposed assumptions introduced in Section 1 to construct positive instances for contrastive learning.

Consider an example to understand our positive instance generation process: In Figure 2 (a), phrase `United States` appears in two different sentences "*He lived on the east coast of the United States*" and "*How much does it cost to fly to the United States*". We expect the phrase (`United States`) representations from the two sentences to be similar to reflect phrase semantics. To encourage the model to learn phrase semantics from context and prevent the model from comparing phrase mentions in contrastive learning, we mask the phrase mentions with `[MASK]` token. The two masked sentences are used as positive instances. To decrease the inconsistency caused by masking between training and evaluation, in a positive pair, we keep one phrase mention unchanged in probability p.

Formally, suppose we have phrase instance $x = (s, [l, r])$ and its positive instance $x^+ = (s', [l', r'])$ where s denotes the sentence and $[l, r]$ are left and right boundaries of a phrase in s, we obtain the phrase representations $\mathbf{h}$ and $\mathbf{h}^+$ by encoder **E** and apply in-batch negatives for pre-training. The training objective of UCTopic becomes:

$$l = -\log \frac{e^{\mathrm{sim}(\mathbf{h}, \mathbf{h}^+)/\tau}}{\sum_{i=1}^{N} e^{\mathrm{sim}(\mathbf{h}, \mathbf{h}_i)/\tau}}, \tag{2}$$

for a mini-batch of N instances, where $\mathbf{h}_i$ is an instance in a batch.

3.2 Cluster-Assisted Contrastive Learning

We find that contrastive learning with in-batch negatives on small datasets can undermine the phrase representations (see Section 4.2). Different from pre-training on a large corpus, in-batch negatives usually contain instances that have similar semantics as positives. For example, one document has three topics and our batch size is 32. Thus, some instances in one batch are from the same topic but in-batch method views these instances as negatives with each other. In this case, contrastive learning has noisy training signals and then results in decreasing performance.

To reduce the noise in negatives while optimizing phrase representations according to topics in documents, we propose cluster-assisted contrastive learning (CCL). The basic idea is to utilize prior knowledge from pre-trained representations and clustering to reduce the noise existing in the negatives. Specifically, we first find the topics in documents with a clustering algorithm based on pre-trained phrase representations from UCTopic. The centroids of clusters are considered as topic representations for phrases. After computing the cosine distance between phrase instances and centroids, we select t percent of instances that are close to centroids and assign pseudo labels to them. Then, the label of a phrase mention p^m [2] is determined by the majority vote of instances $\{x^m_0, x^m_1, \ldots, x^m_n\}$ that contain p^m, where n is the number of sentences assigned pseudo labels. In this way, we get some prior knowledge of phrase mentions for the following contrastive learning. See Figure 2 (b); three phrase mentions (`London`, `James Gunn` and `Apple`) which belong to three different clusters are labeled by different topic categories.

Suppose we have a topic set $\mathcal{C}$ in our documents, with phrases and their pseudo labels, we construct positive pairs $(x_{c_i}, x^+_{c_i})$ by method introduced in Section 3.1 for topic c_i where $c_i \in \mathcal{C}$. To have contrastive instances, we randomly select phrases $p^m_{c_j}$ and instances $x^m_{c_j}$ from topic c_j as negative instances $x^-_{c_j}$ in contrastive learning, where $c_j \in \mathcal{C} \wedge c_j \neq c_i$. As shown in Figure 2 (b), we construct positive pairs for phrase `London`, and use two phrases `James Gunn` and `Apple` from the other two clusters to randomly select negative instances. With pseudo labels, our method can avoid instances that have similar semantics as `London`.

The training objective of finetuning is:

$$l = -\log \frac{e^{\mathrm{sim}(\mathbf{h}_{c_i}, \mathbf{h}^+_{c_i})/\tau}}{e^{\mathrm{sim}(\mathbf{h}_{c_i}, \mathbf{h}^+_{c_i})/\tau} + \sum_{c_j \in \mathcal{C}} e^{\mathrm{sim}(\mathbf{h}_{c_i}, \mathbf{h}^-_{c_j})/\tau}}. \quad (3)$$

As for the masking strategy in pre-training, we conduct masking for all training instances but keep $x^+_{c_i}$ and $x^-_{c_j}$ unchanged in probability p.

To infer the topic y of phrase instance x, we compute the cosine similarity between phrase representation $\mathbf{h}$ and topic representations $\tilde{\mathbf{h}}_{c_i}, c_i \in \mathcal{C}$. The nearest neighbor topic of x is used as phrase topic. Formally,

$$y = \mathrm{argmax}_{c_i \in \mathcal{C}}(\mathrm{sim}(\mathbf{h}, \tilde{\mathbf{h}}_{c_i})) \quad (4)$$

4 Experiments

In this section, we evaluate the effectiveness of UCTopic pre-training by contrastive learning. We start with entity clustering to compare the phrase representations from different methods. For topic modeling, we evaluate the topical phrases from three aspects and compare UCTopic to other topic modeling baselines.

4.1 Implementation Details

To generate the training corpus, we use English Wikipedia [3] and extract text with hyper links as phrases. Phrases have the same entity ids from Wikidata [4] or have the same mentions are considered as the same phrases (i.e., phrases have the same semantics). We enumerate all sentence pairs containing the same phrase as positive pairs in contrastive learning. After processing, the pre-training dataset has 11.6 million sentences and 108.8 million training instances.

For pre-training, we start from a pretrained LUKE-BASE model (Yamada et al., 2020). We follow previous works (Gao et al., 2021; Soares et al., 2019) and two losses are used concurrently: the masked language model loss and the contrastive learning loss with in-batch negatives. Our pre-training learning rate is 5e-5, batch size is 100 and our model is optimized by AdamW in 1 epoch. The probability p of keeping phrase mentions unchanged is 0.5 and the temperature τ in the contrastive loss is set to 0.05.

---

[2] phrase mentions are extracted from sentence s, i.e., $p^m = s[l:r]$

[3] https://en.wikipedia.org/

[4] https://www.wikidata.org/

4.2 Entity Clustering

To test the performance of phrase representations under objective tasks and metrics, we first apply UCTopic on entity clustering and compare to other representation learning methods.

Datasets. We conduct entity clustering on four datasets with annotated entities and their semantic categories are from general, review and biomedical domains: (1) CoNLL2003 (Sang and Meulder, 2003) consists of 20,744 sentences extracted from Reuters news articles. We use Person, Location, and Organization entities in our experiments.[5] (2) BC5CDR (Li et al., 2016) is the BioCreative V CDR task corpus. It contains 18,307 sentences from PubMed articles, with 15,953 chemical and 13,318 disease entities. (3) MIT Movie (MIT-M) (Liu et al., 2013) contains 12,218 sentences with Title and Person entities. (4) W-NUT 2017 (Derczynski et al., 2017) focuses on identifying unusual entities in the context of emerging discussions and contains 5,690 sentences and six kinds of entities [6].

Finetuning Setup. The learning rate for finetuning is 1e-5. We select t (percent of instances) from $\{5, 10, 20, 50\}$. The probability p of keeping phrase mentions unchanged and temperature τ in contrastive loss are the same as in pre-training settings. We apply K-Means to get pseudo labels for all experiments. Because UCTopic is an unsupervised method, we use all data to finetune and evaluate. All results for finetuning are the best results during training process. We follow previous clustering works (Xu et al., 2017; Zhang et al., 2021) and adopt Accuracy (ACC) and Normalized Mutual Information (NMI) to evaluate different approaches.

Compared Baseline Methods. To demonstrate the effectiveness of our pre-training method and finetuning with cluster-assisted contrastive learning (CCL), we compare baseline methods from two aspects:

(1) Pre-trained token or phrase representations:

- **Glove** (Pennington et al., 2014). Pre-trained word embeddings on 6B tokens and dimension is 300. We use averaging word embeddings as the representations of phrases.
- **BERT** (Devlin et al., 2019). Obtains phrase representations by averaging token representations (BERT-Ave.) or following CGExpan (Zhang et al., 2020) to substitute phrases with the `[MASK]` token, and use `[MASK]` representations as phrase embeddings (BERT-MASK).
- **LUKE** (Yamada et al., 2020). Use as backbone model to show the effectiveness of our contrastive learning for pre-training and fine-tuning.
- **DensePhrase** (Lee et al., 2021). Pre-trained phrase representation learning in a supervised way for question answering problem. We use a pre-trained model released from the authors to get phrase representations.
- **Phrase-BERT** (Wang et al., 2021). Context-agnostic phrase representations from pretraining. We use a pre-trained model from the authors and get representations by phrase mentions.
- **Ours w/o CCL**. Pre-trained phrase representations of UCTopic without cluster-assisted contrastive finetuning.

(2) Fine-tuning methods based on pre-trained representations of UCTopic.

- **Classifier**. We use pseudo labels as supervision to train a MLP layer and obtain a classifier of phrase categories.
- **In-Batch Contrastive Learning**. Same as contrastive learning for pre-training which uses in-batch negatives.
- **Autoencoder**. Widely used in previous neural topic and aspect extraction models (He et al., 2017; Iyyer et al., 2016; Tulkens and van Cranenburgh, 2020). We follow ABAE (He et al., 2017) to implement our autoencoder model for phrases.

Experimental Results. We report evaluation results of entity clustering in Table 1. Overall, UCTopic achieves the best results on all datasets and metrics. Specifically, UCTopic improves the state-of-the-art method (Phrase-BERT) by 38.2% NMI in average, and outperforms our backbone model (LUKE) by 73.2% NMI.

---

[5] We do not evaluate on the Misc category because it does not represent a single semantic category.

Table 1: Performance of entity clustering on four datasets from different domains. *Class.* represents using a classifier on pseudo labels. *Auto.* represents Autoencoder. The best results among all methods are bolded and the best results of pre-trained representations are underlined. *In-B.* represents contrastive learning with in-batch negatives.

When we compare different pre-trained representations, we find that our method (Ours w/o CCL) outperforms the other baselines on three datasets except MIT-M. There are two reasons: (1) All words in MIT-M dataset are lower case which is inconsistent with our pretraining dataset. The inconsistency between training and test causes performance to decay. (2) Sentences from MIT-M are usually short (10.16 words in average) compared to other datasets (e.g., 17.9 words in W-NUT2017). Hence, UCTopic can obtain limited contextual information with short sentences. However, the performance decay caused by the two reasons can be eliminated by our CCL finetuning on datasets since on MIT-M UCTopic achieves better results (0.661 NMI) than Phrase-BERT (0.575 NMI) after CCL.

On the other hand, compared to other finetuning methods, our CCL finetuning can further improve the pre-trained phrase representations by capturing data-specific features. The improvement is up to 50% NMI on the MIT-M dataset. Ours w/ Class. performs worse than our pre-trained UCTopic in most cases which indicates that pseudo labels from clustering are noisy and cannot directly be used as supervision for representation learning. Ours w/ In-B. is similar as Ours w/ Class. which verifies our motivation on using CCL instead of in-batch negatives. An autoencoder can improve pre-trained representations on three datasets but the margins are limited and the performance even drops on W-NUT2017. Compared to other finetuning methods, our CCL finetuning consistently improves pre-trained phrase representations on different domains.

Model	**UCTopic**		**LUKE**

Context+Mention	0.44	0.29	0.39	0.21
Mention	0.32 (-27%)	0.15 (-48%)	0.28 (-28%)	0.10 (-52%)
Context	0.43 (-3%)	0.16 (-44%)	0.27 (-31%)	0.07 (-67%)

Table 2: Ablation study on the input of phrase instances of W-NUT 2017. UCTopic here is pre-trained representations without CCL finetuning. Percentages in brackets are changes compared to Context+Mention.

Context or Mentions. To investigate the source of UCTopic phrase semantics (i.e., phrase mentions or context), we conduct an ablation study on the type of input and compare UCTopic to LUKE. To eliminate the influence of repeated phrase mentions on clustering results, we use only one phrase instance (i.e., sentence and position of a phrase) for each phrase mention. As shown in Table 2, there are three types of inputs: (1) Context+Mention: The same input as experiments in Table 1 including the whole sentence that contains the phrase. (2) Mention: Use only phrase mentions as inputs of the two models. (3) Context: We mask the phrase mentions in sentences and models can only get information from the context. We can see that UCTopic gets more information from context (0.43 ACC, 0.16 NMI) than mentions (0.32 ACC, 0.15 NMI). Compared to LUKE, UCTopic is more robust to phrase mentions (when predicting on only context, UCTopic -3% ACC and -44% NMI vs. LUKE -31% ACC and -67% NMI).

4.3 Topical Phrase Mining

In this section, we apply UCTopic on topical phrase mining and conduct human evaluation to show our model outperforms previous topic model baselines.

Experiment Setup. To find topical phrases in documents, we first extract noun phrases by spaCy [7] noun chunks and remove single pronoun words. Before CCL finetuning, we obtain the number of topics for each dataset by computing the Silhouette Coefficient (Rousseeuw, 1987).

Specifically, we randomly sample 10K phrases from the dataset and apply K-Means clustering on pre-trained UCTopic phrase representations with different numbers of cluster. We compute Silhouette Coefficient scores for different topic numbers; the number with the largest score will be used as the topic number in a dataset. Then, we conduct CCL on the dataset with the same settings as described in Section 4.2. Finally, after obtaining topic distribution $\mathbf{z}_x \in \mathbb{R}^{|\mathcal{C}|}$ for a phrase instance x in a sentence, we get context-agnostic phrase topics by using averaged topic distribution $\mathbf{z}_{p^m} = \frac{1}{n}\sum_{1\leq i\leq n}\mathbf{z}_{x_i^m}$, where phrase instances $\{x_i^m\}$ in different sentences have the same phrase mention p^m. The topic of a phrase mention has the highest probability in $\mathbf{z}_{p^m}$.

Dataset. We conduct topical phrase mining on three datasets from news, review and computer science domains.

- **Gest**. We collect restaurant reviews from Google Local[8] and use 100K reviews containing 143,969 sentences for topical phrase mining.
- **KP20k** (Meng et al., 2017) is a collection of titles and abstracts from computer science papers. 500K sentences are used in our experiments.
- **KPTimes** (Gallina et al., 2019) includes news articles from the New York Times from 2006 to 2017 and 10K news articles from the Japan Times. We use 500K sentences for topical phrase mining.

Datasets	**Gest**	**KP20k**	**KPTimes**
# of topics	22	10	16

Table 3: The numbers of topics in three datasets.

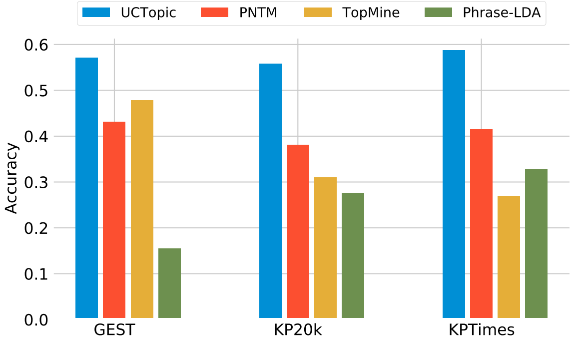

Figure 3: Results of phrase intrusion task.

The number of topics determined by Silhouette Coefficient is shown in Table 3.

Compared Baseline Methods. We compare UCTopic against three topic baselines:

- **Phrase-LDA** (Mimno, 2015). LDA model incorporates phrases by simply converting phrases into unigrams (e.g., "city view" to "city_view").
- **TopMine** (El-Kishky et al., 2014). A scalable pipeline that partitions a document into phrases, then uses phrases as constraints to ensure all words are placed under the same topic.
- **PNTM** (Wang et al., 2021). A topic model with Phrase-BERT by using an autoencoder that reconstructs a document representation. The model is viewed as the state-of-the-art topic model.

We do not include topic models such as LDA (Blei et al., 2003), PD-LDA (Lindsey et al., 2012), TNG (Wang et al., 2007), KERT (Danilevsky et al., 2014) as baselines, because these models are compared in TopMine and PNTM. For Phrase-LDA and PNTM, we use the same phrase list produced by UCTopic. TopMine uses phrases produced by itself.

Topical Phrase Evaluation. We evaluate the quality of topical phrases from three aspects: (1) *topical*

Table 5: Informativeness (tf-idf) and diversity (word-div.) of extracted topical phrases.

separation; (2) *phrase coherence*; (3) *phrase informativeness and diversity*.

To evaluate *topical separation*, we perform the **phrase intrusion** task following previous work (El-Kishky et al., 2014; Chang et al., 2009). The phrase intrusion task involves a set of questions asking humans to discover the 'intruder' phrase from other phrases. In our experiments, each question has 6 phrases and 5 of them are randomly sampled from the top 50 phrases of one topic and the remaining phrase is randomly chosen from another topic (top 50 phrases). Annotators are asked to select the intruder phrase. We sample 50 questions for each method and each dataset (600 questions in total) and shuffle all questions. Because these questions are sampled independently, we asked 4 annotators to answer these questions and each annotator answers 150 questions on average. Results of the task evaluate how well the phrases are separated by topics. The evaluation results are shown in Figure 3. UCTopic outperforms other baselines on three datasets, which means our model can find well-separated topics in documents.

To evaluate *phrase coherence* in one topic, we follow ABAE (He et al., 2017) and ask annotators to evaluate if the top 50 phrases from one topic are coherent (i.e., most phrases represent the same topic). 3 annotators evaluate four models on Gest and KP20k datasets. Numbers of coherent topics are shown in Table 4. We can see that UCTopic, PNTM and TopMine can recognize similar numbers of coherent topics, but the numbers of Phrase-LDA are less than the other three models. For a coherent topic, each of the top phrases will be labeled as correct if the phrase reflects the related topic. Same as ABAE, we adopt *precision@n* to evaluate the results. Figure 4 shows the results; we can see that UCTopic substantially outperforms other models. UCTopic can maintain high precision with a large n when the precision of other models decreases.

Finally, to evaluate *phrase informativeness and diversity*, we use tf-idf and word diversity (word-div.) to evaluate the top topical phrases. Basically, informative phrases cannot be very common phrases in a corpus (e.g., "good food" in Gest) and we use tf-idf to evaluate the "importance" of a phrase. To eliminate the influence of phrase length, we use averaged word tf-idf in a phrase as the phrase tf-idf. Specifically, tf-idf$(p, d) = \frac{1}{m}\sum_{1\le i\le m}$ tf-idf(w_i^p), where d denotes the document and p is the phrase. In our experiments, a document is a sentence in a review.

In addition, we hope that our phrases are diverse enough in a topic instead of expressing the same meaning (e.g., "good food" and "great food"). To evaluate the diversity of the top phrases, we calculate the ratio of distinct words among all words. Formally, given a list of phrases $[p_1, p_2, \dots, p_n]$, we tokenize the phrases into a word list $\mathbf{w} = [w_1^{p_1}, w_2^{p_1}, \dots, w_m^{p_n}]$; $\mathbf{w}'$ is the set of unique words in $\mathbf{w}$. The word diversity is computed by $\frac{|\mathbf{w}'|}{|\mathbf{w}|}$. We only evaluate coherent topics labeled in *phrase coherence*; the coherent topic numbers of Phrase-LDA are smaller than others, hence we evaluate the other three models.

We compute the tf-idf and word-div. on the top 10 phrases and use the averaged value on topics as final scores. Results are shown in table 5. PNTM and UCTopic achieve similar tf-idf scores, because the two methods use the same phrase lists extracted from spaCy. UCTopic extracts the most diverse phrases in a topic, because our phrase representations are more context-aware. In contrast, since PNTM gets representations dependent on phrase mentions, the phrases from PNTM contain

Gest					KP20k	
Drinks		*Dishes*			*Programming*	
UCTopic	PNTM	UCTopic	PNTM	TopMine	UCTopic	TopMine
lager	drinks	cauliflower fried rice	great burger	mac cheese	markup language	software development

tap beer	beverage	tortilla soup	beef burger	bread pudding	python module	support vector machine

Table 6: Top topical phrases on Gest and KP20k and the minimum phrase frequency is 3.

the same words and hence are less diverse.

Case Study. We compare top phrases from UCTopic, PNTM and TopMine in Section 4.3. From examples, we can see the phrases are consistent with our user study and diversity evaluation. Although the phrases from PNTM are coherent, the diversity of phrases is less than others (e.g., “drinks”, “bar drink”, “just drink” from Gest) because context-agnostic representations let similar phrase mentions group together. The phrases from TopMine are diverse but are not coherent in some cases (e.g., “machine learning” and “support vector machine” in the programming topic). In contrast, UCTopic can extract coherent and diverse topical phrases from documents.

5 Related Work

Many attempts have been made to extract topical phrases via LDA (Blei et al., 2003). Wallach (2006) incorporated a bigram language model into LDA by a hierarchical dirichlet generative probabilistic model to share the topic across each word within a bigram. TNG (Wang et al., 2007) applied additional latent variables and word-specific multinomials to model bi-grams and combined bi-grams to form n-gram phrases. PD-LDA (Lindsey et al., 2012) used a hierarchical Pitman-Yor process to share the same topic among all words in a given n-gram. Danilevsky et al. (2014) ranked the resultant phrases based on four heuristic metrics. TOPMine (El-Kishky et al., 2014) proposed to restrict all constituent terms within a phrase to share the same latent topic and assign a phrase to the topic of its constituent words. Compared to previous topic mining methods, UCTopic builds on the success of pre-trained language models and unsupervised contrastive learning on a large-scale dataset. Therefore, UCTopic provides high-quality pre-trained phrase representations and state-of-the-art finetuning for topic mining.

Early works in phrase representation build upon a composition function that combines component word embeddings together into simple phrase embedding. Yu and Dredze (2015) implemented the function by rule-based composition over word vectors. Zhou et al. (2017) applied a pair-wise GRU model and datasets such as PPDB (Pavlick et al., 2015) to learn phrase representations. PhraseBERT (Wang et al., 2021) composed token embeddings from BERT and pretrained on positive instances produced by GPT-2-based diverse paraphrasing model (Krishna et al., 2020). Lee et al. (2021) learned phrase representations from the supervision of reading comprehension tasks and applied representations on open-domain QA. Other works learned phrase embeddings for specific tasks such as semantic parsing (Socher et al., 2011) and machine translation (Bing et al., 2015). In this paper, we present unsupervised contrastive learning method for pre-training phrase representations of general purposes and for finetuning to topic-specific phrase representations.

6 Conclusion

In this paper, we propose UCTopic, a contrastive learning framework that can effectively learn phrase representations without supervision. To finetune on topic mining datasets, we propose cluster-assisted contrastive learning which reduces noise by selecting negatives from clusters. During finetuning, our phrase representations are optimized for topics in the document hence the representations are further improved. We conduct comprehensive experiments on entity clustering and topical phrase mining. Results show that UCTopic largely improves phrase representations. Objective metrics and a user study indicate UCTopic can extract coherent and diverse topical phrases.

Abstract

In this paper, we introduce ELECTRA-style tasks (Clark et al., 2020b) to cross-lingual language model pre-training. Specifically, we present two pre-training tasks, namely multilingual replaced token detection, and translation replaced token detection. Besides, we pretrain the model, named as XLM-E, on both multilingual and parallel corpora. Our model outperforms the baseline models on various cross-lingual understanding tasks with much less computation cost. Moreover, analysis shows that XLM-E tends to obtain better cross-lingual transferability.

1 Introduction

It has become a de facto trend to use a pretrained language model (Devlin et al., 2019; Dong et al., 2019; Yang et al., 2019b; Bao et al., 2020) for downstream NLP tasks. These models are typically pretrained with masked language modeling objectives, which learn to generate the masked tokens of an input sentence. In addition to monolingual representations, the masked language modeling task is effective for learning cross-lingual representations. By only using multilingual corpora, such pretrained models perform well on zero-shot cross-lingual transfer (Devlin et al., 2019; Conneau et al., 2020), i.e., fine-tuning with English training data while directly applying the model to other target languages. The cross-lingual transferability can be further improved by introducing external pre-training tasks using parallel corpus, such as translation language modeling (Conneau and Lample, 2019), and cross-lingual contrast (Chi et al., 2021b). However, previous cross-lingual pre-training based on masked language modeling usually requires massive computation resources, rendering such models quite expensive. As shown in Figure 1, our proposed XLM-E achieves a huge speedup compared with well-tuned pretrained models.

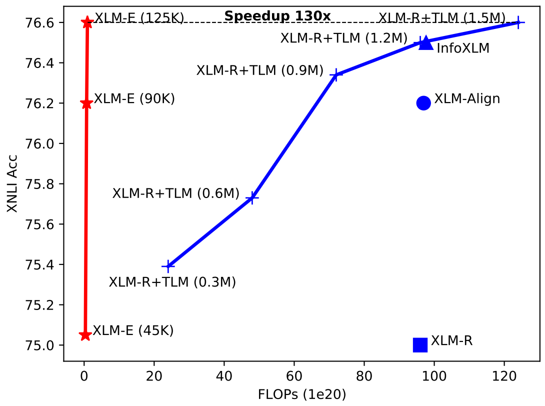

Figure 1: The proposed XLM-E pre-training (red line) achieves 130× speedup compared with an in-house pretrained XLM-R augmented with translation language modeling (XLM-R + TLM; blue line), using the same corpora and code base. The training steps are shown in the brackets. We also present XLM-R (Conneau et al., 2020), InfoXLM (Chi et al., 2021b), and XLM-Align (Chi et al., 2021c). The compared models are all in Base size.

In this paper, we introduce ELECTRA-style tasks (Clark et al., 2020b) to cross-lingual language model pre-training. Specifically, we present two discriminative pre-training tasks, namely multilingual replaced token detection, and translation replaced token detection. Rather than recovering masked tokens, the model learns to distinguish the replaced tokens in the corrupted input sequences. The two tasks build input sequences by replacing tokens in multilingual sentences, and translation pairs, respectively. We also describe the pre-training algorithm of our model, XLM-E, which is pretrained with the above two discriminative tasks. It provides a more compute-efficient and sample-efficient way for cross-lingual language model pre-training.

[*] Equal contribution. Zewen Chi contributes during internship at Microsoft Research.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 6170 - 6182
May 22-27, 2022

We conduct extensive experiments on the XTREME cross-lingual understanding benchmark to evaluate and analyze XLM-E. Over seven datasets, our model achieves competitive results with the baseline models, while only using 1% of the computation cost comparing to XLM-R. In addition to the high computational efficiency, our model also shows the cross-lingual transferability that achieves a reasonably low transfer gap. We also show that the discriminative pre-training encourages universal representations, making the text representations better aligned across different languages.

Our contributions are summarized as follows:

- We explore ELECTRA-style tasks for cross-lingual language model pre-training, and pretrain XLM-E with both multilingual corpus and parallel data.
- We demonstrate that XLM-E greatly reduces the computation cost of cross-lingual pre-training.
- We show that discriminative pre-training tends to encourage better cross-lingual transferability.

2 Background: ELECTRA

ELECTRA (Clark et al., 2020b) introduces the replaced token detection task for language model pre-training, with the goal of distinguishing real input tokens from corrupted tokens. That means the text encoders are pretrained as discriminators rather than generators, which is different from the previous pretrained language models, such as BERT (Devlin et al., 2019), that learn to predict the masked tokens.

ELECTRA trains two Transformer (Vaswani et al., 2017) encoders, serving as generator and discriminator, respectively. The generator G is typically a small BERT model trained with the masked language modeling (MLM; Devlin et al. 2019) task. Consider an input sentence $\boldsymbol{x} = \{x_i\}_{i=1}^{n}$ containing n tokens. MLM first randomly selects a subset $\mathcal{M} \subseteq \{1, \dots, n\}$ as the positions to be masked, and construct the masked sentence $\boldsymbol{x}^{\text{masked}}$ by replacing tokens in $\mathcal{M}$ with `[MASK]`. Then, the generator predicts the probability distributions of the masked tokens $p_G(x|\boldsymbol{x}^{\text{masked}})$. The loss function of the generator G is:

$$\mathcal{L}_G(\boldsymbol{x}; \boldsymbol{\theta}_G) = -\sum_{i \in \mathcal{M}} \log p_G(x_i|\boldsymbol{x}^{\text{masked}}). \quad (1)$$

The discriminator D is trained with the replaced token detection task. Specifically, the discriminator takes the corrupted sentences $\boldsymbol{x}^{\text{corrupt}}$ as input, which is constructed by replacing the tokens in $\mathcal{M}$ with the tokens sampled from the generator G:

$$\begin{cases} x_i^{\text{corrupt}} \sim p_G(x_i|\boldsymbol{x}^{\text{masked}}), & i \in \mathcal{M} \\ x_i^{\text{corrupt}} = x_i, & i \notin \mathcal{M} \end{cases} \quad (2)$$

Then, the discriminator predicts whether x_i^{corrupt} is original or sampled from the generator. The loss function of the discriminator D is

$$\mathcal{L}_D(\boldsymbol{x}; \boldsymbol{\theta}_D) = -\sum_{i=1}^{n} \log p_D(z_i|\boldsymbol{x}^{\text{corrupt}}) \quad (3)$$

where z_i represents the label of whether x_i^{corrupt} is the original token or the replaced one. The final loss function of ELECTRA is the combined loss of the generator and discriminator losses, $\mathcal{L}_E = \mathcal{L}_G + \lambda \mathcal{L}_D$.

Compared to generative pre-training, ELECTRA uses more model parameters and training FLOPs per step, because it contains a generator and a discriminator during pre-training. However, only the discriminator is used for fine-tuning on downstream tasks, so the size of the final checkpoint is similar to BERT-like models in practice.

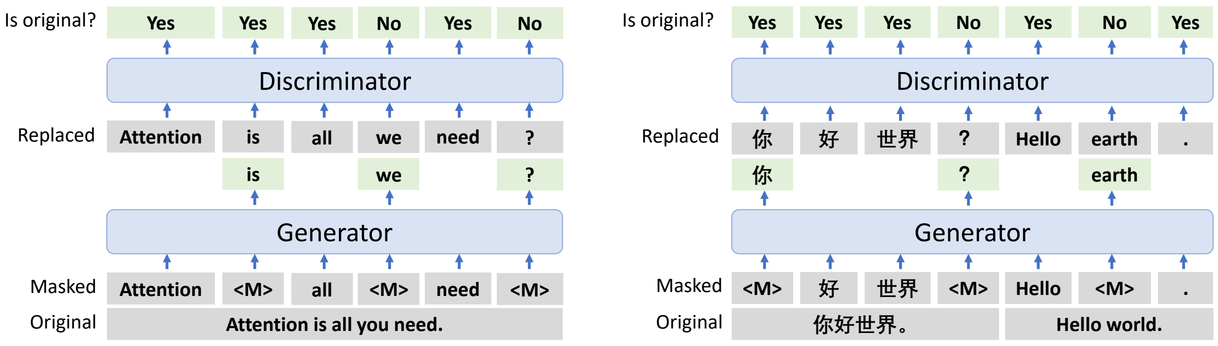
3 Methods

Figure 2 shows an overview of the two discriminative tasks used for pre-training XLM-E. Similar to ELECTRA described in Section 2, XLM-E has two Transformer components, i.e., generator and discriminator. The generator predicts the masked tokens given the masked sentence or translation pair, and the discriminator distinguishes whether the tokens are replaced by the generator.

3.1 Pre-training Tasks

The pre-training tasks of XLM-E are multilingual replaced token detection (MRTD), and translation replaced token detection (TRTD).

Multilingual Replaced Token Detection The multilingual replaced token detection task requires the model to distinguish real input tokens from



(a) Multilingual replaced token detection (MRTD)

(b) Translation replaced token detection (TRTD)

Figure 2: Overview of two pre-training tasks of XLM-E, i.e., multilingual replaced token detection, and translation replaced token detection. The generator predicts the masked tokens given a masked sentence or a masked translation pair, and the discriminator distinguishes whether the tokens are replaced by the generator.

corrupted multilingual sentences. Both the generator and the discriminator are shared across languages. The vocabulary is also shared for different languages. The task is the same as in monolingual ELECTRA pre-training (Section 2). The only difference is that the input texts can be in various languages.

We use uniform masking to produce the corrupted positions. We also tried span masking (Joshi et al., 2019; Bao et al., 2020) in our preliminary experiments. The results indicate that span masking significantly weakens the generator's prediction accuracy, which in turn harms pre-training.

Translation Replaced Token Detection Parallel corpora are easily accessible and proved to be effective for learning cross-lingual language models (Conneau and Lample, 2019; Chi et al., 2021b), while it is under-studied how to improve discriminative pre-training with parallel corpora. We introduce the translation replaced token detection task that aims to distinguish real input tokens from translation pairs. Given an input translation pair, the generator predicts the masked tokens in both languages. Consider an input translation pair $(\boldsymbol{e}, \boldsymbol{f})$. We construct the input sequence by concatenating the translation pair as a single sentence. The loss function of the generator G is:

$$\begin{aligned}\mathcal{L}_G(\boldsymbol{e},\boldsymbol{f};\boldsymbol{\theta}_G) = &-\sum_{i\in\mathcal{M}_e}\log p_G(e_i|\,[\boldsymbol{e};\boldsymbol{f}]^{\text{masked}}) \\ &-\sum_{i\in\mathcal{M}_f}\log p_G(f_i|\,[\boldsymbol{e};\boldsymbol{f}]^{\text{masked}})\end{aligned}$$

where $[;]$ is the operator of concatenation, and $\mathcal{M}_e, \mathcal{M}_f$ stand for the randomly selected masked positions for $\boldsymbol{e}$ and $\boldsymbol{f}$, respectively. This loss function is identical to the translation language modeling loss (TLM; Conneau and Lample 2019). The discriminator D learns to distinguish real input tokens from the corrupted translation pair. The corrupted translation pair $(\boldsymbol{e}^{\text{corrupt}}, \boldsymbol{f}^{\text{corrupt}})$ is constructed by replacing tokens with the tokens sampled from G with the concatenated translation pair as input. Formally, $\boldsymbol{e}^{\text{corrupt}}$ is constructed by

$$\begin{cases} e_i^{\text{corrupt}} \sim p_G(e_i|\,[\boldsymbol{e};\boldsymbol{f}]^{\text{masked}}), & i \in \mathcal{M}_e \\ e_i^{\text{corrupt}} = e_i, & i \notin \mathcal{M}_e \end{cases} \tag{4}$$

The same operation is also used to construct $\boldsymbol{f}^{\text{corrupt}}$. Then, the loss function of the discriminator D can be written as

$$\mathcal{L}_D(\boldsymbol{e},\boldsymbol{f};\boldsymbol{\theta}_D) = -\sum_{i=1}^{n_e+n_f}\log p_D(r_i|\,[\boldsymbol{e};\boldsymbol{f}]^{\text{corrupt}}) \tag{5}$$

where r_i represents the label of whether the i-th input token is the original one or the replaced one. The final loss function of the translation replaced token detection task is $\mathcal{L}_G + \lambda\mathcal{L}_D$.

3.2 Pre-training XLM-E

The XLM-E model is jointly pretrained with the masked language modeling, translation language modeling, multilingual replaced token detection and the translation replaced token detection tasks. The overall training objective is to minimize

$$\begin{aligned}\mathcal{L} \;=\; &\mathcal{L}_{\text{MLM}}(\boldsymbol{x};\theta_G) + \mathcal{L}_{\text{TLM}}(\boldsymbol{e},\boldsymbol{f};\theta_G) \\ &+ \lambda\mathcal{L}_{\text{MRTD}}(\boldsymbol{x};\theta_D) + \lambda\mathcal{L}_{\text{TRTD}}(\boldsymbol{e},\boldsymbol{f};\theta_D)\end{aligned}$$

over large scale multilingual corpus $\mathcal{X} = \{\boldsymbol{x}\}$ and parallel corpus $\mathcal{P} = \{(\boldsymbol{e},\boldsymbol{f})\}$. We jointly pretrain the generator and the discriminator from scratch. Following Clark et al. (2020b), we make the generator smaller to improve the pre-training efficiency.

3.3 Gated Relative Position Bias

We propose to use gated relative position bias in the self-attention mechanism. Given input tokens $\{x_i\}_{i=1}^{|x|}$, let $\{\mathbf{h}_i\}_{i=1}^{|x|}$ denote their hidden states in Transformer. The self-attention outputs $\{\tilde{\mathbf{h}}_i\}_{i=1}^{|x|}$ are computed via:

$$\mathbf{q}_i, \mathbf{k}_i, \mathbf{v}_i = \mathbf{h}_i\mathbf{W}^Q, \mathbf{h}_i\mathbf{W}^K, \mathbf{h}_i\mathbf{W}^V \tag{6}$$

$$a_{ij} \propto \exp\{\frac{\mathbf{q}_i \cdot \mathbf{k}_j}{\sqrt{d_k}} + r_{i-j}\} \tag{7}$$

$$\tilde{\mathbf{h}}_i = \sum_{j=1}^{|x|} a_{ij}\mathbf{v}_i \tag{8}$$

where r_{i-j} represents gated relative position bias, each $\mathbf{h}_i$ is linearly projected to a triple of query, key and value using parameter matrices $\mathbf{W}^Q, \mathbf{W}^K, \mathbf{W}^V \in \mathbb{R}^{d_h \times d_k}$, respectively.

Inspired by the gating mechanism of Gated Recurrent Unit (GRU; Cho et al. 2014), we compute gated relative position bias r_{i-j} via:

$$g^{\text{(update)}}, g^{\text{(reset)}} = \sigma(\mathbf{q}_i \cdot \mathbf{u}), \sigma(\mathbf{q}_i \cdot \mathbf{v})$$
$$\tilde{r}_{i-j} = w g^{\text{(reset)}} d_{i-j}$$
$$r_{i-j} = d_{i-j} + g^{\text{(update)}} d_{i-j} + (1 - g^{\text{(update)}})\tilde{r}_{i-j}$$

where d_{i-j} is learnable relative position bias, the vectors $\mathbf{u}, \mathbf{v} \in \mathbb{R}^{d_k}$ are parameters, σ is a sigmoid function, and w is a learnable value.

Compared with relative position bias (Parikh et al., 2016; Raffel et al., 2020; Bao et al., 2020), the proposed gates take the content into consideration, which adaptively adjusts the relative position bias by conditioning on input tokens. Intuitively, the same distance between two tokens tends to play different roles in different languages.

4 Experiments

4.1 Setup

Data We use the CC-100 (Conneau et al., 2020) dataset for the replaced token detection task. CC-100 contains texts in 100 languages collected from the CommonCrawl dump. We use parallel corpora for the translation replaced token detection task, including translation pairs in 100 languages collected from MultiUN (Ziemski et al., 2016), IIT Bombay (Kunchukuttan et al., 2018), OPUS (Tiedemann, 2012), WikiMatrix (Schwenk et al., 2019), and CCAligned (El-Kishky et al., 2020).

Following XLM (Conneau and Lample, 2019), we sample multilingual sentences to balance the language distribution. Formally, consider the pre-training corpora in N languages with m_j examples for the j-th language. The probability of using an example in the j-th language is

$$p_j = \frac{m_j^\alpha}{\sum_{k=1}^N m_k^\alpha} \tag{9}$$

The exponent α controls the distribution such that a lower α increases the probability of sampling examples from a low-resource language. In this paper, we set $\alpha = 0.7$.

Model We use a Base-size 12-layer Transformer (Vaswani et al., 2017) as the discriminator, with hidden size of 768, and FFN hidden size of $3,072$. The generator is a 4-layer Transformer using the same hidden size as the discriminator (Meng et al., 2021). See Appendix A for more details of model hyperparameters.

Training We jointly pretrain the generator and the discriminator of XLM-E from scratch, using the Adam (Kingma and Ba, 2015) optimizer for 125K training steps. We use dynamic batching of approximately 1M tokens for each pre-training task. We set λ, the weight for the discriminator objective to 50. The whole pre-training procedure takes about 1.7 days on 64 Nvidia A100 GPU cards. See Appendix B for more details of pre-training hyperparameters.

4.2 Cross-lingual Understanding

We evaluate XLM-E on the XTREME (Hu et al., 2020b) benchmark, which is a multilingual multi-task benchmark for evaluating cross-lingual understanding. The XTREME benchmark contains seven cross-lingual understanding tasks, namely part-of-speech tagging on the Universal Dependencies v2.5 (Zeman et al., 2019), NER named entity recognition on the Wikiann (Pan et al., 2017; Rahimi et al., 2019) dataset, cross-lingual natural language inference on XNLI (Conneau et al., 2018), cross-lingual paraphrase adversaries from word scrambling (PAWS-X; Yang et al. 2019a), and cross-lingual question answering on MLQA (Lewis et al., 2020), XQuAD (Artetxe et al., 2020), and TyDiQA-GoldP (Clark et al., 2020a).

Table 1: Evaluation results on XTREME cross-lingual understanding tasks. We consider the cross-lingual transfer setting, where models are only fine-tuned on the English training data but evaluated on all target languages. The compared models are all in Base size. Results of XLM-E and XLM-R are averaged over five runs.

Baselines We compare our XLM-E model with the cross-lingual language models pretrained with multilingual text, i.e., Multilingual BERT (mBERT; Devlin et al. 2019), mT5 (Xue et al., 2021), and XLM-R (Conneau et al., 2020), or pretrained with both multilingual text and parallel corpora, i.e., XLM (Conneau and Lample, 2019), InfoXLM (Chi et al., 2021b), and XLM-Align (Chi et al., 2021c). The compared models are all in Base size. In what follows, models are considered as in Base size by default.

Results We use the cross-lingual transfer setting for the evaluation on XTREME (Hu et al., 2020b), where the models are first fine-tuned with the English training data and then evaluated on the target languages. In Table 1, we report the accuracy, F1, or Exact-Match (EM) scores on the XTREME cross-lingual understanding tasks. The results are averaged over all target languages and five runs with different random seeds. We divide the pretrained models into two categories, i.e., the models pretrained on multilingual corpora, and the models pretrained on both multilingual corpora and parallel corpora. For the first setting, we pretrain XLM-E with only the multilingual replaced token detection task. From the results, it can be observed that XLM-E outperforms previous models on both settings, achieving the averaged scores of 67.6 and 69.3, respectively. Compared to XLM-R, XLM-E (w/o TRTD) produces an absolute 1.2 improvement on average over the seven tasks. For the second setting, compared to XLM-Align, XLM-E produces an absolute 0.4 improvement on average. XLM-E performs better on the question answering tasks and sentence classification tasks while preserving reasonable high F1 scores on structured prediction tasks. Despite the effectiveness of XLM-E, our model requires substantially lower computation cost than XLM-R and XLM-Align. A detailed efficiency analysis in presented in Section 4.5.

Model	XNLI	MLQA
XLM (reimplementation)	73.4	66.2 / 47.8
−TLM	70.6	64.0 / 46.0
XLM-E	**76.6**	**68.3 / 49.8**
−TRTD	75.1	67.8 / 49.7
−TRTD−Gated relative position bias	75.2	67.4 / 49.2

Table 2: Ablation studies of XLM-E. We studies the effects of the main components of XLM-E, and compare the models with XLM under the same pre-training setup, including training steps, learning rate, etc.

4.3 Ablation Studies

For a deeper insight to XLM-E, we conduct ablation experiments where we first remove the TRTD task and then remove the gated relative position bias. Besides, we reimplement XLM that is pretrained with the same pre-training setup with XLM-E, i.e., using the same training steps, learning rate, etc. Table 2 shows the ablation results on XNLI and MLQA. Removing TRTD weakens the performance of XLM-E on both downstream tasks. On this basis, the results on MLQA further decline when removing the gated relative position bias. This demonstrates that XLM-E benefits from both TRTD and the gated relative position bias during pre-training. Besides, XLM-E substantially outperform XLM on both tasks. Notice that when removing the two components from XLM-E, our

Model	Size	Params	XNLI	MLQA
XLM-E	Base	279M	76.6	68.3 / 49.8
XLM-E	Large	840M	81.3	72.7 / 54.2
XLM-E	XL	2.2B	**83.7**	**76.2 / 57.9**
XLM-R	XL	3.5B	82.3	73.4 / 55.3
mT5	XL	3.7B	82.9	73.5 / 54.5

Table 3: Results of scaling-up the model size.

Model	XTREME	Params	FLOPs
mBERT	63.1	167M	6.4e19
XLM-R	66.4	279M	9.6e21
InfoXLM*	-	279M	9.6e21 + 1.7e20
XLM-Align*	68.9	279M	9.6e21 + 9.6e19
XLM-E	69.3	279M	9.5e19
−TRTD	67.6	279M	6.3e19

Table 4: Comparison of the pre-training costs. The models with '*' are continue-trained from XLM-R rather than pre-training from scratch.

model only requires a multilingual corpus, but still achieves better performance than XLM, which uses an additional parallel corpus.

4.4 Scaling-up Results

Scaling-up model size has shown to improve performance on cross-lingual downstream tasks (Xue et al., 2021; Goyal et al., 2021). We study the scalability of XLM-E by pre-training XLM-E models using larger model sizes. We consider two larger model sizes in our experiments, namely Large and XL. Detailed model hyperparameters can be found in Appendix A. As present in Table 3, XLM-E$_{\text{XL}}$ achieves the best performance while using significantly fewer parameters than its counterparts. Besides, scaling-up the XLM-E model size consistently improves the results, demonstrating the effectiveness of XLM-E for large-scale pre-training.

4.5 Training Efficiency

We present a comparison of the pre-training resources, to explore whether XLM-E provides a more compute-efficient and sample-efficient way for pre-training cross-lingual language models. Table 4 compares the XTREME average score, the number of parameters, and the pre-training computation cost. Notice that InfoXLM and XLM-Align are continue-trained from XLM-R, so the total training FLOPs are accumulated over XLM-R.

Table 4 shows that XLM-E substantially reduces the computation cost for cross-lingual language model pre-training. Compared to XLM-R and XLM-Align that use at least 9.6e21 training FLOPs, XLM-E only uses 9.5e19 training FLOPs in total while even achieving better XTREME performance than the two baseline models. For the setting of pre-training with only multilingual corpora, XLM-E (w/o TRTD) also outperforms XLM-R using 6.3e19 FLOPs in total. This demonstrates the compute-effectiveness of XLM-E, i.e., XLM-E as a stronger cross-lingual language model requires substantially less computation resource.

Model	Tatoeba-14		Tatoeba-36	
	en → xx	xx → en	en → xx	xx → en
XLM-R	59.5	57.6	55.5	53.4
InfoXLM	**80.6**	**77.8**	**68.6**	**67.3**
XLM-E	74.4	72.3	65.0	62.3
−TRTD	55.8	55.1	46.4	44.6

Table 5: Average accuracy@1 scores for Tatoeba cross-lingual sentence retrieval. The models are evaluated under two settings with 14 and 36 of the parallel corpora for evaluation, respectively.

4.6 Cross-lingual Alignment

To explore whether discriminative pre-training improves the resulting cross-lingual representations, we evaluate our model on the sentence-level and word-level alignment tasks, i.e., cross-lingual sentence retrieval and word alignment.

We use the Tatoeba (Artetxe and Schwenk, 2019) dataset for the cross-lingual sentence retrieval task, the goal of which is to find translation pairs from the corpora in different languages. Tatoeba consists of English-centric parallel corpora covering 122 languages. Following Chi et al. (2021b) and Hu et al. (2020b), we consider two settings where we use 14 and 36 of the parallel corpora for evaluation, respectively. The sentence representations are obtained by average pooling over hidden vectors from a middle layer. Specifically, we use layer-7 for XLM-R and layer-9 for XLM-E. Then, the translation pairs are induced by the nearest neighbor search using the cosine similarity. Table 5 shows the average accuracy@1 scores under the two settings of Tatoeba for both the xx → en and en → xx directions. XLM-E achieves 74.4 and 72.3 accuracy scores for Tatoeba-14, and 65.0 and 62.3 accuracy scores for Tatoeba-36, providing notable improvement over XLM-R. XLM-E performs slightly worse than InfoXLM. We believe the cross-lingual contrast (Chi et al., 2021b) task explicitly learns the sentence representations, which makes InfoXLM more effective for the cross-lingual sentence retrieval task.

Model	Alignment Error Rate ↓				Avg
	en-de	en-fr	en-hi	en-ro	
fast_align	32.14	19.46	59.90	-	-
XLM-R	17.74	7.54	37.79	27.49	22.64
XLM-ALIGN	16.63	6.61	33.98	26.97	21.05
XLM-E	**16.49**	**6.19**	**30.20**	**24.41**	**19.32**
−TRTD	17.87	6.29	35.02	30.22	22.35

Table 6: Alignment error rate scores (lower is better) for the word alignment task on four language pairs. Results of the baseline models are from Chi et al. (2021c). We use the optimal transport method to obtain the resulting word alignments, where the sentence representations are from the 9-th layer of XLM-E.

For the word-level alignment, we use the word alignment datasets from EuroParl[1], WPT2003[2], and WPT2005[3], containing 1,244 translation pairs annotated with golden alignments. The predicted alignments are evaluated by alignment error rate (AER; Och and Ney 2003):

$$\mathrm{AER} = 1 - \frac{|A \cap S| + |A \cap P|}{|A| + |S|} \tag{10}$$

where $A, S,$ and P stand for the predicted alignments, the annotated sure alignments, and the annotated possible alignments, respectively. In Table 6 we compare XLM-E with baseline models, i.e., fast_align (Dyer et al., 2013), XLM-R, and XLM-ALIGN. The resulting word alignments are obtained by the optimal transport method (Chi et al., 2021c), where the sentence representations are from the 9-th layer of XLM-E. Over the four language pairs, XLM-E achieves lower AER scores than the baseline models, reducing the average AER from 21.05 to 19.32. It is worth mentioning that our model requires substantial lower computation costs than the other cross-lingual pretrained language models to achieve such low AER scores. See the detailed training efficiency analysis in Section 4.5. It is worth mentioning that XLM-E shows notable improvements over XLM-E (w/o TRTD) on both tasks, demonstrating that the translation replaced token detection task is effective for cross-lingual alignment.

4.7 Universal Layer Across Languages

We evaluate the word-level and sentence-level representations over different layers to explore whether the XLM-E tasks encourage universal representations.

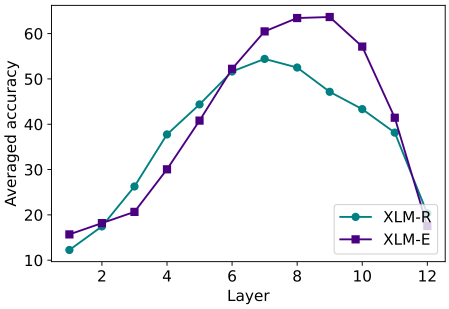

Figure 3: Evaluation results on Tatoeba cross-lingual sentence retrieval over different layers. For each layer, the accuracy score is averaged over all the 36 language pairs in both the xx → en and en → xx directions.

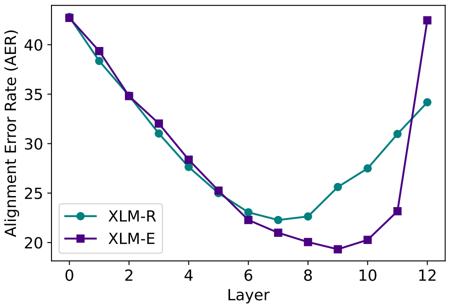

Figure 4: Evaluation results of cross-lingual word alignment over different layers. Layer-0 stands for the embedding layer.

As shown in Figure 3, we illustrate the accuracy@1 scores of XLM-E and XLM-R on Tatoeba cross-lingual sentence retrieval, using sentence representations from different layers. For each layer, the final accuracy score is averaged over all the 36 language pairs in both the xx → en and en → xx directions. From the figure, it can be observed that XLM-E achieves notably higher averaged accuracy scores than XLM-R for the top layers. The results of XLM-E also show a parabolic trend across layers, i.e., the accuracy continuously increases before a specific layer and then continuously drops. This trend is also found in other cross-lingual language models such as XLM-R and XLM-Align (Jalili Sabet et al., 2020; Chi et al., 2021c). Different from XLM-R that achieves the highest accuracy of 54.42 at layer-7, XLM-E pushes it to layer-9, achieving an accuracy of 63.66. At layer-10, XLM-R only obtains an accuracy of 43.34 while XLM-E holds the accuracy score as high as 57.14.

Figure 4 shows the averaged alignment error rate

Table 7: The cross-lingual transfer gap scores on the XTREME tasks. A lower transfer gap score indicates better cross-lingual transferability. We use the EM scores to compute the gap scores for the QA tasks.

(AER) scores of XLM-E and XLM-R on the word alignment task. We use the hidden vectors from different layers to perform word alignment, where layer-0 stands for the embedding layer. The final AER scores are averaged over the four test sets in different languages. Figure 4 shows a similar trend to that in Figure 3, where XLM-E not only provides substantial performance improvements over XLM-R, but also pushes the best-performance layer to a higher layer, i.e., the model obtains the best performance at layer-9 rather than a lower layer such as layer-7.

On both tasks, XLM-E shows good performance for the top layers, even though both XLM-E and XLM-R use the Transformer (Vaswani et al., 2017) architecture. Compared to the masked language modeling task that encourages the top layers to be language-specific, discriminative pre-training makes XLM-E producing better-aligned text representations at the top layers. It indicates that the cross-lingual discriminative pre-training encourages universal representations inside the model.

4.8 Cross-lingual Transfer Gap

We analyze the cross-lingual transfer gap (Hu et al., 2020b) of the pretrained cross-lingual language models. The transfer gap score is the difference between performance on the English test set and the average performance on the test set in other languages. This score suggests how much end task knowledge has not been transferred to other languages after fine-tuning. A lower gap score indicates better cross-lingual transferability. Table 7 compares the cross-lingual transfer gap scores on five of the XTREME tasks. We notice that XLM-E obtains the lowest gap score only on PAWS-X. Nonetheless, it still achieves reasonably low gap scores on the other tasks with such low computation cost, demonstrating the cross-lingual transferability of XLM-E. We believe that it is more difficult to achieve the same low gap scores when the model obtains better performance.

5 Related Work

Learning self-supervised tasks on large-scale multilingual texts has proven to be effective for pre-training cross-lingual language models. Masked language modeling (MLM; Devlin et al. 2019) is typically used to learn cross-lingual encoders such as multilingual BERT (mBERT; Devlin et al. 2019) and XLM-R (Conneau et al., 2020). The cross-lingual language models can be further improved by introducing external pre-training tasks using parallel corpora. XLM (Conneau and Lample, 2019) introduces the translation language modeling (TLM) task that predicts masked tokens from concatenated translation pairs. ALM (Yang et al., 2020) utilizes translation pairs to construct code-switched sequences as input. InfoXLM (Chi et al., 2021b) considers an input translation pair as cross-lingual views of the same meaning, and proposes a cross-lingual contrastive learning task. Several pre-training tasks utilize the token-level alignments in parallel data to improve cross-lingual language models (Cao et al., 2020; Zhao et al., 2021; Hu et al., 2020a; Chi et al., 2021c).

In addition, parallel data are also employed for cross-lingual sequence-to-sequence pre-training. XNLG (Chi et al., 2020) presents cross-lingual masked language modeling and cross-lingual autoencoding for cross-lingual natural language generation, and achieves the cross-lingual transfer for NLG tasks. VECO (Luo et al., 2020) utilizes cross-attention MLM to pretrain a variable cross-lingual language model for both NLU and NLG. mT6 (Chi et al., 2021a) improves mT5 (Xue et al., 2021) by learning the translation span corruption task on parallel data. ΔLM (Ma et al., 2021) proposes to align pretrained multilingual encoders to improve cross-lingual sequence-to-sequence pre-training.

6 Conclusion

We introduce XLM-E, a cross-lingual language model pretrained by ELECTRA-style tasks. Specifically, we present two pre-training tasks, i.e., multilingual replaced token detection, and translation replaced token detection. XLM-E outperforms baseline models on cross-lingual understanding tasks although using much less computation cost. In addition to improved performance and computational efficiency, we also show that XLM-E obtains the cross-lingual transferability with a reasonably low transfer gap.

7 Ethical Considerations

Our work introduces ELECTRA-style tasks for cross-lingual language model pre-training, which requires much less computation cost than previous models and substantially reduces the energy cost.

Appendix

A Model Hyperparameters

Table 8 and Table 9 shows the model hyperparameters of XLM-E in the sizes of Base, Large, and XL. For the Base-size model, we use the same vocabulary with XLM-R (Conneau et al., 2020) that consists of 250K subwords tokenized by SentencePiece (Kudo and Richardson, 2018). For the models in Large size and XL size, we use VoCap (Zheng et al., 2021) to allocate a 500K vocabulary for models in Large size and XL size.

Hyperparameters	Base	Large	XL
Layers	4	6	8
Hidden size	768	1,024	1,536
FFN inner hidden size	3,072	4,096	6,144
Attention heads	12	16	24

Table 8: Model hyperparameters of XLM-E generators in different sizes.

Hyperparameters	Base	Large	XL

Hidden size	768	1,024	1,536
FFN inner hidden size	3,072	4,096	6,144
Attention heads	12	16	24

Table 9: Model hyperparameters of XLM-E discriminators in different sizes.

B Hyperparameters for Pre-Training

As shown in Table 10, we present the hyperparameters for pre-training XLM-E. We use the batch size of 1M tokens for each pre-training task. In multilingual replaced token detection, a batch is constructed by 2,048 length-512 input sequences, while the input length is dynamically set as the length of the original translation pairs in translation replaced token detection.

C Hyperparameters for Fine-Tuning

In Table 11, we report the hyperparameters for fine-tuning XLM-E on the XTREME end tasks.

Hyperparameters	Value
Training steps	125K
Batch tokens per task	1M
Adam ϵ	1e-6
Adam β	(0.9, 0.98)
Learning rate	5e-4
Learning rate schedule	Linear
Warmup steps	10,000
Gradient clipping	2.0
Weight decay	0.01

Nested Named Entity Recognition as Latent Lexicalized Constituency Parsing

Chao Lou, Songlin Yang, Kewei Tu*

Abstract

Nested named entity recognition (NER) has been receiving increasing attention. Recently, Fu et al. (2020) adapt a span-based constituency parser to tackle nested NER. They treat nested entities as partially-observed constituency trees and propose the masked inside algorithm for partial marginalization. However, their method cannot leverage entity heads, which have been shown useful in entity mention detection and entity typing. In this work, we resort to more expressive structures, lexicalized constituency trees in which constituents are annotated by headwords, to model nested entities. We leverage the Eisner-Satta algorithm to perform partial marginalization and inference efficiently. In addition, we propose to use (1) a two-stage strategy (2) a head regularization loss and (3) a head-aware labeling loss in order to enhance the performance. We make a thorough ablation study to investigate the functionality of each component. Experimentally, our method achieves the state-of-the-art performance on ACE2004, ACE2005 and NNE, and competitive performance on GENIA, and meanwhile has a fast inference speed. Our code will be publicly available at: github.com/LouChao98/nner_as_parsing.

1 Introduction

Named Entity Recognition (NER) is a fundamental task in information extraction, playing an essential role in many downstream tasks. Nested NER brings more flexibility than flat NER by allowing nested structures, thereby enabling more fine-grained meaning representations and broader applications (Byrne, 2007; Dai, 2018). Traditional sequence-labeling-based models have achieved remarkable performance on flat NER but fail to handle nested entities. To resolve this problem, there are many layer-based methods (Ju et al., 2018; Fisher and Vlachos, 2019; Shibuya and Hovy, 2020; Wang et al., 2020, 2021) proposed to recognize entities layer-by-layer in bottom-up or top-down manners. However, they suffer from the error propagation issue due to the cascade decoding.

Recently, Fu et al. (2020) adapt a span-based constituency parser to tackle nested NER, treating annotated entity spans as a partially-observed constituency tree and marginalizing latent spans out for training. Their parsing-based method, namely PO-TreeCRF, admits global exact inference thanks to the CYK algorithm (Cocke, 1969; Younger, 1967; Kasami, 1965), thereby eliminating the error propagation problem. However, their method does not consider entity heads, which provide important clues for entity mention detection (Lin et al., 2019; Zhang et al., 2020d) and entity typing (Katiyar and Cardie, 2018; Choi et al., 2018; Chen et al., 2021). For example, *University* and *California* are strong clues of the existence of `ORGEDU` and `STATE` entities in Fig.1. Motivated by this and inspired by head-driven phrase structures, Lin et al. (2019) propose the Anchor-Region Network (ARN), which identifies all entity heads firstly and then predicts the boundary and type of entities governed by each entity head. However, their method is heuristic and greedy, suffering from the error propagation problem as well.

Our main goal in this work is to obtain the best of two worlds: proposing a probabilistically principled method that enables exact global inference like Fu et al. (2020), meanwhile taking entity heads into accounts like Lin et al. (2019). To enable exact global inference, we also view observed entities as partially-observed trees. Since constituency trees cannot model entity heads, we resort to lexicalized trees, in which constituents are annotated with headwords. A lexicalized tree embeds a constituency tree and a dependency tree (Gaifman, 1965), and lexicalized constituency parsing can thus be viewed as joint dependency and constituency parsing (Eisner and Satta,

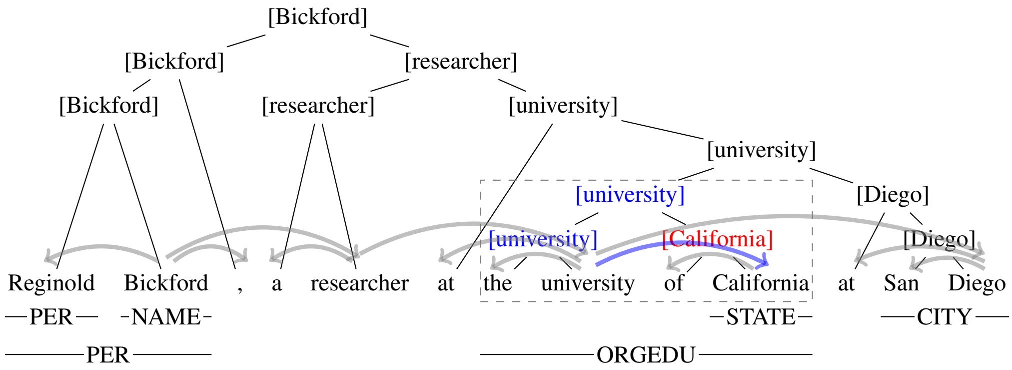

Figure 1: An example sentence with a compatible latent lexicalized constituency tree (top) and observed entities (down). All constituents are annotated by headwords with $[\cdot]$ and we omit the constituent labels. The dotted frame shows an example of inherited head (blue) and non-inherited head (red). We can draw a dependency arc from the inherited head to the non-inherited head. For example, *University* → *California*. Hence a lexicalized constituency tree embeds a constituency tree and a dependency tree.

1999; Collins, 2003). Fig.1 illustrates an example lexicalized tree. Joint dependency and constituency parsing has been shown to outperform standalone constituency parsing (Zhou and Zhao, 2019; Fernández-González and Gómez-Rodríguez, 2020) possibly because modeling dependencies between headwords helps predict constituents correctly. Hence, in the context of nested NER, we have reasons to believe that modeling latent lexicalized constituency trees would bring improvement in predicting entities over modeling latent constituency trees, and we verify this in experiments.

When using a lexicalized constituency tree for nested NER, only part of unlexicalized spans, i.e., entities, are observed, so we need to marginalize latent spans and dependency arcs out for training. Inspired by the masked inside algorithm of Fu et al. (2020), we propose a masked version of the Eisner-Satta algorithm (Eisner and Satta, 1999), a fast lexicalized constituency parsing algorithm, to perform partial marginalization. We also adopt the Eisner-Satta algorithm for fast inference.

Besides the difference in parsing formalism and algorithms, our work also differs from the work of Fu et al. (2020) and Lin et al. (2019) in the following three aspects. First, inspired by Zhang et al. (2020a), we adopt a two-stage parsing strategy, i.e., we first predict an unlabeled tree and then label the predicted constituents, instead of using the one-stage parsing strategy of PO-TreeCRF. We show that two-stage parsing can improve the performance of both PO-TreeCRF and our proposed method. Second, Lin et al. (2019) observe that each entity head governs only one entity span in most cases, so they impose a hard constraint of that during learning and inference, which is potentially harmful since the constraint is not always satisfied. Instead, we add a soft KL penalty term to encourage satisfaction of the constraint, which is reminiscent of posterior regularization (Ganchev et al., 2010; Zhang et al., 2017). Third, considering that gold entity heads are not given, Lin et al. (2019) propose a “bag loss” for entity boundary detection and labeling. However, this loss is heuristic and brings an additional hyperparameter, to which the final performance is sensitive. In contrast, entity boundary detection is learned in the first stage of our method, and in the second stage, we propose a more principled labeling loss based on expectations (i.e., marginal likelihoods) of all possible entity heads within gold entity spans, which can be estimated efficiently and does not introduce new hyperparameters.

We conduct experiments on four benchmark datasets, showing that our model achieves state-of-the-art results on ACE2004, ACE2005 and NNE, and competitive results on GENIA, validating the effectiveness of our method.

2 Preliminary

2.1 One-stage and Two-stage Parsing

A labeled constituency tree can be represented as a rank-3 binary tensor T where $T_{ijk} = 1$ if there is a span from the i-th word to the j-th word with label k in the tree and $T_{ijk} = 0$ otherwise. We assume the 0-th label is preserved for $\emptyset$ (i.e., no label) without loss of generality. Similarly, an unlabeled constituency tree can be represented as a binary matrix T'. One-stage span-based constituency parsers decompose the score of a labeled constituency tree into the scores of constituents s_{ijk}:

$$s(T) = \sum_{ijk} T_{ijk} s_{ijk}$$

They use the CYK algorithm to recover the optimal **labeled** tree. In contrast, two-stage constituency parsers score unlabeled trees and constituent labels independently. They decompose the score of an unlabeled constituency tree into the scores of spans $s_{i,j}$:

$$s(T') = \sum_{ij} T'_{ij} s_{ij}$$

They use the CYK algorithm to recover the optimal **unlabeled** tree in the first stage and then use a separate component to label spans, including the $\emptyset$ label, in the second stage. Zhang et al. (2020c) show that adopting the two-stage parsing strategy leads to a better result in constituency parsing.

2.2 PO-TreeCRF

PO-TreeCRF (Fu et al., 2020) adapts a one-stage constituency parser to tackle nested NER. It views the set of entities $\boldsymbol{y} := \{(i, j, k), \dots\}$ as observed parts of a constituency tree T where (i, j) is the unlabeled entity span and k is the entity label. We refer to other constituents as latent spans. A labeled tree T is compatible with $\boldsymbol{y}$ if $T_{ijk} = 1$ for any entity $(i, j, k) \in \boldsymbol{y}$ and $T_{ij0} = 1$ for all latent spans (i, j) (recall that the 0-th label is $\emptyset$). Define set $\tilde{\mathcal{T}}(\boldsymbol{y})$ as all compatible trees with $\boldsymbol{y}$. PO-TreeCRF maximizes the total likelihood of all compatible trees:

$$s(\boldsymbol{y}) = \log \sum_{T \in \tilde{\mathcal{T}}(\boldsymbol{y})} \exp(s(T))$$
$$\log p(\boldsymbol{y}) = s(\boldsymbol{y}) - \log Z$$

where $\log Z$ is the log-partition function. The difficulty is how to estimate $s(\boldsymbol{y})$ efficiently. Fu et al. (2020) propose the masked inside algorithm to tackle this, in which they set all incompatible span (overlapped but not nested with any of $\boldsymbol{y}$) values to negative infinity before running the inside algorithm. We refer readers to their paper for more details.

2.3 Lexicalized Parsing

Figure 1 shows an example lexicalized constituency tree. We omit all constituent labels for brevity. Each constituent is annotated by a headword. A non-leaf constituent span consists of two adjacent sub-constituents and copies the headword from one of them. We refer to the copied headword as the inherited head and the other headword as the non-inherited head. We can draw a dependency arc from the inherited head to the non-inherited head. A dependency tree can be obtained by reading off all headwords recursively, and hence in this view, a lexicalized constituency tree embeds a dependency tree and a constituency tree.

The $O(n^4)$ Eisner-Satta algorithm (Eisner and Satta, 1999) can be used to calculate the partition function or obtain the best parse if we decompose the score of a lexicalized constituency tree into scores of spans and arcs. We refer interested readers to Appendix A for details of the Eisner-Satta algorithm.

3 Model

Notations Given a length-n sentence $\boldsymbol{x} = x_0, ..., x_{n-1}$ with (gold) entity set $\boldsymbol{y} := \{(i, j, \boldsymbol{\Omega}), \dots\}$, where (i, j) is an unlabeled entity span and $\boldsymbol{\Omega}$ is the set of entity labels (there could be multiple labels for one entity). We denote $\tilde{\boldsymbol{y}}$ as the set of unlabeled entity spans, i.e., $\tilde{\boldsymbol{y}} := \{(i, j), \dots\}$.

3.1 Two-stage Strategy and Training Loss

The first stage always predicts $2n - 1$ spans[1] and most of them are not entities. Hence naively adopting the two-stage parsing strategy to nested NER suffers from the imbalanced classification problem when predicting labels in the second stage because the $\emptyset$ label would dominate all the entity labels. To bypass this problem, we modify unlabeled constituency trees by assigning 0-1 labels to unlabeled constituency trees, where 0 stands for latent spans and 1 stands for entities. It transfers the burden of identifying non-entities to the first stage, in which the binary classification problem is much more balanced and easier to tackle. The total training loss can be decomposed into:

$$L = L_{\text{tree}} + L_{\text{label}} + L_{\text{reg}}$$

where L_{tree} is a 0-1 labeled constituency tree loss, L_{label} is a head-aware labeling loss and L_{reg} is a regularization loss based on the KL divergence.

---

[1] A binary (lexicalized) constituency tree consists of exactly $2n - 1$ constituents.

3.2 Stage I: Structure Module

Encoding and scoring We feed the sentence into the BERT encoder (Devlin et al., 2019), apply scalar mixing (Peters et al., 2018) to the last four layers of BERT, and apply mean-pooling to all subword embeddings to obtain word-level contextual embedding. We concatenate static word embedding, e.g., GloVe (Pennington et al., 2014), to the contextual embedding to obtain the word representation $a = a_0, .., a_{n-1}$. Then we feed a into a three-layer bidirectional LSTM (Hochreiter and Schmidhuber, 1997) network (BiLSTM):

$$\ldots, (\overrightarrow{b_i}, \overleftarrow{b_i}), \cdots = \text{BiLSTM}([\ldots, a_i, \ldots])$$

Next, we use deep biaffine scoring functions (Dozat and Manning, 2017) to calculate span scores $s^c \in \mathbb{R}^{n \times n \times 2}$ and arc scores $s^d \in \mathbb{R}^{n \times n}$:

$$\begin{aligned} e_i^{c,in/out} &= \text{MLP}^{c,in/out}([\overrightarrow{b_i}; \overleftarrow{b_{i+1}}]) \\ e_i^{d,in/out} &= \text{MLP}^{d,in/out}([\overrightarrow{b_i}; \overleftarrow{b_i}]) \\ s^c_{ij} &= \text{PN}([e_i^{c,in}; \mathbf{1}]^T W^c [e_j^{c,out}; \mathbf{1}]) \\ s^d_{ij} &= \text{PN}([e_i^{d,in}; \mathbf{1}]^T W^d [e_j^{d,out}; \mathbf{1}]), \end{aligned}$$

where MLPs are multi-layer perceptrons that project embeddings into k-dimensional spaces; $W^c \in \mathbb{R}^{(k+1) \times 2 \times (k+1)}, W^d \in \mathbb{R}^{(k+1) \times (k+1)}$ are trainable parameters; PN is Potential Normalization, which normalizes scores to follow unit Gaussian distributions and has been shown beneficial (Fu et al., 2020).

Scores of trees A 0-1 labeled lexicalized constituency tree l embeds an unlabeled dependency tree d and a 0-1 labeled constituency tree c. The label set is $\{0, 1\}$, where 0 denotes latent spans and 1 denotes entity spans. We use a binary rank-3 tensor $C \in R^{n \times n \times 2}$ to represent c, where $C_{ijk} = 1$ if and only if there is a span from x_i to x_j with label k in c; and a binary matrix $D \in \mathbb{R}^{n \times n}$ to represent d, where $D_{ij} = 1$ if and only if there is an arc from x_i to x_j in d. We define the score of l as :

$$\begin{aligned} s(l) &= s(c) + s(d) \\ &= \sum_{ijk} C_{ijk} s^c_{ijk} + \sum_{ij} D_{ij} s^d_{ij} \end{aligned}$$

Structural tree loss We marginalize all latent spans and arcs out to define the loss:

$$\begin{aligned} s(\tilde{\boldsymbol{y}}) &= \log \sum_{\tilde{T} \in \tilde{\mathcal{T}}} \exp(s(\tilde{T})) \\ L_{\text{tree}} &= \log Z - s(\tilde{\boldsymbol{y}}) \end{aligned}$$

where $\tilde{\mathcal{T}}$ is the set of all compatible lexicalized trees whose constituents contain $\tilde{\boldsymbol{y}}$; $\log Z$ is the log-partition function that can be estimated by the Eisner-Satta algorithm. For each compatible tree $\tilde{T} \in \tilde{\mathcal{T}}$, the 0-1 labels are assigned in accordance with the entity spans in $\tilde{\boldsymbol{y}}$. We use a masked version of the Eisner-Satta algorithm (Appendix A) to estimate $s(\tilde{\boldsymbol{y}})$.

Regularization loss As previously discussed, entity heads govern only one entity in most cases. But imposing a hard constraint is sub-optimal because there are also cases violating this constraint. Hence we want to encourage the model to satisfy this constraint in a soft manner. Inspired by posterior regularization (Ganchev et al., 2010; Zhang et al., 2017), we build a constrained TreeCRF and minimize the KL divergence between constrained and original unconstrained TreeCRFs. The first problem is how to construct the constrained TreeCRF. We propose to "hack" the forward pass (i.e., inside) of the Eisner-Satta algorithm to achieve this: we decrease the arc scores by a constant value (we typically set to 0.4) whenever the parent has already governed an entity during computing the inside values, so it discourages a head having several children and thus governing several spans. We refer readers to Appendix A for more details. The second problem is how to optimize the KL divergence efficiently for exponential numbers of trees. We adopt the specific semiring designed to calculate KL divergences between structured log-linear models (Li and Eisner, 2009) from the Torch-Struct library (Rush, 2020) [2]. The calculation of KL divergence is fully differentiable and thus is amenable to gradient-based optimization methods. It has the same time complexity as the forward pass of the Eisner-Satta algorithm. We denote the value of KL divergence as L_{reg}.

3.3 Stage II: Labeling Module

To incorporate entity head information when labeling entity spans, we score the assignment of label $l \in \mathcal{L}$ to a span (i, j) with head x_k as follows:

$$\begin{aligned} e_i^{l,in/out} &= \text{MLP}^{l,in/out}([\overrightarrow{b_i}; \overleftarrow{b_{i+1}}]) \\ e_i^{l,head} &= \text{MLP}^{l,head}([\overrightarrow{b_i}; \overleftarrow{b_i}]) \\ s^{label}_{ijkl} &= \text{TriAff}(e_i^{l,in}, e_j^{l,out}, e_k^{l,head}), \end{aligned}$$

---

[2] `https://github.com/harvardnlp/pytorch-struct/blob/master/torch_struct/semirings/semirings.py`

where Triaff is the triaffine scoring function (Zhang et al., 2020b); $\mathcal{L}$ is the set of all labels. We reuse the encoder (BiLSTM) from Stage I.

Nested named entities could have multiple labels. For instance, 7% entity spans in the NNE dataset (Ringland et al., 2019) have multiple labels. We use a multilabel loss introduced by Su (2020). For each $(i, j, \mathbf{\Omega}) \in \boldsymbol{y}$, consider a potential head x_k with $i \leq k \leq j$, we define the loss as:

$$\begin{aligned} l(i, j, k, \mathbf{\Omega}) = & \log(1 + \sum_{l \in \mathcal{L}/\mathbf{\Omega}} \exp(s_{ijkl}^{label})) \\ & + \log(1 + \sum_{l \in \mathbf{\Omega}} \exp(-s_{ijkl}^{label})) \end{aligned}$$

Since the gold entity heads are not given, we define the **head-aware labeling loss** based on expectation over the headword for each entity span:

$$L_{\text{label}} = \sum_{(i,j,\mathbf{\Omega}) \in \boldsymbol{y}} \sum_{i \leq k \leq j} \alpha_{ijk} l(i, j, k, \mathbf{\Omega})$$

where α_{ijk} is the marginal likelihood of x_k being the headword of span (i, j) under the TreeCRF, which satisfies $\sum_{i \leq k \leq j} \alpha_{ijk} = 1$ and can be estimated efficiently via the backward pass (i.e., backpropagation (Eisner, 2016)) of the Eisner-Satta algorithm.

4 Experiment

4.1 Setup

We conduct experiments on four datasets: ACE2004 (Doddington et al., 2004), ACE2005 (Walker, Christopher et al., 2006), GENIA (Kim et al., 2003) and NNE (Ringland et al., 2019). For ACE2004, ACE2005 and GENIA, we use the same data splitting and preprocessing as in Shibuya and Hovy (2020)[3]. For NNE, we use the official preprocessing script[4] to split train/dev/test sets. We refer readers to Appendeix B.1 for implementation details and to Appendix B.2 for data statistics of each dataset. We report span-level labeled precision (P), labeled recall (R) and labeled F1 scores (F1). We select models according to the performance on development sets. All results are averaged over three runs with different random seeds.

4.2 Main Result

We show the comparison of various methods on ACE2004, ACE2005 and GENIA in Table 1. We note that there is an inconsistency in the data prepossessing. For instance, the data statistics shown in Table 1 of (Shibuya and Hovy, 2020) and Table 5 of (Shen et al., 2021) do not match. More seriously, we find Shen et al. (2021); Tan et al. (2021) use context sentences, which plays a crucial role in their performance improvement but is not standard practice in other work. In addition, they report the best result instead of the mean result. Hence we rerun the open-sourced codes of Shen et al. (2021); Tan et al. (2021) using our preprocessed data and no context sentences and we report their mean results over three different runs. We also rerun the code of PO-TreeCRF for a fair comparison.

We can see that our method outperforms PO-TreeCRF, our main baseline, by 0.30/2.42/0.64 F1 scores on the three datasets, respectively. Our method has 87.90 and 86.91 F1 scores on ACE2004 and ACE2005, achieving the state-of-the-art performances. On GENIA, our method achieves competitive performance.

We also evaluate our method on the NNE dataset, whereby there are many multilabeled entities. Table 2 shows the result: our method outperforms Pyramid by 0.27 F1 score.

5 Analysis

5.1 Ablation Studies

We conduct a thorough ablation study of our model on the ACE2005 test set. Table 3 shows the result.

Structured vs. unstructured We study the effect of structural training and structured decoding as a whole. “Unstructured” is a baseline that adopts the local span classification loss and local greedy decoding. “1-stage“ is our re-implementation of PO-TreeCRF, which adopts the latent structural constituency tree loss and uses the CYK algorithm for decoding. “1-stage+`LEX`” adopts the latent structural lexicalized constituency tree loss and uses the Eisner-Satta algorithm for decoding. All methods use the same neural encoders. We can see that “1-stage” outperforms the unstructured baseline by 0.33 F1 score. Further, “1-stage+`LEX`” outperforms “1-stage” by 0.25 F1 score, verifying the effectiveness of using latent lexicalized constituency tree structures.

Model	NNE		
	P	R	F1
Pyramid-Basic	93.97	94.79	94.37
Ours	94.32	94.97	94.64

Table 2: Results on NNE.

1-stage vs. 2-stage On the unstructured model, we adopt a 0-1 local span classification loss in the first stage of the two-stage version, and we observe that the two-stage version performs similarly the one-stage version. On the other hand, we observe improvements on structured methods: “2-stage” outperforms “1-stage” by 0.23 F1 score and “2-stage+`LEX`” outperforms “1-stage+`LEX`” by 0.18 F1 scores, validating the benefit of adopting the two-stage strategy. Moreover, "2-stage(0/1)+`LEX`" outperforms "2-stage+`LEX`" by 0.15 F1 score, suggesting the effectiveness of bypassing the imbalanced classification problem.

Effect of structural training and decoding We study the importance of structural training and decoding in a decoupled way here. “-parsing” denotes the case that we use the latent lexicalized constituency tree loss for training, while we do not use the Eisner-Satta algorithm for parsing and instead predict spans locally whenever their label score of 1 is greater than that of 0. We can see that it causes a performance drop of 0.49 F1 score, indicating the importance of structural decoding, i.e., parsing. It is also worth noting that “-parsing” outperforms the unstructured baseline by 0.42 F1 score, showing the benefit of structural training even without structural decoding.

Effect of head regularization We can see that using the regularization loss brings an improvement of 0.24 F1 score (86.32->86.56). In the case study (Section 5.2), we observe that some common errors are avoided because of this regularization.

Effect of head-aware labeling loss We can see that using the head-aware labeling loss brings an improvement of 0.30 F1 score (86.32 -> 86.62). When combined with the head regularization, we achieve further improvements because of more accurate head estimation (Appendix B.3).

---

[5] They did not report Pyramid-Full with BERT only. However, with BERT+ALBERT, Pyramid-Full only outperforms Pyramid-Basic with a small margin (< 0.1).

[6] The *max* and *logsumexp* versions are the best models for BERT only and BERT+Flair respectively.

Model	P	R	F1
Unstructured(1-stage)	83.76	87.17	85.43

+ both (our final model)	**85.97**	**87.87**	**86.91**

Table 3: Ablation studies on the ACE2005 test set. `LEX` represents lexicalized structures.

5.2 Case Study

Table 4 shows example predictions of our models. In the first pair, "2-stage" predict reasonable structures (visualized in B.5), but fail to label entities, whereas "2-stage (0-1)" predicts further correct labels. The second pair shows that, by constraining head sharing and head-aware entity labeling, "+both" successfully detect bus as a headword, then produce correct entity boundaries and labels. Besides, "+both" can be seen to handle both fine-grained and coarse-grained entities in the last two predictions: *this bus near the airport* is predicted into two entities but *all sites and people in Iraq* remains one multilabeled entity.

Table 5 gives the most common headwords of each type predicted by our model on ACE2005. We find that the most frequently predicted headwords are gold headwords[7], except for some common function words, e.g., *in* and *of*. It proves the ability of our model in recognizing headwords.

5.3 Speed Comparison

One concern regarding our method is that since the Eisner-Satta algorithm has a $O(n^4)$ time complexity, it would be too slow to use for NER practitioners. Fortunately, the Eisner-Satta algorithm is amenable to highly-parallelized implementation so that $O(n^3)$ out of $O(n^4)$ can be computed in parallel (Zhang et al., 2020b; Rush, 2020), which greatly accelerates parsing. We adapt the fast implementation of Yang and Tu (2022b) [8]. Empirically, we observe linear running time on GPUs in most cases. We show the comparison of (both training and decoding) running time in Table 6. We measure the time on a machine with Intel Xeon Gold 6278C CPU and NVIDIA V100 GPU.

We can see that compared with PO-TreeCRF, which also uses a highly-parallelized implementation of the $O(n^3)$ CYK algorithm, our method is around 20% slower in training and decoding, which is acceptable. Notably, both PO-TreeCRF and our method are much faster than Seq2Set (Tan et al., 2021) and Locate&Label(Shen et al., 2021).

6 Related Work

Nested NER Nested NER has been receiving increasing attentions and there are many methods proposed to tackle it. We roughly categorize the methods into the following groups: (1) Span-based methods: Luan et al. (2019); Yu et al. (2020); Li et al. (2021) directly assign scores to each potential entity span. (2) Layered methods: Ju et al. (2018); Fisher and Vlachos (2019) dynamically merge subspans to larger spans and Shibuya and Hovy (2020); Wang et al. (2021) use linear-chain CRFs and recursively find second-best paths for predicting nested entities. (3) Hypergraph-based methods: Lu and Roth (2015); Katiyar and Cardie (2018) propose different hypergraph structures to model nested entities but suffer from the spurious structure issue, and Wang and Lu (2018) solve this issue later. (4) Object-detection-based methods: Shen et al. (2021) adapt classical two-stage object detectors to tackle nested NER and Tan et al. (2021) borrow the idea from DETR (Carion et al., 2020). (5) Parsing-based methods (Finkel and Manning, 2009; Wang et al., 2018; Fu et al., 2020; Yang and Tu, 2022a). (6) Sequence-to-sequence methods (Yan et al., 2021).

Our method belongs to parsing-based methods. Finkel and Manning (2009) use a non-neural TreeCRF parser. Wang et al. (2018) adapt a shift-reduce transition-based parser. Fu et al. (2020) use a span-based neural TreeCRF parser. Recently, Yang and Tu (2022a) propose a bottom-up constituency parser with pointer networks to tackle nested NER as well. All of them cast nested NER to constituency parsing, while we cast nested NER to lexicalized constituency parsing and our method

---

[7] ACE2005 is additionally annotated with headwords. We only use them for evaluation.

is thus able to model entity heads.

Structured models using partial trees Full gold parse trees are expensive to obtain, so there are many methods proposed to marginalize over latent parts of partial trees, performing either approximate marginalization via loopy belief propagation or other approximate algorithms (Naradowsky et al., 2012; Durrett and Klein, 2014) or exact marginalization via dynamic programming algorithms (Li et al., 2016; Zhang et al., 2020b; Fu et al., 2020; Zhang et al., 2021). Naradowsky et al. (2012); Durrett and Klein (2014) construct factor graph representations of syntactically-coupled NLP tasks whose structures can be viewed as latent dependency or constituency trees, such as NER, semantic role labeling (SRL), and relation extraction. Li et al. (2016); Zhang et al. (2020b) perform partial marginalization to train (second-order) TreeCRF parsers for partially-annotated dependency parsing. Zhang et al. (2021) view arcs in SRL as partially-observed dependency trees; Fu et al. (2020) view entities in nested NER as partially-observed constituency trees; and we view entities in nested NER as partially-observed lexicalized constituency trees in this work.

Lexicalized parsing Probabilistic context-free grammars (PCFGs) have been widely used in syntactic parsing. Lexicalized PCFGs (L-PCFGs) leverage headword information to disambiguate parsing and are thus more expressive. Eisner and Satta (1999) propose an efficient $O(n^4)$ algorithm for lexicalized parsing. Collins (2003) conduct a thorough study of lexicalized parsing. Recently, neurally parameterized L-PCFGs have been used in unsupervised joint dependency and constituency parsing (Zhu et al., 2020; Yang et al., 2021). Our work removes the grammar components and adapts the dynamic programming algorithm of lexicalized parsing (Eisner and Satta, 1999) in the spirit of span-based constituency parsing (Stern et al., 2017).

7 Conclusion

We have presented a parsing-based method for nested NER, viewing entities as partially-observed lexicalized constituency trees, motivated by the close relationship between entity heads and entity recognition. Benefiting from structural modeling, our model does not suffer from error propagation and heuristic head choosing and is easy for regularizing predictions. Furthermore, our highly-parallelized implementation enables fast training and inference on GPUs. Experiments on four benchmark datasets validate the effectiveness and efficiency of our proposed method.

A Details of the Eisner-Satta algorithm

Table 7 describes the Eisner-Satta algorithm in the parsing-as-deduction framework. Each deductive rule of the Eisner-Satta algorithm has only one word participating in the computation in addition, e.g., p and h, resulting in one-order higher than the CYK algorithm.

The masked version of the Eisner-Satta algorithm masks scores similar to PO-TreeCRF except for different label sets in our model "2-stage" and "2-stage (0/1)". For the construction of constrained trees, we introduce a minor penalty (0.4 in our paper) on type I items' scores if the item represents a gold entity. We show the pseudocode of the standard Eisner-Satta algorithm, the masked version of the Esiner-Satta algorithm and the construction of constrained trees all in Algorithm 1.

Items:

I $[i, j, h, -]$: span $[i, j]$ is headed by word w_h and its parent is not determined. $i \leq h \leq j$.

II $[i, j, -, p]$: span $[i, j]$ is headed by arbitrary word w_h. The common parent is w_p. $p < i$ or $k < p$.

Axiom items: $[i, i, i, -], 1 \leq i \leq n$
Goal items: $[1, n, r, -], 1 \leq r \leq n$
Deductive rules:

$$\text{I} \quad \frac{[i, k, h, -]}{[i, k, -, p]} \ \text{attach left/right}$$

$$\text{II} \quad \frac{[i, j, -, p] \quad [j+1, k, p, -]}{[i, k, p, -]} \ \text{complete left}$$

$$\text{III} \quad \frac{[i, j, p, -] \quad [j+1, k, -, p]}{[i, k, p, -]} \ \text{complete right}$$

Table 7: The Eisner-Satta algorithm described in the parsing-as-deduction framework.

B Experiments

B.1 Implementation Details

We use BERT (bert-large-cased) and GloVe (6B-100d) to obtain word representations for ACE2004, ACE2005, and NNE. For GENIA, we use BioBERT (biobert-large-cased-v1.1) (Lee et al., 2019) and BioWordvec (Chiu et al., 2016) instead to match its domain. The hidden size of BiLSTM is set to 400. We use an Adam optimizer (Kingma and Ba, 2015) and a linear learning rate scheduler. We warm up training for 2 epochs and decay learning rates to 0 linearly for the rest of the epochs. The peak learning rates are $5e-5$ for BERT/BioBERT and $5e-3$ for the other parts of the neural networks.

B.2 Data statistics

Table 9 shows the statistics of ACE2004, ACE2005, GENIA and NNE. We report the number of multilabeled entities and single-word entities in addition.

B.3 Studies on Headwords

We conduct more experiments to analyze the behavior of head regularization. Table 10 shows the results of models trained with different penalty constants of the head regularization. $c = 0$ means no

	PER	LOC	ORG	GPE	FAC	VEH	WEA

WEA	0.00	0.00	0.00	0.00	0.01	0.00	0.90
$\emptyset$	0.06	0.13	0.08	0.06	0.12	0.18	0.10

Table 8: Error distribution on the ACE2005 test set normalized along with columns. ρ is the gold label distribution. Each row is a gold label and each column is a predicted label. $\emptyset$ denotes entities not recognized by our model.

constraint applied, and larger c means harder constraint. We observe that too hard constraints (e.g., $c = 1$) are less effective than proper constraints (e.g., $c = 0.4$). We choose $c = 0.4$ as the penalty constant for experiments in the main body. Table 11 shows the results if we apply head regularization only when decoding. We observe that the overall performance changes marginally, although the number of shared heads is significantly reduced, possibly because the head accuracy is still low and the labeling module is trained to pay less attention to the headwords as they are noisy. Finally, we analyze the number of shared heads and the head accuracy for models trained with head regularization and head-aware entity labeling. Table 12 shows few shared heads and high head accuracy, consistent with the high overall performance. Besides, we observe that adding the head-aware entity labeling does not reduce the shared headwords much, showing the limitation of models to learn such prior knowledge.

B.4 Error Distribution

We report the error distribution in Table 8. Compared with PO-TreeCRF, we reduce the error rates off all extremely imbalanced classes (VEH, FAC, LOC and WEA).

B.5 Predicted Parse Tree

Here we draw the parse trees in 5.2. Fig. 2a shows a tree produced by "2-stage", which is reasonable. But the label module of "2-stage" fail to label spans correctly due to the label imbalance problem. "2-stage (0-1)" predict the same tree but correct labels. Fig. 2b shows a tree predicted by "2-stage (0-1)". The model fail to detect headwords, e.g., *bus* and *airport*. In contrast, Fig. 2c shows a tree predicted by "2-stage (0-1) + both", in which shared heads are much fewer and correct headwords are found.

Algorithm 1: The Eisner-Satta Algorithm

```
input: $s_c \in \mathbb{R}^{n \times n \times B}$ for span scores, where $B$ is #sent in a batch
input: $s_d \in \mathbb{R}^{n \times n \times B}$ for arc scores
input: $enable\_soft\_constraint$ for whether enable the soft exclusive head constraint
input: $mask \in \mathbb{R}^{n \times n}$ for incompatible spans. (optional)
define: $H \in \mathbb{R}^{n \times n \times n \times B}$ for type I span in Table 7
define: $P \in \mathbb{R}^{n \times n \times n \times B}$ for type II span in Table 7
initialize: $H_{:,:,:} = -\infty, P_{:,:,:} = -\infty$
if $mask$ is given then
    for all $i, j$, $s_c[i, j] = -\infty$ if $mask[i, j]$ is true.
end
for $i = 0$ to $n - 1$ do
    $H[i, i, i] = s_c[i, i]$

Can Explanations Be Useful for Calibrating Black Box Models?

Xi Ye **Greg Durrett**
Department of Computer Science
The University of Texas at Austin
{xiye,gdurrett}@cs.utexas.edu

Abstract

NLP practitioners often want to take existing trained models and apply them to data from new domains. While fine-tuning or few-shot learning can be used to adapt a base model, there is no single recipe for making these techniques work; moreover, one may not have access to the original model weights if it is deployed as a black box. We study how to improve a black box model's performance on a new domain by leveraging *explanations* of the model's behavior. Our approach first extracts a set of features combining human intuition about the task with model attributions generated by black box interpretation techniques, then uses a simple calibrator, in the form of a classifier, to predict whether the base model was correct or not. We experiment with our method on two tasks, extractive question answering and natural language inference, covering adaptation from several pairs of domains with limited target-domain data. The experimental results across all the domain pairs show that explanations are useful for calibrating these models, boosting accuracy when predictions do not have to be returned on every example. We further show that the calibration model transfers to some extent between tasks.[1]

1 Introduction

With recent breakthroughs in pre-training, NLP models are showing increasingly promising performance on real-world tasks, leading to their deployment at scale for translation, sentiment analysis, and question answering. These models are sometimes used as black boxes, especially if they are only available as a service through APIs[2] or if end users do not have the resources to fine-tune the models themselves. This black-box nature poses a challenge when users try to deploy models on a new domain that diverges from the training domain, usually resulting in performance degradation.

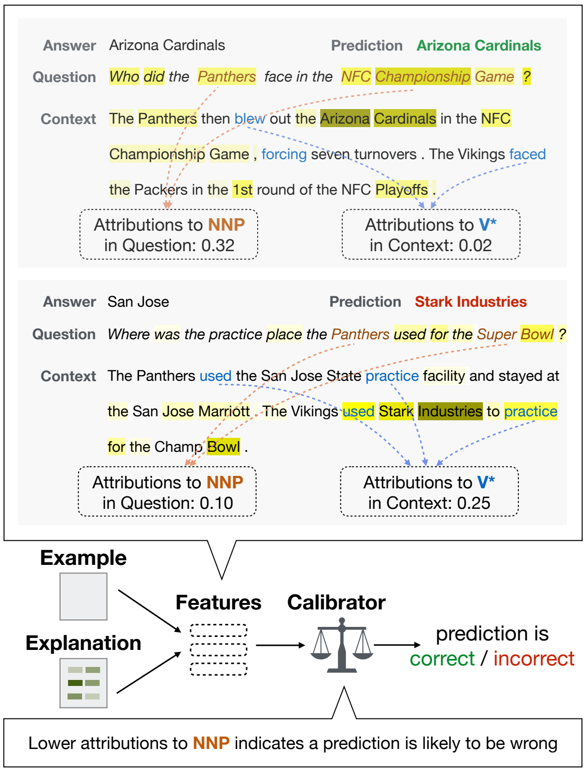

Figure 1: Calibrator pipeline and examples from the SQUAD-ADV dataset. A ROBERTA model trained on SQUAD is correct on the first example but incorrect on the second. Features that inspect attribution values produced by LIME can differentiate these two on the basis of attributions to NNP in the question and V⋆ in the context. A calibrator using these features can predict whether the original model was right or wrong.

We investigate the task of domain adaptation of black box models: given a black box model and a small number of examples from a new domain, how can we improve the model's generalization performance on the new domain? In this setting, note that we are not able to update the model parameters,

which makes transfer and few-shot learning techniques inapplicable. However, we can still make the model more effective in practice by learning a *calibrator*, or a separate model to make a binary decision of whether the black box model is likely to be correct or not on a given instance. While not fully addressing the domain adaptation problem, calibrating the model can make it more useful in practice, as we can recognize when it is likely to make mistakes (Guo et al., 2017; Kamath et al., 2020; Desai and Durrett, 2020) and modify our deployment strategy accordingly.

This paper explores how explanations can help address this task. We leverage black box feature attribution techniques (Ribeiro et al., 2016; Lundberg and Lee, 2017) to identify key input features the model is leveraging, even without access to model internal representations. As shown in Figure 1, we perform calibration by connecting model interpretations with hand-crafted heuristics to extract a set of features describing the "reasoning" of the model. For the question answering setting depicted in the figure, answers turn out to be more reliable when the tokens of a particular set of tags (e.g., proper nouns) in the question are strongly considered. We extract a set of features describing the attribution values of different tags. Using a small number of examples in the target domain, we can train a simple calibrator for the black box model.

Our approach is closely related to the recent line of work on model behavior and explanations. Chandrasekaran et al. (2018); Hase and Bansal (2020) shows explanations can help users predict model decisions in some ways and Ye et al. (2021) show how these explanations can be semi-automatically connected to model behavior based on manually crafted heuristics. Our approach goes further by using a model to learn these heuristics, instead of handcrafting them or having a human inspect the explanations.

We test whether our method can improve model generalization performance on two tasks: extractive question answering (QA) and natural language inference (NLI). We construct generalization settings for 5 pairs of source and target domains across the two tasks. Compared to existing baselines (Kamath et al., 2020) and our own ablations, we find explanations are indeed helpful for this task, successfully improving calibrator performance among all pairs. We even find settings where explanation-based calibrators outperform fine-tuning the model on target domain data, which assumes glass-box access to the model's parameters. Our analysis further demonstrates generalization of the calibrator models themselves: our calibrator trained on one domain can transfer to another new domain in some cases. Moreover, our calibrator can also substantially improves model performance in the Selective QA setting.

2 Using Explanations for Black Box Model Calibration

Let $x = x_1, x_2, ..., x_n$ be a set of input tokens and $\hat{y} = f(x)$ be a prediction from our black box model under consideration. Our task in calibration[3] is to **assess whether the model prediction on** x **matches its ground truth** y. We represent this with the variable t, i.e., $t \triangleq \mathbb{1}\{f(x) = y\}$.

We explore various calibrator models to perform this task, with our main focus being on calibrator models that leverage explanations in the form of *feature attribution*. Specifically, an explanation ϕ for the input x assigns an attribution score ϕ_i for each input token x_i, which represents the importance of that token. Next, we extract features $u(x, \phi)$ depending on the input and explanation, and use the features to learn a calibrator $c : u(x, \phi) \rightarrow t$ for predicting whether a prediction is valid. We compare against baselines that do not use explanations in order to answer the core question posed by our paper's title.

Our evaluation focuses on binary calibration, or classifying whether a model's initial prediction is correct. Following recent work in this setting (Kamath et al., 2020), we particularly focus on domain transfer settings where models make frequent mistakes. A good calibrator can identify instances where the model has likely made a mistake, so we can return a null response to the user instead of an incorrect one.

In the remainder of this section, we'll first introduce how we generate the explanations and then how to extract the features u for the input x.

2.1 Generating Explanations

Since we are calibrating black box models, we adopt LIME (Ribeiro et al., 2016) and SHAP (Lund-

---

[3] We follow Kamath et al. (2020) in treating calibration as a binary classification task. Devising a good classifier is connected to the goal of accurate estimation of posterior probabilities that calibration has more historically referred to (Guo et al., 2017), but our evaluation focuses on binary accuracy rather than real-valued probabilities.

berg and Lee, 2017) for generating explanations for models instead of other techniques that require access to the model details (e.g., integrated gradients (Sundararajan et al., 2017)).

The rest of this work only relies on LIME and SHAP to map an input sequence x and a model prediction y to a set of importance weights ϕ. We will briefly summarize the unified framework shared by both methods, and refer readers to the respective papers for additional details.

LIME and SHAP generate *local explanations* by approximating the model's predictions on a set of perturbations around the base data point x. In this setting, a perturbation x' with respect to x is a simplified input where some of the input tokens are absent (replaced with a `<mask>` token). Let $z = z_1, z_2, ..., z_n$ be a binary vector with each z_i indicating whether x_i is present (using value 1) or absent (using value 0), and $h_x(z)$ be the function that maps z back to the simplified input x'. Both methods seek to learn a local linear classifier g on z which matches the prediction of original model f by minimizing:

$$g(z) = \phi_0 + \sum_{i=1}^{n} \phi_i z_i$$

$$\xi = \arg\min_{g} \sum_{z \in Z} \pi_x(z)[f(h_x(z)) - g(z)]^2 + \Omega(g)$$

where π_x is a local kernel assigning weight to each perturbation z, and Ω is the L2 regularizer over the model complexity. The learned feature weight ϕ_i for each z_i then represents the additive attribution (Lundberg and Lee, 2017) of each individual token x_i. LIME and SHAP differ in the choice of the local kernel π_x. Please refer to the supplementary materials for details of the kernel.

2.2 Extracting Features by Combining Explanations and Heuristics

Armed with these explanations, we now wish to connect the explanations to *the reasoning we expect from the task*: if the model is behaving as we expect, it may be better calibrated. A human might look at the attributions of some important features and decide whether the model is trustworthy in a similar fashion (Doshi-Velez and Kim, 2017). Past work has explored such a technique to compare explanation techniques (Ye et al., 2021), or run studies with human users on this task (Chandrasekaran et al., 2018; Hase and Bansal, 2020).

Our method automates this process by learning what properties of explanations are important. We first assign each token x_i with one or more human-understandable **properties** $V(x_i) = \{v_j\}_{j=1}^{m_i}$. Each property $v_j \in \mathcal{V}$ is an element in the property space, which includes indicators like POS tags and is used to describe an aspect of x_i whose importance might correlate with the model's robustness. We conjoin these properties with aspects of the explanation to render our calibration judgment. Figure 1 shows examples of properties such as whether a token is a proper noun (NNP).

We now construct the feature set for the prediction made on x. For every property $v \in \mathcal{V}$, we extract a single feature $F(v, x, \phi)$ by aggregating the attributions of the tokens associated with v:

$$F(v, x, \phi) = \sum_{i=1}^{n} \sum_{\bar{v} \in V(x_i)} \mathbb{1}\{\bar{v} = v\}\phi_i$$

where $\mathbb{1}$ is the indicator function, and ϕ_i is the attribution value. An individual feature represents the total attribution with respect to property v when the model is making the predictions for x. The complete feature set u for x, given as $u = \{F(v, x, \phi)\}_{v \in \mathcal{V}}$, summarizes model rationales from the perspective of the properties in $\mathcal{V}$.

Properties We use several types of heuristic properties for calibrating QA and NLI models.

Segments of the Input (QA and NLI): In both of our tasks, an input sequence can naturally be decomposed into two parts, namely a question and a context (QA) or a premise and a hypothesis (NLI). We assign each token with the corresponding segment name, which yields features like `Attributions to Question`.

POS Tags (QA and NLI): We use tags from the English Penn Treebank (Marcus et al., 1993) to implement a group of properties. We hypothesize that tokens of some specific tags should be more important, like proper nouns in the questions of the QA tasks. If a model fails to consider proper nouns of a QA pair, it is more likely to make incorrect predictions.

Overlapping Words (NLI): Word overlap between a premise and a hypothesis strongly affects neural models' predictions (McCoy et al., 2019). We assign each token with the `Overlapping` property if a token appears in both the premise and the hypothesis, or `Non-Overlapping` otherwise.

Conjunction of Groups: We can further produce higher-level properties by taking the

Cartesian product of two or more groups. We conjoin `Segment` and `Pos-Tags`, which yields higher-level features like `Attributions to NNP in Question`. Such a feature aggregates attributions of tokens that are tagged with NNP and also required to be in the question (marked with orange).

2.3 Calibrator Model

We train the calibrator on a small number of samples in our target domain. Each sample is labeled using the prediction of the original model compared to the ground truth. Using our feature set $F(v, x, \phi)$, we learn a random forest classifier, shown to be effective for a similar data-limited setting in Kamath et al. (2020), to predict t (whether the prediction is correct). This classifier returns a score, which overrides the model's original confidence score with respect to that prediction.

In Section 4, we discuss several baselines for our approach. As we vary the features used by the model, all the other details of the classifier and setup remain the same.

3 Tasks and Datasets

Our task setup involves transferring from a source domain/task A to a target domain/task B. Figure 2 shows the data conditions we operate in. Our primary experiments focus on using our features to either calibrate or selectively answer in the black box setting (right side in Figure 2). In this setting, we have a black box model trained on a source domain A and a small amount of data from the target domain B. Our task is to train a calibrator using data from domain B to identify instances where the model potentially fails in the large unseen test data in domain B. We contrast this black box setting with glass box settings (left side in Figure 2), where we directly have access to the model parameters and can fine-tune on domain B or train on B from scratch.

English Question Answering We experiment with domain transfer from SQuAD (Rajpurkar et al., 2016) to three different settings: SQuAD-Adv (Jia and Liang, 2017), HotpotQA (Yang et al., 2018), and TriviaQA (Joshi et al., 2017).

SQuAD-Adv is an adversarial setting based on SQuAD, which constructs adversarial QA examples based on SQuAD by appending a distractor sentence at the end of each example's context. The added sentence contains a spurious answer and usually has high surface overlapping with the question so as to fool the model. We use the AddSent setting from Jia and Liang (2017).

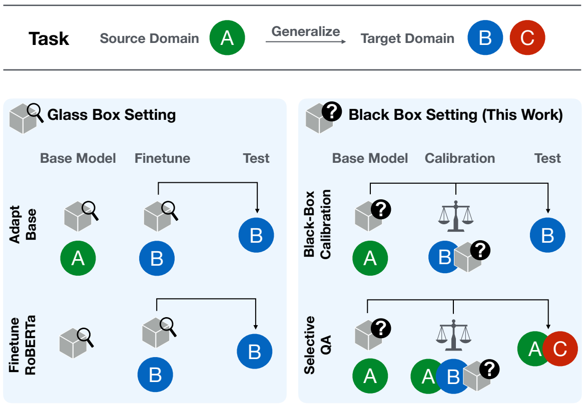

Figure 2: Illustration of different settings in the experiments. In black box settings, a calibrator is trained for improving model performance on OOD data; in glass box settings, the model is finetuned on OOD data from a base model or vanilla RoBERTa LM model.

Similar to SQuAD, HotpotQA also contains passages extracted from Wikipedia, but HotpotQA asks questions requiring multiple reasoning steps, although not all questions do (Chen and Durrett, 2019). TriviaQA is collected from Web snippets, which present a different distribution of questions and passages than SQuAD. For HotpotQA and TriviaQA, we directly use the pre-processed version of dataset from the MRQA Shared Task (Fisch et al., 2019).

English NLI For the task of NLI, we transfer a model trained on MNLI (Williams et al., 2018) to MRPC (Dolan and Brockett, 2005) and QNLI (Wang et al., 2019), similar to the settings in Ma et al. (2019). QNLI contains a question and context sentence pair from SQuAD, and the task is to verify whether a sentence contains the answer to the paired question. MRPC is a paraphrase detection dataset presenting a binary classification task to decide whether two sentences are paraphrases of one another. Note that generalization from MNLI to QNLI or MRPC not only introduces shift in terms of the distribution of the input text, but in terms of the nature of the task itself, since QNLI and MRPC aren't strictly NLI tasks despite sharing some similarity. Both are *binary* classification tasks rather than three-way.

4 Experiments

Baselines We compare our calibrator against existing baselines as well as our own ablations.

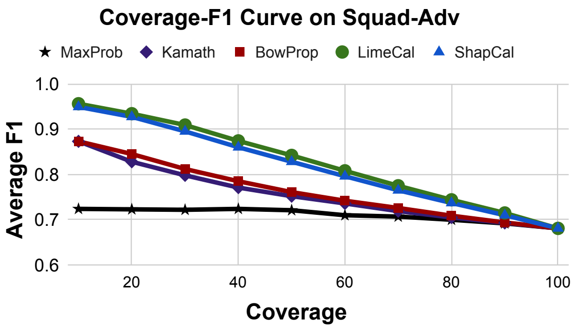

Figure 3: Coverage-F1 curves of different approaches on SQuAD-Adv. As more low-confidence questions are answered, the average F1 scores decrease. We use AUC to evaluate calibration performance.

MaxProb simply uses the thresholded probability of the predicted class to assess whether the prediction is trustworthy.

Kamath (Kamath et al., 2020) (for QA only) is a baseline initially proposed to distinguish out-of-distribution data points from in-domain data points in the selective QA setting (see Section 5), but it can also be applied in our settings. It trains a random forest classifier to learn whether a model's prediction is correct based on several heuristic features, including the probabilities of the top 5 predictions, the length of the context, and the length of the predicted answer. Since we are calibrating black box models, we do not use dropout-based features in Kamath et al. (2020).

ClsProbCal (for NLI only) uses more detailed information than MaxProb: it uses the predicted probability for `Entailment`, `Contradiction`, and `Neutral` as the features for training a calibrator instead of only using the maximum probability.

BowProp adds a set of heuristic property features on top of the Kamath method. These are the same as the features used by the full model *excluding the explanations*. We use this baseline to give a baseline for using general "shape" features on the inputs *not* paired with explanations.

Implementation of Our Method We refer our explanation-based calibration method using explanations produced by Lime and Shap as **LimeCal** and **ShapCal** respectively. We note that these methods also take advantages of the bag-of-word features in BowProp. For QA, the property space is the union of low-level `Segment` and `Segment` × `Pos-Tags`. For NLI, we use the union of `Segment` and `Segment` × `Pos-Tags` × `Overlapping Words` to label the tokens. Detailed numbers of features can be found in the Appendix.

4.1 Main Results: QA

Setup We train a RoBERTa (Liu et al., 2019) QA model on SQuAD as the base model, which achieves 85.5 exact match and 92.2 F1 score. For the experiments on HotpotQA and TriviaQA, we split the dev set, sample 500 examples for training, and leave the rest for testing.[4] For experiments on SQuAD-Adv, we remove the unmodified data points in the Add-Sent setting and also use 500 examples for training. For the experiments across all pairs, we randomly generate the splits, test the methods 20 times, and average the results to alleviate the influence of randomness.

Metrics In addition to *calibration accuracy* (**ACC**) that measures the accuracy of the calibrator, we also use the *area under coverage-F1 curve* (**AUC**) to evaluate the calibration performance for QA tasks in particular. The coverage-F1 curve (Figure 3) plots the average F1 score of the model achieved when the model only chooses to answer varying fractions (coverage) of the examples ranked by the calibrator-produced confidence. A better calibrator should assign higher scores to the questions that the models are sure of, thus resulting in higher area under the curve; note that AUC of 100 is impossible since the F1 is always bounded by the base model when every question is answered. We additionally report the average scores when answering the top 25%, 50%, and 75% questions, for a more intuitive comparison of the performance.

Results Table 1 summarizes the results for QA. First, we show that explanations are helpful for calibrating black box QA models out-of-domain. Our method using Lime substantially improves the calibration AUC compared to Kamath by 7.1, 2.1 and 1.4 on SQuAD-Adv, TriviaQA, and HotpotQA, respectively. In particular, LimeCal achieves an average F1 score of 92.3 at a coverage of 25% on SQuAD-Adv, close to the performance of the base model on original SQuAD examples. Our explanation-based approach is effective at identifying the examples that are robust with respect to the adversarial attacks.

Comparing LimeCal against BowProp, we find that the explanations themselves do indeed help. On SQuAD-Adv and HotpotQA, Bow-

Table 1: Main results on QA tasks. Our explanation-based methods (LimeCal and ShapCal) successfully calibrate a RoBERTa QA model trained on SQuAD when transferring to three new domains, and outperform a prior approach (Kamath) as well as our ablation using only heuristic labels (BowProp). In addition, we show the mean and standard deviation of the deltas w.r.t. BowProp across multiple random seeds in ΔBow.

Prop performs on par with or only slightly better than Kamath. These results show that connecting explanations with annotations is a path towards building better calibrators.

Finally, we compare the performance of our methods based on different explanation techniques. LimeCal slightly outperforms ShapCal in all three settings. As discussed in Section 2.1, Shap assigns high instance weights to those perturbations with few activated features. While such a choice of the kernel is effective in tasks involving tabular data (Lundberg and Lee, 2017), this might not be appropriate for the task of QA when such perturbations may not yield meaningful examples.

4.2 Main Results: NLI

Setup Our base NLI model is a RoBERTa classification model trained on MNLI, which achieves 87.7% accuracy on the development set. We collapse `contradiction` and `neutral` into `non-entailment` when evaluating on QNLI and MRPC. We continue using random forests as the calibrator model. We evaluate the generalization performance on the development sets of QNLI and MRPC. Similar to the settings in QA, we use 500 examples to train the calibrator and test on the rest for each of the 20 random trials.

Metrics Because QNLI and MRPC are binary classification tasks, predicting whether a model is correct (our calibration setting) is equivalent to the original prediction task. We can therefore measure calibrator performance with standard classification accuracy and AUC.

Results We show results on NLI tasks in Table 2. The base MNLI model utterly fails when transferring to QNLI and MRPC and achieves an accuracy of 49% and 57%, respectively, whereas the majority class is 50% (QNLI) and 65% (MRPC). With heuristic annotations, BowProp is able to solve 74% of the QNLI instances and 72% of the MRPC instances. Our heuristic itself is strong for QNLI compared to MaxProb. LimeCal is still the best in both settings, moderately improving accuracy by 1% and 2% over BowProp using explanations. The results on NLI tasks suggest our method can still learn useful signals for indicating model reliability even if the underlying tasks are very different.

4.3 Analysis

Cross-Domain Generalization of Calibrators Our calibrators so far are trained on individual

Table 4: AUC scores of the calibrators trained with varying training data size. Explanation-based calibrators can still learn even with limited training resources, whereas Kamath and BowProp are not effective and underperform the MaxProb baseline on TriviaQA and HotpotQA.

transfer settings. Is the knowledge of a calibrator learned on some initial domain transfer setting, e.g., SQuAD → TriviaQA, generalizable to another transfer setting, e.g. → HotpotQA? This would enable us to take our basic QA model and a calibrator and apply *that pair* of models in a new domain without doing any new training or adaptation. We explore this hypothesis on QA.[5]

For comparison, we also give the performance of a RoBERTa-model first finetuned on Squad and then finetuned on domain A (Adapt, Figure 2). Adapt requires access to the model architecture and is an unfair comparison for other approaches.

We show the results in Table 3. None of the approaches generalize between Squad-Adv and the other domains (either trained or tested on Squad-Adv), which is unsurprising given the synthetic and very specific nature of Squad-Adv.

Between TriviaQA and HotpotQA, both the LimeCal and Kamath calibrators trained on one domain can generalize to the other, even though BowProp is not effective. Furthermore, our LimeCal exhibits a stronger capability of generalization compared to Kamath. We then compare LimeCal against Adapt. Adapt does not always work well, which has also been discussed in Kamath et al. (2020); Talmor and Berant (2019). Adapt leads to a huge drop in terms of performance when being trained on HotpotQA and tested on TriviaQA, whereas LimeCal is the best in this setting. From TriviaQA to HotpotQA, Adapt works well, but Lime is almost as effective.

Overall, the calibrator trained with explanations as features exhibits successful generalizabil-

---

[5] We also tested the hypothesis on the NLI-paraphrase transfer, but did not see evidence of transferability there, possibly due to the fact that these tasks fundamentally differ.

	SQuAD-Adv		TriviaQA		HotpotQA		QNLI	MRPC
Model Performance	Ex	F1	Ex	F1	Ex	F1	Acc	Acc
Base QA/NLI	62.1	68.0	53.2	62.1	50.7	66.3	50.5	57.2

Table 5: Model performance and calibration performance of LimeCal and glass box methods. On QA tasks, LimeCal is better than Finetuning RoBERTa and even outperforms Adapt Base QA/NLI on TriviaQA. LimeCal under-performs glass box methods on NLI due to its easy nature and the poor base-model performance.

ity across the two realistic QA tasks. We believe this can be attributed to the features used in the explanation-based calibrator. Although the task is different, the calibrator can rely on some common rules to decide the reliability of a prediction.

Impacts of Training Data Size Calibrating a model for a new domain becomes cumbersome if large amounts of annotated data are necessary. We experiment with varying the amount of training data the calibrator is exposed to, with results shown in Table 4. Our explanation-based calibrator is still the best in every setting with as few as 100 examples. With 100 examples, Kamath and BowProp perform worse than the MaxProb baseline on TriviaQA and HotpotQA, indicating that more data is needed to learn to use their features.

4.4 Comparison to Finetuned Models

Throughout this work, we have assumed a black box model that cannot be fine-tuned on a new domain. In this section, we compare calibration-based approaches with glass-box methods that require access to the model architectures and parameters. We evaluate two glass-box methods in two different settings (Figure 2): (1) finetuning a base RoBERTa model (Finetune RoBERTa), which needs access to the model's architecture but not parameters; and (2) finetuning a base QA/NLI model, which requires both model architectures as well as parameters. All these models are finetuned with 500 examples, the same as LimeCal. We also give the performance of a model trained with full in-domain training data for different tasks as references (InDomain QA/NLI).

We present the model performance (measured with Exact Match and F1 for QA and Acc for NLI) and calibration results in Table 5. Note that there are no calibrators for glass box methods, so we only report AUC scores for calibration performance.

On QA tasks, the limited training data is not sufficient for successfully finetuning a RoBERTa model. Consequently, Finetune RoBERTa does not achieve credible performance. Finetuning a base QA model greatly improves the performance, surpassing LimeCal on SQuAD-Adv and HotpotQA. However, we still find that on TriviaQA, LimeCal slightly outperforms Adapt. This is a surprising result, and shows that explanation-based calibrators can still be beneficial in some scenarios, even if we have full access to the model.

On NLI tasks that are substantially easier than QA, finetuning either a RoBERTa LM model or a base NLI model can reach an accuracy of roughly 80%. Our explanation-based approach largely lags glass-box methods, likely because the base NLI model utterly fails on QNLI (50.5% accuracy) and MRPC (55.0% accuracy) and does not grant much support for the two tasks. Nonetheless, the results on NLI still support our main hypothesis: explanations can be useful for calibration.

5 Selective QA Setting

Our results so far have shown that a calibrator can use explanations to help make binary judgments of correctness for a model running in a new domain. We now test our model on the selective QA setting from Kamath et al. (2020) (Figure 2). This experiment allows us to more directly compare with prior work and see performance in a setting where in-domain (ID) and out-of-domain (OOD) examples are mixed together.

Given a QA model trained on source domain data, the goal of selective QA is to train a calibrator on a mixture of ID source data and *known* OOD data, and test the calibrator to work well on a

Known \ Unknown		SQ-ADV	TRIVIA	HOTPOT
SQ-ADV	MAXPROB	85.0	88.7	87.5
	KAMATH	88.8	89.5	88.9
	BOWPROP	91.5	90.6	89.0
	LIMECAL	**94.5**	**91.7**	**91.9**
TRIVIA	MAXPROB	85.0	88.7	87.6
	KAMATH	85.6	91.9	88.7
	BOWPROP	85.3	92.1	89.9
	LIMECAL	**90.9**	**92.5**	**92.1**
HOTPOT	MAXPROB	85.0	88.7	87.6
	KAMATH	86.1	91.4	89.4
	BOWPROP	85.1	91.8	91.6
	LIMECAL	**91.7**	**92.3**	**92.5**

Table 6: Area under Coverage-F1 curve in the Selective QA setting. Our explanation-based approach is also strong in this setting, substantially outperforming existing baseline and our own ablation.

mixture of in-domain and an *unknown* OOD data.

We follow the similar experimental setup as in Kamath et al. (2020). The detailed setting is included in the supplementary material.

Results As shown in Table 6, similar to the main QA results. Our explanation-based approach, LIMECAL, is consistently the best among all settings. We point out our approach outperforms KAMATH especially in settings that involve SQUAD-ADV as known or unknown OOD distribution. This can be attributed the similarity between SQUAD and SQUAD-ADV which can not be well distinguished with features used in KAMATH (`Context Length`, `Answer Length`, and etc.). The strong performance of our explanation-based approach in the selective QA setting further verifies our assumption: explanation can be useful and effective for calibrating black box models.

6 Related Work

Our approach is inspired by recent work on the *simulation* test (Doshi-Velez and Kim, 2017), i.e., whether humans can simulate a model's prediction on an input example based on the explanations. Simulation tests have been carried out in various tasks (Ribeiro et al., 2018; Nguyen, 2018; Chandrasekaran et al., 2018; Hase and Bansal, 2020) and give positive results in some tasks (Hase and Bansal, 2020). Our approach tries to mimic the process that humans would use to judge a model's prediction by combining heuristics with attributions instead of having humans actually do the task.

Using "meta-features" to judge a model also appears in literature on system combination for tasks like machine translation (Bojar et al., 2017), question answering (Kamath et al., 2020; Zhang et al., 2021), constituency parsing (Charniak and Johnson, 2005; Fossum and Knight, 2009) and semantic parsing (Yin and Neubig, 2019). The work of Rajani and Mooney (2018) in VQA is most relevant to ours; they also use heuristic features, but we further conjoin heuristic with model attributions. Our meta-feature set is derived from the presence of certain properties, which is similar to the "concepts" used in concept-based explanations (Ghorbani et al., 2019; Mu and Andreas, 2020), but we focus on using them for estimating model performance rather than explaining a prediction.

Our work addresses the problem of calibration (Guo et al., 2017; Desai and Durrett, 2020), which is frequently framed in terms of models' output probabilities. Past work has attempted to tackle this problem using temperature scaling (Guo et al., 2017) or label smoothing (Pereyra et al., 2017), which adjust confidence scores for all predictions. In contrast, we approach this issue by applying a classifier leveraging instance-specific explanations. Past work on generalizing to out-of-domain distribution in NLP largely focuses on using unlabeled data from the target domain and requires finetuning a model (Ma et al., 2019; Ramponi and Plank, 2020; Guo et al., 2020), whereas we improve OOD performance of strictly black-box models.

7 Discussion & Conclusion

Limitations Despite showing promising results in improving model generalization performance, our attribution-based approach does suffer from intensive computation cost. Using either LIME or SHAP to generate attributions requires running inference a fair number of perturbations when the input size is large (see Appendix for details), which limits our method's applicability. But this doesn't undermine the main contribution of this paper, answering the question in the title, and our approach is still applicable as-is in the scenarios where we pay for access to the model but not per query.

Conclusion We have explored whether model attributions can be useful for calibrating black box models. The answer is *yes*. By connecting attributions with human heuristics, we improve model generalization performance on new domains and tasks. Besides, it exhibits promising generalization performance in some settings (cross-domain generalization and Selective QA).

A Details of the Kernel used in LIME and SHAP

LIME heuristically sets π_x as an exponential kernel (with bandwith σ) defined on the cosine distance function between the perturbation and original input, i.e.,

$$\pi_x(z) = \exp(-d_{\cos}(x, h_x(z))/\sigma^2)$$

That is, LIME assigns higher instance weights for perturbations that are closer to the original input, and so prioritizes classifying these correctly with the approximation.

SHAP derives the π_x so the ϕ can be interpreted as Shapley values (Shapley, 1997):

$$\pi_x(z) = \frac{n-1}{\binom{N}{|z|}|z|(n-|z|)}$$

where $|z|$ denotes the number of activated tokens (sum of z). This kernel assigns high weights to perturbations with few or many active tokens, as the predictions when a few tokens' effects are isolated are important. This distinguishes SHAP from LIME, since LIME will place very low weight on perturbations with few active tokens.

B Detailed Setup of Selective QA Setting

We follow the similar experimental setup as in Kamath et al. (2020). We train a ROBERTA QA model on SQUAD, and use on a mixture of 1,000 SQUAD dev examples + 1,000 known OOD examples to train the calibrator. We report test results on both the same type of mixture (1,000 SQUAD + 1,000 known OOD, diagonal blocks in Table 6) and a mixture of 4000 SQUAD examples + 4,000 unknown OOD (2,560 SQUAD + 2,560 SQUAD-ADV as SQUAD-ADV only contains 2,560 examples).

C Feature Importance

We analyze the important features learned by the calibrator. We find explanation-based features are indeed generally among the top used features and more important than Bag-of-Word-based features (see the Appendix for a detailed list). All QA calibrators heavily rely on attribution values of the proper nouns (NNP) and wh-words in the question. BoW features of overlapping nouns are considered important on QNLI, but the top feature is still attribution-based.

These factors give insights into which parts of the QA or NLI reasoning processes are important for models to capture. E.g., the reliance on NNPs in SQUAD-ADV matches our intuitive understanding of this task: distractors typically have the wrong named entities in them, so if the model pays attention to NNPs on an example, it is more likely to be correct, and the calibrator can exploit this.

Table 7 shows the most important features learned by LIMECAL for QA and NLI. For brevity, we present the features related to the probabilities of the top predictions into one feature (`Prob`). Explanation-based features are indeed generally among the top used features and more important than raw property features.

D Details of POS Tag Properties

We use tagger implemented in spaCy API.[6] The tag set basically follows the Penn Treebank tag set except that we merge some related tags to reduce the number of features given the limited amount of training data.[7] Specifically, we merge `JJ,JJR,JJS` into `JJ`, `NN,NNS` into `NN`, `NNP,NNPS` into `NNP`, `RB,RBR,RBS` into `RB`, `VB,VBD,VBG,VBN,VBP,VBZ` into `VB`, and `WDT,WP,WP$,WRB` into `W`. In this way, we obtain a tag set of 25 tags in total.

E Details of Black Box Calibrators

Feature Counts for QA

- KAMATH (Kamath et al., 2020): we use the **7** features described in (Kamath et al., 2020), including `Probability` for the top 5 predictions, `Context Length`, and `Predicted Answer Length`.

- BOWPROP: In addition to the 7 features used in KAMATH. We construct the property space $\mathcal{V}$ as the union of low-level `Segment` and `Segment` $\times$ `Pos-Tags`. Since there are 3 segments `question`, `context`, `answer` in the input, and 25 tags (Section D), the size of the property space $|\mathcal{V}|$ is thereby given as $3 + 3 \times 25 = 78$. Therefore the total number of features (including the 7 from KAMATH) is **85**.

- LIMECAL and SHAPCAL: Recall that the size of the property space is 78. LIMECAL and SHAPCAL uses 78 features describing the attribution related to the corresponding properties in addition to the 85 features used in BOWPROP. The total number of features is therefore **163**.

---

[6] https://spacy.io/api

[7] https://www.ling.upenn.edu/courses/Fall_2003/ling001/penn_treebank_pos.html

SQ-Adv	Trivia	Hotpot	QNLI	MRPC
Attr to NNP in Q	Prob of Top Pred	Prob of Top Pred	Attr Overlapping NN in H	Prob of Top Pred
Attr to VB in C	Answer Length	Attr to Q	BOW Overl- NN in H	Attr to P
Prob of Top Pred	Attr NNP in Q	Attr Wh- in Q	BOW Overl- NN in P	Attr to H
Attr to NN in Q	Attr Wh- in Q	Attr to C	Attr to Non-Overl- NN in P	Attr to Non-Overl- NNP in H
Answer Length	Attr to Question	Attr to NNP in Q	Prob of Top Pred	Attr to Overl- SYM in P

Table 7: Most important features used by the LimeCal in different tasks. For QA, `Attribution of NNP in the question` and `Attribution of Wh- in the question` are generally important. For NLI, features related to overlapping/non-overlapping nouns are more effective.

Feature Counts for NLI

- ClsProbCal (Kamath et al., 2020): we use **2** features in practice, `Probability of Entailment` and `Probability of Contradiction`. We do not include `Probability of Neutral` since it can be inferred from the probabilities of two other classes.
- BowProp: In addition to the 2 features used in ClsProbCal, we construct the property space $\mathcal{V}$ as the union of low-level `Segment` and `Segment` × `Pos-Tags` × `Overalapping Words`. Since there are 2 segments (`Premise`, `Hypothesis`), 25 tags (Section D), and 2 properties for overlapping `Overlapping`, `Non-Overlapping`, the size of the property space $|\mathcal{V}|$ is given as $2 + 2 \times 25 \times 2 = 102$. Therefore the total number of features (including the 2 from ClsProbCal) is **104**.
- LimeCal and ShapCal: LimeCal and ShapCal add another 102 features in addition to the 104 features used in BowProp. The total number of features are therefore **206**.

Cost of Generating Explanations For QA tasks which have relatively long inputs, we sample 2048 perturbations and run inference over them for each example. For simpler NLI tasks, we use about 512 model queries for each example.

Hyperparameters We use the RandomForest implementation from Scikit-Learn (Pedregosa et al., 2011). We list the hyperparameters used in each approach in Table 8. The hyperparameters are determined through grid search using 400 training examples and 100 validation examples. The choices of numbers of trees are [200, 300, 400, 500], and choices of max depth are [4, 6, 8, 10, 15, 20]. Then, for the experimental results in Table 1, Table 2, and Table 4, we always fix the hyper-parameters, and do not perform any further hyper-parameter tuning.

QA		Num. Tree	Max Depth

F Details of Glass Box Methods

Finetuning RoBERTa For QA, we finetune the RoBERTa-base model with a learning rate of 1e-5 for 20 epochs (We also try finetuning for 3 epochs, but the objective does not converge with 500 examples.) We set the batch size to be 32, and warm-up ratio to be 0.06.

For MNLI, we finetune a RoBERTa-base model with a learning rate of 1e-5 for 10 epochs. We set the batch size to be 32, and warm-up ratio to be 0.06, following the hyper-parameters in Liu et al. (2019).

Adapting a Base QA/NLI Model For QA, we adapt the base RoBERTa QA model trained on

SQuAD with a learning rate of 1e-5 for 2 epochs.

For MNLI, we finetune base RoBERTa NLI model trained on MNLI with a learning rate of 1e-5 for 10 epochs. Learning does not converge when finetuning for 2 epochs, as the MNLI task is too different from QNLI and MRPC.

OIE@OIA: an Adaptable and Efficient Open Information Extraction Framework

Abstract

Different Open Information Extraction (OIE) tasks require different types of information, so the OIE field requires strong adaptability of OIE algorithms to meet different task requirements. This paper discusses the adaptability problem in existing OIE systems and designs a new adaptable and efficient OIE system - OIE@OIA as a solution. OIE@OIA follows the methodology of Open Information eXpression (OIX): parsing a sentence to an Open Information Annotation (OIA) Graph and then adapting the OIA graph to different OIE tasks with simple rules. As the core of our OIE@OIA system, we implement an end-to-end OIA generator by annotating a dataset (we make it open available) and designing an efficient learning algorithm for the complex OIA graph. We easily adapt the OIE@OIA system to accomplish three popular OIE tasks. The experimental show that our OIE@OIA achieves new SOTA performances on these tasks, showing the great adaptability of our OIE@OIA system. Furthermore, compared to other end-to-end OIE baselines that need millions of samples for training, our OIE@OIA needs much fewer training samples (12K), showing a significant advantage in terms of efficiency.

1 Introduction

Open Information Extraction (OIE) techniques are gradually attracting more and more attention (Christensen et al., 2011; Mausam et al., 2012; Corro and Gemulla, 2013; Angeli et al., 2015; Bhutani et al., 2016; Cui et al., 2018; Roy et al., 2019; Zhan and Zhao, 2020) as they build a bridge between language to knowledge. OIE tasks are generally designed for its information extraction requirements, which vary from verbal relations between entities (Banko et al., 2007; Etzioni et al., 2004), nominal attributes (Yahya et al., 2014; Pal and Mausam, 2016; Saha et al., 2017), and adverbial components (e.g., time) (Stanovsky et al., 2018). Even for the same type of information, the required facts may still differ. Table 1 shows the required form of facts of three popular OIE tasks: OIE2016 (Stanovsky and Dagan, 2016), Re-OIE2016 (Zhan and Zhao, 2020) and CaRB (Bhardwaj et al., 2019). The diversity of requirements is an essential feature in the field of OIE, which leads to the urgent need for OIE algorithms with strong adaptability.

The adaptability problem in the OIE field has not been well addressed. There are two primary methodologies to obtain an OIE system: the rule-based approach and the end-to-end learning-based approach. The rule-based approaches (Christensen et al., 2011; Corro and Gemulla, 2013; Angeli et al., 2015; Bhutani et al., 2016; Gashteovski et al., 2017) use human-written or bootstrap-learned rules to convert linguistic structures of sentences into target facts. The end-to-end learning approaches (Stanovsky et al., 2018; Sun et al., 2018b,a; Roy et al., 2019; Ro et al., 2020; Kolluru et al., 2020; Liu et al., 2020) first build a dataset containing <sentence, facts> pairs and then use end-to-end learning to train a neural network as the OIE system. However, these methodologies develop a specific machine for every single task. When the requirements change, one must rewrite the complex rule system or re-annotate the data and then retrain the model. These methodologies fail to meet the need for strong adaptability in the OIE field.

Recently, a concept called Open Information eXpression (OIX) was proposed by Sun et al. (2020) to address the adaptability issue of OIE algorithms. The idea of OIX is to introduce an intermediate layer between the language and OIE, which can express the sentence without information loss and be easily adapted to various OIE tasks. Sun et al. (2020) proposed a standard, called Open Information Annotation (OIA), to implement OIX. The OIA standard defines an annotation criterion of

<told, Ms. Lee, Jimmy, she is responsible for this>	✓	✗	✓
<told, Ms. Lee, Lily and Jimmy, she is responsible for this>	✗	✓	✗

Table 1: Facts defined in different OIE tasks, for the expression "*Ms. Lee, the headmaster, told Lily and Jimmy she is responsible for this.*". With OIA, we can easily adapt to these various OIE standards using simple rules.

natural language sentences, which aims to express all information of a sentence into a Predicate-Function-Argument structure, represented by a single-rooted DAG graph. In addition, they implemented a rule-based OIA system that generates OIA graphs from Universal Dependency graphs.

Following the methodology of OIX/OIA, we implement an adaptable and efficient OIE system - OIE@OIA. The framework of OIE@OIA shown in Figure 1 has two components. The first one is the OIA generator, which converts a sentence into an OIA graph. We annotate a large OIA dataset (containing 12,543 training samples, 2,002 development samples, and 2,077 testing samples), develop an efficient learning algorithm to learn and inference the OIA graph, and finally build an end-to-end OIA graph learner. The second component is a group of adaptors, one for each OIE task. We show three popular OIE tasks focused on in this paper in the figure. Furthermore, one can write new adaptors for new OIE tasks, which are very simple, as shown in the following sections. The OIE@OIA system achieves the SOTA (or comparable) performance on three OIE tasks: OIE2016, Re-OIE2016, and CaRB, verifying the adaptability of our OIE@OIA system. Furthermore, our OIE@OIA only needs 12K samples to train, whereas existing end-to-end OIE methods typically need millions of training samples. This verifies the efficiency of our OIE@OIA system.

The **contribution** of this work is as follows:

- An adaptable and efficient OIE system – OIE@OIA, achieving the SOTA performance on different OIE tasks.

- The first end-to-end OIA learning pipeline built on a large human-labeled OIA dataset (we make it open available) and an efficient algorithm for the OIA graph;

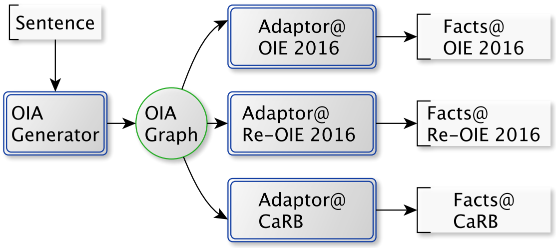

Figure 1: The framework of OIE@OIA.

2 OIE@OIA

In this section, we introduce the OIE@OIA framework, compare it with existing methodologies, and finally discuss its capability and limitation.

2.1 OIA Generator

The core of the OIE@OIA framework is an end-to-end learned OIA generator. To build the generator, we annotate a large dataset using sentences from English-EWT (version 2.4, containing 16K sentences)[1] and design a neural-based algorithm for learning the OIA graph from sentences. The data annotation procedure and the learning procedure are detailed in Section 3.

The standard OIA graph described in Sun et al. (2020) only defined three node types: Constant, Predicate, and Function. However, users may need more fine-grained type information about nodes, especially the type of predicates, to filter wanted facts. For instance, in building OIE systems based on OIA, we need to recognize verbal nodes, which act as the relationship descriptions of the OIE facts. In addition, in event logic graph construction (Ding et al., 2019), logical predicates are essential. With this consideration, we update the type field to a fine-grained version for nodes in the OIA graph according to its semantic function. The fine-grained node types are listed in Table 2.

---

[1] `https://lindat.mff.cuni.cz/repository/xmlui/handle/11234/1-2988`

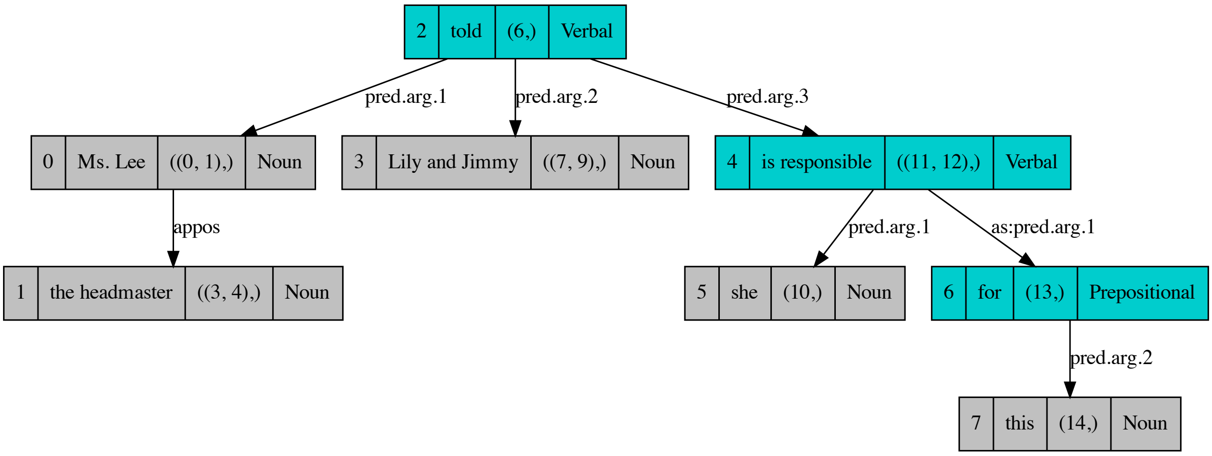

Figure 2: The OIA graph for sentence *"Ms. Lee, the headmaster, told Lily and Jimmy she is responsible for this."*

Fine-grained Type	Original Type	Example
Verbal	Predicate	*know*
Prepositional	Predicate	*to*
Logical	Predicate	*and*
Function	Function	*when*
Noun	Constant	*Chicago*
Modifier	Constant	*well*

Table 2: Node types in OIA graph. Examples are extracted from "*I know him well, and I remember when he went to Chicago*".

Figure 2 shows the OIA graph created by our OIA generator for the example sentence in Table 1, where the predicate nodes are highlighted with color cyan. We can see that all information in the sentence is expressed in the graph, and the *predicate-argument* structures concerned in OIE tasks are accurately captured.

2.2 OIE Adaptors

Next, we illustrate how to design adaptors to accomplish three popular OIE tasks: OIE2016, Re-OIE2016, and CaRB. The OIE2016 and Re-OIE2016 adaptors are built based on the relabeling principle of Zhan and Zhao (2020). The adaptor for CaRB is built based on the labeling instructions in attachment[2] of Bhardwaj et al. (2019). Note that one can always design new adaptors for new OIE tasks.

Figure 2 shows the OIA graph of the example sentence expressing the common units required by these three tasks. First, we design the following simple rules:

Verbal: For each verbal node in the OIA graph, we take the node as the predicate of the OIE fact and take each child sub-tree of the verbal node as an argument of the fact. For instance, given the sample in Figure 2, the extracted facts using the rule are <*"told", "Ms. Lee, the headmaster", "Lily and Jimmy", "she is responsible for this"*> and <*"is responsible", "she", "for this"*>.

VerbalPiP: In the OIA graph, for each verbal node with a prepositional child, we merge the child into the verbal node and apply the *Verbal* rule on the resultant OIA graph. This produces <*"is responsible for", "she", "this"*> for the sample in Figure 2 instead of <*"is responsible", "she", "for this"*>.

Appos(be): All edges like <*A, appos, B*> in OIA graphs are extracted to form the facts <*be, A, B*>.

CoordSep: The fact tuples with coordination arguments are separated into multiple fact tuples, e.g., <*told, ~, Lily and Jimmy, ~*> is separated into <*told, ~, Lily, ~*> and <*told, ~, Jimmy, ~*>.

Then, we implement the adaptors for the three tasks using the combinations of the above rules:

- Adaptor@OIE 2016 = **Verbal** + **CoordSep**;
- Adaptor@Re-OIE 2016 = **Verbal** + **Appos**([is]);
- Adaptor@CaRB = **VerbalPiP** + **Appos**(is) + **CoordSep**.

2.3 Comparisons

In this section, we compare OIE@OIA with existing OIE methodologies and show the difference in Table 3. The traditional rule-based OIE methods are generally based on a sentence annotation structure, such as dependency graphs or constituency graphs, and apply rules to convert the annotation structure into the OIE facts. This

---

[2] https://aclanthology.org/D19-1651/

Methodology	Rule-Based OIE	End-to-End OIE	OIE@OIA
Sentence Annotation	Dependency / Constituency	-	OIA
OIE Sensitiveness of Annotation	No	-	Yes
Rule Complexity	High	-	Low
Training Data	-	1 Million	12K
Training Efficiency	-	Low	High
Adaptation to New Task	Rewrite Rules	Relabel and Retrain	New Adaptor
Adaptation Cost	May Be High	May Be High	Low

Table 3: Comparisons among Rule-based OIE, End-to-End OIE , and OIE@OIA.

pipeline is similar to our OIE@OIA, where OIE@OIA uses the OIA graph as the sentence annotation structure. However, the differences between the traditional annotation and OIA make the substantial differences between the rule-based OIE and our OIE@OIA. Since the traditional annotation - dependency and constituency - is not designed for the OIE task, one needs to write a complex rule system (or construct by bootstrapping) to convert those annotation structures into the OIE facts. However, for OIE@OIA, since the OIA is designed for OIE tasks, one can accomplish the conversion with straightforward rules, just like those described in the above section. As for the end-to-end OIE algorithms, existing methods are generally built on OpenIE4 dataset (Zhan and Zhao, 2020), which contains about 1 million training samples. However, differences may exist in the forms between the training dataset and the target task, so the performance may drop when adapting to new tasks. To limit the differences, one may need many new training samples and retrain the model. Our OIE@OIA can adapt to an extensive range of new tasks by introducing new adaptors, so it has much better adaptability. In addition, our experimental studies show that OIE@OIA needs only 12K samples for training to achieve new SOTA OIE performance, so it is much more efficient to implement an OIE system.

2.4 Capability and Limitations

Besides the type of facts defined in the three popular tasks, one can extract more types of facts from OIA graphs. For example, since OIA graphs are naturally hierarchical, one can easily extract the nested facts, which can implement the target task of NestIE (Bhutani et al., 2016). One can also extract logical relationships between facts since OIA identifies the logical predicate nodes. We believe OIA can act as a general platform for various OIE tasks and provide better facts for downstream tasks based on OIE (Ding et al., 2019; Zhang et al., 2020).

However, the current version of the OIE@OIA pipeline does not separate the compound noun phrase, making it unable to extract nominal relationships between different nominals within a compound noun phrase (Yahya et al., 2014). This is because current OIA graphs are phrase-level graphs and take noun phrases as single nodes. As an example, “*the president of America*" will form a single node in our OIA graph, and it is not able to identify the relationship between “*the president*" and “*America*" based on the graph. We left this problem as one of our future work.

3 Learning the OIA Graphs

Converting a sentence into the OIA graph is the central operation of the OIE@OIA framework. We build an OIA dataset using active-learning-powered human labeling to implement such an operation. Then, we learn equivalent variants of the OIA graphs – Word-OIA graphs and convert them back to OIA-graphs, which overcomes the difficulty of learning the structures of the OIA graphs.

3.1 Dataset

We annotated sentences of English-EWT (version 2.4) for OIA. The annotation mainly follows the OIA graph definition given by Sun et al. (2020) but with some confusing or special cases being clarified. In addition, we introduce more detailed type information for the node. The obtained dataset contains 12,543 training samples, 2,002 development samples, and 2,077 testing samples. Each sample is a sentence-graph pair. On average, a graph has 7.74 nodes and 6.95 edges, and a node comprises 1.98 words. We make the updated annotation standard and dataset open available [3].

Auxiliary Annotation System. To improve data annotation efficiency, we generate an initial OIA graph for each input sentence using the existing rule-based OIA system (Sun et al., 2020). For node types initialization, we align the phrases with the POS tags in English-EWT v2.4 and assign heuristic types based on the POS tags of the head words. Then we develop an annotation tool for the annotator to modify the adapted graphs with ease.

Active Learning. The samples in the dev set and test set are all human-labeled. For the training set, we first randomly labeled 2,000 samples, then trained a model using the proposed learning method (described in § 3.4) and started the active-learning procedure. The data labeling order of unlabeled samples was determined by the difference between the rule-generated results and the predicted results. We labeled 200 samples in each active learning iteration and stopped the iteration when the performance of the trained did not improve on the dev set. As a result, we manually annotated about 74% of the training data and treated the rule-generated results as the true labels of the rest 26% training data.

Quality Control. The data annotation was done by three postgraduate/doctoral students of linguistics. Two annotators first label each sample. If there is a disagreement, the third annotator will be involved for discussion and voting. The initial agreement ratio between the two annotators is about 80%, and the final agreement ratio after the discussion (no vote needed) is higher than 93%. The annotation of the rest 7% data is obtained by voting.

3.2 Complexity in Learning the OIA Graphs

The node of OIA graphs consists of a sequence of symbols, placeholders, and words. We call such a graph *Generalized Phrase Graph* ($G_{GPG} = (\mathbb{P}, \mathbb{S})$, where $\mathbb{P}$ is the set of generalized nodes and $\mathbb{S}$ is the edge set). Directly learning the graph is difficult due to the very large decision space caused by the complexity of OIA nodes. The decision space is large even in the simplest situation that each node consists of consecutive words (a span in the sentence without any symbol or placeholder outside the sentence). Since the target number of nodes is unknown, the number of candidate node sets to be considered is exponential to the number of words in the sentence. Due to this large decision space, it is very difficult to learn a good candidate set of nodes for OIA graphs as the first step task in a stage-wise approach. If one prefers the end-to-end approach to reduce the error propagation between tasks in each stage by jointly leaning the nodes and edges, the decision space will be even much larger.

3.3 Equivalence between OIA and Word-OIA

Fortunately, we have the following proposition connecting the *Generalized Phrase Graph* with *Word Graph*, where *Word Graph* is a graph with each graph node corresponding to one and only one word of the sentence:

Proposition. *For any Generalized Phrase Graph* $G_{GPG} = (\mathbb{P}, \mathbb{S})$*, there is a one-to-one corresponding Word Graph* $G_W = (\mathbb{W}, \mathbb{S}')$ *in the sense that* G_{GPG} *and* G_W *can convert to each other without loss of information, where the labels of* $\mathbb{S}'$ *are independent to word nodes* $\mathbb{W}$*.*

Proof. We split each generalized phrase node into a chain of nodes of symbols, placeholders, or words, connected in order with the edge *next*, and connect all the edges from parents/children to the first node of the chain. In this new graph, each word is a single node. We replace each type of path between two words (or the virtual root) containing only symbols/placeholders into a single edge with a correspondingly designed edge label and remove the original path. The resulting graph is a valid word graph. ☐

A constructive procedure to convert a *General Phrase Graph* into the *Word Graph* is shown in Appendix A. The OIA graphs are special cases of GPG, and the properties of the OIA graphs can make the procedure much simpler. We discuss these details in Appendix B.

With the above procedure, we can convert a complex OIA graph into an equivalent simple Word-OIA graph (as shown in Figure 3), which is a single-rooted DAG where each node is a word in the original sentence. Each node in the Word-OIA graph has one category attribute *type* (by sharing the type of OIA node it belongs to) and two boolean attributes *arg_whether* and *missing_be* (described in Appendix B).

With this conversion, the learning of the OIA graph is equivalently converted into the learning

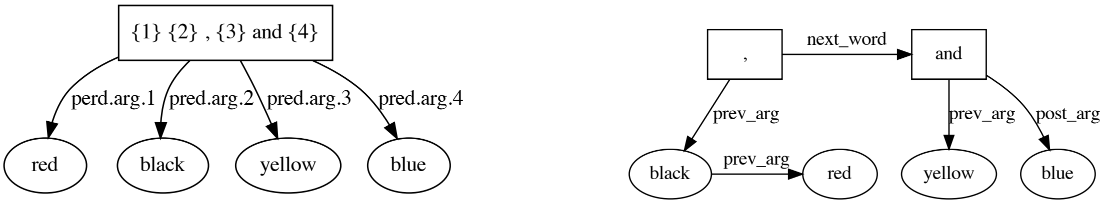
(a) The OIA graph for the sentence A.

(b) The Word-OIA graph for the sentence A.



(c) The OIA graph for the sentence B.

(d) The Word-OIA graph for the sentence B.

Figure 3: The illustration of the equivalence between the OIA graphs and the Word-OIA graphs. The example sentences are: A: "It depends, I don’t know. not sure."; B: "red black, yellow and blue".

of the Word OIA graph. The node number of the Word-OIA graph is fixed N, so we only need to learn the possible $N(N-1)$ edges, and thus the learning complexity is significantly reduced.

3.4 Learning the Word-OIA Graphs

The structure of the Word-OIA graph is similar to that of the dependency graph so that the semantic dependency graph learning procedure can be applied to the learning of the Word-OIA graph. We build our learning procedure based on pre-trained BERT models (Devlin et al., 2019). Given a sentence $S = [w_1, \cdots, w_N]$, we generate the representation $\mathbf{r}_i$ of each word by:

$$R = \mathbf{BERT}(S),$$

where $R = [\mathbf{r}_1, \cdots, \mathbf{r}_N]$. Then we learn the properties of nodes and the graph structures using these representations.

Node Attribute Learning. For node attribute prediction, we build a one-layer MLP classifier above $\mathbf{r}_i$ to learn each attribute a_k for word w_i:

$$\mathbf{p}_{ki}^{(node)} = p(a_k|w_i) = \text{Softmax}(\mathbf{MLP}_k^{(node)}(\mathbf{r}_i)).$$

The loss of node attribute prediction is defined as:

$$\mathcal{L}_{node} = \frac{1}{N}\sum_k\sum_i \ell_{CE}\left(\mathbf{p}_{ki}^{(node)}, y_{ki}^{(node)}\right),$$

where $y_{ki}^{(node)}$ denotes the target attribute value of the corresponding node of w_i and ℓ_{CE} denotes the cross-entropy loss function.

Edge Learning. Following the protocol of Dozat and Manning (2018), we divide the structure learning into two steps: given two nodes, we firstly determine if there is an edge between them; if so, we then determine the type of the edge. It avoids introducing an empty edge type in the second step, which will overwhelm the other edge types. For the two-step learning, we use the biaffine-based graph learning approach (Dozat and Manning, 2017, 2018). In the first step, for two words w_i and w_j, we learn the representations of each word as the start and end node of an edge:

$$\mathbf{h}_i^{(es)} = \mathbf{MLP}^{(es)}(\mathbf{r}_i), \mathbf{h}_i^{(ee)} = \mathbf{MLP}^{(ee)}(\mathbf{r}_i).$$

where es means "as the start of the edge", ee means "as the end of the edge". The probability of there being an edge e_{ij} between w_i and w_j is:

$$\mathbf{s}_{ij}^{(edge)} = \mathbf{Biaff}^{(edge)}(\mathbf{h}_i^{(es)}, \mathbf{h}_j^{(ee)}),$$
$$\mathbf{p}_{ij}^{(edge)} = \sigma\left(\mathbf{MLP}^{(edge)}(\mathbf{s}_{ij}^{(edge)})\right).$$

Here, the i-th dimension of $\mathbf{Biaff}(\mathbf{x}_1, \mathbf{x}_2)$ is:

$$\mathbf{x}_1^\top \mathbf{U}_i \mathbf{x}_2 + \mathbf{w}_i^\top(\mathbf{x}_1 \oplus \mathbf{x}_2) + b_i,$$

where $\mathbf{U}_i$, $\mathbf{w}_i$, b_i denotes a trainable matrix, vector, and scalar, respectively. $\oplus$ is the concatenation operator. The corresponding graph topology loss on S is defined as follows:

$$\mathcal{L}_{topo} = \frac{1}{N^2}\sum_{ij} \ell_{CE}\left(\mathbf{p}_{ij}^{(edge)}, y_{ij}^{(edge)}\right).$$

Then we learn the label of each edge. We learn the representations of start-node and end-node of an edge by:

$$\mathbf{h}_i^{(ls)} = \mathbf{MLP}^{(ls)}(\mathbf{r}_i), \quad \mathbf{h}_j^{(le)} = \mathbf{MLP}^{(le)}(\mathbf{r}_j).$$

The probability of the label l_{ij} is:

$$\mathbf{s}_{ij}^{(label)} = \mathbf{Biaff}^{(label)}(\mathbf{h}_i^{(ls)}, \mathbf{h}_j^{(le)}),$$
$$\mathbf{p}_{ij}^{(label)} = \text{Softmax}\left(\mathbf{MLP}^{(label)}(\mathbf{s}_{ij}^{(label)})\right),$$

and the edge prediction loss on S is defined as:

$$\mathcal{L}_{label} = \frac{\sum_{ij} \mathbb{I}(y_{ij}^{(edge)} = 1)\ell_{CE}\left(\mathbf{p}_{ij}^{(label)}, y_{ij}^{(label)}\right)}{\sum_{ij} \mathbb{I}(y_{ij}^{(edge)} = 1)},$$

where $\mathbb{I}(\cdot)$ is the indicator function.

Multi-Task Learning. We learn the Word-OIA graph in a multi-task style, that is, optimize a linear combination of the losses:

$$\mathcal{L} = \alpha\mathcal{L}_{topo} + \beta\mathcal{L}_{label} + (1 - \alpha - \beta)\mathcal{L}_{node}.$$

In the inference phase, we accomplish the following steps to generate the Word-OIA graph:

Node Attribute Prediction. For each node w_i, its type t_i is predicted by:

$$\hat{y}_{ki} = \arg\max \mathbf{p}_{ki}^{(node)}.$$

Edge Prediction. Edge and label between w_i and w_j are predicted by:

$$\hat{e}_{ij} = \mathbf{p}_{ij}^{(edge)} > 0.5,$$
$$\hat{l}_{ij} = \hat{e}_{ij} \cdot \arg\max \mathbf{p}_{ij}^{(label)}.$$

However, because the label prediction may be incorrect, constructing the graph using the above predictions may result in an invalid graph (disconnected graph, edge conflicted, etc.). So in practice, we develop a greedy search strategy to construct the graph step-by-step while maintaining the validness of the graph all the time. First, we select the edge with the highest value of $\mathbf{p}_{ij}^{(label)}$ for all edges with $\mathbf{p}_{ij}^{(edge)} > 0.5$. Then, we identify conflicted edges with the selected edges and set their corresponding values in $\mathbf{p}_{ij}^{(label)}$ to zero. The above process iterates several times until all edge types are set. In addition, the resulting graph may consist of several disconnected sub-graphs. In this case, we iteratively select the edge with the highest $\mathbf{p}_{ij}^{(label)}$ to connect it to the sub-graph to which the predicted root belongs. It guarantees that the generated Word-OIA graph is valid.

3.5 Recover OIA from Word-OIA

For a predicted Word-OIA graph, we reverse the OIA to the Word-OIA procedure to obtain the OIA graph. Specifically, we first collect nodes in Word-OIA graph chained by *next_word* and related arcs (*prev_arg*, *pos_arg*) to form the nodes in OIA graph. Then we identify the special structure such as edge *upper_parataxis* and add special node like *Parataxis* and *Missing* to OIA graph. We add *(be)* to the node span if *missing_be* is true. The *Whether* node is added as the parent of current node if *arg_whether* is true. Last, we connect the nodes using the learned arc labels in Word-OIA. The type of the phrase node in the OIA graph is set as the majority type of its constituted words in the corresponding Word-OIA graph.

4 Experiment I: OIA Learning

The experiment is conducted on the PaddlePaddle deep learning platform[4], and the pre-trained BERT model is provided by the PaddleNLP project[5]. Following Che et al. (2020), the hidden size of $\mathbf{MLP}^{(edge)}$ and $\mathbf{MLP}^{(label)}$ is set to 500 and 100, respectively. The hidden sizes of MLPs used in node attribute predictions are set to 500. The model is trained with the classifier's dropout rate being set to 0.1 and Adam optimizer with a learning rate of 10^{-5}. α and β in loss function are searched using

Level		Metric	Performance
Node	*type*	Acc	0.951
	arg_whether	Acc	0.998
	missing_be	Acc	0.998
Edge		P/R	0.847 / 0.851
Graph		Acc	0.528

Table 4: Performance of Word-OIA prediction, where P/R means Precision/Recall, Acc means Accuracy.

grid search on dev set and set to 0.2 and 0.4, respectively.

Evaluation Metric. In this experiment, the evaluation metrics for all measurements are based on exact match, that is, score 1 if exactly the same, otherwise 0. For nodes, we compare their node expressions. For a Word-OIA node, the node expression is the word index in the sentence; for an OIA node, the node expression is the phrase based on the word indexes it contains. For edges, we compare the triplets of <*start_node_expression, edge_label, end_node_expression*>. For graphs, we test whether the two graphs' node sets and edge sets are exactly the same.

4.1 Performance on Word-OIA

The node precision and recall of Word-OIA are always 1.0 since the nodes correspond to the words in the sentence. The performance of node attribute prediction is illustrated by the upper part of Table 4. The precision/recall of edge prediction is shown in the middle part of Table 4. We also report the accuracy of graph structure in the last part of Table 4.

4.2 Performance on OIA

We report the performances of the nodes, edges, and the whole graph structure of the recovered OIA graphs in the lower half of the Table 5. Note that the graph-structure accuracy of the OIA graph is slightly lower than that of the Word-OIA graph. It is because the graph structure of the OIA graph is related to the node attributes *arg_whether* and *missing_be*. Since there are tiny proportions of bad cases in predicting these two attributes, the graph-structure accuracy of the OIA graph is lower.

As a comparison, we report the performances of the rule baseline (Sun et al., 2020) in upper part of Table 5. We can see that the proposed method achieves significant improvement over the rule baseline, e.g., improving the graph structure accuracy by 15.2%. We believe the learning-based approach solves several problems in the rule-based approach: 1) limitation of expressiveness of Universal Dependency, 2) mistakes in Universal Dependency and Enhanced++ (Schuster and Manning, 2016) parsers, and 3) failure of rules to cover the complex combination of situations.

Generator	Level	Metric	Performance
Rule	Node	P/R	0.796 / 0.855
Rule	Edge	P/R	0.530 / 0.585
Rule	Graph	Acc	0.373
Neural	Node	P/R	0.893 / 0.877
Neural	Edge	P/R	0.709 / 0.688
Neural	Graph	Acc	0.525

Table 5: Performance of OIA graph prediction.

We also evaluate the accuracy of the node type of the recovered OIA graphs. Among the 89.3% correctly identified nodes, 96.4% of them are labeled with the correct node types by the voting of nodes in the Word-OIA graphs.

4.3 Error Analysis

We reviewed the error cases to find the limitations in the graph generation process. We find several common issues that lead to incorrect graphs.

Long Tail Words and Edges. About 33% errors are caused by the long tail words and edge labels. The out-of-vocabulary words lead to problematical word representations. Rarely used edge labels (e.g., discourse) tend to be predicted as other frequent edge labels.

Granularity Issue. The granularity or boundary of the node may be controversial in prediction results. For example, the phrase 'turn out to be' can be a predicate, but it also makes sense that 'turn out' and 'to be' form a nested relation. Such granularity issues cause about 25% errors in both predicate node and constant node. Mining idioms can further clarify the boundary of expression with refined strategy. This belongs to our future work.

Ambiguous Modification. A prepositional phrase can be used to modify either a noun or a verb in its context. This ambiguity leads to about 17% of graph-level errors. For example, in sentence *I love all the roles in this play*, prepositional phrase *in this play* is the modifier of *all the roles*. Thus, they should be in the same noun node of the ground-truth OIA graph. However, in the predicted graph,

Table 6: OIE performance on OIE2016, Re-OIE2016 and CaRB. Note that BiLSTM+BERT and Multi2OIE Ro et al. (2020) use OIE2016 as validation set, so the performances are not listed.

in this play may become the sub-tree of verb *love*. It is a common error in parsing tasks that a model may incorrectly choose the headword for a modifier. We believe better language modeling will ameliorate this problem.

5 Experiment II: OIE@OIA

We further evaluate the applicability of OIA as an intermediate layer between language and OIE, i.e., OIE@OIA, on three tasks: OIE2016, Re-OIE2016, CaRB. We compared OIE@OIA with six rule-based systems and five learning-based systems.

Evaluation Metric. The performances of baseline systems on OIE2016 are from Zhan and Zhao (2020) while that on Re-OIE2016 and CaRB are from Ro et al. (2020), except that NestIE (Bhutani et al., 2016) is implemented using the code from the author. We evaluate the extraction results of the proposed methods, OIE based on rule OIA and NestIE with metric AUC and optimal F1 following the setting of the released codes[6].

The performance of our OIE@OIA system is shown in Table 6. We observe that OIE@OIA achieves better performance than most existing baselines, including learning-based methods trained on millions of samples. This result justifies the effectiveness of OIE@OIA for OIE.

We think the reason for this phenomenon is three-fold: *Firstly*, compared with the annotation of OIA, the annotation of a single OIE task is sparse. Given a sentence, it will only annotate phrases with interesting relationships. For the other phrases and relationships, it will not annotate. In contrast, in OIA, all the phrases and relationships will be annotated. So based on a single sample, the annotation in OIA is much more informative than that in any single OIE task. *Secondly*, if treating the recognition of a type of facts as a task, learning of OIA can be seen as a multi-task learning scenario, and different tasks can augment each other. *Thirdly*, OIA is designed as an intermediate layer between language and OIE. Thus, during the standard design of OIA, it has considered the compatibility between OIA and OIE, which makes it easier to adapt OIA to different OIE tasks.

6 Conclusion

We introduce an adaptable and efficient Open Information Extract system called OIE@OIA. To implement OIE@OIA, we annotate and release an OIA dataset containing about 16K sentences, design an efficient learning algorithm, and build an easy-to-implement rule system to adapt OIA graphs to different OIE tasks. Empirical studies on three popular OIE tasks show that our OIE@OIA system can achieve new SOTA performances on these tasks, using only 12K training sentences. It verifies the great advantage of our system in both effectiveness and efficiency over the previous learning-based baselines, which usually require millions of training samples to achieve comparable performance.

A Convert Generalized Phrase Graph to Word Graph

We will limit our discussion to a well-formed GPG. First, we assume the relational symbols are not neighbors to each other. That is, they do not form any not continuous sequence. Second, we assume that the relational symbols either appear lonely as a node or connecting/separating two words or placeholders. That is, relational symbols do not appear as prefixes or suffixes in a node. Last, we assume that placeholders must appear together with elements or relational symbols in a node. Since the relational symbols are designed to express relations between nodes, elements, and placeholders, we believe the above constraints are reasonable. OIA graphs naturally satisfy these constraints.

If a graph does not satisfy these constraints, preprocessing can be applied to adapt the graph to meet the constraints. If a continuous sequence of relation symbols exists in the graph, one can merge them into one new relational symbol. If some nodes have prefix/suffix symbols, one can add a boolean attribute to the node indicating that this node has a prefix/suffix symbol. If a node is a sequence of placeholders, one can design a new relational symbol to replace the sequence of placeholders.

Given a well-formed GPG, we can apply Algorithm 1 to convert it to a Word Graph. The sub-procedures used in the algorithm are shown in Algorithm 2. In these procedures, $[x]$ means the label of x, where x can be a node or an edge.

B Specialization for the OIA Graph

OIA graphs have the following properties/internal constraints. We use them to simplify the label system for Word-OIA.

- **Lonely Relational Symbols** In OIA, there are only two Relational Symbols: *Parataxis* and *Missing*. They can only form a node lonely with themselves, which reduce some possible combined edge labels;
- **Ordered Predicate-Argument Labels** In OIA, the predicates connect their arguments with a unified form of edge label *pred.arg.n*, where *n* denote the order of the argument. When processing the *Parataxis*, these arguments are chained by label "*parataxis*", and the *n* is omitted since the order is naturally embedded in the chain;
- **Relational Symbols Nested Up to Two Layers** Nested Relational symbol is the most complex situation for GPG. In OIA, only one symbol *Parataxis* can be nested. From the annotated dataset, we observe that the length of the nested path of *Parataxis* is 2. For this simple situation, after processing the child *Parataxis* nodes, we link the children with edges *upper_parataxis*, *peer_parataxis*, or *lower_parataxis*, according to their depth compared to the depth of the first child. Actually, only *upper_parataxis* is needed in our annotated dataset.

Beyond the above processing, we analyze the label system, remove unnecessary prefixes/suffixes, merge labels, and rename labels for better readability. These steps build a simple edge label system of Word-OIA graphs by introducing few new edge labels.

Besides the label system, when converting the OIA graphs into Word-OIA graphs, we introduce the following node attributes for each node/word to preserve the information of the original OIA graphs:

- *type*: Share the type of the origin OIA node which contains this word;
- *arg_whether*: Boolean attribute that indicate whether the original OIA node is an argument of the *Whether* function;
- *missing_be*: Boolean attribute that indicate whether the original OIA node is a predicate that misses the *be* word.

Algorithm 1: Converting General Phrase Graph to Word-Graph

```
Data: An input $\mathcal{G}$
Result: $y = x^n$
Add a virtual root node to $\mathcal{G}$ and connect it to the original root with edge $root$;;
while visiting node $n$ over a depth first back-track traversal $\mathcal{G}$ do
    switch $n$ do
        case a single element or is virtual root do
            continue
        end
        case a sequence of elements (no symbol) do
            Split the sequence into a sequence of a new node with each contains one element, and
              then connect them in order with edge $next\_elem$;
            Replace $n$ with the first node in the sequence;
        end
        case $n$ is a mixed sequence of placeholders, relational symbols, and elements do
            Make a new node for each element;
            Connect nodes of continuous or placeholder-separated elements with edge $next\_elem$;
            foreach continuous sequences of placeholders and corresponding edges and children
              $[(p_i, e_i, c_i)]_{i=1}^{k}$ do ProcessPlaceholderSequence($[(p_i, e_i, c_i)]_{i=1}^{k}$);
            foreach relational symbol $s$ do BuildRelationalSymbolBridge($s$);
            if element exists in $n$ then
                foreach placeholder $p$ do BridgePlaceholderAndElement($p$);
            else
                /* Currently, $n$ only has one child corresponding to
                   first placeholder                                    */
                Get the only child $c$ with edge $e$;
                Find all parents of $n$ as $\{m_i\}$ with edges $\{e_i\}$;
                foreach $m_i, e_i$ do Connect $m_i$ to $c$ with edge $[e_i]\_sub\_arg\_[e]$ ;
            end
        end
        case $n$ is a relational symbol node do
            ProcessSymbolNode($n$)
        end
    end
end
```

Algorithm 2: Sub-Procedures

```
Procedure ProcessPlaceholderSequence ($[(p_i, e_i, c_i)]_{i=1}^{k}$)
    Merge $[p_i]_{i=1}^{k}$ into one placeholder $p$, set $e_1, c_1$ be the corresponding edge and child of $p$;
    foreach $i > 1$ do  Remove $e_i$, connect $c_i - 1$ to $c_i$ with edge $next\_[p_i]\_[e_i]$;
Procedure BuildRelationalSymbolBridge ($s$)
    Identify the corresponding edge and node of the previous item as $e_p, n_p$ and that of the next
      item as $e_n, n_n$;
    if $n_p$ is a placeholder and $n_n$ is an element then
        Connect $n_n$ to $n_p$ with edge label $prev\_arg\_[s]\_[e_p]$, remove $e_p$;
    else if $n_p$ is an element and $n_n$ is a placeholder then
        Connect $n_p$ to $n_n$ with edge label $next\_arg\_[s]\_[e_n]$, remove $e_n$;
    else
        Connect $n_p$ to $n_n$ with edge label $[s]\_[e_n]$, remove $e_n$;
    end
Procedure BridgePlaceholderAndElement ($p$)
    Find the corresponding edge and node of $p$ as $e_p$ and $n_p$;
    if no correspondings found then return;
    if The nearest previous element $n_e$ exist then
        Connect $n_p$ to $n_e$ with edge $next\_arg\_[e_p]$
    else
        Find the nearest next element $n_e$, connect $n_p$ to $n_e$ with edge $prev\_arg\_[e_p]$
    end
Procedure ProcessSymbolNode ($n$)
    Get the children set $C = \{c_j\}_{j=1}^{k}$ of $n$ and the corresponding edge set $\{e_j\}_{j=1}^{k}$;
    if $|C|$ = 1 then
        Connect parents of $n$ with the only child $c_1$ with label $[n]$; Remove $n$;
    else
        Compute $l = \max(L[c]$ for $c$ in $C) + 1$;
        Connect $c_{j-1}$ to $c_j, j > 1$ with edge $[n]\_l\_[e_j]$; Remove $e_j, j > 1$;
        Add suffix $\_[n]\_l\_[e_1]$ to all parent edge labels of $n$;
        Replace $n$ with $c_1$, preserving all edge connection;
    end
```

ReACC: A Retrieval-Augmented Code Completion Framework

Abstract

Code completion, which aims to predict the following code token(s) according to the code context, can improve the productivity of software development. Recent work has proved that statistical language modeling with transformers can greatly improve the performance in the code completion task via learning from large-scale source code datasets. However, current approaches focus only on code context within the file or project, i.e. internal context. Our distinction is utilizing "external" context, inspired by human behaviors of copying from the related code snippets when writing code. Specifically, we propose a retrieval-augmented code completion framework, leveraging both lexical copying and referring to code with similar semantics by retrieval. We adopt a stage-wise training approach that combines a source code retriever and an auto-regressive language model for programming language. We evaluate our approach in the code completion task in Python and Java programming languages, achieving a state-of-the-art performance on CodeXGLUE benchmark.

1 Introduction

With the growth of software engineering field, large-scale source code corpus gives a chance to train language models in code domain (Hindle et al., 2016; Tu et al., 2014). And benefiting from the large transformer models (Vaswani et al., 2017) and pre-training techniques (Devlin et al., 2018; Radford et al., 2018), a rapid progress has been made in many code-related tasks like code search (Feng et al., 2020; Guo et al., 2020), code summarization (Clement et al., 2020; Ahmad et al., 2020), bug fixing (Mashhadi and Hemmati, 2021; Drain et al., 2021) and code completion (Svyatkovskiy et al., 2020; Liu et al., 2020; Kim et al., 2021; Clement et al., 2020).

Code completion is considered as an essential feature towards efficient software development in modern Integrated Development Environments (IDEs). The task is formulated by predicting the following code token(s) based on the code context. Traditionally, code completion requires real-time program analysis and recommends type-correct code tokens (Tu et al., 2014). Recently, statistical language models trained on large-scale source code data have shown high accuracy in the code completion task. Primitive approaches take the given context only (Liu et al., 2016; Karampatsis et al., 2020), some methods use richer information, e.g., adding code token types (Liu et al., 2020), abstract syntax tree (AST) structures (Li et al., 2018; Kim et al., 2021), or extended hierarchical context (Clement et al., 2021). However, one key limitation of existing methods is the scope of information they utilize; all the information is bounded in the given input file. This is unnatural from human perspective, as studies demonstrate that programmers tend to reuse an existing code snippet by copying part of code with or without minor modifications to accelerate software development (Roy and Cordy, 2008; Baker, 2007), leading a software repository usually containing 7-23% cloned codes (Svajlenko and Roy, 2015).

Motivated by this phenomenon, in this paper, we argue the utility of extending the information scope beyond the input file, i.e., into a large codebase. We conjecture that using codes with similar semantics as auxiliary information are beneficial to predict the following code tokens. Therefore, we propose ReACC – a **Re**trieval-**A**ugmented **C**ode **C**ompletion framework (See Figure 1). The code completion task under our framework can be re-formulated by, given a source code corpus for search and an unfinished code snippet to complete, using the unfinished code as a query to retrieve similar code snippets from search corpus, and predicting the following code tokens by reusing the

```

Figure 1: An illustration of ReACC framework. Given an unfinished code snippet to complete, ReACC first retrieves the similar code from source code database. Then the similar code is concatenated with the unfinished code, the completed code will be generated based on them.

retrieved code. ReACC consists of two core components: (1) a dual-encoder model served as the code-to-code search **retriever** (2) an auto-regressive language model served as the code completion **generator**. ReACC adopts the stage-wise training strategy which is widely used in other tasks like open-domain question answering (Karpukhin et al., 2020; Izacard and Grave, 2021), natural language to code generation (Hashimoto et al., 2018; Parvez et al., 2021), etc.

The simplest technique for retrieving code is to build a sparse vector retriever like TF-IDF or BM25 (Robertson and Zaragoza, 2009) which are both based on keyword matching algorithms. The sparse retriever can capture lexical information and is sensitive to the names of code identifiers. The dense retriever, on the contrary, can capture syntactic and semantic information by mapping a code snippet to a dense vector. In the code completion task, the code retriever is expected to comprehend the source code's intent in order to retrieve the semantically similar codes. On the other hand, considering programmers are prone to copy-and-paste existing code, the retriever should evaluate lexical similarity as well. To that end, we adopt the hybrid retriever (Karpukhin et al., 2020; Ma et al., 2021), which combines results of dense and sparse retriever. We employ a dual-encoder model architecture as the dense retriever since the cross-encoder model has a high computational complexity. To achieve a better understanding ability, we initialize our dense retriever with GraphCodeBERT (Guo et al., 2020), which is a pre-trained BERT-based programming language understanding model. Then we continue pre-training the retriever by contrastive learning to enhance sentence embedding. As the labeled data containing similar code pairs is rare, we utilize various transformations to generate programs with similar functionality for data augmentation.

We implement the generator with a decoder-only transformer model. To incorporate the external information from retrieved similar code, we concatenate the obtained code and code context as input. The generator is initialized by CodeGPT-adapted (Lu et al., 2021) which is a domain-adaptation model from GPT-2 (Radford et al., 2018) pre-trained on code corpus.

We evaluate our ReACC framework on two benchmark datasets – CodeXGLUE (Lu et al., 2021) and CodeNet (Puri et al., 2021), in Python and Java programming languages. ReACC achieves a state-of-the-art performance on both datasets. The experimental results demonstrate that external source code retrieved by our retriever is useful for auto-completing the partial code.

To summarize, our main contributions are:

- We propose a retrieval-augmented method to assist the code auto-completion task. [1]
- To adapt to the code completion scenario, where the retrieval query is an unfinished code snippet, we propose the partial code-to-code search task and create datasets for evaluation.
- We adopt semantic-preserving transformations for data augmentation to pre-train the code retrieval model.

2 Related Work

2.1 Code completion

Code completion is an essential task for code intelligence. Hindle et al. (2016) are the first to use language model for code completion by N-gram technique. Deep neural networks (Liu et al., 2016; Alon et al., 2020; Karampatsis et al., 2020) and pre-training approaches (Liu et al., 2020; Svyatkovskiy et al., 2020) are later frequently utilized to accomplish this. Besides considering source code as code token sequences, some research focuses on completing an abstract syntax tree (AST) by anticipating the next node in the flattened tree (Li et al., 2018; Kim et al., 2021). Guo et al. (2021) complete codes by generating sketches, i.e. code snippets with "holes". Svyatkovskiy et al. (2021) and Clement et al. (2021), on the other hand, investigate ways to improve the efficiency and long-range modeling in the code completion task, respectively.

All of these works employ previously written code context as inputs, along with AST structural information or token types. But none of them has attempted to leverage existing external code as auxiliary information.

2.2 Retrieval on code intelligence

Contrastive learning on code Inspired by the great success of contrastive learning in other domains (Wu et al., 2018; Reimers and Gurevych, 2019; Fang et al., 2020; Chen et al., 2020; He et al., 2020; Radford et al., 2021; Gao et al., 2021), researchers have deployed this technique to source code for better code fragment understanding. Jain et al. (2020) and Bui et al. (2021) propose ContraCode and Corder, respectively. Both models use the self-supervised contrastive learning framework and generate code snippets as data augmentations via compiler-based semantic-preserving transformations. Their models have shown the effectiveness of contrastive learning in code clone detection, code search and code summarization tasks. SYNCOBERT (Wang et al., 2022) and UniXcoder (Guo et al., 2022) are both pre-training models that utilize multi-modal data, including code, comment, and AST, for better code fragment representation through contrastive learning.

Retrieval for code-related tasks Many code intelligence tasks benefit from information retrieval (Xia et al., 2017). A common scenario for information retrieval in code domain is code search with natural language description as a query (Arwan et al., 2015; Gu et al., 2018; Cambronero et al., 2019). As for other code intelligence tasks, Hayati et al. (2018) propose an action subtree retrieval method called ReCode for generating general-purpose code. Hashimoto et al. (2018) propose a retrieve-and-edit framework for code autocompletion and code generation. Luan et al. (2019) propose Aroma, which utilizes code-to-code structural search and intersecting candidate code snippets to recommend relevant code given another code snippet as a query. Both Wei et al. (2020) and Li et al. (2021) leverage the retrieve-and-edit/refine framework to improve model's performance in code summarization. Parvez et al. (2021) propose REDCODER, using a dense retriever trained on paired NL-code pairs to retrieve relevant comments or codes as a supplement for code summarization or code generation tasks.

In most circumstances where a dense retriever is utilized, a natural language comment is treated as a query to retrieve code. In the code completion scenario, however, we focus on using code as query, particularly partial code, which is a more difficult task since there are few labeled data with semantically similar code pairs and in partial code search, semantics in query is incomplete.

3 Approach

We first introduce the formulation of retrieval-augmented code completion task. Then we give detailed descriptions on the retriever and generator in ReACC. We show how we continue pre-training GraphCodeBERT (Guo et al., 2020) with contrastive learning on code and how we address the problem that there is no labeled data for positive instances of similar programs in section 3.2. In section 3.3 we talk about the way to aggregate retrieved code and code context in the generator.

3.1 Task Formulation

Assume that we have a source code database containing a large collection of software repositories, which consist of D source code files, $f_1, f_2, ..., f_D$. Following the Dense Passage Retriever (DPR) model (Karpukhin et al., 2020), we split each of the files into code fragments of equal lengths as the basic retrieval units. Such splitting not only leads to a better retrieval results as stated by Karpukhin et al. (2020), but also supports extreme long code files where each part of a file represents differ-

ent semantics. Thus we get M code fragments as the retrieval database $C = \{c_1, c_2, ..., c_M\}$. Let $X = \{x_1, x_2, ..., x_k\}$ be the unfinished code written previously, a retriever $\mathbf{R} : (X, C) \rightarrow C$ retrieves the most similar code fragment c_s in C. The generator $\mathbf{G}$ predicts the following code token(s) $Y = \{x_{k+1}, ..., x_{k+n}\}$, where $n = 1$ in the token-level code completion task, based on context and retrieved code. Formally, $P(Y) = \prod_{i=1}^{n} P(x_{k+i}|c_s, x_{1:k+i-1})$.

3.2 Retriever

The retrieval module in ReACC is expected to retrieve semantically equivalent code given an incomplete code. We adopt the hybrid retriever (Karpukhin et al., 2020; Ma et al., 2021) framework by combining scores of sparse and dense retriever. The sparse retriever we use is BM25 (Robertson and Zaragoza, 2009) based on the implementation of ElasticSearch[2]. As a term-based retrieval method, BM25 considers each code fragment as a code token sequence and employs bag-of-words representations. The matching score computed by BM25 indicts lexical similarity between the query and document. As for the dense retriever, it maps each code fragment to a d-dimension dense vector. We construct it in this paper based on the DPR model (Karpukhin et al., 2020). Figure 2 illustrates the training process of the dense retriever of ReACC. In the following, we will walk through it in detail.

Dense Retriever Our dense retriever consists of two bidirectional transformer-based encoders E_C and E_Q. E_C encodes each code fragment in the retrieval database C and builds indexes for them. The query is encoded by E_Q. We take the representation of `[CLS]` token as output and the similarity is computed by $sim(q, c) = E_C(c)^T E_Q(q)$. Since both E_C and E_Q take source code as inputs with the only difference being whether they are partial or not, the dual encoders share weights in ReACC. At the training stage, following DPR (Karpukhin et al., 2020), we adopt in-batch negatives to calculate the contrastive loss by InfoNCE (Oord et al., 2018):

$$\begin{aligned} & L(q, c^+, c_1^-, c_2^-, ..., c_m^-) \\ = & -log \frac{e^{sim(q,c^+)}}{e^{sim(q,c^+)} + \sum_{i=1}^{m} e^{sim(q,c_i^-)}} \end{aligned} \tag{1}$$

However, unlike DPR, we don't employ "hard" negatives which are retrieved from BM25. Because programmers tend to copy tokens directly, a code with distinct semantics but substantial lexical similarity can help with code completion.

Data Augmentation The purpose of contrastive learning of the dense retriever in ReACC is to learn a representation of code fragments that keeps codes with similar or equivalent semantics close and dissimilar codes far apart. It requires numerous positive and negative code pairs. However, it is difficult to identify similar programs based on an unlabeled code corpus, e.g., certain widely used datasets (Allamanis and Sutton, 2013; Raychev et al., 2016; Husain et al., 2019) mined from GitHub repositories.

Searching semantically equivalent code requires extra code compilation and execution costs (Massalin, 1987; Churchill et al., 2019), which is unrealistic in a large database. Instead of searching, an alternative way is to create code snippets with same functionalities for data augmentation. To do so, we apply several semantic-preserving transformations to the original source code to construct a set of variants. There exists several attempts to apply such transformation to code (Jain et al., 2020; Rabin et al., 2021; Bui et al., 2021). In this paper, we mainly adopt identifier renaming and dead code (unreachable or unused code) insertion. Figure 3 shows an example of performing such transformations to a Python code.

- **Identifier renaming** is a method of renaming an identifier with another. We only rename variable and method names as other identifiers cannot be changed arbitrarily like built-in types or API calls. Different from previous works, we preserve

original python code

After renaming all variables

After inserting dead code

Figure 3: An example of applying semantic-preserving transformations to Python code.

part of the lexical information while modifying the names at the same time based on the consideration that identifier names typically convey the meanings for humans and lexical similarity contributes a lot for retrieving (It is verified in section 4.4). To do so, we mask all the identifiers in a program and leverage GraphCodeBERT (Guo et al., 2020) to predict each identifier like in the masked language model task. The top-10 predictions (excluding the original identifier) are selected as the candidate set for renaming.

- **Dead code insertion** is to insert a dead code into a code fragment at a proper location. Dead code is a code snippet which can never be reached (Xi, 1999) or is reachable but whose result can never be used in any other computation (Debray et al., 2000). In software engineering, dead code insertion is one of the most common techniques for code obfuscation (You and Yim, 2010), whose goal is to modify a code to make it hard to understand but remain its functionality, which is similar to our goal. We first randomly select variable names which don't appear in this program and then use them to form a statement from a predefined set of dead code (See Appendix A for details), such as assignment, method invocations, looping statement, conditional statement and so on. We traverse the AST and identify all the statements. Then we choose a statement at random and insert the dead code after it, leading a new subtree in the AST.

Input Format We integrate both the code token sequence and the API usage sequence as inputs. API usage sequence is highly related to the functionality of a code snippet (Gu et al., 2016; Hu et al., 2018). To improve the code representation, we extract the API sequence and append it to the source code token sequence. Finally, we use a random truncation of the original code as the query and the entire created program as the positive example during training to address the problem on how to retrieve based on incomplete semantics.

3.3 Generator

The output of retriever is the retrieved code c_s. Considering c_s is queried by code context x while our target is the following code of x, so we propose *fragment alignment* – using the next fragment c'_s of c_s in the same file (we have split each file into code fragments for retrieval as discussed in Section 3.1) for completing the next fragment of x. Thus, the input sequence for the generator is the concatenation of c'_s and x: $x' = c'_s \oplus x$.

The generator module in ReACC supports any model architecture that can perform code completion task. In our experiments, we adopt CodeGPT-adapted (Lu et al., 2021), which is a decoder-only transformer model pre-trained on Python and Java datasets from CodeSearchNet (Husain et al., 2019) via casual language model. CodeGPT-adapted has shown promising results in the code completion task in CodeXGLUE benchmark (Lu et al., 2021) on two widely used code completion datasets.

4 Experiments: Code Clone Detection

In order to evaluate the effectiveness of the code-to-code retrieval module in ReACC, we perform code clone detection task which aims to retrieve semantic equivalent programs. In this section, we describe how we create the test dataset for this task and how we evaluate the performance of ReACC's retriever.

4.1 Dataset

CodeNet (Puri et al., 2021) dataset consists of a large collection of programs which are derived from online judge websites. We respectively create a code clone detection evaluation dataset from CodeNet in Python and Java with zero-shot setting.

Dataset	Language	Task	Train	Valid	Test	Desc.
CodeNet (Puri et al., 2021)	Python	Clone	-	-	15,594	Solutions for 2,072 problems
	Java	Clone	-	-	14,426	Solutions for 1,599 problems
	Python	Completion	2,636,118	32,984	10,000	For line-level completion
CodeXGLUE (Lu et al., 2021)	Python	Completion	95,000	5,000	50,000 / 10,000	Use PY150
	Python†	Completion	95,000	5,000	- / 20,000	Applying eWASH
	Java	Completion	12,934	7,176	8,268 / 3,000	Use JavaCorpus

Table 1: Dataset statistics. The two numbers in **Test** of CodeXGLUE denote the examples for token-level and line-level code completion, respectively. † is a newly created test set, see the text for details.

We collect code solutions for thousands problems and solutions for the same problem are considered as semantically equivalence. The data statistics are shown in Table 1.

Retrieval Training Set The dense retriever in ReACC is pre-trained on CodeSearchNet dataset (Husain et al., 2019), a large-scale source code corpus extracted from GitHub repositories. We employ 1.6M Java methods and 1.2M Python functions from it.

4.2 Baseline Methods

CodeBERT (Feng et al., 2020) is a pre-trained model for programming language, which is trained on NL-PL pairs from CodeSearchNet dataset in six programming languages.

GraphCodeBERT (Guo et al., 2020) is also pre-trained on CodeSearchNet NL-PL pairs and considers the inherent structure of code i.e. data flow.

4.3 Experiment Setup

The retrieval encoder is initialized with GraphCodeBERT. It is continual pre-trained with both masked language model objective and contrastive learning. We use in-batch negatives with a batch size of 256. With a learning rate of 5e-5, We train the retriever for Python and Java for 30 epochs each.

We implement the code clone detection experiment in the *partial search* way, which is ideally adapted to code completion scenarios as it accepts a partial program as a query while maintaining the same goal.

4.4 Results

Table 2 shows the results in the zero-shot code clone detection task on CodeNet dataset, with the *partial search* setting. Models are measured by MAP@K (Mean Average Precision at K), which is the evaluation metric in the CodeXGLUE clone detection task, and precision at 1, as we only care about the most similar code for code completion. From the comparison with other transformer-based encoders, we can see CodeBERT and GraphCodeBERT can hardly retrieve equivalent code. While our model significantly outperforms them, which indicts our model is capable of retrieving the semantically equivalent code even when the query's semantics is incomplete.

We also find that BM25 performs splendidly in this task, which is quite different from the performance on other tasks like open-domian QA (Karpukhin et al., 2020), code summarization (Parvez et al., 2021), etc. The findings suggest that semantically related codes are likely to be lexically similar, which leads lexical similar to contribute more for retrieval, making code-to-code search easier than text-to-code or question-to-passage search using the term-based retrieval method.

5 Experiments: Code Completion

In this section, we evaluate ReACC on end-to-end code completion.

5.1 Dataset

CodeXGLUE (Lu et al., 2021) is a benchmark dataset containing 14 datasets for 10 diversified code intelligence tasks. We use PY150 dataset (Raychev et al., 2016) in Python and GitHub Java Corpus dataset (Allamanis and Sutton, 2013) in Java from it for code completion task. Table 1 shows the data statistics.

5.2 Baseline Methods

CodeGPT/CodeGPT-adapted (Lu et al., 2021) are both pre-trained on Python and Java datasets from CodeSearchNet. CodeGPT is trained from scratch while CodeGPT-adapted is a domain adaptation model which is initialized by GPT-2 (Radford et al., 2019).

PLBART (Ahmad et al., 2021) is based on BART (Lewis et al., 2020) architecture which employs denoising sequence-to-sequence (Seq2Seq)

Model	Python		Java	
	MAP@100	Precision	MAP@100	Precision

ReACC-dense	39.67	71.80
ReACC-hybrid	40.15	**72.01**

Table 4: Results on the new testset created from PY150 in CodeXGLUE

pre-training and is pre-trained on unlabeled data across PL and NL.

CodeT5 (Wang et al., 2021) is also an encoder-decoder pre-trained model which adapts T5 (Raffel et al., 2019) architecture and considers the identifier-aware token type information in code.

X-CodeGPT is a variant of CodeGPT which adapts eWASH (Clement et al., 2021) to CodeGPT. Clement et al. (2021) propose eWASH, a method for leveraging the syntax hierarchy of source code to give the model wider field of vision in a file and achieving a new SOTA performance on the CodeXGLUE code completion task. We reproduce their method and develop X-CodeGPT by adapting eWASH to CodeGPT-adapted.

5.3 Experiment Setup

Fine-tune We fine-tune CodeGPT-adapted on PY150 and GitHub Java Corpus datasets, respectively, and use it as the generator in ReACC. The number of epochs for training PY150 is 30 and Java Corpus is 10, with a batch size of 96 and a learning rate of 2e-5. Except for X-CodeGPT, all other baseline models are fine-tuned with the same settings.

As for X-CodeGPT, we pre-train it with a training set extracted from CodeSearchNet in eWASH format, where each example is a function body with its corresponding extended context, as described by Clement et al. (2021). Since eWASH requires codes parsed into ASTs but codes in CodeXGLUE have been tokenized and cannot be parsed, we build a new dataset from PY150 to fine-tune X-CodeGPT on CodeXGLUE. As a result, we download the origin files in PY150 and create a new dataset that retains the train/valid/test split, as seen in Table 1.

Evaluation Following Lu et al. (2021), we conduct two code completion scenarios, token-level and line-level completion, to measure models' ability of predicting one and more tokens. Perplexity is the evaluation metric for token-level completion, whereas exact match accuracy (EM) and edit similarity are used for line-level completion. For token-level completion, based on the consideration of efficiency, instead of applying retrieval at each step, we retrieve similar codes based on current context after predicting the first 100 tokens, and leverage it for further prediction.

Retrieval Database We use the training set of PY150 and Java Corpus as retrieval database for test. We don't use the contrastive pre-training corpus (i.e., CodeSearchNet) in order to avoid the duplication between CodeXGLUE and CodeSearchNet as they are both extracted from GitHub.

	Exact Match	Edit Sim
CodeGPT-adapted	46.38	74.10
ReACC-bm25	55.88	79.62
ReACC-dense	64.21	84.57
ReACC-hybrid	**64.74**	**84.93**

Table 5: Results on the code completion task created from CodeNet Python dataset

Hybrid Retriever A linear combination of scores from BM25 and our dense retriever forms a hybrid retriever. Specifically, we calculate the score by $sim(q, c) + \alpha \cdot BM25(q, c)$ and let $\alpha = 0.9$ based on the results on dev set for both PY150 and Java Corpus datasets.

5.4 Results

Table 3 and Table 4 compare different baseline models on code completion task in the CodeXGLUE Python and Java datasets. ReACC framework with the hybrid retriever outperforms consistently than other baselines on all datasets, which proves our conjection that the "external" context is beneficial to the code completion task. The comparison with X-CodeGPT in Table 4 demonstrates that utilizing "external" context could be more useful than making the most of the current code file. Among three configurations of the retriever in ReACC, hybrid retriever performs best on almost all metrics except the exact match score in the new test set of PY150.

From Table 3, we can observe that comparing the two datasets, the improvement in the PY150 dataset is greater than that in the Java Corpus dataset. The reason for this is that the retrieval database for Java (i.e., the training set) is much smaller. The CodeXGLUE Java Corpus dataset contains only 12,934 files for training so that it's more difficult to retrieve similar code from them.

Another finding is that BM25 shows comparable results with dense retriever and even performs better in perplexity and exact match metrics. The findings indict that the code completion task can benefit from both semantically and lexically similar codes.

5.5 Analysis

ReACC in specific domain Both PY150 and Java Corpus datasets are extracted from GitHub repositories which are distributed in a wide domain. As some people frequently write codes in a more specific domain, e.g., data mining/pattern recognition domain for Kaggle[3] users, algorithm domain for ACM community, etc. To evaluate ReACC in a specific code domain, we construct a code completion Python dataset from CodeNet, which can be considered in algorithm domain. Table 5 reveals that ReACC significantly outperforms CodeGPT-adapted in CodeNet by 10% and 18% absolute improvement in edit similarity and exact match, respectively. According to the findings, ReACC is more effective in a specific domain. We also notice that ReACC with dense retriever outperforms BM25 significantly in CodeNet. It can be explained by the fact that in algorithm domain, semantically similar code may be more valuable than for code completion lexically similar code.

	EM	Edit Sim
ReACC-dense	**45.32**	**73.95**
Retriever		
- identifier renaming	44.91	73.14
- dead code insertion	45.11	73.57
- API sequence	44.77	73.01
- query truncation	43.93	72.65
Generator		
- fragment alignment	45.08	73.56

Table 6: Ablation study for both retriever and generator module. Experiments are run in CodeXGLUE PY150 dataset.

Ablation study To further understand how our training options affect model performance, we conduct ablation experiments. As seen in Table 6, when data argumentation and training strategies in retriever or generator are eliminated, the metrics degrade. The most essential factor among them is query truncation. Comparing the two semantic-preserving transformations, identifier renaming contributes more than dead code insertion.When fragment alignment is removed from generator, i.e. using the retrieved code snippet itself for generator, performance suffers slightly.

ReACC vs GitHub Copilot GitHub Copilot[4] is a powerful technique for code completion which uses OpenAI Codex (Chen et al., 2021) as the model backend. We run some qualitative examples with its extension in VSCode, which are shown in the Appendix B. It worth noting that Codex is more powerful than CodeGPT since it is a large-scale pre-trained model that is trained on all source codes in GitHub based on GPT-3 (Brown et al., 2020). However, in some cases, ReACC with CodeGPT as

---

[3] https://www.kaggle.com/

[4] https://copilot.github.com/

the generator outperforms Copilot. And in 6 Copilot itself can benefit from ReACC when it takes advantage of ReACC's retriever, which indicates the effectiveness of retrieval-augmented method for strong generative models.

6 Conclusion

We propose ReACC, a retrieval-augmented code completion framework that utilizes "external" context for the code completion task by retrieving semantically and lexically similar codes from existing codebase. We pre-train a dual-encoder as a retriever for partial code search, which retrieves code fragments given a partial code. Our method can adopt any architecture that can perform code completion as the generator. On the CodeXGLUE benchmark, ReACC achieves a state-of-the-art performance in the code completion task.

A Predefined Dead Code

We define a set of dead code to choose from for both Python and Java. We focus on four kinds of common statements, i.e., declaration statement, expression statement, conditional statement and looping statement. Examples are shown in figure 4. To generate a dead code snippet, we can use one kind of them or combine different statements together.

B Qualitative Examples

Figure 5 and figure 6 show qualitative examples of generated code by different models. ReACC + Copilot denotes ReACC framework with Copilot as the generator.

Category	Python	Java
Declaration	`var1 = 1`	`int var1 = 1;`
	`var1, var2, var3 = 1, [2,3], "name"`	`String var2 = "abc";`
		`int[] var3;`
Expression	`var1+var2`	`var1 += 2;`
	`var2.extend(var3)`	`var2.append("def");`
	`sorted(var2)`	`var3[0]--;`

Conditional statement	`var1 = 1`
	`if var1 < 10:`
	`    # several random simple statements here`
	`else:`
	`    # statements here`
		`int var = 4;`
		`if (var1 < 10){`
		`    // compound statement`
		`}`

	`var1 = 1 if True else 2`

Does Recommend-Revise Produce Reliable Annotations? An Analysis on Missing Instances in DocRED

Abstract

DocRED is a widely used dataset for document-level relation extraction. In the large-scale annotation, a *recommend-revise* scheme is adopted to reduce the workload. Within this scheme, annotators are provided with candidate relation instances from distant supervision, and they then manually supplement and remove relational facts based on the recommendations. However, when comparing DocRED with a subset relabeled from scratch, we find that this scheme results in a considerable amount of false negative samples and an obvious bias towards popular entities and relations. Furthermore, we observe that the models trained on DocRED have low recall on our relabeled dataset and inherit the same bias in the training data. Through the analysis of annotators' behaviors, we figure out the underlying reason for the problems above: the scheme actually discourages annotators from supplementing adequate instances in the revision phase. We appeal to future research to take into consideration the issues with the recommend-revise scheme when designing new models and annotation schemes. The relabeled dataset is released at `https://github.com/AndrewZhe/Revisit-DocRED`, to serve as a more reliable test set of document RE models.

1 Introduction

Relation Extraction (RE) is an important task which aims to identify relationships held between entities in a given piece of text. While most previous methods focus on extracting relations from a single sentence (Lin et al., 2016; Zhang et al., 2018), recent studies begin to explore RE at document level (Peng et al., 2017; Zeng et al., 2020; Nan et al., 2020; Huang et al., 2021; Zhang et al., 2021), which is more challenging as it often requires reasoning across multiple sentences.

The rapid development of document-level RE in the past two years has benefited from the proposal of DocRED (Yao et al., 2019), the first large-scale and human-annotated dataset for this task. Noticeably, longer documents introduce an unprecedented difficulty in annotating the relation instances: as the total number of entities dramatically increases in accordance to text length, the expected number of *entity pairs* surges *quadratically*, intensively increasing the workload to check relationships between every pair. To address this problem, Yao et al. (2019) applies a *recommend-revise* process: in the *recommendation* phase, a small set of candidate relation instances is generated through distant supervision; then, annotators are required to *revise* the candidate set, removing the incorrect relation instances and supplementing the instances not identified in the recommendation phase.

Shifting the construction process from scratch to an edit-based task, it seems that the recommend-revise scheme cuts down the effort of annotating by a large margin. However, whether the *quality* of the annotation maintains a reliable standard in practice remains in doubt. To what extent can the accuracy of annotation be sacrificed due to the automated recommendation? And, how does the provided recommendation affect the behaviours of the annotators in the revision phase? Moreover, what are the real effects on the models trained on a dataset annotated with this scheme?

To answer these questions, we aim to provide a thorough comparison between careful annotations from scratch and the annotations under the recommend-revise scheme. We randomly select 96 documents from DocRED and ask two experts to relabel them from scratch independently. After annotating, the two experts come to a consensus of gold labels via discussion. This revised dataset is publicly available at `https://github.com/AndrewZhe/Revisit-DocRED`, and we hope it can be used to evaluate the model's perfor-

mance on real data distribution[1]. With the help of these annotations, we discovered three sobering issues regarding the effects of the recommend-revise scheme:

(1) A noticeable portion of relation instances is left out, and the distributional bias in the recommendation output is inherited, even after the revision process. It is not surprising that recommendations alone fail to recognize all the relation instances, since RE models are far from perfect. Ideally, these unidentified instances should be added by human annotators during the revision phase. However, it turns out that 95.7% of these missing instances are still left out even after revision. Furthermore, while the recommendations from distant supervision favor instances associated with popular entities and relations in the source Knowledge Base (Wikidata), this bias is still maintained and inherited even after human revision, leaving less popular relations and entities to be neglected.

(2) Worryingly, we find the models trained on DocRED have low recall on our relabeled dataset and they also inherit the same bias towards popular relations and entities. We train recent models on DocRED and test them with the dataset relabeled by us. We notice that all models have much lower recalls on our dataset than previously reported on DocRED due to the numerous false negatives in training data, and those models are also biased to popular entities and relations. Further investigation reveals that the models' bias comes from the training set by comparing different strategies of negative sampling. Since one straightforward real-world application of relation extraction is to acquire novel knowledge from text, a RE model would be much less useful if it has a low recall, or perform poorly on less popular entities and relations.

(3) The recommendations actually also impacts the behaviors of annotators, making them unlikely to supplement the instances left out. This is the underlying reason for the two concerns above. We argue that the revision process fails to reach its goal, since it puts the annotators in a dilemma: while they are supposed to "add" new instances left out by the recommendations, finding these missing instances may force the annotators to thoroughly check out the entities pair-by-pair, which is time-consuming and against the goal of this scheme. As a result, annotators can hardly make effective supplementation and would tend to perform the easier goal of *validating existing relation instances*.

2 Recommend-Revise Annotation Scheme

The major challenge for annotating document-level RE datasets comes from the quadratic number of potential entity pairs with regard to the total number of entities in a document. As reported by Yao et al. (2019), a document in DocRED contains 19.5 entities on average, thus rendering 360 entity pairs with potential relationships. Therefore, for the 5,053 documents to be annotated, around 1,823,000 entity pairs are to be checked. Such workload will be around 14 times more than TACRED (Zhang et al., 2017), the biggest human-labeled sentence-level RE dataset. Therefore, exhaustively labeling relations between each entity pair involves intensive workload and does not seem feasible for document-level RE datasets.

To alleviate the huge burden of manual labeling, Yao et al. (2019) divides the annotation task into two steps: *recommendation* and *revision*. First, in the *recommendation* phase, Yao et al. (2019) takes advantage of Wikidata (Vrandecic and Krötzsch, 2014) and an off-the-shelf RE model to collect all the possible relations between any two entities in the same document. This process is automated and does not require human involvement. Then, during the *revision* phase, the relations that exist in Wikidata or are inferred by the RE model for a specific entity pair will be shown to the annotators. Rather than annotating each entity pair from scratch, the annotators are required to review the recommendations, remove the incorrect triples and supplement the missing ones.

3 Dataset

DocRED The *Document-Level Relation Extraction Dataset* (DocRED), introduced by Yao et al. (2019), is one of the largest and most widely used dataset for document-level relation extraction. DocRED consists of 5,053 English Wikipedia documents, each containing 19.5 entities on average. Every entity pair within a document may have one of the 96 types of relations or no relations, i.e., the additional *no_relation* label for negative instances. In order to explore the supplementation in the re-

---

[1] While we cannot guarantee that the relabeled data is totally error-free, we believe the quality is high enough to be approximated as a real distribution because each entity pair is examined by two annotators.

vision phase and the influence of it on the released dataset, we acquire the original recommendations generated by distant supervision from the authors of DocRED. As we focus on the effect of missing instances, we do not consider the samples removed during the revision phase. The remaining annotations in the recommendations that are not removed later are denoted as $\mathbf{D_{Recommend}}$, and the annotations after human revision are denoted as $\mathbf{D_{Revise}}$.

DocRED from scratch To analyze the effect of the recommend-revise scheme, we re-annotate a subset of the documents used in DocRED from scratch and compare it with $\mathbf{D_{Recommend}}$ and $\mathbf{D_{Revise}}$. We randomly select 96 documents from the validation set of DocRED, and each document is assigned to two experts to be annotated independently. They are explicitly required to check every entity pair in the documents and decide the relationships entirely based on the original text with no recommendation. This turns out to be an extraordinarily difficult task where each document takes up half an hour for annotation on average. The inter-annotator Cohen's Kappa is 0.68 between our two experts, indicating a high annotation quality. After that, the two experts discuss the inconsistent instances together and reach an agreement on the final labels. As this paper focuses on the bias caused by *false negatives* in the recommend-revise scheme, we assume the labeled instances in DocRED are all correct.

For the instances labeled in DocRED but not by our experts, we add them to our annotation. We denote this new annotation set as $\mathbf{D_{Scratch}}$.

4 Dataset Comparison

Table 1 shows the statistics and comparison of $\mathbf{D_{Scratch}}$, $\mathbf{D_{Recommend}}$ and $\mathbf{D_{Revise}}$ on the 96 randomly-selected documents in DocRED.

4.1 False Negatives in Recommendation

Comparing $\mathbf{D_{Recommend}}$ with $\mathbf{D_{Scratch}}$, it is noticeable that huge amounts of ground-truth annotation labels are left out. While $\mathbf{D_{Recommend}}$ captures 1167 relation instances in the documents, a more careful, entity-by-entity examination as did in $\mathbf{D_{Scratch}}$ would reveal that there are as much as 3308 relation instances within the same documents. This shocking fact reveals that almost two-thirds of the relation instances are missing and wrongly labeled as negative.

Another unexpected fact is that annotators hardly added anything during the revision phase. The final version reports 1214 relation instances, with a mere increase of 47 (1.4%) cases in total, or 0.49 instances on average for each document. This suggests that while we had great hopes of our revision process to make things right, it is not working to a sensible extent: the majority of the unlabeled instances, which take up nearly two-thirds of the instances, simply remain out there as they were.

4.2 Dataset Bias

Given the analysis above, another even more serious issue arises: since the changes introduced by the revision are so limited, the output after revision may still contain the same bias as in the recommendation. That is, if the recommendations contain a systematic flaw, the new dataset will probably keep on inheriting it. In this section, we verify that such biases largely exist in the recommendation phase and are thus inherited to the DocRED dataset.

The recommendations of DocRED are collected from two sources: Wikidata and a relation extraction model. However, if we consider the facts reserved after revision by annotators, where wrongly labeled ones get removed, the majority of them are taken directly from Wikidata[2].

We suggest that as a collaborative knowledge base, the relation instances related to common entities and properties are more likely to be collected and added to Wikidata. In such cases, the recommendation from Wikidata will naturally favor popular entities and relations, while the less common ones would be left out. We validate this hypothesis in the following sections, where we investigate the bias of DocRED from the perspective of both relations and entities.

4.2.1 Bias of Relations

To determine whether the data set has a preference for popular relationships, we divide the 96 relationships in DocRED into two categories using Wikidata statistics and then compute their distribution. Specifically, we acquire the *List of top 100 properties by quantity of item pages that link to them* from Wikidata's official website[3] and consider a relation as popular if it appears on this list. Among the 96 relationships in DocRED, 25 are in top 100,

---

	# Instance	# Pop Rel	# Unpop Rel	$popularity_{max}$	$popularity_{min}$
$\mathbf{D_{Recommend}}$	1167	659 (56.5%)	508 (43.5%)	294.4	85.2
$\mathbf{D_{Revise}}$	1214	676 (55.7%)	538 (44.3%)	291.5	84.4
$\mathbf{D_{Scratch}}$	3308	1615 (48.8%)	1693 (51.2%)	266.3	67.4
$\mathbf{D_{Revise}} - \mathbf{D_{Recommend}}$	47	17 (36.2%)	30 (63.8%)	221.3	66.0
$\mathbf{D_{Scratch}} - \mathbf{D_{Recommend}}$	2141	956 (44.7%)	1185 (55.3%)	251.0	57.7
$\mathbf{D_{Scratch}} - \mathbf{D_{Revise}}$	2094	939 (44.8%)	1155 (55.2%)	251.7	57.5

Table 1: Statistics of datasets. #Instance means the total relation instance in the dataset. # Pop Rel and # Unpop Rel shows the number of instances associated with popular relations and unpopular relations respectively. The last two columns represent the average entity popularity across all the relation instances, with the *popularity*$_{max}$ indicating the higher popularity of head and tail entities in an instance, and *popularity*$_{min}$ indicating the lower one.

including *country*, *publication date*, and so on.

The center two columns of Table 1 illustrate the distribution of these two categories of relationships across multiple datasets. First, we can see that in the real distribution, i.e., in $\mathbf{D_{Scratch}}$, the percentages of these two types of relations are 48.8% and 51.2%, respectively, which is close to 1:1 with slightly *fewer* popular relations. However, the proportion of all instances belonging to the popular relationship reached 56.5% in recommendations, $\mathbf{D_{Recommend}}$, which is significantly higher than the 43.5% for unpopular ones. Further study of those instances that were mistakenly excluded during the recommendation phase, $\mathbf{D_{Scratch}} - \mathbf{D_{Recommend}}$, reveals that cases involving unpopular relationships are more likely to be missing. This demonstrates that the recommendation phase in DocRED does have a systematic bias related to the popularity of relations. The instances supplemented during the revision phase, $\mathbf{D_{Revise}} - \mathbf{D_{Recommend}}$, help to mitigate this bias marginally, whereas annotators label more instances belonging to unpopular relations. However, in comparison to $\mathbf{D_{Scratch}}$, which represents the real relation distribution, $\mathbf{D_{Revise}}$ still prefers popular relations. This is because the annotators place an excessive amount of trust in the recommendations and do not add sufficient missing instances during the revision phase. According to the statistics in the Table 1, the recommendation's bias toward the relation is ultimately inherited by the dataset that passed manual inspection.

4.2.2 Bias of Entities

We hypothesize that the instances involving very popular entities are more likely to appear in Wikidata recommendations, whereas instances related to extremely rare entities are more likely to be disregarded. To determine whether such bias exists, we analyze the popularity of entities engaged in relation instances across multiple data sets. Each named entity in DocRED is linked with a Wikidata item based on the literal matching of names or aliases[4]. The popularity of an entity is represented by how many times the matched item appears in a relation instance in Wikidata (either as head or tail); if an entity matches more than one Wikidata items, the highest count among the matched items is taken as its popularity. For those entities that cannot be linked to Wikidata, we assign a popularity of -1.

For each relation instance, we compute two types of popularities. Since an instance contains a pair of entities (head and tail) usually with different popularities, we define *popularity*$_{max}$ to be the higher popularity of the pair of entities, and *popularity*$_{min}$ to be the lower one. We report the average popularity of relation instances in each dataset in Table 1.

Comparing $\mathbf{D_{Recommend}}$ and $\mathbf{D_{Scratch}}$, we find that the former's *popularity*$_{max}$ is 294.4, far more than the latter's 266.3. This means that instances containing popular entities will be more likely to be retained during the recommendation phase. Regarding those instances that were incorrectly excluded during the recommendation phase, $\mathbf{D_{Scratch}} - \mathbf{D_{Recommend}}$, their *popularity*$_{min}$ is 57.7, which is less than the 67.4 in $\mathbf{D_{Scratch}}$. This demonstrates that instances involving uncommon entities are more likely to be ignored during the recommendation phase.

This entity-related bias is apparent in the revised data set as well. The *popularity*$_{max}$ kept by $\mathbf{D_{Revise}}$ remains larger than that of $\mathbf{D_{Scratch}}$, while the *popularity*$_{min}$ of $\mathbf{D_{Scratch}} - \mathbf{D_{Revise}}$ is also lower than that of $\mathbf{D_{Scratch}}$. This is mostly because the facts supplemented at the revision phase is too few to eliminate such bias.

---

[4] Items in Wikidata may have multiple *aliases*; we say an item is matched with an entity if any one of the aliases is the same with the entity name.

	Revise			Scratch

DocuNet	66.9	59.9	63.2	89.1	29.3	44.1

Table 2: Results for different RE models evaluated on $\mathbf{D}_{\mathbf{Revise}}$ and $\mathbf{D}_{\mathbf{Scratch}}$.

5 Model Bias

To investigate if RE models trained on such data will likewise learn the same bias, we train and select RE models on the recommend-scheme-labeled dataset, $\mathbf{D}_{\mathbf{Revise}}^{\mathbf{Train}}$ and $\mathbf{D}_{\mathbf{Revise}}^{\mathbf{Valid}}$ and then assess the models' performance on the real data distribution, $\mathbf{D}_{\mathbf{Scratch}}$. The construction process of $\mathbf{D}_{\mathbf{Revise}}^{\mathbf{Train}}$ and $\mathbf{D}_{\mathbf{Revise}}^{\mathbf{Valid}}$ is the same as $\mathbf{D}_{\mathbf{Revise}}$, while the former is actually the original train set and the latter is the validation set in DocRED excluding the 96 documents in $\mathbf{D}_{\mathbf{Revise}}$. In those settings, we examine the performance of recent models: BiLSTM (Yao et al., 2019), GAIN-BERT$_{base}$ (Zeng et al., 2020), SSAN-Roberta$_{large}$ (Xu et al., 2021), ATLOP-Roberta$_{large}$ (Zhou et al., 2021) and DocuNet-Roberta$_{large}$ (Zhang et al., 2021). The last three models are the most competitive ones for DocRED currently, while the others are shown to make sure that our analysis can generalize to models of smaller sizes.

5.1 Overall Performance

Table 2 summarizes the evaluation results of five models on $\mathbf{D}_{\mathbf{Revise}}$ and $\mathbf{D}_{\mathbf{Scratch}}$. All results were reported using micro-average F1-scores as in prior literature (Zeng et al., 2020; Zhou et al., 2021).

Notably, we observe a significant decline in F1 for all the 5 models on $\mathbf{D}_{\mathbf{Scratch}}$ which is mainly due to the dramatic drop in the recall. The drop is the result of the bias in training data, i.e., the model trained on biased data lacks the generalization ability to extract relation instances that are systematically missed in the dataset. We will validate this point in the following section.

5.2 Bias from Data to Model

To better understand the different performances on the two datasets, we analyze the model capability over different relations and entities. Not surprisingly, we find that models trained on $\mathbf{D}_{\mathbf{Revise}}^{\mathbf{Train}}$ prefer popular entities and relations as well. Additional experiments suggest that this may be because missing instances are considered as negative samples during training. Given that a substantial proportion of unlabelled instances are associated with unpopular entities and relations, the model will be forced to disregard those unpopular ones under the incorrect penalty for the missing instances.

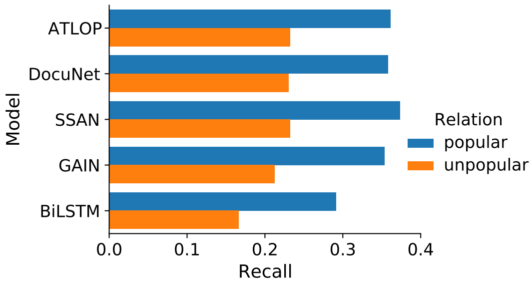

Figure 1: The recall of models on instances associated with popular and unpopular relations.

Relation Bias Figure 1 shows the recall of the models on the instances associated with popular and unpopular relations respectively. As is depicted, if an instance's relation is popular, it is almost twice as likely to be successfully extracted compared with an instance whose relation is not popular. This gap does not narrow with the improvement of the model's overall performance. The difference between the probability of successfully extracting popular and unpopular relations is 0.129 for the best model ATLOP, which is even greater than the 0.125 for BiLSTM. This indicates that all models trained on the original DocRED favor popular relations and ignore the unpopular ones.

Entity Bias Figure 2 shows the model's recall curve as the $popularity_{max}$ of instances in $\mathbf{D}_{\mathbf{Scratch}}$ increases[5]. We divide all instances in $\mathbf{D}_{\mathbf{Scratch}}$ into 5 groups based on the $popularity_{max}$ in each instance, and we calculate the recall for each group independently. As seen in Figure 2, all the curves exhibit a clear rising trend, indicating that the probability of discovering an instance is positively correlated with its $popularity_{max}$. Additionally, we can see that the middle of the ATLOP's and DocuNET's curves is nearly horizontal, which means that they are more sensitive to extremely popular or particularly rare entities.

---

[5] The curve with $popularity_{min}$ is shown in Appendix B.

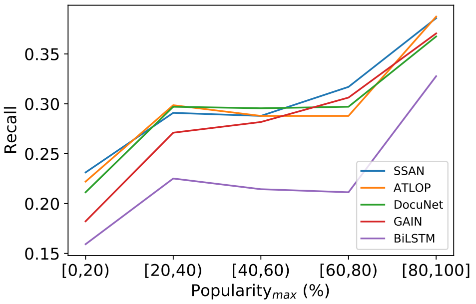

Figure 2: Model's recall in instances with entities of different popularity. We divide all instances in $\mathbf{D}_{\mathbf{Scratch}}$ into 5 groups based on the *popularity*$_{max}$ in each instance and we can see that the probability of discovering an instance is positively correlated with its *popularity*$_{max}$.

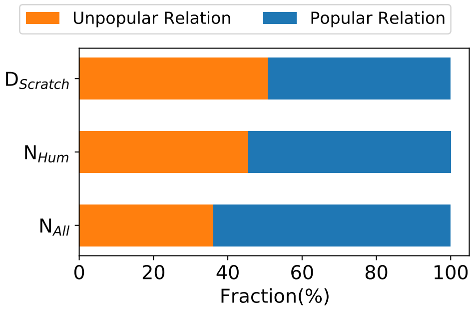

Figure 3: The proportion of instances associated with popular and unpopular relationships in the correct prediction of GAIN. In comparison to N_{All}, the model trained with N_{Hum} predicts more unpopular relation associated instances, and the ratio between popular and unpopular relationships is closer to the distribution in $\mathbf{D}_{\mathbf{Scratch}}$.

5.3 Missing Instances as Negative Samples

Previous works (Zeng et al., 2020; Zhou et al., 2021; Zhang et al., 2021) regard any instances that are not annotated with any relations as label *no_relation*, which means the missing instances are treated as negative samples during training and a model will be punished for predicting them as positive. We thus hypothesize the model's bias originates from the incorrect penalty for missing instances in the training process. To demonstrate this, we generate the negative samples in a different approach, using the instances manually eliminated during the revision step only. We denote such construction of negative samples as $\mathbf{N}_{\mathbf{Hum}}$, and the method that treats all samples other than the positive instances as negative is called $\mathbf{N}_{\mathbf{All}}$. Due to the fact that the sample generated by $\mathbf{N}_{\mathbf{Hum}}$ has been manually verified, there is no issue with false no_relation instances. We train the same models using $\mathbf{D}^{\mathbf{Train}}_{\mathbf{Revise}}$ with negative samples constructed by $\mathbf{N}_{\mathbf{Hum}}$ and $\mathbf{N}_{\mathbf{All}}$ and compare models' preference for popular entities and relations.

Figure 3 depicts the fraction of instances that correspond to the popular relationship among the instances accurately predicted by GAIN trained with $\mathbf{D}^{\mathbf{Train}}_{\mathbf{Revise}} + \mathbf{N}_{\mathbf{Hum}}$ and $\mathbf{D}^{\mathbf{Train}}_{\mathbf{Revise}} + \mathbf{N}_{\mathbf{All}}$. Additionally, we mark the true distribution of the data in $\mathbf{D}_{\mathbf{Scratch}}$. As can be seen, when trained with $\mathbf{D}^{\mathbf{Train}}_{\mathbf{Revise}} + \mathbf{N}_{\mathbf{Hum}}$, GAIN can find more unpopular relation associated instances and the gap between the proportion of unpopular relation associated in model's prediction and $\mathbf{D}_{\mathbf{Scratch}}$ is narrowed down.

Based on the entity popularity in each instance, we partition all instances in $\mathbf{D}_{\mathbf{Scratch}}$ into five categories and calculate the recall for each group independently. Figure 4 shows the improvement of GAIN's recall compared with the group which includes the instances with the most unpopular entities (0-20%). In comparison to $\mathbf{N}_{\mathbf{All}}$, using $\mathbf{N}_{\mathbf{Hum}}$ to construct negative samples to train a model will dramatically lessen the rising trend of the model's recall as the entity's popularity grows.

6 Annotators' Dilemma

Finally, we move on to discuss another more implicit influence of the recommend-revise scheme on the *annotators'* aspect. As discussed in Section 4.1, while we expected the revision process to help supplement the instances left out, it turns out that an incredibly low number is added indeed. Given that the annotators are trained to accomplish the revision task, we wonder why they still fail in such a uniform manner. We would like to argue that it is the nature of the revision process that puts the annotators in a dilemma, where they have to choose between a huge effort and insufficiency of supplementation.

Recall that there is a distinct difference in the settings of *examining* a labeled relationship and *supplementing* an unidentified relationship. For the former, annotators are required to find evidence for a recommended relation instance and remove it if there is conflicting or no evidence. This process only requires checking a single entity pair and collecting the information related to the two specific entities. However, this is not the case for *supplementing* a possible, unidentified relation instance, which can exist between any entity pair. There is

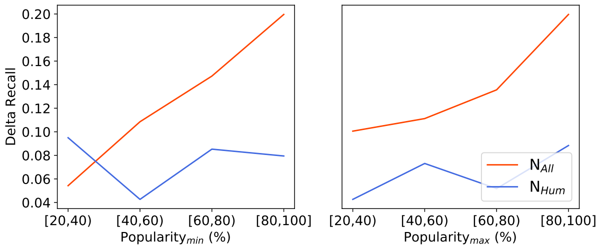

Figure 4: The gain of recall in instances with different *popularity*$_{min}$ and *popularity*$_{max}$, compared with the [0-20) group.

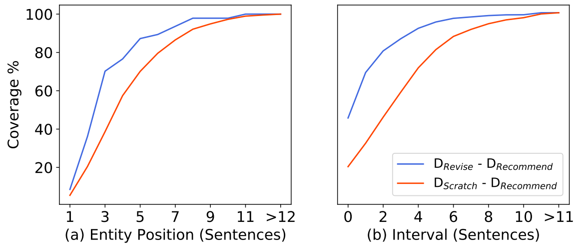

Figure 5: (a) illustrates the relations coverage measuring the position of head entity's first appearance. (b) shows the coverage measuring the minimum distance in sentences between the mentions of the head and tail entities of a relation.

no clear range of searching or indicating information; all they can do is to check pair-by-pair, just like what they do from scratch. This puts annotators in an awkward dilemma, especially when they understand the motivation of this scheme: if they are to be fully responsible for the missing instances at large, they will always have to complete the thorough pairwise checking one by one; however, this would make the whole process of the recommend-revise scheme meaningless in return, as it's just like a practice from scratch.

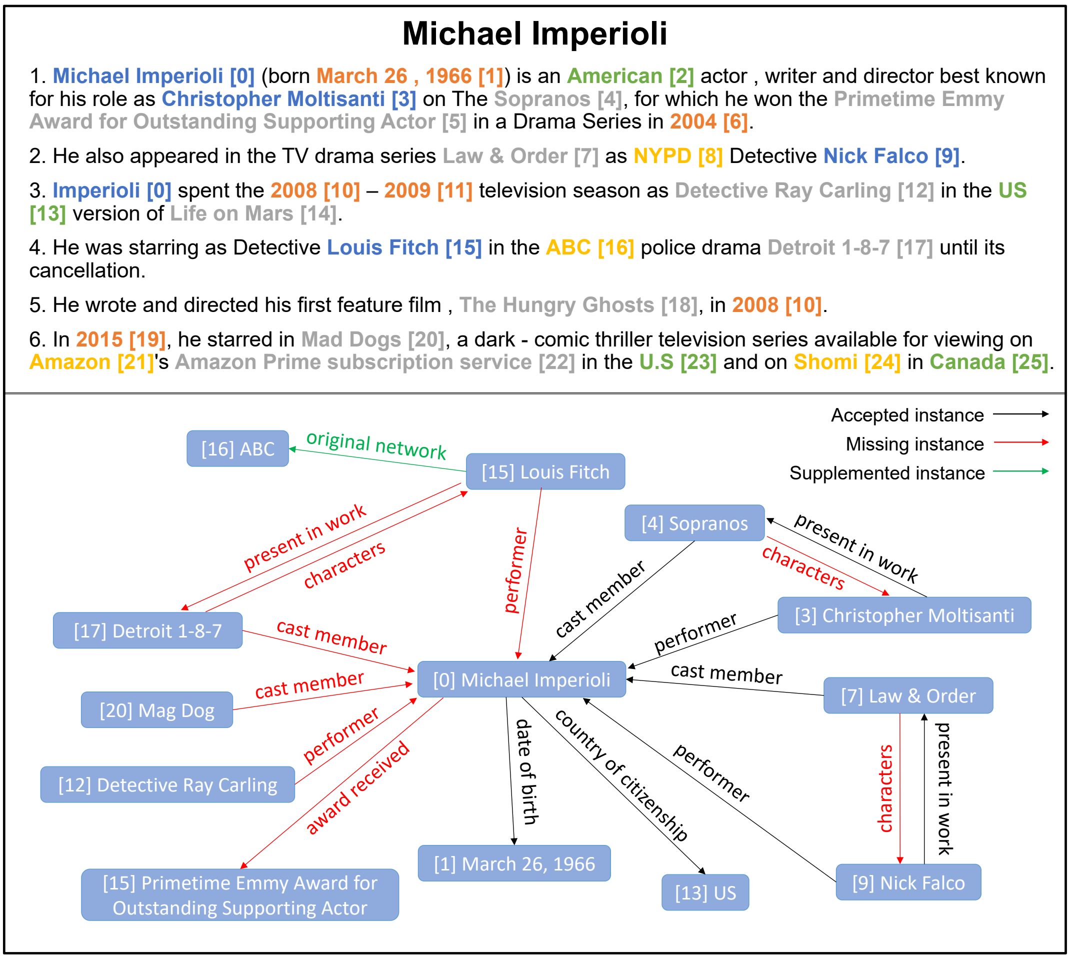
The harsh requirements of supplementing push annotators to overly rely on the recommendation results and simply examine them. This is especially worth worrying about in real practice, where annotators are recruited to complete a certain number of annotations, and typically paid according to the estimated number of hours or the total number of instances they devote to the annotation(Draws et al., 2021). Under this dilemma, it is a natural result that they are especially unmotivated to carry out the exhaustive checking for supplementation in order to get a reasonable pay in the given time.

In fact, we observe an interesting phenomenon that annotators largely tend to just pick some most obvious missing instances, convince themselves that they have accomplished the supplementation, and simply move on to the next document. This can be seen in Figure 5, where we compare the distributional characteristics of the successfully supplemented instances ($\mathbf{D_{Revise}}$ - $\mathbf{D_{Recommend}}$) and all the missing instances in general ($\mathbf{D_{Scratch}}$ - $\mathbf{D_{Revise}}$). Sub-figure (a) shows the accumulative statistics of the position of the head entity's first appearance in the document. We can see that the instances added by annotators in DocRED exhibit an extremely obvious tendency to occur earlier in the text, where more than 70% added instances are in the first 3 sentences. In contrast, all missing relation instances as a whole are almost distributed in every part of the document uniformly. This reveals the interesting fact that humans typically tend to pick up the relations where the entities in it are mentioned earlier in the document. Sub-figure (b) further compares the minimum distance between the mentions of the head and tail entities of one relation instance. We once again see the interesting fact that annotators have a strong tendency to add the "most easily identifiable" instances where the head and tail entities are quite close. Specifically, the proportion of entity pairs mentioned in just one single sentence (Interval=0) is around 20% for all missing facts, but is as high as 45% for the ones chosen by annotators to be supplemented. This tells us how annotators naturally avoid burdens of reading brought by longer intervals, which possibly indicates more complicated inference with multiple sentences.

From these observations, we see that there exist clear patterns among the very few instances added by human annotators. This reveals a serious fact that annotators are intentional in "pretending" to be supplementing with the least possible effort. Given the consensus behavior of annotators and the very limited number of additional, it is most likely that the nature of the annotation task pushes the annotators to this embarrassing dilemma of adding and abandoning. Thus, we propose a call to the NLP community that researchers should always be aware that annotation schemes, like the recommend-revise scheme, can have a direct impact on the annotation workers, affecting their willingness and behaviors, and thus have a deeper influence on the collected data.

7 Case Study

We can summarize all these problems mentioned above in the annotation with a concrete case in Do-



Michael Imperioli

1. Michael Imperioli [0] (born March 26 , 1966 [1]) is an American [2] actor , writer and director best known for his role as Christopher Moltisanti [3] on The Sopranos [4], for which he won the Primetime Emmy Award for Outstanding Supporting Actor [5] in a Drama Series in 2004 [6].

2. He also appeared in the TV drama series Law & Order [7] as NYPD [8] Detective Nick Falco [9].

3. Imperioli [0] spent the 2008 [10] – 2009 [11] television season as Detective Ray Carling [12] in the US [13] version of Life on Mars [14].

4. He was starring as Detective Louis Fitch [15] in the ABC [16] police drama Detroit 1-8-7 [17] until its cancellation.

5. He wrote and directed his first feature film , The Hungry Ghosts [18], in 2008 [10].

6. In 2015 [19], he starred in Mad Dogs [20], a dark - comic thriller television series available for viewing on Amazon [21]'s Amazon Prime subscription service [22] in the U.S [23] and on Shomi [24] in Canada [25].

Figure 6: A case from DocRED. The upper part shows the original documents with entities highlighted according to their types (PER, TIME, ORG, LOC, MISC). The lower part is an illustration of DocRED's annotation related to entity *Michael Imperioli*, where the black arrows indicate the instances that are recommended and accepted by annotators, the red ones indicate those not recommended and eventually missed in the dataset, and the green ones indicate those not recommended but correctly supplemented by annotators. The instances that are recommended but rejected by annotators are not shown in the figure.

cRED shown in Figure 6. The figure depicts the annotations associated with the entity *Michael Imperi*, as well as the relation that is added in revision. Let's first focus on the red edges, which indicate the relation triples that are neither recommended nor supplemented by human. Regrettably, half of the total 18 relation triples remain missing, and just one triple is added during revision (the green edge). Compared with black edges, which indicated correctly annotated instances, the red edges are more likely to be associated with less popular entities. For example, "Sopranos" [4] and "Law & Order" [7], two popular series with at least 100K+ comments on IMDB, and about 200 edges in Wikidata, are connected with "Michael Imperioli" [0] with the relation "cast member" in the annotation, but "Detroit 1-8-7" [17] and "Mad Dogs" [20], supposed to hold the same relation to "Michael Imperioli" [0], are missed. In the text, all these series appear in similar circumstances, and the only difference is the latter ones are not recommended to the annotators, essentially because of their less popularity (less than 10K comments on IMDB, and less than 50 edges in Wikidata). We can also see the effect on the popularity of relations in the connection between [7] and [9]. "present in work" and "characters" should occur symmetrically according to the definitions, but the latter one is missed in the recommendation. Correspondingly, in Wikidata, the latter relation has 19057 links, which is less than the former's 82250 links. The last point to notice is the only green edge between Louis Fitch

[15] and ABC [16], which is not recommended, but supplemented by annotators. Among all the missed instances in the recommendation, the annotators only supplement this one, which is easy to identify in the text due to both the head and tail entities being mentioned in the same sentence. This is consistent with our analysis of annotators' behavior above.

8 Related Works

With the advance of deep learning models, the annotation sometimes becomes the bottleneck for a machine learning system. Recently, analyzing the annotation quality has received increasing attention. Northcutt et al. (2021) collects and analyzes the label errors in the test sets of several popular benchmarks, showing label errors are ubiquitous and destabilize machine learning benchmarks. More specific to RE task, Alt et al. (2020) addresses the annotation problems in TACRED (Zhang et al., 2017), a popular sentence-level RE dataset. They find label errors account for 8% absolute F1 test error and more than 50% of the examples need to be relabeled. Stoica et al. (2021) expands this research to the whole dataset, resulting in a complete re-annotated version, Re-TACRED, and conducts thorough analysis on the models' performance. Our work differs from them in that we delve into the nature of document-level RE task, and especially explore how the error is systematically introduced into the dataset through *recommend-revise* scheme.

Methodologies to solve incomplete annotations for information extraction tasks have been widely discussed in previous works. Different from classification tasks, information extraction requires annotators to actively retrieve positive samples from texts, instead of just assigning a label for a given text. The problem is also attributed to the use of distant supervision (Reiplinger et al., 2014) where the linked KG is not perfect. Some works apply general approaches like positive unlabeled learning (Xie et al., 2021; Peng et al., 2019) or inference learning (Roller et al., 2015). Task-specific models are also designed, like Partial CRF (Tsuboi et al., 2008) for NER (Yang et al., 2018), and novel paradigm for joint RE (Xie et al., 2021). However, none of them examine the distribution bias in the training data, and those methods are not validated in the context of the document-level RE task.

Prevalent effective methods on document-level RE include graph-based models and transformer-based models. Graph-based models like Zeng et al. (2020) and Zhang et al. (2021) are designed to conduct relational reasoning over the document, and transformer-based models (Zhou et al., 2021; Xu et al., 2021) are good at recognizing long-distance dependencies. However, all previous models treat unlabeled samples in the dataset as negative samples, and do not concern the problems in annotations. We believe our analysis and re-annotated dataset will help future work focus more on the discrepancy between the annotation and real-world distribution, instead of just overfitting the dataset.

9 Conclusion

In this paper, we show how the recommend-revise scheme for DocRED can cause bias and false negative issues in the annotated data. The flaws of dataset affect the model's recall on real data and also teach the model the same bias in training data. As this scheme cannot reduce the human labor essentially without the loss of annotation quality, more efficient strategies for annotation are to be explored. On the other hand, considering that building a reliable training set for document RE is extremely expensive, it is also a meaningful topic that how to alleviate the dataset shift problem (Moreno-Torres et al., 2012) by injecting appropriate inductive bias into the model's structure, instead of inheriting the bias in the training data. We believe the in-depth analysis provided in this paper can benefit future designs of document-level RE models, and our *Scratch* dataset can serve as a fairer test set.

Ethical Considerations

This work focuses on quality checking and re-annotations of DocRED, a publicly available dataset constructed from Wikipedia pages. All source documents and types of relationships are provided and utilized in the original DocRED dataset, and no additional annotation rule that may involve unexamined ethical concerns was introduced. Annotators receive a competitive pay of 100 yuan per hour (more than 4 times the local minimum wage) under the approval of the institute, and both the annotation and discussion stage count towards the paid working time. Annotators are required to read the ACM Code of Ethics before annotating and report any document that violates the code. These documents are removed from the sampled documents. However, there may still be sentences or entities that are from Wikipedia pages with potentially improper content. The possible adoption of such content is not a decision of the authors, and all content in the dataset does not reflect the views or stances of the authors. The resulting re-annotations from the agreement of two expert annotators form a decent approximation of the gold labels, but may still not be the ground truth due to natural error rates. Further use of the dataset should be aware of the limitations and other possible issues, and we are not responsible for issues in further model training processes using our data.

A Source of Recommendations in DocRED

According to Yao et al. (2019), Wikidata recommends an average of 19.9 relation instances per document and annotators reserve 57.2% of these, implying that Wikidata provides an average of 11.4 accurate relations every article. The number of correct relation instances recommended by Wikidata and the RE system does not exceed the number of the instances after the revision phase, which is 12.5 per document. This indicates that at least 90% of recommendations originate from Wikidata. As a result, when we analyze the bias of DocRED's recommendation, we are mainly discussing the bias of Wikidata.

B Entity Bias

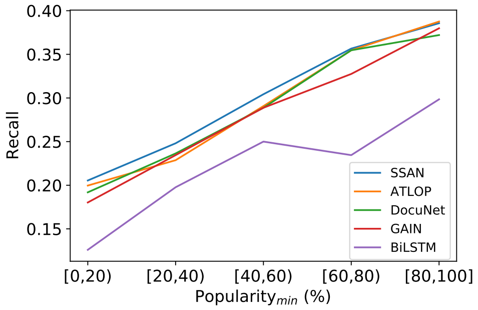

Figure 7: Model's recall in instances with entities of different popularity. We divide all instances in $\mathbf{D_{Scratch}}$ into 5 groups based on the *popularity*$_{min}$ in each instance and we can see that the probability of discovering an instance is positively correlated with its *popularity*$_{min}$.

UniPELT: A Unified Framework for Parameter-Efficient Language Model Tuning

Abstract

Recent parameter-efficient language model tuning (PELT) methods manage to match the performance of fine-tuning with much fewer trainable parameters and perform especially well when training data is limited. However, different PELT methods may perform rather differently on the same task, making it nontrivial to select the most appropriate method for a specific task, especially considering the fast-growing number of new PELT methods and tasks. In light of model diversity and the difficulty of model selection, we propose a unified framework, UniPELT, which incorporates different PELT methods as submodules and learns to activate the ones that best suit the current data or task setup via gating mechanism. On the GLUE benchmark, UniPELT consistently achieves 1~4% gains compared to the best individual PELT method that it incorporates and outperforms fine-tuning under different setups. Moreover, UniPELT generally surpasses the upper bound that takes the best performance of all its submodules used individually on each task, indicating that a mixture of multiple PELT methods may be inherently more effective than single methods.[1]

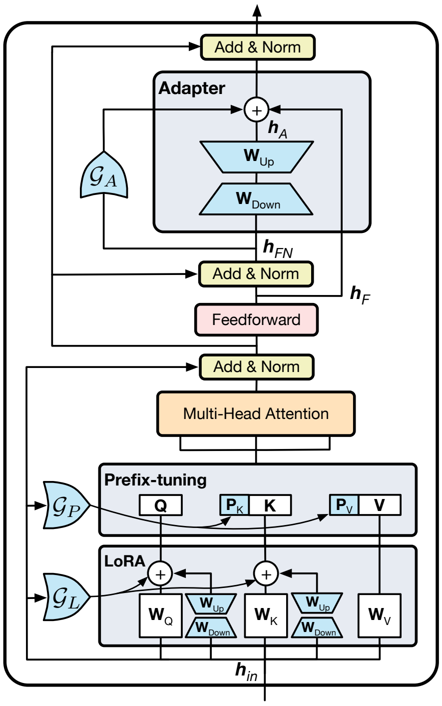

Figure 1: Illustration of UniPELT, which subsumes existing PELT methods as submodules and controls them via gating mechanism $\mathcal{G}$. Different (combinations of) submodules can be activated for different samples. The **trainable parameters** are shown in blue.

1 Introduction

As pre-trained language models (PLMs) (Devlin et al., 2019) grow larger and larger (Brown et al., 2020), it becomes increasingly infeasible to perform conventional fine-tuning, where separate replicas of the model parameters are modified per single task. To solve the issue, there has recently been a surge of studies on **p**arameter-**e**fficient **l**anguage model **t**uning (PELT), namely how to effectively tune the PLMs with fewer trainable parameters.

Existing PELT research generally aims at achieving performance comparable to fine-tuning with as few trainable parameters as possible, which has seen significant progress – the task-specific trainable parameters used in most recent approaches (Lester et al., 2021; Guo et al., 2021) are almost negligible compared to the total parameters of the PLM (<1%). A more challenging yet less studied problem is whether one can achieve better performance than fine-tuning with fewer parameters. Recent studies (He et al., 2021; Li and Liang, 2021; Karimi Mahabadi et al., 2021b) find that some PELT methods are more effective than fine-tuning on certain tasks when training data is limited, possibly due to the reduced risk of overfitting. However, as found in our experiments (Table 1), different PELT methods exhibit diverse characteristics and perform rather differently on the same task, which

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 6253 - 6264
May 22-27, 2022

makes it nontrivial to select the most appropriate method for a specific task, especially considering the fast-growing number of new PELT methods and tasks (Ding and Hu, 2021).

In light of the diverse performance of PELT methods and the cost of selecting the best method, we propose a unified PELT framework, named UniPELT, which incorporates different PELT methods as submodules and learns to dynamically activate the (combination of) submodules that best suit the current data or task setup. As a result, model selection is no longer needed and consistently better performance is achieved under different setups. The activation of each submodule in UniPELT is controlled by *gating mechanism*, which learns to favor (assign more weight to) the submodules that positively contribute to a given task. In addition, since the number of parameters introduced by each submodule is generally small, combining multiple methods leads to negligible losses in model efficiency.

We select four representative PELT methods for our study – adapter (Houlsby et al., 2019), prefix-tuning (Li and Liang, 2021), LoRA (Hu et al., 2021), and BitFit (Ben Zaken et al., 2021), which largely cover the major categories of PELT methods. We perform two sets of analysis that carefully examines (i) the characteristics of individual PELT methods and (ii) their effectiveness when coordinated by UniPELT under various setups.[2]

Extensive experiments on the GLUE benchmark (Wang et al., 2019), with 32 setups (8 tasks ×4 data sizes) and 1,000+ runs, not only reveal the diverse behavior of PELT methods, but also show that UniPELT is more effective and robust than using each method alone in various task and data setups. Specifically, UniPELT consistently improves the best submodule that it incorporates by 1~4 points and even outperforms fine-tuning, achieving the best average performance on the GLUE benchmark under different setups. Moreover, UniPELT generally surpasses the upper bound that takes the best performance of all its submodules used individually on each task, which suggests that UniPELT maintains (near) optimal performance under different setups. The fact that UniPELT outperforms the upper bound also implies that a mixture of PELT methods involving different parts of the PLM architecture may be inherently more effective than individual methods.

Contributions. (1) We conduct a comprehensive study of representative PELT methods and carefully examine their differences and commonalities in terms of performance and characteristics. (2) We propose a unified PELT framework that can incorporate existing methods as submodules and automatically learn to activate the appropriate submodules for a given task. (3) Our proposed framework achieves better average performance than fine-tuning and the PELT methods that it incorporates under various setups, often performing the best and never the worst at per-task level, exhibiting superior effectiveness and robustness with negligible losses in model efficiency.

2 Preliminaries

2.1 PELT Methods without Additional Parameters

PLMs can be used as feature extractors where only the top layers or prediction head are fine-tuned without additional parameters (Lee et al., 2019). However, such fine-tuning approaches generally lead to degenerate model performance that is much worse than fine-tuning all parameters (Lee et al., 2019; Pfeiffer et al., 2021). A recent method BitFit (Ben Zaken et al., 2021) only tunes the bias terms of the PLM and is shown to achieve performance comparable to fine-tuning on certain tasks when training data is limited. Therefore, we select BitFit as the representative of this category for analysis.

2.2 PELT Methods with Additional Parameters

Alternatively, one may fix the entire PLM and introduce a small number of new trainable parameters. Notable examples in this category include adapter (Houlsby et al., 2019) and its extensions (Pfeiffer et al., 2021; Karimi Mahabadi et al., 2021b), prefix-tuning (Li and Liang, 2021) and its extensions (Lester et al., 2021), and additive methods (Guo et al., 2021; Hu et al., 2021).

Next, we will briefly describe these methods to facilitate the introduction of our proposed framework. An illustration is shown in Fig. 1 for better understanding.

Adapter. Adapter (Houlsby et al., 2019) adds a trainable *bottleneck layer* after the feedforward network in each Transformer layer of the PLM. A bottleneck layer consists of a down+up projection pair that shrinks and recovers the size of token hidden

---

[2] BitFit is not included in UniPELT as it typically performs the worst in our preliminary experiments.

states. Mathematically, if we denote the output of the **f**eedforward network after residual connection and layer **n**ormalization as $\boldsymbol{h}_{FN}$ with hidden size D_{hidden} and bottleneck size D_{mid}, then the output of a bottleneck layer $\boldsymbol{h}_A$ is:

$$\boldsymbol{h}_A = \boldsymbol{W}_{\text{up}}^{\intercal}\phi(\boldsymbol{W}_{\text{down}}^{\intercal}\boldsymbol{h}_{FN}), \tag{1}$$

where $\boldsymbol{W}_{\text{down}} \in \mathbb{R}^{D_{\text{hidden}}\times D_{\text{mid}}}$, $\boldsymbol{W}_{\text{up}} \in \mathbb{R}^{D_{\text{mid}}\times D_{\text{hidden}}}$, ϕ is a nonlinear activation function, and the bias terms are omitted for brevity. The parameters in layer normalization and the final prediction head sometimes are also fine-tuned depending on the specific adapter variants.

Adapter has shown to be on par with fine-tuning and sometimes exhibits better effectiveness in the low-resource setting (He et al., 2021). Later studies extend adapter to multi-lingual (Pfeiffer et al., 2020b) and multi-task (Karimi Mahabadi et al., 2021b) settings, or further reduce its trainable parameters (Karimi Mahabadi et al., 2021a), which can be easily incorporated into UNIPELT as a replacement of the vanilla adapter.

Prefix-tuning. Prefix-tuning (Li and Liang, 2021) prepends a number of task-specific trainable vectors to the input of multi-head attention in *each* Transformer layer, which the original tokens can attend to as if they were virtual tokens. Specifically, we denote the original sequence length L_0, the number of trainable vectors (*i.e.*, prefix length) L, and the Transformer layer input $\boldsymbol{h}_{\text{in}} \in \mathbb{R}^{D_{\text{hidden}}\times L_0}$. First, three linear projections $\boldsymbol{W}_Q$, $\boldsymbol{W}_K$, $\boldsymbol{W}_V \in \mathbb{R}^{D_{\text{hidden}}\times D_{\text{hidden}}}$ transform $\boldsymbol{h}_{\text{in}}$ into Query $\boldsymbol{Q}$, Key $\boldsymbol{K}$, and Value $\boldsymbol{V}$. Then, two prefix matrices $\boldsymbol{P}_K$ and $\boldsymbol{P}_V \in \mathbb{R}^{D_{\text{hidden}}\times L}$ are prepended to $\boldsymbol{K}$ and $\boldsymbol{V}$. To stabilize optimization, the prefix matrix $\boldsymbol{P}$ is reparameterized by a feedforward network:

$$\boldsymbol{P}' = \boldsymbol{W}_{\text{up}}^{\intercal}\phi(\boldsymbol{W}_{\text{down}}^{\intercal}\boldsymbol{P}), \tag{2}$$

where $\boldsymbol{W}_{\text{down}} \in \mathbb{R}^{D_{\text{hidden}}\times D_{\text{mid}}}$, $\boldsymbol{W}_{\text{up}} \in \mathbb{R}^{D_{\text{mid}}\times 2N_{\text{layer}}D_{\text{hidden}}}$, and N_{layer} denotes the number of Transformer layers. The parameters of this network can be discarded after training, and only $2N_{\text{layer}}$ prefix matrices $\in \mathbb{R}^{D_{\text{hidden}}\times L}$ are needed (2 matrices for each layer).

Prefix-tuning is originally evaluated on natural language generation and we adapt it to understanding tasks. A follow-up method named prompt-tuning (Lester et al., 2021) further reduces task-specific parameters by limiting the prefix to the first layer but only performs competitively with very large model sizes (billions of total parameters), and is thus not considered in our study. Note that prefix-tuning (or prompt-tuning) is different from prompt-based *fine-tuning* methods (Schick and Schütze, 2021; Gao et al., 2021) (see App. A for specific differences).

Additive Methods. Additive PELT methods treat the model parameters after fine-tuning as an addition of the pre-trained parameters $\theta_{\text{pre-trained}}$ and task-specific differences δ_{task}, where $\theta_{\text{pre-trained}}$ is fixed and a new (sub)set of model parameters are added on top: $\theta_{\text{task}} = \theta_{\text{pre-trained}} + \delta_{\text{task}}$. There are various ways to parameterize δ_{task}, leading to different additive methods such as LoRA (Hu et al., 2021), diff pruning (Guo et al., 2021), and side-tuning (Zhang et al., 2020). We take LoRA as a representative and incorporate it into UNIPELT. Other methods are conceptually similar and can be incorporated in the same fashion.

LoRA introduces trainable low-rank matrices and combines them with the original matrices in the multi-head attention. Specifically, two matrices $\boldsymbol{W}_{\text{down}} \in \mathbb{R}^{D_{\text{hidden}}\times D_{\text{mid}}}$ and $\boldsymbol{W}_{\text{up}} \in \mathbb{R}^{D_{\text{mid}}\times D_{\text{hidden}}}$ are added for the query and key projections along with the original matrix $\boldsymbol{W}_Q$ and $\boldsymbol{W}_K \in \mathbb{R}^{D_{\text{hidden}}\times D_{\text{hidden}}}$:

$$\boldsymbol{Q} = (\boldsymbol{W}_Q^{\intercal} + \alpha\boldsymbol{W}_{\text{up}}^{\intercal}\boldsymbol{W}_{\text{down}}^{\intercal})\boldsymbol{h}_{\text{in}}, \tag{3}$$

where α is a fixed scalar hyperparameter for scaling the task-specific differences. The form of the trainable matrices in LoRA is quite similar to those in adapter or prefix-tuning, but there is no activation function ϕ in between.

3 Unifying PELT Methods

3.1 Task Formulation

Given a large PLM $\mathcal{M}$ with size $|\mathcal{M}|$ that cannot be fine-tuned directly due to computational or storage cost, suppose that we have a list of PELT methods $\{m_i\}$, the trainable parameters of which are negligible (*i.e.*, $\sum_i |m_i| \ll |\mathcal{M}|$), our goal is to design a unified PELT framework that incorporates $\{m_i\}$ as submodules and learns to dynamically activate (upweight) different submodules when appropriate under different scenarios, such that one could achieve satisfactory results in terms of both model effectiveness and robustness without the hassle of permuting all the method×task×data combinations.

3.2 Proposed Method

Motivation & Intuition. During the analysis of individual PELT methods, we observe that different PELT methods exhibit diverse characteristics and perform rather differently on the same task. For example, prefix-tuning generally performs well on natural language inference tasks regardless of the size of training data. Also, as can be seen in Fig. 1 and Sec. 2, different PELT methods often involve different parts of the PLM architecture (*e.g.*, before multi-head attention for prefix-tuning and after feedforward layer for adapter), making it feasible to combine multiple PELT methods without (directly) interfering with each other.

In light of the two observations above, we propose a unified PELT framework, UNIPELT, which takes a hybrid approach by incorporating multiple PELT methods as submodules. At a high level, UNIPELT improves over single PELT methods due to two factors. First, UNIPELT learns to activate (upweight) the submodules that best suit the current task or specific data sample and deactivate (downweight) the rest. Second, we find that UNIPELT generally performs better than taking the best performance of all its submodules used individually on each task, suggesting that there could be some compounding effects that lead to better model effectiveness when multiple PELT methods (that modify different parts of the PLM) are used.

Next, we will introduce how different PELT methods can be incorporated into UNIPELT via gating mechanism.

Gating Mechanism. To achieve fine-grained control of submodule (de)activation, we add a trainable gate $\mathcal{G}_{m_i}$ for each submodule $m_i \in \{\text{A, P, L}\}$ in every Transformer layer (see Fig. 1). The letters A, P, L stand for Adapter, Prefix-tuning, and LoRA, respectively. Intuitively, if m_i is useful for a given data × task setup (or a particular instance), the gate output for m_i would be higher such that m_i plays a more important role. The actual interplay of submodules, however, is more complicated given the interdependency of the submodules and the compounding effects of multiple layers.

Specifically, for adapter, there is a residual connection between the feedforward network and the adapter submodule that sums the adapter input (before normalization) $\boldsymbol{h}_F$ and output $\boldsymbol{h}_A$ as its final output: $\boldsymbol{h}'_A = \boldsymbol{h}_A + \boldsymbol{h}_F$. We design a gating function $\mathcal{G}_A \in (0, 1)$ that estimates the importance of adapter by its direct input $\boldsymbol{h}_{FN}$ using a feedforward network with sigmoid activation and then scales its output: $\boldsymbol{h}'_A = \mathcal{G}_A \boldsymbol{h}_A + \boldsymbol{h}_F$. The adapter submodule is effectively bypassed if $\mathcal{G}_A \approx 0$.

Similarly, for prefix-tuning, we design a gating function $\mathcal{G}_P \in (0, 1)$ that is applied to the prefix vectors ($\boldsymbol{P}_K$ and $\boldsymbol{P}_V$) with the representation of the original tokens ($\boldsymbol{K}$ and $\boldsymbol{V}$) intact. In this way, the impact of the prefix would be diminished if the gate output of the prefix-tuning submodule is low.[3] The gating function $\mathcal{G}_P$ is estimated by the Transformer layer input $\boldsymbol{h}_{\text{in}}$ with another feedforward network.

As for LoRA, we note that there is already a *constant* scaling factor α in its original design that resembles the purpose of our gating mechanism. We thus simply make the factor learnable per layer by a third feedforward network that takes $\boldsymbol{h}_{\text{in}}$ as input instead of specifying a constant manually: $\theta_{\text{task}} = \theta_{\text{pre-trained}} + \mathcal{G}_L \delta_{\text{task}}$.

Despite the seeming simplicity of UNIPELT, we note that it is nontrivial for a unified approach to work well under different scenarios. Naively combining different PELT methods as a hybrid approach could lead to mixed or worse performance than using individual methods, as observed in both our experiments and prior studies (Hu et al., 2021).

4 Experiments

We conduct extensive experiments with 8 tasks × 4 data sizes × 7 methods × 5 runs per setup, along with additional analysis for particular methods, resulting in 1,000+ runs in total.

4.1 Experiment Setup

Task Setup. We conduct experiments on the General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2019), which involves four types of natural language understanding tasks including linguistic acceptability (CoLA), sentiment analysis (SST-2), similarity and paraphrase tasks (MRPC, STS-B, QQP), and natural language inference (MNLI, QNLI, RTE). We exclude the WNLI dataset following prior studies (Houlsby et al., 2019; Devlin et al., 2019).

Data Setup. We mainly consider a low-resource setting where training data is limited and the performance of different methods varies much. We sample a small subset of the training set for each task with size $K = \{100, 500, 1000\}$. As it is infeasible to submit considerable runs to the GLUE

---

[3] Prefix-tuning cannot be fully eliminated as adapter or LoRA due to the softmax operation in multi-head attention.

Table 1: Results on the GLUE benchmark with $K = \{100, 500, 1000\}$ training samples. The evaluation metrics are Matthew's Correlation for CoLA, F1 for MRPC and QQP, Spearman's correlation for STS-B, and accuracy for the rest. For MNLI, we evaluate on the matched dataset. We report average performance on five random seeds with standard deviation as the subscript. **Best** and <u>2nd best</u> methods under each setup are bold and underlined.

leaderboard (2 submissions/day), we take 1,000 samples on the training set as the development set to select the best checkpoint and use the original development set as the test set. To reduce variance, we shuffle the data with 5 random seeds and report the average performance. Additionally, we consider a high-resource setting where the whole training set is used and the best performance on the GLUE development set is reported.

Compared Methods. We mainly compare UniPELT with fine-tuning and four representative PELT methods: adapter (Houlsby et al., 2019), prefix-tuning (Li and Liang, 2021), BitFit (Ben Zaken et al., 2021), and LoRA (Hu et al., 2021). For completeness, we consider two model variants UniPELT (AP) and UniPELT (APL), which incorporate 2 and 3 PELT methods, respectively.

Implementation Details. We use $\text{BERT}_{\text{base}}$ (Devlin et al., 2019) as the base model in the experiments. Consistent results are observed in our preliminary experiments with $\text{BART}_{\text{large}}$ (Lewis et al., 2020) (provided in App. C). We implement and evaluate all the methods in the same codebase to ensure a fair comparison. We largely follow the default hyperparameters of different methods and keep them the same on all the tasks for generalizability. We set the prefix length $L = 10$, adapter bottleneck size $D_{\text{mid}} = 48$, LoRA rank $D_{\text{mid}} = 8$ if not specified otherwise.[4] More implementation and hyperparameter details can be found in App. B.

4.2 Analysis of Individual PELT Methods

In Table 1, we show the performance of different methods on the GLUE benchmark with various sizes of training data. The results on the development sets are generally consistent with the test sets and provided in App. D. Although the average performance of different methods over 8 tasks is sometimes similar, the differences between tasks are quite significant under certain setups and can be as large as 5~9 points on a specific task (*e.g.*, STS-B and MNLI, $K = 500$) even when excluding cases where some methods fail to learn effectively (*e.g.*, prefix-tuning on QQP, $K = 100$).

---

[4] While these hyperparameters may lead to differences in trainable parameters, we keep them for analysis as they are used by the official implementation. Also, we observe that more trainable parameters do not guarantee better results.

Next, we will analyze and examine each individual PELT method more closely.

Analysis of Adapter. The performance of adapter is relatively stable – there is no significantly better or worse result than fine-tuning consistent on different tasks or sizes of training data. In general, adapter is slightly worse than fine-tuning in most cases. We do not observe that adapter consistently outperforms fine-tuning in the low-resource setting as in He et al. (2021), possibly because they tune model hyperparameters on each task, which could be computationally prohibitive when there are considerable tasks. For example, they choose the bottleneck size D_{mid} from {64, 128, 256}, while $D_{\text{mid}} = 48$ is fixed across tasks in our experiments. Also, we only add one adapter in each Transformer layer instead of two following Pfeiffer et al. (2021). These two differences result in 62.4%~90.5% fewer parameters than the adapter used in He et al. (2021).

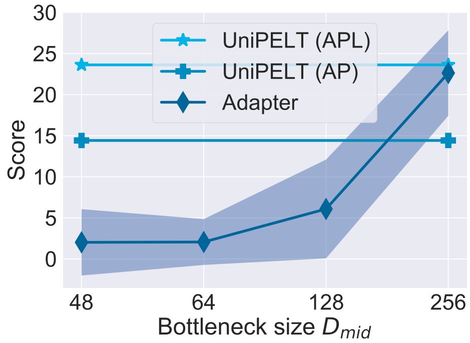

Figure 2: Performance changes when the bottleneck size of adapter is increased (on CoLA, $K = 100$).

To further study the effect of bottleneck size D_{mid} in adapter, we increase D_{mid} and re-evaluate adapter on a setup that it performs poorly (CoLA, $K = 100$). As shown in Fig. 2, the performance of adapter is increased gradually and becomes significantly better only when $D_{\text{mid}} = 256$, which involves 5.3× trainable parameters than the adapter used originally ($D_{\text{mid}} = 48$), 4.3× than UniPELT (AP), and 3.4× than UniPELT (APL), suggesting that a larger bottleneck size could be beneficial when adapter learns ineffectively.

On the other hand, there are certain tasks (*e.g.*, STS-B) that adapter largely outperforms competitive methods such as prefix-tuning and LoRA regardless of the size of training data, suggesting that one should favor adapter over other PELT methods under certain scenarios as well.

Analysis of Prefix-tuning. Prefix-tuning performs poorly with $K = \{100, 500\}$ and becomes on par with fine-tuning when K reaches 1000. We also observe that prefix-tuning fails to learn effectively on certain tasks when the training data is limited (*e.g.*, $K = 100$ on SST-2 and $K = 500$ on QQP), leading to unsatisfactory performance and (or) large variance across different runs. Similar phenomena have been observed in a concurrent study (Gu et al., 2021) on few-shot prompt-tuning.

To ensure that the poor performance of prefix-tuning is not due to its fewer trainable parameters (based on its default setting), we further increase the prefix length to $L = 50$ such that its trainable parameters are comparable to adapter, and re-evaluate prefix-tuning on all 8 tasks with $K = 100$. For the 4 tasks where prefix-tuning ($L = 10$) performs poorly (SST2, CoLA, STS-B, and QQP), while its performance is significantly improved on 3 tasks, it also performs significantly worse on the other task (STS-B), which suggests that training instability in the low-resource regime is still an issue for prefix-tuning even with more trainable parameters.[5] Besides, prefix-tuning ($L = 50$) still lags behind adapter or UniPELT (AP) on 3 of the 4 tasks. Furthermore, the average performance of prefix-tuning ($L = 50$) on 8 tasks is even slightly worse than with $L = 10$, which indicates that increasing prefix length may not be a panacea for all the scenarios. A larger L also leads to significant training/inference slowdown due to the costly multi-head attention. More broadly, such results suggest that using more trainable parameters does not guarantee better performance.

On the bright side, prefix-tuning performs well on certain tasks such as natural language inference (RTE and MNLI) with various sizes of training data, which suggests that one should also prefer prefix-tuning in certain cases.

Analysis of BitFit & LoRA. Tuning only the bias terms of the model does not lead to very satisfactory results in our experiments – BitFit never performs the best and generally performs the worst in different data and task setups. Therefore, we do not consider BitFit in the following experiments and exclude BitFit as a submodule of UniPELT. As for LoRA, there are a few setups where LoRA fails to learn effectively as well, such as STS-B and QQP ($K = \{100, 500\}$), leading to high variance across runs. Apart from that, LoRA performs

---

[5] Tuning other hyperparameters like learning rate does not appear to alleviate the issue either.

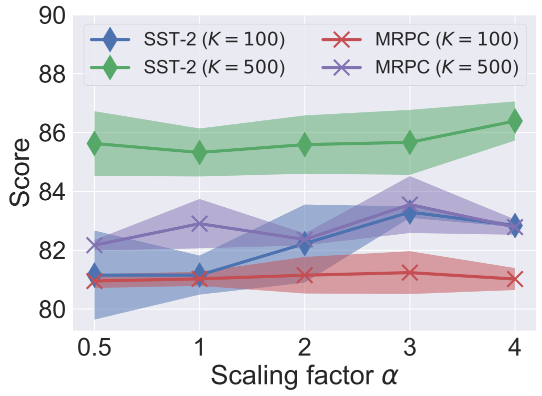

Figure 3: Performance comparison of various scaling factors for LoRA on 2×2 task and data setups.

quite competitively despite using fewer trainable parameters than methods like adapter, especially when $K = 1000$, achieving the best or 2nd best performance on 4 of 8 tasks.

As LoRA has a scaling factor α that can be seen as a static gating function under our formulation, we further investigate its importance by evaluating LoRA with different α. As shown in Fig. 3, LoRA is quite sensitive to the scaling factor and there seems to be no single optimal value that works well across multiple task and data setups. Such findings suggest that gating is critical and motivate us to use more fine-grained and dynamic control for UniPELT. Besides, we observe that increasing α consistently results in faster convergence, possibly because the trainable parameters would receive larger gradient updates with a larger α.

4.3 Analysis of UniPELT

Next, we will turn to our proposed framework UniPELT, which incorporates multiple existing PELT methods as submodules.

Low-Resource Performance. Overall, UniPELT (APL) and UniPELT (AP) consistently achieve the best and second best average performance on both the development and test sets regardless of the number of training samples. The gains are generally 1~4% over the submodule that performs the best (when used individually). Such results demonstrate the advantages of our hybrid approach regarding model effectiveness and generalizability.

At the per-task level, UniPELT (APL) and UniPELT (AP) perform the best or second best on 7/6/7 of 8 tasks when trained with 100/500/1,000 samples, and never perform the worst in any setup. When comparing the two variants, UniPELT (APL) outperforms UniPELT (AP) on 4/6/8 of 8 tasks when trained with 100/500/1,000 samples. Such results indicate that UniPELT is quite robust and performs reliably under different scenarios. The improvements of UniPELT over its submodules are generally larger when having fewer training samples, suggesting that UniPELT performs especially well in the low-resource regime. In particular, on the tasks where other PELT methods fail to learn effectively such as CoLA and QQP ($K = 100$), UniPELT manages to achieve performance better than fine-tuning.

UniPELT vs. Upper Bound. In Table 2, we show the comparison of UniPELT and the upper bound that takes the best performance of its submodules on each task. We observe that both UniPELT (AP) and UniPELT (APL) perform similarly or even better than their upper bound, which suggests that UniPELT successfully learns to leverage different submodules and maintains (near) optimal performance under different setups. The fact that UniPELT can outperform the upper bound also hints that a mixture of PELT methods (involving different parts of the PLM) might be inherently more effective than single methods (with a limited scope of the PLM architecture).

K	$\max(\{A, P\})$	UniPELT	$\max(\{A, P, L\})$	UniPELT
100	58.86	**60.80**	60.60	**62.59**
500	69.69	**69.79**	**70.02**	69.98
1000	72.58	**72.61**	73.19	**73.31**

Table 2: Comparison of average test performance between UniPELT and the upper bound that takes the best performance of its submodules on each task.

High-Resource Performance. In Table 3, we list the performance of different methods when all training samples are used. UniPELT again achieves the best overall performance. The gains are not as significant as in the low-resource setting, which is somewhat expected as existing PELT methods typically perform on par with fine-tuning given abundant training data and the potential of improvement is not as high. That said, the performance of UniPELT is still the best or 2nd best on all 8 tasks, and generally comparable to the best submodule used individually on each task. Besides, simply combining multiple PELT methods without gating does not work well in the high-resource setting – although UniPELT-NoGate never performs the worst in each task, its average performance is unsatisfactory (-0.89 vs. UniPELT).

UniPELT (APL)	1.4M (1.26%)	67%	127%

Table 4: Number of trainable parameters and Training/Inference time relative to fine-tuning.

4.4 Efficiency of PELT Methods

We benchmark the efficiency of PELT methods and list in Table 4 their number of trainable parameters and training/inference time relative to fine-tuning.

Parameter Efficiency. As the trainable parameters in PELT methods are almost negligible, combining multiple methods does not lead to significant losses in parameter efficiency. UniPELT still has few trainable parameters compared to fine-tuning (0.99%~1.26%). The parameters can be further reduced if one uses more parameter-efficient variants (*e.g.*, Karimi Mahabadi et al. (2021a)), which can be easily swapped with the vanilla version used in our current framework. Also, note that more trainable parameters do not always lead to better performance, as shown in our experiments and prior studies (He et al., 2021; Pfeiffer et al., 2021).

Training and Inference Efficiency. Due to parameter efficiency, all PELT methods train 30%~50% faster than fine-tuning and incorporating multiple PELT methods into UniPELT does not suffer from slower training. On the other hand, the inference time of PELT methods is generally longer since they involve more FLOPs. UniPELT has a slightly larger inference overhead (4%~11% compared to its slowest submodule), which we argue is insignificant since larger models that may achieve similar performance gains (*e.g.*, BERT$_{\text{large}}$) need around 300% inference time (Wolf et al., 2020).

5 Related Work

Parameter-Efficient Tuning of PLMs. As it is increasingly infeasible to train and store full copies of large PLMs for various downstream tasks, how to efficiently tune the PLMs with few trainable parameters becomes critical. Existing PELT methods can be largely divided into two categories based on whether new trainable parameters are introduced. Specifically, one may either train a subset of the model parameters such as the prediction head (Lee et al., 2019) and bias terms (Ben Zaken et al., 2021), or introduce task-specific parameters to different parts of the PLM such as before multi-head attention (Li and Liang, 2021) or after feedforward layer (Houlsby et al., 2019). As the number of PELT methods keeps increasing, the purpose of UniPELT is to better understand and leverage the distinctions of various methods instead of proposing yet another method.

Mixture-of-Experts. UniPELT is also related to approaches that involve a high-capacity network and activate (upweight) different parts of the network given different inputs. One notable example is Mixture-of-Experts (MoE) (Jacobs et al., 1991; Shazeer et al., 2017), which maintains a set of experts (neural networks) and one or more trainable gates that select a combination of the experts specific to each input. Despite being conceptually similar, UniPELT is different from MoE: the submodules in UniPELT are not combined explicitly by summation like MoE but in sequential order and affect each other implicitly. Moreover, the "experts" are diverse in UniPELT while usually homogeneous or identical in MoE methods.

6 Conclusion

In this paper, we present a comprehensive study of representative parameter-efficient language model tuning (PELT) methods and propose a unified framework, which incorporates different PELT methods as submodules and learns to activate the most appropriate submodules for a given task or data setup. Our proposed framework consistently outperforms conventional fine-tuning as well as the submodules that it incorporates under different setups, and generally surpasses the upper bound that takes the best performance of each submodule used individually on each task. Our findings suggest that a mixture of multiple PELT methods that involve different parts of the PLM may be favorable regarding both model effectiveness and robustness. For future work, we will try to better understand the discrepancy of various PELT methods in different scenarios. We also plan to investigate a multi-task setting where multiple submodules can be activated and cooperate at the task level.

A Prefix-tuning vs. Prompt-based Fine-tuning

We note that prefix-tuning (or prompt-tuning) is different from prompt-based *fine-tuning* methods (Schick and Schütze, 2021; Gao et al., 2021) in many ways: (1) Prompt-based fine-tuning is not parameter-efficient as it updates all model parameters while prefix-tuning only updates the prefix matrix $\boldsymbol{P}$. (2) The prompts are only used in model input for prompt-based fine-tuning but added to *every* Transformer layer in prefix-tuning (stored as different vectors). (3) Prompt-based fine-tuning typically leverages carefully designed *natural language* prompts while prefix-tuning uses continuous prompts (virtual tokens).

B Implementation Details

Data Preparation. We shuffle the training set with seed s, take the first K samples as the new training set, and the next 1,000 samples as the development set. We use $s = \{111, 222, 333, 444, 555\}$ as the data seeds and the same seed ($s = 42$) for model training. We also conduct another set of preliminary experiments by fixing the data and using 5 different random seeds for model training, the results of which are similar (Table 5).

Hyperparameters. We adopt AdapterHub (Pfeiffer et al., 2020a), a library based on HuggingFace Transformers (Wolf et al., 2019), as our codebase. We largely follow the recommended hyperparameters used in different methods for a fair comparison. We set the input length to 128 and the training batch size to 16. We set the number of epochs to 50 and adopt early stopping with a patience of 10 non-increasing epochs. We set the learning rate of fine-tuning and adapter to 2e-5 and 1e-4 according to the findings in prior studies (Pfeiffer et al., 2020a; He et al., 2021). For prefix-tuning and UniPELT, as they are not previously evaluated on NLU tasks, we tune their learning rates from {1e-4, 2e-4, 5e-4} on the development set and set to 2e-4 and 5e-4, respectively. For BitFit and LoRA, we choose the learning rates commonly used in their own experiments (1e-4 and 5e-4, respectively). We set $\alpha = 2$ and $r = 8$ in LoRA according to its official scripts.

C BART Results

In our preliminary experiments, we also evaluated UniPELT on BART$_{\text{large}}$ (Lewis et al., 2020). We show the results of fine-tuning, adapter, prefix-tuning, and UniPELT (AP) in Table 5. 1000 training examples are used and the average best performance on the GLUE development set is reported (excluding QQP). The results are largely consistent with those on BERT$_{\text{base}}$. UniPELT again achieves the best performance with notably smaller variance.

Setup	**Fine-tuning**	**Adapter**	**Prefix-tuning**	**UniPELT (AP)**
Model seed	$78.39_{2.92}$	$77.12_{0.50}$	$73.16_{2.89}$	$\mathbf{78.66}_{0.24}$
Data seed	$77.55_{2.94}$	$76.87_{0.55}$	$71.90_{2.47}$	$\mathbf{79.02}_{0.44}$

Table 5: Average performance with $K = 1000$ on the GLUE benchmark with BART$_{\text{large}}$ as the base model. Results are averaged over 5 runs by changing the model or data seeds.

D Detailed Performance

In Table 6, we list the detailed results on both development and test sets of the GLUE benchmark. The observations and findings are largely consistent on the two evaluation splits.

Abstract

A recent study by Feldman (2020) proposed a long-tail theory to explain the memorization behavior of deep learning models. However, memorization has not been empirically verified in the context of NLP, a gap addressed by this work. In this paper, we use three different NLP tasks to check if the long-tail theory holds. Our experiments demonstrate that top-ranked memorized training instances are likely atypical, and removing the top-memorized training instances leads to a more serious drop in test accuracy compared with removing training instances randomly. Furthermore, we develop an attribution method to better understand why a training instance is memorized. We empirically show that our memorization attribution method is faithful and share our interesting finding that the top-memorized parts of a training instance tend to be features negatively correlated with the class label.

1 Introduction

In recent years, there has been an increasing amount of interest in the machine learning community to understand the *memorization* behaviour of deep neural network models. Studies have shown that deep learning models often have sufficient capacities to "memorize" training examples (Zhang et al., 2017; Arpit et al., 2017). A number of recent studies tried to understand how memorization helps generalization (Chatterjee, 2018; Feldman, 2020; Montanari and Zhong, 2020; Khandelwal et al., 2020, 2021)

In NLP, memorization of training examples by deep learning models is also often observed (Li and Wisniewski, 2021; Lewis et al., 2021; Raunak et al., 2021), and existing studies usually see memorization as something that hinders generalization. For example, Elangovan et al. (2021) tried to measure the amount of "data leakage" in NLP datasets in order to assess a model's ability to memorize vs. its ability to generalize.

However, recently Feldman (2020) proposed a long-tail theory, which states that memorization is necessary for generalization if the data follows a long-tail distribution. This theory was later empirically validated by Feldman and Zhang (2020), but their validation was done in only the computer vision domain. It is therefore interesting and useful for us to study whether the long-tail theory also holds in NLP; such validation would help us better understand the utility of memorization in the context of NLP.

The long-tail theory states that if the training data form a long-tail distribution, where there are many small "sub-populations" that are atypical instances, and if these small sub-populations are also present in the test data, then memorizing these atypical instances helps the model generalize to the test data. In order to validate this long-tail theory in the context of NLP, we follow the experiments and analyses on image classification done by Feldman and Zhang (2020). Specifically, we aim to answer the following questions in this paper: (1) On a few typical NLP tasks, are the training instances memorized by deep learning models indeed *atypical* instances? (2) Does memorizing these training instances lead to *lower generalization error* on the test instances?

In addition, observing that it is not always straightforward to understand why a training instance is being memorized, we study the following novel research question: (3) Can we provide some explanation about why a training instances is memorized? To be more specific, can we attribute the memorization score of a training instance to its individual tokens such that we can quantify which tokens require the most memorization by the model?

To answer these research questions, we first adopt self-influence (Koh and Liang, 2017) as our memorization scoring function. Compared with the estimator proposed by Feldman and Zhang (2020), our self-influence function is also theoretically mo-

Volume 1: Long Papers, pages 6265 - 6278
May 22-27, 2022

tivated but has the advantage that it is easy for us to derive a memorization attribution method for the third research question above. We present the self-influence function in Section 2.1, and in Section 2.2, we present our novel memorization attribution method. We conduct experiments on three NLP tasks: sentiment classification, natural language inference (NLI) and text classification.

Our experiments and analyses demonstrate that *the training instances with the highest memorization scores tend to be atypical*, at least on sentiment classification and NLI. On all three tasks, we find that removing the top-memorized training instances results in significantly dropped test performance, and the drop is markedly higher compared with removing a random subset of training instances. We also evaluate our memorization attribution method and find that our method can indeed identify input tokens that require the most memorization. Finally, we apply our memorization attribution method to sentiment classification and to an image classification dataset, and we share the interesting finding that the highly-memorized input features tend to be those that are negatively correlated with the class labels. Our code and data are available at `https://github.com/xszheng2020/memorization`.

2 Our Approach

To validate the long-tail theory in the context NLP, let us first review the main claims of the theory. First, the long-tail theory hypothesizes that training instances with the same class label has a long-tail distribution, with instances at the tail end being those atypical instances that need to be memorized. To verify this assumption, we first identify those training instances that are memorized by a trained deep learning model and then check if they are indeed atypical. Specifically, we follow Feldman and Zhang (2020) and adopt "self-influence" to measure memorization, but we use the influence function proposed by Koh and Liang (2017) to define self-influence. Second, the long tail theory states that memorization of the atypical training instances leads to lower generalization error, because the atypical training instances belong to subpopulations that also have presence in the test data. To verify this statement, we check whether removing the memorized training instances would lead to more significant performance drop on the test data than removing a random sample of training instances.

It is worth noting that the approach outlined above follows the experiments conducted by Feldman and Zhang (2020) to validate the long tail theory on image classification.

Furthermore, we want to pinpoint which parts of a memorized instance are most critical for memorization. In other words, since each training instance is assigned a memorization score, can we attribute the memorization score to different parts of the input of this instance? This presumably can help us better understand which parts of the input need to be memorized the most. We follow the idea from Integrated Gradients (IG) (Sundararajan et al., 2017) and derive a formula to compute memorization attribution.

2.1 Memorization: Self-Influence

The high level idea of Feldman (2020) to define memorization is that memorization measures how the prediction on a training instance $z = (x, y)$ (where x is the observation and y is the label) changes when z is removed from the training data. This notion is closely related to the influence function defined by Koh and Liang (2017), which measures how much the loss at a test point z_{test} is influenced by a slight upweighting of a training instance z in the training loss function. While influence function is generally used to measure the influence of a training instance on a *test* instance, if we use it to measure the influence of a training instance on *itself*, i.e., to measure "self-influence," then this self-influence corresponds to the general notion of memorization defined by Feldman (2020).

Adopting the influence function defined by Koh and Liang (2017), we define the memorization score for a training instance z as follows:

$$\mathcal{M}_{\text{remove}}(z) \overset{\text{def}}{=} -\left.\frac{dP(y|x;\hat{\theta}_{\epsilon,-z})}{d\epsilon}\right|_{\epsilon=0}, \quad (1)$$

where $\hat{\theta}_{\epsilon,-z}$ represents the parameters of the model trained with the instance z down-weighted by ϵ, $P(y|x;\theta)$ is the conditional probability using θ. Thus $\mathcal{M}_{\text{remove}}(z)$ is the amount of change of $P(y|x;\theta)$ when the instance z is down-weighted by a small amount ϵ.

After several steps of derivation (details to be given in Appendix A), the computation of Eqn 1 follows the following formula:

$$\mathcal{M}_{\text{remove}}(z) = -\nabla_\theta P(y|x;\hat{\theta})^\top H_{\hat{\theta}}^{-1} \nabla_\theta L(z,\hat{\theta}), \quad (2)$$

where $\hat{\theta}$ is the parameters of the model trained with all instances, L is the loss function (cross entropy in our implementation) and $H_{\hat{\theta}} = \frac{1}{n}\sum_{i=1}^{n} \nabla_{\theta}^{2} L(z_i, \hat{\theta})$, where $(z_1, z_2, \ldots, z_n)$ are the training instances.

2.2 Memorization Attribution

In order to better understand why an instance is memorized, we propose a fine-grained notion of memorization at "feature" level instead of instance level, i.e., to attribute the memorization score of an instance to its individual features. Our proposed memorization attribution method is general and can be applied to any input representation. For NLP tasks, this means we attribute the memorization score defined above to each token of the input sequence. For images, this would be to attribute the memorization scores to pixels.

For this memorization attribution, we borrow the idea from Integrated Gradients (IG) (Sundararajan et al., 2017), which is a gradient-based attribution method for understanding which parts of a test instance are more responsible for its prediction. In particular, the IG method requires an *uninformative* baseline input x' as a reference point. Similarly, here we also assume a baseline x'. This baseline is supposedly an instance that does not have any influence on any test instance, and in our implementation, we use an sequence of the same length as x but consisting of only the `[MASK]` tokens.

We first consider the influence of replacing $z = (x, y)$ with the baseline $z' = (x', y)$ (which is similar to perturbation-based influence from (Koh and Liang, 2017)):

$$\mathcal{M}_{\text{replace}}(z) \overset{\text{def}}{=} -\left.\frac{dP(y|x;\hat{\theta}_{\epsilon,z',-z})}{d\epsilon}\right|_{\epsilon=0}, \qquad (3)$$

where $\hat{\theta}_{\epsilon,z',-z}$ represents the parameters resulting from moving ϵ mass from z to z', i.e., adding z' to the training data and giving it a weight of ϵ in the loss function while reducing the weight of the original z by ϵ. Thus $\mathcal{M}_{\text{replace}}(z)$ is the amount of change of $P(y|x;\theta)$ when a small amount ϵ of z is replaced by the uninformative z'.

It is worth pointing out that we can regard $\mathcal{M}_{\text{replace}}(z)$ as an alternative way of measuring the amount of memorization of z, similar to how perturbation-based influence is an alternative way of measuring influence in (Koh and Liang, 2017).

With similar derivation steps, the computation of Eqn 3 is as follows:

$$\mathcal{M}_{\text{replace}}(z) = -s^{\top}\left(\nabla_{\theta} L(z, \hat{\theta}) - \nabla_{\theta} L(z', \hat{\theta})\right), \qquad (4)$$

where $s = H_{\hat{\theta}}^{-1} \nabla_{\theta} P(y|x;\hat{\theta})$. (For more details, please refer to Appendix B.)

The advantage of using this alternative measure of memorization is that $\mathcal{M}_{\text{replace}}(z)$ can be decomposed into a linear combination of scores, each corresponding to a single token in the input sequence. For NLP applications, the input x usually corresponds to an embedding matrix $\mathbf{X} \in \mathbb{R}^{N\times d}$ (where N is the number of tokens and d is the embedding dimensions). We can show that

$$\mathcal{M}_{\text{replace}}(z) = -\sum_{t=1}^{N}\sum_{l=1}^{d} r_{t,l}(\mathbf{X}_{t,l} - \mathbf{X}'_{t,l}), \qquad (5)$$

where $r = \left[\int_{\alpha=0}^{1} \frac{dg(\mathbf{X}'+\alpha(\mathbf{X}-\mathbf{X}'))}{dx} d\alpha\right] s$ and $g(\mathbf{X}) = \nabla_{\theta} L((\mathbf{X}, y), \hat{\theta})$, which can be efficiently computed by the hessian-vector product (Pearlmutter, 1994). For more details, please refer to Appendix B.

The memorization attribution of the t-th token is thus given by $-\sum_{l=1}^{d} r_{t,l} \times (\mathbf{X}_{t,l} - \mathbf{X}'_{t,l})$.

3 Experiments

With the memorization score defined in Eqn 2 and the memorization attribution score defined in Eqn 5, we now conduct experiments to answer the three research questions raised in Section 1.

3.1 Experiment Settings

We conduct our experiments on the following three datasets:

SST-2 (Socher et al., 2013): This is a dataset for sentence-level binary (positive vs. negative) sentiment classification. It consists of 6,920 training instances, 872 development instances and 1,821 test instances.

SNLI (MacCartney and Manning, 2008): This is a dataset for natural language inference, which aims to predict the entailment relation (contradiction, neutral or entailment) between a premise and a hypothesis. We combine the *contradiction* and *neutral* classes into a single *non-entailment* class, and randomly sample 10k training instances, 6,658 development instances and 6,736 test instances.

Yahoo! Answers (Zhang et al., 2015): This is a collection of question-answer pairs categorized into 10 topic-based classes. We randomly sample 10k training instances, 10k development instances and 10k test examples.

In addition, we also use **CIFAR-10** (Krizhevsky et al., 2009), which is a dataset for 10-class image classification. We randomly sample 10k training instances, 5k development instances and 10k test instances. For some tasks, we down-sample the training set because influence function is known to be expensive to compute.

For all NLP tasks, we adopt the pre-trained Distill-BERT model (Sanh et al., 2019) that consists of 6 transformer layers, where each layer consists of 12 attention heads. We use the final hidden state of the `[CLS]` token for classification.[1] For CIFAR-10, we extract visual grid features using a pre-trained ResNet50 (He et al., 2016) first and then train a MLP classifier on top of that.

We use the SGD optimizer, setting the learning rate, momentum and batch size to 0.01, 0.9 and 32, respectively. We tune other hyper-parameters on the development set manually.

Although influence function is model-dependent and therefore models trained with different random seeds may produce different memorization scores for the same training instance, we found that in practice, ranking training instances based on memorization scores obtained from models trained by different random seeds produces similar rankings across different models. Thus, we only consider a single model checkpoint for computing our self-influence based memorization scores in the following experiments. (See Appendix C for the exact description.) For memorization attribution, the number of Riemann Sum steps is set to be 50.

3.2 Checking Memorized Instances

Group	Negative	Positive
Top-10%	35.80	74.00
All	23.24	86.39
Bottom-10%	14.92	94.52

Table 1: The average percentage of *positive phrases* over (1) the top-10% memorized positive/negative instances, (2) all positive/negative instances, and (3) the bottom-10% memorized positive/negative instances.

In the first set of experiments, we use our self-influence-based memorization scoring function as defined in Eqn. 1 to rank the training instances.

Our goal is to check if the top-memorized instances are indeed atypical instances. However, it is difficult to measure the typicality of instances. We note that in the prior work (Feldman and Zhang, 2020) where the authors tried to validate the long-tail theory on computer vision datasets, there was not any quantitative experiment, and the authors relied only on qualitative analysis (i.e., manual inspection of the top-ranked instances) to show that memorized instances tend to be atypical. In our experiments, we perform two kinds of checking: (1) First, we adopt qualitative evaluation as Feldman and Zhang (2020) did on both SST-2 and SNLI. For Yahoo! Answers, however, because each instance contains a long document, it is not easy for humans to judge whether or not an instance is atypical. (2) Second, we define quantitative measures of typicality on sentiment analysis because annotations are available on this dataset and these annotations allow us to define some form of typicality.

SST-2

For SST-2, we judge whether or not the top-ranked memorized instances are atypical in two ways: (1) The first is based on a heuristic metric. We check the percentage of positive phrases in an instance, where phrase-level sentiment polarity labels are from the annotations provided by SST-2. Intuitively, a typical positive sentence should have a relatively high percentage of positive phrases and a typical negative sentence should have a relatively low percentage of positive phrases. We collect such statistics from SST-2 based on the phrase-level annotations and found that this is to a large extent true. For example, more than 75% of positive sentences have at least 78.31% of positive phrases and more than 75% of negative sentences have at most 35.73% of positive phrases. (See Appendix D for details.) Therefore, by checking the percentage of positive phrases inside a positive or negative instance, we can in a way judge whether that instance is typical or atypical. When calculating the percentage of positive phrases inside a sentence, we apply Laplace smoothing. (2) We also manually inspect the top-ranked and bottom-ranked training instances based on the memorization scores and use our human knowledge to judge whether the top-ranked ones are atypical while the bottom-ranked ones are typical.

---

[1] Following Han et al. (2020); Guo et al. (2021), we "freeze" the word embedding layer and the first 4 transformer layers, only fine-tuning the last 2 transformer layers and the final projection layer because of the computation limits.

Table 3: Top-3 and Bottom-3 memorized training examples from the SNLI task. Note that there are many examples having zero memorization score, we randomly sample 3 out of them.

Table 1 shows the average percentage of positive phrases in the top-10% of the memorized positive (or negative) training instances and the bottom-10% of the memorized positive (or negative) training instances. As a reference point, we also show the average percentage over all positive (or negative) training instances. We can see that the top-10% memorized instances indeed are atypical. Specifically, those negative sentences with high memorization scores have a high percentage of positive phrases on average (35.80%), clearly higher than the average percentage of positive phrases of all negative instances (23.24%). This makes the top-memorized negative instances very different from typical negative instances. On the other hand, the bottom-10% negative instances (i.e., those instances that are not memorized) have clearly much lower percentage of positive phrases (14.92%), which is what we expect for typical negative instances. Similar observations can be made with the positive training instances. Overall, the results in Table 1 suggest that indeed the top-memorized training instances in SST-2 are atypical.

Next, we manually inspect the top-ranked and bottom-ranked training instances of SST-2 in Table 2. We can see that the top-ranked memorized instances tend to express their overall opinions in an indirect way. These sentences often contain a contrast between positive and negative opinions. We therefore believe that they are atypical for sentiment classification. On the other hand, the bottom-ranked instances, i.e., those with 0 memorization scores, tend to directly expression their opinions with strong opinion phrases, and we believe these represent common instances.

SNLI

For the task of natural language inference, it is hard to come up with a heuristic metric like the one used for sentiment classification. We therefore focus on manual inspection of the top-ranked and bottom-ranked training instances. In Table 3 we show the top-3 and bottom-3 memorized training instances from SNLI. We can see from the table that in the top-ranked memorized non-entailment instances, the hypothesis tends to be much shorter than the premise and there tends to be no obvious contradiction. In contrast, the bottom-ranked non-entailment instances tend to be contradictions where there are obvious contradictory words/phrases in the premise and the hypothesis, such as "bicycle" vs. "motorcycle," "player" vs. "cat" and "posing for a picture" vs. "eating his lunch." We hypothesize that the top-ranked non-entailment instances are atypical because they do not have obvious signals of non-entailment such as the contradictory word pairs we see in the bottom-ranked non-entailment instances. For entailment cases, we find that the top-ranked instances often contain word pairs that are synonyms but are rare in the training data. For example, we find that the word pair "keyboard" and "piano" appears only two times in the training data, which implies that this instance is an atypical example. Similarly, we find that the word/phrase pair "iPod" and "mp3 player" appear only once in the training data. On the other hand, the bottom-ranked entailment instances tend to be those where the hypothesis contains less information than the premise, which may be a common type of entailment instances.

3.3 Marginal Utility of Memorized Instances

In the second set of experiments, we check whether memorizing those training instances with the highest memorization scores leads to better performance on the unseen test data. To do so, we compare the performance of the model on test data when top-ranked memorized training instances are removed during training versus the performance when the same number of *randomly* selected training instances are removed. If memorization is beneficial for the test data, then we would expect to see larger performance drop when top-ranked memorized training instances are removed than when random training instances are removed. Therefore, the amount of performance drop represents the marginal effect of the memorized instances on the test accuracy. We show the test accuracy in Figure 1 when $X\%$ of the training instances are removed, where we set X to a few different values. We re-train the model 5 times and show the average test accuracy as well as the standard deviation. We also show the lowest absolute memorization score of the top-$X\%$ of training instances in Figure 1. For reference, here we also use CIFAR-10 to verify that our self-influence estimation using the influence function works similarly to the influence estimator used by Feldman and Zhang (2020).

We can observe the following from Figure 1: (1) On CIFAR-10 (Figure 1(d)), we see that clearly the test accuracy drops more significantly when top-ranked memorized training instances instead of random training instances are removed. Because Feldman and Zhang (2020) reported the same observation, this suggests that our memorization score based on the influence function proposed by Koh and Liang (2017) works similarly to the memorization estimator used by Feldman and Zhang (2020). This verifies the reliability of our memorization scoring function. (2) On SST-2, Yahoo! Answers and SNLI, we can see that consistently when the same percentage of training instances are removed, removing top-ranked memorized instances has a clearly bigger impact on the test accuracy compared with removing random instances. For example, on SST-2, the marginal utility of the top-30% memorized training example is about 1.44 percentage points (vs. 0.70 percentage points for random subset of 30% of training examples).

This verifies that on SST-2, Yahoo! Answers and SNLI, memorizing those training instances could help improve the performance on the test data.

3.4 Evaluating Memorization Attribution

In this section, we evaluate whether our memorization attribution method is faithful, i.e., whether it indeed picks up tokens that have higher self-influence.

Intuitively, if the memorization attribution method detects those memorized tokens in a training instance faithfully, then removing these tokens in that instance should result in a lower influence $\mathcal{I}$ of the perturbed instance on its original form (details to be given in Appendix A). We therefore define a metric called Reduction Rate as follows:

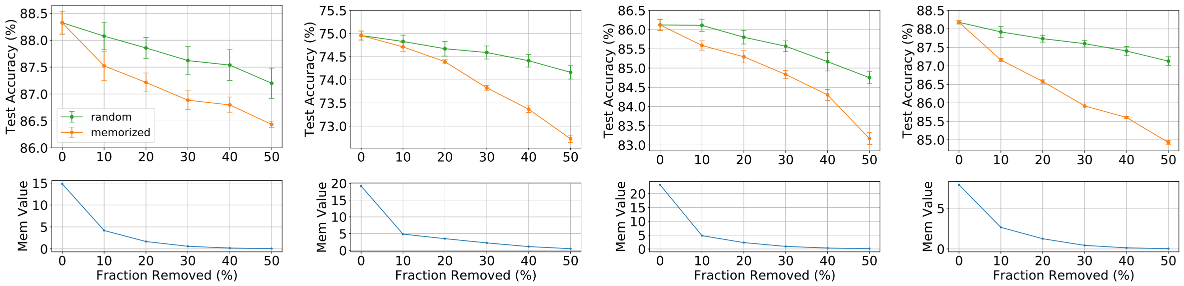
$$\frac{1}{|\mathcal{Z}|}\sum_{z\in\mathcal{Z}}\frac{\mathcal{I}(z,z)-\mathcal{I}(z^{\backslash\text{attr}},z)}{\mathcal{I}(z,z)}, \quad (6)$$

where $\mathcal{Z}$ is the set of top memorized training instances and $z^{\backslash\text{attr}}$ is the perturbed input where the top-$k\%$ memorized tokens are replace by the baseline token `[MASK]`. We can see that this Reduction Rate measures how much self-influence has been reduced after the top-memorized tokens are replaced with `[MASK]`.[2]

Figure 2 demonstrates the significant effect of the removal of the top-memorized tokens from the top-memorized training instances. One could ask whether this effect is solely due to the input perturbation. To answer this question we include in the

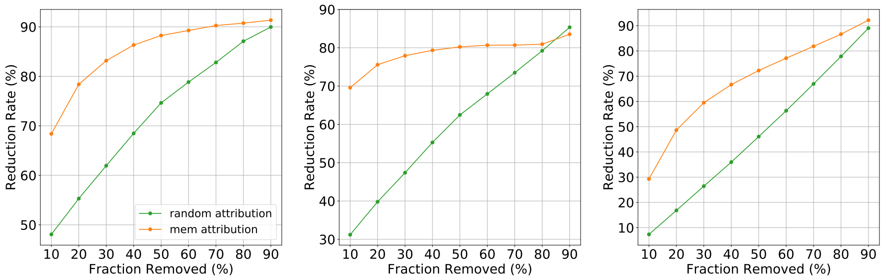
---

[2] We consider only top-10% memorized instances due to computation constraints.



(a) SST-2 (b) Yahoo! Answers (c) SNLI (d) CIFAR-10

Figure 1: For each dataset, the top figure shows the test accuracy after we remove the top-$X\%$ memorized training instances or the same number of randomly selected training instances. The test accuracy is averaged over 5 runs of retraining with different random seeds, and standard deviation is shown with the bars. The bottom figure shows the lowest memorization score of the top-$X\%$ of the memorized training instances.



(a) SST-2 (b) Yahoo! Answers (c) CIFAR-10

Figure 2: For each dataset, the top figure shows the reduction rate of removing the top-$k\%$ memorized tokens and of removing the same number of randomly selected training tokens.

comparison the reduction rate of random attribution, i.e., we randomly remove some tokens from the training instances. We can see that removing tokens picked up by our memorization attribution method results in a much larger Reduction Rate until almost 90% of the tokens are removed. This result suggests that our memorization attribution method can indeed identify those tokens in a training instance that have high self-influence on that instance.

3.5 Examples of Memorization Attribution

To better understand why certain training instances are memorized, we apply our memorization attribution method to SST-2, Yahoo! Answers and CIFAR-10. We do not discuss our memorization attribution method applied to the NLI task because we find that it is not easy to interpret the results. In some other studies (e.g., Han et al. (2020)), people have also reported different behaviours of NLI from tasks relying on shallow features such as sentiment classification and topic-based text classification.

We find that on SST-2, Yahoo! Answers and CIFAR-10, in most cases our memorization attributions are easy to be interpreted by humans. In particular, without any cherry-picking, we select those instances with the highest memorization scores to present. We find that interestingly, for both SST-2 and CIFAR-10, the trained deep learning model tends to memorize those parts of an instance that are negatively correlated with the class label of that instance, as shown in Table 4 and Figure 3.[3] On SST-2, for example, the model needs to memorize positive phrases such as “tremendous promise” and “intriguing and alluring” that show up in an overall negative instance. On CIFAR-10, we observe that for images that are easily mis-classified, the model memorizes those pixels that are associated with the wrong class label, or in other words, pixels that are negatively correlated with the correct class label. For example, the “cat” image shown in Figure 3 looks like a frog. The model memorizes those pixels (shown in red) around the tummy of the cat

---

[3] For Yahoo! Answers, because each instance is long, due to the space limit, we show the memorization attributions in the Appendix E.

Content	**Label**
starts out with tremendous promise introducing an intriguing and alluring premise only to fall prey to a boatload of screenwriting cliches that sink it faster than a leaky freighter	Neg
mr wollter and ms seldhal give strong and convincing performances but neither reaches into the deepest recesses of the character to unearth the quaking essence of passion grief and fear	Neg
this is a monumental achievement in practically every facet of inept filmmaking joyless idiotic annoying heavy handed visually atrocious and often downright creepy	Neg
the director mark pellington does a terrific job conjuring up a sinister menacing atmosphere though unfortunately all the story gives us is flashing red lights a rattling noise and a bump on the head	Pos
this is a fascinating film because there is no clear cut hero and no all out villain	Pos
the film is reasonably entertaining though it begins to drag two thirds through when the melodramatic aspects start to overtake the comedy	Pos

Table 4: The top-3 memorized training instances for each class from SST-2. Highlighted words are those with high attribution values (red for positive memorization attribution and blue for negative memorization attribution) as computed by our memorization attribution method.

Figure 3: The top-1 memorized training instance for each class from CIFAR-10. Highlighted patches are those having high attribution values (red for positive memorization attribution and blue for negative memorization attribution) as computed by our memorization attribution method.

because those pixels make the image look like a frog image. Similarly, in the "dog" image, which looks like a horse, the memorized pixels (shown in red) are around the body of the dog, and these pixels make the image look like a horse image. On the other hand, the dog's head in this image, which is a typical dog's head, has negative memorization attribution scores, which means it does not need to be memorized.

Given the interesting results above, we believe that model developers can gain insights about what a model finds hard to learn from other training instances (and thus has to memorize), and model developers can subsequently take actions like upweighting memorized instances or collecting similar data to improve the performance on certain subpopulations if desired.

4 Related Work

The long-tail theory: The long-tail theory proposed by Feldman (2020) is relatively new and has not been systematically validated in NLP. Our work is the first to empirically check the validity of this theory on NLP tasks. Raunak et al. (2021) used the long-tail theory to explain hallucinations under source perturbations in Neural Machine Translation. They assume the theory holds in NMT rather than validating the theory itself as we do. Kong and Chaudhuri (2021) investigated the memorization phenomenon for Variational Auto-Encoder also via self-influence.

Memorization vs. generalization: It is well-known that deep learning models possess strong capabilities to memorize training instances (Zhang et al., 2017; Arpit et al., 2017). In the context of NLP, Li and Wisniewski (2021) showed that BERT is more likely to memorize shallow patterns from the training data rather than uncover abstract properties. Some recent work has tried to combine interpolation methods with deep learning methods to generalize via memorization (Khandelwal et al., 2020, 2021). However, previous work using interpolation methods did not explain why memorization is necessary in the first place. Our work follows the long-tail theory that views memorization as beneficial to generalization when the data follows a certain type of long-tail distribution. There has also been some work studying "forgetting," which is related to memorization (Toneva et al., 2018; Yaghoobzadeh et al., 2021). However, in this paper we do not study this "forgetting" phenomenon.

Influence functions: Influence functions have been studied for large-scale deep neural networks by Koh and Liang (2017) and gained much attention in recent years. In the context of NLP, Han et al. (2020) explored the usage of influence functions to explain model predictions and unveil data artifacts. Meng et al. (2020) proposed a combination of gradient-based methods and influence functions to examine training history and test stimuli simultaneously. Our work, however, adopts influence function as a tool to measure memorization.

5 Conclusions

In this paper, we empirically examine a recently proposed long-tail theory in the context of NLP. We use sentiment classification, natural language inference and text classification to check the validity of the long-tail theory in NLP. We also propose a memorization attribution method to reveal which parts of an instance are being memorized. There are two major takeaway messages: (1) Our experiments empirically validated the long-tail theory on the three NLP datasets, showing that memorization is important for generalization, offers an alternative view and helps NLP researchers to see the value of memorization. (2) Our attribution method can be a tool to help model developers better understand the memorization behaviours of a model and possibly further improve the model.

6 Ethical Considerations

Our work empirically validated the long-tail theory in the context of NLP, offering an alternative view to the relationship between memorization and generalization. This will help NLP researchers see the value of memorization. However, previous work showed that neural networks can be vulnerable to privacy attacks such as membership inference attacks because these models are able to memorize training instances, and sometimes sensitive private information may be contained in the training instances (Shokri et al., 2017; Zhang et al., 2017; Feldman and Zhang, 2020). Thus, there is a tradeoff between the accuracy of a model and the privacy of the data. In other words, although memorization can help reduce generalization error (as we showed in this paper), it also increases the vulnerability of the system to privacy attacks, which raises ethical concerns.

The computation of influence functions used in our work is massive because of the computation of inverting the hessian matrices. To reduce the computation costs, i.e., power consumption, we may adopt other influence estimators like TracIn (Pruthi et al., 2020), which is hessian-free and thus faster.

A Derivation of the Memorization Scores

For clarity, here we repeat the derivation of Influence Functions by Koh and Liang (2017) and provide self-influence functions as its special case. Note that self-influence functions are used as our memorization scores.

Given training points $z_1, ..., z_n$, where $z_i = (x_i, y_i)$, x_i is the observation and y_i is the label, we train a predictor via minimizing the empirical risk $R(\theta) \overset{\text{def}}{=} \frac{1}{n}\sum_{i=1}^{n} L(z_i, \theta)$ to pick parameters $\theta \in \Theta$. I.e., the optimal parameters are obtained by $\hat{\theta} = \arg\min_{\theta\in\Theta} R(\theta)$. We assume that R is twice-differentiable and strongly convex.

i.e.,

$$H_{\hat{\theta}} \overset{\text{def}}{=} \nabla^2 R(\hat{\theta}) = \frac{1}{n}\sum_{i=1}^{n} \nabla_{\theta}^2 L(z_i, \hat{\theta}) \tag{7}$$

exists and is positive definite. This guarantees the existence of $H_{\hat{\theta}}^{-1}$, which we will use in the following derivation.

The high-level idea of Influence Functions is to approximate leave-one-out retraining, which corresponds to a removing operation, via computing the parameter change if z were up-weighted or down-weighted by some small amount ϵ.

If we up-weight the training point z, the perturbed parameters $\hat{\theta}_{\epsilon,z}$ can be written as

$$\hat{\theta}_{\epsilon,z} = \arg\min_{\theta\in\Theta} \left(R(\theta) + \epsilon L(z, \theta)\right). \tag{8}$$

Consider the parameter change $\Delta_\epsilon = \hat{\theta}_{\epsilon,z} - \hat{\theta}$, and note that, as $\hat{\theta}$ does not depend on ϵ, the quantity we want to compute can be written in terms of it:

$$\frac{d\hat{\theta}_{\epsilon,z}}{d\epsilon} = \frac{d\Delta_\epsilon}{d\epsilon}. \tag{9}$$

Since $\hat{\theta}_{\epsilon,z}$ is a minimizer of Eqn 8, let us examine its first-order optimality condition:

$$0 = \nabla R(\hat{\theta}_{\epsilon,z}) + \epsilon \nabla L(z, \hat{\theta}_{\epsilon,z}). \tag{10}$$

Let us define $f(\theta)$ to be $\nabla R(\theta) + \epsilon \nabla L(z, \theta)$.

Next, since $\hat{\theta}_{\epsilon,z} \to \hat{\theta}$ as $\epsilon \to 0$, we perform a Taylor expansion on $f(\hat{\theta}_{\epsilon,z})$. Given Taylor's Formula $f(\theta + \Delta\theta) = f(\theta) + f'(\theta)\Delta\theta + o(\Delta\theta)$, we have:

$$\begin{aligned} 0 &= f(\hat{\theta}_{\epsilon,z}) \\ &= f(\hat{\theta} + \Delta_\epsilon) \\ &\approx f(\hat{\theta}) + f'(\hat{\theta})\Delta_\epsilon \\ &= [\nabla R(\hat{\theta}) + \epsilon \nabla L(z, \hat{\theta})] \\ &\quad + [\nabla^2 R(\hat{\theta}) + \epsilon \nabla^2 L(z, \hat{\theta})]\Delta_\epsilon, \end{aligned} \tag{11}$$

where we have dropped the term $o(\|\Delta_\epsilon\|)$.

Solving for Δ_ϵ, we get $\Delta_\epsilon \approx -[\nabla^2 R(\hat{\theta}) + \epsilon \nabla^2 L(z, \hat{\theta})]^{-1}[\nabla R(\hat{\theta}) + \epsilon \nabla L(z, \hat{\theta})]$.

Since $\hat{\theta}$ minimizes R, we have $\nabla R(\hat{\theta}) = 0$. Then we have:

$$\Delta_\epsilon \approx -[\nabla^2 R(\hat{\theta}) + \epsilon \nabla^2 L(z, \hat{\theta})]^{-1} \epsilon \nabla L(z, \hat{\theta}). \tag{12}$$

Referring to (Henderson and Searle, 1981), we have:

$$\begin{aligned} (A + B)^{-1} &= (I + A^{-1}B)^{-1}A^{-1} \\ &= A^{-1} - A^{-1}B(I + A^{-1}B)^{-1}A^{-1} \\ &= A^{-1} - A^{-1}B(A + B)^{-1}, \end{aligned} \tag{13}$$

which only requires A and $A+B$ to be nonsingular matrix. As mentioned above, the matrices that we are considering are positive definite. The determinant of a positive definite matrix is always positive, so a positive definite matrix is always nonsingular.

Substituting $A = \nabla^2 R(\hat{\theta})$ and $B = \epsilon \nabla^2 L(z, \hat{\theta})$ and dropping $o(\epsilon)$ terms, we have

$$\Delta_\epsilon \approx -\nabla^2 R(\hat{\theta})^{-1} \nabla L(z, \hat{\theta})\epsilon. \tag{14}$$

Combining with Eqn 7 and Eqn 9, we conclude that:

$$\left.\frac{d\hat{\theta}_{\epsilon,z}}{d\epsilon}\right|_{\epsilon=0} = -H_{\hat{\theta}}^{-1} \nabla L(z, \hat{\theta}). \tag{15}$$

We instead down-weight the training point z to keep consistency with our memorization attribution method introduced later, the perturbed parameters $\hat{\theta}_{\epsilon,-z}$ can be written as

$$\hat{\theta}_{\epsilon,-z} = \arg\min_{\theta\in\Theta} \left(R(\theta) - \epsilon L(z, \theta)\right). \tag{16}$$

It is easy to see that

$$\left.\frac{d\hat{\theta}_{\epsilon,-z}}{d\epsilon}\right|_{\epsilon=0} = H_{\hat{\theta}}^{-1} \nabla L(z, \hat{\theta}). \tag{17}$$

Next, we apply the chain rule to measure how down-weighting z changes functions of $\hat{\theta}$.

$$\begin{aligned} \mathcal{I}(z, z_{\text{test}}) &\overset{\text{def}}{=} \left.\frac{dF(y_{\text{test}}, x_{\text{test}}; \hat{\theta}_{\epsilon,-z})}{d\epsilon}\right|_{\epsilon=0} \\ &= \nabla_\theta F(y_{\text{test}}, x_{\text{test}}; \hat{\theta})^\top \left.\frac{d\hat{\theta}_{\epsilon,-z}}{d\epsilon}\right|_{\epsilon=0} \\ &= \nabla_\theta F(y_{\text{test}}, x_{\text{test}}; \hat{\theta})^\top H_{\hat{\theta}}^{-1} \nabla_\theta L(z, \hat{\theta}), \end{aligned} \tag{18}$$

where F is usually the loss function.

While influence function is generally used to measure the influence of a training instance on a test instance, if we use it to measure the influence of a training instance on itself, i.e., to measure self-influence, then this self-influence corresponds to the general notion of memorization defined by Feldman (2020); Feldman and Zhang (2020). Based on this notion, we set F as the negative estimated conditional probability $-P(y|x;\theta)$ and define the memorization score for a training instance z as follows:

$$\begin{aligned}\mathcal{M}_{\text{remove}}(z) &\overset{\text{def}}{=} -\left.\frac{dP(y|x;\hat{\theta}_{\epsilon,-z})}{d\epsilon}\right|_{\epsilon=0} \\ &= -\nabla_{\theta}P(y|x;\hat{\theta})^{\top}\left.\frac{d\hat{\theta}_{\epsilon,-z}}{d\epsilon}\right|_{\epsilon=0} \\ &= -\nabla_{\theta}P(y|x;\hat{\theta})^{\top}H_{\hat{\theta}}^{-1}\nabla_{\theta}L(z,\hat{\theta}).\end{aligned} \tag{19}$$

B Derivation of Memorization Attribution

In order to better understand why an instance is memorized, we propose a fine-grained notion of memorization at "feature" level instead of instance level, i.e., to attribute the memorization score of an instance to its individual features.

To conduct attribution, a natural requirement is to introduce a baseline. Thus we first consider a variant of the Influence Functions that approximates the resulting effect of *replacing* a training point z with a baseline training point z', which is similar to the perturbation-based influence by Koh and Liang (2017).

The perturbed parameter $\hat{\theta}_{\epsilon,z_{\delta},-z}$ can be written as:

$$\hat{\theta}_{\epsilon,z',-z} = \arg\min_{\theta\in\Theta}\left(R(\theta) + \epsilon L(z',\theta) - \epsilon L(z,\theta)\right). \tag{20}$$

Similar to the derivation shown the previous section, we can derive the following definition of a memorization score based on such perturbation:

$$\begin{aligned}\mathcal{M}_{\text{replace}}(z) &\overset{\text{def}}{=} -\left.\frac{dP(y|x;\hat{\theta}_{\epsilon,z',-z})}{d\epsilon}\right|_{\epsilon=0} \\ &= -\nabla_{\theta}P(y|x;\hat{\theta})^{\top}\left.\frac{d\hat{\theta}_{\epsilon,z',-z}}{d\epsilon}\right|_{\epsilon=0} \\ &= -s^{\top}\left(\nabla_{\theta}L(z,\hat{\theta}) - \nabla_{\theta}L(z',\hat{\theta})\right),\end{aligned} \tag{21}$$

where $s = H_{\hat{\theta}}^{-1}\nabla_{\theta}P(y|x;\hat{\theta})$.

We now show that $\mathcal{M}_{\text{replace}}(z)$ can be decomposed into a linear combination of scores, each corresponding to a single token in the input sequence. For NLP applications, the input x usually corresponds to an embedding matrix $\mathbf{X} \in \mathbb{R}^{N\times d}$ (where N is the number of tokens and d is the embedding dimensions). Let us denote $\nabla_{\theta}L\left((\cdot,y),\hat{\theta}\right)$ as $g(\cdot)$ and consider the path integral along a straight line between $\mathbf{X}$ and $\mathbf{X}'$, yielding

$$g(\mathbf{X}) - g(\mathbf{X}') = H'(\mathbf{X}-\mathbf{X}'), \tag{22}$$

where $H' = \left[\int_{\alpha=0}^{1}\frac{dg(\mathbf{X}'+\alpha(\mathbf{X}-\mathbf{X}'))}{dx}d\alpha\right]$ and could be efficiently approximated by Riemann Sum as suggested by Sundararajan et al. (2017).

The reason of using path integral rather than the gradient at the input $\mathbf{X}$ is that a function's gradient may saturate around the input and integrating along a path can alleviate this issue. As for the reasons of choosing a straight line between the input and the baseline, first of all, it is obviously the simplest path. Besides, using a straight line allows the Integrated Gradients to meet the Symmetry-Preserving property. For more details, please check the original paper on IG (Sundararajan et al., 2017).

Substituting Eqn (22) into Eqn (21), we get

$$\begin{aligned}\mathcal{M}_{\text{replace}}(z) &= -s^{\top}\left(g(\mathbf{X}) - g(\mathbf{X}')\right) \\ &= -s^{\top}H'(\mathbf{X}-\mathbf{X}') \\ &= -r^{\top}(\mathbf{X}-\mathbf{X}') \\ &= -\sum_{t=1}^{N}\sum_{l=1}^{d} r_{t,l}(\mathbf{X}_{t,l} - \mathbf{X}'_{t,l}),\end{aligned} \tag{23}$$

where $r = H's$, which could be efficiently computed by the the hessian-vector product (Pearlmutter, 1994).

C The Effect of Different Checkpoints

Our self-influence-based memorization score is dependent on the model used to compute the influence function. A model trained with different random seeds will have different self-influence values, so there is inherently some stochasticity in the measurement of influence or self influence.

To address this issue, on SST-2, we train the model using different random seeds to obtain three checkpoints and compute the corresponding memorization scores. We found that the instance rankings produced by these different checkpoints are highly correlated, based on Spearman's Rank Correlation Coefficient, as shown in Table 5. Thus, we only consider one checkpoint when computing the memorization scores.

		a	b	c
seed	a	1.00	0.99	0.98
	b	0.99	1.00	0.99
	c	0.98	0.99	1.00

Table 5: Spearman's rank correlation coefficients between different rankings of the training instances produced by different checkpoints of the trained model on SST-2.

D The Distribution of Positive Phrase Fraction

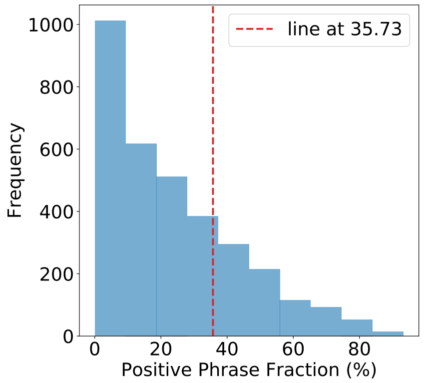
For the task of sentiment classification, i.e., the experiments on SST-2, we hypothesize that a typical positive sentence should have a relatively high percentage of positive phrases and a typical negative sentence should have a relatively low percentage of positive phrases. Note that here we consider phrase-level sentiment instead of word-level sentiment because we want to take into account the negation phenomena such as the phrase "not bad" expressing a positive sentiment although the word "bad" contains a negative sentiment. To support our hypothesis, we conduct the following quantitative experiment.

Given the phrase-level sentiment annotations provided by the SST-2 dataset (Socher et al., 2013), for every instance z, we count how many positive phrases and negative phrases it contains, respectively. Then, we turn the absolute counts into a relative fraction:

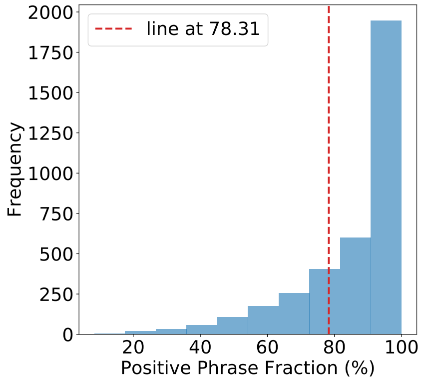
$$\text{frac}(z)_c = \frac{\text{count}(z)_c + k}{\sum_{c' \in \{\text{neg},\text{pos}\}} (\text{count}(z)_{c'} + k)}, \quad (24)$$

where $\text{count}(z)_c$ is the number of phrases with sentiment c in instance z, and add-k-smoothing is used to avoid division by zero. Here k is set as 0.01.

We plot the distributions of positive phrase fractions for both positive instances and negative instances. The results are shown in Figure 4. The results demonstrate that if we use the positive fraction to characterize the SST-2 data, then SST-2 instances of each class follow a long-tail distribution, and in the main body of our paper, we show that the top-memorized positive and negative instances likely lie in the tail end of the two distributions, judging by their average positive fraction value.



(a) Negative Class



(b) Positive Class

Figure 4: The distribution of positive phrase fraction on SST-2.

E Examples of Memorization Attribution

Some examples of Memorization Attribution on Yahoo! Answers are shown in Table 6. In particular, without any cherry-picking, we select those instances with the highest memorization scores to present. We can observe that on Yahoo! Answers, for most cases, the model tends to memorize those atypical parts of an instance. For example, the model needs to memorize the word "business" that shows up in an instance labeled as "Health" and the word "sports" in the "Education & Reference" instance. However, one might wonder why words like "football" and "field" received high memorization scores for the example in "Sports". Although we are not certain, we hypothesize that this might be due to the fact that the span "football field" is atypical for the "Sports" category, because we find that this span shows up in only 2 instances out of 1000 "Sports" instance in our training set.

Abstract

Pretrained multilingual models are able to perform cross-lingual transfer in a zero-shot setting, even for languages unseen during pretraining. However, prior work evaluating performance on unseen languages has largely been limited to low-level, syntactic tasks, and it remains unclear if zero-shot learning of high-level, semantic tasks is possible for unseen languages. To explore this question, we present AmericasNLI, an extension of XNLI (Conneau et al., 2018) to 10 Indigenous languages of the Americas. We conduct experiments with XLM-R, testing multiple zero-shot and translation-based approaches. Additionally, we explore model adaptation via continued pretraining and provide an analysis of the dataset by considering hypothesis-only models. We find that XLM-R's zero-shot performance is poor for all 10 languages, with an average performance of 38.48%. Continued pretraining offers improvements, with an average accuracy of 43.85%. Surprisingly, training on poorly translated data by far outperforms all other methods with an accuracy of 49.12%.

1 Introduction

Pretrained multilingual models such as XLM (Lample and Conneau, 2019), multilingual BERT (mBERT; Devlin et al., 2019), and XLM-R (Conneau et al., 2020) achieve strong cross-lingual transfer results for many languages and natural language processing (NLP) tasks. However, there exists a discrepancy in terms of zero-shot performance between languages present in the pretraining data and those that are not: performance is generally highest for well-represented languages and decreases with less representation. Yet, even for unseen languages, performance is generally above chance, and model adaptation approaches have been shown to yield further improvements (Muller et al., 2020; Pfeiffer et al., 2020a,b; Wang et al., 2020).

Table 1: The languages in AmericasNLI, along with their ISO codes, language families, and dataset sizes.

Importantly, however, there are currently no datasets for high-level, semantic tasks which focus solely on low-resource languages. As these languages are most likely to be unseen to commonly used pretrained models, practically all work evaluating unseen language performance and language adaptation methods has been limited to low-level, syntactic tasks such as part-of-speech tagging, dependency parsing, and named-entity recognition (Muller et al., 2020; Wang et al., 2020). This largely limits our ability to draw more general conclusions with regards to the zero-shot learning abilities of pretrained multilingual models for unseen languages.

In this work, we introduce AmericasNLI, an extension of XNLI (Conneau et al., 2018) – a natural language inference (NLI; cf. §2.3) dataset covering 15 high-resource languages – to 10 Indigenous languages spoken in the Americas: Asháninka, Aymara, Bribri, Guaraní, Nahuatl, Otomí, Quechua, Rarámuri, Shipibo-Konibo, and Wixarika. All of them are *truly* low-resource languages: they have little to no digitally available labeled or unlabeled

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 6279 - 6299
May 22-27, 2022

data, and they are not typically studied by the mainstream NLP community. The goal of this work is two-fold: First, we hope to increase the visibility of these languages by providing a portion of the resources necessary for NLP research. Second, we aim to allow for a more comprehensive study of multilingual model performance on unseen languages, where improvements will help extend the reach of NLP techniques to a larger set of languages. We are specifically interested in the following research questions: (1) Do pretrained multilingual models still perform above random chance for a high-level, semantic task in an unseen language? (2) Do methods aimed at adapting models to unseen languages – previously exclusively evaluated on low-level, syntactic tasks – also increase performance on NLI? (3) Are translation-based approaches effective for truly low-resource languages, where translation quality is typically very poor?[1]

We experiment with XLM-R, both with and without model adaptation via continued pretraining on monolingual corpora in the target language. Our results show that the performance of XLM-R out-of-the-box is moderately above chance, and model adaptation leads to improvements of up to 5.86 percentage points. Training on machine-translated training data, however, results in an even larger performance gain of 11.13 percentage points over the corresponding XLM-R model without adaptation. We further perform an analysis via experiments with hypothesis-only models, to examine potential artifacts which may have been inherited from XNLI and find that performance is above chance for most models, but still below that for using the full example.

AmericasNLI is publicly available[2] and we hope that it will serve as a benchmark for measuring the zero-shot natural language understanding abilities of multilingual models for unseen languages. Additionally, we hope that our dataset will motivate the development of novel pretraining and model adaptation techniques which are suitable for truly low-resource languages.

2 Background and Related Work

2.1 Pretrained Multilingual Models

Prior to the widespread use of pretrained transformer models, cross-lingual transfer was mainly achieved through word embeddings (Mikolov et al., 2013; Pennington et al., 2014; Bojanowski et al., 2017), either by aligning monolingual embeddings into the same embedding space (Lample et al., 2018b,a; Grave et al., 2018) or by training multilingual embeddings (Ammar et al., 2016; Artetxe and Schwenk, 2019). Pretrained multilingual models represent the extension of multilingual embeddings to pretrained transformer models.

These models follow the standard pretraining–finetuning paradigm: they are first trained on unlabeled monolingual corpora from various languages (the *pretraining languages*) and later finetuned on target-task data in a – usually high-resource – source language. Having been exposed to a variety of languages through this training setup, cross-lingual transfer results for these models are competitive with the state of the art for many languages and tasks. Commonly used models are mBERT (Devlin et al., 2019), which is pretrained on the Wikipedias of 104 languages with masked language modeling (MLM) and next sentence prediction (NSP), and XLM, which is trained on 15 languages and introduces the translation language modeling objective, which is based on MLM, but uses pairs of parallel sentences. XLM-R has improved performance over XLM, and trains on data from 100 different languages with only the MLM objective. Common to all models is a large shared subword vocabulary created using either BPE (Sennrich et al., 2016) or SentencePiece (Kudo and Richardson, 2018) tokenization.

2.2 Evaluating Pretrained Multilingual Models

Just as in the monolingual setting, where benchmarks such as GLUE (Wang et al., 2018) and SuperGLUE (Wang et al., 2019) provide a look into the performance of models across various tasks, multilingual benchmarks (Hu et al., 2020; Liang et al., 2020) cover a wide variety of tasks involving sentence structure, classification, retrieval, and question answering.

Additional work has been done examining what mechanisms allow multilingual models to transfer across languages (Pires et al., 2019; Wu and Dredze, 2019). Wu and Dredze (2020) examine transfer performance dependent on a language's representation in the pretraining data. For languages with low representation, multiple methods have been proposed to improve performance, in-

---

[1] We provide a sample of sentence pairs in Table D.3.

[2] `https://github.com/abteen/americasnli`

cluding extending the vocabulary, transliterating the target text, and continuing pretraining before finetuning (Lauscher et al., 2020; Chau et al., 2020; Muller et al., 2020; Pfeiffer et al., 2020a,b; Wang et al., 2020). In this work, we focus on continued pretraining to analyze the performance of model adaptation for a high-level, semantic task.

2.3 Natural Language Inference

Given two sentences, the *premise* and the *hypothesis*, the task of NLI consists of determining whether the hypothesis logically entails, contradicts, or is neutral to the premise. The most widely used datasets for NLI in English are SNLI (Bowman et al., 2015) and MNLI (Williams et al., 2018). XNLI (Conneau et al., 2018) is the multilingual expansion of MNLI to 15 languages, providing manually translated evaluation sets and machine-translated training sets. While datasets for NLI or the similar task of recognizing textual entailment exist for other languages (Bos et al., 2009; Alabbas, 2013; Eichler et al., 2014; Amirkhani et al., 2020), their lack of similarity prevents a generalized study of cross-lingual zero-shot performance. This is in contrast to XNLI, where examples for all 15 languages are parallel. To preserve this property of XNLI, when creating AmericasNLI, we choose to translate Spanish XNLI as opposed to creating examples directly in the target language.

However, NLI datasets are not without issue: Gururangan et al. (2018) show that artifacts from the creation of MNLI allow for models to classify examples depending on only the hypothesis, showing that models may not be reasoning as expected. Motivated by this, we provide further analysis of AmericasNLI in Section 6 by comparing the performance of hypothesis-only models to models trained on full examples.

3 AmericasNLI

3.1 Data Collection Setup

AmericasNLI is the translation of a subset of XNLI (Conneau et al., 2018). As translators between Spanish and the target languages are more frequently available than those for English, we translate from the Spanish version. Additionally, some translators reported that code-switching is often used to describe certain topics, and, while many words without an exact equivalence in the target language are worked in through translation or interpretation, others are kept in Spanish. To minimize the amount of Spanish vocabulary in the translated examples, we choose sentences from genres that we judged to be relatively easy to translate into the target languages: "face-to-face," "letters," and "telephone." We choose up to 750 examples from each of the development and test set, with exact counts for each language in Table 1.

3.2 Languages

We now discuss the languages in AmericasNLI. For additional background on previous NLP research on Indigenous languages of the Americas, we refer the reader to Mager et al. (2018). A summary of this information can be found in Table C.1.

Aymara Aymara is a polysynthetic Amerindian language spoken in Bolivia, Chile, and Peru by over two million people (Homola, 2012). Aymara follows an SOV word order and has multiple dialects, including Northern and Southern Aymara, spoken on the southern Peruvian shore of Lake Titicaca as well as around La Paz and, respectively, in the eastern half of the Iquique province in northern Chile, the Bolivian department of Oruro, in northern Potosi, and southwest Cochabamba. AmericasNLI examples are translated into the Central Aymara variant, specifically Aymara La Paz.

Asháninka Asháninka is an Amazonian language from the Arawak family, spoken by 73,567 people[3] in Central and Eastern Peru, in a geographical region located between the eastern foothills of the Andes and the western fringe of the Amazon basin (Mihas, 2017). Asháninka is an agglutinating and polysynthetic language with a VSO word order.

Bribri Bribri is a Chibchan language spoken by 7,000 people in Southern Costa Rica (INEC, 2011). It has three dialects, and while it is still spoken by children, it is currently a vulnerable language (Moseley, 2010; Sánchez Avendaño, 2013). Bribri is a tonal language with SOV word order. There are several orthographies which use different diacritics for the same phenomena, however even for researchers who use the same orthography, the Unicode encoding of similar diacritics differs amongst authors. Furthermore, the dialects of Bribri differ in their exact vocabularies, and there are phonological processes, like the deletion of unstressed vowels, which also change the tokens found in texts. As

Table 2: A parallel example in AmericasNLI with the *entailment* label.

Bribri has only been a written language for about 40 years, existing materials have a large degree of idiosyncratic variation. These variations are standardized in AmericasNLI, which is written in the Amubri variant.

Guaraní Guaraní is spoken by between 6 to 10 million people in South America and roughly 3 million people use it as their main language, including more than 10 native nations in Paraguay, Brazil, Argentina, and Bolivia, along with Paraguayan, Argentinian, and Brazilian peoples. According to the Paraguayan Census, in 2002 there were around 1.35 million monolingual speakers, which has since increased to around 1.5 million people (Dos Santos, 2017; Melià, 1992).[4] Although the use of Guaraní as spoken language is much older, the first written record dates to 1591 (Catechism) followed by the first dictionary in 1639 and linguistic descriptions in 1640. The official grammar of Guaraní was approved in 2018. Guaraní is an agglutinative language, with ample use of prefixes and suffixes.

Nahuatl Nahuatl belongs to the Nahuan subdivision of the Uto-Aztecan language family. There are 30 recognized variants of Nahuatl spoken by over 1.5 million speakers across Mexico, where Nahuatl is recognized as an official language (SEGOB, 2020b). Nahuatl is polysynthetic and agglutinative, and many sentences have an SVO word order or, for contrast and focus, a VSO order, and for emphasis, an SOV order (MacSwan, 1998). The translations in AmericasNLI belong to the Central Nahuatl (Náhuatl de la Huasteca) dialect. As there is a lack of consensus regarding the orthographic standard, the orthography is normalized to a version similar to Classical Nahuatl.

Otomí Otomí belongs to the Oto-Pamean language family and has nine linguistic variants with different regional self-denominations. Otomí is a tonal language following an SVO order, and there are around 307,928 speakers spread across 7 Mexican states. In the state of Tlaxcala, the *yuhmu* or *ñuhmu* variant is spoken by fewer than 100 speakers, and we use this variant for the Otomí examples in AmericasNLI.

Quechua Quechua, or *Runasimi*, is an Indigenous language family spoken primarily in the Peruvian Andes. It is the most widely spoken pre-Columbian language family of the Americas, with around 8-10 million speakers. Approximately 25% (7.7 million) of Peruvians speak a Quechuan language, and it is the co-official language in many regions of Peru. There are multiple subdivisions of Quechua , and AmericasNLI examples are translated into the standard version of Southern Quechua, Quechua Chanka, also known as Quechua Ayacucho, which is spoken in different regions of Peru and can be understood in different areas of other countries, such as Bolivia or Argentina. In AmericasNLI, the apostrophe and pentavocalism from other regions are not used.

Rarámuri Rarámuri, also known as *Tarahumara*, which means *light foot* (INALI, 2017), belongs

to the Taracahitan subgroup of the Uto-Aztecan language family (Goddard, 1996), and is polysynthetic and agglutinative. Rarámuri is an official language of Mexico, spoken mainly in the Sierra Madre Occidental region by a total of 89,503 speakers (SEGOB, 2020c). AmericasNLI examples are translated into the Highlands variant (INALI, 2009), and translation orthography and word boundaries are similar to Caballero (2008).

Shipibo-Konibo Shipibo-Konibo is a Panoan language spoken by around 35,000 native speakers in the Amazon region of Peru. Shipibo-Konibo uses an SOV word order (Faust, 1973) and postpositions (Vasquez et al., 2018). The translations in AmericasNLI make use of the official alphabet and standard writing supported by the Ministry of Education in Peru.

Wixarika The Wixarika, or *Huichol*, language, meaning *the language of the doctors and healers* (Lumholtz, 2011), is a language in the Corachol subgroup of the Uto-Aztecan language family (Campbell, 2000). Wixarika is a national language of Mexico with four variants , spoken by a total of around 47,625 speakers (SEGOB, 2020a). Wixarika is a polysynthetic language and follows an SOV word order. Translations in AmericasNLI are in Northern Wixarika and use an orthography common among native speakers (Mager-Hois, 2017).

4 Experiments

In this section, we detail the experimental setup we use to evaluate the performance of various approaches on AmericasNLI.

4.1 Zero-Shot Learning

Pretrained Model We use XLM-R (Conneau et al., 2020) as the pretrained multilingual model in our experiments. The architecture of XLM-R is based on RoBERTa (Liu et al., 2019), and it is trained using MLM on web-crawled data in 100 languages. It uses a shared vocabulary consisting of 250k subwords, created using SentencePiece (Kudo and Richardson, 2018) tokenization. We use the `Base` version of XLM-R for our experiments.

Adaptation Methods To adapt XLM-R to the various target languages, we continue training with the MLM objective on monolingual text in the target language before finetuning. To keep a fair comparison with other approaches, we only use target data which was also used to train the translation models, which we describe in Section 4.2. However, we note that one benefit of continued pretraining for adaptation is that it does not require parallel text, and could therefore benefit from text which could not be used for a translation-based approach. For continued pretraining, we use a batch size of 32 and a learning rate of 2e-5. We train for a total of 40 epochs. Each adapted model starts from the same version of XLM-R, and is adapted individually to each target language, which leads to a different model for each language. We denote models adapted with continued pretraining as `+MLM`.

Finetuning To finetune XLM-R, we follow the approach of Devlin et al. (2019) and use an additional linear layer. We train on either the English MNLI data or the machine-translated Spanish data, and we call the final models XLM-R (en) and XLM-R (es), respectively. Following Hu et al. (2020), we use a batch size of 32 and a learning rate of 2e-5. We train for a maximum of 5 epochs, and evaluate performance every 2500 steps on the XNLI development set. We employ early stopping with a patience of 15 evaluation steps and use the best performing checkpoint for the final evaluation. All finetuning is done using the Huggingface Transformers library (Wolf et al., 2020) with up to two Nvidia V100 GPUs. Using Lacoste et al. (2019), we estimate total carbon emissions to be 75.6 kgCO_2eq.

Table 4: Results for zero-shot, translate-train, and translate-test averaged over 3 runs with different seeds. The majority baseline represents expected performance when predicting only the majority class of the test set. Random guessing would result in an accuracy of 33.33%. Standard deviations in the Avg. column are calculated by taking the square root of the average variance of the languages in that row.

4.2 Translation-based Approaches

We also experiment with two translation-based approaches, translate-train and translate-test, detailed below along with the translation model used.

Translation Models For our translation-based approaches, we train two sets of translation models: one to translate from Spanish into the target language, and one in the opposite direction. We use transformer sequence-to-sequence models (Vaswani et al., 2017) with the hyperparameters proposed by Guzmán et al. (2019). Parallel data used to train the translation models can be found in Table B.1. We employ the same model architecture for both translation directions, and we measure translation quality in terms of BLEU (Papineni et al., 2002) and ChrF (Popović, 2015), cf. Table 3. We use fairseq (Ott et al., 2019) to implement all translation models.[5]

Translate-train For the translate-train approach, the Spanish training data provided by XNLI is translated into each target language. It is then used to finetune XLM-R for each language individually. Along with the training data, we also translate the Spanish development data, which is used for validation and early stopping. We discuss the effects of using a translated development set in Section F.1. Notably, we find that the finetuning hyperparameters defined above do not reliably allow the model to converge for many of the target languages. To find suitable hyperparameters, we tune the batch size and learning rate by conducting a grid search over {5e-6, 2e-5, 1e-4} for the learning rate and {32, 64, 128} for the batch size. In order to select hyperparameters which work well across all languages, we evaluate each run using the average performance on the machine-translated Aymara and Guaraní development sets, as these languages have moderate and high ChrF scores, respectively. We find that decreasing the learning rate to 5e-6 and keeping the batch size at 32 yields the best performance. Other than the learning rate, we use the same approach as for zero-shot finetuning.

Translate-test For the translate-test approach, we translate the test sets of each target language into Spanish. This allows us to apply the model finetuned on Spanish, XLM-R (es), to each test set. Additionally, a benefit of translate-test over translate-train and the adapted XLM-R models is that we only need to finetune once overall, as opposed to once per language. For evaluation, we use the checkpoint with the highest performance on the Spanish XNLI development set.

5 Results and Discussion

Zero-shot Models We present our results in Table 4. Results for the development set are presented in Table E.1. Zero-shot performance is low for all 10 languages, with an average accuracy of 38.48% and 37.99% for the English and Spanish model, respectively. However, in all cases the performance is higher than the majority baseline. As shown in

Table 5: Hypothesis-only results. The *Avg.* column represents the average of the hypothesis-only results, while the *Avg.+P* column, taken from Table 4, represents the average of the languages when using both the premise and hypothesis.

Table E.3 in the appendix, the same models achieve an average of 74.20% and 75.35% accuracy respectively, when evaluated on the 15 XNLI languages.

Interestingly, even though code-switching with Spanish is encountered in many target languages, finetuning on Spanish labeled data on average slightly underperforms the model trained on English, however performance is better for 3 of the languages. The English model achieves a highest accuracy of 42.59%, when evaluated on Nahuatl, while the Spanish model achieves a highest accuracy of 39.51%, when evaluated on Quechua. The lowest performance is achieved when evaluating on Aymara and Rarámuri, for the English and Spanish model, respectively.

We find that model adaptation via continued pretraining improves both models, with an average gain of 5.22 percentage points for English and 5.86 percentage points for Spanish. Notably, continued pretraining increases performance for Quechua by 24.53 percentage points when finetuning on English, and 22.89 points when finetuning on Spanish. Performance decreases for Bribri and Otomí when finetuning on English, however performance for all languages improves when using Spanish.

Translate-test Performance of the translate-test model improves over both zero-shot baselines. We see the largest increase in performance for Guaraní and Quechua, with gains of 7.16 and, respectively, 11.87 points over the best performing zero-shot model without adaptation. Considering the translation metrics in Table 3, models for Guaraní and Quechua achieve the two highest scores for both metrics. On average, translate-test does worse when compared to the adapted zero-shot models, and in all but two cases, both adapted models perform better than translate-test. We hypothesize that translate-test is more sensitive to noise in the translated data; sentences may lose too much of their original content, preventing correct classification.

Translate-train The most surprising result is that of translate-train, which considerably outperforms the performance of translate-test for all languages, and outperforms the zero-shot models for all but two languages. Compared to the best non-adapted zero-shot model, the largest performance gain is 20.40 points for Quechua. For the language with the lowest performance, Otomí, translate-train performs 2.32 points worse than zero-shot; however, it still outperforms translate-test. When averaged across all languages, translate-train outperforms the English zero-shot model by 10.64 points, and translate-test by 8.9 points. It is important to note that the translation performance from Spanish to each target language is not particularly high: when considering ChrF scores, the highest is 0.33, and the highest BLEU score is 3.26. Performance of both translation-based models is correlated with ChrF scores, with a Pearson correlation coefficient of 0.82 and 0.83 for translate-train and translate-test. Correlations are not as strong for BLEU, with coefficients of 0.37 and 0.59.

The sizable difference in performance between translate-train and the other methods suggests that translation-based approaches may be a valuable asset for cross-lingual transfer, especially for low-resource languages. While the largest downsides to this approach are the requirement for parallel data and the need for multiple models, the potential performance gain over other approaches may prove worthwhile. Additionally, we believe that the performance of both translation-based approaches would improve given a stronger translation system, and future work detailing the necessary level of translation quality for the best performance would offer great practical usefulness for NLP applications for low-resource languages.

6 Analysis

6.1 Hypothesis-only Models

As shown by Gururangan et al. (2018), SNLI and MNLI – the datasets AmericasNLI is based on – contain artifacts created during the annotation process which models exploit to artificially inflate performance. To analyze whether similar artifacts exist in AmericasNLI and if they can also be exploited, we train and evaluate models using only the hypothesis, and present results in Table 5. We can see that the average performance across languages is better than chance for all models except for XLM-R without adaptation. Translate-train obtains the highest result with 44.23% accuracy, and as shown in Table E.2, hypothesis-only performance of translate-test is higher than standard performance for 5 languages. Thus, as with SNLI and MNLI, artifacts in the hypotheses can be used to predict, to some extent, the correct labels. However all but 1 zero-shot and translate-train models perform better in the standard setting, indicating that the models are learning something beyond just exploiting artifacts in the hypotheses, even with the additional challenge of unseen languages.

6.2 Case Study: Human Evaluation

Following Conneau et al. (2018), AmericasNLI was created by translating sentences individually, in order to prevent additional context being added into the hypotheses. However, this strategy may break the original semantic relationship between the premise and the hypothesis. Furthermore, for some examples the logical relationship may be dependent on context or subtext which can be lost through translation, or simply not make sense in the target language. To verify the validity of the labels of AmericasNLI, we conduct a human evaluation experiment, focusing on examples translated to Bribri. We create a balanced, random sample of 450 examples taken from the Bribri development set. An annotator familiar with the task was then asked to classify the pairs of sentences. For comparison, we also annotate parallel examples taken from the English and Spanish development sets. For Bribri, we recover the original XNLI label for 76.44% of examples. For English and Spanish, we achieve 81.78% and 71.56% accuracy, respectively. Due to the relatively small differences in performance across languages, we conclude that translation to Bribri has a minimal effect on the semantic relationship between the premise and the hypothesis.

7 Limitations and Future Work

While the case study above provides strong evidence for the validity of our Bribri examples, we cannot currently generalize this claim to the remaining languages. For future work, we plan on extending our human evaluation to more languages and provide a more detailed analysis.

Additionally, due to the limited availability of annotators and the difficulties of translation for languages that are less frequently studied, the size of the AmericasNLI test set is relatively small. As such, care must be taken to carefully evaluate conclusions drawn using the dataset; following Card et al. (2020) we present a power analysis of our results in Section D.1. Future work expanding the dataset size will help create a stronger baseline. Furthermore, while we do not make any model-specific assumptions in our experiments, our results are based on only one pretrained model and adaptation method. Methods using vocabulary extension or adapters may offer additional improvements. Similarly, other pretrained models could perform differently, depending on, e.g., the model size or the set of languages in their pretraining data. In Table F.3, we present results using XLM-R Large, and find that, while the relationship between the approaches differs from the main experiments, the overall highest average performance is still achieved by the translate-train approach with XLM-R Base. We provide a longer discussion in Section F.3.

8 Conclusion

To better understand the zero-shot abilities of pretrained multilingual models for semantic tasks in unseen languages, we present AmericasNLI, a parallel NLI dataset covering 10 low-resource languages indigenous to the Americas. We conduct experiments with XLM-R, and find that the model's zero-shot performance, while better than a majority baseline, is poor. However, it can be improved by model adaptation via continued pretraining. Additionally, we find that translation-based approaches outperform a zero-shot approach, which is surprising given the low quality of the employed translation systems. We hope that this work will not only spur further research into improving model adaptation to unseen languages, but also motivate the creation of more resources for languages not frequently studied by the NLP community.

Ethics Statement

In this work, we present a new dataset created through the translation of an existing resource, XNLI (Conneau et al., 2018). While this allows for results that are directly comparable, it also means that this dataset inherits any biases and flaws which are contained in the previous dataset. Furthermore, research involving languages spoken by Indigenous communities raises ethical concerns regarding the exploitation of these languages and communities: it is crucial that members of the community are able to directly benefit from the research. Translation for AmericasNLI was done by either paper authors or translators who were compensated at a rate based on the average rate for translation and the minimum wage in their country of residence. Additionally, many authors are members of, and/or have a record of close work with communities who speak a language contained in AmericasNLI.

Acknowledgments

We thank the following people for their work on the translations: Francisco Morales for Bribri, Feliciano Torres Ríos for Asháninka, Perla Alvarez Britez for Guaraní, Silvino González de la Crúz for Wixarika, Giovany Martínez Sebastián, Pedro Kapoltitan, and José Antonio for Nahuatl, José Mateo Lino Cajero Velázquez for Otomí, Liz Chávez for Shipibo-Konibo, and María del Cármen Sotelo Holguín for Rarámuri. We would also like to thank Dallas Card for his help with power analysis. This work would not have been possible without the financial support of Facebook AI Research, Microsoft Research, Google Research, the Institute of Computational Linguistics at the University of Zurich, the NAACL Emerging Regions Fund, Comunidad Elotl, and Snorkel AI.

C Additional Information for AmericasNLI Languages

C.1 Aymara

A rare linguistic phenomenon found in Aymara is vowel elision, a deletion of certain vowel sounds triggered by complex phonological, morphological, and syntactic factors.

C.2 Asháninka

While Asháninka in a strict sense refers to the linguistic varieties spoken in Ene, Tambo and Bajo Perené rivers, the name is also used to talk about the following nearby and closely-related Asheninka varieties: Alto Perené, Pichis, Pajonal, Ucayali-Yurua, and Apurucayali. Although Asháninka is the most widely spoken Amazonian language in Peru, certain varieties, such as Alto Perené, are highly endangered.

The verb is the most morphologically complex word class, with a rich repertoire of aspectual and modal categories. The language lacks case, except for one locative suffix, so the grammatical relations of subject and object are indexed as affixes on the verb itself. Other notable linguistic features of the language include obligatory marking of a realis/irrealis distinction on the verb, a rich system of applicative suffixes, serial verb constructions, and a pragmatically conditioned split intransitivity.

C.3 Bribri

As previously noted, Bribri is a vulnerable language, and there are few settings where the language is written or used in official functions. The language does not have official status and it is not the main medium of instruction of Bribri children, but it is offered as a class in primary and secondary schools. Bribri features fusional morphology and an ergative-absolutive case system. Bribri grammar also includes phenomena like head-internal relative clauses, directional verbs and numerical classifiers (Jara Murillo, 2018a).

C.4 Guaraní

While the first written record dates to 1591, Guaraní usage in text continued until the Paraguay-Triple Alliance War (1864-1870) and declined thereafter. From the 1920s on, Guaraní has slowly re-emerged and received renewed focus. In 1992, Guaraní was the first American language declared an official language of a country, followed by a surge of local, national, and international recognition in the early 21st century.[6]

C.5 Nahuatl

Nahuatl is spoken in 17 different states of Mexico. In Nahuatl, different roots with or without affixes are combined to form new words. The suffixes that are added to a word modify the meaning of the original word (Sullivan and León-Portilla, 1976), and 18 prepositions stand out based on postpositions of names and adjectives (Siméon, 1977).

C.6 Otomí

The various regional self-denominations of Otomí include *ñähñu* or *ñähño*, *hñähñu, ñuju, ñoju, yühu, hnähño, ñühú, ñanhú, ñöthó, ñható* and *hñothó* (INALI, 2014). Many words are homophonous to Spanish (Cajero, 1998, 2009). When speaking *ñuhmu*, pronunciation is elongated, especially on the last syllable. The alphabet is composed of 19 consonants, 12 vowel phonemes.

C.7 Rarámuri

Rarámuri is mainly spoken in the state of Chihuahua. There are five variants of Rarámuri.

C.8 Shipibo-Konibo

Shipibo-Konibo is a language with agglutinative processes, a majority of which are suffixes. However, clitics are also used, and are a widespread element in Panoan literature (Valenzuela, 2003).

C.9 Wixarika

The four variants of Wixarika are the Northern, Southern, Eastern, and Western variants (INEGI, 2008). It is spoken mainly in the three Mexican states of Jalisco, Nayari, and Durango. Features of Wixarika include head-marking (Nichols, 1986), a head-final structure (Greenberg, 1963), nominal incorporation, argumentative marks, inflected adpositions, possession marks, as well as instrumental and directional affixes (Iturrioz and Gómez-López, 2008).

Table F.1: Results from models adapted with augmented data before finetuning. Zero-shot, zero-shot +MLM, and translate-train results are taken from the main experiments, however we only take results from the run corresponding to the same random seed as the newly trained models.

F.1 Early Stopping

While early stopping is vital for machine learning, in the case of zero-shot learning hand-labeled development sets in the target language are often assumed to be unavailable (Kann et al., 2019). Thus, in our main experiments we use either a machine-translated development set or one from a high-resource language. In both cases, performance on the development set is an imperfect signal for how the model will ultimately perform. To explore how this affects final performance, we present the difference in results for translate-train models when an oracle translation is used for early stopping in Table F.2. We find that performance is 2.34 points higher on average, with a maximum difference of 7.28 points for Asháninka, suggesting that creating ways to better approximate a development set may lead to higher performance.

aym	bzd	cni	gn	hch	nah	oto	quy	shp	tar	Avg.
2.13	0.98	7.28	0.58	0.53	2.12	3.03	1.42	0.93	4.36	2.34

Table F.2: Difference between translate-train results obtained using the oracle development set and the translated development set for early stopping.

F.2 Data Augmentation with Translated Data

Due to the success of translate-train, we also investigate if we can improve performance further by creating data for language adaptation (+MLM) through translation. To do so, we create a random sample of sentences taken from Spanish Wikipedia, and translate them into each target language. The sample is sized to contain the same number of subword tokens as the original pretraining data. We combine the original pretraining data and translated data to create a new set of sentences for continued pretraining, doubling the size of the original. We also finetune the original adapted models using translate-train. We present results in Table F.1. When finetuning on English and translate-train data, the average performance is highest when using the models adapted on the original data. When finetuning on Spanish, the models adapted on augmented data are best on average. While on average performance increases are not drastic, for some languages the performance increase is notable, and these mixed and/or augmented models may be worth looking into when interested in a particular language.

F.3 XLM-R Large

In this section we provide results for XLM-R Large. Due to computational restrictions, we slightly modify the experimental setup from the main experiments: we use mixed precision training and a more aggressive early stopping patience of 3 evaluation steps. Additionally, we use a learning rate of 5e-6 for all finetuning experiments, as we found that the original learning rate of 2e-5 failed to converge. However, even when using the modified hyperparameters, we experience some instability during training. The zero-shot model trained on Spanish data did not converge with the original random seed, but successfully trained after changing the seed. For translate-train, the models trained on Asháninka and Otomí failed to converge, regardless of the seed used, and further hyperparameter tuning will be required, which we leave for future work.

In this experiment, we can see that the results are more varied in comparison to the main results. Translate-train achieves the highest performance for five languages, with the adapted models achieving a combined highest performance for the remaining five. On average, the adapted model finetuned on English labeled data achieved the highest performance, followed closely by the other adapted model, and the translate-train model. This indicates that translate-train may be a viable approach when faced with limited compute, but might also have a restrictive upper limit on performance; in contrast, adaptation may allow for more potential performance gain, especially when larger models and datasets are available. Interestingly, when considering average performances across only the languages for which all models converged (i.e. removing Asháninka and Otomí from the calculation), we find that translate-train offers an average performance of 51.91%, while adaptation approaches achieve 49.39% and 49.83% accuracy on average.

Comparing XLM-R Large to XLM-R Base in Table F.4, we see that for all but one language the Large model outperforms the Base model in all adaptation and zero-shot runs. Notably, the Base model trained on translated data outperforms the Large model, and retains the highest overall performance across all languages and models.

Abstract

Understanding the functional (dis)-similarity of source code is significant for code modeling tasks such as software vulnerability and code clone detection. We present DISCO (*DIS-similarity of COde*), a novel self-supervised model focusing on identifying (dis)similar functionalities of source code. Different from existing works, our approach does not require a huge amount of randomly collected datasets. Rather, we design structure-guided code transformation algorithms to generate synthetic code clones and inject real-world security bugs, augmenting the collected datasets in a targeted way. We propose to pre-train the Transformer model with such automatically generated program contrasts to better identify similar code in the wild and differentiate vulnerable programs from benign ones. To better capture the structural features of source code, we propose a new cloze objective to encode the local tree-based context (*e.g.,* parents or sibling nodes). We pre-train our model with a much smaller dataset, the size of which is only 5% of the state-of-the-art models' training datasets, to illustrate the effectiveness of our data augmentation and the pre-training approach. The evaluation shows that, even with much less data, DISCO can still outperform the state-of-the-art models in vulnerability and code clone detection tasks.

1 Introduction

Understanding the functional similarity/dissimilarity of source code is at the core of several code modeling tasks such as software vulnerability and code clone detection, which are important for software maintenance (Kim et al., 2017; Li et al., 2016). Existing pre-trained Transformer models (Guo et al., 2021; Feng et al., 2020; Ahmad et al., 2021) show promises for understanding code syntax (*i.e.,* tokens and structures). However, they still get confused when trying to identify functional (dis)-similarities. For instance, syntax-based models can embed two code fragments with identical functionality but very different tokens and structures as distinct vectors and fail to identify them as semantically similar. Likewise, these models cannot distinguish between two code fragments that differ in functionalities but share a close syntactic resemblance. For example, consider an if statement `if(len(buf) < N)` checking buffer length before accessing the buffer. Keeping the rest of the program the same, if we simply replace the token '$<$' with '$\leq$,' the modification can potentially trigger security vulnerability, *e.g.,* buffer overflow bug[1]. It is challenging for existing pre-training techniques to tell apart such subtle differences in the functionalities.

In addition, existing pre-training techniques rely on a huge volume of training corpus that is randomly selected. For fine-tuning tasks like code clone detection or vulnerability detection, such random selection of training data is never tailored to teach the model about code functionalities.

To address these limitations, we present DISCO, a self-supervised pre-trained model that jointly learns the general representations of source code and specific functional features for identifying source code similarity/dis-similarity. Similar to state-of-the-art pre-trained Transformer models (Devlin et al., 2019; Liu et al., 2019), we apply the standard masked language model (MLM) to capture the token features of source code. To learn about the structural code properties, we propose a new auxiliary pre-training task that consumes additional inputs of local tree-based contexts (*e.g.,* parent or sibling nodes in abstract syntax trees) and embeds such structural context, together with the token-based contexts, into each token representation. On top of such well-learned general code representations, we further incorporate prior knowledge of code clones and vulnerable programs into the pre-training to help the model learn the functional (dis)-similarity. We design structure-guided

code transformation heuristics to automatically augment each training sample with one synthetic code clone (*i.e.,* positive samples) that is structurally different yet functionally identical and one vulnerable contrast (*i.e.,* hard negative samples) that is syntactically similar but injected with security bugs. During the pre-training, DISCO learns to bring similar programs closer in the vector space and differentiate the benign code from its vulnerable contrast, using a contrastive learning objective. Since we augment the dataset in a more targeted way than existing works and the model *explicitly* learns to reason about a code *w.r.t.* its functional equivalent and different counterparts during pre-training, DISCO can learn sufficient knowledge for downstream applications from a limited amount of data, consequently saving computing resources. In particular, we evaluate DISCO for clone detection and vulnerability detection, as the knowledge of similar/dissimilar code fragments is at the core of these tasks.

To this end, we pre-train DISCO on a *small* dataset, with only 865 MB of C code and 992 MB Java code from 100 most popular GitHub repositories, and evaluate the model on four different datasets for vulnerability and code clone detection. Experiments show that our small models outperform baselines that are pre-trained on 20× larger datasets. The ablation study (§5.4) also reveals that pre-training our model with 10× larger datasets further improves the performance up to 8.2%, outperforming state-of-the-art models by 1% for identifying code clones and up to 9.6% for vulnerability detection, even if our dataset is still smaller.

In summary, our contributions are: 1) We design structure-guided code transformation heuristics to automatically augment training data to integrate prior knowledge of vulnerability and clone detection without human labels. 2) We propose a new pre-training task to embed structural context to each token embedding. 3) We develop DISCO, a self-supervised pre-training technique that jointly and efficiently learns the textual, structural, and functional properties of code. Even though pre-trained with significantly less data, DISCO matches or outperforms the state-of-the-art models on code clone and vulnerability detection.

2 Related Works

Pre-training for Source Code. Researchers have been passionate about pre-training Transformer models (Vaswani et al., 2017) for source code with two categories: encoder-only and encoder-decoder (Ahmad et al., 2021; Wang et al., 2021; Rozière et al., 2021; Phan et al., 2021). Our work focuses on pre-training encoder-only Transformer models to understand code. Existing models are pre-trained with different token level objectives, such as masked language model (MLM) (Kanade et al., 2020; Buratti et al., 2020), next sentence prediction (NSP) (Kanade et al., 2020), replaced token detection, and bi-modal learning between source code and natural languages (Feng et al., 2020). However, these approaches ignore the underlying structural information to fully understand the syntax and semantics of programming languages. Recently, more works aimed to understand the strict-defined structure of source code leveraging abstract syntax tree (AST) (Zügner et al., 2021; Jiang et al., 2021), control/data flow graphs (CFG/DFG) (Guo et al., 2021). DISCO leverages code structures differently from existing works in two ways: (a.) with AST/CFG/DFG, we automatically generate program contrasts to augment the datasets targeting specific downstream tasks. (b.) DISCO takes an additional input of local AST context, and we propose a new cloze task to embed local structural information into each token representation.

Self-supervised Contrastive Learning. Self-supervised contrastive learning, originally proposed for computer vision (Chen et al., 2020), has gained much interest in language processing (Giorgi et al., 2021; Wu et al., 2020; Gao et al., 2021). The common practice of self-supervised contrastive learning is building similar counterparts, without human interference, for the original samples and forcing the model to recognize such similarity from a batch of randomly selected samples. Corder (Bui et al., 2021) leverages contrastive learning to understand the similarity between a program and its functionally equivalent code. While Corder approach will help code similarity detection type of applications, their pre-training does not learn to differentiate syntactically very close, but functionally different programs. Such differentiation is crucial for models to work well for bug detection (Ding et al., 2020). ContraCode (Jain et al., 2020) also leverages contrastive learning. However, they generate negative contrast for a program from unrelated code examples, not from variants of the same code. They also do not encode the structural information into the code as we do. Inspired by the empirical findings that hard negative image and text samples are beneficial for contrastive learning (Gao et al., 2021; Robinson et al., 2021), DISCO learns both from equivalent code as the positive contrast, and functionally different yet syntactically close code as the *hard-negative* contrast. We generate hard-negative samples by injecting small but crucial bugs in the original code (§3.1).

3 Data Augmentation Without Human Labels

Our pre-training aims to identify similar programs that can be structurally different (positive sample) and differentiate the buggy programs (negative sample) that share structural resemblances with the benign ones. Thus, we need a labeled positive and a negative example for each original sample. Manually collecting them is expensive, especially at the scale of pre-training. To this end, we design code transformation heuristics to automatically generate such positive and negative samples so that the transformation can be applied to any amount of programs without human efforts.

We first represent a code sample as Abstract Syntax Tree (AST), and build a control/data flow graph from the AST. The code transformation heuristics are then applied to this graph. For every original code sample (x), we apply semantic preserving transformation heuristics (§3.2) to generate a positive sample (x^+) and a bug injection heuristics (§3.1) to generate a hard-negative code example (x^-). We design the heuristics in a way that makes x^+ be the functional equivalent or semantic clone of x and x^- be the buggy/noisy version of x. Noted that not all heuristics are applicable to all code samples; we decide on applicable heuristics based on the flow graph of the original code. Figure 1 shows an example of the code transformation.

3.1 Bug Injection

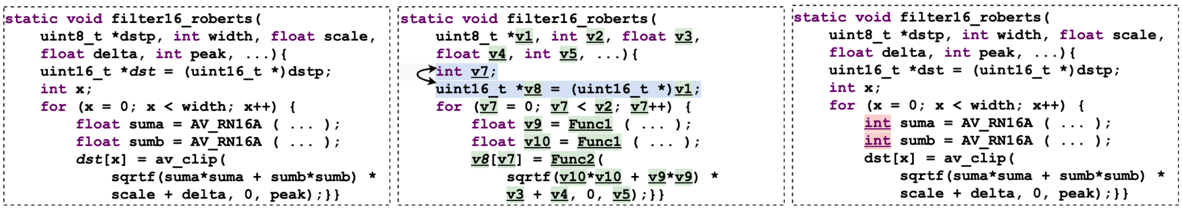
To generate a hard negative sample (x^-) from a given code (x), we define six categories of bug injection heuristics. Here our goal is to maintain maximum token-level similarity to the original code, so that the model can learn to analyze source code beyond token-level similarity. These heuristics are inspired by the buggy code patterns from a wide range of Common Weakness Enumeration (CWE) types (Appendix A.1). While it is challenging to guarantee that x^- will exhibit vulnerability or security bug, our heuristics will force x^- to exhibit different functionality than x. Compared with a concurrent work from Allamanis et al. (2021), our methods are significantly different. First, we focus on concrete types of security bugs that have been identified by the security experts, while they mainly target regular bugs. Second, our scope is not only bug detection but clone detection as well, and we apply contrastive learning to differentiate the code functionalities of code clones and vulnerabilities.

Misuse of Data Type. Usage of the wrong data type can trigger several security flaws. For instance, using a smaller data type (*e.g.,* `short`) to replace a larger one (*e.g.,* `long`) may result in an overflow bug (*e.g.,* CVE-2021-38094 (2021)). Such errors are complicated to track since they are usually exhibited in input extremities (*i.e.,* very large or very small values). For languages allowing implicit typecasting, such an incorrect type may even cause imprecision, resulting in the unpredictable behavior of the code. We intentionally change the data types in x to inject potential bugs, while ensuring the code can still be compiled (*e.g.,* we will not replace `int` with `char`).

Misuse of Pointer. Incorrect pointer usage is a major security concern. Accessing uninitialized pointers may lead to unpredictable behavior. A `NULL` pointer or freed pointer could lead to Null Pointer Dereferencing vulnerability (*e.g.,* CVE-2021-3449 (2021)). To inject such bugs, we randomly remove the initialization expression during pointer declaration, or set some pointers to `NULL`.

Change of Conditional Statements. Programmers usually check necessary preconditions using `if-statement` before doing any safety-critical operation. For instance, before accessing an array with an index, a programmer may add a condition checking the validity of the index. Lack of such checks can lead to buffer-overflow bugs in code (*e.g.,* CVE-2020-24020 (2020)). We introduce bugs in the code by removing such small `if-statements`. In addition, we also inject bugs by modifying randomly selected arithmetic conditions— replace the comparison operator ($<$, $>$, $\leq$, $\geq$, $==$, $!=$) with another operator, to inject potential out-of-bound access, forcing the program to deviate from its original behavior.

Misuse of Variables. When there are multiple variables present in a code scope, incorrect use of variables may lead to erroneous behavior of the program. Such errors are known as VARMISUSE bug (Allamanis et al., 2018). We induce code with such bugs by replacing one variable with another.



```
static void filter16_roberts(
    uint8_t *dstp, int width, float scale,
    float delta, int peak, ...){
    uint16_t *dst = (uint16_t *)dstp;
    int x;
    for (x = 0; x < width; x++) {
        float suma = AV_RN16A ( ... );
        float sumb = AV_RN16A ( ... );
        dst[x] = av_clip(
            sqrtf(suma*suma + sumb*sumb) *
            scale + delta, 0, peak);}}
```

(a) Original Code

```
static void filter16_roberts(
    uint8_t *v1, int v2, float v3,
    float v4, int v5, ...){
    int v7;
    uint16_t *v8 = (uint16_t *)v1;
    for (v7 = 0; v7 < v2; v7++) {
        float v9 = Func1 ( ... );
        float v10 = Func1 ( ... );
        v8[v7] = Func2(
            sqrtf(v10*v10 + v9*v9) *
            v3 + v4, 0, v5);}}
```

(b) Functionally Equivalent Code

```
static void filter16_roberts(
    uint8_t *dstp, int width, float scale,
    float delta, int peak, ...){
    uint16_t *dst = (uint16_t *)dstp;
    int x;
    for (x = 0; x < width; x++) {
        int suma = AV_RN16A ( ... );
        int sumb = AV_RN16A ( ... );
        dst[x] = av_clip(
            sqrtf(suma*suma + sumb*sumb) *
            scale + delta, 0, peak);}}
```

(c) Bug Injected Code

Figure 1: An example illustrating data augmentation. 1a shows the original code that is adapted from the CVE-2021-38094 patch. 1b shows functionality equivalent code of 1a where the original code is transformed by renaming and statements permutation. 1c shows a variation from 1a where a potential integer overflow bug is injected.

To keep the resultant code compilable, we perform scope analysis on the AST and replace a variable with another variable reachable in the same scope.

Misuse of Values. Uninitialized variables or variables with wrong values may alter the program behaviors and consequently cause security flaws (*e.g.,* CVE-2019-12730 (2019)). We modify the original code by removing the initializer expression of some variables. In addition, to induce the code with `divide-by-zero` vulnerability, we identify the potential divisor variables from the flow graph and forcefully assign zero values to them immediately before the division.

Change of Function Calls. We induce bugs in the code by randomly changing arguments of function calls. For a randomly selected function call, we add, remove, swap, or assign `NULL` value to arguments, forcing the code to behave unexpectedly.

3.2 Similar Code Generation

To generate positive samples (x^+) from a given code, we use three different heuristics. In this case, our goal is to generate functionally equivalent code while inducing maximum textual difference. These heuristics are inspired by code clone literature (Funaro et al., 2010; Sheneamer et al., 2018).

Variable Renaming. Variable renaming is a typical code cloning strategy and frequently happens during software development (Ain et al., 2019). To generate such a variant of the original code, we either (a.) rename a variable in the code with a random identifier name or (b.) with an abstract name such as `VAR_i` (Rozière et al., 2021). While choosing random identifier names, we only select available identifiers in the dataset. We ensure that both the definition of the variable and subsequent usage(s) are renamed for any variable renaming. We also ensure that a name is not used to rename more than one variable.

Function Renaming. We rename function calls with abstract names like `FUNC_i`. By doing this, we make more tokens different compared with the original code but keep the same syntax and semantics. We do not rename library calls for the code (*e.g.,* `memcpy()` in C).

Noted that even if tokens like `VAR_i` and `FUNC_i` are rare in normal code, the model will not bias towards identifying samples with these tokens as positive samples. The reason is that, as shown in Figure 2, x^+, y^+ and z^+ all potentially have these abstract tokens, but the model learns to move EMB_x closer to EMB_{x^+} and further from EMB_{y^+} and EMB_{z^+}, regardless of the existence of abstract tokens.

Statement Permutation. The relative order among the program statements that are independent of each other can be changed without altering the code functionality. More specifically, we focus on the variable declaration or initialization statements. We first conduct the dependency analysis to identify a set of local variables that do not depend on other values for initialization. Then we move their declaration statements to the beginning of the function and permute them.

4 DISCO

This section presents the model architecture, input representation, and pre-training tasks. DISCO uses a 12-layered Transformer encoder model similar to BERT. We feed the model with both source code text and structure (AST) information (§4.1). We pre-train DISCO using three different pre-training tasks (§4.2). Figure 2 depicts an example workflow of DISCO. We randomly select tokens in the original sample, mask them and their node types, and then use the embedding of these masks to predict them back. We further extract the sequence embeddings within a minibatch and contrast them based on the code functionality.

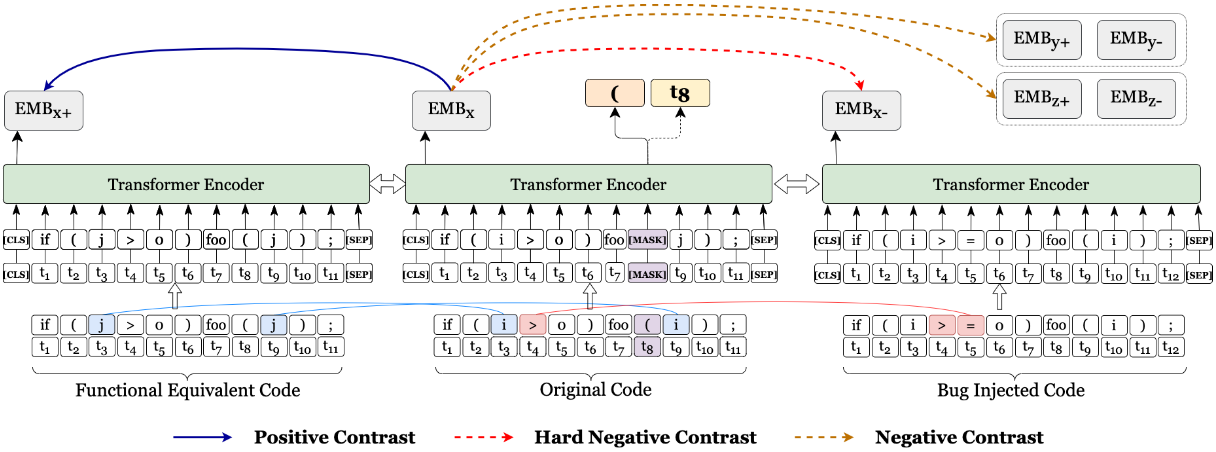


Figure 2: An illustration of DISCO pre-training with a minibatch of three. The original code and its node types will be randomly masked with $[MASK]$, and the final representation of masked tokens will be used to recover their source tokens and node types. The original code, say x, will also be transformed to build (x, x^+, x^-). Then the triplet will be fed into the **same** Transformer encoder and get the embedding of each sequence with $[CLS]$ tokens for contrastive learning.

4.1 Input Representation

Source Code. Given a program (x), we apply a lexical analyzer to tokenize it based on the language grammar and flatten the program as a token sequence ($x_1 x_2 ... x_m$, where x_i is ith token in the code). We further train a sentencepiece (Kudo and Richardson, 2018) tokenizer based on such flattened code token sequences with vocabulary size 20,000. We use this tokenizer to divide the source code tokens into subtokens. We prepend the subtoken sequence with a special token `[CLS]` and append with a special token `[SEP]`. Finally, DISCO converts the pre-processed code sequence $C = \{[CLS], c_1, c_2, ..., c_k, [SEP]\}$ to vectors $V^{src} = \{v^{src}_{[CLS]}, v^{src}_1, v^{src}_2, ..., v^{src}_k, v^{src}_{[SEP]}\}$ with a token embedding layer.

Local AST Types. For every token in the input code, we extract the node type (tt) from the syntax tree. Since such types are all terminal node types (*e.g.,* keyword, identifier, punctuation), we do not get enough information about the structure only with these types. In order to add more information about the tree, we also extract its parent type (pt) for each token. Such parent type provides us with information about the structural context of a token. For instance, when the parent type of an `identifier` is `Function-Declarator`, we know that the identifier is a function name. In contrast, when the `identifier`'s parent is a `Binary Expression`, it should be a variable. Consequently, we annotate each code subtoken c_i with a local AST-type token $t = tt\#pt$. It is worth noting that sub-tokens coming from the same code token will all have the same type. Therefore, we have the AST-type sequence for the code $T = \{[CLS], t_1, t_2, ..., t_k, [SEP]\}$, and DISCO converts it as vectors $V^{type} = \{v^{type}_{[CLS]}, v^{type}_1, v^{type}_2, ..., v^{type}_k, v^{type}_{[SEP]}\}$ with a type embedding layer. Appendix Table 7 shows an example of code tokens and their AST types. DISCO generates token representation v_i of subtoken c_i as a sum of token embedding v^{src}_i and type embedding v^{type}_i. Thus, $V = V^{src} + V^{type}$.

4.2 Pre-training

We aim to pre-train the DISCO to learn the representation of source code based on (a.) token-based context, (b.) AST-based context, and (c.) code functionality. In that spirit, we pre-train DISCO to optimize on three different objectives, *i.e.,* masked language model (MLM), local AST node type-MLM (NT-MLM), and Contrastive Learning (CLR).

For a given program x, we first embed the tokens and node-types to vectors $V = \{v_{[CLS]}, v_1, ..., v_{[SEP]}\}$. We optimize MLM loss ($\mathcal{L}_{MLM}$) (§4.2.1) and NT-MLM loss ($\mathcal{L}_{NT-MLM}$) (§4.2.2) based on x. These two loss functions learn about the textual and syntactic context of source code. For every code sample x in a minibatch of input, we generate a positive example x^+ and a hard-negative example x^- using the heuristics described in Section 3. We optimize CLR loss ($\mathcal{L}_{CLR}$) (§4.2.3) considering the original code and its positive and hard-negative counterparts. The final loss function to optimize for pre-training DISCO is

$$\mathcal{L}(\theta) = \mathcal{L}_{MLM}(\theta) + \mathcal{L}_{NT-MLM}(\theta) + \mathcal{L}_{CLR}(\theta)$$

4.2.1 Encoding Token-based Context

We apply the standard masked language model to the original code (x). Given a source code sequence C, we randomly choose 15% of tokens and replace them with a special token $[MASK]$ for 80% of the time and a random token for 10% of the time and leave the rest 10% unchanged. We record the indices of masked token as loc_m, replaced token as loc_r and unchanged tokens as loc_u for node-type MLM. We define the union of these indices as $M = loc_m \cup loc_r \cup loc_u$. MLM will learn to recover the masked source code $\{c_i | i \in M\}$ given the Transformer encoder's output h_i. We present the loss for MLM as $\mathcal{L}_{MLM} = \sum_{i \in M} -logP(c_i|h_i)$

4.2.2 Encoding AST-based Context

Token-based MLM re-builds the token using its surrounding tokens and successfully encodes the contextual information into each token representation. Motivated by MLM, we propose the tree-based context-aware pre-training task, to encode the structural context, such as parent, sibling, and children nodes. As we have shown in Figure 2, we flatten the ASTs as sequences and we expect the flattened trees can preserve the local structure information (i.e., sub-trees containing terminal nodes), and existing work (Chakraborty et al., 2020; Hellendoorn et al., 2020) has empirically shown such potentials. To this end, we introduce AST node-type masked language model (NT-MLM). Given the corresponding AST-type sequence T of source code C, we mask the AST types $\{t_p | p \in loc_m\}$ with the special token $[MASK]$, and replace the AST types $\{t_q | q \in loc_r\}$ with random tokens. Specifically, by doing this, we make sure that if a source code token is chosen to be masked or replaced, its corresponding AST type will perform the same operation. NT-MLM will learn to recover the masked AST type $\{t_i | i \in M\}$ given the Transformer encoder's output h_i. We present the loss for NT-MLM as $\mathcal{L}_{NT-MLM} = \sum_{i \in M} -logP(t_i|h_i)$

A recent work, CodeT5 (Wang et al., 2021), proposes to predict token type as well. However, our new objective is different from them in both high-level designs and the detailed implementation. First, their objective only predicts one single token type: identifiers, while our approach predicts all possible AST types. Also, we do not only consider the AST node type of tokens, but also include their AST parents to embed the local sub-tree context (§4.1). Second, CodeT5 implements the identifier tagging task as a binary classification (0/1) for each token, while our NT-MLM reconstructs the local ASTs out of hundreds of distinct types.

4.2.3 Contrastive Learning

We adopt contrastive learning to focus on the functional characteristics of code. With the structure-guided code transformation algorithms in Section 3, we are able to generate a positive sample (x^+ in Figure 2) and a hard negative sample (x^- in Figure 2) for each program in the dataset. More specifically, we have a minibatch of N programs, and for each program, we extract the sequence representation from the Transformer outputs $\mathbf{h} = h_{[CLS]}$. We will augment every sequence in the minibatch with positive and negative samples, and then the minibatch is extended to N triplets of $(\mathbf{h}, \mathbf{h}^+, \mathbf{h}^-)$. We refer to the contrastive loss with hard negative samples from Gao et al. (2021) and we adapt it to our scope as follows. We use cosine similarity as the $sim()$ function and τ is the temperature parameter to scale the loss, and we use $\tau = 0.05$.

$$\mathcal{L}_{CLR} = -\log \frac{\mathbf{e}^{\mathrm{sim}\left(\mathbf{h},\mathbf{h}^+\right)/\tau}}{\sum_{n=1}^{N}\left(\mathbf{e}^{\mathrm{sim}\left(\mathbf{h},\mathbf{h}_n^+\right)/\tau} + \mathbf{e}^{\mathrm{sim}\left(\mathbf{h},\mathbf{h}_n^-\right)/\tau}\right)}$$

We also consider to pre-train the model with only positive counterparts as a variation. In such a case, the minibatch will contain N pairs of $(\mathbf{h}, \mathbf{h}^+)$ and the loss is computed as

$$\mathcal{L}_{CLR} = -\log \frac{\mathbf{e}^{\mathrm{sim}\left(\mathbf{h},\mathbf{h}^+\right)/\tau}}{\sum_{n=1}^{N}\left(\mathbf{e}^{\mathrm{sim}\left(\mathbf{h},\mathbf{h}_n^+\right)/\tau}\right)}$$

5 Experiments

In this section, we will explain our experimental settings and report the results. We evaluate our model on vulnerability and code clone detection.

5.1 Experimental Settings

Data. We collect our pre-training corpus from open-source C and Java projects. We rank Github repositories by the number of stars and focus on the most popular ones. After filtering out forks from existing repositories, we collect the dataset for each language from top-100 repositories. We only consider the ".java" and ".c" files for Java and C repositories respectively, and we further remove comments and empty lines from these files. The corresponding datasets for Java and C are of size of 992MB and 865MB, respectively. Our datasets are significantly *smaller* than existing pre-training models (Feng et al., 2020; Ahmad et al., 2021; Guo et al., 2021). For example, while CodeBERT and GraphCodeBERT are trained on 20GB data, we used an order of magnitude less data. Details of our datasets and the comparison can be found in Appendix Table 5.

Models. To study the different design choices, we train four variations of DISCO. (i) **MLM+CLR$^{\pm}$+NT-MLM** is trained by all three tasks with hard negative samples. (ii) **MLM+CLR$^{\pm}$**. The input of this model only considers the source code sequence and ignores the AST-type sequence. This model helps us understand the impact of NT-MLM. (iii) **MLM+CLR^{+}**. This variant evaluates the effectiveness of hard negative code samples, by contrasting its performance with MLM+CLR$^{\pm}$. (iv) **MLM**. This is the baseline trained with only MLM objective. We provide detailed model configuration in Appendix A.4 to ensure the reproducibility.

Baselines. We consider two types of baselines: encoder-only pre-trained Transformers and existing deep-learning tools designed for code clone and vulnerability detection. We do not consider encoder-decoder pre-trained Transformers as baselines, since such generative models always need much more pre-training data and training steps to converge, so it is unfair to compare our model with them. For example, PLBART uses 576G source code for pre-training, while we only use less than 1G. Based on the data size. As future work, we plan to pre-train the model on much larger datasets.

5.2 Vulnerability Detection (VD)

VD is the task to identify security bugs: given a source code function, the model predicts 0 (benign) or 1 (vulnerable) as binary classification.

Dataset and Metrics. We consider two datasets for VD task: REVEAL (Chakraborty et al., 2021) and CodeXGLUE (Lu et al., 2021; Zhou et al., 2019). In the real-world scenario, vulnerable programs are always rare compared to the normal ones, and Chakraborty et al. (2021) have shown such imbalanced ratio brings challenges for deep-learning models to pinpoint the bugs. To imitate the real-world scenario, they collect REVEAL dataset from Chromium (open-source project of Chrome) and Linux Debian Kernel, which keeps the ratio of vulnerable to benign programs to be roughly 1:10. Following Chakraborty et al. (2021), we consider precision, recall and F1 as the metrics.

CodeXGLUE presents another dataset of security vulnerabilities. It is less real-world than REVEAL, since it a balanced dataset, but it has been frequently used by existing Transformer-based models to evaluate their tools for VD task. To compare with these baselines, we use CodeXGLUE train/valid/test splits for training and testing. We use accuracy as the metric, following the design of the benchmark.

REVEAL. Table 1 shows the results. We compare with four deep-learning-based VD tools. VulDeePecker (Li et al., 2018b) and SySeVR (Li et al., 2018a) apply program slices and sequence-based RNN/CNN to learn the vulnerable patterns. Devign (Zhou et al., 2019) uses graph-based neural networks (GNN) to learn the data dependencies of program. REVEAL (Chakraborty et al., 2021) applies GNN + SMOTE (Chawla et al., 2002) + triplet loss during training to handle the imbalanced distribution. We also consider pre-trained RoBERTa, CodeBERT and GraphCodeBERT, and a 12-Layer Transformer model trained from scratch.

Table 1: Vulnerability Detection Results on REVEAL.

Model	Prec. (%)	Rec. (%)	F1 (%)
VulDeePecker	17.7	13.9	15.7
SySeVR	24.5	40.1	30.3
Devign	34.6	26.7	29.9
REVEAL	30.8	**60.9**	41.3
Transformer	41.6	45.3	43.4
RoBERTa	44.5	39.0	41.6
CodeBERT	44.6	45.8	45.2
GraphCodeBERT	47.9	43.9	45.8
DISCO			
MLM	45.5	31.0	36.9
MLM+CLR^{+}	38.6	47.7	42.6
MLM+CLR$^{\pm}$	39.4	50.5	44.2
MLM+CLR$^{\pm}$+NT-MLM	**48.3**	44.6	**46.4**

Table 2: Results on CodeXGLUE for vulnerability detection

Model	Acc (%)
Transformer	62.0
RoBERTa	61.0
CodeBERT	62.1
GraphCodeBERT	63.2
C-BERT	63.6*
DISCO	
MLM	61.8
MLM+CLR^{+}	**64.4**
MLM+CLR$^{\pm}$	63.6
MLM+CLR$^{\pm}$+NT-MLM	63.8

*We take this result from Buratti et al. (2020). They did not use CodeXGLUE splits, so the test data can be different with other baselines.

In our case, the best DISCO variation with contrastive learning and NT-MLM objective outperforms all the baselines, including the graph-based approaches and models pre-trained with larger datasets. This empirically proves that DISCO can efficiently understand the code semantics and data dependencies from limited amount of data, helping the identification of the vulnerable patterns. We notice that hard negative samples (*i.e.,* buggy code contrasts) helps DISCO improve the performance. The reason is that REVEAL contains thousands of (buggy version, fixed version) pairs for the same function. Two functions in such a pair are different by only one or a few tokens. Such real-world challenges align well with our automatically generated buggy code, and pre-training with these examples teaches the model better distinguish the buggy code from the benign ones. We provide an example in Appendix Figure 3 to illustrate this.

CodeXGLUE. We consider four pre-trained models: RoBERTa, CodeBERT, GraphCodeBERT and C-BERT. The first three are pre-trained on much larger datasets than ours. However, even trained with small dataset, three variations of DISCO outperforms the baselines. Unlike REVEAL, CodeXGLUE does not have those challenging pairs of functions' buggy and patched version; thus the hard negative contrast in DISCO does not help the model much.

Table 3: Clone detection on POJ104 and BigCloneBench

Model	POJ104	BigCloneBench		
	MAP@R	Prec.(%)	Rec.(%)	F1(%)
Transformer	62.11	-	-	-
MISIM-GNN	82.45	-	-	-
RoBERTa	76.67	-	-	-
CodeBERT*	82.67	94.7	93.4	94.1
GraphCodeBERT*	-	94.8	**95.2**	**95.0**
DISCO				
MLM	**83.32**	93.4	93.8	93.6
MLM+CLR^{+}	82.44	93.9	93.7	93.8
MLM+CLR$^{\pm}$	82.73	**95.1**	93.3	94.2
MLM+CLR$^{\pm}$+NT-MLM	82.77	94.2	94.6	94.4

*The authors of both works fixed bugs in their evaluation tool and updated the results in their Github repositories. We directly take their latest results and use their latest evaluation tool for fair comparisons.

5.3 Clone Detection

Clone detection aims to identify the programs with similar functionality. It also can help detecting security vulnerabilities—given a known vulnerability, we can scan the code base with clone detector and check for similar code snippets.

Dataset and Metrics. We consider POJ-104 (Mou et al., 2016) and BigCloneBench (Svajlenko et al., 2014) as the evaluation datasets. We again strictly follow the CodeXGLUE train/dev/test splits for experiments. Following CodeXGLUE's design, we use MAP@R as the metric for POJ-104 and precision/recall/F1 as the metric for BigCloneBench.

POJ-104. We consider three pre-trained models, one graph-based model (Ye et al., 2020) and one 12-layer Transformer model trained from scratch as baselines. Table 3 shows that, with hard negative contrast and NT-MLM, DISCO outperforms all baselines including CodeBERT, which is pre-trained on much larger datasets. This highlights the significance of learning the code contrasts together with syntactical information to better capture the functional similarities. Interestingly, we notice that DISCO-MLM performs the best among all variations. This indicates that our current positive heuristics might not align with all the clone patterns in this benchmark. As future work, we will propose more code transformation rules to imitate more real-world clone patterns.

BigCloneBench. Our best model achieves slightly better precision than the baselines indicating that our designs with contrastive learning and structure information can compensate the loss brought by less data. However, our recall is slightly worse than GraphCodeBERT, since they are pre-trained on large datasets with code graph. We conclude that enlarging our Java pre-training dataset is necessary for code clone detection and we regard this as future work.

5.4 Medium Pre-trained Model

As shown in Section 5, DISCO trained on a small dataset achieves comparable or even better performance than models pre-trained on large datasets in vulnerability and clone detection (Let's call this version DISCO$_{small}$). We further explore the benefits of pre-training using larger data. We pre-train a MEDIUM model, DISCO$_{medium}$, on our extended datasets with more C-language Github repositories (13G). Note that our medium dataset is still smaller than the large dataset of the baseline models (13G vs. 20G). We evaluate DISCO$_{medium}$ on C-language tasks. The results are shown in Table 4. Increasing the pre-training dataset improves the performance of downstream tasks, outperforming the best baselines' results.

Table 4: Results for the best baselines, small- and medium-DISCO. POJ-104 is for code clone task; VD-CXG and VD-RV are VD tasks for CodeXGLUE and REVEAL datasets.

Model	POJ-104 (MAP@R)	VD-CXG (Acc)	VD-RV (F1)
DISCO$_{small}$	82.8	63.8	46.4
DISCO$_{medium}$	**83.8**	**64.6**	**50.2**
Baseline$_{large}$	82.7	63.6	45.8

6 Conclusion

In this work, we present DISCO, a self-supervised contrastive learning framework to both learn the general representations of source code and specific characteristics of vulnerability and code clone detections. Our evaluation reveals that DISCO pretrained with smaller dataset can still outperform the large models' performance and thus prove the effectiveness of our design.

Acknowledgements

We would appreciate the insightful feedback and comments from the anonymous reviewers. This work was partially done when Yangruibo Ding was an intern at IBM Research. This work is also supported in part by NSF grants CCF-2107405, CCF-1845893, IIS-2040961, and IBM.

Ethical Considerations

The main goal of DISCO is to generate functionality-aware code embeddings, producing similar representations for code clones and differentiating security bugs from the benign programs. Our data is collected from either the open-source projects, respecting corresponding licences' restrictions, or publicly available benchmarks. Meanwhile, throughout the paper we make sure to summarize the paper's main claims. We also discussed DISCO's limitation and potential future work for clone detection in Section 5.3. We report our model configurations and experiment details in Appendix A.4.

A Appendix

A.1 Bug Injection Heuristics and Common Weakness Enumeration Types

Our automated bug injection heuristics are motivated by the real-world security bugs that are always small but hazardous. We empirically conclude the frequently happened vulnerable patterns based on the concrete CWE types. Table 6 shows that each of our operation is relating to several CWE types. We inject all these security issues automatically and ask model to distinguish them with the benign samples.

A.2 Node Type Details

We parse the source code into ASTs and extract the node type and parent node type for each token. Table 7 shows an example after parsing. We can see that, with the parent node type, each token can be well embedded with its local structure contexts. Considering two tokens that are distant from each other: `if` and `else`. With only node types, we just know these two tokens are keywords, but with parent node type, we can easily know that they are from the same `if-statement` and they are siblings in the AST.

Table 5: Comparison of pre-training dataset size between ours and other related work

Dataset	Instance Count	Total Size
DISCO		
Java SMALL	187 K	992 MB
C SMALL	64 K	865 MB
C MEDIUM	860 K	12 GB
CodeBERT	8.5 M	20 GB
GraphCodeBERT	2.3 M	20 GB
CuBERT	7.4 M	-
DOBF	-	45 GB
PLBART	-	576 GB

A.3 Dataset

Pre-training We collect our dataset from C and Java Github repositories. Our main dataset is the combination of Java SMALL and C SMALL. From Table 5, we can see that our dataset is significantly smaller than the existing pre-trained models. For an ablation study (§ 5.4) with enlarged dataset, we collect a MEDIUM dataset of C language. We have seen the improvement using such larger dataset, but even MEDIUM dataset is still much smaller than other datasets.

Datasets for downstream tasks We provide dataset details of our downstream tasks in Table 8. Noted that for POJ-104 (Mou et al., 2016), Table 8 only shows the number of code samples, and we follow the design of CodeXGLUE that build positive and negative pairs during the minibatch generation. The amount of pairs for training is much larger than the number of samples.

A.4 Configuration

DISCO is built based on a stack of 12 layers transformer encoder with 12 attention heads and 768 hidden sizes. The model is implemented with PyTorch-1.9.0 and Huggingface-transformer-4.12.3 [2]. Longer sequences are disproportionately expensive so we follow the original BERT design by pre-training the model with short sequence length for first 70% steps and long sequence length for the rest 30% steps to learn the positional embeddings. DISCO is trained with Java SMALL and C SMALL for 24 hours in total with two 32GB NVIDIA Tesla V100 GPUs, using batch size of 128 with max sequence length of 256 tokens and batch

```

Patched Code

Figure 3: An example in REVEAL dataset. The patched code happens to be in the train split and the buggy code is in the test split. During inference, DISCO MLM+CLR$^{\pm}$ model can correctly predict the buggy code as vulnerable, while MLM+CLR^{+}predicts it as benign.

size of 64 sequences with max sequence length 512 tokens. DISCO is also trained with C MEDIUM for 3 days, using batch size of 1024 sequences with max sequence length of 256 tokens and batch size of 512 sequences and max sequence length of 512 tokens. We use the Adam optimizer and 1e-4 as the pre-training learning rate. For fine-tuning tasks, we use batch size of 8 and the learning of 8e-6. We train the model with train split and evaluate the model during the training using validation split. We pick the model with best validation performance for testing.

A.5 Case Study

We studied the model performance on REVEAL dataset for vulnerability detection. Figure 3 shows two samples inside REVEAL. We can recognize that they are from the same program. We further checked the details of these two example and we found the code on the left is a buggy version, and it is fixed by adding an argument of value 0 to the function call. This real-world situation actually matches our "Change of Function Calls" (§ 3.1) bug injection operation. In the REVEAL dataset, the patched code is in the training corpus while the buggy one is in the test split. Interestingly, during the inference, DISCO MLM+CLR$^{\pm}$ can correctly predict the buggyiess while MLM+CLR^{+}fails. This empirically prove our bug injected samples can help the model identify small but siginicant real-world vulnerabilities.

Guided Attention Multimodal Multitask Financial Forecasting with Inter-Company Relationships and Global and Local News

Abstract

Most works on financial forecasting use information directly associated with individual companies (e.g., stock prices, news on the company) to predict stock returns for trading. We refer to such company-specific information as local information. Stock returns may also be influenced by global information (e.g., news on the economy in general), and inter-company relationships. Capturing such diverse information is challenging due to the low signal-to-noise ratios, different time-scales, sparsity and distributions of global and local information from different modalities. In this paper, we propose a model that captures both global and local multimodal information for investment and risk management-related forecasting tasks. Our proposed Guided Attention Multimodal Multitask Network (GAME) model addresses these challenges by using novel attention modules to guide learning with global and local information from different modalities and dynamic inter-company relationship networks. Our extensive experiments show that GAME outperforms other state-of-the-art models in several forecasting tasks and important real-world application case studies.

1 Introduction

Forecasting stock prices or returns is an important task in trading. Such forecasts can also be used in investment and risk management applications such as portfolio allocation and risk forecasting. Stock returns in financial markets are influenced by large volumes of textual information from diverse sources, e.g., news, blogs, social media. Such textual information can be directly associated with a specific company (*local*), e.g, a company's CEO stepping down; or relevant to multiple companies (*global*), e.g., disruptions in supply chains due to export curbs in key countries, airline industry bankruptcies. In this paper, articles with company tags are treated as local information. All articles are treated as global information as any article could be potentially relevant to a company.

Direct and indirect relationships between companies also serve as channels through which the effects of information from both global and local textual and numerical information propagate and influence stock returns, e.g., a disruption in company A could affect all its suppliers; a scandal involving company A's CEO may affect company B if the CEO is a member of company B's board. We illustrate such diverse information and effects in Figure 1.

Apart from low signal-to-noise ratios in financial time-series due to market forces, there are other challenges in modeling such diverse information. Time scales of information from different modalities are of different granularity, e.g., numerical financial information may be available daily, while publication of financial text happens at irregular times. Companies' local financial news are typically sparse and long-tailed, e.g., a company may not be in the news for an extended period of time, but suddenly becomes the focus of many news reports in a short period due to a scandal. Local textual information may also be noisy with regards to its relevance to the company's stock returns, e.g., a news article on a company's HR practices may have little effect on its stock returns, whereas a news article on a sector's outlook can have a significant effect on the company's stock returns even without any mention of the company.

More research on financial forecasting is required to address such challenges. Most existing works model financial information of a single modality (Ding et al., 2015; Ziniu et al., 2018; Du and Tanaka-Ishii, 2020; Sawhney et al., 2021b), and do not model the effects of inter-company relationships. Some works (Feng et al., 2019; Xu et al., 2021; Sawhney et al., 2021a) model both unimodal financial information and the effects of inter-company relationships. There are however few

works capturing multimodal financial information and inter-company relationships (Ang and Ee-Peng, 2021; Sawhney et al., 2020b,a). Ang and Ee-Peng (2021) utilizes both numerical and global textual information, as well as inter-company relationships but does not address challenges related to capturing global and local multimodal information. Most works also focus on a single task - forecasting stock returns for trading. Another equally important set of forecasting tasks which has many investment and risk management applications involves similar challenges. It involves a multivariate multitask setting, where there is a need to manage the returns and risks of financial portfolios that comprise many stocks (multivariate), and make investment and risk decisions based on multiple forecasts (multitask): forecast stock i) mean returns and ii) risks (volatilities) over a future horizon to balance potential returns and risks when making investment decisions, as well as forecast iii) correlations between stocks in portfolios over a future horizon.

To address financial data challenges in multitask settings, we propose the Guided Attention Multimodal Multitask Network (GAME) model. Our key idea is to use attention to guide learning between information from different sources and modalities. GAME incorporates several important components: i) guided latent cross-attention learning between modalities of different time-scales and sparsity; ii) graph-guided representation learning based on inter-company relationships with dynamic weights learnt from multimodal information; and iii) guided cross-attention learning between global and local information. GAME is trained on multiple tasks - forecasting means, volatilities and correlations over a future horizon, which could be used for portfolio allocation and risk management. While existing works for financial forecasting capture either local or global information, or network information with either global or local information, GAME jointly captures global, local and network information. Compared to existing works that utilize transformers for time-series forecasting (Zerveas et al., 2021), GAME proposes novel cross-attention mechanisms that enable i) more effective modelling of local information of different lengths and granularity from different modalities by first encoding such information to a common latent representation; and ii) the extraction of global information by leveraging such local information. Hence, our key contributions are as follows:

- To our knowledge, this is the first work to propose a model for capturing global and local information from multiple modalities for multivariate multitask financial forecasting;

- We propose an attention-based module that encodes multimodal information of different sequence lengths and time granularity to a latent representation space for efficient mutually guided cross-attention learning;

- We design a graph encoding module that uses inter-company relationships to propagate multimodal information across companies; and dynamically updates relationship weights with learnt importances;

- We design an attention-based module that uses cross-attention between local and global information to guide learning of relevant global information;

- We train the model on multiple forecasting tasks to lower the risk of over-fitting, and demonstrate the effectiveness of GAME on forecasting tasks and real-world applications against state-of-the-art baselines on real-world datasets.

2 Related Work

As this work involves time-series forecasting and network learning, we review key related works in these areas.

Time Series Forecasting. Classical methods (Box and Jenkins, 1990; Bollerslev, 1986) are commonly applied to time-series forecasting. However, they are designed for numerical data but not unstructured financial text. Deep learning models have been increasingly applied to time-series forecasting. They include feed-forward networks (Yoojeong et al., 2019; Ding et al., 2015; Oreshkin et al., 2020), convolutional neural networks (Pantiskas et al., 2020; Borovykh et al., 2017; Wan et al., 2019), recurrent neural networks (Flunkert et al., 2020; Qin et al., 2017; Liu et al., 2020), and transformers (Wu et al., 2020; Zerveas et al., 2021). A detailed review of these works can be found in Lim and Zohren (2021); Jiang (2021); Torres et al. (2021).

Time-series Transformer (**TST**) (Zerveas et al., 2021) is a recent model based on the transformer encoder architecture designed for numerical inputs. StockEmbed (**SE**) (Du and Tanaka-Ishii, 2020) is designed for global textual features, while Financial News and Tweet Based Time Aware Network (**FAST**) (Sawhney et al., 2021b) is designed for local textual features. To encode sequences of textual features, SE utilizes bidirectional GRUs, while FAST utilizes Time-aware LSTMs (Baytas et al., 2017). These works are designed for information from a single modality, do not model the effects of company-to-company relationships, and do not address the challenges of capturing global and local multimodal information.

Network Learning. Graph neural networks (GNN) compose messages based on network features, and propagate them to update the embeddings of nodes and/or edges over multiple neural network layers (Gilmer et al., 2017). In particular, Graph Convolutional Network (GCN) (Kipf and Welling, 2017) aggregates features of neighboring nodes and normalizes aggregated representations by node degrees. Graph Attention Network (GAT) (Veličković et al., 2018) assigns neighboring nodes with different importance weights during aggregation. Such GNNs are designed for static networks with static node attributes and cannot be directly applied to networks where attributes are evolving time series.

A few recent works extend GNNs to prediction tasks on financial time-series data (Ang and Ee-Peng, 2021; Feng et al., 2019; Sawhney et al., 2020b,a, 2021a). Relational Stock Ranking (**RSR**) (Feng et al., 2019) uses LSTM to generate output embeddings for numerical time-series data of companies before feeding the latter to learn company embeddings in a network using a GCN-based model, but does not consider textual information. Knowledge Enriched Company Embedding (**KECE**) (Ang and Ee-Peng, 2021) captures numerical and global textual information and uses a GAT-based model to capture inter-company relationships but does not address the challenges of capturing global and local multimodal information. RSR and KECE also do not learn the dynamic importance of inter-company relationships.

3 Guided Attention Multimodal Multitask Network Model

GAME represents companies in a network $G = (V, E, X)$, where V represents a set of company nodes, E represents relationships between companies, X represents sequences of multimodal attributes. Given a time step t, we define numerical features $X_j^{num}(t) = [x_j^{num}(t-K), ..., x_j^{num}(t-1)]$ to be the sequence of numerical price-related data associated with company v_j over a window of K time steps up to $t-1$. Textual news features include local and global textual features, i.e. $X^{txt} = \{X^{txt,loc}, X^{txt,glo}\}$. The pre-encoded local news textual features directly associated with a company v_j within the same window are denoted as $X_j^{txt,loc}(t) = [x_{j,1}^{txt,loc}(t-K), \cdots, x_{j,M}^{txt,loc}(t-K), x_{j,M+1}^{txt,loc}(t-K+1), \cdots, x_{j,S}^{txt,loc}(t-1)]$. $S = M \times K$ and assumes M news articles are captured for each company at each time-step. Where there are less than M articles for any company at any given time-step, we add PAD values of zero to the sequence (Devlin et al., 2019). We denote pre-encoded global news features over the window period K as $X^{txt,glo}(t) = [x^{txt,glo}(t-K), ..., x^{txt,glo}(t-1)]$, with varying number of news articles binned into each time step.

As shown in Figure 2, GAME first encodes

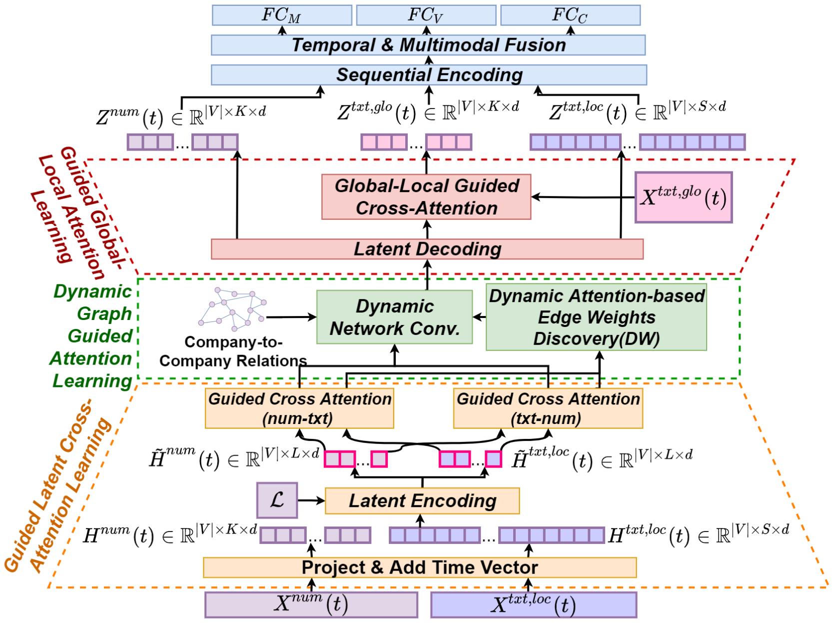

Figure 2: Architecture of GAME

both $X^{num}(t) \in \mathbb{R}^{|V| \times K \times d^{num}}$ and $X^{txt,loc}(t) \in \mathbb{R}^{|V| \times S \times d^{txt}}$, where d^{num}, d^{txt} are embedding dimension sizes, to a common latent sequence length L and dimension d by using latent attention-based encoders inspired by Jaegle et al. (2021a), where $L \ll K$ as part of the *Guided Latent Cross-Attention Learning* step. We introduce guided cross-attention to enable information from one modality to guide the attention learning of another. In the next *Dynamic Graph-Guided Attention Learning* step, representations of both modalities are used to discover and update importance weights of inter-company relationships before applying dynamic graph convolutions. A latent decoder inspired by Jaegle et al. (2021b) then decodes the numerical and local textual representations to the original sequence lengths K and S. In the *Guided Global-Local Attention Learning* step, we use the decoded local representations to guide the attention extraction of the sequence of global textual features relevant to each company v_j. The resultant representations are then combined and sequentially encoded with a transformer, followed by attention-based temporal and multimodal fusion. Finally, GAME generates forecasts of means, volatilities and correlations of financial returns over a selected future horizon of K' time-steps, i.e. the means, volatilities and correlations of $Y^{returns}(t) = [y^{returns}(t), ..., y^{returns}(t + K')]$, where $y^{returns}(t) = (price(t) - price(t - 1))/price(t - 1)$ and $price(t)$ denote the percentage return and stock price at time step t respectively. We further elaborate on GAME modules below.

Guided Latent Cross-Attention Learning. This step addresses the challenge of learning information from modalities of different sequence lengths, degrees of sparsity and distributions, specifically $X^{num}(t) \in \mathbb{R}^{|V| \times K \times d^{num}}$ and $X^{txt,loc}(t) \in \mathbb{R}^{|V| \times S \times d^{txt}}$. For $X^{num}(t)$, we first **project the inputs to common dimension d and add a learnt time vector** (Kazemi et al., 2019; Godfrey and Gashler, 2018). The time vector is learned from the time-stamps $T(t)$ corresponding to the inputs. In this paper, we use day of week, week and month of year for $T^{num}(t)$, and further include seconds of day for $T^{txt,loc}(t)$ as these are most relevant to the respective inputs. The time vector $P^{num}(t) \in \mathbb{R}^{|V| \times K \times d}$ is learned by combining functional forms and learnable weights and could be viewed as a time-sensitive version of positional encodings used in transformers (Vaswani et al., 2017). For GAME, the empirically chosen components used to generate the time vectors are $\Phi_1^{num} = sigmoid(Linear(T^{num}(t)))$ and $\Phi_2^{num} = cos(Linear(T^{num}(t)))$, which enable the model to extract non-linear and seasonality-based temporal patterns. We then concatenate these components and project them: $P^{num}(t) = Linear([\Phi_1^{num} || \Phi_2^{num}])$. The output of the projection and addition of time vectors step is: $H^{num}(t) \in \mathbb{R}^{|V| \times K \times d}$. For the **latent encoding** step, we introduce latent units $\mathcal{L} \in \mathbb{R}^{L \times d}$. We repeat $\mathcal{L}$ by $|V|$ times to get $\mathbb{R}^{|V|\times L\times d}$, and apply linear layers to generate queries from $\mathcal{L}$, and keys and values from $H^{num}(t)$. That is, $Q^{num}(t) = Linear_Q(\mathcal{L})$, $K^{num}(t) = Linear_K(H^{num}(t))$, $V^{num}(t) = Linear_V(H^{num}(t))$. We then apply scaled dot-product attention $\tilde{H}^{num}(t) = softmax(Q^{num}(t)\cdot K^{num}(t)^T)V^{num}(t)/\sqrt{d}$. To elaborate, the dot-product between $Q^{num}(t) \in \mathbb{R}^{|V|\times L\times d}$ and $K^{num}(t) \in \mathbb{R}^{|V|\times K\times d}$ gives us attention weights of dimensions $|V| \times L \times K$. We use these attention weights to map $V^{num}(t) \in \mathbb{R}^{|V|\times K\times d}$ to $\tilde{H}^{num}(t) \in \mathbb{R}^{|V|\times L\times d}$. The same set of steps is repeated for $X^{txt,loc}(t)$ to obtain $\tilde{H}^{txt,loc}(t)$. Hence, after the latent encoding step, both $\tilde{H}^{num}(t)$ and $\tilde{H}^{txt,loc}(t)$ have the same sequence length L and dimension d, i.e. $\tilde{H}^{num}(t), \tilde{H}^{txt,loc}(t) \in \mathbb{R}^{|V|\times L\times d}$, and share a common latent space due to the common $\mathcal{L}$.

In the next **guided cross-attention** step, information from each of the modalities guide attention learning of the other. Sharing a common latent space facilitates mutually guided learning between the modalities and is more efficient as $L \ll K \ll S$. For this step, we generate queries, keys, and values from the numerical and local text representations: $\tilde{Q}^{num}(t) = Linear_Q(\tilde{H}^{num}(t))$,
$\tilde{K}^{num}(t) = Linear_K(\tilde{H}^{num}(t))$,
$\tilde{V}^{num}(t) = Linear_V(\tilde{H}^{num}(t))$,
$\tilde{Q}^{txt,loc}(t) = Linear_Q(\tilde{H}^{txt,loc}(t))$,
$\tilde{K}^{txt,loc}(t) = Linear_K(\tilde{H}^{txt,loc}(t))$,
$\tilde{V}^{txt,loc}(t) = Linear_V(\tilde{H}^{txt,loc}(t))$.
Queries of one modality are used to guide the learning of the other modality as follows:

$$\tilde{H}^{num\text{-}txt}(t) = softmax(\frac{\tilde{Q}^{txt,loc}(t)\cdot\tilde{K}^{num}(t)^T}{\sqrt{d}})\tilde{V}^{num}(t) \tag{1}$$

$$\tilde{H}^{txt\text{-}num}(t) = softmax(\frac{\tilde{Q}^{num}(t)\cdot\tilde{K}^{txt,loc}(t)^T}{\sqrt{d}})\tilde{V}^{txt,loc}(t) \tag{2}$$

Dynamic Graph-Guided Attention Learning. We then utilize inter-company relationships E to guide learning. While these relationships do not frequently change (e.g., common sector relationships), their importances vary across time. Hence, we discover dynamic relationship weights with the **dynamic attention-based edge weights discovery (DW)** module. We concatenate and project $\tilde{H}^{num\text{-}txt}(t)$ and $\tilde{H}^{txt\text{-}num}(t)$ with a linear layer to obtain: $\tilde{H}(t) = Linear[\tilde{H}^{num\text{-}txt}(t)||\tilde{H}^{txt\text{-}num}(t)]$. We then generate: $Q^{DW}(t) = Linear_{Q\text{-}DW}(\tilde{H}(t))$; $K^{DW}(t) = Linear_{K\text{-}DW}(\tilde{H}(t))$. To learn the importance of inter-company relationships in a dynamic manner, we compute attention weights:

$$W_{att}(t) = tanh(Q^{DW}(t)\cdot W_{DW}\cdot K^{DW}(t)^T/\sqrt{d}) \tag{3}$$

where $W_{DW} \in \mathbb{R}^{L\times d\times d}$. As we carry out this operation in the latent space with dimension L, $W_{att}(t) \in \mathbb{R}^{|V|\times|V|\times L}$. We then repeat the adjacency matrix corresponding to the inter-company relationships E by L times to get $A(t) \in \mathbb{R}^{|V|\times|V|\times L}$ and compute the Hadamard product between $A(t)$ and $W_{att}(t)$: $\tilde{A}(t) = A(t) \odot W_{att}(t)$. This results in the weighted adjacency tensor $\tilde{A}(t) \in \mathbb{R}^{|V|\times|V|\times L}$ with $\tilde{A}_{ij}(t) \in \mathbb{R}^L$ representing the weighted relational edges between asset i and j across latent dimension L. Next, in the **dynamic network convolution** step, we utilize the encoded company representations $\tilde{H}(t)$ and the weighted adjacency tensor $\tilde{A}(t)$ as inputs to a weighted dynamic graph convolution step to encode network representations of companies. For company v_i, we compute its network representations $Z_i(t) \in \mathbb{R}^{L\times d}$ across L dimension by aggregating representations from its neighbors $N(i,t)$ based on $\tilde{A}_{i,j}(t), j \in V$:

$$Z_i(t) = \sum_{j\in N(i,t)} \frac{exp(\tilde{A}_{ij}(t))}{\sum_{j'\in N(i,t)} exp(\tilde{A}_{ij'}(t))}\cdot\tilde{H}_j(t) \tag{4}$$

Across all assets, we obtain $Z(t) \in \mathbb{R}^{|V|\times L\times d}$. We adopt this approach instead of other GNNs for computational efficiency as it allows us to apply graph convolution across multiple dimensions in parallel.

Guided Global-Local Attention Learning. We then apply **latent decoding** to decode the representation $Z(t)$ from the latent dimension L to the original sequence length K and S for the numerical and local text modalities respectively. To decode the numerical information, the numerical representations after the projection and addition of time vectors $H^{num}(t)$ are used as queries to decode the keys and values of the representation $Z(t)$. We generate: $Q^{num}_{dec}(t) = Linear_Q(H^{num}(t))$, $K^{num}_{dec}(t) = Linear_K(Z(t))$, $V^{num}_{dec}(t) = Linear_V(Z(t))$, and apply scaled dot-product attention:

$$Z^{num}(t) = softmax(\frac{Q^{num}_{dec}(t)\cdot K^{num}_{dec}(t)^T}{\sqrt{d}})V^{num}_{dec}(t) \tag{5}$$

To elaborate, the dot-product between $Q^{num}_{dec}(t) \in \mathbb{R}^{|V|\times K\times d}$ and $K^{num}_{dec}(t) \in \mathbb{R}^{|V|\times L\times d}$ gives us attention weights of dimensions $|V| \times K \times L$. We then use these attention weights to map $V_{dec}^{num}(t) \in \mathbb{R}^{|V|\times L\times d}$ to $Z^{num}(t) \in \mathbb{R}^{|V|\times K\times d}$. Similarly, to decode the local textual representation, the queries of the local textual representations after the projection and addition of time vectors $H^{txt,loc}(t)$ are used to decode the keys and values of $Z(t)$. We generate: $Q_{dec}^{txt,loc}(t) = Linear_Q(H^{txt,loc}(t))$, $K_{dec}^{txt,loc}(t) = Linear_K(Z(t))$, $V_{dec}^{txt,loc}(t) = Linear_V(Z(t))$, and again apply scaled dot-product attention:

$$Z^{txt,loc}(t) = softmax(\frac{Q_{dec}^{txt,loc}(t) \cdot K_{dec}^{txt,loc}(t)^T}{\sqrt{d}})V_{dec}^{txt,loc}(t) \tag{6}$$

resulting in $Z^{txt,loc}(t) \in \mathbb{R}^{|V|\times S\times d}$. The **global-local guided cross-attention** step uses the decoded $Z^{num}(t)$ to guide the learning of global textual features relevant to each company v_j from $X^{txt,glo}(t)$. We utilize $Z^{num}(t)$ instead of $Z^{txt,loc}(t)$ as we extract global textual features for each time-step $t-k$ in window K rather than S. $Z^{num}(t)$ also contains information relating to $Z^{txt,loc}(t)$ due to the prior guided latent cross-attention learning step. For each time step $t-k$ in window K, we generate $Q^{txt,glo}(t-k) = Linear_Q(Z^{num}(t-k))$, $K^{txt,glo}(t-k) = Linear_K(X^{txt,glo}(t-k))$, $V^{txt,glo}(t-k) = Linear_V(X^{txt,glo}(t-k))$. We apply scaled dot-product attention: $Z^{txt,glo}(t-k) = softmax(K^{txt,glo}(t-k) \cdot W^{txt,glo} \cdot Q^{txt,glo}(t-k)^T/\sqrt{d})^T \cdot V^{txt,glo}(t-k)$ where $W^{txt,glo} \in \mathbb{R}^{d\times d}$ is an inner weight shared across all time steps $t-k$ to improve attention extraction of global textual information. Across the window period, we get $Z^{txt,glo}(t) \in \mathbb{R}^{|V|\times K\times d}$.

Sequential Encoding and Fusion. Transformer encoders (Vaswani et al., 2017) are then used to encode the resultant sequence of representations: $Z^{num\prime}(t) = \text{TransformerEnc}(Z^{num}(t))$, $Z^{txt,loc\prime}(t) = \text{TransformerEnc}(Z^{txt,loc}(t))$, and $Z^{txt,glo\prime}(t) = \text{TransformerEnc}(Z^{txt,glo}(t))$. The transformer encoded sequence of representations are combined with temporal attention fusion, which weights contributions of each time step $t-k$ based on its importance. A non-linear transformation is applied to the respective representations, say $Z^{num\prime}(t-k)$, to obtain scalar $\alpha(t-k)$ for each time step $t-k$ in the window of t: $\alpha(t-k) = W_\tau^{(1)} tanh(W_\tau^{(0)} Z^{num\prime}(t-k) + b_\tau)$, where $W_\tau^{(0)}$ and $W_\tau^{(1)}$ are learnable weight matrices and b_τ is the bias vector. We normalize each $\alpha(t-k)$ to obtain the weights: $\beta(t-k) = \frac{exp(\alpha(t-k))}{\sum_{k=1}^{K} exp(\alpha(t-k))}$. We then fuse the sequence of representations: $Z^{num\prime\prime}(t) = \sum_{k=1}^{K} \beta(t-k) Z^{num\prime}(t-k)$, where $Z^{num\prime\prime}(t) \in \mathbb{R}^{|V|\times d}$. This temporal attention fusion step is repeated across K time-steps for $Z^{txt,glo\prime}(t)$ to obtain $Z^{txt,glo\prime\prime}(t) \in \mathbb{R}^{|V|\times d}$ and across S time-steps for $Z^{txt,loc\prime}(t)$ to obtain $Z^{txt,loc\prime\prime}(t) \in \mathbb{R}^{|V|\times d}$. The representations from the three modalities are then fused with multimodal attention fusion. We denote each of the modalities as r, for a total of $R = 3$ modalities for the numerical, local textual and global textual modalities respectively. A non-linear transformation is applied to the representations to obtain scalars $s(r) = W_\omega^{(1)} tanh(W_\omega^{(0)} \bar{Z}^{r\prime\prime}(t) + b_\omega)$, where $W_\omega^{(0)}$ and $W_\omega^{(1)}$ are learnable weight matrices and b_ω is the bias vector. Parameters are shared across modalities. We normalize the scalars with a softmax function to obtain the weights: $\beta_r = \frac{exp(s(r))}{\sum_{r=1}^{R} exp(s(r))}$, which are used to fuse representations across the three modalities: $Z^{\prime\prime\prime}(t) = \sum_{r=1}^{R} \beta_r Z^{r\prime\prime}(t)$, where $Z^{\prime\prime\prime}(t) \in \mathbb{R}^{|V|\times d}$.

Forecasting and Loss Functions. We use fully connected layers to generate forecasts of means and volatilities of stock returns over the selected horizon period $[t, t+K']$: $\hat{Y}_{mean}^{returns}(t) = FC_M(Z^{\prime\prime\prime}(t))$; and $\hat{Y}_{vol}^{returns}(t) = FC_V(Z^{\prime\prime\prime}(t))$. To forecast correlations of asset returns over the horizon period $[t, t+K']$, we use weights from linear layers in DW: $Q_{corr}(t) = Linear_{Q\text{-}DW}(Z^{\prime\prime\prime}(t))$; $K_{corr}(t) = Linear_{K\text{-}DW}(Z^{\prime\prime\prime}(t))$. This allows what was learnt in the DW step to be utilized here: $\hat{Y}_{corr}^{returns}(t) = FC_C(tanh(\frac{Q_{corr}(t) \cdot K_{corr}(t)^T}{\sqrt{d'}}))$. We then compute losses between the forecasts above and respective ground-truths, i.e. actual means, volatilities and correlations over the horizon $[t, t+K']$ (see Appendix A.2 for ground-truth definitions) with root mean squared loss (RMSE), and use total losses as the training objective:

$$\begin{aligned}\mathcal{L}_{total} &= \mathcal{L}_{mean}(Y_{mean}^{returns}(t), \hat{Y}_{mean}^{returns}(t)) \\ &+ \mathcal{L}_{vol}(Y_{vol}^{returns}(t), \hat{Y}_{vol}^{returns}(t)) \\ &+ \mathcal{L}_{corr}(Y_{corr}^{returns}(t), \hat{Y}_{corr}^{returns}(t))\end{aligned} \tag{7}$$

We do not weight the losses differently as we want the model to perform equally well on all three tasks.

Table 2: Forecast Results. Lower better for all metrics. Best model(s) in bold; second-best model(s) underlined.

4 Experiments

Datasets. We conduct experiments with four datasets, comprising global and local textual information of news articles from financial news portals - Investing news (**IN**) and Benzinga news (**BE**); and numerical information of daily stock market price-related information of two stock markets - NYSE (**NY**) and NASDAQ (**NA**) from 2015 to 2019. The coverage of these datasets - across five years, more than 1.5m articles and 2,000 companies - is more extensive than most existing works and provides strong assurance to our experiment findings. Following Ang and Ee-Peng (2021), we utilize relationships between companies extracted from Wikidata knowledge graphs for the inter-company relationships E from Wikidata dumps dated 7 Jan. 2019. Companies such as Google, Apple and Microsoft are present within the Wikidata KG as entities, and relationships between them, e.g., Alphabet as a parent company of Google (first-order), both Apple and Microsoft are producing computer hardware (second-order), can be extracted from Wikidata. We use a pre-trained Wikipedia2Vec (Yamada et al., 2020) model to pre-encode textual news to capture the rich knowledge present within the Wikipedia knowledge base (see Table 1 and Appendix A.1 for more details on datasets).

Tasks and Metrics. We compare GAME with state-of-the-art baselines on three predictive tasks: **forecasting of i) means, ii) volatilities, and iii) correlations of stock price percentage returns**. We use RMSE, mean absolute error (MAE) and symmetric mean absolute percentage error (SMAPE) as metrics. RMSE and MAE are common scale-dependent metrics used to evaluate forecasting performance with RMSE being more sensitive to outliers than MAE. SMAPE is a scale-independent metric that gives equal importance to under- and over-forecasts required in our evaluation context (see Appendix A.3 for more details on SMAPE). Datasets are divided into non-overlapping training/validation/test sets in the ratios 0.7/0.15/0.15 for experiments.

Baselines and Settings. We compare GAME against state-of-the-art baselines (see Section 2): **TST** (Zerveas et al., 2021) that captures numerical information; **SE** (Du and Tanaka-Ishii, 2020) that captures global textual information; **FAST** (Sawhney et al., 2021b) that captures local textual information; **RSR** (Feng et al., 2019) that captures numerical information and inter-company relationships; and **KECE** (Ang and Ee-Peng, 2021) that captures numerical, global textual information and inter-company relationships. We add fully-connected layers to baselines for them to forecast means, volatilities and correlations of percentage stock returns. We set the window period $K = 20$ days; and horizon period $K' = 10$. $K = 20$ corresponds to a trading month, and $K' = 10$ days corresponds to a global regulatory requirement for VaR computations, which we examine in the case-study (in Section 6). Following Sawhney et al. (2021b), we set M for local news text sequences to be 10. We empirically set L to 16. Dimensions of hidden representations are fixed at 100 across all models. Models are implemented in Pytorch and trained for 100 epochs on a 3.60GHz AMD Ryzen 7 Windows desktop with NVIDIA RTX 3090 GPU and 64GB RAM. Training GAME, which has 1.01e6 parameters, takes around two hours on the IN datasets and nine hours on the BE datasets (see Appendix A.4 for more details on settings).

Results. Table 2 sets out the results of the forecasting experiments. Across all tasks, GAME outperforms all baselines. On the task of **forecasting means**, dispersion in model performances for IN datasets is more narrow than for BE datasets. On the tasks of **forecasting volatilities** and **forecasting correlations**, baseline models (RSR, KECE) that perform better for BE datasets utilize textual and relational information. Performance differences between GAME and baselines are more significant for the larger BE datasets than for the IN datasets due to the larger volume of news textual information. Differences in performances between GAME and baselines are more pronounced for volatilities and correlations forecasting than means forecasting as these are harder tasks that require the model to capture global and local news effects and the propagation of news effects between companies, which are key features of the GAME model.

5 Ablation Studies

Table 3 shows the results of ablation studies for GAME on IN-NY. We observe similar sensitivities for other datasets. When we exclude the guided co-attention module (**w/o. guided co-attn.**), the drop in performance is more significant for volatility and correlation forecasting tasks, while performance decline is more significant for the correlation forecasting task when we exclude the dynamic graph-guided attention module (**w/o. graph-guided enc.**). When we vary the multi-task aspect of GAME by training on mean, volatility or correlation forecast losses only (i.e. **w. mean loss only, w. vol. loss only, w. corr. loss only**), we see significant drops in performance, even on tasks that correspond to the training loss, e.g., performance of mean forecasts when we train only on mean loss is poorer than when we train GAME with multiple tasks.

Table 3: Ablation Studies

6 Application Case Studies

We use model forecasts for investment and risk management applications to evaluate the quality of forecasts. **Portfolio allocation** optimizes the proportion of capital invested in each stock in a portfolio by finding an optimal set of investment weights $\mathbb{W}$ that maximize portfolio returns while minimizing portfolio risk. We use model forecasts as optimization inputs to find $\mathbb{W}$ that maximizes risk-adjusted returns in a future horizon. **Value-at-Risk (VaR)** (Linsmeier and Pearson, 2000) is a key measure of risk used in financial institutions that measures potential losses in a pre-defined horizon with a probability of $p\%$, e.g., 10 day 95% VaR of \$1m means a 5% probability of losses exceeding \$1m over a 10 day horizon. When realized losses exceed forecasted VaR, we call it a VaR breach. We use model forecasts to compute 10 day 95% portfolio VaR forecasts, and evaluate model performances by the total number of VaR breaches. Details on computation methodologies are provided in Appendix A.5. Table 4 depicts results for the IN-NY/IN-NA datasets. For **portfolio allocation**, portfolios constructed using GAME's forecasts achieve highest average risk-adjusted returns. For **VaR**, GAME out-performs baselines with significantly less VaR breaches. Baselines utilizing textual information or inter-company relationships (SE, FAST, RSR and KECE) generally perform better.

Table 4: Portfolio Allocation and VAR. Higher better for average risk-adjusted returns (%Ret.). Lower better for number of VaR breaches (Br.) & percentage of VaR breaches (%Br.).

	IN-NY			**IN-NA**		
	%Ret.	**Br.**	**%Br.**	**%Ret.**	**Br.**	**%Br.**
TST	1.37%	40	21.2%	0.48%	32	16.9%

KECE	1.45%	59	31.2%	1.21%	12	6.4%
GAME	**1.61%**	**6**	**3.2%**	**2.85%**	**2**	**1.1%**

7 Conclusion and Future Work

In this paper, we designed GAME, a model that captures global and local multimodal information with modules that i) enable mutual guidance between modalities with different time-scales, sparsity and distributions; ii) propagation of multimodal information between companies via real-world relationships with dynamic weights to guide learning; iii) guided attention learning between global and local information to extract relevant global information; and iv) was trained in a multivariate multi-task setting. The model performs strongly on three forecasting tasks and two real-world applications, demonstrating the value of guided attention learning for global and local multimodal information. The datasets used are more extensive than most similar works and provide strong assurance on the validity of the results across different companies and textual information. Future work could extend GAME to capture information from other modalities (e.g., audio, visual), textual sources (e.g., Twitter, Reddit), and inter-company relationships (e.g., DBPedia, GDELT). In relation to the *societal impact* of this work, we see opportunities for GAME to support better investment and risk management decisions, and also benefit a range of real-world applications, such as investment portfolio allocation and risk management, as we demonstrated in our paper. We should however recognize that models such as GAME generate forecasts based on past historical patterns that may not always hold in the future, particularly for non-stationary financial time-series. Hence, model risk management, e.g., monitoring significant changes in input information and model performance, is particularly important to avoid negative impacts, such as investment losses.

A Appendix

A.1 Datasets

The four datasets (across two news article sources and two stock markets) differ in the companies covered and news sources as depicted in Table 1 in the main paper. The news article sources are: i) Investing news datasets (**IN**)[1]; and ii) Benzinga news datasets (**BE**)[2]. The datasets contain news articles and commentaries collected from Investing and Benzinga investment news portals, which are drawn from a wide range of mainstream providers, analysts and blogs, such as Seeking Alpha and Zacks.

We also collected daily stock market price-related information - opening, closing, low & high prices, and trading volumes - of two stock markets - NYSE (**NY**) and NASDAQ (**NA**) - from the Center for Research in Security Prices. We filter out stocks from NYSE and NASDAQ that are not traded in the respective time periods and not mentioned in any articles for the respective news article sources. GAME can be used for datasets that contain more stocks, i.e., even those that are not mentioned in any news articles, as it captures both global and local textual news information as well as numerical information. However, we restrict the experiments to stocks that are mentioned in the articles for a fair comparison with models such as FAST that are designed to only capture local textual news information, i.e. they cannot capture any news information not associated with any specific companies.

For inter-company relationships, we use Wikidata, one of the largest and most active collaboratively constructed KGs. Companies such as Google, Apple and Microsoft are present within the Wikidata KG as entities, and relationships between them, e.g., Alphabet as a parent company of Google (first-order), both Apple and Microsoft are producing computer hardware (second-order), can be extracted from Wikidata. We extracted instances of 57 first and second-order relationship-types identified by (Feng et al., 2019) from the Wikidata dumps dated 7 Jan. 2019. The earliest Wikidata dumps were from 2014. We used Wikidata dumps from 7 Jan. 2019 and not earlier as we found that knowledge graphs extracted from earlier Wikidata dumps were too sparse to be useful for our experiments. We did not use Wikidata dumps that were more recent so that the starting date of the test sets will be after the 7 Jan. 2019 date of the Wikidata dump used to construct the KG.

A.2 Ground-truth Definitions

For $Y^{returns}(t) = [y^{returns}(t), ..., y^{returns}(t + K')]$ over a horizon of K' time-steps, the ground-truth labels for means and volatilities are defined as follows:

$$Y^{returns}_{mean}(t) = \frac{1}{K'}\sum_{k'=0}^{K'} y^{returns}(t + k') \quad (8)$$

$$Y^{returns}_{vol}(t) = \sqrt{\frac{1}{K'}\sum_{k'=0}^{K'} (y^{returns}(t + k') - \mu)^2} \quad (9)$$

where $\mu = Y^{returns}_{mean}(t)$. For correlations between any two assets i and j:

$$Y^{returns}_{corr,ij}(t) = \frac{\sum_{k'=0}^{K'}(x_i - \mu_i)(x_j - \mu_j)}{\sqrt{\sum_{k'=0}^{K'}(x_i - \mu_i)^2}\sqrt{\sum_{k'=0}^{K'}(x_j - \mu_j)^2}} \quad (10)$$

where $x_i = y^{returns}_i(t + k'), \;\; x_j = y^{returns}_j(t + k')$.

A.3 Metrics

SMAPE is defined as:

$$SMAPE = \frac{100\%}{n}\sum_{i=1}^{n}\frac{|Y^{returns}_i(t) - \hat{Y}^{returns}_i(t)|}{(|Y^{returns}_i(t)| + |\hat{Y}^{returns}_i(t)|)/2} \quad (11)$$

where n is the number of observations. We choose SMAPE instead of mean absolute percentage error (MAPE) as SMAPE gives equal importance to both under- and over-forecasts required in this evaluation context while MAPE favors under-forecast.

A.4 Settings

To train GAME, we chose the window and horizon periods $K = 20$ and $K' = 10$ days based on experiments with different periods $K, K' \in \{5, 10, 20, 60\}$ which correspond to a trading week, fortnight, month and quarter. Differences in performance between GAME and baselines were generally consistent across all window and horizon periods. Hence, we set the window period $K = 20$ days; and horizon period $K' = 10$ as $K = 20$ corresponds to a trading month, and $K' = 10$ days corresponds to a global regulatory requirement for VaR computations, which we examined in the case-study (see Section 6 of the paper). For the latent

---

[1] Subset extracted from https://www.kaggle.com/gennadiyr/us-equities-news-data

[2] Subset extracted from https://www.kaggle.com/miguelaenlle/massive-stock-news-analysis-db-for-nlpbacktests

$\mathcal{L}$, we chose the latent dimension $L = 16$ based on experiments with different periods $L \in \{8, 16, 32\}$. For $K = 20$ and $K' = 10$, we found that $L = 16$ led to the best overall performance, and enabled more efficient scaled dot-product operations than if we had chosen larger values for L. An Adam optimizer with a learning rate of 1e-3 with a cosine annealing scheduler is used. Models are implemented in Pytorch and trained for 100 epochs on a 3.60GHz AMD Ryzen 7 Windows desktop with NVIDIA RTX 3090 GPU and 64GB RAM. Training GAME, which has 1.01e6 parameters, takes around two hours on the IN datasets and nine hours on the BE datasets.

A.5 Methodology for Application Case Studies

In this section, we describe the detailed methodology for portfolio allocation and VaR risk measurement used in this paper.

A.5.1 Portfolio Allocation Methodology

Investment portfolio allocation is an important task for many financial institutions. The aim of investment portfolio allocation is to optimize the proportion of capital invested in each stock in a portfolio, by finding an optimal set of weights $\mathbb{W}$ that determine how much capital to invest in each stock, so that portfolio returns can be maximized while minimizing portfolio risk. In this paper, we adopt the risk aversion formulation (Fabozzi et al., 2007) of the mean-variance risk minimization model by Markowitz (1952), which models both portfolio return and risk. Under the risk aversion formulation, the classical mean-variance risk minimization model by Markowitz (1952) is re-formulated to maximize the risk-adjusted portfolio return:

$$max_{\mathbb{W}} \left(\mathbb{W}^T \mu - \lambda \mathbb{W}^T \Sigma \mathbb{W} \right) \tag{12}$$

subject to $\mathbb{W}^T \mathbf{1} = 1$. λ, known as the Arrow-Pratt risk aversion index, is used to express risk preferences and is typically set from 2 to 4 (Fabozzi et al., 2007). In this paper, we set $\lambda = 2$ for the experiments. Higher values of $\lambda = 2$ will reduce returns across all models, but the relative differences between models were generally consistent. In this paper, we use the forecasted means of asset returns for μ, i.e. $\tilde{\mu} = \hat{Y}^{returns}_{mean}(t)$; and compute Σ with the forecasted volatilities and correlations of asset returns:

$$\tilde{\Sigma} = D(t) \cdot \hat{Y}^{returns}_{corr}(t) \cdot D(t) \tag{13}$$

where $D(t)$ is the diagonal matrix filled with $\hat{Y}^{returns}_{vol}(t)$ along the diagonals. We choose to forecast correlations of asset returns over the selected horizon period $[t, t + K']$, instead of directly forecasting co-variances as the co-variances need to be positive semi-definite (PSD) so that the matrix is invertible, which is important for applications such as portfolio allocation. Forecasting co-variances directly does not guarantee PSD, but forecasting volatilities and correlations separately and computing the co-variance matrix using the volatilities and correlations with the formula: $\tilde{\Sigma} = D(t) \cdot \hat{Y}^{returns}_{corr}(t) \cdot D(t)$, where $D(t)$ is the diagonal matrix filled with $\hat{Y}^{returns}_{vol}(t)$ along the diagonals, allows the co-variance matrix to be PSD.

This application can be viewed as a predictive task as we are using the returns from the window period $t - K$ to $t - 1$ to make forecasts over the future horizon t to $t + K'$ and using these forecasts to determine the resultant weights $\mathbb{W}$ to invest in stocks over the future horizon; and then measuring the portfolio returns realized in this future horizon: $E^{real} = \mathbb{W}^T R^{real}$, where R^{real} is a vector of realized percentage stock returns over the future horizon.

Given that the aim is to maximize portfolio returns while minimizing portfolio risk (volatility), we choose risk-adjusted realized portfolio returns over the selected future period as the evaluation metric, defined as: $\tilde{E} = \frac{E^{real}}{\sigma(E^{real})}$, where $\sigma(E^{real})$ is portfolio return volatility, defined as the one standard deviation of the portfolio returns over the same future period. For this application, the datasets are similarly divided into non-overlapping training/validation/test sets in the ratios 0.7/0.15/0.15, and we evaluate performance based on the average of the risk-adjusted realized portfolio returns across the test set.

A.5.2 Value-at-Risk (VaR) Measurement Methodology

VaR is a key measure of risk used in financial institutions for the measurement, monitoring and management of financial risk. Financial regulators require important financial institutions such as banks to measure and monitor their VaR over a 10 day horizon and maintain capital based on this VaR as loss buffers. Exchanges may also collect margins from individual investors based on the VaR of their investment portfolios. VaR measures the loss that an institution may face in the pre-defined horizon with a probability of $p\%$, for e.g., if the 10 day

95% VaR is \$1,000,000, it means that there is a 5% probability of losses exceeding \$1,000,000 over a 10 day horizon. Whenever the realized losses exceed the VaR, it is regarded as a VaR breach. More formally, we define VaR as:

$$Pr[E^{real} \leq -VaR(p)] = p \tag{14}$$

where E^{real} is the realized portfolio value and the minus sign is added to VaR as we are dealing with losses, i.e. the probability of realized portfolio value (i.e. losses) being more negative than negative VaR. For this application, the portfolio is constructed based on the approach described for the portfolio allocation application at each time-step. This mimics a real-world scenario where financial institutions continually update their portfolios based on market conditions. VaR can be computed as a multiple of the portfolio's volatility:

$$VaR = \phi^{-1}(p) \times \sigma \tag{15}$$

where ϕ is the inverse cumulative distribution function of the standard normal distribution, for e.g. if $p = 95\%$ then $\phi^{-1}(p) = 1.645$. In the classical approach, σ is the historical portfolio volatility over a pre-defined window period. To evaluate the baseline models, we instead use the forecasted portfolio volatility $\tilde{\sigma} = \sqrt{\tilde{\Sigma}}$ where $\tilde{\Sigma}$ is computed using the forecasted volatilities and correlations of asset returns as defined in equation (13). Similar to the portfolio allocation application, this can also be viewed as a predictive task as we are using the returns from the window period $t-K$ to $t-1$ to make forecasts over the future horizon t to $t+K'$ and using these forecasts to determine the VaR in the future horizon. We evaluate model performances by counting the total number of 95% VaR breaches, i.e. where the realized portfolio loss exceeds the forecasted VaR in the testing dataset (using the same training/validation/test sets as the portfolio allocation application). We choose the 95% VaR for our experiments as it is a common confidence level used by banks to monitor their risks. Models that are able to make accurate forecasts of VaR should have less VaR breaches.

On Vision Features in Multimodal Machine Translation

Abstract

Previous work on multimodal machine translation (MMT) has focused on the way of incorporating vision features into translation but little attention is on the quality of vision models. In this work, we investigate the impact of vision models on MMT. Given the fact that Transformer is becoming popular in computer vision, we experiment with various strong models (such as Vision Transformer) and enhanced features (such as object-detection and image captioning). We develop a selective attention model to study the patch-level contribution of an image in MMT. On detailed probing tasks, we find that stronger vision models are helpful for learning translation from the visual modality. Our results also suggest the need of carefully examining MMT models, especially when current benchmarks are small-scale and biased. Our code could be found at `https://github.com/libeineu/fairseq_mmt`.

1 Introduction

Multimodal machine translation (MMT) has emerged as an active field of research which marries the worlds of computer vision (CV) and natural language processing (NLP) (Specia et al., 2016). Early models of this kind produce a translation given the fused representation of both the visual and textual inputs (Caglayan et al., 2016; Libovický and Helcl, 2017; Calixto and Liu, 2017). As expected, such a paradigm achieves promising BLEU improvements and inspires the community to follow up.

But soon researchers found that MMT systems did not act as what they ordinarily designed: the visual modality contributes to translation little. For example, it is not harmful to MMT systems when the input image is irrelevant to the text (Grönroos et al., 2018; Lala et al., 2018), or even when the vision features are absent (Elliott, 2018). More recently, Wu et al. (2021) have pointed out that the use of the visual modality is a way of regularization for training but not a complement to the text modality. As another response to the analysis of MMT, Caglayan et al. (2019) investigate how the vision features correlate to the text. They find that the input image helps translation when some of the input words are masked.

Note that previous work has for the most part focused on integrating off-the-shelf vision models (such as ResNet-50) into MMT. The underlying assumption here is that the existing vision models are powerful enough to encode the image. This implicitly ignores the quality of vision models in representing images. But computer vision is facing a new trend by moving from CNNs to Transformer as the backbone model (Dosovitskiy et al., 2021; Liu et al., 2021b; Carion et al., 2020). A natural question that arises is: *how will MMT systems behave if stronger vision models are adopted?*

In this work, we address this question by a systematic study of using various vision models in MMT, in particular using the most successful models in recent studies (such as Vision Transformer, or ViT for short). We find that the patch method used in Transformer-based vision models offers an opportunity to detail the patch-level contribution of the image. This leads us to develop a selective attention model to correlate words with image patches. Beyond this, we introduce object-detection and image captioning features into MMT for further improvements of the vision models (Carion et al., 2020; Fang et al., 2021).

Following Caglayan et al. (2019)'s work, we design more detailed probing tasks to examine to what degree the visual modality contributes to MMT. We run an extensive set of experiments on En-De and En-Fr MMT tasks. Our findings are

- Stronger vision models help. For example, ViT can beat ResNet-50 on the probing tasks though the superiority is not significant on standard MMT data.

Table 1: An example of the proposed probing tasks. We replace the masked token by four symbols respectively.

- Automatic evaluation on current MMT tasks might not be a good indicator for the effectiveness of MMT models. For example, models enhanced with object-detection and image captioning features yield good BLEU scores on the original MMT task but show modest or no contributions on the probing tasks.

We hope that the results here can inspire more research on exploring better vision models and evaluation methods for multimodal NLP.

2 Preliminary

We start with a description of the probing tasks. It is followed by a design of vision features and a selective attention mechanism for introducing ViT-like representations into MMT.

2.1 Insufficient Text Generation

To know how an image contributes to translation, a way is to mask some of the input words (call this insufficient text) and force the translation model to learn from the image. Following the previous design of color deprivation and entity-based masking, we present detailed probing tasks which are complementary to Caglayan et al. (2019)'s work. In preliminary experiments[1], we find that "color", "character" and "noun" are three kinds of words which could be complemented according to the visual modality once the corresponding texts are masked. The following probing tasks are designed accordingly.

Color-based Probing In training, all source words referring to a color are replaced by a special token [`Mask_C`]. There are $8,919$ sentences involving color words, and nearly one third of them involve more than one color. It is worth noting that each color may have two or more translations due to the rich morphology in German and French. For example, the English "green" can be translated to "grün", "grüne", "grünes", "grüner", "grünen" and "grünem" in German. We design two criteria to measure the accuracy of translation. The first criterion is strict. The correct translation requires generating the same color and the same gender as in reference translations. The second criterion is relaxed and all translations expressing the same color are correct.

Character-based Probing For character words, we choose "man", "woman", "people", "men", "girl" and "boy". More than 60% sentences contain character words in our training data, so they are reasonable indicators of assessing the ability to infer correct translations from the input image. Here we use [`MASK_P`] for masking. Note that some character words have more than two translations, e.g. "people", we also use the same evaluation metric with the color-based probing task, including relaxed and strict two criteria.

Noun-based Probing For more complex scenarios, a sentence can be masked with several kinds of ambiguous words, such as animals, clothing, and vehicles, provided by Flickr30K (Plummer et al., 2015). High-frequency words labeled with noun (or nouns) are more likely to be masked as [`MASK_N`] (or [`MASK_NS`])). See Table 1 for example insufficient text with different numbers of masks.

2.2 Various Vision Features

In addition to ResNet-50, we choose several Transformer-based vision models.

- General Backbone. Vision Transformer (ViT) and Swin Transformer are popular models in computer vision (Dosovitskiy et al., 2021; Liu et al., 2021b). We use ViT with various model capacities to vary from weak to strong ViT models.
- Object-detection. For pretrained object-detection vision models, we choose DETR (Carion et al., 2020) and QueryInst (Fang et al., 2021) for their strong performance.

---

[1] We choose the Multi30K En-De and En-Fr datasets for experiments.

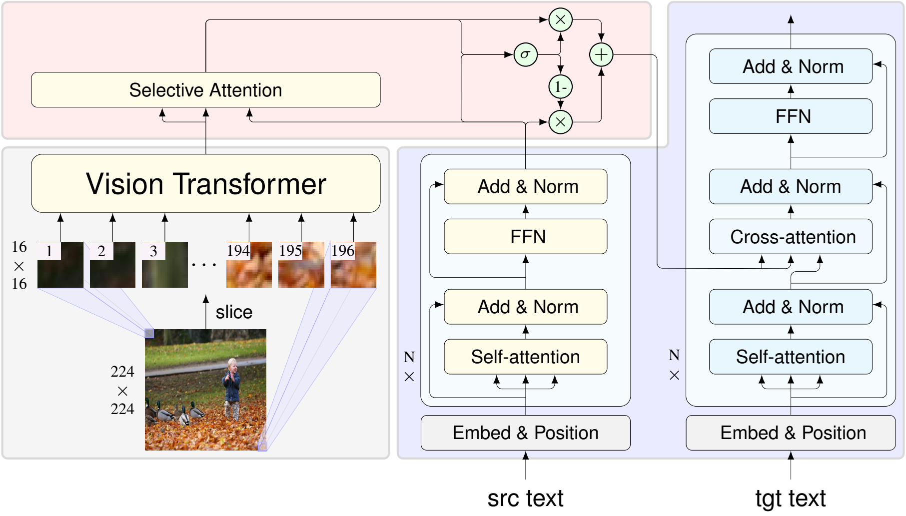

Figure 1: The overview of selective attention multimodal Transformer when using ViT as the vision feature.

- Image Captioning. For image captioning models, we choose CATR[2] because it is a Transformer-based image captioning architecture and can be easily implemented on top of ViT.

We form a number of vision features by combining the methods described above. More details are presented in Section 3.

2.3 Selective Attention

ViT and related models perform in almost the same way as Transformer in NLP (Vaswani et al., 2017). Unlike the general models in CV, ViT does not represent the image as a single vector. Instead, it generates a sequence of patches for image representation. An advantage of this design is that we can use the attention mechanism to correlate image patches to words. Thus, we present a selective attention model to model the patch-level contribution of the image. See Figure 1 for the architecture.

Text-only Transformer Transformer follows an encoder-decoder paradigm (the purple region in Figure 1) . The encoder is a stack of identical layers. Each layer consists of a self-attention (SAN) block and a feedforward network (FFN) block. The decoder shares a similar design with the encoder, but with an additional cross-attention block.

Gated Fusion Gated fusion mechanism is a popular technique for fusing representations from different sources (Wu et al., 2021; Zhang et al., 2020; Lin et al., 2020; Yin et al., 2020). Given the text input X^{text} and the image input X^{img}, the text representation H^{text} and the image feature H^{img} can be defined as:

$$H^{\text{text}} = \text{TransformerEncoder}(X^{\text{text}}) \quad (1)$$

$$H^{\text{img}} = W\ \text{ViT}(X^{\text{img}}) \quad (2)$$

where W is a projection matrix to convert the shape of $\text{ViT}(X^{\text{img}})$ into that of H^{text}. Note that $\text{ViT}(\cdot)$ can be replaced by other vision models, e.g. DETR, Swin Transformer and etc. Then, the gate $\lambda \in [0, 1]$ and the fuzed output are defined as:

$$\lambda = \text{Sigmoid}(UH^{\text{text}} + VH^{\text{img}}) \quad (3)$$

$$H^{\text{Out}} = (1 - \lambda) \cdot H^{\text{text}} + \lambda \cdot H^{\text{img}} \quad (4)$$

where U and V are trainable variables. λ controls how much visual information is kept. Then, the fusion vector H^{Out} is fed into the decoder. See the right side of the pink region in Figure 1 for an illustration of the gated fusion models.

Selective Attention After obtaining the text and image representations (or features), we use a single-head attention network to correlate words with image patches, where the query, key and value are H^{text}, H^{img} and H^{img}, respectively. Then the selective attention output H^{img}_{attn} is defined to be:

$$H^{\text{img}}_{attn} = \text{Softmax}\left(\frac{QK^{\text{T}}}{\sqrt{d_k}}\right)V \quad (5)$$

where d_k is the same as the dimension of H^{text} because a single head is used. Then the fused representation could be obtained by using Eqs. 3 and 4 and replacing H^{img} with H^{img}_{attn}.

Table 2: BLEU (left) and METEOR (right) scores of En→De and En→Fr tasks. Some of the results are from Wu et al. (2021)'s work.

3 Experiments

3.1 Datasets

We conducted experiments on the widely used Multi30K benchmark (Elliott et al., 2016). The training and validation sets consisted of $29,000$ and $1,014$ instances, respectively. We reported the results on the Test2016, Test2017 and MSCOCO test sets (Elliott et al., 2017). Note that MSCOCO is more challenging for MMT models due to the out-of-domain instances with ambiguous verbs. Following the setup in (Wu et al., 2021), we learned a joint BPE code for $10,000$ merging operations for both the source and target languages, resulting in vocabularies of $9,716$ and $9,548$ entries for the En-De and En-Fr tasks.

3.2 Experimental Setups

We followed the Wu et al. (2021)'s work to conduct experiments with Transformer-Tiny configuration, which is more suited for small datasets like Multi30K. Note that smaller models even obtain higher BLEU scores than pervious MMT models. Similar observations have been discussed when building context-aware machine translation models (Li et al., 2020). The model consists of 4 encoder and decoder layers. The hidden size is 128 and the filter size of FFN is 256. There are 4 heads in the multi-head self-attention mechanism. We set the dropout as 0.3 and the label smoothing as 0.1.

Our implementation was based on Fairseq (Ott et al., 2019). For training, we used Adam Optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\epsilon = 10^{-8}$. We adopted the same learning rate schedule as (Vaswani et al., 2017), where the learning rate first increased linearly for $warmup = 2000$ steps from $1e^{-7}$ to $5e^{-3}$. After the warmup, the learning rate decayed proportionally to the inverse square root of the current step. Each training batch contained $4,096$ tokens. We also adopted the early-stop training strategy (Zhang et al., 2020) to avoid the overfitting issue.

For evaluation, we averaged the last 10 checkpoints for more reliable results. The width of beam size was set to 5. The performance was measured by BLEU and METEOR for all test sets. Also, we used accuracy for evaluation on the probing tasks.

3.3 Results

Table 2 summarizes the results on standard MMT data. Each model was evaluated on three test sets on two language pairs. We see, first of all, that the improvements of previous methods (Rows 2-4) over the tiny baseline are marginal in terms of both BLEU and METEOR. This confirms the assumption that the visual features are not fully used if the text is complete (Caglayan et al., 2019). When switching the vision features from ResNet (Row.5) to ViT (Row.6), there are no significant BLEU gains. Then, we test them on the proposed probing tasks to examine the "real" contribution to MMT.

Color-based Probing Table 3 shows the accuracy on the color-based probing task. We see that the accuracy improvement of the gated fusion method is marginal by both restrict and relaxed criteria. However, replacing ResNet with ViT yields gains of over 8 accuracy points across three test

Table 4: The accuracy of MMT systems when applied character-based probing.

sets on En-De task. Similar improvements are observed on the En-Fr task. The finding here indicates that stronger vision features are helpful for representing the visual information. Moreover, selective attention can make better use of the ViT features, achieving over 20 accuracy gains on three test sets. This verifies the conjecture that the selective attention can further enhance the fused representation for the ViT features.

Character-based Probing Table 4 shows similar results as in Table 3. ViT with selective attention performs the best on most scenarios, it is only slightly inferior to Gated Fusion + ViT on the MSCOCO dataset. While the gated fusion method with ResNet feature behaves far from desirable. It even underperforms the text-only Transformer, though the text-only Transformer is carefully regularized. A potential explanation is the character-based probing task is more challenging than the color-based probing task because it is more difficult for the model to find the correct corresponding region of the masked character word and provide useful signals to the text encoder.

Noun-based Probing Figure 2 plots the results of noun-based masking. It again verifies the above conjecture. The histograms in blue and red denote the results on the En-De and En-Fr tasks, respectively. The ViT features can significantly outperform the ResNet features across all masking methods on the two language pairs. We also observe that the gap between the ResNet and ViT features is gradually enlarged as more nouns are masked. This confirms the results in (Dosovitskiy et al., 2021).

4 Analysis

4.1 How Vision Features Improve the MMT

We further explore the impact of model capacity. Here, we report the results of ViT and Swin Transformer because they are strong models in recent studies. Our conjecture here is that larger ViT/Swin models can describe the image more accurately, which enables the text encoder to receive richer complementary information. Figure 3 depicts the BLEU scores in progressive noun masking scenarios. Intuitively, larger ViT and Swin models provide more complementary knowledge to complete the insufficient text representations.

Nevertheless, a counterintuitive phenomenon is the inferiority of Swin across all scenarios in the same configuration, though it outperforms ViT on most computer vision benchmarks. We attribute the reason to the short length of the patch sequence. In patch, ViT has a length of 577 (576 sequence

(c) Results on MSCOCO

Figure 2: Comparison of systems 5-7 in Table 2 with limited textual context on three test sets. Blue/Red pillars denote the results evaluated on the En-De and En-Fr tasks, respectively. We exhibit the BLEU scores of three MMT models with different masking granularities. The shadow denotes the score obtained by text-only Transformer.

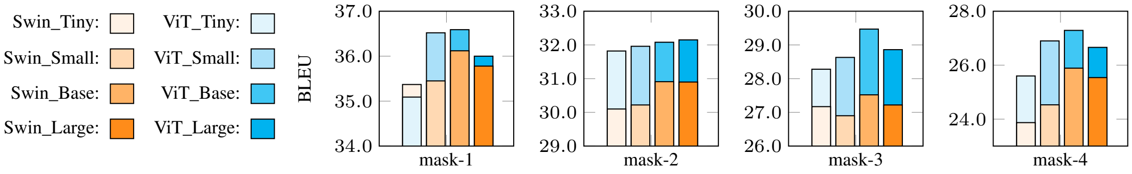

Figure 3: BLEU scores[%] for MMT models with ViT/Swin in various capacities on En-De Test2016.

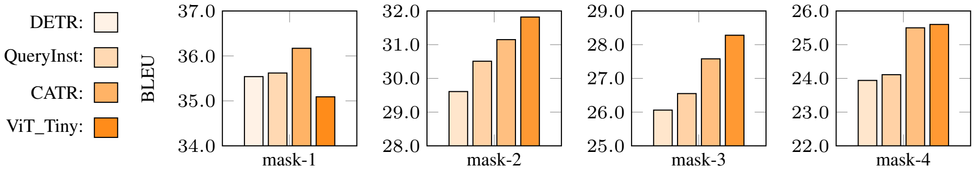

Figure 4: BLEU scores [%] of various vision features on En-De Test2016.

segments and a special token `CLS`) when the image resolution and the patch size are 384 × 384 and 16×16. However, Swin has a fixed sequence length (49) restricted by the shifted window operation. This leads to more fine-grained local features for ViT, which is beneficial to the selective attention mechanism for extracting more relevant pieces.

4.2 Impact of Learning Objectives

Then, we investigate the impact of the enhanced vision features on MMT. Previous studies have already attempted to leverage object-detection features (Zhao et al., 2020; Wang and Xiong, 2021) but the observation here is slightly different. Beyond the object-detection pretrained features, we also take the image captioning task into account.

Rows 11-13 in Table 2 summarize the results of the three enhanced vision features on the standard MMT data, and Figure 4 depicts the results on insufficient texts. Here we choose ViT-Tiny-based models for comparison due to the similar model capacity they own[3]. We see that not only the object-detection (DETR and QueryInst), but also the image captioning (CATR) pretrained fea-

tures obtain superior performance compared with ViT-tiny (Row 8) when the text is complete. It is consistent with previous findings (Yin et al., 2020; Zhao et al., 2020). However, the advantages do not persist when switching to limited text scenarios. A possible explanation is that these methods are sensitive to the quality of the extracted objects. We leave this as future work.

4.3 Impact of Resolution and Patch Size

It is well-known that higher resolutions are beneficial to the accuracy improvement in computer vision tasks (Dosovitskiy et al., 2021). Despite the success of the Transformer architecture, recent studies show that the success of ViT mainly comes from the successful use of the patch schema (Dosovitskiy et al., 2021). Here, we compare MMT systems with different resolutions and patch sizes based on ViT-Base. The results on three probing tasks (see Table 5) again confirm the above assumption that fine-grained vision features are more suited for the selective attention. Also, the attention map visualized in Figure 5 demonstrates that high resolution with fine-grained patch schema can attend to correct regions of the image for each masked token. For example, both models pay the right attention to the masked character and noun, but the model with low resolution fails to detect the right region of color. The finding here may shed light to other multimodal tasks, such as VQA.

4.4 Incongruent Decoding

Incongruent decoding is a widely used manner to evaluate whether the visual modality contributes to the text (Caglayan et al., 2019, 2021). Table 6 shows that incongruent decoding causes obvious BLEU drops except for the ResNet feature. ViT beats the ResNet with gated fusion. It yields higher BLEU scores with congruent decoding and exhibits a larger BLEU drop with incongruent decoding. We also find that the ViT features learned from scratch are also insensitive to the visual modality. This is reasonable that the learned vision systems are not sufficiently strong due to the data scarcity of Multi30K. Thus the visual modality acts more like noise signals. In addition, focusing on the results of pretrained selective attention + ViT, the gap between congruent and incongruent decoding gradually becomes larger.

We also investigate whether the ensemble vision features can help. Concretely, we choose ViT and CATR to independently generate the fused representations with the text feature, and then the ensemble feature is obtained based on them. We see that the ensemble vision feature performs the best on the congruent decoding, and achieves the largest

Table 6: The impact of incongruent decoding for the noun masking strategy. Here Cong./Icong. denotes congruent and incongruent decoding, respectively. The results (BLEU [%]) were measured on En-De Test2016.

	`SRC`: a brown-haired [man] in a [green] [shirt] plays a [trumpet] outdoors . `REF`: ein **mann** mit braunen haaren in einem **grünen** **hemd** spielt im freien **trompete** . `MK` : a brown-haired `[MASK_P]` in a `[MASK_C]` `[MASK_N]` plays a `[MASK_N]` outdoors . `CNN`: eine braunhaarige ~~frau~~ in einem ~~roten~~ ~~kleid~~ spielt im freien ~~gitarre~~ . *(a brown-haired ~~woman~~ in a ~~red~~ ~~dress~~ plays a ~~guitar~~ outdoors.)* `ViT`: ein braunhaariger **mann** in einem **grünen** **hemd** spielt im freien **trompete** . *(a brown-haired **man** in a **green** **shirt** plays a **trumpet** outdoors.)*
	`SRC`: a [boy] is leaning on a [car] with [flowers] on the [hood] . `REF`: ein junge lehnt sich an ein auto mit blumen auf der motorhaube . `MK` : a `[MASK_P]` is leaning on a `[MASK_N]` with `[MASK_NS]` on the `[MASK_N]` . `CNN`: ein ~~mann~~ lehnt an einer ~~wand~~ mit ~~bäumen~~ auf der ~~straße~~ . *(a ~~man~~ is leaning on a ~~wall~~ with ~~trees~~ on the ~~street~~.)* `ViT`: ein kind lehnt sich an einem **auto** mit **blumen** auf dem ~~gehweg~~ . *(a child is leaning on a **car** with **flowers** on the ~~sidewalk~~.)*

Table 7: Qualitative examples from two complex scenarios. ~~Strikethrough~~ and **bold** words present the incorrect and good lexical choices. Underline denotes the acceptable but not totally right translation.

BLEU gaps on four masking scenarios compared with other systems. These results again indicate that stronger visual contexts indeed help.

4.5 Case Study

Finally, we compare several real cases. We choose gated fusion (`CNN`) (Wu et al., 2021) and selective attention + ViT_Base (`ViT`) for comparison. The qualitative examples in Table 7 demonstrate that the visual modality is complementary rather than redundant if the text is insufficient. To figure out whether the German translation is right or not, we provide the human-translation results. First, we see the top half case of Table 7, `ViT` can fill in the masked entities and generate the correct translations even four entities were masked. Unfortunately, `CNN` incorrectly judges the man as a woman. Also, it cannot distinguish the right color of shirt due to the complex background. When given a more complex image (the bottom half case), it is still a challenge for ViT to generate the right translation. The observation here inspires us to design a more powerful fusion method. Also, the data scarcity problem is a root issue to prevent us from further improving the cross-modal translation quality.

5 Related Work

Multimodal machine translation is a cross-domain task in the field of machine translation. Early attempts mainly focused on enhancing the MMT model by better incorporation of the vision features (Calixto and Liu, 2017; Elliott and Kádár, 2017; Delbrouck and Dupont, 2017). However, directly encoding the whole image feature brings additional noise to the text (Yao and Wan, 2020; Liu et al., 2021a). To address the above issue, Yao and Wan (2020) proposed a multimodal self-attention to consider the relative difference of information between two modalities. Similarly, Liu et al. (2021a) used a Gumbel Softmax to achieve the same goal.

Researchers also realize that the visual modality may be redundant. Irrelevant images have little impact on the translation quality, and no significant BLEU drop is observed even the image is absent (Elliott, 2018). Encouraging results appeared in

Caglayan et al. (2019)'s work. They pointed out that the visual modality is still useful when the linguistic context is scarce, but is less sensitive when exposed to complete sentences. More recently, Wu et al. (2021) attributed the BLEU gain on MMT tasks to the regularization training, and they again emphasized the imperative of constructing proper insufficient textual input. It is worthy to note that the proposed probing task is an improved version based upon previous work (Caglayan et al., 2019; Wu et al., 2021). We also opensource the preprocessed data and the corresponding scripts for the subsequent researchers to experiment on.

Another line of research is to explore large-scale cross-modal pretraining models. In this way, the MMT task is regarded as a downstream task. For example, CLIP (Radford et al., 2021) is a general cross-modal pretraining model, which learns to perform a wide variety of tasks via natural language prompting. Caglayan et al. (2021) presented a MMT-specific pretraining model which combines the translation language modeling with masked region classification objectives. In this work, we make a systematic study on whether stronger vision features are helpful. We also extend the research to enhanced features, such as object-detection and image captioning, which are complementary to previous work.

6 Conclusions

In this work, we show that stronger vision features (e.g. ViT-like models) strengthen MMT systems on three proposed probing tasks. We present a selective attention method for ViT-based models to make better use of the patch-level representation. The result here shows a promising line of research on developing better vision models for multimodal tasks. As far as we know, this is the first attempt to build MMT systems with Transformer only. In future work, we are willing to investigate whether it is possible to use a single set of parameters to encode the vision and text modalities.

Abstract

Named Entity Recognition (NER) in Few-Shot setting is imperative for entity tagging in low resource domains. Existing approaches only learn *class-specific* semantic features and intermediate representations from source domains. This affects generalizability to unseen target domains, resulting in suboptimal performances. To this end, we present CONTAINER, a novel contrastive learning technique that optimizes the inter-token distribution distance for Few-Shot NER. Instead of optimizing class-specific attributes, CONTAINER optimizes a generalized objective of differentiating between token categories based on their Gaussian-distributed embeddings. This effectively alleviates overfitting issues originating from training domains. Our experiments in several traditional test domains (OntoNotes, CoNLL'03, WNUT '17, GUM) and a new large scale Few-Shot NER dataset (Few-NERD) demonstrate that, on average, CONTAINER outperforms previous methods by 3%-13% absolute F1 points while showing consistent performance trends, even in challenging scenarios where previous approaches could not achieve appreciable performance. The source code of CONTAINER will be available at: `https://github.com/psunlpgroup/CONTaiNER`.

1 Introduction

Named Entity Recognition (NER) is a fundamental NLU task that recognizes mention spans in unstructured text and categorizes them into a predefined set of entity classes. In spite of its challenging nature, recent deep-learning based approaches (Huang et al., 2015; Ma and Hovy, 2016; Lample et al., 2016; Peters et al., 2018; Devlin et al., 2018) have achieved impressive performance. As these supervised NER models require large-scale human-annotated datasets, few-shot techniques that can effectively perform NER in resource constraint settings have recently garnered a lot of attention.

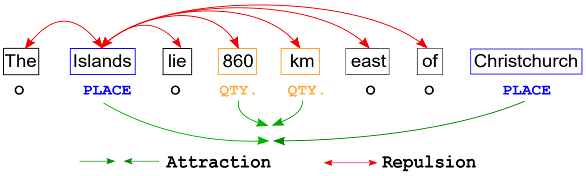

Figure 1: Contrastive learning dynamics of a token (*Islands*) with all other tokens in an example sentence from GUM (Zeldes, 2017). CONTAINER decreases the embedding distance between tokens of the same category (`PLACE`) while increasing the distance between different categories (QTY. and O).

Few-shot learning involves learning unseen classes from very few labeled examples (Fei-Fei et al., 2006; Lake et al., 2011; Bao et al., 2020). To avoid overfitting with the limited available data, meta-learning has been introduced to focus on *how to learn* (Vinyals et al., 2016; Bao et al., 2020). Snell et al. (2017) proposed Prototypical Networks to learn a metric space where the examples of a specific unknown class cluster around a single prototype. Although it was primarily deployed in computer vision, Fritzler et al. (2019) and Hou et al. (2020) also used Prototypical Networks for few-shot NER. Yang and Katiyar (2020), on the other hand, proposed a supervised NER model that learns class-specific features and extends the intermediate representations to unseen domains. Additionally, they employed a Viterbi decoding variant of their model as "StructShot".

Few-shot NER poses some unique challenges that make it significantly more difficult than other few-shot learning tasks. First, as a sequence labeling task, NER requires label assignment according to the concordant context as well as the dependencies within the labels (Lample et al., 2016; Yang and Katiyar, 2020). Second, in NER, tokens that do not refer to any defined set of entities are labeled as `Outside` (`O`). Consequently, a token that is labeled as `O` in training entity set may correspond to a valid target entity in test set. For prototypical networks, this challenges the notion of entity exam-

May 22-27, 2022 ©2022 Association for Computational Linguistics

ples being clustered around a single prototype. As for Nearest Neighbor based methods such as Yang and Katiyar (2020), they are initially "pretrained" with the objective of source class-specific supervision. As a result, the trained weights will be closely tied to the source classes and the network will project training set `O-tokens` so that they get clustered in embedding space. This will force the embeddings to drop a lot of useful features pertaining to its true target entity in the test set. Third, in few-shot setting, there are not enough samples from which we can select a validation set. This reduces the capability of hyperparameter tuning, which particularly affects template based methods where prompt selection is crucial for good performance (Cui et al., 2021). In fact, the absence of held-out validation set puts a lot of earlier few-shot works into question whether their strategy is truly "Few-Shot" (Perez et al., 2021).

To deal with these challenges, we present a novel approach , CONTAINER that harnesses the power of contrastive learning to solve Few-Shot NER. CONTAINER tries to decrease the distance of token embeddings of similar entities while increasing it for dissimilar ones (Figure 1). This enables CONTAINER to better capture the label dependencies. Also, since CONTAINER is trained with a generalized objective, it can effectively avoid the pitfalls of `O-tokens` that the prior methods struggle with. Lastly, CONTAINER does not require any dataset specific prompt or hyperparameter tuning. Standard settings used in prior works (Yang and Katiyar, 2020) works well across different domains in different evaluation settings.

Unlike traditional contrastive learners (Chen et al., 2020; Khosla et al., 2020) that optimize similarity objective between point embeddings, CONTAINER optimizes distributional divergence effectively modeling Gaussian Embeddings. While point embedding simply optimizes sample distances, Gaussian Embedding faces an additional constraint of maintaining class distribution through the variance estimation. Thus Gaussian Embedding explicitly models entity class distributions which not only promotes generalized feature representation but also helps in few-sample target domain adaptation. Previous works in Gaussian Embedding has also shown that mapping to a density captures representation uncertainties (Vilnis and McCallum, 2014) and expresses natural asymmetries (Qian et al., 2021) while showing better generalization requiring less data to achieve optimal performance (Bojchevski and Günnemann, 2017). Inspired by these unique qualities of Gaussian Embedding, in this work we leverage Gaussian Embedding in contrastive learning for Few-Shot NER.

A nearest neighbor classification scheme during evaluation reveals that on average, CONTAINER significantly outperforms previous SOTA approaches in a wide range of tests by up to 13% absolute F1-points. In particular, we extensively test our model in both in-domain and out-of-domain experiments as proposed in Yang and Katiyar (2020) in various datasets (CoNLL '03, OntoNotes 5.0, WNUT '17, I2B2) . We also test our model in a large dataset recently proposed for Few-Shot NER - Few-NERD (Ding et al., 2021) where CONTAINER outperforms all other SOTA approaches setting a new benchmark result in the leaderboard.

In summary, our contributions are as follows: (1) We propose a novel Few-Shot NER approach CONTAINER that leverages contrastive learning to infer distributional distance of their Gaussian Embeddings. To the best of our knowledge we are the first to leverage Gaussian Embedding in contrastive learning for Named Entity Recognition. (2) We demonstrate that CONTAINER representations are better suited for adaptation to unseen novel classes, even with a low number of support samples. (3) We extensively test CONTAINER in a wide range of experiments using several datasets and evaluation schemes. In almost every case, our model largely outperforms present SOTAs establishing new benchmark results.

2 Task Formulation

Given a sequence of n tokens $\{x_1, x_2, \ldots x_n\}$, NER aims to assign each token x_i to its corresponding tag label y_i.

Few-shot Setting For Few-shot NER, a model is trained in a source domain with a tag-set $\{C^s_{(i)}\}$ and tested in a data-scarce target domain with a tag-set $\{C^d_{(j)}\}$ where i, j are index of different tags. Since $\{C^s_{(i)}\} \cap \{C^d_{(j)}\} = \emptyset$, it is very challenging for models to generalize to unseen test tags. In an *N-way K-shot* setting, there are N tags in the target domain $|\{C^d_{(j)}\}| = N$, and each tag is associated with a support set with K examples.

Tagging Scheme For fair comparison of CONTAINER against previous SOTA models, we follow an IO tagging scheme where `I-type` repre-

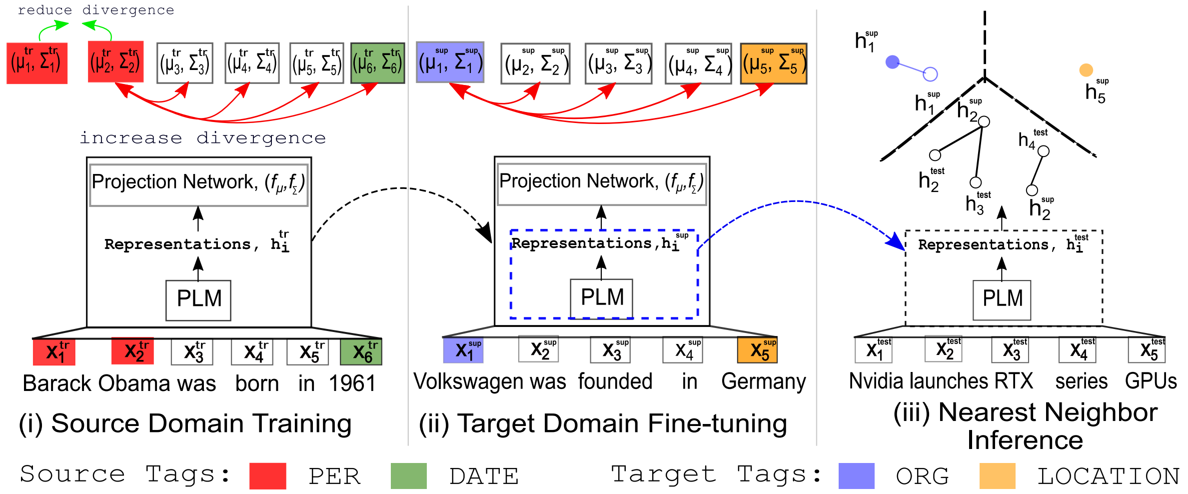

Figure 2: Illustration of our proposed CONTAINER framework based on Contrastive Learning over Gaussian Embedddings: (i) Training in source domains using training NER labels `PER` and `DATE`, (ii) Fine-tuning to target domains using target NER labels `ORG` and `LOCATION`, (iii) Assigning labels to test samples via Nearest Neighbor support set labels.

sents that all of the tokens are inside an entity, and `O-type` denotes all the other tokens (Yang and Katiyar, 2020; Ding et al., 2021).

Evaluation Scheme To compare with SOTA models in Few-NERD leaderboard (Ding et al., 2021), we adpot *episode evaluation* as done by the authors. Here, a model is assessed by calculating the micro-F1 score over multiple number of test episodes. Each episode consists of a *K-shot* support set and a *K-shot* unlabeled query (test) set to make predictions . While Few-NERD is explicitly designed for episode evaluation, traditional NER datasets (e.g., OntoNotes, CoNLL'03, WNUT '17, GUM) have their distinctive tag-set distributions. Thus, sampling test episodes from the actual test data perturbs the true distribution that may not represent the actual performance. Consequently, Yang and Katiyar (2020) proposed to sample multiple support sets from the original development set and use them for prediction in the original test set. We also use this evaluation strategy for these traditional NER datasets.

3 Method

CONTAINER utilizes contrastive learning to optimize distributional divergence between different token entity representations. Instead of focusing on label specific attributes, this contradistinction explicitly trains the model to distinguish between different categories of tokens. Furthermore, modeling Gaussian Embedding instead of traditional point representation effectively lets CONTAINER model the entity class distribution, which incites generalized representation of tokens. Finally, it lets us carefully finetune our model even with a small number of samples without overfitting which is imperative for domain adaptation.

As demonstrated in Figure 2, we first **train** our model in source domains. Next, we **finetune** model representations using few-sample support sets to adapt it to target domains. The training and finetuning of CONTAINER is illustrated in Algorithm 1. Finally, we use an **instance level nearest neighbor classifier** for inference in test sets.

3.1 Model

Figure 2 shows the key components of our model. To generate contextualized representation of sentence tokens, CONTAINER incorporates a pretrained language model encoder `PLM`. For proper comparison against existing approaches, we use BERT (Devlin et al., 2018) as our `PLM` encoder. Thus given a sequence of n tokens $[x_1, x_2, \ldots, x_n]$, we take the final hidden layer output of the `PLM` as the intermediate representations $\boldsymbol{h}_i \in \mathbb{R}^{l'}$.

$$[\boldsymbol{h}_1, \boldsymbol{h}_2, \ldots, \boldsymbol{h}_n] = \texttt{PLM}([x_1, x_2, \ldots, x_n]) \quad (1)$$

These intermediate representations are then channeled through simple projection layer for generating the embedding. Unlike SimCLR (Chen et al., 2020) that uses projected point embedding for contrastive learning, we assume that token embeddings follow Gaussian distributions. Specifically, we employ projection network f_μ and f_Σ for producing Gaussian distribution parameters:

$$\boldsymbol{\mu}_i = f_\mu(\boldsymbol{h}_i),\ \ \boldsymbol{\Sigma}_i = \mathrm{ELU}\left(f_\Sigma(\boldsymbol{h}_i)\right) + (1+\epsilon) \quad (2)$$

where $\boldsymbol{\mu}_i \in \mathbb{R}^l, \boldsymbol{\Sigma}_i \in \mathbb{R}^{l \times l}$ represents mean and diagonal covariance (with nonzero elements only along the diagonal of the matrix) of the Gaussian Embedding respectively; f_μ and f_Σ are implemented as ReLU followed by single layer networks; ELU for exponential linear unit; and $\epsilon \approx e^{-14}$ for numerical stability.

3.2 Training in Source Domain

For calculating the contrastive loss, we consider the KL-divergence between all valid token pairs in the sampled batch. Two tokens x_p and x_q are considered as positive examples if they have the same label $y_p = y_q$. Given their Gaussian Embeddings $\mathcal{N}(\boldsymbol{\mu}_p, \boldsymbol{\Sigma}_p)$ and $\mathcal{N}(\boldsymbol{\mu}_q, \boldsymbol{\Sigma}_q)$, we can calculate their KL-divergence as following:

$$\begin{aligned} D_{\mathrm{KL}}[\mathcal{N}_q || \mathcal{N}_p] &= D_{\mathrm{KL}}[\mathcal{N}(\boldsymbol{\mu}_q, \boldsymbol{\Sigma}_q) || \mathcal{N}(\boldsymbol{\mu}_p, \boldsymbol{\Sigma}_p)] \\ &= \frac{1}{2}\Bigg(\mathrm{Tr}(\boldsymbol{\Sigma}_p^{-1}\boldsymbol{\Sigma}_q) \\ &\quad + (\boldsymbol{\mu}_p - \boldsymbol{\mu}_q)^T \boldsymbol{\Sigma}_p^{-1}(\boldsymbol{\mu}_p - \boldsymbol{\mu}_q) \\ &\quad - l + \log\frac{|\boldsymbol{\Sigma}_p|}{|\boldsymbol{\Sigma}_q|}\Bigg) \end{aligned} \quad (3)$$

Both directions of the KL-divergence are calculated since it is not symmetric.

$$d(p,q) = \frac{1}{2}\left(D_{\mathrm{KL}}[\mathcal{N}_q || \mathcal{N}_p] + D_{\mathrm{KL}}[\mathcal{N}_p || \mathcal{N}_q]\right) \quad (4)$$

We first train our model in resource rich source domain having training data $\mathcal{X}_{\mathrm{tr}}$. At each training step, we randomly sample a batch of sequences (without replacement) $\mathcal{X} \in \mathcal{X}_{\mathrm{tr}}$ from the training set having batch size of b. For each $(x_i, y_i) \in \mathcal{X}$, we obtain its Gaussian Embedding $\mathcal{N}(\mu_i, \Sigma_i)$ by channeling the corresponding token sequence through the model (Algorithm 1: Line 3-6). We find in-batch positive samples $\mathcal{X}_p$ for sample p and subsequently calculate the Gaussian embedding loss of x_p with respect to that of all other valid tokens in the batch:

$$\mathcal{X}_p = \{(x_q, y_q) \in \mathcal{X} \mid y_p = y_q, p \neq q\} \quad (5)$$

$$\ell(p) = -\log \frac{\sum\limits_{(x_q,y_q)\in\mathcal{X}_p} \exp(-d(p,q))/|\mathcal{X}_p|}{\sum\limits_{(x_q,y_q)\in\mathcal{X}, p\neq q} \exp(-d(p,q))} \quad (6)$$

In this way we can calculate the distributional divergence of all the token pairs in the batch (Algorithm 1: Line 7-10). We do not scale the contrastive loss by any normalization factor as proposed by Chen et al. (2020) since we did not find it to be beneficial for optimization.

3.3 Finetuning to Target Domain using Support Set

After training in source domains, we finetune our model using a small number of target domain support samples following a similar procedure as in the training stage. As we have only a few samples for finetuning, we take them in a single batch. When multiple few-shot samples (e.g., 5-shot) are available for the target classes, the model can effectively adapt to the new domain by optimizing KL-divergence of Gaussian Embeddings as in Eq. 4. In contrast, for 1-shot case, it turns out challenging for models to adapt to the target class distribution. If the model has no prior knowledge about target classes (either from direct training or indirectly from source domain training where the target class entities are marked as `O-type`), a single example might not be sufficient to deduce the variance of the target class distribution. Thus, for 1-shot scenario, we optimize $d'(p,q) = ||\boldsymbol{\mu}_p - \boldsymbol{\mu}_q||_2^2$, the squared euclidean distance between mean of the embedding distributions. When the model has direct/indirect prior knowledge about the target classes involved, we still optimize the KL-divergence of the distributions similar to the 5-shot scenario.

We demonstrate in Table 7 that optimizing with squared euclidean distance gives us slightly better performance in 1-shot scenario. Nevertheless, in all cases with 5-shot support set, optimizing the KL-divergence between the Gaussian Embeddings gives us the best result.

Early Stopping Finetuning with a small support set runs the risk of overfitting and without access to a held out validation set due to data scarcity in the target domain, we cannot keep tabs on the saturation point where we need to stop finetuning. To alleviate this, we rely on the calculated contrastive loss and use it as our early stopping criteria with a patience of 1. (Algorithm 1: Line 16-17, 24)

3.4 Instance Level Nearest Neighbor Inference

After training and finetuning the network with train and support data respectively, we extract the pretrained language model encoder `PLM` for inference. Similar to SimCLR (Chen et al., 2020), we found that representations before the projection layers actually contain more information than the final output representation which contributes to better performance, so f_μ and f_Σ projection heads are not used for inference. We thus calculate the representations of the test data from `PLM` and find nearest neighbor support set representation for inference (Wang et al., 2019; Yang and Katiyar, 2020).

The `PLM` representations $\boldsymbol{h}_j^{\text{sup}}$ of each of the support token $(x_j^{\text{sup}}, y_j^{\text{sup}}) \in \mathcal{X}_{\text{sup}}$ can be calculated as in Eq. 1. Similarly for test data $\mathcal{X}_{\text{test}}$, we get the `PLM` representations $\boldsymbol{h}_i^{\text{test}}$ where $x_i^{\text{test}} \in \mathcal{X}_{\text{test}}$. Here we assign x_i^{test} the same label as the support token that is nearest in the `PLM` representation space:

$$y_i^{\text{test}} = \mathop{\arg\min}_{y_k^{\text{sup}} \text{ where } (x_k^{\text{sup}}, y_k^{\text{sup}}) \in \mathcal{X}_{\text{sup}}} ||\boldsymbol{h}_i^{\text{test}} - \boldsymbol{h}_k^{\text{sup}}||_2^2 \quad (7)$$

Table 1: Summary Statistics of Datasets

Viterbi Decoding Most previous works (Hou et al., 2020; Yang and Katiyar, 2020; Ding et al., 2021) noticed a performance improvement by using CRFs (Lafferty et al., 2001) which removes false predictions to improve performance. Thus we also employ Viterbi decoding in the inference stage with an abstract transition distribution as in StructShot (Yang and Katiyar, 2020). For the **transition probabilities**, the transition between three abstract tags `O`, `I`, and `I-other` is estimated by counting their occurrences in the training set. Then for the target domain tag-set, these transition probabilities are evenly distributed into corresponding target distributions. The **emission probabilities** are calculated from Nearest Neighbor Inference stage. Comparing domain transfer results (Table 3) against other tasks (Table 2,4,5) we find that, interestingly, if there is no significant domain shift involved in the test data, contrastive learning allows CONTAINER to automatically extract label dependencies, obviating the requirement of extra Viterbi decoding stage.

4 Experiment Setups

Datasets For evaluation, we use datasets across different domains: General (OntoNotes 5.0 (Weischedel et al., 2013)), Medical (I2B2 (Stubbs and Uzuner, 2015)), News (CoNLL'03 (Sang and De Meulder, 2003)), Social (WNUT'17 (Derczynski et al., 2017)). We also test on GUM (Zeldes, 2017) that represents wide variety of texts: interviews, news articles, instrumental texts, and travel guides. The miscellany of domains makes it a challenging dataset to work on. Ding et al. (2021) argue that the distribution of these datasets may not be suitable for proper representation of Few-Shot capability. Thus, they proposed a new large scale dataset Few-NERD that contains 66 fine-grained entities across 8 coarse grained entities, significantly richer than previous datasets. A summary of these datasets is given in Table 1.

Model	**1-shot**				**5-shot**

Baselines We compare the performance of CONTAINER with state-of-the-art Few-Shot NER models on different datasets across several settings. We first measure the model performance in traditional NER datasets in tag-set extension and domain transfer tasks as proposed in Yang and Katiyar (2020). We then evaluate our model in Few-NERD (Ding et al., 2021) dataset that is explicitly designed for Few-Shot NER, and compare it against the Few-NERD leaderboard baselines. Similar to Ding et al. (2021), we take Prototypical Network based ProtoBERT (Snell et al., 2017; Fritzler et al., 2019; Hou et al., 2020), nearest neighbor based metric method NNShot that leverages the locality of in-class samples in embedding space, and additional Viterbi decoding based Structshot (Yang and Katiyar, 2020) as the main SOTA baselines.

4.1 Tag-set Extension Setting

A common use-case of Few-Shot NER is that new entity types may appear in the same existing text domain. Thus (Yang and Katiyar, 2020) proposed to experiment tag-set extension capability using OntoNotes (Weischedel et al., 2013) dataset. The eighteen existing entity classes are split in three groups: A, B, and C, each having six classes. Models are tested in each of these groups having few sample support set while being trained in the remaining two groups. During training, all test group entities are replaced with `O`-tag. Since the source and destination domains are the same, the training phase will induce some indirect information about unseen target entities. So, during finetuning of CONTAINER, we optimize the KL-divergence between ouptut embeddings as in Eq. 4.

We use the same entity class splits as used by Yang and Katiyar (2020) and used `bert-base-cased` as the backbone encoder for all models. Since they could not share the sampled support set for licensing reasons, we sampled five sets of support samples for each group and averaged the results, as done by the authors. We show these results in Table 2. We see that in different entity groups, CONTAINER outperforms present SOTAs by upto 12.75 absolute F1 points, a substantial improvement in performance.

4.2 Domain Transfer Setting

In this experiment a model trained on a source domain is deployed to a previously unseen novel text domain. Here we take OntoNotes (General) as our source text domain, and evaluate the Few-Shot performance in I2B2 (Medical), CoNLL (News), WNUT (Social) domains as in (Yang and Katiyar, 2020). We also evaluate the performance in GUM (Zeldes, 2017) dataset due to its particularly challenging nature. We show these results in Table 3. While all the other domains have almost no intersection with OntoNotes, target entities in CoNLL are fully contained within OntoNotes entities, that makes it comparable to supervised learning.

4.3 Few-NERD Setting

For few-shot setting, Ding et al. (2021) proposed two different settings: **Few-NERD (INTRA)** and **Few-NERD (INTER)**. In Few-NERD

Model	5-way		10-way		Avg.
	1∼2 shot	5∼10 shot	1∼2 shot	5∼10 shot	
StructShot	35.92	38.83	25.38	26.39	31.63
ProtoBERT	23.45	41.93	19.76	34.61	29.94
NNShot	31.01	35.74	21.88	27.67	29.08
CONTaiNER	**40.43**	**53.70**	**33.84**	**47.49**	**43.87**
+ Viterbi	**40.40**	**53.71**	**33.82**	**47.51**	**43.86**

Table 4: F1 scores in FEW-NERD (INTRA).

Model	5-way		10-way		Avg.
	1∼2 shot	5∼10 shot	1∼2 shot	5∼10 shot	
StructShot	**57.33**	57.16	**49.46**	49.39	53.34
ProtoBERT	44.44	58.80	39.09	53.97	49.08
NNShot	54.29	50.56	46.98	50.00	50.46
CONTaiNER	55.95	**61.83**	48.35	**57.12**	**55.81**
+ Viterbi	56.1	**61.90**	48.36	**57.13**	**55.87**

Table 5: F1 scores in FEW-NERD (INTER).

(INTRA) train, dev, and test sets are divided according to coarse-grained types. As a result, fine-grained entity types belonging to `People, Art, Product, MISC` coarse grained types are put in the train set, `Event, Building` coarse grained types in dev set, and `ORG, LOC` in test set. So, there is no overlap between train, dev, test set classes in terms of coarse grained types. On the other hand, in Few-NERD (INTER) coarse grained types are shared, although all the fine grained types are mutually disjoint. Because of the restrictions of sharing coarse-grained types, Few-NERD (INTRA) is more challenging. Since, few-shot performance of any model relies on the sampled support set, the authors also released train, dev, test split for both **Few-NERD (INTRA)** and **Few-NERD (INTER)**. We evaluate our model performance using these provided dataset splits and compare the performance in Few-NERD leaderboard. All models use `bert-base-uncased` as the backbone encoder. As shown in Table 4 and Table 5, CONTaiNER establishes new benchmark results in the leaderboard in both of these tests.

5 Results and Analysis

We prudently analyze different components of our model and justify the design choices made in the scheming of CONTaiNER. We also examine the results discussed in Section 4 that gives some intuitions about few-shot NER in general.

5.1 Overall Results
