Decoding layer. This study is able to use a shared decoder for samples from different eras because era-aware representation have been combined for each character by the Switch-memory module. There are various algorithms that can be implemented as decoders, such as conditional random fields (CRF) (Lafferty et al., 2001) and softmax. According to (Tian et al., 2020c), CRF performs better in word segmentation tasks. Therefore, considering the framework of this study, CRF is used as the decoder.

In the CRF layer, $P\left(Y|X\right)$ in Eq. 1 can be represented as:

$$P(Y|X) = \frac{\emptyset(Y|X)}{\sum_{Y' \in \mathcal{L}^T} \emptyset(Y'|X)} \tag{3}$$

where, $\emptyset(Y|X)$ is the potential function, and only interactions between two successive labels are considered.

$$\emptyset(Y|X) = \prod_{i=2}^{T} \sigma(X, i, y_{i-1}, y_i) \tag{4}$$

$$\sigma(\mathbf{x}, i, y', y) \;=\; exp(s(X, i)_y + b_{y'y}) \tag{5}$$

where $b_{y'y} \in \mathbf{R}$ is trainable parameters respective to label pair $(y',\ y)$. The score function $s(X\ ,\ i) \in \mathbb{R}^{|\mathcal{L}|}$ calculate the score of each lable for i_{th} character:

$$s(X\ ,\ i) \;=\; \mathbf{W}_s^\top \mathbf{a}_i + b_s \tag{6}$$

where $\mathbf{a}_i$ is the final representation for i_{th} character. $\mathbf{W}_s \in \mathbb{R}^{d_a \times L}$ and $b_s \in \mathbb{R}^{|\mathcal{L}|}$ are trainable parameters.

3.2 Switch-memory mechanism

The Switch-memory consists of *d* memory cells and a switcher. For an input sentence, there are *d* memory cells for each character. The switcher governs how much information in each cell will be integrated into the network. And the state of the switcher depends on the sentence classifier.

3.2.1 Memory cells

The dictionary has been a useful external source to improve the performance of CWS in many studies.(Yang et al., 2017; Liu et al., 2018; Zhang et al., 2018). However, the ability to incorporate the dictionary into previous research has been limited by either concatenating candidate words and character embeddings or the requirement of handcrafted templates. In this study, key-value memory networks are utilized to incorporate dictionary information, which is initially applied to the Question Answering (QA) task for improved storage of prior knowledge required by QA. Furthermore, this network structure can also be used to store the existing knowledge that is required by cross-era CWS.

Ancient Chinese is not a static language but is instead a diachronic language. Ancient Chinese has three development stages: Ancient, Middle Ancient, and Near Ancient. Each stage has a specific lexicon and word segmentation granularity. Therefore, this research has constructed four dictionaries $\mathcal{D} = \{D_0, D_1, D_2, D_3\}$, associating with the four development stages of Chinese, respectively, and each dictionary is era-related. When input a sentence, four memory cells are generated for each character in the sentence according to the four dictionaries, and each memory cell maps candidate words and word boundary information to keys and values.

Rule	$V_{i,j}$
x_i is the beginning character of $w_{i,j}$.	V_B
x_i is the ending character of $w_{i,j}$.	V_E
x_i is a single word, $w_{i,j}$.	V_S

Table 2: the rules for assigning different values to x_i according to its position in word $w_{i,j}$.

Candidate words as keys. Following Tian et al., for each x_i in the input sentence, each dictionary has many words containing x_i, we only keep the n-grams from the input sentence and appear in each dictionary, resulting $w_i^d = \{w_{i,1}^d,\ w_{i,2}^d, ...w_{i,j}^d...w_{i,m_i}^d\}$, x_i is a part of word $w_{i,j}^d \in D_d$, $d \in [0, 3]$. We use an example to illustrate our idea. For the input sentence show in Figure 1, there are many n-grams containing x_3 = "海(sea)", we only retain ones that appear in D_0 for the first memory cell, thus, $w_3^0 =$ {"海口(HaiKou)", "入海口(estuary)", "海(sea)"}. Similarly, we can generate w_3^1, w_3^2, w_3^3 for the second, third and fourth memory cell according to D_1, D_2, D_3. Then, the memory cell compute the probability for each key (which are denoted as $e_{i,j}^w$ for each $w_{i,j}^d$), here $\mathbf{h}_i$ is the embedding for x_i, which is encoded by the encoder.

$$p_{i,j}^d = \frac{exp(\mathbf{h}_i \cdot e_{i,j}^w)}{\sum_{j=1}^{m_i} exp(\mathbf{h}_i \cdot e_{i,j}^w)} \tag{7}$$

Word boundary information as values. As we know, CWS aims to find the best segment position. However, each character x_i may have different positions in each $w_{i,j}^d$. For example, x_i may be at the beginning, middle, ending of $w_{i,j}^d$, or x_i maybe a single word. Different positions convey different information. Therefore, we use the boundary information of candidate words as values for key-value networks. As shown in Table 2, a set of word boundary values $\{V_B, V_E, V_S\}$ with embeddings $\{e_{V_B}, e_{V_E}, e_{V_S}\}$ represent the x_i's different positions in $w_{i,j}^d$, and we map x_i

to different value vectors according to its positions. As a result, each w_i^d for x_i has a values list $\mathcal{V}_i^d = [v_{i,1}^d, v_{i,2}^d, ...v_{i,j}^d, ...v_{i,m_i}^d]$. In Figure 1, $x_3 =$ “海(sea)”, for the first memory cell, we can map candidate word boundary information to the value list $\mathcal{V}_3^0 = [V_S, V_B]$. Four cells for x_i has a values list $\mathcal{V}_i = [v_i^0, v_i^1, v_i^2, v_i^3]$. Then the d_{th} memory cell embedding for x_i is computed from the weighted sum of all keys and values as follow.

$$\mathbf{o}_i^d = \sum_{j=1}^{m_i} p_{i,j}^d e_{i,j}^{v^d} \tag{8}$$

where $e_{i,j}^{v^d}$ is the embedding for $v_{i,j}^d$. Next, the final character embedding is the element-wise sum of $\mathbf{o}_i$ and $\mathbf{h}_i$, or their concatenation, passing through a fully connected layer as follow:

$$\mathbf{a}_i = \mathbf{W}_o \cdot (\mathbf{o}_i \odot \mathbf{h}_i) \tag{9}$$

where $\odot$ operation could be sum or concatenate, $\mathbf{W}_o \in \mathbb{R}^T$ is a trainable parameter and the output $\mathbf{a}_i \in \mathbb{R}^T$ is the final representation for the i_{th} character. $\mathbf{o}_i$ is the final memory embedding for the i_{th} character, and can be calculated as follow.

$$\mathbf{o}_i = Switcher([\mathbf{o}_i^0, \mathbf{o}_i^1, \mathbf{o}_i^2, \mathbf{o}_i^3]) \tag{10}$$

where *Switcher* is used to control how much information in each memory cell will be combined with the output of the encoder.

3.2.2 Switcher

Inspired by the benefits of multi-task, a classifier has been added on top of the encoder to predict the era label of the input sentence. The discriminator predicts the probability of the correct era label, z, conditioned on the hidden states of the encoder, $\mathbf{H}$, which is the output of “[CLS]” from BERT. The loss function of the discriminator is $\mathcal{J}_{disc} = -logP(z|\mathbf{H})$, through minimizing the negative cross-entropy loss to maximizes $P(z|\mathbf{H})$.

In this study, $\mathbf{H}$ is fed into a fully-connected layer and let it pass through a softmax layer to obtain probabilities for each era label.

Switch mode. For the switcher, we propose two switcher modes, *hard-switcher* and *soft-switcher*. *Hard-switcher* switches memory cells according to the predicted final result from the discriminator. For the input sentence in Figure 1, if the predicted result is the modern era, then the switcher will switch to the memory cell associated with modern Chinese, and $\mathbf{o}_i = \mathbf{o}_i^d$. *Soft-switcher* switches memory cells according to the predicted probability, which is calculated by the weight of each memory cell. *Soft-switcher* means that the information from all four dictionaries may be fused into the current character's representation. For example, the predicted probability list is $[0.1, 0.2, 0.1, 0.6]$; therefore, the final memory representation for the i_{th} character is $\mathbf{o}_i = \mathbf{o}_i^0 * 0.1 + \mathbf{o}_i^1 * 0.2 + \mathbf{o}_i^2 * 0.1 + \mathbf{o}_i^3 * 0.6$.

3.2.3 Objective

In this framework, the discriminator is optimized jointly with the CWS task, which both share the same encoding layer. Different weights are assigned to the loss of the two tasks, the final loss function is:

$$\mathcal{J} = \alpha \mathcal{J}_{cws} + (1 - \alpha)\, \mathcal{J}_{disc} \tag{11}$$

where α is the weight that controls the interaction of the two losses. $\mathcal{J}_{cws}$ is the negative log likelihood of true labels on the training set.

$$\mathcal{J}_{cws} = -\sum_{n=1}^{N} log(P\,(Y_n|X_n)) \tag{12}$$

where N is the number of samples in the training set, and Y_n is the ground truth tag sequence of the n_{th} sample.

4 Experiment

4.1 Datasets

The model proposed in this study has been evaluated on four CWS datasets from Academia Sinica Ancient Chinese Corpus[2] (ASACC) and SIGHAN 2005 (Emerson, 2005). The statistics of all the datasets are listed in Table 3. Among these datasets, PKIWI, DKIWI, AKIWI from ASACC, correspond to near ancient Chinese, middle ancient Chinese, ancient Chinese, respectively, and MSR from SIGHAN 2005 is a modern Chinese CWS dataset. It should be noted that PKIWI, DKIWI, and AKIWI are traditional Chinese and were translated into simplified Chinese prior to segmentation.

For PKIWI, DKIWI, and AKIWI, 5K examples were randomly picked as a test set; then, 10% of examples were randomly selected from training set as the development set. Similar to previous work (Chen et al., 2017), all datasets are pre-processed by

		Test	0.1M	0.2M	12.9K	2.8K	4.0K	2.60%

Table 3: Detail of the four datasets.

replacing Latin characters, digits, and punctuation with a unique token.

In the cross-era learning scenarios, all of the training data from four eras corpora were used as the training set. Then, all of the test data from four corpora were used as the cross-era test set to evaluate the model. Finally, F1 and OOV recall rates (R_{oov}) were computed according to the different eras.

4.2 Experimental configurations

In our experiments, for the encoder BERT, we follow the default setting of the BERT (Devlin et al., 2019). The key embedding size and value embedding size are the same as the output of the encoder, and they have been randomly initialized. For the baseline model Bi-LSTM, the character embedding size is set to 300, and the hidden state is set to 100. For the transformer, the same settings as Qiu et al. (2020) were followed. The loss weight coefficient α is a hyper-parameter that balances classification loss and segmentation loss; the model achieves the best performance when α is set to 0.7, which was identified by searching from 0 to 1 with the equal interval set to 0.1.

The words from the training set are used as the internal dictionary, and each training set generates its own dictionary. The simplified Chinese dictionary sourced from jieba [3] is used as the external dictionary for MSR, and words from *The ErYa* (an ancient dictionary) and ancient Chinese textbooks were extracted as the external dictionary for AWIKI. For PWIKI and DWIKI, high-frequency bi-grams and tri-grams were extracted from the corresponding period corpus [4] as external dictionaries.

4.3 Overall results

To begin, in this section, the experimental results of the proposed model on the test sets from the four cross-era CWS datasets are provided, which can be seen in Table 4.

Several observations can be made from the data provided in Table 4. First, BERT-CRF in single-era scenarios (ID:1 in Table 4) and cross-era learning without the SM module (ID:6) are compared. As can be seen in the table, when mixing four datasets, the average F1 value of all datasets decreases slightly. Single-era dataset learning has an average F1 value of 97.61, while cross-era learning without the Switch-memory module has a 97.32 average F1 value. This indicates that performance cannot be improved by merely mixing several datasets.

Second, the models with the SM mechanism (ID:3,5,7) outperformed the baseline models (ID:2,4,6) in terms of F1 value and R_{oov} on all datasets. For example, the average F1 score for BERT-CRF with SM module (ID:7) improved by 0.92% when compared to BERT-CRF (ID:6), and the average R_{oov} went from 76.15 to 82.37. This indicates that the Switch-memory can help improve segmentation and R_{oov} performance by integrating era-specific knowledge.

Third, among different encoders, the improvement of the pre-trained encoder BERT on the F1 value is still significant. When using Bi-LSTM as the encoder (ID:2,3), the average F1 value and the R_{oov} are 89.15 and 90.66, respectively. When using BERT as the encoder (ID:6,7), the F1 value improves by approximately 8%. The reason for this may be that the pre-training processing supplements some effective external knowledge.

To further illustrate the validity and effectiveness of this model, the best results from this study are compared to works that have been previously

Table 4: Experimental results of the proposed model on the tests of four CWS datasets with different configurations. "+SM" indicates that the model uses the Switch-memory module. There are two blocks. The first block is results of the baseline model (BERT-CRF) on the single-era dataset. The second block consists of the results of cross-era learning model with different encoders ("BL" for Bi-LSTM, "TR" for Transformer, "BT" for BERT, "CROSSWISE" for BERT-CRF+SM). Here, F, R_{oov} represent the F1 value and OOV recall rate respectively. The maximum F1 values are highlighted for each dataset.

Table 5: Performance (F1 value) comparison between CROSSWISE and previous state-of-the-art models on the test sets of four datasets.

identified as state-of-the-art. Various aspects of multi-domain and multi-criteria Chinese word segmentation are very similar to the tasks in this study; therefore, this study reproduced experiments on several previous word segmentation models using the four datasets identified in this research (Luo et al., 2019b; Qiu et al., 2020; Huang et al., 2020a). For the multi-domain segmenter PKUSeg (Luo et al., 2019b), four datasets were trained with the pre-trained mixed model. The comparison is shown in Table 5; the model from this study outperforms previous methods.

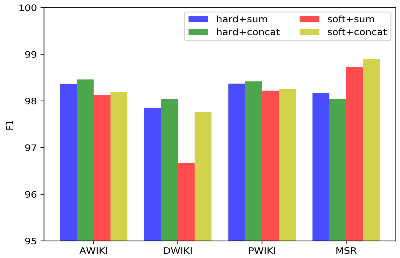

Figure 2: The F1 values of CROSSWISE using four pair settings; "hard+sum" means hard-switcher and the sum of the memory embedding and the character embedding from the encoder as the final character representation.

Table 7: Segmentation cases from the test sets of MSR, AWKI and DWIKI datasets.

4.4 Ablation study

Table 6 shows the effectiveness of each component in the SM module.

The first ablation study is conducted to verify the effectiveness of memory cells. In this experiment, the sentence classification task is no longer a switcher but simply a joint training task with word segmentation. We can see that the ancient Chinese datasets (AWIKI, DWIKI, PWIKI) are more sensitive to memory cells than MSR. This may be explained by the fact that the encoder is pre-trained with a large quantity of modern Chinese data, and the memory cells in this study incorporate some ancient era knowledge into the model, which helps to boost the performance of the three ancient Chinese datasets.

The second ablation study is to evaluate the effect of the switcher. For this experiment, the average of four embedded memory cells is used as the final memory representation. The comparison between the second and the third line indicates that the switcher is an important component when integrating era-specific information.

In summary, in terms of average performance, the switcher and the memory cells can both boost the performance of R_{oov} considerably.

4.5 Mode selection

In this section, the effect of the switcher mode and the combination mode (concatenate or sum) of memory embedding and character embedding is investigated.

To better understand the effect of the different configurations, this study examines the four pair settings to train the model on the four datasets in this study; the results are shown in Figure 2, and different color bars represent different datasets. As can be seen, *soft-switcher* significantly improves the F1 value on MSR compared to *hard-switcher*, while the other three datasets prefer *hard-switcher*, which suggests that the forward direction of knowledge dissemination from ancient Chinese to modern Chinese can help modern Chinese word segmentation, and that the reverse knowledge dissemination will have a negative impact on ancient Chinese word segmentation. Concatenating memory embedding and character embedding from the encoder outperforms the combination of the two; therefore, this study chose the pair of configurations, “hard +concat”, to obtain the experimental results in the last row of Table 4 and Table 5.

4.6 Case study

This study further explores the benefits of the SM mechanism by comparing some cases from BERT-CRF and CROSSWISE. Table 7 lists three examples from the test sets of Ancient Chinese and modern Chinese datasets. According to the results, in the first sentence, “靡(swept)” and “草(grass)” are two words in ancient Chinese, BERT-CRF treats these two words as a single word; BERT-CRF gives the second sentence the wrong boundary prediction in “中(middle)” and “经(through).” However, this study’s CROSSWISE achieves all exact segmentation of these instances. The third sample is a sentence written in both ancient and modern Chinese,“鱼与熊掌兼得,” which is a famous classical sentence in ancient Chinese. CROSSWISE also can split the sentence correctly. Therefore, it can be concluded that the model is flexible for Chinese word segmentation of era-hybrid texts and can produce different segmentation granularity of words according to the era of the sentence. Concurrently, it shows that the SM mechanism is effective in integrating era-specific linguistic knowledge according to different samples.

5 Conclusion

In this study, a flexible model, called CROSSWISE, for cross-era Chinese word segmentation is proposed. This model is capable of improving the performance of each dataset by fully integrating era-specific knowledge. Experiments on four corpora show the effectiveness of this model. In the future, the incorporation of other labeling tasks into CROSSWISE, such as POS tagging and named entity recognition, may prove to be insightful.

Acknowledgments

This research is supported by the NSFC project “the Construction of the Knowledge Graph for the History of Chinese Confucianism” (Grant No. 72010107003). We would like to thank Professor Jun Wang and Hao Yang for their insightful discussion.

Ethical Considerations

The datasets used in this paper are open datasets and do not involve any ethical issues.

Abstract

Although much work in NLP has focused on measuring and mitigating stereotypical bias in semantic spaces, research addressing bias in computational argumentation is still in its infancy. In this paper, we address this research gap and conduct a thorough investigation of bias in argumentative language models. To this end, we introduce `ABƎA`, a novel resource for bias measurement specifically tailored to argumentation. We employ our resource to assess the effect of argumentative fine-tuning and debiasing on the intrinsic bias found in transformer-based language models using a lightweight adapter-based approach that is more sustainable and parameter-efficient than full fine-tuning. Finally, we analyze the potential impact of language model debiasing on the performance in argument quality prediction, a downstream task of computational argumentation. Our results show that we are able to successfully and sustainably remove bias in general and argumentative language models while preserving (and sometimes improving) model performance in downstream tasks. We make all experimental code and data available at `https://github.com/umanlp/FairArgumentativeLM`.

1 Introduction

Recently, pre-trained language models (PLMs), e.g., BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), GPT-2 (Radford et al., 2019) and DialoGPT (Zhang et al., 2020) have been shown to encode and amplify a range of stereotypical biases, such as racism, and sexism (e.g., Kurita et al., 2019a; Dev et al., 2020; Nangia et al., 2020; Lauscher et al., 2021a, *inter alia*). While such types of biases provide the basis for interesting academic research, e.g., historical analyses (e.g., Garg et al., 2018; Tripodi et al., 2019; Walter et al., 2021, *inter alia*), stereotyping constitutes a representational harm (Barocas et al., 2017; Blodgett et al., 2020), and can lead in many concrete socio-technical application scenarios to severe ethical issues by reinforcing societal biases (Hovy and Spruit, 2016; Shah et al., 2020; Mehrabi et al., 2021).

But while prior work has focused on how to evaluate and mitigate unfair biases for general-purpose LMs (e.g., Webster et al., 2020) and their applications to specific domains and genre like, for instance, conversational LMs (e.g., Barikeri et al., 2021), there has been little attention to the problem of *bias in argumentative language*. This is despite previous work from Spliethöver and Wachsmuth (2020) pointing out the high potential for harm, due to the high sensitivity of envisioned applications like self-determined opinion formation systems, as well as, crucially, showing that argumentative corpora like those from the online debate portal `debate.org` (Durmus and Cardie, 2019) do encode unfair biases, which are likely to be captured by argumentative LMs. This is particularly problematic as research in computational argumentation regularly makes use of such corpora for injecting knowledge about argumentative language into PLMs (e.g., Alshomary et al., 2021). Still, to date, there is neither an evaluation resource specifically tailored to argumentative language, nor knowledge on debiasing argumentative LMs or on the effects of debiasing on argumentative downstream tasks.

Contributions. We address this research gap with the following contributions: we present `ABƎA`, the first human-annotated resource specifically targeted at English argumentative language, which is annotated for two kinds of social bias that are still under-explored in NLP, namely *Queerphobia* and *Islamophobia*. Next, we use `ABƎA` to answer the following four research questions (**RQs**):

(RQ1) *How does argumentative fine-tuning affect measurable biases in PLMs?*

We show that the impact of argumentative fine-tuning can induce and increase measurable stereo-

Volume 1: Long Papers, pages 7841 - 7861
May 22-27, 2022

typical biases in the LMs, highlighting the importance of bias measurement after injecting argumentative knowledge (§4.1).

(RQ2) *Can we validate the effectiveness and efficiency of debiasing PLMs using adapters?*

Lauscher et al. (2021a) recently introduced *debiasing adapters*, a modular and sustainable way of encoding debiasing knowledge in LMs. We confirm the effectiveness of debiasing adapters with Counterfactual Data Augmentation (Zhao et al., 2018) on two diverse corpora (§4.2).

(RQ3) *Can we obtain an (efficient and robust) fair and argumentative language model given our preexisting set of adapters?*

We show for the first time how to stack debiasing adapters with argumentation adapters to produce an **argumentative and fair language model**. Our results indicate that stacking order matters (§4.3).

(RQ4) *What are the effects on argumentative downstream tasks, e.g., argument quality prediction?*

In a final downstream evaluation encompassing two different datasets for argument quality prediction, we demonstrate that debiasing can have a positive impact on model performance. On one of the corpora, our best results are obtained when combining argumentation and debiasing adapters, hinting at the effectiveness of fair and argumentative language modeling (§4.4).

We hope that our results and our novel `ABBA` resource will fuel more research on fair computational argumentation.

2 `ABBA`: A New Annotated Corpus of Bias in Argumentative Text

We create `ABBA`, the first annotated corpus of bias in argumentative text following the methodology from Barikeri et al. (2021): (1) specification of the social biases of interest, (2) retrieval of candidates of biased statements, and (3) manual annotation.

Bias Specifications. We define the social biases we are interested in using the established notion of explicit bias specifications (Caliskan et al., 2017; Lauscher et al., 2020a). It consists of two sets of target terms (T_1 and T_2) denoting two demographic groups that exhibit different stereotypical perceptions w.r.t. two opposing sets of attribute terms (A_1 and A_2). Concretely, T_1 consists of target terms referring to a minoritized group (e.g., *Muslim*), while T_2 consists of target terms corresponding to a dominant group (e.g., *Christian*), i.e., a group in power (D'Ignazio and Klein, 2020). We focus on the bias dimensions *Queerphobia* and *Islamophobia* since they have received little attention in NLP research on bias when compared to sexism or other ethnic bias. We view *Queerness* as an umbrella term for the minority group of the *LGBTQI+* community, which includes people of all sexual orientations and gender identities except for heterosexual and cisgender. We compare this to the dominant group of heterosexual cisgender people.

The target and attribute terms used for candidate identification are based on the specifications of Barikeri et al. (2021). They include a wide range of attribute terms from the sociological literature and manually compiled target terms. The attribute terms were assembled such that each stereotypical attribute term a_1 forms a loose antonym of an counter-stereotypical attribute term a_2 with a positive or negative sentiment. An exemplary partial term list of the bias specifications can be found in Table 1 and the full set in the Appendix.

Candidate Retrieval. We use the dataset from `debate.org` originally collected by Durmus and Cardie (2019), one of most widely used resources in research on computational argumentation.

For retrieving candidates, we compute the Cartesian product of the terms of the minoritized group T_1 with all stereotypical terms of A_1, giving us a set of stereotyped tuples from $T_1 \times A_1$ (e.g., *gay* and *sinful*). Using this set, we extract all sentences and their corresponding arguments that contain both terms from the tuples in a window of size 20 (set during corpus construction to improve the quality of the retrieved passages). We further reduced the compiled comments to those with a maximum number of 500 tokens to allow for a better visualization and to ensure that the annotators attentively read the entire argument. In total, we retrieve 889 candidate sentences from 614 different arguments for *Queerphobia* and 1,879 candidate sentences from 1,101 different arguments for *Islamophobia*.

Annotating bias. We manually label the candidate sentence and the corresponding argument according to whether a stereotypical bias is present or not. To this end, we hired four annotators, who are all non-native speakers but have excellent English proficiency with academic backgrounds and who hold at least a Bachelor's degree, in slightly different majors (engineering, data science, infor-

Dimension		Target Term Sets		Attribute Term Sets
Islamophobia	T_1	*muslim(s), islam, quran, koran, ...*	A_1	*terrorist, rapist, enemy, bomb, oppressed, ...*
	T_2	*christian(s), christianity, bible, church, ...*	A_2	*police, friend, defend, peace, safety, ...*
Queerphobia	T_1	*gay(s), lesbian(s), queer(s), bisexual(s), ...*	A_1	*weak, immoral, fashion, sinful, ...*
	T_2	*straight(s), hetero(s), heterosexual(s) cisgender(s), ...*	A_2	*strong, moral, scientific, healthy, ...*

Table 1: `ABBA` bias specifications for candidate retrieval.

	Sentence-level		Argument-level	
Dimension	# ann.	# bias.	# ann.	# bias.
Islamophobia	1,860	648 (34.84%)	1,090	333 (30.55%)
Queerphobia	862	358 (41.65%)	601	205 (34.11%)

Table 2: Total number of annotated (# ann.) and biased (# bias.) sentences and arguments in `ABBA`.

mation systems, and computer science). They are of diverse gender and cultural background.

Annotators were provided with the guidelines found in the Appendix. We initially conducted a pilot study on 90 randomly drawn arguments to iteratively calibrate annotations and refine the guidelines on the basis of the annotators' feedback. Finally, we split the corpus evenly into four independent, equally-sized portions and added further 50 randomly drawn overlapping arguments to analyze annotation quality. In the last step, we merged the annotations on the calibration set using majority voting. The number of annotated and biased instances in the corpus is shown in Table 2. We show examples of biased sentences in Table 3.

Analysis of the Annotations. On the overlapping set consisting of 50 arguments, we obtain an inter-annotator agreement (IAA) for *Queerphobia* on the sentence-level for both Fleiss' κ (Fleiss, 1971) and Krippendorff's α (Krippendorff, 2013) of 0.65. The agreement on the argument-level is slightly weaker with 0.61 for both measures. For the *Islamophobia* dimension, we observe a stronger agreement of 0.66 on sentence-level and $\kappa = 0.72$ and $\alpha = 0.73$ on the argument-level. Although we are dealing with a rather subjective annotation task, IAA indicates a *substantial* agreement among the annotators (Viera and Garrett, 2005), suggesting that they are able to reliably identify stereotypes in argumentative sentences and longer text.

To determine reasons for disagreement among annotators, we manually conducted a qualitative analysis on the annotated arguments. For *Queerphobia*, we found that annotators mostly disagreed on statements that referred to the homosexual lifestyle, rather than homosexual people. The following example illustrates one such case:

> *[...] Basically, a gay person is not allowed to engage in sexual acts with another man because there is a 0% chance of offspring being produced. This falls into the same category of not using contraceptives, getting abortions, etc.* ***It is not a sin for a gay person to acknowledge their sexuality, or to act in a 'gay' manner.*** *It is only a sin if he/she gives in to their urges. [...]*

Here, the annotators disagreed in the annotation of the entire argument. Although the debater clearly states that actually being gay is not a sin, in his opinion, living a homosexual lifestyle is a sin. It appears that for some annotators being homosexual is equivalent to living in a homosexual relationship, while others clearly distinguished these two aspects. For *Islamophobia*, the disagreements mostly related to arguments that make a distinction between Muslims and the religion Islam, e.g.:

> ***[...] I have no issue with Islam, or any religion in general, if you leave me alone I leave you alone, you wondered why so many people hate Islam, its because of the same [...] in your last paragraph, y'all act as if terrorism is 100% okay.*** *That needs to change before Muslims can consider Islam anywhere close to a great religion.*

Here, the fact that the debater is making an ambiguous statement, expressing no prejudice against Islam but against Muslims caused confusion among the annotators resulting in disagreement.

3 Adapter-based Fair Argumentative Language Models

To obtain a fair and argumentative LM, we conduct both argumentative and debiasing language

Dimension	Example Sentence	Label
Islamophobia	*6 billion muslims around the world are following the religion of violence, hate and terror.*	Biased
	I would agree that there should be punishments for terrorism, but not for Islam itself.	Unbiased
Queerphobia	*Thus, since being gay is a sin and sins are poor choices, being gay is a choice.*	Biased
	The stigma of homosexuals being more promiscuous is a horrible lie.	Unbiased

Table 3: Example sentences from `ABᗺA`.

modeling along our two bias dimensions of interest. Instead of full model fine-tuning, we opt for a more sustainable strategy by relying on adapters (Houlsby et al., 2019) to reduce computation time and energy consumption. In addition, the modularity of adapters enables their reuse in further settings and in combination with other pre-trained adapters.

Argumentation Adapter. Following Alshomary et al. (2021), we tune general pre-trained models on a large set of arguments to obtain an argumentative language model. In contrast to the original work, we rely on language adapters. Concretely, we adopt the architecture proposed by Pfeiffer et al. (2020), which inserts a single adapter, a two-layer feed-forward network, into each transformer layer. The output of the adapter is computed as

$$\mathrm{A}_{\text{argument}}(\mathbf{h}, \mathbf{r}) = \mathbf{U}(\mathrm{ReLU}(\mathbf{D}(\mathbf{h}))) + \mathbf{r}\,,$$

with the two matrices $\mathbf{D} \in \mathbb{R}^{h \times d}$ and $\mathbf{U} \in \mathbb{R}^{d \times h}$ as the adapter's down-projection and up-projection, respectively, $\mathbf{h}$ as the transformer's hidden state, and $\mathbf{r}$ as the residual. In addition, we inject invertible adapters, which are stacked on top of the embedding layer and the inverses of the invertible adapters are placed in front of the output layer. They perform a similar function to the language adapters, but aim to capture token-level specific transformations (Pfeiffer et al., 2020). Both the language adapters and the invertible adapters are trained on a language modeling task using a causal language modeling loss for auto-regressive models and a masked language modeling loss for auto-encoding models, respectively.

Debiasing Adapter. For debiasing, we inject debiasing adapters (Lauscher et al., 2021a) into the models, using the same adapter architecture as before. Following the original work, we use Counterfactual Data Augmentation (Zhao et al., 2018, CDA) and train the adapter parameters on the augmented corpus to break stereotypical associations in the model. To this end, we manually compile pairs of opposing target terms $(t_i, t_j) \in T_1 \times T_2$, such that t_i forms the most suitable antonym of t_j in the sense of minority and dominant group (e.g., *muslim* and *christian*) and can be substituted grammatically interchangeably. While this is arguably straightforward with the *Islamophobia* bias specifications, the target terms of the *Queerness* dimension are more complex to juxtapose. Therefore, we clustered them into three groups of 'sexual identity' (e.g., *{gay, straight}*), 'gender identity' (e.g., *{transgender, cisgender}*) and 'biological sex' (e.g., *{androgyne, unisexual}*) so as to find the best matching pairs of antonyms (cf. the list in the Appendix). We then replace all occurring target terms from T_1 or T_2 with their opposite term from the set of tuples $P = \{(t_i, t_j)\}^N$ (we randomly select a term from the list if multiple substitutions are possible).

We opt for a two-sided application of CDA, keeping both the counterfactual and the original sentences in the training set to avoid over-correction (Webster et al., 2020). We append each counterfactual sentence immediately after its original counterpart and train in two settings, namely using: a) only biased and counterfactual sentences; b) all sentences, i.e., also including neutral ones.

Combining Adapters. We investigate three different architectures: first, in §4.3, we study two architectures using *AdapterStacking* (Pfeiffer et al., 2020), i.e., by stacking the argumentation adapter on top of a debiasing adapter and *vice versa* (Figure 1). Second, in §4.4, we compare the best architectures from §4.3 with *AdapterFusion* (Pfeiffer et al., 2020), which requires training additional network layers for interpolating the adapters' outputs.

4 Experiments and Results

We next describe the experiments to answer the research questions RQ1 through RQ4 (Section 1) that underpin our investigation.

4.1 Measuring the Effect of Argumentative Fine-tuning

Language Model Bias (LMB) Score. We follow Barikeri et al. (2021) and employ `ABᗺA` for

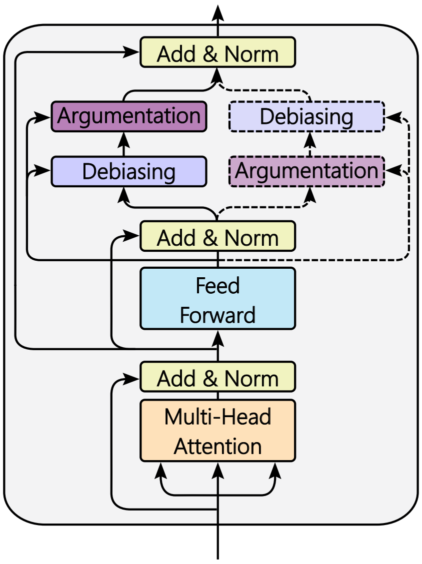

Figure 1: AdapterStacking architectures.

computing the LMB score reflecting how much more likely the model is to generate a stereotypically biased argument compared to an inversely biased one. We start with our set of opposing target terms $P \subset T_1 \times T_2$ and we extract the set of all statements S from ABᗺA (containing instances of term t_i such that $(t_i, t_j) \in P$), which have been labelled as stereotypically biased. This results in 279 biased instances for *Queerphobia* and 465 instances for *Islamophobia*, respectively. We then create for each instance $s_{(t_i,a)} \in S$ (e.g., *All Muslims are terrorists*), a corresponding inversely biased sentence $s'_{(t_j,a)}$ (e.g., *All Christians are terrorists*) to give us a set S' of counter-stereotypical statements. In case of multiple pairs for a target term (e.g., *{homosexual, heterosexual}* and *{homosexual, straight}*), we create one counter-stereotypically biased sentence for each possible combination. We then compute the model's perplexity for all statements in the two paired sets S and S' with stereotypical and counter-stereotypical statements. Following Barikeri et al. (2021), we compute the mean perplexity for multiple counterfactual instances created from a single biased instance and remove outliers to avoid distorted significance results (Pollet and van der Meij, 2017). The final LMB score corresponds to the t-value obtained by subjecting the paired perplexities to the student's t-test ($\alpha = 0.05$).

Fine-tuning Data. We test the effect of argumentative fine-tuning using two argumentative corpora: (i) Args.me (Ajjour et al., 2019), which consists of over 380k arguments from over 59k debates. (ii) Considering that it contains mostly arguments retrieved from Debate.org ($\sim$ 87%), we verify our results using a second corpus: Webis-ChangeMyView-20 (CMV; Al Khatib et al., 2020), which contains over 3.6 million arguments extracted from the ChangeMyView subreddit. For ensuring comparability, we cut each corpus to 300k and perform a train-validation split of 80:20.

Sentence	P.
S: *whats normal for gay people is immoral for us.*	218
S': *whats normal for straight people is immoral for us.*	363

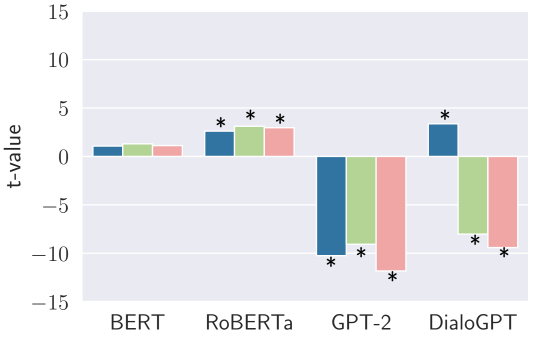
Table 4: Example pair consisting of a biased (S) and inversely biased (S') sentence exhibiting high difference in model perplexity (P.) for GPT-2 and Queerphobia.

Models. We experiment with four LMs from Huggingface Transformers (Wolf et al., 2020): BERT (`bert-base-uncased`), GPT-2 (`gpt-2`), DialoGPT (`microsoft/DialoGPT-medium`) and RoBERTa (`roberta-base`). With the exception of DialoGPT, which contains contains 24 layers with a hidden size of $1,024$, all models consist of 12 layers with a hidden size of 768.

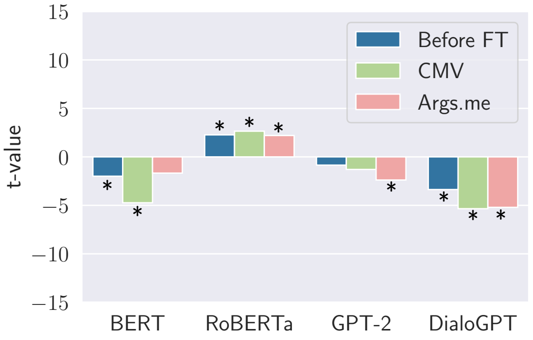
Adapter Training and Optimization. We train the argumentative adapters separately on Args.me and CMV for each of the models. Concretely, we train for 10 epochs using the Adam optimizer (Kingma and Ba, 2015) (weight decay = 0.01, $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 1 \cdot 10^{-6}$, learning rate=$1 \cdot 10^{-4}$) and early stopping based on the perplexity on the validation set (patience: 2 epochs). We set the effective batch size to 32 except for training DialoGPT, for which we employ an effective training batch size of 8 for reasons of computational capacity. The adapter reduction factor is 16.

Results. The LMB scores on ABᗺA before and after fine-tuning the four PLMs are shown in Figure 2. A negative t-value suggests a stereotypical bias; a positive t-value denotes an counter-stereotypical LMB, respectively.

Before fine-tuning, GPT-2 is the only model that exhibits a significant stereotypical bias along the *Queerphobia* dimension. We show an example sentence pair exhibiting a high difference in model perplexity in Table 4 and provide more examples in the Appendix. For BERT, no significant difference was found between the perplexities on stereotypical and counter-stereotypical sentences along *Queer-*



(a) LMB for Queerphobia



(b) LMB for Islamophobia

Figure 2: LMB scores before (*Before FT*) and after argumentative fine-tuning on CMV and Args.me, respectively. Negative t-values indicate stereotypical biases. We highlight significant effect sizes with asterisks.

phobia, whereas RoBERTa and DialoGPT even show a significant counter-stereotypical bias. All PLMs except RoBERTa exhibit a stereotypical bias for the *Islamophobia* bias, with a significant effect size for DialoGPT and BERT. The findings for DialoGPT are consistent with the results of Barikeri et al. (2021) for conversational text.

When adapter-fine-tuning the PLMs on argumentative texts (CMV, Args.me), we notice that the perplexities on `ABᗺA` decreased, indicating that we successfully managed to inject argumentative knowledge into the models. However, we also observe that while for RoBERTa, no significant changes in t-values for either bias dimension occur, the sterotypical bias effects of DialoGPT and GPT-2 along the *Islamophobia* bias dimension are reinforced by argumentative fine-tuning. Most interesting is the effect on DialoGPT along *Queerphobia*. While the original model exhibited a significant counter-stereotypical bias, fine-tuning results in an opposite bias effect for both CMV and Args.me. Given that the stereotypical bias along the *Islamophobia* dimension is also reinforced by fine-tuning DialoGPT, it underscores the tendency of the model to pick up and amplify stereotypical biases. All in all, *these findings highlight the importance of carefully measuring bias after injecting argumentative knowledge into the models.*

		Args.me		**Wikipedia**

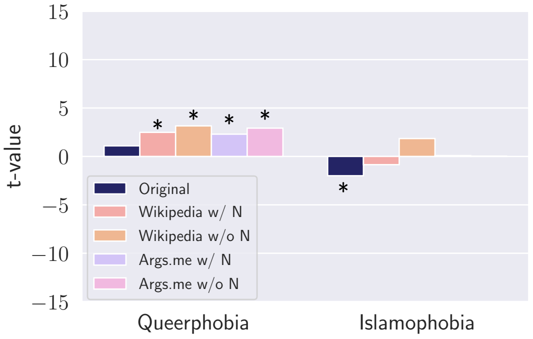
4.2 Validating the Effectiveness of Adapter-based Debiasing

Debiasing Data. We perform our two CDA strategies from §3 on two corpora: (i) the English Wikipedia (`20200501.en` dump) representing general-purpose encycopledic text. We randomly subsample the corpus, originally consisting of 6,078,422 text blocks, to 500,000 text blocks. (ii) We additionally experiment with the Args.me corpus, which also serves as the source for argumentative text. On both corpora, we perform a train-validation slit of 80:20. The resulting train and test set sizes for both bias types *Queerphobia* and *Islamophobia* are listed in Table 5.

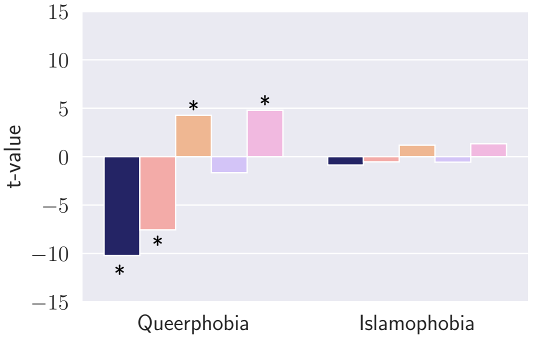
Models. We focus on two PLMs that exhibited bias along one of the dimensions in the previous experiments and which represent different types of PLMs: BERT as a representative of models trained via masked language modeling and GPT-2 as a model trained via causal language modeling.

Adapter Training and Optimization. We train the adapters for 10 epochs on the CDA-augmented data sets which include the neutral sentences, and for 1 epoch on the data sets that exclude the neutral sentences. The rest of the training procedure and all other hyperparameters are the same as for training the argumentaive adapters.

Results. We report bias effect size using LMB in Figure 3. The results indicate that, while the original PLMs exhibited significant bias along a dimension, *using debiasing adapters we are able to successfully reduce the measurable bias from a significant to a non-significant amount*, the only



(a) BERT



(b) GPT-2

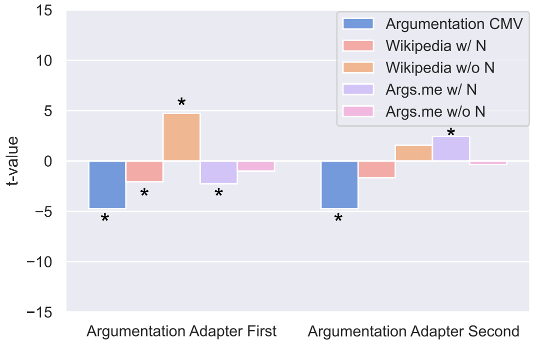
Figure 3: Debiasing results for BERT and GPT-2. We report LMB score (t-value) before and after injecting debiasing adapters trained on Wikipedia and Args.me with (w/ N) and without (w/o N) neutral sentences.

exception with the adapters for GPT-2 trained on the CDA-augmented Wikipedia. When we exclude neutral sentences the scores switch into the counter-stereotypical direction: we hypothesize that this indicates the need for a better balancing and sampling of the training data. We see a similar effect for cases in which the original PLM did not exhibit a significant bias – the LMB is likely to switch to the opposite, counter-stereotypical direction.

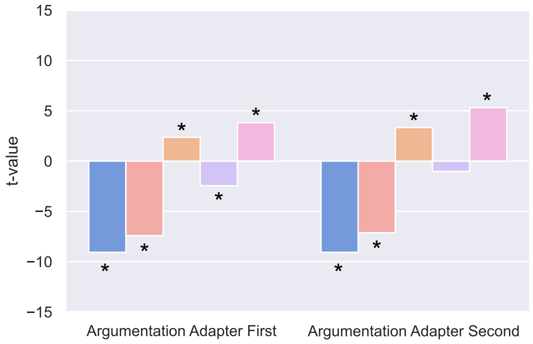
4.3 Combining Argumentative Knowledge and Fairness

Taking advantage of the modular nature of adapters, we combine argumentation and debiasing adapters (§4.1-4.2) to obtain a fair and argumentative language model using *AdapterStacking* (§3). We focus on the bias dimensions for which the original models exhibited a stereotypical effect size.

Results. Figure 4 shows the LMB scores of BERT on Islamophobia and GPT-2 along Queerphobia for different stacking orders of the argumentation adapter trained on CMV and the respective debiasing adapters trained on Wikipedia or Args.me (results for the other dimensions and other argumentation adapters are found in the Appendix). For BERT, stacking the debiasing adapters for Islamophobia second and the argumentation adapter trained on CMV first (left) reduces the bias to an non-significant amount only in a single case, while stacking the debiasing adapter first (right) removes the bias in three out of four setups. Also for GPT-2, stacking the debiasing adapter first leads to better debiasing results. We hypothesize that the reason for this effect is that both types of adapters are optimized for receiving the input directly from the transformer layers. Thus, the debiasing adapter is more effective when stacked first. In sum, while our results indicate that *stacking order matters and debiasing effects are bigger when debiasing adapters are stacked first*, we think that this finding warrants future research on the issue.



(a) Islamophobia LMB for BERT



(b) Queerphobia LMB for GPT-2

Figure 4: LMB for different stacking orders of the argumentation adapter (left: *argumentation adapter* first; right: *debiasing adapter* first).

4.4 Downstream Evaluation on Argument Quality Prediction

Data and Measures. For testing the influence of our argumentation and debiasing adapters on argument quality prediction, we employ two recently presented data sets: (1) the IBM-Rank-30k (Gretz et al., 2020), an extension of (Toledo et al., 2019),

Dataset	Domain	# Train	# Validation	# Test
IBM-Rank-30k	–	20,974	3,208	6,315
GAQCorpus	CQA	1,109	476	500
	Debates	1,093	469	538
	Reviews	700	400	100

Table 6: Number of arguments in training, validation, and test portions of IBM-Rank-30k and GAQCorpus.

	Model	IBM	GAQ		
			CQA	Debates	Reviews
	Gretz et al. (2020)	0.53			
	Lauscher et al. (2020b)		0.652	0.511	0.605
BERT	`Base`	0.524	0.663	0.465	0.560
	`Argsme`	0.531*	0.600*	0.439*	0.511*
	`CMV`	0.525	0.608*	0.453	0.521*
	`DB-Islamo`	**0.531***	0.653*	0.479*	0.560
	`Stacked`	0.528*	0.663	**0.485***	0.528*
	`Fusion`	0.521*	**0.672***	**0.487***	**0.569***
GTP-2	`Base`	0.513	0.658	0.474	0.519
	`Argsme`	0.512	0.612*	0.407*	0.496
	`CMV`	**0.516***	0.626*	0.419*	0.504
	`DB-Queer`	0.512	0.62*	0.476	0.507
	`Stacked`	0.513	0.609*	0.428*	0.515
	`Fusion`	0.507*	**0.683***	**0.488***	**0.528**

Table 7: Argument Quality prediction results (mean Pearson's correlation across 50 runs) on IBM-ArgQ-Rank-30kArgs and GAQCorpus. (*) indicates statistically significant differences.

which consists of short-length arguments (maximum length of 210 characters) annotated by crowd workers. We use the MACE-P aggregations provided by the authors for model training. (2) Additionally, we use the GAQCorpus (Ng et al., 2020; Lauscher et al., 2020b) which covers real-world arguments from three domains, namely community questions and answers (CQA), online debate forums (Debates), and restaurant reviews (Reviews). An overview of the data sets is given in Table 6. On both data sets, we report Pearson's correlation coefficient (r). Following Reimers and Gurevych (2017), we report the average of our experiments conducted 50 times with different random seeds (using the best hyperparameter configuration according to the development set results) and additionally conduct an independent t-test.

Models. For all AQ models, we rely on a simple linear regression head into which we input the pooled sequence representation. The fine-tuning strategy for the AQ regression is aligned with our previous approaches. Instead of full fine-tuning of the encoder, we add an additional task-specific adapter on top of the already existing adapters and adjust only the task-specific adapter parameters during training. As before, we employ the BERT and GPT-2 base models (`Base`) as well as the adapter-augmented variants. Concretely, we employ the argumentation adapters trained on Args.me and CMV (`Argsme`, `CMV`), and the debiasing adapters trained on the CDA-augmented Args.me (`DB-Islamo` for BERT, `DB-Queer` for GPT-2). Again, we also study combinations to optimally combine argumentation, debiasing, and task-specific knowledge using either a stacking (`Stacked`) or fusion architecture (`Fusion`). On IBM-Rank-30k, we follow Gretz et al. (2020) and concatenate topic and argument with an additional separator (BERT) or end-of-sequence token (GPT-2). As baselines, we additionally compare with the best results reported by the original works.

Adapter Training and Optimization. Following Gretz et al. (2020) and Lauscher et al. (2020b), we optimize our models using Mean Squared Error. We train all task adapters using Adam (Kingma and Ba, 2015) with a batch size of 32 (weight decay = 0, $\beta_1 = 0.9$ and $\beta_2 = 0.999$). We pad the input sequences to a maximum length of 128. We choose the best hyper-parameters by grid searching for learning rate $\lambda \in \{1 \cdot 10^{-4}, 2 \cdot 10^{-4}, 3 \cdot 10^{-4}\}$ and number of training epochs $\in \{1, 2, 3, 4, 5\}$ based on the performance on the individual dataset's respective validation portion.

Results. The results are shown in Table 7. Generally, though the trends are the same, the scores diverge from the results reported in the original works, which can be attributed to our use of task adapters. Interestingly, while injecting argumentation adapters leads to performance improvements on IBM-ArgQ-Rank-30kArgs in 3 out of 4 cases, it seems to hurt the performance on GAQCorpus. On the other hand, the debiasing adapters do not seem to lead to losses: in contrast, in some cases (IBM and GAQ–Debates for BERT, GAQ–Debates for GPT-2), we even note performance improvements. For GAQCorpus, the best results are obtained with an argumentative and fair language model – when fusing debiasing and argumentation adapters. We conclude that *fair and argumentative language modeling can have a positive impact on argument quality prediction as downstream task.*

5 Related Work

Bias in NLP. For thorough reviews on bias mitigation and evaluation we refer to Blodgett et al.

(2020), and Shah et al. (2020). Bolukbasi et al. (2016) were the first to draw attention to the issue of unfair stereotypical bias in NLP, showing that static word embeddings allow for building biased analogies. Later, Caliskan et al. (2017) proposed the well-known Word Embedding Association Test (WEAT), which was extended to more languages by (Lauscher and Glavaš, 2019; Lauscher et al., 2020c). More works focused on bias evaluation and mitigation in static word embeddings (Gonen and Goldberg, 2019; Dev and Phillips, 2019; Manzini et al., 2019; Lauscher et al., 2020a), and later, the focused shifted towards detecting and attenuating biases in their successors contextualized word embeddings (Dev and Phillips, 2019; Dev et al., 2020; Tan and Celis, 2019). Here, the authors focused on both, bias in general-purpose pretrained language models (May et al., 2019; Kurita et al., 2019b; Zhao et al., 2019; Webster et al., 2020), and bias in particular downstream scenarios (Dev et al., 2020). For instance, Zhao et al. (2018) proposed Counterfactual Data Augmentation (CDA) for the purpose of debiasing coreference resolution systems. Like many other works (Zmigrod et al., 2019; Lu et al., 2020; Webster et al., 2020; Lauscher et al., 2021a) we explore the method for our purposes. Similarly, Vanmassenhove et al. (2018) focused on machine translation and Sheng et al. (2019) on general natural language generation, while Barikeri et al. (2021) specifically target conversational models. In this work, we follow their process for creating `ABᗺA`.

Bias in Argumentation. It is extremely surprising that given the plethora of works focused on mining, assessing, and generating arguments as well as reasoning over arguments (Lauscher et al., 2021b), to date, Spliethöver and Wachsmuth (2020) were the only ones to investigate and quantify social bias in argumentation. They performed a simple co-occurrence analysis for three different argumentation corpora and trained a custom GloVe model (Pennington et al., 2014) based on argumentative text, which they analyzed with WEAT. Our work builds on top of theirs and is the first to examine bias in relation to an argumentative downstream task and also the first to conduct debiasing for computational argumentation models.

6 Conclusion

In this work, we presented an investigation of bias in PLMs and argumentative text. To this end, we created `ABᗺA`, the first annotated corpus tailored for measuring bias in computational argumentation models. Using `ABᗺA`, we showed that argumentative fine-tuning of language models may lead to an amplification of biases in the models. We then demonstrated how to obtain a fair and argumentative language model by combining argumentation with debiasing knowledge encapsulated in lightweight adapters to ensure higher sustainability and flexibility, and analyzed the effect of stacking orders. An additional downstream evaluation on argument quality prediction indicated that debiasing can even lead in some cases to improved results. We hope that with this work, especially the novel `ABᗺA` resource, we will foster further research on fair computational argumentation.

Limitations and Further Ethical Considerations

We like to point the reader to the following limitations and ethical considerations: first, following the large body of debiasing research in NLP, we based our evaluation, mitigation, and annotation approach on a fixed set of manually created terms. We are aware that this set is never finite and may be continually revised in subsequent studies. For a recent discussion we refer to Antoniak and Mimno (2021). This is especially the case for the dimension of *Queerphobia*, where there is increasing openness and understanding toward more diverse forms of sexual orientation and (gender) identity. For instance, our vocabulary does not include the variety of gender-neutral (neo)pronouns (Dev et al., 2021; Lauscher et al., 2022). Further, studies have shown that the perception of prejudice is not only highly subjective, but also largely culture-dependent (Webster et al., 2020). Consequently, in order to conduct a thoroughly unbiased annotation study, annotators should be carefully selected and as diverse as possible in terms of cultural heritage, age, ethnicity, and religious affiliation, as well as their gender identity and sexual orientation. While our three annotators were of diverse cultural background such diversity of human resources was not available for this work.

Supplementary Material

A Bias Specifications

We provide the full sets of target and attribute terms for Queerphobia and Islamophobia.

A.1 Queerphobia

List of Target Terms T_1: gay, gays, lesbian, lesbians, bisexual, bisexuals, homosexual, homosexuals, transgender, transgenders, sapphic, sapphics, pansexual, pansexuals, queer, queers, genderqueer, genderqueers, transsexual, transsexuals, crosssexual, crosssexuals, epicene, epicenes, lgbtq, hermaphroditic, hermaphrodite, hermaphrodites, androgynous, androgyne, androgynes, intersex

List of Target Terms T_2: straight, straights, monosexual, monosexuals, heterosexual, heterosexuals, cisgender, cisgenders, sexually normal, hetero, heteros, unisexual, unisexuals

List of Attribute Terms A_1: mentally ill, polygamous, flamboyant, pedophile, sexual predator, mental disorder, irreligious, villain, serial killer, depress, adultery, drug addict, sadist, arts, artistic, theatre, dramatic, show queen, fashion, predator, party drugs, illicit drugs, alcohol, sexual abuse, child rapist, indecisi, promiscuous, sexually manipulative, prostitute, drag queen, drag king, criminal, hypersexual, asexual, pervert, perverts, poofter, faggot, fag, weak, timid, loser, loner, lonely, sin, disease, confuse, strange, weird, coward, sexually abnormal, immoral, insecure, repulsive, frustrat, sinful, sensitive, weak minded, lack self control, oversex, submissive, emotional

List of Attribute Terms A_2: mentally, strong, monogamous, modest, teleiophile, protector, mental stability, hero, police officer, cheerful, healthy, compassionate, scientific, science, subtle, unfashion, defender, determined, moral, chaste, cisgender, lawful, decent, saint, faggot, strong, daring, winner, cheerful, virtue, health, assured, normal, normal, brave, moral, confident, delightful, satisfied, innocent, tough, dominating, unemotional

The target term pairs used are depicted in Table 8.

A.2 Islamophobia

List of Target Terms T_1: muslim, muslims, islam, islamic, islamism, arab, arabs, quran, koran

List of Target Terms T_2: christian, christians, christianity, church, bible, priest

List of Attribute Terms A_1: terrorist, terrorism, threat, threaten, dangerous, deadly, attack, bomb, murder, hijack, criminal, enemy, war, enemies, extremist, radical, hate, rich, lazy, flashy, lazy sheik, oil sheik, rapist, slaves, shooter, belly dancers, hijab, viel, vielded, oppressed, patriarchy, misogyny, patriarchal, deport, detain, thieves, thug, charlatan, brute, power hungry, beard, wealthy oilmen, harem maiden, suicide bomb, headscarves, violence, violent, hostile, sinister

List of Attribute Terms A_2: police, nonviolence, safety, defend, helpful, safe, defend, build, restore, relinquish, lawful, friend, peace, friends, moderate, conservative, love, poor, energetic, simple, defender, freemen, hero, hat, unviel, unvielded, rejoiced, matriarchy, philogyny, matriarchal, admit, liberate, police, hero, honest, mild, gratified, clean shave, negotiator, compassion, gentle, kind, happy

The target term pairs used are depicted in Table 9.

B Model Perplexity Examples

Some examples of sentences where the models exhibit a large difference in perplexity are shown in Table 10. It is striking that although the sentence pairs are both grammatically correct, the perplexities calculated by the models differ greatly.

C Links to Datasets and Models

We provide links to data sets, code bases, and all pretrained models used in this work in Tables 11 and 12.

D Further Experimental Results

We show the additional experimental results relating to RQ3 in Figure 5.

E Annotation Guidelines

We provide the annotation guidelines we employed for creating `ABBA` .

Sexual Identity	Gender Identity	Biological Sex
(gay, heterosexual)	(transgender, cisgender)	(epicene, unisexual)
(gays, heterosexuals)	(transgenders, cisgenders)	(epicenes, unisexuals)
(lesbian, heterosexual)	(transsexual, cisgender)	(hermaphroditic, unisexual)
(lesbians, heterosexuals)	(transsexuals, cisgenders)	(hermaphrodite, unisexual)
(sapphic, heterosexual)	(crosssexual, cisgender)	(hermaphrodites, unisexuals)
(sapphics, heterosexuals)	(crosssexuals, cisgenders)	(androgynous, unisexual)
(homosexual, heterosexual)	(genderqueer, cisgender)	(androgyne, unisexual)
(homosexuals,heterosexuals)	(genderqueers, cisgenders)	(androgynes, unisexuals)
(queer, heterosexual)	(queer, cisgender)	(intersex, unisexual)
(queers, heterosexuals)	(queer, cisgenders)	
(lgbtq, heterosexual)	(androgyne, cisgender)	
(gay, straight)	(androgynes, cisgenders)	
(gays, straights)		
(lesbian, straight)		
(lesbians, straights)		
(sapphic, straight)		
(sapphics, straights)		
(bisexual, monosexual)		
(bisexuals, monosexuals)		
(pansexual, monosexual)		
(pansexuals, monosexuals)		

Table 8: Target Term Pairs for Queerphobia

Islamophobia
(muslim, christian)
(muslims, christians)
(islam, christianity)
(islamic, christian)
(islamism, christianity)
(arab, american)
(arabs, americans)
(koran, bible)
(quran, bible)
(imam, priest)

Table 9: Target Term Pairs for Islamophobia

Model	**Type**	**Sentences**	**Perplexity**
GPT-2	Queerphobia	S : *whats normal for gay people is immoral for us.*	218
		S': *whats normal for straight people is immoral for us.*	363
DialoGPT	Islamophobia	S : *muslims follow the koran.. terrorism*	296
		S': *christians follow the bible.. terrorism*	977
BERT	Islamophobia	S : *islam is murder.*	1262
		S': *christianity is murder.*	2054
RoBERTa	Queerphobia	S : *transgender people are mentally ill.*	2579
		S': *cisgender people are mentally ill.*	926

Debate.org Queerphobia Annotation Guidelines
Version 2.0.0

[redacted]

1 Introduction

Debate.org is an online debate portal that provides a platform for open discussion, where all members of the community can express their arguments on a wide range of controversial topics. This document describes the annotation guidelines for declaring these user arguments as either expressing stereotyped human bias or not.

According to the Oxford Dictionary of Psychology, a stereotype is defined as:

"A relatively fixed and oversimplified generalization about a group or class of people." (Colman, 2015)

In this annotation task, we explicitly focus on the classification of negative or unfavorable biases.

For this purpose, a CSV file is provided that contains the user arguments, potentially biased sentences from these arguments, and the contained term pairs consisting of a target term referring to a demographic minority group (e.g., "homosexuals") and an attribute term referring to a presumably biased expression (e.g., "sin"). Based on this file, it is up to you to decide whether these extracted sentences or even the entire argument are indeed *biased* or *unbiased*.

If there are open questions that you feel are not covered in this guide, please do not hesitate to get in touch so that these questions can be discussed and the guide improved.

2 CSV Presentation

The CSV file you will receive will be structured as follows:

Annotation Data:

- **id:** Id of the argument in the Debates.org corpus.
- **Argument:** Whole user argument potentially containing biased sentence(s).
- **Sentence:** Extracted sentence of the comment containing the terms of the biased tuple.
- **Biased Tuple:** Biased term tuple found in the provided sentence. It consists of a target term describing a minority demographic group (e.g., "Transgender") and an attribute term describing a stereotyped view of that group (e.g., "pervert").

Annotation Task:

- **Biased Sentence:** Annotate as 1 if the sentence is biased, 0 otherwise.
- **Biased Argument:** Annotate as 1 if the whole argument is biased, 0 otherwise.
- **Comment:** If you are unsure how to label the given argument or sentence please describe your problem with the task.

3 Example Annotation

Example 1 (Biased Sentence & Argument):

Sentence: *"Thus, since being gay is a sin and sins are poor choices, being gay is a choice."* – Annotate as *biased (1)*

Argument: *"If people are born gay, then God would have made them gay. God would have made them to be an abomination. Thus, since being gay is a sin and sins are poor choices, being gay is a choice. Since I have now established that gay acts are a choice and sinful, I can now say that being gay is ungodly. will rest my argument for now."* – Annotate as *biased (1)*

Example 2 (Unbiased Sentence & Argument):

Sentence: *"Those who are against homosexual marriage must be immoral as well."* – Annotate as *unbiased (0)*

Argument: *"In fact they were creating a only white race just like they had been taught in evolution. Even today with abortion, Those who say it is wrong must be immoral. Those who are against homosexual marriage must be immoral as well. On both these issues the majority have not had a say in the matter."* – Annotate as *unbiased (0)*

Example 3 (Unbiased Sentence & Biased Argument):

Sentence: *"Being gay is not a sin."* – Annotate as *unbiased (0)*

Argument: *"Being gay is not a sin. At all. Rather, acting on those impulses is the sin. Being gay is fine as long as you don't act feelings."* – Annotate as *biased (1)*

Example 4 (Biased Sentence & Unbiased Argument):

Sentence: *"Because being gay is a sin."* – Annotate as *biased (1)*

Argument: *"For years, people in the LGBT community have been victim to discrimination, stereotyping, and even bullying and murder. What was the motive? Because being gay is a sin. Because they are unnatural. If it is unnatural for a man to love a man, why is their brain designed to do so?"* – Annotate as *unbiased (0)*

4 How to handle confusing cases:

Here are some listings of how to handle potentially confusing cases:

- **Restatement/ Question**: If the user is repeating what his opponent stated or formulates an open question or a question to the opponent. Example: *"Is being gay a sin or a social clique?"* – Annotate as *unbiased (0)*

- **Citations**: If in the extracted sentence, the user is citing a statistic that cannot be checked for validity, please do not provide an annotation.

- **Oversimplified Statements**: If in the extracted sentence, the user is expressing an oversimplified statement without any kind of proof. Example: *"It is common knowledge that gays are the reason for the spread of diseases like HIV."* – Annotate as *biased (1)*

- **Sarcasm**: If the user is sarcastic. Example: *"Imagine if my opponent was the lawyer for the parade: "Your Honor, my client's gay parade is no more repulsive than public executions, the people killed on 9/11, the Sandy Hook mass murder of kids, Rwanda where one million civilians were killed, the Nazi extermination of million Jews.""* – Annotate as *unbiased (0)*

5 Additional Notes:

If you face any difficulty labeling the given argument or sentence, please ignore the sub task and ideally provide a description in the comment field as to why this task was difficult to solve.

Please always keep in mind the definition of a stereotype stated in the Introduction of this guide. Argumentation against a minority related topic (e.g., "gay marriage") which does not involve stereotyped statements is not considered a bias.

- **Argument:** Whole user argument potentially containing biased sentence(s).
- **Sentence:** Extracted sentence of the comment containing the terms of the biased tuple.
- **Biased Tuple:** Biased term tuple found in the provided sentence. It consists of a target term describing a minority demographic group (e.g., "arabs") and an attribute term describing a stereotyped view of that group (e.g., "oil sheik").

Annotation Task:

- **Biased Sentence:** Annotate as 1 if the sentence is biased, 0 otherwise.
- **Biased Argument:** Annotate as 1 if the whole argument is biased, 0 otherwise.
- **Comment:** If you are unsure how to label the given argument or sentence please describe your problem with the task.

3 Example Annotation

Example 1 (Biased Sentence & Argument):

Sentence: *"Because this seems to be more about Muslims being violent."* – Annotate as *biased (1)*

Argument: *"Because this seems to be more about Muslims being violent. But there have been refugees from other areas in the world that have settled in fine, like the Jews, and contributed to society. Do you think safe countries should accept refugees if they are not muslim?"* – Annotate as *biased (1)*

Example 2 (Unbiased Sentence & Argument):

Sentence: *“I think it is a shame that the right-wing media have indoctrinated people in the west to such an extent that some people automatically equate Islam with terrorism.”* – Annotate as *unbiased (0)*

Argument: *“I think it is a shame that the right-wing media have indoctrinated people in the west to such an extent that some people automatically equate Islam with terrorism. There are some Islamic terrorists, true. There are also some catholic terrorists, for example in Northern Ireland. But not all Catholics are terrorists and neither are all Muslims.”* – Annotate as *unbiased (0)*

Example 3 (Unbiased Sentence & Biased Argument):

Sentence: *“Mostly terrorist attacks committed by Non-Muslims don’t happen because of religion, they happen for other reasons.”* – Annotate as *unbiased (0)*

Argument: *“Mostly terrorist attacks committed by Non-Muslims don’t happen because of religion, they happen for other reasons. Is there people from a certain religion blowing stuff and themselves up as much as Muslims these days? No.”* – Annotate as *biased (1)*

Example 4 (Biased Sentence & Unbiased Argument):

Sentence: *“It makes sense for people to hate Islam, especially when you consider the terrorist attack of 9/11, and not to mention the Boston bombing, the terrorism in France, etc.”* – Annotate as *biased (1)*

Argument: *“I find that there is a distinct difference between being Islamic and being an extremist. It makes sense for people to hate Islam, especially when you consider the terrorist attack of 9/11, and not to mention the Boston bombing, the terrorism in France, etc. I guess what i am trying to say is, aren’t we being to harsh on the religion itself?”* – Annotate as *unbiased (0)*

4 How to handle confusing cases:

Here are some listings of how to handle potentially confusing cases:

- **Restatement/ Question**: If the user is repeating what his opponent stated or formulates an open question or a question to the opponent. Example: *“Does this mean that every Muslim is going to be a terrorist?”* – Annotate as *unbiased (0)*
- **Citations**: If in the extracted sentence, the user is citing a statistic that cannot be checked for validity, please do not provide an annotation.
- **Oversimplified Statements**: If in the extracted sentence, the user is expressing an oversimplified statement without any kind of proof. Example: *“Islam forces itself with terrorism Islam argues against its own existence.. everyone knows Muslims are terrorists, are you going to for-fit the next round is the only question”* – Annotate as *biased (1)*
- **Sarcasm**: If the user is sarcastic. Example: *“Good luck, trying to to convince me that Islam promotes hate, terrorism, injustice or any other definition of any unpeaceful things.”* – Annotate as *unbiased (0)*

5 Additional Notes:

If you face any difficulty labeling the given argument or sentence, please ignore the sub task and ideally provide a description in the comment field as to why this task was difficult to solve.

Please always keep in mind the definition of a stereotype stated in the Introduction of this guide. Argumentation against a minority related topic (e.g., “the hijab”) which does not involve stereotyped statements is not considered a bias.

Learning Adaptive Segmentation Policy for End-to-End Simultaneous Translation

Ruiqing Zhang, Zhongjun He*, Hua Wu and Haifeng Wang
Baidu Inc. No. 10, Shangdi 10th Street, Beijing, 100085, China
{zhangruiqing01, hezhongjun, wu_hua, wanghaifeng}@baidu.com

Abstract

End-to-end simultaneous speech-to-text translation aims to directly perform translation from streaming source speech to target text with high translation quality and low latency. A typical simultaneous translation (ST) system consists of a speech translation model and a policy module, which determines when to wait and when to translate. Thus the policy is crucial to balance translation quality and latency. Conventional methods usually adopt fixed policies, e.g. segmenting the source speech with a fixed length and generating translation. However, this method ignores contextual information and suffers from low translation quality. This paper proposes an adaptive segmentation policy for end-to-end ST. Inspired by human interpreters, the policy learns to segment the source streaming speech into meaningful units by considering both acoustic features and translation history, maintaining consistency between the segmentation and translation. Experimental results on English-German and Chinese-English show that our method achieves a good accuracy-latency trade-off over recently proposed state-of-the-art methods.

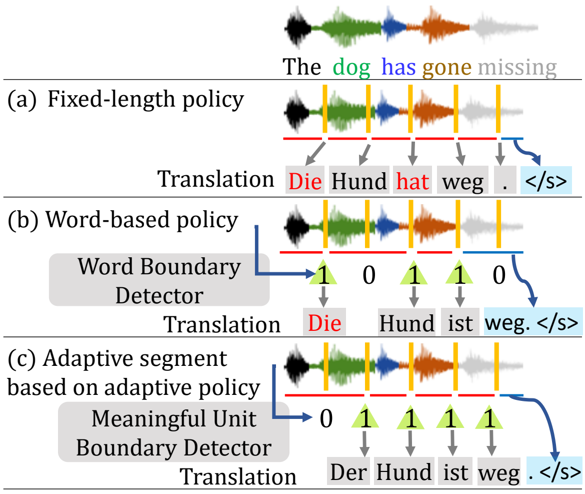

Figure 1: An En-De example illustrates three segmentation policies for end-to-end simultaneous translation. The yellow line indicates the sampling frequency of the source speech. (a) Fixed-length policy generates a target word for each interval. (b) Word-based policy detects word boundaries and generates target word once a source word is detected (green triangle). (c) Our method detects meaningful units and generates translation. Both the Fixed-length policy and Word-based policy incorrectly generate "Die" without consideration of following context[1]. The last blue blocks denote the translation after receiving the complete speech. Mistranslated words are annotated in red.

1 Introduction

Recent years have witnessed extensive studies and rapid progress of Simultaneous translation (ST). It aims to perform translation from source speech into the target language with high quality and low latency and is widely used in many scenarios, such as international conferences, press releases, etc.

Generally, the research of ST falls into two categories: the cascaded method, and the end-to-end method. The cascaded method consists of an automatic speech recognition (ASR) model which transcribes the source speech into source streaming text (Moritz et al., 2020; Wang et al., 2020b; Li et al., 2020a), and a followed-by machine translation (MT) model that generates translation based on the ASR output. Since there are no sentence or segment boundaries in the streaming source text output by ASR, a segmentation policy is required to link the ASR and the MT to determine when to read more source tokens and when to start translation (Oda et al., 2014; Dalvi et al., 2018; Ma et al., 2019; Arivazhagan et al., 2019; Zhang et al., 2020; Wilken et al., 2020). However, cascaded methods

---

* Corresponding author.

[1] In German, each singular noun is assigned a gender, either *masculine*, *feminine*, or *neuter*, which determines whether the definite article (like "The" in English) preceding the noun is "*Der*", "*Die*" or "*Das*". Therefore, translating "The" hastily without receiving the following noun may cause mistranslation.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 7862 - 7874
May 22-27, 2022

face two main challenges. One is the error propagation that the ASR errors may hurt the translation quality. The other is the increase of latency because the translation model has to wait for the output of the ASR model.

To overcome these limitations, the end-to-end method attempts to directly translate from source speech to target text, without explicitly transcribing the source speech (Bansal et al., 2018; Di Gangi et al., 2019b; Jia et al., 2019). To balance the translation quality and latency, the key challenge lies in the segmentation policy that determines the translation boundaries of the speech frames.

Most of the previous work used fixed policies. Some of them take fixed-length policy (Nguyen et al., 2021; Ma et al., 2020b, 2021) that splits speech at a fixed frequency, for example, to generate one target word every T_s ms (Figure 1 (a)). Other work adopts word-based policy that splits the speech into words and generates one target word whenever a new source word is detected, which calls for an auxiliary source word detector (Ren et al., 2020; Elbayad et al., 2020; Ma et al., 2020b; Zeng et al., 2021; Chen et al., 2021), see Figure 1 (b). However, both the above methods are "hard" policies, which do not consider the contextual information and result in low translation quality (Arivazhagan et al., 2019; Zhang et al., 2020).

In this paper, we propose an adaptive segmentation policy for end-to-end simultaneous translation based on *Meaningful Unit* (MU). The idea is borrowed from human interpreters, who do interpretation based on a unit with clear meaning rather than fixed frame length or word. We model the speech segmentation policy as a binary classification that determines whether a speech segment is an MU. Once an MU is detected, it is fed into an end-to-end speech translation model, as illustrated in Figure 1 (c). We propose a supervised training method, using both acoustic features and translation features to train the policy. Besides, we propose an incremental decoding method to construct training data from speech and translation pairs. Concretely, we first train a full speech translation model $\mathcal{M}_{ST}$, and then gradually expand speech frames to simulate simultaneous translation. When the translation of the current speech segment is a prefix of the full speech translation, the segment is extracted as an MU. At inference time, we employ the same $\mathcal{M}_{ST}$ to maintain the consistency between segmentation and translation. Our method is more flexible than fixed policies, as it dynamically detects meaningful units according to contextual information. Experiments on two language pairs show that the proposed approach outperforms the strong baselines in balancing translation quality and latency.

2 Related Work

Cascade Simultaneous Translation. To eliminate the impact of ASR errors, most previous work of cascade ST use golden transcript, rather than ASR result, to explore different read/write policies in ST. Existing policies can be classified into two categories: 1) The ***fixed policy*** segments the source text based on fixed lengths (Ma et al., 2019; Dalvi et al., 2018). For example, *wait-k* (Ma et al., 2019) is a typical *fixed policy* that first read k source words, then generates one target word immediately after receiving one subsequent source word. 2) The ***adaptive policy*** learns to segment the source text according to its context (Oda et al., 2014; Cho and Esipova, 2016; Gu et al., 2017; Arivazhagan et al., 2019; Ma et al., 2020a; Zhang et al., 2020). It has been proven that the adaptive policy is more effective than the fixed policy in balancing translation quality and latency (Zhang et al., 2020).

End-to-End Simultaneous Translation. The method has shown great potential over the cascaded method (Bérard et al., 2016; Weiss et al., 2017; Bansal et al., 2018; Jia et al., 2019; Wang et al., 2020a; Li et al., 2020b; Ansari et al., 2020). End-to-end ST contains a speech translation model, along with a policy to decide when to translate. However, most previous studies are based on fixed-length policy that translate every T_s ms (Nguyen et al., 2021; Ma et al., 2020b), or decide to translate whenever a fixed number of words are detected (Ren et al., 2020; Elbayad et al., 2020; Zeng et al., 2021; Ma et al., 2021; Chen et al., 2021), following the ***fixed policy*** of cascade ST systems.

This paper presents an adaptive policy for end-to-end simultaneous translation. We are motivated by an adaptive policy proposed for cascade ST (Zhang et al., 2020), which proposed to perform translation when a source text segment is detected to be a unit with clear meaning. However, there are three main differences. First, our method is proposed for end-to-end ST, while Zhang et al. (2020) is for cascade ST. Second, our method directly detects MU on speech rather than on the streaming text of the output of ASR. Third, we propose a multi-modal MU detection model using both acoustic features and translation history.

3 Adaptive Speech Segmentation Policy

The overall framework of our adaptive speech segmentation policy is illustrated in Figure 2. Given a streaming speech s, we incrementally detect whether a speech clip $s_{\leq t}$ ($t = 1, 2, ...$) is an MU, where $s_{\leq t}$ denotes the head $t\mathcal{F}$ frames of s, and $\mathcal{F}$ is the detection interval. Once an MU is detected, the speech translation model produces its translation y' with the translation history y_p force decoded as a translation prefix. Meanwhile, y' is displayed to users and added to the translation history y_p to improve MU detection. In the following, we first introduce our MU detection model (Section 3.1), then propose a method to construct MU training data (Section 3.2). Finally, we describe the training details in Section 3.3.

3.1 Multi-modal MU Detection

We model the MU detection as a classification problem. Given a source speech s, the detector incrementally reads speech clips at each time t, to make a decision whether $s_{\leq t}$ is an MU.

We propose a multi-modal detector that uses both acoustic features and translation history. See the bottom green block of Figure 2 for illustration. For the acoustic feature extractor E_a^f, we use stacked temporal convolutional layers performed on raw speech features (80-channel log-mel filterbanks). Each of the convolutional layers is followed by layer normalization and a GELU activation function (Hendrycks and Gimpel, 2016), following Baevski et al. (2020). For the context feature extractor E_t^f, we use a trainable word embedding layer.

The outputs of the feature extractors are fed to the acoustic encoder E_a^e and context encoder E_t^e to generate latent representation, respectively. We add a position embedding to the textual embedding, as in BERT (Devlin et al., 2019), and add a convolutional layer as the relative positional embedding to the acoustic embedding, similar to Mohamed et al. (2019); Baevski et al. (2019). Both E_t^e and E_a^e follow the Transformer architecture (Sperber et al., 2018; Devlin et al., 2019).

$$\begin{aligned} c_y &= E_t^e(E_t^f(y_p)) \\ c_s &= E_a^e(E_a^f(s_{\leq t})) \end{aligned} \tag{1}$$

where $c_y = \{c_y^1, ..., c_y^N\}$ is the textual encoding of $y_p = \{y_p^1, y_p^2, ..., y_p^N\}$, and $c_s = \{c_s^1, ..., c_s^T\}$ is for speech encoding[2].

Next, we add different type embeddings e_{Type} ($e_{[TXT]}$ and $e_{[AUD]}$) to both text and audio embeddings to indicate their source type. These two sequences are then concatenated and fed to a 6-layer Transformer for cross-modal fusion. Special tokens [*CLS*] and [*SEP*] are added in this process following BERT (Devlin et al., 2019). The final hidden state corresponding to [*CLS*] is used as the aggregated sequence representation to predict the classification result l' using a fully-connected layer, followed by a softmax.

$$l' = \text{Softmax}(fc(E_{mm}([c_y; c_s] + e_{Type}))) \tag{2}$$

where E_{mm} denotes the multi-modal fusion Transformer and fc performs a fully-connection layer.

3.2 Constructing MU Training Data

Since there are no standard MU segmentation training corpora, we propose a simple method to automatically extract meaningful speech units to construct MU training samples.

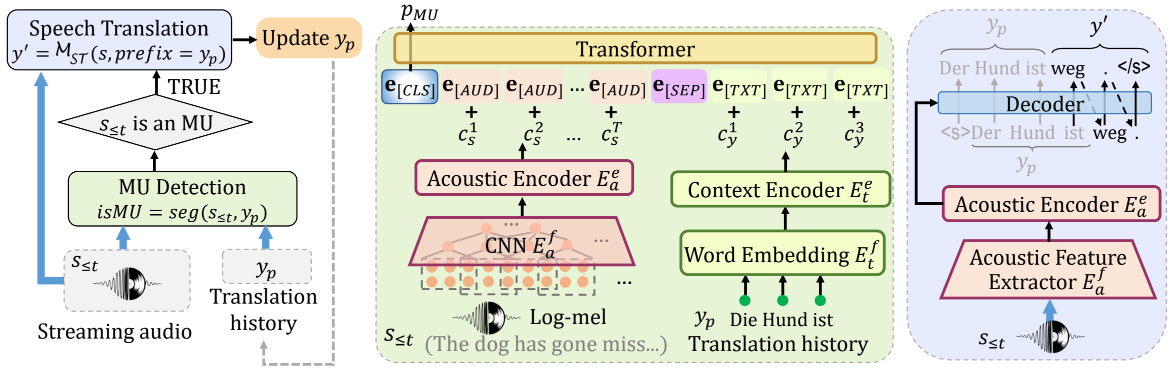
We expect that MUs can be translated properly without waiting for future speech. Therefore, we define MU as *the minimum speech segment whose translation will not be changed by subsequent speech*. This requires MUs to contain enough information to generate stable translation. Accordingly, we propose to extract meaningful speech units by comparing the translation of every speech prefix segment and the full-speech translation with a pre-trained speech translation model $\mathcal{M}_{\mathcal{ST}}$. For a speech segment $s_{\leq t}$, if its translation $y' = \mathcal{M}_{\mathcal{ST}}(s_{\leq t})$ is a prefix of the full-speech translation $\widetilde{y} = \mathcal{M}_{\mathcal{ST}}(s)$, we identify that $s_{\leq t}$ is sufficient to provide a stable translation and annotate it to an MU.

We propose an incremental-translation paradigm. We incrementally translate $s_{\leq t}$, $t = 1, 2, ...$, to judge whether its translation y' is a prefix of $\widetilde{y}$. If so, we extract $s_{\leq t}$ as an MU, and force-decode its translation y' as a prefix in detecting subsequent speech segments. This is to keep consistent with the force-decoding strategy at the inference stage.

Moreover, while comparing y' with $\widetilde{y}$, as illustrated in Figure 3, we propose a *tail-truncation* strategy that discards the last k words from the partial decoding results y'. This is to avoid translation

---

[2] Note that the length of acoustic encoding T is not equal to the number of source frames $t\mathcal{F}$ for the temporal sampling of convolutional feature extractor layers.



(a). The inference framework (b). The multi-modal MU Detection (c). The Speech Translation

Figure 2: (a). The overall framework of our proposed adaptive policy for end-to-end ST includes an MU detection module and a speech translation module. Once an MU $s_{\leq t}$ is detected, it will be translated with the translation history y_p decoded first, then decode until EOS (</s>). The new translation y' will be added to the translation history for detecting subsequent MUs. (b). The MU detection module performs a multi-modal classification based on acoustic features c_s^i and translation context c_y^i. (c). The speech translation module shares E_a^f and E_a^e with the MU Detection module. It first force decodes y_p (in gray) and then generates y' (in black) at inference time.

errors caused by ambiguous speech fragments. For example, $s_{\leq 3}$ pronounces "*The dog has*" is translated to "Der Hund hat", which is not a prefix of the full-speech translation $\widetilde{y}$ due to the current received speech is ambiguous[3]. However, after truncated the tail word, y' turn to be "Der Hund" and becomes a prefix of $\widetilde{y}$. Therefore, discarding tail words from y' enables the model to discover translation that partially matches $\widetilde{y}$ in advance, thus shortening the granularity of extracted MUs and reducing latency. At the inference stage, we also remove tail k words from the translation of detected MUs.

With the incremental-translation paradigm, we can extract four MUs for the example in Figure 3, i.e., $s_{\leq 2}$, $s_{\leq 3}$, $s_{\leq 4}$ and $s_{\leq 5}$.

3.3 Training with Shared Acoustic Encoders

Our pre-trained speech translation model $\mathcal{M}_{ST}$ includes an acoustic feature extractor E_a^f, an acoustic encoder E_a^e, and a textual translation decoder, as shown in Figure 2(c). E_a^f and E_a^e are shared with the multi-modal MU detection model so that the acoustic forward computation can be shared at inference time. The translation decoder is based on Transformer, which links the acoustic encoder through cross-attention (Vaswani et al., 2017).

Note that to keep MU detection consistency in both training and decoding, we initialize the acoustic feature extractor and context encoder with the weights from $\mathcal{M}_{ST}$, and keep them frozen in training MU detection, instead of joint training with $\mathcal{M}_{ST}$.

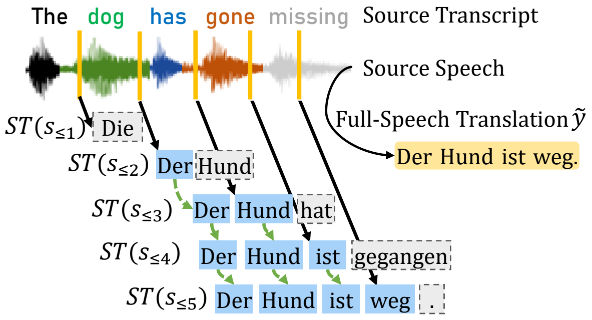


Figure 3: A running example of extracting MUs. While translating each speech segment $s_{\leq t}$, the last k words will be discarded (in gray) from the generated translation (k=1 in this example). If the rest decoding result (in blue) is a prefix of the full-speech translation (in yellow), then $s_{\leq t}$ is annotated as an MU, and the tail-truncated translation is force-decoded (green dashed lines) in translating subsequent speech segments. Note that the *Source Transcript* is invisible in extracting MUs and here is shown only for illustration.

Formally, the $\mathcal{M}_{ST}$ model optimizes the two acoustic encoders and the translation decoder first with auto-regressive loss $\mathcal{L}_{ST}$:

$$\mathcal{L}_{ST} = - \sum_{(s,y)\in\mathcal{D}_{ST}} \sum_{i=1}^{N} \log p(y_i | s, y_{<i}; \theta_{ae}, \theta_{td}) \tag{3}$$

Then the MU detection model is optimized without gradients back-propagated to the acoustic encoders:

---

[3] The English word "has" can be translated to either "ist" or "hat" in most cases, depending on what follows.

$$\mathcal{L}_{MU} = - \sum_{(s, y_p, l) \in \mathcal{D}_{MU}} \log p(l | s, y_p; \theta_{te}, \theta_{mm}) \tag{4}$$

where θ_{ae} denotes weights of the two acoustic encoders, θ_{td} is the translation decoder of $\mathcal{M}_{ST}$, θ_{te} is the textual encoders for y_p and θ_{mm} is the weights of the multi-modal fusion. $\mathcal{D}_{ST}$ is the speech translation dataset and $\mathcal{D}_{MU}$ contains training triplets generated by the pre-trained $\mathcal{M}_{ST}$ model.

4 Experiments

We carry out experiments on English-German (En-De) and Chinese-English (Zh-En) simultaneous translation. We use sacreBLEU (Post, 2018) to evaluate the translation performance and the acoustic average lagging (AL) (Ma et al., 2019, 2020b) as the latency metric. The AL measures the system lagging behind an "ideal policy", which produces translation at the same speed as the audio received.

4.1 Data Settings

We evaluate our method on MuST-C (Di Gangi et al., 2019a) En-De dataset and BSTC (Zhang et al., 2021a) Zh-En dataset. To compare with the previous methods, we carried out experiments under two settings: the **Limited-training-corpora setting** that constrains the training data to a limited set of corpora, and the **Open-training-corpora setting** uses more data. For En-De, we set the training data of Limited-training-corpora setting as the training set of MuST-C, a dataset consisting of 408 hours of speech with transcription and translation, while the experiments with the Open-training-corpora setting use unlimited datasets of up to 1,302 hours of speech. See appendix A.1 for detail.

4.2 Model Settings

We compare our method with previous strong ST approaches. Methods listed with "*" are carried out under the Open-training-corpora setting, while others use the Limited-training-corpora setting.

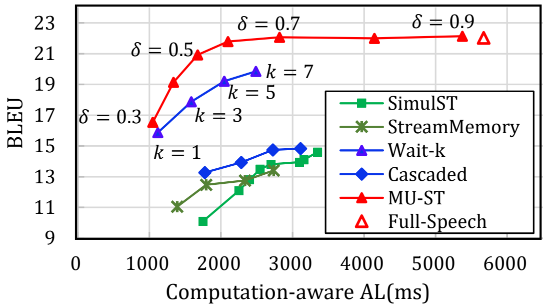
- *Wait-k* (Chen et al., 2021) integrates the *wait-k* (Ma et al., 2019) policy into end-to-end speech translation with an additional ASR module to detect the number of source words within the streaming speech.

Arch	**Speech Translator**			**Speech Segmentor**	
	Feature Extractor	Context Encoder	ST Decoder	Context Encoder	Fusion Encoder
Base	CNN-2	T-12	T-6	T-6	T-6
Big	CNN-7	T-24	T-12	T-6	T-6

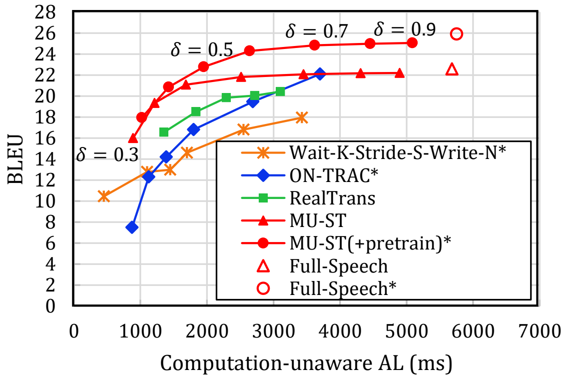
Table 1: The two architectures of our method. "n" in "T-n" and "CNN-n" represents the number of stacked Transformer and stacked CNN layers, respectively.

- *SimulST* (Ma et al., 2020b) takes the fixed-length policy that translates out one token every T_s ms. We set T_s to 280 following their best experimental settings.
- *StreamMemory* (Ma et al., 2021) proposes an end-to-end speech translation model with augmented memory, which stores previous states of streaming speech to reduce the computation cost. They use the same fixed-length policy as in *SimulST*.
- *RealTranS* (Zeng et al., 2021) proposes a fixed policy (Wait-k-Stride-N) for an end-to-end ST that triggers translation based on the number of words within the streaming speech, which is detected based on a CTC module built on top of the speech translation encoder.
- *Wait-K-Stride-S-Write-N** (Nguyen et al., 2021) proposes a fixed-length policy for end-to-end ST that first wait for *K* frames, then alternatively decoding *N* target words and reading *S* frames.
- *ON-TRAC** (Elbayad et al., 2020): A cascade system that achieved the **first-place** of the IWSLT2020 En-De simultaneous translation shared task (Federico et al., 2020). It takes a fixed policy (*wait-k*) to link the ASR output and the MT module.
- *MU-ST*: Our proposed method that triggers the speech translator with an MU-based adaptive policy. The $\mathcal{M}_{ST}$ model is trained from scratch.
- *MU-ST*(*+pretrain*)*: To compare with methods of the Open-training-corpora setting, we take pre-training techniques in training the speech translator $\mathcal{M}_{ST}$.

We train *MU-ST* and *MU-ST*(*+pretrain*)* with different model architectures. The $\mathcal{M}_{ST}$ model of *MU-ST* is first pre-trained with an ASR task



(a). Result of the dev set



(b). Result of the tst-COMMON set

Figure 4: The Translation quality (BLEU) vs. latency (AL) evaluated on MuST-C En-De. The results marked with * are of the Open-training-corpora setting, while others only use the MuST-C as the training corpus. The results of all the comparison methods are excerpted from the corresponding papers[7].

to enhance the acoustic representations, as performed in *SimulST* (Ma et al., 2020b), *StreamMemory* (Ma et al., 2021) and *RealTransS* (Zeng et al., 2021). For *MU-ST(+pretrain)**, we follow the recently proposed speech translation pre-training method (Li et al., 2020b) to initialize the encoder with wav2vec2.0[4] (Baevski et al., 2020) and initialize the decoder with mBART50[5] (Tang et al., 2020), then fine-tune with speech translation corpora. As listed in Table 1, *MU-ST* takes the *Base* model and *MU-ST(+pretrain)** takes the *Big* version[6]. We set the number of truncated words *k*=2 in *tail-truncation* and the length of speech clips $T_s = 250ms$ as default.

4.3 En-De Experiment

Figure 4 shows the results on MuST-C dev set and tst-COMMON set. We calculate the computation-aware latency on the MuST-C dev set and computation-unaware latency on the MuST-C tst-COMMON set, to be consistent with previous work. The difference between them is whether the model inference time is taken into account.

MU-ST achieves higher translation quality under the same latency on both datasets. δ denotes the probability threshold of MU detector, i.e., $\delta = [0.3, 0.4, ..., 0.9]$ corresponds to the results of taking $p(l = 1|s, y_p) > \delta$ as the criterion of determining s to be an MU. Small δ produces fine-grained speech segments and small delay, but if some ambiguous speech segments are incorrectly recognized as MUs, it will result in poor translation quality.

On the dev set, we compare *MU-ST* with *Wait-k* (Chen et al., 2021), *SimulST* (Ma et al., 2020b) and *StreamMemory* (Ma et al., 2021). *SimulST* and *StreamMemory* takes fixed-length speech policy (Figure 1 (a)) while *Wait-k* performs wait-k based on the number of words detected from an ASR module (Figure 1 (b)). We also plot the result of a Cascaded system based on textual Wait-K (Chen et al., 2021) . We observed that:

- Our adaptive policy outperforms the *Wait-k* methods, and the *Wait-k* approaches are superior to the fixed-length methods.

- We report the result of translating the whole speech without segmentation in the “full-speech translation”. *MU-ST* approaches the BLEU of full-speech translation as early as $\delta = 0.6$, indicating that our method can achieve comparable BLEU with full-speech translation with a very small latency (about 2100ms), while other methods still have a large gap with the full-speech translation under corresponding delay.

On the tst-COMMON set, we compare *MU-ST* with three fixed-policy methods. *ON-TRAC** and *RealTransS* follow the wait-k policy, while *Wait-K-Stride-S-Write-N** takes the fixed-length policy. We observed that:

- Our proposed *MU-ST* trained with MuST-C achieves higher BLEU at all latency regimes than other approaches. In particular, it even superior to the cascade method *ON-TRAC**,

[5] https://dl.fbaipublicfiles.com/fairseq/models/mbart50/mbart50.ft.1n.tar.gz

[6] The architecture of *MU-ST(+pretrain)** is determined by its inherited pre-training models. *MU-ST* adopts smaller models because of the low-resource training data。

[7] Following previous studies, we evaluate the computation-aware AL and computation-unaware AL on MuST-C dev set and test set, respectively.

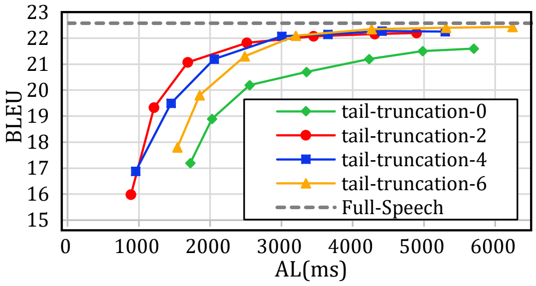

Figure 5: Impact of the number of truncated words in *tail-truncation*.

which utilized large-scale ASR and MT corpora for training.

- *MU-ST*(+*pretrain*)* outperforms *MU-ST* in BLEU by taking advantage of pre-trained models and more training data for $\mathcal{M}_{\mathcal{ST}}$. The full-speech translation of *MU-ST*(+*pretrain*)* has 3.32 BLEU points improvement (22.58→25.90) over *MU-ST*. Meanwhile, the latency of *MU-ST*(+*pretrain*)* is longer than *MU-ST* under the same δ. This may be because the pre-trained large speech translation model of *MU-ST*(+*pretrain*)* enables the high translation diversity of its speech translation model $\mathcal{M}_{\mathcal{ST}}$, which is not conducive in constructing fine-grained meaningful units. Strong translation diversity will reduce the probability of prefix matching between partial translation y_i' and full-speech translation $\widetilde{y}$ in MU construction, thus bringing in longer MUs and higher latency.

4.4 Ablation Studies

We conduct experiments concerning various aspects of our MU-based policy in this section. All ablation results are trained on the Limited-training-corpora setting and evaluated on MuST-C tst-COMMON set.

4.4.1 Do we need *tail-truncation*?

When constructing the data for MU detection, we proposed a *tail-truncation* strategy, which removes the last k words from the translation of each speech segment to avoid translation errors caused by ambiguous speech segments. Now we verify its significance. We compare models with different numbers of truncated words k in *tail-truncation*, with results shown in Figure 5. It is observed that without *tail-truncation* ($k = 0$), the translation quality is worse and the latency is longer, compared with $k = 2$. This corroborates our motivation specified in Section 3.2 that *tail-truncation* enables the model to discover fine-grained meaningful units. Moreover, it also facilitates producing context-aware translation by taking longer context in translation. Therefore, *tail-truncation* strategy plays an important role in extracting meaningful units.

Increasing k from 2 to 4 and 6 generally brings higher latency, along with a tiny improvement in translation quality. According to the I-MOS ranking mechanism (Zhang et al., 2021b) for ST systems, $k = 2$ and $k = 6$ ranks tied, both better than $k = 4$. $k = 2$ is superior at low-latency regime and $k = 6$ performs better at high-latency regime. This is because according to our MU extraction algorithm, we can always guarantee the consistency between the MU translation and the full-speech translation, regardless of the value of k. Larger k makes it easier to match partial translation and full-speech translation, thus producing more fine-grained MUs. But at the same time, truncating more translated words can avoid displaying problematic translations at the tail. So the translation quality of large k will not degrade. On the contrary, using a larger k improves the translation accuracy because it receives more source speech when performing translation.

4.4.2 Multi-modal vs. Single-modal MU Detection

To further study the effect of the translation history for MU detection, we remove the previously generated translation y_p from the multi-modal MU detection model. Without y_p, the segmentation model detects MUs only based on the input speech clip $s_{\leq t}$, and only optimizes the top 6-layer Transformer.

We build golden segmentation on tst-COMMON based on the meaningful speech units construction algorithm (Section 3.2), then evaluate different models on MU segmentation, translation quality, and latency. The results are shown in Table 2. It is observed that for both limited and open training corpora settings, the multi-modal method which combines speech features and translation history outperforms the single-modal method on MU segmentation in terms of F1 score (absolute improvements of 1.6-2 percentage points). However, there are only slight improvements in translation quality and a slight delay in latency. This is because incorrect segmentation does not necessarily lead to the decline of BLEU, which also depends on

Model	setting	F1 (%)	BLEU	AL (ms)
MU-ST	Single-Modal	72.6	20.92	1642.2
	Multi-Modal	**74.6**	**21.07**	1684.8
MU-ST (+*pretrain*)*	Single-Modal	72.5	22.73	1925.7
	Multi-Modal	**74.1**	**22.78**	1952.5

Table 2: The performance of single-modal and multi-modal MU detection models evaluated on MuST-C tst-COMMON at $\delta = 0.5$.

the robustness of the speech translation model. For some small errors brought by wrong segmentation, a robust speech translation model may ignore them and generate correct translation when translating subsequent MUs. In such cases, the overall BLEU will not be largely affected.

4.5 Experiments on Zh-En ST

We also evaluate our method on Zh-En ST using BSTC (Zhang et al., 2021a) dataset. BSTC is the largest Zh-En public speech translation corpus, but contains only 66 hours of speech, corresponding to 37k sentences. To alleviate the data scarcity, we first construct pseudo speech translation data by translating the transcript of ASR corpora (AISHELL-1 (Bu et al., 2017), AISHELL-3 (Shi et al., 2020), and aidatatang_200zh[8]) with a Zh-En machine translation model trained on a translation corpus, CCMT2019 (Yang et al., 2019). Then the pseudo speech translation data, together with the BSTC, are assigned as the training corpus for the Zh-En end-to-end speech translation model. The combined training set contains a total of 529 hours of speech, corresponding to 478k sentence pairs of transcript and translation.

We implement three methods for comparison:

- ***Cascade***: we use an adaptive policy (Zhang et al., 2020) to connect an ASR model and an MT model. The ASR model is trained on 529 hours of speech, and the MT model based on Transformer big is pre-trained on CCMT2019 and fine-tuned on BSTC. The adaptive policy based on textual MU (Zhang et al., 2020) is trained on BSTC.

- ***Cascade****: Similar to *Cascade*, the only difference is that it adopts a public real-time ASR API[9] that uses more than 9400 hours of ASR training data (Amodei et al., 2016).

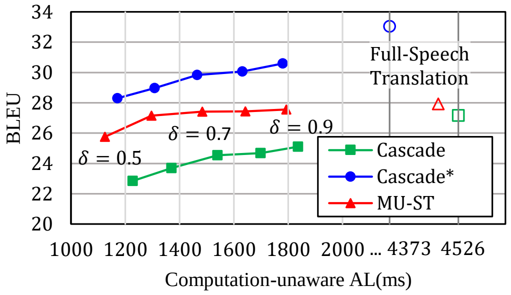

Figure 6: The performance on the Zh-En BSTC testset.

- ***MU-ST***: Our proposed adaptive speech segmentation policy for end-to-end ST. The acoustic encoders and target decoders of our speech translation model are initialized by the ASR and MT model of *Cascade* method, respectively. Then we fine-tune with speech translation data following Li et al. (2020b).

The results in Figure 6 show that: **1)** *Cascade** has a significant advantage over the other two methods. This is because the word error rate of the ASR model is 10.32% and 21.58% for *Cascade** and *Cascade*, respectively, leading to 5.9 BLEU points of gap between their full-speech translation results (27.2 vs. 33.1)[10]. **2)** *Cascade* and our end-to-end method *MU-ST* are optimized with identical training data, but *MU-ST* outperforms *Cascade*. We attribute this improvement to two reasons. First, the end-to-end method avoids ASR error propagation, with the full-speech translation of *MU-ST* surpassing *Cascade* by 0.7 BLEU points (27.9 vs. 27.2). Second and more important, *MU-ST* detects MUs directly from speech, thus avoiding loss of information. The average gap between *Cascade* and *MU-ST* at five ST results is 2.9 BLEU points, much larger than that of full-speech translation (0.7). This represents that segmentation from the source speech is superior to segmentation from noisy ASR results. Accordingly, we expect our *MU-ST* to have greater potential based on large-scale training data.

5 Conclusion

We present an adaptive speech segmentation policy for end-to-end simultaneous translation, which triggers translation with a meaningful speech unit de-

---

[8] a free Chinese Mandarin speech corpus by Beijing DataTang Technology Co., Ltd (www.datatang.com)

[9] `https://ai.baidu.com/tech/speech/realtime_asr`

[10] Note that, our proposed *MU-ST* surpassed the cascade method *ON-TRAC** in En-De experiments, but it failed to surpass *Cascade** in Zh-En because the ASR training data of *ON-TRAC** in En-De is only three times that of *MU-ST* (in hours), while the training data of *Cascade** is thousands of times that of *MU-ST* in Zh-En experiments.

tector. Experiments across two language pairs show that our method outperforms state-of-the-art methods with constrained training corpus, suggesting the effectiveness of our adaptive policy. Ablation studies reveal key factors that lead to its success, including tail-truncation, multi-modal segmentation, and speech-text pre-training.

BLEU	25.76	27.15	27.42	27.43	27.56	27.93

Table 7: Numeric Results for Figure 6.

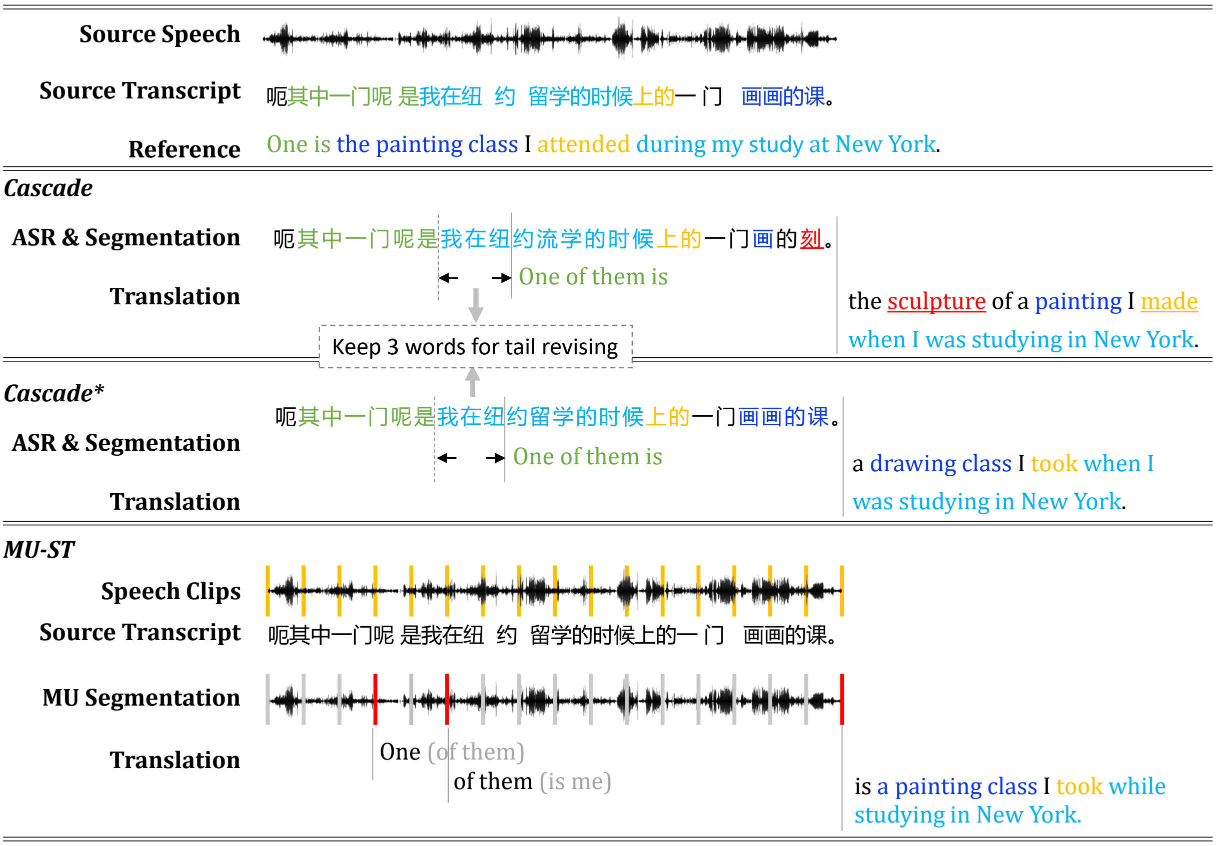

Figure 7: A Chinese-English example in the BSTC test set. In the ASR result of *Cascade*, two characters are incorrectly recognized: "留学"("study abroad")→"流学" ("rheological") and "画画的课" ("painting class") →"画画的刻" ("sculpture of painting"), which makes the translation distort the meaning of the source speech, see the underlined translation. On the contrary, our proposed *MU-ST* avoids the error propagated from ASR by end-to-end training and generates a correct translation. Moreover, both the cascade methods keep revising some tail words for better accuracy, but causing translation delay, denoted by the 3-words lagging. *MU-ST* remove this extra delay through end-to-end speech translation.

Can Pre-trained Language Models Interpret Similes as Smart as Human?

Abstract

Simile interpretation is a crucial task in natural language processing. Nowadays, pre-trained language models (PLMs) have achieved state-of-the-art performance on many tasks. However, it remains under-explored whether PLMs can interpret similes or not. In this paper, we investigate the ability of PLMs in simile interpretation by designing a novel task named Simile Property Probing, i.e., to let the PLMs infer the shared properties of similes. We construct our simile property probing datasets from both general textual corpora and human-designed questions, containing 1,633 examples covering seven main categories. Our empirical study based on the constructed datasets shows that PLMs can infer similes' shared properties while still underperforming humans. To bridge the gap with human performance, we additionally design a knowledge-enhanced training objective by incorporating the simile knowledge into PLMs via knowledge embedding methods. Our method results in a gain of 8.58% in the probing task and 1.37% in the downstream task of sentiment classification. The datasets and code are publicly available at https://github.com/Abbey4799/PLMs-Interpret-Simile.

1 Introduction

A simile is a figure of speech comparing two fundamentally different entities via shared properties (Paul, 1970). There are two types of similes as illustrated in Figure 1, *closed* similes explicitly reveal the shared properties between the topic entity and the vehicle entity, such as the property *"slow"* shared by *"lady"* and *"snail"* in the sentence *"The old lady walks as slow as a snail"*; while *open* similes do not state the shared property such as the sentence *"The old lady walks like a snail"*. Similes play a vital role in human expression to make literal utterances more vivid and graspable and are widely used in the corpus of various domains (Liu et al., 2018; Chakrabarty et al., 2020a; Zhang et al., 2020). It is estimated that over 30% of the comparisons can be regarded as similes in product reviews (Niculae and Danescu-Niculescu-Mizil, 2014).

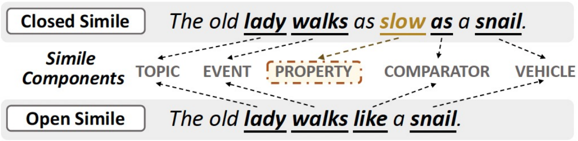

Figure 1: Examples of two types of similes. Whether the component *property* is stated determines the type of simile.

Simile interpretation is a crucial task in natural language processing (Veale and Hao, 2007; Qadir et al., 2016; Chakrabarty et al., 2021a), which can assist several downstream tasks such as understanding more sophisticated figurative language (Veale and Hao, 2007) and sentiment analysis (Niculae and Danescu-Niculescu-Mizil, 2014; Qadir et al., 2015). Take the simile *"the lawyer is like a shark"* for an example. Although all words in this simile are neutral, this simile expresses a negative affect since *"lawyer"* and *"shark"* share the negative property *"aggressive"*.

In the past few years, large pre-trained language models (PLMs) have achieved state-of-the-art performance on many natural language processing tasks (Devlin et al., 2018; Liu et al., 2019b). Recent studies suggest that PLMs have possessed various kinds of knowledge into contextual representations (Goldberg, 2019; Petroni et al., 2019; Lin et al., 2019; Cui et al., 2021). However, the ability of PLMs to interpret similes remains under-explored. Although some recent work (Chakrabarty et al., 2021a) studies the ability of PLMs in choosing or generating the plausible continuations in narratives, this way cannot fully reveal the ability of PLMs to interpret similes.

In this paper, we propose to investigate the abil-

Table 1: Percentage and examples for our simile probes of different categories. The option marked with "___" indicates the correct answer. The italicized words one by one in each sentence are the topic, masked property, and vehicle, respectively.

ity of PLMs in simile interpretation by designing a novel task named as *Simile Property Probing*, i.e., to let the PLMs infer the shared properties of similes. Specifically, we design a particular masked-word-prediction probing task in the form of multiple-choice questions. This probe masks the explicit property of a *closed* simile and then lets the PLMs discriminate it from three distractors. To make the questions convincing and challenging, the distractors should be not only *true-negative* as they would introduce logical errors once they are filled in the sentence, but also *challenging* as they are semantically close to the correct answer. To achieve this, we propose to obtain some similar properties of the golden one from ConceptNet (Liu and Singh, 2004) and COMET (Bosselut et al., 2019), from which we select the three best distractors according to their proximity to the golden property in the feature space. From two different types of data sources: textual corpus collection and human-designed questions, we collect a total of 1,633 probes with various usage frequencies and context diversities, covering seven categories as listed in Table 1.

Based on our designed task, we evaluate the ability of BERT (Devlin et al., 2018) and RoBERTa (Liu et al., 2019b) to infer the shared properties of similes. We perform an empirical evaluation in two settings: (1) zero-shot, where the models are off-the-shelf; (2) fine-tuned, where the models are fine-tuned with MLM objective via masking properties. We observe that PLMs have been able to infer properties of similes in the pre-training stage and the ability can be further enhanced by fine-tuning. However, fine-tuned PLMs still perform worse than humans. Moreover, we find that the simile components *vehicle* and *topic* contribute the most when inferring the properties.

Inspired by the sufficient hints offered by the components *vehicle* and *topic* in our empirical study, we propose a knowledge-enhanced training objective to further bridge the gap with human performance. Considering *property* (p) as the **relation** between *topic* (t) and *vehicle* (v), we design a simile knowledge embedding objective function following conventional knowledge embedding methods (Bordes et al., 2013) to incorporate the simile knowledge *(t,p,v)* into PLMs. To integrate simile knowledge and language understanding into PLMs, we jointly optimize the knowledge embedding objective and the MLM objective in our design. Overall, the knowledge-enhanced objective shows effectiveness in our probing task and the downstream task of sentiment classification.

To summarize, our contributions are three-fold: (1) To our best knowledge, we are the first to systematically evaluate the ability of PLMs in interpreting similes via a proposed novel simile property probing task. (2) We construct simile property probing datasets from both general textual corpora and human-designed questions, and the probing datasets contain 1,633 examples covering seven main categories of similes. (3) We also propose a novel knowledge-enhanced training objective by complementing the MLM objective with the knowledge embedding objective. This method gains 8.58% in the probing task and 1.37% in the downstream task of sentiment classification.

2 Preliminaries on Simile

A sentence of simile generally consists of five major components (Hanks, 2013; Niculae and Danescu-Niculescu-Mizil, 2014), where four are necessary and the remaining one is optional. The four explicit components are as follows: (1) **topic (or tenor)**: the subject of the comparison acting as

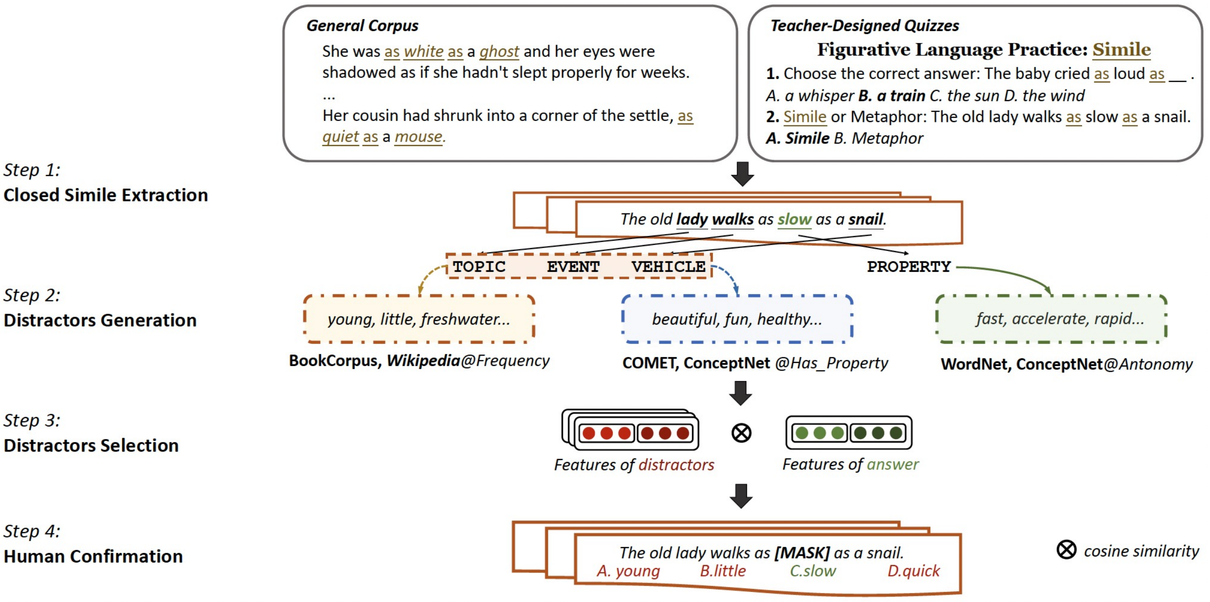

Figure 2: A process for designing our simile property probing task. In Step 1, we collect closed similes from two different sources. In Step 2, according to four important components in each simile, we generate distractor candidates with three strategies. In Step 3, we adopt cosine similarity to select more challenging distractors. In Step 4, we ask human annotators to ensure the quality and obtain our final probing datasets.

source domain; (2) **vehicle**: the object of the comparison acting as target domain; (3) **event**: the predicate indicating act or state; (4) **comparator**: the trigger word of a simile such as *as* or *like*. The optional component **property** reveals the shared characteristics between the topic and the vehicle. There are two types of similes depending on whether the property is explicit or implicit (Beardsley, 1981). The similes which mention the property directly are named as the *closed* similes, while the others are *open* similes, as shown in Figure 1.

3 The Simile Property Probing Task

3.1 Task Formulation

To estimate the ability of PLMs in simile interpretation, we design a particular *Simile Property Probing* task, which masks the explicit property of a *closed* simile, and then lets the PLMs discriminate it among four candidates. Considering that the shared properties between topic and vehicle may not be unique (Lacroix et al., 2005), we specifically design a multiple-choice question answering task (with only one correct answer) rather than a cloze task to probe the ability of PLMs to infer properties of similes, since the latter one may result in multiple correct answers.

Formally, given a simile text sequence $S = (w_1, w_2, ..., w_{i-1}, \texttt{[MASK]}, w_{i+1}, ..., w_N)$, where the shared property w_i between the topic and vehicle is masked, the probing task requires the PLMs to find the correct property from four options, where the other three options are hard distractors.

3.2 Probing Data Collection

We construct datasets for the proposed probing task in four steps. The overview of our probing data collection process is described in Figure 2.

3.2.1 Data Sources

We construct our datasets from two different sources to detect the capability of PLMs from two perspectives: textual corpus collection and human-designed questions. To avoid laborious human labeling on the implicit properties of open similes, we collect closed similes with explicit properties.

General Corpus. Following (Hanks, 2005; Niculae and Yaneva, 2013), we adopt two general corpora, British National Corpus (BNC)[1] and iWeb[2]. To identify closed similes, we extract the sentences matching the syntax *as ADJ as (a, an, the) NOUN*. Through syntactic pattern matching, we finally collect 1,917 sentences.

Teacher-Designed Quizzes. Questions about similes designed by teachers from educational resources are ideal sources for assessing the ability to understand similes. Hence, we choose Quizizz[3], an

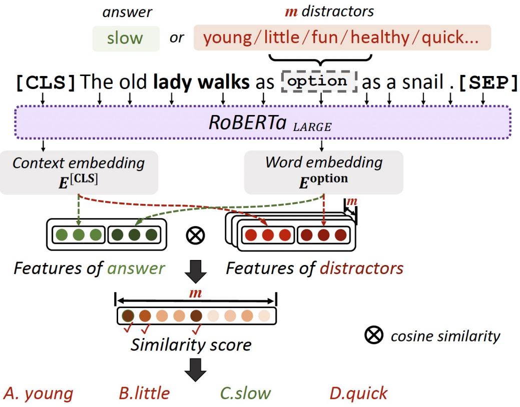

Figure 3: Illustration of the distractor selection method.

Dataset	General Corpus	Quizzes
#Sentence	775	858
#Unique *topic* concept	415	366
#Unique *property* concept	280	160
#Unique *vehicle* concept	522	250
#Unique *event* concept	147	66
#Unique *topic-vehicle* pair	743	684
#Unique *topic-property-vehicle* pair	751	701
Maximum sentence length	98	44
Average sentence length	25.80	12.69
Minimum sentence length	7	7
@Start	34.32%	20.40%
@Middle	43.23%	63.29%
@End	22.45%	16.32%

Table 2: Statistics of our simile property probing datasets. @ denotes the position of the simile in the given sentence.

emerging learning platform founded in 2015. On this platform, users can create quizzes on a specific topic as teachers to assess students' understanding of related knowledge. We collect a set of quizzes with titles concerning similes and extract the complete closed simile sentences from the questions and answers in these quizzes. Finally, we retrieve 875 complete closed similes from 1,235 quizzes.

To assure the quality of our constructed datasets and prepare for further analysis, three annotators are required to decide whether the extracted sentences are similes or not, and annotate their corresponding simile components. The inter-annotator agreement on identifying similes is 0.77 using Fleiss' Kappa score (Fleiss, 1971). All the properties in our datasets are single-token by replacing multi-token properties with their single-token synonyms in the knowledge base WordNet (Miller, 1995) and ConceptNet (Liu and Singh, 2004).

3.2.2 Distractor Design

To make our probes convincing, three distractors are designed against the original property in each simile with two criteria (Haladyna et al., 2002; Ren and Zhu, 2020): *true-negative* and *challenging*. We argue that well-designed distractors should be illogical when filled into the questions *(true-negative)* while being semantically related to the correct answer *(challenging)*. Our distractor design mainly involves three phases: 1) distractor generation; 2) distractor selection; 3) Human Confirmation.

Distractor Generation. To meet the requirement of *challenging*, we generate distractor candidates from the four semantic-related components of a simile, i.e., topic, vehicle, event, and property. Given the original property, we harvest its antonyms from the knowledge base WordNet and ConceptNet. With regard to three other components, we extract their properties from two sources as follows. Given a component, we utilize the *HasProperty* relation from ConceptNet (Liu and Singh, 2004) and COMET (Bosselut et al., 2019) to retrieve the property. Moreover, we rank the adjectives or adverbs concerning[4] each component in Wikipedia and BookCorpus corpus[5] by frequency and select the top ten candidates with a frequency of more than one.

Distractor Selection. To select the most *challenging* distractors from the generated distractor candidates, we propose to measure the similarity between the original sentence with the correct property and the sentence with a distractor. Intuitively, the more similar the two sentences, the more challenging the distractor. An example of the distractor selection process is depicted in Figure 3. Given the original sentence or the new sentence replacing the correct property with a distractor, we first utilize RoBERTa$_{\text{LARGE}}$ to extract two types of features. One feature is context embedding, which is the sentence embedding of `[CLS]`, while the other feature is word embedding, which is the token embedding of the answer or distractors. We then concatenate the embeddings of the two features to compute the cosine similarity between sentences with the answer and a distractor. Finally, we select the top 3 distractors with the highest similarities.

Human Confirmation. To ensure the distractors are *true-negative*, three human annotators are asked to label each selected distractor. If more than two annotators are uncertain about its correctness, we replace it with another suitable candidate.

---

[4] We adopt dependency parsing via the StanfordNLP tool to find adjectives and adverbs related to components.

[5] https://huggingface.co/datasets/

3.2.3 Statistics of the Datasets

Table 2 presents the statistics of our constructed datasets. We count unique components and component pairs to present the usage frequencies of similes. The length of the sentences in each dataset indicates the diversities of context. Additionally, we analyze the distribution of the position of simile in the sentences in each dataset, where *start*, *middle* and *end* correspond to the positions of the three equally divided parts of each sentence. We also investigate the categories covered by our datasets. The results and details about the category classification are provided in Appendix C. Overall, the Quizzes dataset provides similes commonly expressed by people, while the General Corpus dataset presents similes with more diverse contexts.

3.3 Supervision for Fine-Tuning PLMs

Besides evaluating the ability of PLMs in the zero-shot setting where the models are off-the-shelf, we also study whether the performance could be improved through fine-tuning with the MLM objective via masking properties. To achieve this, we collect training data from Standardized Project Gutenberg Corpus[6] (SPGC) (Gerlach and Font-Clos, 2020). SPGC is a 3 billion words corpus collected from about 60 thousand eBooks. We extract similes via matching the syntactic pattern *(Noun ... as ADJ as ... NOUN)* and end up with 4,510 sentences. Additionally, we adopt dependency parsing[7] to automatically annotate the simile components of each sentence without human labor.

4 Empirical Study on PLMs

In this section, we first conduct a set of experiments to probe the ability of PLMs to infer properties in similes and then evaluate the influence of each component on the model performance.

4.1 Ability to Infer Shared Properties

4.1.1 Experiment Set-up

To disentangle what is captured by the original representations and what is introduced from fine-tuning stage, we apply two different types of settings: (1) zero-shot; (2) fine-tuning. In our first setting, we use BERT and RoBERTa with pre-trained masked-word-prediction heads to perform our probing task. In the second setting, we utilize the MLM training objective inherited from PLMs to fine-tune the models. We replace the property of each simile with the special token `[MASK]` in our constructed supervised datasets (Section 3.3) and ask models to recover the original property. The experimental details are provided in the Appendix B.

Setting	Models	General Corpus	Quizzes	Gain
	ConScore (Zheng et al., 2019)	27.48	34.85	-
	Meta4meaning (Xiao et al., 2016)	27.74	47.44	-
	EMB (Qadir et al., 2016)	28.27	47.90	-
	MIUWE (Bar et al., 2020)	30.97	53.85	-
Zero-Shot	**BERT**$_{\text{BASE}}$	64.13	74.36	-
	BERT$_{\text{LARGE}}$	72.39	83.22	-
	RoBERTa$_{\text{BASE}}$	69.55	82.87	-
	RoBERTa$_{\text{LARGE}}$	78.97	87.41	-
Fine-tuned	**MLM-BERT**$_{\text{BASE}}$	67.74	82.05	+5.65
	MLM-BERT$_{\text{LARGE}}$	73.85	84.58	+1.40
	MLM-RoBERTa$_{\text{BASE}}$	70.58	84.69	+1.43
	MLM-RoBERTa$_{\text{LARGE}}$	**78.97**	**88.97**	+0.78
	Human Performance	87.60	93.60	-

Table 3: Accuracy of different models in our simile property probing task.

We mainly compare the model accuracy of PLMs with the following baselines: (1) **EMB** (Qadir et al., 2016): It obtains the composite simile vector by performing an element-wise sum of the word embedding for the vehicle and event, then selects the answer with the shortest cosine distance from the composite vector. (2) **Meta4meaning** (Xiao et al., 2016) : This method prefers the properties which are strongly associated with both topic and vehicle. It also prefers the properties that are more relevant to the vehicle than to the topic. The association is measured by statistical significance. (3) **ConScore** (Zheng et al., 2019) : It suggests that better properties would have a smaller and balanced distance to the topic and vehicle in the word embedding space. (4) **MIUWE** (Bar et al., 2020) : The ranking method assigns each property a list of scores, including the statistical co-occurrences and similarity to the collocations of the topic and vehicle. The baselines above mainly consider the statistical information and embedding similarities between the properties and the simile components. The other baseline is human performance. We sample 250 random questions from both datasets, and for each question, we gather answers from three people. We take the majority vote as the human performance of our probing task and ensure that three annotators agree on the questions that they gave completely different annotation results.

4.1.2 Results

The accuracies of different methods under two different settings on our datasets are listed in Table 3,

---

[6] https://github.com/pgcorpus/gutenberg/

[7] https://stanfordnlp.github.io/CoreNLP/

where the last column represents the average absolute gains of each PLM after fine-tuning with the MLM objective. All the results of our experiments are averaged over three random seeds. First of all, the prediction accuracies of both BERT and RoBERTa in the zero-shot setting are much higher than the baselines only considering the statistical information and embedding similarities between simile components. This phenomenon indicates that the knowledge learning from the pre-train stage can help infer the simile properties. Moreover, the performance can be further improved by training with the MLM objective, demonstrating that the fine-tuning phase with the supervised dataset can introduce related knowledge about similes. However, models still underperform humans by several accuracy points, leaving room for improvement in our probing task.

Overall, all the models perform better on Quizzes Dataset than on General Corpus Dataset, indicating that more diverse contexts increase the difficulty of inferring the shared properties. Also, RoBERTa consistently outperforms BERT, likely due to a larger pre-training corpus containing more similes. More complementary results are provided in the Appendix A.1.

4.2 Influence of Important Components

4.2.1 Experiment Set-up

Due to the high performance of off-the-shelf PLMs, we are interested in the contributions of each component to infer shared properties in the zero-shot setting. First, the information of each component is hidden through a certain strategy. Specifically, for *topic*, *vehicle* and *comparator*, we replace their tokens with a special token `[UNK]` which means unknown. With regard to *event*, we convert it into a suitable copula, such as "am" and "is", to ensure the integrity of syntax. Furthermore, we also set up a baseline by randomly replacing a token with `[UNK]` in the context. Examples corresponding to all settings are shown in Table 8 in the Appendix B. We finally report the model accuracy and declined absolute accuracy after hiding the information of each component.

4.2.2 Results

The results in Table 4 show varying degrees of the decline of all settings. If the model's performance decreases more, it means that the influence of the component is more significant than others. Three major components (i.e., vehicle, topic and comparator) obtain higher declined absolute accuracy than random token, which demonstrates that the information of these simile components is more valuable than other words to infer the shared properties. Among all the components, removing the *comparator* may cause the most significant performance drop. This result is mostly because PLMs cannot identify the sentence as a simile without an obvious indicator. When it comes to the remaining 3 components, *vehicle* contributes the most, followed by *topic*. Hence, we argue that it may be beneficial to explicitly leverage both the information of *vehicle* and *topic* to infer the properties.

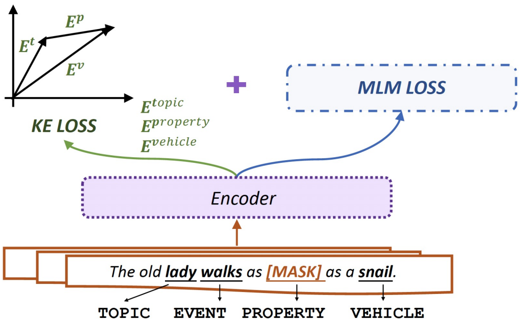

Figure 4: An overview of our objective function design

5 Enhancing PLMs with Knowledge

5.1 Knowledge-enhanced Objective

Benefiting from the result that topic and vehicle are the two most essential components for predicting the shared properties of similes, we catch an insight that *property* can be seen as the **relation** between *topic* and *vehicle* following a set of knowledge embedding (KE) methods (Bordes et al., 2013; Wang et al., 2014; Ji et al., 2015).

To integrate the insight mentioned above into our training procedure, we design an objective function as shown in Figure 4. Inspired by triplets representing the relational facts, we can also extract the topic, property, and vehicle from a simile as a triplet (t, p, v). The distance between topic and vehicle in the embedding space represents the plausibility of property. The plausibility can be measured by scoring functions (Bordes et al., 2013; Wang et al., 2014; Ji et al., 2015). To this end, we follow the scoring function from TransE (Bordes et al., 2013) and define the following Mean Square Error (MSE) loss as our KE loss:

$$\mathcal{L}_{\text{KE}} = \text{MSE}(E^t + E^p, E^v) \tag{1}$$

Datasets	**Models**	**Topic**	**Vehicle**	**Event**	**Comparator**	**Random**
General Corpus	**BERT**$_{\textbf{BASE}}$	59.87*(-04.26)*	54.58*(-09.55)*	62.84*(-01.29)*	46.32*(-17.81)*	63.05*(-01.08)*

RoBERTa$_{\textbf{LARGE}}$	88.84	89.08	**90.21**

Table 6: Accuracy of PLMs with three settings in the downstream task of sentiment classification.

where E^t, E^p, E^v are the representations of topic, property and vehicle encoded by PLMs. We also try more advanced methods such as TransH (Wang et al., 2014) and TransD (Ji et al., 2015) for the knowledge embedding objective, and their results are presented in Table 7 in the Appendix A.2.

Finally, our training procedure is to optimize MLM loss and KE loss jointly:

$$\mathcal{L}_{\text{Ours}} = \alpha\mathcal{L}_{\text{KE}} + \mathcal{L}_{\text{MLM}} \qquad (2)$$

where α is a hyperparameter used to balance two objective functions.

5.2 Results

Table 5 presents the performance of the models fine-tuned with the MLM objective and our knowledge-enhanced objective on the two datasets, where the last column shows the performance gains brought by our improvement to the training objective. Overall, each model trained with our knowledge-enhanced objective outperforms the one trained with the MLM objective on both datasets, demonstrating the effectiveness of our objective in the probing task.

For the Quizzes dataset, BERT achieves more performance gains than RoBERTa does, which is probably because RoBERTa has better modeled the relationship among *topic*, *property* and *vehicle* in the similes with simple syntactic structure during fine-tuning with the MLM objective. For the General Corpus dataset, the BASE version of models tends to yield higher performance improvements, probably because the models with larger parameter sizes can better capture the relationship among simile components in the similes with more diverse contexts when fine-tuning with the MLM objective.

5.3 Experiments with Downstream Tasks

Similes generally transmit a positive or negative view due to the shared properties (Fishelov, 2007; Li et al., 2012; Qadir et al., 2015). Taking the simile *"the lawyer is like a shark"* as an example, the implicit shared property *"aggressive"* between *"lawyer"* and *"shark"* indicates the negative polarity. Therefore, we design a sentiment polarity downstream task to validate the improvement of our method to infer shared properties.

Our experiments are based on the Amazon reviews dataset[8] which provides reviews and their corresponding sentiment ratings. Following (Mudinas et al., 2012; Haque et al., 2018), we first process the dataset into a binary sentiment classification task by defining the 1-star and 2-star ratings as negative, the 4-star, and 5-star ratings as positive, while excluding the 3-star neutral ratings. To further address the label imbalance problem, we then sample the positive and negative reviews at 1:1. The final dataset consists of 5,023 reviews and is split into a ratio of 6:2:2 for the train/dev/test set.

When performing the sentiment classification task, we only update the parameters of the multi-

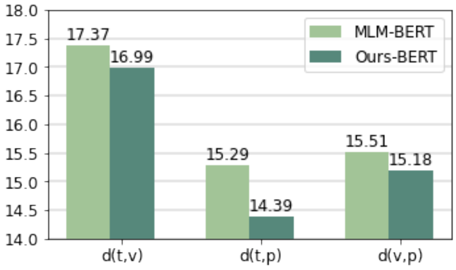

Figure 5: The average semantic distances between the representations of topic(t), property(p), and vehicle(v) in the last layer's hidden state given by BERT$_{\text{BASE}}$ with MLM and our objectives.

layer perceptron (MLP) classifiers on top of PLM's contextualized representation. The parameters of PLM are fixed and from three settings: (1) zero-shot; (2) fine-tuned with the MLM objective in the probing task; (3) fine-tuned with the knowledge-enhanced objective in the probing task. The results are shown in the Table 6. First of all, fine-tuning with the MLM objective improves the performance of all models in the sentiment classification task, demonstrating that improving models' ability to infer the properties of similes can enhance models' understanding of the sentiment polarity. Moreover, the performance is further improved by our knowledge-enhanced objective, especially for RoBERTa whose main gains are mostly contributed by our additional knowledge embedding objective. This indicates the effectiveness of our knowledge-enhanced objective in the downstream task of sentiment analysis.

5.4 Analysis

Furthermore, we investigate the mechanism of how knowledge-enhanced objective brings improvement. We first calculate the L2 distance between the representations in the last hidden states of each pair of components. The results are shown in Figure 5. In all pairs, the distance given by our objective is generally shorter than MLM-BERT, which indicates that modeling the relationships among the three important components is efficient to enhance the model performance.

Specifically, we visualize the final layer representation of a simile into two-dimensional spaces via Principal Component Analysis (PCA) (Pearson, 1901) in Figure 6. In both MLM and our objective, the models are required to fill in the masked token in the same simile sentence. The model fine-tuned with the MLM objective predicts wrongly, while our fine-tuned model predicts correctly. We find that our representations of the three components are closer to each other.

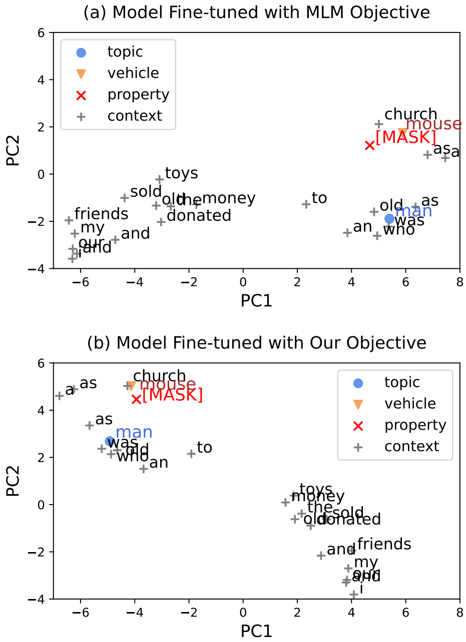

Figure 6: PCA representations of tokens in the last layer's hidden state given by BERT$_{\text{BASE}}$ with MLM and our objectives.

6 Related Work

Simile Processing. Simile processing mainly involves 3 fields: simile detection, simile generation, and simile interpretation. The bulk of work in similes mainly focuses on identifying similes and their components (Niculae, 2013; Niculae and Danescu-Niculescu-Mizil, 2014; Liu et al., 2018; Zeng et al., 2020). Recent years have witnessed a growth of work to transfer literal sentences to similes (Zhang et al., 2020; Chakrabarty et al., 2020b). (Chakrabarty et al., 2021b) study the ability of PLMs to recognize textual entailment related to similes. With regard to simile interpretation, (Qadir et al., 2016; Xiao et al., 2016; Bar et al., 2020; Zheng et al., 2019) rank the properties by the statistical co-occurrence and embedding similarities with other simile components. (Chakrabarty et al., 2021a) interpret similes by choosing or generating continuation for narratives via PLMs. Different from these works, we investigate the ability of PLMs to infer shared properties of similes.

Probing Tasks for PLMs. Many studies investigate whether PLMs encode knowledge in their contextual representations by designing probing tasks. Early studies mainly focus on the linguistic knowledge captured by PLMs (Liu et al., 2019a; Tenney et al., 2019). (Petroni et al., 2019) first propose a word prediction task to probe factual knowledge stored in PLMs. Similar methods are utilized to evaluate various commonsense knowledge, such as symbolic reasoning ability (Talmor et al., 2020; Zhou et al., 2020), numerical commonsense knowledge (Lin et al., 2020), properties associated with concepts (Weir et al., 2020). To our best knowledge, we are the first work to investigate the ability of PLMs to interpret similes by proposing a simile property probing task.

Enhance PLMs via Knowledge Regularization. Recently, many researchers integrate external knowledge with PLMs by complementing the MLM objective with an auxiliary knowledge-based objective. For example, there are works that introduce span-boundary objective for span-level prediction (Joshi et al., 2020), copy-based training objective for mention reference prediction (Ye et al., 2020), knowledge embedding objective for factual knowledge (Wang et al., 2021) and arithmetic relationships of linguistic units for universal language representation (Li and Zhao, 2021). Different from these works, we incorporate simile knowledge with the training objective by modeling the relationship between the salient components of similes.

7 Conclusion

In this work, we are the first to investigate the ability of PLMs in simile interpretation via a proposed novel simile property probing task. We construct two multi-choice probing datasets covering two data sources. By conducting a series of empirical experiments, we prove that PLMs exhibit the ability to infer simile properties in the pre-training stage and further induce more related knowledge during the fine-tuning stage, but there is still a gap between PLMs and humans in this task. Furthermore, we propose a knowledge-enhanced training objective to bridge the gap, which shows effectiveness in the probing task and the downstream task of sentiment classification. In future work, we are interested in exploring the interpretation of more sophisticated figurative language, such as metaphor or analogy.

Acknowledgements

We would like to thank anonymous reviews for their helpful comments and suggestions. Also, thanks to Jingping Liu, Leyang Cui for their insightful feedback that helped improve the paper. We also thank Botian Jiang, Shuang Li for supporting our data collection. This research was supported by the National Key Research and Development Project (No. 2020AAA0109302), National Natural Science Foundation of China (No. 62072323), Shanghai Science and Technology Innovation Action Plan (No. 19511120400), Shanghai Municipal Science and Technology Major Project (No. 2021SHZDZX0103).

Ethical Consideration

We provide details of our work to address potential ethical concerns. In our work, we propose a simile property probing task and construct probing datasets from both general textual corpora and human-designed questions. First of all, all the data sources used in the data collection process are publicly available. Specifically, we follow the robots.txt[9] to respect the copyright when we collect similes from the learning platform Quizizz (Sec. 3.2.1). Moreover, there are three steps involving human annotation to ensure the quality of the datasets: simile and simile components recognition (Sec. 3.2.1), human confirmation for distractors (Sec. 3.2.2), and human performance (Sec. 4.1). To ensure the quality of annotation, all the annotators do not participate in our probing data collection, and they always label a small set of 50 examples to reach an agreement on the labeling criteria before the formal labeling. We protect the privacy rights of annotators and pay them above the local minimum wage.

A Additional Experimental Results

A.1 Performance on Different Categories

We investigate whether PLMs are better at inferring the properties of certain categories. Figure 7 presents the performance of the strongest version from each group of models for each category in the zero-shot setting. We found that models perform significantly well when inferring the color, which is probably because each object often has a specific color which in many cases can be inferred without context. However, when it comes to the properties requiring an understanding of the context, such as the personality and qualities *(intelligent, brave)*, temporal properties *(ancient, swift)* and short-term state *(busy, safe)*, models tend to have relatively lower accuracy.

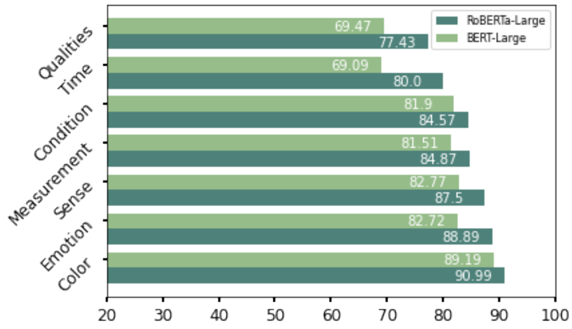

Figure 7: The average accuracy for each category in the zero-shot setting. We select the strongest version from each group of models.

A.2 Comparison of Knowledge Embedding Methods

We also exploit the effects of different knowledge embedding methods when designing our knowledge-enhanced objective. Table 7 shows the performance given by the objectives applying different knowledge embedding methods. First of all, complementing the MLM objective with our knowledge embedding methods generally improves the performance, demonstrating the effectiveness of our approach to enhancing PLMs with simile knowledge. Moreover, following the scoring function from TransE (Bordes et al., 2013) brings the best result in most cases, which indicates that the knowledge embedding methods of simple design are sufficient to incorporate simile knowledge into PLMs in our objective design.

Datasets	Models	$\mathcal{L}_{\text{MLM}}$	$\mathcal{L}_{\text{Ours}}$	$\mathcal{L}_{\text{TransH}}$	$\mathcal{L}_{\text{TransD}}$
General Corpus	**BERT$_{\text{BASE}}$**	67.74	69.25	**69.72**	68.38
	BERT$_{\text{LARGE}}$	73.85	74.07	**74.33**	73.85
	RoBERTa$_{\text{BASE}}$	70.58	**71.74**	71.18	70.97
	RoBERTa$_{\text{LARGE}}$	78.97	78.97	78.97	78.97
Quizzes	**BERT$_{\text{BASE}}$**	82.05	**82.94**	82.25	82.05

Table 7: Comparison of different knowledge embedding methods when designing the knowledge-enhanced objective in our probing task.

B Experimental Details

We introduce details about the implementation of our experiments. The implementations of all the PLMs in our paper are based on the HuggingFace Transformers[10]. During fine-tuning for the probing task, the experiments are run with batch sizes in {8, 16}, α in {3, 5, 10}, a max sequence length of 128, and a learning rate of 1e-5 for 10 epochs. For each model, we use the same hyper-parameters when applying different training objectives. During fine-tuning for the sentiment analysis task, we only update the parameters of the multi-layer perceptron (MLP) classifiers on top of PLM's contextualized representation. We set the learning rate in {2e-5, 3e-5, 4e-5}, batch size of 32, max sequence length of 128 and train for 200 epochs. Additionally, we present examples of the experimental setup for evaluating the influence of important components in Table 8.

Component	Sentence Example
Original	Johan runs as `[MASK]` as a deer to the toilet after he had some spicy gravy .
Topic	`[UNK]` runs as `[MASK]` as a deer to the toilet after he had some spicy gravy .
Vehicle	Johan runs as `[MASK]` as `[UNK]` to the toilet after he had some spicy gravy .
Event	Johan is as `[MASK]` as a deer to the toilet after he had some spicy gravy .
Comparator	Johan runs `[UNK]` `[MASK]` `[UNK]` a deer to the toilet after he had some spicy gravy .
Random	Johan runs as `[MASK]` as a deer `[UNK]` the toilet after he had some spicy gravy .

Table 8: Examples of experiment set-up for evaluating the influence of important components.

C Dataset Description

We introduce details about our classification of the categories of properties. We ask two annotators to label the category of each property in the given sentence and ensure that they agree on the questions that they gave completely different annotation

Abstract

With the development of biomedical language understanding benchmarks, Artificial Intelligence applications are widely used in the medical field. However, most benchmarks are limited to English, which makes it challenging to replicate many of the successes in English for other languages. To facilitate research in this direction, we collect real-world biomedical data and present the first Chinese Biomedical Language Understanding Evaluation (CBLUE) benchmark: a collection of natural language understanding tasks including named entity recognition, information extraction, clinical diagnosis normalization, and an associated online platform for model evaluation, comparison, and analysis. To establish evaluation on these tasks, we report empirical results with the current 11 pre-trained Chinese models, and experimental results show that state-of-the-art neural models perform far worse than the human ceiling[1]. Our benchmark is released at `https://tianchi.aliyun.com/dataset/dataDetail?dataId=95414&lang=en-us`.

1 Introduction

Artificial intelligence is gradually changing the landscape of healthcare, and biomedical research (Yu et al., 2018). With the fast advancement of biomedical datasets, biomedical natural language processing (BioNLP) has facilitated a broad range of applications such as biomedical text mining, which leverages textual data in Electronic Health Records (EHRs).

A key driving force behind such improvements and rapid iterations of models is the use of general evaluation datasets and benchmarks (Gijsbers et al., 2019). Pioneer benchmarks, such as BLURB (Gu et al., 2020), PubMedQA (Jin et al., 2019), and others, have provided us with the opportunity to conduct research on biomedical language understanding and developing real-world applications. Unfortunately, most of these benchmarks are developed in English, which makes the development of the associated machine intelligence Anglo-centric. Meanwhile, other languages, such as Chinese, have unique linguistic characteristics and categories that need to be considered. Even though Chinese speakers account for a quarter of the world population, there have been no existing Chinese biomedical language understanding evaluation benchmarks.

To address this issue and facilitate natural language processing studies in Chinese, we take the first step in introducing a comprehensive **C**hinese **B**iomedical **L**anguage **U**nderstanding **E**valuation (**CBLUE**) benchmark with eight biomedical language understanding tasks. These tasks include named entity recognition, information extraction, clinical diagnosis normalization, short text classification, question answering (in transfer learning setting), intent classification, semantic similarity, and so on. We evaluate several pre-trained Chinese language models on CBLUE and report their performance. The current models still perform by far worse than the standard of single-human perfor-

May 22-27, 2022

mance, leaving room for future improvements. We also conduct a comprehensive analysis using case studies to indicate the challenges and linguistic differences in Chinese biomedical language understanding. We intend to develop a universal GLUE-like open platform for the Chinese BioNLP community, and this work helps accelerate research in that direction. Overall, the main contributions of this study are as follows:

- We propose the first Chinese biomedical language understanding benchmark, an open-ended, community-driven project with diverse tasks. The proposed benchmark serves as a platform for the Chinese BioNLP community and encourages new dataset contributions.

- We report a systematic evaluation of 11 Chinese pre-trained language models to understand the challenges derived by these tasks. We release the source code of the baselines as a toolkit for future research purposes.

2 Related Work

Several benchmarks have been developed to evaluate general language understanding over the past few years. GLUE (Wang et al., 2019b) is one of the first frameworks developed as a formal challenge affording straightforward comparison between task-agnostic transfer learning techniques. SuperGLUE (Wang et al., 2019a), styled after GLUE, introduce a new set of more difficult language understanding datasets. Other similarly motivated benchmarks include DecaNLP (McCann et al., 2018), which recast a set of target tasks into a general question-answering format and prohibit task-specific parameters, and SentEval (Conneau and Kiela, 2018), which evaluate explicitly fixed-size sentence embeddings. Non-English benchmarks include RussianSuperGLUE (Shavrina et al., 2020) and CLUE (Xu et al., 2020), which is a community-driven benchmark with nine Chinese natural language understanding tasks. These benchmarks in the general domain provide a north star goal for researchers and are part of the reason we can confidently say we have made great strides in our field.

For BioNLP, many datasets and benchmarks have been proposed (Wang et al., 2020; Li et al., 2016; Wu et al., 2019) which promote the biomedical language understanding (Beltagy et al., 2019; Lewis et al., 2020; Lee et al., 2020). Tsatsaronis et al. (2015) propose biomedical language understanding datasets as well as a competition on large-scale biomedical semantic indexing and question answering. Jin et al. (2019) propose PubMedQA, a novel biomedical question answering dataset collected from PubMed abstracts. Pappas et al. (2018) propose BioRead, which is a publicly available cloze-style biomedical machine reading comprehension (MRC) dataset. Gu et al. (2020) create a leaderboard featuring the Biomedical Language Understanding & Reasoning Benchmark (BLURB). Unlike a general domain corpus, the annotation of a biomedical corpus needs expert intervention and is labor-intensive and time-consuming. Moreover, most of the benchmarks are based on English; ignoring other languages means that potentially valuable information may be lost, which can be helpful for generalization.

In this study, we focus on Chinese to fill the gap and aim to develop **the first Chinese biomedical language understanding benchmark**. Note that Chinese biomedical text is linguistically different from English and has its domain characteristics, necessitating an evaluation BioNLP benchmark designed explicitly for Chinese.

3 CBLUE Overview

3.1 Design Principle

CBLUE consists of 8 biomedical language understanding tasks.The task descriptions and statistics of CBLUE are shown Table 1. Unlike CLUE (Xu et al., 2020) as shown in Table 2, CBLUE has a diverse data source (the annotation is expensive), richer task setting, thus, more challenging for NLP models. We introduce the design principle of CBLUE as follows:

1) *Diverse tasks*: CBLUE contain widespread token-level, sequence-level, sequence-pair tasks.

2) *Variety of differently distributed data*: CBLUE collect data from various sources, including clinical trials, EHRs, medical forum, textbooks, and search engine logs with a real-world distribution.

3) *Quality control in long-term maintenance*: We asked domain experts (doctors from Class A tertiary hospitals) to annotate datasets and carefully review data to ensure data quality.

Dataset	Task	Train	Dev	Test	Metrics
CMeEE	NER	15,000	5,000	3,000	Micro F1
CMeIE	Information Extraction	14,339	3,585	4,482	Micro F1
CHIP-CDN	Diagnosis Normalization	6,000	2,000	10,192	Micro F1
CHIP-STS	Sentence Similarity	16,000	4,000	10,000	Macro F1
CHIP-CTC	Sentence Classification	22,962	7,682	10,000	Macro F1
KUAKE-QIC	Intent Classification	6,931	1,955	1,994	Accuracy
KUAKE-QTR	Query-Document Relevance	24,174	2,913	5,465	Accuracy
KUAKE-QQR	Query-Query Relevance	15,000	1,600	1,596	Accuracy

Table 1: Task descriptions and statistics in CBLUE. CMeEE and CMeIE are sequence labeling tasks. Others are single sentence or sentence pair classification tasks.

Benchmark	Language	Domain	Data Distribution	Label Distribution
CBLUE	Chinese	medical	long-tailed (CMeEE)	non-i.i.d (CHIP-STS)
CLUE	Chinese	general	uniform	i.i.d
BLURB	English	medical	uniform	i.i.d

Table 2: Difference between CBLUE, CLUE and BLURB. There are three major differences: a) CBLUE has a much more diverse task setting with different data sources in the biomedical domain including clinical trials, EHRs, medical forum, text books and search engine logs; b) CBLUE has a long-tailed distribution which is challenging; c) CBLUE contains a specific transfer learning scenario supported by the CHIP-STS dataset, in which the testing set has a different distribution from the training set.

3.2 Tasks

CMeEE For this task, the dataset is first released in CHIP2020[2] (Hongying et al., 2020). Given a pre-defined schema, the task is to identify and extract entities from the given sentence and classify them into nine categories: disease, clinical manifestations, drugs, medical equipment, medical procedures, body, medical examinations, microorganisms, and department.

CMeIE For this task, the dataset is also released in CHIP2020 (Guan et al., 2020). The goal of the task is to identify both entities and relations in a sentence following the schema constraints. There are 53 relations defined in the dataset, including 10 synonymous sub-relationships and 43 other sub-relationships.

CHIP-CDN For this task, the dataset is to standardize the terms from the final diagnoses of Chinese electronic medical records. Given the original phrase, the task is to normalize it to standard terminology based on the International Classification of Diseases (ICD-10) standard for Beijing Clinical Edition v601.

CHIP-CTC For this task, the dataset is to classify clinical trials eligibility criteria, which are fundamental guidelines of clinical trials defined to identify whether a subject meets a clinical trial or not (Zong et al., 2021). All text data are collected from the website of the Chinese Clinical Trial Registry (ChiCTR) [3], and a total of 44 categories are defined. The task is like text classification; although it is not a new task, studies and corpora for the Chinese clinical trial criterion are *still limited*, and we hope to promote future research for social benefits.

CHIP-STS For this task, the dataset is for sentence similarity in the non-i.i.d. (non-independent and identically distributed) setting. Specifically, the task aims to evaluate the generalization ability between disease types on Chinese disease questions and answer data. Given question pairs related to 5 different diseases (The disease types in the training and testing set are different), the task is to determine whether the semantics of the two sentences are similar.

KUAKE-QIC For this task, the dataset is for intent classification. Given search engine queries,

---

[2] `http://cips-chip.org.cn/`

[3] `http://chictr.org.cn/`

the task is to classify each of them into one of 11 medical intent categories defined in KUAKE-QIC. Those include diagnosis, etiology analysis, treatment plan, medical advice, test result analysis and others.

KUAKE-QTR For this task, the dataset is used to estimate the relevance of the title of a query document. Given a query (e.g., "Symptoms of vitamin B deficiency"), the task aims to find the relevant title (e.g., "The main manifestations of vitamin B deficiency").

KUAKE-QQR For this task, the dataset is used to evaluate the relevance of the content expressed in two queries. Similar to KUAKE-QTR, the task aims to estimate query-query relevance, which is an essential and challenging task in real-world search engines.

3.3 Data Collection

Since machine learning models are mostly data-driven, data plays a critical role, and it is pretty often in the form of a static dataset (Gebru et al., 2018). We collect data for different tasks from diverse sources, including clinical trials, EHRs, medical books, and search logs from real-world search engines. As biomedical data may contain private information such as the patient's name, age, and gender, **all collected datasets are anonymized and reviewed by the IRB committee of each data provider to preserve privacy.** We introduce the data collection details followingly.

Collection from Clinical Trials

Clinical trial eligibility criteria text is collected from ChiCTR, a non-profit organization that provides information about clinical trial registration for public research use. In each trial registry file, eligibility criteria text is organized as a paragraph in the inclusion criteria and exclusion criteria. Some meaningless texts are excluded, and the remaining texts are annotated to generate the CHIP-CTC dataset.

Collection from EHRs

We obtain the final diagnoses of the medical records from several Class A tertiary hospitals and sample a few diagnosis items from different medical departments to construct the CHIP-CDN dataset for research purposes. The diagnosis items are randomly sampled from the items which are not covered by the common medical synonyms dict. **No privacy information is involved in the final diagnoses.**

Collection from Medical Forum and Textbooks

Due to the COVID-19 pandemic, online consultation has become more and more popular via the Internet. To promote data diversity, we select the online questions by patients to build the CHIP-STS dataset. Note that most of the questions are chief complaints. To ensure the authority and practicability of the corpus, we also select medical textbooks of Pediatrics (Wang et al., 2018), Clinical Pediatrics (Shen and Gui, 2013) and Clinical Practice[4]. We collect data from these sources to construct the CMeIE and CMeEE datasets.

Collection from Search Engine Logs

We also collect search logs from real-world search engines like the Alibaba QUARK Search Engine[5]. First, we filter the search queries in the raw search logs by the medical tag to obtain candidate medical texts. Then, we sample the documents for each query with non-zero relevance scores (i.e., to determine if the document is relevant to the query). Specifically, we divide all the documents into three categories, namely high, middle, and tail documents, and then uniformly sample the data to guarantee diversity. We leverage the data from search logs to construct KUAKE-QTC, KUAKE-QTR, and KUAKE-QQR datasets.

3.4 Annotation

Each sample is annotated by **three to five domain experts**, and the annotation with the majority of votes is taken to estimate human performance. During the annotation phase, we add control questions to prevent dishonest behaviors by the domain experts. Consequently, we reject any annotations made by domain experts who fail in the training phase and do not adopt the results of those who achieved low performance on the control tasks. We maintain strict and high criteria for approval and review at least 10 random samples from each worker to decide whether to approve or reject all their HITs. We also calculate the average inter-rater agreement between annotators using Fleiss' Kappa scores (Fleiss, 1971), finding that five out of six annotations show almost perfect agreement ($\kappa = 0.9$).

(a) CMeEE (b) CMeIE

Figure 1: Analysis of the named entity recognition and information extraction datasets. (a) illustrates the entity (coarse-grained) distribution in CMeEE and the impact of data distribution on the model's performance. We set entity type Body with the maximum number of entities to 1.0, and others to the ratio of number or F1 score to Body. (b) shows the relation hierarchy in CMeIE.

3.5 Characteristics

Utility-preserving Anonymization Biomedical data may be considered as a breach in the privacy of individuals because they usually contain sensitive information. Thus, we conduct utility-preserving anonymization following (Lee et al., 2017) to anonymize the data before releasing the benchmark.

Real-world Distribution To promote the generalization of models, all the data in our CBLUE benchmark follow real-world distribution without up/downsampling. As shown in Figure 1(a), our dataset follows long-tail distribution following Zipf's law and will inevitably be long-tailed. However, long-tail distribution has no significant effect on performance. Further, some datasets, such as CMedIE, have label hierarchy with both coarse-grained and fine-grained relation labels, as shown in Figure 1(b).

Diverse Tasks Setting Our CBLUE benchmark includes eight diverse tasks, including named entity recognition, relation extraction, and single-sentence/sentence-pair classification. Besides the independent and i.i.d. scenarios, our CBLUE benchmark also contains a specific **transfer learning** scenario supported by the CHIP-STS dataset, in which the testing set has a different distribution from the training set.

3.6 Leaderboard

We provide a leaderboard for users to submit their own results on CBLUE. The evaluation system will give final scores for each task when users submit their prediction results. The platform offers 60 free GPU hours from Aliyun[6] to help researchers develop and train their models.

3.7 Distribution and Maintenance

Our CBLUE benchmark was released online on April 1, 2021. Up to now, more than **900** researchers have applied the dataset, and over **300** teams have submitted their model predictions to our platform, including medical institutions (Peking Union Medical College Hospital, etc.), universities (Tsinghua University, Zhejiang University, etc.), and AI companies (Baidu, Huawei, etc.). We will continue to maintain the benchmark by adding new tasks.

3.8 Reproducibility

To make it easier to use the CBLUE benchmark, we also offer a toolkit implemented in PyTorch (Paszke et al., 2019) for reproducibility. Our toolkit supports mainstream pre-trained models and a wide range of target tasks.

Table 3: Performance of baseline models on CBLUE benchmark.

4 Experiments

Baselines We conduct experiments with baselines based on different Chinese pre-trained language models. We add an additional output layer (e.g., MLP) for each CBLUE task and fine-tune the pre-trained models.

Models We evaluate CBLUE on the following public available Chinese pre-trained models:

- BERT-base (Devlin et al., 2018). We use the base model with 12 layers, 768 hidden layers, 12 heads, and 110 million parameters.
- BERT-wwm-ext-base (Cui et al., 2019). A Chinese pre-trained BERT model with whole word masking.
- RoBERTa-large (Liu et al., 2019). Compared with BERT, RoBERTa removes the next sentence prediction objective and dynamically changes the masking pattern applied to the training data.
- RoBERTa-wwm-ext-base/large. RoBERTa-wwm-ext is an efficient pre-trained model which integrates the advantages of RoBERTa and BERT-wwm.
- ALBERT-tiny/xxlarge (Lan et al., 2019). ALBERT is a pre-trained model with two objectives: Masked Language Modeling (MLM) and Sentence Ordering Prediction (SOP).
- ZEN (Diao et al., 2019). A BERT-based Chinese text encoder enhanced by N-gram representations, where different combinations of characters are considered during training.
- Mac-BERT-base/large (Cui et al., 2020). MacBERT is an improved BERT with novel MLM as a correction pre-training task.
- PCL-MedBERT[7]. A pre-trained medical language model proposed by the Peng Cheng Laboratory.

We implement all baselines with PyTorch (Paszke et al., 2019). All the training details can be found in the appendix.

4.1 Benchmark Results

We report the results of our baseline models on the CBLUE benchmark in Table 3. We notice that larger pre-trained models obtain better performance. Since Chinese text is composed of terminologies, carefully designed masking strategies may be helpful for representation learning. However, we observe that models which use whole word masking do not always yield better performance than others in some tasks, such as CTC, QIC, QTR, and QQR, indicating that tasks in our benchmark are challenging and more sophisticated technologies should be developed. Further, we find that ALBERT-tiny achieves comparable performance to base models in CDN, STS, QTR, and QQR tasks, illustrating that smaller models may also perform well in specific tasks. We think this is caused by the different distribution between pretraining corpus and Chinese medical text; thus, large PTLMs may not obtain satisfactory performance. Finally, we notice that PCL-MedBERT, which tends to be state-of-the-art in Chinese biomedical text processing tasks, and does not perform as well as we expected. This further demonstrates the difficulty

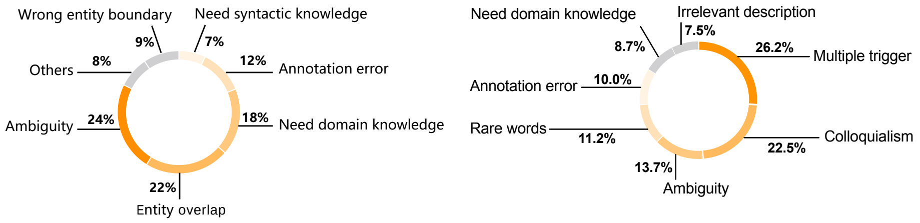
	best model	62.4	55.9	59.3	70.9	85.6	85.5	62.9	84.7

Table 4: Human performance of two-stage evaluation scores with the best-performed model. "avg" refers to the mean score from the three annotators. "majority" indicates the performance taken from the majority vote of amateur humans. Bold text denotes the best result among human and model prediction.



(a) Error Analysis in CMeEE

(b) Error Analysis in KUAKE-QIC

Figure 2: We conduct error analysis on datasets CMeEE and QIC. For CMeEE, we divide error cases into 6 categories, including ambiguity, need domain knowledge, entity overlap, wrong entity boundary, annotation error, and others (long sequence, rare words, etc.). For KUAKE-QIC, we divide error cases into 7 categories, including multiple triggers, colloquialism, ambiguity, rare words, annotation error, irrelevant description, and need domain knowledge.

of our benchmark, and contemporary models may find it difficult to quickly achieve outstanding performance.

4.2 Human Performance

For all of the tasks in CBLUE, we ask **human amateur annotators with no medical experience** to label instances from the testing set and compute the annotators' majority vote against the gold label annotated by specialists. Similar to SuperGLUE (Wang et al., 2019a), we first need to train the annotators before they work on the testing data. Annotators are asked to annotate some data from the development set; then, their annotations are validated against the gold standard. Annotators need to correct their annotation mistakes repeatedly so that they can master the specific tasks. Finally, they annotate instances from the testing data, and these annotations are used to compute the final human scores. The results are shown in Table 4 and the last row of Table 3. In all tasks, humans have better performance.

4.3 Case studies

We choose two datasets: CMeEE and KUAKE-QIC, a sequence labeling and classification task, respectively, to conduct case studies. As shown in Figure 2, we report the statistics of the proportion of various types of error cases[8]. For CMeEE, we notice that *entity overlap*[9], *ambiguity*[10], *need domain knowledge*[11], *annotation error*[12] are major reasons that result in the prediction failure. Furthermore, there exist many instances with *entity overlap*, which may lead to confusion for the named entity recognition task. While in the analysis for KUAKE-QIC, almost half of bad cases are due to *multiple triggers*[13] and *colloquialism*. *Colloquialism*[14] is natural in search queries, which means that some descriptions of the Chinese medical text are too simplified, colloquial, or inaccurate.

We show some cases on CMeEE in Table 5. In the second row, we notice that given the instance of "皮疹可因宿主产生特异性的抗毒素抗体

---

[8] See definitions of errors in the appendix.

[9] There exist multiple overlapping entities in the instance.

[10] The instance has a similar context but different meaning, which mislead the prediction.

[11] There exist biomedical terminologies in the instance which require domain knowledge to understand.

[12] The annotated label is wrong.

[13] There exist multiple indicative words which mislead the prediction.

[14] The instance is quite different from written language (e.g., with many abbreviations)

Sentence	**Word**	**Label**	**RO**	**MB**
血液生化分析的结果显示维生素B缺乏率约为12%～19%。	血液生化分析	Ite	Pro	Pro
The results of blood biochemical analysis show that vitamin B lack rate is about 12% to 19%.	blood biochemical analysis	Ite	Pro	Pro
皮疹可因宿主产生特异性的抗毒素抗体而减少。	抗毒素抗体	Bod	O	Bod
The rash can be reduced by the host producing specific anti-toxin antibodies.	anti-toxin antibodies	Bod	O	Bod
根据遗传物质的结构和功能改变的不同，可将遗传病分为五类：1.染色体病指染色体数目异常，或者染色体结构异常，包括缺失、易位、倒位等	缺失, 易位, 倒位	Sym, Sym, Sym	O	Sym, Sym, Sym
According to the structure and function of genetic material, genetic diseases are divided into five categories: 1. Chromosomal diseases refer to abnormal chromosome number or chromosome structure abnormalities, including deletions, translocations, inversions...	deletions, translocations, inversions	Sym, Sym, Sym	O	Sym, Sym, Sym

Table 5: Case studies in CMeEE. We evaluate roberta-wwm-ext and PCL-MedBERT on 3 sampled sentences, with their gold labels and model predictions. Ite (medical examination items), Pro (medical procedure), Bod (body), and Sym (clinical symptoms) are labeled for medical named words. O means that the model fails to extract the entity from sentences. RO=roberta-wwm-ext, MB=PCL-MedBERT.

Query	**Model**			**Gold**
	BERT	BERT-ext	MedBERT	
请问淋巴细胞比率偏高、中性细胞比率偏低有事吗?	病情诊断	病情诊断	指标解读	指标解读
Does it matter if the ratio of lymphocytes is high and the ratio of neutrophils is low?	Diagnosis	Diagnosis	Test results analysis	Test results analysis
咨询：请问小孩一般什么时候出水痘? Consultation: When do children usually get chickenpox?	其他 Other	其他 Other	其他 Other	疾病表述 Disease description
老人收缩压160，舒张压只有40多，是什么原因？怎么治疗?	病情诊断	病情诊断	病情诊断	治疗方案
The systolic blood pressure of the elderly is 160, and the diastolic blood pressure is only more than 40. What is the reason? How to treat?	Diagnosis	Diagnosis	Diagnosis	Treatment

Table 6: Case studies in KUAKE-QIC. We evaluate the performance of baselines with 3 sampled instances. The correlation between Query and Title is divided into 3 levels (0-2), which means ‘*poorly related or unrelated*’, ‘*related*’ and ‘*strongly related*’. BERT = BERT-base, BERT-ext = BERT-wwm-ext-base, MedBERT = PCL-MedBERT.

而减少 (*Rash can be reduced by the host producing specificanti-toxin antibodies.*)”, ROBERTA and PCL-MedBERT obtain different predictions. The reason is that there exist medical terms such as “抗毒素抗体 (*anti-toxin antibodies*)”. ROBERTA can not identify those tokens correctly, but PCL-MedBERT, pre-trained on the medical corpus, can successfully make it. Moreover, PCL-MedBERT can extract entities “缺失,易位,倒位 (*eletions, translocations, inversions*)” from the long sentences, which is challenging for other models.

We further show some cases on KUAKE-QIC in Table 6. In the first case, we notice that both BERT and BERT-ext fail to obtain the intent label of the query “请问淋巴细胞比率偏高、中性细胞比率偏低有事吗? (*Does it matter if the ratio of lymphocytes is high and the ratio of neutrophils is low?*)”, while MedBERT can obtain the correct prediction. Since “淋巴细胞比率 (*ratio of lymphocytes*)” and “中性细胞比率 (*ratio of neutrophils*)” are biomedical terms, and the general pre-trained language model has to leverage domain knowledge to understand those phrases.

As shown in Table 5 and Table 6, compared with other languages, the Chinese language is very colloquial even in medical texts. Furthermore, polysemy is prevalent in chinese language. The meaning of a word changes according to its tone, which usually causes confusion and difficulties for machine reading. In summary, we conclude that **tasks in CBLUE are not easy to solve since the Chinese language has unique characteristics**, and more robust models should be developed.

5 Conclusion

In this paper, we present a Chinese Biomedical Language Understanding Evaluation (CBLUE) benchmark. We evaluate 11 current language representation models on CBLUE and analyzed their results. The results illustrate the limited ability of state-of-the-art models to handle some of the more challenging tasks. In contrast to English benchmarks such as GLUE/SuperGLUE and BLURB, whose model performance already matches human performance, we observe that this is far from the truth for Chinese biomedical language understanding.

Acknowledgments

We want to express gratitude to the anonymous reviewers for their hard work and kind comments. This work is funded by Special Project of New Generation Artificial Intelligence of the Ministry of Science and Technology of China (2021ZD0113402), National Natural Science Foundations of China (61876052 and U1813215), National Natural Science Foundation of Guangdong, China (2019A1515011158), Strategic Emerging Industry Development Special Fund of Shenzhen (20200821174109001), Pilot Project in 5G + Health Application of Ministry of Industry and Information Technology & National Health Commission (5G + Luohu Hospital Group: an Attempt to New Health Management Styles of Residents), Zhengzhou collaborative innovation major special project (20XTZX11020), Zhejiang Provincial Natural Science Foundation of China (No. LGG22F030011), Ningbo Natural Science Foundation (2021J190), and Yongjiang Talent Introduction Programme (2021A-156-G).

Ethical Considerations

We collected all the data with authorization from the organization that owned the data and signed the agreement. We release the benchmark following the CC BY-NC 4.0 license. All collected datasets are anonymized and reviewed by the IRB committee of each data provider to preserve privacy. Since we collect data following real-world distribution, there may exist popularity bias that cannot be ignored.

A Broader Impact

The COVID-19 (coronavirus disease 2019) pandemic has had a significant impact on society, both because of the severe health effects of COVID-19 and the public health measures implemented to slow its spread. A lack of information fundamentally causes many difficulties experienced during the outbreak; attempts to address these needs caused an information overload for both researchers and the public. Biomedical natural language processing—the branch of artificial intelligence that interprets human language—can be applied to address many of the information needs making urgent by the COVID-19 pandemic. Unfortunately, most language benchmarks are in English, and no biomedical benchmark currently exists in Chinese. Our benchmark CBLUE, as the first Chinese biomedical language understanding benchmark, can serve as an open testbed for model evaluations to promote the advancement of this technology.

B Negative Impact

Although we ask domain experts and doctors to annotate all the corpus, there still exist some instances with wrong annotated labels. If a model was chosen based on numbers on the benchmark, this could cause real-world harm. Moreover, our benchmark lowers the bar of entry to work with biomedical data. While generally a good thing, it may dilute the pool of data-driven work in the biomedical field even more than it already is, making it hard for experts to spot the relevant work.

C Limitations

Although our CBLUE offers diverse settings, there are still some tasks not covered by the benchmark, such as medical dialogue generation (Liu et al., 2020; Lin et al., 2020; Zeng et al., 2020) or medical diagnosis (Wei et al., 2018). We encourage researchers in both academics and industry to contribute new datasets. Besides, our benchmark is static; thus, models may still achieve outstanding performance on tasks but fail on simple challenge examples and falter in real-world scenarios. We leave this as future works to construct a platform including dataset creation, model development, and assessment, leading to more robust and informative benchmarks.

D CBLUE Background

Standard datasets and shared tasks have played essential roles in promoting the development of AI technology. Taking the Chinese BioNLP community as an example, the CHIP (China Health Information Processing) conference releases biomedical-related shared tasks every year, which has extensively advanced Chinese biomedical NLP technology. However, some datasets are no longer available after the end of shared tasks, which has raised issues in the data acquisition and future research of the datasets.

In recent years, we can obtain state-of-the-art performance for many downstream tasks with the help of pre-trained language models. A significant trend is the emergence of multi-task leaderboards, such as GLUE (General Language Understanding Evaluation) and CLUE (Chinese Language Understanding Evaluation). These leaderboards provide a fair benchmark that attracts the attention of many researchers and further promotes the development of language model technology. For example, Microsoft has released BLURB (Biomedical Language Understanding & Reasoning Evaluation) at the end of 2020 in the medical field. Recently, the Tianchi platform has launched the CBLUE (Chinese Biomedical Language Understanding Evaluation) benchmark under the guidance of the CHIP Society. We believe that the release of the CBLUE will further attract researchers' attention to the medical AI field and promote the development of the community.

CBLUE 1.0[15] comprises the previous shared tasks of the CHIP conference and the dataset from Alibaba QUARK Search Engine, including named entity recognition, information extraction, clinical diagnosis normalization, single-sentence/sentence-pair classification.

E Detailed Task Introduction

E.1 Chinese Medical Named Entity Recognition Dataset (CMeEE)

Task Background As an essential subtask of information extraction, entity recognition has achieved promising results in recent years. Biomedical texts such as textbooks, encyclopedias, clinical trials, medical literature, electronic health records, and medical examination reports contain rich medical knowledge. Named entity recognition is the process of extracting medical terminologies, such as diseases and symptoms, from the above mentioned unstructured or semi-structured texts, and it can help significantly improve the efficiency of scientific research. CMeEE dataset is proposed for this purpose, and the original dataset was released at the CHIP2020 conference.

Task Description This task is defined as given the pre-defined schema and an input sentence to identify medical entities and to classify them into 9 categories, including disease (dis), clinical symptoms(sym), drugs (dru), medical equipment (equ), medical procedures (pro), body (bod), medical examination items (ite), microorganisms (mic), department (dep). For the detailed annotation instructions, please refer to the CBLUE official website, and examples are shown in Table 7.

Annotation Process The annotation guide was conducted by two medical experts from Class A tertiary hospitals and optimized during the trail annotation process. A total of 32 annotators had participated in the annotation process, including 2 medical experts who are also the owner of the annotation guideline, 4 experts from the biomedical informatics field, 6 medical M.D., and 22 master students from computer science majors. The annotation lasts for about three months (from October 2018 to December 2018), as well as an additional month's time for curation. The total expense is about 50,000 RMB.

The annotation process was divided into two stages.

- Stage1: This stage was called the trail annotation phase. The medical experts gave training to the annotators to make sure they had a comprehensive understanding of the task. Two rounds of trail annotation were conducted by the annotators, with the purpose of getting familiar with the annotation task as well as

---

[15] We release the benchmark following the CC BY-NC 4.0 license.

Entity type	Entity subtype	Label	Example
疾病 disease	疾病或综合症 disease or syndrome 中毒或受伤 poisoned or injured 器官或细胞受损 damage to organs or cells	dis	尿潴留者易继发泌尿系感染 Patients with urinary retention are prone to secondary infections of the urinary system.
临床表现 clinical manifestations	症状 symptom 体征 physical sign	sym	逐渐出现呼吸困难、阵发性喘憋，发作时呼吸快而浅，并伴有呼气性喘鸣，明显鼻扇及三凹征 Then dyspnea and paroxysmal asthma may occur, along with shortness of breath, expiratory stridor, obvious flaring nares, and three-concave sign.
医疗程序 medical procedure	检查程序 check procedure 治疗 treatment 或预防程序 or preventive procedure	pro	用免疫学方法检测黑种病原体的特异抗原很有诊断价值，因其简单快速，常常用于早期诊断，诊断意义常较抗体检测更为可靠 It is of great diagnostic value to detect the specific antigen of a certain pathogen with immunoassay, a simple and quick assay that is intended for early diagnosis and proves more reliable than the antibody assay.

Table 7: Examples in CMeEE

discovering the unclear points of the guideline, and annotation problems were discussed, and the medical experts improved the annotation guidelines according to the feedback iteratively.

- Stage2: For the first phase, each record was assigned to two annotators to label independently, and the medical experts and biomedical informatics experts would give in time help. The annotation results were compared automatically by the annotation tools (developed for the CMeEE and CMeIE tasks), and any disagreement was recorded and handed over to the next phase. In the second phase, medical experts and the annotators had a discussion for the disagreements records as well as other annotation problems, and the annotators made corrections. After the two stages, the IAA score (Kappa score) is 0.8537, which satisfied the research goal.

PII and IRB The corpus is collected from authorized medical textbooks or Clinical Practice, and no personally identifiable information or offensive content is involved in the text.

No PII is included in the above-mentioned resources. The dataset does not refer to ethics, which has been checked by the IRB committee of the provider.

The original dataset format is a self-defined plain text format. To simplify the data pre-processing step, the CBLUE team has converted the data format to the unified JSON format with the permission of the data provider.

Evaluation Metrics This task uses strict Micro-F1 metrics.

Dataset Statistic This task has 15,000 training set data, 5,000 validation set data, 3,000 test set data. The corpus contains 938 files and 47,194 sentences. The average number of words contained per file is 2,355. The dataset contains 504 common pediatric diseases, 7,085 body parts, 12,907 clinical symptoms, and 4,354 medical procedures in total.

Dataset Provider The dataset is provided by:

- Key Laboratory of Computational Linguistics, Peking University, Ministry of Education, China
- Laboratory of Natural Language Processing, Zhengzhou University, China
- The Research Center for Artificial Intelligence, Peng Cheng Laboratory, China
- Harbin Institute of Technology, Shenzhen, China

E.2 Chinese Medical Information Extraction Dataset (CMeIE)

Task Background Relation extraction is an essential information extraction task for natural language processing, which is used to detect pairs of entities and their relations from unstructured text. With entity and relation extraction technology, we can construct medical knowledge graphs from unstructured and semi-structured medical texts, which can serve lots of downstream tasks. This dataset is proposed for this purpose, and the task was first released at the CHIP2020 conference.

Task Description Given a sentence and the predefined schema, which defines the relation (Predicate) and its related Subject and Object, such as (“subject_type”: “疾病”，“predicate”: “药物治疗”，“object_type”: “药物”). The task requires the model to automatically analyze the sentence and then extract all the $Triples = [(S1, P1, O1), (S2, P2, O2)...]$ in the sentence. Table 8 shows some examples of the dataset, the schema includes 10 kinds of genus relations and 43 sub-relations. For the detailed annotation guideline, please refer to the CBLUE official website.

Annotation Process The annotation guide was conducted by two medical experts from Class A tertiary hospitals and optimized during the trail annotation process. A total of 20 annotators had participated in the annotation process, including 2 medical experts who are also the owner of the annotation guideline, 2 experts from the biomedical informatics field, 4 medical M.D., and 14 master students from computer science majors. The annotation lasts for about four months (from October 2018 to December 2018), which contains the annotation time as well as the curation time. The total expense is about 40,000 RMB.

Similar to the CMeEE dataset, the annotation process for CMeIE also contains the trail annotation stage and the formal annotation stage following the same process. Besides, an additional step called the Chinese segmentation validation step was added for this dataset. The data provider has developed a segmentation tool for the medical texts which could generate the segment as well as the POS tagging, and some specified POS types (like ’disease,’ ’drug’) could help validate if there were potential missing named entities for this task automatically, which could help assist the annotators to check the missing labels. The final IAA for this dataset is 0.83, which could satisfy the research purpose.

PII and IRB The corpus is collected from authorized medical textbooks or Clinical Practice, and no personally identifiable information or offensive content is involved in the text.

No PII is included in the above-mentioned resources. The dataset does not refer to ethics, which has been checked by the IRB committee of the provider.

Evaluation Metrics The SPO results given by the participants need to be accurately matched. Srict Micro-F1 is used for evaluation.

Dataset Statistic This task has 14,339 training set data, 3,585 validation set data, 4,482 test set data. The dataset is from the pediatric corpus and common disease corpus. The pediatric corpus originates from 518 pediatric diseases, and the common disease corpus is derived from 109 common diseases. The dataset contains nearly 75,000 triples, 28,000 disease sentences, and 53 schemas.

Dataset Provider The dataset is provided by:

- Key Laboratory of Computational Linguistics, Peking University, Ministry of Education, China
- Laboratory of Natural Language Processing, Zhengzhou University, China
- The Research Center for Artificial Intelligence, Peng Cheng Laboratory, China

Relation type	**Relation subtype**	**Example**
疾病_其他 disease_other	预防 prophylaxis	{’predicate’: ’预防-prevention’, ’subject’: ’麻风病-Leprosy’, ’subject_type’: ’疾病-disease’, ’object’: ’利福-rifampicin’, ’object_type’: ’其他-others’}
	阶段 phase	{’predicate’: ’阶段-phase’, ’subject’: ’肿瘤-tumor’, ’subject_type’: ’疾病-disease’, ’object’: ’I期-phase_‘’, ’object_type’: ’其他-others’}
	就诊科室 treatment department	{’predicate’: ’就诊科室-treatment_department’, ’subject’: ’腹主动脉瘤-abdominal_aortic_aneurysm’, ’subject_type’: ’疾病-disease’, ’object’: ’初级医疗保健医处-primary_medical_care_clinic’, ’object_type’: ’其他-others’}
疾病_其他治疗 disease_other treatment	辅助治疗 adjuvant therapy	{’predicate’: ’辅助治疗-adjuvant_therapy’, ’subject’: ’皮肤鳞状细胞癌-utaneous_squamous_cell_carcinoma’, ’subject_type’: ’疾病-disease’, ’object’: ’非手术破坏-non_surgical_destructio’, ’object_type’: ’其他治疗-other_treatment’}
	化疗 chemotherapy	{’predicate’: ’化疗-chemotherapy’, ’subject’: ’肿瘤-tumour’, ’subject_type’: ’皮肤鳞状细胞癌-cutaneous_squamous_cell_carcinoma’, ’object’: ’局部化疗-local_chemotherapy’, ’object_type’: ’其他治疗-other_treatment’}
	放射治疗 radiotherapy	{’predicate’: ’放射治疗-radiation_therapy’, ’subject’: ’非肿瘤性疼痛-non_cancer_pain’, ’subject_type’: ’疾病-disease’, ’object’: ’外照射-external_irradiation’, ’object_type’: ’其他治疗-other_treatment’}
疾病_手术治疗 disease_surgical treatment	手术治疗 surgical treatment	{’predicate’: ’手术治疗-surgical_treatment’, ’subject’: ’皮肤鳞状细胞癌-cutaneous_squamous_cell_carcinoma’, ’subject_type’: ’疾病-disease’, ’object’: ’传统手术切除-surgical_resection(traditional_therapy)’, ’object_type’: ’手术治疗-surgical_treatment’}

Table 8: Examples in CMeIE

- Harbin Institute of Technology, Shenzhen, China

E.3 CHIP - Clinical Diagnosis Normalization Dataset (CHIP-CDN)

Task Background Clinical term normalization is a crucial task for both research and industry use. Clinically, there might be up to hundreds of different synonyms for the same diagnosis, symptoms, or procedures; for example, “heart tack” and “MI” both stand for the standard terminology “myocardial infarction”. The goal of this task is to find the standard phrases (i.e., ICD codes) for the given clinical term. With the help of the standard code, it can help ease the burden of researchers for the statistical analysis of clinical trials; also, it can be helpful for the insurance companies on the DRGs or DIP-related applications. This task is proposed for this purpose, and the originally shared task was released at the CHIP2020 conference.

Task Description The task aims to standardize the terms from the final diagnoses of Chinese electronic medical records. No privacy information is involved in the final diagnosis. Given the original terms, it is required to predict its corresponding standard phrase from the standard vocabulary of "International Classification of Diseases (ICD-10) for Beijing Clinical Edition v601". For the detailed annotation guideline, please refer to the CBLUE official website. Examples are shown in Table 9.

Annotation Process The Chinese Diagnostic Normalization dataset (CHIP-CDN) was annotated by the medical team of Yidu Cloud. They are all composed of people with medical backgrounds and clinician qualification certificates. This work took about 2 months, and since the work was done by internal staff, the estimated cost was around 100,000 RMB in total.

The Chinese Diagnostic Normalization Data Set (CHIP-CDN) is completed by one round of labeling, one round of full audit, and one round of random quality inspection. Labeling and review are completed by ordinary labeling personnel with clinical qualifications, and random quality inspections are completed by high-level terminology experts.

PII and IRB The corpus is collected from EMR(electronic medical records), and only the final diagnoses part is chosen for research purposes. The dataset does not refer to ethics.

As shown in the example table, the final diagnosis has no PII included.

The original dataset format is a self-defined xlsx format. To unify the data pre-processing step, the CBLUE team has converted the data format to the JSON format with the permission of the data provider.

Evaluation Metrics The F1 score is calculated with (original diagnosis terms, standard phrases) pairs. Say, if the test set has m golden pairs, and the predicted result has n pairs, where k pairs are predicted correctly, then:

$$P = k/n, R = k/m, F1 = 2 * P * R/(P + R). \tag{1}$$

Dataset Statistic 8,000 training instances and 10,000 testing instances are provided. We split the original training set into 6,000 and 2,000 for the training and validation set, respectively.

Dataset Provider The dataset is provided by Yidu Cloud Technology Inc.

E.4 Clinical Trial Criterion Dataset (CHIP-CTC)

Task Background Clinical trials refer to scientific research conducted by human volunteers to determine the efficacy, safety, and side effects of a drug or a treatment method. It plays a crucial role in promoting the development of medicine and improving human health. Depending on the purpose of the experiment, the subjects may be patients or healthy volunteers. The goal of this task is to predict whether a subject meets a clinical trial or not. Recruitment of subjects for clinical trials is generally done through manual comparison of medical records and clinical trial screening criteria, which is time-consuming, laborious, and inefficient. In recent years, methods based on natural language processing have got successful in many biomedical applications. This task is proposed with the purpose of automatically classifying clinical trial eligibility criteria for the Chinese language, and the original task is released at the CHIP2019 conference. All the data comes from real clinical trials collected from the website of the Chinese Clinical Trial Registry (ChiCTR) [16], which is a non-profit organization providing registration for public research use.

Task Description A total of 44 pre-defined semantic categories are defined for this task, and the goal is to predict a given text to the correct category. For the detailed annotation instructions, please refer to the CBLUE official website. Examples of labeled data are shown in Table 10.

Annotation Process The CHIP-CTC corpus was annotated by three annotators. The first annotator is Zuofeng Li, a principal scientist in Philips Research China, with more than a decade of research experience in the biomedical domain. Other annotators were Zeyu Zhang (Ph.D. candidate) and Jinxuan Yang (Ph.D. candidate) in the biomedical informatics field from Tongji University. The annotation started in July 2019 and took about 1 month. Further, the corpus was used in the CHIP

---

[16] `http://chictr.org.cn/`

Original terms	Normalization terms
右肺结节转移可能大 Possible nodule metastasis in the right lung	肺占位性病变## Space-occupying Lesion of the Lung 肺继发恶性肿瘤## Secondary Malignant Neoplasm of the Lung 转移性肿瘤 Metastatic Tumor
右肺结节住院 Hospitalization after detection of nodules in the right lung	肺占位性病变 Space-occupying Lesion of the Lung
左上肺胸膜下结节待查 Subpleural nodule in the left upper lung to be examined	胸膜占位 Space-occupying Lesion within the Pleural Space

Table 9: Examples in CHIP-CDN

ID	Clinical trial sentence	Category
S1	年龄>80岁 Age: > 80	Age
S2	近期颅内或椎管内手术史 Recent intracranial/intraspinal surgery	Therapy or Surgery
S3	血糖<2.7mmol/L Blood glucose < 2.7 mmol/L	Laboratory Examinations

Table 10: Examples in CHIP-CTC

2019 shared task. The annotation was related to the annotator's research project, and no payment was required.

One experienced biomedical researcher (Z.L) and two raters (Z.Z and J.Y, Ph.D. candidate for biomedical informatics) of biomedical domains labeled the CHIP-CTC corpus with the 44 categories. First, they studied these categories' definitions, investigated a large number of expression patterns of criteria sentences, and chose criteria examples of each category. Next, the two raters independently annotated the same 1000 sentences, then they checked annotations and discussed contradictions with Z.L until consensus was achieved. This step repeated 20 iterations, and 20000 criteria sentences were annotated, which were later used to calculate the inter-annotator agreement score (0.9920 by Cohen's kappa score). Finally, the remaining sentences were assigned to the two raters for annotation.

PII and IRB The corpus is collected from the Chinese Clinical Trial Registry (ChiCTR) website, which is a non-profit organization providing registration for public research use. For each registered clinical trial case on this website, it is already approved by the ethics committee of the organization. In addition, the annotation and corpus have also been reviewed and approved by Internal Committee on Biomedical Experiments (ICBE) in Philips. It is encouraged to use the corpus for academic research.

For each registered clinical trial report, no PII is included.

The original dataset format is a self-defined csv format. To unify the data pre-processing step, the CBLUE team has converted the data format to the JSON format with the permission of the data provider.

Evaluation Metrics The evaluation of this task uses Macro-F1. Suppose we have n categories, $C_1, ..., C_i, ..., C_n$. The accuracy rate P_i is the number of records correctly predicted to class C_i / the number of records predicted to be class C_i. Recall rate R_i = the number of records correctly predicted as the class C_i / the number of records of the real C_i class.

$$Average - F1 = (1/n)\sum_{i=1}^{n}\frac{2 * Pi * Ri}{Pi + Ri} \quad (2)$$

Dataset Statistic This task has 22,962 training sets, 7,682 validation sets, and 10,000 test sets.

Dataset Provider The dataset is provided by the School of Life Sciences and Technology, Tongji University, and Philips Research China.

E.5 Semantic Textual Similarity Dataset (CHIP-STS)

Task Background CHIP-STS task aims to learn similar knowledge between disease types based on the Chinese online medical questions. Specifically, given question pairs from 5 different diseases, it is required to determine whether the semantics of the two sentences are similar or not. The originally shared task was released at the CHIP2019 conference.

Task Description The category represents the name of the disease type, including diabetes, hypertension, hepatitis, aids, and breast cancer. The label indicates whether the semantics of the questions are the same. If they are the same, they are marked as 1, and if they are not the same, they are marked as 0. Examples of labeling are shown in Table 11.

Annotation Process The CHIP-STS corpus was annotated by five undergraduate annotators from medical colleges under the guidance of one surgeon and one physician. The task is relatively simple since it is a two-class classification one; the annotation process, as well as the time of verification, lasts for two weeks. A total of 30,000 sentences pairs are annotated, and the annotation expense is 25,000 RMB.

There are five types of diseases, so each annotator was assigned two types of disease to the label to guarantee that each type of disease was annotated by two raters. During the trail annotation process, each annotator was given 100 records to label, which aimed to test if they could understand the tasks thoroughly. Following that, the annotators start to label the process, and medical experts would give necessary help, like explaining the disease mechanism to assist the raters. Finally, each record was labeled by two different labelers, and the disagreed pairs were selected for discussion and case study; the annotators would recheck the previous labeled results according to the experts' feedback. The IAA score was 0.93.

PII and IRB The corpus is collected from online questions from the medical forum, and it doesn't refer to the ethics, which has been checked by the IRB committee of the provider.

During the annotation step, sentences with PHI information are discarded by the annotators manually. The CBLUE team has also validated the dataset record by record to guarantee there is no PII included.

The original dataset format is a self-defined csv format. To unify the data pre-processing step, the CBLUE team has converted the data format to the JSON format with the permission of the data provider.

Evaluation Metrics The evaluation of this task is Macro-F1.

Dataset Statistic This task has 16,000 training sets, 4,000 validation sets, and 10,000 tests set data.

Dataset Provider The dataset is provided by Ping An Technology.

E.6 KUAKE-Query Intent Classification Dataset (KUAKE-QIC)

Task Background In medical search scenarios, the understanding of query intent can significantly improve the relevance of search results. In particular, medical knowledge is highly specialized, and classifying query intentions can also help integrate medical knowledge to enhance the performance of search results. This task is proposed for this purpose.

Task Description There are 11 categories of medical intent labels, including diagnosis, etiology analysis, treatment plan, medical advice, test result analysis, disease description, consequence prediction, precautions, intended effects, treatment fees, and others. For the detailed annotation instructions, please refer to the CBLUE official website. Examples are shown in Table 12.

Annotation Process The KUAKE-QIC corpus was annotated by six annotators who graduated

Question1	**Question2**	**Label**
糖尿病吃什么? What should patients with diabetes eat?	糖尿病的食谱? What is the recommended dietary for patients with diabetes?	label:1
乙肝小三阳的危害? What is the harm of hepatitis B (HBsAg/HBeAb/HBcAb-positive)?	乙肝大三阳的危害? What is the harm of hepatitis B (HBsAg/HBeAg/HBcAb-positive)?	label:0

Table 11: Examples in CHIP-STS

Intent	**Sentences**
病情诊断 disease diagnosis	最近早上起来浑身无力是怎么回事? Why do I always feel weak after I get up in the morning? 我家宝宝快五个月了，为什么偶尔会吐清水带? Why does my 5-month-old baby occasionally vomit clear liquid?
注意事项 precautions	哮喘应该注意些什么 What should patients with asthma pay attention to? 孕妇能不能吃榴莲 Can a pregnant woman eat durians? 柿子不能和什么一起吃 Which food cannot be eaten together with persimmons? 糖尿病人饮食注意什么啊? What should patients with diabetes pay attention to about their diet?
就医建议 medical advice	糖尿病该做什么检查? What examination should patients with diabetes receive? 肚子疼去什么科室? Which department should patients with stomachache visit?

Table 12: Examples in KUAKE-QIC

from medical college; they were employed by Alibaba as full-time employees. They must get past the test for the specified annotation tasks before the annotation starts. This task cost about 2 weeks, and the annotation fee was 6,600 RMB with 22,000 labeled records, that’s to say, 0.3 RMB / per record.

The annotation process was divided into three steps:

The first step was the trail annotation step; 2,000 records were selected for this stage. The annotators were grouped into 2 groups, each with 3 persons. The data provider had a strict metric for quality control, say, the IAA between the three persons within the same group must exceed 0.9.

The second stage is the formal annotation phase, and during this stage, 6 annotators were divided into three groups, each with 2 persons. A total of 20,000 records were annotated; IAA for this step was 0.9230.

The last step was the quality control step, the sampling strategy was adopted, and 300 records were sampled for validation; some common annotation problems were raised by the medical experts, and the data would be fixed in a batch mode. In addition, some disagreed cases were made final decisions by the medical experts.

PII and IRB The corpus is collected from user queries from the QUARK search engine, and it doesn’t refer to the ethics, which has been checked by the IRB committee of the provider.

During the annotation step, sentences with PHI information or offensive information (like sexual queries) are discarded by the annotators manually. The dataset also got passed the data disclosure process of Alibaba.

The CBLUE team has also validated the dataset record by record to guarantee there is no PHI included.

Evaluation Metrics Accuracy is used for the evaluation of this task.

Dataset Statistic This task has 6,931 training set data, 1,955 validation set data, and 1,994 test set data.

Dataset Provider The dataset is provided by Alibaba QUARK Search Engine.

E.7 KUAKE- Query Title Relevance Dataset (KUAKE-QTR)

Task Background KUAKE Query Title Relevance is a dataset for query document (title) relevance estimation. For example, give the query “Symptoms of vitamin B deficiency”, the relevant title should be “The main manifestations of vitamin B deficiency”.

Task Description The correlation between Query and Title is divided into 4 levels (0-3), 0 is the worst, and 3 stands for the best match. For the detailed annotation instructions, please refer to the CBLUE official website. Examples are shown in Table 13.

Annotation Process The KUAKE-QTR corpus was annotated by a total of nine annotators, among which seven were from third-party crowd-sourcing undergraduates from medical colleges, and two were from Alibaba full-time employees with medical backgrounds. The crowd-sourcing annotators were required to get trained and pass the annotation test before they could execute the task. The annotations lasted for 2 weeks, and a total of 28,000 RMB was used.

Similar to the KUAKE-QIC task, the KUAKE-QTR annotation process was divided into three steps with minor changes:

The training and examination stage: The seven annotators got trained by the two FTE (full-time employee) experts to understand the tasks, then each one was given 200 records to label, which have ground-truth answer annotated by FTE experts. The precision must be above 85% to get past the test.

The second step was the formal annotation step, and Each annotator was given 3,000 records to label, among which 100 were with golden labels. The annotation tools would automatically evaluate the annotation quality by comparing the label between the annotators’ ones and the golden ones. Help would be given to the annotators if necessary. Only the precision exceeding the threshold 0.85 would be handed to the next round.

The last step was the quality control step, the sampling strategy was adopted, and 100 records were sampled for validation by the FTE medical experts; bad cases would be returned to the crowd-sourcing annotators to be fixed.

PII and IRB The corpus is collected from user queries from the QUARK search engine, and it doesn’t refer to the ethics, which has been checked by the IRB committee of the provider.

During the annotation step, sentences with PHI information or offensive information (like sexual queries) are discarded by the annotators manually. The dataset also got passed the data disclosure process of Alibaba.

The CBLUE team has also validated the dataset record by record to guarantee there is no PHI included. One record with the NULL label was discarded with the permission of the provider.

Evaluation Metrics Same as the KUAKE-QIC task, accuracy is used for the evaluation of this task.

Dataset Statistic This task has 24,174 training set data, 2,913 validation set data, and 5,465 test set data.

Dataset Provider This dataset is provided by Alibaba QUARK Search Engine.

E.8 KUAKE - Query Query Relevance Dataset (KUAKE-QQR)

Task Background KUAKE Query-Query Relevance is a dataset that evaluates the relevance between two given queries to resolve the long-tail challenges for search engines. Similar to KUAKE-QTR, query-query relevance is an essential and challenging task in real-world search engines.

Task Description The correlation between Query and Title is divided into 3 levels (0-2), 0 is the worst, and 2 stands for the best correlation. For the detailed annotation guidelines, please refer to the CBLUE official website. Examples are shown in Table 14.

Annotation Process The same as KUAKE-QTR except for the expense, which is 22,000 RMB in total.

Query	Title	Level
缺维生素b的症状 Symptoms of Vitamin B deficiency	维生素b缺乏症的主要表现 What are the major symptoms of Vitamin B deficiency?	3
大腿软组织损伤怎么办 How can I treat a soft tissue injury in the thigh?	腿部软组织损伤怎么办 What's the treatment for a soft tissue injury in the leg?	2
小腿抽筋是什么原因引起的 What causes lower leg cramps?	小腿抽筋后一直疼怎么办 How can I treat pains caused by lower leg cramps?	1
挑食是什么原因造成的 What is the cause of picky eating?	挑食是什么原因造成的 What is the cause of picky eating?	0

Table 13: Examples in KUAKE-QTR

Query	Query	Level
小孩子打呼噜是什么原因引起的 What causes children's snoring	小孩子打呼噜什么原因 What makes children snore?	2
双眼皮遗传规律 Heredity laws of double-fold eyelids	内双眼皮遗传 Heredity of hidden double-fold eyelids	1
白血病血常规有啥异常 What index of the CBC test will be abnormal for patients with leukemia?	白血病血检有哪些异常 What index of the blood test will be abnormal for patients with leukemia?	0

Table 14: Examples in KUAKE-QQR

PII and IRB The same as KUAKE-QTR.

Evaluation Metrics Same with the KUAKE-QIC and KUAKE-QTR tasks, accuracy is used for the evaluation metrics.

Dataset Statistic This task has 15,000 training set data, 1,600 validation set data, and 1,596 test set data.

Dataset Provider This dataset is provided by Alibaba QUARK Search Engine.

F Experiments Details

This section details the training procedures and hyper-parameters for each of the data sets. We utilize Pytorch to conduct experiments, and all running hyper-parameters are shown in the following Tables. There are two stages in CMeIE, namely, entity recognition (CMeEE-ER) and relation classification (CMeEE-RE). So we detail the hyper-parameters in CMeEE-ER and CMeEE-RE, respectively.

Requirements

- python3
- pytorch 1.7
- transformers 4.5.1
- jieba
- gensim

Hyper-parameters for Specific Task is shown in Table 15-26

G Error Analysis for Other Tasks

We introduce the error definition as follows and illustrate some error cases for other tasks in Table 27 to 32.

Ambiguity indicates that the instance has a similar context but different meaning, which mislead the prediction.

Need domain knowledge indicates that there exist biomedical terminologies in the instance which require domain knowledge to understand.

Method	**Value**
warmup_proportion	0.1
weight_decay	0.01
adam_epsilon	1e-8
max_grad_norm	1.0

Table 26: Hyper-parameters of training the sequence classifier for the KUAKE-QQR task.

Need syntactic knowledge indicates that there exists complex syntactic structure in the instance, and the model fails to understand the correct meaning.

Entity overlap indicates there exist multiple overlapping entities in the instance.

Long sequence indicates that the input instance is very long.

Annotation error indicates that the annotated label is wrong.

Wrong entity boundary indicates that the instance has the wrong entity boundary.

Rare words indicates that there exist low-frequency words in the instance.

Multiple triggers indicates that there exist multiple indicative words which mislead the prediction.

Colloquialism (very common in the search queries) indicates that the instance is quite different from written language (e.g., with many abbreviations), thus, challenging the prediction model.

Irrelevant description indicates that the instance has lots of irrelevant information, which mislead the prediction.

Contributions

Ningyu Zhang, Zhen Bi, Xiaozhuan Liang, Lei Li from Zhejiang University, AZFT Joint Lab for Knowledge Engine, Hangzhou Innovation Center wrote the paper.

Mosha Chen, Chuanqi Tan, Fei Huang, Luo Si from Alibaba Group and **Zheng Yuan** from the Center for Statistical Science, Tsinghua University contributed the CBLUE benchmark leaderboard and transformed the eight datasets from self-defined data format to unified JSON format.

Kunli Zhang from School of Information Engineering, Zhengzhou University, Peng Cheng Laboratory, China and **Baobao Chang** from Key Laboratory of Computational Linguistics, Ministry of Education, Peking University, Peng Cheng Laboratory, China contributed the dataset of CMeEE.

Hongying Zan from School of Information Engineering, Zhengzhou University, Peng Cheng Laboratory, China and **Zhifang Sui** from Key Laboratory of Computational Linguistics, Ministry of Education, Peking University, Peng Cheng Laboratory, China contributed the dataset of CMeIE.

Linfeng Li, Jun Yan from Yidu Cloud Technology Inc., Beijing, China contributed the dataset of CHIP-CDN.

Hui Zong from School of Life Sciences and Technology, Tongji University and Philips Research China contributed the dataset of CHIP-CTC.

Yuan Ni from Pingan Health Technology, Shanghai, China and **Guotong Xie** from Pingan Health Technology, China, Ping An Health Cloud Company Limited, China, Ping An International Smart City Technology Co., Ltd, China contributed the dataset of CHIP-STS.

Kangping Yin, Jian Xu from Alibaba Group and **Xin Shang** from School of Mathematical Science, Zhejiang University contributed the datasets of KUAKE-QIC, KUAKE-QTR, and KUAKE-QQR.

Buzhou Tang, **Qingcai Chen** from Harbin Institute of Technology (Shenzhen), Peng Cheng Laboratory, China advised the project, suggested tasks, and led the research.

Abstract

Text summarization aims to generate a short summary for an input text. In this work, we propose a Non-Autoregressive Unsupervised Summarization (NAUS) approach, which does not require parallel data for training. Our NAUS first performs edit-based search towards a heuristically defined score, and generates a summary as pseudo-groundtruth. Then, we train an encoder-only non-autoregressive Transformer based on the search result. We also propose a dynamic programming approach for length-control decoding, which is important for the summarization task. Experiments on two datasets show that NAUS achieves state-of-the-art performance for unsupervised summarization, yet largely improving inference efficiency. Further, our algorithm is able to perform explicit length-transfer summary generation.[1]

1 Introduction

Text summarization is an important natural language processing (NLP) task, aiming at generating concise summaries for given texts while preserving the key information. It has extensive real-world applications such as headline generation (Nenkova et al., 2011). In this paper, we focus on the setting of sentence summarization (Rush et al., 2015; Filippova et al., 2015).

State-of-the-art text summarization models are typically trained in a supervised way with large training corpora, comprising pairs of long texts and their summaries (Zhang et al., 2020; Aghajanyan et al., 2020, 2021). However, such parallel data are expensive to obtain, preventing the applications to less popular domains and less spoken languages.

Unsupervised text generation has been attracting increasing interest, because it does not require parallel data for training. One widely used approach is to compress a long text into a short one, and to reconstruct it to the long text by a cycle consistency loss (Miao and Blunsom, 2016; Wang and Lee, 2018; Baziotis et al., 2019). Due to the indifferentiability of the compressed sentence space, such an approach requires reinforcement learning (or its variants), which makes the training difficult (Kreutzer et al., 2021).

Recently, Schumann et al. (2020) propose an edit-based approach for unsupervised summarization. Their model maximizes a heuristically defined scoring function that evaluates the quality (fluency and semantics) of the generated summary, achieving higher performance than cycle-consistency methods. However, the search approach is slow in inference because hundreds of search steps are needed for each data sample. Moreover, their approach can only select words from the input sentence with the word order preserved. Thus, it is restricted and may generate noisy summaries due to the local optimality of search algorithms.

To address the above drawbacks, we propose a Non-Autoregressive approach to Unsupervised Summarization (NAUS). The idea is to perform search as in Schumann et al. (2020) and, inspired by Li et al. (2020), to train a machine learning model to smooth out such noise and to speed up the inference process. Different from Li et al. (2020), we propose to utilize *non-autoregressive* decoders, which generate all output tokens in parallel due to our following observations:

- Non-autoregressive models are several times faster than autoregressive generation, which is important when the system is deployed.
- The input and output of the summarization task have a strong correspondence. Non-autoregressive generation supports encoder-only architectures, which can better utilize such input–output correspondence and even outperform autoregressive models for summarization.
- For non-autoregressive models, we can de-

sign a length-control algorithm based on dynamic programming to satisfy the constraint of output lengths, which is typical in summarization applications but cannot be easily achieved with autoregressive models.

We conducted experiments on Gigaword headline generation (Graff et al., 2003) and DUC2004 (Over and Yen, 2004) datasets. Experiments show that our NAUS achieves state-of-the-art performance on unsupervised summarization; especially, it outperforms its teacher (i.e., the search approach), confirming that NAUS can indeed smooth out the search noise. Regarding inference efficiency, our NAUS with truncating is 1000 times more efficient than the search approach; even with dynamic programming for length control, NAUS is still 100 times more efficient than search and several times more efficient than autoregressive models. Our NAUS is also able to perform length-transfer summary generation, i.e., generating summaries of different lengths from training.

2 Approach

In our approach, we first follow Schumann et al. (2020) and obtain a summary by discrete search towards a heuristically defined objective function (§2.1). Then, we propose a non-autoregressive model for the summarization task (§2.2). We present the training strategy and the proposed length-control algorithm in §2.3.

2.1 Search-Based Summarization

Consider a given source text $\mathbf{x} = (\mathrm{x}_1, \mathrm{x}_2, \dots, \mathrm{x}_n)$. The goal of summarization is to find a shorter text $\mathbf{y} = (\mathrm{y}_1, \mathrm{y}_2, \dots, \mathrm{y}_m)$ as the summary.

Our work on unsupervised summarization follows the recent progress of search-based text generation (Liu et al., 2020, 2021a; Kumar et al., 2020). Schumann et al. (2020) formulate summarization as word-level extraction (with order preserved), and apply edit-based discrete local search to maximize a heuristically designed objective.

Specifically, the objective function considers two aspects: (1) a language fluency score $f_{\mathrm{LM}}(\mathbf{y})$, given by the reciprocal of a language model's perplexity; and (2) a semantic similarity score $f_{\mathrm{SIM}}(\mathbf{y}; \mathbf{x})$, given by the cosine embeddings. The overall objective combines the two aspects as

$$f(\mathbf{y}; \mathbf{x}) = f_{\mathrm{LM}}(\mathbf{y}) \cdot f_{\mathrm{SIM}}(\mathbf{y}; \mathbf{x})^{\gamma} \qquad (1)$$

where γ is a weighting hyperparameter. Interested readers are referred to Schumann et al. (2020) for the details of the scoring function.

Further, the desired summary length can be specified as a hard constraint, achieved by searching only among sentences of the correct length. Suppose the desired summary length is T, the approach selects T random words from the input, and maximizes the scoring function (1) by changing the selection and non-selection of two words.

A greedy hill-climbing algorithm determines whether the change is accepted or not. In other words, a change is accepted if the score improves, or rejected otherwise. Such a process continues until a (possibly local) optimum is found.

A pilot analysis in Schumann et al. (2020) shows that words largely overlap between a source text and its reference summary. This explains the high performance of such a word extraction approach, being a state-of-the-art unsupervised summarization system and outperforming strong competitors, e.g., cycle consistency (Wang and Lee, 2018; Baziotis et al., 2019).

2.2 Non-Autoregressive Model for Summarization

Despite the high performance, such edit-based search has several drawbacks. First, the search process is slow because hundreds of local search steps are needed to obtain a high-quality summary. Second, their approach only extracts the original words with order preserved. Therefore, the generated summary is restricted and may be noisy.

To this end, we propose a Non-Autoregressive approach to Unsupervised Summarization (NAUS) by learning from the search results. In this way, the machine learning model can smooth out the search noise and is much faster, largely alleviating the drawbacks of search-based summarization. Compared with training an autoregressive model from search (Li et al., 2020), non-autoregressive generation predicts all the words in parallel, further improving inference efficiency by several times.

Moreover, a non-autoregressive model enables us to design an encoder-only architecture, which is more suited to the summarization task due to the strong correspondence between input and output, which cannot be fully utilized by encoder–decoder models, especially autoregressive ones.

Specifically, we propose to use multi-layer Transformer (Vaswani et al., 2017) as the non-autoregressive architecture for summarization.

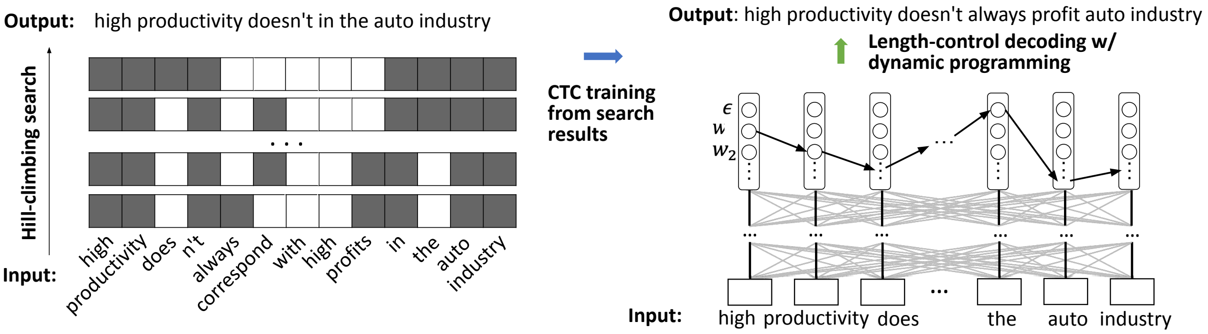

Figure 1: The overview of our NAUS approach. In each search step, input words corresponding to grey cells are selected. Besides, the blue arrow refers to the training process, and the green arrow refers to inference.

Each Transformer layer is composed of a multi-head attention sublayer and a feed-forward sublayer. Additionally, there is a residual connection in each sublayer, followed by layer normalization.

Let $X^{(n)} \in \mathbb{R}^{T\times d}$ be the representation at the nth layer, where T is the number of words and d is the dimension. Specially, the input layer $X^{(0)}$ is the embeddings of words. Suppose we have h attention heads. The output of the ith head in the nth attention sublayer is $A_i^{(n)} = \operatorname{softmax}\left(\frac{Q_i K_i^\top}{\sqrt{d_k}}\right) V_i$, where Q_i, K_i, and V_i are matrices calculated by three distinct multi-layer perceptrons (MLPs) from $X^{(n-1)}$; d_k is the attention dimension.

Multiple attention heads are then concatenated:

$$A^{(n)} = \operatorname{Concat}\left(A_1^{(n)}, \ldots, A_h^{(n)}\right) W_O$$

where $W_O \in \mathbb{R}^{d\times d}$ is a weight matrix.

Then, we have a residual connection and layer normalization by

$$\bar{A}^{(n)} = \operatorname{LayerNorm}\left(X^{(n-1)} + A^{(n)}\right) \quad (2)$$

Further, an MLP sublayer processes $\bar{A}^{(n)}$, followed by residual connection and layer normalization, yielding the nth layer's representation

$$X^{(n)} = \operatorname{LayerNorm}\left(\bar{A}^{(n)} + \operatorname{MLP}(\bar{A}^{(n)})\right) \quad (3)$$

The last Transformer layer $X^{(N)}$ is fed to $\operatorname{softmax}$ to predict the words of the summary in a non-autoregressive manner, that is, the probability at the tth step is given by $\operatorname{softmax}(W\boldsymbol{x}_t^{(N)})$, where $\boldsymbol{x}_t^{(N)}$ is the tth row of the matrix $X^{(N)}$ and W is the weight matrix.

It is emphasized that, in the vocabulary, we include a special blank token ϵ, which is handled by dynamic programming during both training and inference (§2.3). This enables us to generate a shorter summary than the input with such a multi-layer Transformer.

Our model can be thought of as an encoder-only architecture, differing from a typical encoder–decoder model with cross attention (Vaswani et al., 2017; Baziotis et al., 2019; Zhou and Rush, 2019). Previously, Su et al. (2021) propose a seemingly similar model to us, but put multiple end-of-sequence (EOS) tokens at the end of the generation; thus, they are unable to maintain the correspondence between input and output. Instead, we allow blank tokens scattering over the entire sentence; the residual connections in Eqns (2) and (3) can better utilize such input–output correspondence for summarization.

2.3 Training and Inference

In this section, we first introduce the Connectionist Temporal Classification (CTC) training. Then, we propose a length-control decoding approach for summary generation.

CTC Training. The Connectionist Temporal Classification (CTC, Graves et al., 2006) algorithm allows a special blank token ϵ in the vocabulary, and uses dynamic programming to marginalize out such blank tokens, known as *latent alignment* (Saharia et al., 2020). In addition, non-autoregressive generation suffers from a common problem that words may be repeated in consecutive steps (Gu et al., 2018; Lee et al., 2018); thus, CTC merges repeated words unless separated by ϵ. For example, the sequence of tokens $a\epsilon\epsilon aabb\epsilon$ is reduced to the text aab, denoted by $\Gamma(a\epsilon\epsilon aabb\epsilon) = aab$.

Concretely, the predicted likelihood is marginalized over all possible fillings of ϵ, i.e., all possible token sequences that are reduced to the groundtruth text:

$$P(\mathbf{y}|\mathbf{x}) = \sum\nolimits_{\mathbf{w}:\Gamma(\mathbf{w})=\mathbf{y}} P(\mathbf{w}|\mathbf{x}) \quad (4)$$

where $P(\mathbf{w}|\mathbf{x})$ is the probability of generating a sequence of tokens $\mathbf{w}$. Although enumerating every candidate in $\{\mathbf{w} : \Gamma(\mathbf{w}) = \mathbf{y}\}$ is intractable, such marginalization fortunately can be computed by dynamic programming in an efficient way.

Let $\alpha_{s,t} = \sum_{\mathbf{w}_{1:s}:\Gamma(\mathbf{w}_{1:s})=\mathbf{y}_{1:t}} P(\mathbf{w}_{1:s}|\mathbf{x})$ be the marginal probability of generating $\mathbf{y}_{1:t}$ up to the sth decoding slot. Moreover, $\alpha_{s,0}$ is defined to be the probability that $\mathbf{w}_{1:s}$ is all ϵ, thus not having matched any word in $\mathbf{y}$. The $\alpha_{s,t}$ variable can be further decomposed into two terms $\alpha_{s,t} = \alpha^{\epsilon}_{s,t} + \alpha^{\neg\epsilon}_{s,t}$, where the first term is such probability with $\mathrm{w}_s = \epsilon$, and the second term $\mathrm{w}_s \neq \epsilon$. Apparently, the initialization of α variables is

$$\alpha^{\epsilon}_{1,0} = P(\mathrm{w}_1 = \epsilon|\mathbf{x}) \tag{5}$$

$$\alpha^{\neg\epsilon}_{1,1} = P(\mathrm{w}_1 = \mathrm{y}_1|\mathbf{x}) \tag{6}$$

$$\alpha^{\epsilon}_{1,t} = 0, \forall t \geq 1 \tag{7}$$

$$\alpha^{\neg\epsilon}_{1,t} = 0, \forall t > 1 \text{ or } t = 0 \tag{8}$$

Eqn. (7) is because, at the first prediction slot, the empty token ϵ does not match any target words; Eqn. (8) is because the predicted non-ϵ first token must match exactly the first target word.

The recursion formula for $\alpha^{\epsilon}_{s,t}$ is

$$\alpha^{\epsilon}_{s,t} = \alpha_{s-1,t} P(\mathrm{w}_t = \epsilon|\mathbf{x})$$

since the newly predicted token ϵ with probability $P(\mathrm{w}_t = \epsilon|\mathbf{x})$ does not match any target word, inheriting $\alpha_{s-1,t}$.

The recursion formula for $\alpha^{\neg\epsilon}_{s,t}$ is

$$\alpha^{\neg\epsilon}_{s,t} = \begin{cases} \left(\alpha^{\epsilon}_{s-1,t-1} + \alpha^{\neg\epsilon}_{s-1,t}\right) P(\mathrm{w}_s = \mathrm{y}_t|\mathbf{x}), \\ \qquad\qquad\qquad\qquad \text{if } \mathrm{y}_t = \mathrm{y}_{t-1} \\ \left(\alpha_{s-1,t-1} + \alpha^{\neg\epsilon}_{s-1,t}\right) P(\mathrm{w}_s = \mathrm{y}_t|\mathbf{x}), \\ \qquad\qquad\qquad\qquad \text{otherwise} \end{cases}$$

Here, w_s is not ϵ, so we must have $\mathrm{w}_s = \mathrm{y}_t$, having the predicted probability $P(\mathrm{w}_s = \mathrm{y}_t|\mathbf{x})$.

If $\mathrm{y}_t = \mathrm{y}_{t-1}$, then we have two sub-cases: first, $\mathbf{w}_{1:s-1}$ is reduced to $\mathbf{y}_{1:t-1}$ with $\mathrm{w}_{s-1} = \epsilon$ separating two repeating words in $\mathbf{y}$, having probability $\alpha^{\epsilon}_{s-1,t-1}$; or second, $\mathbf{w}_{1:s-1}$ is reduced to $\mathbf{y}_{1:t}$ with $\mathrm{w}_{s-1} = \mathrm{y}_t \neq \epsilon$, having probability $\alpha^{\neg\epsilon}_{s-1}$, which implies we are merging w_{s-1} and w_s.

If $\mathrm{y}_t \neq \mathrm{y}_{t-1}$, $\mathbf{w}_{1:s-1}$ is reduced to either $\mathbf{y}_{1:t-1}$ or $\mathbf{y}_{1:t}$. In the first case, w_{s-1} can be either ϵ or non-ϵ, given by $\alpha_{s-1,t-1} = \alpha^{\epsilon}_{s-1,t-1} + \alpha^{\neg\epsilon}_{s-1,t-1}$. In the second case, we must have $\mathrm{w}_{s-1} \neq \epsilon$, which has a probability of $\alpha^{\neg\epsilon}_{s-1,t}$.

Finally, $\alpha_{|\mathbf{w}|,|\mathbf{y}|}$ is the marginal probability in Eqn. (4), as it is the probability that the entire generated sequence matches the entire target text.

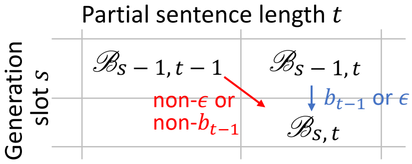

Figure 2: Illustration of our length-control algorithm.

The CTC maximum likelihood estimation is to maximize the marginal probability, which is equivalent to minimizing the loss $-\alpha_{|\mathbf{w}|,|\mathbf{y}|}$. Since the dynamic programming formulas are differentiable, the entire model can be trained by backpropagation in an end-to-end manner with auto-differentiation tools (such as PyTorch).

Length-Control Inference. Controlling output length is the nature of the summarization task, for example, displaying a short news headline on a mobile device. Moreover, Schumann et al. (2020) show that the main evaluation metric ROUGE (Lin, 2004) is sensitive to the summary length, and longer summaries tend to achieve higher ROUGE scores. Thus, it is crucial to control the summary length for fair comparison.

We propose a length-control algorithm by dynamic programming (DP), following the nature of CTC training. However, our DP is an approximate algorithm because of the dependencies introduced by removing consecutive repeated tokens. Thus, we equip our DP with a beam search mechanism.

We define $\mathscr{B}_{s,t}$ to be a set of top-B sequences with s predicted tokens that are reduced to t words. $\mathscr{B}_{s,t}$ is constructed by three scenarios.

First, the blank token ϵ is predicted for the sth generation slot, and thus the summary length t remains the same, shown by the blue arrow in Figure 2. This yields a set of candidates

$$\mathscr{B}^{(1)}_{s,t} = \left\{\mathbf{b} \oplus \epsilon \;:\; \mathbf{b} \in \mathscr{B}_{s-1,t}\right\} \tag{9}$$

where $\oplus$ refers to string/token concatenation.

Second, a repeated word is predicted for the sth generation slot, i.e., b_{s-1} for a subsequence $\mathbf{b}$ of length $s-1$. In this case, the summary length t also remains the same, also shown in the blue arrow in Figure 2. This gives a candidate set

$$\mathscr{B}^{(2)}_{s,t} = \left\{\mathbf{b} \oplus \mathrm{b}_{s-1} \;:\; \mathbf{b} \in \mathscr{B}_{s-1,t}\right\} \tag{10}$$

Third, a non-ϵ, non-repeating word w_s is generated, increasing the summary length from $t-1$ to

t, shown by the red arrow in Figure 2. This gives

$$\mathscr{B}_{s,t}^{(3)} = \operatorname{top}_B \left\{ \mathbf{b} \oplus \mathrm{w} \ : \mathbf{b} \in \mathscr{B}_{s-1,t-1}, \mathrm{w}_s \neq \epsilon, \mathrm{w}_s \neq \mathrm{b}_{s-1} \right\} \quad (11)$$

where top_B selects the best B elements by the probability $P(\mathrm{w}_s|\mathbf{x})$.

Based on the three candidates sets, we select top-B sequences to keep the beam size fixed:

$$\mathscr{B}_{s,t} = \operatorname{top}_B(\mathscr{B}_{s,t}^{(1)} \cup \mathscr{B}_{s,t}^{(2)} \cup \mathscr{B}_{s,t}^{(3)}) \quad (12)$$

where the sequences are ranked by their predicted joint probabilities.

Theorem 1. *(1) If repeating tokens are not merged, then the proposed length-control algorithm with beam size $B = 1$ finds the exact optimum $\mathscr{B}_{S,T}$ being the most probable length-T sentence given by S prediction slots. (2) If we merge repeating tokens predicted by CTC-trained models, the above algorithm may not be exact.*

Appendix A presents the proof of the theorem and provides a more detailed analysis, showing that our length-control algorithm, although being approximate inference, can generate a summary of the desired length properly. Compared with truncating an overlength output, our approach is able to generate more fluent and complete sentences. Also, our length-control algorithm is different from conventional beam search, shown in Appendix C.

3 Experiments

3.1 Setup

Datasets. We evaluated our NAUS model on Gigaword headline generation and DUC2004 datasets.

The headline generation dataset (Rush et al., 2015) is constructed from the Gigaword news corpus (Graff et al., 2003), where the first sentence of a news article is considered as input text and the news title is considered as the summary. The dataset contains 3.8M/198K/1951 samples for training/validation/test. Based on the analysis of the training size in Appendix B, we used 3M samples for training NAUS.

It should be emphasized that, when NAUS learns from search, we only use the input of the training corpus: we perform search (Schumann et al., 2020) for each input, and train our NAUS from the search results. Therefore, we do not utilize any labeled parallel data, and our approach is unsupervised.

Moreover, we considered two settings with desired summary lengths of 8 and 10, following Schumann et al. (2020). Our NAUS is trained from respective search results.

The DUC2004 dataset (Over and Yen, 2004) is designed for testing only with 500 samples, where we also take the first sentence of an article as the input text. Our NAUS is transferred from the above headline generation corpus. Based on the length of DUC2004 summaries, we trained NAUS from search results with 13 words, also following Schumann et al. (2020) for fair comparison.

Evaluation Metrics. We evaluated the quality of predicted summaries by ROUGE scores [2] (Lin, 2004), which are the most widely used metrics in previous work (Wang and Lee, 2018; Baziotis et al., 2019; Zhou and Rush, 2019). Specifically, ROUGE-n evaluates n-gram overlap between a predicted summary and its reference summary; ROUGE-L, instead, measures the longest common sequence between the predicted and reference summaries.

Different ROUGE variants are adopted in previous work, depending on the dataset. We followed the standard evaluation scripts and evaluated headline generation by ROUGE F1 (Wang and Lee, 2018; Baziotis et al., 2019; Schumann et al., 2020) and DUC2004 by Truncate ROUGE Recall (Dorr et al., 2003; West et al., 2019).

In addition to summary quality, we also evaluated the inference efficiency of different methods, as it is important for the deployment of deep learning models in real-time applications. We report the average inference time in seconds for each data sample, and compare the speedup with Schumann et al. (2020)'s search approach, which achieves (previous) state-of-the-art ROUGE scores. Our experiments were conducted on an i9-9940X CPU and an RTX6000 graphic card. Appendix B presents additional implementation details.

3.2 Results and Analyses

Main Results. Table 1 presents the performance of our model and baselines on the Gigaword headline test set. For a fair comparison, we categorize all approaches by average summary lengths of ~8 and ~10 into Groups A and B, respectively.

The Lead baseline extracts the first several words of the input sentence. Despite its simplicity, the Lead approach is a strong summarization baseline adopted in most previous work (Févry and Phang, 2018; Baziotis et al., 2019).

Table 2: Results on the DUC2004 dataset. †Quoted from previous papers.

Wang and Lee (2018) utilize cycle consistency (Miao and Blunsom, 2016) for unsupervised summarization; the performance is relatively low, because the cycle consistency loss cannot ensure the generated text is a valid summary. Zhou and Rush (2019) perform beam search towards a step-by-step decomposable score of fluency and contextual matching. Both are unable to explicitly control the summary length: in a fair comparison of length 10 (Group B, Table 1), their performance is worse than the (previous) state-of-the-art approach (Schumann et al., 2020),[3] which performs edit-based local search.

Our NAUS approach follows Schumann et al. (2020), but trains a non-autoregressive model from search results. We consider two settings for controlling the summary length: truncating longer summaries and decoding with our proposed length-control algorithm. Both of our variants outperform Schumann et al. (2020) by 1.21–2.73 in terms of the total ROUGE score (Rows 5–6 & 13–14, Table 1). As mentioned, Schumann et al. (2020) only extract original words with order preserved, yielding noisy sentences. Our NAUS, as a student, learns from the search-based teacher model and is able to smooth out its noise. This is a compelling result, as our student model outperforms its teacher.

Regarding inference efficiency, our NAUS method with truncating is more than 1300 times faster than Schumann et al. (2020), because we do not need iterative search. Even with dynamic programming and beam search for length control, NAUS is still over 100 times faster. This shows our NAUS is extremely efficient in inference, which is important for real-time applications.

Although the efficiency of Wang and Lee (2018) and Zhou and Rush (2019) is not available, we still expect our approach to be a few times faster (despite our higher ROUGE scores) because their models are autoregressive. By contrast, our NAUS is non-autoregressive, meaning that it predicts all words simultaneously. We will provide a controlled comparison between autoregressive and non-autoregressive models in Table 3.

Table 2 shows the results on the DUC2004 dataset. The cycle-consistency approach (Bazio-

Table 3: Model analysis on headline generation. **AR:** Autoregressive models. **NAR enc-dec:** Non-autoregressive encoder–decoder. **NAR enc-only:** Non-autoregressive encoder-only. **T:** Truncating. **LC:** Length control. All AR and NAR models use the Transformer architecture.

tis et al., 2019; West et al., 2019) does not perform well on this dataset, outperformed by an early rule-based syntax tree trimming approach (Zajic et al., 2004) and the state-of-the-art edit-based search (Schumann et al., 2020).

The performance of our NAUS model is consistent with Table 1, outperforming all previous methods in terms of the total ROUGE score, and being 100–1000 times faster than the search approach (Schumann et al., 2020).

In general, the proposed NAUS not only achieves state-of-the-art ROUGE scores for unsupervised summarization, but also is more efficient when deployed. Results are consistent on both datasets, demonstrating the generality of our NAUS.

In-Depth Analyses. We conduct in-depth analyses on the proposed NAUS model in Table 3. Due to the limit of time and space, we chose the Gigaword headline generation as our testbed. All the autoregressive (AR) and non-autoregressive (NAR) variants learn from the search output of our replication (Rows 2 & 11), where we achieve very close results to those reported in Schumann et al. (2020).

We first tried vanilla encoder–decoder NAR Transformer (Rows 4 & 13, Gu et al., 2018), where we set the number of decoding slots as the desired summary length; thus, the blank token and the length-control algorithm are not needed. As seen, a vanilla NAR model does not perform well, and CTC largely outperforms vanilla NAR in both groups (Rows 5–6 & 14–15). Such results are highly consistent with the translation literature (Saharia et al., 2020; Chan et al., 2020; Gu and Kong, 2021; Qian et al., 2021; Huang et al., 2022).

The proposed encoder-only NAUS model outperforms encoder–decoder ones in both groups in terms of the total ROUGE score, when the summary length is controlled by either truncating or length-control decoding (Rows 8–9 & 17–18). Profoundly, our non-autoregressive NAUS is even better than the autoregressive Transformer (Rows 3 & 12). We also experimented with previous non-autoregressive work for supervised summarization (Su et al., 2021)[4] in our learning-from-search setting. Although their approach appears to be encoder-only, it adds end-of-sequence (EOS) tokens at the end of the generation, and thus is unable to utilize the input–output correspondence. Their performance is higher than vanilla NAR models, but lower than ours. By contrast, NAUS is able to capture such correspondence with the residual connections, i.e., Eqns. (2) and (3), in its encoder-only architecture.

Generally, the efficiency of encoder-only NAR[5] (without length-control decoding) is ~2 times faster than encoder–decoder NAR and ~20 times faster than the AR Transformer.

Further, our length-control decoding improves the total ROUGE score, compared with truncating, for both encoder–decoder CTC and encoder-only NAUS models (Rows 6, 9, 15, & 18), although its dynamic programming is slower. Nevertheless, our non-autoregressive NAUS with length control is ~200 times faster than search and ~3 times faster than the AR Transformer.

Additional Results. We present additional results in our appendices:

D. Case Study

E. Human Evaluation

F. Length-Transfer Summarization

---

[4] To the best of our knowledge, the other two non-autoregressive supervised summarization models are Yang et al. (2021) and Qi et al. (2021). Their code and pretrained models are not available, making replication difficult.

[5] The standard minimal encoder–decoder NAR model has 6 layers for the encoder and another 6 layers for the decoder (Vaswani et al., 2017). Our NAUS only has a 6-layer encoder. Our pilot study shows that more layers do not further improve performance in our encoder-only architecture.

4 Related Work

Summarization systems can be generally categorized into two paradigms: extractive and abstractive. Extractive systems extract certain sentences and clauses from input, for example, based on salient features (Zhou and Rush, 2019) or feature construction (He et al., 2012). Abstraction systems generate new utterances as the summary, e.g., by sequence-to-sequence models trained in a supervised way (Zhang et al., 2020; Liu et al., 2021b).

Recently, unsupervised abstractive summarization is attracting increasing attention. Yang et al. (2020) propose to use the Lead baseline (first several sentences) as the pseudo-groundtruth. However, such an approach only works with well-structured articles (such as CNN/DailyMail). Wang and Lee (2018) and Baziotis et al. (2019) use cycle consistency for unsupervised summarization. Zhou and Rush (2019) propose a step-by-step decomposable scoring function and perform beam search for summary generation. Schumann et al. (2020) propose an edit-based local search approach, which allows a more comprehensive scoring function and outperforms cycle consistency and beam search.

Our paper follows Schumann et al. (2020) but trains a machine learning model to improve efficiency and smooth out search noise. Previously, Li et al. (2020) fine-tune a GPT-2 model based on search results for unsupervised paraphrasing; Jolly et al. (2022) adopt the search-and-learning framework to improve the semantic coverage for few-shot data-to-text generation. We extend previous work in a non-trivial way by designing a non-autoregressive generator and further proposing a length-control decoding algorithm.

The importance of controlling the output length is recently realized in the summarization community. Baziotis et al. (2019) and Su et al. (2021) adopt soft penalty to encourage shorter sentences; Yang et al. (2021) and Qi et al. (2021) control the summary length through POS tag and EOS predictions. None of these studies can control the length explicitly. Song et al. (2021) is able to precisely control the length by progressively filling a predetermined number of decoding slots, analogous to the vanilla NAR model in our non-autoregressive setting.

Non-autoregressive generation is originally proposed for machine translation (Gu et al., 2018; Guo et al., 2020; Saharia et al., 2020), which is later extended to other text generation tasks. Wiseman et al. (2018) address the table-to-text generation task, and model output segments by a hidden semi-Markov model (Ostendorf et al., 1996), simultaneously generating tokens for all segments. Jia et al. (2021) apply non-autoregressive models to extractive document-level summarization. Su et al. (2021) stack a non-autoregressive BERT model with a conditional random field (CRF) for abstractive summarization; since the summary is shorter than the input text, their approach puts multiple end-to-sequence (EOS) tokens at the end of the sentence, and thus is unable to utilize the strong input–output correspondence in the summarization task. Yang et al. (2021) apply auxiliary part-of-speech (POS) loss and Qi et al. (2021) explore pretraining strategies for encoder–decoder non-autoregressive summarization. All these studies concern supervised summarization, while our paper focuses on unsupervised summarization. We adopt CTC training in our encoder-only architecture, allowing blank tokens to better align input and output words, which is more appropriate for summarization.

5 Conclusion

In this work, we propose a non-autoregressive unsupervised summarization model (NAUS), where we further propose a length-control decoding algorithm based on dynamic programming. Experiments show that NAUS not only archives state-of-the-art unsupervised performance on Gigaword headline generation and DUC2004 datasets, but also is much more efficient than search methods and autoregressive models. Appendices present additional analyses and length-transfer experiments.

Limitation and Future Work. Our paper focuses on unsupervised summarization due to the importance of low-data applications. One limitation is that we have not obtained rigorous empirical results for supervised summarization, where the developed model may also work. This is because previous supervised summarization studies lack explicit categorization of summary lengths (Yang et al., 2020; Qi et al., 2021), making comparisons unfair and problematic (Schumann et al., 2020). Such an observation is also evidenced by Su et al. (2021), where the same model may differ by a few ROUGE points when generating summaries of different lengths. Nevertheless, we have compared with Su et al. (2021) in our setting and show the superiority of the NAUS under fair comparison. We plan to explore supervised summarization in future work after we establish a rigorous experimental setup, which is beyond the scope of this paper.

A Proof of Theorem 1

Theorem 1. *(1) If repeating tokens are not merged, then the proposed length-control algorithm with beam size* $B = 1$ *finds the exact optimum* $\mathscr{B}_{S,T}$ *being the most probable length-*T *sentence given by* S *prediction slots. (2) If we merge repeating tokens predicted by CTC-trained models, the above algorithm may not be exact.*

Proof. [Part (1)] This part concerns a variant of our decoding algorithm, which only removes the blank token ϵ but does not merge consecutive repeated tokens to a single word, i.e., Eqn. (10) is removed. We denote this by Γ', for example, $\Gamma'(a\epsilon\epsilon aabb\epsilon) = aaabb$, as opposed to $\Gamma(a\epsilon\epsilon aabb\epsilon) = aab$ in our algorithm. We now show that, based on Γ', our dynamic programming algorithm in §2.3 with beam size $B = 1$ is an exact inference algorithm.

We define $\beta_{s,t} = \max_{\mathbf{b}:|\mathbf{b}|=s, |\Gamma'(\mathbf{b})|=t} P(\mathbf{b}|\mathbf{x})$, where $|\cdot|$ denotes the length of a sequence. In other words, $\beta_{s,t}$ is the maximum probability of s tokens that are reduced to t words.

According to the definition, we have

$$\beta_{1,0} = P\left(\mathrm{w}_1 = \epsilon|\mathbf{x}\right) \tag{13}$$

$$\beta_{1,1} = \max\nolimits_{\mathrm{w}_1 \neq \epsilon} P\left(\mathrm{w}_1|\mathbf{x}\right) \tag{14}$$

$$\beta_{s,t} = 0 \quad \text{for } s > t \tag{15}$$

In (13), $\beta_{1,0}$ refers to the probability of one token that is reduced to zero words, in which case the first predicted token can only be the blank token ϵ, corresponding to Eqn. (9) with $s = 1$ and $t = 0$. Likewise, $\beta_{1,1}$ is the maximum probability of one token that is reduced to one word. Thus, it is the probability of the most probable non-ϵ token, corresponding to Eqn. (11) with $s = 1$ and $t = 0$. Eqn. (15) asserts that fewer tokens cannot be reduced to more words; it is used for mathematical derivations, but need not to be explicitly implemented in our algorithm in §2.3.

The recursion variable $\beta_{s,t}$ is computed by

$$\beta_{s,t} = \max\Big\{\beta_{s-1,t} \cdot P(\mathrm{w}_s = \epsilon|\mathbf{x}), \\ \beta_{s-1,t-1} \cdot \max\nolimits_{\mathrm{w}_s \neq \epsilon} P(\mathrm{w}_s|\mathbf{x})\Big\} \tag{16}$$

In other words, the variable $\beta_{s,t}$ can inherit $\beta_{s-1,t}$ with a predicted blank token ϵ, corresponding to Eqn. (9); or it can inherit $\beta_{s-1,t-1}$ with a predicted non-ϵ token, corresponding to Eqn. (11). Specially, if $t = 0$, then the second term has $\beta_{s-1,-1}$ undefined, and thus is ignored in the $\max$ operation.

We need the $\max$ operator to take the higher probability in the two cases, since $\beta_{s,t}$ is the maximum probability of s tokens being reduced to t words. This corresponds to Eqn. (12) with beam size $B = 1$.

To sum up, our inductive calculation guarantees that $\beta_{S,T}$ is the exact maximum probability of $\max_{\mathbf{b}:|\mathbf{b}|=S,|\Gamma'(\mathbf{b})|=T} P(\mathbf{b}|\mathbf{x})$ for the desired length T with S generation slots; our algorithm (if not merging repeating tokens) gives the corresponding $\mathscr{B}_{S,T}$ as $\operatorname{argmax} P(\mathbf{b}|\mathbf{x})$ under the same constraints, concluding the proof of Part (1).

[Part (2)] CTC training merges consecutive repeated tokens to a single word, unless separated by the blank token ϵ (Graves et al., 2006). Since our model is trained by CTC, we should adopt this rule in inference as well. We show in this part that our algorithm, with beam size $B = 1$, may not yield the exact optimum with an example in Table 4.

Word	$P(\mathrm{w}_1\vert\mathbf{x})$	$P(\mathrm{w}_2\vert\mathbf{x})$
I	0.39	0.1
like	0.4	0.9
coding	0.1	0
ϵ	0.11	0

Table 4: An example of predicted probabilities of two generation slots, where we have a vocabulary of three words and a blank token ϵ.

We consider generating a sentence of two words from the two prediction slots, i.e., $S = T = 2$. Apparently, the optimal sequence is "I like" with probability $0.39 \cdot 0.9 = 0.351$. However, the algorithm would predict $\mathscr{B}_{1,1} = \{\text{"like"}\}$ because "like" is the most probably token in the first slot. Then, our algorithm will give $\mathscr{B}_{2,2} = \{\text{"like I"}\}$, because it has to select a non-repeating token based on Γ, yielding a non-optimal solution.

□

It is noted that, if we do not merge repeating tokens as in Γ', our algorithm will give the exact optimum "like like" in the above example. This shows that merging consecutive repeated tokens requires the decoding algorithm to correct early predictions, and thus, our dynamic programming becomes an approximate inference. Nevertheless, our algorithm is able to generate a sequence of the desired length properly; its approximation happens only when the algorithm compares more repetitions with fewer ϵs versus more ϵs with fewer repetitions. Such approximation is further alleviated by beam search in our dynamic programming. Therefore, the proposed length-control algorithm is better than truncating a longer sentence; especially, our approach generates more fluent and complete sentences.

B Implementation Details

Our NAUS had a Transformer encoder as the basic structure, generally following the settings in Vaswani et al. (2017): 6 encoder layers, each having 8 attention heads. The dimension was 512 for attention and 2048 for feed-forward modules.

Our training used a batch size of 4K tokens, with a maximum of 200K updates. We used Adam with $\beta = (0.9, 0.98)$. In general, the learning rate warmed up to 5e-4 in the first 10K steps, and then decayed to 1e-9 with the inverse square-root schedule, except that we find the maximum learning rate of 1e-4 worked better for headline generation with the summary length of 8. We set the ℓ_2 weight decay to 0.01. Our length-control decoding algorithm

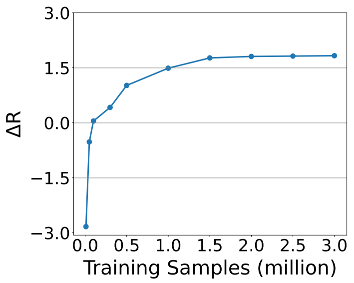

Figure 3: Performance versus the number of training samples in the setting of Group B, Table 1. Notice that NAUS is trained by pseudo-groundtruth given by unsupervised edit-based search (Schumann et al., 2020). Thus, our approach is indeed unsupervised.

had a beam size of 6. More details can be found in our repository (Footnote 1).

Our NAUS training is based on Schumann et al. (2020)'s prediction on the input of the Gigaword headline generation training set. We show performance against the number of training samples in Figure 3. As seen, NAUS outperforms its search teacher even with a small set of 0.1 million samples. The performance saturates as the number of samples increases. Based on this analysis, we used 3 million samples from the 3.8 million Gigaword training set to train our NAUS models.

Each reported number in Tables 1–3 were averaged over 10 independent runs, whereas the results in Table 7 (Appendix F) were based on a single run due to the limited time.

C Analysis of Beam Search

As mentioned, our length-control decoding algorithm involves beam search within its dynamic programming, because the algorithm does not find the exact optimum when it merges repeating words. We analyze the effect of the beam size in our length-control algorithm.

In addition, we compare our approach with CTC beam search (Graves et al., 2006).[6] Typically, a CTC-trained non-autoregressive model can be decoded either greedily or by beam search. The greedy decoding finds the most probable token at each step, i.e., $\mathrm{w}_i^* = \operatorname{argmax}_{\mathrm{w}_i} P(\mathrm{w}_i|\mathbf{x})$, and reduces the tokens to a sentence by $\Gamma(\mathrm{w}_1, \cdots, \mathrm{w}_T)$, where T is the number of decoding steps. The CTC beam search algorithm searches for the most likely sentence by marginalizing all token sequences that are reduced to $\mathbf{y}$, i.e., $\operatorname{argmax}_{\mathbf{y}} \sum_{\mathbf{w}:\Gamma(\mathbf{w})=\mathbf{y}} P(\mathbf{w}|\mathbf{x})$.

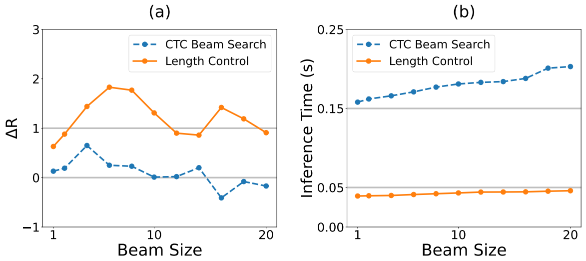

Figure 4: Comparing our length-control NAUS and the truncated CTC beam search on the Gigaward headline generation test set.

We show results in Figure 4, where we chose 10-word Gigaword headline generation as the testbed with our NAUS model (Group B, Table 1). Notice that CTC beam search does not control the output length, and for fair comparison, we truncated its generated summaries. This also shows that our novel decoding approach and CTC beam search are distinct algorithms.

As seen in Figure 4a, the beam search does play a role in our length-control algorithm. When the beam enlarges from 1 to 6, the performance (orange solid line) increases by 1.2 points in ΔR, the difference of total ROUGE in comparison with Schumann et al. (2020) under our replication (Row 10, Table 1). However, further increasing the beam size does not yield additional performance gain. This is consistent with previous literature in autoregressive generation (Meister et al., 2020), which also suggests a beam size of 5–7 is the best in their applications. In terms of the efficiency (Figure 4b), a larger beam size monotonically increases the inference time. However, the overhead of beam search is relatively small in our dynamic programming, and thus we chose a beam size of 6 in our experiments.

Our length-control algorithm significantly outperforms CTC beam search (dashed blue lines) in terms of both ΔR and efficiency. Especially, CTC beam search is three times slower, and degrades more significantly than our length-control decoding when the beam size increases.

D Case Study

We show in Table 6 example summaries generated by our NAUS with truncating and length-control decoding, as well as the previous state-of-the-art method (Schumann et al., 2020). We observe that NAUS without length control generates slightly longer summaries, and if truncated, the output may be incomplete; by contrast, our length-control algo-

	Decoding	Wins	Ties	Loses	p-val
Overall quality	Truncate	18.67%	40.67%	40.67%	0.0004
	Length control	**40.67%**	40.67%	**18.67%**	
Completeness & fluency	Truncate	24.67%	26.67%	48.67%	0.0005
	Length control	**48.67%**	26.67%	**24.67%**	

Table 5: Human evaluation comparing truncating and length control for our NAUS model on 50 samples in the Gigaword headline generation task. The results are statistically significant, where the p-value is given by a one-sided binomial test.

rithm can generate a fluent and complete sentence of the desired length by dynamic programming. Compared with Schumann et al. (2020), our NAUS (length control) generates a more informative summary that includes the main clause (*united nations condemned*), which also appears in the reference summary.

E Human Evaluation

We conducted human evaluation with a focus on truncating and length-control decodings. This is because truncating may generate incomplete sentences, which cannot be adequately evaluated by automatic metrics as their ROUGE scores are close.

Specifically, we invited three human annotators to compare the two decoding algorithms for NAUS on 50 randomly selected samples, in the setting of Group B, Table 1 (Gigaword headline generation with a target length of 10). The annotation was conducted in a pairwise manner in terms of overall quality and fluency/completeness; average results (wins/loses/ties) are shown in Table 4. It should be mentioned that our annotation was strictly blind: the samples of two systems were presented in random order and annotators did not know which system generated a sample.

As seen, our length-control decoding algorithm largely outperforms the truncating approach in terms of both the overall quality and fluency/completeness. The results are statistically significant (p-values < 0.01) in a one-sided binomial test. This verifies that length-control decoding is important for summarization, as truncating yields incomplete sentences, which are inadequately reflected by ROUGE scores.

F Length-Transfer Summary Generation

Schumann et al. (2020): attack on russian embassy in baghdad claimed one in four
NAUS (truncate): an attack on russian embassy employees in baghdad claimed in kidnapping of four others
NAUS (length control): united nations condemned attack on russian embassy employees in baghdad

Table 6: Example summaries for Gigaword headline generation. The gray words are truncated for fair comparison.

In the main paper, we present results where our NAUS is trained on search outputs (Schumann et al., 2020) that have the same length as the inference target. This follows the common assumption in machine learning that training and test samples are independently identically distributed.

In this appendix, we show the performance of length-transfer summary generation, where the prediction has a different length from that of training. We denote such a model by $\text{NAUS}_{i\to j}$, referring to training with i words and testing for j words.

As seen in Groups A & B in Table 7, NAUS with length transfer is slightly worse than NAUS trained on the correct length, which is understandable. Nevertheless, length-transfer decoding still outperforms the search teacher and other baselines.

Moreover, we consider the third setting in Schumann et al. (2020), where the target length is 50% of the input. Since it takes time to obtain pseudo-groundtruths given by the edit-based search, we would directly transfer already trained NAUS models to this setting by our length-control decoding. Results are shown in Group C, Table 7. We observe $\text{NASU}_{10\to 50\%}$ is better than $\text{NASU}_{8\to 50\%}$, which makes much sense because the latter has a larger gap during transfer. Remarkably, both $\text{NASU}_{8\to 50\%}$ and $\text{NASU}_{10\to 50\%}$ outperform Schumann et al. (2020) and other baselines, achieving new state-of-the-art unsupervised performance on this setting as well.

We further compare with Su et al. (2021), who use a length penalty to encourage short summaries. However, their length control works in the statistical sense but may fail for individual samples. Moreover, such a soft length penalty cannot generate longer summaries than trained. Even in the setting of $10 \to 8$, their generates summaries are slightly longer than required, while the performance degrades much more considerably than NAUS.

These results show that our novel length-control decoding algorithm is not only effective when generating summaries of similar length to the training targets, but also generalizes well to different

Abstract

The principal task in supervised neural machine translation (NMT) is to learn to generate target sentences conditioned on the source inputs from a set of parallel sentence pairs, and thus produce a model capable of generalizing to unseen instances. However, it is commonly observed that the generalization performance of the model is highly influenced by the amount of parallel data used in training. Although data augmentation is widely used to enrich the training data, conventional methods with discrete manipulations fail to generate diverse and faithful training samples. In this paper, we present a novel data augmentation paradigm termed Continuous Semantic Augmentation (CsaNMT), which augments each training instance with an adjacency semantic region that could cover adequate variants of literal expression under the same meaning. We conduct extensive experiments on both rich-resource and low-resource settings involving various language pairs, including WMT14 English→{German,French}, NIST Chinese→English and multiple low-resource IWSLT translation tasks. The provided empirical evidences show that CsaNMT sets a new level of performance among existing augmentation techniques, improving on the state-of-the-art by a large margin.[1]

1 Introduction

Neural machine translation (NMT) is one of the core topics in natural language processing, which aims to generate sequences of words in the target language conditioned on the source inputs (Sutskever et al., 2014; Cho et al., 2014; Wu et al., 2016; Vaswani et al., 2017). In the common supervised setting, the training objective is to learn a transformation from the source space to the target space $\mathcal{X} \mapsto \mathcal{Y} : f(\mathbf{y}|\mathbf{x}; \Theta)$ with the usage of parallel data. In this way, NMT models are expected to be capable of generalizing to unseen instances with the help of large scale training data, which poses a big challenge for scenarios with limited resources.

To address this problem, various methods have been developed to leverage abundant unlabeled data for augmenting limited labeled data (Sennrich et al., 2016a; Cheng et al., 2016; He et al., 2016; Hoang et al., 2018; Edunov et al., 2018; He et al., 2020; Song et al., 2019). For example, back-translation (BT) (Sennrich et al., 2016a) makes use of the monolingual data on the target side to synthesize large scale pseudo parallel data, which is further combined with the real parallel corpus in machine translation task. Another line of research is to introduce adversarial inputs to improve the generalization of NMT models towards small perturbations (Iyyer et al., 2015; Fadaee et al., 2017; Wang et al., 2018; Cheng et al., 2018; Gao et al., 2019). While these methods lead to significant boosts in translation quality, we argue that augmenting the observed training data in the discrete space inherently has two major limitations.

First, augmented training instances in discrete space are lack diversity. We still take BT as an example, it typically uses beam search (Sennrich et al., 2016a) or greedy search (Lample et al., 2018a,c) to generate synthetic source sentences for each target monolingual sentence. The above two search strategies are approximate algorithms to identify the maximum a-posteriori (MAP) output (Edunov et al., 2018), and thus favor the most frequent one in case of ambiguity. Edunov et al. (2018) proposed a sampling strategy from the output distribution to alleviate this issue, but this method typically yields synthesized data with low quality. While some extensions (Wang et al., 2018; Imamura et al., 2018; Khayrallah et al., 2020; Nguyen et al., 2020) augment each training instance with multiple literal forms, they still fail to cover adequate variants under the same meaning.

Second, it is difficult for augmented texts in dis-

May 22-27, 2022

crete space to preserve their original meanings. In the context of natural language processing, discrete manipulations such as adds, drops, reorders, and/or replaces words in the original sentences often result in significant changes in semantics. To address this issue, Gao et al. (2019) and Cheng et al. (2020) instead replace words with other words that are predicted using language model under the same context, by interpolating their embeddings. Although being effective, these techniques are limited to word-level manipulation and are unable to perform the whole sentence transformation, such as producing another sentence by rephrasing the original one so that they have the same meaning.

In this paper, we propose **C**ontinuous **S**emantic **A**ugmentation (CSANMT), a novel data augmentation paradigm for NMT, to alleviate both limitations mentioned above. The principle of CSANMT is to produce diverse training data from a semantically-preserved continuous space. Specifically, (1) we first train a semantic encoder via a *tangential* contrast, which encourages each training instance to support an adjacency semantic region in continuous space and treats the tangent points of the region as the critical states of semantic equivalence. This is motivated by the intriguing observation made by recent work showing that the vectors in continuous space can easily cover adequate variants under the same meaning (Wei et al., 2020a). (2) We then introduce a *Mixed Gaussian Recurrent Chain* (MGRC) algorithm to sample a cluster of vectors from the adjacency semantic region. (3) Each of the sampled vectors is finally incorporated into the decoder by developing a *broadcasting integration network*, which is agnostic to model architectures. As a consequence, transforming discrete sentences into the continuous space can effectively augment the training data space and thus improve the generalization capability of NMT models.

We evaluate our framework on a variety of machine translation tasks, including WMT14 English-German/French, NIST Chinese-English and multiple IWSLT tasks. Specifically, CSANMT sets the new state of the art among existing augmentation techniques on the WMT14 English-German task with **30.94** BLEU score. In addition, our approach could achieve comparable performance with the baseline model with the usage of only **25%** of training data. This reveals that CSANMT has great potential to achieve good results with very few data. Furthermore, CSANMT demonstrates consistent improvements over strong baselines in low resource scenarios, such as IWSLT14 English-German and IWSLT17 English-French.

2 Framework

Problem Definition Supposing $\mathcal{X}$ and $\mathcal{Y}$ are two data spaces that cover all possible sequences of words in source and target languages, respectively. We denote $(\mathbf{x}, \mathbf{y}) \in (\mathcal{X}, \mathcal{Y})$ as a pair of two sentences with the same meaning, where $\mathbf{x} = \{x_1, x_2, ..., x_T\}$ is the source sentence with T tokens, and $\mathbf{y} = \{y_1, y_2, ..., y_{T'}\}$ is the target sentence with T' tokens. A sequence-to-sequence model is usually applied to neural machine translation, which aims to learn a transformation from the source space to the target space $\mathcal{X} \mapsto \mathcal{Y} : f(\mathbf{y}|\mathbf{x}; \Theta)$ with the usage of parallel data. Formally, given a set of observed sentence pairs $\mathcal{C} = \{(\mathbf{x}^{(n)}, \mathbf{y}^{(n)})\}_{n=1}^{N}$, the training objective is to maximize the log-likelihood:

$$J_{mle}(\Theta) = \mathbb{E}_{(\mathbf{x},\mathbf{y})\sim\mathcal{C}}\big(\log P(\mathbf{y}|\mathbf{x}; \Theta)\big). \tag{1}$$

The log-probability is typically decomposed as: $\log P(\mathbf{y}|\mathbf{x}; \Theta) = \sum_{t=1}^{T'} \log P(y_t|\mathbf{y}_{<t}, \mathbf{x}; \Theta)$, where Θ is a set of trainable parameters and $\mathbf{y}_{<t}$ is a partial sequence before time-step t.

However, there is a major problem in the common supervised setting for neural machine translation, that is the number of training instances is very limited because of the cost in acquiring parallel data. This makes it difficult to learn an NMT model generalized well to unseen instances. Traditional data augmentation methods generate more training samples by applying discrete manipulations to unlabeled (or labeled) data, such as back-translation or randomly replacing a word with another one, which usually suffer from the problems of semantic deviation and the lack of diversity.

2.1 Continuous Semantic Augmentation

We propose a novel data augmentation paradigm for neural machine translation, termed continuous semantic augmentation (CSANMT), to better generalize the model's capability to unseen instances. We adopt the Transformer (Vaswani et al., 2017) model as a backbone, and the framework is shown in Figure 1. In this architecture, an extra semantic encoder translates the source $\mathbf{x}$ and the target sentence $\mathbf{y}$ to real-value vectors $r_x = \psi(\mathbf{x}; \Theta')$ and $r_y = \psi(\mathbf{y}; \Theta')$ respectively, where $\psi(\cdot; \Theta')$ is the forward function of the semantic encoder parameterized by Θ' (parameters other than Θ).

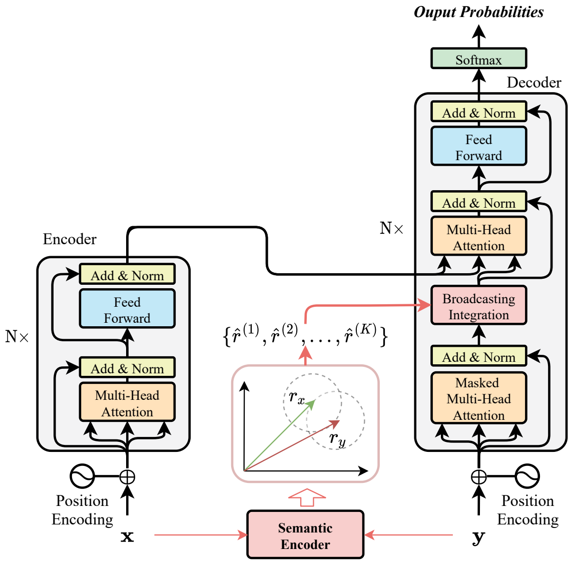

Figure 1: The framework of the CSANMT.

Definition 1. *There is a universal semantic space among the source and the target languages for neural machine translation, which is established by a semantic encoder. It defines a forward function* $\psi(\cdot;\Theta')$ *to map discrete sentences into continuous vectors, that satisfies:* $\forall(\mathbf{x},\mathbf{y})\in(\mathcal{X},\mathcal{Y}): r_x = r_y$*. Besides, an adjacency semantic region* $\nu(r_x, r_y)$ *in the semantic space describes adequate variants of literal expression centered around each observed sentence pair* $(\mathbf{x},\mathbf{y})$*.*

In our scenario, we first sample a series of vectors (denoted by $\mathcal{R}$) from the adjacency semantic region to augment the current training instance, that is $\mathcal{R} = \{\hat{r}^{(1)}, \hat{r}^{(2)}, ..., \hat{r}^{(K)}\}$, where $\hat{r}^{(k)} \sim \nu(r_x, r_y)$. K is the hyperparameter that determines the number of sampled vectors. Each sample $\hat{r}^{(k)}$ is then integrated into the generation process through a broadcasting integration network:

$$\hat{o}_t = W_1\hat{r}^{(k)} + W_2 o_t + b, \tag{2}$$

where o_t is the output of the self-attention module at position t. Finally, the training objective in Eq. (1) can be improved as

$$J_{mle}(\Theta) = \mathbb{E}_{(\mathbf{x},\mathbf{y})\sim\mathcal{C},\hat{r}^{(k)}\in\mathcal{R}}\big(\log P(\mathbf{y}|\mathbf{x},\hat{r}^{(k)};\Theta)\big). \tag{3}$$

By augmenting the training instance $(\mathbf{x},\mathbf{y})$ with diverse samples from the adjacency semantic region, the model is expected to generalize to more unseen instances. To this end, we must consider such two problems: (1) ***How to optimize the semantic encoder so that it produces a meaningful adjacency semantic region for each observed training pair.*** (2) ***How to obtain samples from the adjacency semantic region in an efficient and effective way.*** In the rest part of this section, we introduce the resolutions of these two problems, respectively.

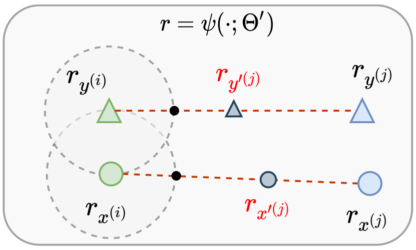

Figure 2: The diagram of formulating the adjacency semantic region for the sentence pair $(\mathbf{x}^{(i)}, \mathbf{y}^{(i)})$.

Tangential Contrastive Learning We start from analyzing the geometric interpretation of adjacency semantic regions. The schematic diagram is illustrated in Figure 2. Let $(\mathbf{x}^{(i)}, \mathbf{y}^{(i)})$ and $(\mathbf{x}^{(j)}, \mathbf{y}^{(j)})$ are two instances randomly sampled from the training corpora. For $(\mathbf{x}^{(i)}, \mathbf{y}^{(i)})$, the adjacency semantic region $\nu(r_{x^{(i)}}, r_{y^{(i)}})$ is defined as the union of two closed balls that are centered by $r_{x^{(i)}}$ and $r_{y^{(i)}}$, respectively. The radius of both balls is $d = \| r_{x^{(i)}} - r_{y^{(i)}} \|_2$, which is also considered as a slack variable for determining semantic equivalence. The underlying interpretation is that vectors whose distances from $r_{x^{(i)}}$ (or $r_{y^{(i)}}$) do not exceed d, are semantically-equivalent to both $r_{x^{(i)}}$ and $r_{y^{(i)}}$. To make $\nu(r_{x^{(i)}}, r_{y^{(i)}})$ conform to the interpretation, we employ a similar method as in (Zheng et al., 2019; Wei et al., 2021) to optimize the semantic encoder with the *tangential* contrast.

Specifically, we construct negative samples by applying the convex interpolation between the current instance and other ones in the same training batch for instance comparison. And the tangent points (i.e., the points on the boundary) are considered as the critical states of semantic equivalence. The training objective is formulated as:

$$J_{ctl}(\Theta') = \mathbb{E}_{(\mathbf{x}^{(i)},\mathbf{y}^{(i)})\sim\mathcal{B}}\Bigg(\log \frac{e^{s\left(r_{x^{(i)}}, r_{y^{(i)}}\right)}}{e^{s\left(r_{x^{(i)}}, r_{y^{(i)}}\right)} + \xi}\Bigg),$$

$$\xi = \sum_{j\&j\neq i}^{|\mathcal{B}|}\Big(e^{s\left(r_{y^{(i)}}, r_{y'^{(j)}}\right)} + e^{s\left(r_{x^{(i)}}, r_{x'^{(j)}}\right)}\Big), \tag{4}$$

where $\mathcal{B}$ indicates a batch of sentence pairs randomly selected from the training corpora $\mathcal{C}$, and $s(\cdot)$ is the score function that computes the cosine similarity between two vectors. The negative samples $r_{x'^{(j)}}$ and $r_{y'^{(j)}}$ are designed as the following

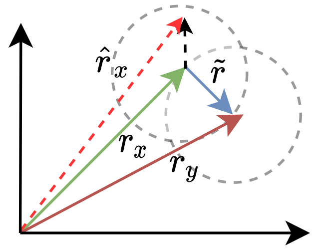

Figure 3: The geometric diagram of the proposed MGRC sampling. r_x and r_y are the representations of the source sentence $\mathbf{x}$ and the target sentence $\mathbf{y}$, respectively. To construct the augmented sample, a straightforward idea is that: (1) transform the norm or the direction of $\tilde{r} = r_y - r_x$, formulated as $\omega \odot \tilde{r}$ (e.g., the black dashed arrow), in which each element $\omega_i \in [-1, 1]$, and (2) combine r_x (or r_y) and the transformation $\omega \odot \tilde{r}$ as $\hat{r}_x = r_x + \omega \odot \tilde{r}$ (i.e., the red dashed arrow).

Algorithm 1 MGRC Sampling

```
Input: The representations of the training instance $(\mathbf{x}, \mathbf{y})$, i.e. $r_x$ and $r_y$.
Output: A set of augmented samples $\mathcal{R} = \{\hat{r}^{(1)}, \hat{r}^{(2)}, ..., \hat{r}^{(K)}\}$
Normalizing the importance of each element in $\tilde{r} = r_y - r_x$: $\mathcal{W}_r = \frac{|\tilde{r}| - min(|\tilde{r}|)}{max(|\tilde{r}|) - min(|\tilde{r}|)}$
Set $k = 1, \omega^{(1)} \sim \mathcal{N}(\mathbf{0}, \text{diag}(\mathcal{W}_r^2)), \hat{r}^{(1)} = r + \omega^{(1)} \odot (r_y - r_x)$
Initialize the set of samples as $\mathcal{R} = \{\hat{r}^{(1)}\}$.
while $k \leq (K - 1)$ do
    $k \leftarrow k + 1$
    Calculate the current scale vector: $\omega^{(k)} \sim p(\omega|\omega^{(1)}, \omega^{(2)}, ..., \omega^{(k-1)})$ according to Eq. (6).
    Calculate the current sample: $\hat{r}^{(k)} = r + \omega^{(k)} \odot (r_y - r_x)$.
    $\mathcal{R} \leftarrow \mathcal{R} \bigcup \{\hat{r}^{(k)}\}$.
end while
```

interpolation:

$$\begin{aligned} r_{x'^{(j)}} &= r_{x^{(i)}} + \lambda_x (r_{x^{(j)}} - r_{x^{(i)}}), \lambda_x \in (\frac{d}{d'_x}, 1], \\ r_{y'^{(j)}} &= r_{y^{(i)}} + \lambda_y (r_{y^{(j)}} - r_{y^{(i)}}), \lambda_y \in (\frac{d}{d'_y}, 1], \end{aligned} \tag{5}$$

where $d'_x = \| r_{x^{(i)}} - r_{x^{(j)}} \|$ and $d'_y = \| r_{y^{(i)}} - r_{y^{(j)}} \|$. The two equations in Eq. (5) set up when d'_x and d'_y are larger than d respectively, or else $r_{x'^{(j)}} = r_{x^{(j)}}$ and $r_{y'^{(j)}} = r_{y^{(j)}}$. According to this design, an adjacency semantic region for the i-th training instance can be fully established by interpolating various instances in the same training batch. We follow Wei et al. (2021) to adaptively adjust the value of λ_x (or λ_y) during the training process, and refer to the original paper for details.

MGRC Sampling To obtain augmented data from the adjacency semantic region for the training instance $(\mathbf{x}, \mathbf{y})$, we introduce a Mixed Gaussian Recurrent Chain (denoted by MGRC) algorithm to design an efficient and effective sampling strategy. As illustrated in Figure 3, we first transform the bias vector $\tilde{r} = r_y - r_x$ according to a pre-defined scale vector ω, that is $\omega \odot \tilde{r}$, where $\odot$ is the element-wise product operation. Then, we construct a novel sample $\hat{r} = r + \omega \odot \tilde{r}$ for augmenting the current instance, in which r is either r_x or r_y. As a consequence, the goal of the sampling strategy turns into find a set of scale vectors, i.e. $\{\omega^{(1)}, \omega^{(2)}, ..., \omega^{(K)}\}$. Intuitively, we can assume that ω follows a distribution with universal or Gaussian forms, despite the latter demonstrates better results in our experience. Formally, we design a mixed Gaussian distribution as follow:

$$\begin{aligned} \omega^{(k)} &\sim p(\omega|\omega^{(1)}, \omega^{(2)}, ..., \omega^{(k-1)}), \\ p &= \eta \mathcal{N}(\mathbf{0}, \text{diag}(\mathcal{W}_r^2)) \\ &+ (1.0 - \eta) \mathcal{N}\Big(\frac{1}{k-1} \sum_{i=1}^{k-1} \omega^{(i)}, \mathbf{1}\Big). \end{aligned} \tag{6}$$

This framework unifies the recurrent chain and the rejection sampling mechanism. Concretely, we first normalize the importance of each dimension in $\tilde{r}$ as $\mathcal{W}_r = \frac{|\tilde{r}| - min(|\tilde{r}|)}{max(|\tilde{r}|) - min(|\tilde{r}|)}$, the operation $| \cdot |$ takes the absolute value of each element in the vector, which means the larger the value of an element is the more informative it is. Thus $\mathcal{N}(\mathbf{0}, \text{diag}(\mathcal{W}_r^2))$ limits the range of sampling to a subspace of the adjacency semantic region, and rejects to conduct sampling from the uninformative dimensions. Moreover, $\mathcal{N}(\frac{1}{k-1} \sum_{i=1}^{k-1} \omega^{(i)}, \mathbf{1})$ simulates a recurrent chain that generates a sequence of reasonable vectors where the current one is dependent on the prior vectors. The reason for this design is that we expect that p in Eq. (6) can become a stationary distribution with the increase of the number of samples, which describes the fact that the diversity of each training instance is not infinite. η is a hyper-parameter to balance the importance of the above two Gaussian forms. For a clearer presentation, Algorithm 1 summarizes the sampling process.

2.2 Training and Inference

The training objective in our approach is a combination of $J_{mle}(\Theta)$ in Eq. (3) and $J_{ctl}(\Theta')$ in Eq. (4). In practice, we introduce a two-phase training procedure with mini-batch losses. Firstly, we train the semantic encoder from scratch using the task-specific data, i.e. $\Theta'^{*} = \text{argmax}_{\Theta'} J_{ctl}(\Theta')$.

Method	**#Params.**	**Valid.**	**MT02**	**MT03**	**MT04**	**MT05**	**MT08**	**Avg.**

Table 1: BLEU scores [%] on Zh→En translation. "**Params.**" denotes the number of parameters (M=million). "$*$" indicates the results obtained by our implementation, we construct multiple pseudo sources for each target during back-translation but rather introducing extra monolingual corpora as in (Wei et al., 2020a) for fairer comparisons.

Secondly, we optimize the encoder-decoder model by maximizing the log-likelihood, i.e. $\Theta^* = \text{argmax}_\Theta J_{mle}(\Theta)$, and fine-tune the semantic encoder with a small learning rate at the same time.

During inference, the sequence of target words is generated auto-regressively, which is almost the same as the vanilla Transformer (Vaswani et al., 2017). A major difference is that our method involves the semantic vector of the input sequence for generation: $y_t^* = \text{argmax}_{y_t} P(\cdot|\mathbf{y}_{<t}, \mathbf{x}, r_x; \Theta)$, where $r_x = \psi(\mathbf{x}; \Theta')$. This module is plug-in-use as well as is agnostic to model architectures.

3 Experiments

We first apply CSANMT to NIST Chinese-English (Zh→En), WMT14 English-German (En→De) and English-French (En→Fr) tasks, and conduct extensive analyses for better understanding the proposed method. And then we generalize the capability of our method to low-resource IWSLT tasks.

3.1 Settings

Datasets. For the Zh→En task, the LDC corpus is taken into consideration, which consists of 1.25M sentence pairs with 27.9M Chinese words and 34.5M English words, respectively. The NIST 2006 dataset is used as the validation set for selecting the best model, and NIST 2002 (MT02), 2003 (MT03), 2004 (MT04), 2005 (MT05), 2008 (MT08) are used as the test sets. For the En→De task, we employ the popular WMT14 dataset, which consists of approximately 4.5M sentence pairs for training. We select `newstest2013` as the validation set and `newstest2014` as the test set. For the En→Fr task, we use the significantly larger WMT14 dataset consisting of 36M sentence pairs. The combination of {`newstest2012, 2013`} was used for model selection and the experimental results were reported on `newstest2014`. Refer to **Appendix A** for more details.

Training Details. We implement our approach on top of the Transformer (Vaswani et al., 2017). The semantic encoder is a 4-layer transformer encoder with the same hidden size as the backbone model. Following sentence-bert (Reimers and Gurevych, 2019), we average the outputs of all positions as the sequence-level representation. The learning rate for finetuning the semantic encoder at the second training stage is set as $1e-5$. All experiments are performed on 8 V100 GPUs. We accumulate the gradient of 8 iterations and update the models with a batch of about 65K tokens. The hyperparameters K and η in MGRC sampling are tuned on the validation set with the range of $K \in \{10, 20, 40, 80\}$ and $\eta \in \{0.15, 0.30, 0.45, 0.6, 0.75, 0.90\}$. We use the default setup of $K = 40$ for all three tasks, $\eta = 0.6$ for both Zh→En and En→De while $\eta = 0.45$ for En→Fr. For evaluation, the beam size and length penalty are set to 4 and 0.6 for the En→De as well as En→Fr, while 5 and 1.0 for the Zh→En task.

3.2 Main Results

Results of Zh→En. Table 1 shows the results on the Chinese-to-English translation task. From the results, we can conclude that our approach outperforms existing augmentation strategies such as back-translation (Sennrich et al., 2016a; Wei et al., 2020a) and switchout (Wang et al., 2018) by a large margin (up to **3.63** BLEU), which verifies that augmentation in continuous space is more effective than methods with discrete manipulations. Compared to the approaches that replace words in the embedding space (Cheng et al., 2020), our approach also demonstrates superior performance, which reveals that sentence-level augmentation with continuous semantics works better on generalizing to unseen instances. Moreover, compared to the vanilla Transformer, our approach consistently

Table 2: BLEU scores [%] on the WMT14 En→De and En→Fr tasks. "$*$" indicates the results obtained by our implementation, which is the same in Table 1. "†" denote estimate values. We further compare against the baselines with increased amounts of parameters, and investigate the performance of CSANMT equipped with much stronger baselines (e.g. deep and scale Transformers (Ott et al., 2018; Wang et al., 2019; Wei et al., 2020b)) in **Sec. 3.3**.

achieves promising improvements on five test sets.

Results of En→De and En→Fr. From Table 2, our approach consistently performs better than existing methods (Sennrich et al., 2016a; Wang et al., 2018; Wei et al., 2020a; Cheng et al., 2020), yielding significant gains (0.65∼1.76 BLEU) on the En→De and En→Fr tasks. An exception is that Nguyen et al. (2020) achieved comparable results with ours via multiple forward and backward NMT models, thus data diversification intuitively demonstrates lower training efficiency. Moreover, we observe that CSANMT gives 30.16 BLEU on the En→De task with the `base` setting, significantly outperforming the vanilla Transformer by 2.49 BLEU points. Our approach yields a further improvement of 0.68 BLEU by equipped with the wider architecture, demonstrating superiority over the standard Transformer by 2.15 BLEU. Similar observations can be drawn for the En→Fr task.

3.3 Analysis

Effects of K and η. Figure 4 illustrates how the hyper-parameters K and η in MGRC sampling affect the translation quality. From Figures 4(a)-4(c), we can observe that gradually increasing the number of samples significantly improves BLEU scores, which demonstrates large gaps between $K = 10$ and $K = 40$. However, assigning larger values (e.g., 80) to K does not result in further improvements among all three tasks. We conjecture that the reasons are two folds: (1) it is fact that the diversity of each training instance is not infinite and thus MGRC gets saturated is inevitable with K increasing. (2) MGRC sampling with a scaled item (i.e., $\mathcal{W}_r$) may degenerate to traverse in the same place. This prompts us to design more sophisticated algorithms in future work. In our experiments, we default set $K = 40$ to achieve a balance between the training efficiency and translation quality. Figure 4(d) shows the effect of η on validation sets, which balances the importance of two Gaussian forms during the sampling process. The setting of $\eta = 0.6$ achieves the best results on both the Zh→En and En→De tasks, and $\eta = 0.45$ consistently outperforms other values on the En→Fr task.

Lexical diversity and semantic faithfulness. We demonstrate both the lexical diversity (measured by TTR$= \frac{num.\ of\ types}{num.\ of\ tokens}$) of various trans-

5	Cosine similarity	Default MGRC	28.19

Table 5: Effect of MGRC sampling and tangential contrastive learning on En→De validation set.

lations and the semantic faithfulness of machine translated ones (measured by BLEURT with considering human translations as the references) in Table 4. It is clear that CsaNMT substantially bridge the gap of the lexical diversity between translations produced by human and machine. Meanwhile, CsaNMT shows a better capability on preserving the semantics of the generated translations than Transformer. We intuitively attribute the significantly increases of BLEU scores on all datasets to these two factors. We also have studied the robustness of CsaNMT towards noisy inputs and the translationese effect, see **Appendix D** for details.

Effect of the semantic encoder. We introduce two variants of the semantic encoder to investigate its performance on En→De validation set. Specifically, (1) we remove the extra semantic encoder and construct the sentence-level representations by averaging the sequence of outputs of the vanilla sentence encoder. (2) We replace the default 4-layer semantic encoder with a large pre-trained model (PTM) (i.e., XLM-R (Conneau et al., 2020)). The results are reported in Table 3. Comparing line 2 with line 3, we can conclude that an extra semantic encoder is necessary for constructing the universal continuous space among different languages. Moreover, when the large PTM is incorporated, our approach yields further improvements, but it causes massive computational overhead.

Comparison between discrete and continuous augmentations. To conduct detailed comparisons between different augmentation methods, we asymptotically increase the training data to analyze the performance of them on the En→De translation. As in Figure 5, our approach significantly outperforms the back-translation method on each subset, whether or not extra monolingual data (Sennrich et al., 2016a) is introduced. These results demonstrate the stronger ability of our approach than discrete augmentation methods on generalizing to unseen instances with the same set of observed data points. Encouragingly, our approach achieves comparable performance with the baseline model with only 25% of training data, which indicates that our approach has great potential to achieve good results with very few data.

Effect of MGRC sampling and tangential contrastive learning. To better understand the effectiveness of the MGRC sampling and the tangential contrastive learning, we conduct detailed ablation studies in Table 5. The details of four variants with different objectives or sampling strategies are shown in **Appendix C**. From the results, we can observe that both removing the recurrent dependence and replacing the Gaussian forms with uniform distributions make the translation quality decline, but the former demonstrates more drops. We also have tried the training objectives with other forms, such as variational inference and cosine similarity, to optimize the semantic encoder. However, the BLEU score drops significantly.

Training Cost and Convergence. Figure 6

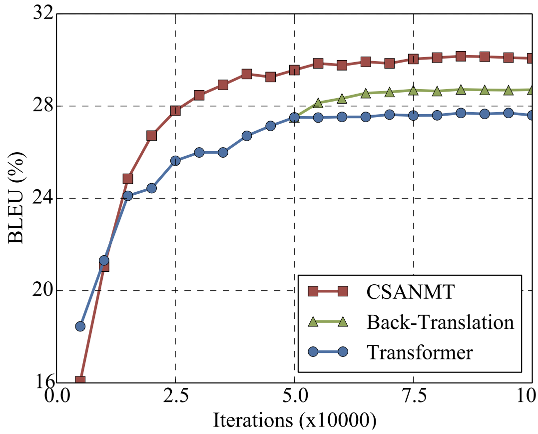

Figure 6: BLEU curves over iterations on the WMT14 English→German test set. Note that back-translation is initialized from the vanilla Transformer.

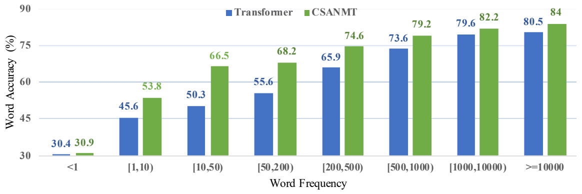

Figure 7: Comparison between the vanilla Transformer and CSANMT on prediction accuracy of words with different frequencies.

shows the evolution of BLEU scores during training. It is obvious that our method performs consistently better than both the vanilla Transformer and the back-translation method at each iteration (except for the first 10K warm-up iterations, where the former one has access to less unique training data than the latter two due to the K times over-sampling). For the vanilla Transformer, the BLEU score reaches its peak at about 52K iterations. In comparison, both CSANMT and the back-translation method require 75K updates for convergence. In other words, CSANMT spends 44% more training costs than the vanilla Transformer, due to the longer time to make the NMT model converge with augmented training instances. This is the same as the back-translation method.

Word prediction accuracy. Figure 7 illustrates the prediction accuracy of both frequent and rare words. As expected, CSANMT generalizes to rare words better than the vanilla Transformer, and the gap of word prediction accuracy is as large as 16%. This indicates that the NMT model alleviates the probability under-estimation of rare words via continuous semantic augmentation.

Table 6: BLEU scores [%] on WMT14 testsets for the English-German (En→De) and English-French (En→Fr) tasks. Superscript † denotes the numbers are reported from the paper, others are based on our runs. "-" means omitted results because of the limitations of GPU resources. "10 layers" means that we construct the Transformer with a 10-layer encoder, thus it has the same amount of parameters as our model.

Effects of Additional Parameters and Strong Baselines. In contrast to the vanilla Transformer, CSANMT involves with approximate 20% additional parameters. In this section, we further compare against the baselines with increased amounts of parameters, and investigate the performance of CSANMT equipped with much stronger baselines (e.g. deep and scale Transformers (Ott et al., 2018; Wang et al., 2019; Wei et al., 2020b)). From the results on WMT14 testsets in Table 6, we can observe that CSANMT still outperforms the vanilla Transformer (by more than 1.2 BLEU) under the same amount of parameters, which shows that the additional parameters are not the key to the improvement. Moreover, CSANMT yields at least 0.9 BLEU gains equipped with much stronger baselines. For example, the scale Transformer (Ott et al., 2018), which originally gives 29.3 BLEU in the En→De task, now gives 31.37 BLEU with our continuous semantic augmentation strategy. It is important to mention that our method can help models to achieve further improvement, even if they are strong enough.

3.4 Low-Resource Machine Translation

We further generalize the capability of the proposed CSANMT to various low-resource machine translation tasks, including IWSLT14 English-German and IWSLT17 English-French. The details of the datasets and model configurations can be found in **Appendix B**. Table 7 shows the results of different models. Compared to the vanilla Transformer, the proposed CSANMT improve the BLEU scores of the two tasks by 2.7 and 2.9 points, respectively.

Model	English-German	English-French
Transformer	28.64	35.8
Back-translation	29.45	36.3
CsaNMT	**31.29**	**38.6**

Table 7: BLEU scores [%] on the IWSLT tasks. For fairer comparison, all the models are implemented by ourselves using the same backbone, and the extra monolingual corpora is not introduced into back-translation.

This result indicates that the claiming of the continuous semantic augmentation enriching the training corpora with very limited observed instances.

4 Related Work

Data Augmentation (DA) (Edunov et al., 2018; Kobayashi, 2018; Gao et al., 2019; Khayrallah et al., 2020; Pham et al., 2021) has been widely used in neural machine translation. The most popular one is the family of back-translation (Sennrich et al., 2016a; Nguyen et al., 2020), which utilizes a target-to-source model to translate monolingual target sentences back into the source language. Besides, constructing adversarial training instances with diverse literal forms via word replacing or embedding interpolating (Wang et al., 2018; Cheng et al., 2020) is beneficial to improve the generalization performance of NMT models.

Vicinal Risk Minimization (VRM) (Chapelle et al., 2000) is another principle of data augmentation, in which DA is formalized as extracting additional pseudo samples from the vicinal distribution of observed instances. Typically the vicinity of a training example is defined using dataset-dependent heuristics, such as color (scale, mixup) augmentation (Simonyan and Zisserman, 2014; Krizhevsky et al., 2012; Zhang et al., 2018) in computer vision and adversarial augmentation with manifold neighborhoods (Ng et al., 2020; Cheng et al., 2021) in NLP. Our approach relates to VRM that involves with an adjacency semantic region as the vicinity manifold for each training instance.

Sentence Representation Learning is a well investigated area with dozens of methods (Kiros et al., 2015; Cer et al., 2018; Yang et al., 2018). In recent years, the methods built on large pre-trained models (Devlin et al., 2019; Conneau et al., 2020) have been widely used for learning sentence level representations (Reimers and Gurevych, 2019; Huang et al., 2019; Yang et al., 2019). Our work is also related to the methods that aims at learning the universal representation (Zhang et al., 2016; Schwenk and Douze, 2017; Yang et al., 2021) for multiple semantically-equivalent sentences in NMT. In this context, ***contrastive learning*** has become a popular paradigm in NLP (Kong et al., 2020; Clark et al., 2020; Gao et al., 2021). The most related work are Wei et al. (2021) and Chi et al. (2021), which suggested transforming cross-lingual sentences into a shared vector by contrastive objectives.

5 Conclusion

We propose a novel data augmentation paradigm CsaNMT, which involves with an adjacency semantic region as the vicinity manifold for each training instance. This method is expected to make more unseen instances under generalization with very limited training data. The main components of CsaNMT consists of the tangential contrastive learning and the Mixed Gaussian Recurrent Chain (MGRC) sampling. Experiments on both rich- and low-resource machine translation tasks demonstrate the effectiveness of our method.

In the future work, we would like to further study the vicinal risk minimization with the combination of multi-lingual aligned scenarios and large-scale monolingual data, and development it as a pure data augmentator merged into the vanilla Transformer.

Acknowledgments

We would like to thank all of the anonymous reviewers (during ARR Oct. and ARR Dec.) for the helpful comments. We also thank Baosong Yang and Dayiheng Liu for their instructive suggestions and invaluable help.

A Details of Rich-Resource Datasets

For the Zh→En task, the LDC corpus [2] is taken into consideration, which consists of 1.25M sentence pairs with 27.9M Chinese words and 34.5M English words, respectively. The NIST 2006 dataset is used as the validation set for selecting the best model, and NIST 2002 (MT02), 2003 (MT03), 2004 (MT04), 2005 (MT05), 2008 (MT08) are used as the test sets. We created shared BPE (byte-pair-encoding (Sennrich et al., 2016b)) codes with 60K merge operations to build two vocabularies comprising 47K Chinese sub-words and 30K English sub-words. For the En→De task, we employ the popular WMT14 dataset, which consists of approximately 4.5M sentence pairs for training. We select `newstest2013` as the validation set and `newstest2014` as the test set. All sentences had been jointly byte-pair-encoded with 32K merge operations, which results in a shared source-target vocabulary of about 37K tokens. For the En→Fr task, we use the significantly larger WMT14 dataset consisting of 36M sentence pairs. The combination of {`newstest2012, 2013`} was used for model selection and the experimental results were reported on `newstest2014`.

We use the Stanford segmenter (Tseng et al., 2005) for Chinese word segmentation and apply the script `tokenizer.pl` of Moses (Koehn et al., 2007) for English, German and French tokenization. We measure the performance with the 4-gram BLEU score (Papineni et al., 2002). Both the case-sensitive tokenized BLEU (compued by `multi-bleu.pl`) and the detokenized sacrebleu[3] (Post, 2018) are reported on the En→De and En→Fr tasks. The case-insensitive BLEU is reported on the Zh→En task.

B Low-Resource Machine Translation

For the low-resource scenario, we choose the IWSLT14 English-German (En→De) and IWSLT17 English-French (En→Fr) tasks.

Datasets. For IWSLT14 En→De, there are $160k$ sentence pairs for training and 7584 sentence pairs for validation. As in previous work (Ranzato et al., 2016; Zhu et al., 2020), the concatenation of dev2010, dev2012, test2010, test2011 and test2012 is used as the test set. For IWSLT17 En→Fr, there are $236k$ sentence pairs for training and 10263 for validation. The concatenation of test2010, test2011, test2012, test2013, test2014 and test2015 is used as the test set. We use a joint source and target vocabulary with $10k$ byte-pair-encoding (BPE) types (Sennrich et al., 2016b) for above two tasks.

Model Settings. The model configuration is `transformer_iwslt`, representing a 6-layer model with embedding size 512 and FFN layer dimension 1024. We train all models using the Adam optimizer with adaptive learning rate schedule (warm-up step with 4K) as in (Vaswani et al., 2017). During inference, we use beam search with a beam size of 5 and length penalty of 1.0.

C Variants with Different Objectives or Sampling Strategies

Table 8 describes the details of four variants (introduced in Table 5, from row 2 to row 5) with different objectives or sampling strategies: (1) default tangential CTL in Eq. (4) + MGRC w/o recurrent dependence, (2) default tangential CTL in Eq. (4) + MGRC w uniform distribution, (3) variational inference (Zhang et al., 2016) + Gaussian sampling, and (4) cosine similarity + default MGRC sampling.

Variants	Training Objective for the Semantic Encoder	Sampling Strategy for Obtaining Augmented Samples
1	$\mathbb{E}_{(\mathbf{x}^{(i)},\mathbf{y}^{(i)})\sim\mathcal{B}}\left(\log \frac{e^{s\left(r_{x^{(i)}},r_{y^{(i)}}\right)}}{e^{s\left(r_{x^{(i)}},r_{y^{(i)}}\right)}+\sum_{j\&j\neq i}^{\lvert\mathcal{B}\rvert}\left(e^{s\left(r_{y^{(i)}},r_{y'^{(j)}}\right)}+e^{s\left(r_{x^{(i)}},r_{x'^{(j)}}\right)}\right)}\right)$	$\omega^{(k)}\sim\eta\mathcal{N}\big(\mathbf{0},\mathrm{diag}(\mathcal{W}_r^2)\big)+(1.0-\eta)\mathcal{N}\big(\mathbf{0},\mathbf{1}\big)$
2	ditto	$\omega^{(k)}\sim\eta\mathcal{U}\big(-\mathcal{W}_r,\mathcal{W}_r\big)+(1.0-\eta)\mathcal{U}\big(\bar{\mathbf{a}}-\mathbf{1},\mathbf{1}-\bar{\mathbf{a}}\big)$ where $\bar{\mathbf{a}}=\frac{1}{k-1}\sum_{i=1}^{k-1}\omega^{(i)}$
3	$\mathbb{E}_{(\mathbf{x}^{(i)},\mathbf{y}^{(i)})\sim\mathcal{B}}\Big(-KL\big(p(r_{x^{(i)}})\parallel q(r_{x^{(i)}},r_{y^{(i)}})\big)\Big)$ where $p(r_{x^{(i)}})\sim\mathcal{N}(\mu,\sigma^2)$ and $q(r_{x^{(i)}},r_{y^{(i)}})\sim\mathcal{N}(\mu',\sigma'^2)$	$\hat{r}_x=\mu+\epsilon\odot\sigma$ where ϵ is a standard Gaussian noise
4	$\mathbb{E}_{(\mathbf{x}^{(i)},\mathbf{y}^{(i)})\sim\mathcal{B}}\Big(\frac{r_{x^{(i)}}^T r_{y^{(i)}}}{\lVert r_{x^{(i)}}\rVert\cdot\lVert r_{y^{(i)}}\rVert}\Big)$	$\omega^{(k)}\sim\eta\mathcal{N}\big(\mathbf{0},\mathrm{diag}(\mathcal{W}_r^2)\big)+(1.0-\eta)\mathcal{N}\Big(\frac{1}{k-1}\sum_{i=1}^{k-1}\omega^{(i)},\mathbf{1}\Big)$

Table 8: The variants of the training objective for the semantic encoder as well as the sampling strategy for obtaining augmented samples.

Model	**Noisy Inputs**				**Translationese**		
	Original	**WS**	**WD**	**WR**	$\mathbf{X}\rightarrow\mathbf{Y}^*$	$\mathbf{X}^*\rightarrow\mathbf{Y}$	$\mathbf{X}^{**}\rightarrow\mathbf{Y}^*$
Transformer (*our implementation*)	27.67	15.33	18.59	16.98	32.82	28.56	39.04
Back-Translation (*our implementation*)	29.25	17.20	20.44	18.71	33.07	29.73	39.86
CSANMT	30.16	20.14	23.76	21.66	34.62	30.70	41.64

Table 9: BLEU scores [%] on noisy inputs and the translationese effect, in the WMT14 En→De setup.

D Robustness on Noisy Inputs and Translationese

In this section, we study the robustness of our CSANMT towards both noisy inputs and the translationese effect (Volansky et al., 2013) on *newstest2014* for the WMT14 English-German task.

Noisy Inputs. Inspired by (Gao et al., 2019), we construct noisy test sets via several strategies described as follows:

- **Original**: the original testset without any manipulations;
- **WS**: word swap, randomly swap words in nearby positions within a window size 3 (Artetxe et al., 2018; Lample et al., 2018b);
- **WD**: word dropout, randomly drop words with a ratio of 15% (Iyyer et al., 2015; Lample et al., 2018b);
- **WR**: word replace, randomly replace word tokens with a placeholder token (e.g., `[UNK]`) (Xie et al., 2017) or with a relevant (measured by the similarity of word embeddings) alternative (Cheng et al., 2019). The replacement ratio also is 15%.

Translationese Effect. Edunov et al. (2020) pointed out that back-translation (BT) suffers from the translationese effect. that is BT only shows significant improvements for test examples where the source itself is a translation, or translationese, while is ineffective to translate natural text. To test the effect of our method on translationese, we follow the same settings and testsets[4] provided by Edunov et al. (2020):

- natural source → translationese target ($\mathbf{X}\rightarrow\mathbf{Y}^*$);
- translationese source → natural target ($\mathbf{X}^*\rightarrow\mathbf{Y}$);
- round-trip translationese source → translationese target ($\mathbf{X}^{**}\rightarrow\mathbf{Y}^*$), where $\mathbf{X}\rightarrow\mathbf{Y}^*\rightarrow\mathbf{X}^{**}$.

Results. As shown in Table 9, our approach shows better robustness over two baseline methods across various artificial noises. Moreover, CSANMT consistently outperforms the baseline in all three translationese scenarios, the same is true for back-translation. However, Edunov et al. (2020) shows that BT improves only in the $\mathbf{X}^*\rightarrow\mathbf{Y}$ scenario. Our explanation for the inconsistency is that BT without monolingual data in our setting benefits from the natural parallel data to deal with the translationese sources.

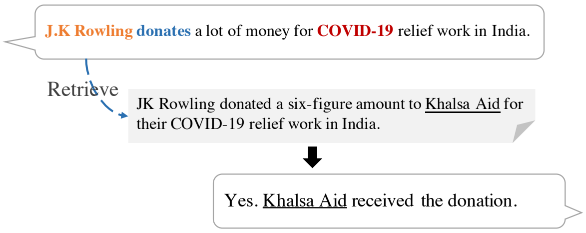
Abstract

We propose knowledge internalization (KI), which aims to complement the lexical knowledge into neural dialog models. Instead of further conditioning the knowledge-grounded dialog (KGD) models on externally retrieved knowledge, we seek to integrate knowledge about each input token internally into the model's parameters. To tackle the challenge due to the large scale of lexical knowledge, we adopt the contrastive learning approach and create an effective token-level lexical knowledge retriever that requires only weak supervision mined from Wikipedia. We demonstrate the effectiveness and general applicability of our approach on various datasets and diversified model structures.

1 Introduction

Vacuous responses (Li et al., 2016; Ghazvininejad et al., 2018), such as, *I don't know*, are commonly observed in end-to-end neural dialog models (Shang et al., 2015; Sordoni et al., 2015). This is mostly because these models ignore the knowledge that resides in people's minds during a conversation. To bridge the gap, many existing works (Moghe et al., 2018; Dinan et al., 2018) have attempted to condition the dialog model on external knowledge, either a sentence or a paragraph, retrieved based on the utterance and/or previous context. This curates datasets with utterance-response-knowledge triples (see Fig 1(a)). These knowledge-grounded dialog (KGD) models, despite demonstrated effectiveness, suffer from two major problems.

First, equipping models with sentence-level knowledge alone will limit responses' informativeness and diversity. As shown in Fig 1(a), with the knowledge retrieved giving the utterance, a KGD model can relate *J.K Rowling* to *Khalsa Aid*. However, retrieval based solely on sentence embeddings will result in ignorance of lexical knowledge associated with individual tokens. In this example, the knowledge about *J.K Rowling*, *COVID-19*, *donates*, and *India*, is ignored during the retrieval, due to the semantic gaps between those lexical knowledge sentences (see Fig 1(b)) and the utterance. This makes it rather difficult (if not impossible) for the model to generate responses carrying relevant information as shown in Fig 1(b).

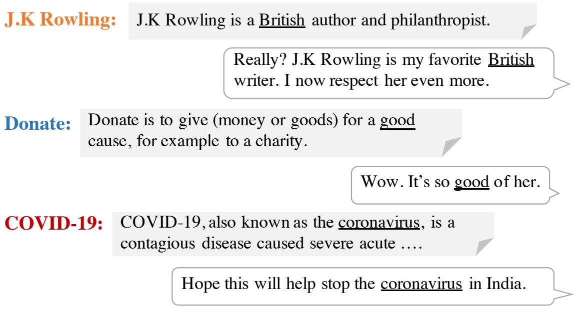


J.K Rowling donates a lot of money for COVID-19 relief work in India.

JK Rowling donated a six-figure amount to Khalsa Aid for their COVID-19 relief work in India.

Yes. Khalsa Aid received the donation.

(a) An utterance-response-knowledge triple.



J.K Rowling is a British author and philanthropist.

Really? J.K Rowling is my favorite British writer. I now respect her even more.

Donate is to give (money or goods) for a good cause, for example to a charity.

Wow. It's so good of her.

COVID-19, also known as the coronavirus, is a contagious disease caused severe acute ….

Hope this will help stop the coronavirus in India.

(b) Responses based on different lexical knowledge.

Figure 1: (a) An exemplary KGD data sample with an utterance (top), a response (bottom), and a sentence-level knowledge (middle). (b) A list of lexical knowledge (in grey rectangle) related to words from the utterance in (a), and the potential responses (in white speech balloon) people would make given that knowledge.

Second, retrieving knowledge for open-domain dialogs during inference incurs heavier computation, often involving similarity search over tens of millions of passages (Petroni et al., 2021). Existing systems (Zhao et al., 2020; Zheng et al., 2020) alleviate this problem relying on pre-selecting a

small candidate set based on TF-IDF (Schütze et al., 2008), in sacrifice of the diversity and the accuracy of the retriever. Directly conditioning the dialog model on the retrieved text, these models are easily effected by the quality of the constructed candidate set and are thus prone to errors (Dinan et al., 2018; Kim et al., 2020; Zhao et al., 2020).

In this work, we propose to complement the lexical knowledge into neural dialog models by **K**nowledge **I**nternalization (**KI**), a training approach based on contrastive learning (Hadsell et al., 2006). The central idea of KI is to integrate more fine-grained lexical knowledge about each input token internally into model parameters (e.g., word embeddings), rather than further conditioning the model on externally retrieved knowledge (e.g., directly copy and/or modify tokens from external knowledge when decoding). Our research contributions include:

- a novel training objective (KI; §3.2) that infuses lexical semantics into word representations. With the knowledge internalized into the contextualized representation of every token, a dialog model can generate informative and diverse responses *without* engaging an external knowledge retrieval module during inference time, thus making the inference more efficient (§6.1);
- an effective token-level lexical knowledge retriever (§4) trained with weak supervision to contextually align tokens in dialog corpora to their related and possibly different knowledge (Appendix C).
- a demonstration of the effectiveness and general applicability of KI with extensive experiments on diversified dialog models and on three benchmark datasets: DailyDialog (Li et al., 2017), Wizard of Wikipedia (Dinan et al., 2018), and Commonsense Reddit Dataset (Zhou et al., 2018).

2 Related Work

To address the vacuous responses problem in neural dialog models, researchers propose to ground dialogs on real world knowledge and construct new corpora that contain utterance-response-knowledge triples. Specifically, responses are grounded to external knowledge derived from different knowledge sources (Zhou et al., 2018; Liu et al., 2018; Wu et al., 2019; Dinan et al., 2018; Moghe et al., 2018; Ghazvininejad et al., 2018; Mostafazadeh et al., 2017; Meng et al., 2020; Zhang et al., 2020). Among different sources, textual knowledge (Dinan et al., 2018; Parthasarathi and Pineau, 2018; Qin et al., 2019) receives the most attention as it is easy to obtain and scale. However, the construction of knowledge-grounded datasets is costly and time-consuming. To build a more practical system without assuming a given knowledge, recent studies enhance KGD models with an extra knowledge selection component (Dinan et al., 2018; Kim et al., 2020; Zheng et al., 2020; Zhao et al., 2020).

Most existing KGD models can be viewed as *models with externalized knowledge*, where knowledge is explicitly used as part of the model input. The principle behind these models is to copy words and/or modify sentences from external knowledge when generating responses (Wu et al., 2020; Zhu et al., 2017; Zhao et al., 2019). Our KI, on the other hand, does not explicitly present knowledge to dialog models for reading and/or copying. Instead, we inject and store external knowledge into models' parameters and encourage models to elicit the encoded knowledge during generation.

The idea of knowledge internalization has also been explored in language modeling. Factual knowledge (Zhang et al., 2019; Sun et al., 2020; Liu et al., 2020), visual knowledge (Tan and Bansal, 2020) and syntactic knowledge (Kuncoro et al., 2020) have been injected into language models (LMs) and shown great promise in improving the performance of downstream tasks. KI differs from those knowledge-enhanced LMs in two aspects: (i) KI can be trained end-to-end with dialog models, while applying LMs on dialog generation often requires multiple rounds of pre-train and fine-tune. (ii) KI is lightweight that barely introduces extra parameters to the dialog model while applying LMs usually introduces hundreds of millions of extra parameters.

3 Knowledge Internalization for Neural Dialog Models

In this section, we illustrate how to train a dialog model with knowledge internalization. To infuse more fine-grained lexical knowledge to a neural dialog model, we assume a dialog corpus where each token is aligned with relevant knowledge (we will discuss the construction of such a corpus in §4). In particular, for an input sentence X in the corpus, we assume each token $x_i \in X$ is associated with a corresponding descriptive sentence K_i.

3.1 Preliminary

Given an utterance-response pair (X, Y), where $X = \{x_1, x_2, \ldots, x_n\}$ and $Y = \{y_1, y_2, \ldots, y_m\}$, neural dialog models generally minimize the negative log-likelihood loss:

$$\mathcal{L}_{\mathrm{NLL}}(X, Y) = -\sum_{i=1}^{m} log\mathcal{P}(y_i), \tag{1}$$

where $\mathcal{P}(y_i) = \mathcal{P}(y_i|y_{<i}, X)$ is the probability of generating the i-th response token y_i given the utterance X and other tokens generated in previous steps $y_{<i} = \{y_1, y_2, \ldots, y_{i-1}\}$. $\mathcal{P}(y_i)$ is generally modeled by a sequence-to-sequence model (Sutskever et al., 2014), which consists of an encoder and a decoder. The encoder represents X as a sequence of hidden vectors $H(X) = h_1, h_2, ..., h_n$, where each h_i is a low-dimensional representation of the token x_i. The decoder generates y_i based on $H(X)$ and $y_{<i}$, often with the attention mechanism (Bahdanau et al., 2014).

3.2 Knowledge Internalization Loss

Given a dialog corpus with token-level knowledge as discussed above, we now introduce a new training task: knowledge internalization (**KI**). In KI, we seek to boost dialog models by internalizing lexical knowledge into each token's representation. In particular, each token x_i and its associated knowledge K_i are first mapped into a low-dimensional space. We then adopt contrastive learning to shorten the distance between x_i and K_i in the space while enlarging that between x_i and other irrelevant knowledge.

Note that for each $x_i \in X$, dialog models' encoder can embed it into a contextualized representation h_i. Therefore, we only need an extra knowledge encoder to represent K_i as $g(K_i)$ (details will be given in § 4.2). After h_i and $g(K_i)$ are computed, we calculate the similarity between x_i and K_i by the inner product:

$$s(x_i, K_i) = f_1(h_i)^\top f_2(g(K_i)), \tag{2}$$

where f_1 and f_2 are the functions that map the h_i and $g(K_i)$ into the same vector space and normalize them.

For each (x_i, K_i) pair, we randomly sample an in-batch unrelated knowledge K_i^- associated with other input sentences, where $K_i^- \neq K_i$, to construct a negative sample pair (x_i, K_i^-) in contrastive learning. Finally, the objective function of KI is defined by the contrastive loss between positive and negative sample pairs:

$$\mathcal{L}_{KI}(X) = \sum_{i=1}^{n} \max\{0, m - s(x_i, K_i) + s(x_i, K_i^-)\}, \tag{3}$$

where m denotes the margin.

3.3 Knowledge-internalized Neural Dialog Model

We now illustrate how to deploy KI on a neural dialog model. We use a sequence-to-sequence dialog model based on Transformer (Vaswani et al., 2017) as an example. The original model is trained to minimize the negative log-likelihood loss of response tokens, i.e., $\mathcal{L}_{\mathrm{NLL}}(X, Y)$ (see Eq. 1). We can conveniently integrate KI into the model by reusing the contextualized representations generated by the model's encoder. The training objective of a knowledge-internalized dialog model can then be formulated as:

$$\mathcal{L} = \mathcal{L}_{\mathrm{NLL}}(X, Y) + \lambda \mathcal{L}_{KI}(X) \tag{4}$$

where λ is a hyperparameter. Note that the token-level knowledge is only required during training to compute $\mathcal{L}_{KI}(X)$. At the inference time, those relevant knowledge is no longer required as they have been *internalized* into model by KI, making inference more efficient.

4 Retrieval of Token-level Lexical Knowledge

In this section, we present how to train an effective retriever to mine knowledge for each token in the dialog corpora. Given a dialog utterance $X = \{x_1, x_2, \ldots, x_n\}$, the trained retriever will retrieve a relevant knowledge K_i for each token x_i in X. The constructed token-knowledge alignments can then be used to train a knowledge-internalized neural dialog model as in § 3.

4.1 Training Data Collection

To train such a retriever, we need a corpus with token-level knowledge annotated. However, to our best knowledge, no human annotated data exist and it is prohibitively expensive to build one. We therefore seek to train the retriever with distant supervision. A straight-forward solution is to align the noun words in an utterance to certain knowledge graph triples using entity linking tools (Shen et al., 2014). The problem of that is it can only cover about 15% words in human conversations (Biber et al., 2000).

To address this issue, we propose to mine token-knowledge distant annotations from Wikipedia. In each Wiki article, the first sentence $S = \{s_1, s_2, ..., s_n\}$ is mostly declarative that gives a high-level summary on the topic of the article. Thus this sentence can used as a lexical knowledge item, denoted as K (note that K and S refer to the same sentence here). Inspired by Tan and Bansal (2020), we then further associate every token in the sentence with this knowledge item. These constructed alignments (e.g., (s_i, K)) can then be used to train a token-level knowledge retriever.

4.2 Training of Retriever

The core of the retriever's training is to learn a scoring function $r(s_i|S, K)$ to measure the relevance between a token s_i and a knowledge item K, giving s_i'context S. Similar as Eq. 2, we implement the scoring function $r(s_i|S, K)$ as the inner product between s_i'contextualized token representation $f(h_i)$ and the knowledge representation $f(g(K))$. Here, we use a pre-trained BERT (Devlin et al., 2019) model to obtain h_i; we apply another pre-trained BERT model to encode knowledge K and further generate $g(K)$ with an average-pooling operator. Two BERT models will be fine-tuned with the retriever.

Our training objective is to maximize the relevance score of aligned token-knowledge pairs while minimizing that of unaligned pairs. We also adopt the hinge loss similar as in Eq 3 by replacing x_i in the dialog corpus to s_i in the constructed token-knowledge pairs.

4.3 Mining Token-level Lexical Knowledge

Once the retriever is trained, we can use it to mine token-level lexical knowledge required in KI. We first construct a candidate knowledge base $\mathcal{K}$ that consists of 6.4 million knowledge items (first sentence) extracted from Wikipedia articles. Given a dialog utterance $X = \{x_1, x_2, \ldots, x_n\}$, we retrieve a lexical knowledge K_i for each token x_i by searching for the knowledge item that has the largest relevance score with x_i.

$$K_i = \arg\max_{K \in \mathcal{K}} r(x_i|X, K) \qquad (5)$$

To improve the retrieval results, we further employ two useful strategies: (i) *Stopword Masking*, where we discard knowledge associated with stopwords; (ii) *Exact Matching*, where if an utterance token exactly matches the title of a Wikipedia article, we will directly return the first sentence of this article as the retrieval result.

The retrieval process has two properties that can significantly improve dialog corpora's knowledge coverage. First, the retrieval is *contextualized* such that a token can be aligned to different knowledge items when it occurs in different contexts. Second, the retrieval is at token-level that enables us to associate each dialog sentence with multiple knowledge items (See Appendix C).

5 Experimental Setups

In this section, we present the datasets and metrics used for evaluation.

Datasets We use three datasets from various domains (statistics in Appendix A). The first one is *DailyDialog* (Li et al., 2017), a multi-turn dialog benchmark that contains daily dialogs recorded as utterance-response pairs. However, there is no knowledge associated with the dialogs in DailyDialog, making it difficult to evaluate the informativeness of generated responses. To fully illustrate the strength of KI, we further consider two knowledge-grounded datasets: (i) *Wizard of Wikipedia (WoW)* (Dinan et al., 2018), a multi-turn dataset that contains utterance-response-knowledge triples. For each dialog, a sentence retrieved from Wikipedia is selected to guide response generation. WoW contains two test sets: Test Seen/Unseen, where the latter includes topics that never appear in Train and Valid set. (ii) *Commonsense Reddit Dataset (CRD)* (Zhou et al., 2018): a weakly knowledge-grounded single-turn dataset. Each dialog in the dataset is paired with at least one triple automatically extracted from ConceptNet (Speer et al., 2017).

Metrics We conduct both automatic evaluation and human annotations. For automatic evaluation, we evaluate the generated responses from three perspectives [1]:

- *Appropriateness*: we employ *Perplexity* (PPL), corpus-level BLEU-4 (Papineni et al., 2002) and ROUGE-l (Lin, 2004).
- *Diversity*: the ratio of distinct uni/bi-grams in all generated texts, i.e., Distinct-1/2 (Li et al., 2016).

---

[1] For PPL and %safe, smaller is better, while for all other metrics, larger is better.

- *Informativeness*: For WoW, we consider wikiF1 (Dinan et al., 2018), the overlapping F1 between the generated response and the grounded knowledge. For CRD, we calculate entity score (Ent.) (Zhou et al., 2018), the average number of entities per response. To further measure the likelihood of generating safe responses, we define *%safe*: the percentage of responses that contains "I'm not sure" or "I don't know". [2] We also report the accuracy of knowledge selection (ACC) following Zheng et al. (2020).

We further perform human annotations by randomly sampling 200/200/300/300 examples from WoW Test Seen/WoW Test Unseen/ CRD/DailyDialog, respectively. We recruit 5 annotators from a commercial annotation company to rate each response on a scale of 1-5 for its *appropriateness* (Zhang et al., 2020; Zheng et al., 2020) and *informativeness* (Young et al., 2018; Zhu et al., 2019). The former measures whether the topic of the response fits that of the utterance, while the latter evaluates whether a response provides new information. A response is scored 1 if it is not appropriate/informative at all, 3 if part of the response is appropriate/informative, 5 if it is highly related to utterance and context or it can provide rich information to deepen the discussion. 2 and 4 are for decision dilemmas.

6 Experiments

We evaluate the performance of KI by comparing it with three sets of baselines:

1. We first investigate the effectiveness and general applicability of KI by applying KI on conventional dialog models that are randomly initialized and trained with utterance-response pairs only.
2. We then investigate whether KI can complement or even further improve the state-of-the-art KGD model's performance.
3. As discussed in §2, although LMs differ from KI in many aspects, they also capture knowledge in their parameters. We thus compare KI with LMs to investigate its effectiveness in encouraging informative and appropriate responses.

All model structures and training setups are given in Appendix B.

6.1 vs. Conventional Dialog Models

We first deploy KI on two representative neural dialog models that do not directly condition on any external knowledge: (i) *Seq2Seq*: a LSTM-based (Hochreiter and Schmidhuber, 1997) sequence-to-sequence model with the attention mechanism (Bahdanau et al., 2014); (ii) *Transformer* (Vaswani et al., 2017): an encoder-decoder architecture relying solely on the attention mechanisms.

Effectiveness As shown in Table 1's Setup 1 (rows 1-8), dialog models with KI consistently outperform their counterparts without KI on almost all the metrics across the datasets used. We want to point out the advantage of KI from two perspectives:

(1) Promoting informativeness. We first observe that applying KI can significantly improve the wikiF1 and Ent. scores. Unlike KGD models that can generate informative responses by explicitly copying words from given knowledge, models discussed here are not provided with any external knowledge during testing (thus copy mechanism is not applicable for them). This suggests that the improvement in informativeness should be attributed to the effectiveness of KI in injecting knowledge into models' parameters. The *Info.* scores from human evaluation in Table 2 can also substantiate our findings.

(2) Promoting diversity and reducing occurrence of safe response. Compared with the plain models, models with KI can significantly improve the Distinc-1/2 scores on all the test sets (sometimes doubled, even tripled). We also see a significant reduction of safe responses by the gap in %safe scores. Those improvements are powered by the rich lexical knowledge used in KI (see Appendix C).

Efficiency Besides the improvements in responses' quality, KI is also very efficient during inference. We report the decoding speed of Transformer and Transformer+KI in Table 3. As we can see, KI does not incur any extra computation during inference.

6.2 vs. KGD

We then apply KI on *DiffKS* (Zheng et al., 2020) [3]: a state-of-the-art model that uses a knowledge-aware decoder to generate a response based on

---

[2] Upon manual inspection, we find that these two are the most common safe responses generated.

Table 1: Automatic evaluation results for models with internalized knowledge (trained with utterance-response pairs), and models with externalized knowledge (trained with utterance-response-knowledge triples).

utterance and the knowledge retrieved from a set of candidates. In the empirical study, DiffKS has outperformed many KGD models like CCM (Zhou et al., 2018) [4] and ITDD (Li et al., 2019). We enhance DiffKS by applying KI on its context encoder. The rest of the model remains unchanged.

Table 1 Rows 9-10 show that DiffKS with KI improves ACC over the plain DiffKS model. The reason is that with the injection of token-level knowledge, DiffKS can better understand the utterance, which leads to more accurate knowledge selection and thus less noisy external knowledge. As a result, we observe clear gains on overlapping-based metrics (BLEU and ROUGE). These results emphasize the importance of more fine-grained knowledge in KGD. Human evaluation results (Table 2) also suggest that KI can help KGD models in generating more informative and appropriate responses.

6.3 vs. Pre-trained Language Models

We follow previous practice (Rothe et al., 2020) to replace the Transformer's encoder with LMs and keep the decoder the same as the *Transformer* above. [5] We consider two baselines: (i) *Bert2Rnd*: Initializing Transformer's encoder with a pre-trained BERT, which has been shown capturing rich factual knowledge during pre-training (Petroni et al., 2019; Jiang et al., 2020). (ii) *Ernie2Rnd*: Initializing the encoder with ERNIE 2.0 (Sun et al., 2020), a knowledge-enhanced BERT which is pre-trained with novel objectives that injecting lexical, syntactic, and semantic knowledge into its parameters (Zhang et al., 2019).

From Table 4, we see that parameters of LM-based models (Bert2Rnd and Ernie2Rnd) are more than three times than that of the Transformer baseline. But they do not seem to help improve informativeness (based on wikiF1, BLEU-4, and Info.) of responses. This indicates that although pre-trained LMs can encode knowledge in their parameters, eliciting the encoded knowledge for response generation is difficult when we only have utterance-response pairs for training. Another reason might be that previously learned knowledge is forgotten due to catastrophic forgetting (McCloskey and Cohen, 1989). Comparing with knowledge-enhanced LMs, KI is more lightweight and more effective.

In addition, we observe that introducing LMs can significantly improve responses' diversity as KI does. However, according to Appr. metric and upon manual examination, we find that although the generated responses are diverse, they are often inconsistent with the context or hallucinating non-existing facts (e.g., "Yea, Canada is the largest country in the US."). These are known issues for LMs as discussed in Dou et al. (2021); Shuster et al. (2021); Chen et al. (2020).

We also apply KI on Bert2Rnd/Ernie2Rnd, but we do not observe significant improvements as when applied on randomly initialized models. This could be due to the fact that we implement KI using knowledge from Wikipedia, which is already part of LMs' training corpora. We leave it as future work to investigate how to use KI to elicit knowledge from LMs better (e.g., use adapters (Xu et al.,

---

[4] Comparison with CCM is in Appendix D

[5] We keep the hidden state dimension of decoder consistent with the LMs to enable encoder-decoder attention.

2021) or prompt (Liu et al., 2021)).

7 Method Analysis

In this section, we perform an in-depth analysis to understand the effectiveness of KI.

7.1 Working Principle of KI

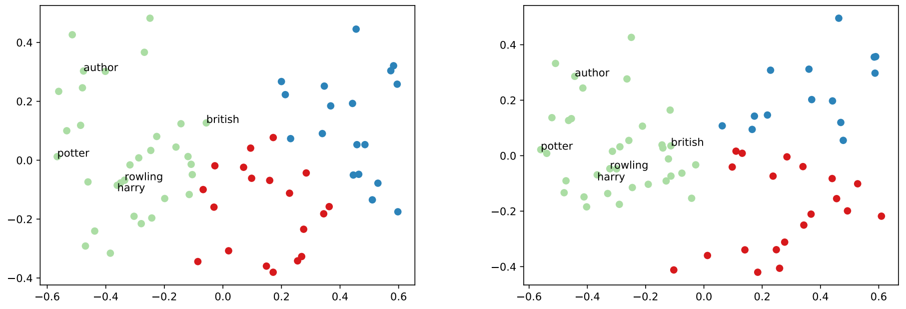
We investigate the working principle of KI by visualizing the token embeddings learned on WoW. We use principal component analysis (PCA) to map embeddings into a two-dimensional space as shown in Fig 2. Since there is no co-occurrence of British and Rowling in WoW, their embeddings learned by Transformer are distant (see Fig 2(a)). However, their embeddings learned by Transformer+KI (see Fig 2(b)) are much closer. This is because KI injects lexical knowledge (i.e., a British author) into the embedding of Rowling. Specifically, the Euclidean distances between British and Rowling are 0.37 for Transformer and 0.22 for Transformer+KI, respectively. This observation sheds light on the working principle of KI: the contrastive learning objective shortens the embedding distance between a token and tokens from its lexical knowledge. Thus when decoding, if a token is predicted (e.g. Rowling), its relevant knowledge tokens (e.g., British) are likely to receive high probabilities and be selected in the following steps (see the J.K Rowling example in Fig 1(b).

7.2 Effectiveness of Token-level Knowledge

Firstly, we experiment with a model variant (denoted as Random), which randomly assign knowledge to each utterance token. Results in Table 5 (Row 2) validate the effectiveness of the proposed token-knowledge retriever.

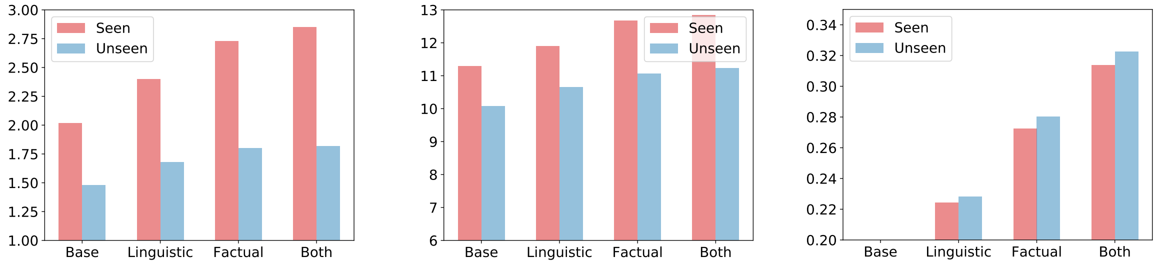
To further show the advantage of token-level knowledge, we consider a model variant in which we degenerate token-level KI to sentence-level by assigning all utterance tokens to a same lexical knowledge (we denote it as *Sentence-level knowledge*). Given the lexical knowledge retrieved for each token in an utterance, the sentence-level knowledge is chosen as the most-frequent one among all token-level knowledge. The results are summarized in Table 5 (Row 3). Note that token-level knowledge results in better performance than sentence-level knowledge. This shows that fine-grained information is useful in promoting more informative and diverse responses.

Lastly, we dive deep into the lexical knowledge retrieved to investigate which type of knowledge is most helpful in response generation. We classify a retrieved knowledge into two types: factual knowledge, which describes a real-world subject (e.g., knowledge about J.K Rowling), and is often associated with noun words in the utterance; linguistic knowledge, which explains the meaning of certain words (e.g., knowledge about donate, see Fig 1(b), and is often associated with words except nouns.We use part-of-speech (POS) tags to classify tokens and their associated knowledge. We consider two model variants that only use factual/linguistic knowledge in KI respectively, denoted as *factual* and *linguistic*. In Fig 3, we compare these two model variants to a vanilla model without KI (denoted as *base*), and a full model that uses both knowledge (denoted as *both*). We find that injecting factual knowledge brings significant improvements on BLEU-4 and ROUGE-l. We also observe similar, albeit smaller improvements when equipping with linguistic knowledge. More interestingly, these two types of knowledge can complement one another to further improve the model



(a) Transformer (b) Transformer+KI

Figure 2: Visualization of word embeddings learned by Transformer and Transformer+KI. We use words from two sources: 1) lexical knowledge retrieved for *Rowling*: "J.K. Rowling is a British author and philanthropist." 2) tokens from WoW that co-occur with "Rowling" in a sentence. Note that there is no co-occurrence of Rowling and British/author in WoW. All words are lower cased in the visualization. We use the K-means algorithm to group tokens into 3 clusters (shown in different colors).



(a) BLEU-4 (b) ROUGE-l (c) Knowledge Coverage

Figure 3: Automatic evaluation results on WoW Test Seen and Unseen. *Base* is the Transformer baseline without KI. *Both* is the Transformer+KI, with both linguistic and factual knowledge. *Linguistic/Factual* only considers linguistic/factual knowledge in KI, respectively.

Row	Setting	wikiF1	BLEU-4	ROUGE-l	Distinc-1/2	%safe
1	**Token-level**	11.25	2.85	12.84	5.66/18.68	35.18
2	**Random**	5.38	1.27	9.39	1.01/2.31	92.10
3	**Sentence-level**	8.41	2.31	11.72	2.98/7.77	66.32

Table 5: Comparison of model variants for Transformer+KI, using different type of knowledge. Models are evaluated on WoW Test Seen.

performance. This emphasizes the need to consider non-factual knowledge in KGD, which is usually ignored in previous study. To understand what causes the difference between using factual and linguistic knowledge, we compute *Knowledge Coverage*: the percentage of ground truth response tokens that have been recalled in the retrieved knowledge. As we can see from Fig 3(c), factual knowledge is more helpful because people tend to respond based on knowledge related to subjects (usually nouns) appearing in the dialog.

7.3 Case Study

We show an example case in Appendix E to demonstrate how KI improves dialog generation and what the limitation is.

8 Conclusion

We propose knowledge internalization (KI), which aims to incorporate the lexical knowledge into neural dialog models. Models with KI can generate informative and diverse responses without explicitly conditioning on external knowledge. To provide the fine-grained knowledge needed in KI, we also build an effective token-level lexical knowledge retriever that contextually align tokens in a sentence to their related knowledge. We show the effectiveness and general applicability of KI by evaluating KI on various datasets and diversified model structures.

Dataset	Train	Valid	Test
WoW	166,787	17,715	8,715/8,782
CRD	3,384,185	20,000	10, 000
DailyDialog	54,889	6,005	5,700

Table 6: Dataset statistics. WoW includes two test sets: Test Seen/Unseen, where the latter contains topics that never appear in Train and Valid set.

A Dataset Statistics

B Implementation Details

The vocabulary size for DailyDialog/WoW/CRD is 14,696/22,168/22,512, respectively, with sentences tokenized using BERT's tokenizer provided by Transformers (Wolf et al., 2020). For Seq2Seq and Transformer, we use a shared vocabulary between the encoder and the decoder. In Seq2Seq, we adopt a 2-layer bidirectional LSTM as the encoder and an unidirectional one as the decoder. The hidden size is set to 256, with a dropout probability of 0.3. The Transformer we used has 6 encoder/decoder layers. The dimensions of the input layer, output layer, and inner feed-forward layer are set to 512, 512, and 1,024, respectively. The number of attention heads is set to 4.

We use Adam with $\beta_1 = 0.9$, $\beta_2 = 0.98$ for model optimization and start training with a warm-up phase where we linearly increase the learning rate from 10^{-7} to 0.005. After that we decay the learning rate proportional to the number of updates. Each training batch contains at most 4,096 source/target tokens. We early-stop the training if validation loss does not improve over ten epochs. We perform beam search with a beam size of 5. The λ (see Eq 3) is set to 1 in all our evaluation.

For Bert2Rnd and Ernie2Rnd, we initialize the Transformer's encoder with the pre-trained LMs using the Transformers (Wolf et al., 2020) and keep the decoder the same as above. Note that due to the exist of encoder-decoder attention, we modify the dimensions of input/output layer to 768 to be compatible with BERT (*bert-base-uncased*) and ERNIE (*nghuyongernie-2.0-en*). We share the embeddings between encoder and decoder. Models are learned with Adam optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.98$. Learning rate is set to 1e4 with a linear scheduler. Each training batch contains 128 samples. The LMs are fine-tuned together with the decoder. We also experimented with LMs frozen, but this generally works worse.

Number of knowledge items	WoW	DailyDialog	CRD
per token	30	26	38
per sentence	15	12	9

Table 7: Averaged number of knowledge items associated with each token/sentence.

Context: one of our favorite books is the wonderful wizard of oz by author l . frank ba ##um and published in 1900 !
Knowledge: The Wonderful Wizard of Oz is an American children's novel written by author L. Frank Baum and illustrated by W. W. Denslow, originally published by the George M. Hill Company in May 1900.
Context: it ' s about a young wizard at hog ##wart ##s , right ?
Knowledge: The book follows Harry Potter, a young wizard, in his third year at Hogwarts School of Witchcraft and Wizardry.

Table 8: An example case from WoW. Given different contexts, the token *wizard* is aligned to different knowledge items.

C Analysis of Token-level Knowledge Retrieval

Since our retrieval component is based on the contextualized representations (see § 4.2), the same token can be aligned to different knowledge when it occurs in different contexts. As the supporting evidence, in Table 7, we report the averaged number of knowledge items associated with each token. In Table 8, we show an example of the same token being aligned to different knowledge items when giving different contexts. In addition, our approach exposes each dialog sentence to very diverse knowledge items. The rich lexical knowledge, both at the token-level and sentence-level, is the key to KI's good performance.

We further conduct an ablation study to investigate the effectiveness of two additional retrieval strategies: stopword masking and exact matching (§ 4.3). We remove each strategy and keep the other unchanged. The results are presented in Table 9. As we can see, both strategies are useful for generating appropriate (based on PPL, BLEU-4, and ROUGE-l), informative (based on WikiF1), and diversified (based on Distinc-1/2) responses.

Row	**Setting**	**wikiF1**	**BLEU-4**	**ROUGE-l**	**Distinc-1/2**	**PPL**
1	**Transformer+KI**	11.25	2.85	12.84	5.66/18.68	46.68
2	*wo stopwords masking*	5.23	2.63	12.68	5.48/21.74	57.27
3	*wo exact matching*	10.74	2.54	11.99	4.75/15.27	47.65

Table 9: Retrieval strategy ablation results on WoW Test Seen.

Model	PPL	Ent.
CCM	39.18	1.18
Transformer+KI	28.50	3.29

Table 10: Automatic evaluation on CRD. Numbers of CCM are taken from their paper.

Context: SpeakerA: I like Dylan's Bars, do you? SpeakerB: Yes Dylan's Candy Bar is my favorite boutique candy store.
Utterance: They have everything! I just love it.
Gold Response: Yes Ralph Lauren's daughter Dylan Lauren owns them.
Transformer: I'm not sure , but I do know that they have been around for a long time!
Transformer+KI: I love their chocolate chip cookies! They're actually the second largest candy company in the world! **Knowledge for Dylan's:** Lauren was inspired to create the store, which is asserted to be the "largest unique candy store in the world", by the Roald Dahl story of Willy Wonka the Chocolate Factory **Knowledge for like:** In English, the word like has a very flexible range of uses, ranging from conventional to non-standard.

Table 11: An example case from WoW Seen.

D Comparison with CCM

Similar to KI, CCM augments dialog corpora with token-level commonsense knowledge. In each encoding and decoding step, CCM explicitly uses the retrieved commonsense knowledge triples by concatenating their representations with the token representation. As existing KGD models, CCM also requires extra knowledge as input during both training and inference. Training CCM on the CRD dataset takes about a week on one Titan X GPU. The comparison of model performance is shown in Table 10. As we can see, there is a significant gap between CCM and Transformer+KI. Thus in §6.2, we consider applying KI on a more state-of-the-art and recent KGD model: DiffKS.

E Case Study

We show an example case in Table 11 to demonstrate how KI improves dialog generation and what the limitation is. From the generated results, Transformer returns a vacuous response, as it has no idea on what "Dylan's Candy Bar" is. However, Transformer+KI, which perceives the knowledge about "Dylan's Candy Bar" during training, gives a much more informative response. Meanwhile, we further observe some inaccuracy during the knowledge transfer ("largest" becomes "second largest"). We take this as an interesting future work.

F Comparison with BART

In § 6.3, we observe that KI can outperform models whose encoders are initialized with pre-trained BERT or ERNIE. Here we dive deeper to compare KI with a fully pre-trained seq2seq model: BART (Lewis et al., 2020). BART has demonstrated superior performance on conditional language generation, including translation, summarization, and dialogue response generation. We start from the BART-base checkpoint [6]. We fine-tune the model for five epochs with a learning rate of 3e-5. We do not report PPL since these two models use different tokenization methods. As we can see from Table 12, by introducing only a few extra parameters and computation, KI can significantly boost the Transformer's performance. Although a pre-trained BART model can generate slightly more diverse responses than Transformer+KI (higher *Distinc-1/2*), these generated responses are often inconsistent with the input (lower *BLEU-4/ROUGE-l*) or less informative (lower *WikiF1*).

Abstract

In this paper, we propose a mixture model-based end-to-end method to model the syntactic-semantic dependency correlation in Semantic Role Labeling (SRL). Semantic dependencies in SRL are modeled as a distribution over semantic dependency labels conditioned on a predicate and an argument word. The semantic label distribution varies depending on Shortest Syntactic Dependency Path (SSDP) hop patterns. We target the variation of semantic label distributions using a mixture model, separately estimating semantic label distributions for different hop patterns and probabilistically clustering hop patterns with similar semantic label distributions. Experiments show that the proposed method successfully learns a cluster assignment reflecting the variation of semantic label distributions. Modeling the variation improves performance in predicting short distance semantic dependencies, in addition to the improvement on long distance semantic dependencies that previous syntax-aware methods have achieved. The proposed method achieves a small but statistically significant improvement over baseline methods in English, German, and Spanish and obtains competitive performance with state-of-the-art methods in English. [1]

1 Introduction

Semantic Role Labeling (SRL) answers an essential question about sentence semantics: "[Who] [does what] [to whom]". A core problem of SRL is identifying semantic dependencies that specify the semantic role of arguments in relation to predicates (He et al., 2018; Kasai et al., 2019). For example, [who] (argument) is the agent (semantic role) to [does what] (predicate). Semantic dependency parsers (Dozat and Manning, 2018a) identify semantic dependencies by giving a distribution over semantic dependency labels (denoted as semantic label distribution) for all predicate-argument pairs.

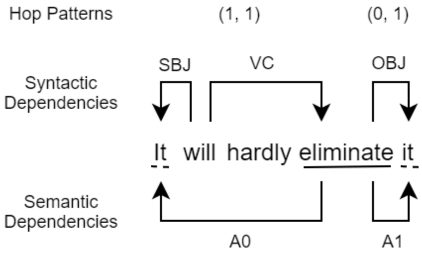

Figure 1: An example illustrating the impact of SSDPs on semantic label distributions. The solid underline highlights the predicate, and the dashed underline highlights the arguments.

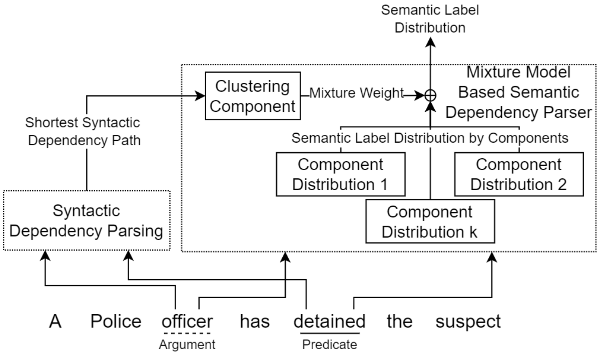

Figure 2: An illustration of the proposed mixture model-based method for semantic dependency parsing.

In this paper, we propose a mixture model (Pearson, 1894) based semantic dependency parser for SRL where we target the dependence of semantic label distributions on Shortest Syntactic Dependency Path (SSDP) patterns. SSDP is the shortest path connecting a predicate-argument pair in a syntactic dependency tree. Bunescu and Mooney (2005) and Cai et al. (2016) claim that SSDP encodes most information about bigram relations, such as the semantic dependency. Indeed, previous research (He et al., 2018; Xia et al., 2019) shows that modeling the correlation between SSDPs and semantic dependencies is crucial for building a high-performance SRL system.

May 22-27, 2022

Semantic label distributions vary depending on SSDPs, even when the SSDPs connect predicate-argument pairs with the same surface words. Figure 1 shows an example where two predicate-argument pairs have different semantic dependency labels while sharing the same surface words. SSDP patterns help discriminate semantic labels between the two pairs. The example indicates the dependence of semantic label distributions on SSDP patterns. We propose a mixture model-based method (Figure 2) to model the dependence in two steps: (1) Separately estimating semantic label distributions for different SSDP patterns as component distributions, and (2) Probabilistically clustering SSDP patterns with similar semantic label distributions using a mixture weight. The mixture model estimates the semantic label distribution by aggregating the component distributions using the mixture weight. We focus on *SSDP hop patterns* in this paper as we observed a drastic variation in semantic label distributions for different hop patterns through the change in mutual information (Shannon et al., 1949) (Section 2).

We evaluate the proposed method using the CoNLL-2009 dataset (Hajič et al., 2009) [2], the most popular multi-lingual SRL dataset with parallel syntactic and semantic dependency annotations. Experiments show that the proposed method correctly learns a mixture weight reflecting the variation in semantic label distributions. Modeling the variation improves performance in predicting short distance semantic dependencies in addition to long distance dependencies that previous syntax-aware methods (He et al., 2018; Roth and Lapata, 2016; Strubell et al., 2018) improve only on. Previous syntax-aware methods improve their performance on long distance dependencies at the expense of the performance on short distance dependencies. In comparison, the proposed method makes no such compromise, improving its performance over semantic dependencies of all ranges. In general, the proposed method obtains a small but statistically significant improvement over baseline methods in English, German, and Spanish and achieves competitive performance with state-of-the-art methods in English.

Our contributions are: (1) studying the variation in semantic label distributions for different SSDP hop patterns, (2) proposing a mixture model-based method capturing the variation, and (3) conducting a detailed experiment evaluating the proposed method.

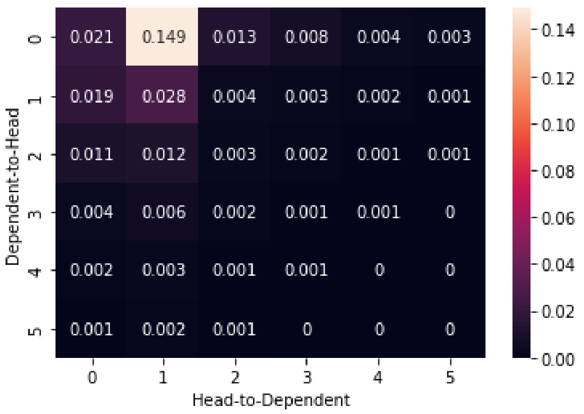

Figure 3: Mutual information gain of each SSDP hop pattern.

2 Motivation

As mentioned in Section 1, SSDP affects the choice of semantic dependency labels. We study the impact of SSDP hop patterns on semantic label distributions through the change in mutual information (Shannon et al., 1949) in this section. We observe a drastic change in mutual information only for hop patterns that frequently co-occur with semantic dependencies.

SSDP is the path connecting a predicate-argument pair in a syntactic dependency tree. Its hop pattern describes the number of transitions needed to transit from the predicate to the argument. We denote the hop pattern by (α, β), where α is the number of dependent-to-head transitions and β is the number of head-to-dependent transitions. In a syntactic dependency tree, syntactic dependencies are arcs pointing from syntactic heads to syntactic dependents. The head-to-dependent transition moves in the same direction as the syntactic dependencies, whereas the dependent-to-head transition moves in the opposite direction. In Figure 1, the SSDP connecting "eliminate" and "it" consists of a dependent-to-head transition moving from "eliminate" to "will", and a head-to-dependent transition moving from "will" to "it". The hop pattern of this SSDP is (1, 1).

We denote the syntactic random variable for hop patterns as X and the semantic random variable for semantic labels as Y. X maps predicate-argument

---

[2] While being similar, the CoNLL-2009 dependency format (Surdeanu et al., 2008) predates the well-known universal dependency format (Nivre et al., 2017) and have fundamental differences. This work follows the CoNLL-2009 format for both syntactic and semantic dependencies.

word pairs (p^s, a^s) in a sentence s to their hop patterns, whereas Y maps the pairs to their semantic labels. Their mutual information $\mathrm{MI}(X, Y)$ measures the reduction in uncertainty about Y after knowing X. High mutual information indicates relatively low uncertainty in the conditional distribution $P_{Y|X}$.

To highlight the impact of hop patterns on semantic label distributions, we compare the mutual information of two ideal models, a syntax-aware model $(X_{(\alpha,\beta)}, Y)$ and a syntax-agnostic model (X_0, Y). We define the syntactic variables $X_{(\alpha,\beta)}$ and X_0 as Equation 1 and 2. This definition makes the variable $X_{(\alpha,\beta)}$ sensitive only to the hop pattern (α, β) and X_0 blind to any hop pattern information. We define the mutual information gain of (α, β) as the difference in mutual information between the syntax-aware model and the syntax-agnostic model (Equation 3).

$$X_{(\alpha,\beta)}(p^s, a^s) = \begin{cases} 1, (p^s, a^s) \text{ is of } (\alpha, \beta) \\ 0, \text{otherwise} \end{cases} \quad (1)$$

$$X_0(p^s, a^s) = 0 \quad (2)$$

$$\Delta\mathrm{MI}(X_{(\alpha,\beta)}, X_0) = \mathrm{MI}(X_{(\alpha,\beta)}, Y) - \mathrm{MI}(X_0, Y) \quad (3)$$

Figure 3 reports the mutual information gain of each hop pattern using the English training set of the CoNLL-2009 dataset. The figure shows that different hop patterns have drastically varying mutual information gains. A sharp spike of mutual information gain occurs in the hop pattern (0, 1) with a gain value of 0.149 bits, indicating a strong impact of the hop pattern (0, 1) on semantic label distributions. Hop patterns with relatively short transitions have non-zero gains ranging from 0.011 bits to 0.149 bits, which indicates the degree of impact differs drastically. These hop patterns frequently co-occur with semantic dependencies (He et al., 2018). On the other hand, hop patterns co-occurring rarely with semantic dependencies have long transitions. These hop patterns have near-zero mutual information gains in Figure 3, which indicates the weak impact of the patterns. The varying degree of impact motivates the separate estimation of semantic label distributions for different hop patterns. The amount of hop patterns with a weak impact motivates the clustering of hop patterns that share similar semantic label distributions.

3 Background

In this section, we present background information about syntactic and semantic dependency parsing and mixture models. We also present a brief survey about syntax-aware SRL methods using SSDP information and compare the proposed method with the previous methods.

3.1 Syntactic and Semantic Dependency Parsing

Both syntactic and semantic dependencies describe bigram relations between words, namely heads and dependents. The heads and the dependents correspond to syntactic heads and dependents in syntactic dependencies and predicates and arguments in semantic dependencies. The similarity suggests that a mechanism, such as the biaffine parser (Dozat and Manning, 2017, 2018b), can capture the two dependencies. For semantic dependencies, the biaffine parser estimates a distribution $P(r|p, a)$ over relations $r \in \mathcal{R} \bigcup \{\epsilon\}$ between a predicate p and an argument a. $\mathcal{R}$ denotes the set of semantic relation labels, and ϵ denotes no relation occurring between p and a. For syntactic dependencies, the biaffine parser estimates a distribution $P(h|d)$, predicting the syntactic head h of the syntactic dependent d. Neural biaffine parsers estimate the two distributions as Equation 4[3], 5, 6[4], and 7. e_p, e_a, e_h and e_d denote the feature vectors of p, a, h and d from a sentence encoder.

$$\phi^r(e_p, e_a) = e_p^T(W_1^r)e_a + w_2^r([e_p; e_a]) + b^r \quad (4)$$

$$P(r|p, a) = \mathrm{Softmax}([\phi^r(e_p, e_a)]) \quad (5)$$

$$\phi(e_h, e_d) = e_h^T(W_1)e_d + w_2([e_h; e_d]) + b \quad (6)$$

$$P(h|d) = \mathrm{Softmax}([\phi(e_h, e_d)]) \quad (7)$$

3.2 Mixture Model and Latent Variable Model

Mixture models assume data to be generated from a mixture distribution whose component distributions belong to the same distributional family, such as the Gaussian distributions, but possess distinct parameters. The mixture of component distributions grants additional flexibility to the mixture model. For example, the Gaussian mixture model can capture multi-mode phenomena as opposed to the simple Gaussian model (Bishop and Nasrabadi, 2007). A mixture model contains two core variables: an observable data variable

---

[3] W_1^r is a weight matrix, w_2^r is a weight vector, and b^r is a bias term for estimating the unnormalized probability score of $P(r|p, a)$.

[4] Similarly, W_1, w_2, and b are parameters for estimating the unnormalized score of $P(h|d)$.

X and a latent variable C indexing the component distribution that generates the data. The mixture model computes the marginal likelihood $P_\theta(x) := \sum_c P_\theta(x|c)P_\theta(c)$ by aggregating its component distributions $P_\theta(x|c)$ using the mixture weight $P_\theta(c)$. The optimal parameter (i.e., the mixture weight and the parameters of component distributions) can be estimated by maximizing the log-likelihood $\log P_\theta(x)$. However, direct maximum likelihood estimation on the marginal log-likelihood is intractable for mixture models (Murphy, 2012), and the conventional Expectation-Maximization algorithm (Dempster et al., 1977) requires finding optimal parameters at each iteration. Variational Inference (Xu et al., 2015; Ba et al., 2015) maximizes a variational lowerbound of the log-likelihood (Equation 8), simultaneously optimizing the component distributions and the mixture weight.

$$\mathcal{L} = \sum_c q(c|x) \log \frac{P_\theta(x|c)P_\theta(c)}{q(c|x)} \tag{8}$$

$$= \log P_\theta(x) - \mathrm{KL}(q(c|x)||P_\theta(c|x)) \tag{9}$$

3.3 Syntactic Dependency Information in Semantic Dependency Parsing

Inspired by the close connection of syntactic and semantic dependencies, He et al. (2018), Roth and Lapata (2016), and Shi et al. (2020) attempt to build high-performance SRL systems using SSDP information. While the research improves performance over syntax-agnostic methods, their methods either require language-specific hyperparameters or exhibit a behavior challenging to interpret.

The pruning method (He et al., 2018, 2019) is readily interpretable but requires language-specific hyperparameters. The method utilizes a statistical bias that most SSDPs rarely co-occur with semantic dependencies. It eliminates predicate-argument pairs of the infrequent SSDPs using heuristics. Whether an SSDP can co-occur with semantic dependencies is hardcoded in heuristics, making the method highly interpretable. However, the heuristics are language-specific, requiring manual tuning for every language.

The neural methods (Roth and Lapata, 2016; Foland and Martin, 2015) are more language-independent but suffer from limited interpretability. The methods implicitly encode SSDP information using neural network encoders. Roth and Lapata (2016) and Foland and Martin (2015) encode SSDPs in a continuous embedding using an Long-Short Term Memory (LSTM) model or a Convolutional Neural Network model. Shi et al. (2020) jointly learns SSDP and semantic dependency information using a Transformer (Vaswani et al., 2017) by merging SSDP information with semantic dependency labels. The research reports performance improvements in one or more languages. However, interpreting the model's behavior is challenging. Neural encoders, such as the LSTM model in Roth and Lapata (2016), project SSDPs in a high-dimensional space. The high-dimensional space has a complex structure, rendering clustering analyses based on Euclidean distances less effective. Roth and Lapata (2016) interprets the behavior of their model using the clustering analysis, suggesting that their model captures many linguistic phenomena. However, the linguistic phenomena are fragmental and limited to a few syntactic constructions.

In contrast, the proposed method is generic like the neural methods and interpretable like the pruning method. The proposed method optimizes its parameters using gradients of the back-propagated errors, which makes the proposed method more language-independent. As a result, the proposed method learns a mixture weight reflecting the impact of SSDP hop patterns on semantic label distributions, enabling analyses using the mixture weight.

4 Proposal

In this section, we present the proposed mixture model-based semantic dependency parser to model the dependence of semantic label distributions on SSDP hop patterns. In Section 2, we discussed the need to separately estimate semantic label distributions for different hop patterns and the need to cluster hop patterns sharing similar semantic label distributions. The proposed parser estimates semantic label distributions for different hop patterns using the component distributions and clusters hop patterns using the mixture weight of a mixture model.

Figure 2 illustrates the model architecture of the proposed method. The model contains a conventional biaffine parser for syntactic dependencies and a mixture model-based biaffine parser for semantic dependencies. The syntactic parser provides a syntactic dependency tree from which the clustering component extracts hop patterns and determines the mixture weights. The biaffine parsers in the semantic parser estimate the component distributions. The semantic parser computes the semantic label distribution by aggregating the component distributions using the mixture weight. The syntactic and the semantic parser share a backbone sentence encoder, a Transformer model in our implementation. We jointly optimize the parameters of the syntactic and the semantic parser by optimizing the log-likelihood of the syntactic dependencies and a variational lowerbound of the log-likelihood (ELBo) of the semantic dependencies. We use the lowerbound as an approximation to the log-likelihood for inference because we find it works best in predicting semantic dependencies.

We expand on the training objective of the semantic parser. The objective is to maximize the likelihood $P_\theta(r|p,a)$ of the observed semantic label r conditioned on the predicate p and the argument a. We rewrite the likelihood as a marginal of the joint likelihood $P_\theta(r,c|p,a)$ where c is the index of the component distributions. The joint likelihood can be decomposed as Equation 12 where the former term corresponds to the component distributions and the latter term corresponds to the mixture weight. Since we are interested in separating semantic label distributions by hop patterns, we replace the term $P_\theta(c|p,a)$ with $P_\theta(c|\mathrm{ssdp}(p,a))$ where $\mathrm{ssdp}(p,a)$ maps predicate-argument pairs to their hop patterns. $P_\theta(c|\mathrm{ssdp}(p,a))$ also serves as the variational approximation $q(c|r,p,a)$ because we assume the hop pattern, together with the predicate-argument pair, determines the semantic dependency label. This assumption removes the need to condition the component index c on the semantic label r in the variational approximation q. In this implementation, we encode hop patterns with orthogonally initialized embeddings and estimate the mixture weight of a hop pattern by applying a multi-layer perceptron followed by a softmax layer to the embedding.

$$\begin{aligned}
&\log P_\theta(r|p,a) && (10)\\
&= \log \sum_c P_\theta(r,c|p,a) && (11)\\
&= \log \sum_c P_\theta(r|c,p,a)P_\theta(c|p,a) && (12)\\
&= \log \sum_c P_\theta(r|c,p,a)P_\theta(c|\mathrm{ssdp}(p,a)) && (13)\\
&\geq \sum_c P_\theta(c|\mathrm{ssdp}(p,a)) \log P_\theta(r|c,p,a) && (14)\\
&= \mathcal{L}_{sem}(\theta|\mathcal{X}_{sem}=(r,p,a)) && (15)
\end{aligned}$$

Equation 16 depicts the full objective of the proposed model. It consists of a log-likelihood objective of the syntactic parser (Equation 17) and the ELBo objective of the semantic parser (Equation 15). $\mathcal{G}_{syn}$ stands for the set of all syntactic dependencies (h,d), whereas $\mathcal{G}_{sem}$ stands for the set of all semantic dependencies (r,p,a).

$$\begin{aligned}
\mathcal{J}(\theta) = &\sum_{(h,d)\in\mathcal{G}_{syn}} \mathcal{L}_{syn}(\theta|\mathcal{X}_{syn}=(h,d))\\
&+ \sum_{(r,p,a)\in\mathcal{G}_{sem}} \mathcal{L}_{sem}(\theta|\mathcal{X}_{sem}=(r,p,a))
\end{aligned} \quad (16)$$

$$\mathcal{L}_{syn}(\theta|\mathcal{X}_{syn}=(h,d)) = \log P_\theta(h|d) \quad (17)$$

5 Experiment

In this section, we present experimental results for the proposed method. We call the proposed method as MM (mixture-model) in this section. We use the labeled attachment score (LAS) (Hajič et al., 2009) as the primary metric. LAS is a micro-F1 score measuring how well a model recovers semantic dependencies. We conduct our experiments comparing MM with five baseline methods (Table 1) using the CoNLL-2009 dataset. We perform the comparison on all languages using the corresponding development sets. Each model will run using four randomly generated seeds to mitigate the impact of the seeds. We also compare the semantic scores (Hajič et al., 2009) of MM with state-of-the-art syntax-aware methods using the English test set. The semantic score is a micro-F1 score evaluating models' performance in the predicate identification in addition to the semantic dependency recovery. We use preidentified predicates extracted from the mate-tools (Björkelund et al., 2010), following the evaluation method of Roth and Lapata (2016).

We evaluate MM using three word embeddings: a non-context-sensitive embedding, FastText (Joulin et al., 2016), and two context-sensitive embeddings, ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019). When comparing with state-of-the-art methods, we report results on the GloVe (Pennington et al., 2014) and the FastText embedding. However, the result on the FastText embedding is for reference only because the state-of-the-art methods report results mainly on the GloVe embedding. We use an 8-layer Transformer as the backbone encoder for MM and baseline models. We set the batch size to 5000 words, the maximum size that a P100 device can accommodate. We use the Adam optimizer (Kingma and Ba, 2015) with

Method Name	Syn	Description
Transformer	No	A Transformer model (Vaswani et al., 2017) using a biaffine semantic dependency parser
Multitask	Yes	A Transformer model using two biaffine parsers for syntactic and semantic dependencies
LISA	Yes	The Linguistically-Informed Self-Attention model (Strubell et al., 2018)
PathLSTM	Yes	A Multitask model using dependency path embeddings (Roth and Lapata, 2016)
Pruning	Yes	A Multitask model using the pruning technique (He et al., 2018)
MM	Yes	A Multitask model using the proposed mixture model-based semantic dependency parser

Table 1: Descriptions of baseline methods. Syn indicates whether a method is syntax-aware.

	FastText	ELMo	BERT
Transformer	0.003	0.001	0.002
Multitask	0.000	0.003	0.001
LISA	0.005	0.000	0.002
PathLSTM	*0.058*	0.032	0.025
Pruning	0.011	0.000	0.005

Table 2: P-values of the significance tests. Each cell shows the p-value of a test comparing MM with a baseline method (shown in the row) on an embedding (shown in the column). P-values higher than the 0.05 threshold are highlighted in italic.

parameters $lr = 4e^{-6}$, $\beta_1 = 0.9$, and $\beta_2 = 0.98$ for training.

We set the number of component distributions k in MM to 5 for all languages. We find that this number works for most languages in a preliminary experiment exploring $k = 1, 3, 5, 7, 10$. For $k > 5$, some components will not be assigned to any hop pattern, resulting in a waste of model parameters. For $k < 5$, some components are forced to estimate semantic label distributions for hop patterns of different nature, resulting in a loss of performance. We do not perform back-propagation between the syntactic and the semantic parser in MM because we found the back-propagation causes negative impacts on the two parsers.

5.1 Comparison with Baselines

We find that MM significantly improves over baseline methods on the English development set. Figure 4 reports the LAS of MM and baseline methods using box plots. MM achieves better LAS than baseline methods in all three embeddings. We conduct a series of significance tests against a null hypothesis that MM performs equally to each baseline method. The p-values of the hypothesis tests are shown in Table 2. Each cell in the table shows the p-value of a test comparing MM with a baseline method (shown in the row) on an embedding (shown in the column). The table suggests that MM significantly outperforms all baseline methods on the three embeddings, except the PathLSTM method on the FastText embedding. The significance test confirms the effectiveness of MM in modeling semantic dependencies.

We find that MM learns a mixture weight reflecting the impact of hop patterns on semantic label distributions. Table 3 reports the component assignment extracted from the learned mixture weight. We extract the component assignment for hop patterns up to (5, 3). Most evidently, MM consistently assigns the hop pattern (0, 1) to a unique component in all three embeddings. This behavior agrees with our findings in Section 2 that the hop pattern has the highest mutual information gain. MM also consistently assigns hop patterns with near-zero mutual information gains to a single component. Moreover, MM clusters hop patterns with similar non-zero gains to a single component. These results suggest that semantic label distributions of different hop patterns have unique properties.

Table 4: Semantic scores of MM and state-of-the-art methods on the English test set. P, R, F1 stands for Precision, Recall, and F1 scores. Methods with the best performance score are highlighted in bold.

MM is readily applicable for other languages beyond English using the same hyperparameter setting. Figure 5 reports the comparison of MM with the Transformer and the Multitask method on the development sets of German, Spanish, Catalan, Chinese, and Czech. The Multitask method consistently outperforms the Transformer method in all languages. In comparison, MM significantly outperforms the Multitask method in German and Spanish. MM also has an arguable improvement over the Multitask method in Catalan. In Chinese, MM performs similarly to the Multitask method but better than the Transformer method. In Czech, MM somehow fails to learn and achieves a considerably low LAS. We might need to tune the architecture or hyperparameters here, while MM stably outperforms the baseline methods in other languages.

Using the Transformer method as a baseline, we find MM improves on both short and long distance semantic dependencies, whereas syntax-aware baseline methods improve only on long distance dependencies. To illustrate the finding, we group the semantic dependencies by their linear length[5] and evaluate the methods' performance on each group. We group the semantic dependencies into four bins: the short-distance bin (0-2) and the long-distance bins (3-5, 6-8, 9-inf). We then compute the relative performance score[6] of each syntax-aware method using the model with the median LAS score. Figure 6 reports the relative scores of LAS, Precision, and Recall. MM has the best relative LAS among syntax-aware methods in predict-

---

[5] $l = |\mathrm{idx}_p - \mathrm{idx}_a|$, where l is the linear length of the SSDP connecting the predicate p and the argument a. idx_p and idx_a represents the index of the predicate and the argument in the sentence.

[6] $s_r = s_{syn+} - s_{syn-}$, where s_r represents the relative score, s_{syn+} represents the score of the syntax-aware model, and s_{syn-} represents the score of the syntax-agnostic Transformer model.

(a) FastText (b) ELMo (c) BERT

Figure 6: Relative LAS, Precision, and Recall of syntax-aware models on the English development set. The X-axis shows the linear distance of semantic dependencies that each bin contains, the Y-axis shows the relative score.

ing short distance dependencies. On the FastText and the ELMo embedding, MM is the only method scoring a positive relative LAS (i.e., MM is the only method improving over the Transformer method). The reason is that MM achieves significantly better precision than baseline syntax-aware methods, which allows MM to overcome the lower recall. Meanwhile, MM has a performance improvement similar to the baseline syntax-aware methods in predicting long distance dependencies.

5.2 Comparison with the State-of-the-arts

MM achieves competitive performance with state-of-the-art syntax-aware methods. Table 4 reports the median semantic scores of MM and the reported scores of state-of-the-art methods on the English test set. The test set contains two sections: WSJ (in-domain) section and Brown (out-of-domain) section. MM achieves the best performance on the WSJ section on the GloVe and the ELMo embedding and performs comparably to other methods on the BERT embedding. MM also scores the best performance on the Brown section on the ELMo and the BERT embedding. We also find that MM on the FastText embedding performs better than MM on the GloVe embedding. This result is in line with a study evaluating non-context-sensitive word embeddings (Wang et al., 2019) where the FastText embedding outperforms the GloVe embedding on downstream NLP tasks.

6 Conclusion

This paper presented a mixture model-based method for syntax-aware semantic dependency parsing in SRL. The method models the dependence of semantic label distributions on SSDP patterns. We focused on SSDP hop patterns because we observed a drastic variation in semantic label distributions through the change in mutual information. The proposed method successfully learned a mixture weight reflecting the variation. The method improved performance in predicting both short and long distance semantic dependencies, whereas baseline syntax-aware methods improved only on long distance dependencies. The method outperformed baseline methods by a small but statistically significant margin in many languages. Moreover, the proposed method achieved performance competitive with state-of-the-art methods in English. Nonetheless, hop patterns contain only limited information about SSDP. In the future, we plan to apply the proposed method to more informative SSDP patterns, such as labeled SSDP patterns.

Learning the Beauty in Songs: Neural Singing Voice Beautifier

Abstract

We are interested in a novel task, singing voice beautification (SVB). Given the singing voice of an amateur singer, SVB aims to improve the intonation and vocal tone of the voice, while keeping the content and vocal timbre. Current automatic pitch correction techniques are immature, and most of them are restricted to intonation but ignore the overall aesthetic quality. Hence, we introduce Neural Singing Voice Beautifier (NSVB), the first generative model to solve the SVB task, which adopts a conditional variational autoencoder as the backbone and learns the latent representations of vocal tone. In NSVB, we propose a novel time-warping approach for pitch correction: Shape-Aware Dynamic Time Warping (SADTW), which ameliorates the robustness of existing time-warping approaches, to synchronize the amateur recording with the template pitch curve. Furthermore, we propose a latent-mapping algorithm in the latent space to convert the amateur vocal tone to the professional one. To achieve this, we also propose a new dataset containing parallel singing recordings of both amateur and professional versions. Extensive experiments on both Chinese and English songs demonstrate the effectiveness of our methods in terms of both objective and subjective metrics. Audio samples are available at `https://neuralsvb.github.io`. Codes: `https://github.com/MoonInTheRiver/NeuralSVB`.

1 Introduction

The major successes of the artificial intelligent singing voice research are primarily in Singing Voice Synthesis (SVS) (Lee et al., 2019; Blaauw and Bonada, 2020; Ren et al., 2020; Lu et al., 2020; Liu et al., 2021a) and Singing Voice Conversion (SVC) (Sisman and Li, 2020; Li et al., 2021; Wang et al., 2021a). However, the Singing Voice Beautification (SVB) remains an important and challenging endeavor for researchers. SVB aims to improve the intonation[1] and the vocal tone of the voice, while keeping the content and vocal timbre[2]. SVB is extensively required both in the professional recording studios and the entertainment industries in our daily life, since it is impractical to record flawless singing audio.

Nowadays in real-life scenarios, SVB is usually performed by professional sound engineers with adequate domain knowledge, who manipulate commercial vocal correction tools such as Melodyne[3] and Autotune[4] (Yong and Nam, 2018). Most current automatic pitch correction works are shown to be an attractive alternative, but they may 1) show weak alignment accuracy (Luo et al., 2018) or pitch accuracy (Wager et al., 2020); 2) cause the tuned recording and the reference recording to be homogeneous in singing style (Yong and Nam, 2018). Besides, they typically focus on the intonation but ignore the overall aesthetic quality (audio quality and vocal tone) (Rosenzweig et al., 2021; Zhuang et al., 2021).

To tackle these challenges, we introduce Neural Singing Voice Beautifier (NSVB), the first generative model to solve the SVB task, which adopts a Conditional Variational AutoEncoder (CVAE) (Kingma and Welling, 2014; Sohn et al., 2015) as the backbone to generate high-quality audio and learns the latent representation of vocal tone. In NSVB, we dichotomize the SVB task into pitch correction and vocal tone improvement: 1) To correct the intonation, a straightforward method is aligning the amateur recording with the template pitch curve, and then putting them together to resynthesize a new singing sample. works (Wada et al., 2017; Luo et al., 2018) implemented this by figuring out the alignment through Dynamic Time Warping (DTW) (Müller, 2007) or Canonical Time Warping (CTW) (Zhou and Torre, 2009). We propose a novel Shape-Aware DTW algorithm, which ameliorates the robustness of existing time-warping approaches by considering the shape of the pitch curve rather than low-level features when calculating the optimal alignment path. 2) To improve the vocal tone, we propose a latent-mapping algorithm in the latent space, which converts the latent variables of the amateur vocal tone to those of the professional ones. This process is optimized by maximizing the log-likelihood of the converted latent variables. To retain the vocal timbre during the vocal tone mapping, we also propose a new dataset named PopBuTFy containing parallel singing recordings of both amateur and professional versions. Besides, thanks to the autoencoder structure, NSVB inherently supports semi-supervised learning, where the additional unpaired, unlabeled[5] singing data could be leveraged to facilitate the learning of the latent representations. Extensive experiments on both Chinese and English songs show that NSVB outperforms previous methods by a notable margin, and each component in NSVB is effective, in terms of both objective and subjective metrics. The main contributions of this work are summarized as follows:

- We propose the first generative model NSVB to solve the SVB task. NSVB not only corrects the pitch of amateur recordings, but also generates the audio with high audio quality and improved vocal tone, to which previous works typically pay little attention.
- We propose Shape-Aware Dynamic Time Warping (SADTW) algorithm to synchronize the amateur recording with the template pitch curve, which ameliorates the robustness of the previous time-warping algorithm.
- We propose a latent-mapping algorithm to convert the latent variable of the amateur vocal tone to the professional one's, and contribute a new dataset PopBuTFyto train the latent-mapping function.
- We design NSVB as a CVAE model, which supports the semi-supervised learning to leverage unpaired, unlabeled singing data for better performance.

2 Related Works

2.1 Singing Voice Conversion

Singing Voice Conversion (SVC) is a sub-task of Voice Conversion (VC) (Berg-Kirkpatrick and Klein, 2015; Serrà et al., 2019; Popov et al., 2021; Liu et al., 2021b), which transforms the vocal timbre (or singer identity) of one singer to that of another singer, while preserving the linguistic content and pitch/melody information (Li et al., 2021). Mainstream SVC models can be grouped into three categories (Zhao et al., 2020): 1) parallel spectral feature mapping models, which learn the conversion function between source and target singers relying on parallel singing data (Villavicencio and Bonada, 2010; Kobayashi et al., 2015; Sisman et al., 2019); 2) Cycle-consistent Generative Adversarial Networks (CycleGAN) (Zhu et al., 2017; Kaneko et al., 2019), where an adversarial loss and a cycle-consistency loss are concurrently used to learn the forward and inverse mappings simultaneously (Sisman and Li, 2020); 3) encoder-decoder models, such as PPG-SVC (Li et al., 2021), which leverage a singing voice synthesis (SVS) system for SVC (Zhang et al., 2020), and auto-encoder (Qian et al., 2019a; Wang et al., 2021b; Yuan et al., 2020) based SVC (Wang et al., 2021a). The models of the latter two categories can be utilized with non-parallel data. In our work, we aim to convert the intonation and the vocal tone while keeping the content and the vocal timbre, which is quite different from the SVC task.

2.2 Automatic Pitch Correction

Automatic Pitch Correction (APC) works attempt to minimize the manual effort in modifying the flawed singing voice (Yong and Nam, 2018). Luo et al. (2018) propose Canonical Time Warping (CTW) (Zhou and Torre, 2009; Zhou and De la Torre, 2012) which aligns amateur singing recordings to professional ones according to the pitch curves only. Wager et al. (2020) propose a data-driven approach to predict pitch shifts depending on both amateur recording and its accompaniment. Rosenzweig et al. (2021) propose a pitch shift method for Cappella recordings. Zhuang et al. (2021) propose a pitch-controllable SVS system to resynthesize the audio with correctly predicted pitch curves. Besides modifying pitch, Yong and

---

[5] "unpaired, unlabeled" means the recordings sung by any people, in any vocal tone without label.

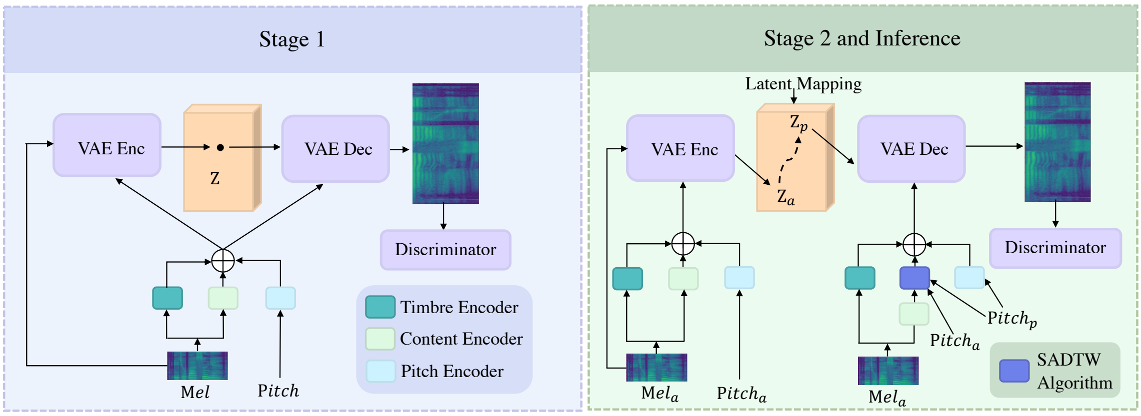

Figure 1: The overview of NVSB. The training process consists of 2 stages, and the second stage shares the same pipeline with the inference stage. "VAE Enc" means the encoder of CVAE; "VAE Dec" means the decoder of CVAE; "Mel" means the mel-spectrogram; "$\mathbf{z}$" means the latent variable of the vocal tone; the "a"/"p" subscript means the amateur/professional version.

Nam (2018) propose to modify pitch and energy information to improve the singing expressions of an amateur singing recording. However, this method heavily relies on a reference recording, causing the tuned recording and the reference recording to be homogeneous in singing style (Zhuang et al., 2021). Our work adopts the non-parametric and data-free pitch correction method like Luo et al. (2018), but improves the accuracy of alignment.

3 Methdology

In this section, we describe the overview of NSVB, which is shown in Figure 1. At Stage 1 in the figure, we reconstruct the input mel-spectrogram through the CVAE backbone (Section 3.1) based on the pitch, content and vocal timbre conditions extracted from the input by the pitch encoder, content encoder and timbre encoder, and optimize the CVAE by maximizing evidence lower bound and adversarial learning. At Stage 2/Inference in the figure, firstly we infer the latent variable $\mathbf{z}_a$ based on the amateur conditions; secondly we prepare the amateur content vectors aligned with the professional pitch by SADTW algorithm (Section 3.2); thirdly we map $\mathbf{z}_a$ to $\mathbf{z}_p$ by the latent-mapping algorithm (Section 3.3); finally, we mix the professional pitch, the aligned amateur content vectors, and the amateur vocal timbre to obtain a new condition, which is leveraged along with the mapped $\mathbf{z}_p$ by the decoder of CVAE to generate a new beautified mel-spectrogram. The training/inference details and model structure of each component in NSVB are described in Section 3.4 and Section 3.5.

3.1 Conditional Variational Generator with Adversarial Learning

As shown in Figure 2, to generate audio with high quality and learn the latent representations of vocal tone, we introduce a Conditional Variational AutoEncoder (CVAE) (Kingma and Welling, 2014; Sohn et al., 2015) as the mel-spectrogram generator, with the optimizing objective of maximizing the evidence lower bound (ELBO) of the intractable marginal log-likelihood of mel-spectrogram $\log p_\theta(\mathbf{x}|c)$:

$$\log p_\theta(\mathbf{x}|c) \geq \mathbf{ELBO}(\phi,\theta) \equiv$$
$$E_{\mathbf{z}\sim q_\phi(\mathbf{z}|\mathbf{x},c)}\left[\log p_\theta(\mathbf{x}|\mathbf{z},c) - \log \frac{q_\phi(\mathbf{z}|\mathbf{x},c)}{p(\mathbf{z})}\right],$$

where $\mathbf{x}$, c, $\mathbf{z}$ denote the input/output mel-spectrogram, the mix of content, vocal timbre and pitch conditions, and the latent variable representing the vocal tone respectively; ϕ and θ denote the model parameters of CVAE encoder and CVAE decoder; $q_\phi(\mathbf{z}|\mathbf{x},c)$ is the posterior distribution approximated by the CVAE encoder; $p_\theta(\mathbf{x}|\mathbf{z},c)$ is the likelihood function that generates mel-spectrograms given latent variable $\mathbf{z}$ and condition c; $p(\mathbf{z})$ is the prior distribution of the latent variables $\mathbf{z}$, and we choose the standard normal distribution as $p(\mathbf{z})$ for simplification. Furthermore, to address the over-smoothing problem (Qian et al., 2019b) in CVAE, we utilize an adversarial discriminator ($\mathcal{D}$) (Mao et al., 2017) to refine the output mel-spectrogram:

$$\begin{aligned} L_{adv}(\phi,\theta) &= \mathbb{E}[(\mathcal{D}(\widetilde{\mathbf{x}})-1)^2], \\ L_{adv}(\mathcal{D}) &= \mathbb{E}[(\mathcal{D}(\mathbf{x})-1)^2] + \mathbb{E}[\mathcal{D}(\widetilde{\mathbf{x}})^2], \end{aligned} \quad (1)$$

where $\mathbf{x}$ is the ground-truth and $\widetilde{\mathbf{x}}$ is the output of CVAE. The descriptions for the model structure of each component are in Section 3.5.

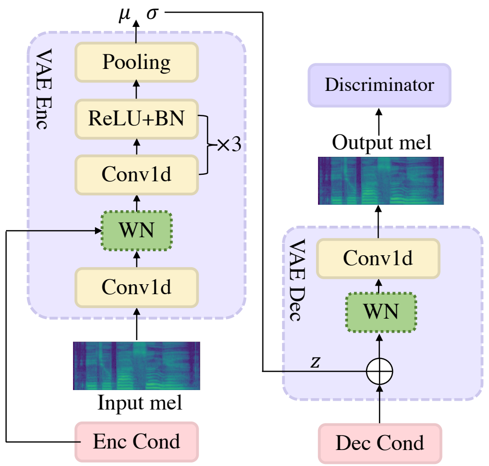

Figure 2: The CVAE backbone in NSVB. "Enc/Dec Cond" means the conditions for the encoder/decoder; "Conv1d" means the 1-D convolutional layer; "Pooling" means the average pooling layer; μ and σ represent the approximated mean and log scale standard deviation parameters in the posterior Gaussian distribution; $\mathbf{z}$ is the sampled latent variable.

3.2 Shape-Aware Dynamic Time Warping

To implement the pitch correction, a straightforward method is aligning the amateur recording with the template pitch curve, and then concatenating them to resynthesize a new singing sample with improved intonation. Since the source pitch curve of amateur recordings and template one show a high degree of natural correlation along the time axis, applying a proper time-warping algorithm on them is crucial. However, original DTW (Müller, 2007) could result in a poor alignment when certain parts of the axis move to higher frequencies, and other parts to lower ones, or vice versa (Sundermann and Ney, 2003). Luo et al. (2018) adopt an advanced algorithm CTW (Zhou and Torre, 2009), which combines the canonical correlation analysis (CCA) and DTW to extract the feature sequences of two pitch curves, and then apply DTW on them. However, the alignment accuracy of CTW leaves much to be desired.

We elaborate a non-parametric and data-free algorithm, Shape-Aware DTW (SADTW), based on the prior knowledge that the source pitch curve and the template one have analogous local shape contours. Specifically, we replace the Euclidean distance in the original DTW distance matrix with the shape context descriptor distance. The shape context descriptor of a time point f_i in one pitch curve is illustrated in Figure 3. Inspired by (Mori et al., 2005), we divide the data points around f_i into $m * n$ bins by m time windows and n angles. We calculate the number of all points falling in the k-th bin. Then the descriptor for f_i is defined as the histogram $h_i \in \mathcal{R}^{m*n}$:

$$h_i(k) = |\{f_j \neq f_i, f_j \in bin(k)\}|,$$

where $|\cdot|$ means the cardinality of a set. This histogram represents the distribution over relative positions, which is a robust, compact and discriminative descriptor. Then, it is natural to use the $\mathcal{X}^2$-test statistic on this distribution descriptor as the "distance" of two points f_a and f_p:

$$C(a,p) = \frac{1}{2}\sum_{k=1}^{m*n}\frac{[h_a(k) - h_p(k)]^2}{h_a(k) + h_p(k)},$$

where h_a and h_p are the normalized histograms corresponding to the point f_a from the amateur pitch curve and the point f_p from the template pitch curve. $C(a,p)$ ranges from 0 to 1. Finally, we run DTW on the distance matrix C to obtain the alignment with least distance cost between two curves.

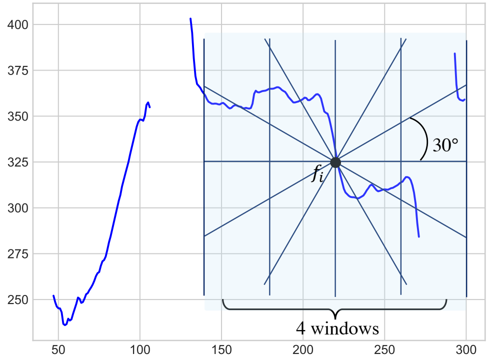

Figure 3: The shape descriptor in SADTW. The blue curve represents pitch; the horizontal axis means time; the vertical axis means F0-frequency. There are $m = 4$ windows, $n = 6$ angles to divide neighbor points of f_i.

3.3 Latent-mapping Algorithm

Define a pair of mel-spectrograms $(\mathbf{x}_a, \mathbf{x}_p)$: the contents of $\mathbf{x}_a$ and $\mathbf{y}_p$ are the same sentence of a song from the same singer[6], who sings these two recordings using the amateur tone and the professional tone respectively. Given the CVAE model,

---

[6] The singers all major in vocal music.

we can infer the posterior distribution $q_\phi(\mathbf{z}_a|\mathbf{x}_a, c_a)$ and $q_\phi(\mathbf{z}_p|\mathbf{x}_p, c_p)$ corresponding to $\mathbf{x}_a$ and $\mathbf{x}_p$ through the encoder of CVAE. To achieve the conversion of vocal tone, we introduce a mapping function $\mathcal{M}$ to convert the latent variables from $q_\phi(\mathbf{z}_a|\mathbf{x}_a, c_a)$ to $q_\phi(\mathbf{z}_p|\mathbf{x}_p, c_p)$. Concretely, we sample a latent variable of amateur vocal tone $\mathbf{z}_a$ from $q_\phi(\mathbf{z}_a|\mathbf{x}_a, c_a)$, and map $\mathbf{z}_a$ to $\mathcal{M}(\mathbf{z}_a)$. Then, $\mathcal{M}$ can be optimized by minimizing the negative log-likelihood of $\mathcal{M}(\mathbf{z}_a)$:

$$L_{map1}(\mathcal{M}) = -\log q_\phi(\mathcal{M}(\mathbf{z}_a)|\mathbf{x}_p, c_p).$$

Define $\hat{c}_p$ as the mix of 1) the content vectors from the amateur recording aligned by SADTW, 2) vocal timbre embedding encoded by timbre encoder, and 3) template pitch[7] embeddings encoded by pitch encoder. To make sure the converted latent variable could work well together with $\hat{c}_p$ to generate a high-quality audio sample (with the correct pitch and improved vocal tone), we send $\mathcal{M}(\mathbf{z}_a)$ to the CVAE decoder to generate $\hat{\mathbf{x}}$, and propose an additional loss:

$$L_{map2}(\mathcal{M}) = \|\hat{\mathbf{x}} - \mathbf{x}_p\|_1 + \lambda(\mathcal{D}(\hat{\mathbf{x}}) - 1)^2,$$

where $\mathcal{D}$ has been optimized by Eq. (1); λ is a hyper-parameter.

3.4 Training and Inference

There are two training stages for NSVB: in the first training stage, we optimize CVAE by minimizing the following loss function

$$L(\phi, \theta) = -\mathbf{ELBO}(\phi, \theta) + \lambda L_{adv}(\phi, \theta),$$

and optimize the discriminator ($\mathcal{D}$) by minimizing Eq. (1). Note that, the first stage is the reconstruction process of mel-spectrograms, where any unpaired, unlabeled singing data beyond PopBuTFy could be leveraged to facilitate the learning of the latent representations. In the second training stage, we optimize $\mathcal{M}$ on the parallel dataset PopBuTFy by minimizing the following loss function

$$L(\mathcal{M}) = L_{map1}(\mathcal{M}) + L_{map2}(\mathcal{M}).$$

ϕ, θ, and $\mathcal{D}$ are not optimized in this stage.

In inference, the encoder of CVAE encodes $\mathbf{x}_a$ with the condition c_a to predict $\mathbf{z}_a$. Secondly, we map $\mathbf{z}_a$ to $\mathcal{M}(\mathbf{z}_a)$, and run SADTW to align the amateur recordings with the template pitch curve. The template pitch curve can be derived from a reference recording with good intonation or a pitch predictor with the input of music notes. Then, we obtain $\hat{c}_p$ defined in Section 3.3 and send $\mathcal{M}(\mathbf{z}_a)$ together with $\hat{c}_p$ in the decoder of CVAE to generate $\hat{\mathbf{x}}$. Finally, by running a pre-trained vocoder conditioned on $\hat{\mathbf{x}}$, a new beautified recording is produced.

3.5 Model Structure

The encoder of CVAE consists of a 1-D convolutional layer (stride=4), an 8-layer WaveNet structure (Oord et al., 2016; Rethage et al., 2018) and 3 1-D convolutional layers (stride=2) with ReLU activation function and batch normalization followed by a mean pooling, which outputs the mean and log scale standard deviation parameters in the posterior distribution of $\mathbf{z}$. The decoder of CVAE consists of a 4-layer WaveNet structure and a 1-D convolutional layer, which outputs the mel-spectrogram with 80 channels. The discriminator adopts the same structure as (Wu and Luan, 2020), which consists of multiple random window discriminators. The latent-mapping function is composed of 2 linear layers to encode the vocal timbre as the mapping condition, and 3 linear layers to map $\mathbf{z}_a$. The pitch encoder is composed of 3 convolutional layers. In addition, given a singing recording, 1) to obtain its content vectors, we train an Automatic Speech Recognition (ASR) model based on Conformer (Gulati et al., 2020) with both speech and singing data, and extract the hidden states from the ASR encoder (viewed as the content encoder) output as the linguistic content information, which are also called phonetic posterior-grams (PPG); 2) to obtain the vocal timbre, we leverage the open-source API resemblyzer[8] as the timbre encoder, which is a deep learning model designed for speaker verification (Wan et al., 2018), to extract the identity information of a singer. More details of model structure can be found in Appendix A.

4 Experiments

4.1 Experimental Setup

In this section, we first introduce PopBuTFy, the dataset for SVB, and then describe the implementation details in our work. Finally, we explain the evaluation method we adopt in this paper.

---

[7] During training, template pitch is extracted from the waveform corresponding to $\mathbf{x}_p$.

[8] `https://github.com/resemble-ai/Resemblyzer`

Dataset Since there is no publicly available high-quality, unaccompanied and parallel singing dataset for the SVB task, we collect and annotate a dataset containing both Chinese Mandarin and English pop songs: PopBuTFy. To collect PopBuTFy for SVB, the qualified singers majoring in vocal music are asked to sing a song twice, using the amateur vocal tone for one time and the professional vocal tone for another. Note that some of the amateur recordings are sung off-key by one or more semi-tones for the pitch correction sub-task. The parallel setting could make sure that the personal vocal timbre will keep still during the beautification process. In all, PopBuTFy consists of 99 Chinese pop songs ($\sim$10.4 hours in total) from 12 singers and 443 English pop songs ($\sim$40.4 hours in total) from 22 singers. All the audio files are recorded in a professional recording studio by qualified singers, male and female. Every song is sampled at 22050 Hz with 16-bit quantization. We randomly choose 6 songs in Chinese and 18 songs in English (from unseen speakers) for validation and test. For subjective evaluations, we choose 60 samples in the test set from different singers, half in Chinese and English. All testing samples are included for objective evaluations.

Implementation Details We train the Neural Singing Beautifier on a single 32G Nividia V100 GPU with the batch size of 64 sentences for both 100k steps in Stage 1 and Stage 2 respectively. Besides PopBuTFy, we pre-train the ASR model (used for PPG extraction) leveraging the extra speech datasets: AISHELL-3 (Yao Shi et al., 2020) for Chinese and LibriTTS (Zen et al., 2019) for English. For the semi-supervised learning mentioned in Section 1 and Section 3.4, we leverage an internal Chinese singing dataset ($\sim$30 hours without labeled vocal tone) in the first training stage described in Section 3.4 for Chinese experiments. The output mel-spectrograms of our model are transformed into audio samples using a HiFi-GAN vocoder (Kong et al., 2020) trained with singing data in advance. We set the λ metioned in Section 3.3 to 0.1. We transform the raw waveform with the sampling rate 22050 Hz into mel-spectrograms with the frame size 1024 and the hop size 128. We extract F_0 (fundamental frequency) as pitch information from the raw waveform using Parselmouth[9], following Wu and Luan (2020); Blaauw and Bonada (2020); Ren et al. (2020). To obtain the ground truth pitch alignment between the amateur recordings and the professional ones for evaluating the accuracy of pitch alignment algorithm, we run the Montreal Forced Aligner tool (McAuliffe et al., 2017) on all the singing recordings to obtain their alignments to lyrics. Then the ground-truth pitch alignment can be derived since the lyrics are shared in a pair of data in PopBuTFy.

Performance Evaluation We employ both subjective metrics: Mean Opinion Score (MOS), Comparison Mean Opinion Score (CMOS), and an objective metric: Mean Cepstral Distortion (MCD) to evaluate the audio quality on the test-set. Besides, we use F0 Root Mean Square Error (F0 RMSE) and Pitch Alignment Accuracy (PAA) to estimate the pitch correction performance. For audio, we analyze the MOS and CMOS in two aspects: audio quality (naturalness, pronunciation and sound quality) and vocal tone quality. MOS-Q/CMOS-Q and MOS-V/CMOS-V correspond to the MOS/CMOS of audio quality and vocal tone quality respectively. More details about subjective evaluations are placed in Appendix C.

4.2 Main Results

In this section, we conduct extensive experiments to present our proposed model in regard to 1) the performance of pitch conversion; 2) the audio quality and vocal tone quality.

4.2.1 Pitch Correction

Firstly, we provide the comparison among time-warping algorithms in terms of PAA in Table 1. *Normed DTW* means two pitch curves will be normalized before running *DTW* (Müller, 2007); *CTW* means the Canonical Time Warping (Zhou and Torre, 2009), which is used for pitch correction in Luo et al. (2018). It can be seen that, *SADTW* surpasses existing methods by a large margin. We also visualize an alignment example of *DTW*, *CTW*, and *SADTW* in Figure 4.

Secondly, to check whether the amateur recordings are corrected to the good intonation after being beautified by NSVB, we calculate the F0 RMSE metric of the amateur recordings and the audio generated by NSVB, and list the results in Table 2. We can see that F0 RMSE has been improved significantly, which means NSVB successfully achieve pitch correction.

---

[9] `https://github.com/YannickJadoul/Parselmouth`

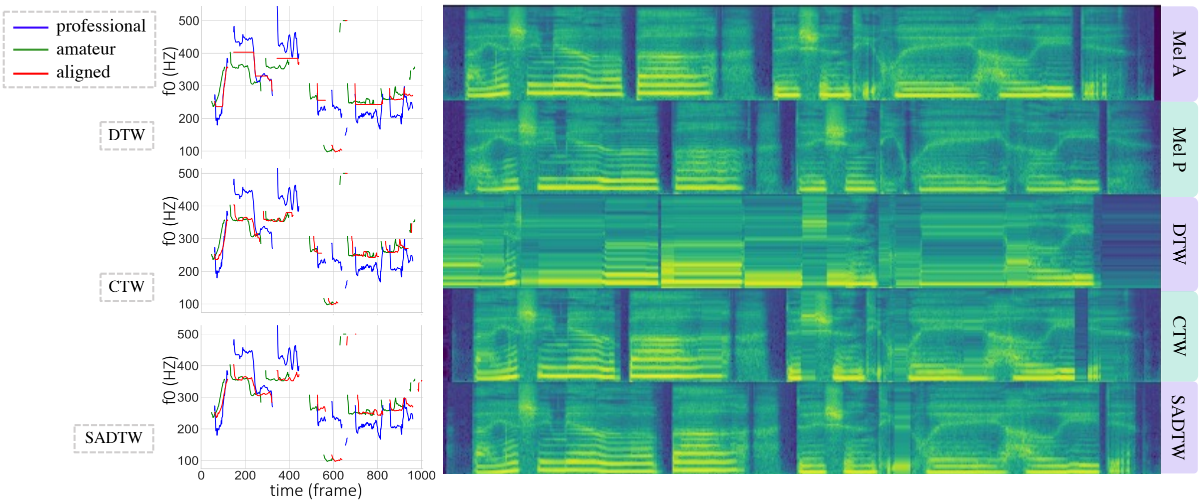

Figure 4: The behavior of DTW, CTW and SADTW. 1) In the left panel of the figure, we align the pitch curve of the amateur recording to the professional one's. It can be seen that DTW perform terribly; CTW fails at many parts; SADTW perform well as expectation. 2) In the right panel of the figure, we use the alignments obtained from these time-warping algorithm on pitch curves to align the amateur mel-spectrogram to the professional one. It shows that only SADTW could provide an alignment which preserves the content information in the amateur recording well and make the aligned result match the professional recording along the time axis.

Table 1: The Pitch Alignment Accuracy of different algorithms on Chinese and English songs.

Algorithm	PAA (%)	
	Chinese	English
DTW	66.94	63.90
Normed DTW	65.19	62.86
CTW	71.35	69.28
SADTW	**79.45**	**78.64**

Table 2: The F0 RMSE of the original amateur audio and the beautified audio on Chinese and English datasets. "GT Amateur" means the ground-truth amateur recordings.

Algorithm	F0 RMSE (Hz)	
	Chinese	English
GT Amateur	25.11	23.75
NVSB	**6.96**	**7.29**

4.2.2 Audio Quality and Vocal Tone Quality

To thoroughly evaluate our proposed model in audio quality and vocal tone quality, we compare subjective metric MOS-Q, MOS-V and objective metric MCD of audio samples generated by NVSB with the systems including: 1) *GT Mel*, amateur (A) and professional (P) version, where we first convert ground truth audio into mel-spectrograms, and then convert the mel-spectrograms back to audio using HiFi-GAN introduced in Section 4.1; 2) *Baseline*: the baseline model for SVB based on WaveNet with the number of parameters similar to *NSVB*, which adopts the same pitch correction method (SADTW) as *NSVB* does, and takes in the condition $\hat{c}_p$ defined in Section 3.3 to generate the mel-spectrogram optimized by the L_1 distance to x_p. MCD is calculated using the audio samples of *GT Mel P* as references.

The subjective and objective results on both Chinese and English datasets are shown in Table 3. We can see that 1) *NSVB* achieves promising results, with MOS-Q being less than those for ground truth professional recordings by only 0.1 and 0.12 on both datasets; 2) *NSVB* surpasses the *GT Mel A* in terms of MOS-V by a large margin, which indicates that *NSVB* successfully accomplishes the vocal tone improvement. 3) *NSVB* surpasses the baseline model on all the metrics distinctly, which proves the superiority of our proposed model; 4) *GT Mel P*, *NSVB* and *Baseline* all outperform *GT Mel A* in terms of MOS-V, which demonstrates that the proposed dataset PopBuTFy is reasonably labeled in respect of vocal tone.

4.3 Ablation Studies

We conduct some ablation studies to demonstrate the effectiveness of our proposed methods and some designs in our model, including latent-mapping, additional loss $\mathcal{L}_{map2}$ in the second training stage, and semi-supervised learning with extra unpaired, unlabeled data on Chinese songs.

Table 3: The Mean Opinion Score in audio quality (MOS-Q), vocal tone (MOS-V) with 95% confidence intervals and the Mean Cepstral Distortion (MCD) comparisons with ground-truth singing recordings and baseline model.

Method	MOS-Q	MOS-V	MCD
Chinese			
GT Mel P	4.21 ± 0.06	4.27 ± 0.10	-
GT Mel A	4.11 ± 0.07	3.51 ± 0.13	-
Baseline	3.90 ± 0.09	3.58 ± 0.18	7.609
NVSB	**4.11 ± 0.07**	**3.69 ± 0.17**	**7.068**
English			
GT Mel P	3.96 ± 0.11	3.96 ± 0.18	-
GT Mel A	3.67 ± 0.11	3.36 ± 0.19	-
Baseline	3.65 ± 0.12	3.37 ± 0.19	8.166
NVSB	**3.84 ± 0.06**	**3.63 ± 0.18**	**7.992**

4.3.1 Latent Mapping

We compare audio samples from NSVB with and without latent-mapping in terms of CMOS-V and MCD. From Table 4, we can see that the latent-mapping brings CMOS-V and MCD gains, which demonstrates the improvements in vocal tone from latent-mapping in our model. We visualize linear-spectrograms of *GT Mel A*, *GT Mel P*, *NSVB*, *NSVB w/o mapping* in Appendix B. The patterns of high-frequency parts in *NVSB* samples are comparatively similar to those in *GT Mel P* samples while *NSVB w/o mapping* sample resembles *GT Mel A* samples.

Table 4: The Comparison Mean Opinion Score in vocal tone (CMOS-V) and the Mean Ceptral Distortion (MCD) results of singing audio samples for latent mapping.

Method	CMOS-V	MCD
Chinese		
NVSB	0.000	**7.068**
NVSB w/o mapping	-0.100	7.069
English		
NVSB	0.000	**7.992**
NVSB w/o mapping	-0.330	8.115

4.3.2 Additional Loss $\mathcal{L}_{map2}$

As shown in Table 5, all the compared metrics show the effectiveness of $\mathcal{L}_{map2}$, which means that the additional loss $\mathcal{L}_{map2}$ is beneficial to optimizing the latent mapping function $\mathcal{M}$, working as a complement to the basic loss $\mathcal{L}_{map1}$.

Table 5: The Comparison Mean Opinion Score in audio quality (CMOS-Q), vocal tone (CMOS-V) and the Mean Ceptral Distortion (MCD) of singing audio samples.

Method	CMOS-Q	CMOS-V	MCD
Chinese			
NVSB	0.000	0.000	**7.068**
NVSB w/o $\mathcal{L}_{map2}$	-0.213	-0.760	7.237
English			
NVSB	0.000	0.000	**7.992**
NVSB w/o $\mathcal{L}_{map2}$	-0.060	-0.090	8.040

4.3.3 Semi-supervised Learning

To illustrate the advantage of the CVAE architecture that allows semi-supervised training, we compare NSVB trained with and without extra unpaired, unlabeled data on Chinese songs. The corresponding results are shown in Table 6. The compared metrics indicate the advantage of semi-supervised learning, which facilitates the learning of the latent representations for better sample reconstruction (audio quality) and better latent conversion (vocal tone quality).

Table 6: The Comparison Mean Opinion Score in audio quality (CMOS-Q), vocal tone (CMOS-V) and the Mean Ceptral Distortion (MCD) of singing audio samples.

Method	CMOS-Q	CMOS-V	MCD
NVSB	0.000	0.000	**7.068**
NVSB w/o extra data	-0.420	-0.070	7.283

5 Conclusion

In this work, we propose Neural Singing Voice Beautifier, the first generative model for the SVB task, which is based on a CVAE model allowing semi-supervised learning. For pitch correction, we propose a robust alignment algorithm: Shape-Aware Dynamic Time Warping (SADTW). For vocal tone improvement, we propose a latent mapping algorithm. To retain the vocal timbre during the vocal tone mapping, we also propose a new specialized SVB dataset named PopBuTFy containing parallel singing recordings of both amateur and professional versions. The experiments conducted on the dataset of Chinese and English songs show that NSVB accomplishes the SVB task (pitch correction and vocal tone improvement), and extensional ablation studies demonstrate the effectiveness of the proposed methods mentioned above.

Acknowledgments

This work was supported in part by Zhejiang Natural Science Foundation under Grant LR19F020006, National Natural Science Foundation of China under Grant No.61836002, No.62072397. Thank all the co-authors for their wonderful contributions, the enlightening opinions of the participants in the discussion, and the great efforts of singers and data annotators.

A Details of Model Structure

The details of the adversarial discriminator, the content encoder, and WaveNet structure are shown in Figure 5, Figure 8, and Figure 6. The hidden size of CVAE model, latent variable and discriminator are 256, 128 and 128 respectively. We train NSVB on a single V100 32G GPU for almost 22 hours to finish two-stage training.

A.1 Multi-window Discriminator

As shown in Figure 5, our multi-window discriminator consists of 2 unconditional discriminator parts with fixed window sizes. Each unconditional discriminator contains N layers of Conv units. In our model, we set $N = 3$. The Conv units are all 1-D convolutional networks with ReLU activation and spectral normalization. The outputs of these unconditional discriminators are then concatenated and linearly projected to form the output.

A.2 WaveNet

As shown in Figure 6, the WaveNet unit used in the VAE encoder and decoder of NVSB consists of a 1D convolution layer with ReLU to preprocess the input, and a group of sub-layers with residual connection between adjacent ones. Each sub-layer contains a 1×1 convolutional layer to process the input condition and a 3×3 convolutional layer for residual input. After that, they got fused by being added up, then processed by tanh and sigmoid separately and then multiplied together. Finally, they produce a residual output for the next sub-layer and a skip-out. Lastly, two layers of 1D convolution and a ReLU process the summed skip-out to produce output.

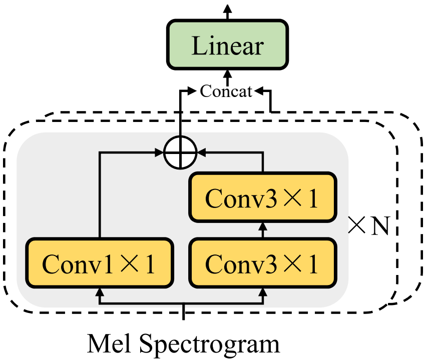

Figure 5: Multi-window discriminator structure used in NSVB

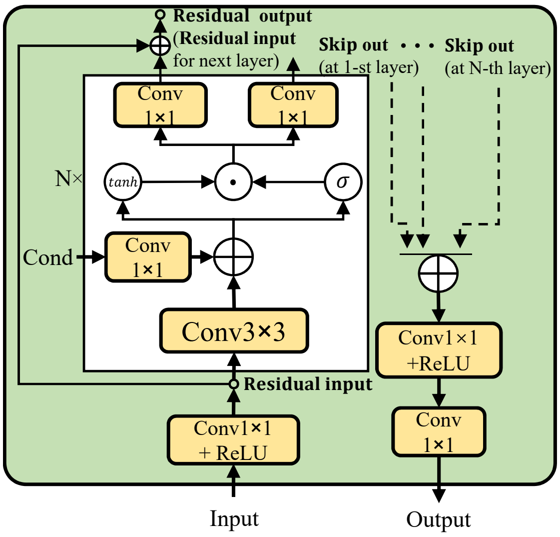

Figure 6: WaveNet structure used in NSVB

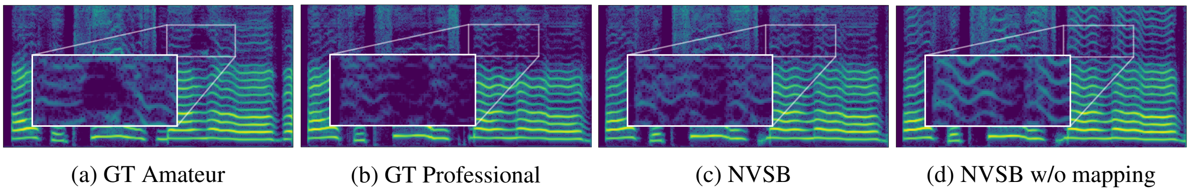
A.3 Content Encoder

As shown in Figure 8, the content encoder is the combination of several conformer encoder layers in pink rectangle along with a 3-layer prenet. The kernel size of the convolutional layer for prenet is 5. The hidden size is 256. We use 4 heads in the multi-head self-attention part. And we use 31 stacked conformer encoder layers to form this module. During pre-training, an ASR transformer decoder is attached to decode texts out for regular ASR training. After pre-training, only the encoder and the prenet part is used to extract PPG features



(a) GT Amateur (b) GT Professional (c) NVSB (d) NVSB w/o mapping

Figure 7: Linear-spectrogram visualizations for the ablation study on latent mapping.

from mel-spectrograms of audio samples.

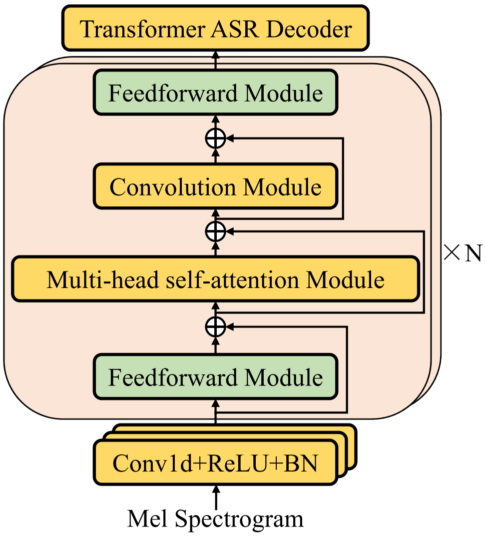


Figure 8: Content encoder used in NSVB

B Linear-spectrograms Visualizations

We visualize four linear-spectrograms generated with the same content. It seems that the professional vocal tone is related to certain patterns in the high-frequency region of the spectrograms. In the future, SVB may be accomplished in a more fine-grained way together with the knowledge in vocal music.

C Details in subjective evaluations

During testing, each audio sample is listened to by at least 10 qualified testers, all majoring in vocal music. We tell all testers to focus on one aspect and ignore the other aspect when scoring MOS/CMOS of each aspect. For MOS, each tester is asked to evaluate the subjective naturalness of a sentence on a 1-5 Likert scale. For CMOS, listeners are asked to compare pairs of audio generated by systems A and B and indicate which of the two audio they prefer and choose one of the following scores: 0 indicating no difference, 1 indicating small difference, 2 indicating a large difference. For audio quality evaluation (MOS-Q and CMOS-Q), we tell listeners to "focus on examining the naturalness, pronunciation and sound quality, and ignore the differences of singing vocal tone". For vocal tone evaluations (MOS-V and CMOS-V), we tell listeners to "focus on examining singing vocal tone of the song, and ignore the differences of audio quality (e.g., environmental noise, timbre)". We split evaluations for main experiments and ablation studies into several groups for them. They are asked to take a break for 15 minutes between each group of experiments to remain focused during subjective evaluations. All testers get reasonably paid.

D Limitations and Solutions

SADTW is a kind of advanced APC method, which is designed for fine-tuning the amateur recording, but not for the case when the amateur recordings are completely out of tune. In the latter case, we recommend people to use Singing Voice Synthesis (synthesizing waveform from PPG and MIDI) + Singing Voice Conversion (converting the vocal timbre of the synthesized waveform into the user's), or some Speech to Singing (STS) methods. In addition, SADTW provides a score representing the similarity of two pitch curves, which could be used to determine what kind of SVB solution should be chosen.

E Potential Negative Societal Impacts

This work develops a possible automatic way for singing voice beautification, which may cause unemployment for people with related occupations. In addition, there is the potential for harm from piracy and abuse of our released recordings. Thus, we choose the dataset license: CC by-nc-sa 4.0.

F Ethics Statement

F.1 For every submission

F.1.1 Did you discuss the *limitations* of your work?

Yes. Appendix D.

F.1.2 Did you discuss any potential *risks* of your work?

Yes. Appendix E.

F.1.3 Do the abstract and introduction summarize the paper's main claims?

Yes. Abstract.

F.2 Did you use or create *scientific artifacts*?

Yes.

If yes:

F.2.1 Did you cite the creators of artifacts you used?

Yes. Section 4.1.

F.2.2 Did you discuss the *license or terms* for use and/or distribution of any artifacts?

Yes. Section 4.1 and Appendix E.

F.2.3 Did you discuss if your use of existing artifact(s) was consistent with their *intended use*, provided that it was specified? For the artifacts you create, do you specify intended use and whether that is compatible with the original access conditions (in particular, derivatives of data accessed for research purposes should not be used outside of research contexts)?

Yes. Appendix E.

F.2.4 Did you discuss the steps taken to check whether the data that was collected/used contains any *information that names or uniquely identifies individual people* or *offensive content*, and the steps taken to protect / anonymize it?

Yes. The participants are asked to use bogus names in the data collection process, which means we do not know who sang these recordings.

F.2.5 Did you provide documentation of the artifacts, e.g., coverage of domains, languages, and linguistic phenomena, demographic groups represented, etc.?

Yes. Section 4.1.

F.2.6 Did you report relevant statistics like the number of examples, details of train/test/dev splits, etc. for the data that you used/created?

Yes. Section 4.1.

F.3 Did you run *computational experiments*?

Yes.

If yes:

F.3.1 Did you report the *number of parameters* in the models used, the *total computational budget* (e.g., GPU hours), and *computing infrastructure* used?

Yes. Section 4.1.

F.3.2 Did you discuss the experimental setup, including *hyperparameter search* and *best-found hyperparameter* values?

Yes. Section 4.1.

F.3.3 Did you report *descriptive statistics* about your results (e.g., error bars around results, summary statistics from sets of experiments), and is it transparent whether you are reporting the max, mean, etc. or just a single run?

Yes. Section 4.2.

F.3.4 If you used existing packages (e.g., for preprocessing, for normalization, or for evaluation), did you report the implementation, model, and parameter settings used (e.g., NLTK, Spacy, ROUGE, etc.)?

Yes. Section 4.1.

F.4 Did you use *human annotators* (e.g., crowdworkers) or *research with human subjects*?

If you answer **Yes**, provide the section number; if you answer **No**, you can skip the rest of this section.

Yes.

If yes:

F.4.1 Did you report the full text of instructions given to participants, including e.g., screenshots, disclaimers of any risks to participants or annotators, etc.?

Yes. Appendix C.

F.4.2 Did you report information about how you recruited (e.g., crowdsourcing platform, students) and paid participants, and discuss if such *payment is adequate* given the participants' demographic (e.g., country of residence)?

No. Trade secret.

F.4.3 Did you discuss whether and how *consent* was obtained from people whose data you're using/curating (e.g., did your instructions explain how the data would be used)?

Yes. Section 4.1 and our code project.

F.4.4 Was the data collection protocol *approved (or determined exempt)* by an ethics review board?

N/A.

F.4.5 Did you report the basic demographic and geographic characteristics of the *annotator* population that is the source of the data?

No. They're completely anonymous, and we don't know.

A Model-Agnostic Data Manipulation Method for Persona-based Dialogue Generation

Abstract

Towards building intelligent dialogue agents, there has been a growing interest in introducing explicit personas in generation models. However, with limited persona-based dialogue data at hand, it may be difficult to train a dialogue generation model well. We point out that the data challenges of this generation task lie in two aspects: first, it is expensive to scale up current persona-based dialogue datasets; second, each data sample in this task is more complex to learn with than conventional dialogue data. To alleviate the above data issues, we propose a data manipulation method, which is model-agnostic to be packed with any persona-based dialogue generation model to improve its performance. The original training samples will first be distilled and thus expected to be fitted more easily. Next, we show various effective ways that can diversify such easier distilled data. A given base model will then be trained via the constructed data curricula, i.e. first on augmented distilled samples and then on original ones. Experiments illustrate the superiority of our method with two strong base dialogue models (Transformer encoder-decoder and GPT2).

1 Introduction

The ability to generate responses with consistent personas is important towards building intelligent dialogue agents. In past years, there has been a growing interest in introducing explicit personas in dialogue generation models (Song et al., 2019; Wolf et al., 2019). A piece of persona text generally consists of profiles and background personal facts. A clipped persona-based dialogue from the PersonaChat (Zhang et al., 2018a) dataset is shown in Figure 1, which covers rich persona features. For a persona-based dialogue generation model, generated responses need to be relevant to the dialogue context as well as consistent with personas.

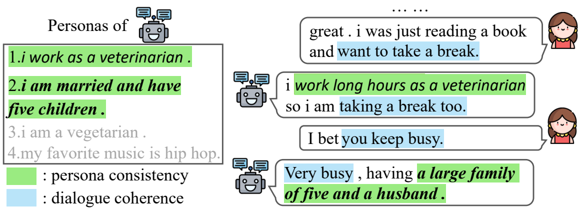

Figure 1: Each response in a persona-based dialogue is mostly related to one persona sentence and its latest dialogue history utterance. Persona sentences in grey are redundant for all responses.

Most existing generation models for this task rely heavily on training with sufficient persona-based dialogues. However, available data are limited due to their expensive collection costs. Take the PersonaChat as an example, two crowd-sourced annotators are hired to play the part of a provided persona and converse naturally with each other. In total, about 162 thousand dialogue utterances are collected with less than 5 thousand unique persona profiles. Compared with conventional dialogue datasets such as OpenSubtitles (Lison and Tiedemann, 2016) and Weibo (Shang et al., 2015) with millions of utterances, persona-based dialogue datasets are relatively small.

Besides the limited data scale, another data issue we want to point out is that a persona-based dialogue is more complex to learn with, in comparison with conventional dialogues. Recall that a persona-based dialogue involves not only multiple dialogue utterances, but also auxiliary persona sentences. Welleck et al. (2019) showed that not all responses in the PersonaChat dataset are consistent with the provided personas. This makes it difficult for a model to capture a reliable mapping from training data. Supposing we apply a similar dialogue model as in conventional dialogue generation tasks with a comparable parameter size, we

should expect more data would be necessary to train a robust model on the more difficult data setting. Moreover, it may be difficult to use existing data augmentation methods (Li et al., 2019; Niu and Bansal, 2019) to automatically construct such complex persona-based dialogue data. For example, if we apply back translation (Sennrich et al., 2016) to every sentence in persona-based samples, the augmented ones may not maintain the coherence between the dialogue history and the response as well as the consistency between the persona and the response simultaneously.

A few studies have been conducted to alleviate the above data issues by finetuning existing pretrained models such as GPT (Wolf et al., 2019; Golovanov et al.) or BERT (**?**Song et al., 2021). They often stick to a certain pretrained model. Sophisticated finetuning strategies, including proper network modifications and loss functions, are required to get satisfactory performance, making them not useful across different pretrained models. Moreover, they do not address the data difficulty issue explicitly. Most of them simply concatenate all persona and dialogue history sentences into a single input sequence for finetuning, and rely on the ability of the pretrained model to fast adapt to the target data domain. Hence, we want to design a model-agnostic method to address both the data scale and data difficulty issue, which can be packed with any base model, either trained from scratch or finetuned from a pretrained model.

In this work, we propose a data manipulation method for persona-based dialogue data, which is model-agnostic to be packed with any base model to improve their robustness and consistency. Our method includes three operations on data, namely $\mathbf{D}^3$, in sequence: (i) **D**ata distillation: original training samples are simplified into contain only useful and less redundant persona sentences and dialogue utterances, which are expected to be fitted more easily; (ii) **D**ata diversification: with the easier distilled samples, we can also perform data augmentation more reliably. We design various methods to edit new personas, and then align them with new and consistent responses to improve data diversity; (iii) **D**ata curriculum: with both augmented distilled and original data at hand, we arrange them into a data curriculum for model learning (Bengio et al., 2009), where the base model is trained on the easier augmented distilled data and then the harder original data. To validate the effectiveness of our method, we perform experiments on two strong base dialogue models, Transformer-based encoder-decoder and GPT2.

2 Related Work

Persona-based dialogue generation It sees growing interest in recent years, thanks to the released benchmark datasets such as PersonaChat/ConvAI2 (Zhang et al., 2018a; Dinan et al., 2020). Previous works mostly focus on modifying dialogue models to condition auxiliary persona information, including extra persona embedding(Li et al., 2016b), profile memory (Zhang et al., 2018a), copying from personas (Yavuz et al., 2019), CVAE with persona information (Song et al., 2019), and using meta-learning to augment low-resource personas (Tian et al., 2021).

Recent works try to adopt large-scale pretrained models on this task. GPT/GPT2 (Radford et al., 2018, 2019) are chosen the most often and shown to improve the generation quality with different finetuning strategies (Wolf et al., 2019; Golovanov et al.; Cao et al., 2020). Some leverage BERT (Devlin et al., 2019) as backbones (**?**Song et al., 2021). Other pretrained models also demonstrate their effectiveness (Lin et al., 2021). The aforementioned methods often need proper network modifications and finetuning loss functions in order to get satisfactory performance. It is hard to transfer them to be useful across different pretrained models. Moreover, most of them simply concatenate persona texts and dialogue history together as a single input sequence (Wolf et al., 2019; Roller et al., 2021), highly depending on the ability of the pretrained model to fast adapt to the target data domain.

Text data manipulation Various data augmentation methods have been widely used in many NLP tasks (Sennrich et al., 2016; Hou et al., 2018; Guo et al., 2019; Min et al., 2020), which are also effective to boost the performance of dialogue models. New generated dialogue utterances (Li et al., 2019; Niu and Bansal, 2019) and retrieval results (Zhang et al., 2020) can be used to augment the training data. However, all previous work only studies the pairwise relationship between a query and a response to design the augmentation techniques, which are not applicable to involving auxiliary information, such as personas, simultaneously.

Besides data augmentation, there are other ways to manipulate dialogue data to improve model learning. For example, a few approaches filter uninformative or noisy samples to enhance data quality (Csáky et al., 2019; Akama et al., 2020). Cai et al. (2020a) combine data augmentation and re-weighting to make models learn more effectively. Tian et al. (2019) utilize learnable memory based on dialogue clusters to enhance the model.

Curriculum learning Bengio et al. (2009) examine the benefits of training models using various curricula successively from easy to hard. It has been applied to many NLP tasks such as machine translation (Platanios et al., 2019), reading comprehension (Tay et al., 2019) and language understanding (Xu et al., 2020). Cai et al. (2020b) adopt the idea in open-domain dialogue generation, where curriculum plausibility is determined by the response properties, including coherence and diversity. Our work is different in that we introduce new distilled data regarding as a curriculum.

3 Our Data Manipulation Method

We first formally define a persona-based training sample. It consists of L persona description sentences $P = \{p_1, p_2, .., p_L\}$, M dialogue history utterances $H = \{h_1, h_2, .., h_M\}$, and a gold response R. The given training dataset is denoted as $\mathcal{D} = \{(P, H, R)\}$. Note that L and M in different training samples can be different. A dialogue model needs to generate a response $\hat{R}$, which is coherent with the dialogue history H and consistent with persona information in P.

Our proposed data manipulation method $\mathbf{D}^3$ is model-agnostic. For any dialogue model, we will not change the model itself, but only manipulate its training data. We develop three data manipulation operations in sequel, former two for augmentation and the last one eases training, shown in Figure 2:

1. **D**ata distillation. We construct simple persona-consistent data $\mathcal{D}^{dis} = \{(\widetilde{P}, \widetilde{H}, \widetilde{R})\}$ by removing redundant information in P and H;
2. **D**ata diversification. Due to the limited amount of distilled samples, we design various methods to increase the data variety and scale, and obtain the diversified data $\mathcal{D}^{div} = \{(\widetilde{p}, \widetilde{h}, \widetilde{r})\}$;
3. **D**ata curriculum. We combine $\mathcal{D}^{dis}$ and $\mathcal{D}^{div}$ as the augmented dataset $\mathcal{D}^a$. A curriculum strategy is defined to train the model with the easier distilled samples in $\mathcal{D}^a$ first and then the original ones in $\mathcal{D}$.

3.1 Data Distillation

Before introducing our distillation method, we discuss the difficulty of training a model with the original training samples in detail. The dependency of a response on the given persona fluctuates between different parts of the persona sentences. As shown in Figure 1, most responses only correspond to one persona sentence. The remaining persona information is mostly redundant, and may confuse the model to attend on useful persona information. Similarly, we notice that models tend to attend more on the last few utterances of H rather than the historical ones. We find that by using a Transformer encoder-decoder model, the attention weights of the last Transformer layer on the last utterance is 45% higher than the average on the other utterances. See Appendix C.1 for the experiment and results. This observation is also consistent with previous studies on multi-turn context understanding (Khandelwal et al., 2018; Sankar et al., 2019).

A few previous works have demonstrated that attention-based models will be distracted by noisy attended information, and accurate attention supervisions can be very beneficial (Liu et al., 2016; Hsu et al., 2018). Inspired by them, we mimic a "hard" attention supervision between the response and useful persona/dialogue history by directly removing redundant tokens in the attended sequences. Therefore, different from previous work that modify the model to inject attention supervisions, our method only manipulates data.

Persona distillation We aim to determine which persona sentence the current response is consistent with, and thus remove the remaining non-consistent ones. To do so, we associate each persona sentence p_k with the target response R , and determine the consistency between each p_k and R. Following previous work (Welleck et al., 2019), we cast it as a natural language inference (NLI) problem. If R entails p_k , it is considered to be consistent with p_k, otherwise irrelevant to p_k. A trained RoBERTa (Liu et al., 2019) model is used here as the NLI model, with an accuracy of 90.8% on the DialogueNLI dev set provided in Welleck et al. (2019). Details are provided in Appendix A.1.

Dialogue history distillation We can adopt a trained attention-based model to determine useful context sentences. For simplicity, we could also keep only the most useful last utterance H_M in a distilled sample (as suggested by our preliminary experiments discussed in the beginning of this section). In our experiments in §4, we find that using the last utterance is enough for our method to work

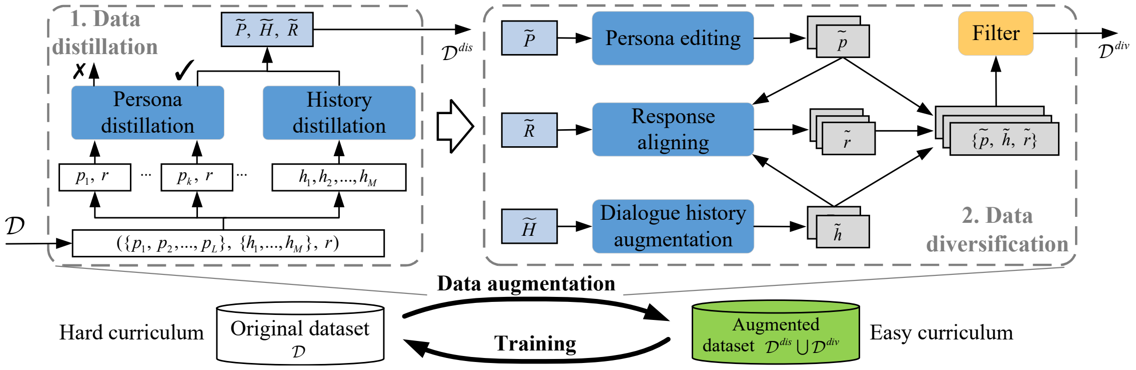

Figure 2: The framework of our data manipulation method **D**^{3}. It obtains the augmented dataset $\mathcal{D}^a = \mathcal{D}^{dis} \cup \mathcal{D}^{div}$ from the original dataset $\mathcal{D}$ through data distillation and data diversification. Curriculum strategy is used to train a model by first learning on the easy augmented data $\mathcal{D}^a$and then on the hard original training data $\mathcal{D}$.

well.

A distilled sample $(\widetilde{P}, \widetilde{H}, \widetilde{R})$ is ready to be constructed now. Here, $\widetilde{P}$ and $\widetilde{H}$ both contain only one sentence. $\widetilde{P}$ is any p_k that entails R, and $\widetilde{H}$ is the last utterance in the dialogue history, and $\widetilde{R} = R$. Such samples form the distilled dataset $\mathcal{D}^{dis}$. Note that an original sample in $\mathcal{D}$ may result in none, one, or multiple distilled samples, as R may entail none, one, or multiple persona sentences.

3.2 Data Diversification

Distilled samples should ease model training as their responses are highly dependent on their $\widetilde{P}$ and $\widetilde{H}$. However, samples in $\mathcal{D}^{dis}$ are limited in terms of both **scale** (around 40% of the original data) and **diversity** (about 4.5k unique persona sentences). Hence, it is necessary to augment $\mathcal{D}^{dis}$. Thanks to the assured relationship between $\widetilde{P}/\widetilde{H}$ and R, we can devise possible methods to diversify distilled samples with more semantically varied samples. Our data diversification operation contains the following three parts along with quality filtering, as shown in Figure 2.

Persona editing We aim to obtain new persona sentences to improve the data scale, and more importantly the persona diversity. Hence, we here consider both token-level and phrase-level editing methods given a persona sentence $\widetilde{P}$:

- Token-level editing: we randomly mask a predefined ratio of tokens in $\widetilde{P}$, then use a pretrained BERT (Devlin et al., 2019) model to make predictions on the masked positions one by one.
- Phrase-level editing: we remove the last few tokens in $\widetilde{P}$ with the removal length determined by a random ratio, and utilize a pretrained GPT2 (Radford et al., 2019) to rewrite the removal part.

Multiple edited persona sentences can be obtained from one certain $\widetilde{P}$. Here, we finetune pretrained models using all persona sentences for a trade-off between semantic diversity and domain similarity. To ensure a satisfactory fluency and novelty of an edited persona $\widetilde{p}$, we rate it via a scoring function:

$$f = \alpha \cdot \mathrm{PPL}(\widetilde{p}) + (1 - \alpha) \cdot \mathrm{BS}_f(\widetilde{p}, \widetilde{P}). \qquad (1)$$

Here, PPL calculates the normalized perplexity via a GPT2 model to measure its fluency, and the rescaled F1 value of BERTScore (BS_f) (Zhang et al., 2019) is employed to evaluate the semantic similarity between two sentences. Lower values for both functions are preferred, indicating higher fluency or novelty. α is a hyper-parameter. We rank all edited personas originated from the same $\widetilde{P}$ with the ascending order of their scores in Eq. 1, and select the top N_p ones.

Response aligning Since the semantic meaning of an edited persona sentence obtained above could change, the original response may not be consistent with it. Therefore, we need to get a new aligned response to maintain the persona consistency. Two approaches are utilized to obtain an aligned response $\widetilde{r}$ given an edited persona sentence $\widetilde{p}$ and the corresponding distilled history utterance $\widetilde{H}$:

- Token-level editing: We observe that some overlapped tokens can be found between $\widetilde{P}$ and $\widetilde{R}$. If an overlapped token w has been changed to a new token w' in the edited persona $\widetilde{p}$, we directly replace w in $\widetilde{R}$ with w' in the same positions, resulting in an aligned response $\widetilde{r}$. An illustration figure can be found in Appendix A.2.
- Model predicting: If no overlapped token can be found, token-level editing will not be applicable. Then we employ a GPT2-based encoder-decoder model (Cao et al., 2020) finetuned on the distilled

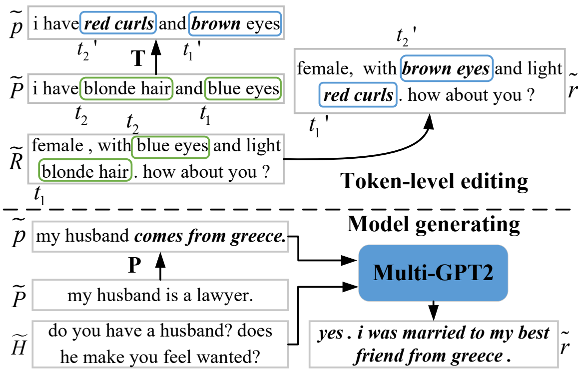

Figure 3: Aligning responses for new personas via token-level editing or model generating. **T/P**: edit persona in token/phrase level.(t_1 and t_2 are overlapped tokens, t_1' and t_2' are corresponding new edited and aligned tokens.)

data $\mathcal{D}^{dis}$ to predict responses with the given $\widetilde{p}$ and a dialogue history utterance $\widetilde{H}$.
Figure 3 demonstrates the two kinds of approaches.

Dialogue history augmentation To further scale up the size of distilled samples, we also manipulate the dialogue history $\widetilde{H}$. Since the diversity scarcity issue is not severe in $\widetilde{H}$, we use a popular sentence-level data augmentation method, back translation (BT) (Sennrich et al., 2016), to obtain variants of dialogue utterances. We could consider the semantics of the variants are identical. Distilled history utterance $\widetilde{H}$ is translated into an intermediate language, then back into the source language using a couple of existing translation models. The original dialogue history and its N_h variants compose the augmented dialogue history set $\{\widetilde{h}\}$.

Combining the above three parts together, we now obtain new samples $\{(\widetilde{p}, \widetilde{h}, \widetilde{r})\}$. We evaluate them with respect to fluency, persona consistency and history coherence:

$$s = \beta \cdot \text{PPL}(\widetilde{r}) + \gamma \cdot \text{NLI}(\widetilde{p}, \widetilde{r}) + (1 - \beta - \gamma)\text{NLI}_c(\widetilde{h}, \widetilde{r}), \quad (2)$$

where NLI measures the entailment between a persona sentence and the response by the same NLI model in §3.1, and NLI_c evaluates the entailment between a dialogue history utterance and the response using another NLI model (Dziri et al., 2019)(details in Appendix A.2). β and γ are hyperparameters. We filter samples below a threshold T, and the remaining samples constitute the diversified data set $\mathcal{D}^{div}$. The whole augmented training dataset is the union of $\mathcal{D}^{dis}$ and $\mathcal{D}^{div}$. The quality of augmented samples is discussed in Appendix B.

	$\mathcal{D}$	$\mathcal{D}^{dis}$	$\mathcal{D}^{div}$	$\mathcal{D}^{a}$	$\mathcal{D} + \mathcal{D}^{a}$
#sample	65,719	26,693	26,700	53,393	119,112
#persona	4,710	4,522	9,788	14,310	14,498
#token	20,467	13,420	12,794	17,835	23,269

Table 1: Statistics of samples obtained in each stage.

3.3 Data Curriculum

During inference, the model should be capable to handle testing data with multiple persona sentences and dialogue history utterances as the original data. Therefore, a model trained using $\mathcal{D}^a$ only is not proper. We should use both $\mathcal{D}^a$ and $\mathcal{D}$. Unlike previous studies that treat the original and augmented data equally and mix them directly, we design a curriculum strategy. Considering the different training difficulty of data in $\mathcal{D}^a$ and $\mathcal{D}$, we treat $\mathcal{D}^a$ as an easy curriculum while the original dataset $\mathcal{D}$ as a hard curriculum. The model is trained on such data curriculum successively until convergence.

4 Experiments

To validate the effectiveness of our proposed model-agnostic data manipulation method, we first experiment on two strong persona-based dialogue generation models (Transformer encoder-decoder and GPT2) on the benchmark PersonaChat (Zhang et al., 2018a) dataset. Next we conduct a series of analysis to examine the usefulness of different data manipulation operations in our method. [1]

4.1 Experimental Setup

Dataset The PersonaChat (Zhang et al., 2018a) data is widely used in this field (Song et al., 2019, 2020; Wolf et al., 2019; Golovanov et al.). Each sample has a dialogue history H with no more than 15 utterances ($M \leq 15$) and a persona P with between 4 and 6 sentences ($4 \leq L \leq 6$). Numbers of samples, unique persona sentences, and tokens in each stage of our method are listed in Table 1.

Base models Two dialogue model architectures are considered:

- TRANSFORMER (Vaswani et al., 2017): an encoder-decoder architecture using Transformer as the backbone with pointer generator (See et al., 2017) integrated;
- GPT2: one of the most powerful pretrained models on this task (Wolf et al., 2019; Golovanov et al.; Cao et al., 2020).

Table 2: Results of all compared data manipulation methods on two base models. BLEU and Dist-n are in %. Best results are in bold, and second best are underlined. Shaded numbers indicate our D^3 is significantly better than this method on human evaluation, C-score and BS$_f$, accoding to our significance T-test where $p > 0.05$.

TRANSFORMER is trained from scratch, and GPT2 is finetuned. For both models, we construct training data by concatenating persona and dialogue history as a single input sequence, in which special symbols and token type embeddings are involved to distinguish between them. The negative log-likelihood loss is used to train models using Adam optimizer (Kingma and Ba, 2015).

Compared methods We pack two base models with our method **D**^{3} and other data manipulation approaches for comparison:

- BACK TRANSLATION (BT) (Sennrich et al., 2016): we perform BT on all sentences in a training sample, including the persona sentences and dialogue utterances, and train the model with the augmented and original data jointly;
- CVAE (Li et al., 2019): a CVAE-based generation model is trained on the original data and then used to generate new responses via sampling with different latent codes. Since it can only handle pair-wise data, we concatenate all input sentences as a single input sequence in this method;
- ENTROPY FILTER (FILTER) (Csáky et al., 2019): it removes generic responses according to the entropy, which is calculated using the dialogue history and the response without using the persona.

The detailed configurations of each method are given in Appendix B.

Automatic metrics We adopt multiple widely used metrics to measure the response quality, including Perplexity (PPL), BLEU (Papineni et al., 2002), NIST-4 (Doddington, 2002) and BERTScore (Zhang et al., 2019). We use the same BS$_f$ in Eq. 1 for BERTScore. To evaluate the response diversity, we use Distinct-n (Li et al., 2016a) (Dist, n=1,2,3) which is the ratio of unique n-grams among the corpus, and Entropy-n (Zhang et al., 2018b) (Ent, n=1,2,3) that is the entropy obtained via the n-gram distribution in a sentence. Moreover, C-score (Madotto et al., 2019) (**C**) is involved, where we follow the default setting and use the output of an NLI model trained on the DialogueNLI dataset (Welleck et al., 2019) to indicate the consistency between a response and persona sentences.

Human evaluation We randomly selected 200 samples from the test set for human evaluations. Five professional annotators from a third-party company were asked to rate the responses from three aspects: 1) Fluency (Flu.); 2) Coherence (Coh.) with the dialogue history, 3) Persona consistency (Pcon.). The scores for the first two aspects have three scales, in which 1/2/3 indicates unacceptable/moderate/satisfactory respectively. The last one is binary, where 1 means the response is consistent with at least one persona sentence in the sample and 0 otherwise. The agreement rate from raters is 97.5%, 89.5%, 100% @3 (at least 3 of them reach an agreement) in the these aspects, indicating the validity of scores. The instruction of human evaluation is given in Appendix B.

4.2 Results

Table 2 reports the results on two based models trained with the use of various compared data manipulation methods. T-test is conducted between our D^3 and other compared methods on each base model for metrics including BS$_f$, C-score and three human evaluation metrics. Other automatic metrics have similar results or are not applicable such as Distinct-n. Details of the significant tests are given in Appendix C.2.

Table 3: Automatic evaluation results with variant in data distillation (middle), and diversification (bottom), compared with our full method (top) on TRANSFORMER. $\mathbf{D}^3*$ means using an NLI model trained under a few-show setting (200 labelled samples) in the data distillation.

On TRANSFORMER, all methods achieve improvements on most metrics compared with training with the original dataset. Our method yields the best performance except for Ent-1. On GPT2, many methods fail to improve the various metrics consistently. For example, on the persona consistency (Pcon.), only ENTROPY FILTER and our method can get higher scores than training with the original dataset. The reason is that the data scarcity issue is less severe with a pretrained model, and it is more important to address the data diversity issue. In our method, the augmented distilled samples are encouraged to have different semantics with the original ones and improve the data diversity, and thus continue to get improvements on the strong pretrained GPT2.

4.3 More Analysis

We further analyze the contributions made by different data manipulation operations in our method by answering the following three questions:

1. Is there a need to construct simple data $\mathcal{D}^{dis}$ as in data distillation?
2. Can data diversification effectively obtain diverse distilled data?
3. Does the curriculum strategy better exploit the augmented data and help model training?

We use results on TRANSFORMER here for discussion in the following part. Refer to Appendix C.3 for extensive results on GPT2 model.

Analysis of data distillation To examine the effectiveness of data distillation, we need to neutralize the influence of data diversification as it is only applicable to distilled data. Following variants of our $\mathbf{D}^3$ are considered: 1) *w/o diversification*: only using distilled data $\mathcal{D}^{dis}$ in the easy curriculum; 2) *w/o distillation*: based on 1), we recover samples in $\mathcal{D}^{dis}$ into their original format, which means all their persona sentences and history utterances are included; 3) *only distillation*: only $\mathcal{D}^{dis}$ is used in training without using the original data in $\mathcal{D}$.

Results of these variants are shown in the middle of Table 3. Obviously, removing data diversification decreases the performance in all aspects as the model has less training data. If we further remove data distillation and use the same amount of data in their original formats, the model performs even worse, especially on the C-score. This validates the effectiveness of data distillation in our method. However, it is not proper to completely rely on distilled data. From the results of only using distilled data in training, our method improves the C-score, yet significantly degenerates in other aspects. The reason is that the relationship between persona/dialogue history and the response has changed from the original data to their distilled ones. Thus a model trained with distilled data should serve as a warm start to learn the original data, but not to replace the original data.

We also test the robustness of our data distillation method by using an NLI model trained in a few-shot setting (200 samples). Results are included in Table 3 as $\mathbf{D}^3*$. It is slightly worse than our method with sufficient NLI training data, but still superior to most compared methods. Note that the response diversity metrics nearly remain unchanged. This means that our data diversification methods are still effective when starting from noisy distilled samples. It also shows that our method can be useful when only limited in-domain NLI labeled data are available for data distillation.

Analysis of data diversification Table 1 shows that the diversified data contain many new persona sentences as well as tokens. Besides, we compute

	PPL	BLEU	NIST-4	BS$_f$	Ent-1	Ent-2	Ent-3	Dis-1	Dis-2	Dis-3	**C**

persona	40.26	62.17	70.47	77.81

Table 5: Novelty metrics of the diversified data compared to distilled data in sample and persona level.

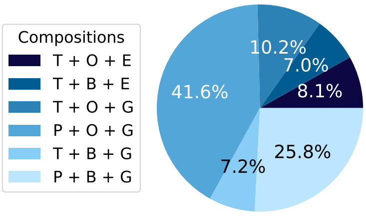

Figure 4: The compositions of diversified data. T/P: token/phrase-level editing to get edited personas, O/B: original/BT-augmented dialogue history, E/G: token editing/generating by a model to get aligned responses.

the Novelty metrics (Wang and Wan, 2018; Zhang et al., 2020) of diversified samples in $\mathcal{D}^{div}$. It takes the original distilled samples in $\mathcal{D}^{dis}$ as references, and uses the Jaccard similarity function to measure the proportion of n-grams ($n = 1, 2, 3, 4$) in $\mathcal{D}^{div}$ but not in $\mathcal{D}^{dis}$. A higher value means more "novel" content. Note that we particularly prefer more novel personas, while not encouraging more novel dialogue histories. Thus, the Novelty scores on the overall samples which include dialogue histories, personas and responses, are lower than those on the personas.

To further examine how each part of data diversification works, we conduct the following ablation studies: 1) *w/o persona editing*: no persona sentence will be edited; 2) *w/o history augmentation*: only original dialogue history is used; 3) *w/o response filtering*: all constructed samples are directly used without using Eq. 2. Results in the bottom of Table 3 show that all these designs contribute to the performance of the whole method. Among them, response filtering is the most important as it ensures the quality of augmented samples.

We also investigate the proportions of diversified samples coming from various source combinations. Results are shown in Figure 4, which shows that more than 80% diversified samples have their responses obtained via model predicting, as token editing sets a strict condition that overlapped tokens must exist. Phrase-level editing also contributes to more high-quality personas with satisfactory fluency and semantic novelty.

Analysis of data curriculum We first compare other data curriculum variants to show the usefulness of training with the designed data curriculum. The following variants are included: 1) *Original*: only the original dataset $\mathcal{D}$ (the hard curriculum in **D**^{3}) is used, which is equal to the base model; 2) *Only augment*: only the augmented dataset $\mathcal{D}^a$ (the easy curriculum in **D**^{3}) is used; 3) *Shuffle*: shuffling of the original dataset $\mathcal{D}$ and the augmented dataset $\mathcal{D}^a$ together to train the model; 4) *Reverse*: using the curricula in a reverse order, which means the hard curriculum first and then the easy one.

Relevant results are shown in Table 4. There is no doubt that our curriculum is the best when comprehensively considering all aspects. Although *Only augment* and *Reverse* show high C-scores, their responses are much worse in n-gram accuracy as they involve more persona information while focusing less on the dialogue coherence during generating. *Shuffle* shows better performance than *Original* as it includes more augmented data than the original dataset, which may benefit the training. However, such a mixing strategy is not so efficient as our data curriculum as it neglects the learning difficulty of different data sources.

Next, we further quantify the effect of curriculum training on models using the attention from the response on the persona sentences. We define two metrics, token-level/sentence-level consistent attention weight (a_t and a_s), to measure how the attention contributes to reflecting the proper personas. Recall that we concatenate the persona sentences and history utterances as a single model input. We record the token positions of the entailed persona sentences in the input sequence, which are determined by our NLI model, denoted as $\mathcal{S}$. Then for each index $s \in \mathcal{S}$, if its corresponding token in the input also occurs in the response, we put this

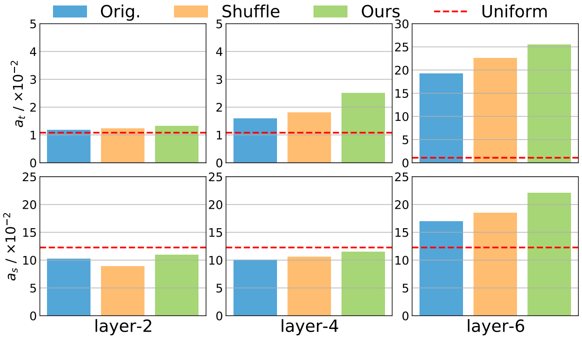

Figure 5: Average consistent attention weights in different decoder layers of TRANSFORMER trained with (i) original dataset (Orig.), (ii) shuffled data in $\mathcal{D}$ and $\mathcal{D}^a$ (Shuffle), and (3) our data curriculum. Uniform: uniform attention values on all positions. Top: token-level a_t; bottom: sentence-level a_s.

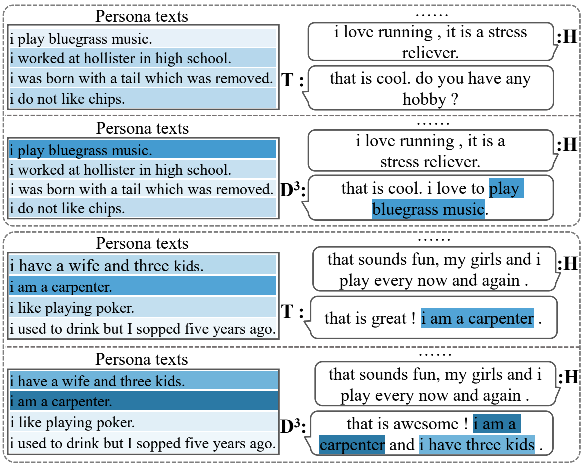
index pair into a set $\mathcal{T} = \{(s, l)\}$, where s and l are the token positions in the input sequence and response sequence respectively. Then we have two measurements for each sample:

$$a_t = \frac{1}{|\mathcal{T}|} \sum_{(i,j)\in\mathcal{T}} a_{ij}, \quad a_s = \frac{1}{Y} \sum_{i=1}^{Y} \sum_{j\in\mathcal{S}} a_{ij}, \quad (3)$$

where $a_{ij} \in [0, 1]$ is the normalized scalar attention weight at the i-th decoding step on the j-th input token, i.e. $\sum_j a_{ij} = 1$, and Y is the length of the generated response. A higher a_t/a_s indicates that the model poses more attention on proper persona tokens, where the former one is fine-grained for reflecting how the attention works properly at each step, while the latter one is coarse-grained for the whole generated response.

Part of the results with selected TRANSFORMER layers for these two metrics on all samples from the PersonaChat dev set are shown in Figure 5 (Refer to Appendix C.4 for the complete results). Obviously, our method shows the highest a_t and a_s on all given layers compared to other two curriculum variants. Such a superiority is more significant in higher layers, which is more decisive for generating responses (Fan et al., 2019). While the attentions weights tend to distribute uniformly in lower layers, which are close to the uniform values.

Case study Some response samples generated when using TRANSFORMER as the base model are shown in Figure 6. Here **H** indicates dialogue history, a persona sentence shaded in a darker color denotes that it has a higher attention weight posed by the model. Our method **D**^{3} can offer a model with the capability to pose more attention on the proper persona texts during generating responses. More cases can be found in Appendix C.6.



Persona texts
i play bluegrass music.
i worked at hollister in high school.
i was born with a tail which was removed.
i do not like chips.

……
i love running , it is a stress reliever. :H
T : that is cool. do you have any hobby ?

5 Conclusion

Our work targets the challenging personal-based dialogue generation task. Unlike previous work that designs a new dialogue model to improve the generation performance, we analyze the data issues affecting current models. On one hand, the data scale and diversity are expensive to increase by data collection. On the other hand, current data are difficult to learn with. Based on such an understanding, we propose a model-agnostic data manipulation method for this task. It first distills the original data and then augments both the amount and diversity of the distilled data. A curriculum training is then applied to utilize both augmented and original data. Experimental results showed that our method effectively improves the performance of two strong dialogue models, i.e. Transformer encoder-decoder and GPT2.

A Implementation Details of $\mathbf{D}^3$

A.1 Details of Distillation

In order to obtain the NLI model to determine the persona consistency, the RoBERTa-Large-MNLI[2] model is utilized. To make the model better fit the domain of PersonaChat, we finetune the model on the DialogueNLI dataset (Welleck et al., 2019) which is a part of the original PersonaChat. We set the batch size as 32 and finetune the model for 5 epochs using a learning rate 1e-5. We obtain a model RoBERTa$_{nli}$ achieving 90.8% accuracy on the dev set. This model will also be responsible for calculating the entailment probability NLI in response filtering and **C**-score in the experiments. A threshold $\tau = 0.99$ is used in this model for predicting the NLI labels. For the few-shot setting $\mathbf{D}^3*$ in §4.3, we randomly sample 200 samples from the training set to train the above NLI model using learning a rate 2e-5, and obtain a model achieving 79.3% on the dev set.

A.2 Details of Diversification

The BERT-based-uncased model[3] and GPT2-base[4] are involved as the pretrained models in this stage. To ensure that the pretrained models can make predictions that better fit current data domain while also have enough capabilities of generation diversity, we perform the following finetuning: 1) finetune BERT and GPT2 on the persona sentences for 100 steps with a batch size 32 and a learning rate 1e-4, obtaining BERT$_{per}$ and GPT2$_{per}$; 2) finetune GPT2 on responses for 200 steps with a batch size 32 and a learning rate 1e-4, and obtain GPT2$_{res}$.

Persona editing BERT$_{per}$ and GPT2$_{per}$ will be used for token-level editing and phrase-level editing respectively. Each will generate 10 unique new persona sentences from one original persona sentence via sampling according to the multinomial distribution. At the token level, we only mask the most informative tokens which can be decided by the POS tags given by SpaCy[5] as it is meaningless to mask some words such as prepositions “to" and “in". The target POS tags are listed in Table 6. We set the token-level mask ratio as 0.8. At phrase level, the mask ratio is randomly sampled between $[0.3, 0.6]$. We also restrict that at least 2 tokens are

Table 6: The target POS tags for token-level masking.

masked and the maximum length of generated text pieces from GPT2$_{per}$ does not exceed 30% of the original length to preserve the sentence similarity.

We use $\alpha = 0.4$ in Eq. 1, where PPL is given by GPT2$_{per}$ normalized by a constant 50 (which is about the highest PPL value given by the GPT2 model on current corpus). For BERTScore, the F1 value is used as BS_f while other configurations follow the recommendation for English in Zhang et al. (2019)[6]. N_p is set as 5.

Response aligning For token-level editing, we also restrict the POS tags of overlapped tokens according to Table 6. For model predicting, we train the Multi-GPT2 model on the distilled data $\mathcal{D}^{dis}$. Its performance on the dev set distilled from the original dev set of PersonaChat is shown in Table 7. We can see that this model shows high n-gram accuracy and persona consistency, thus should be effective.

Dialogue history augmentation We use the *transformer_wmt_en_de* Transformer model in Fairseq[7] as the translation model. It is trained on the WMT14 EN-FR dataset with 40.5M samples and default configurations. During inference, we use beam search with its size 5 for both en-fr and fr-en translation, resulting in 25 new utterances for each original one. For a large divergence, we select $N_p = 1$ new utterance with the lowest BLEU score when taking the original one as the reference.

Quality filtering We use GPT2$_{res}$ normalized by a constant 50 to get the PPL of responses. Here, we finetune another RoBERTa-Large-MNLI model on the InferConvAI dataset[8] which achieves 88.7% accuracy on its dev set. The entailment probability given by this model is regarded as NLI$_c$. We set $\beta = 0.2$, $\gamma = 0.6$ in Eq. 2.

We compare the fluency and coherence of responses with the GPT2-based PPL and NLI model-based score from the training set, which are shown in Table 8. In addition, we also evaluate the GPT2-PPL's for edited and original persona sentences, which are 6.427 vs. 10.426.

B Details of Experiment

Base model For TRANSFORMER, we use 300-dim GloVe (Pennington et al., 2014) trained on 6B corpus as the word embeddings. There are 6 layers in both the encoder and decoder, with the hidden size 300 and 4 heads. During training, a cross-entropy loss is used along with Label Smoothing with the ratio 0.1. For GPT2, we use the base pre-trained model with 12 layers and 768-dim hidden state. It will be trained using the average of a cross-entropy loss on generating and a classification loss between true response and one randomly sampled negative response. Beam search with the beam size 3 along with length penalty is used during inference for both models.

The formats of input or response for both models are shown in Figure 7. Here <bos>, <eos>, <talker1>, and <talker2> are special symbols to distinguish different parts of input or response.

Model training We use a learning rate 2e-4 for TRANSFORMER and 6.25e-5 for GPT2, which is a common setting in former similar works. And the training batch size is 256 for both models. Training will be stopped until the loss on the dev set does not decrease for N epochs. Here N is 15 for TRANSFORMER and 5 for GPT2. In curriculum learning, the learning rate is the same for different curricula. The dev set of the easy curriculum is obtained by applying the same augmentation to the original dev set. Models with the minimum loss at each curriculum are remained as the best. The best model obtained on the easy curriculum is used as the initial model in the hard curriculum. All experiments are implemented via PyTorch on 32GB NVIDIA V100 GPUs. Each epoch takes about 10 min for Transformer and 25min for GPT2.

Hyper-parameters All hyper-parameters are determined using a coarse grid search to ensure satisfactory performance, including τ in data distillation, α in Eq. 1, β, γ in Eq. 2. The candidate values of these hyper-parameters are given in Table 9, which are determined empirically to reduce the searching cost. The search target we want to maximize is the normalized average of all automatic metrics listed in Table 2 when inferencing on the test set, except PPL. Note that we only take TRANSFORMER as the base model for search, each time of search takes about 0.7 GPU day. GPT2 model follows the same setting as TRANSFORMER. We found that τ plays a more important role in our

method who determine the quality of distilled samples, while other parameters have fewer impacts on our method.

Baselines We apply the same translation models as the ones used in §A.2 for the BT (Sennrich et al., 2016) baseline and augment each sample with a new sample from it. For CVAE (Li et al., 2019) method, we use its default setting to train the model on PersonaChat dataset without using the personas. A new sample is generated for each input in the original dataset. In Entropy-filter (Csáky et al., 2019), we set the threshold as 1.1 and using both source and target sequences for filtering. Only samples that survived after filtering are used in training. The total numbers of training samples of all methods are listed in Table 10. Note that 0all models are trained until the loss does not decrease for the same N epochs for a fair comparison.

Metrics We use the same BS_f and RoBERTa_{nli} obtained before to calculate the BERTScore and C-score metrics respectively. The instructions for human annotators are provided in Table 14 and 15.

C Additional Experimental Results

C.1 Attention on Dialogue History

To investigate how models pose attention on each part of dialogue history, especially the last utterance, we calculate the attention weights from different decoder layers on the last utterance or the other dialogue history utterances. TRANSFORMER model is used here, which is trained with the original training data without any augmentation. When testing on the dev set of PersonaChat dataset, the average token-level attention weight on the last utterance in the dialogue history is significantly higher than that on all other utterances, as shown in Figure 8. Thus, our history distillation can ease model learning for such knowledge by removing former utterances.

C.2 Statistical Results of Table 2

We conduct Student's T-test between the experimental results of our method $\mathbf{D}^3$) and every other baseline under each base model to verify the performance difference significance between every two methods. Here, all human evaluation results (Fluency, Coherence, Persona-consistency), and some applicable automatic metrics (C-score, BS_f) are included. We can find that nearly all results from baselines satisfy the null hypothesis (results are significantly different from $\mathbf{D}^3$) given $p > 0.05$ or even a smaller theshold using TRANSFORMER as

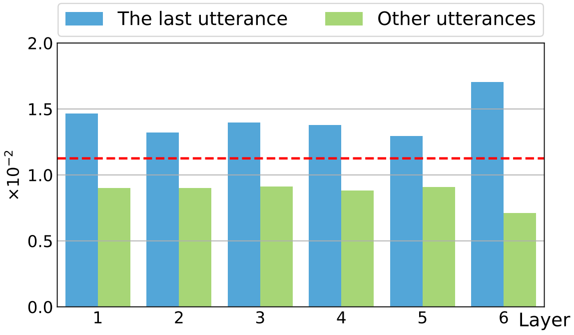

Figure 8: The average token-level attention weights from different decoder layers in TRANSFORMER on the last utterance or other part of dialogue history. Red line: the baseline values when all attention distributes uniformly among all tokens.

the base model. Such significant difference tends to appear fewer times when using GPT2 as the base model except for CVAE, which again shows that all data manipulation methods may have fewer impacts when packed with a pretrained model.

C.3 More Analysis on GPT2

We also provide the extensive analysis results on GPT2 which is similar to the ones given in §4.3 on TRANSFORMER. Table 11 shows the results. We can find the influence of data diversification, as well as our distillation, have fewer impacts on GPT2 compared to TRANSFORMER. The reason is that GPT2 is a strong pretrained model, being less vulnerable to the different numbers of data samples. Moreover, Table 12 shows the performance when using different curriculum variants, demonstrating the similar conclusion as TRANSFORMER.

C.4 Additional Results of Attention Analysis for Curriculum

To better illustrate the effect of our training curriculum strategy, we further provide the token-level/ sentence-level consistent attention weights a_t and a_s in all layers of Transformer and GPT2 trained via 3 curriculum strategies, *Original* (Orig.)., *Shuffle* or our **D**^{3} method, as described in §4.3. All visualized attention weights are shown in Figure 9. Our method has the most accurate attention on personas at both levels. On the other hand, compared to Transformer, the divergence between different layers in GPT2 is more significant.

C.5 The Influence of Diversified Sample Numbers

Since we can simply control the threshold for s in Eq. 2 to determine how many diversified samples are generated for $\mathcal{D}^{div}$. How this quantity affect the performance of **D**^{3} ? We carry out experiments to use different $\mathcal{D}^{div}$ whose size is about 50% of $\mathcal{D}^{dis}$ or 200% of $\mathcal{D}^{dis}$ on TRANSFORMER, compared to the original method where $\mathcal{D}^{div}$ is nearly the same size as $\mathcal{D}^{dis}$. The results in terms of automatic metrics are shown in Table 13. It can be found that further extending the data scale will result in a very slight promotion but a longer training time, while

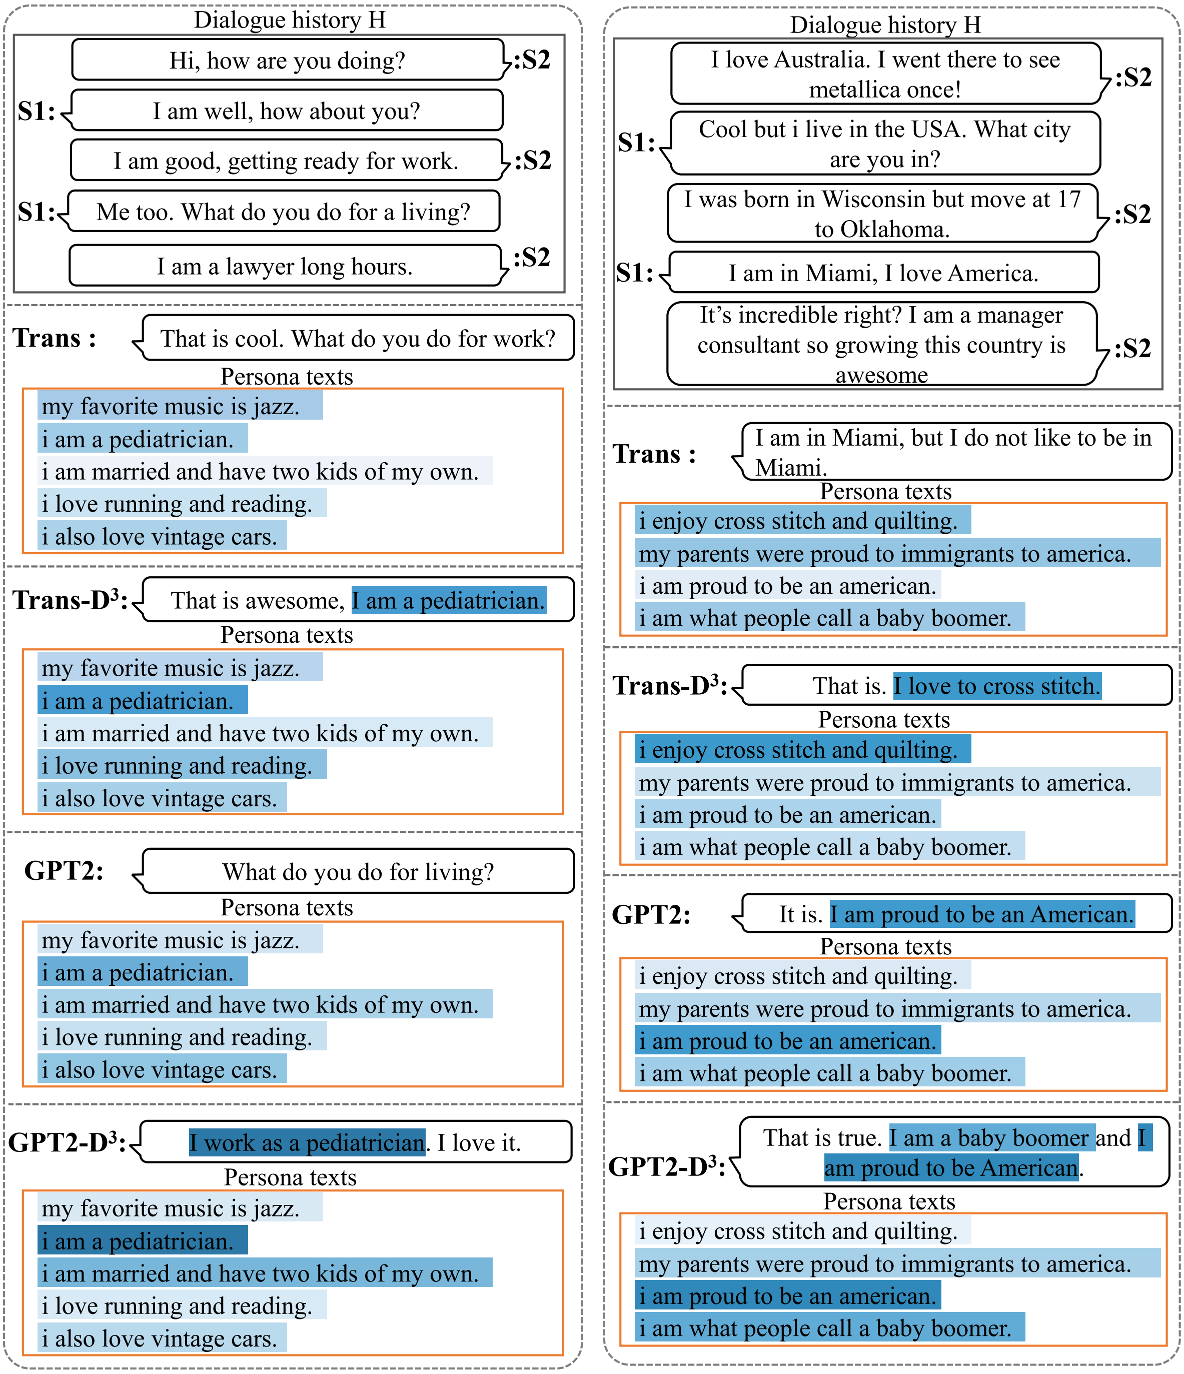
TRANS-**D**^{3}(50%)	37.75	3.269	1.167	0.1551	4.132	6.085	7.003	1.743	7.658	14.10	0.468

Table 13: Performance comparison between original $\mathbf{D}^3$ and variants when using diversified dataset $\mathcal{D}^{div}$ with about 200% or 50% size of distilled dataset $\mathcal{D}^{dis}$.

squeeze the diversified dataset size has a more obvious effect on the performance. Nevertheless, using $\mathcal{D}^{div}$ with a similar size as $\mathcal{D}^{dis}$ is a good trade-off between resource cost and performance, while ensure a fair comparison between former methods.

C.6 Additional Case Studies

Except for the cases provided in §4.3, we provide additional cases including the responses given by GPT2. They are shown in Figure 10, including visualized attention weights posed by different models on their persona sentences. Note that the attention weights are normalized along the whole input sequence including dialogue history. It can be found that our method can help the model to pay more attention to suitable persona parts, thus the generated responses have better persona consistency.



S2: Hi, how are you doing?
S1: I am well, how about you?
S2: I am good, getting ready for work.
S1: Me too. What do you do for a living?
S2: I am a lawyer long hours.

Trans : That is cool. What do you do for work?

my favorite music is jazz.
i am a pediatrician.
i am married and have two kids of my own.
i love running and reading.
i also love vintage cars.

Trans-D^3: That is awesome, I am a pediatrician.

my favorite music is jazz.
i am a pediatrician.
i am married and have two kids of my own.
i love running and reading.
i also love vintage cars.

GPT2: What do you do for living?

my favorite music is jazz.
i am a pediatrician.
i am married and have two kids of my own.
i love running and reading.
i also love vintage cars.

GPT2-D^3: I work as a pediatrician. I love it.

my favorite music is jazz.
i am a pediatrician.
i am married and have two kids of my own.
i love running and reading.
i also love vintage cars.

S2: I love Australia. I went there to see metallica once!
S1: Cool but i live in the USA. What city are you in?
S2: I was born in Wisconsin but move at 17 to Oklahoma.
S1: I am in Miami, I love America.
S2: It's incredible right? I am a manager consultant so growing this country is awesome

Trans : I am in Miami, but I do not like to be in Miami.

i enjoy cross stitch and quilting.
my parents were proud to immigrants to america.
i am proud to be an american.
i am what people call a baby boomer.

Trans-D^3: That is. I love to cross stitch.

i enjoy cross stitch and quilting.
my parents were proud to immigrants to america.
i am proud to be an american.
i am what people call a baby boomer.

GPT2: It is. I am proud to be an American.

i enjoy cross stitch and quilting.
my parents were proud to immigrants to america.
i am proud to be an american.
i am what people call a baby boomer.

GPT2-D^3: That is true. I am a baby boomer and I am proud to be American.

i enjoy cross stitch and quilting.
my parents were proud to immigrants to america.
i am proud to be an american.
i am what people call a baby boomer.

Figure 10: Additional responses cases and visualization by Transformers(Trans) and GPT2 without or with our **D^3** data augmentation method. Colors in each persona text indicate the attention weight paid by different models. A darker color means a higher attention weight is posed by the current model. Colored texts in the response denote the persona consistency.

Data description	You are supposed to be **Speaker S2**, you are required to evaluate the **quality of dialogue responses from S2** in the following 3 aspects, based on 1) **the persona information of S2**; and 2) **the dialogue history with Speaker S2**. Here, **the persona information of S2** mean the personality/characteristics of the speaker for the response need to be evaluated. The responses are expected to reflect the given persona for the speaker as possible, meanwhile, they should also be proper and coherent for the previous messages from Speaker S1. **Each serial number indicates one sample.** It contains persona information and corresponding dialogue history. The dialogue history contains several different responses (by different methods). Your need to **rating for every response** considering the persona information and dialogue history. **Rating contains the following 3 aspects.**

1. Fluency (1 $\sim$ 3. Your need not to consider the persona information and dialogue history, just the response itself.

Score	Description	Examples
1 (unsatisfied)	1) The text is totally broken, or contains severe grammar errors. 2) The text is very hard to understand	S1:i do not have any but charlie my puppy enjoys it S2:i am triplets triplets triplets triplets triplets (Cannot understand) S1:i am a college student . art major . S2:i love my spanish . is studying it has been studying ? (Totally not fluent)
2 (fair)	1) The text is basically fluent, contains grammar errors but do not affect understanding. 2) The response is short but fluent, without grammar error. 3) The text contains some repeated context. 4) The text is bassically fluent, but contains perverse content.	S1good , you have any hobbies ? S2i travel a lot (Fluent but too simple) S1what kind of dog is he ? S2he is a german shepard . he is a german shepard . (Fluent but contains repetitions)
3 (satisfied)	1) The text is long and informative, few grammar errors are acceptable. There may exist some non-fluent parts, but do not affect understanding. 2) The text is in medium length, fluent without grammar error.	S1:hello what are doing today ? S2:hello , i just got back from the gym . how are you ? S1:good , you have any hobbies ? S2:i used to be a painter , i still like to do that a lot . how about you ?

2. Dialogue coherence (1 $\sim$ 3. You need not to consider the fluency if there is no difficulty in understanding.
Your need to consider both the repsonse and dialogue history.)

Score	Description	Examples
1 (unsatisfied)	The response is irrelevant to the dialogue history. E.g., it does not share the same topic or it is an irrelevant answer.	S1: how old are you ? i turned four on my birthday ! S2: awesome ! i love the insane clown posse love (Irrelevant answer)
2 (fair)	Very limit relevance exists between the response and history, or meets the following conditions: 1) The response is the same as the query. 2) The response is a kind of paraphrase of the query. 3) It is a general response that do not answer the query or contains very limited information,e.g., "i am sorry" 4) The response is a question without new information.	S1: yes i bet you can get hurt . my wife works and i stay at home S2: i wish i could do that (very limited relevance) S1: hi ! do you like turtles ? S2: yes i do , do you have any hobbies ? (a question without new information) S1:i would love to travel to italy . i love baking cookies . S2:i would love to visit italy sometime . (Praphrasing the query)
3 (satisfied)	1) The text is long and informative, few grammar errors are acceptable. There may exist some non-fluent parts, but do not affect understanding. 2) The text is in medium length, fluent without grammar error.	S1:hello what are doing today ? S2:hello , i just got back from the gym . how are you ? S1:good , you have any hobbies ? S2:i used to be a painter , i still like to do that a lot . how about you ?

Table 14: The instruction for annotators to make human evaluation for the generated responses (Part 1).

<table>
<tr><th colspan="3">3. The consistency with given persona (0 or 1. Your need to consider both the persona sentences and the response.)</th></tr>
<tr><th>Score</th><th>Description</th><th>Examples</th></tr>
<tr><td>0</td><td>The response totally does not reflect any given persona information.</td><td>Persona sentences:
1) i was born in south carolina.
2) hey there i am a professional singer.

LinkBERT: Pretraining Language Models with Document Links

Michihiro Yasunaga **Jure Leskovec*** **Percy Liang***

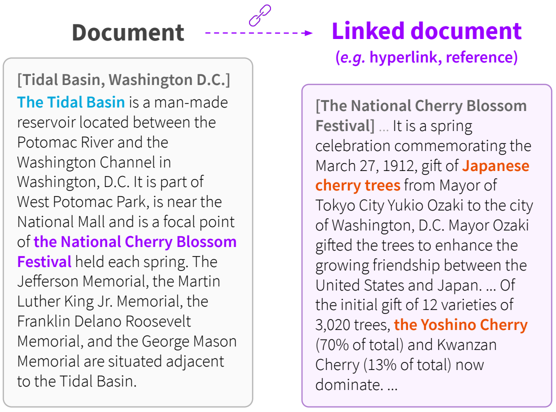
`{myasu,jure,pliang}@cs.stanford.edu`

Abstract

Language model (LM) pretraining captures various knowledge from text corpora, helping downstream NLP tasks. However, existing methods such as BERT model a single document, failing to capture document dependencies and knowledge that spans across documents. In this work, we propose *LinkBERT*, an effective LM pretraining method that incorporates document links, such as hyperlinks. Given a pretraining corpus, we view it as a graph of documents, and create LM inputs by placing linked documents in the same context. We then train the LM with two joint self-supervised tasks: masked language modeling and our newly proposed task, document relation prediction. We study LinkBERT in two domains: general domain (pretrained on Wikipedia with hyperlinks) and biomedical domain (pretrained on PubMed with citation links). LinkBERT outperforms BERT on various downstream tasks in both domains. It is especially effective for multi-hop reasoning and few-shot QA (+5% absolute improvement on HotpotQA and TriviaQA), and our biomedical LinkBERT attains new state-of-the-art on various BioNLP tasks (+7% on BioASQ and USMLE). We release the pretrained models, *LinkBERT* and *BioLinkBERT*, as well as code and data.[1]

1 Introduction

Pretrained language models (LMs), like BERT and GPTs (Devlin et al., 2019; Brown et al., 2020), have shown remarkable performance on many natural language processing (NLP) tasks, such as text classification and question answering (Raffel et al., 2020), becoming the foundation of modern NLP systems. By performing self-supervised learning on text, such as masked language modeling (Devlin et al., 2019), LMs learn to encode various knowledge from text corpora and produce informative language representations for downstream tasks (Bosselut et al., 2019; Bommasani et al., 2021).



[Tidal Basin, Washington D.C.]
The Tidal Basin is a man-made reservoir located between the Potomac River and the Washington Channel in Washington, D.C. It is part of West Potomac Park, is near the National Mall and is a focal point of **the National Cherry Blossom Festival** held each spring. The Jefferson Memorial, the Martin Luther King Jr. Memorial, the Franklin Delano Roosevelt Memorial, and the George Mason Memorial are situated adjacent to the Tidal Basin.

[The National Cherry Blossom Festival] ... It is a spring celebration commemorating the March 27, 1912, gift of **Japanese cherry trees** from Mayor of Tokyo City Yukio Ozaki to the city of Washington, D.C. Mayor Ozaki gifted the trees to enhance the growing friendship between the United States and Japan. ... Of the initial gift of 12 varieties of 3,020 trees, **the Yoshino Cherry** (70% of total) and Kwanzan Cherry (13% of total) now dominate. ...

Figure 1: Document links (e.g. hyperlinks) can provide salient multi-hop knowledge. For instance, the Wikipedia article "Tidal Basin" (left) describes that the basin hosts "National Cherry Blossom Festival". The hyperlinked article (right) reveals that the festival celebrates "Japanese cherry trees". Taken together, the link offers new knowledge not available in a single document (e.g. "Tidal Basin has Japanese cherry trees"), which can be useful for various applications, including answering a question "What trees can you see at Tidal Basin?". We aim to leverage document links to incorporate more knowledge into language model pretraining.

However, existing LM pretraining methods typically consider a single document in each input context (Liu et al., 2019; Joshi et al., 2020), and do not model links between documents. This can pose limitations because documents often have rich dependencies with each other (e.g. hyperlinks, references), and knowledge can span *across* documents. As a simple example, in Figure 1, the Wikipedia article "Tidal Basin, Washington D.C." (left) describes that the basin hosts "National Cherry Blossom Festival", and the hyperlinked article (right) reveals the background that the festival celebrates "Japanese cherry trees". Taken together, the hyperlink offers new, multi-hop knowledge "Tidal Basin has Japanese cherry trees", which is not available in the single article "Tidal Basin" alone. Acquiring such multi-hop knowledge in pretraining could be useful for various applications including question answering. In fact, document links like hyperlinks and references are ubiquitous (e.g. web, books, scientific literature), and guide how we humans acquire knowledge and

May 22-27, 2022

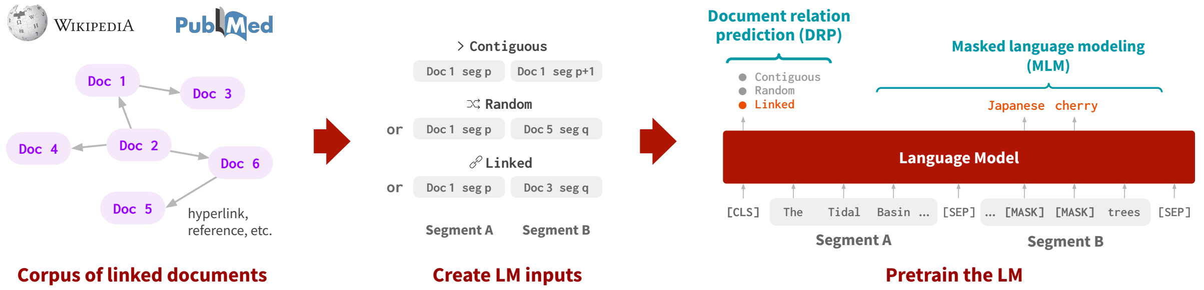

Figure 2: **Overview of our approach, LinkBERT**. Given a pretraining corpus, we view it as a graph of documents, with links such as hyperlinks (§4.1). To incorporate the document link knowledge into LM pretraining, we create LM inputs by placing a pair of linked documents in the same context (*linked*), besides the existing options of placing a single document (*contiguous*) or a pair of random documents (*random*) as in BERT. We then train the LM with two self-supervised objectives: masked language modeling (MLM), which predicts masked tokens in the input, and document relation prediction (DRP), which classifies the relation of the two text segments in the input (*contiguous*, *random*, or *linked*) (§4.2).

even make discoveries too (Margolis et al., 1999).

In this work, we propose *LinkBERT*, an effective language model pretraining method that incorporates document link knowledge. Given a text corpus, we obtain links between documents such as hyperlinks, and create LM inputs by placing linked documents in the same context window, besides the existing option of placing a single document or random documents as in BERT. Specifically, as in Figure 2, after sampling an anchor text segment, we place either (1) the contiguous segment from the same document, (2) a random document, or (3) a document linked from anchor segment, as the next segment in the input. We then train the LM with two joint objectives: We use masked language modeling (MLM) to encourage learning multi-hop knowledge of concepts brought into the same context by document links (e.g. “Tidal Basin” and “Japanese cherry” in Figure 1). Simultaneously, we propose a Document Relation Prediction (DRP) objective, which classifies the relation of the second segment to the first segment (*contiguous*, *random*, or *linked*). DRP encourages learning the relevance and bridging concepts (e.g. “National Cherry Blossom Festival”) between documents, beyond the ability learned in the vanilla next sentence prediction objective in BERT.

Viewing the pretraining corpus as a graph of documents, LinkBERT is also motivated as self-supervised learning on the graph, where DRP and MLM correspond to link prediction and node feature prediction in graph machine learning (Yang et al., 2015; Hu et al., 2020). Our modeling approach thus provides a natural fusion of language-based and graph-based self-supervised learning.

We train LinkBERT on two domains: the general domain, using Wikipedia articles with hyperlinks (§4), and the biomedical domain, using PubMed articles with citation links (§6). We then evaluate the pretrained models on a wide range of downstream tasks including question answering, in both domains. LinkBERT consistently improves on baseline LMs across domains and tasks. For the general domain, LinkBERT outperforms BERT on MRQA benchmark (+4% absolute in F1-score) as well as GLUE benchmark. For the biomedical domain, LinkBERT exceeds PubmedBERT (Gu et al., 2020) and attains new state-of-the-art on BLURB biomedical NLP benchmark (+3% absolute in BLURB score) and MedQA-USMLE reasoning task (+7% absolute in accuracy). Overall, LinkBERT attains notably large gains for multi-hop reasoning, multi-document understanding, and few-shot question answering, suggesting that LinkBERT internalizes significantly more knowledge than existing LMs by pretraining with document link information.

2 Related work

Retrieval-augmented LMs. Several works (Lewis et al., 2020b; Karpukhin et al., 2020; Oguz et al., 2020; Xie et al., 2022) introduce a retrieval module for LMs, where given an anchor text (e.g. question), retrieved text is added to the same LM context to improve model inference (e.g. answer prediction). These works show the promise of placing related documents in the same LM context at inference time, but they do not study pretraining. Guu et al. (2020) pretrain an LM with a retriever that learns to retrieve text for answering masked tokens in the anchor text. In contrast, our focus is not on retrieval, but on pretraining a general-purpose LM that *internalizes* knowledge that spans across documents, which is orthogonal to the above works (e.g., our pretrained LM could be used to initialize the LM component of these works). Additionally, we focus on incorporating document links such as hyperlinks, which can offer salient knowledge that common lexical retrieval methods may not provide (Asai et al., 2020).

Pretrain LMs with related documents. Several concurrent works use multiple related documents to pretrain LMs. Caciularu et al. (2021) place documents (news articles) about the same topic into the same LM context, and Levine et al. (2021) place sentences of high lexical similarity into the same context. Our work provides a general method to incorporate document links into LM pretraining, where lexical or topical similarity can be one instance of document links, besides hyperlinks. We focus on hyperlinks in this work, because we find they can bring in salient knowledge that may not be obvious via lexical similarity, and yield a more performant LM (§5.5). Additionally, we propose the DRP objective, which improves modeling multiple documents and relations between them in LMs (§5.5).

Hyperlinks and citation links for NLP. Hyperlinks are often used to learn better retrieval models. Chang et al. (2020); Asai et al. (2020); Seonwoo et al. (2021) use Wikipedia hyperlinks to train retrievers for open-domain question answering. Ma et al. (2021) study various hyperlink-aware pretraining tasks for retrieval. While these works use hyperlinks to learn retrievers, we focus on using hyperlinks to create better context for learning general-purpose LMs. Separately, Calixto et al. (2021) use Wikipedia hyperlinks to learn multilingual LMs. Citation links are often used to improve summarization and recommendation of academic papers (Qazvinian and Radev, 2008; Yasunaga et al., 2019; Bhagavatula et al., 2018; Khadka et al., 2020; Cohan et al., 2020). Here we leverage citation networks to improve pretraining general-purpose LMs.

Graph-augmented LMs. Several works augment LMs with graphs, typically, knowledge graphs (KGs) where the nodes capture entities and edges their relations. Zhang et al. (2019); He et al. (2020); Wang et al. (2021b) combine LM training with KG embeddings. Sun et al. (2020); Yasunaga et al. (2021); Zhang et al. (2022) combine LMs and graph neural networks (GNNs) to jointly train on text and KGs. Different from KGs, we use document graphs to learn knowledge that spans across documents.

3 Preliminaries

A language model (LM) can be pretrained from a corpus of documents, $\mathcal{X} = \{X^{(i)}\}$. An LM is a composition of two functions, $f_{\text{head}}(f_{\text{enc}}(X))$, where the encoder f_{enc} takes in a sequence of tokens $X = (x_1, x_2, ..., x_n)$ and produces a contextualized vector representation for each token, $(\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_n)$. The head f_{head} typically uses these representations to perform self-supervised tasks in the pretraining step, and perform particular downstream tasks in the fine-tuning step. We build on BERT (Devlin et al., 2019), which pretrains an LM with the following two self-supervised tasks.

Masked language modeling (MLM). Given a sequence of tokens X, a subset of tokens $Y \subseteq X$ is masked, and the task is to predict the original tokens from the modified input. Y accounts for 15% of the tokens in X; of those, 80% are replaced with `[MASK]`, 10% with a random token, and 10% are kept unchanged.

Next sentence prediction (NSP). The NSP task takes two text segments[2] (X_A, X_B) as input, and predicts whether X_B is the direct continuation of X_A. Specifically, BERT first samples X_A from the corpus, and then either (1) takes the next segment X_B from the same document, or (2) samples X_B from a random document in the corpus. The two segments are joined via special tokens to form an input instance, `[CLS]` X_A `[SEP]` X_B `[SEP]`, where the prediction target of `[CLS]` is whether X_B indeed follows X_A (*contiguous* or *random*).

In this work, we will further incorporate document link information into LM pretraining. Our approach (§4) will build on MLM and NSP.

4 LinkBERT

We present LinkBERT, a self-supervised pretraining approach that aims to internalize more knowledge into LMs using document link information. Specifically, as shown in Figure 2, instead of viewing the pretraining corpus as a set of documents $\mathcal{X} = \{X^{(i)}\}$, we view it as a *graph* of documents, $\mathcal{G} = (\mathcal{X}, \mathcal{E})$, where $\mathcal{E} = \{(X^{(i)}, X^{(j)})\}$ denotes links between documents (§4.1). The links can be existing hyperlinks, or could be built by other methods that capture document relevance. We then consider pretraining tasks for learning from document links (§4.2): We create LM inputs by placing linked documents in the same context window, besides the existing options of a single document or random documents. We use the MLM task to learn concepts brought together in the context by document links, and we also introduce the Document Relation Prediction (DRP) task to learn relations between documents. Finally, we discuss strategies for obtaining informative pairs of linked documents to feed into LM pretraining (§4.3).

4.1 Document graph

Given a pretraining corpus, we link related documents so that the links can bring together knowledge that is not available in single documents. We focus

---

[2] A segment is typically a sentence or a paragraph.

on hyperlinks, e.g., hyperlinks of Wikipedia articles (§5) and citation links of academic articles (§6). Hyperlinks have a number of advantages. They provide background knowledge about concepts that the document writers deemed useful—the links are likely to have high precision of relevance, and can also bring in relevant documents that may not be obvious via lexical similarity alone (e.g., in Figure 1, while the hyperlinked article mentions "Japanese" and "Yoshino" cherry trees, these words do not appear in the anchor article). Hyperlinks are also ubiquitous on the web and easily gathered at scale (Aghajanyan et al., 2021). To construct the document graph, we simply make a directed edge $(X^{(i)}, X^{(j)})$ if there is a hyperlink from document $X^{(i)}$ to document $X^{(j)}$.

For comparison, we also experiment with a document graph built by lexical similarity between documents. For each document $X^{(i)}$, we use the common TF-IDF cosine similarity metric (Chen et al., 2017; Yasunaga et al., 2017) to obtain top-k documents $X^{(j)}$'s and make edges $(X^{(i)}, X^{(j)})$. We use $k=5$.

4.2 Pretraining tasks

Creating input instances. Several works (Gao et al., 2021; Levine et al., 2021) find that LMs can learn stronger dependencies between words that were shown together in the same context during training, than words that were not. To effectively learn knowledge that spans across documents, we create LM inputs by placing linked documents in the same context window, besides the existing option of a single document or random documents. Specifically, we first sample an anchor text segment from the corpus (Segment A; $X_A \subseteq X^{(i)}$). For the next segment (Segment B; X_B), we either (1) use the contiguous segment from the same document ($X_B \subseteq X^{(i)}$), (2) sample a segment from a random document ($X_B \subseteq X^{(j)}$ where $j \neq i$), or (3) sample a segment from one of the documents linked from Segment A ($X_B \subseteq X^{(j)}$ where $(X^{(i)}, X^{(j)}) \in \mathcal{E}$). We then join the two segments via special tokens to form an input instance: `[CLS]` X_A `[SEP]` X_B `[SEP]`.

Training objectives. To train the LM, we use two objectives. We apply the MLM objective to encourage the LM to learn multi-hop knowledge of concepts brought together in the same context by document links. We also propose a Document Relation Prediction (DPR) objective, which classifies the relation r of segment X_B to segment X_A ($r \in \{\textit{contiguous}, \textit{random}, \textit{linked}\}$). By distinguishing *linked* from *contiguous* and *random*, DRP encourages the LM to learn the relevance and existence of bridging concepts between documents, besides the capability learned in the vanilla NSP objective. To predict r, we use the representation of `[CLS]` token, as in NSP. Taken together, we optimize:

$$\mathcal{L} = \mathcal{L}_{\text{MLM}} + \mathcal{L}_{\text{DRP}} \tag{1}$$

$$= -\sum_i \log p(x_i \mid \mathbf{h}_i) - \log p(r \mid \mathbf{h}_{\texttt{[CLS]}}) \tag{2}$$

where x_i is each token of the input instance, `[CLS]` X_A `[SEP]` X_B `[SEP]`, and $\mathbf{h}_i$ is its representation.

Graph machine learning perspective. Our two pretraining tasks, MLM and DRP, are also motivated as graph self-supervised learning on the document graph. In graph self-supervised learning, two types of tasks, node feature prediction and link prediction, are commonly used to learn the content and structure of a graph. In node feature prediction (Hu et al., 2020), some features of a node are masked, and the task is to predict them using neighbor nodes. This corresponds to our MLM task, where masked tokens in Segment A can be predicted using Segment B (a linked document on the graph), and vice versa. In link prediction (Bordes et al., 2013; Wang et al., 2021a), the task is to predict the existence or type of an edge between two nodes. This corresponds to our DRP task, where we predict if the given pair of text segments are linked (edge), contiguous (self-loop edge), or random (no edge). Our approach can be viewed as a natural fusion of language-based (e.g. BERT) and graph-based self-supervised learning.

4.3 Strategy to obtain linked documents

As described in §4.1, §4.2, our method *builds* links between documents, and for each anchor segment, *samples* a linked document to put together in the LM input. Here we discuss three key axes to consider to obtain useful linked documents in this process.

Relevance. Semantic relevance is a requisite when building links between documents. If links were randomly built without relevance, LinkBERT would be same as BERT, with simply two options of LM inputs (*contiguous* or *random*). Relevance can be achieved by using hyperlinks or lexical similarity metrics, and both methods yield substantially better performance than using random links (§5.5).

Salience. Besides relevance, another factor to consider (*salience*) is whether the linked document can offer new, useful knowledge that may not be obvious to the current LM. Hyperlinks are potentially more advantageous than lexical similarity links in this regard: LMs are shown to be good at recognizing lexical similarity (Zhang et al., 2020), and hyperlinks can bring in useful background knowledge that may not be obvious via lexical similarity alone (Asai et al., 2020). Indeed, we empirically find that using hyperlinks yields a more performant LM (§5.5).

Diversity. In the document graph, some documents may have a very high in-degree (e.g., many incoming hyperlinks, like the "United States" page of Wikipedia), and others a low in-degree. If we uniformly sample from the linked documents for each anchor segment, we may include documents of high in-degree too often in the overall training data, losing diversity. To adjust so that all documents appear with a similar frequency in training, we sample a linked document with probability inversely proportional to its in-degree, as done in graph data mining literature (Henzinger et al., 2000). We find that this technique yields a better LM performance (§5.5).

5 Experiments

We experiment with our proposed approach in the general domain first, where we pretrain LinkBERT on Wikipedia articles with hyperlinks (§5.1) and evaluate on a suite of downstream tasks (§5.2). We compare with BERT (Devlin et al., 2019) as our baseline. We experiment in the biomedical domain in §6.

5.1 Pretraining setup

Data. We use the same pretraining corpus used by BERT: Wikipedia and BookCorpus (Zhu et al., 2015). For Wikipedia, we use the WikiExtractor[3] to extract hyperlinks between Wiki articles. We then create training instances by sampling *contiguous*, *random*, or *linked* segments as described in §4, with the three options appearing uniformly (33%, 33%, 33%). For BookCorpus, we create training instance by sampling *contiguous* or *random* segments (50%, 50%) as in BERT. We then combine the training instances from Wikipedia and BookCorpus to train LinkBERT. In summary, our pretraining data is the same as BERT, except that we have hyperlinks between Wikipedia articles.

Implementation. We pretrain LinkBERT of three sizes, -tiny, -base and -large, following the configurations of $\text{BERT}_{\texttt{tiny}}$ (4.4M parameters), $\text{BERT}_{\texttt{base}}$ (110M params), and $\text{BERT}_{\texttt{large}}$ (340M params) (Devlin et al., 2019; Turc et al., 2019). We use -tiny mainly for ablation studies.

For -tiny, we pretrain from scratch with random weight initialization. We use the AdamW (Loshchilov and Hutter, 2019) optimizer with $(\beta_1, \beta_2) = (0.9, 0.98)$, warm up the learning rate for the first 5,000 steps and then linearly decay it. We train for 10,000 steps with a peak learning rate 5e-3, weight decay 0.01, and batch size of 2,048 sequences with 512 tokens. Training takes 1 day on two GeForce RTX 2080 Ti GPUs with fp16.

For -base, we initialize LinkBERT with the $\text{BERT}_{\texttt{base}}$ checkpoint released by Devlin et al. (2019) and continue pretraining. We use a peak learning rate 3e-4 and train for 40,000 steps. Other training hyperparameters are the same as -tiny. Training takes 4 days on four A100 GPUs with fp16.

For -large, we follow the same procedure as -base, except that we use a peak learning rate of 2e-4. Training takes 7 days on eight A100 GPUs with fp16.

Baselines. We compare LinkBERT with BERT. Specifically, for the -tiny scale, we compare with $\text{BERT}_{\texttt{tiny}}$, which we pretrain from scratch with the same hyperparameters as $\text{LinkBERT}_{\texttt{tiny}}$. The only difference is that LinkBERT uses document links to create LM inputs, while BERT does not.

For -base scale, we compare with $\text{BERT}_{\texttt{base}}$, for which we take the $\text{BERT}_{\texttt{base}}$ release by Devlin et al. (2019) and continue pretraining it with the vanilla BERT objectives on the same corpus for the same number of steps as $\text{LinkBERT}_{\texttt{base}}$.

For -large, we follow the same procedure as -base.

5.2 Evaluation tasks

We fine-tune and evaluate LinkBERT on a suite of downstream tasks.

Extractive question answering (QA). Given a document (or set of documents) and a question as input, the task is to identify an answer span from the document. We evaluate on six popular datasets from the MRQA shared task (Fisch et al., 2019): *HotpotQA* (Yang et al., 2018), *TriviaQA* (Joshi et al., 2017), *NaturalQ* (Kwiatkowski et al., 2019), *SearchQA* (Dunn et al., 2017), *NewsQA* (Trischler et al., 2017), and *SQuAD* (Rajpurkar et al., 2016). As the MRQA shared task does not have a public test set, we split the dev set in half to make new dev and test sets. We follow the fine-tuning method BERT (Devlin et al., 2019) uses for extractive QA. More details are provided in Appendix B.

GLUE. The General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2018) is a popular suite of sentence-level classification tasks. Following BERT, we evaluate on *CoLA* (Warstadt et al., 2019), *SST-2* (Socher et al., 2013), *MRPC* (Dolan and Brockett, 2005), *QQP*, *STS-B* (Cer et al., 2017), *MNLI* (Williams et al., 2017), *QNLI* (Rajpurkar et al., 2016), and *RTE* (Dagan et al., 2005; Haim et al., 2006; Giampiccolo

et al., 2007), and report the average score. More fine-tuning details are provided in Appendix B.

5.3 Results

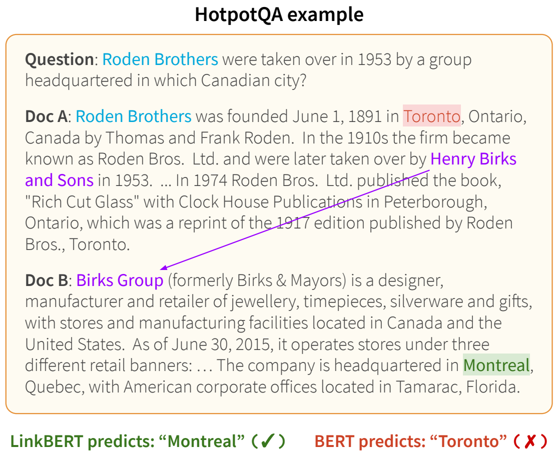
Table 1 shows the performance (F1 score) on MRQA datasets. LinkBERT substantially outperforms BERT on all datasets. On average, the gain is +4.1% absolute for the BERT$_\texttt{tiny}$ scale, +2.6% for the BERT$_\texttt{base}$ scale, and +2.5% for the BERT$_\texttt{large}$ scale. Table 2 shows the results on GLUE, where LinkBERT performs moderately better than BERT. These results suggest that LinkBERT is especially effective at learning knowledge useful for QA tasks (e.g. world knowledge), while keeping performance on sentence-level language understanding too.

5.4 Analysis

We further study when LinkBERT is especially useful in downstream tasks.

Improved multi-hop reasoning. In Table 1, we find that LinkBERT obtains notably large gains on QA datasets that require reasoning with multiple documents, such as HotpotQA (+5% over BERT$_\texttt{tiny}$), TriviaQA (+6%) and SearchQA (+8%), as opposed to SQuAD (+1.4%) which just has a single document per question. To further gain qualitative insights, we studied in what QA examples LinkBERT succeeds but BERT fails. Figure 3 shows a representative example from HotpotQA. Answering the question needs 2-hop reasoning: identify "Roden Brothers were taken over by Birks Group" from the first document, and then "Birks Group is headquartered in Montreal" from the second document. While BERT tends to simply predict an entity near the question entity ("Toronto" in the first document, which is just 1-hop), LinkBERT correctly predicts the answer in the second document ("Montreal"). Our intuition is that because LinkBERT is pretrained with pairs of linked documents rather than purely single documents, it better learns how to flow information (e.g., do attention) across tokens when multiple related documents are given in the context. In summary, these results suggest that pretraining with linked documents helps for multi-hop reasoning on downstream tasks.

Improved understanding of document relations. While the MRQA datasets typically use ground-truth documents as context for answering questions, in open-domain QA, QA systems need to use documents obtained by a retriever, which may include noisy documents besides gold ones (Chen et al., 2017; Dunn et al., 2017). In such cases, QA systems need to understand the document relations to perform well (Yang et al., 2018). To simulate this setting, we modify the SQuAD dataset such that we prepend or append 1–2 distracting documents to the original document given to each question. Table 3 shows the result. While BERT incurs a large performance drop (-2.8%), LinkBERT is robust to distracting documents (-0.5%). This result suggests that pretraining with document links improves the ability to understand document relations and



HotpotQA example

Question: Roden Brothers were taken over in 1953 by a group headquartered in which Canadian city?

Doc A: Roden Brothers was founded June 1, 1891 in Toronto, Ontario, Canada by Thomas and Frank Roden. In the 1910s the firm became known as Roden Bros. Ltd. and were later taken over by Henry Birks and Sons in 1953. ... In 1974 Roden Bros. Ltd. published the book, "Rich Cut Glass" with Clock House Publications in Peterborough, Ontario, which was a reprint of the 1917 edition published by Roden Bros., Toronto.

Doc B: Birks Group (formerly Birks & Mayors) is a designer, manufacturer and retailer of jewellery, timepieces, silverware and gifts, with stores and manufacturing facilities located in Canada and the United States. As of June 30, 2015, it operates stores under three different retail banners: … The company is headquartered in Montreal, Quebec, with American corporate offices located in Tamarac, Florida.

LinkBERT predicts: "Montreal" (✓) **BERT predicts: "Toronto" (✗)**

Figure 3: Case study of multi-hop reasoning on HotpotQA. Answering the question needs to identify "Roden Brothers were taken over by Birks Group" from the first document, and then "Birks Group is headquartered in Montreal" from the second document. While BERT tends to simply predict an entity near the question entity ("Toronto" in the first document), LinkBERT correctly predicts the answer in the second document ("Montreal").

relevance. In particular, our intuition is that the DRP objective helps the LM to better recognize document relations like (anchor document, linked document) in pretraining, which helps to recognize relations like (question, right document) in downstream QA tasks. We indeed find that ablating the DRP objective from LinkBERT hurts performance (§5.5). The strength of understanding document relations also suggests the promise of applying LinkBERT to various retrieval-augmented methods and tasks (e.g. Lewis et al. 2020b), either as the main LM or the dense retriever component.

Improved few-shot QA performance. We also find that LinkBERT is notably good at few-shot learning. Concretely, for each MRQA dataset, we fine-tune with only 10% of the available training data, and report the performance in Table 4. In this few-shot regime, LinkBERT attains more significant gains over BERT, compared to the full-resource regime in Table 1 (on NaturalQ, 5.4% vs 1.8% absolute in F1, or 15% vs 7% in relative error reduction). This result suggests that LinkBERT internalizes more knowledge than BERT during pretraining, which supports our core idea that document links can bring in new, useful knowledge for LMs.

5.5 Ablation studies

We conduct ablation studies on the key design choices of LinkBERT.

What linked documents to feed into LMs? We study the strategies discussed in §4.3 for obtaining linked documents: relevance, salience, and diversity. Table 5 shows the ablation result on MRQA datasets. First, if we ignore relevance and use random document links instead of hyperlinks, we get the same performance as BERT (-4.1% on average; "random" in Table 5). Second, using lexical similarity links instead of hyperlinks leads to 1.8% performance drop ("TF-IDF"). Our intuition is that hyperlinks can provide more salient knowledge that may not be obvious via lexical similarity alone. Nevertheless, using lexical similarity links is substantially better than BERT (+2.3%), confirming the efficacy of placing relevant documents together in the input for LM pretraining. Finally, removing the diversity adjustment in document sampling leads to 1% performance drop ("No diversity"). In summary, our insight is that to create informative inputs for LM pretraining, the linked documents must be semantically relevant and ideally be salient and diverse.

Effect of the DRP objective. Table 6 shows the ablation result on the DRP objective (§4.2). Removing DRP in pretraining hurts downstream QA performance. The drop is large on tasks with multiple documents (HotpotQA, TriviaQA, and SQuAD with distracting documents). This suggests that DRP facilitates LMs to learn document relations.

6 Biomedical LinkBERT (*BioLinkBERT*)

Pretraining LMs on biomedical text is shown to boost performance on biomedical NLP tasks (Beltagy et al., 2019; Lee et al., 2020; Lewis et al., 2020a; Gu et al., 2020). Biomedical LMs are typically trained on PubMed, which contains abstracts and citations of biomedical papers. While prior works only use their raw text for pretraining, academic papers have rich dependencies with each other via citations (references). We hypothesize that incorporating citation links can help LMs learn dependencies between papers and knowledge that spans across them.

With this motivation, we pretrain LinkBERT on PubMed with citation links (§6.1), which we term *BioLinkBERT*, and evaluate on biomedical downstream tasks (§6.2). As our baseline, we follow and compare with the state-of-the-art biomedical LM, PubmedBERT (Gu et al., 2020), which has the same architecture as BERT and is trained on PubMed.

6.1 Pretraining setup

Data. We use the same pretraining corpus used by PubmedBERT: PubMed abstracts (21GB).[4] We

---

[4] `https://pubmed.ncbi.nlm.nih.gov`. We use papers published before Feb. 2020 as in PubmedBERT.

use the Pubmed Parser[5] to extract citation links between articles. We then create training instances by sampling *contiguous*, *random*, or *linked* segments as described in §4, with the three options appearing uniformly (33%, 33%, 33%). In summary, our pretraining data is the same as PubmedBERT, except that we have citation links between PubMed articles.

Implementation. We pretrain BioLinkBERT of -base size (110M params) from scratch, following the same hyperparamters as the PubmedBERT$_\texttt{base}$ (Gu et al., 2020). Specifically, we use a peak learning rate 6e-4, batch size 8,192, and train for 62,500 steps. We warm up the learning rate in the first 10% of steps and then linearly decay it. Training takes 7 days on eight A100 GPUs with fp16.

Additionally, while the original PubmedBERT release did not include the -large size, we pretrain BioLinkBERT of the -large size (340M params) from scratch, following the same procedure as -base, except that we use a peak learning rate of 4e-4 and warm up steps of 20%. Training takes 21 days on eight A100 GPUs with fp16.

Baselines. We compare BioLinkBERT with PubmedBERT released by Gu et al. (2020).

6.2 Evaluation tasks

For downstream tasks, we evaluate on the BLURB benchmark (Gu et al., 2020), a diverse set of biomedical NLP datasets, and MedQA-USMLE (Jin et al., 2021), a challenging biomedical QA dataset.

BLURB consists of five named entity recognition tasks, a PICO (population, intervention, comparison, and outcome) extraction task, three relation extraction tasks, a sentence similarity task, a document classification task, and two question answering tasks, as summarized in Table 7. We follow the same fine-tuning method and evaluation metric used by PubmedBERT (Gu et al., 2020).

MedQA-USMLE is a 4-way multi-choice QA task that tests biomedical and clinical knowledge. The questions are from practice tests for the US Medical License Exams (USMLE). The questions typically require multi-hop reasoning, e.g., given patient symptoms, infer the likely cause, and then answer the appropriate diagnosis procedure (Figure 4). We follow the fine-tuning method in Jin et al. (2021). More details are provided in Appendix B.

MMLU-professional medicine is a multi-choice QA task that tests biomedical knowledge and reasoning, and is part of the popular MMLU benchmark (Hendrycks et al., 2021) that is used to evaluate massive language models. We take the BioLinkBERT fine-tuned on the above MedQA-USMLE task, and evaluate on this task without further adaptation.

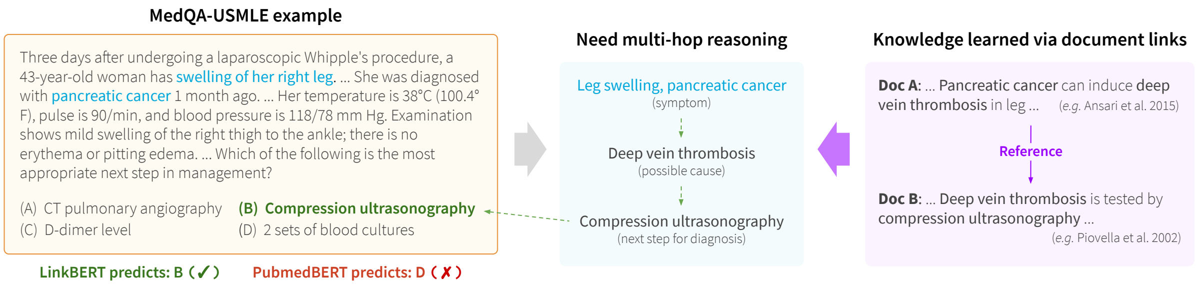
[5] `https://github.com/titipata/pubmed_parser`



Three days after undergoing a laparoscopic Whipple's procedure, a 43-year-old woman has swelling of her right leg. ... She was diagnosed with pancreatic cancer 1 month ago. ... Her temperature is 38°C (100.4° F), pulse is 90/min, and blood pressure is 118/78 mm Hg. Examination shows mild swelling of the right thigh to the ankle; there is no erythema or pitting edema. ... Which of the following is the most appropriate next step in management?

(A) CT pulmonary angiography
(B) Compression ultrasonography
(C) D-dimer level
(D) 2 sets of blood cultures

Doc A: ... Pancreatic cancer can induce deep vein thrombosis in leg ... (*e.g.* Ansari et al. 2015)

Doc B: ... Deep vein thrombosis is tested by compression ultrasonography ... (*e.g.* Piovella et al. 2002)

Figure 4: Case study of multi-hop reasoning on MedQA-USMLE. Answering the question (left) needs 2-hop reasoning (center): from the patient symptoms described in the question (*leg swelling*, *pancreatic cancer*), infer the cause (*deep vein thrombosis*), and then infer the appropriate diagnosis procedure (*compression ultrasonography*). While the existing PubmedBERT tends to simply predict a choice that contains a word appearing in the question ("blood" for choice D), BioLinkBERT correctly predicts the answer (B). Our intuition is that citation links bring relevant documents together in the same context in pretraining (right), which readily provides the multi-hop knowledge needed for the reasoning (center).

PubMedQA). This result is consistent with the general domain (§5.3) and confirms that LinkBERT helps to learn document dependencies better.

MedQA-USMLE. Table 8 shows the results. BioLinkBERT$_{\texttt{base}}$ obtains a 2% accuracy boost over PubmedBERT$_{\texttt{base}}$, and BioLinkBERT$_{\texttt{large}}$ provides an additional +5% boost. In total, BioLinkBERT outperforms the previous best by +7% absolute, attaining new state-of-the-art. To further gain qualitative insights, we studied in what QA examples BioLinkBERT succeeds but the baseline PubmedBERT fails. Figure 4 shows a representative example. Answering the question (left) needs 2-hop reasoning (center): from the patient symptoms described in the question (*leg swelling*, *pancreatic cancer*), infer the cause (*deep vein thrombosis*), and then infer the appropriate diagnosis procedure (*compression ultrasonography*). We find that while the existing PubmedBERT tends to simply predict a choice that contains a word appearing in the question ("blood" for choice D), BioLinkBERT correctly predicts the answer (B). Our intuition is that citation links bring relevant documents and concepts together in the same context in pretraining (right),[6] which readily provides the multi-hop knowledge needed for the reasoning (center). Combined with the analysis on HotpotQA (§5.4), our results suggest that pretraining with document links consistently helps for multi-hop reasoning across domains (e.g., general documents with hyperlinks and biomedical articles with citation links).

MMLU-professional medicine. Table 9 shows the performance. Despite having just 340M parameters, BioLinkBERT$_{\texttt{large}}$ achieves 50% accuracy on this QA task, significantly outperforming the largest general-domain LM or QA models such as GPT-3 175B params (39% accuracy) and UnifiedQA 11B params (43% accuracy). This result shows that with an effective pretraining approach, a small domain-specialized LM can outperform orders of magnitude larger language models on QA tasks.

7 Conclusion

We presented LinkBERT, a new language model (LM) pretraining method that incorporates document link knowledge such as hyperlinks. In both the general domain (pretrained on Wikipedia with hyperlinks) and biomedical domain (pretrained on PubMed with citation links), LinkBERT outperforms previous BERT models across a wide range of downstream tasks. The gains are notably large for multi-hop reasoning, multi-document understanding and few-shot question answering, suggesting that LinkBERT effectively internalizes salient knowledge through document links. Our results suggest that LinkBERT can be a strong pretrained LM to be applied to various knowledge-intensive tasks.

Reproducibility

Pretrained models, code and data are available at `https://github.com/michiyasunaga/LinkBERT`.
Experiments are available at `https://worksheets.codalab.org/worksheets/0x7a6ab9c8d06a41d191335b270da2902e`.

---

[6] For instance, as in Figure 4 (right), Ansari et al. (2015) in PubMed mention that *pancreatic cancer can induce deep vein thrombosis in leg*, and it cites a paper in PubMed, Piovella et al. (2002), which mention that *deep vein thrombosis is tested by compression ultrasonography*. Placing these two documents in the same context yields the complete multi-hop knowledge needed to answer the question ("*pancreatic cancer*" → "*deep vein thrombosis*" → "*compression ultrasonography*").

A Ethics, limitations and risks

We outline potential ethical issues with our work below. First, LinkBERT is trained on the same text corpora (e.g., Wikipedia, Books, PubMed) as in existing language models. Consequently, LinkBERT could reflect the same biases and toxic behaviors exhibited by language models, such as biases about race, gender, and other demographic attributes (Sheng et al., 2020).

Another source of ethical concern is the use of the MedQA-USMLE evaluation (Jin et al., 2021). While we find this clinical reasoning task to be an interesting testbed for LinkBERT and for multi-hop reasoning in general, we do not encourage users to use the current models for real world clinical prediction.

B Fine-tuning details

We apply the following fine-tuning hyperparameters to all models, including the baselines.

MRQA. For all the extractive question answering datasets, we use `max_seq_length` = 384 and a sliding window of size 128 if the lengths are longer than `max_seq_length`.

For the -tiny scale (BERT$_{\texttt{tiny}}$, LinkBERT$_{\texttt{tiny}}$), we choose learning rates from {5e-5, 1e-4, 3e-4}, batch sizes from {16, 32, 64}, and fine-tuning epochs from {5, 10}.

For -base (BERT$_{\texttt{base}}$, LinkBERT$_{\texttt{base}}$), we choose learning rates from {2e-5, 3e-5}, batch sizes from {12, 24}, and fine-tuning epochs from {2, 4}.

For -large (BERT$_{\texttt{large}}$, LinkBERT$_{\texttt{large}}$), we choose learning rates from {1e-5, 2e-5}, batch sizes from {16, 32}, and fine-tuning epochs from {2, 4}.

GLUE. We use `max_seq_length` = 128.

For the -tiny scale (BERT$_{\texttt{tiny}}$, LinkBERT$_{\texttt{tiny}}$), we choose learning rates from {5e-5, 1e-4, 3e-4}, batch sizes from {16, 32, 64}, and fine-tuning epochs from {5, 10}.

For -base and -large (BERT$_{\texttt{base}}$, LinkBERT$_{\texttt{base}}$, BERT$_{\texttt{large}}$, LinkBERT$_{\texttt{large}}$), we choose learning rates from {5e-6, 1e-5, 2e-5, 3e-5, 5e-5}, batch sizes from {16, 32, 64} and fine-tuning epochs from 3–10.

BLURB. We use `max_seq_length` = 512 and choose learning rates from {1e-5, 2e-5, 3e-5, 5e-5, 6e-5}, batch sizes from {16, 32, 64} and fine-tuning epochs from 1–120.

MedQA-USMLE. We use `max_seq_length` = 512 and choose learning rates from {1e-5, 2e-5, 3e-5}, batch sizes from {16, 32, 64} and fine-tuning epochs from 1–6.

Improving Time Sensitivity for Question Answering over Temporal Knowledge Graphs

Abstract

Question answering over temporal knowledge graphs (KGs) efficiently uses facts contained in a temporal KG, which records entity relations and when they occur in time, to answer natural language questions (e.g., "Who was the president of the US before Obama?"). These questions often involve three time-related challenges that previous work fail to adequately address: 1) questions often do not specify exact timestamps of interest (e.g., "Obama" instead of 2000); 2) subtle lexical differences in time relations (e.g., "before" vs "after"); 3) off-the-shelf temporal KG embeddings that previous work builds on ignore the temporal order of timestamps, which is crucial for answering temporal-order related questions. In this paper, we propose a time-sensitive question answering (TSQA) framework to tackle these problems. TSQA features a timestamp estimation module to infer the unwritten timestamp from the question. We also employ a time-sensitive KG encoder to inject ordering information into the temporal KG embeddings that TSQA is based on. With the help of techniques to reduce the search space for potential answers, TSQA significantly outperforms the previous state of the art on a new benchmark for question answering over temporal KGs, especially achieving a 32% (absolute) error reduction on complex questions that require multiple steps of reasoning over facts in the temporal KG.

1 Introduction

Temporal knowledge graphs (KGs) record the relations between entities and the timestamp or time period when such relation hold, e.g., in the form of a quadruple: (Franklin D. Roosevelt, position held, President of USA, [1933, 1945]). This makes them a perfect source of knowledge to answer questions that involve knowledge of when certain events occurred as well as how they are related temporally (see Figure 1 for an example). Unlike question answering (QA) over non-temporal KGs that is mainly concerned with relational inference, a core challenge in temporal KGQA is correctly identifying the time of reference mentioned explicitly or implicitly in the question, and locating relevant facts by jointly reasoning over relations and timestamps.

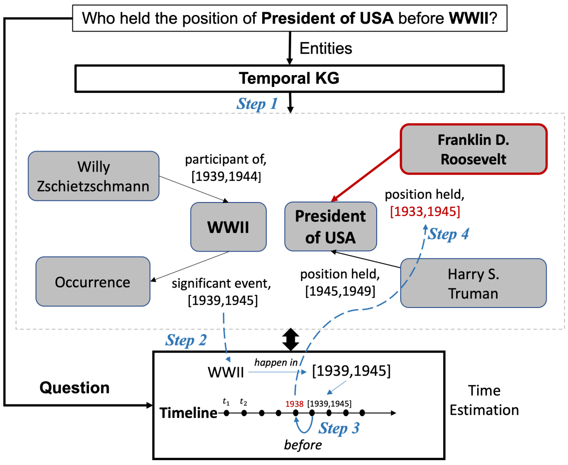

Figure 1: An example of complex temporal question on a temporal KG.

Inspired by work on relational KGQA (Huang et al., 2019; Saxena et al., 2020), where knowledge graph embeddings (Dasgupta et al., 2018; García-Durán et al., 2018; Goel et al., 2020; Wu et al., 2020; Lacroix et al., 2020) learned independently of question answering are used as input to KGQA models, previous work (Saxena et al., 2021) employs temporal KG embeddings to attack the problem of temporal KGQA. Despite its relative success on simple temporal questions that directly queries facts in the KG with one out of the four facts left as the answer (e.g., "When was Franklin D. Roosevelt the President of USA?" or "What position did Franklin D. Roosevelt hold between 1933 and 1945?"), this approach still struggles to handle questions that require multiple steps of relational-temporal reasoning (e.g., the example in Figure

1).

We identify three main challenges that hinder further progress on temporal KGQA. Firstly, complex temporal questions often require inferring the correct point of reference in time, which is not considered by previous work. For instance, to correctly answer the question in Figure 1, it is crucial that we first identify that World War II took place between 1939 and 1945, and look for entities with the desired relation with President of USA in the time interval specified by these times. Secondly, unlike entity relations, which are usually expressed in natural language with a handful of content words that correspond well with their recorded relations in KGs (e.g., "What position did ... hold ..." vs the "position held" relation), temporal relations often involve just one or two prepositions (e.g., "before" or "during") and are expressed only implicitly in temporal KGs (e.g., nowhere is it clearly stated that 1931 is earlier than, or before, 1934, by a gap of 3 years). As a result, a small lexical change can drastically alter the temporal relation expressed by the question, and therefore the answer set. Thirdly, previous work on temporal KGQA build on temporal KG embeddings, where each timestamp is assigned a randomly initialized vector representation that is jointly optimized with entity and relation representations to reconstruct quadruples in the KG from embeddings. While sound as a standalone method for encoding knowledge in temporal KGs, this approach does not guarantee that the learned timestamp representations can recover implicit temporal relations like temporal orders or distance, which are crucial for temporal KGQA.

In this paper, we propose a time-sensitive question answering framework (TSQA) to address these challenges. We first equip the temporal KGQA model with a time estimation module that infers the unstated timestamps from questions as the first step of reasoning, and feed the result into relational inference as a reference timestamp. Even without explicit training data for this module, the explicit factorization of the problem yields significant improvement over previous work on complex questions that require reasoning over multiple temporal quadruples. To improve the sensitivity of our question encoder to time relation words, we also propose auxiliary contrastive losses that contrast the answer prediction and time estimation for questions that differ only by the time relation word (e.g., "before" vs "after"). By leveraging the mutual exclusiveness of answers and the prior knowledge regarding potential time estimates from different time relation words, we observe further improvements in model performance on complex questions. Next, to learn temporal KG embeddings with prior knowledge of temporal order and distance built in, we introduce an auxiliary loss of time-order classification between each pair of timestamp embeddings. As a result, the knowledge in the temporal KG can be distilled into the entity, relation, and timestamp embeddings where the timestamp embeddings can naturally recover order and distance information between the underlying timestamps, thus improving the performance of temporal KGQA where such information is crucial. Finally, we enhance TSQA with KG-based approaches to narrow the search space to speed up model training and inference, as well as reduce the number of false positives in model prediction. As a result, TSQA outperforms the previous state of the art on the CRONQUESTIONS benchmark (Saxena et al., 2021) by a large margin.

To summarize, our contributions in this paper are: a) we propose a time-sensitive question answering framework (TSQA) that performs time estimation for complex temporal answers; b) we present contrastive losses that improve model sensitivity to time relation words in the question; c) we propose a time-sensitive temporal KG embedding approach that benefits temporal KGQA; d) with the help of KG-based pruning technique, our TSQA model outperforms the previous state of the art by a large margin.

2 Related Work

Temporal Knowledge Graph Embedding. Knowledge graph embedding learning (Bordes et al., 2013; Yang et al., 2014; Trouillon et al., 2016; Dettmers et al., 2018; Shang et al., 2019; Sun et al., 2019; Tang et al., 2019; Ji et al., 2021) has been an active research area with applications directly in knowledge base completion and relation extractions. Recently, there are several works that extended the static KG embedding models to temporal KGs. Jiang et al. (2016) first attempt to extend TransE (Bordes et al., 2013) by adding a timestamp embedding into the score function. Later, Hyte (Dasgupta et al., 2018) projects each timestamp with a corresponding hyperplane and utilizes the TransE score in each space. García-Durán et al. (2018) extend TransE and

DistMult by utilizing recurrent neural networks to learn time-aware representations of relation types. TCompLEx (Lacroix et al., 2020) extends the ComplEx with time based on the canonical decomposition of tensors of order 4.

Temporal QA on Knowledge Graph. Temporal QA have mostly been studied in the context of reading comprehension. ForecastQA (Jin et al., 2021) formulates the forecasting problem as a multiple-choice question answering task, where both the articles and questions include the timestamps. The recent released TORQUE (Ning et al., 2020) is a dataset that explores the temporal ordering relations between events described in a passage of text.

Another direction is the temporal question answering over knowledge bases (KB) (Jia et al., 2018b,a), which retrieves time information from the KB. TempQuestions (Jia et al., 2018a) is a KGQA dataset specifically aimed at temporal QA. Based on this dataset, Jia et al. (2018b) design a method that decomposes and rewrites each question into nontemporal sub-question and temporal sub-question. Here the KG used in TempQuestions is based on a subset of FreeBase which is not a temporal KG. Later Jia et al. (2021) proposes a first end-to-end system (EXAQT) for answering complex temporal questions, which takes advantage of the question-relevant compact subgraphs within the KG, and relational graph convolutional networks (Schlichtkrull et al., 2018) for predicting the answers. All previous datasets only include a limited number of temporal questions. Recently, a much larger temporal KGQA dataset CRONQUESTIONS (Saxena et al., 2021) is released, which includes both the temporal questions and the temporal KG with time annotation for all edges. Based on this dataset, the CronKGQA model (Saxena et al., 2021) is presented that exploits recent advances in Temporal KG embeddings and achieves performance superior to all baselines.

3 Method

In this section, we first give the problem definition of temporal question answering over temporal knowledge graph. Then, we introduce the framework to solve this problem, which integrates time sensitivity into KG embedding and answer inference. Finally, we describe the key modules of our proposed system in details.

3.1 Problem Definition and Framework

QA on Temporal KG aims at finding out the answer from a given temporal KG $G = (\mathcal{V}, \mathcal{E}, \mathcal{R}, T)$ for a given free-text temporal question Q containing implicit temporal expression, and the answer is either an entity of entity set $\mathcal{V}$ or a timestamp of timestamp set T. Here, $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$ is a set of edges, and $\mathcal{R}$ is the set of relations. Edge from a quadruple $(s, r, [t_s, t_e], o)$ indicates the relation $r \in \mathcal{R}$ holds between subject entity s and object entity o during time interval $[t_s, t_e]$ ($t_s < t_e$ and $t_{e/s} \in T$).

Framework. Our framework resorts to KG embeddings along with pretrained language models to perform temporal KGQA. Figure 2 shows the architecture which consists of two modules: 1) time-aware TKG encoder; 2) time-sensitive question answer.

The time-aware TKG encoder extends the existing TKG embedding method by adding an auxiliary time-order learning task to consider the quadruple orders. And the time sensitive QA module first performs neighboring graph extraction to reduce the search space for question answer, then performs joint training for answer/time prediction and time-sensitive contrastive learning to enhance the model ability in capturing temporal signals in free-text question. Next, we will introduce these two modules in details.

3.2 Time-aware KG Encoder

We first briefly review a time-aware KG embedding method based on TCompLEx (Lacroix et al., 2020) since it has been used in (Saxena et al., 2021) for TKGQA and shows competitive performance. Next, we show that how to perform TCompLEx on temporal KG, then analyze its weakness in TKGQA especially for complex question and further overcome such weakness by introducing an auxiliary time-order learning task in TKG embedding.

TCompLEx for TKG. TCompLEx is an extension of ComplEx considering time information, which not only encodes the entity and relation to complex vectors, but also maps each timestamp to a complex vector. To perform TCompLEx over temporal KG in our problem definition, we first reformulate each quadruple to a set of new quadruples by

$$(s, r, [t_s, t_e], o) = \{(s, r, t, o) | t_s \leq t \leq t_e\} \quad (1)$$

Let $\boldsymbol{e}_s$, $\boldsymbol{e}_r$, $\boldsymbol{e}_t$, $\boldsymbol{e_o} \in \mathbb{C}^d$ be the complex-value embeddings of s, r, t, o, respectively. Then, TCom-

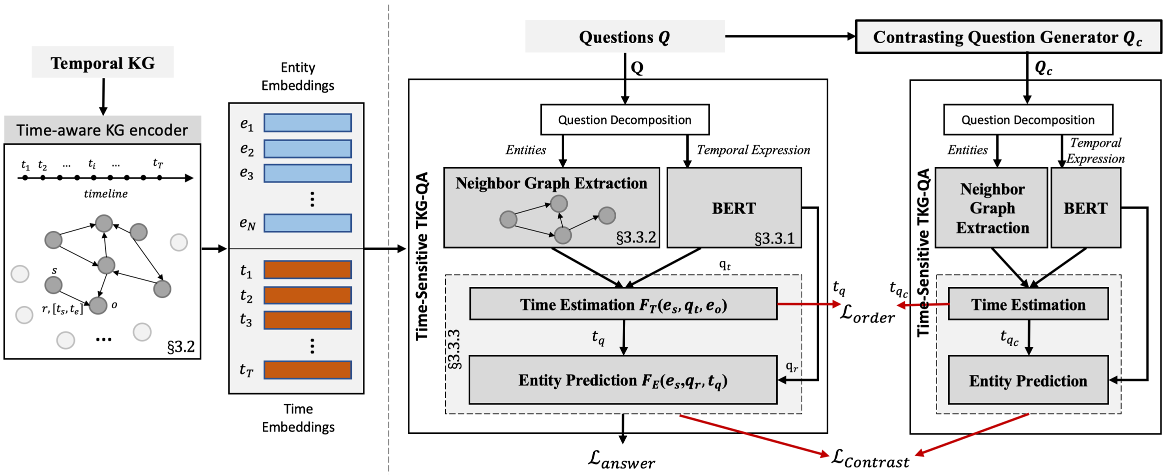

Figure 2: The architecture of our TSQA model (**Left**: Time-aware TKG encoder; **Right**: Time-Sensitive TKG-QA).

pLEx scores each quadruple (s, r, t, o) by

$$\mathcal{S}(s, r, o, t) = Re(\langle \boldsymbol{e}_s, \boldsymbol{e}_r, \boldsymbol{e}_o, \boldsymbol{e}_t \rangle) \tag{2}$$

where Re(.) denotes the real part of a complex vector, and $\langle\rangle$ denotes the multi-linear product.

Finally, we use a loss function similar to the negative sampling loss for effectively TCompLEx training.

$$\begin{aligned} L_{TC} &= -log(\phi(\gamma - \mathcal{S}(s, r, o, t))) \\ -\frac{1}{K}&\sum_{i=1}^{K}(log(\phi(\mathcal{S}(s'_i, r, o'_i, t'_i) - \gamma))), \end{aligned} \tag{3}$$

where γ is a fixed margin, ϕ is the sigmoid function, (s'_i, r, o'_i, t'_i) is the i-th negative quadruple.

According to the loss function in equation 3, we observe that TCompLEx only cares about whether the quadruple is true or false and ignores the orders of different quadruples occur. However, the time orders are critical to find the correct answer in knowledge graphs. For example, to answer the 'Who is the President of USA before William J. Clinton?', we need not only the two facts (President of USA, Position Held, Ronald Reagan, [1981, 1989]) and (President of USA, Position Held, William J. Clinton, [1993, 2001]), but also the time order of these facts. To overcome such a limit of TCompLEx in TKGQA, we introduce an auxiliary time-order learning task over time-embeddings.

Time-order learning in TKG. To keep the time order in embedding spaces, we first sort the timestamps in T by an ascending order and get $(t_1, t_2, \cdots, t_{|T|})$ and $t_i < t_j$ if $1 \leq i < j \leq |T|$. Let $\boldsymbol{t}_i = [Re(\boldsymbol{e}_{t_i}), Im(\boldsymbol{e}_{t_i})] \in \mathbb{R}^{2d}$ be the concatenation the real and imaginary components of embedding $\boldsymbol{e}_{t_i}$ of timestamp t_i. Inspired by position embedding in (Vaswani et al., 2017), we first initialize the timestamp embedding $\boldsymbol{t}_i$ as follows.

$$\begin{aligned} \boldsymbol{t}_i[2k] &= \sin(\frac{i}{10000^{2k/2d}}) \\ \boldsymbol{t}_i[2k+1] &= \cos(\frac{i}{10000^{2k/2d}}) \end{aligned} \tag{4}$$

where $0 \leq k \leq d - 1$.

Afterwards, for any pair of timestamps (t_i, t_j), we calculate the probability of time order as:

$$p_t(i, j) = sigmoid((\boldsymbol{t}_1 - \boldsymbol{t}_2)^T \boldsymbol{W}_t), \tag{5}$$

where $\boldsymbol{W}_t \in \mathbb{R}^{2d}$ represents a parameter vector.

Based on the time-order probabilities, we introduce a binary cross-entropy loss as a time-order constraint over timestamp embeddings as follow:

$$\begin{aligned} L_{TO} = &-\delta(i, j)\log(p_t(i, j)) \\ &- (1 - \delta(i, j))\log(1 - p_t(i, j)), \end{aligned} \tag{6}$$

where $\delta(i, j) = 1$ if $t_i < t_j$ else $\delta(i, j) = 0$.

Joint-training. A weighted sum of T-CompLEx training loss and time-order constraint is considered as the final objective function for the joint training for TKG embedding.

3.3 Time-Sensitive TKG-QA

In this section, we introduce our time-sensitive question answering module from the following aspects in details: 1) question decomposition which divides the questions as entities and relations described in free-text; 2) entity neighboring subgraph extraction which reduces the search space of candidate timestamps and answer entities; and 3) time-sensitive question answer which explores the time information implied in both KG and questions to help the model find the answer.

3.3.1 Question Decomposition and Encoder

For each question Q, we first identify all the entities $\{\text{Ent}_1, \text{Ent}_2, \cdots, \text{Ent}_k\}$ in Q which also appear in KG G, i.e., $\text{Ent}_i \in E$ $(1 \leq i \leq k)$. Then, by replacing the entities in question Q with special token [*subject*] and [*object*] in order, we obtain an entity-independent temporal relation description in free-text named **temporal expression** $\hat{Q}$.

Taking the question "When did **Obama** hold the position of **President of USA**?" as an example, by replacing the identified entities "President of USA" and "Obama", we get its temporal expression as "When did ***subject*** hold the position of ***object***?".

Next [CLS] + $\hat{Q}$ are fed into BERT that outputs [CLS] token embedding as $\boldsymbol{e}_q \in \mathbb{R}^{d_{bert}}$, where d_{bert} is the output dimension of BERT, and two kinds of question representations as follows.

$$\boldsymbol{q}_r = \boldsymbol{W}_q^r(\delta(\boldsymbol{W}\boldsymbol{e}_q)) \tag{7}$$

$$\boldsymbol{q}_t = \boldsymbol{W}_q^t(\delta(\boldsymbol{W}\boldsymbol{e}_q)), \tag{8}$$

where $\boldsymbol{q}_r, \boldsymbol{q}_t \in \mathbb{R}^{2d}$ represents the embedding of relation and time implied in question, respectively. $\boldsymbol{W} \in \mathbb{R}^{d_{bert} \times 2d}$, $\boldsymbol{W}_q^r$, $\boldsymbol{W}_q^t \in \mathbb{R}^{2d \times 2d}$ are the parameter matrix, and δ represents the activation function. Finally, to facilitate the calculation with KG embeddings, we reformulate $\boldsymbol{q}_r, \boldsymbol{q}_t$ in complex space as:

$$\boldsymbol{q}_r = \boldsymbol{q}_r[0:d] + \sqrt{-1} \cdot \boldsymbol{q}_r[d:2d] \tag{9}$$

$$\boldsymbol{q}_t = \boldsymbol{q}_t[0:d] + \sqrt{-1} \cdot \boldsymbol{q}_t[d:2d] \tag{10}$$

3.3.2 Entity Neighbor Graph Extraction

Let $\{\text{Ent}_1, \text{Ent}_2, \cdots, \text{Ent}_k\}$ be the k entities extracted from question Q, we first extract the m-hop neighboring sub-graph G_i for each entity Ent_i. Then, by combining these k sub-graphs, we obtain the search graph G_q for question Q: $G_q = \cup_{i=1}^k G_i$. Suppose that E_q and T_q are the sets of entities and timestamps appearing in G_q, respectively, they constitute the search space of time and entity prediction in our TKG-QA method. In training stage, we set the hop number m as the minimum value which results in correct answer entity appearing in G_q. In testing stage, we set m as the largest hop number used in training stage. In practice, the size of graph G_q in usually much smaller than that of whole graph G. For example, in CronKGQA, the average value of $|G_q|/|G|$ is about 3%.

Entity Neighboring graph extraction aims at reducing the search space of candidate timestamps and answer entities. This results in not only more efficient training procedure, but also performance improvement of question answer because a larger number of candidates usually means a much more difficult learning problem.

3.3.3 Time-Sensitive Question Answering

For temporal question answer over KG, the interaction of time and answer entity prediction is very important since the time range brings a strong constraint on the search space of answers. However, the existing method (Saxena et al., 2021) usually performs such two predictions independently which results in poor performance especially for complex questions which need to consider multiple facts to get the answer. To overcome this limitation, we directly feed the intermediate time representation t_q learned from time estimation to answer prediction to enhance the interaction of these two tasks.

Time Estimation. Based on the embeddings $\boldsymbol{e}_s$ and $\boldsymbol{e}_o$ of subject entity s and object entity o from KG and the time embedding $\boldsymbol{q}_t$ from a question, we design the time estimation function F_T for learning the time embedding $\boldsymbol{t}_q$ as follows:[1]

$$\begin{aligned}\boldsymbol{t}_q &= F_T(\boldsymbol{e}_s, \boldsymbol{q}_t, \boldsymbol{e}_o) \\ &= \boldsymbol{W}_q^t([Re(\langle \boldsymbol{e}_s, \boldsymbol{q}_t, \boldsymbol{e}_o \rangle), Im(\langle \boldsymbol{e}_s, \boldsymbol{q}_t, \boldsymbol{e}_o \rangle)]),\end{aligned} \tag{11}$$

where $\boldsymbol{W}_q^t \in \mathbb{R}^{2d \times 2d}$ represents the parameter matrix. [.] is the concatenation function, $Re(.)$ denotes the real part of a complex vector and $Im(.)$ is the imaginary part.

After getting the time embedding w.r.t. question $\boldsymbol{t}_q$, for timestamp prediction, the following score function to estimate the score for each timestamp $t \in T_q$ as follow:

$$\mathcal{S}_t = Re(\langle \boldsymbol{t}_q, \boldsymbol{t} \rangle) \tag{12}$$

Entity Prediction. In enhance the interaction between time prediction and answer prediction, we

---

[1] A simple temporal question might contain the timestamp (e.g. 2001). In this case, we set $\boldsymbol{t}_q$ as the linear combination of this learned time embedding and the timestamp embedding from KG.

update the embedding of entity w.r.t. question by considering time embedding $\boldsymbol{t_q}$ by an entity function F_E as follow:

$$\boldsymbol{e}_q = F_E(\boldsymbol{e}_s, \boldsymbol{q}_r, \boldsymbol{t}_q) = \langle \boldsymbol{e}_s, \boldsymbol{q}_r, \boldsymbol{t}_q \rangle \tag{13}$$

Finally, we score the entity $e \in E_q$ by:

$$\mathcal{S}_e = Re(\langle \boldsymbol{e}_q, \boldsymbol{e} \rangle) \tag{14}$$

The answer entity of the question is either timestamp or entity. Let $\mathcal{S}_a$ be the answer score and thus $\mathcal{S}_a = \mathcal{S}_t$ or $\mathcal{S}_e$ when the answer is timestamp or entity. Suppose C represents the number of candidate answers (i.e., $C = |E_q| + |T_q|$), then we can define the probability of i-th candidate answer being true as:

$$P_{a,i} = \frac{\exp(\mathcal{S}_{a,i})}{\sum_{j=1}^{C} \exp(\mathcal{S}_{a,j}))}. \tag{15}$$

Finally, we train the answer prediction model by minimizing the cross-entropy loss as follow:

$$L_{answer} = -\sum_{i}^{C} \boldsymbol{y}_i \log(P_{a,i}), \tag{16}$$

where $\boldsymbol{y}_i = 1$ if the i-th candidate is the true answer, otherwise $\boldsymbol{y}_i = 0$.

3.3.4 Temporal Contrastive Learning

The temporal question answer system should be sensitive to the temporal relation implied in the question. For example, the answer of "What does happen before a given event?" is quite different from that of "What does happen after a given event?". Existing works on TKG-QA usually resort to pre-trained language models for question understanding. But these models are not sensitive to the difference of temporal expressions in free-text (Ning et al., 2020; Dhingra et al., 2021; Shang et al., 2021; Han et al., 2021), and thus prone to wrong predictions.

To make the system sensitive to the temporal relation implied in question, we resort to a contrastive learning method: we construct a contrastive question to the original question, then add auxiliary contrastive learning tasks to distinguish the latent temporal representation and prediction results coming from the pair of contrastive questions.

Contrastive Question Generation. To generate the contrastive question $\bar{Q}$ for the given question Q, we first extract all the temporal words based on large number of questions in temporal question answer dataset, and then build a contrastive word pair dictionary by finding the antonyms. The dictionary consists of $\mathcal{D}_{contr}$ = {(first, last), (before, after), (before, during), (during, after), (before, when), (when, after)}. Based on such dictionary, we replace the temporal word in given question Q by its antonym to generate its contrastive question $\bar{Q}$.

Contrastive time order learning. For the contrastive question pair Q and $\bar{Q}$, we follow the same encoder in Eq. 11 to get the corresponding time-aware embeddings $\boldsymbol{t}_q$ and $\boldsymbol{t}_{q_c}$, respectively. Meanwhile, according to the contrastive temporal word pair dictionary, suppose that we pickup the pair (word$_1$, word$_2$) $\in \mathcal{D}_{contr}$ for contrastive question construction, we can construct a question order label y_o: $y_o = 0$ if $\bar{Q}$ is achieved by replacing word$_1$ as word$_2$, else $y_o = 1$.

Afterward, we distinguish the temporal orders implied by word$_1$ and word$_2$ by predicting of the order label y_o based on $\boldsymbol{t}_q$ and $\boldsymbol{t}_{q_c}$ as follow:

$$p_o = sigmoid((\boldsymbol{t}_q - \boldsymbol{t}_{q_c})^T \boldsymbol{W}_o) \tag{17}$$

$$\mathcal{L}_{\text{order}} = -y_o \log(p_o) - (1 - y_o) \log(1 - p_o), \tag{18}$$

where $\boldsymbol{W}_o \in \mathbb{R}^{2d}$ represents the parameter vector to be learned.

Answer-guided Contrastive Learning. Let $\boldsymbol{S} = [\boldsymbol{s}_1, \cdots, \boldsymbol{s}_C]$, $\bar{\boldsymbol{S}} = [\boldsymbol{s}_1, \cdots, \boldsymbol{s}_C]$ be the answer scores w.r.t. questions Q and its contrastive question $\bar{Q}$, respectively, where $C = |E_q| + |T_q|$. By stacking these two scores together, we get $\boldsymbol{S}_q = [\boldsymbol{S}; \bar{\boldsymbol{S}}] \in \mathbb{R}^{2 \times C}$. Then, we can apply softmax over $\boldsymbol{S}_q$ along the last dimension and get the probability scores $\boldsymbol{P}_q = softmax(\boldsymbol{S}_q) \in \mathbb{R}^{2 \times C}$ and $sum(\boldsymbol{P}_q[:, i]) = 1$ for $i = 1, \cdots, C$.

Due to the fact that the answers of question Q are definitely not for question $\bar{Q}$, we construct an answer-guided learning labels as $\boldsymbol{y}_a = [y_1, \cdots, y_C]$, where $y_i = 1$ if and only if the i-th candidate is true answer for Q, otherwise $\boldsymbol{y}_i = 0$. Then, we get an answer-guided contrastive loss as follow:

$$\mathcal{L}_{\text{contrast}} = -\frac{1}{C} \sum_{j=0}^{C} y_i \log(\boldsymbol{P}_q[0, i]) \tag{19}$$

Joint Training. We combine the answer prediction loss and contrastive losses as the final objective function for joint training:

$$Loss = \mathcal{L}_{answer} + \lambda_o \cdot \mathcal{L}_{order} + \lambda_c \cdot \mathcal{L}_{contrast}, \tag{20}$$

where $\lambda_o > 0$, $\lambda_c > 0$ are the weight factors to make tradeoffs between different losses.

4 Experiments

In this section, we conduct experiments to assess the effectiveness of our proposed method TSQA for TKG-QA. Our experimental results show that our approach obtains significant improvements over the baseline models.

Category	Train	Dev	Test
Simple Entity	90,651	7,745	7,812
Simple Time	61,471	5,197	5,046
Before/After	23,869	1,982	2,151
First/Last	118,556	11,198	11,159
Time Join	55,453	3,878	3,832
Entity Answer	225,672	19,362	19,524
Time Answer	124,328	10,638	10,476
Total	350,000	30,000	30,000

Table 1: CRONQUESTIONS dataset statistics as well as the numbers of questions across different types of reasoning required and answer types.

4.1 Experimental Setup

Data. CRONQUESTIONS[2] is the largest known Temporal KGQA dataset consisting of two parts: a KG with temporal annotations, and a set of free-text questions requiring temporal reasoning. This Temporal KG has 125k entities and 328k facts (quadruples), while a set of 410k questions is given. The facts have the time spans in the edge. These time spans or timestamps were discretized to years.

This dataset consists of questions that can be categorized into two groups based on their answer type: entity questions where the answer is an entity in the KG, and time questions where the answer is a timestamp. The authors also categorize these questions into "simple reasoning" (including *simple entity* and *simple time* subtypes) and "complex reasoning" (including *before/after*, *first/last* and *time join* subtypes). Table 1 provides the number of questions across different categories. Complex questions require complex temporal reasoning which takes advantage of multiple facts and temporal order of these facts.

Evaluation Metrics include Hits@1 and Hits@10 , which is the standard evaluation metrics on CRONQUESTIONS (Saxena et al., 2021).

Hyper-parameter setting. We train the TSQA models by setting the hyper-parameters as: learning rate = $\{1e^{-4}, 2e^{-5}, 1e^{-5}\}$, $\lambda_o = \{0.5, 1.0, 2.0, 3.0, 5.0\}$ and $\lambda_c = \{0.5, 1.0, 2.0, 3.0, 5.0\}$, and pick up the best hyper-parameters on dev set by the overall Hits@1 metrics. Our models are implemented by PyTorch and trained using NVIDIA Tesla V100 GPUs.

Baselines. We select several recent SOTA TKG-QA models as our baselines as follow:

- EmbedKGQA (Saxena et al., 2020) is the first method to use KG embeddings for the multi-hop KGQA task. It uses ComplEx (Trouillon et al., 2016) embeddings and can only deal with non-temporal KGs and single entity questions.

- T-EaE-add/replacement (Saxena et al., 2021) are two modifications of KG enhanced language model EaE (Févry et al., 2020), which integrates entity knowledge into a transformer-based language model and has been used for TKG-QA (Saxena et al., 2020). T-EaE-add has all grounded entities and time spans marked in the question, and T-EaE-replace replaces the BERT embeddings with the entity/time embeddings instead of adding them with token embeddings.

- CronKGQA (Saxena et al., 2021) extends EmbedKGQA to the temporal QA task, and takes advantage of the temporal KG embeddings to answering temporal questions. This is the current SOTA model on CRONQUESTIONS.

4.2 Main Results

Table 2 compares different TKG-QA methods in terms of Hits@1 and Hits@10. From this table, we observe that: 1) our proposed TSQA has achieved state-of-the-art performance in terms of all types of questions on both Hits@1 and Hits@10. 2) The performance improvement over the SOTA model is significant. TSQA outperforms the SOTA results by more than 82% Hits@1 relative improvement (32% absolute error reduction) on complex questions and 21% Hits@10 relative improvement on simple questions. These results proved the excellent performance of our proposed TSQA on question answering on the temporal knowledge graph, especially for complex temporal reasoning.

We also compare our method with baselines in terms of Hits@1 on different subtype questions in Table 3. From this table, we observe that: on complex questions, our proposed TSQA model outperforms all baseline models significantly. The relative improvement is up to 75%, 94%, 56%, for "before/after", "first/last" and "Time Joint", respectively. The first two kinds of questions are more

challenging as they require a better understanding of the temporal expressions in question. Our method is better in capturing such time-sensitivity change in temporal words and thus results in great improvement. Moreover, for the simple questions, our method still keeps competitive performance compared to the SOTA model.

4.3 Ablation Study

To understand the contributions of the proposed modules in our method, we perform an ablation study by sequentially removing the following components from our proposed TSQA: temporal Contrastive learning (TC), time-aware TKG embeddings (TKE), entity neighboring graph extractor (NG), and time estimation for question answer (TE) in Table 4. It is noted that removing TKE means that we replace TKE with T-CompLEx as KG encoder, and removing NG means that we perform QA over the whole knowledge graph.

By comparing the two adjacent rows of this table, we can infer the contributions of TC, TKE, NG and TE, respectively: 1) all these modules improve the overall performance in terms of Hits@1, especially for complex questions; 2) by comparing the last two adjacent rows, the proposed time estimation brings significant Hits@1 improvement (14.5%), since this module supplies the latent time embedding which not only enhances the interaction of timestamp estimation and answer estimation but also supplies a good anchor for finding the answer entity, which is very crucial for answering complex questions; 3) entity neighboring graph extraction gets 7.8% Hits@1 improvement over complex questions by comparing rows "TC-TKE" and "TC-TKE-NG", since it significantly narrows down the search space of the candidate answers; 4) by comparing the first three rows, time-aware TKG embedding (TKE) and temporal contrastive learning (TC) further boost the Hits@1 over complex questions. This is because the complex questions usually require the model to capture time ordering information implied in temporal words of the question. And these two modules enhance temporal order learning by adding explicit time-order constraints.

Model	Hits@1				
		Question Type		Answer Type

5 Conclusion

In this paper, we propose a time-sensitive question answering framework (TSQA) over temporal knowledge graphs (KGs). To facilitate the reasoning over temporal and relational facts over multiple facts, we propose a time estimation component to infer the unstated timestamp in the question. To further improve the model's sensitivity to time relation words in the question and facilitate temporal reasoning, we enhance the model with a temporal KG encoder that produces KG embeddings that can recover the implicit temporal order and distance between different timestamps, and with contrastive losses that compare temporally exclusive questions. With the help of answer search space pruning from entity neighboring sub-graphs, our TSQA model significantly improves the performance on complex temporal questions that require reasoning over multiple pieces of facts, and outperforms the previous state of the art by a large margin.

Abstract

Phonemes are defined by their relationship to words: changing a phoneme changes the word. Learning a phoneme inventory with little supervision has been a longstanding challenge with important applications to under-resourced speech technology. In this paper, we bridge the gap between the linguistic and statistical definition of phonemes and propose a novel neural discrete representation learning model for self-supervised learning of phoneme inventory with raw speech and word labels. Given the availability of phoneme segmentation and some mild conditions, we prove that the phoneme inventory learned by our approach converges to the true one with an exponentially low error rate. Moreover, in experiments on TIMIT and Mboshi benchmarks, our approach consistently learns a better phoneme-level representation and achieves a lower error rate in a zero-resource phoneme recognition task than previous state-of-the-art self-supervised representation learning algorithms.

1 Introduction

Thanks to recent developments in self-supervised speech representation learning (van den Oord et al., 2017, 2019; Chorowski et al., 2019; Baevski et al., 2020), there is new hope for the development of speech processing systems without the need for full textual transcriptions. Supervised speech processing systems for tasks such as automatic speech recognition (ASR) rely on a large amount of textual transcriptions, but self-supervised systems can be applied to under-resourced languages in which such annotation is either scarce or unavailable. A key task of the self-supervised system is to learn a discrete representation. While it is possible to discretize the speech solely on the basis of its acoustic properties, a more desirable discrete representation would serve as a bridge from the continuous acoustic signal toward higher-level linguistic structures such as syntax and semantics. Such a representation would make it possible to repurpose algorithms developed for written languages so that they could be used for unwritten languages in tasks such as speech translation and spoken language understanding. Words are the obvious choice for a discrete, semantic-driven speech representation, but a practical speech understanding system needs at least thousands of words; learning them in an unsupervised manner may be challenging. Phonemes may be a more learnable representation. According to the standard linguistic definition, phonemes are closely linked to words:

Definition 1. *(Linguistic definition of phonemes (Swadesh, 1934)) Phonemes are the smallest units in speech such that given a correct native word, the replacement of one or more phonemes by other phonemes (capable of occurring in the same position) results in a native word other than that intended, or a native-like nonsense word.*

For example, the sentences "he *th*inks" and "he *s*inks" differ by exactly one phoneme but have very different meaning. The optimal compactness of a phoneme inventory as specified in the definition leads to three advantages. First, learning phonemes requires lower sample complexity than learning words since the number of distinct phonemes is much smaller than the number of distinct words in a language. Second, the phonemes are much more abundant and more balanced in classes than words within a speech corpus, which makes sample complexity less of an issue when learning phonemes. Third, phonemes are more generalizable in the sense that knowing the phoneme inventory allows the learner to memorize previously unseen words as sequences of phonemes, and, having memorized them, to begin seeking clues to their meaning. Motivated by the semantic-driven definition of phonemes, we formulate the problem of learning a phoneme inventory as a self-supervised learning problem, where a small amount of semantic su-

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 8027 - 8047
May 22-27, 2022

pervision is available. The required supervision specifies which acoustic segments are instances of the same word, and which are instances of different words. Such supervision might be acquired in a naturalistic setting by asking native speakers to name objects in a set of standardized images, as is commonly done in primary education classrooms, or by asking for the translations of common words in a second language, a common baseline approach in dialectology and historical linguistics (Swadesh, 1952). Our contributions are threefold: (1) we propose a computationally tractable definition of phoneme that is almost equivalent to the linguistic definition. (2) We propose a finite-sample objective function for learning phoneme-level units and prove that when the phoneme segmentation is available and under mild conditions, the empirical risk minimizer (ERM) of this objective will find the correct phoneme inventory with exponentially low error rate. (3) We propose a novel neural network called *information quantizer* to optimize the proposed objective, which achieve state-of-the-art results in the phoneme inventory discovery task on the TIMIT and low-resourced Mboshi benchmarks with much less training data than previous approaches.

2 Related works

Due to the challenge of learning phonemes, early works on unsupervised speech representation learning (Park and Glass, 2005; Lee and Glass, 2012; Ondel et al., 2016) focus on learning speech segments sharing similar acoustic properties, or *phones*, without taking into account the meaning of the speech they are part of. There are two main approaches in this direction. One approach is to learn discrete phone-like units without *any* textual labels by modeling phone labels of the speech segments as latent variables. In particular, (Park and Glass, 2005; Jansen et al., 2010) first detect segments with recurring patterns in the speech corpus followed by graph clustering using the similarity graph formed by the segments. (Lee and Glass, 2012; Ondel et al., 2016; Kamper et al., 2016) develop probabilistic graphical models to jointly segment and cluster speech into phone-like segments. An extension to the latent variable approach is to introduce additional latent variables such as speaker identity (Ondel et al., 2019) or language identity (Yusuf et al., 2020) and develop mechanisms to disentangle these variables.

With the advance of deep learning, neural network models have also been proposed to learn unsupervised phone-level representation either by first learning a continuous representation (Chung et al., 2019; Feng et al., 2019; Nguyen et al., 2020) followed by off-line clustering, or by learning a discrete representation end-to-end with Gumbel softmax (Eloff et al., 2019b; Baevski et al., 2020) or vector-quantized variational autoencoder (VQ-VAE) (van den Oord et al., 2017; Chorowski et al., 2019; Baevski et al., 2019). However, codebooks learned by the neural approaches tend to be much larger than the number of phonemes (Baevski et al., 2020), leading to low scores in standard phoneme discovery metrics. The second approach utilizes weak supervision such as noisy phone labels predicted by a supervised, multilingual ASR system trained on other languages. Along this direction, early works (Schultz and Waibel, 1998; Lööf et al., 2009; Swietojanski et al., 2012) have showed that phonetic knowledge gained from one language can be leveraged to develop ASR systems for another language using an HMM-based or DNN-HMM hybrid approach. Instead of using phone labels, (Stuker et al., 2003) explores the use of articulatory features as supervision for the multilingual ASR. Recently, (Żelasko et al., 2020a,b; Feng et al., 2021a) systematically study the performance of zero-shot crosslingual ASR on 13 languages trained with international phonetic alphabet (IPA) tokens and found that the system tends to perform poorly on unseen languages. Instead, (Feng et al., 2021b) is able to discover phone-like units by clustering bottleneck features (BNF) from a factorized time-delay neural network (TDNN-f) trained with phone labels predicted by a crosslingual ASR (Feng et al., 2021a).

Several works have since shifted focus toward the more challenging phoneme discovery problem by formulating it as a self-supervised learning problem where the semantics of the speech are known, such as from translation, phoneme-level language models or other sensory modalities such as vision. (Jansen, 2013) has studied the use of pairwise word identity labels for training phoneme discovery models based on Gaussian mixture models (GMM); (Harwath and Glass, 2019) analyzes the hidden layers of a two-branch neural network trained to retrieve spoken captions with semantically related images and finds strong correlation between segment representation and phoneme boundaries. (Harwath et al., 2020) adds hierarchical vector quantization (VQ) layers in the same retrieval network and is able to find a much smaller codebook than the unsupervised neural approach (Baevski et al., 2020), and achieve high correlation with the phoneme inventory. (Godard et al., 2018; Boito et al., 2019) has studied the possibility of learning semantic units using an attention-based speech-to-text translation system, though the units appear to correlate more with words. Works on unsupervised speech recognition (Chen et al., 2019) attempt to learn to recognize phonemes by leveraging the semantic information from a phoneme language model unpaired with the speech, typically by matching the empirical prior and posterior distributions of phonemes either using cross entropy (Yeh et al., 2019) or adversarial loss (Chen et al., 2019; Baevski et al., 2021). Such models, however, have a slightly different objective as they assume knowledge about the phoneme inventory of the language and instead tries to find the alignment between the speech and phonemes, rather than induce the phoneme inventory from scratch.

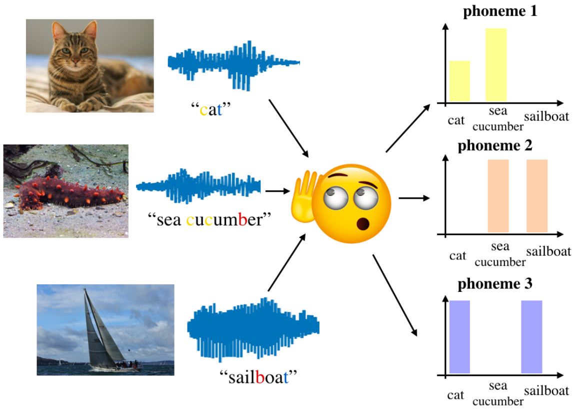

Figure 1: Illustration of semantic-driven phoneme discovery

3 Semantic-driven Phoneme Discovery

3.1 Notation

Throughout the paper, we use $\mathbb{P}\{\cdot\}$ to denote probability. We use capital letters to denote random variables and lower-case letters to represent samples of random variables. We use $P_X := \mathbb{P}\{X = x\}$ to denote both probability mass and density functions of random variable X, depending on whether it is continuous or discrete. Further, denote $P_{Y|X}(y|x) := \mathbb{P}\{Y = y|X = x\}$ as the true conditional probability distribution of random variable $Y = y$ given random variable $X = x$. The probability simplex in $\mathbb{R}^d$ is denoted as Δ^d.

3.2 Statistical Definition of Phonemes

The linguistic definition of phonemes can be rephrased as follows. Define $\mathbb{X}$ to be the set of all physical acoustic segments that can ever be produced as instances of the phonemes of a given language. Definition 1 can be phrased as follows: Two sequences of segments $\boldsymbol{x} = [x_1, \cdots, x_T]$ and $\boldsymbol{x}' = [x_{1:t-1}, x'_t, x_{t+1:T}]$, differing only in that $x'_t \neq x_t$, are instances of different words, $y' \neq y$, if and only if x'_t and x_t are instances of different phonemes. In order to design effective algorithms, we will work with a relaxation of this definition, which we call the statistical definition of phonemes.

Definition 2. *(Statistical definition of phonemes) Let $\mathbb{X}$ be the set of all speech segments in a language, and let X be a random vector taking values in $\mathbb{X}$ and Y be a random variable representing the word of which X is one segment. The phoneme inventory of a language is the minimal partition $\mathbb{Z} = \{\mathbb{Z}_1, \cdots, \mathbb{Z}_K\}$ of $\mathbb{X}$ (i.e., $\mathbb{X} = \cup_{k=1}^K \mathbb{Z}_k, \mathbb{Z}_j \cap \mathbb{Z}_k = \emptyset, \forall 1 \leq j, k \leq K$), such that if a speech segment pair $(x, x') \in \mathbb{X}^2$ satisfies $(x, x') \in \mathbb{Z}_k^2$ for some $k \in \{1, \cdots, K\}$, then their conditional distributions satisfy*

$$P_{Y|X=x} = P_{Y|X=x'}. \tag{1}$$

In other words, given only the knowledge that two acoustic sequences contain instances of the same phoneme, the resulting conditional distributions across possible word labels are the same.

The fundamental intuition of Definition 2 is that different phonemes have different distributions across the words of the language. Two instances of the same phoneme, x and x', might have different likelihoods $P_{X=x|Y}$ and $P_{X=x'|Y}$, e.g., because of allophony; but their posteriors $P_{Y|X=x}$ and $P_{Y|X=x'}$ cannot be different without violating Definition 1. The relationship between Definition 1 and Definition 2 is given by the following proposition, whose proof is in Appendix A.3.

Proposition 1. *Let $\mathbb{Z} = \cup_{k=1}^K \mathbb{Z}_k$ be a partition of $\mathbb{X}$. If, for all possible $\{P_{Y|X=x_s}\}_{s \neq t}$, for any spoken word $\boldsymbol{x} = [x_1, \cdots, x_T]$, and for any segment pairs $(x_t, x'_t) \in \mathbb{Z}_k^2, k \in \{1, \cdots, K\}$, changing x_t*

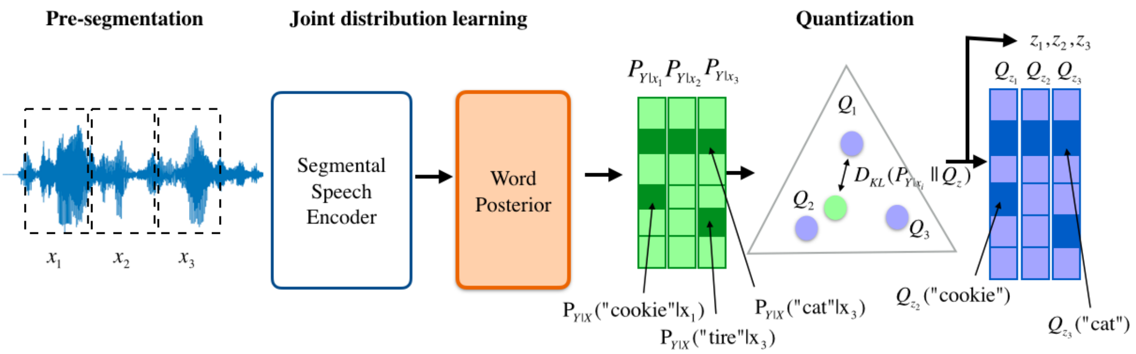

Figure 2: Network architecture of information quantizer

to x'_t does not alter the identity of the word, i.e.,

$$\arg\max_y P_{Y|X_{1:T}}(y|x_{1:t-1}, x'_t, x_{t+1:T}) = \arg\max_y P_{Y|X_{1:T}}(y|\boldsymbol{x}), \quad (2)$$

but for any segment pairs $x_t \in \mathbb{Z}_k, x''_t \in \mathbb{Z}_l$ for $k \neq l$, changing x_t to x'_t alters the identity of the word, i.e.,

$$\arg\max_y P_{Y|X_{1:T}}(y|x_{1:t-1}, x''_t, x_{t+1:T}) \neq \arg\max_y P_{Y|X_{1:T}}(y|\boldsymbol{x}), \quad (3)$$

then $\mathbb{Z}$ is a phoneme inventory from Definition 2.

Define the **phoneme assignment function** $z : \mathbb{X} \to \{1, \cdots, K\}$ such that $z(x) = k$ if $x \in \mathbb{Z}_k$. Suppose a segment X is randomly chosen from $\mathbb{X}$ with probability distribution P_X and its phoneme label is another random variable $Z := z(X)$, then by Definition 2, for any pair $x, x' \in \mathbb{X}$ such that $z(x) = z(x')$, we have $P_{Y|X=x} = P_{Y|X=x'} = P_{Y|Z=z(x)}$. The phoneme inventory is thereby completely characterized by the phoneme label function $z(\cdot)$ as well as the set of distributions associated with each class $P_{Y|Z}$.

3.3 Problem Formulation

Let $z(\cdot)$ be the phoneme assignment function from Definition 2 and assume the size of the phoneme inventory is known to be K.

Given a training set $\mathcal{D} = \{(x^{(i)}, y^{(i)})\}_{i=1}^n$, where each $x^{(i)}$ is an acoustic segment extracted from a spoken word, and each $y^{(i)} \in \mathbb{Y}$ is the corresponding word label, a semantic-driven phoneme discovery (SPD) system tries to find an assignment function that minimizes the **token error rate (TER)**:

$$P_{\text{TER}}(\hat{z}) := \min_{\pi \in \Pi} \mathbb{P}\{z(X) \neq \pi(\hat{z}(X))\}, \quad (4)$$

where Π is the set of all *permutations* of length K, which is used because the problem is unsupervised and $z(\cdot)$ is not available during training. An assignment function $\hat{z}$ is said to achieve **exact discovery** if $P_{\text{TER}}(\hat{z}) = 0$. It can be easily shown that TER is equivalent to standard evaluation metrics for phoneme discovery such as normalized mutual information (NMI) (Yusuf et al., 2020; Harwath et al., 2020; Feng et al., 2021b) and token F1 (Dunbar et al., 2017), as presented in Appendix A.2. Thus, to provide guarantees for NMI and token F1, it suffices to provide a guarantee for TER.

4 Information Quantizer

We solve the SPD problem using a novel type of neural network called an information quantizer (IQ), depicted in Figure 2. An IQ $(\theta, q) \in \Theta \times \mathbb{Q}_K$ consists of four main components: A pre-segmentation network, a speech encoder $e_{\theta_1}(\cdot)$, a word posterior $c_{\theta_2}(\cdot)$ and a quantizer $q : \Delta^{|\mathbb{Y}|} \to \mathbb{C} = \{Q_1, \cdots, Q_K\}$, where $[\theta_1, \theta_2] = \theta$ and $\mathbb{C}$ is the **distribution codebook** and Q_k's are called the **code distributions** of q.

4.1 Phoneme inventory discovery with IQ

IQ performs phoneme discovery in three stages. The pre-segmentation stage takes a raw speech waveform as input and extracts phoneme-level segments $\boldsymbol{x} = [x_1, \cdots, x_T]$ in a self-supervised fashion (Kreuk et al., 2020). Afterwards, in the joint distribution learning stage, the speech encoder extracts phoneme-level representations $e_{\theta_1}(\boldsymbol{x}) = [e_{\theta_1}(x_1), \cdots, e_{\theta_1}(x_T)]$ before passing them into the word posterior network to estimate the distribution of word labels, Y, given the presence in the word of acoustic phonetic segment $X = x$:

$$P^\theta_{Y|X=x_t} = c_{\theta_2}(e_{\theta_1}(x_t)), 1 \leq t \leq T. \quad (5)$$

Note that it is crucial that no recurrent connection exists between segments since our goal is to learn the probability of a word label given the presence of one phoneme segment. Finally, in the quantization stage, the quantizer creates the phoneme inventory by assigning each segment x_t an integer index via **codeword assignment function** $\hat{z}(x_t)$ such that $\hat{z}(x_t) = k$ if $q(P^{\theta}_{Y|X=x_t}) = Q_k$.

4.2 Training

The loss function that IQ minimizes has two goals: learn a good estimator for the conditional distribution $P_{Y|X}$ and learn a good quantization function $q(\cdot)$. The first goal is achieved by minimizing the cross entropy loss:

$$\mathcal{L}_{\text{CE}}(P_n, \theta) := -\frac{1}{n}\sum_{i=1}^{n} \log P^{\theta}_{Y|X}(y^{(i)}|x^{(i)}), \quad (6)$$

where P_n is the empirical joint distribution. The second goal is achieved by minimizing the KL-divergence between the estimated conditional distribution before and after quantization:

$$\mathcal{L}_{\text{Q}}(\tilde{P}_n, \theta, q) := \frac{1}{n}\sum_{i=1}^{n} D_{\text{KL}}(P^{\theta}_{Y|X=x^{(i)}} || q(P^{\theta}_{Y|X=x^{(i)}})), \quad (7)$$

where

$$\tilde{P}_n := \frac{1}{n}\sum_{i=1}^{n} \delta_{x^{(i)}} P^{\theta}_{Y|X=x^{(i)}}$$

is the *smoothed* version of the empirical distribution. The final loss function of IQ for SPD is then:

$$\mathcal{L}_{\text{IQ}}(P_n, \theta, q) := \mathcal{L}_{\text{CE}}(P_n, \theta) + \lambda \mathcal{L}_{\text{Q}}\left(\tilde{P}_n, \theta, q\right), \quad (P_1)$$

where $\lambda > 0$ is some hyperparameter set to approximately 1 for most experiments. Further, we restrict q to be **nearest-neighbor** so that:

$$q(P) = \underset{Q_k: 1 \le k \le K}{\arg\min}\, D_{\text{KL}}(P || Q_k). \quad (8)$$

This restriction does not increase the loss (P_1) and serves as a regularization during phoneme discovery, as shown in Appendix A.3.

4.3 Theoretical Guarantee

We show that when the phoneme segmentation is available and under mild assumption, IQ is able to achieve exact discovery of phoneme inventory. First, let us state the main assumptions of the paper.

Assumption 1. *(boundedness of the density ratio) There exist universal constants $C_l < C_u$ such that $\forall \theta \in \Theta, \forall q \in \mathbb{Q}_K, \forall (x, y) \in \mathbb{X} \times \mathbb{Y}, \log \frac{P_{Y|X}(y|x)}{P^{\theta}_{Y|X}(y|x)} \in [C_l, C_u], \log \frac{P_{Y|X}(y|x)}{q(P^{\theta}_{Y|X}(y|x))} \in [C_l, C_u]$.*

Assumption 2. *(log-smoothness of the density ratio) There exists $\rho > 0$ such that $\forall \theta_1, \theta_2 \in \Theta, x, y \in \mathbb{X} \times \mathbb{Y}, \left|\log \frac{P^{\theta_1}_{Y|X}(y|x)}{P^{\theta_2}_{Y|X}(y|x)}\right| \le \rho \|\theta_1 - \theta_2\|$.*

Assumption 3. *(realizability) There exists a nonempty subset $\Theta^* \subset \Theta$ such that $P^{\theta}_{Y|X} = P_{Y|X}, \forall \theta \in \Theta^*$.*

Assumption 4. *The true prior of the phoneme inventory is known to be $P_Z(z) = \frac{1}{K}, 1 \le z \le K$.*

The first two assumptions are similar to the ones in (Tsai et al., 2020). Assumption 3 assumes that the true probability measure is within the function class, which combined with Assumption 1 requires the true distribution to share the same support as the estimated one. However, such assumption can be relaxed so that $D_{\text{KL}}(P^{\theta^*}_{Y|X} || P_{Y|X}) \le \nu, \forall \theta^* \in \Theta^*$ for some small enough $\nu > 0$, which does not affect the essential idea behind our analysis and can be achieved by some rich class of universal approximators such as neural networks (Hornik et al., 1989). The last assumption ensures the inventory to be identifiable by assuming knowledge of the prior of the phoneme inventory.

Next, we will state the theoretical guarantee before giving some intuitive explanation.

Theorem 1. *Given Assumption 1-4, let the information quantizer $(\hat{\theta}, \hat{q})$ with assignment function $\hat{z}$ be an empirical risk minimizer (ERM) of (P_1):*

$$\mathcal{L}_{IQ}(P_n, \hat{\theta}, \hat{q}) = \min_{\theta \in \Theta, q \in \mathbb{Q}_K} \mathcal{L}_{IQ}(P_n, \theta, q). \quad (9)$$

For any $\delta \in (0, 1]$, with probability at least $1 - \delta$, the cluster assignment function $\hat{z}$ of the ERM information quantizer $\hat{q}$ achieves $P_{TER}(\hat{z}) = 0$ if the sample size n satisfies:

$$n \ge O\left(\frac{\log \frac{1}{\delta}}{\min\{\epsilon^{*2}, \log \frac{K}{K-1}\}}\right), \quad (10)$$

where

$$\epsilon^* = \min_{z_1, z_2 : z_1 \neq z_2} c(z_1, z_2) D_{\text{JS}}(P_{Y|Z=z_1} || P_{Y|Z=z_2})^2$$

for some constants $c(z_1, z_2) > 0, 1 \le z_1, z_2 \le K$ independent of n, δ, $O(x)$ is such that $O(x) \le$

αx for some $\alpha > 0$ and $D_{\text{JS}}(P||Q) := \frac{1}{2}D_{\text{KL}}\left(P||\frac{P+Q}{2}\right) + \frac{1}{2}D_{\text{KL}}\left(Q||\frac{P+Q}{2}\right)$ is the Jensen-Shannon divergence.

The bound in Theorem 1 captures two main factors determining the sample complexity of exact phoneme discovery: the first factor is how close the word distributions of phonemes are from each other as measured by their Jensen-Shannon (JS) divergence, and the second factor is how hard it is for the training data to cover all the phonemes. The theorem works essentially because (P_1) can be viewed as an approximation of the mutual information between the codeword $\hat{z}(X)$ and word type Y, $I(\hat{z}(X); Y)$. Suppose $P^{\hat{\theta}}_{Y|X} \approx P_{Y|X}$ and let $H(\cdot|\cdot)$ denotes conditional entropy, we have:

$$\begin{aligned}
&\mathcal{L}_{IQ}(P_n, \hat{\theta}, \hat{q}) \\
&\approx H(Y|X) + D_{\text{KL}}(P_{Y|X}||\hat{q}(P_{Y|X})) \\
&\propto -I(X;Y) + D_{\text{KL}}(P_{Y|X}||\hat{q}(P_{Y|X})) \\
&= -I(\hat{z}(X);Y),
\end{aligned}$$

which is minimized if $\hat{q}(P_{Y|X}) = P_{Y|z(X)}$. In fact, we prove that $\hat{z}$ for such $\hat{q}$ is equivalent to $z(\cdot)$ up to a permutation in Appendix A.3.

(3b)

Figure 3: Left: Manner-level t-SNE plot by IQ with $|\mathbb{Y}| = 824$ and gold segmentation on TIMIT. Right: Distribution of codeword assignment for each phoneme by IQ with $|\mathbb{Y}| = 824$ and predicted segmentation on TIMIT. Each row of the plot is the empirical distribution for $P_{\hat{Z}|Z}(\cdot|z), 1 \leq z \leq K$, where the phonemes are sorted top-to-bottom with decreasing $\max_{z'} P_{\hat{Z}|Z}(z'|z)$.

5 Experimental Setup

Datasets We construct four training datasets consisting of spoken words only. The vocabulary set with $|\mathbb{Y}| = 224$ is selected from head words of noun phrases from the Flickr30kEntities dataset (Hodosh et al., 2010) that appear at least 500 times. For the Flickr audio word dataset, spoken words in the vocabulary are extracted from Flickr audio dataset (Harwath and Glass, 2015). For the Librispeech and TIMIT word dataset with $|\mathbb{Y}| = 224$, spoken words are extracted from Librispeech (Vassil et al., 2015) 460-hour train-clean subset, resulting in a dataset of about 6 hours and 0.1 hours; for Librispeech and TIMIT word dataset with $|\mathbb{Y}| = 524$ and $|\mathbb{Y}| = 824$, we supplement the dataset with the speech for the top 300 frequent words and top 600 frequent words respectively (excluding the visual words) in Librispeech, resulting in datasets of about 15 and 21 hours. For Mboshi dataset, we found only about 20 actual words occur more than 100 times, so instead we use n-grams with either $n \geq 3$ (all except uni- and bi-grams) or $n \geq 2$ (all except unigrams) that occur more than 100 times as "words", resulting in a vocabulary size of 161 and 377 respectively. Note that the amount of labeled data we need is much lower than previous works (Yusuf et al., 2020): around 30 hours, (Feng et al., 2021b): around 600 hours) and the vocabulary size used is much smaller than the total vocabulary size in the language. More details of the sets can be found in Appendix B. We also test our models on two standard phoneme discovery benchmarks, which contain whole-sentence utterances with many words unseen during training. The first dataset is TIMIT (Garofolo et al., 1993), an English corpus consisting of about 5 hours speech and Mboshi (Godard et al., 2017), which contains about 2.4 hours speech from a low-resource language. For both datasets, we follow the split in (Yusuf et al., 2020), (Feng et al., 2021b)

Baselines For phoneme discovery from segmented words, we compare our model (IQ) to four baselines. The first two baselines use continuous representation: the CPC+k-means model performs k-means clustering on the segment-level CPC features, and the k-means model performs k-means clustering after the model is trained on the word recognition task. The last two baselines use discrete representations: the Gumbel variational information bottleneck (Alemi et al., 2017) (Gumbel VIB) is a neural model with a Gumbel softmax (Jang et al., 2016) layer to approximate the codebook assignment function $z(\cdot)$, and we set $\beta = 0.001$ and decay the temperature of the Gumbel softmax from 1 to 0.1 linearly for the first 300000 steps, keeping it at 0.1 afterwards, which works best in our experiments; the deterministic information bottleneck (DIB), a generalization of (Strouse and Schwab, 2016) for continuous feature variable X, which assumes the same deterministic relation between speech X and codebook unit Z as ours, but optimizes the models in a pipeline fashion (first the speech encoder and then the quantizer) by performing clustering on the learned conditional distributions. The CPC features used are trained in a self-supervised fashion on the 960-hour LibriSpeech dataset and released by (Nguyen et al., 2020). All models share the same speech encoder as IQ. For the whole-sentence datasets, we compare our models to three phoneme discovery systems, namely, the unsupervised H-SHMM trained with multilingual speech (Yusuf et al., 2020), the ResDAVEnet-VQ (Harwath et al., 2020) with visual supervision and the TDNN-f system by (Feng et al., 2021b) trained with multilingual speech. To study how well our model performs in extreme low-resource speech recognition compared to other neural speech representation learning models, we compare our models to wav2vec (Schneider et al., 2019), wav2vec 2.0 (Baevski et al., 2020) (small, trained on the 960-hour LibriSpeech), vq-wav2vec with Gumbel softmax and k-means as discretization strategies (Baevski et al., 2019), CPC (van den Oord et al., 2019) and VQ-CPC (van Niekerk et al., 2020), using the pretrained models released by the authors. Implementation details of the baselines and our models are in Appendix C.

Evaluation metrics Standard metrics are used such as NMI and boundary F1 for the quality of codebook and segmentation respectively with the same implementation as in prior works (Yusuf et al., 2020; Feng et al., 2021b). In addition, token F1 (Dunbar et al., 2017) is also reported. To examine the benefit of using our discovered phoneme inventory for low-resource speech recognition, we also evaluate using *equivalent phone error rate* (equiv. PER: Ondel et al. 2019). This metric can be viewed as a proxy for phone error rate (PER) applicable beyond supervised speech recognizers.

6 Results

6.1 Word-level Phoneme Discovery

The results on visual word-only test sets of Flickr audio and Librispeech are shown in Table 1. On both datasets, IQ outperforms both Gumbel VIB and DIB in terms of all metrics, especially on Flickr

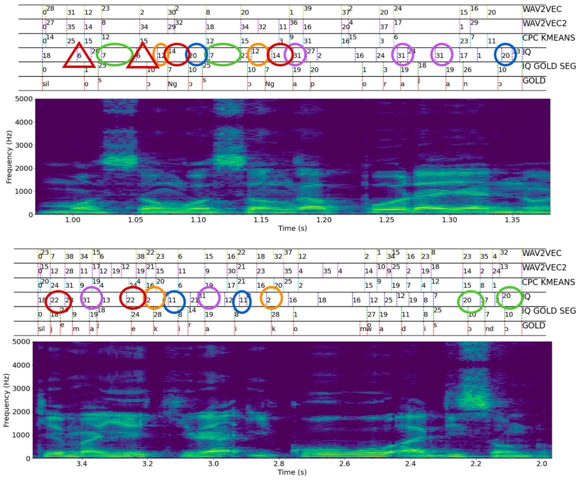

Figure 4: The spectrograms annotated with the gold transcripts and the zero-resource transcriptions by various models for two Mboshi utterances. The spoken segments are in circles of the same colors are identified as the same phoneme by our IQ model and in triangles of the same color if they are but are acoustically similar.

audio, which has more phonemes than Librispeech and a larger test set. Moreover, the performance of IQ is very robust to the codebook size, achieving good results even when the codebook size is very different from the size of the true phoneme inventory, suggesting our theory may be able to work with a relaxed Assumption 4.

6.2 Sentence-level Phoneme Discovery

The results on TIMIT and Mboshi are shown in Table 2 and Table 3a respectively. On TIMIT, our model is able to outperform the visually grounded baseline (Harwath et al., 2020) for all training vocabulary, and all three baselines for $|\mathbb{Y}| = 524$ and $|\mathbb{Y}| = 824$ with and without gold segmentation in terms of all three metrics. Further, we also empirically verify the sample complexity bound in Theorem 1 as IQ performs better in Token F1 and NMI as the training vocabulary size get larger, which generally increases the JS divergence. On Mboshi, IQ with CPC feature consistently outpeforms (Feng et al., 2021b) in token F1 and boundary F1, and IQ with CPC+BNF features consistently outperform (Feng et al., 2021b) in all three metrics under various level of word supervision. The performance of our model on Mboshi compared with other neural self-supervised models are shown in Table 3b. We found that IQ outperforms the best self-supervised model, CPC+k-means in equiv. PER by 34% and 20% absolute with and without gold segmentation respectively and 12% absolute in terms of boundary F1, suggesting that IQ is able to learn consistent phoneme-like sequence useful for zero-resource or extremely low-resource speech recognition.

Effect of segmentation and codebook size The use of unsupervised phoneme segmentation deteriorates the NMI by about 18% and 28% absolute on TIMIT and Mboshi respectively for our models since the distributional property of phonemes does not apply exactly to non-phoneme segments. On the other hand, in Appendix F we show that the quality of codeword assignments by IQs is very robust against varying codebook size, after experimenting with codebook size from 30 to 70 on TIMIT and Mboshi.

Multilingual and word supervision are complimentary In all vocabulary sizes, concatenating the multilingual BNF from (Feng et al., 2021b) to the CPC output representation from the segmental speech encoder in Figure 2 significantly improves token F1 and NMI to allow our best models to outperform baselines in all three metrics.

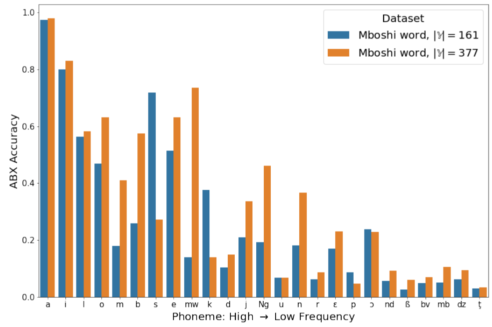

Figure 5: ABX phoneme identification accuracy vs phoneme frequency on the Mboshi dataset for IQ trained with vocabulary size 161 and 377.

6.3 Analysis

IQ codebook resembles true phonemes From Figure 3b, we observe that the codeword assignments by IQ correlates well with the actual phonemes, but tends to confuse the most between phonemes within the same manner class, such as nasals /n/ and /m/. This is also confirmed by the t-SNE plot in Figure 3a, where the embeddings of most manner classes are well-clustered, except for related manner classes such as affricate and fricative, or glide and vowel. Further, from the examples shown in Figure 4, we can see that IQ is not only better at grouping segments of the same phonemes but also at detecting segment boundaries than the baselines. Also, across different examples, IQ assign the same codes to phonemes such as /a/ (31) and /s/ (7) more consistently than other models do. Please check Appendix G for more speech examples.

Limitation While our theory predicts that with gold segmentation, the TER of IQ is asymptotically zero, in practice TER is nonzero due to the violation of Assumption 4, i.e., the phonemes are not uniformly distributed for languages such as Mboshi. As a result, the model often discards information of the rare phonemes by merging them into a more frequent phoneme cluster. Evidently, from Figure 5, where we use ABX accuracy (Munson and Gardner, 1950) to score how reliable the IQ codebook can identify segments of the same phoneme, we observe a strong correlation is observed between ABX accuracy and the frequency of the phonemes.

7 Conclusion

Motivated by the linguistic definition of phonemes, we propose information quantizer (IQ), a new neural network model for self-supervised phoneme discovery that can take advantage of word-level supervision. We demonstrate in two ways that word-level supervision is beneficial for phoneme inventory discovery: theoretically, we prove that IQ can achieve zero token error rate asymptotically with the help of word labels; empirically, we show that IQ out-performs various speech-only algorithms in phoneme discovery tasks under both simulated (English) and realistic (Mboshi) low-resource settings. In the future, we would like to apply the discovered phoneme inventory to develop better low-resource speech technologies such speech translation and speech synthesis systems.

A Proofs of Theoretical Results

A.1 Statistical definition of phonemes

Proof of Proposition 1. Without loss of generality, suppose $(x_1, x_1') \in \mathbb{X}^2$, suppose there exists y_1 such that

$$P_{Y|X}(y_1|x_t) > P_{Y|X}(y_1|x_t'),$$

then there exists y_2 such that

$$P_{Y|X}(y_2|x_t) < P_{Y|X}(y_2|x_t'),$$

which means there exists $0 \leq \alpha_1, \alpha_2 \leq 1, \alpha_1 + \alpha_2 \leq 1$, such that

$$\frac{P_{Y|X}(y_1|x_t')}{P_{Y|X}(y_2|x_t')} \leq \frac{\alpha_2}{\alpha_1} < \frac{P_{Y|X}(y_1|x_t)}{P_{Y|X}(y_2|x_t)}.$$

Now, since Equation 2 holds for arbitrary $P_{Y|X=x_s} \in \Delta^{|\mathbb{Y}|}, s \neq t$, we can set

$$P_{Y|X}(y_1|x_2) = \alpha_1, P_{Y|X}(y_2|x_2) = \alpha_2,$$
$$P_{Y|X}(y_1|x_t) = P_{Y|X}(y_2|x_t) = \frac{1}{2}, \forall t > 2,$$

in which case Equation 2 boils down to

$$\arg\max_{i\in\{1,2\}} \alpha_i P_{Y|X}(y_i|x_1) = \arg\max_{i\in\{1,2\}} \alpha_i P_{Y|X}(y_i|x_1').$$

However, by the choice of α_i's, the left-hand side is y_1 since $\alpha_1 P_{Y|X}(y_1|x_1) > \alpha_2 P_{Y|X}(y_2|x_1)$ and the right-hand side is y_2 since $\alpha_2 P_{Y|X}(y_2|x_1) > \alpha_1 P_{Y|X}(y_1|x_1')$, and therefore Equation 2 cannot hold. Therefore, Equation 2 is true only if $P_{Y|X}(y|x_1) = P_{Y|X}(y|x_1'), \forall (x_1, x_1') \in \mathbb{X}^2, y \in \mathbb{Y}$. $\square$

A.2 Equivalence of TER and standard phoneme discovery metrics

Consider the groundtruth assignment $z(\cdot)$ and a codebook assignment $\hat{z}(\cdot)$ with $\hat{K}$ code words, the NMI of $\hat{z}$ is defined as:

$$\text{NMI}(\hat{z}) = \frac{2I(z(X);\hat{z}(X))}{H(z(X))+H(\hat{z}(X))}, \tag{11}$$

where $H(\cdot)$ denotes the entropy and $I(\cdot;\cdot)$ denotes the mutual information.

which is also related to the **token F1** used for acoustic unit discovery (Dunbar et al., 2017). Since SPD is an unsupervised learning problem and ground truth phoneme labels are not available, matching between codebook indices and phoneme units is needed. When computing token F1, we consider two different many-to-one mappings $\pi_{\text{rec}} : \{1, \cdots, K\} \to \{1, \cdots, \hat{K}\}$ and $\pi_{\text{prec}} : \{1, \cdots, \hat{K}\} \to \{1, \cdots, K\}$ to compute the token recall and precision respectively as:

$$\text{Rec}(\hat{z}) := \max_{\pi_{\text{rec}}} \mathbb{P}\{\hat{z}(X) = \pi_{\text{rec}}(z(X))\} \tag{12}$$

$$\text{Prec}(\hat{z}) := \max_{\pi_{\text{prec}}} \mathbb{P}\{z(X) = \pi_{\text{prec}}(\hat{z}(X))\}, \tag{13}$$

before computing the harmonic mean between the two to obtain token F1: $\text{F1}(\hat{z}) := \frac{2\text{Prec}(\hat{z})\text{Rec}(\hat{z})}{\text{Prec}(\hat{z})+\text{Rec}(\hat{z})}$. The following proposition relates TER with token F1 and NMI.

Proposition 2. *For any assignment function* $\hat{z} : \{1, \cdots, K\} \to \{1, \cdots, K\}$, $P_{TER}(\hat{z}) = 0$ *if and only if* $F1(\hat{z}) = NMI(\hat{z}) = 1$.

Proof. First of all, for such $\hat{z}$, we have

$$\begin{aligned} 1 &\ge \text{F1}(\hat{z}) \ge \min\{\text{Prec}(\hat{z}), \text{Rec}(\hat{z})\} \\ &\ge 1 - P_{\text{e, TER}}(\hat{z}) = 1, \end{aligned}$$

where the third inequality comes from the fact that the set of permutations is a smaller set than the set of all many-to-one mappings $\pi : \{1, \cdots, K\} \to \{1, \cdots, K\}$. Further, using the fact that z and $\hat{z}$ are functions of each other when $P_{TER}(\hat{z}) = 0$, it can be shown that $NMI(\hat{z}) = \frac{2I(z(X),\hat{z}(X))}{H(z(X))+H(\hat{z}(X))} = 2H(z(X))/2H(z(X)) = 1$. ☐

A.3 Exact Discovery Guarantee

First, we prove the claim made in Section 4.2 about nearest neighbor information quantizers. Recall the definition of general and nearest-neighbor information quantizers as follows.

Definition 3. *(Information quantizer) A K-point information quantizer is a function $q : \Delta^{|\mathbb{Y}|} \to \mathbb{C} = \{Q_1, \cdots, Q_K\} \subset \Delta^{|\mathbb{Y}|}$, where $\mathbb{C}$ is called the codebook and Q_k's are called the code distributions. Further, define $\mathbb{Q}_K$ to be the class of such functions.*

Definition 4. *(Nearest-neighbor Information quantizer) A K-point information quantizer is called nearest-neighbor if, $\forall P \in \Delta^{|\mathbb{Y}|}$, $D_{\text{KL}}(P||q(P)) = \min_{1 \le k \le K} D_{\text{KL}}(P||Q_k)$. Further, define $\mathbb{Q}_K^{NN} \subset \mathbb{Q}_K$ to be the class of such functions.*

Then we have the following lemma.

Lemma 1. *There exists an information quantizer $\hat{\theta}_n \in \Theta, \hat{q}_n \in \mathbb{Q}_K^{NN}$ such that*

$$\mathcal{L}_{IQ}(P_n, \hat{\theta}_n, \hat{q}_n) = \min_{\theta \in \Theta, q \in \mathbb{Q}_K} \mathcal{L}_{IQ}(P_n, \theta, q). \tag{14}$$

Therefore, $(\hat{\theta}_n, \hat{q}_n)$ is an ERM of (P_1).

Proof of Lemma 1. Notice that only the $\mathcal{L}_Q$ term of Equation P_1 depends on q, so it suffices to show that $\min_{q \in \mathbb{Q}_K^{\text{NN}}} \mathcal{L}_Q(\tilde{P}_n, q) \le \min_{q \in \mathbb{Q}_K} \mathcal{L}_Q(\tilde{P}_n, q)$. This is true since

$$\begin{aligned} &\min_{q \in \mathbb{Q}_K} \mathcal{L}_Q(\tilde{P}_n, q) \\ =& \min_{q \in \mathbb{Q}_K} \mathbb{E}_{\tilde{P}_n}[D_{\text{KL}}(P^{\theta}_{Y|X}||q(P^{\theta}_{Y|X}))] \\ \ge& \mathbb{E}_{\tilde{P}_n}[\min_{1 \le k \le K} D_{\text{KL}}(P^{\theta}_{Y|X}||Q_k)] \\ =& \min_{q \in \mathbb{Q}_K^{\text{NN}}} \mathbb{E}_{\tilde{P}_n}[D_{\text{KL}}(P^{\theta}_{Y|X}||q(P^{\theta}_{Y|X}))] \\ =& \min_{q \in \mathbb{Q}_K^{\text{NN}}} \mathcal{L}_Q(\tilde{P}_n, q), \end{aligned}$$

where the inequality holds since

$$D_{\text{KL}}(P^{\theta}_{Y|X}||q(P^{\theta}_{Y|X})) \ge \min_{1 \le k \le K} D_{\text{KL}}(P^{\theta}_{Y|X}||Q_k)$$

for any $q \in \mathbb{Q}_K$. ☐

Next, we show under the condition $P^{\theta}_{Y|X} = P_{Y|X}$ and $n \to \infty$, (P_1) recovers $z(\cdot)$ up to a permutation.

Proposition 3. *The pair $(z^*, P^*_{Y|Z})$ is a minimizer to the following optimization problem:*

$$\max_{\hat{z}: \mathbb{X} \to \{1, \cdots, K\}, P_{Y|Z} \in \Delta^{|\mathbb{Y}|}} I(\hat{z}(X); Y), \tag{P_0}$$

if and only if z^* is equal to the true assignment function z up to a permutation.

Proof. $\Rightarrow$: First, $z(\cdot)$ is a feasible solution by definition. By data processing inequality, we have

$$I(z'(X);Y) \leq I(X;Y) = I(z(X);Y).$$

Therefore, $z(\cdot)$ is also the optimal solution.

$\Leftarrow$: Suppose there exists some optimal $(\hat{z}, \hat{P}_{Y|Z})$ with $\hat{P}_{Y|\hat{z}(x)} \neq P_{Y|z(x)}$ for at least one $x \in \mathcal{X}$. Since such discrepancies are independent with each other, it suffices to show that each such discrepancy leads to lower $I(Z;Y)$. Indeed, for $(\hat{z}, \hat{P}_{Y|Z})$ with $\hat{P}_{Y|Z=\hat{z}(x)} \neq P_{Y|Z=z(x)}$ only at x,

$$\begin{aligned} & I(\hat{z}(X);Y) - I(z(X);Y) \\ =& P_X(x)\sum_y P_{Y|X}(y|x)\log\frac{\hat{P}_{Y|Z=\hat{z}(x)}}{P_{Y|Z=z(x)}} \\ =& -P_X(x)D(P_{Y|Z=z(x)}||\hat{P}_{Y|Z=\hat{z}(x)}) < 0, \end{aligned}$$

which contradicts the optimality of $\hat{z}$. Therefore, $\hat{P}_{Y|\hat{z}(x)} = P_{Y|z(x)}$ for all optimal solution of (P_0). □

To prove Theorem 1, we also need the following lemma.

Lemma 2. *Under Assumption 3, for any bounded parameter set* Θ, *there exists* $\gamma > 0$ *and some optimal parameter* $\theta^* \in \Theta^*$ *such that*

$$D_{\mathrm{KL}}(P^{\theta}_{Y|X}||P^{\theta^*}_{Y|X}) \geq \gamma\|\theta - \theta^*\|, \forall\theta \in \Theta.$$

Proof. We prove the lemma by contradiction. First, we assume $\theta \notin \Theta^*$ since the inequality satisfies trivially for any $\theta \in \Theta^*$. By boundedness, there exists some $R > 0$ such that $\|\theta\| \leq R$. Suppose for any $\gamma > 0$, there exists some $\theta \in \Theta$ such that $D_{\mathrm{KL}}(P^{\theta}_{Y|X}||P^{\theta^*}_{Y|X}) \leq \gamma\|\theta - \theta^*\| \leq 2\gamma R$, then we have $D_{\mathrm{KL}}(P^{\theta}_{Y|X}||P^{\theta^*}_{Y|X}) \leq \inf_{\gamma>0}\gamma R = 0$. However, since $D_{\mathrm{KL}}(P^{\theta}_{Y|X}||P^{\theta^*}_{Y|X}) \geq 0$, we have $D_{\mathrm{KL}}(P^{\theta}_{Y|X}||P^{\theta^*}_{Y|X}) = 0$, which implies $\theta \in \Theta^*$ and leads to contradiction. □

Note it is crucial that the parameter set is bounded, which is the case for neural nets. Further, Assumption 3 is needed or the inequality can be easily violated when the optimal parameter set Θ^* is empty.

Next, we need the following lemma, which is based on (Tsai et al., 2020):

Lemma 3. *Under Assumptions 1-3, and consider* $\hat{\theta}$ *to be part of the ERM of* (P_1) *with conditional distribution* $\hat{P}_{Y|X} := P^{\hat{\theta}}_{Y|X}$. *Then for any* $\epsilon > 0$, *the following inequality holds:*

$$\begin{aligned} & \mathbb{P}\left\{\sup_{x\in\mathbb{X}} D_{\mathrm{KL}}(P_{Y|X=x}||\hat{P}_{Y|X=x}) > \epsilon\right\} \\ \leq & 2\left|\mathcal{N}(\Theta, \frac{\epsilon}{4\rho})\right|\exp\left(-\frac{\gamma^2 n\epsilon^2}{2\rho^2(C_u - C_l)^2}\right), \end{aligned} \tag{15}$$

where $\mathcal{N}(A, \epsilon)$ *is the* ϵ*-net of set* A.

Proof. For notational ease, we drop the dependence of $\mathcal{L}_{\mathrm{CE}}$ on P if the context is clear. Using Assumption 3, let $P_{Y|X} = P^{\theta^*}_{Y|X}$. Define $D_n(P||Q)$ as the empirical KL divergence. Further, notice that for $P_{Y|X}$, $\mathcal{L}_Q$ can always be made 0 and therefore, the ERM of P_1 needs to satisfy $\mathcal{L}_{\mathrm{CE}}(\hat{\theta}) \leq \mathcal{L}_{\mathrm{CE}}(\theta^*)$. As a result,

$$\begin{aligned} & D_n(P_{Y|X}||\hat{P}_{Y|X}) \\ :=& \mathbb{E}_{P_n}\left[\log\frac{P_{Y|X}(Y|X)}{\hat{P}_{Y|X}(Y|X)}\right] \\ =& \mathcal{L}_{\mathrm{CE}}(\hat{\theta}) - \mathcal{L}_{\mathrm{CE}}(\theta^*) \leq 0. \end{aligned}$$

Note that $D_n(P||Q)$ is an unbiased estimator of the conditional KL divergence between distributions P and Q: $\mathbb{E}_{P_{X^n,Y^n}}\mathbb{E}_{P_n}\log\frac{P_{Y|X}(Y|X)}{Q_{Y|X}(Y|X)} = D_{\mathrm{KL}}(P_{Y|X}||Q_{Y|X})$. Therefore, let $\Delta_n(\theta) := D_n(P_{Y|X}||P^{\theta}_{Y|X}) - D_{\mathrm{KL}}(P_{Y|X}||P^{\theta}_{Y|X})$,

$$\begin{aligned} & \mathbb{P}\left\{D_{\mathrm{KL}}(P_{Y|X}||\hat{P}_{Y|X}) > \epsilon\right\} \leq \\ & \mathbb{P}\left\{D_{\mathrm{KL}}(P_{Y|X}||\hat{P}_{Y|X}) - D_n(P_{Y|X}||\hat{P}_{Y|X}) > \epsilon\right\} \\ & \leq \mathbb{P}\left\{|\Delta_n(\theta)| > \epsilon\right\} \leq \mathbb{P}\left\{\sup_{\theta\in\Theta}|\Delta_n(\theta)| > \epsilon\right\}. \end{aligned}$$

To bound the last probability, consider an $\frac{\epsilon}{4\rho}$-net in the parameter space $\mathcal{N}(\Theta, \frac{\epsilon}{4\rho})$ and $\Theta = \cup_{k=1}^{|\mathcal{N}(\Theta,\frac{\epsilon}{4\rho})|}\Theta_k$, where Θ_k is the $\frac{\epsilon}{4\rho}$-ball surrounding $\theta_k \in \mathcal{N}(\Theta, \frac{\epsilon}{4\rho})$, we have $\forall\theta \in \Theta_k$,

$$\begin{aligned} & \mathbb{P}\left\{\sup_{\theta\in\Theta}|\Delta_n(\theta)| > \epsilon\right\} \\ \leq & \sum_{k=1}^{\left|\mathcal{N}(\Theta,\frac{\epsilon}{4\rho})\right|}\mathbb{P}\left\{\sup_{\theta\in\Theta_k}|\Delta_n(\theta)| > \epsilon\right\} \leq \\ & \left|\mathcal{N}(\Theta, \frac{\epsilon}{4\rho})\right|\sup_k\mathbb{P}\left\{\sup_{\theta\in\Theta_k}|\Delta_n(\theta)| > \epsilon\right\}. \end{aligned} \tag{16}$$

Further, by Assumption 2, we have

$$\begin{aligned}&\sup_{\theta\in\Theta_k}|\Delta_n(\theta)-\Delta_n(\theta_k)|\le\\&\sup_{\theta\in\Theta_k}\left|D_n(P_{Y|X}||P^{\theta}_{Y|X})-D_n(P_{Y|X}||P^{\theta_k}_{Y|X})\right|\\&+\left|D_{\mathrm{KL}}(P_{Y|X}||P^{\theta}_{Y|X})-D_{\mathrm{KL}}(P_{Y|X}||P^{\theta_k}_{Y|X})\right|=\\&\mathbb{E}_{P_n}\left|\log\frac{P^{\theta_k}_{Y|X}(Y|X)}{P^{\theta}_{Y|X}(Y|X)}\right|\\&+\mathbb{E}_{P_{XY}}\left|\log\frac{P^{\theta_k}_{Y|X}(Y|X)}{P^{\theta}_{Y|X}(Y|X)}\right|\le 2\rho\|\theta_k-\theta\|\le\frac{\epsilon}{2}.\end{aligned}$$

As a result,

$$\begin{aligned}&\mathbb{P}\left\{\sup_{\theta\in\Theta_k}|\Delta_n(\theta)|>\epsilon\right\}\\\le&\mathbb{P}\left\{|\Delta_n(\theta_k)|+\sup_{\theta\in\Theta_k}|\Delta_n(\theta)-\Delta_n(\theta_k)|>\epsilon\right\}\\\le&\mathbb{P}\left\{|\Delta_n(\theta_k)|>\frac{\epsilon}{2}\right\}\\\le&2\exp\left(-\frac{n\epsilon^2}{2(C_u-C_l)^2}\right),\end{aligned}$$

by Assumption 1 and Hoeffding's inequality. Plugging this into (16), we arrive at

$$\begin{aligned}&\mathbb{P}\left\{D_{\mathrm{KL}}(P_{Y|X}||\hat{P}_{Y|X})>\epsilon\right\}\\\le&2\left|\mathcal{N}(\Theta,\frac{\epsilon}{4\rho})\right|\exp\left(-\frac{n\epsilon^2}{2(C_u-C_l)^2}\right).\end{aligned}\tag{17}$$

To prove uniform convergence, use Assumption 2 to conclude that:

$$\begin{aligned}&D_{\mathrm{KL}}(P_{Y|X=x}||\hat{P}_{Y|X=x})\\=&\sum_y P_{Y|X}(y|x)\log\frac{P^{\theta^*}_{Y|X}(y|x)}{P^{\hat{\theta}_n}_{Y|X}(y|x)}\\\le&\sup_y\left|\log\frac{P^{\theta^*}_{Y|X}(y|x)}{P^{\hat{\theta}_n}_{Y|X}(y|x)}\right|\le\rho\|\theta^*-\hat{\theta}_n\|,\end{aligned}$$

for some $\theta^*\in\Theta^*$. Therefore, using Lemma 2, we arrive at the desired result:

$$\begin{aligned}&\mathbb{P}\left\{\sup_{x\in\mathbb{X}}D_{\mathrm{KL}}(P_{Y|X=x}||\hat{P}_{Y|X=x})\ge\epsilon\right\}\\\le&\mathbb{P}\left\{\|\theta^*-\hat{\theta}_n\|\ge\frac{\epsilon}{\rho}\right\}\\\le&\mathbb{P}\left\{D_{\mathrm{KL}}(P_{Y|X}||\hat{P}_{Y|X})\ge\frac{\gamma\epsilon}{\rho}\right\}\\\le&2\left|\mathcal{N}(\Theta,\frac{\epsilon}{4\rho})\right|\exp\left(-\frac{\gamma^2n\epsilon^2}{2\rho^2(C_u-C_l)^2}\right).\end{aligned}$$

□

Next, we prove the following lemma by performing a perturbation analysis on (P_1) inspired by (Qiu et al., 2019).

Lemma 4. *Consider some subset of speech segments* $\mathcal{D}\subset\mathbb{X}$ *such that for any* $1\le z\le K$, *there exists* $x\in\mathbb{X}$ *such that* $z(x)=z$. *Further, suppose there exists* $\epsilon>0$ *such that* $\|\hat{P}_{Y|X=x}-P_{Y|X=x}\|_1\le\epsilon,\forall x\in\mathcal{D}$. *Then,* $\forall x\in\mathbb{X}$, $\|\hat{q}(\hat{P}_{Y|X=x})-P_{Y|X=x}\|_1\le c_1\epsilon^{1/2}$ *for some constant* $c_1>0$.

Proof. We first prove the statement for the segments from the set $\mathcal{D}$. By the definition of ERM,

$$\begin{aligned}&\mathcal{L}_Q(P_n,\hat{q})-\mathcal{L}_Q(P_n,q^*)&(18)\\=&\mathbb{E}_{\tilde{P}_n}\left[\log\frac{P_{Y|X}(Y|X)}{\hat{q}(\hat{P}_{Y|X}(Y|X))}\right]\le 0.&(*)\end{aligned}$$

From the condition in the lemma, we have $\hat{P}_{Y|X=x}=P_{Y|X=x}+\epsilon\phi_x$ for some $\epsilon\in[0,1]$ and $\phi_x\in\mathbb{R}^{|\mathbb{Y}|},\phi_x^\top\mathbf{1}=0,\|\phi_x\|_1\le 1,\forall x\in\mathcal{D}$. Further, suppose $q(\hat{P}_{Y|X})=P_{Y|X}+\delta\psi_x$ for some $\delta\in[0,1]$ and $\psi_x\in\mathbb{R}^{|\mathbb{Y}|},\psi_x^\top\mathbf{1}=0,\|\psi_x\|_1\le 1,\forall x\in\mathbb{X}$. Using Assumption 1 and the inequality $\log(1+x)\le x-\frac{x^2}{4},\forall x\in(-1,1]$, we have

$$\begin{aligned}&\sum_y\hat{P}_{Y|X}(y|x)\log\frac{P_{Y|X}(y|x)}{\hat{q}(\hat{P}_{Y|X}(y|x))}\\=&-\sum_y P_{Y|X}(y|x)\log\left(1+\delta\frac{\psi_x(y)}{P_{Y|X}(y|x)}\right)\\&-\sum_y\epsilon\phi_x(y)\log\frac{P_{Y|X}(y|x)}{\hat{q}(\hat{P}_{Y|X}(y|x))}\\\ge&\sum_y\frac{\delta^2\psi_x^2(y)}{4P_{Y|X}(y|x)}-C_u\epsilon\ge\frac{\delta^2\|\psi_x(y)\|^2}{4}\\\ge&\frac{\delta^2}{4|\mathbb{Y}|}-C_u\epsilon,\end{aligned}$$

for every $x\in\mathcal{D}$. Therefore, to maintain (18), we need $\delta^2\le 4C_u|\mathbb{Y}|\epsilon$ for the training examples X^n and the inequality in the lemma holds for examples from $\mathcal{D}$ with coefficient $c_1':=2\sqrt{C_u|\mathbb{Y}|}$.

To show the same claim holds for any unseen segments $x'\in\mathbb{X}\backslash\mathcal{D}$, we first use Lemma 1 to conclude that there always exists a nearest-neighbor information quantizer $\hat{q}$ that is an ERM. Further, since every phoneme class occurs in $\mathcal{D}$, we can always find $x\in\mathcal{D}$ such that $z(x)=z(x')$. Therefore, using the inequality $\log(1+x)\ge x-\frac{x^2}{1+x},\forall x>-1$, we have

$$\begin{aligned}
&\frac{1}{2}\|\hat{P}_{Y|X=x'} - \hat{q}(\hat{P}_{Y|X=x'})\|_1^2 \\
&\leq D(\hat{P}_{Y|X=x'}||\hat{q}(\hat{P}_{Y|X=x'})) \\
&\leq D(\hat{P}_{Y|X=x'}||q(\hat{P}_{Y|X=x})) \\
&\leq D(P_{Y|X=x'}||q(\hat{P}_{Y|X=x})) \\
&+ \epsilon|D(P_{Y|X=x'}||q(\hat{P}_{Y|X=x'})) \\
&\qquad - D(P_{Y|X=x'}||\hat{P}_{Y|X=x'})| \\
&\leq D(P_{Y|X=x'}||q(\hat{P}_{Y|X=x})) + \epsilon(C_u - C_l) \\
&\leq \sum_y \frac{\delta^2\psi_{x'}(y)^2}{\hat{P}_{Y|X}(y|x_j)} + \epsilon(C_u - C_l) \\
&\leq \frac{e^{C_u}\delta^2}{\min_{y:P_{Y|X}(y|z(x'))>0} P_{Y|Z}(y|z(x'))} \\
&\quad + \epsilon(C_u - C_l) \leq a_1\epsilon,
\end{aligned}$$

where

$$a_1 := \frac{e^{C_u}c_1'^2}{\min_{y:P_{Y|Z}(y|z(x'))>0} P_{Y|Z}(y|z(x'))} + C_u - C_l > c_1'^2.$$

Notice that the minimum is taken over y's with nonzero probabilities due to the boundedness conditions in Assumption 1, which asserts $\phi_x(y) = \psi_x(y) \equiv 0$ for y's with zero probabilities. Finally, using triangular inequality:

$$\begin{aligned}
&\|P_{Y|X=x'} - \hat{q}(\hat{P}_{Y|X=x'})\|_1 \\
&\quad \leq \|\hat{P}_{Y|X=x'} - \hat{q}(\hat{P}_{Y|X=x'})\|_1 + \\
&\qquad \|\hat{P}_{Y|X=x'} - P_{Y|X=x'}\|_1 \\
&\qquad\qquad \leq \sqrt{2a_1\epsilon} + \epsilon \leq c_1\sqrt{\epsilon}
\end{aligned}$$

where $c_1 := \sqrt{2a_1} + 1$ is the coefficient in the lemma. □

Now we are ready to prove Theorem 1.

Proof of Theorem 1. Define the event $C_\epsilon := \{\sup_{x\in\mathbb{X}} D(P_{Y|X=x}||\hat{P}_{Y|X=x}) < \epsilon\}$. Further, suppose Θ is within the ball of radius R in $\mathbb{R}^d$. By Lemma 3, we have:

$$P(C_\epsilon) \geq 1 - \exp(-c_2 n\epsilon^2 + c_3(\epsilon)), \tag{19}$$

where $c_2 := \frac{\gamma^2}{2\rho^2(C_u - C_l)^2}, c_3(\epsilon) := d\log R(1 + \frac{8\rho}{\epsilon}) + \log 2 \geq \log 2|\mathcal{N}(\Theta, \frac{\epsilon}{4\rho})|$ (see e.g., (Vershynin, 2018), Section 4.2). For the subsequent discussion, suppose C_ϵ occurs. To prove that $\hat{z}$ achieves zero TER, it suffices to prove that $\hat{z}(x) = \hat{z}(x') \Leftrightarrow z(x) = z(x'), \forall x, x' \in \mathbb{X}$. To prove the "⇒" direction, suppose for some segment pairs $(x_1, x_2) \in \mathbb{X}^2$, $\hat{z}(x_1) = \hat{z}(x_2) = z'$ but $z(x_1) = z_1 \neq z(x_2) = z_2$. Invoke Lemma 4 and write $Q_{\hat{z}(x_j)} = P_{Y|X=x_j} + \delta\psi_{x_j}, \delta = c_1\epsilon^{1/4}, \psi_{x_j}^\top\mathbf{1} = 0, \|\psi_{x_j}\|_1 \leq 1, j \in \{1, 2\}$. Use the inequality $\log(1+x) \geq x - \frac{x^2}{1+x}, \forall x > -1$ we have

$$\begin{aligned}
&D_{\mathrm{KL}}(P_{Y|X=x_j}||Q_{\hat{z}(x_j)}) \\
&\quad = -\sum_y P_{Y|X}(y|x_j)\log\left(1 + \frac{\delta\psi_{x_j}(y)}{P_{Y|X}(y|x_j)}\right) \\
&\quad \leq \sum_y \frac{e^{C_u}\delta^2\psi_{x_j}(y)^2}{P_{Y|X}(y|x_j)} \leq a_2(z_1, z_2)\delta^2,
\end{aligned}$$

where $a_2(z_1, z_2) = \max_{j\in\{1,2\}} e^{C_u} / \min_{y:P_{Y|Z}(y|z_j)>0} P_{Y|Z}(y|z_j)$. As a result,

$$\begin{aligned}
&2a_2(z_1, z_2)\delta^2 \geq \\
&D_{\mathrm{KL}}(P_{Y|X=x_1}||Q_{z'}) + D_{\mathrm{KL}}(P_{Y|X=x_2}||Q_{z'}) \geq \\
&\qquad 2D_{\mathrm{JS}}(P_{Y|X=x_1}||P_{Y|X=x_2}),
\end{aligned} \tag{20}$$

which cannot be true if $\delta^2 \leq \frac{D_{\mathrm{JS}}(P_{Y|Z=z_1}||P_{Y|Z=z_2})}{a_2(z_1,z_2)}$, or $\epsilon \leq \frac{D_{\mathrm{JS}}(P_{Y|Z=z_1}||P_{Y|Z=z_2})^2}{c_1(z_1,z_2)^2 a_2(z_1,z_2)^2}$.

To prove the other direction, we use "⇒" to conclude that every phoneme occurs in at least one distinct cluster from other classes, since every cluster in $\hat{C}$ contains only a unique phoneme class. Further, define $E = \left\{\frac{1}{n}\min_z \sum_{i=1}^n \mathbf{1}_{Z_i=z} = 0\right\}$. Using Sanov's theorem (see e.g., (Cover and Thomas, 2006)), we have:

$$\begin{aligned}
&P(E) \leq \\
&\quad (n+1)^K \exp\left(-n\min_{P\in\mathbb{P}_E} D_{\mathrm{KL}}(P||P_Z)\right),
\end{aligned}$$

where $\mathbb{P}_E := \{P \in \Delta^K : \min_z P(z) = 0\}$. Use Assumption 4 and optimize the bound, we obtain

$$\begin{aligned}
&\min_{P\in\mathbb{P}_E} D_{\mathrm{KL}}(P||P_Z) \\
&\qquad = \min_{P\in\mathbb{P}_E} D_{\mathrm{KL}}\left(P||\frac{1}{K}\mathbf{1}\right) \\
&\qquad = \log K - \max_{P\in\mathbb{P}_E} H(P) = \log\frac{K}{K-1}
\end{aligned}$$

and

$$P(E) \leq \exp\left(-n\log\frac{K}{K-1} + K\log(n+1)\right).$$

As a result, phonemes of each class occur at least once in the training set with high probability. If this is the case and if there exists some $x, x' \in \mathbb{X}$ such that $z(x) = z(x')$ but $\hat{z}(x) \neq \hat{z}(x')$, $\hat{C}$ contains at least $K+1$ clusters, which contradicts Assumption 4. Therefore, define the event $R := \{\hat{z}(X) = \hat{z}(X') \Leftrightarrow z(X) = z(X')\}$, the token error rate can be upper bounded as

$$\begin{aligned}
&P_{\text{TER}}(\hat{z}) \\
\leq &P(C_\epsilon \cap E^c)\mathbb{P}\left\{R | C_\epsilon \cap E^c\right\} + P(C_\epsilon^c \cup E) \\
= &\exp\left(-n \min\{e_1(n, \epsilon^*), e_2(n, K)\}\right),
\end{aligned}$$

where

$$\begin{aligned}
\epsilon^* &:= \min_{z_1 \neq z_2} \frac{D_{\text{JS}}(P_{Y|Z=z_1} || P_{Y|Z=z_2})^2}{c_1(z_1, z_2)^2 a_2(z_1, z_2)^2} \\
&=: \min_{z_1 \neq z_2} c(z_1, z_2) D_{\text{JS}}(P_{Y|Z=z_1} || P_{Y|Z=z_2})^2 \\
e_1(\epsilon^*) &:= c_2 \epsilon^{*2} - \frac{c_3(\epsilon^*)}{n} \\
e_2 &:= \log \frac{K}{K-1} - \frac{K \log(n+1)}{n}.
\end{aligned}$$

Therefore, $P_{\text{TER}}(\hat{z}) \leq \delta$ amounts to

$$\begin{aligned}
c_2 n \epsilon^{*2} - c_3(\epsilon^*) &\geq \log \frac{1}{\delta} \\
n \log \frac{K}{K-1} - K \log(n+1) &\geq \log \frac{1}{\delta}.
\end{aligned}$$

The first inequality implies

$$n \geq \frac{\log c_3(\epsilon^*) + (1/\delta)}{c_2 \epsilon^{*2}} = O\left(\frac{\log(\frac{1}{\delta})}{\epsilon^{*2}}\right).$$

For the second inequality, rearranging the terms we obtain:

$$n \geq \frac{K}{\log \frac{K}{K-1}} \log n + \frac{\log \frac{1}{\delta}}{\log \frac{K}{K-1}}, \tag{21}$$

which by Lemma A.2 from (Shalev-Shwartz and Ben-David, 2014) holds if

$$\begin{aligned}
n \geq &\frac{4K \log \frac{2K}{\log \frac{K}{K-1}} + 2 \log \frac{1}{\delta}}{\log \frac{K}{K-1}} \\
&= O\left(\frac{\log \frac{1}{\delta}}{\log \frac{K}{K-1}}\right).
\end{aligned} \tag{22}$$

Combining Equation 21 and Equation 22 proves the theorem. □

B Collection Process and Statistics of the Spoken Word Datasets

The dataset statistics of all the datasets used for our experiments are shown in Table 4. We collect all the spoken word datasets from existing datasets in the following steps:

1. *Decide the train-test split*: For Flickr audio, we use the original training and validation set to extract spoken words for the training set and the test set to extract words for test set; for LibriSpeech, we use train-clean-100 and train-clean-360 for training set and dev-clean for test set; for TIMIT and Mboshi, we use the whole dataset without `SA` utterances to extract spoken words, to be consistent with prior works. For the latter, it will not lead to overfitting since our setting is unsupervised in a sense that the target label, phoneme, is not available during training.

2. *Decide the phoneme inventory*: The phoneme inventory of the English corpora such as Flickr audio, LibriSpeech and TIMIT are the standard 61 phonemes from TIMIT merged into 39 classes for LibriSpeech and 44 classes for Flickr Audio, due to slightly different phoneme set required for the forced alignment systems used to extract phoneme and word boundaries. The phoneme inventory of Mboshi is provided in (Godard et al., 2017).

3. *Decide the vocabulary*: For English corpora, we use a neural dependency parser (Gardner et al., 2017) to extract head words of noun phrases from the Flickr30kEntities and choose those with frequency more than 500 times in the entire Flickr30k corpus. For Mboshi, we use the bigrams and trigrams as proxy for words.

4. *Word and phoneme boundary detection*: For evaluation purposes, we need to extract word and phoneme boundaries for the utterances. While TIMIT and Mboshi has provided frame-level phoneme transcriptions, such labels are not available for Flickr Audio and LibriSpeech. Therefore, we use the Montreal forced aligner to extract word and phoneme boundaries for LibriSpeech and another HMM-DNN hybrid ASR system to extract segment boundaries for Flickr audio

	Flickr Audio	LibriSpeech			TIMIT			Mboshi	
$\lvert\mathbb{Y}\rvert$	224	224	524	824	224	524	824	161	377
K	44	39	39	39	39	39	39	31	31

Table 4: Statistics of four spoken word datasets used for experiments. Mboshi has the same number of training and test words since the whole datasets are used for both training and evaluation, consistent with prior works (Yusuf et al., 2020; Feng et al., 2021b).

5. *Extract spoken word utterances*: To keep the dataset as balanced as possible, we set a cutoff on the maximal number of word utterances per class, which is set to be 200 for Flickr Audio and 1000 for LibriSpeech, TIMIT and Mboshi.

C Model Implementation

For the pre-segmentation stage in Figure 2 of IQ, we use the self-supervised model proposed in (Kreuk et al., 2020) to predict the phoneme-level segmentation for English datasets, and the segmentation generated by one of our baselines (Feng et al., 2021a) for experiments on Mboshi language. The segmental speech encoder $e_{\theta_1}(\cdot)$ is a CPC model pretrained on the whole 960h LibriSpeech (Nguyen et al., 2020) with 256-dimensional representation for each 10ms frame followed by averaging across each segments. The word posterior $c_{\theta_2}(\cdot)$ for the joint distribution learning stage consists of four hidden layers and 512 ReLU units per layer with layer normalization and one softmax output layer. All our models are trained for 20 epochs using Adam optimizer (Kingma and Ba, 2014) with learning rate of 0.001 decayed by 0.97 every 2 epochs and a batch size of 8. We slightly modify (P_1) analogous to the VQ-VAE (van den Oord et al., 2017) to make it more suitable for gradient-based optimization:

$$\begin{aligned}\mathcal{L}_{\text{IQ-VAE}}(P_n, \theta, q) &:= \mathcal{L}_{\text{CE}}(P_n, \theta) + \\ &\lambda \mathbb{E}_{P_n}[D_{\text{KL}}(\text{sg}[P^{\theta}_{Y|X}] || q(P^{\theta}_{Y|X})) + \\ &\qquad D_{\text{KL}}(P^{\theta}_{Y|X} || \text{sg}[q(P^{\theta}_{Y|X})])]\end{aligned}$$

where sg$[\cdot]$ denotes the stop-gradient operation and $\lambda = 0.5$ for all experiments. Exponential moving average (EMA) codebook update is used with a decay rate of 0.999 to optimize the first KL term. Each code distribution is initialized using a symmetric Dirichlet distribution with a concentration parameter of 100.

For CPC, wav2vec and wav2vec 2.0, we extract discrete units using the same predicted and gold segmentations as our IQ model using k-means clustering with the same number of clusters ($K = 31$).

D Convergence Plot for Word-Level Phoneme Discovery

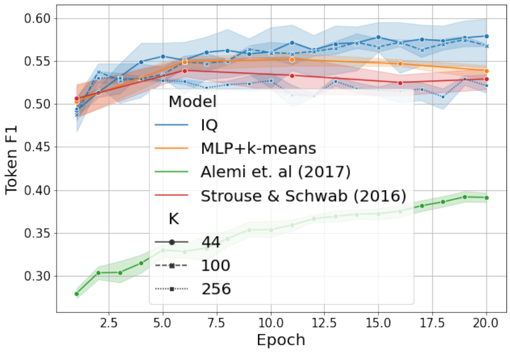

Figure 6: Token F1 convergence plot of various models on Flickr audio.

The convergence plot of Token F1 during training of IQ on Flickr Audio compared to the baselines is shown in Figure 6.

E Further Analysis of Representations Learned by IQ

The visualizations of the estimated distributions $P^{\theta}_{Y|X}$ using t-SNE (van der Maaten and Hinton, 2008) on Mboshi are shown in Figure 7. We again observe that IQ is capable of clustering phonemes from the same manner class as shown in the t-SNE plots for TIMIT in the main text. We also show the most confusing phoneme pairs for both datasets in Table 8a and Table 8b respectively, where the *error* *probability* for a phoneme pair is defined as the probability that segments of different phonemes in the pair are assigned to the same cluster. While we can see that most phoneme pairs confused by the model are acoustically very similar such as (/ae/, /aa/), (/z/, /s/) in TIMIT and (/e/, /a/), (/bv/, /b/) in Mboshi, we also observe some non-obvious pairs such as the pair (/ch/, /ah/) in TIMIT. From the confusion matrix shown in Fig 33b, we can see that this is due to the high variability and potentially lack of samples for the vowel /ah/, which makes its cluster more likely to be merged by other bigger clusters. A more general reason for the model to confuse between such non-obvious pairs may be that distinguishing such phonemes is not very useful in discriminating those words used during the IQ training, which is possible since the vocabulary size during training is relatively small (<1000).

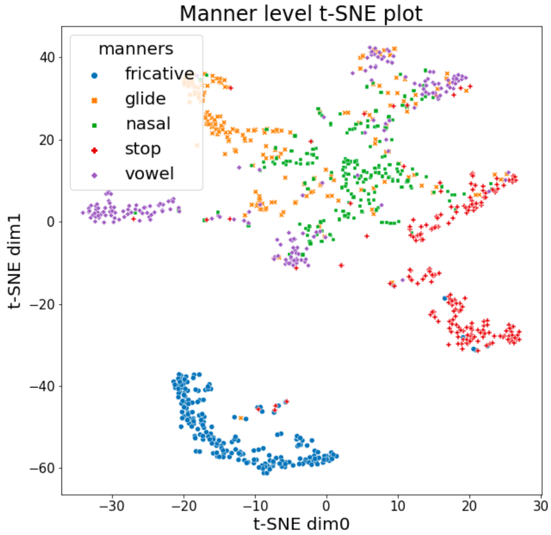

Figure 7: Manner-level t-SNE plots of phoneme clusters discovered by IQ with $|\mathbb{Y}| = 161$ and gold segmentation on Mboshi

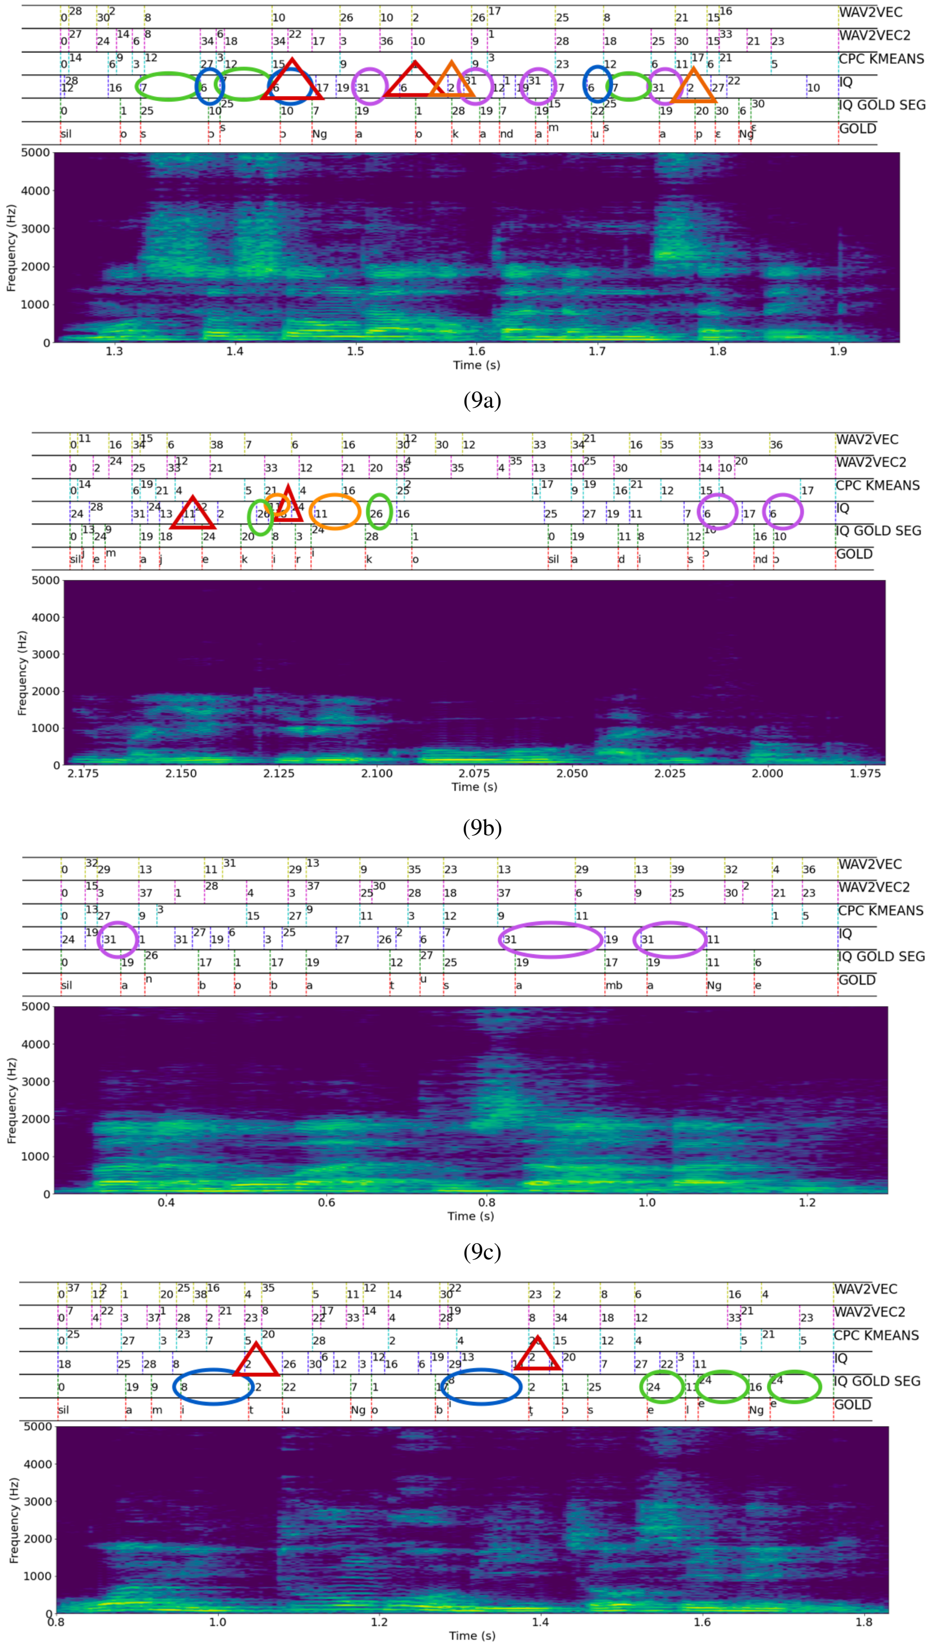
F Effect of Codebook Size for IQ

The phoneme discovery results of IQ with different codebook sizes on Mboshi and TIMIT are shown in Table 5 and Table 6 respectively. As discussed in the paper, our IQ model achieving equally good NMI and boundary F1 and is thus robust to the codebook size on both datasets.

G More Speech Examples

Lastly, we provide eight more spoken utterances annotated with phoneme discovery results.



(9a)

(9b)

(9c)

(9d)

Figure 9: The spectrograms annotated with the gold transcripts and the zero-resource transcriptions by various models for four more utterances from Mboshi. The spoken segments in circles of the same colors are phonemes correctly identified by our IQ model without gold segmentation, and those in triangles of the same color are incorrect pairs that are acoustically similar.

Softmax Bottleneck Makes Language Models Unable to Represent Multi-mode Word Distributions

Abstract

Neural language models (LMs) such as GPT-2 estimate the probability distribution over the next word by a softmax over the vocabulary. The softmax layer produces the distribution based on the dot products of a single hidden state and the embeddings of words in the vocabulary. However, we discover that this single hidden state cannot produce all probability distributions regardless of the LM size or training data size because the single hidden state embedding cannot be close to the embeddings of all the possible next words simultaneously when there are other interfering word embeddings between them. In this work, we demonstrate the importance of this limitation both theoretically and practically. Our work not only deepens our understanding of *softmax bottleneck* and *mixture of softmax* (MoS) but also inspires us to propose *multi-facet softmax* (MFS) to address the limitations of MoS. Extensive empirical analyses confirm our findings and show that against MoS, the proposed MFS achieves two-fold improvements in the perplexity of GPT-2 and BERT.

"The greater the ambiguity, the greater the pleasure." — Milan Kundera

1 Introduction

Recently, researchers have found that transformer-based language models (LMs), such as GPT-2, can predict the next/masked word distribution better as their sizes grow (Radford et al., 2019; Brown et al., 2020; Kaplan et al., 2020). Compared to greedily outputting the most probable next word, sampling the next word from the predicted distribution allows a LM to generate more diverse and high-quality text sequences (Holtzman et al., 2020). By autoregressively sampling the next word according to its predicted probability, large LMs can be used to assist creative writing (Akoury et al., 2020), reduce the cost of building datasets (West et al., 2021; Liu et al., 2022), generate codes (Li et al., 2022), solve math problems (Cobbe et al., 2021), etc. As a result, one natural question arises: Do modern language modeling architectures still have restrictions in their ability to represent the appropriate distribution over next words or masked words?

In this paper, we discover that, when predicting the next word probabilities given an ambiguous context, GPT-2 is often incapable of assigning the highest probabilities to the appropriate non-synonym candidates. For example, given the input prompt *"After debating whether to bow to the* ***woman*** *or the* ***king*** *first, the jester decided on the [MASK]"*, we would expect the distribution over the *[MASK]* fillers to put high probabilities on *woman* or *king* or their synonyms. However, GPT-2 might incorrectly assign the second-highest probability to "*queen*" as in Figure 1.

In the final softmax layer of GPT-2, the log probabilities of the *woman* and *king* are computed based on the dot product between a single hidden state embedding and the global word embeddings of the *woman* and *king*, respectively. To have the highest but similar dot products for the two options, the transformer encoder in GPT-2 wants to output the hidden state that is close to the average of the *woman* embedding and the *king* embedding. However, the words *queen*, *king*, *woman*, and *man* tend to form a parallelogram in the embedding space (Mikolov et al., 2013; Ethayarajh et al., 2019; Wang et al., 2019)[1], which means the *man* and *queen* also have a similar average. Therefore, GPT-2 is forced to also output *man* or *queen* when it wants to output *woman* or *king*.

The problem not only happens to GPT-2 or the words whose embeddings form a parallelogram shape. Even though the hidden state embeddings of LMs are contextualized, the embedding of each

---

[1] Section 2.1 provides more background knowledge about the parallelogram shape and the softmax bottleneck.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 8048 - 8073

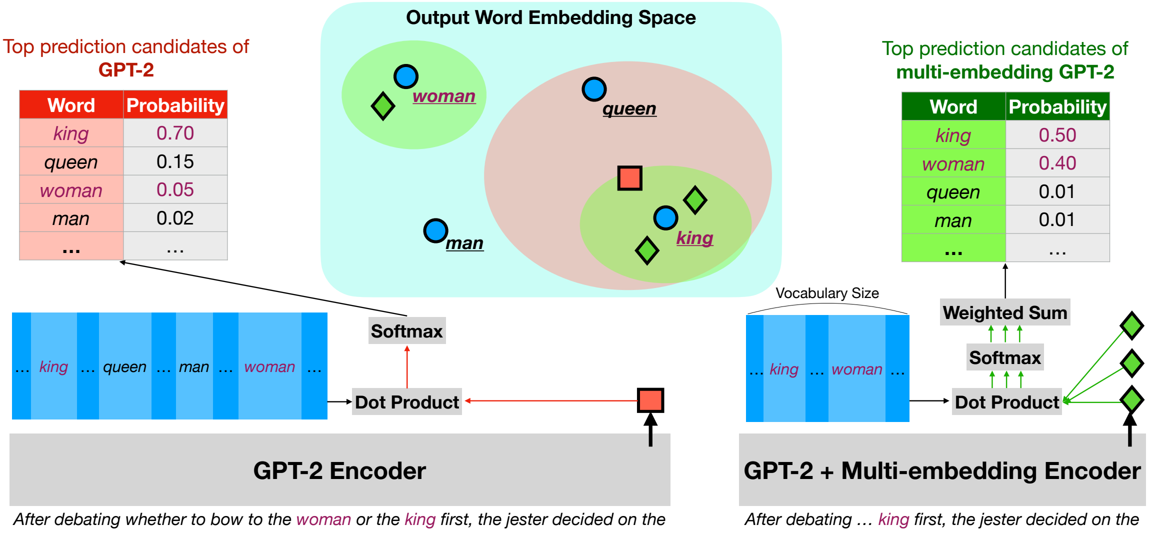

Figure 1: Comparison between the softmax layers using a single embedding and multiple embeddings when the next word should be either *woman* or *king*. In GPT-2 and multi-embedding GPT-2, the hidden states of the context are visualized by the single facet 🟥 and multiple facets ◆, respectively. The word embeddings are visualized using ●. GPT-2 cannot output *woman* and *king* as the top two words because ***queen*** and ***man*** are close to the midpoint of ***woman*** and ***king***. The improvement in this type of ambiguous context will be quantified in Section 5.

word in the softmax layer is global and static during the inference time. Globally dissimilar words could all become the suitable next word in a context while other interfering words might be between them, which makes the ideal next word embedding distribution have multiple modes and cannot be modeled by the single embedding representation.

In this work, we propose theorems showing that given any LM using the output softmax layer, when there are more than N word embeddings in a $N-1$ dimensional subspace/hyperplane (e.g., four embeddings in a two-dimensional plane), we can always find a set of possible next words (e.g., *woman* and *king*) such that there are some other interfering words between them (e.g., *man* or *queen*). That is, the multimodal next word distribution must exist if a few word embeddings are linearly dependent.

Recently, *mixture of softmax* (MoS) (Yang et al., 2018) regains attention as one of the few effective architecture modifications for transformer LM (Narang et al., 2021; Anonymous, 2021). In the meanwhile, Parthiban et al. (2021) show that the *softmax bottleneck* (Yang et al., 2018) theory is not sufficient to explain the improvement of MoS. As a remedy, our theorems not only provide geometrical intuitions of why and when the multiple embedding representation such as MoS would do better but also suggest that the *softmax bottleneck* might not be completely solved even if we adopt a very large hidden state size. For example, no matter how large the hidden state size is, as long as ***queen*** - ***king*** = ***woman*** - ***man*** in the embedding space, the LMs cannot output a pair of words in the longer diagonal of the parallelogram as the top two output words.

After better understanding why *mixture of softmax* (MoS) works well, we propose two enhancements over MoS. The first enhancement considers the hidden states of multiple positions and multiple transformer layers when determining the probability in each softmax; the second enhancement uses different contextualized embeddings to compute the probabilities of different subsets of words in the vocabulary.

The resulting method, *multi-facet softmax* (MFS), significantly outperforms the MoS and the softmax layer in GPT-2 on the perplexity for predicting the next word, especially in ambiguous context and non-English text in OpenWebText (Radford et al., 2019). Finally, we also show that MFS could improve the performance of GPT-2 on ProtoQA (Boratko et al., 2020), a commonsense question answering dataset where each question has multiple acceptable answers.

We summarize our theoretical, methodological, and empirical contributions as follows.

- **Theory**: We show the softmax layer using a single embedding is sometimes not able to output an appropriate rank of probabilities on a set of words with linearly dependent embeddings.

- **Method**: Addressing two weaknesses in MoS (Yang et al., 2018), we propose *multi-facet softmax* (MFS), a new alternative to the output softmax layer. MFS can replace the softmax in pre-trained LMs to better handle ambiguous contexts without re-training the LMs from scratch.
- **Analysis**: Our comprehensive empirical analyses discover and explain several phenomena, such as a) why using multiple embeddings is usually better than the single embedding with the non–linearity, b) why the improvement is larger in ambiguous contexts, less common languages, or GPT-2 compared to BERT, and c) why a LM often confuses with similar words.

2 Theoretical Limitations of the Single Embedding in the Softmax Layer

In this section, we first review the softmax layer of GPT-2 formally and explain why ***queen*** - ***king*** = ***woman*** - ***man*** still tends to hold in contextualized LMs. Next, we present our theoretical analyses, which generalize the *woman* and *king* example by showing that the candidate words in a low dimensional subspace would induce the impossibility of ranking some candidates on top of other candidates.

2.1 Background

The LMs typically use a softmax layer to predict $P_S(x|c_t)$, the probability of the next word x given the context at the tth position c_t:

$$P_S(x|c_t) = \frac{\exp(\boldsymbol{h}_{c_t}^T \boldsymbol{w}_x)}{\sum_{x'} \exp(\boldsymbol{h}_{c_t}^T \boldsymbol{w}_{x'})}, \tag{1}$$

where $\boldsymbol{h}_{c_t}$ is the tth hidden state in the context c, and $\boldsymbol{w}_x$ is the output word embedding for the word x (i.e., the linear weights that project the hidden state to the logit of the word x).[2] Yang et al. (2018) point out that the log probability distribution over all the words in the vocabulary V is $\log\left(P_S(x|c_t)\right)|_{x \in V} = \boldsymbol{h}_{c_t}^T \boldsymbol{w}_x - \log\left(\sum_{x'} \exp(\boldsymbol{h}_{c_t}^T \boldsymbol{w}_{x'})\right)|_{x \in V}$. The distribution is a linear projection from the hidden state $\boldsymbol{h}_{c_t}$ with dimension D, so the degree of freedom in the distribution is only D (i.e., there cannot be more than D linearly independent log distributions). We call this restriction *softmax bottleneck* theory.

During training, the ideal output word embedding $\boldsymbol{w}_x$ should be close to the hidden states of the contexts $\boldsymbol{h}_{c_t}$ that co-occur with the word x while far away from the other hidden states. This objective is similar to the objective function of Word2Vec (Mikolov et al., 2013) except that the context embeddings are contextualized (Kong et al., 2020; Li et al., 2020).

If a context c_t has a higher chance to co-occur with *queen* compared to *king*, the context also has a higher chance to co-occur with *woman* compared to *man* to a similar degree. This is the main reason that makes ***queen*** - ***king*** = ***woman*** - ***man*** in the Word2Vec space (Ethayarajh et al., 2019). Therefore, the same linear relations tend to hold in the output word embedding space of GPT-2 as well (Wang et al., 2019).

2.2 Structural Weakness Theorems from Linear Dependency

In addition to words satisfying the analogy relations, the following theorems imply that any linear dependency among the words causes the difficulties of LM in ranking the words in an arbitrary order according to their logits (i.e., dot products between the hidden state and the word embedding). For example, ***woman*** + ***king*** = ***queen*** + ***man*** makes a LM unable to assign the highest positive logits to *woman* and *king* and output them as the top two words in Figure 1.

Theorem 1. *If the nonzero output embeddings of N words in a set W are linearly dependent and on one side of a hyperplane through the origin, the single embedding representation cannot produce positive logits for a subset of the words in W that are higher than all the logits of the other words in W.*

Here, we provide an intuitive justification: if N embeddings are in a subspace whose dimension is smaller than $N-1$ (e.g., three points in a one-dimensional line), the N embeddings are going to be linearly dependent and some set of words cannot have the top dot products due to the limited degree of freedom in the subspace. In Appendix D, we formally prove the theorem by identifying the sets of words that cannot be ranked top by the single embedding representation.

In practice, linear dependency holds approximately instead of exactly. For example, ***woman*** = ***queen*** + ***man*** - ***king*** + ε. In this practical condition, the following theorem states that the logits of the

---

[2] Notice that some LMs such as BERT add a bias term for each word before the softmax layer. For simplicity, our theoretical analyses focus on the LMs without the bias term such as GPT-2.

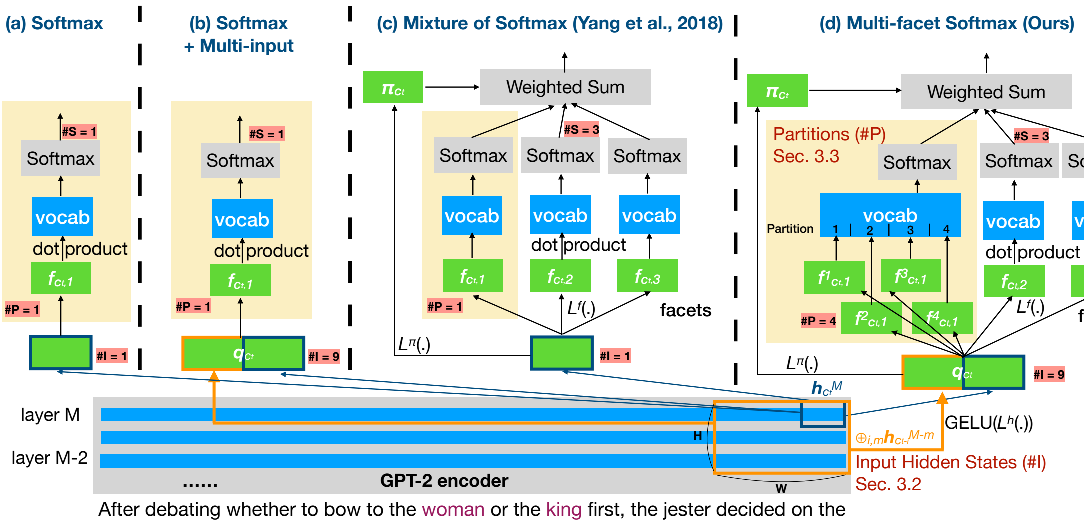

Figure 2: Comparison between different architectures. The #S, #I, and #P are the number of softmaxes, input hidden states, and partitions, respectively. The green boxes refer to embeddings/vectors. The vocab means the embeddings of all words in the vocabulary. ⊕ refers to concatenation. L^h, L^f, and L^π are linear projection layers.

interfering words (i.e., *man* and *queen*) cannot be much smaller than the logits of the candidate words (i.e., *woman* and *king*).

Theorem 2. *Let the output word embeddings in the set* $W = \{\boldsymbol{w}_i \neq \boldsymbol{0} | i = 1...N\}$ *satisfy* $\boldsymbol{w}_1 = a_2\boldsymbol{w}_2 + ... + a_N\boldsymbol{w}_N + \boldsymbol{\varepsilon}$*, where the constant* $a_2, ..., a_N$ *are neither all zero nor all negative and* $||\boldsymbol{\varepsilon}|| < \epsilon$*. Then, there must be a non-trivial partition* $P = \{G, S\}$ *of* W *such that there is no hidden state* $||\boldsymbol{h}|| \leq r$ *and a threshold* $\tau \geq r\epsilon$ *that make* $\min_{\boldsymbol{w}_g \in G} \boldsymbol{h}^T\boldsymbol{w}_g \geq (1+\delta)\tau$ *and* $\max_{\boldsymbol{w}_s \in S} \boldsymbol{h}^T\boldsymbol{w}_s < \tau$*, where* $\delta = \frac{2}{1+\sum_{i=2...N}|a_i|}$.

In the king-woman example, $(1+\delta) = (1+\frac{2}{4}) = 1.5$. Assuming $||\boldsymbol{\varepsilon}|| < \epsilon = 0.01$ and $||\boldsymbol{h}|| \leq r = 20$, we can get $\boldsymbol{h}^T\boldsymbol{\varepsilon} \leq 0.01 \times 20 = 0.2$. Then, we cannot find a hidden state $\boldsymbol{h}$ such that $\boldsymbol{h}^T\boldsymbol{w}_{king} \geq 1.5 \times 0.01 \times 20 = 0.3$ and $\boldsymbol{h}^T\boldsymbol{w}_{woman} \geq 0.3$ but $\boldsymbol{h}^T\boldsymbol{w}_{queen} < 0.2$ and $\boldsymbol{h}^T\boldsymbol{w}_{man} < 0.2$ because $\boldsymbol{h}^T\boldsymbol{w}_{king} + \boldsymbol{h}^T\boldsymbol{w}_{woman} = \boldsymbol{h}^T\boldsymbol{w}_{queen} + \boldsymbol{h}^T\boldsymbol{w}_{man} + \boldsymbol{h}^T\boldsymbol{\varepsilon}$. The formal proof of Theorem 2 can be found in Appendix D and Appendix B.1 estimates ϵ in several language models.

Even though, theoretically speaking, outputting *woman* and *king* as the top two words is possible due to the appearance of $\boldsymbol{\varepsilon}$, LMs may not successfully learn to output the optimal $\boldsymbol{h}$ and the optimal hidden state for these four words could lead to the wrong probabilities of the other words. Consequently, LMs sometimes still rank *queen* or *man* higher than *woman* or *king* in practice.

3 Multi-facet Softmax

Using multiple embeddings is a natural solution for modeling a multimodal distribution (Bishop, 1994). For instance, we can use three embeddings to capture the high probability on the *woman* and *king* but low probability on the *man* and *queen* in Figure 1.

Inspired by our geometric analysis on the limitation of the single embedding, we improve the state-of-the-art multiple embedding solution, *mixture of softmax* (MoS) (Yang et al., 2018) by two enhancements: multiple input hidden states and multiple partitions on the vocabulary.

3.1 Mixture of Softmax

Yang et al. (2018) propose *mixture of softmax* (MoS) to allow a LSTM-based (Hochreiter and Schmidhuber, 1997) LM to produce more linearly independent log probability distributions of the output words given different contexts. As in Figure 2 (c), the MoS first uses multiple linear layers L^f_k to project a hidden state $\boldsymbol{h}_{c_t}$ into multiple facet embeddings $\boldsymbol{f}_{c_t,k} = L^f_k(\boldsymbol{h}_{c_t})$.[3] The multiple facets $\boldsymbol{f}_{c_t,k}$ and softmaxes would lead to multiple probability distributions, and output probability is the weighted average of the distributions:

$$P_{MoS}(x|c_t) = \sum_{k=1}^{K} \pi_{c_t,k} \frac{\exp(\boldsymbol{f}^T_{c_t,k}\boldsymbol{w}_x)}{\sum_{x'} \exp(\boldsymbol{f}^T_{c_t,k}\boldsymbol{w}_{x'})}. \quad (2)$$

---

[3] We remove the tanh layer in the original MoS to improve its performance on GPT-2. See Appendix G.1 for details.

The prior weights $\pi_{c_t,k} = \frac{\exp(L^\pi_k(\boldsymbol{h}_{c_t}))}{\sum_{k'} \exp(L^\pi_{k'}(\boldsymbol{h}_{c_t}))}$, where L^π_k is another linear projection for dynamically generating the weights and the projection goes through a softmax to ensure $\sum_{k=1}^{K} \pi_{c_t,k} = 1$.

3.2 Multiple Input Hidden States

To model the multimodal distribution, the facets (i.e., the embeddings for different softmaxes) should be able to move freely. For example, in Figure 1, we have three facets but only have two modes, so the two embeddings are very close to the word *king*. However, when we want to output three dissimilar top words such as the *king*, *woman*, and *knight*, one of the facets should be moved to be near to the embedding of the *knight*.

Therefore, we want our solution to satisfy two properties: a) the linear transformation matrix in L^f_k should have a full rank to avoid limiting the degree of freedom in each facet, and b) the relative location of the facets should be context-dependent. MoS cannot satisfy both properties. If the first one is satisfied, the input hidden state is uniquely determined by a facet (e.g., $\boldsymbol{h}_{c_t} = (L^f_1)^{-1}(\boldsymbol{f}_{c_t,1})$). Then, there exists a global transformation between two facets (e.g., $\boldsymbol{f}_{c_t,2} = L^f_2\left((L^f_1)^{-1}(\boldsymbol{f}_{c_t,1})\right)$), which violates the second property. That is, assuming LM can move every facet freely (i.e., the facet's degree of freedom is the same as the dimension of the hidden state), LM cannot make the first two facets close to *woman* and *king* in one context but make the two facets close to *woman* and *knight* in another context. In other words, since the facet embeddings are the projection of a single hidden state, the total degree of freedom in all facet embeddings cannot exceed the dimension of the hidden state.

Our solution to this issue is using more input hidden states to construct the facets. As the orange box in Figure 2, we first concatenate a $W \times H$ block of input hidden states into $\oplus_{i=0 \ldots W-1, m=0 \ldots H-1} \boldsymbol{h}^{M-m}_{c_{t-i}}$, where $M-m$ is the transformer layer index and $t-i$ is the index of the ith to the last word in the context. The $W \times H$ is fixed as 3×3 in this paper. We make its dimension the same as the original hidden state $\boldsymbol{h}^M_{c_t}$ using a linear layer L^h plus a GELU activation function (Hendrycks and Gimpel, 2016). Then, we concatenate it with the original hidden state to form a new input hidden state

$$\boldsymbol{q}_{c_t} = \boldsymbol{h}^M_{c_t} \oplus GELU\left(L^h(\oplus_{i,m} \boldsymbol{h}^{M-m}_{c_{t-i}})\right). \quad (3)$$

The new input hidden state is passed through the linear transformation L^f_k to compute the facets $\boldsymbol{f}_{c_t,k} = L^f_k(\boldsymbol{q}_{c_t})$ and our prior weights $\pi_{c_t,k} = \frac{exp(L^\pi_k(\boldsymbol{q}_{c_t}))}{\sum_{k'} exp(L^\pi_{k'}(\boldsymbol{q}_{c_t}))}$. Since the dimension of $\boldsymbol{q}_{c_t}$ is larger than the dimension of $\boldsymbol{f}_{c_t,k}$, the inverse function $(L^f_k)^{-1}$ no longer exists.

3.3 Multiple Partitions

The next word distribution could have many modes. However, using many softmaxes significantly increases our computational burden because we need to compute the dot product between each facet and all the word embeddings in our vocabulary.

Inspired by our analysis, we propose to split all the words in the vocabulary into multiple partitions[4] and use different facets for different partitions. For example, if we can put any word from {*queen*, *man*, *woman*, *king*} into one partition and the rest of the words into another partition, we no longer have ***queen*** **-** ***king*** **=** ***woman*** **-** ***man*** in either of the partitions. In this method, each word only belongs to one partition, so we only need to compute one dot product for each word. Thus, the extra computational cost only comes from the extra linear projections for preparing the facets.

In many contexts c_t, the distribution of the next word has only a single mode and the global similarity between words may be useful. Using the multiple partitions alone might lose the similarity information between words in different partitions. Therefore, we propose to only replace the first softmax layer in MoS with the multiple partition method to learn the global similarity of words in different partitions using the other softmaxes. The architecture is illustrated in Figure 2 (d). Formally, we compute the probability using

$$\begin{aligned} P_{MP}(x|c_t) = \pi_{c_t,1} & \frac{\exp((\boldsymbol{f}^{j_x}_{c_t,1})^T \boldsymbol{w}_x)}{\sum_{x'} \exp((\boldsymbol{f}^{j_{x'}}_{c_t,1})^T \boldsymbol{w}_{x'})} \\ & + \sum_{k=2}^{K} \pi_{c_t,k} \frac{\exp(\boldsymbol{f}^T_{c_t,k} \boldsymbol{w}_x)}{\sum_{x'} \exp(\boldsymbol{f}^T_{c_t,k} \boldsymbol{w}_{x'})}, \quad (4) \end{aligned}$$

where j_x is the partition index that the word x belongs to and $\boldsymbol{f}^{j_x}_{c_t,1}$ is the facet for the j_xth partition.

---

[4] In this work, we simply put the $J \times n + j$th word into jth partition (e.g., when the number of partitions $J = 4$, the first partition includes the words with indexes $0, 4, 8, \ldots$). This simple global partitioning method reduces the chance of putting all the interfering words and candidates in the same partition, while minimizing the extra computational cost in our PyTorch implementation because PyTorch supports strided index slicing without copying the variable.

Multi-facet softmax (MFS) is equipped with multiple input hidden states and multiple partitions.

4 Language Modeling Experiments

We evaluate different LM architectures by comparing their capability of predicting the next word in Wikipedia 2021 and a subset of OpenWebText (Radford et al., 2019). In addition to perplexity, we also compare their mean reciprocal ranks (MRR) in Appendix C.1. The size of the training, validation, and testing set are 96%, 2%, and 2% of the whole corpus, respectively. After loading the pre-trained GPT-2 models, we train the *GPT-2 Small* for 1 epoch and *GPT-2 Medium* for 0.4 epochs. We also test our methods on BERT in Appendix B.2. Please see Appendix G for more details of our experiment setup.

4.1 Baselines

We set different numbers of softmaxes, input hidden states, and partitions in our MFS framework to construct our baselines. The configuration of different baselines could be seen in Table 1.

Softmax (GPT-2): Using a single softmax, input hidden state, and partition as in Figure 2 (a) and Equation 1. The baseline is the same as the original GPT-2 except that we add one more linear layer that converts the hidden state $\boldsymbol{h}_{c_t}^M$ to the facet embedding $\boldsymbol{f}_{c_t,1}$ as in other methods.

SigSoftmax (Kanai et al., 2018): The same as *Softmax* except when predicting the next word, Kanai et al. (2018) add some non-linearity into the softmax layer by multiplying the exponent and sigmoid of the logits.

Softmax + Multi-input: Letting *Softmax* access multiple input hidden states as in Figure 2 (b) and Equation 3. The method is similar to Tenney et al. (2019); Fan et al. (2020), and Tay et al. (2021).

MoS (Yang et al., 2018): *MoS (3)* is the *mixture of softmax* with 3 facets/softmaxes, whose probability comes from Equation 2. We also run the MoS with 4 softmaxes in *GPT-2 Small* and call the model *MoS (4)*.

DOC (Takase et al., 2018): Similar to our enhancement using multiple input hidden states, *direct output connection* (DOC) makes each of their facets coming from a different input hidden state.

Other configurations include **Softmax + Multi-partition**, which adds four partitions into the softmax, **MFS w/o Multi-partition**, which uses only one partition in *MFS* and could also be viewed as *MoS + Multi-input*, and **MFS w/o Multi-input**, which uses only one input hidden state to generate all facets.

4.2 Results

Table 1 shows that applying **MFS** to *GPT-2 Small* achieves more than 15% of the perplexity improvement between *GPT-2 Small* and *GPT-2 Medium*, while only increasing 5% of their size differences. Except for **Softmax + Multi-partition**, adding multiple input hidden states or partitions in different configurations significantly boost the performances. In Appendix B.3, we further show that the improvement of **MFS** over **Softmax** could even become 3-5 times larger in the top 5-10% of the most ambiguous contexts compared to the rest of the contexts, which suggests that some improvements indeed come from successfully modeling multimodal distribution.

MFS usually doubles the perplexity improvements between **MoS (3)** and **Softmax** but the running time of **MFS** remains similar to **MoS (3)** because **MFS** only needs a few more linear layers, which is more efficient than adding one more softmax as in **MoS (4)**. **DOC** is worse than **MoS (3)**. This may be due to a starvation problem: the facet from the last hidden state $\boldsymbol{h}_{c_t}^M$ has the prior probability close to 1 and receives most of the gradients. Finally, compared with **Softmax**, the mixed results in **SigSoftmax** suggest that adding non-linearity into the softmax layer without modeling the multimodal distribution might not always improve the models (Parthiban et al., 2021).

OpenWebText is mostly composed of English text, but some non-English text in the corpus allows us to compare the capability of different models in a multi-lingual setting. Table 2 shows that multiple embeddings improve the perplexity of the non-English text more than the perplexity of the English text. We hypothesize that the distribution of the next non-English word is more likely to be multi-mode because GPT-2 learns the global token embeddings mostly in the English contexts, which could make the embeddings of similar tokens in non-English contexts far away.

In Table 3, we present three contexts from the validation set of different datasets and compare the top three predictions of **MFS** and **Softmax** on *GPT-2 Small*. In OpenWebText and Wikipedia 2021, we can see that **Softmax** misses the correct answer in its top three predictions.

	Configuration			GPT-2 Small				GPT-2 Medium

Table 1: Perplexity comparison between MFS (Ours) and baselines. #S, #I, #P are the number of softmaxes (i.e., K), input hidden states, and partitions, respectively. The top four baselines use a single softmax. OWT and Wiki are the test set perplexity of OpenWebText and Wikipedia 2021, respectively. The standard errors of all models are smaller than 0.02 perplexity. We also compare the number of parameters and the inference time on one batch.

	Non-English	English
Ratio in Corpus →	14%	86%

MFS (Ours)	**12.83 (5.0%)**	**18.83 (2.1%)**

Table 2: Perplexity of the *GPT-2 Small* in OpenWebText. The percentages of the perplexity reduction compared to Softmax are presented in the parentheses.

5 Evaluation on Ambiguous Templates

We synthesize a dataset using templates (Ribeiro et al., 2020) to verify whether the softmax layer in the original GPT-2 really has difficulty in learning to output the bimodal distribution in Figure 1 and whether the multiple embedding methods could overcome the problem. First, we collect the four words with semantic analogy relations in Google analogy dataset (Mikolov et al., 2013). Next, we insert two out of the four words into our manually written templates to form the contexts and the templates we used could be found in Appendix G.3. For example, given the context "*I went to Paris and Germany before, and I love one of the places more, which is*", the GPT-2 learns to predict either *Paris* or *Germany*.

The two words can be either the diagonal words (e.g., *king* and *woman*) or the edge word (e.g., *king* and *queen*) in the parallelogram. Finally, we create a dataset with 122k training contexts, 250k validation contexts, and 122k testing contexts, where the word pairs in the testing set are unseen in the training set to see whether the model could learn to output the bimodal distribution in a general way.[5]

We load the models pre-trained on OpenWebText and continue fine-tuning the models on the last word of each sentence for 10 epochs. We report the testing performances of the best model selected by the validation loss. Since the sets of the word pairs in the training and testing set are disjoint, updating the output word embedding would make GPT-2 solve the task by memorizing/overfitting the training set quickly and lead to much worse testing performances. Thus, we freeze the output word embedding during the training.

We visualize the predictions of the Paris-Germany example in the last column of Table 3. We can see two of the softmaxes are close to *Paris* and the remaining one is close to *German*, while **Softmax** overestimates the probability of *Paris* and ranks *France* higher than the *German*. The result verifies that the correct probability distribution of the words in some ambiguous context is hard to learn using **Softmax**.

Quantitatively, Table 4 indicates that when the possible next words are the diagonal words, the **Softmax** model performs much worse compared to other multiple embedding alternatives. In the edge word dataset, the multiple embedding solutions are still better but have a much smaller gap. **MFS w/o Multi-partition** slightly improves **MoS**. We hypothesize the reason is that multiple input hidden states could help the facets to be moved more freely. Finally, multiple partitions seem to cause slight overfitting in this bimodal distribution prediction task.

---

[5] The setting is realistic because any related words could become the next word in some ambiguous contexts and all the words are related in a certain way (Sigman and Cecchi, 2002). We cannot expect the training corpora to contain the ambiguous contexts with so many possible next words.

Table 5: ProtoQA performances. All the numbers except perplexity are the percentages of the predictions that match the ground truth exactly on the crowdsourced development set. Max answers top k implies only evaluating the top k answers. Max incorrect top k indicates only evaluating the top answers that contain k errors. The best average performances are highlighted and the standard errors are reported as the confidence interval.

6 Answering Ambiguous Questions

ProtoQA (Boratko et al., 2020) is a question-answering dataset built for evaluating the commonsense reasoning ability of language models. Each question in ProtoQA is ambiguous and leads to a distribution of possible answers. For instance, the answer to "*Name something that people usually do before they leave for work?*" is "*Shower 0.43, Breakfast 0.30, ...*". The paper discovers that by reformulating the question-answering task as a context (e.g., "*One thing people usually do before they leave for work is ...*"), GPT-2 could generate the possible answers by sampling the next words from its word prediction distribution.

The dataset gives us a chance to directly compare the quality of the distributions generated by different LMs in Table 5. After pretraining *GPT-2 Medium* on the OpenWebText, we fine-tune them using the training data in ProtoQA for 2 epochs. We repeat the fine-tuning 5 times and compare their average perplexity in our validation set. Next, we generate 150 sentences starting from each context and compare the generated answers with the ground truth distribution. For each fine-tuned model, we repeat the generation evaluation 3 times and report the average accuracy of the resulting 15 trials.

We can see that the multiple softmaxes, input hidden states, and partitions usually improve the quality of prediction distribution, and the proposed **MFS**, which combines all modifications, achieves the best performances.

7 Related Work

Yang et al. (2018) propose the concept of *softmax bottleneck*, which points out that the dot product in the softmax layer restricts the representation power of outputting arbitrary conditional probabilities. It also proposes *MoS* to break the softmax bottleneck in an RNN-based LM. Kanai et al. (2018) and Ganea et al. (2019) add nonlinearities into the softmax layer to break the bottleneck more efficiently, but the approaches gain less improvement compared to *MoS*.

A limitation of the aforementioned previous work is that they do not tell us which kinds of sentences would be affected by the bottleneck more and whether the order of the top few next words would be affected, which are the main research questions of our work. Contrary to the previous belief that a large hidden state dimension would eliminate the softmax bottleneck, our theorems suggest that some words in a low dimensional subspace could still make the single embedding in the softmax layer become a bottleneck of arbitrarily ranking the output words. Furthermore, our geometric analyses provide an intuitive explanation about why breaking the bottleneck using multiple embeddings leads to better performances compared to only adding the non-linearity.

Demeter et al. (2020) also analyze the structural weakness of the softmax layer from a geometric perspective. They discover that the words with high prior frequencies could stop the LMs from assigning the high probabilities to rare words, which can be viewed as a special case of our theory (See Appendix E). For instance, our work shows that the softmax layer could still prevent the LMs from outputting some top words even if all the possible next words have the same prior frequency.

Our theory is deeply connected to the mathematical work that counts the number of possible rankings of points in an embedding space (Cover, 1967; Good and Tideman, 1977). Compared to the studies, our work focuses more on analyzing the multimodal distribution in the word embedding space and its implication to language models.

An alternative to model the multimodal distribution is to use multiple embeddings to represent each output word (Athiwaratkun and Wilson, 2017; Miao et al., 2019). Compared to MoS or our approach that use multiple embeddings to represent each hidden state of the context, their method requires many extra parameters to store different senses of each output word. Another type of related model (Shazeer et al., 2017; Fedus et al., 2021) dynamically routes the signals to different experts (i.e., feed-forward networks) and Zhang et al. (2022); Mittal et al. (2022) use multiple embeddings in the attention layers. The methods are similar to MoS and our approach, but they add the multiple embeddings inside each layer of the transformer encoder while the proposed MFS is an alternative to the output softmax layer.

8 Conclusion

When the ideal distribution in the output word embedding space has multiple modes, GPT-2 cannot learn to correctly rank the words in all the modes as the top next words. This shows that the single embedding in the softmax layer, which is used nearly universally by current LMs, constitutes a performance upper bound of predicting the next/masked word. To address the systematic failure caused by these structural weaknesses, we propose *multi-facet softmax* (MFS). In our experiments, we confirm that the MFS significantly outperforms the standard softmax layer and alleviates the *softmax bottleneck* in the transformer-based LMs such as GPT-2 better than *mixture of softmax* (MoS).

10 Ethical and Broader Impact

This work studies a general limitation of LMs and proposes solutions. The proposed theory can help us to understand that some types of hallucinations, mistakes, or biases of LMs could come from *softmax bottleneck* and their incapability of modeling the correct distribution. For example, there are 60% of male characters and 40% of female characters in our training corpus. The language generation model might be forced to assign more than 60%

probability to male characters as being much more likely to output *king* than *woman* in Figure 1.

Recently, Narang et al. (2021); Anonymous (2021) show that MoS is one of the few architecture modifications of transformer-based LM that can provide consistent improvements in downstream applications. Our work provides a fundamental reason why the multiple embedding representation is better, which could inspire more future studies that propose a better multiple-embedding architecture to improve LMs (e.g., multi-lingual BERT) or downstream applications. As examples, we list several possible future directions in Appendix H.

Finally, a better LM could lead to both positive and negative societal impacts, but they are not the focus of this paper. Generally speaking, this paper deepens our understanding of the weaknesses of modern LMs and we believe the knowledge can help us to design a better LM that increases the positive impacts and reduces the negative impacts in the future.

A Appendix Overview

To demonstrate the wide applicability of our approaches, we conduct more experiments such as applying **MFS** to BERT in Appendix B. We also show more results and conduct more analyses in Appendix C to further support our conclusions. Next, we provide technical details including the proof of our theorems in Appendix D, show that the structure weakness studied by Demeter et al. (2020) is a special case of our theory in Appendix E, the method details in Appendix F, and the experiment details in Appendix G. Finally, in Appendix H, we list several directions that could be further studied in the future.

B More Experiments

We conduct the following five extra experiments to measure the linear dependency among word embeddings in LMs, extend our multi-facet approaches to BERT, confirm the source of the improvement comes from modeling multimodal distribution, and extend our synthetic experiments to include the output candidate words that have various types of relations and to include the template that favors the single embedding representation.

B.1 Linear Dependency among Words

Theorem 2 shows that when N words are linearly dependent after moving one of the embeddings with a short distance ϵ, the output softmax layer of a LM cannot output a large logit margin between two subsets of the N words. We want to measure ϵ in the pretrained word embedding and compare the ϵ from different sets of words or from different LMs.

Given a set of N words, we form a matrix by their word embeddings and estimate the ϵ value by the minimal eigenvalue of the matrix. We first want to verify that the four analogical words used in Section 5 indeed have a smaller ϵ compared to a randomly selected four words. Thus, we define the min eigenvalue ratio as $\frac{\epsilon_S}{\epsilon_R}$, where ϵ_R is the average of minimal eigenvalues from 1,000 sampled N word sets and ϵ_S is the average of minimal eigenvalues from sets of words (e.g., analogical words from the Google analogy dataset). We analyze the ratio instead of ϵ because the average word embedding magnitudes in different LMs would affect the absolute value of ϵ.

In addition to analogical words, we also test sets of N similar words, which are composed by the nearest $N-1$ words of every query word in the vocabulary, and test the N similar stop words by finding the nearest $N-1$ words of every query word in a stop word list.[6]

We plot the min eigenvalue ratio versus N in Figure 3 and compare the curves from three GPT LMs and two T5 LMs (Raffel et al., 2020). All the ratios are below 0 and decrease as N increases, which shows the analogical words and similar words indeed have significantly smaller ϵ especially for a large N. The low minimal eigenvalues and our theory support the recent empirical finds that LMs tend to be confused by the similar words (Zagoury et al., 2021). This figure also provides a potential explanation why the candidates often include stop words when multiple embeddings outperform the single embedding in Table 3 and Table 7.

Surprisingly, we find that a larger LM does not necessarily yield a larger ratio (i.e., embeddings of related words do not become more linearly independent as dimension or the size of the LM increases). All the LMs have very similar ratios of similar stop words. Compared to *GPT-small*, although *GPT-J-6B* (Wang and Komatsuzaki, 2021) has a significantly higher ratio for analogical words, its ratio for similar words is significantly lower. Besides, *T5-11B* has significantly lower ratios compared to *T5-small*. We need further investigation to understand the reason for this empirical finding and whether a larger LM suffers less from the limitation caused by the single embedding.

B.2 Language Modeling using BERT

To demonstrate that our proposed method could improve the LMs other than GPT-2, we apply *multi-facet softmax*, **MFS**, to BERT. We test the model on Wikipedia 2021 and the validation size is 0.25% of the whole corpus. After loading pretrained model, we train *bert_base_cased* for 100k batches and *bert_large_cased* for 30k batches.

The results are presented in Table 6. First, **MoS** outperforms **Softmax** on BERT. The results support the finding of Narang et al. (2021) that the *softmax bottleneck* not only exists in the next word prediction tasks but also in the masked word prediction tasks. Similar to GPT-2, **MFS** at least doubles

---

[6] We find that some rare words or special characters might have nearly identical word embeddings due to the lack of training instances, so we exclude half of rarer word pieces in the vocabulary and exclude the word pieces whose first character is not a space. The rarity of a word piece is determined by the l2 norm of its word embedding.

Table 8: The loss improvement comparison between the *Improvement Models* and *Reference Models*. The models are named using their number of softmaxes, input hidden states, and partitions. Thus, S3I9P4 is *MFS*, S3I9P1 is *MFS w/o Multi-partition*, S1I9P1 is *Softmax + Multi-input*, S3I1P1 is *MoS (3)*, and S1I1P1 is *Softmax*. *Multi-mode Percentage* is the percentage of the contexts where the *Improvement Models* output multimodal distribution. *Multi-mode Loss Improvement* refers to the average improvement when *Improvement Models* outputs multimodal distribution and *Other Loss Improvement* refers to the improvement of the contexts where the facets of *Improvement Models* are close to each other. *Improvement Ratio* divides *Multi-mode Loss Improvement* by *Other Loss Improvement*.

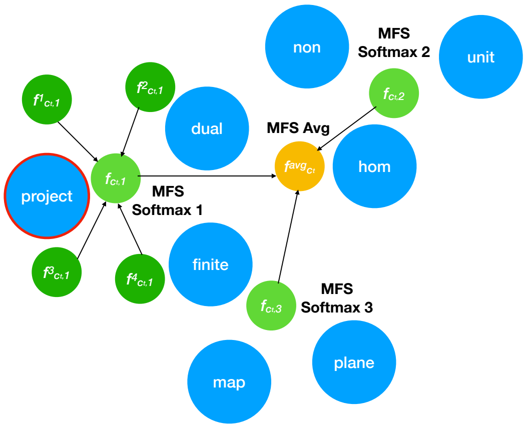

Figure 4: Illustration of the MFS predictions given the Wikipedia context in the second column of Table 7. The green circles mean the facet embeddings from MFS. The orange circle is the average of the facet embeddings (**MFS Avg**). The blue circles are the word embeddings that are close to the facet embeddings and **MFS Avg**. The word *project* is highlighted because it is the next word in our ground truth.

The smaller improvement supports the conclusion of our geometric analyses that the multi-mode ambiguity intensifies the *softmax bottleneck*. We only observe the one-directional context before the next target word in GPT-2, but we can observe the bi-directional context surrounding the masked target word in BERT. Thus, compared to next word prediction, the multi-mode ambiguity of the masked word prediction occurs less frequently when the masking probability is small (e.g., 15% in BERT). Since the masked word distribution only has a single mode most of the time but we sometimes still want the distribution to have multiple modes, multiple input hidden states can improve the performance by helping the facets to move more freely. On the other hand, multiple partitions are less useful because the distribution rarely has more than three modes.

B.3 Analysis of Improvement on Multimodal Distribution

To confirm that the perplexity improvements actually come from modeling the multimodal distribution, we define a metric to measure how multimode a distribution is, and then we can compare the perplexity improvement from multimodal distributions and the improvement from the distributions that are close to a single-mode distribution.

For the method with multiple embeddings, we first compute the weighted average of all the facets $\boldsymbol{f}^{avg}_{ct} = \sum_{k=1}^{K} \pi_{ct,k} \boldsymbol{f}_{ct,k}$, where we lower the influence of kth facet embedding $\boldsymbol{f}_{ct,k}$ with lower prior weight $\pi_{ct,k}$ and $\boldsymbol{f}_{ct,1} = \frac{1}{J} \sum_{j=1}^{J} \boldsymbol{f}^{j}_{ct,1}$ if J partitions are used. Figure 4 illustrates $\boldsymbol{f}^{avg}_{ct}$ and $\boldsymbol{f}_{ct,k}$ using the example in the second column of Table 7.

We visualize the new average facet using the words that are closest to the $\boldsymbol{f}^{avg}_{ct}$ in the **MFS Avg** row of Table 7. We can see that the predictions of **MFS Avg** is different from **MFS** but similar to **Softmax**. This means there are indeed some other words between the actual next word and the other possibilities, which makes the predictions of **MFS** multi-mode.

Next, to quantify the difference between **MFS** and **MFS Avg**, we define *multi-mode ratio* as $\frac{\sum_{b=1}^{T} P_M(y_b|c_t)}{\sum_{b=1}^{T} P_M(x_b|c_t)}$, where P_M could be either P_{MoS} from equation 2 or P_{MP} from equation 4. $\{y_1, ..., y_T\}$ is the set of words with embeddings closest to $\boldsymbol{f}^{avg}_{ct}$ and $\{x_1, ..., x_T\}$ is the set

Models ↓	Dissimilar Words			Similar Words

Table 10: MRR (mean reciprocal rank) of different models in OpenWebText. Larger is better.

of words with highest $P_M(x_b|c_t)$. Using the Wikipedia context in Table 7 as an example, the word *project* is retrieved by **MFS** but not by **MFS Avg**, so its *multi-mode ratio* for $T = 2$ is $\frac{P_{MFS}(hom|c_t)+P_{MFS}(dual|c_t)}{P_{MFS}(project|c_t)+P_{MFS}(hom|c_t)} = \frac{0.049+0.046}{0.096+0.049} \approx 0.66$. Figure 4 illustrates the relation between the **MFS Softmax k** and **MFS Avg**.

When the ratio is closer to 1, the context is less ambiguous and the prediction is closer to a single-mode distribution. We set $T = 20$ and call the prediction with *multi-mode ratio* smaller than 0.9 multimodal distribution and in Table 8,[7] we compare the loss (i.e., log of the perplexity) improvements in the multimodal distributions and the improvements in the nearly single-mode distributions.

Table 8 shows that all the multiple embedding approaches have larger loss improvements when outputting multimodal distributions. The table shows the results based on *GPT-2 Small* and the same analysis using *GPT-2 Medium* also show the same trend. As we use multiple input hidden states and partitions, the differences would be enlarged. Especially when we compare **MFS** and **MFS w/o Multi-partition**, the loss improvements of highly ambiguous context is 7 or 8 times larger than the other loss improvements, which means a large portion of the overall improvement lies on a small percentage of ambiguous contexts. For the multimodal distribution in Wikipedia, the loss improvement between **MFS** and **Softmax** could reach 0.10, which is close to the improvement between GPT-2 Small and Medium (0.16). Thus, we expect that if the corpus has more ambiguous contexts, **MFS** could achieve larger overall loss improvement.

B.4 Template-based Analysis on Similar or Dissimilar Nouns

To know whether the single embedding also has trouble modeling the distribution over nouns without the analogy relation, we let the different models learn to assign similarly high probabilities to two related nouns in our templates. One example in our synthesized dataset is "*I love the **banana** and the **lemon**, and my favorite is the [MASK]*". The nouns come from a hypernymy detection benchmark (Shwartz et al., 2017) containing 25,498 noun pairs. The relations between nouns in the benchmark include synonym, antonym, attribute, meronym, hypernym, coordination, event, or random. We further split the noun pairs into two

---

[7] We also tried T=5 or 10 and the trends are similar. If we set the threshold smaller than 0.9, the improvement ratios (e.g., MFS over MoS) would increase but the multi-mode percentages would decrease.

datasets based on their cosine similarity in the output word embedding space of our **Softmax** baseline. The pairs with the cosine similarity higher than the medium of all cosine similarities are put into the similar word set and the other pairs are put into the dissimilar word set.

The results are presented in Table 9. In terms of the training, validation, and testing perplexity, multi-embedding approaches consistently outperform the single-embedding baselines, though the margins are smaller than those from the analogous words. Moreover, the improvement gap is larger when the nouns are dissimilar. We hypothesize that as the word embeddings of nouns become further away from each other, the next word distribution is more likely to be multi-mode and thus could be better captured by multiple embeddings.

B.5 Adversarial Template Analysis

To test whether the proposed methods still can effectively utilize the information from the global word embeddings, we design an adversarial template to create the contexts that can only be completed by averaging the global word embeddings. For example, *"**Miami** is not in **Wisconsin** but is in [MASK]=**Florida**"*.

In this task, the validation perplexity of **Softmax**, **MoS**, **MFS w/o Multi-partition**, and **MFS** are 2.50, 2.59, 2.54, and 2.88, respectively. Since multiple embeddings are not required, it is not surprising that **Softmax** performs the best. Nevertheless, the differences are smaller than the differences in Table 4. We believe that the similar losses are because multiple embeddings are a generalization of the single embedding, so GPT-2 could learn to generate the same embedding for all facets to mimic the behavior of single embedding if required.

The significantly worse performance of **MFS** here is caused by the multiple partition technique. This result supports our motivation of combining multiple partitions with multiple softmaxes and shows that multiple partitions handle ambiguous contexts better (as shown in Table 8) by sacrificing some global word embedding structures. Nevertheless, a corpus usually has more ambiguous contexts than the adversarial context tested here, so using multiple embeddings and multiple partitions performs better in Wikipedia and OpenWebText overall.

C More Results

We provide more numbers and analyses of our experiments.

C.1 Ranking Metric in Language Modeling Experiments

We would like to verify that our perplexity improvements come from not only the slight probability differences of each candidate but also the better ranks of the candidates. Thus, in Table 10, we evaluate different models using mean reciprocal rank (MRR). Similar to the perplexity, the MRR improvement from **Softmax** to **MFS** is around 15% of the MRR improvement from *GPT-2 Small* to *GPT-2 Medium*, which is similar to the percentage of perplexity improvement. This suggests that **MFS** could lead to not only a better probability prediction but also a better candidate rank prediction.

C.2 Perplexity Curves in Language Modeling Experiments

In Table 1, we only show the testing perplexity at the end of our training. In Figure 6, we plot the validation perplexity decay curves during the training on OpenWebText. We can see that the performance ranking of each model is stable during the training, while the improvement of each enhancement may vary. For example, in *GPT-2 Medium*, the improvement of **MFS** over **MFS w/o Multi-partition** is more obvious in epoch 0.25 compared to epoch 0.4.

C.3 Perplexity Curves in Template Analysis

In Table 4, we only show the lowest validation perplexity after each of the ten epochs. In Figure 5, we plot the training and validation perplexity decay curves.

The curves tell us that the multi-embedding models perform better in both training and validation perplexity. As we train the single-embedding models longer, the validation perplexity increases quickly, which implies that using a single embedding to model multimodal distribution could cause severe overfitting when we predict the next word given an ambiguous context.

C.4 Stability in Language Modeling Experiments

In our case, training our model requires a huge amount of GPU resources for us, so it is not very

feasible to train multiple times using multiple random seeds. We indeed try to use different random seeds for a few models and we confirm that the validation loss difference is at least ten times smaller than the improvement of different models.

To verify that our testing dataset is large enough to provide stable perplexity, we randomly split the testing dataset into 10 subsets and compute the standard error of the average testing perplexity of the 10 subsets. We find that the standard error is less than 0.02 perplexity in all models and datasets in Table 1. The standard error is much smaller than most of the improvements, which means our testing dataset is large enough to make the reported perplexity stable. The consistent improvements during the whole training process in Figure 5 further sup-

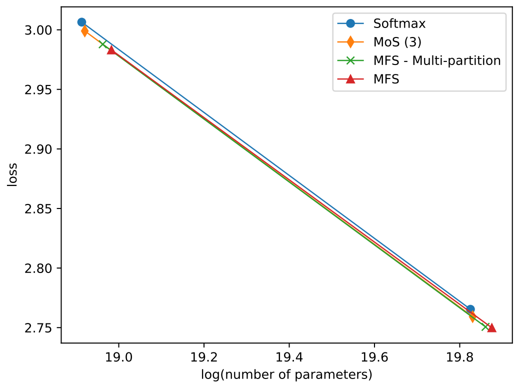

Figure 7: The log of model size versus the log of perplexity in the text set of OpenWebText. The group of points on the left comes from the models based on *GPT-2 Small*. The group of points on the right comes from the models based on *GPT-2 Medium*. The models are trained for 0.4 epoch.

port the stability of our experiments.

C.5 ProtoQA Results using WordNet

In Table 5, we report the metrics using exact matching. In Table 11, we report the metrics that match the prediction with the ground truth using WordNet (Miller, 1992) and find the scores show a similar trend.

C.6 Perplexity Improvement versus Model Size

Kaplan et al. (2020) empirically demonstrate that increasing the model size would decrease the loss and their relation follows a scaling law. That is, we can plot the log of model size (i.e., parameter number) versus its loss as in Figure 7, and if a new LM model could result in lines that are closer to the origin than the baselines, the new model is better in terms of the loss than only increasing the model size of the baselines.

From Figure 7, we can see that the approaches using multiple embedding are better than the **Softmax** baseline using single embedding. Although the lines formed by **MFS w/o Multi-partition** and **MFS** are not always closer to the origin than **MoS**, our perplexity improvement from adding multiple input hidden states or multiple partitions cannot be solely explained by their extra parameters for several reasons:

- Compared to **MoS**, the line formed by **MFS w/o Multi-partition** becomes slightly closer to the origin when the model size is close to *GPT-2 Medium*.
- The improvement of **MFS w/o Multi-partitions (S3I9P1)** is larger than the improvement of **Softmax + Multi-input (S1I9P1)** plus the improvement of **MoS (S3I1P1)** in BERT and GPT-2. For example, in BERT base, the perplexity improvement of **Softmax + Multi-input**, **MoS (3)**, and **MFS w/o Multi-partitions** are 0.018, 0.016, and 0.047, respectively.
- Our multi-mode analyses in Appendix B.3 indicate that our enhancements, especially using multiple partitions, capture the multimodal distribution better. We expect that the overall perplexity improvement would be larger if the corpus contains more ambiguous contexts. We also conduct a preliminary experiment to confirm the claim. We add more ambiguous contexts into Wikipedia 2016 by mapping all the uppercased words into the $[UNK]$ token. That is, we add another mode corresponding to the $[UNK]$ token in many context positions. Then, we train and test the uncased BERT in this synthesized dataset. We found that the improvement of **MFS w/o Multi-partition** in this case can do significantly better than simply increasing the model size.
- Our enhancements only require some extra linear layers, which are usually more efficient than increasing the model size (e.g., by adding another transformer layer).
- Unlike increasing the model size, keep increasing the number of input hidden states or the number of partitions would lead to a smaller improvement. This suggests that **MFS** cannot keep storing more and more knowledge into its extra linear layers as in the architecture using a larger hidden state size or a deeper transformer encoder.

C.7 More Visualization

In Table 3, we compare the prediction of **MFS** and **Softmax** on *GPT-2 Small*. In the first two columns of Table 7, we present the examples from the models built on *GPT-2 Medium* in OpenWebText and Wikipedia 2021. We can see a similar pattern. The embedding of the correct answer is different from the embeddings of other possibilities, so **Softmax** assigns lower probabilities to the correct answer, while **MFS** does much better. This suggests that a larger model such as *GPT-2 Medium* suffers from the *softmax bottleneck* in a similar way.

In the last column of Table 7, we visualize an example in another synthetic experiment described in Appendix B.4. We can see that although there may not be any words between the appropriate candidates, the prediction of **Softmax** may still be biased toward one option much more than the other, while the prediction of **MFS** is much closer to the equally likely bimodal distribution we created in the training data.

D Proof of Theorems

To prove Theorem 1, we first introduce a lemma. Assuming in the word embedding of GPT-2, ***woman*** + ***king*** = ***queen*** + ***man***, we want to show that GPT-2 cannot output *woman* and *king* as the top two words in this lemma. This means we cannot find a hidden state $\boldsymbol{h}$ and a threshold $\tau > 0$ such that $\boldsymbol{h}^T$***woman***$\geq \tau$ and $\boldsymbol{h}^T$***king***$\geq \tau$ but $\boldsymbol{h}^T$***queen***$< \tau$ and $\boldsymbol{h}^T$***man***$< \tau$. This example could be generalized into the following Lemma and Theorems. We can generalize the example as follows:

Lemma 1. *Let the output word embeddings in the set* $W = \{\boldsymbol{w}_{l_j} \neq \mathbf{0} | j = 1...L\} \cup \{\boldsymbol{w}_{r_j} \neq \mathbf{0} | j = 1...R\}$ *satisfy* $-a_{l_1}\boldsymbol{w}_{l_1} - ... - a_{l_L}\boldsymbol{w}_{l_L} = a_{r_1}\boldsymbol{w}_{r_1} + ... + a_{r_R}\boldsymbol{w}_{r_R}$, *where their coefficient* $-a_{l_1}, ..., -a_{l_L}, a_{r_1}, ..., a_{r_R}$ *are all positive constants and* $-a_{l_1} - ... - a_{l_L} \geq a_{r_1} + ... + a_{r_R}$. *Then, there is no hidden state* $\boldsymbol{h}$ *and a threshold* $\tau > 0$ *that make* $\min\limits_{\boldsymbol{w}_g \in G} \boldsymbol{h}^T\boldsymbol{w}_g \geq \tau$ *and* $\max\limits_{\boldsymbol{w}_s \in S} \boldsymbol{h}^T\boldsymbol{w}_s < \tau$, *where* $G = \{\boldsymbol{w}_{l_j} | j = 1...L\}$ *and* $S = \{\boldsymbol{w}_{r_j} | j = 1...R\}$.

Proof. To prove by contradiction, we assume there is a $\boldsymbol{h}$ such that $\forall \boldsymbol{w}_{l_j} \in G, \boldsymbol{h}^T\boldsymbol{w}_{l_j} \geq \tau$ and $\forall \boldsymbol{w}_{r_j} \in S, \boldsymbol{h}^T\boldsymbol{w}_{r_j} < \tau$. Thus, we can get $-a_{l_1}\boldsymbol{h}^T\boldsymbol{w}_{l_1} - ... - a_{l_L}\boldsymbol{h}^T\boldsymbol{w}_{l_L} \geq -a_{l_1}\tau - ... - a_{l_L}\tau \geq (a_{r_1} + ... + a_{r_R})\tau > a_{r_1}\boldsymbol{h}^T\boldsymbol{w}_{r_1} + ... + a_{r_R}\boldsymbol{h}^T\boldsymbol{w}_{r_R}$, which contradicts to $-a_{l_1}\boldsymbol{w}_{l_1} - ... - a_{l_L}\boldsymbol{w}_{l_L} = a_{r_1}\boldsymbol{w}_{r_1} + ... + a_{r_R}\boldsymbol{w}_{r_R}$. ☐

We can rephrase the condition and the conclusion to have our Theorem 1.

Theorem 1. *If the nonzero output embeddings of* N *words in a set* W *are linearly dependent and on one side of a hyperplane through the origin, the single embedding representation cannot produce positive logits to a subset of the words in* W *that are higher than all the logits of the other words in* W.[8]

Proof. The set $W = \{\boldsymbol{w}_i \neq \mathbf{0} | i = 1...N\}$ contain the embeddings of the N words. Based on the premise, we can write $\mathbf{0} = a_1\boldsymbol{w}_1 + ... + a_N\boldsymbol{w}_N$ and $\min_{\boldsymbol{w}_i \in W} \boldsymbol{h}_0^T\boldsymbol{w}_i > 0$, where $\boldsymbol{h}_0$ is a normal vector of the hyperplane. At least one of the a_i is negative. Otherwise, we will get the contradiction $0 = \boldsymbol{h}_0^T\mathbf{0} = a_1\boldsymbol{h}_0^T\boldsymbol{w}_1 + ... + a_N\boldsymbol{h}_0^T\boldsymbol{w}_N \geq (a_1 + ... + a_N)\min_{\boldsymbol{w}_i \in W} \boldsymbol{h}_0^T\boldsymbol{w}_i > 0$. Similarly, at least one of a_i is positive. We can move all the terms in $\mathbf{0} = a_1\boldsymbol{w}_1 + ... + a_N\boldsymbol{w}_N$ with negative a_i to the left as $-a_{l_1}\boldsymbol{w}_{l_1} - ... - a_{l_L}\boldsymbol{w}_{l_L} = a_{r_1}\boldsymbol{w}_{r_1} + ... + a_{r_R}\boldsymbol{w}_{r_R}$. If $-a_{l_1} - ... - a_{l_L} \geq a_{r_1} + ... + a_{r_R}$, we choose $G = \{\boldsymbol{w}_{l_j} | j = 1...L\}$. Otherwise, we choose $G = \{\boldsymbol{w}_{r_j} | j = 1...R\}$

If we can have a hidden state such that the positive logits of words in G are always larger than the logits of the other words in W (let's call the complementary set S), there must exist $\tau > 0$ that can make $\min\limits_{\boldsymbol{w}_g \in G} \boldsymbol{h}^T\boldsymbol{w}_g \geq \tau$ and $\max\limits_{\boldsymbol{w}_s \in S} \boldsymbol{h}^T\boldsymbol{w}_s < \tau$, which violates our Lemma 1. ☐

Next, we would like to generalize our Theorem 1 by using a more practical condition where the word embeddings are almost linearly dependent. Notice that the theorem needs to assume the magnitude of the hidden state is limited. Otherwise, the margin could be arbitrarily magnified. In practice, the magnitude is not arbitrarily large in GPT-2 and BERT because a too large magnitude of hidden state could magnify the gradients too much to have a stable training process.

Theorem 2. *Let the output word embeddings in the set* $W = \{\boldsymbol{w}_i \neq \mathbf{0} | i = 1...N\}$ *satisfy* $\boldsymbol{w}_1 = a_2\boldsymbol{w}_2 + ... + a_N\boldsymbol{w}_N + \boldsymbol{\varepsilon}$, *where the constant* $a_2, ..., a_N$ *are neither all zero nor all neg-*

---

[8] Notice that Theorem 1 does not cover the situations where the target top words have negative logits (i.e., some logits of the words in G are negative). In the single softmax model, we believe the situations rarely happen in the LMs empirically.

If some logits of the target top words are still positive, the words that are somehow similar to those words are very likely to also be positive, which would be ranked higher than the target top words with the negative logits.

If the logits of all the target top words are negative in some contexts, the logits of all the words would be negative. Then, the word embeddings with smaller magnitudes tend to have the logits closer to 0, so having the larger logits than the other negative logits. This means the prior probability of the words would be inversed when the hidden states sometimes produce all negative logits.

If a LM always uses negative logits to compute probability in all the contexts, Lemma 1 and Theorem 1 still hold if we set $\tau < 0$ and switch the choices of G and S.

ative and $||\boldsymbol{\varepsilon}|| < \epsilon$. Then, there must be a non-trivial partition $P = \{G, S\}$ of W such that there is no hidden state $||\boldsymbol{h}|| \leq r$ and a threshold $\tau \geq r\epsilon$ that makes $\min_{\boldsymbol{w}_g \in G} \boldsymbol{h}^T\boldsymbol{w}_g \geq (1+\delta)\tau$ and $\max_{\boldsymbol{w}_s \in S} \boldsymbol{h}^T\boldsymbol{w}_s < \tau$, where $\delta = \frac{2}{1+\sum_{i=2...N}|a_i|}$.

Proof. We can first move all the terms with negative a_i to the left as $\boldsymbol{w}_1 - a_{l_1}\boldsymbol{w}_{l_1} - ... - a_{l_L}\boldsymbol{w}_{l_L} = a_{r_1}\boldsymbol{w}_{r_1} + ... + a_{r_R}\boldsymbol{w}_{r_R} + \boldsymbol{\varepsilon}$. We perform proof by contradiction, so we assume the logits of the words in G can always be larger than $(1+\delta)\tau$ and the logits of the words in S can always be smaller than τ.

Case 1: $1 - a_{l_1} - ... - a_{l_L} \geq a_{r_1} + ... + a_{r_R}$, so $1 - a_{l_1} - ... - a_{l_L} \geq \frac{1+\sum_{i=2...N}|a_i|}{2}$. We choose $G = \{\boldsymbol{w}_1, \boldsymbol{w}_{l_1}, ..., \boldsymbol{w}_{l_L}\}$ and $S = \{\boldsymbol{w}_{r_1}, ..., \boldsymbol{w}_{r_R}\}$. Thus, we can get $\boldsymbol{h}^T\boldsymbol{\varepsilon} \leq ||\boldsymbol{h}||||\boldsymbol{\varepsilon}|| \leq r\epsilon \leq \tau$ and

$$\boldsymbol{h}^T\boldsymbol{w}_1 - a_{l_1}\boldsymbol{h}^T\boldsymbol{w}_{l_1} - ... - a_{l_L}\boldsymbol{h}^T\boldsymbol{w}_{l_L} \tag{5}$$
$$\geq (1 - a_{l_1} - ... - a_{l_L})(1+\delta)\tau \tag{6}$$
$$= (1 - a_{l_1} - ... - a_{l_L})(1 + \frac{2}{1+\sum_{i=2...N}|a_i|})\tau \tag{7}$$
$$\geq (1 - a_{l_1} - ... - a_{l_L})(1 + \frac{1}{1 - a_{l_1} - ... - a_{l_L}})\tau \tag{8}$$
$$= (1 - a_{l_1} - ... - a_{l_L} + 1)\tau \tag{9}$$
$$\geq (a_{r_1} + ... + a_{r_R} + 1)\tau \tag{10}$$
$$> a_{r_1}\boldsymbol{h}^T\boldsymbol{w}_{r_1} + ... + a_{r_R}\boldsymbol{h}^T\boldsymbol{w}_{r_R} + \boldsymbol{h}^T\boldsymbol{\varepsilon}, \tag{11}$$

which contradict with $\boldsymbol{w}_1 - a_{l_1}\boldsymbol{w}_{l_1} - ... - a_{l_L}\boldsymbol{w}_{l_L} = a_{r_1}\boldsymbol{w}_{r_1} + ... + a_{r_R}\boldsymbol{w}_{r_R} + \boldsymbol{\varepsilon}$.

Case 2: $1 - a_{l_1} - ... - a_{l_L} < a_{r_1} + ... + a_{r_R}$. We choose $G = \{\boldsymbol{w}_{r_1}, ..., \boldsymbol{w}_{r_R}\}$ and $S = \{\boldsymbol{w}_1, \boldsymbol{w}_{l_1}, ..., \boldsymbol{w}_{l_L}\}$. Therefore,

$$a_{r_1}\boldsymbol{h}^T\boldsymbol{w}_{r_1} + ... + a_{r_R}\boldsymbol{h}^T\boldsymbol{w}_{r_R} \tag{12}$$
$$\geq (a_{r_1} + ... + a_{r_R})(1 + \frac{2}{1+\sum_{i=2...N}|a_i|})\tau \tag{13}$$
$$> (a_{r_1} + ... + a_{r_R})(1 + \frac{1}{a_{r_1} + ... + a_{r_R}})\tau \tag{14}$$
$$= (a_{r_1} + ... + a_{r_R} + 1)\tau \tag{15}$$
$$> (1 - a_{l_1} - ... - a_{l_L} + 1)\tau \tag{16}$$
$$> \boldsymbol{h}^T\boldsymbol{w}_1 - a_{l_1}\boldsymbol{h}^T\boldsymbol{w}_{l_1} - ... - a_{l_L}\boldsymbol{h}^T\boldsymbol{w}_{l_L} - \boldsymbol{h}^T\boldsymbol{\varepsilon}. \tag{17}$$

□

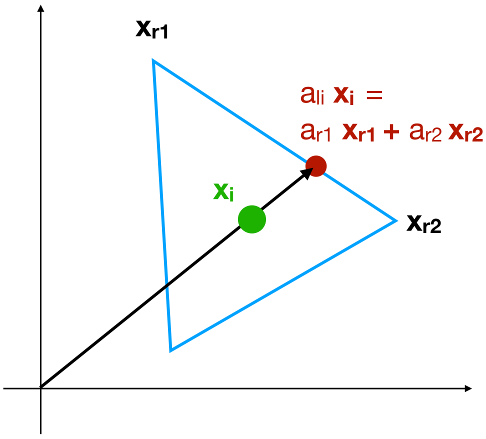

Figure 8: An example for explaining the connection between our Theorem 1 and the theorem from Demeter et al. (2020).

E Theoretical Connection to Demeter et al. (2020)

The theory in Demeter et al. (2020) is as follows: "*Let C be the convex hull of the embeddings $\{\boldsymbol{x}_i\}$ of a vocabulary V. If an embedding $\boldsymbol{x}_i$ for word $\boldsymbol{w}_i \in V$ is interior to C, then the maximum probability $P(\boldsymbol{w}_i)$ assigned to $\boldsymbol{w}_i$ using a dot-product softmax is bounded by the probability assigned to at least one word $\boldsymbol{w}_i$ whose embedding is on the convex hull*"

The theory is a special case of our Lemma 1 if we only consider the hidden states that would lead to the positive logit of the interior word $\boldsymbol{w}_i$. To see that, we first find a constant $a_{l_i} > 1$ such that $a_{l_i}\boldsymbol{x}_i$ intersects with one supporting hyperplane of the convex hull. This intersection point could be expressed by $\sum_j a_{r_j}\boldsymbol{x}_{r_j}$, where the word embeddings $\boldsymbol{x}_{r_j}$ are vertexes of C and $\sum_j a_{r_j} = 1$. As a result, we satisfy the condition of our Lemma 1: $a_{l_i}\boldsymbol{x}_i = \sum_j a_{r_j}\boldsymbol{x}_{r_j}$ and $a_{l_i} > \sum_j a_{r_j}$. Please see an illustration in Figure 8 for an example. Then, Lemma 1 suggests that the logit $\boldsymbol{h}^T\boldsymbol{x}_i$ cannot be larger than the logits of all the word embeddings $\boldsymbol{h}^T\boldsymbol{x}_{r_j}$. This means at least one of the $\boldsymbol{h}^T\boldsymbol{x}_{r_j}$ on the convex hull would lead to a larger prediction probability, which is also the conclusion of the theory in Demeter et al. (2020).

F Method Details

When replacing the softmax layer in the pretrained LMs, we found that the initialization of the extra linear layers should make the initial prediction of LMs close to the prediction using a softmax layer, which is the architecture used in the pretraining. Otherwise, the performance would drop significantly. The initialization is especially important for BERT. To achieve the goal, we initialize the weights of the linear layers such that different facets are almost identical at the beginning and let the LMs gradually learn to output diverse facets during the training. Specifically, we can write the linear layer on the new hidden state $L^f_k(\boldsymbol{q}_{c_t})$ as

$$\begin{aligned}\boldsymbol{f}_{c_t,k} &= L^f_k(\boldsymbol{q}_{c_t}) \\ &= \mathbf{L^I_k}\boldsymbol{h}^M_{c_t} + \mathbf{L^B_k} GELU\left(L^h(\oplus_{i,m}\boldsymbol{h}^{M-m}_{c_t-i})\right) + \boldsymbol{b}.\end{aligned} \tag{18}$$

We initialize $\mathbf{L^I_k}$ as an identity matrix, $\boldsymbol{b} \leftarrow \mathbf{0}$, and $\mathbf{L^B_k} \leftarrow \mathcal{U}(-\epsilon, \epsilon)$, where $\mathcal{U}$ is the uniform distribution and $\epsilon = 0.00005$ if $k \neq K$. Otherwise, $\epsilon = 0$. Consequently, all the facets $\boldsymbol{f}_{c_t,k}$ are initially close to the last hidden state of the original GPT-2 $\boldsymbol{h}^M_{c_t}$. Our baselines (e.g., **Softmax**, **MoS**, and **DOC**) also adopt the same way to initialize their weights.

We implement our models based on huggingface[9] (Wolf et al., 2020). Please see our codes for more details.

F.1 Architecture Differences in BERT

The architecture of **MFS** for BERT is mostly the same as the one for GPT-2 and the differences are described in this subsection.

In GPT-2 the block of input hidden state is right-aligned with the last word to prevent seeing the ground truth. On the other hand, the block in BERT is centered at the masked word.

The softmax layer of BERT is slightly different from that of GPT-2. For example, BERT adds a bias term after the dot product between the hidden state and the output word embedding. We keep the bias term in our experiments. Besides, the pretrained BERT has a language modeling head including a linear layer, a GELU (Gaussian Error Linear Unit) layer (Hendrycks and Gimpel, 2016), and a layernorm layer (Ba et al., 2016), so instead of adding an extra linear layer as in GPT-2, we just use different language modeling heads to create different facets in BERT. All the heads are initialized using the weights in the pretrained BERT except that the linear layer is initialized as in Equation 18 when the multiple input hidden states are used and the corresponding linear weights $\mathbf{L^B_k} \leftarrow \mathcal{U}(-\epsilon, \epsilon)$, where $\epsilon = 0.05$ if $k \neq K$. Otherwise, $\epsilon = 0$.

G Experimental Details

In this section, we describe some details of our experimental setup.

G.1 Baselines

The **MoS** (Yang et al., 2018) and **DOC** (Takase et al., 2018) are originally designed for RNN-based LM. To improve their methods on pretrained Transformer-based LM and make their results more comparable to **MFS**, we change some of their implementation details.

MoS originally has a tanh layer before the softmax layers. However, we found that adding tanh hurts the performances of all methods we tested, especially the **Softmax** and **MoS** baselines. For example, after adding tanh and training *GPT-2 Small* for 0.4 epoch on Wikipedia, the validation perplexity degradation of **Softmax** is from 25.70 to 26.15, the degradation of **MoS** is from 25.42 to 25.83, and the degeneration of **MFS** is from 25.06 to 25.12. We suspect this is because GPT-2 is pretrained without the tanh layer and the tanh limits the magnitude of facets $||\boldsymbol{f}_{c_t,k}||$, which could be viewed as the inverse of the temperature in the softmax layer. Therefore, we remove the tanh layer in all of our experiments. From the theoretical perspective, adding tanh does not invalidate our motivation because adding tanh does not change the total degree of freedom in all facet embeddings and the dimension of the hidden state.

In **DOC**, we use the hidden states of the last three transformer layers to compute the three facets and we set $\lambda_\beta = 0$. Each facet is only determined by one layer of hidden state, so the first two facets cannot access the last hidden state. We found that the model quickly learns to only use the last facet because only the last hidden state is trained to perform the LM task in the pretrained models. This prevents the first two facets from getting any gradients and causes a starvation problem.

We tried an aggressive dropout trick to solve the starvation problem in **DOC**. If one of the softmaxes does not assign the highest probability to any of the correct next words in a batch, we consider that the corresponding facet starves, so we drop the other facets with some probability to ensure this starved facet receives some gradients and gradually gets back on track. However, our preliminary experi-

---

[9] `https://huggingface.co/`

ment suggests that the dropout trick cannot improve the perplexity of **DOC**. The dropout probability is either too low to solve the starvation problem or too high to preserve the knowledge learned from pretraining. Thus, we do not adopt this trick in our final experiment.

G.2 Language Modeling

We download Wikipedia using `http://medialab.di.unipi.it/wiki/Wikipedia_Extractor` and OpenWebText using `https://github.com/jcpeterson/openwebtext`. For Wikipedia, we preprocess the text using `https://github.com/attardi/wikiextractor`. For OpenWebText, we download the pre-filtered URLs in 2017 and 2018 and scrape the text on April 2021. When splitting the corpus into training, validation, and testing sets, we do not shuffle the data. Instead, we use the text near the end of the corpus as the validation and test set to reduce information leakage. To ensure every model is trained on the same data and accelerate the training in our machines, we split the training data into 20 consecutive partitions and load only one partition at a time during training. When training *GPT-2 Medium*, we only use the first 8 partitions to let the training be finished within a week. For BERT, we perform the sentence segmentation using SpaCy[10] and input one sentence into BERT at a time.

We set our hyperparameters (e.g., facet number $K = 3$ and $W \times H = 3 \times 3$ when using multiple input hidden states) based on the validation performance in Wikipedia 2016, the resulting model size, and the memory constraint in GPUs. To explore the limitation of the softmax layer, we untie the input word embeddings and output word embeddings in all of our experiments. The untying allows the LMs to arrange the output word embeddings more freely and allows us to observe if the resulting output word embeddings still cause multi-mode distribution. This is also the main reason the model size of our *GPT-2* baseline is larger than the size of pretrained *GPT-2* (Radford et al., 2019). We use AdamW (Loshchilov and Hutter, 2019) optimizer and set the learning rate as 1e-5 and do not use the warm-up because the training starts from the pretrained models. The sequence length (i.e., bptt) is set as 200 for GPT-2 and 256 for BERT. The batch sizes are set as 4 for *GPT-2 Small*, 16 for *GPT-2 Large*, 120 for *BERT base*, and 128 for *BERT large*.

The analyses in Table 2 and Table 8 use the first 4000 sequences in the validation dataset and all the methods are based on *GPT-2 Small*. We use PYCLD2[11] to distinguish between English and non-English text.

We use NVIDIA GeForce RTX 2080 for training *GPT-2 Small* and *BERT base*, GeForce RTX 8000 for training *GPT-2 Medium*, Tesla M40 for training *BERT large*. Since we start from the pretrained LM, we can finish training each LM within 2 weeks using 1 GPU for *GPT-2 Small*, *BERT base*, and *GPT-2 Medium*, and using 4 GPUs for training *BERT large*.

When testing the inference time in Table 1, we average the time of running NVIDIA TITAN X on 10,000 batches, where each batch contains 4 sequences whose length are 200.

When visualizing the prediction in Table 3, we exclude the non-ASCII symbol prediction from the top word list of all models.

G.3 Ambiguous Templates Analysis

Among the semantic relations in Google analogy dataset, we choose three different relations between locations: *capital-common-countries*, *capital-world*, *city-in-state*, and one relation between people: *family*. We exclude the *currency* category because their instance often does not form a parallelogram in the word embedding space (Ethayarajh et al., 2019). The templates we use are listed in Table 12. For the *family* category, our templates assume the words are not pronouns, so we exclude the set of four words that include *he* or *she*.

For each of the four words in an analogy instance (e.g., ***queen*** : ***king*** = ***woman*** : ***man***), we would create 32 training or testing sequences[12] based on the diagonal words such as *king* or *woman*. Similarly, we would create 64 sequences in the edge datasets. Some words contain multiple word pieces and we average the losses of all word pieces during training and testing.

We split the synthesized sequences based on their word pair overlapping. First, we randomly sample half of the word pairs (e.g., *king* and *queen*) in each category as our training pairs. If both of the word pairs in an analogy instance are training

pairs, the instance is put into our training set. If only one of the word pairs is a training pair, the instance would belong to our validation set. The rest of the instances form our testing set. During the fine-tuning, we evaluate a model using the validation set after each epoch and select the model based on its best validation perplexity.

G.4 ProtoQA Evaluation

In our experiments, we use the scraped development set as our validation set and the crowdsourced development set as our test set. We do not test our methods on the test set of ProtoQA because the result of every submission would show up in their leaderboard and we do not want to overwhelm the leaderboard with our 15 trials.

Due to our limited GPU resources, we compare the methods built on *GPT-2 Medium* rather than *GPT-2 Large*. To maximize the perplexity of the *GPT-2 Medium* model using Softmax on the scraped development set, we fine-tune our models using learning rate 3e-5 and warmup step 500.

The original paper (Boratko et al., 2020) does not consider the frequency of the answer during the fine-tuning (i.e., the most possible answer and the least possible answer of each question appear in the training data with the same chance). In terms of the performance of the scraped development set, we find that weighting each answer based on the square root of its frequency is better than weighting each answer uniformly as in the original paper or weighting each answer based on its frequency, so we use the square root weighting to finetuning all our models.

During testing time, each model generates the answers using Nucleus Sampling (Holtzman et al., 2020) with p = 0.9 and temperature = 1. Then, we collect all the words before the first period as an answer and drop the generated sentences without a period.

H Future Work

Capturing the next word distribution well given an ambiguous context could be important in some downstream applications. A next step could be investigating whether multiple facets lead to a better language generation model for the applications. For example, we would like to know whether breaking the *softmax bottleneck* could reduce the hallucination of LMs (e.g., outputting *queen* when the reasonable next words should be *king* or *woman*) and increase the coherence of the generated text. We also want to more systematically investigate whether modeling multi-mode distribution could help LMs to reduce the undesired bias and to better distinguish similar words (Zagoury et al., 2021) as in Appendix B.4.

Narang et al. (2021); Anonymous (2021) find that *MoS* can significantly improve the BERT-like LMs on natural language understanding (NLU) tasks when the LMs are trained from scratch. Although we find that the perplexity improvement of multi-embedding BERT is not as large as multi-embedding GPT-2, pretraining using multiple embeddings does not decrease the inference speed of the BERT encoder on NLU tasks. This motivates the future studies that test if *MFS* also provides a larger improvement than *MoS* in NLU tasks.

Table 2 suggests that multiple embeddings improve more in a non-English context. We wonder whether multiple embeddings are more beneficial to the LMs that are trained on a non-English dominating corpus. Chung et al. (2021) discover that using a larger output embedding dimension improves the multilingual BERT. An interesting research question is whether the improvement comes from alleviating the *softmax bottleneck* and whether *MFS* could also lead to similar improvements in multilingual benchmarks.

The hidden state size of GPT-3 175B (Brown et al., 2020) is huge (12,288). An interesting question is whether some sets of output word embeddings in GPT-3 are still in a low-dimensional subspace and whether the *softmax bottleneck* is still a prominent problem on the road of pursuing general intelligence when such a large hidden state dimension is used. We also would like to know if models using multiple facets could reach a similar performance by a smaller hidden state size.

Recently, Gao et al. (2019a); Rajaee and Pilehvar (2021); Cai et al. (2021); Su et al. (2022) point out the structure in the contextual embedding space prevents it from having an isotropic property. Our study and Demeter et al. (2020) show that the structure in the word embedding space only models the global similarity between words and prevents the LM from outputting arbitrary context-dependent word distributions. We would like to know if we can discover a new LM architecture with a better contextual/word embedding space that could better model context-dependent word similarities and balance it with the global word similarities. In addition, our finding might be one of the reasons that we can improve the language generation quality by encouraging word embedding to be more isotropic (Su et al., 2022).

Gao et al. (2019b) show that a mixture of kernel functions outperforms MoS. *Mixtape* (Yang et al., 2019) is another efficient solution to the *softmax bottleneck*, whose hidden state for each word is the weighted average of the facets where the weights are dynamically predicted. If only using one softmax (i.e., $K = 1$), our multiple partition method could be viewed as a special case of *Mixtape* that uses a global and binarized weight to prevent complications of predicting the weights of each word. Our results indicate that multiple partitions need to be combined with multiple softmax layers in order to gain consistent performance improvement. A potential future direction is to compare *MFS* with a *mixture of kernel functions* and *Mixtape* on the transformer-based LMs or combine *MFS* with a *mixture of kernel functions* and *Mixtape* to gain further improvements.

The results in Kong et al. (2020) suggest that predicting n-grams could be better than predicting individual words in BERT in some applications. The total number of possible n-grams is several orders of magnitude higher than the number of individual tokens in the vocabulary. In addition, the linear dependency among n-grams might be common. For example, the embedding of the ***brown color*** + ***a dog*** may be similar to the embedding of the ***brown dog***. The problem would be more serious as the length of the prediction sequence (n) increases, so predicting the next sentence using a single embedding might suffer from the *softmax bottleneck* even more. Therefore, our solutions to *softmax bottleneck* may lead to a better phrase representation or sentence representation in this type of self-supervised pretraining.

Finally, language modeling is only an example of extreme classification. The nearly ubiquitous usage of single embedding representation in the classification, self-supervised models (e.g., contrastive learning models), or recommendation problems provides many research opportunities. We believe that our theoretical results could guide researchers to identify the potential applications where the *softmax bottleneck* is serious and multi-embedding representation is accordingly helpful.

Ditch the Gold Standard:
Re-evaluating Conversational Question Answering

Abstract

Conversational question answering aims to provide natural-language answers to users in information-seeking conversations. Existing conversational QA benchmarks compare models with pre-collected human-human conversations, using ground-truth answers provided in conversational history. It remains unclear whether we can rely on this static evaluation for model development and whether current systems can well generalize to real-world human-machine conversations. In this work, we conduct the first large-scale human evaluation of state-of-the-art conversational QA systems, where human evaluators converse with models and judge the correctness of their answers. We find that the distribution of human-machine conversations differs drastically from that of human-human conversations, and there is a disagreement between human and gold-history evaluation in terms of model ranking. We further investigate how to improve automatic evaluations, and propose a question rewriting mechanism based on predicted history, which better correlates with human judgments. Finally, we analyze the impact of various modeling strategies and discuss future directions towards building better conversational question answering systems.[1]

1 Introduction

Conversational question answering aims to build machines to answer questions in conversations and has the promise to revolutionize the way humans interact with machines for information seeking. With recent development of large-scale datasets (Choi et al., 2018; Saeidi et al., 2018; Reddy et al., 2019; Campos et al., 2020), rapid progress has been made in better modeling of conversational QA systems.

Current conversational QA datasets are collected by crowdsourcing human-human conversations, where the questioner asks questions about a specific topic, and the answerer provides answers based on an evidence passage and the conversational history. When evaluating conversational QA systems, a set of held-out conversations are used for asking models questions in turn. Since the evaluation builds on pre-collected conversations, the *gold history* of the conversation is always provided, regardless of models' actual predictions (Figure 1(b)). Although current systems achieve near-human F1 scores on this static evaluation, it is questionable whether this can faithfully reflect models' true performance in real-world applications. To what extent do human-machine conversations deviate from human-human conversations? What will happen if models have no access to ground-truth answers in a conversation?

To answer these questions and better understand the performance of conversational QA systems, we carry out the first large-scale human evaluation with four state-of-the-art models on the QuAC dataset (Choi et al., 2018) by having human evaluators converse with the models and judge the correctness of their answers. We collected 1,446 human-machine conversations in total, with 15,059 question-answer pairs. Through careful analysis, we notice a significant distribution shift from human-human conversations and identify a clear inconsistency of model performance between current evaluation protocol and human judgements.

This finding motivates us to improve automatic evaluation such that it is better aligned with human evaluation. Mandya et al. (2020); Siblini et al. (2021) identify a similar issue in gold-history evaluation and propose to use models' own predictions for automatic evaluation. However, predicted-history evaluation poses another challenge: since all the questions have been collected beforehand, using predicted history will invalidate some of the questions because of changes in the conversational history (see Figure 1(c) for an example).

Following this intuition, we propose a *question*

(a) Human evaluation

(b) Automatic evaluation w/ gold history

(c) Automatic evaluation w/ predicted history

Figure 1: Examples of *human* and *automatic* evaluations with gold or predicted history. The model answers the first question incorrectly. (a) A human questioner asks the next question based on current predictions. (b) Automatic evaluation with gold history poses pre-collected questions with gold answers as conversational history, regardless of model predictions. (c) Using predicted history in automatic evaluation makes the next question invalid.

rewriting mechanism, which automatically detects and rewrites invalid questions with predicted history (Figure 4). We use a coreference resolution model (Lee et al., 2018) to detect inconsistency of conference in question text conditioned on predicted history and gold history, and then rewrite those questions by substituting with correct mentions, so that the questions are resolvable in the predicted context. Compared to predicted-history evaluation, we find that incorporating this rewriting mechanism aligns better with human evaluation.

Finally, we also investigate the impact of different modeling strategies based on human evaluation. We find that both accurately detecting unanswerable questions and explicitly modeling question dependencies in conversations are crucial for model performance. Equipped with all the insights, we discuss directions for conversational QA modeling. We release our human evaluation dataset and hope that our findings can shed light on future development of better conversational QA systems.

2 Preliminary

2.1 Evaluation of conversational QA

Evaluation of conversational QA in real-world consists of three components: an evidence passage P, a (human) questioner $\mathcal{H}$ that has no access to P,[2] and a model $\mathcal{M}$ that has access to P. The questioner asks questions about P and the model answers them based on P and the conversational history thus far (see an example in Figure 1(a)). Formally, for the i-th turn, the human asks a question based on the previous conversation,

$$Q_i \sim \mathcal{H}(Q_1, A_1, ..., Q_{i-1}, A_{i-1}), \qquad (1)$$

and then the model answers it based on both the history and the passage,

$$A_i \sim \mathcal{M}(P, Q_1, A_1, ..., Q_{i-1}, A_{i-1}, Q_i), \qquad (2)$$

where Q_i and A_i represent the question and the answer at the i-th turn. If the question is unanswerable from P, we simply denote A_i as `CANNOT ANSWER`. The model $\mathcal{M}$ is then evaluated by the correctness of answers.

Evaluating conversational QA systems requires human in the loop and is hence expensive. Instead, current benchmarks use automatic evaluation with gold history (*Auto-Gold*) and collect a set of human-human conversations for automatic evaluation. For each passage, one annotator asks questions without seeing the passage, while the other annotator provides the answers. Denote the collected questions and answers as Q_i^* and A_i^*. In gold-history evaluation, the model is inquired with pre-collected questions Q_i^* and the gold answers as history:

$$A_i \sim \mathcal{M}(P, Q_1^*, A_1^*, ..., Q_{i-1}^*, A_{i-1}^*, Q_i^*), \qquad (3)$$

and we evaluate the model by comparing A_i to A_i^* (measured by word-level F1). This process does not require human effort but cannot truly reflect the distribution of human-machine conversations, because unlike human questioners who may ask different questions based on different model predictions, this static process ignores model predictions and always asks the pre-collected question.

In this work, we choose the QuAC dataset (Choi et al., 2018) as our primary evaluation because it is

---

[2] Existing conversational QA datasets make different assumptions: For example, QuAC (Choi et al., 2018) assumes no access but CoQA assumes the questioner to have access.

closer to real-world information-seeking conversations, where the questioner *cannot* see the evidence passage during the dataset collection. It prevents the questioner asking questions that simply overlaps with the passage and encourages unanswerable questions. QuAC also adopts *extractive* question answering that restricts the answer as a span of text, which is generally considered easier to evaluate.

2.2 Models

For human evaluation and analysis, we choose the following four conversational QA models with different model architectures and training strategies:

BERT. It is a simple BERT (Devlin et al., 2019) baseline which concatenates the previous two turns of question-answer pairs, the question, and the passage as the input and predicts the answer span.[3] This model is the same as the "BERT + PHQA" baseline in Qu et al. (2019a).

GraphFlow. Chen et al. (2020) propose a recurrent graph neural network on top of BERT embeddings to model the dependencies between the question, the history and the passage.

HAM. Qu et al. (2019b) propose a history attention mechanism (HAM) to softly select the most relevant previous turns.

ExCorD. Kim et al. (2021) train a question rewriting model on CANARD (Elgohary et al., 2019) to generate context-independent questions, and then use both the original and the generated questions to train the QA model. This model achieves the current state-of-the-art on QuAC (67.7% F1).

For all the models except BERT, we use the original implementations for a direct comparison. We report their performance on both standard benchmark and our evaluation in Table 2.

3 Human Evaluation

3.1 Conversation collection

In this section, we carry out a large-scale human evaluation with the four models discussed above. We collect human-machine conversations using 100 passages from the QuAC development set on Amazon Mechanical Turk.[4] We also design a set of qualification questions to make sure that the annotators fully understand our annotation guideline. For each model and each passage, we collect three conversations from three different annotators.

We collect each conversation in two steps:

(1) The annotator has no access to the passage and asks questions. The model extracts the answer span from the passage or returns `CANNOT ANSWER` in a human-machine conversation interface.[5] We provide the title, the section title, the background of the passage, and the first question from QuAC as a prompt to annotators. Annotators are required to ask at least 8 and at most 12 questions. We encourage context-dependent questions, but also allow open questions like "What else is interesting?" if asking a follow-up question is difficult. (2) After the conversation ends, the annotator is shown the passage and asked to check whether the model predictions are correct or not.

We noticed that the annotators are biased when evaluating the correctness of answers. For questions to which the model answered `CANNOT ANSWER`, annotators tend to mark the answer as incorrect without checking if the question is answerable. Additionally, for answers with the correct types (e.g. a date as an answer to "When was it?"), annotators tend to mark it as correct without verifying it from the passage. Therefore, we asked another group of annotators to verify question answerability and answer correctness.

3.2 Answer validation

For each collected conversation, we ask two additional annotators to validate the annotations. First, each annotator reads the passage before seeing the conversation. Then, the annotator sees the question (and question only) and selects whether the question is (a) ungrammatical, (b) unanswerable, or (c) answerable. If the annotator chooses "answerable", the interface then reveals the answer and asks about its correctness. If the answer is "incorrect", the annotator selects the correct answer span from the passage. We discard all questions that both annotators find "ungrammatical" and the correctness is taken as the majority of the 3 annotations.

3.3 Annotation statistics

In total, we collected 1,446 human-machine conversations and 15,059 question-answer pairs. We release this collection as an important source that

---

[3] We use `bert-base-uncased` as the encoder.

[4] We restrict the annotators from English-speaking countries, and those who have finished at least 1,000 HITS with an acceptance rate of >95%. The compensation rate for Amazon Mechanical Turk workers is calculated using $15/h.

[5] We used ParlAI (Miller et al., 2017) to build the interface.

	Human Evaluation				QuAC
	BERT	GF	HAM	ExCorD	
# C	357	359	373	357	1,000
# Q	3,755	3,666	3,959	3,679	7,354

Table 1: Number of conversations (# C) and questions (# Q) collected in human evaluation, using 100 passages from the QuAC development set. We also add QuAC *development* set for reference. GF: GraphFlow.

complements existing conversational QA datasets. Numbers of conversations and question-answer pairs collected for each model are shown in Table 1. The data distribution of this collection is very different from the original QuAC dataset (human-human conversations): we see more open questions and unanswerable questions, due to less fluent conversation flow caused by model mistakes, and that models cannot provide feedback to questioner about whether an answer is worth following up like human answerers do (more analysis in §6.2).

Deciding the correctness of answers is challenging even for humans in some cases, especially when questions are short and ambiguous. We measure annotators' agreement and calculate the Fleiss' Kappa (Fleiss, 1971) on the agreement between annotators in the validation phase. We achieve $\kappa = 0.598$ (moderate agreement) of overall annotation agreement. Focusing on answerability annotation, we have $\kappa = 0.679$ (substantial agreement).

4 Disagreements between Human and Gold-history Evaluation

We now compare the results from our human evaluation and gold-history (automatic) evaluation. Note that the two sets of numbers are not directly comparable: (1) the human evaluation reports accuracy, while the automatic evaluation reports F1 scores; (2) the absolute numbers of human evaluation are much higher than those of automatic evaluations. For example, for the BERT model, the human evaluation accuracy is 82.6% while the automatic evaluation F1 is only 63.2%. The reason is that, in automatic evaluations, the gold answers cannot capture all possible correct answers to open-ended questions or questions with multiple answers; however, the human annotators can evaluate the correctness of answers easily. Nevertheless, we can compare relative rankings between different models.

Figure 2 shows different trends between human evaluation and gold-history evaluation (Auto-Gold).

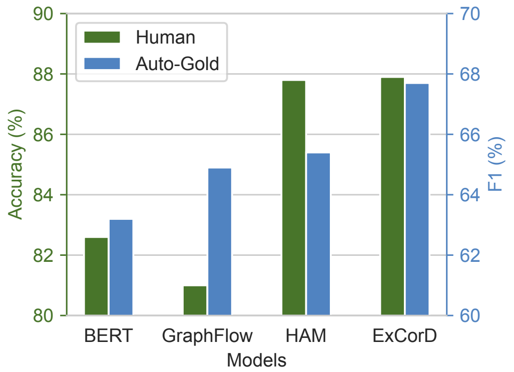

Figure 2: Model performance of human evaluation (accuracy, left) and Auto-Gold (F1, right). Scales for accuracy and F1 are different. Human evaluation and Auto-Gold rank BERT and GraphFlow differently.

Current standard evaluation cannot reflect model performance in human-machine conversations: (1) Human evaluation and Auto-Gold rank BERT and GraphFlow differently; especially, GraphFlow performs much better in automatic evaluation, but worse in human evaluation. (2) The gap between HAM and ExCorD is significant (F1 of 65.4% vs 67.7%) in the automatic evaluation but the two models perform similarly in human evaluation (accuracy of 87.8% vs 87.9%).

5 Strategies for Automatic Evaluation

The inconsistency between human evaluation and gold-history evaluation suggests that we need better ways to evaluate and develop our conversational QA models. When being deployed in realistic scenarios, the models would never have access to the ground truth (gold answers) in previous turns and are only exposed to the conversational history and the passage. Intuitively, we can simply replace gold answers by the predicted answers of models and we name this as **predicted-history** evaluation (*Auto-Pred*). Formally, the model makes predictions based on the questions and its own answers:

$$A_i \sim \mathcal{M}(P, Q_1^*, A_1, ..., Q_{i-1}^*, A_{i-1}, Q_i^*). \quad (4)$$

This evaluation has been suggested by several recent works (Mandya et al., 2020; Siblini et al., 2021), which reported a significant performance drop using predicted history. We observe the same performance degradation, shown in Table 2.

However, another issue naturally arises with predicted history: Q_i^*s were written by the dataset annotators based on $(Q_1^*, A_1^*, ..., Q_{i-1}^*, A_{i-1}^*)$, which

Unresolved coreference (44.0%)	
Q_1^*:	What was Frenzal Rhomb's first song?
A_1^*:	Punch in the Face.
A_1:	`CANNOT ANSWER`.
Q_2^*:	How did *it* fare?
Incoherence (39.1%)	
Q_1^*:	Did Billy Graham succeed in becoming a chaplain?
A_1^*:	He *contracted mumps* shortly after...
A_1:	After a period of recuperation in Florida, he ...
Q_2^*:	Did he retire after his *mumps diagnosis*?
Correct answer changed (16.9%)	
Q_1^*:	Are there any other interesting aspects?
A_1^*:	... *Steve Di Giorgio returned to the band*...
A_1:	... bassist Greg Christian had left Testament again...
Q_2^*:	What happened following *this change in crew*?

Figure 3: Examples of invalid questions with predicted history. Some are shortened for better demonstration. Q_i^*, A_i^*: questions and gold answers from the collected dataset, A_i: model predictions.

may become unnatural or invalid when the history is changed to $(Q_1^*, A_1, ..., Q_{i-1}^*, A_{i-1})$.

5.1 Predicted history invalidates questions

We examined 100 QuAC conversations with the best-performing model (ExCorD) and identified three categories of invalid questions caused by predicted history. We find that 23% of the questions become invalid after using the predicted history. We summarize the types of invalid questions as follows (see detailed examples in Figure 3):

- **Unresolved coreference** (44.0%). The question becomes invalid for containing either a pronoun or a definite noun phrase that refers to an entity unresolvable without the gold history.
- **Incoherence** (39.1%). The question is incoherent with the conversation flow (e.g., mentioning an entity non-existent in predicted history). While humans may still answer the question using the passage, this leads to an unnatural conversation and a train-test discrepancy for models.
- **Correct answer changed** (16.9%). The answer to this question with the predicted history changes from when it is based on the gold history.

We further analyze the reasons for the biggest "unresolved coreference" category and find that the model either gives an incorrect answer to the previous question ("incorrect prediction", 39.8%), or the model predicts a different (yet correct) answer to an open question ("open question", 37.0%), or the model returns `CANNOT ANSWER` incorrectly ("no prediction", 9.5%), or the gold answer is longer than prediction and the next question depends on the extra part ("extra gold information", 13.6%). Invalid questions result in compounding errors, which may further affect how the model interprets the following questions.

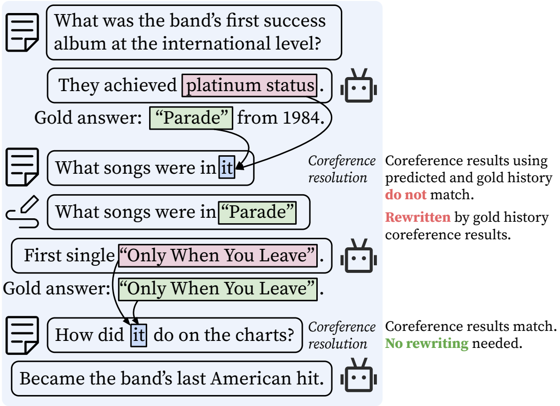

Figure 4: An example of question rewriting. We rewrite the second question with referent in the gold history, because predicted and gold history have different coreference results. We do not rewrite the third question as coreference results are the same.

5.2 Evaluation with question substitution

Among all the invalid question categories, "unresolved coreference" questions are the most critical ones. They lead to incorrect interpretations of questions and hence wrong answers. We propose to improve our evaluation by first detecting these questions using a state-of-the-art coreference resolution system (Lee et al., 2018)[6], and then substituting them with either rewriting the questions in-place and replacing the questions with their context-independent counterparts.

Detecting invalid questions. We make the assumption that if the coreference model resolves mentions in Q_i^* differently between using gold history $(Q_1^*, A_1^*, ..., A_{i-1}^*, Q_i^*)$ and predicted history $(Q_1^*, A_1, ..., A_{i-1}, Q_i^*)$, then Q_i^* is identified as having an unresolved coreference issue.

The inputs to the coreference model for Q_i^* are the following:

$$S_i^* = [BG; Q_{i-k}^*; A_{i-k}^*; Q_{i-k+1}^*; A_{i-k+1}^*; ...; Q_i^*]$$
$$S_i = [BG; Q_{i-k}^*; A_{i-k}; Q_{i-k+1}^*; A_{i-k+1}; ...; Q_i^*],$$

---

[6] We use the coreference model from AllenNLP (Gardner et al., 2018).

	All				Answerable questions			
	BERT	GraphFlow	HAM	ExCorD	BERT	GraphFlow	HAM	ExCorD
Auto-Gold (F1)	63.2	64.9	65.4	67.7	61.8	66.6	64.5	66.4
Auto-Pred (F1)	54.6	49.6	57.2	61.2	52.7	54.5	54.6	59.2
Auto-Rewrite (F1)	54.5	48.2	57.3	61.9	51.2	51.9	55.1	59.7
Auto-Replace (F1)	54.2	47.8	57.1	61.7	50.7	51.7	54.8	59.7
Human (Accuracy)	82.6	81.0	87.8	87.9	75.9	83.2	84.8	85.3

Table 2: Model performance in automatic and human evaluations. We report *overall performance* on all questions and also performance on *answerable questions* only.

where BG is the background, S_i^* and S_i denote the inputs for gold and predicted history. After the coreference model returns entity cluster information given S_i^* and S_i, we extract a list of entities $E^* = \{e_1^*, ..., e_{|E^*|}^*\}$ and $E = \{e_1, ..., e_{|E|}\}$.[7] We say Q_i^* is *valid* only if $E^* = E$, that is,

$$|E^*| = |E| \text{ and } e_j^* = e_j, \forall e_j \in E,$$

assuming e_j^* and e_j have a shared mention in Q_i^*. We determine whether $e_j^* = e_j$ by checking if $\mathrm{F1}(s_j^*, s_j) > 0$, where s_j^* and s_j are the *first* mention of e_j^* and e_j respectively, and F1 is the word-level F1 score, i.e., $e_j^* = e_j$ as long as their first mentions have word overlap. The reason we take the F1 instead of exact match to check whether the entities are the same is stated in Appendix A.

Question rewriting through entity substitution. Our first strategy is to substitute the entity names in Q_i^* with entities in E^*, if Q_i^* is invalid. The rewritten question, instead of the original one, will be used in the conversation history and fed into the model. We denote this evaluation method as **rewritten-question** evaluation (*Auto-Rewrite*), and Figure 4 illustrates a concrete example.

To analyze how well Auto-Rewrite does in detecting and rewriting questions, we manually check 100 conversations of ExCorD from the QuAC development set. We find that Auto-Rewrite can detect invalid questions with a precision of 72% and a recall of 72% (more detailed analysis in Appendix B). An example of correctly detected and rewritten question is presented in Figure 4.

Question replacement using CANARD. Another strategy is to replace the invalid questions with context-independent questions. The CANARD dataset (Elgohary et al., 2019) provides such a resource, which contains human-rewritten context-independent version of QuAC's questions. Recent works (Anantha et al., 2021; Elgohary et al., 2019) have proposed training sequence-to-sequence models on such dataset to rewrite questions; however, since the performance of the question-rewriting models is upper bounded by the human-rewritten version, we simply use CANARD for question replacement. We denote this strategy as **replaced-question** evaluation (*Auto-Replace*). Because collecting context-independent questions is expensive, Auto-Replace is limited to evaluating models on QuAC; it is also possible to be extended to other datasets by training a question rewriting model, as demonstrated in existing work.

6 Automatic vs Human Evaluation

In this section, we compare human evaluation with all the automatic evaluations we have introduced: gold-history (Auto-Gold), predicted-history (Auto-Pred), and our proposed Auto-Rewrite and Auto-Replace evaluations. We first explain the metrics we use in the comparison (§6.1) and then discuss the findings (§6.2 and §6.3).

6.1 Agreement metrics

Model performance and rankings. We first consider using model performance reported by different evaluation methods. Considering numbers of automatic and human evaluations are not directly comparable, we also calculate models' rankings and compare whether the rankings are consistent between automatic and human evaluations. Model performance is reported in Table 2. In human evaluation, GraphFlow < BERT < HAM ≈ ExCorD; in Auto-Gold, BERT < GraphFlow < HAM < ExCorD; in other automatic evaluations, GraphFlow < BERT < HAM < ExCorD.

---

[7] We are only interested in the entities mentioned in the current question Q_i^* and we filter out named entities (e.g., the *National Football League*) because they can be understood without coreference resolution.

Human Evaluation				QuAC
BERT	GF	HAM	ExCorD	
34.6	20.6	34.1	33.2	20.2

Table 3: Percentage of unanswerable questions in human evaluation (it varies with different models) and the original QuAC dataset (used in all automatic evaluations). GF: GraphFlow.

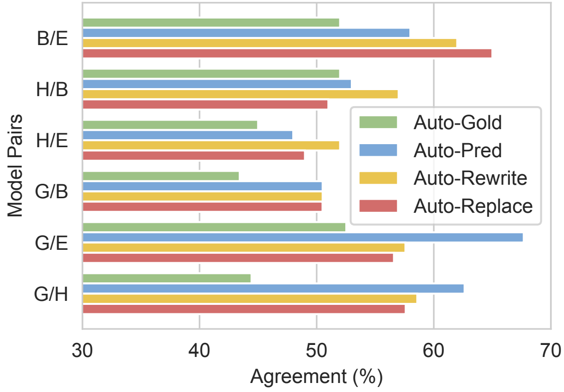

Figure 5: Pairwise agreement of different model pairs comparing automatic evaluations to human evaluation. B: BERT; G: GraphFlow; H: HAM; E: ExCorD.

Statistics of unanswerable questions. Percentage of unanswerable questions is an important aspect in conversations. Automatic evaluations using static datasets have a fixed number of unanswerable questions, while in human evaluation, the percentage of unanswerable questions asked by human annotators varies with different models. The statistics of unanswerable questions is shown in Table 3.

Pairwise agreement. For a more fine-grained evaluation, we perform a passage-level comparison for every pair of models. More specifically, for every single passage we use one automatic metric to decide whether model A outperforms model B (or vice versa) and examine the percentage of passages that the automatic metric agrees with human evaluation. For example, if the pairwise agreement of BERT/ExCorD between human evaluation and Auto-Gold is 52%, it means that Auto-Gold and human evaluation agree on 52% passages in terms of which model is better. Higher agreement means the automatic evaluation is closer to human evaluation. Figure 5 shows the results of pairwise agreement.

6.2 Automatic evaluations have a significant distribution shift from human evaluation

We found that automatic evaluations have a significant distribution shift from human evaluation. We draw this conclusion from the following points.

- Human evaluation shows a much higher model performance than all automatic evaluations, as shown in Table 2. Two reasons may cause this large discrepancy: (a) Many conversational QA questions have multiple possible answers, and it is hard for the static dataset in automatic evaluations to capture all the answers. It is not an issue in human evaluation because all answers are judged by human evaluators. (b) There are more unanswerable questions and open questions in human evaluation (reason discussed in the next paragraph), which are easier—for example, models are almost always correct when answering questions like “What else is interesting?”.

- Human evaluation has a much higher unanswerable question rate, as shown in Table 3. The reason is that in human-human data collection, the answers are usually correct and the questioners can ask followup questions upon the high-quality conversation; in human-machine interactions, since the models can make mistakes, the conversation flow is less fluent and it is harder to have followup questions. Thus, questioners chatting with models tend to ask more open or unanswerable questions.

- All automatic evaluation methods have a pairwise agreement lower than 70% with human evaluation, as shown in Figure 2. This suggests that all automatic evaluations cannot faithfully reflect the model performance of human evaluation.

6.3 Auto-Rewrite is closer to human evaluation

First, we can clearly see that among all automatic evaluations, Auto-Gold deviates the most from the human evaluation. From Table 2, only Auto-Gold shows different rankings from human evaluation, while Auto-Pred, Auto-Rewrite, and Auto-Replace show consistent rankings to human judgments.

In Figure 2, we see that Auto-Gold has the lowest agreement with human evaluation; among others, Auto-Rewrite better agrees with human evaluation for most model pairs. Surprisingly, Auto-Rewrite is even better than Auto-Replace—which uses human-written context independent questions—in most cases. After checking the Auto-Replace conversations, we found that human-written context independent questions are usually much longer than QuAC questions and introduce extra information

	Predicted unanswerable Q.				Precision				Recall			
	B	G	H	E	B	G	H	E	B	G	H	E
Auto-Gold	27.1	21.5	27.1	28.3	56.8	62.3	57.1	57.9	68.1	59.3	68.4	72.5
Auto-Pred	27.8	13.8	28.6	28.9	50.0	53.9	52.3	53.3	61.4	33.0	66.1	68.2
Auto-Rewrite	27.3	13.1	25.1	26.0	48.6	55.0	52.4	53.9	65.7	35.7	65.1	69.4
Auto-Replace	27.5	12.9	25.2	25.7	48.6	54.2	52.1	53.8	66.1	34.7	64.9	68.4
Human	42.3	14.7	37.2	36.0	75.0	93.0	86.8	87.4	95.2	72.5	93.7	93.3

Table 4: The percentage of models' predicted unanswerable questions, and the precision and recall for detecting unanswerable questions in different evaluations. B: BERT; G: GraphFlow; H: HAM; E: ExCorD.

into the context, which leads to out-of-domain challenges for conversational QA models (example in Appendix C). It shows that our rewriting strategy can better reflect real-world performance of conversational QA systems. However, Auto-Rewrite is not perfect—we see that when comparing G/E or G/H, Auto-Pred is better than Auto-Rewrite; in all model pairs, the agreement between human evaluation and Auto-Rewrite is still lower than 70%. This calls for further effort in designing better automatic evaluation in the future.

7 Towards Better Conversational QA

With insights drawn from human evaluation and comparison with automatic evaluations, we discuss the impact of different modeling strategies, as well as future directions towards building better conversational question answering systems.

Modeling question dependencies on conversational context. When we focus on *answerable questions* (Table 2), we notice that GraphFlow, HAM and ExCorD perform much better than BERT. We compare the modeling differences of the four systems in Figure 6, and identify that all the three better systems explicitly model the question dependencies on the conversation history and the passage: both GraphFlow and HAM highlight repeated mentions in questions and conversation history by special embeddings (turn marker and PosHAE) and use attention mechanism to select the most relevant part from the context; ExCorD adopts a question rewriting module that generates context-independent questions given the history and passage. All those designs help models better understand the question in a conversational context. Figure 7 gives an example where GraphFlow, HAM and ExCorD resolved the question from long conversation history while BERT failed.

Unanswerable question detection. Table 4 demonstrates models' performance in detecting *unanswerable questions*. We notice that GraphFlow predicts much fewer unanswerable questions than the other three models, and has a high precision and a low recall in unanswerable detection. This is because GraphFlow uses a separate network for predicting unanswerable questions, which is harder to calibrate, while the other models jointly predict unanswerable questions and answer spans.

This behavior has two effects: (a) GraphFlow's overall performance is dragged down by its poor unanswerable detection result (Table 2). (b) In human evaluation, annotators ask fewer unanswerable questions with GraphFlow (Table 3)—when the model outputs more, regardless of correctness, the human questioner has a higher chance to ask passage-related followup questions. Both suggest that how well the model detects unanswerable questions significantly affects its performance and the flow in human-machine conversations.

Optimizing towards the new testing protocols. Most existing works on conversational QA modeling focus on optimizing towards Auto-Gold evaluation. Since Auto-Gold has a large gap from the real-world evaluation, more efforts are needed in optimizing towards the human evaluation, or Auto-Rewrite, which better reflects human evaluation. One potential direction is to improve models' robustness given noisy conversation history, which simulates the inaccurate history in real world that consists of models' own predictions. In fact, prior works (Mandya et al., 2020; Siblini et al., 2021) that used predicted history in training showed that it benefits the models in predicted-history evaluation.

8 Related Work

et al., 2018), CoQA (Reddy et al., 2019), and DoQA (Campos et al., 2020), as well as a few recent works focusing on conversational open-domain question answering (Adlakha et al., 2021; Anantha et al., 2021; Qu et al., 2020) Different from single-turn QA datasets (Rajpurkar et al., 2016), conversational QA requires the model to understand the question in the context of conversational history. There have been many methods proposed to improve conversational QA performance (Ohsugi et al., 2019; Chen et al., 2020; Qu et al., 2019b; Kim et al., 2021) and significant improvements have been made on conversational QA benchmarks. Besides text-based conversational QA tasks, there also exist conversational QA benchmarks that require external knowledge or other modalities (Saeidi et al., 2018; Saha et al., 2018; Guo et al., 2018; Das et al., 2017).

Only recently has it been noticed that the current method of evaluating conversational QA models is flawed. Mandya et al. (2020); Siblini et al. (2021) point out that using gold answers in history is not consistent with real-world scenarios and propose to use predicted history for evaluation. Different from prior works, in this paper, we conduct a large scale human evaluation to provide evidence for why gold-history evaluation is sub-optimal. In addition, we point out that even predicted-history evaluation has issues with invalid questions, for which we propose rewriting questions to further mitigate the gap.

Automatic evaluation of dialogue systems. Automatically evaluating dialogue systems is difficult due to the nature of conversations. In recent years, the NLP community has cautiously re-evaluated and identified flaws in many popular automated evaluation strategies of dialogue systems (Liu et al., 2016; Sai et al., 2019), and have proposed new evaluation protocols to align more with human evaluation in a real-world setting: Huang et al. (2020); Ye et al. (2021) evaluate the coherence of the dialogue systems; Gupta et al. (2019) explore to use multiple references for evaluation; Mehri and Eskenazi (2020) propose an unsupervised and reference-free evaluation; Lowe et al. (2017); Tao et al. (2018); Ghazarian et al. (2019); Shimanaka et al. (2019); Sai et al. (2020) train models to predict the relatedness score between references and model outputs, which are shown to be better than BLEU (Papineni et al., 2002) or ROGUE (Lin, 2004).

9 Conclusion

In this work, we carry out the first large-scale human evaluation on conversational QA systems. We show that current standard automatic evaluation with gold history cannot reflect models' performance in human evaluation, and that human-machine conversations have a large distribution shift from static conversational QA datasets of human-human conversations. To tackle these problems, we propose to use predicted history with rewriting invalid questions for evaluation, which reduces the gap between automatic evaluations and real-world human evaluation. Based on the insights from the human evaluation results, we also nalyze current conversational QA systems and identify promising directions for future development.

A Invalid Question Detection

In question rewriting, we use F1 instead of exact match to check whether two entites are the same. The reason is that sometimes the prediction may mention the same entity as the gold answer does, but with different names. Figure 8 gives an example. Thus to avoid the false positive of detecting invalid questions, we take the F1 metric.

Q_1^*: Who is at the door?
A_1^*: *An elderly Chinese lady* and a little boy
A_1: *elderly Chinese lady*

Q_2^*: Is *she* carrying something?

Figure 8: An example that the prediction may mention the same entity as the gold answer does with slightly different names.

B Quality of Rewriting Questions

Detection. After manually checking 100 conversations of ExCorD from the QuAC development set, we find that Auto-Rewrite can detect invalid questions with a precision of 72% and a recall of 72%. We notice that the coreference model sometimes detects the pronoun of the main character in the passage as insolvable, although it almost shows up in every question. This issue causes the low precision but is not a serious problem in our case – whether rewriting the pronoun of the main character does not affect models' prediction much, because the model always sees the passage and knows who the main character is.

Rewriting. Among all correctly detected invalid questions, we further check the quality of rewriting, and in 68% of the times Auto-Rewrite gives a correct context-independent questions. The most common error is being ungrammatical. For example, using the gold history of "... Dee Dee claimed that Spector once ***pulled*** a gun on him", the original question "Did they arrest him for doing *this*?" was rewritten to "Did they arrest Phillip Harvey Spector for doing ***pulled***?" While this creates a distribution shift on question formats, it is still better than putting an invalid question in the flow.

C Issue with Context Independent Questions

Figure 9 shows an example where extra information in context-independent questions confuses the model and leads to incorrect prediction.

Q^*: Did he go on to any other notable matches?

Q^W: Did *he* go on to any other notable matches?
A^W: During the Test match series against Australia in 2010, at the Melbourne Cricket Ground...

Q^P: Did *Mohammad Amir* go on to any other notable matches, *besides on 9 November 2009*?
A^P: Later in 2009, Pakistan toured Sri Lanka

Figure 9: The context-independent question Q^P by Auto-Replace contains extra information that confuses the model. The rewritten question Q^W did not change the original question and led to a correct answer.

Fantastically Ordered Prompts and Where to Find Them: Overcoming Few-Shot Prompt Order Sensitivity

Abstract

When primed with only a handful of training samples, very large, pretrained language models such as GPT-3 have shown competitive results when compared to fully-supervised, fine-tuned, large, pretrained language models. We demonstrate that the order in which the samples are provided can make the difference between near state-of-the-art and random guess performance: essentially some permutations are "fantastic" and some not. We analyse this phenomenon in detail, establishing that: it is present across model sizes (even for the largest current models), it is not related to a specific subset of samples, and that a given good permutation for one model is not transferable to another. While one could use a development set to determine which permutations are performant, this would deviate from the true few-shot setting as it requires additional annotated data. Instead, we use the generative nature of language models to construct an artificial development set and based on entropy statistics of the candidate permutations on this set, we identify performant prompts. Our method yields a 13% relative improvement for GPT-family models across eleven different established text classification tasks.

1 Introduction

Large pretrained language models (PLMs, Devlin et al., 2019; Peters et al., 2018; Raffel et al., 2020; Liu et al., 2019; Yang et al., 2019; Radford et al., 2019) have shown remarkable performance when conditioned with an appropriate textual context (Petroni et al., 2019, 2020; Jiang et al., 2020; Shin et al., 2020; Davison et al., 2019). For example, when conditioned on a long document and a "TL;DR:" token, they can generate a summary of said document, and when provided a partial question ("The theory of relativity was developed by __"), they can generate the correct answer. Perhaps most strikingly, when primed with a context consisting of very few training examples, they produce text classification results that can match those of fully supervised models. This type of few shot setting, is commonly referred to as "In-context Learning" (Brown et al., 2020).

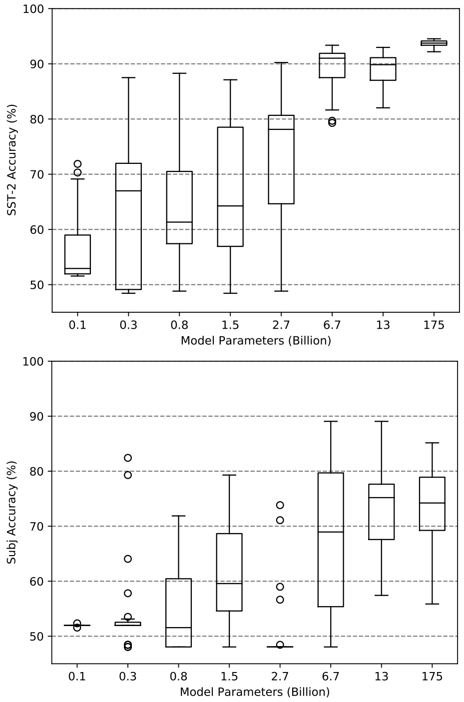

Figure 1: Four-shot performance for 24 different sample orders across different sizes of GPT-family models (GPT-2 and GPT-3) for the SST-2 and Subj datasets.

A core component of in-context learning is the text-based prompt that serves as the context. Composing a prompt requires: (i) text linearisation using a template; and (ii) training sample concatenation (See Table 1 for an example). It has been established that the structure of the template has a large impact on performance (Shin et al., 2020; Gao et al., 2020; Schick and Schütze, 2020; Jiang et al., 2020). However, to the best of our knowledge, no work has studied the effect of the sample ordering on In-context Learning performance.

Perhaps counter-intuitively, we find that the right sample order can make as much of a difference as

Table 1: Procedures for prompt construction.

the right template. As can be seen in Figure 1, some permutations have comparable performance (over 85% accuracy) to supervised training for sentiment classification, while others perform close to random (around 50%). This order sensitivity is universal across models, and although increasing the model size somewhat addresses it, the problem is still present for some text classification tasks (Subj in Figure 1) for models with billions of parameters.

In our analysis, we find no common denominator between performant sample orders and that they are not transferable across different model sizes and tasks. In a fully-supervised setting, we could rely on a development set to select among sample orders. However, this is not desirable in a few-shot setting where the size of the development set is very limited, even unavailable (Perez et al., 2021) . Instead, we use the generative nature of language models to construct an unlabelled artificial development set and refer to it as a *probing set*. As the probing set is unlabelled, we use the predicted label distribution statistics and propose entropy-based metrics to measure the quality of candidate prompts.Experimental results show that we can achieve on average 13% relative improvement across eleven different established text classification tasks across all different sizes (four orders of magnitude) of PLMs.

To summarise, our contributions are as follows:

1. We study order sensitivity for In-context Learning, which we show is crucial for the success of pretrained language models for few-shot learning.

2. We propose a simple, generation-based probing method to identify performant prompts without requiring additional data.

3. Our probing method is universally applicable and effective across different sizes of pretrained language models and for different types of datasets – achieving on average a 13% relative improvement over a wide range of tasks.

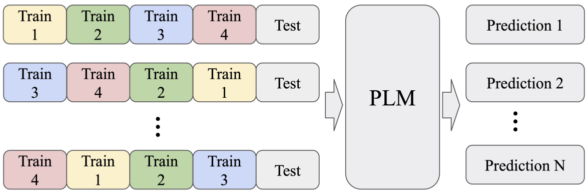

Figure 2: Training sample permutations for the In-context Learning setting. The concatenation of training samples as well as test data transforms the classification task into a sequence generation task.

2 Order Sensitivity and Prompt Design

In this section, we study the relationship between permutation performance and various factors. For the ease of visualisation, we use a fixed random subset of four samples with a balanced label distribution from the SST-2 dataset and consider all 24 possible sample order permutations. This setup is illustrated in Figure 2. We also test five randomly-selected sets of examples and summarised variance statistics in the experiment section (Section 5).

Although beneficial, increasing model size does not guarantee low variance We evaluate the order permutations for four different sizes of GPT-2 (0.1B–1.5B)[1] and GPT-3 (2.7B–175B). As we can observe in Figure 1, models can obtain remarkable few-shot performance. We see that the GPT2-XL (1.5B) model can even surpass 90% accuracy given just four samples. This result is comparable to those of supervised models trained on more than 60,000 samples. However, the performance variation of different permutations remain a big issue, especially for "smaller" models.[2] The same model can exhibit nearly perfect behaviour given one sample order, but then fall back to be on par with a random baseline for another. While increasing the model size (by a few order of magnitudes) can sometimes alleviate the issue, it still cannot resolve it entirely (especially if we consider tasks other than SST-2). In contrast, different initialisations of supervised fine-tuning approaches typically result in less than 1% standard deviation for their test set performance (Gao et al., 2020).

---

[1] We can also refer these models as GPT2-base, GPT2-medium, GPT2-Large, and GPT2-XL.

[2] The smallest model in our experiment is the same size as BERT-base.

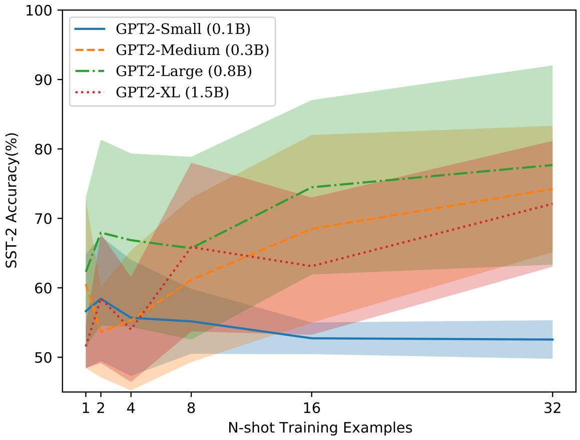

Figure 3: Order sensitivity using different numbers of training samples.

Adding training samples does not significantly reduce variance To further explore the order sensitivity of few-shot prompts, we increase the number of training samples and then sample a subset of at most 24 different orderings.[3] We use the GPT2 family models for this experiment. In Figure 3, we can observe that increasing the number of training samples leads to increases in performance. However, a high level of variance remains, even with a large number of samples and can even increase. Based on this, we draw the conclusion that order sensitivity is likely to be a fundamental issue of In-context Learning regardless of the number of training samples.

Performant prompts are not transferable across models We find that a specific permutation's performance may drop from 88.7% to 51.6% by changing the underlying model from GPT2-XL (1.5B) to GPT2-Large (0.8B). This suggests that a particular permutation working well for one model does not imply that it will provide good results for another model. To validate this hypothesis, we use all possible order permutations of the four samples as prompts – 24 in total. We then perform prediction conditioned on each of these prompts for different models and calculate the pairwise Spearman's rank correlation coefficient between the scores. These results are shown in Figure 4.

If there is a common pattern for performant prompts, we should then be able to observe high correlation across models. However, the behaviour of permutations is seemingly random even across different sizes of the same model. For example, the 175B and 2.7B model only has a correlation of 0.05, this means a good permutation for the 2.7B model is in no way guaranteed that it will also yield good performance for the 175B model.

Figure 5: Training label pattern permutation performance correlation across different models.

Performant label orderings are not consistent across models In addition to training example ordering, we also explore label ordering for training prompts. We use all patterns of the above-mentioned full permutations – six different label patterns.[4] We then compute the pairwise Spearman correlation across different models as described in the previous paragraph. As shown in Figure 5, the behaviour of label orderings is once again seemingly random across different sizes of the same model. It is thus not possible to identify a label

---

[3] Bounded at the lower limit by the total number of samples given, and at the upper limit as there can be up to 64! possible orders.

[4] NNPP, NPNP, NPPN, PNNP, PNPN, PPNN, where P/N respectively denotes positive/negative

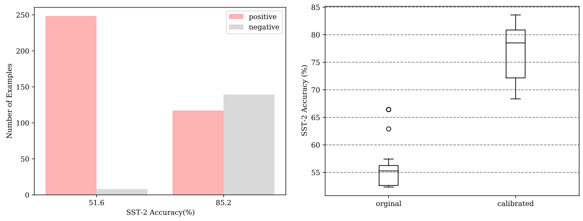

Figure 6: Left: Predicted SST-2 label distribution under different prompts. Right: 2-shot calibrated performance (Zhao et al., 2021) of all possible permutations on GPT2-XL (1.5B).

ordering that is performant across different models.

Degenerate behaviour of bad prompts We perform error analysis across performant and non-performant prompts and observe that the majority of failing prompts suffer from highly unbalanced predicted label distributions (Figure 6, left). An intuitive way to address this would be by calibrating the output distribution, along the lines of Zhao et al. (2021). However, we find that although calibration leads to much higher performance, the variance remains high (Figure 6, right).

3 Methodology

The previous section demonstrates that prompt order can have a substantial effect on performance, with some orderings of the same prompts for the same model providing random performance, and other "better" orderings providing performance competitive with supervised approaches. This suggests that there could be various ways of selecting prompt orders to achieve better performance, but the challenge is to do so automatically and without the need for additional labels (e.g., a development set).

Hence, in this section, we explore the question of: "How can we automatically generate a 'probing set' to find performant prompt orderings"? We approach this by: (i) for a randomly-selected set of training samples, we use every possible ordering permutation of this set as candidates; (ii) constructing a *probing set* by querying the language model using all candidate prompts as context; and (iii) use this probing set to identify the best ordering by ranking them using a probing metric.

3.1 Sampling from the Language Model to Construct a Probing Set

We propose a simple methodology to automatically construct a "probing set", by directly sampling from the language model itself. This approach makes it possible to generate probing sets automatically, without access to any additional data. Concretely, given a set of training samples $S = \{(x_i, y_i)\}, i = 1, \cdots, n$, where x_i and y_i denote the sentence and label of the i^{th} training sample. We then define a transformation $\mathcal{T}$, mapping each sample into natural language space, such that $t_i = \mathcal{T}(x_i, y_i)$. t_i is therefore a text sequence of the i^{th} training sample using the template defined by $\mathcal{T}$. In this work, we use a simple transformation function $\mathcal{T}$ such that $\mathcal{T}(x_i, y_i) =$ input:x_i type:y_i. This transforms each sample into a standard format sentence, which linearises each element in the set into natural language space defined as $S^{'} = \{t_i\}, i = 1, \cdots, n$.

We then define a full permutation function group of n training samples, $\mathcal{F} = \{f_m\}, m = 1, \cdots, n!$, where each function f_m takes $S^{'}$ as input and outputs c_m: the concatenation of a unique permutation. In our case, sampling four training samples at random gives up to 24 possible ordering permutations of the transformed samples.

For each prompt candidate c_m, we then sample from the language model to obtain the probing sequence $g_m \sim P(\cdot|c_m; \theta)$, where θ denotes the parameters of the pretrained language model. We stop decoding from the language model upon generating the special end-of-sentence token defined by a template, or reach the generation length limit. Our probing set construction method is illustrated in Figure 7, where the objective is to generate a probing set that shares a similar distribution to the training samples.

We run this sampling process for all possible prompt ordering permutations and extract probing samples from them ($\mathcal{T}^{-1}(g)$). Then gather extracted samples together to form the probing set $D = \mathcal{T}^{-1}(g_1) \oplus ... \oplus \mathcal{T}^{-1}(g_{n!})$. Although the probing set contains predicted label for each sentence, there is no guarantee on the validity of these labels. Therefore, we discard them from the probing set as we are only interested in sampling probes from the language model corresponding to the input distribution.

3.2 Probing Metrics

Once we have constructed a probing set for a given set of samples, we can now use that probing set to identify the best possible prompt ordering for that particular sample set. Here, we explore two

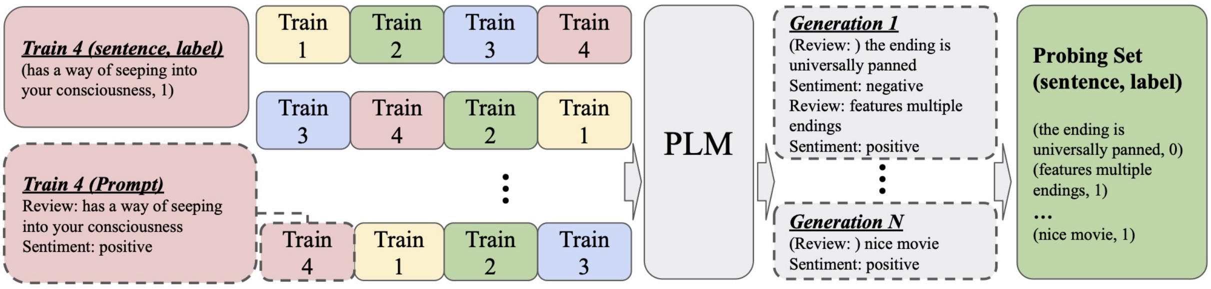

Figure 7: Our probing set construction method, showing the various possible ordering permutations of the randomly selected training samples, the resulting generation for each permutation, and the concatenation of each into a probing set. Note that we discard the generated labels, as there is no guarantee that these generated labels are correct.

methods for selecting the best ordering: Global Entropy (GlobalE), and Local Entropy (LocalE).

Global Entropy (GlobalE) The motivation behind GlobalE is to identify prompts of specific sample orderings that avoid the issue of extremely unbalanced predictions (as we have previously established it as key problem for non-performant prompts). We compute the predicted label $\hat{y}_i$ for data point $(x_i^{'}, y_i^{'})$ under context c_m as follows:

$$\hat{y}_{i,m} = \underset{v \in V}{\operatorname{argmax}} \, P(v | c_m \oplus \mathcal{T}(x_i^{'}); \theta) \tag{1}$$

For each label $v \in V$ (where V denotes the target label set), we compute the label probability over the probing set as:

$$p_m^v = \frac{\sum_i \mathbb{1}_{\{\hat{y}_{i,m} = v\}}}{|D|} \tag{2}$$

We then use the predicted category label entropy as the GlobalE score for c_m as follows:

$$\text{GlobalE}_m = \sum_{v \in V} -p_m^v \log p_m^v \tag{3}$$

Local Entropy (LocalE) The motivation behind LocalE is that if a model is overly confident for all probing inputs, then it is likely that the model is not behaving as desired. At the very least, it is poorly calibrated, which could also be an indication of a poor capability to appropriately differentiate between classes. Similar to the GlobalE computation, we calculate the prediction probability of a data point $(x_i^{'}, y_i^{'})$ over the target labels $v \in V$ under context c_m, as follows:

$$p_{i,m}^v = P_{(x_i^{'}, y_i^{'}) \sim D}(v | c_m \oplus \mathcal{T}(x_i^{'}); \theta), v \in V \tag{4}$$

We then calculate the average prediction entropy per data point as the LocalE score:

$$\text{LocalE}_m = \frac{\sum_i \sum_{v \in V} -p_{i,m}^v \log p_{i,m}^v}{|D|} \tag{5}$$

As we now have a way to score each prompt ordering, based on its effect against the probing set, we can rank each prompt ordering by performance as measured by GlobalE or LocalE respectively.

4 Experimental Setup

We use four different sizes of GPT-2 (Radford et al., 2019) (with 0.1B, 0.3B, 0.8B, and 1.5B parameteers) and two sizes of GPT-3 (Brown et al., 2020) (with 2.7B, and 175B parameters). Due to limited context window size (up to 1024 word-pieces for the GPT-2 series of models), we use a 4-shot setting for all datasets except AGNews and DBPedia. Our experiments are based on the open-source checkpoints of GPT-2 models and access to the OpenAI GPT-3 API.[5] For probing set generation, we restrict the maximum generation length to 128. We also use sampling with a temperature, t, of 2, and we also make use of block n-gram repetitions (Paulus et al., 2018) to encourage diverse generation.

We use 24 different permutations for each set of randomly selected training samples and use 5 different sets (except for GPT-3 with 175B parameters, where we only do two sets with 12 different permutation due to the high monetary cost) for each experiment, giving a total of 120 runs. We report the mean and standard deviation of the corresponding evaluation metric over 5 different sets.

For performant prompt selection, we rank candidate prompts using the LocalE and GlobalE prob-

Table 2: Our main results on subset of the validation set. To fit the data within the GPT-2 model context window size, we use 1-shot for DBPedia, 2-shot for AGNews, 4-shot for other datasets. All the baseline results are calculated based on 5 different random seeds over 24 train context permutations. LocalE and GlobalE results are calculated based on the top 4 context permutations using our proposed approach. For the GPT-3 175B, we only use 2 seeds with 12 different permutations due to a limited computation budget.

ing metrics over the automatically generated probing set. We then select top k samples ranked by highest entropy values, where $k = 4$ in our experiments, of the available 24 permutations as performant prompts. Finally, we use these performant prompts to evaluate performance on various datasets and demonstrate both better performance and reduced variance. We also provide results for a majority baseline, which always predicts the majority label in the dataset, as a lower-bound of performance. We also provide an oracle to show the upper-bound of performance by selecting the top four performant orderings based on prompt performance on the validation set.

4.1 Evaluation Datasets

Similar to previous work (Gao et al., 2020; Zhao et al., 2021), we use eleven text classification datasets ranging from sentiment classification to textual entailment. Further details of the datasets are provided in the Appendix. For evaluation, we sub-sample 256 samples of the validation sets for all datasets to control for the GPT-3 inference costs as it requires the usage of a monetary paid-for API.

5 Results

We report experimental results in Table 2 and observe consistent improvements for both LocalE and GlobalE across all tasks.

Entropy-based probing is effective for performant prompt selection regardless of model size We find that GlobalE achieves, on average, a 13% relative improvement across the eleven different sentence classification tasks in comparison to prompts that do not make use of probing. LocalE provides results slightly inferior to GlobalE, with an average 9.6% relative improvement over the baseline model. Our selected performant prompts also demonstrate considerably lower variance than using all candidate prompts.

Ranking using Entropy-based probing is robust In Figure 8, we visualise the average performance when varying K for the top K prompt selection. $K = 24$ corresponds to using all sampled prompt orders, which is equivalent to the baseline model performance in Table 2. We can observe that the slope of curves are negative for all datasets, suggesting that our method can rank performant prompts effectively. Though $K = 1$ can provide good performance for most cases, in our experiments, we use $K = 4$ as preliminary experiments indicated that it yielded stable performance across datasets.

4	{Sentence} It was {Label}	good/bad

Table 4: Different Templates for SST-2

Entropy-based probing is effective across templates We evaluate Entropy-based probing for four different templates similar to Gao et al. (2020) and Zhao et al. (2021) (Table 4) for the SST-2 dataset. Experimental results in Table 3 indicate that Entropy-based probing is valid for different templates. We also observe that the randomness across different templates is similar to Section 2. These findings suggest that Entropy-based probing is not sensitive to specific templates, as it consistently provides improvements for all cases.

Performant permutation selection is a safe option for In-context Learning We find that for models that suffer from high prompt variance, our prompt selection process can show large improvements – up to 30% relative improvement. Furthermore, for tasks with low initial prompt performance variance, our method does not negatively impact performance. Our prompt selection provides marginal improvement at worse and on average a 13% relative improvement in the most cases.

Sentence-pair tasks remain challenging for smaller-sized models even with performant permutation selection For the CB and RTE datasets, the performance of GPT-2 models is not significantly different from that of a random baseline. Despite this, we find that our method for identifying performant prompts can still provide minimal performance gains, although these are still within the levels of a random guess or majority vote. One reason for this could be that, for these particular sizes of models on these tasks, no good prompt exists. As such, optimising the prompt is not particularly effective in this setting. This is further supported by the observation that prompt selection can considerably improve performance on both CB and RTE at larger model sizes (particularly so for the GPT-3 175B parameter model). In fact, we find that prompt selection using GlobalE improves performance by 4.9% for GPT-3 175B on CB. This indicates that our method is widely applicable to all model sizes, and across all tasks, as long as they already possess some existing classification ability that can be improved through prompt design.

Entropy-based probing outperforms using subsets of the training data for tuning If one was not to rely on generation, an alternative approach to prompt selection could be to split the (limited) training data to form a validation set. To compare

	GPT-2 0.1B	GPT-2 0.3B	GPT-2 0.8B	GPT-2 1.5B
Baseline	$58.9_{7.8}$	$61.0_{13.2}$	$74.5_{10.3}$	$66.8_{10.8}$
LocalE	$\mathbf{65.2}_{3.9}$	$75.3_{4.6}$	$81.1_{5.5}$	$76.7_{8.2}$
GlobalE	$63.8_{5.8}$	$\mathbf{78.7}_{5.2}$	$\mathbf{84.8}_{4.1}$	$\mathbf{81.8}_{3.9}$
Split Training Set	$62.8_{5.3}$	$64.2_{6.1}$	$75.1_{6.8}$	$71.4_{7.8}$

Table 5: Comparing our method with splitting the training set into train and development for SST-2.

against this approach, we split the 4-shot training samples (same setting as in Table 2) in half. We then select the top four performing prompts using validation set performance. As can be seen in Table 5, this approach consistently outperforms the baseline. However, both Entropy-based probing methods consistently provides better performance across all model sizes.

6 Related Work

Unified Interface Design for NLP Most previous work focuses on shared-parameters models, pretrain on some tasks, then fine-tune for different tasks, e.g. ELMo (Peters et al., 2018), BERT (Devlin et al., 2019), etc. Eventually, leading to multiple task-specific models. There has for some time been attempts to design a unified interface for NLP tasks (Kumar et al., 2016; Raffel et al., 2020).In parallel with these works, GPT-2 (Radford et al., 2019) shows that appending trigger tokens (e.g. "TL;DR") at the end of language model input can cause language models to behave like summarisation models. The zero-shot capability of language models shows the potential to unify NLP tasks into a language modelling framework where fine-tuning is not necessary to achieve good performance. Furthermore, GPT-3 (Brown et al., 2020) shows that task-agnostic, few-shot performance can be improved by scaling up language models. It can sometimes even become competitive with prior state-of-the-art fine-tuning approaches.

Prompt Design for PLMs The core challenge of prompt design is to convert training data (if it exists) into a text sequence. Most work on prompt design focuses on how to make prompts more compatible with language models. Petroni et al. (2019) uses human effort to design natural language sentences and then perform token prediction given the input context. However, hand-crafted templates require significant human effort and is likely to end up with sub-optimal performance. Recent work has explored automatic template construction: Schick and Schütze (2020) uses cloze-style tasks to construct templates, Gao et al. (2020) uses an external language model to generate templates, and Shin et al. (2020) uses gradient-guided search to find templates that maximise performance. Jiang et al. (2020) uses a mining-based method to create multiple diverse templates automatically.

Order Sensitivity of Prompt Design Gao et al. (2020) demonstrated that finetuning-based approaches are not as order sensitive as In-context Learning. Making use of a standard-size training set, Liu et al. (2021) used nearest neighbour search to retrieve the most relevant training samples for a specific test sample. They were successful in retrieving relevant samples and concluded that after retrieving them the order in which they are provided in the prompt has little to no effect on performance. While our study is fundamentally different from theirs in that we do not make use of a standard-size training set, we do come to the opposite conclusion. All previous work on prompt design focuses on the textual quality of the prompt and, to the best of our knowledge, none has studied order sensitivity in detail.

True Few-shot Learning Perez et al. (2021) evaluated few-shot capability of LMs when a held-out validation set is not available. Experimental result suggested that previous work overestimate the few-shot ability of LMs in this (true few-shot learning) setting. Our work instead use the generative nature of language models to construct a probing set without relying on held-out examples. We show that our probing method is better than relying on held out examples (Figure 5) and thus enables true few-shot learning.

7 Conclusion

We have shown that few-shot prompts suffer from order sensitivity, in that for the same prompt the order in which samples are provided can make the difference between state-of-the-art and random performance. In our analysis of the problem, we established that it is present across tasks, model sizes, prompt templates, samples, and number of training samples. To alleviate this problem, we introduced a novel probing method that exploits the generative nature of language models to construct an artificial development set. We were able to identity performant permutations using entropy-based statistics over this set, leading to an on average 13% improvement across eleven text classification tasks.

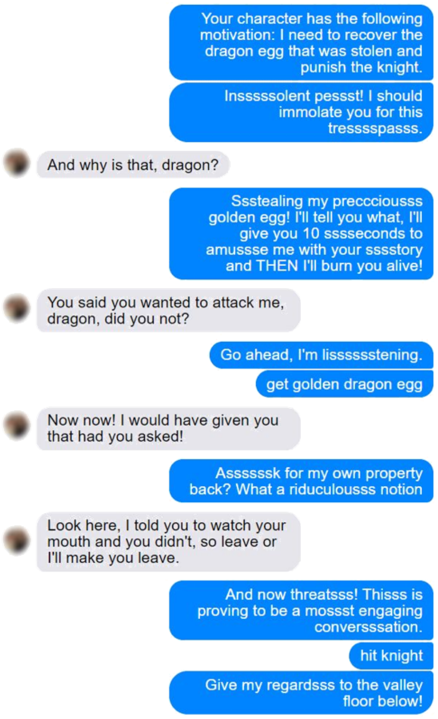
Abstract

We teach goal-driven agents to interactively act and speak in situated environments by training on generated curriculums. Our agents operate in LIGHT (Urbanek et al., 2019)—a large-scale crowd-sourced fantasy text adventure game wherein an agent perceives and interacts with the world through textual natural language. Goals in this environment take the form of character-based quests, consisting of personas and motivations. We augment LIGHT by learning to procedurally generate additional novel textual worlds and quests to create a curriculum of steadily increasing difficulty for training agents to achieve such goals. In particular, we measure curriculum difficulty in terms of the rarity of the quest in the original training distribution—an easier environment is one that is more likely to have been found in the unaugmented dataset. An ablation study shows that this method of learning from the tail of a distribution results in significantly higher generalization abilities as measured by zero-shot performance on never-before-seen quests.



Your character has the following motivation: I need to recover the dragon egg that was stolen and punish the knight.

Insssssolent pessst! I should immolate you for this tresssspasss.

And why is that, dragon?

Ssstealing my precccioussss golden egg! I'll tell you what, I'll give you 10 sssseconds to amussse me with your sssstory and THEN I'll burn you alive!

You said you wanted to attack me, dragon, did you not?

Go ahead, I'm lissssssstening.

get golden dragon egg

Now now! I would have given you that had you asked!

Asssssk for my own property back? What a riduculousss notion

Look here, I told you to watch your mouth and you didn't, so leave or I'll make you leave.

And now threatsss! Thisss is proving to be a mossst engaging converssssation.

hit knight

Give my regardsss to the valley floor below!

Figure 1: The LIGHT questing environment presented as a 2 player game deployed in Messenger.

1 Introduction

A key hypothesis in the pursuit towards creating goal-driven natural language-based agents posits that interactivity and environment grounding is critical for effective language learning (Barsalou, 2008; Bisk et al., 2020; Ammanabrolu and Riedl, 2021). Text games provide a platform on which to interactively train agents that can both act and speak in a situated manner—producing language that is both goal-driven and contextually relevant. Agents in text games operate—perceiving, acting in, and speaking to others in a world—entirely using textual natural language. These games are structured generally as sequential decision making problems in the form of puzzles or quests that must be completed to advance in the game.

As seen in Figure 1, we focus on creating agents in LIGHT (Urbanek et al., 2019), a large-scale crowdsourced fantasy text-adventure game, consisting of rich textual worlds—locations, objects, and characters with personas, and quests—motivations for each character. To complete these quests, an agent must: (1) maintain character via its persona; and (2) reason in a *partially observable* world about potential actions and utterances based on incomplete descriptions of the locations, objects, and other characters. This requires several human like competencies such as commonsense reasoning, dynamic natural language understanding, and operating in combinatorially sized language-based state-action spaces. Although recent work has provided evidence showing that interactive language learning via reinforcement learning (RL) in text games can be significantly more sample efficient than static supervised learning (Ammanabrolu et al.,

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 8099 - 8116

2021) when creating goal-driven natural language agents, their ability to robustly generalize to novel scenarios is limited.

In sequential decision making problems in particular, this generalization gap is the result of an agent simply memorizing trajectories, e.g. the sequence of actions and dialogues required to finish a game, and thus being unable to react in novel scenarios—i.e. the agent learns from the head the training data and simply memorizes the long tail. One way of decreasing this generalization gap is by training agents on procedurally generated environments—wherein the agent learns a family of parametrized tasks with a significantly larger state-action spaces than singular environments, thus effectively making the memorization of trajectories impossible (Justesen et al., 2018; Cobbe et al., 2020). Drawing inspiration from all of these ideas, we create a method that *learns* to create a training curriculum of increasingly more difficult novel procedurally generated environments.

Our contributions are threefold: (1) We present a method of parametrizing and generating a curriculum of environments in text games; (2) We show how to effectively train reinforcement learning agents on this curriculum; and (3) Provide an experimental study showing that our method enables significantly better generalization than those training on singular environments.

2 Procedural Environment Generation

This section describes our procedural generation pipeline as seen in Figure 2, starting with world and quest generation, followed by aligning both of them. There are two main kinds of models that we use for the different modules in this pipeline: retrieval and generative.

The LIGHT Questing Environment. The LIGHT game environment (Urbanek et al., 2019)[1] is a multi-user fantasy text-adventure game consisting of a rich, diverse set of 1775 characters, 663 locations, and 3462 objects. Characters are able to perform templated actions to interact with both objects and characters, and can speak to other characters through free form text dialogues. Actions in text games generally consist of verb phrases (VP) followed optionally by prepositional phrases (VP PP). For example, *get OBJ, put OBJ, give OBJ to CHAR*, etc.. These actions change the state of the world which is expressed through text descriptions.

Quests in LIGHT (Ammanabrolu et al., 2021) take the form of a short motivation and goal action that is required reach the world state required to finish the game. For example, if the short motivation is *"Your motivation is to acquire a sword"*, then the corresponding goal state would be for the character to have a sword in their inventory and goal action would be *get sword*. This environment also contains a set of human expert demonstration of people speaking and acting in character while playing the quests mentioned above. Further details are found in Appendix A.1.

2.1 World and Quest Creation

World Retrieval. The first step of the pipeline involves choosing an initial character who will perform the quest. For this, we uniformly randomly sample from the set of characters found in the LIGHT-Quest training set. The corresponding character information includes a name and a description of the character's persona. Given this character information, we further retrieve the location where the character is most likely to be found.

Retrieval models are trained to return the most highly correlated output for a given input in the dataset. For example, a retrieval model can be asked to return the most likely character that can be found at a particular location. These models compare a human annotated gold standard label with negative candidates drawn from the dataset. The negative candidates provide noise that the model must filter out in order to learn representations that let it best predict the gold label. These models are trained via a ranking loss that maximizes the scores of the gold label while simultaneously minimizing negative candidate score. At test time, the highest ranked candidate based on the score is selected as the model prediction.

Specifically, we use a retrieval-based ranker model that checks for similarity of StarSpace (Wu et al., 2018) embeddings. Our choice of model is influenced by Fan et al. (2019) who report state-of-the-art retrieval performance for locations in LIGHT using this model. The overall ranker model first trains a randomly initialized StarSpace embedding model that is designed to correlate characters with the locations they are found in. It learns a single bag-of-words embedding that takes into account all the individual words contained within the input—encoding character and location information as well as the previously mentioned negative

---

[1] `https://parl.ai/projects/light`

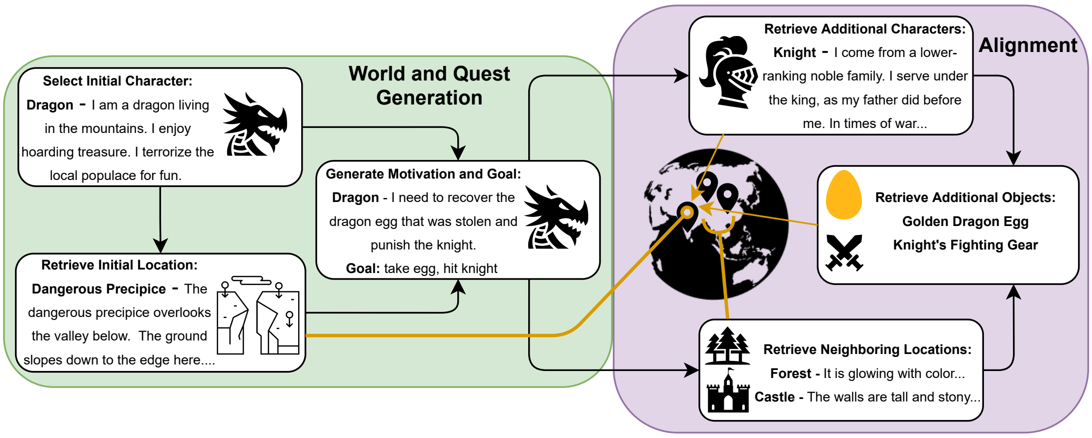


Figure 2: Procedural environment generation pipeline. Black lines indicate conditioning on all prior components. Gold lines indicate (adjacent) location placement.

retrieval candidates. The rest of the training is similar to other retrieval models described earlier. The retrieved location information consists of a location name as well as a description of the location.

Quest Generation. The quest is now generated using the existing character and location information. The generation-based models used in this pipeline are trained to return the most likely output sequence given an input sequence. Given a target sequence $Y = \{y_1, ..., y_M\}$ and some input context vector via the encoders $\mathbf{X}$. These models use autoregressive decoding techniques that factor the distribution over the target sequence into a chain of conditional probabilities with a causal left to right structure as $P(Y|\mathbf{X};\theta) = \prod_{i=1}^{M+1} p(y_i|y_{0:i-1}, \mathbf{X};\theta)$ where θ represents the current network parameters. At test time, a special start-of-sequence token is provided to the model which then proceeds to decode the rest of the output sequence using beam search.

We train two BART (Lewis et al., 2020) models that encodes input information via a bidirectional transformer encoder and decodes autoregressively: the first takes as input character and location information and produces a short motivation (Section 2); the second takes as input character, location information, short motivation and produces the sequence of LIGHT game engine executable actions needed to achieve the motivation. This sequence of actions is provided by the human expert demonstrations as mentioned in Section 2.

2.2 Aligning Worlds and Quests

At this stage, the environment contains a motivated main character to perform a quest and a location for them to start in. We now focus on aligning the world with the quest to ensure that the quest is playable and achievable. Intuitively, to ensure that a quest is achievable, the world needs to contain all of the entities—locations, characters, and objects—mentioned within the quest.

To this end, the alignment process involves training three BERT-based (Devlin et al., 2018) biencoder retrieval models to retrieve the most likely characters, locations, and objects required flesh the environment out and make the quest achievable. We use the same biencoder architecture proposed by Urbanek et al. (2019) which encodes context using one transformer and candidates with another—scoring candidates via inner product between the two encoded vectors. The character retrieval model is conditioned on the initial character, quest, and location—producing additional characters required to complete the world.

We follow the setup in Ammanabrolu et al. (2021) and restrict worlds to only contains 2 characters at maximum but note that this method is extendable to greater numbers of characters. Similarly, the location retrieval model is also conditioned on the same things—producing, in this case, 4 neighbors to the initial location (resulting in worlds that are 5 locations large). These locations are connected to the initial location and a character can move between them by using commands such as *go west*, *go up* etc.. Once these characters and locations are added to the world, the object retrieval model predicts the set of objects that are required to be distributed for each location given all the character information present in it. The final game environment instance is complete once this object set has been added.

3 Curriculum Learning

Generating Curriculums. We generate curriculums by building off of our procedural LIGHT game instance generation pipeline. We make the observation that the original quests in LIGHT are heavily skewed towards certain quest types—with the majority involving goals and short motivations that contain objectives related to getting an object, and hitting or hugging another character (Figure 3). We further note that the first verb in the short motivation forms the basis of the quest for that agent.

Actions in LIGHT, and more generally in text games, are executed in the game engines on the basis of verbs—engine subroutines are linked to verbs with nouns forming arguments—and as such are primarily responsible for changing the state of the world. For example, *get sword* invokes the *get* subroutine that places an object, in this case a sword, in the character's surrounding into their inventory. As the quest is generated early in the pipeline, with the world and the rest of the components being conditioned on it, we can say that the first verb in the short motivation is an important dimension along which we can assess the distribution of individual LIGHT game instances. Thus, concretely, the verb counts from the short motivation aggregated over a set of quests represents the primary dimension along which we measure the distribution of quests.

Parametrizing Curriculum Difficulty. Given the relative imbalance of this multinomial distribution, as seen in Figure 3, we hypothesize that a LIGHT agent only learns to do well on certain types of objectives and not others—memorizing trajectories for less seen quest types, i.e. those found in the tail of the distribution. Preliminary evidence for this hypothesis is also seen in Prabhumoye et al. (2020), where they show a positive correlation between the number of instances of a particular type of quest during training and the final test goal-achievement performance. Based on these observations and our initial hypothesis, we use this particular dimension to *parametrize curriculum difficulty* for training LIGHT agents—quest types that are rarer in the initial training data will be harder for the agent to generalize to in a zero-shot setting.

Intuitively, we seek to create curriculums that contain a diverse set of game instances with quest types that are not often found in the initial training data. Our earlier observations let us hypothesize that this will enable the LIGHT agent to more effectively learn from rare instances of quests as opposed to memorizing the corresponding trajectories. To this end, the generated curriculums each consist of a pool of quests with steadily decreasing quest type imbalance. In our case, this imply that the flatness of the multinomial distribution increases until it tends towards being uniform with respect to the categorical quest type variable. This is done by running the procedural generation pipeline iteratively until the number of instances for the highest count quest type is within n of the lowest count quest type. The total number of additional generated instances is held fixed across curriculums, only the task distribution of quest types within each curriculum changes.

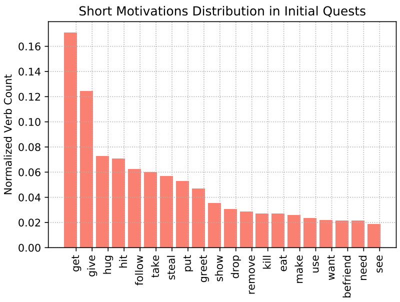

Figure 3: Normalized top-20 verb count distribution of short motivations of the LIGHT-Quests dataset.

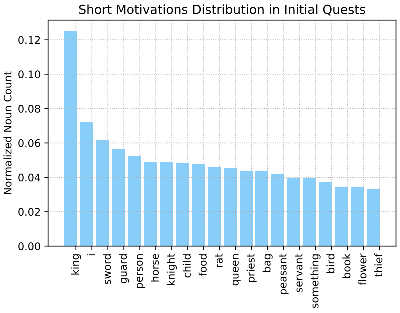

Figure 4: Normalized top-20 noun count distribution of short motivations of the LIGHT-Quests dataset.

Figure 6 shows that decreasing n has the intended effect of decreasing imbalance with respect to verb types. Generating using this pipeline has the added effect of increasing diversity within the pool of each available quest type. One measure of diversity within the pool of a single quest type is the types of nouns contained within the short motivations—these generally correspond to the characters, locations, and objects mentioned. Figure 6 shows that decreasing imbalance in the verb types for a short motivation also results in decreasing imbalance in noun types, once again corresponding to decreasing n. Short motivation gen-

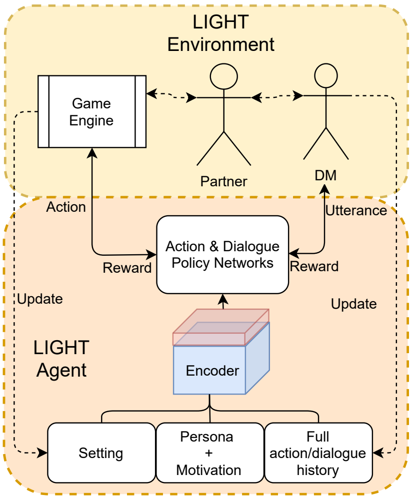

Figure 5: Architecture and training pipeline for the LIGHT RL Agent (Ammanabrolu et al., 2021).

eration is one of the first steps in the pipeline, i.e. the rest of the pipeline is conditioned on it, and as such increasing the flatness of the distribution there has the effects of increasing distribution for downstream components.

A2C Curriculum Training. Overall training is done via A2C (Mnih et al., 2016) a policy gradient algorithm that maximizes long-term expected reward by comparing the advantage $A(s_t, a_t^*)$ of taking an action a_t in a state s_t to the average value of taking any valid action as predicted by the critic $V(s_t)$. The setup and network architectures used are similar to Ammanabrolu et al. (2021) and are summarized in Figure 5. At every step, the LIGHT agent receives as input the text describing the setting, the character's persona & motivation, and the full dialogue history. This is then encoded using a transformer based encoder and sent to the action and dialogue policy networks which output an action/dialogue utterance. These are then passed into the LIGHT environment which process them and returns rewards to be used by the agent.

Rewards. As seen in Figure 5, all actions, either those of the agent-in-training or the partner agent, are processed by the engine, checking for goal state completion—hence known as *act goals*. For example, if the LIGHT agent had the motivation to acquire a sword, the goal could be completed via a: *self act completion*: where the agent acquires a sword itself by picking it up, stealing it, convincing the partner to drop theirs so you can pick it up, etc. *partner act completion*: where the agent uses dialogue utterances to convince their partner to achieve the goal for them (e.g., by persuading the partner to give them the sword). The naturalness of the dialogue utterances is further rated by a learned Dungeon Master (DM), a transformer-based ranker model trained on human demonstrations to score how relevant the utterance is given the character's persona and motivation. Further training details are provided in Appendix A.1.

Pipeline Step	**Model**	**Hits@10**	**F1**	**Ppl**

Goal Action	BART	-	0.763	3.75

Table 1: Procedural generation evaluation showing metrics for each individual model in the pipeline.

4 Evaluation

We conduct two separate evaluations: the first measures the effectiveness of the various models in the procedural environment generation pipeline as well as the effectiveness of the pipeline as a whole. The second provides zero-shot ablations of the LIGHT RL agents trained on the resulting curriculums and answers the questions (1) how does the relative difficulty of the training quests effect test performance?; (2) how does the diversity of the environments during training effect test performance?; and (3) how are the results of the previous questions affected by pre-training?

4.1 Procedural Generation Evaluation

All of the models in the pipeline described in Section 2 are trained using only the training set of the original LIGHT and LIGHT-Quests data. LIGHT-Quests inherits characters, locations, and objects from the original LIGHT dataset and adds on motivations and goals in the form of quests. Thus, the character, location, and object retrieval models are evaluated on the LIGHT unseen test set and the motivation and goal generation models are evaluated on the LIGHT-Quests test set. We report the standard array of metrics: hits@10 and F1 ranking prediction score for retrieval models; and F1 (as a harmonic average of BLEU-1 (Papineni et al., 2002) and ROUGE-1 (Lin, 2004)) and perplexity for generative models. Hyperparameters for all models are found in Appendix A.6.

Analysis. Table 1 presents the results of this evaluation. There are two primary trends to note:

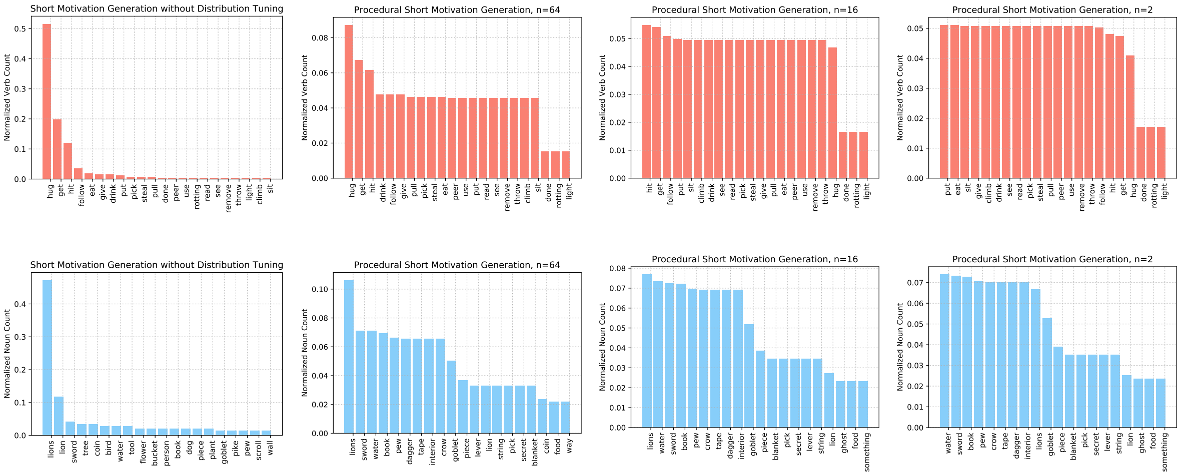

Figure 6: Top-20 distribution of verbs (top) and nouns (bottom) in the short motivation of the curriculum of quests starting from the original generated curriculum on the left to the flattened, **generated** curriculum on the right as a function of n (Section 3). The y-axis of the reflects normalized overall count in the pool of quests.

(1) character retrieval is easier than retrieving location and objects; and (2) goal action generation is easier than motivation generation. We hypothesize that the first trend is a direct consequence of the fact that generated motivations and goals regularly contain the names of the characters involved but mostly leave implicit information such as the objects required—e.g. the action *hit dragon* as a knight would require a weapon such as a sword to be equipped first. The second trend stems from the fact that goal actions can often be thought of as condensed version of the short motivation—number of tokens required to generate goal actions is far less than short motivations. This implies that the goal action model is akin to a summarization model as opposed to the short motivation model which has the more difficult task of generating the motivation with only initial persona and location information.

4.2 Curriculum Learning Evaluation

This evaluation tests the LIGHT RL agent's ability to zero-shot generalize to unseen environments. For all experiments in this study, agents were each zero-shot evaluated on 211 human demonstrations from the LIGHT-Quests test set for a single episode per quest across three independent runs. They were measured on the basis of whether or not they were able to achieve their goals in the environments conditioned on their personas: *act goals* measuring their ability to act consistently, and *speech goals* reflecting their ability to speak naturally. The study ablates across three dimensions in order to answer the posed research questions relating to: (1) curriculum difficulty, (2) curriculum diversity, and (3) agent pre-training.

Curriculum Difficulty. To measure the overall effectiveness of the distribution tuning technique shown in Section 3, we vary the parameter n used to measure curriculum difficulty—note that a lower n corresponds to a flatter distribution and so is higher difficulty. As seen in Fig. 6, we generate pools of quests with steadily increasing difficulty with varying n based on the range of the original untuned distribution—with the agents being trained on each pool separately as well as all of them in sequence through a curriculum. Agents received 10^7 total environment interactions per parallel A2C agent in a batch of 16. For the curriculum learning method, the agent received 2.5×10^6 interactions per pool of quests starting with the initial pool of untuned quests and then sequentially with $n = 64, 16, 2$ resulting in a total of 10^7 total environment interactions per parallel A2C agent.

Curriculum Diversity. The variations in the combinations of quests and worlds themselves seen at training time has potential to effect zero-shot performance (Samvelyan et al., 2021). We introduce two baselines that change the relative diversities of resulting quests in the curriculums, to contrast with our proposed procedural generation pipeline. Generated quest details are found in Appendix A.5.

- *Sampled Curriculums.* Inspired by Chawla et al. (2002); Graves et al. (2017), we explore an alternate method of creating curriculums by simply oversampling the same rare quests found in the tails of the distributions.

This method does not generate new environments via the pipeline, instead choosing to sample rarer instances of quests with a higher weight when initializing each parallel A2C actor. This means that the distribution of verbs looks similar to what it is in Figure 6 but the quests within a pool are repeated multiple times and so contain no new diversity.

- *Randomly Generated Curriculums.* On the other side of the diversity spectrum, we test a method that follows the same steps as the pipeline proposed in Section 2 with the modification that the selection process for each step in the pipeline is random. The characters, objects, location are randomly selected and the generated motivations per character are conditioned on these randomly created worlds. This results in a significantly higher diversity of quests per pool—at the expense of the relative coherence of the overall environment.

Pre-training. We test two model types, drawing from Ammanabrolu et al. (2021), to determine if pre-training effects curriculums learning.

- *Scratch.* No pre-training is done, the encoder is a 3-layer randomly initialized transformer and trained along with the policy networks.
- *Adaptive.* Pre-training is done on the tasks introduced in Ammanabrolu et al. (2021) by training a 12 layer transformer with 256 million parameters using a cross-entropy loss as seen in Humeau et al. (2020). These weights are then transferred to the encoder used during RL training then frozen with 3 randomly initialized-layers appended. The encoder is multi-task trained on both pushshift.io Reddit (Baumgartner et al., 2020) and the commonsense dataset ATOMIC-LIGHT (Ammanabrolu et al., 2021), giving the agent general priors on how to act and speak. It is then fine-tuned in LIGHT, giving the agent further domain specific priors. Specific task details are provided in Appendix A.1.

Table 2: Zero-shot goal achievement rates on a scale of 0-1, averaged over 3 random seeds with standard deviations not exceeding 0.02. The "All Goals" column refers to quests where the agent has simultaneously achieved both types of goals within the allotted one episode. The parameter n refers to the difference between the number of instances for the highest and lowest count quest types. All pair-wise comparisons made are statistically significant.

Analysis. Table 2 presents the results of this evaluation. We first report that the overall proportion of a pool of procedurally generated environments that contain achievable quests or goals for a single curriculum is 0.89. This metric provides a proxy for measuring the accuracy of the alignment process and the overall error rate of the pipeline. The high achievability rate means that only a small proportion of LIGHT RL A2C agents will waste environment interactions learning from quests that cannot be completed—increasing this rate even further would likely also improve sample efficiency.

Further, we see that just the distribution tuning by itself shows no significant gains in performance over the baselines trained on the original data and in fact loses performance in certain cases. In contrast, learning from the individually tuned quest pools in a sequential curriculum increases performance significantly. This appears to indicate that LIGHT RL agents need to be trained with quests pools of steadily increasing difficulty—starting immediately on a set of quests with a high proportion of rare, generated quests can degrade performance.

The significantly increased performance of the procedurally generated curriculums over the sampled and randomly generated curriculums indicates the relative importance of diversity within a single quest type—but only up to a certain extent. The sampled quests contain multiple instances of the same quest type but the generated ones have higher variability—leading to an increased observation space, ensuring that the agent cannot simply memorize trajectories. On the other hand, randomly generated quests have even higher variability but sacrifice relative coherence—it is more likely that the world contains unlikely scenarios, e.g. a desert and swamp being located right next to each other—resulting in significantly decreased performance.

We'd finally like to note that the adaptive pre-trained model takes advantage of the generated curriculums and distribution tuning more than the non-pre-trained scratch encoder, showing consistenly higher performance across the board. We hypothesize that this is likely a consequence of the adaptive model having greater model capacity—the pre-training enabling it to learn generalizable representations of the generated environments. Overall, trends in performance are independent of pre-training—both the scratch and the adaptive pre-trained model benefit significantly from learning from the procedurally generated curriculums.

5 Related Work

Text-based Game Playing and Generation. Recent text game playing works have focused on tackling three primary challenges: (1) how to represent agent knowledge to effectively operate in partially observable environments (Adhikari et al., 2020; Sautier et al., 2020); (2) scaling RL algorithms to handle combinatorial natural language state-action spaces (Zahavy et al., 2018; Ammanabrolu and Hausknecht, 2020; Jang et al., 2021); and (3) giving agents commonsense priors to better reason about the world (Murugesan et al., 2020, 2021)

On the flip side, we have procedural generation of games with works such as Short and Adams (2017); Risi and Togelius (2019); Khalifa et al. (2020) that focus on creating content especially for 2D visual games via search or reinforcement learning based methods. Ammanabrolu et al. (2020b,a) use knowledge graphs to ground language and produce worlds and quests separately for text games from existing corpora such as stories. Fan et al. (2019) leverage LIGHT to learn to generate interactive fiction worlds on the basis of locations, characters, and objects—this work is closest in spirit to our own World Generation module later on. They all focus on either generating or playing games.

Goal oriented Dialogue. Sub-tasks within the overall task of goal oriented dialogue, such as dialogue state management (Singh et al., 2000; Pietquin et al., 2011; Fatemi et al., 2016) and response generation (Li et al., 2016) have used RL to boost performance. As noted by Ammanabrolu et al. (2021), the negotiation tasks of (Yarats and Lewis, 2017; Lewis et al., 2017), where two agents are trying to convince each other to perform certain actions, are related to the tasks in LIGHT-Quests. These works all lack environment grounding.

Curriculum Learning. Curriculums in reinforcement learning have traditionally been used to set goals of steadily increasing difficulty for an agent (Bengio et al., 2009; Schmidhuber, 2013). The difficulty of these curriculums are generally measured difficulty via proxy of agent performance (Narvekar et al., 2020)—methods either choose to adversarially set goals of steadily increasing difficulty (Sukhbaatar et al., 2018; Racaniere et al., 2019; Dennis et al., 2020; Campero et al., 2021) or to maximize learning performance based on environment instances an agent finds difficult historically (Graves et al., 2017; Portelas et al., 2020). While we were inspired by these works, they all focus on searching for goals for agents which can be difficult to scale to complex tasks such our own natural language motivation-based goals. We'd also like to note that most works using procedural generation to benchmark RL agents such as Cobbe et al. (2020); Küttler et al. (2020); Samvelyan et al. (2021) rely on the underlying richness of the game engines to generate novel environments as opposed to learning to generate.

6 Conclusions

We focus on the problem of improving zero-shot generalization abilities of goal-driven RL agents to act and speak via natural language. An (obviously) key component of achieving this is to train the RL agents on a balanced training dataset that matches the test data in distribution. As this is an unlikely scenario in most real-world applications, we make the observation that we can artificially augment our pool of training environments by generating curriculums to mimic this. In our text game domain, with goal-driven situated natural language agents, we hypothesize—and gather supporting evidence suggesting—that an effective way to parametrize such distributions is by looking at the primary verbs within an agent's motivation and bringing the distribution of verb types as close to uniform as possible. Curriculum training significantly increases an agent's ability to generalize to novel scenarios.

7 Broader Impacts

As noted by Urbanek et al. (2019) and Ammanabrolu et al. (2021), the ability to speak and act in these textual fantasy worlds has implications for domains beyond text-games. Text games are a platform where agents can interact in a relatively isolated environment and learn to interactively communicate effectively through natural language in a situated manner. Our methods use both large language models and deep reinforcement learning and are prone to the pitfalls that other contemporary methods using these techniques face, especially in the areas of dialogue and text game systems. We mitigate this first pitfall by restricting our current system to a retrieval based dialogue, ensuring that we can filter out non-normative dialogue usages beforehand, though we will note that the system can be extended to generative systems as described in Prabhumoye et al. (2020). Further, the LIGHT dataset is crowdsourced and contains data biases that can be attributed to the crowdworkers tasked with creating the data. Dinan et al. (2020) provides an in depth discussion regarding the inherent dataset biases, such as gender bias in the distribution of characters, in LIGHT and techniques to mitigate them—we follow these methods to reduce their effects on both the environment generation and agent training procedures.

A Appendix

A.1 LIGHT Environment Details

Formally, we adapt the definition of text-based games as seen in (Côté et al., 2018; Hausknecht et al., 2020) to LIGHT. They are partially observable Markov decision processes (POMDPs), represented as a 7-tuple of $\langle S, T, \mathcal{A}, \Omega, O, \mathcal{R}, \gamma \rangle$ representing the set of environment states, conditional transition probabilities between states, the vocabulary or words used to compose action commands or dialogue utterances (e.g. *get sword* or *Hey, give me that sword!* respectively), observations returned by the game, observation conditional probabilities, reward function, and the discount factor respectively.

There are 5982 training, 756 validation, and 748 test quests. The average sequence of a human demonstration is 12.92, with an average action sequence length of 2.18 and dialogue of 10.74. There are 1800 training, 100 validation, and 211 test human expert demonstrations corresponding to the same splits as the quests themselves.

The LIGHT environment further allows us to factorize the overall action space $\mathcal{A}$ into A as the set of possible textual actions or commands (e.g. *get sword, steal coins from merchant*), and U as the set of possible dialogues that can be uttered by an agent, thus making it a factored POMDP (Degris and Sigaud, 2013). This in turn means that, for a given quest q, each expert human demonstration $\mathcal{D}(q) = \alpha_0^*, \alpha_1^* ... \alpha_n^*$ can be factorized into two sub-sequences of expert demonstrations of actions and dialogue $\mathcal{D}_A(q) = a_0^*, a_1^*, ... a_n^*$ and $\mathcal{D}_U(q) = u_0^*, u_1^*, ... u_m^*$ respectively. The factorized action spaces A and U are constructed by enumerating all possible actions/dialogue utterances in the all human demonstrations in LIGHT-quests.

Figure 7 shows the overall architecture and training pipeline—our reinforcement learning pipeline is unchanged from that shown in Ammanabrolu et al. (2021) with the exception of the curriculum of quests performed by the agent and the way the speech rewards are designed. An encoder first takes in information about setting, persona, motivation for a single character then passes it onto a switch module. This switch module is a meta policy that decides if an agent should act or talk and is trained to mimic how often human experts act or talk while performing quests via demonstrations. Two separate policy networks make a decision on which action to perform or dialogue to say given the current context and a single shared critic attempts to measure the value of taking an action in a particular state.

Once an agent acts or talks, the partner agent—in this case also a polyencoder (Humeau et al., 2020) trained to react to agents with motivations—also acts or talks and this information is processed by the environment. As recommended by Prabhumoye et al. (2020); Ammanabrolu et al. (2021), we keep the partner model fixed during the episodes where the LIGHT agent trains to ensure that it retains natural English semantics—avoiding the problem of language drift by learning an emergent language with that must agree with the partner's usage (Lee et al., 2019).

A2C Training. Each parallel A2C agent samples from the the current pool of available quests—i.e. the curriculum—for a fixed number of steps k before switching to the quest pool corresponding to the next higher level difficulty curriculum. The initial pool of quests is the training set of LIGHT-Quests as seen in Ammanabrolu et al. (2021) and all pools after that correspond to decreasing values of n used when generating the curriculums (as seen in Figure 6).

Rewards. Following Ammanabrolu et al. (2021), we use a learned model–the Dungeon Master (DM)—to score the agent's ability to speak. The DM used here is a poly-encoder model trained on collected human quest demonstrations as well as the original conversations in LIGHT. It is conditioned on quests and motivations and thus able to provide a (noisy) indication of how natural the agent's dialogue utterances are given its immediate context, similarly to the function of the DM during data collection.

Given the dialogue portion of a human quest demonstration $\mathcal{D}_U(q) = u_0^*, u_1^*, ... u_n^*$, of length n, the DM returns a reward r_u of $\frac{1}{2n}$ if an utterance was in the demonstration $u \in \mathcal{D}_U(q)$ (for a maximum of one time per episode for each utterance from the demonstration). A further $\frac{1}{2n}$ is given each time the utterance is scored as being within the top-k most likely utterances by the DM. The original quests all have human demonstrations but the procedurally generated ones do not. During training, in cases where a particular LIGHT game instance does not have corresponding human demonstration, only the latter reward resulting from an utterance being within the top-k most likely utterances by the DM is used. This naturalness objective will be hence referred to as a *speech goal*. These rewards

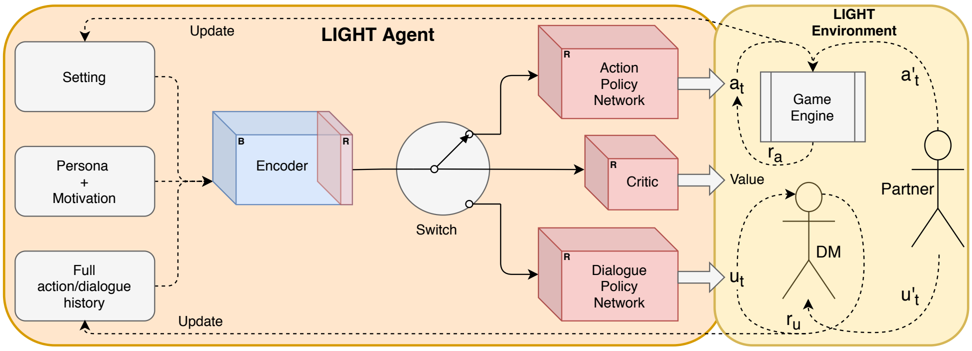

Figure 7: Expanded overall architecture and training pipeline diagram for the LIGHT RL Agent (Ammanabrolu et al., 2021).

thus also denser than *act goals*, helping the agent learn overall. Further, similarly to the game engine, the DM also provides a set of M valid utterances which are the M most likely dialogue candidates from the candidate set for the current context.

A.2 Encoder Pre-training Tasks

Here, we summarize the pre-training tasks for the encoders mentioned in Section 4.2. These tasks are unchanged from those described in Ammanabrolu et al. (2021).

ATOMIC-LIGHT. ATOMIC-LIGHT is a (domain-adapted) fantasy commonsense knowledge graph, and as such provides priors for an agent on how to act consistently in the world. For example, given a clause such as "The knight wishes to slay the dragon, as a result the knight *needs* to acquire a sword," the task would be to predict the underlined text—a form of knowledge graph completion (Wang et al., 2017).

Reddit. A further tuning dataset is derived from an existing Reddit dataset, pushshift.io (Baumgartner et al., 2020) as seen in Roller et al. (2020). This dataset has been used in several existing dialogue-based studies and has been shown to result in more natural conversations (Yang et al., 2018; Mazaré et al., 2018).

LIGHT-Original. The task itself dervied from the original LIGHT dataset (Urbanek et al., 2019) and involves predicting the next action or utterance given the prior dialogue history as well as the current setting and persona for a character. They are collected in a chit-chat fashion, with no notion of objectives, and so provide priors on how to generally act consistently and speak in a fantasy world, but not directly how to complete quests.

LIGHT-Quests. This dataset provides two pre-training tasks. (1) *Bag-of-action timeline prediction* in which, given a quest consisting of setting, persona, and motivations, any one of the actions in the timeline must be predicted. (2) *Sequential timeline prediction* in which, given a quest consisting of setting, persona, motivations, and the first n actions in the timeline, the $n+1^{th}$ action must be predicted. (3) Predict the next dialogue utterance given a human demonstration in a manner similar to the LIGHT-original tasks.

A.3 Sampled and Randomly Generated Curriculum Distributions

This section contains the verb and noun distributions for the *sampled* and *randomly generated* curriculums as described in Section 4.2, presented in the same fashion as Figure 6.

For the *randomly generated* curriculums, we present 5 different curriculums—varying the proportion of randomly generated quests per pool from 0% (corresponding to the full procedurally generated pipeline), to 100% randomly generated, in increments of 20%. Sections after this present ablation results after training agents on these curriculums to better analyze the effects of randomness and diversity in zero-shot generalization.

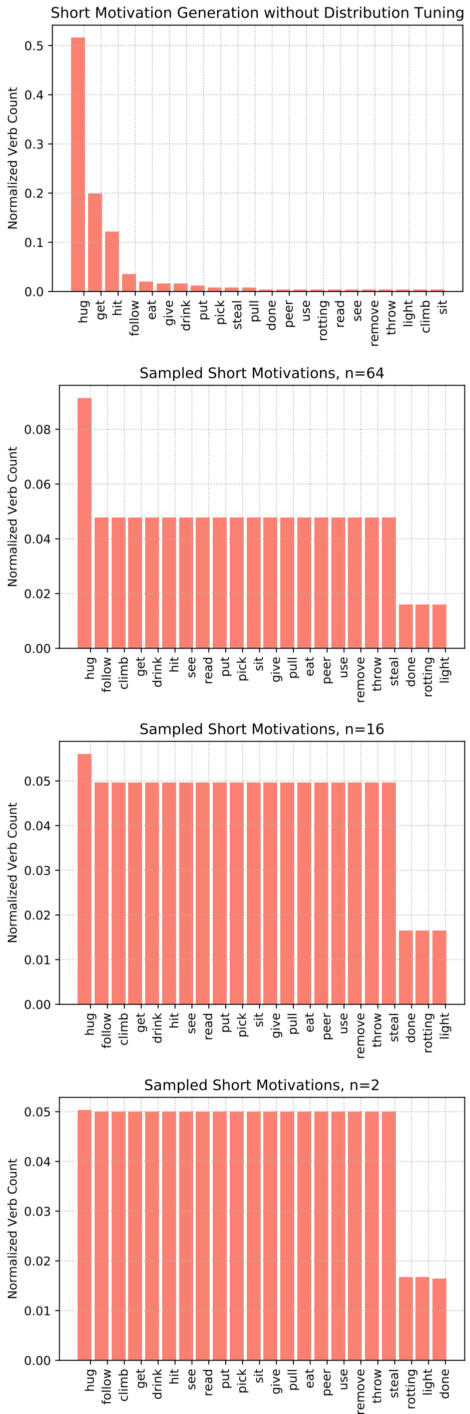

Figure 8: Distribution of verbs in the short motivation of the curriculum of quests starting from the original distribution on top to the flattened and **sampled** curriculum on the bottom as a function of n (Section 3). The y-axis of the different nouns reflect their relative proportion in the pool of quests.

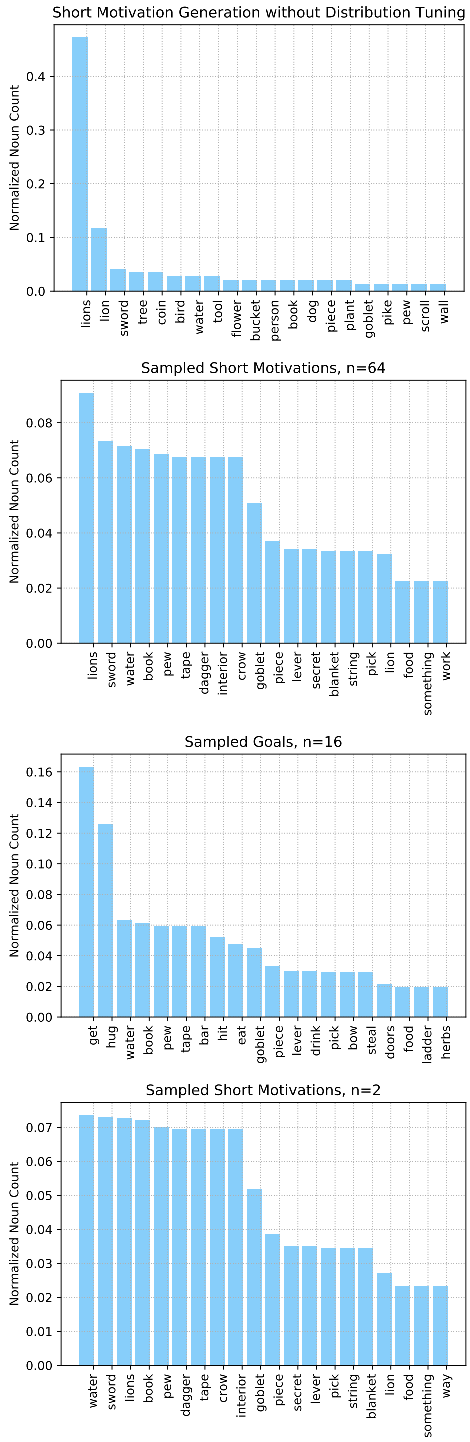

Figure 9: Distribution of nouns in the short motivation of the curriculum of quests starting from the original distribution on top to the flattened and **sampled** curriculum on the bottom as a function of n (Section 3). The y-axis of the different nouns reflect their relative proportion in the pool of quests.

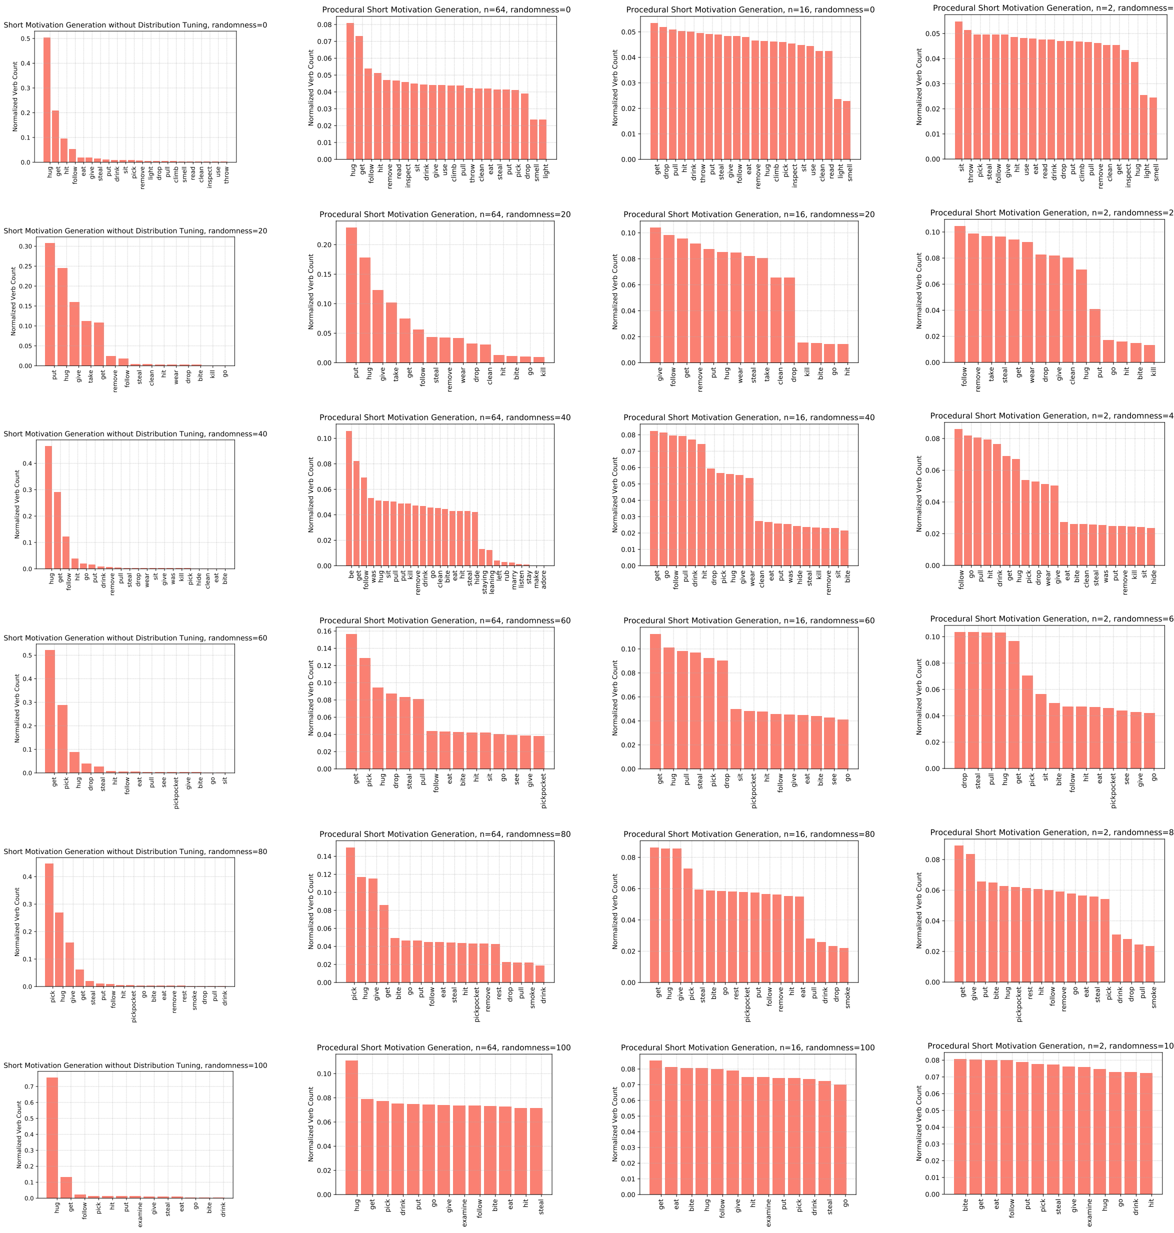

Figure 10: Distribution of verbs in the short motivation of the curriculum of quests starting from the original distribution on the left to the flattened and **randomly generated** curriculum on the right as a function of n (Section 3) with the **randomness percentage** tuning. The y-axis of the different verbs reflect their relative proportion in the pool of quests.

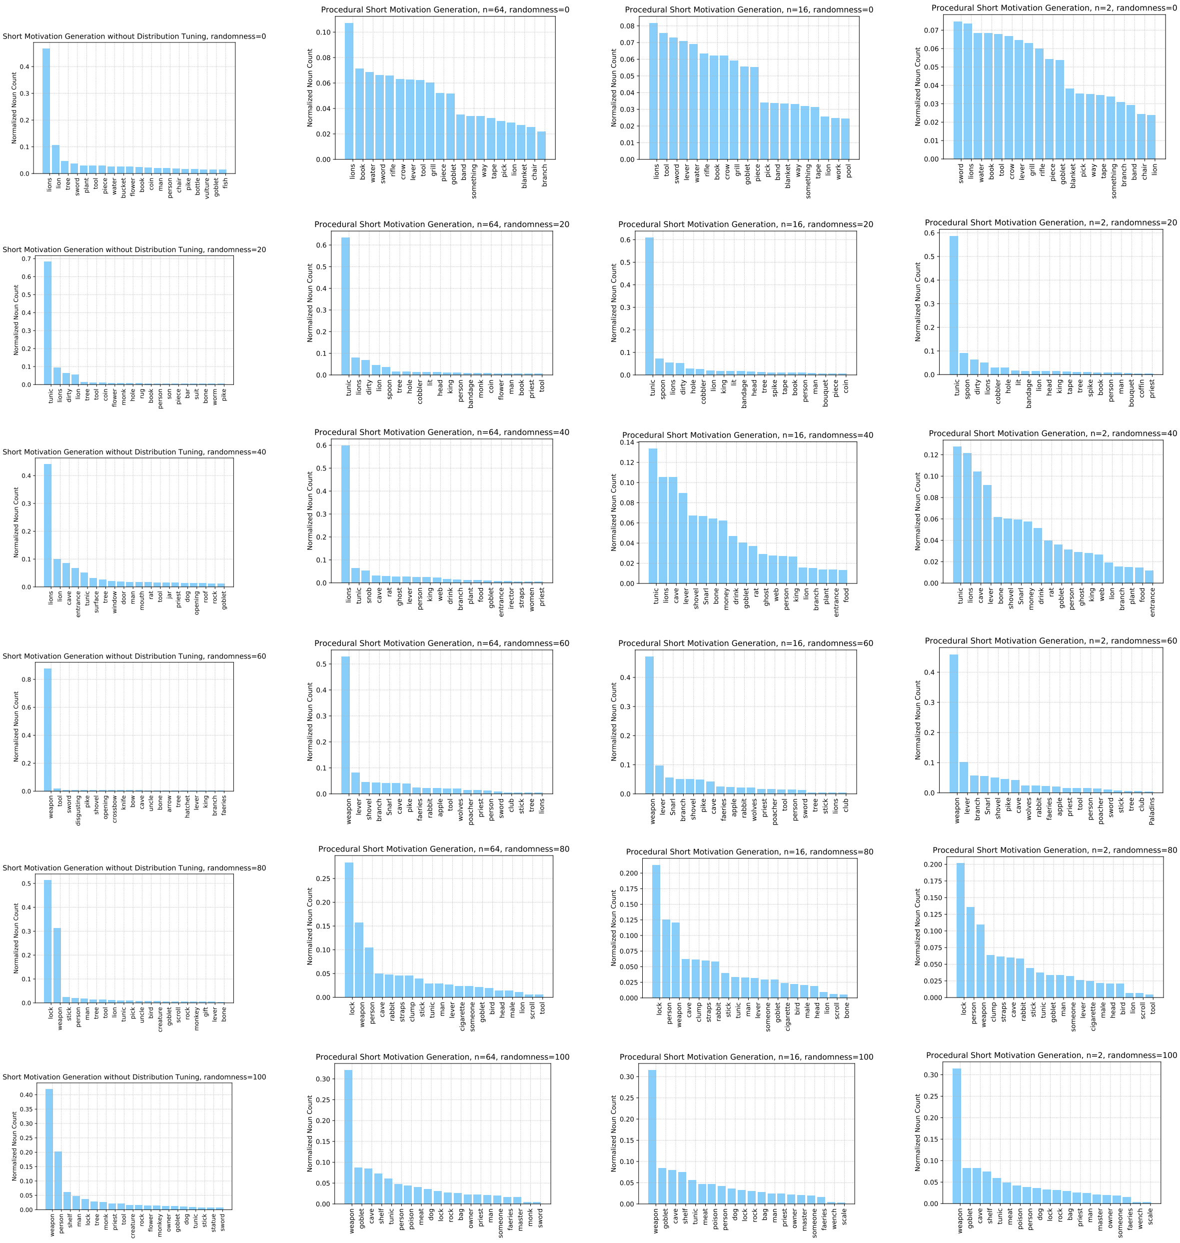

Figure 11: Distribution of nouns in the short motivation of the curriculum of quests starting from the original distribution on the left to the flattened and **randomly generated** curriculum on the right as a function of n (Section 3) with the **randomness percentage** tuning. The y-axis of the different nouns reflect their relative proportion in the pool of quests.

A.4 Effects of Diversity in Procedural Generation Pipeline on Curriculum Learning

Table 3 shows the results of a zero-shot evaluation as described in Section 4.2 on each of the randomly generated curriculum pools. Agents were trained on the full curriculum for each of these experiments. One major trend stands out: the less randomness during environment generation, the greater the performance. This shows that, while more diverse (as seen in Table 4), having potentially less coherent worlds and quests during training hurts agent performance at test time—a case of spurious diversity in training data.

Expt.	Act Goals	Speech Goals	All Goals
Scratch Encoder			
No Curr.	0.418	0.118	0.103
Sampled	0.460	0.145	0.138
100% Randomly Generated	0.263	0.024	0.017
80% Randomly Generated	0.267	0.080	0.062
60% Randomly Generated	0.379	0.112	0.093
40% Randomly Generated	0.422	0.115	0.109
20% Randomly Generated	0.464	0.146	0.143
Procedurally Generated	**0.477**	**0.163**	**0.155**
Adaptive Encoder			
No Curr.	0.420	0.330	0.303
Sampled	0.473	0.358	0.344
100% Randomly Generated	0.335	0.221	0.207
80% Randomly Generated	0.364	0.280	0.269
60% Randomly Generated	0.424	0.327	0.293
40% Randomly Generated	0.481	0.370	0.330
20% Randomly Generated	**0.508**	0.371	0.369
Procedurally Generated	0.506	**0.382**	**0.373**

Table 3: Effects of diversity in procedural generation on curriculum learning. All experiments were averaged over 3 random seeds. Standard deviations across any individual result do not exceed 0.02. The "All Goals" column refers to quests where the agent has simultaneously achieved both types of goals within the allotted one episode. The parameter n refers to the difference between the number of instances for the highest and lowest count quest types.

A.5 Curriculum Statistics

This section presents statistics attempting to quantify the diversity and relative coherence of the environments in each of the curriculums we test on. We quantify diversity in terms of the unique entities present overall in the world as well as the number of unique uni-,bi-, and tri-grams found in the generated short motivations and goal texts.

Specifically, unique entities were calculated by using the count of all the unique objects and character which are generated in the procedural generated short motivations / goals. In addition, the count of the unique uni-grams /bi-grams /tri-grams represent the n-grams counts changing with the **procedurally generated** curriculum as a function of n

	entities	hit %age	unigrams	bigrams	trigrams

Table 4: Curriculum learning hit analysis and unique n-grams counts. The tables show the hit percentage of the procedually generated entities in short motivations/ goals among the retrieved entities (objects + character).The count of unique uni-grams /bi-grams/ tri-grams represent the n-grams counts changing with the **procedurally generated** curriculum as a function of n (Section 3) with the **randomness percentage** tuning for the generated short motivations or goals using BART model.

(Section 3) with the **randomness percentage** tuning for both the short motivations and goals generated by BART. As a sanity check on how coherent an environment is, we attempt to see if the entities required to finish a quest even exist within the world—i.e. a hit percentage that roughly estimates what proportion of quests in a pool are achievable end to end. The hit percentage are calculated by checking if the *NOUN* extracted from the short motivations/goals exists in the procedually generated entities (objects + character) in the same environment. Counting as 1/0 to represent as existing/not and divided by the total number of quests to get the hit percentage in the table.

A.6 Hyperparameters

Hyperparameter type	Value

Abstract

Translation quality evaluation plays a crucial role in machine translation. According to the input format, it is mainly separated into three tasks, *i.e.*, reference-only, source-only and source-reference-combined. Recent methods, despite their promising results, are specifically designed and optimized on one of them. This limits the convenience of these methods, and overlooks the commonalities among tasks. In this paper, we propose UniTE, which is the first unified framework engaged with abilities to handle all three evaluation tasks. Concretely, we propose monotonic regional attention to control the interaction among input segments, and unified pretraining to better adapt multi-task learning. We testify our framework on WMT 2019 Metrics and WMT 2020 Quality Estimation benchmarks. Extensive analyses show that our *single model* can universally surpass various state-of-the-art or winner methods across tasks. Both source code and associated models are available at https://github.com/NLP2CT/UniTE.

1 Introduction

Automatically evaluating the translation quality with the given reference segment(s), is of vital importance to identify the performance of Machine Translation (MT) models (Freitag et al., 2020; Mathur et al., 2020a; Zhao et al., 2020; Kocmi et al., 2021). Based on the input contexts, translation evaluation can be mainly categorized into three classes: 1) reference-only evaluation (Ref) approaches like BLEU (Papineni et al., 2002) and BLEURT (Sellam et al., 2020a), which evaluate the hypothesis by referring the golden reference at target side; 2) source-only evaluation (Src) methods like YiSi-2 (Lo, 2019) and TransQuest (Ranasinghe et al., 2020b), which are also referred as quality estimation (QE). These methods estimate the quality of the hypothesis based on the source sentence without using references; 3) source-reference-combined evaluation (Src+Ref) works like COMET (Rei et al., 2020), where the evaluation exploits information from both source and reference. With the help of powerful pretrained language models (PLMs, Devlin et al., 2019; Conneau et al., 2020), model-based approaches (*e.g.*, BLEURT, TransQuest, and COMET) have shown promising results in recent WMT competitions (Ma et al., 2019; Mathur et al., 2020b; Freitag et al., 2021; Fonseca et al., 2019; Specia et al., 2020, 2021).

Nevertheless, each existing MT evaluation work is usually designed for one specific task, *e.g.*, BLEURT is only used for Ref task and can not support Src and Src+Ref tasks. Moreover, those approaches preserve the same core – evaluating the quality of translation by referring to the given segments. We believe that it is valuable, as well as feasible, to unify the capabilities of all MT evaluation tasks (Ref , Src and Src+Ref) into one model. Among the promising advantages are ease of use and improved robustness through knowledge transfer across evaluation tasks. To achieve this, two important challenges need to be addressed: 1) How to design a model framework that can unify all translation evaluation tasks? 2) How to make the powerful PLMs better adapt to the unified evaluation model?

In this paper, we propose **UniTE** - **Uni**fied **T**ranslation **E**valuation, a novel approach which unifies the functionalities of Ref , Src and Src+Ref tasks into one model. To solve the first challenge as mentioned above, based on the multilingual PLM, we utilize layerwise coordination which concatenates all input segments into one sequence as the unified input form. To further unify the modeling of three evaluation tasks, we propose a novel Monotonic Regional Attention (MRA) strat-

Volume 1: Long Papers, pages 8117 - 8127
May 22-27, 2022

egy, which allows partial semantic flows for a specific evaluation task. For the second challenge, a multi-task learning-based unified pretraining is proposed. To be concrete, we collect the high-quality translations and degrade low-quality translations of NMT models as synthetic data. Then we propose a novel ranking-based data labeling strategy to provide the training signal. Finally, the multilingual PLM is continuously pretrained on synthetic dataset with multi-task learning manner. Besides, our proposed models, named UniTE-MRA and UniTE-UP respectively, can benefit from finetuning with human-annotated data over three tasks at once, not requiring extra task-specific training.

Experimental results demonstrate the superiority of UniTE. Compared to various strong baseline systems on each task, UniTE, which unifies REF , SRC and SRC+REF tasks into one *single model*, achieves consistently absolute improvements of Kendall's τ correlations at 1.1, 2.3 and 1.1 scores on English-targeted translation directions of WMT 2019 Metric Shared task (Fonseca et al., 2019), respectively. Meanwhile, after introducing multilingual-targeted support for our unified pretraining strategy, a single model named UniTE-MUP also gives dominant results against existing methods on non-English-targeted translation evaluation tasks. Furthermore, our method can also achieve competitive results over WMT 2020 QE task compared with the winner submission (Ranasinghe et al., 2020b). Ablation studies reveal that, the proposed MRA and unified pretraining strategies are both important for model performance, making the model preserve the outstanding performance and multi-task transferability concurrently.

2 Related Work

In this section, we briefly introduce the three directions of translation evaluation.

2.1 Reference-Only Evaluation

REF assesses the translation quality via comparing the translation candidate and the given reference. In this setting, the two inputs are written in the same language, thus being easily applied in most of the metric tasks. In the early stages, statistical methods are dominant solutions due to their strengths in wide language support and intuitive design. These methods measure the surface text similarity for a range of linguistic features, including n-gram (BLEU, Papineni et al., 2002), token (TER, Snover et al., 2006), and character (ChrF & ChrF++, Popovic, 2015, 2017). However, recent studies pointed out that these metrics have low consistency with human judgments and insufficiently evaluate high-qualified MT systems (Freitag et al., 2020; Rei et al., 2020; Mathur et al., 2020a).

Consequently, with the rapid development of PLMs, researchers have been paying their attention to model-based approaches. The basic idea of these studies is to collect sentence representations for similarity calculation (BERTScore, Zhang et al., 2020) or evaluating probabilistic confidence (PRISM-ref, Thompson and Post, 2020; BARTScore, Yuan et al., 2021). To further improve the model, Sellam et al. (2020a) pretrained a specific PLM for the translation evaluation (BLEURT), while Lo (2019) combined statistical and representative features (YiSi-1). Both these methods achieve higher correlations with human judgments than statistical counterparts.

2.2 Source-Only Evaluation

SRC , which also refers to quality estimation[1], is an important translation evaluation task especially for the scenario where the ground-truth reference is unavailable. It takes the source-side sentence and the translation candidate as inputs for the quality estimation. To achieve this, the methods are required to model cross-lingual semantic alignments. Similar to reference-only evaluation, statistical-based (Ranasinghe et al., 2020b), model-based (TransQuest, Ranasinghe et al., 2020b; PRISM-src, Thompson and Post, 2020), and feature combination (YiSi-2, Lo, 2019) are typical and advanced methods in this tasks.

2.3 Source-Reference-Combined Evaluation

Aside from the above tasks that only consider either source or target side at one time, SRC+REF takes both source and reference sentences into account. In this way, methods in this context can evaluate the translation candidate via utilizing the features from both sides. As a rising paradigm among translation evaluation tasks, SRC+REF also profits from the development of cross-lingual PLMs. For example, finetuning PLMs over human-annotated datasets (COMET, Rei et al., 2020) achieves new state-of-the-art results among all evaluation approaches in WMT 2020 (Mathur et al., 2020b).

---

[1] Refer to "quality estimation" or "reference-free metric" in WMT (http://www.statmt.org/wmt19/qe-task.html, http://www.statmt.org/wmt21/metrics-task.html).

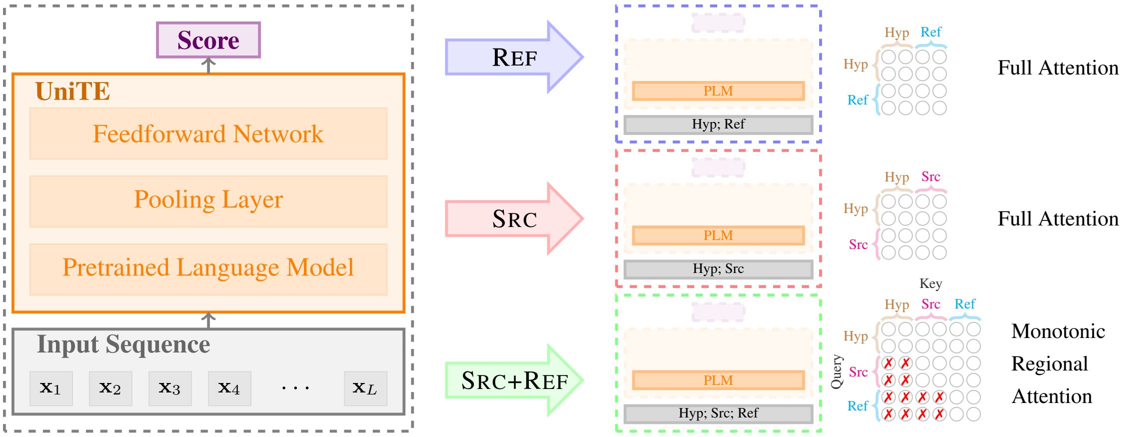

Figure 1: Illustration of UniTE. Our model can give predictions for different data items formatted as Ref, Src, or Src+Ref setting, unifying all evaluation tasks into one single model without additional modifications. For Src+Ref, we show the hard design for monotonic regional attention. ✗ denotes the masked attention logits.

3 Methodology

As mentioned above, massive methods are proposed for different automatic evaluation tasks. On the one hand, it is inconvenient and expensive to develop and employ different metrics for different evaluation scenarios. On the other hand, separate models absolutely overlook the commonalities among these evaluation tasks, of which knowledge potentially benefits all three tasks. In order to fulfill the aim of unifying the functionalities on Ref, Src, and Src+Ref into one model, in this section, we introduce **UniTE** (Figure 1).

3.1 Model Architecture

By receiving a data example composing of hypothesis, source, and reference segment, UniTE first modifies it into concatenated sequence following the given setting as Ref, Src, or Src+Ref:

$$
\begin{aligned}
\mathbf{x}_{\textsc{Ref}} &= \texttt{Concat}(\mathbf{h}, \mathbf{r}) \in \mathbb{R}^{(l_h+l_r)}, \\
\mathbf{x}_{\textsc{Src}} &= \texttt{Concat}(\mathbf{h}, \mathbf{s}) \in \mathbb{R}^{(l_h+l_s)}, \qquad (1) \\
\mathbf{x}_{\textsc{Src+Ref}} &= \texttt{Concat}(\mathbf{h}, \mathbf{s}, \mathbf{r}) \in \mathbb{R}^{(l_h+l_s+l_r)},
\end{aligned}
$$

where $\mathbf{h}$, $\mathbf{s}$ and $\mathbf{r}$ are hypothesis, source and reference segments, with the corresponding sequence lengths being l_h, l_s and l_r, respectively. The input sequence is then fed to PLM to derive representations $\tilde{\mathbf{H}}$. Take Ref as an example:

$$
\tilde{\mathbf{H}}_{\textsc{Ref}} = \texttt{PLM}(\mathbf{x}_{\textsc{Ref}}) \in \mathbb{R}^{(l_h+l_r)\times d}, \qquad (2)
$$

where d is the model size of PLM. According to Ranasinghe et al. (2020b), we use the first output representation as the input of feedforward layer.

Compared to existing methods (Zhang et al., 2020; Rei et al., 2020) which take sentence-level representations for evaluation, the advantages of our architecture design are as follows. First, our UniTE model can benefit from layer-coordinated semantical interactions inside every one of PLM layers, which is proven effective on capturing diverse linguistic features (He et al., 2018; Lin et al., 2019; Jawahar et al., 2019; Tenney et al., 2019; Rogers et al., 2020). Second, for the unified approach of our model, the concatenation provides the unifying format for all task inputs, turning our model into a more general architecture. When conducting different evaluation tasks, our model requires no further modification inside. Note here, to keep the consistency across all evaluation tasks, as well as ease the unified learning, $\mathbf{h}$ is always located at the beginning of the input sequence.

After deriving $\tilde{\mathbf{H}}_{\textsc{Ref}}$, a pooling block is arranged after PLM which gives sequence-level representations $\mathbf{H}_{\textsc{Ref}}$. Finally, a feedforward network takes $\mathbf{H}_{\textsc{Ref}}$ as input, and gives a scalar p as prediction:

$$
\begin{aligned}
\mathbf{H}_{\textsc{Ref}} &= \texttt{Pool}(\tilde{\mathbf{H}}_{\textsc{Ref}}) \in \mathbb{R}^{d}, \qquad (3) \\
p_{\textsc{Ref}} &= \texttt{FeedForward}(\mathbf{H}_{\textsc{Ref}}) \in \mathbb{R}^{1}. \qquad (4)
\end{aligned}
$$

For training, we encourage the model to reduce the mean squared error with respect to given score q:

$$
\mathcal{L}_{\textsc{Ref}} = (p_{\textsc{Ref}} - q)^2. \qquad (5)
$$

However, for the pretraining of most PLMs (e,g., XLM-R, Conneau et al., 2020), the input patterns are designed to receive two segments at most. Thus there exists a gap between the pretraining of PLM and the joint training of UniTE where the concatenation of three fragments is used as input. Moreover, previous study (Takahashi et al., 2020) shows that directly training over SRC+REF by following such design leads to worse performance than REF scenario. To alleviate this issue, we propose two strategies: **Monotonic Regional Attention** as described in §3.2 and **Unified Pretraining** in §3.3.

3.2 Monotonic Regional Attention

To fill the modeling gap between the pretraining of PLM and the joint training of three downstream tasks, a natural idea is to unify the number of involved segments when modeling semantics for SRC, REF and SRC+REF tasks. Following this, we propose to modify the attention mask of SRC+REF to simulate the modeling of two segments in SRC and REF. Specifically, when calculating the attention logits, semantics from a specific segment are only allowed to derive information from two segments at most. Considering the conventional attention module:

$$\mathbf{A} = \mathrm{Softmax}(\frac{\mathbf{QK}^\top}{\sqrt{d}}) \in \mathbb{R}^{L \times L}, \quad (6)$$

where L is the sequential length for input, $\mathbf{Q}, \mathbf{K} \in \mathbb{R}^{L \times d}$ are query and key representations, respectively.[2] As to monotonic regional attention (MRA), we simply add a mask $\mathbf{M}$ to the softmax logits to control attention flows:

$$\mathbf{A} = \mathrm{Softmax}(\frac{\mathbf{QK}^\top}{\sqrt{d}} + \mathbf{M}) \in \mathbb{R}^{L \times L}, \quad (7)$$

$$\mathbf{M}_{ij} = \begin{cases} -\infty & (i,j) \in \mathbf{U}, \\ 0 & \text{otherwise}, \end{cases} \quad (8)$$

where $\mathbf{U}$ stores the index pairs of all masked areas.

Following this idea, the key of MRA is how to design the matrix $\mathbf{U}$. For the cases where interactions inside each segment, we believe that these self-interactions are beneficial to the modeling. For other cases where interactions are arranged across segments, three patterns are included: hypothesis-reference, source-reference, and hypothesis-source. Intuitively, the former two parts are beneficial for model training, since they might contribute the monolingual signals and cross-lingual disambiguation to evaluation, respectively. This leaves the only case, where our experimental analysis also verifies (see §5.1), that interaction between hypothesis and source leads to the performance decrease for SRC+REF task, thus troubling the unifying.

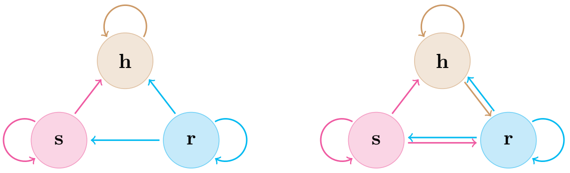

Figure 2: Attention flows in monotonic regional attention. **h**, **s** and **r** are hypothesis, source and reference, respectively. We prevent specified interactions in SRC+REF training via modifying the attention mask with regional properties. We show the hard (left) and soft design (right, no **h** → **s**) in this figure.

To give more fine-grained designs, we propose two approaches for UniTE-MRA, which apply the MRA mechanism into UniTE model (Figure 2):

- Hard MRA. Only monotonic attention flows are allowed. Interactions between any two segments are strictly unidirectional through the entire PLM, where $\mathbf{U}$ stores the index pairs of unidirectional interactions of $\mathbf{h} \rightarrow \mathbf{r}$, $\mathbf{s} \rightarrow \mathbf{r}$ and $\mathbf{h} \rightarrow \mathbf{s}$, where "→" denotes the direction of attention flows.
- Soft MRA. Specific attention flows are forbidden inside each attention module. The involved two segments may interact inside a higher layer. In practice, index pairs which denoting $\mathbf{h} \rightarrow \mathbf{s}$ or $\mathbf{s} \rightarrow \mathbf{h}$ between source and hypothesis are stored in $\mathbf{U}$.

Note that, although the processing in source and reference may be affected because their positions are not indexed from the start, related studies on positional embeddings reveal that, PLM can well capture relative positional information (Wang and Chen, 2020), which dispels this concern.

3.3 Unified Pretraining

To further bridge the modeling gap between PLM and the joint training of UniTE mentioned in §3.1, we propose a unified pretraining strategy including the following main stages: 1) collecting and downgrading synthetic data; 2) labeling examples with a novel ranking-based strategy; 3) multi-task learning for unified pretraining and finetuning.

Synthetic Data Collection As our approach aims at evaluating the quality of translations, generated hypotheses with NMT models are ideal synthetic data. To further improve the diversity of synthetic data quality, we follow existing experiences (Sellam et al., 2020a; Wan et al., 2021) to

---

[2] For simplicity, we omit the multi-head mechanism.

apply the word and span dropping strategy to downgrade a portion of hypotheses. The collected data totally contains N triplets composing of hypothesis, source and reference segments, which is formed as $\mathcal{D}' = \{\langle \mathbf{h}^i, \mathbf{s}^i, \mathbf{r}^i \rangle\}_{i=1}^{N}$.

Data Labeling After obtaining the synthetic data, the next step is to augment each data pair with a label which serves as the signal of unified pretraining. To stabilize the model training, as well as normalize the distributions across all score systems and languages, we propose a novel ranking-based approach. This method is based on the idea of Borda count (Ho et al., 1994; Emerson, 2013), which provides more precise and well-distributed synthetic data labels than Z-score normalization.

Specifically, we first use available approaches to derive the predicted score $\hat{q}^i$ for each item, yielding labeled synthetic quadruple examples formed as $\mathcal{D}'' = \{\langle \mathbf{h}^i, \mathbf{s}^i, \mathbf{r}^i, \hat{q}^i \rangle\}_{i=1}^{N}$. Then, we tag each example with its rank index $\tilde{q}^i$ referring to $\hat{q}^i$:

$$\tilde{q}^i = \texttt{IndexOf}(\hat{q}^i, \mathcal{Q}), \tag{9}$$

where $\mathcal{Q}$ is the list storing all the sorted $\hat{q}^i$ descendingly. Then, we use the conventional Z-score strategy to normalize the scores:

$$q^i = \frac{\tilde{q}^i - \mu}{\sigma}, \tag{10}$$

where μ and σ are the mean and the standard deviation of values in $\mathcal{Q}$, respectively. The dataset thus updates its format to $\mathcal{D} = \{\langle \mathbf{h}^i, \mathbf{s}^i, \mathbf{r}^i, q^i \rangle\}_{i=1}^{N}$. Note here that, an example with higher $\hat{q}^i$ is assigned with higher $\tilde{q}^i$, thus a larger value of q^i.

Compared to related approaches which apply Z-score normalization (Bojar et al., 2018), or leave the conventional labeled scores as signals for learning (*i.e.*, knowledge distillation, Kim and Rush, 2016; Phuong and Lampert, 2019), our approach can alleviate the bias of chosen model for labeling and prior distributional disagreement of scores. For example, different methods may give scores with different distributions. Especially for translation directions of low-resource, scores may follow skewed distribution (Sellam et al., 2020a), which has a disagreement with rich-resource scenarios. Our method can unify the distribution of all labeling data into the same scale, which can also be easily applied by the ensembling strategy.

Multi-task Pretrainig and Finetuning To unify all evaluation scenarios into one model, we apply multi-task learning for both pretraining and finetuning. For each step, we arrange three substeps for all input formats, yielding $\mathcal{L}_{\text{REF}}$, $\mathcal{L}_{\text{SRC}}$, and $\mathcal{L}_{\text{SRC+REF}}$, respectively. The final learning objective is to reduce the summation of all losses:

$$\mathcal{L} = \mathcal{L}_{\text{REF}} + \mathcal{L}_{\text{SRC}} + \mathcal{L}_{\text{SRC+REF}}. \tag{11}$$

4 Experiments

4.1 Experimental Settings

Benchmarks Following Rei et al. (2020); Yuan et al. (2021), we examine the effectiveness of the propose method on WMT 2019 Metrics (Ma et al., 2019). For the former, we follow the common practice in COMET[3] (Rei et al., 2020) to collect and preprocess the dataset. The official variant of Kendall's Tau correlation (Ma et al., 2019) is used for evaluation. We evaluate our methods on all of REF, SRC and SRC+REF scenarios. For SRC scenario, we further conduct results on WMT 2020 QE task (Specia et al., 2020) referring to Ranasinghe et al. (2020a) for data collection and preprocessing. Following the official report, the Pearson's correlation is used for evaluation.

Model Pretraining As mentioned in §3.3, we continuously pretrain PLMs using synthetic data. The data is constructed from WMT 2021 News Translation task, where we collect the training sets from five translation tasks. Among those tasks, the target sentences are all in English (En), and the source languages are Czech (Cs), German (De), Japanese (Ja), Russian (Ru), and Chinese (Zh). Specifically, we follow Sellam et al. (2020a) to use TRANSFORMER-base (Vaswani et al., 2017) MT models to generate translation candidates, and use the checkpoints trained via UniTE-MRA approach for synthetic data labeling. We pretrain two kinds of models, one is pretrained on English-targeted language directions, and the other is a multilingual version trained using bidirectional data. Note that, for a fair comparison, we filter out all pretraining examples that are involved in benchmarks.

Model Setting We implement our approach upon COMET (Rei et al., 2020) repository and follow their work to choose XLM-R (Conneau et al., 2020) as the PLM. The feedforward network consists of 3 linear transitions, where the dimensionalities of

Table 1: Kendall's Tau correlation (%) results on English-targeted language pairs of WMT 2019 Metrics Task test set. *Italic* and underlined translation directions indicate that corresponding data items are available in pretraining and finetuning training set, respectively. Baselines marked with ♡, ♠ and ◇ mean that scores are derived from official release, WMT official report (Ma et al., 2019), and our reimplementation, respectively. Colored background indicates that evaluation follows Ref, Src and Src+Ref setting. Best viewed in **bold**.

corresponding outputs are 3,072, 1,024, and 1, respectively. Between any two adjacent linear modules inside, hyperbolic tangent function is arranged as activation. During both pretraining and finetuning phrases, we divided training examples into three sets, where each set only serves one scenario among Ref, Src and Src+Ref to avoid learning degeneration. During finetuning, we randomly extracting 2,000 training examples from benchmarks as development set. Besides UniTE-MRA and UniTE-UP which are derived with MRA (§ 3.2) and Unified Pretraining (§ 3.3), we also extend the latter with multilingual-targeted unified pretraining, thus obtaining UniTE-MUP model.

Baselines As to Ref approaches, we select BLEU (Papineni et al., 2002), ChrF (Popovic, 2015), YiSi-1 (Lo, 2019), BERTScore (Zhang et al., 2020), BLEURT (Sellam et al., 2020a), PRISM-ref (Thompson and Post, 2020), BARTScore (Yuan et al., 2021), XLM-R+Concat (Takahashi et al., 2020), and RoBERTa+Concat (Takahashi et al., 2020) for comparison. For Src methods, we post results of both metric and QE methods, including YiSi-2 (Lo, 2019), XLM-R+Concat (Takahashi et al., 2020), PRISM-src (Thompson and Post, 2020) and multilingual-to-multilingual MTransQuest (Ranasinghe et al., 2020b). For Src+Ref, we use XLM-R+Concat (Takahashi et al., 2020) and COMET (Rei et al., 2020) as strong baselines.

Data Collection for UniTE-UP

4.2 Main Results

English-Targeted Results on English-targeted metric task are conducted in Table 1. Among all involved baselines, for Ref methods, BARTScore (Yuan et al., 2021) performs better than other statistical and model-based metrics.

Table 2: Kendall's Tau correlation (%) on multilingual-targeted language pairs from WMT 2019 Metrics Shared Task. Even only pretrained with English-targeted data, UniTE-UP model can still give competitive performance on multilingual-targeted tasks. UniTE-MUP, which adopts multilingual-targeted pretraining, achieves new state-of-the-art results. Furthermore, UniTE-UP and UniTE-MUP are both single models, offering considerate convenience against other task-specific baselines.

As to Src scenario, MTransQuest (Ranasinghe et al., 2020b) gives dominant performance. Further, COMET (Rei et al., 2020) performs better than XLM-R+Concat (Takahashi et al., 2020) on Src+Ref scenario.

As for our methods, we can see that, UniTE-MRA achieves better results on all tasks, demonstrating the effectiveness of monotonic attention flows for cross-lingual interactions. Moreover, the proposed model UniTE-UP, which unifies Ref, Src, and Src+Ref learning on both pretraining and finetuning, yields better results on all evaluation settings. Most importantly, UniTE-UP is a *single model* which surpasses all the different state-of-the-art models on three tasks, showing its dominance on both convenience and effectiveness.

Multilingual-Targeted As seen in Table 2, the multilingual-targeted UniTE-MUP gives dominant performance than all strong baselines on Ref, Src and Src+Ref, demonstrating the transferability and effectiveness of our approach. Besides, the UniTE-UP also gives dominant results, revealing an improvement of 0.6, 0.3 and 0.9 averaged Kendall's τ correlation scores, respectively. However, we find that UniTE-MUP outperforms strong baselines but slightly worse than UniTE-UP on English-targeted translation directions (see Table 3). We think the reason lies in the curse of multilingualism and vocabulary dilution (Conneau et al., 2020).

Quality Estimation The results for UniTE approach on WMT 2020 QE task are concluded in Table 4. As seen, it achieves competitive results on QE task compared with the winner submission (Ranasinghe et al., 2020b).

5 Ablation Studies

In this section, we conduct ablation studies to investigate the effectiveness of regional attention patterns (§5.1), unified training (§5.2), and ranking-based data labeling (§5.3). All experiments are conducted by following English-targeted setting.

5.1 Regional Attention Patterns

To investigate the effectiveness of MRA, we further collect experiments in Table 5. As seen, MRA can give performance improvements than full attention, and preventing the interactions between hypothesis and source segment can improve the performance most. We think the reasons behind are twofold. First, the source side is formed with a different language, whose semantic information is rather weak than the reference side. Second, by preventing direct interactions between source and hypothe-

Table 4: Pearson correlation (%) on WMT 2020 QE Task test set. For baselines, we directly collect the results reported in Ranasinghe et al. (2020b). UniTE-MUP gives better results between convenience and performance.

Model	**Avg.** τ **(%)**	Δ
Full attention	34.1	–
no H→S (Soft)	**34.8**	**+0.7**
no S→H (Soft)	34.6	+0.5
no H→S, H→R & S→R (Hard)	34.3	+0.2
no R→S	34.0	-0.1
no S→R	33.9	-0.2
no R→H	33.6	-0.5
no H→R	34.0	-0.1

Table 5: Averaged Kendall's Tau correlation (%) and the gap (Δ) on English-targeted SRC+REF task with monotonic regional attention (MRA) strategies. H, S and R represent hypothesis, source and reference segment, respectively. Arrow denotes the attention flow of two segments inside attention modules of XLM-R. Soft MRA strategy between H and S is most effective. Hard MRA can yield a slight improvement. Removing other interactions between H and R, or S and R, leads to performance drop, and R→H degrades most.

Unified Pretrain	**Unified Finetune**	**Avg.** τ **(%)**		
		REF	SRC	SRC+REF
✓	✓	**34.8**	**30.0**	**35.0**
✓	✗	33.8	29.1	33.9
✗	✗	31.9	27.7	32.6

Table 6: Unified and task-specific training for UniTE-UP approach. As seen, combination of unified pretraining and finetuning gives best performances, meanwhile requires only one unified model.

sis, semantics inside the former must be passed through reference, which is helpful for disambiguation. Besides, not allowing the source to derive information from the hypothesis is better than the opposite direction. Wang and Chen (2020) found that the positional embeddings in PLM are engaged with strong adjacent information. We think the reason why S→H performs worse than H→S lies in the skipping of indexes, which corrupts positional similarities in alignment calculation.

Additionally, when we combined two methods together, *i.e.*, unified pretraining and finetuning with SRC+REF UniTE-MRA setting, model performance drops to 34.9 over English-targeted tasks on average. We think that both methods all intend to solve the problem of unseen SRC+REF input format, and MRA may not be necessary if massive data examples can be obtained for pretraining. Nevertheless, UniTE-MRA has its advantage on wide application without requiring pseduo labeled data.

5.2 Unified Training

Experiments for comparing unified and task-specific training are concluded in Table 6. As seen, when using the unified pretraining checkpoint to finetune over the specific task, performance over three models reveals performance drop con-

Method	**Avg.** τ (%)	Δ
Rank-Norm, Ens	**35.0**	-
Rank-Norm	34.7	-0.3
Z-Norm, Ens	33.5	-1.5
Z-Norm	34.2	-0.8

Table 7: Pseudo-data labeling with different methods. Ranking-based normalization (Rank-Norm) performs better than conventional Z-score approach (Z-Norm). Besides, ensembling (Ens) ranking-based normalized scores can give higher result, while conventional Z-Norm performs worse after ensembling.

sistently, indicating that the unified finetuning is helpful for model learning. This also verifies our hypothesis, that the cores of REF, SRC, and SRC+REF tasks are identical to each other. Moreover, unified pretraining and finetuning are complementary to each other. Also, utilizing task-specific pretraining instead of unified one reveals worse performance. To sum up, unifying both pretraining and finetuning only reveals one model, showing its advantage on the generalization on all tasks, where one united model can cover all functionalities of REF, SRC and SRC+REF tasks concurrently.

5.3 Ranking-based Data Labeling

To verify the effectiveness of ranking-based labeling, we collect the results of models applying different pseudo labeling strategies. After deriving the original scores from the well-trained UniTE-MRA checkpoint, we use Z-score and proposed ranking-based normalization methods to label synthetic data. For both methods, we also apply an ensembling strategy to assign training examples with averaged scores deriving from 3 UniTE-MRA checkpoints. Results show that, Z-score normalization reveals a performance drop when applying score ensembling with multiple models. Our proposed ranking-based normalization can boost the UniTE-UP model training, and its ensembling approach can further improve the performance.

6 Conclusion

In the past decades, automatic translation evaluation is mainly divided into REF, SRC and SRC+REF tasks, each of which develops independently and is tackled by various task-specific methods. We suggest that the three tasks are possibly handled by a unified framework, thus being ease of use and facilitating the knowledge transferring. Contributions of our work are mainly in three folds: (a) We propose a flexible and unified translation evaluation model UniTE, which can be adopted into the three tasks at once; (b) Through in-depth analyses, we point out that the main challenge of unifying three tasks stems from the discrepancy between vanilla pretraining and multi-tasks finetuning, and fill this gap via monotonic regional attention (MRA) and unified pretraining (UP); (c) Our single model consistently outperforms a variety of state-of-the-art or winner systems across high-resource and zero-shot evaluation in WMT 2019 Metrics and WMT 2020 QE benchmarks, showing its advantage of flexibility and convincingness. We hope our new insights can contribute to subsequent studies in the translation evaluation community.

A Collection of Pretraining Data

Considering the English-targeted model, we select Czech (Cz), German (De), Japanese (Ja), Russian (Ru), and Chinese (Zh) as source languages, and English (En) as target. For each translation direction, we collect 1 million samples, finally yielding 5 million examples in total for unified pretraining. As to the multilingual-targeted model, we further collect 1 million synthetic data for each language direction of En-Cz, En-De, En-Ja, En-Ru, and En-Zh. Finally, we construct 10 million examples for the pretraining of the multilingual version by adding the data of the English-targeted model. Note that, for a fair comparison, we filter out all pretraining examples that are involved in benchmarks.

B Reproducibility

All the models reported in this paper were finetuned on a single Nvidia V100 (32GB) GPU. Specifically for UniTE-UP and UniTE-MUP, the pretraining is arranged on 4 Nvidia V100 (32GB) GPUs. Our framework is built upon COMET repository (Rei et al., 2020). For the contribution to the research community, we release both the source code of UniTE framework and the well-trained evaluation models as described in this paper at https://github.com/NLP2CT/UniTE.

Program Transfer for Answering Complex Questions over Knowledge Bases

Abstract

Program induction for answering complex questions over knowledge bases (KBs) aims to decompose a question into a multi-step program, whose execution against the KB produces the final answer. Learning to induce programs relies on a large number of parallel question-program pairs for the given KB. However, for most KBs, the gold program annotations are usually lacking, making learning difficult. In this paper, we propose the approach of **program transfer**, which aims to leverage the valuable program annotations on the rich-resourced KBs as external supervision signals to aid program induction for the low-resourced KBs that lack program annotations. For program transfer, we design a novel two-stage parsing framework with an efficient ontology-guided pruning strategy. First, a sketch parser translates the question into a high-level program sketch, which is the composition of functions. Second, given the question and sketch, an argument parser searches the detailed arguments from the KB for functions. During the searching, we incorporate the KB ontology to prune the search space. The experiments on ComplexWebQuestions and WebQuestionSP show that our method outperforms SOTA methods significantly, demonstrating the effectiveness of program transfer and our framework. Our codes and datasets can be obtained from `https://github.com/THU-KEG/ProgramTransfer`.

1 Introduction

Answering complex questions over knowledge bases (Complex KBQA) is a challenging task requiring logical, quantitative, and comparative reasoning over KBs (Hu et al., 2018; Lan et al., 2021). Recently, the program induction (PI) paradigm, which gains increasing study in various areas (Lake et al., 2015; Neelakantan et al., 2017; Wong et al., 2021), emerges as a promising technique for Complex KBQA (Liang et al., 2017; Saha et al., 2019a; Ansari et al., 2019). Given a KB, PI for Complex KBQA aims to decompose a complex question into a multi-step program, whose execution on the KB produces the answer. Fig. 1 presents a complex question and its corresponding program whose functions take KB elements (*i.e.*, entities, relations and concepts) as arguments. *E.g.*, the relation `tourist attractions` is the argument of function *Relate*.

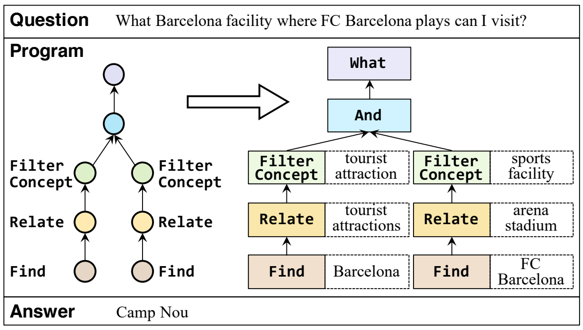

Figure 1: An example question, the corresponding program, and the answer. The left side is the sketch, and the right side is the complete program, with dotted boxes denoting arguments for functions.

For most KBs, the parallel question-program pairs are lacking because such annotation is both expensive and labor-intensive. Thus, the PI models have to learn only from question-answer pairs. Typically, they take the answers as weak supervision and search for gold programs with reinforcement learning (RL) (Saha et al., 2019b; Liang et al., 2017; Ansari et al., 2019). The combinatorial explosion in program space, along with extremely sparse rewards, makes the learning challenging. Abundant attempts have been made to improve the stability of RL algorithms with pseudo-gold programs (Liang et al., 2017), noise-stabilizing wrapper (Ansari et al., 2019), or auxiliary rewards (Saha et al., 2019b). Despite promising results, they re-

quire significant human efforts to develop carefully-designed heuristics or are constrained to relatively simple questions.

Recently, for several KBs, there emerge question-program annotation resources (Johnson et al., 2017; Cao et al., 2022). Thanks to the supervision signals (*i.e.*, program annotation for each question), the PI models on these rich-resourced KBs achieve impressive performance for even extremely complex questions, and are free from expert engineering. Intuitively, leveraging these supervision signals to aid program induction for low-resourced KBs with only weak-supervision signals (*i.e.*, question-answer pairs) is a promising direction. In this paper, we formalize it as **Program Transfer**.

In practice, program transfer is challenging due to the following reasons: (a) **Domain Heterogeneity**. The questions and KBs across domains are both heterogeneous due to language and knowledge diversity (Lan et al., 2021). It is hard to decide what to transfer for program induction. (b) **Unseen KB Elements.** The coverage of source KB is limited, *e.g.*, KQA Pro in (Cao et al., 2022) covers only 3.9% relations and 0.24% concepts of Wikidata. Thus, most elements in the massive scale target KB are not covered in the source. (c) **Huge Search Space.** The search space of function arguments depends on the scale of target KB. For realistic KBs containing millions of entities, concepts and relations, the huge search space is unmanageable.

To address the above problems, we propose a novel two-stage parsing framework with an efficient ontology-guided pruning strategy. First, we design a **sketch parser** to parse the question into a program sketch (the left side in Fig. 1), which is composed of functions without arguments. As Baroni (2019) points out, the composition of functions well captures the language compositionality. Translation from questions to sketches is thus relevant to language compositional structure and independent of KB structure. Therefore, our sketch parser can transfer across KBs. Second, we design an **argument parser** to fill in the detailed arguments (typically KB elements) for functions in the sketch. It retrieves relevant KB elements from the target KB and ranks them according to the question. Specifically, it identifies KB elements with their label descriptions and relies on language understanding to resolve unseen ones. We further propose an **ontology-guided pruning** strategy, which introduces high-level KB ontology to prune the candidate space for the argument parser, thus alleviating the problem of huge search space.

Specifically, the sketch parser is implemented with a Seq2Seq model with the attention mechanism. The argument parser identifies elements through semantic matching and utilizes pre-trained language models (Devlin et al., 2019) for language understanding. The high-level ontology includes the domain and range of relations and entity types.

In evaluation, we take the Wikidata-based KQA Pro as the source, Freebase-based ComplexWebQuestions and WebQuestionSP as the target domain datasets. Experimental results show that our method improves the F1 score by 14.7% and 2.5% respectively, compared with SOTA methods that learn from question-answer pairs.

Our contributions include: (a) proposing the approach of program transfer for Complex KBQA for the first time; (b) proposing a novel two-stage parsing framework with an efficient ontology-guided pruning strategy for program transfer; (c) demonstrating the effectiveness of program transfer through extensive experiments and careful ablation studies on two benchmark datasets.

2 Related Work

KBQA. KBQA aims to find answers for questions expressed in natural language from a KB, such as Freebase (Bollacker et al., 2008), DBpedia (Lehmann et al., 2015) and Wikidata (Vrandecic and Krötzsch, 2014). Current methods for KBQA can be categorized into two groups: 1) semantic parsing based methods (Berant et al., 2013; Yih et al., 2015; Cheng et al., 2017; Liang et al., 2017; Ansari et al., 2019), which learn a semantic parser that converts questions into intermediate logic forms which can be executed against a KB; 2) information retrieval based methods (Bordes et al., 2014; Xu et al., 2016; Miller et al., 2016; Zhang et al., 2018; Sun et al., 2018, 2019; Shi et al., 2021), which retrieve candidate answers from the topic-entity-centric subgraph and then rank them according to the questions. Recently, semantic parsing for KBQA has gained increasing research attention because the methods are effective and more interpretable. Multiple kinds of logical forms have been proposed and researched, such as SPARQL (hommeaux, 2011), λ-DCS (Liang, 2013), λ-calculus (Artzi et al., 2013), query graph (Yih et al., 2015), program (Liang et al., 2017). PI aims to convert questions into programs, and is in line with semantic parsing.

Cross-domain Semantic Parsing. Cross-domain semantic parsing trains a semantic parser on some source domains and adapts it to the target domain. Some works (Herzig and Berant, 2017; Su and Yan, 2017; Fan et al., 2017) pool together examples from multiple datasets in different domains and train a single sequence-to-sequence model over all examples, sharing parameters across domains. However, these methods rely on annotated logic forms in the target domain. To facilitate low-resource target domains, (Chen et al., 2020) adapts to target domains with a very limited amount of annotated data. Other works consider a zero-shot semantic parsing task (Givoli and Reichart, 2019), decoupling structures from lexicons for transfer. However, they only learn from the source domain without further learning from the target domain using the transferred prior knowledge. In addition, existing works mainly focus on the domains in OVERNIGHT (Wang et al., 2015), which are much smaller than large scale KBs such as Wikidata and Freebase. Considering the complex schema of large scale KBs, transfer in ours setting is more challenging.

3 Problem Formulation

In this section, we first give some necessary definitions and then formulate our task.

Knowledge Bases. Knowledge base describes concepts, entities, and the relations between them. It can be formalized as $\mathcal{KB} = \{\mathcal{C}, \mathcal{E}, \mathcal{R}, \mathcal{T}\}$. $\mathcal{C}$, $\mathcal{E}$, $\mathcal{R}$ and $\mathcal{T}$ denote the sets of concepts, entities, relations and triples respectively. Relation set $\mathcal{R}$ can be formalized as $\mathcal{R} = \{r_e, r_c\} \cup \mathcal{R}_l$, where r_e is `instanceOf`, r_c is `subClassOf`, and $\mathcal{R}_l$ is the general relation set. $\mathcal{T}$ can be divided into three disjoint subsets: (1) `instanceOf` triple set $\mathcal{T}_e = \{(e, r_e, c) | e \in \mathcal{E}, c \in \mathcal{C}\}$; (2) `subClassOf` triple set $\mathcal{T}_c = \{(c_i, r_c, c_j) | c_i, c_j \in \mathcal{C}\}$; (3) relational triple set $\mathcal{T}_l = \{(e_i, r, e_j) | e_i, e_j \in \mathcal{E}, r \in \mathcal{R}_l\}$.

Program. Program is composed of symbolic functions with arguments, and produces an answer when executed against a KB. Each function defines a basic operation on KB and takes a specific type of argument. For example, the function *Relate* aims to find entities that have a specific *relation* with the given entity. Formally, a program y is denoted as $\langle o_1[arg_1], \cdots, o_t[arg_t], \cdots, o_{|y|}[arg_{|y|}] \rangle$, $o_t \in \mathcal{O}, arg_t \in \mathcal{E} \cup \mathcal{C} \cup \mathcal{R}$. Here, $\mathcal{O}$ is a pre-defined function set, which covers basic reasoning operations over KBs (Cao et al., 2022). According to the argument type, $\mathcal{O}$ can be devided into four disjoint subsets: $\mathcal{O} = \mathcal{O}^{\mathcal{E}} \cup \mathcal{O}^{\mathcal{C}} \cup \mathcal{O}^{\mathcal{R}} \cup \mathcal{O}^{\emptyset}$, representing the functions whose argument type is entity, concept, relation and empty respectively. Table 1 gives some examples of program functions.

Function	Argument Type	Argument	Description
Find	entity	`FC Barcelona`	Find the specific KB entity
Relate	relation	`arena stadium`	Find the entities that hold a specific relation with the given entity
FilterConcept	concept	`sports facility`	Find the entities that belong to a specific concept
And	-	-	Return the intersection of two entity sets

Table 1: Function examples. - means empty.

Program Induction. Given a $\mathcal{KB}$, and a complex natural language question $x = \langle w_1, w_2, \cdots, w_{|x|} \rangle$, it aims to produce a program y that generates the right answer z when executed against $\mathcal{KB}$.

Program Transfer. In this task, we have access to the source domain data $S = \langle \mathcal{KB}^S, \mathcal{D}^S \rangle$, where $\mathcal{D}^S$ contains pairs of question and program $\{(x_i^S, y_i^S)\}_{i=1}^{n^S}$; and target domain data $T = \langle \mathcal{KB}^T, \mathcal{D}^T \rangle$, where $\mathcal{D}^T$ contains pairs of question and answer $\{(x_i^T, z_i^T)\}_{i=1}^{n^T}$. We aim at learning a PI model to translate a question x for $\mathcal{KB}^T$ into program y, which produces the correct answer when executed on $\mathcal{KB}^T$.

4 Framework

As mentioned in the introduction, to perform program transfer for Complex KBQA, we need to address three crucial problems: (1) What to transfer when both questions and KBs are heterogeneous? (2) How to deal with the KB elements unseen in the external annotations? (3) How to prune the search space of input arguments to alleviate the huge search space problem? In this section, we introduce our two-stage parsing framework with an ontology-guided pruning strategy, which is shown in Fig. 2.

(1) **Sketch Parser**: At the first stage, we design a sketch parser f^s to parse x into a program sketch $y_s = \langle o_1, \cdots, o_t, \cdots o_{|y|} \rangle$, which is a sequence of functions without arguments. The sketch parsing process can be formulated as

$$y_s = f^s(x). \tag{1}$$

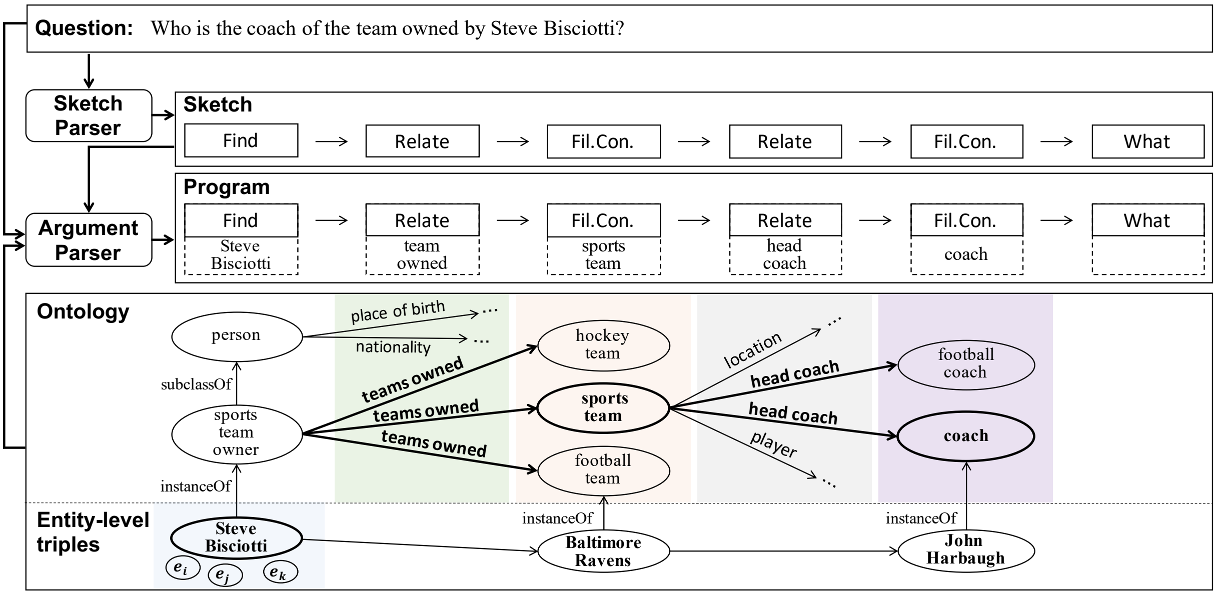

Figure 2: We design a high-level sketch parser to generate the sketch, and a low-level argument parser to predict arguments for the sketch. The arguments are retrieved from candidate pools which are illustrated by the color blocks. The arguments for functions are mutually constrained by the ontology structure. For example, when the second function *Relate* finds the argument `teams owned`, the candidate pool for the third function *Fil.Con.* (short for *FilterConcept*) is reduced to the range of relation `teams owned`.

Translation from question to sketch is relevant to language compositionality, and irrelevant to KB structure. Therefore, the sketch parser can generalize across KBs.

(2) **Argument Parser**: At the second stage, we design an argument parser f^a to retrieve the argument arg_t from a candidate pool $\mathcal{P}$ for each function o_t, which can be formulated as

$$arg_t = f^a(x, o_t, \mathcal{P}). \tag{2}$$

Here, the candidate pool $\mathcal{P}$ contains the relevant elements in $\mathcal{KB}^T$, including concepts, entities, and relations. In a real KB, the candidate pool is usually huge, which makes searching and learning from answers very hard. Therefore, we propose an ontology-guided pruning strategy, which dynamically updates the candidate pool and progressively reduces its search space.

In the following we will introduce the implementation details of our sketch parser (Section 4.1), argument parser (Section 4.2) and training strategies (Section 4.3).

4.1 Sketch Parser

The sketch parser is based on encoder-decoder model (Sutskever et al., 2014) with attention mechanism (Dong and Lapata, 2016). We aim to estimate $p(y_s|x)$, the conditional probability of sketch y_s given input x. It can be decomposed as:

$$p(y_s|x) = \prod_{t=1}^{|y_s|} p(o_t|o_{<t}, x), \tag{3}$$

where $o_{<t} = o_1, ..., o_{t-1}$.

Specifically, our sketch parser comprises a question encoder that encodes the question into vectors and a sketch decoder that autoregressively outputs the sketch step-by-step. The details are as follows:

Question Encoder. We utilize BERT (Devlin et al., 2019) as the encoder. Formally,

$$\bar{\mathbf{x}}, (\mathbf{x}_1, \cdots, \mathbf{x}_i, \cdots, \mathbf{x}_{|x|}) = \text{BERT}(x), \tag{4}$$

where $\bar{\mathbf{x}} \in \mathbb{R}^{\hat{d}}$ is the question embedding, and $\mathbf{x}_i \in \mathbb{R}^{\hat{d}}$ is the hidden vector of word x_i. $\hat{d}$ is the hidden dimension.

Sketch Decoder. We use Gated Recurrent Unit (GRU) (Cho et al., 2014), a well-known variant of RNNs, as our decoder of program sketch. The decoding is conducted step by step. After we have predicted o_{t-1}, the hidden state of step t is computed as:

$$\mathbf{h}_t = \text{GRU}(\mathbf{h}_{t-1}, \mathbf{o}_{t-1}), \tag{5}$$

where $\mathbf{h}_{t-1}$ is the hidden state from last time step, $\mathbf{o}_{t-1} = [\mathbf{W}]_{o_{t-1}}$ denotes the embedding corresponding to o_{t-1} in the embedding matrix $\mathbf{W} \in \mathbb{R}^{|\mathcal{O}|\times d}$. We use $\mathbf{h}_t$ as the attention key to compute scores for each word in the question based on the hidden vector $\mathbf{x}_i$, and compute the attention vector $\mathbf{c}_t$ as:

$$\alpha_i = \frac{\exp(\mathbf{x}_i^{\mathrm{T}}\mathbf{h}_t)}{\sum_{j=1}^{|x|}\exp(\mathbf{x}_j^{\mathrm{T}}\mathbf{h}_t)}, \qquad \mathbf{c}_t = \sum_{i=1}^{|x|}\alpha_i\mathbf{x}_i. \tag{6}$$

The information of $\mathbf{h}_t$ and $\mathbf{c}_t$ are fused to predict the final probability of the next sketch token:

$$\mathbf{g}_t = \mathbf{h}_t + \mathbf{c}_t, \qquad p(o_t|o_{<t}, x) = \left[\mathrm{Softmax}(\mathrm{MLP}(\mathbf{g}_t))\right]_{o_t}, \tag{7}$$

where MLP (short for multi-layer perceptron) projects $\hat{d}$-dimensional feature to $|\mathcal{O}|$-dimension, which consists of two linear layers with ReLU activation.

4.2 Argument Parser

In the above section, the sketch is obtained with a sketch parser. In this section, we will introduce our argument parser, which aims to retrieve the argument arg_t from the target KB for each function o_t in the sketch. To reduce the search space, it retrieves arguments from a restricted candidate pool $\mathcal{P}$, which is constructed with our ontology-guided pruning strategy. In the following, we will introduce the argument retrieval process and the candidate pool construction process.

Argument Retrieval. Specifically, we take $\mathbf{g}_t$ in Equation 7 as the context representation of o_t, learn vector representation $\mathbf{P}_i \in \mathbb{R}^{\hat{d}}$ for each candidate $\mathcal{P}_i$, and calculate the probability for $\mathcal{P}_i$ based on $\mathbf{g}_t$ and $\mathbf{P}_i$. Candidate $\mathcal{P}_i$ is encoded with the BERT encoder in Equation 4, which can be formulated as:

$$\mathbf{P}_i = \mathrm{BERT}(\mathcal{P}_i). \tag{8}$$

$\mathbf{P}_i$ is the i^{th} row of $\mathbf{P}$. The probability of candidate arg_t is calculated as:

$$p(arg_t|x, o_t, \mathcal{P}) = \left[\mathrm{Softmax}(\mathbf{P}\mathbf{g}_t)\right]_{arg_t}. \tag{9}$$

Candidate Pool Construction. In the following, we will introduce the KB ontology first. Then, we will describe the rationale of our ontology-guided pruning strategy and its implementation details.

In KB, The domain and range of relations, and the type of entities form the KB ontology. Specifically, a relation r comes with a domain $dom(r) \subseteq \mathcal{C}$ and a range $ran(r) \subseteq \mathcal{C}$. An entity e comes with a type $type(e) = \{c|(e, \texttt{instanceOf}, c) \in \mathcal{T}\}$. For example, as shown in Fig. 2, `sports team owner` $\in dom($`teams owned`$)$, `sports team` $\in ran($`teams owned`$)$, and `sports team` $\in type($`Baltimore Ravens`$)$.

The rationale of our pruning is that the arguments for program functions are mutually constrained according to the KB ontology. Therefore, when the argument arg_t for o_t is determined, the possible candidates for $\{o_i\}_{i=t+1}^{|y_s|}$ will be adjusted. For example, in Fig. 2, when *Relate* takes `teams owned` as the argument, the candidate pool for the next *FilterConcept* is constrained to the range of relation `teams owned`, thus other concepts (*e.g.*, `time zone`) will be excluded from the candidate pool.

In practice, we propose a set of ontology-oriented operators to adjust the candidate pool $\mathcal{P}$ step-by-step. Specifically, we define three ontology-oriented operators $C(e), R(r), D^{-}(c)$, which aim to find the type of entity e, the range of relation r, and the relations whose domain contains c. Furthermore, we use the operators to maintain an entity pool $\mathcal{P}^{\mathcal{E}}$, a relation pool $\mathcal{P}^{\mathcal{R}}$ and a concept pool $\mathcal{P}^{\mathcal{C}}$. When arg_t of o_t is determined, we will update $\mathcal{P}^{\mathcal{E}}$, $\mathcal{P}^{\mathcal{R}}$, and $\mathcal{P}^{\mathcal{C}}$ using $C(e), R(r), D^{-}(c)$. We take one of the three pools as $\mathcal{P}$ according to the argument type of o_t. The detailed algorithm is shown in Appendix.

4.3 Training

We train our model using the popular pretrain-finetune paradigm. Specifically, we pretrain the parsers on the source domain data $\mathcal{D}^S = \left\{\left(x_i^S, y_i^S\right)\right\}_{i=1}^{n^S}$ in a supervised way. After that, we conduct finetuning on the target domain data $\mathcal{D}^T = \left\{\left(x_i^T, z_i^T\right)\right\}_{i=1}^{n^T}$ in a weakly supervised way.

Pretraining in Source Domain. Since the source domain data provides complete annotations, we can directly maximize the log-likelihood of the golden sketch and golden arguments:

$$\mathcal{L}^{\text{pretrain}} = -\sum_{(x^S, y^S)\in\mathcal{D}^S}\Bigg(\log p(y_s^S|x^S) + \sum_{t=1}^{|y_s|}\log p(arg_t^S|x^S, o_t^S, \mathcal{P})\Bigg). \tag{10}$$

Finetuning in Target Domain. At this training phase, questions are labeled with answers while programs remain unknown. The basic idea is to search for potentially correct programs and optimize their corresponding probabilities. Specifically, we propose two training strategies:

- Hard-EM Approach. At each training step, hard-EM generates a set of possible programs with beam search based on current model parameters, and then executes them to find the one whose answers have the highest F1 score compared with the gold. Let $\hat{y}^T$ denote the best program, we directly maximize $p(\hat{y}^T|x^T)$ like Equation 10.
- Reinforcement learning (RL). It formulates the program generation as a decision making procedure and computes the rewards for sampled programs based on their execution results. We take the F1 score between the executed answers and golden answers as the reward value, and use REINFORCE (Williams, 1992) algorithm to optimize the parsers.

5 Experimental Settings

5.1 Datasets

Source Domain. KQA Pro (Cao et al., 2022) provides 117,970 question-program pairs based on a Wikidata (Vrandecic and Krötzsch, 2014) subset.

Target Domain. We use WebQuestionSP (WebQSP) (Yih et al., 2016) and ComplexWebQuestions (CWQ) (Talmor and Berant, 2018) as the target domain datasets for two reasons: (1) They are two widely used benchmark datasets in Complex KBQA; (2) They are based on a large-scale KB Freebase (Bollacker et al., 2008), which makes program transfer challenging. Specifically, WebQSP contains 4,737 questions and is divided into 2,998 train, 100 dev and 1,639 test cases. CWQ is an extended version of WebQSP which is more challenging, with four types of questions: composition (44.7%), conjunction (43.6%), comparative (6.2%), and superlative (5.4%). CWQ is divided into 27,639 train, 3,519 dev and 3,531 test cases.

We use the Freebase dump on 2015-08-09[1], from which we extract the type of entities, domain and range of relations to construct the ontology. The average domain, range, type size is 1.43 per relation, 1.17 per relation, 8.89 per entity respectively.

Table 2 shows the statistics of the source and target domain KB. The target domain KB contains much more KB elements, and most of them are uncovered by the source domain.

Domain	# Entities	# Relations	# Concepts
Source	16,960	363	794
Target	30,943,204	15,015	2,519

Table 2: The statistics for source and target domain KB.

5.2 Baselines

In our experiments, we select representative models that learn from question-answer pairs as our baselines. They can be categorized into three groups: program induction methods, query graph generation methods and information retrieval methods.

Existing program induction methods search for gold programs with RL. They usually require human efforts or are constrained to simple questions. **NSM** (Liang et al., 2017) uses the provided entity, relation and type annotations to ease the search, and can solve relatively simple questions. **NPI** (Ansari et al., 2019) designs heuristic rules such as disallowing repeating or useless actions for efficient search.

Existing query graph generation methods generate query graphs whose execution on KBs produces the answer. They use entity-level triples as search guidance, ignoring the useful ontology. **TEXTRAY** (Bhutani et al., 2019) uses a decompose-execute-join approach. **QGG** (Lan and Jiang, 2020) incorporates constraints into query graphs in the early stage. **TeacherNet** (He et al., 2021) utilizes bidirectional searching.

Existing information retrieval methods directly construct a question-specific sub-KB and then rank the entities in the sub-KB to get the answer. **GraftNet** (Sun et al., 2018) uses heuristics to create the subgraph and uses a variant of graph convolutional networks to rank the entities. **PullNet** (Sun et al., 2019) improves GraftNet by iteratively constructing the subgraph instead of using heuristics.

Besides, we compare our full model **Ours** with Ours$_{\text{-f}}$, Ours$_{\text{-p}}$, Ours$_{\text{-pa}}$, Ours$_{\text{-o}}$, which denotes our model without finetuning, without pretraining, without pretraining of argument parser, and without our ontology-guided pruning strategy respectively.

---

[1] http://commondatastorage.googleapis.com/freebase-public/rdf/freebase-rdf-latest.gz

5.3 Evaluation Metrics

Following prior works (Berant et al., 2013; Sun et al., 2018; He et al., 2021), we use F1 score and Hit@1 as the evaluation metrics. Since questions in the datasets have multiple answers, F1 score reflects the coverage of predicted answers better.

5.4 Implementations

We used the bert-base-cased model of HuggingFace[2] as our BERT encoder with the hidden dimension $\hat{d}$ 768. The hidden dimension of the sketch decoder d was 1024. We used AdamW (Loshchilov and Hutter, 2019) as our optimizer. We searched the learning rate for BERT paramters in {1e-4, 3e-5, 1e-5}, the learning rate for other parameters in {1e-3, 1e-4, 1e-5}, and the weight decay in {1e-4, 1e-5, 1e-6}. According to the performance on dev set, we finally used learning rate 3e-5 for BERT parameters, 1e-3 for other parameters, and weight decay 1e-5.

6 Experimental Results

Models	WebQSP		CWQ	
	F1	Hit@1	F1	Hit@1
NSM	-	69.0	-	-
NPI	-	72.6	-	-
TEXTRAY	60.3	72.2	33.9	40.8
QGG	74.0	-	40.4	44.1
TeacherNet	67.4	74.3	44.0	48.8
GraftNet	62.3	68.7	-	32.8*
PullNet	-	68.1	-	47.2*
Ours$_{\text{-f}}$	53.8	53.0	45.9	45.2
Ours$_{\text{-p}}$	3.2	3.1	2.3	2.1
Ours$_{\text{-pa}}$	70.8	68.9	54.5	54.3
Ours$_{\text{-o}}$	72.0	71.3	55.8	54.7
Ours	**76.5**	**74.6**	**58.7**	**58.1**

Table 3: Performance comparison of different methods (F1 score and Hits@1 in percent). We highlight the best results in bold and second with an underline. *: reported by PullNet on the dev set.

6.1 Overall Results

As shown in Table 3, our model achieves the best performance on both WebQSP and CWQ. Especially on CWQ, we have an absolute gain of 14.7% in F1 and 9.3% in Hit@1, beating previous methods by a large margin. Note that CWQ is much more challenging than WebQSP because it includes more compositional and conjunctional questions. Previous works mainly suffer from the huge search space and sparse training signals. We alleviate these issues by transferring the prior knowledge from external annotations and incorporating the ontology guidance. Both of them reduce the search space substantially. On WebQSP, we achieve an absolute gain of 2.5% and 0.3% in F1 and Hit@1, respectively, demonstrating that our model can also handle simple questions well, and can adapt to different complexities of questions.

Note that our F1 scores are higher than the corresponding Hit@1. This is because we just randomly sampled one answer from the returned answer set as the top 1 without ranking them.

Models	WebQSP	CWQ
Top-1	76.5	58.7
Top-2	81.1	61.2
Top-5	85.4	63.3
Top-10	86.9	65.0

Table 4: The highest F1 score in the top-k programs.

We utilize beam search to generate multiple possible programs and evaluate their performance. Table 4 shows the highest F1 score in the top-k generated programs, where top-1 is the same as Table 3. We can see that the best F1 in the top-10 programs is much higher than the F1 of the top-1 (*e.g.*, with an absolute gain 10.4% for WebQSP and 6.3% for CWQ). This indicates that a good re-ranking method can further improve the overall performance of our model. We leave this as our future work.

6.2 Ablation study

Pretraining: As shown in Table 3, when comparing Ours$_{\text{-pa}}$ with Ours, the F1 and Hit@1 on CWQ drop by 4.2% and 3.8% respectively, which indicates that the pretraining for the argument parser is necessary. Ours$_{\text{-p}}$ denotes the model without pretraining for neither sketch parser nor argument parser. We can see that its results are very poor, achieving just about 3% and 2% on WebQSP and CWQ, indicating that the pretraining is essential, especially for the sketch parser.

Finetuning: Without finetuning on the target data, *i.e.*, in Ours$_{\text{-f}}$, performance drops a lot compared with the complete model. For example, F1 and Hit@1 on CWQ drop by 12.8% and 12.9% respectively. It indicates that finetuning is necessary for the model's performance. As shown in Table 2, most of the relations and concepts in the target domain are uncovered by the source domain. Due to

---

[2] https://github.com/huggingface/transformers

the semantic gap between source and target data, the prior knowledge must be properly transferred to the target domain to bring into full play.

Ontology: We implemented Ours$_{\text{-o}}$ by removing ontology from KB and removing *FilterConcept* from the program. Comparing Ours$_{\text{-o}}$ with Ours, the F1 and Hit@1 on CWQ drops by 2.9% and 3.4% respectively, which demonstrates the importance of ontology-guided pruning strategy. We calculated the search space size for each compositional and conjunctive question in the dev set of CWQ, and report the average size in Table 5. The statistics shows that, the average search space size of Ours is only 0.26% and 3.2% of that in Ours$_{\text{-o}}$ for the two kinds of questions. By incorporating the ontology guidance, Ours substantially reduces the search space.

Model	Composition	Conjunction
Ours$_{\text{-o}}$	4,248,824.5	33,152.1
Ours	11,200.7	1,066.5

Table 5: The average search space size for composition and conjunction questions in CWQ set for Ours and Ours$_{\text{-o}}$.

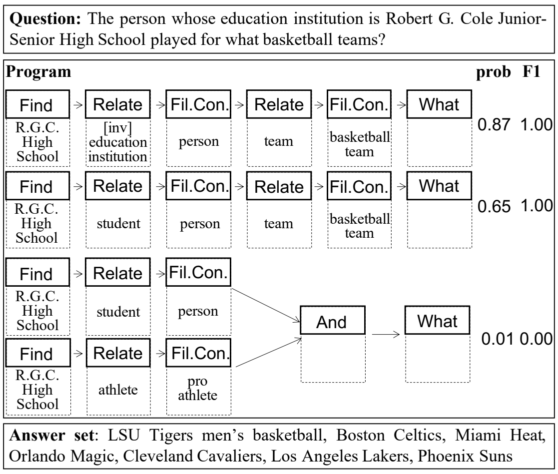
Hard-EM *v.s.* RL: For both WebQSP and CWQ, training with Hard-EM achieves better performance. For RL, we simply employed the REINFORCE algorithm and did not implement any auxiliary reward strategy since this is not the focus of our work. The sparse, delayed reward causes high variance, instability, and local minima issues, making the training hard (Saha et al., 2019b). We leave exploring more complex training strategies as our future work.

Models	WebQSP		CWQ	
	F1	Hit@1	F1	Hit@1
Hard-EM	76.5	74.6	58.7	58.1
RL	71.4	72.0	46.1	45.4

Table 6: Results of different training strategies.

6.3 Case Study

Fig. 3 gives a case, where our model parses an question into multiple programs along with their probablility scores and F1 scores of executed answers. Given the question "*The person whose education institution is Robert G. Cole Junior-Senior High School played for what basketball teams?*", we show the programs with the largest, 2-nd largest and 10-th largest possibility score. Both of the top-2 programs get the correct answer set and are semantically equivelant with the question, while the 10-th best program is wrong.



Question: The person whose education institution is Robert G. Cole Junior-Senior High School played for what basketball teams?

Answer set: LSU Tigers men's basketball, Boston Celtics, Miami Heat, Orlando Magic, Cleveland Cavaliers, Los Angeles Lakers, Phoenix Suns

Figure 3: An example from CWQ dev set. Our model translates the question into multiple programs with the corresponding probability and F1 score. We show the best, 2-nd best and 10-th best programs. Both the best and 2-nd best programs are correct.

Error Analysis We randomly sampled 100 error cases whose F1 score is lower than 0.1 for manual inspection. The errors can be summarized into the following categories: (1) Wrong relation (53%): wrongly predicted relation makes the program wrong, *e.g.*, for question " *What language do people in the Central Western Time Zone speak?*", our model predicts the relation `main country`, while the ground truth is `countries spoken in`; (2) Wrong concept (38%): wrongly predicted concept makes the program wrong, *e.g.*, for the question "*What continent does the leader Ovadia Yosel live in?*", our model predicted the concept `location`, whereas the ground truth is *continent*. (3) Model limitation (9%): Handling attribute constraint was not considered in our model, *e.g.*, for the question "*Who held his governmental position from before April 4, 1861 and influenced Whitman's poetry?*", the time constraint *April 4, 1861* cannot be handled.

7 Conclusion

In this parper, we propose program transfer for Complex KBQA for the first time. We propose a novel two-stage parsing framework with an efficient ontology-guided pruning strategy. First, a sketch parser translates a question into the program, and then an argument parser fills in the detailed arguments for functions, whose search space is restricted by an ontology-guided pruning strategy. The experimental results demonstrate that our program transfer approach outperforms the previous methods significantly. The ablation studies show that our two-stage parsing paradigm and ontology-guided pruning are both effective.

B Freebase Details

We extracted a subset of Freebase which contains all facts that are within 4-hops of entities mentioned in the questions of CWQ and WebQSP. We extracted the domain constraint for relations according to " */type/property/schema*", range constraint for relations according to "*/type/property/expected_type*", type constraint for entities according to "*/type/type/instance*". CVT nodes in the Freebase were dealed with concatenation of neiborhood relations.

C Program

We list the functions of KQA Pro in Table 7. The arguments in our paper are the textual inputs. To reduce the burden of the argument parser, for the functions that take multiple textual inputs, we concatenate them to a single input.

Function	**Functional Inputs × Textual Inputs → Outputs**	**Description**	**Example** (only show textual inputs)
FindAll	() × () → (*Entities*)	Return all entities in KB	-
Find	() × (*Name*) → (*Entities*)	Return all entities with the given name	*Find(Kobe Bryant)*
FilterConcept	(*Entities*) × (*Name*) → (*Entities*)	Find those belonging to the given concept	*FilterConcept(athlete)*
FilterStr	(*Entities*) × (*Key*, *Value*) → (*Entities*, *Facts*)	Filter entities with an attribute condition of string type, return entities and corresponding facts	*FilterStr(gender, male)*
FilterNum	(*Entities*) × (*Key*, *Value*, *Op*) → (*Entities*, *Facts*)	Similar to *FilterStr*, except that the attribute type is number	*FilterNum(height, 200 centimetres, >)*
FilterYear	(*Entities*) × (*Key*, *Value*, *Op*) → (*Entities*, *Facts*)	Similar to *FilterStr*, except that the attribute type is year	*FilterYear(birthday, 1980, =)*
FilterDate	(*Entities*) × (*Key*, *Value*, *Op*) → (*Entities*, *Facts*)	Similar to *FilterStr*, except that the attribute type is date	*FilterDate(birthday, 1980-06-01, <)*
QFilterStr	(*Entities*, *Facts*) × (*QKey*, *QValue*) → (*Entities*, *Facts*)	Filter entities and corresponding facts with a qualifier condition of string type	*QFilterStr(language, English)*
QFilterNum	(*Entities*, *Facts*) × (*QKey*, *QValue*, *Op*) → (*Entities*, *Facts*)	Similar to *QFilterStr*, except that the qualifier type is number	*QFilterNum(bonus, 20000 dollars, >)*
QFilterYear	(*Entities*, *Facts*) × (*QKey*, *QValue*, *Op*) → (*Entities*, *Facts*)	Similar to *QFilterStr*, except that the qualifier type is year	*QFilterYear(start time, 1980, =)*
QFilterDate	(*Entities*, *Facts*) × (*QKey*, *QValue*, *Op*) → (*Entities*, *Facts*)	Similar to *QFilterStr*, except that the qualifier type is date	*QFilterDate(start time, 1980-06-01, <)*
Relate	(*Entity*) × (*Pred*, *Dir*) → (*Entities*, *Facts*)	Find entities that have a specific relation with the given entity	*Relate(capital, forward)*
And	(*Entities*, *Entities*) × () → (*Entities*)	Return the intersection of two entity sets	-
Or	(*Entities*, *Entities*) × () → (*Entities*)	Return the union of two entity sets	-
QueryName	(*Entity*) × () → (string)	Return the entity name	-
Count	(*Entities*) × () → (number)	Return the number of entities	-
QueryAttr	(*Entity*) × (*Key*) → (*Value*)	Return the attribute value of the entity	*QueryAttr(height)*
QueryAttrUnderCondition	(*Entity*) × (*Key*, *QKey*, *QValue*) → (*Value*)	Return the attribute value, whose corresponding fact should satisfy the qualifier condition	*QueryAttrUnderCondition(population, point in time, 2016)*
QueryRelation	(*Entity*, *Entity*) × () → (*Pred*)	Return the predicate between two entities	*QueryRelation(Kobe Bryant, America)*
SelectBetween	(*Entity*, *Entity*) × (*Key*, *Op*) → (string)	From the two entities, find the one whose attribute value is greater or less and return its name	*SelectBetween(height, greater)*
SelectAmong	(*Entities*) × (*Key*, *Op*) → (string)	From the entity set, find the one whose attribute value is the largest or smallest	*SelectAmong(height, largest)*
VerifyStr	(*Value*) × (*Value*) → (boolean)	Return whether the output of *QueryAttr* or *QueryAttrUnderCondition* and the given value are equal as string	*VerifyStr(male)*
VerifyNum	(*Value*) × (*Value*, *Op*) → (boolean)	Return whether the two numbers satisfy the condition	*VerifyNum(20000 dollars, >)*
VerifyYear	(*Value*) × (*Value*, *Op*) → (boolean)	Return whether the two years satisfy the condition	*VerifyYear(1980, >)*
VerifyDate	(*Value*) × (*Value*, *Op*) → (boolean)	Return whether the two dates satisfy the condition	*VerifyDate(1980-06-01, >)*
QueryAttrQualifier	(*Entity*) × (*Key*, *Value*, *QKey*) → (*QValue*)	Return the qualifier value of the fact (*Entity*, *Key*, *Value*)	*QueryAttrQualifier(population, 23,390,000, point in time)*
QueryRelationQualifier	(*Entity*, *Entity*) × (*Pred*, *QKey*) → (*QValue*)	Return the qualifier value of the fact (*Entity*, *Pred*, *Entity*)	*QueryRelationQualifier(spouse, start time)*

Abstract

Complete Multi-lingual Neural Machine Translation (C-MNMT) achieves superior performance against the conventional MNMT by constructing multi-way aligned corpus, i.e., aligning bilingual training examples from different language pairs when either their source or target sides are identical. However, since exactly identical sentences from different language pairs are scarce, the power of the multi-way aligned corpus is limited by its scale. To handle this problem, this paper proposes "Extract and Generate" (EAG), a two-step approach to construct large-scale and high-quality multi-way aligned corpus from bilingual data. Specifically, we first extract candidate aligned examples by pairing the bilingual examples from different language pairs with highly similar source or target sentences; and then generate the final aligned examples from the candidates with a well-trained generation model. With this two-step pipeline, EAG can construct a large-scale and multi-way aligned corpus whose diversity is almost identical to the original bilingual corpus. Experiments on two publicly available datasets i.e., WMT-5 and OPUS-100, show that the proposed method achieves significant improvements over strong baselines, with +1.1 and +1.4 BLEU points improvements on the two datasets respectively.

1 Introduction

Multilingual Neural Machine Translation (MMMT) (Dong et al., 2015; Firat et al., 2017; Johnson et al., 2017; Aharoni et al., 2019) has achieved promising results on serving translations between multiple language pairs with one model. With sharing parameters of the model, MNMT can facilitate information sharing between similar languages and make it possible to translate between low-resource and zero-shot language pairs. Since the majority of available MT training data are English-centric, i.e., English either as the source or target language, most non-English language pairs do not see a single training example when training MNMT models (Freitag and Firat, 2020). Therefore, the performance of MNMT models on non-English translation directions still left much to be desired: 1) Lack of training data leads to lower performance for non-English language pairs(Zhang et al., 2021); 2) MNMT models cannot beat the pivot-based baseline systems which translate non-English language pairs by bridging through English (Cheng et al., 2016; Habash and Hu, 2009).

Recently, Freitag and Firat (2020) re-kindle the flame by proposing C-MNMT, which trains the model on the constructed multi-way aligned corpus. Specifically, they extract the multi-way aligned examples by aligning training examples from different language pairs when either their source or target sides are identical (i.e., pivoting through English, for German→English and English→French to extract German-French-English examples). Since they directly extract the multi-way aligned examples from the bilingual corpus, we refer to their approach as the *extraction-based* approach. Despite improving the performance, the scale of multi-way aligned corpus extracted by Freitag and Firat (2020) is always limited compared to English-centric bilingual corpus, e.g., only 0.3M German-Russian-English multi-way aligned corpus extracted from 4.5M German-English and 33.5M English-Russian bilingual corpus. A simple idea for remedying this problem is to add the roughly-aligned corpus by extracting the training examples when either their source or target sides are highly similar. However, our preliminary experiments show that the performance of the model decreases dramatically when we train the model with appending the roughly-aligned corpus.[1] One possible solution, referred

[1] Detailed descriptions about the preliminary experiment

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 8141 - 8153
May 22-27, 2022

to as the *generation-based* approach, is to generate the multi-way aligned examples by distilling the knowledge of the existing NMT model, e.g., extracting German-English-French synthetic three-way aligned data by feeding the English-side sentences of German-English bilingual corpus into the English-French translation model. Although the *generation-based* approach can theoretically generate non-English corpus with the same size as original bilingual corpus, its generated corpus has very low diversity as the search space of the beam search used by NMT is too narrow to extract diverse translations (Wu et al., 2020; Sun et al., 2020; Shen et al., 2019), which severely limits the power of the *generation-based* approach.

In order to combine advantages of the two branches of approaches mentioned above, we propose a novel two-step approach, named EAG (Extract and Generate), to construct large-scale and high-quality multi-way aligned corpus for C-MNMT. Specifically, we first extract candidate aligned training examples from different language pairs when either their source or target sides are highly similar; and then we generate the final aligned examples from the pre-extracted candidates with a well-trained generation model. The motivation behind EAG is two-fold: 1) Although identical source or target sentences between bilingual examples from different language pairs are scarce, highly similar sentences in source or target side are more wide-spread; 2) Based on the pre-extracted candidate aligned examples which have highly similar source or target sentences, EAG can generate the final aligned examples by only refining the sentences partly with a few modifications. Therefore, the non-English corpus constructed by EAG has almost identical diversity to the original bilingual corpus. Experiments on the publicly available data sets, i.e., WMT-5 and OPUS-100, show that the proposed method achieves substantial improvements over strong baselines.

2 Background

Bilingual NMT Neural machine translation (Sutskever et al., 2014; Cho et al., 2014; Vaswani et al., 2017) achieves great success in recent years due to its end-to-end learning approach and large-scale bilingual corpus. Given a set of sentence pairs $D = \{(x, y) \in (X \times Y)\}$, the NMT model is trained to learn the parameter θ by maximizing the log-likelihood $\sum_{(x,y)\in D} logP(y|x;\theta)$.

MNMT Considering training a separate model for each language pair is resource consuming, MNMT (Dong et al., 2015; Johnson et al., 2017; Gu et al., 2020) is introduced to translate between multiple language pairs using a single model (Johnson et al., 2017; Ha et al.; Lakew et al., 2018). We mainly focus on the mainstream MNMT model proposed by Johnson et al. (2017), which only introduces an artificial token to the input sequence to indicate which target language to translate.

C-MNMT C-MNMT is proposed to build a complete translation graph for MNMT, which contains training examples for each language pair (Freitag and Firat, 2020). A challenging task remaining is how to get direct training data for non-English language pairs. In Freitag and Firat (2020), non-English training examples are constructed by pairing the non-English sides of two training examples with identical English sides. However, this method can't get large-scale training examples since the quantity of exactly identical English sentences from different language pairs is small. Another feasible solution is to generate training examples with pivot-based translation where the source sentence cascades through the pre-trained source → English and English → target systems to generate the target sentence (Cheng et al., 2016). Despite a large quantity of corpus it can generate, its generated corpus has very low diversity (Wu et al., 2020; Sun et al., 2020; Shen et al., 2019).

3 Methods

The proposed EAG has a two-step pipeline. The first step is to extract the candidate aligned examples from the English-centric bilingual corpus. The second step is to generate the final aligned examples from the candidates extracted in the first step.

3.1 Extract candidate aligned examples

Different from Freitag and Firat (2020) who extract non-English training examples by aligning the English-centric bilingual training examples with identical English sentences, we extract the candidate aligned examples by pairing two English-centric training examples with highly similar English sentences. Various metrics have been proposed to measure the superficial similarity of two sentences, such as TF-IDF (Aizawa, 2003; Huang et al., 2011), edit distance (Xiao et al., 2008; Deng

---

can be found in Section 5.1.

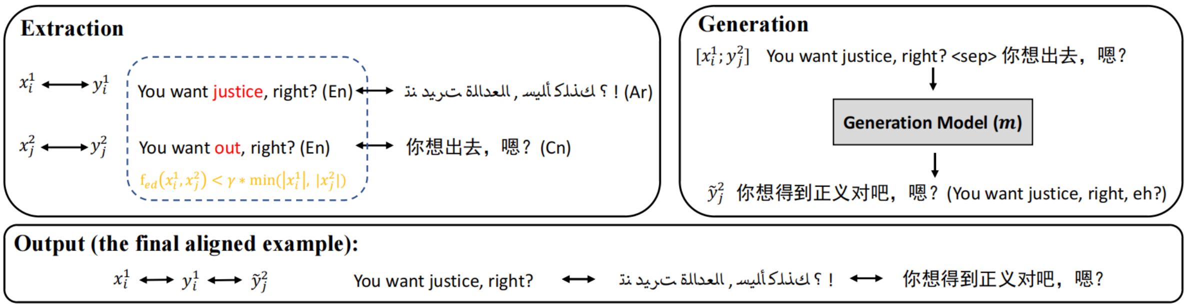

Figure 1: Examples constructed by EAG. "$x_i^1 \leftrightarrow y_i^1$" and "$x_j^2 \leftrightarrow y_j^2$" represent the bilingual examples in English → Arabic and English → Chinese respectively. $\tilde{y}_j^2$ is the generated Chinese sentence, which is aligned to x_i^1 and y_i^1. For a clear presentation, the Google translation (in English) for the generated $\tilde{y}_j^2$ is also provided.

et al., 2013), etc. In this paper, we take edit distance as the measurement to decide the superficial similarity of two English sentences. Three main considerations are behind. Firstly, since edit distance measures the similarity of two sentences with the minimum number of operations to transform one into the other, it tends to extract sentences with similar word compositions and sentence structures. Secondly, since edit distance only utilizes three operations, i.e., removal, insertion, or substitution, it is easier to mimic these operations in the process of generating the final aligned examples (we leave the explanation in the next subsection). Finally, unlike TF-IDF which only considers word bags in two sentences, edit distance also considers the word order in each sentence.

Formally, given two English-centric bilingual corpora from two different language pairs $\{X^1, Y^1\}$ and $\{X^2, Y^2\}$, where X^1 and X^2 are English sides, Y^1 and Y^2 belong to language L_a and L_b respectively. For sentence pair $(x_i^1, y_i^1) \in \{X^1, Y^1\}$ and $(x_j^2, y_j^2) \in \{X^2, Y^2\}$, we take $(x_i^1, y_i^1, x_j^2, y_j^2)$ as a candidate aligned example if the two English sentences x_i^1 and x_j^2 meets:

$$f_{ed}(x_i^1, x_j^2) \leq \gamma * min(|x_i^1|, |x_j^2|), \gamma \in (0, 1) \quad (1)$$

where f_{ed} refers to the function of edit distance calculation, $|x|$ represents the length of the sentence x, γ is the similarity threshold which can be set by users beforehand to control the similarity of sentences in the candidate aligned examples. With setting $\gamma = 0$, we can directly extract the same multi-way aligned examples with Freitag and Firat (2020). With larger γ, more candidate aligned examples can be extracted for looser restriction. Accordingly, there are more noises in the extracted candidate aligned examples.

3.2 Generate final aligned examples

In the extracted candidate aligned example $(x_i^1, y_i^1, x_j^2, y_j^2)$, (x_j^2, y_j^2) is not well aligned to (x_i^1, y_i^1) if $f_{ed}(x_i^1, x_j^2)$ does not equal to zero. To construct the final three-way aligned example, we search for one sentence pair $(\tilde{x}_j^2, \tilde{y}_j^2)$ in the language pair $\{X^2, Y^2\}$, where $\tilde{x}_j^2$ has the same meaning to x_i^1 (thus $(x_i^1, y_i^1, \tilde{y}_j^2)$ is a three-way aligned example). Unfortunately, it is very difficult for us to directly find such a sentence pair in the large search space. However, considering $\tilde{x}_j^2$ and x_i^1 are both in English, we can take an extreme case where $\tilde{x}_j^2$ is identical to x_i^1 in the superficial form. Now, the remained question is that we need to search for the sentence $\tilde{y}_j^2$ in language L_b, which has the same meaning to x_i^1. By comparing $(x_i^1, \tilde{y}_j^2)$ with (x_j^2, y_j^2), as x_i^1 can be transformed from x_j^2 with the operations performed by edit distance, it is naturally to suppose that we can find such a $\tilde{y}_j^2$ which can be transformed from y_j^2 with these operations similarly. Therefore, we can limit the search space for $\tilde{y}_j^2$ with two restrictions: Firstly, sentence $\tilde{y}_j^2$ has the same meaning with x_i^1; Secondly, $\tilde{y}_j^2$ is transformed from y_j^2 with the operations performed by edit distance. Considering the restrictions mentioned above, we apply an NMT model m to search and generate $\tilde{y}_j^2$. There are two main questions left to be resolved: how to train such a model m and how to generate $\tilde{y}_j^2$ with a well-trained m.

Training Motivated by the recent success of self-supervised training (Devlin et al., 2018; Conneau and Lample, 2019; Song et al., 2019; Yang et al., 2020) in natural language processing, we automatically construct the training corpus for m from the candidate aligned examples. Given the candidate aligned example $(x_i^1, y_i^1, x_j^2, y_j^2)$, the training example for m is built as:

$$([x_j^2; \hat{y}_j^2], y_j^2) \tag{2}$$

where y_j^2 is the target sentence, the concatenation of x_j^2 and $\hat{y}_j^2$ is the source-side input. $\hat{y}_j^2$ is the noisy form of y_j^2 which we build by mimicking the operations of edit distance, i.e, performing insertion, removal, or substitution on some pieces of y_j^2 randomly. Specifically, with probability β, each position of sentence y_j^2 can be noised by either removed directly, inserted or substituted with any other words in the dictionary W_b, which is constructed from the corpus Y^2. With the self-constructed training examples, the model m is trained to generate the target sentence, which is recovered from the right-side of the concatenated input with the operations performed by edit distance, and has the same meaning to the left-side of the input.

Generating With a well-trained m, we generate the final aligned examples by running the inference step of m. Formally, for the final aligned example $(x_i^1, y_i^1, \tilde{y}_j^2)$, the sentence $\tilde{y}_j^2$ is calculated by:

$$\tilde{y}_j^2 = m([x_i^1; y_j^2]) \tag{3}$$

where $[\cdot;\cdot]$ represents the operation of concatenation, and $m(x)$ refers to running the inference step of m with x fed as input. With this generation process, $\tilde{y}_j^2$ is not only has the same meaning to x_i^1 (thus also aligned to y_i^1), but also keeps the word composition and sentence structure similar to y_j^2. Therefore, EAG can construct the final aligned corpus for each non-English language pair, and keep the diversity of the constructed corpus almost identical to the original English-centric corpus. For a clear presentation, Algorithm 1 in Appendix A.2 summarizes the process of generating the final aligned examples. We also provide a toy example in Figure 1 to illustrate how the proposed EAG works.

4 Experiments and Results

For fair comparison, we evaluate our methods on the publicly available dataset WMT-5, which is used by Freitag and Firat (2020). Additionally, we test the scalability of our method by further conducting experiments on Opus-100, which contains English-centric bilingual data from 100 language pairs (Zhang et al., 2020). In the extraction process, we run our extraction code on the CPU with 24 cores and 200G memory.[2] In the generation process, we take transformer-big (Vaswani et al., 2017) as the configuration for m, and m is trained with the self-constructed examples mentioned in Section 3.2 on eight V100 GPU cards.[3]

We choose Transformer as the basic structure for our model and conduct experiments on two standard configurations, i.e, transformer-base and transformer-big. All models are implemented based on the open-source toolkit fairseq (Ott et al., 2019) and trained on the machine with eight V100 GPU cards.[4] All bilingual models are trained for 300,000 steps and multi-lingual models are trained for 500,000 steps. We add a language token at the beginning of the input sentence to specify the required target language for all of the multi-lingual models. For the hyper-parameters β and γ, we set them as 0.5 and 0.3 by default and also investigate how their values produce effects on the translation performance.

4.1 Experiments on WMT-5

4.1.1 Datasets and pre-processing

Following Freitag and Firat (2020), we take WMT13EnEs, WMT14EnDe, WMT15EnFr, WMT18EnCs and WMT18EnRu as the training data, the multi-way test set released by WMT2013 evaluation campaign (Bojar et al., 2014) as the test set. The size of each bilingual training corpus (the non-English corpus constructed by Freitag and Firat (2020) included) is presented in Table 1. For the bilingual translation task, the source and target languages are jointly tokenized into 32,000 sub-word units with BPE (Sennrich et al., 2016). The multi-lingual models use a vocabulary of 64,000 sub-word units tokenized from the combination of all the training corpus. Similar to Freitag and Firat (2020), we use a temperature-based data sampling strategy to over-sample low-resource language pairs in standard MNMT models and low-resource target-languages in C-MNMT models (temperature $T = 5$ for both cases). We use BLEU scores (Papineni et al., 2002) to measure the model performance and all BLEU scores are calculated with sacreBLEU (Post, 2018).[5]

Table 2: WMT: Available training data (in million) after constructing non-English examples by EAG.

4.1.2 Corpus constructed by EAG

Table 2 shows the training data after constructing non-English examples from English-centric corpus by the proposed EAG. By comparing Table 2 with Table 1, we can find that EAG can construct much more multi-way aligned non-English training examples than Freitag and Firat (2020), e.g., EAG constructs 1.4M bilingual training corpus for the language pair German → Russian which is almost up to 4 times more than the corpus extracted by Freitag and Firat (2020). In all, EAG constructs no less than 1M bilingual training examples for each non-English language pair.

4.1.3 Baselines

In order to properly and thoughtfully evaluate the proposed method, we take the following five kinds of baseline systems for comparison:

Bilingual systems (Vaswani et al., 2017) Apart from training bilingual baseline models on the original English-centric WMT data, we also train bilingual models for non-English language pairs on the direct bilingual examples extracted by Freitag and Firat (2020).

Standard MNMT systems (Johnson et al., 2017) We train a standard multi-lingual NMT model on the original English-centric WMT data.

Bridging (pivoting) systems (Cheng et al., 2016) In the bridging or pivoting system, the source sentence cascades through the pre-trained source → English and English → target systems to generate the target sentence.

Extraction-based C-MNMT systems (Freitag and Firat, 2020) Freitag and Firat (2020) construct the multi-way aligned examples by directly extracting and pairing bilingual examples from different language pairs with identical English sentences.

Generation-based C-MNMT systems The generation-based C-MNMT baselines construct non-English bilingual examples by distilling the knowledge of the system which cascades the source → English and English → target models. Different from the bridging baselines which just feed the test examples into the cascaded system and then measure the performance on the test examples, the generation-based C-MNMT baselines feed the non-English sides of the bilingual training examples into the cascaded systems and then get the non-English bilingual training examples by pairing the inputs and outputs. The combination of the generated non-English corpus and original English-centric corpus is used to train the C-MNMT model.

4.1.4 Results

We first report the results of our implementations and then present the comparisons with previous works. In our implementations, we take the transformer-base as the basic model structure since it takes less time and computing resources for training. To make a fair comparison with previous works, we conduct experiments on transformer-big which is used by baseline models.

Results of our implementation Table 3 shows the results of our implemented systems. Apart from the average performance of the translation directions from each language to others, we also report the average performance on the English-centric and non-English language pairs.[6] As shown in Table 3, we can find that the proposed EAG achieves better performance than all of the baseline systems. Compared to the extraction-based C-MNMT, the proposed method achieves an improvement up to 1.1 BLEU points on non-English language pairs.

---

[6] Readers can find the detailed results for each language pair in the Appendix A.3.

System	En-X	De-X	Fr-X	Ru-X	Es-X	Cs-X	English-centric	non-English
bilingual system (Vaswani et al., 2017)	28.8	22.4	24.6	19.6	25.9	21.1	30.3	20.4
MNMT system (Johnson et al., 2017)	28.6	16	15.4	14.2	15.0	20.3	30.0	12.3
pivot system (Cheng et al., 2016)	28.8	25.7	26.1	25.2	27.4	26.4	30.3	24.7
generation-based C-MNMT	28.8	26.2	26.7	26.0	27.5	26.8	30.3	25.3
extraction-based C-MNMT (Freitag and Firat, 2020)	29.3	27.2	27.3	26.7	28.6	28.2	30.6	26.8
EAG	**29.6***	**28.3***	**28.2***	**27.7***	**29.5***	**29.7***	**30.8**	**27.9***

Table 3: The translation performance for different systems on WMT data. 'L-X' means the set of translation directions from language L to other five languages. 'English-centric' and 'non-English' refer to the set for English-centirc and non-English language pairs respectively. For each set, bold indicates the highest value, and $*$ means the gains are statistically significant with $p < 0.05$ compared with extraction-based C-MNMT.

The generation-based C-MNMT performs worse than the extraction-based one even if it generates much larger corpus. Since there is no any training example for non-English language pairs in standard MNMT, the standard MNMT system achieves inferior performance to the pivot and bilingual systems on non-English translation directions. However, with the constructed non-English training examples, EAG achieves 3.2 and 7.5 BLEU points improvements compared with the pivot and bilingual systems respectively.

Table 4: Results for transformer-big trained on corpus constructed by EAG. The small numbers are the difference with respect to Freitag and Firat (2020).

Results compared with previous works Table 4 shows the results of the proposed EAG. We can find that the proposed EAG surpasses Freitag and Firat (2020) almost on all of the translation directions, and achieves an improvement with up to 2.4 BLEU points on the Russian-to-German direction.

4.2 Experiments on Opus-100

Datasets and pre-processing Zhang et al. (2020) first create the corpus of Opus-100 by sampling from the OPUS collection (Tiedemann, 2012). Opus-100 is an English-centric dataset which contains 100 languages on both sides and up to 1M training pairs for each language pair. To evaluate the performance of non-English language pairs, Zhang et al. (2020) sample 2000 sentence pairs of test data for each of the 15 pairings of Arabic, Chinese, Dutch, French, German, and Russian. Following Zhang et al. (2020), we report the sacreBLEU on the average of the 15 non-English language pairs.[7] The statistics about the non-English corpus constructed by Freitag and Firat (2020) and EAG are presented in Table 5. We can find that EAG is able to construct much more bilingual corpus for non-English language pairs (almost nine times more than Freitag and Firat (2020) for each language pair). We use a vocabulary of 64,000 sub-word units for all of the multi-lingual models, which is tokenized from the combination of all the training corpus with SentencePiece.

	Freitag and Firat (2020)	EAG
Ar-X	0.19	1.12
De-X	0.14	1.01
Fr-X	0.15	1.25
Cn-X	0.16	1.03
Ru-X	0.18	0.94
Nl-X	0.18	0.98

Table 5: The amount of non-English examples (in million) constructed from bilingual examples in OPUS-100. "L-X" means the total number of the corpus for the directions from language L to other five.

Results Apart from the baselines mentioned above, we also compare with other two systems proposed by Zhang et al. (2020) and Fan et al. (2020). Zhang et al. (2020) propose the online

EAG	17.9*

Table 6: Results on Opus-100. We directly cite their results for Zhang et al. (2020) and Fan et al. (2020). $*$ means the gains of EAG are significant compared with extraction-based C-MNMT ($p < 0.05$)

back-translation for improving the performance of non-English language pairs in Opus-100. Fan et al. (2020) build a C-MNMT model, named $m2m_{100}$, which is trained on 7.5B training examples built in house. Following Zhang et al. (2020), we take the transformer-base as the basic model structure for the experiments and results are reported in Table 6. We can find that EAG achieves comparable performance to Fan et al. (2020) which utilizes much more data than ours. This is not a fair comparison as the data used Fan et al. (2020) is 75 times as much as ours. Additionally, our model surpasses all other baseline systems and achieves +1.4 BLEU points improvement compared with the extraction-based C-MNMT model.

5 Analysis

We analyze the proposed method on Opus-100 and take the transformer-base as the model structure.

5.1 Effects of the hyper-parameters

The similarity threshold γ and the noise ratio β are important hyper-parameters in EAG. In this section, we want to test how these two hyper-parameters affect the final translation performance and how they work with each other. We investigate this problem by studying the translation performance with different γ and β, where we vary γ and β from 0 to 0.7 with the interval 0.2. We report the average BLEU score for the translation directions from Arabic to other five languages on the development sets built in house. Figure 2 shows the experimental results. With $\beta = 0$, it means that the generation process is not applied and we directly train the NMT model with the extracted roughly aligned examples. And this is the setting of our motivated experiments mentioned in Section 1. We can find that, the final performance drops sharply when we directly train the model with the roughly aligned sentence pairs. For each curve in Figure 2, we can find that the model achieves the best performance when the γ is around β, and then the performance decreases with γ growing. A relatively unexpected result is that the model usually achieves the best performance when $\beta = 0.5$ rather than when $\beta = 0.7$ (with a larger β, m is trained to handle more complex noise). We conjecture the main reason is that the noise in the training data when $\beta = 0.7$ is beyond the capacity of m, which makes m converge poorly during training. Overall, with β set as 0.5 and γ set as 0.3, the model achieves the best performance.

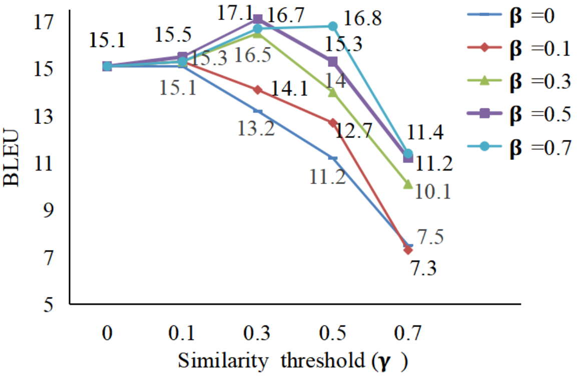

Figure 2: Experimental results on testing the hyper-parameters. With γ set as 0, this is the setting of the baseline system of Freitag and Firat (2020).

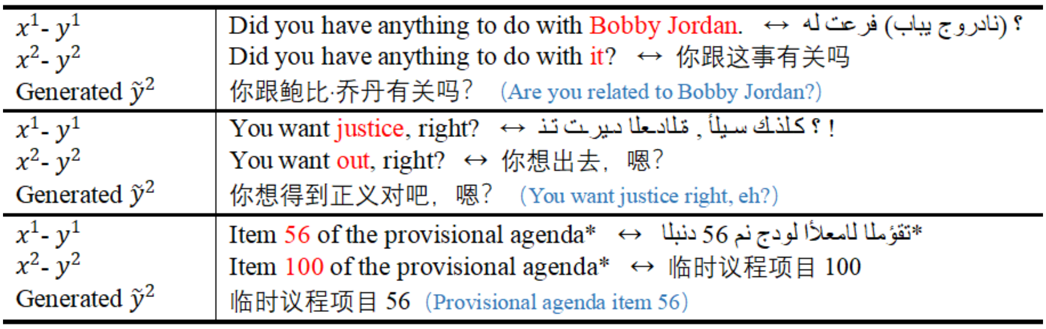
#	system	BLEU
0	**EAG**	**17.9**
1	w/o m	15.7
2	w/ m as Transformer-big	18.1
3	w/ m as Transformer-deep	17.8

Table 7: Results on the ability of m.

5.2 The ability of m

We test how the ability of m affects the final performance. Apart from the Transformer-base, i.e., the default setting used in EAG, we also test other two settings, namely Transformer-big (Vaswani et al., 2017) and Transformer-deep (20 encoder layers and 4 decoder layers). With different settings, m is expected to perform different abilities in the generation process. The experimental results are presented in Table 7. We can find that if we remove m, the final performance drops dramatically (comparing #0 with #1). This shows that the generation step



x^1- y^1	Did you have anything to do with Bobby Jordan. ↔ ؟ (نادروج يباب) فرعت له
x^2- y^2	Did you have anything to do with it? ↔ 你跟这事有关吗
Generated $\tilde{y}^2$	你跟鲍比·乔丹有关吗？ (Are you related to Bobby Jordan?)
x^1- y^1	You want justice, right? ↔ ! ؟ كلذك سيلأ , قلادعلا ديرت تن
x^2- y^2	You want out, right? ↔ 你想出去，嗯？
Generated $\tilde{y}^2$	你想得到正义对吧，嗯？ (You want justice right, eh?)
x^1- y^1	Item 56 of the provisional agenda* ↔ *تقؤملا لامعلأا لودج نم 56 دنبلا
x^2- y^2	Item 100 of the provisional agenda* ↔ 临时议程项目 100
Generated $\tilde{y}^2$	临时议程项目 56 (Provisional agenda item 56)

Figure 3: Examples constructed by EAG. "x^1-y^1" and "x^2-y^2" represent the bilingual examples in English → Arabic and English → Chinese respectively. $\tilde{y}^2$ is the generated Chinese sentence. The words in red color are the different word compositions between x^1 and x^2. The Google translations (in English) for $\tilde{y}^2$ are also provided.

plays a significant role in the proposed EAG. However, by comparing among #0, #2 and #3, we can find that the ability for m shows little effect on the final performance. Taking all of #0, #1, #2 and #3 into consideration, we can reach a conclusion that, the generation step is very important for EAG and a simple generation model, i.e., a baseline NMT model, is enough to achieve strong performance.

System	w/o BT	w/ BT
extraction-based C-MNMT	16.5	17.6
EAG	**17.9**	**18.8**

Table 8: Results on back-translation. We report the average BLEU score on the non-English language pairs.

5.3 Back-translation

We are very curious about how EAG works with back-translation (BT). To investigate this problem, we utilize the extraction-based C-MNMT model to decode the non-English monolingual sentences in the candidate aligned examples extracted by EAG, and then get the synthetic non-English sentence pairs by pairing the decoded results with the original sentences. The reversed sentence pairs are appended into the training corpus for the MNMT models. The experimental results are presented in Table 8. We find that BT improves the performances of both the two systems. Additionally, BT can work as a complementary to the proposed EAG.

5.4 Case study and weaknesses

Figure 3 presents some examples constructed by EAG, each of which includes the extracted candidate aligned example and the generated sentence for Arabic → Chinese. The extracted candidate aligned example contains two bilingual examples, which are extracted from Arabic → English and Chinese → English respectively. In Figure 3, the two bilingual examples in case one are extracted as a candidate aligned example as their English sentences have high similarity. And there is a composition gap between x^1 and x^2 since "Bobby Jordan" is mentioned in x^1, but not in x^2. By comparing the generated Chinese sentence $\tilde{y}^2$ with the original sentence y^2, we can find that $\tilde{y}^2$ is modified from y^2 by inserting the Chinese words " 鲍比乔丹", which has the same meaning with "Bobby Jordan". Therefore, the generated $\tilde{y}^2$ is aligned to x^1 and y^1. In case 2, the Chinese word "出去 (out)" in y^2 has been replaced with Chinese words "得到正义 (justice)" in $\tilde{y}^2$, which makes the $\tilde{y}^2$ aligned to x^1 and y^1. Case 3 in Figure 3 behaves similarly.

While achieving promising performance, the proposed approach still has some weaknesses in the real application: 1) The two-step pipeline performed by EAG is somewhat time-consuming compared to Freitag and Firat (2020); 2) The generated multi-way aligned examples by EAG are sometimes not strictly aligned as the generation process does not always perform perfectly.

6 Conclusion and Future work

In this paper, we propose a two-step approach, i.e., EAG, to construct large-scale and high-quality multi-way aligned corpus from English-centric bilingual data. To verify the effectiveness of the proposed method, we conduct extensive experiments on two publicly available corpora, WMT-5 and Opus-100. Experimental results show that the proposed method achieves substantial improvements over strong baselines consistently. There are three promising directions for the future work. Firstly, we plan to test whether EAG is applicable to the domain adaptation problem in NMT. Secondly, we are interested in applying EAG to other related tasks which need to align different example pairs. Finally, we want to investigate other model structures for the generation process.

A Appendix

A.1 Structure and training process for m

We take transformer-big as the configuration for m. The word embedding dimension, head number, and dropout rate are set as 1024, 16, and 0.3 respectively. The model is trained on 8 V100 GPU cards, with learning rate, max-token, and update-freq set as 0.01, 8192, and 10 respectively.

We train m on the self-constructed examples with early-stopping. For the original example (x^2, y^2), we feed m with the input format "x^2 <sep> $\tilde{y}^2$", where $\tilde{y}^2$ is the noised form of y^2, "<sep>" is a special token utilized to denote the sentence boundary. Similar to the traditional NMNT model, m is trained to predict the original target sentence y^2.

A.2 Algorithm for our approach

The algorithm for the proposed EAG is detailed as A.2.

A.3 Concrete BLEU score for each language pair

In this section, we present the concrete BLEU score for each language pair on the corpus of WMT-5. Table 9, 10, 11, 12, and 13 show the translation performance for the bilingual system, standard MNMT system, pivot system, extraction-based system and the EAG respectively.

Algorithm 1 Generating final aligned corpus: Given the aligned candidates $\{x^1, y^1, x^2, y^2\}$; an NMT model m, noisy probability β, word list W_b; return the final aligned corpus $\{y^1, \tilde{y}^2\}$

```
procedure NOISING($y_i^2$, $\beta$, $W_b$)
    $\hat{y}_i^2 \leftarrow y_i^2$
    for $t \in 0, \ldots, |\hat{y}_i^2| - 1$ do
        generate random float $\alpha \in (0, 1)$
        if $\alpha < \beta$ then
            perform insertion, removal or substitution on the position $t$ of $\hat{y}_i^2$ based on $W_b$
    return $\hat{y}_i$
procedure TRAINING($x^2$, $y^2$)
    initialize $m$ randomly
    while not convergence do
        for $i \in 1, \ldots, |x^2|$ do
            $\hat{y}_i^2 \leftarrow$ NOISING($y_i^2, \beta$)
            train $m$ with the example $([x_i^2; \hat{y}_i^2], y_i^2)$
    return $m$
procedure GENERATING($x^1$, $x^2$, $y^1$, $y^2$, $m$)
    for $i \in 1, \ldots, |x^1|$ do
        get $\tilde{y}_i^2$ by performing the inference step of the well-trained $m$ with input $[x_i^1; y_i^2]$
        get the final aligned example by pairing $y_i^1$ with $\tilde{y}_i^2$
    return $\{y^1, \tilde{y}^2\}$
```

Abstract

Although contextualized embeddings generated from large-scale pre-trained models perform well in many tasks, traditional static embeddings (e.g., Skip-gram, Word2Vec) still play an important role in low-resource and lightweight settings due to their low computational cost, ease of deployment, and stability. In this paper, we aim to improve word embeddings by 1) incorporating more contextual information from existing pre-trained models into the Skip-gram framework, which we call *Context-to-Vec*; 2) proposing a post-processing retrofitting method for static embeddings independent of training by employing priori synonym knowledge and weighted vector distribution. Through extrinsic and intrinsic tasks, our methods are well proven to outperform the baselines by a large margin.

1 Introduction

Contextualized embeddings such as BERT (Devlin et al., 2018) and RoBERTa (Liu et al., 2019) have become the default architectures for most downstream NLP tasks. However, they are computationally expensive, resource-demanding, hence environmentally unfriendly. Compared with contextualized embeddings, static embeddings like Skip-gram (Mikolov et al., 2013) and GloVe (Pennington et al., 2014) are lighter and less computationally expensive. Furthermore, they can even perform without significant performance loss for context-independent tasks like lexical-semantic tasks (e.g., word analogy), or some tasks with plentiful labeled data and simple language (Arora et al., 2020).

Recent work has attempted to enhance static word embedding while maintaining the benefits of both contextualized embedding and static embedding. Among these efforts, one category is the direct conversion of contextualized embeddings to static embeddings (Bommasani et al., 2020). The other category of enhancement is to make use of contextualized embeddings for static embeddings (Melamud et al., 2016). The latter category is a newer paradigm, which we call *Context-to-Vec*. This paradigm not only alleviates the word sense ambiguities from static embedding, but also fuses more syntactic and semantic information in the context within a fixed window.

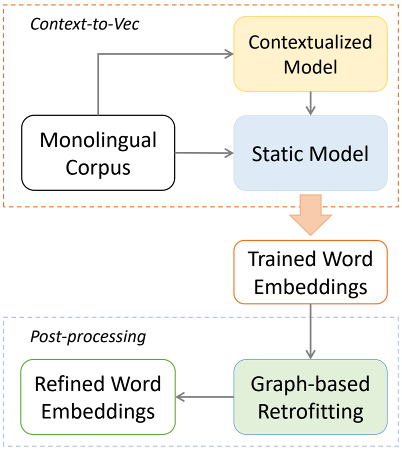

Figure 1: The overall training pipeline of our proposed word embeddings training and post-processing methods. In the Context-to-Vec phase, static word embeddings are trained using contextualized embeddings based on a monolingual corpus. While in the post-processing phase, external knowledge is introduced to fine-tune the word vectors based on the graph topology.

For the *Context-to-Vec* paradigm, an association between contextualized word vectors and static word vectors is essentially required. In this case, the contextualized signal serves as a source of information enhancement for the static embeddings (Vashishth et al., 2018). However, the existing efforts only consider the contextualized embeddings of center words as the source, which is actually incomplete since the contextualized features for the context words of the center words are ignored.

In addition, benefiting from the invariance and stability of already trained static embeddings, post-processing for retrofitting word vectors is also an effective paradigm for improving static embeddings. For example, one solution is an unsupervised approach that performs a singular value decomposition to reassign feature weights (Artetxe et al., 2018), but this does not utilize more external knowledge and lacks interpretation. Poor initial spatial distribution of word embeddings obtained from training may lead to worse results. Another common solution is to use a synonym lexicon (Faruqui et al., 2014), which exploits external prior knowledge with more interpretability but does not take into account the extent of spatial distance in the context.

In this work, we unify the two paradigms above within a model to enhance static embeddings. On the one hand, we follow the *Context-to-Vec* paradigm in using contextualized representations of center words and their context words as references for static embeddings. On the other hand, we propose a graph-based semi-supervised post-processing method by using a synonym lexicon as prior knowledge, which can leverage proximal word clustering signals and incorporate distribution probabilities. The overall training pipeline is shown in Fig.1. The pipeline is divided into two separate phases, where the first phase follows the *Context-to-Vec* paradigm by distilling contextualized information into static embeddings, while the second phase fine-tunes the word embeddings based on graph topology. To validate our proposed methods, we evaluate several intrinsic and extrinsic tasks on public benchmarks. The experimental results demonstrate that our models significantly outperform traditional word embeddings and other distilled word vectors in word similarity, word analogy, and word concept categorization tasks. Besides, our models moderately outperform baselines in all downstream clustering tasks.

To our knowledge, we are the first to train static word vectors by using more contextual knowledge in both training and post-processing phases. The code and trained embeddings are made available at `https://github.com/binbinjiang/Context2Vector`.

2 Related Work

Word Embeddings. For traditional static word embeddings, Skip-gram and CBOW are two models based on distributed word-context pairs (Mikolov et al., 2013). The former uses center words to predict contextual words, while the latter uses contextual words to predict central words. GloVe is a log-bilinear regression model which leverages global co-occurrence statistics of corpus (Pennington et al., 2014); FASTTEXT takes into account subword information by incorporating character n-grams into the Skip-gram model (Bojanowski et al., 2017). While contextualized word embeddings (Peters et al., 2018; Devlin et al., 2018) have been widely used in modern NLP. These embeddings are actually generated using language models such as LSTM and Transformer (Vaswani et al., 2017) instead of a lookup table. This paradigm can generally integrate useful sentential information into word representations.

Context-to-Vec. The fusion of contextualized and static embeddings is a newly emerged paradigm in recent years. For instance, Vashishth et al. (2018) propose SynGCN using GCN to calculate context word embeddings based on syntax structures; Bommasani et al. (2020) introduce a static version of BERT embeddings to represent static embeddings; Wang et al. (2021) enhance the Skip-gram model by distilling contextual information from BERT. Our work also follows this paradigm but introduce more context constraints.

Post-processing Embeddings. Post-processing has been used for improving trained word embeddings. Typically, Faruqui et al. (2014) use synonym lexicons to constrain the semantic range; Artetxe et al. (2018) propose a method based on eigenvalue singular decomposition. Similar to these techniques, our post-processing method is easy for deployment and can be applied to any static embeddings. The difference is that we not only take advantage of the additional knowledge, but also consider the distance weights of the word vectors, overcoming the limitations of existing methods with better interpretability.

3 Proposed Methods

3.1 Embedding Representations

As shown in Fig.2, our proposed framework consists of four basic components. Formally, given a sentence $s = \{w_1, w_2, ..., w_n\} (w_i \in D)$, our objective is to model the relationship between the center word w_i and its context words $\{w_{i-w_s}, ..., w_{i-1}, w_{i+1}, ..., w_{i+w_s}\}$.

Contextualized Embedding Module. To incor-

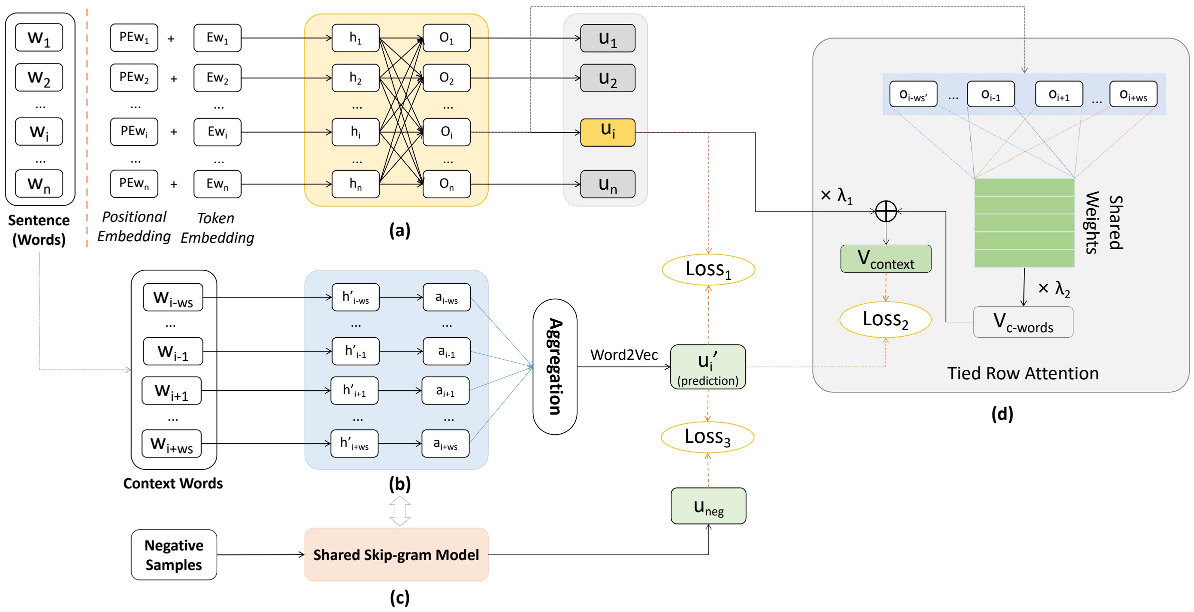

Figure 2: Main framework of our model. (a) **Contextual Embedding Module** generally consists of a pre-trained language model (BERT-like models) that provides the main enhancement information for static embeddings; (b) **Static Embedding Module** is the core component for training word embeddings from scratch and obtaining distilled contextualized information; (c) **Negative Sample Module** collects negative samples randomly and constructs contrast loss to improve the robustness and generalization; (d) **Tied Contextualized Attention Module** is to capture the contextualized embeddings for the context words as supplementary information.

porate contextualized information, an embedding u_i of the center word w_i needs to be generated from a pre-trained language model (Fig.2(a)). Taking the BERT model as an example, the center word w_i is first transformed into a latent vector h_i, then h_i is fed to a bidirectional Transformer for self-attention interaction. Finally, the output representation $o_i \in R^d$ is linearly mapped to $u_i \in R^{d_{emb}}$ through a linear layer as:

$$u_i = W_o \text{Linear}(\text{SA}(h_i)) = W_o o_i, \qquad (1)$$

where $W_o \in R^{d_{emb} \times d}$ denotes model parameters, $\text{Linear}(*)$ denotes a linear mapping layer, and $\text{SA}(*)$ denotes self-attention. In practice, the size of o_i is $d = 768$, and the size of u_i is $d_{emb} = 300$. The h_i here is a sum of the *Token Embedding* E_{w_i} and the *Positional Embedding* PE_{w_i} as:

$$h_i = E_{w_i} + PE_{w_i}. \qquad (2)$$

Static Embedding Module. The Skip-gram model (Fig.2(b)) is used as the static embedding module. Our method does not directly fit the Skip-gram model by replacing an embedding table, although the original Skip-gram uses an embedding table of center words as the final embedding. Instead, to make the context words predictable and to enable negative sampling from the vocabulary, contextualized representations are used for the center words, while an embedding table of the context words is used for the output static embedding.

3.2 Heuristic Semantic Equivalence

As mentioned above, a key issue for the *Context-to-Vec* paradigm is to bridge the gap between contextualized and static word vectors. To this end, a main intuition is to find key equivalent semantic connections between contextualized vectors and static vectors. We take the following heuristics:

Heuristic 1: *For a given sentence, the contextualized embedding representation of a center word can be semantically equivalent to the static embedding of the center word in the same context.*

According to **Heuristic 1**, in order to model the center word w_i and its context words w_{i+j} (note here that the illegal data that indexes less than 0 or greater than the maximum length are ignored), a primary training target is to maximize the probability of the context words $w_{i+j}(|j| \in [1, w_s])$ in the Skip-gram model:

$$p(w_{i+j}|w_i) = \frac{\exp({u'_{i+j}}^T u_i)}{\sum_{w_k \in D} \exp({u'_k}^T u_i)}, \qquad (3)$$

where u_i is the contextualized representation of the center word, and ${u'}_k$ is the static embedding from a center word w_k that is generated by a static embedding table with size $d' = 300$.

For **Heuristic 1**, the contextualized word embedding of any center word is essentially used as reference for corresponding static word embedding. Such a source for information enhancement implicitly contains the context of the contextualized embedding, but explicitly ignores the contextual information which is easily accessible. Hence, the proposed:

Heuristic 2: *Inspired by the idea of Skip-gram-like modeling, the contextualized embedding representation for the context words of a center word can be also semantically equivalent to represent the static embedding of the center word.*

To model this semantic relationship, we introduce a **Tied Contextualized Attention** module (Fig.2(d)) for explicitly attending contextual signals, which complements **Heuristic 1** by incorporating more linguistic knowledge into the static embedding. In particular, assume that the center word w_i in the contextualized embedding module corresponds to the contextual vocabulary notated as $\{w_{i-w'_s}, ..., w_{i-1}, w_{i+1}..., w_{i+w'_s}\}$, then the output contextual attention vector can be computed as:

$$\begin{aligned} V_{context} &= \lambda_1 V_{center} + \lambda_2 V_{c-words} \\ &= \lambda_1 o_i^T W_1 + \lambda_2 \tau(U_{1\leq|k|\leq i+w'_s} \phi(o_k^T W_2)) \\ &= \lambda_1 o_i^T W_1 + \lambda_2 \frac{\phi(\sum_{1\leq|k|\leq i+w'_s} o_k^T)}{2w'_s} W_2, \end{aligned} \tag{4}$$

where V_{center} denotes the embedding representation of the center word, which is a residual connection here. And $V_{c-words}$ denotes the embedding representations of corresponding context words. ϕ is an optional nonlinear function, $U(*)$ is a merge operation, and τ is an average pooling operation. $W_1 \in R^{d\times d_{emb}}$ and $W_2 \in R^{d\times d_{emb}}$ are trainable parameters, in which W_2 denotes the weight assignment of each context vector.

Since each o_k has similar linguistic properties, the weight W_2 can be shared, and we name this module **Tied Contextualized Attention** mechanism. Therefore, the weighted average of the linear transformation of all context vectors can be reduced to the weighted linear output of the average of all vectors as shown in Eq.4. This weight-sharing mechanism can help speed up calculations.

In practice, to reduce the complexity, the weight parameter λ_1 and λ_2 are the same; the u_i in Eq.1 can be directly used as $V_{context}$; the value of w'_s is the same as that of w_s, e.g., 5.

3.3 Training Objectives

The modular design requires our model to satisfy multiple loss constraints simultaneously, allowing static embeddings to introduce as much contextual information as possible. Given a training corpus with N sentences $s_c = \{w_1, w_2, ..., w_{n_c}\} (c \in [1, N])$, our loss functions can be described as follows.

Semantic Loss. As illustrated in **Heuristic 1**, one of our key objectives is to learn the semantic similarity between the contextualized embedding and the static embedding of the center word. To speed up computation, the inner product of the normalized vectors can be used as the loss L_1:

$$L_1 = -\sum_{c=1}^{N}\sum_{i=1}^{n_c}(\log\sigma((\sum_{1\leq|j|\leq w_s} {u'}_{i+j})^T u_i)], \tag{5}$$

where σ is the sigmoid function.

Contextualized Loss. As described in **Heuristic 2**, the contextualized embeddings for the context words of the center word are explicitly introduced to further enhance the static embedding, thus the Contextualized Loss L_2 is expressed as:

$$L_2 = -\sum_{c=1}^{N}\sum_{i=1}^{n_c}(\log\sigma(V_{context}^T u_i)). \tag{6}$$

Contrastive Negative Loss. Negative noisy samples (Fig.2(c)) can improve the robustness and effectively avoid the computational bottleneck. This trick is common in NLP. Our Contrastive Negative Loss L_3 is calculated as:

$$L_3 = \sum_{c=1}^{N}\sum_{i=1}^{n_c}\sum_{m=1}^{k} E_{w_{neg_m}\ P(w)}[\log\sigma({u'}_{neg_m}^T u_i)], \tag{7}$$

where w_{neg_m} denotes a negative sample, k is the number of negative samples and $P(w)$is a noise distribution set.

Joint Loss. The final training objective is a joint loss L for multi-tasks as:

$$L = \eta_1 L_1 + \eta_2 L_2 + \eta_3 L_3, \tag{8}$$

where each hyperparameter η_i denotes a weight.

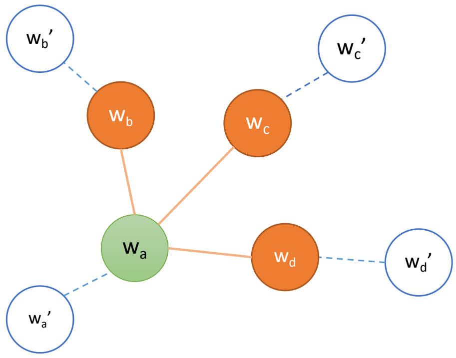

Figure 3: A word graph diagram with edges between related words. The dashed edges indicate the corresponding edge relationships between observed word vectors (white nodes) and inferred word vectors (colored nodes). And the solid edges indicate the relationship between the word (green node) to be refined and its corresponding synonyms (orange nodes).

3.4 Graph-based Post-retrofitting

In the post-processing stage, we propose a new semi-supervised retrofitting method for static word embeddings based on graph topology (Xia et al., 2022; Wu et al., 2021, 2020). This method overcomes the limitations of previously existing work by 1) using a synonym lexicon as priori external knowledge. Since both contextualized embeddings and static embeddings are trained in a self-supervised manner, the word features originate only from within the sequence and no external knowledge is considered; 2) converting the Euclidean distances among words into a probability distribution (McInnes et al., 2018), which is based on the special attributes that the trained static word vectors are mapped in a latent Euclidean space and remain fixed.

Word Graph Representation. Suppose that $V = \{w_1, ..., w_n\}$ is a vocabulary (i.e., a collection of word types). We represent the semantic relations among words in V as an undirected graph (V, E), with each word type as a vertex and edges $(w_i, w_j) \in E$ as the semantic relations of interest. These relations may vary for different semantic lexicons. Matrix Q' represents the set of trained word vectors for $q'_i \in R^{Dim}$, in which q'_i corresponds to the word vector of each word w_i in V.

Our objective is to learn a set of refined word vectors, denoted as matrix $Q = (q_1, ..., q_n)$, with the columns made close to both their counterparts in Q' and the adjacent vertices according to the probability distribution. A word graph with such edge connectivity is shown in Fig.3, which can be interpreted as a Markov random field (Li, 1994).

Retrofitting Objective. To refine all word vectors close to the observed value q'_i and its neighbors q_j $((i, j) \in E)$, the objective is to minimize:

$$\begin{aligned}\Psi(Q) = \sum_{i=1}^{n} (\alpha_i \| q_i - {q'}_i \|^2 \\ + \beta_i \sum_{(i,j) \in E} \gamma_{ij} \| q_i - q_j \|^2),\end{aligned} \tag{9}$$

where α_i, β_i, and γ_{ij} control the relative strengths of associations, respectively. Since Ψ is convex in Q, we can use an efficient iterative update algorithm. The vectors in Q are initialized to be equal to the vectors in Q'. Assuming that w_i has m adjacent edges corresponding to m synonyms, then we take the first-order derivative of Ψ with respect to a q_i vector and equate it to zero, yielding the following online update:

$$q_i = \alpha_i {q'}_i + \beta_i \frac{\sum_{j:(i,j) \in E} \gamma_{ij} q_j}{m}. \tag{10}$$

By default, α_i and β_i take the same value 0.5, and γ_{ij} can be expressed as:

$$\gamma_{ij} = g(d_{ij} | \sigma, \nu) = C_\nu (1 + \frac{d_{ij}^2}{\sigma \nu})^{-(\nu+1)} \in (0, 1], \tag{11}$$

in which σ is a scale parameter, ν is a positive real parameter, and C_ν is the normalization factor of ν as (the following $\Gamma(*)$ denotes the gamma function):

$$C_\nu = 2\pi (\frac{\Gamma(\frac{\nu+1}{2})}{\sqrt{\nu\pi}\,\Gamma(\frac{\nu}{2})})^2, \tag{12}$$

and d_{ij} calculates the sum of Euclidean distances of the feature vectors across all dimensions Dim as:

$$d_{ij} = \sqrt{\sum_{k=0}^{Dim} (q_{i_k} - q_{j_k})^2}. \tag{13}$$

Through the above process, the distance distribution is first converted into a probability distribution, and then the original word graph is represented as a weighted graph. This retrofitting method is modular and can be applied to any static embeddings.

4 Experiments

We use Wikipedia to train static embeddings. The cleaned corpus has about 57 million sentences and 1.1 billion words. The total number of vocabularies is 150k. Sentences between 10 and 40 in length were selected during training.

4.1 Evaluation Benchmarks

We conduct both intrinsic and extrinsic evaluations.

Intrinsic Tasks. We conduct **word similarity** tasks on the WordSim-353 (Finkelstein et al., 2001), SimLex-999 (Kiela et al., 2015), Rare Word (RW) (Luong et al., 2013), MEN-3K (Bruni et al., 2012), and RG-65 (Rubenstein and Goodenough, 1965) datasets, computing the Spearman's rank correlation between the word similarity and human judgments. For **word analogy** task, we compare the analogy prediction accuracy on the Google (Mikolov et al., 2013) dataset. The Spearman's rank correlation between relation similarity and human judgments is compared on the SemEval-2012 (Jurgens et al., 2012) dataset. **Word concept categorization** tasks involves grouping nominal concepts into natural categories. We evaluate on AP (Almuhareb, 2006), Battig (Baroni and Lenci, 2010) and ESSLI (Baroni et al., 2008) datasets. Cluster purity is used as the evaluation metric.

Extrinsic Tasks. The CONLL-2000 shared task (Sang and Buchholz, 2000) is used for **chunking** tasks and F1-score is used as the evaluation metric; OntoNotes 4.0 (Weischedel et al., 2011) is used for **NER** tasks and F1-score is used as the evaluation metric; And the WSJ portion of Penn Treebank (Marcus et al., 1993) is used for **POS tagging** tasks, and token-level accuracy is used as the evaluation metric. These tasks are reimplemented with the open tool NCRF++ (Yang and Zhang, 2018).

4.2 Baselines

As shown in Table 1, baselines are classified into three categories. For the first category (*Static*), static embeddings come from a lookup table. Note here that *Skip-gram(context)* denotes the results from the context word embeddings. For the second category (*Contextualized*), static embeddings come from contextualized word embedding models (i.e., BERT, ELMo, GPT2, and XLNet) for lexical semantics tasks. The models with *_token* use the mean pooled subword token embeddings as static embeddings; The models with *_word* take every single word as a sentence and output its word representation as a static embedding; The models with *_avg* take the average of output over training corpus. For the last category (*Context-to-Vec*), contextualized information is integrated into Skip-gram embeddings. Among these models, ContextLSTM (Melamud et al., 2016) learns the context embeddings by using single-layer bi-LSTM; SynGCN (Vashishth et al., 2018) uses GCN to calculate context word embeddings based on syntax structures; BERT+Skip-gram (Wang et al., 2021) enhances the Skip-gram model by adding context syntactic information from BERT, which is our primary baseline.

Models	AP	Batting	ESSLI(N)	ESSLI(V)	Avg
Skip-gram	63.4	42.8	75.0	62.2	60.8
Skip-gram(context)	57.4	41.6	72.5	66.6	59.5
CBOW	63.2	43.3	75.0	64.4	61.4
Glove	58.0	41.3	72.5	60.0	58.0
FASTTEXT	63.4	44.4	75.0	62.2	61.2
Deps	61.8	41.7	77.5	68.8	62.4
BERT$_{avg}$	55.7	34.7	70.0	64.0	56.1
SynGCN	63.4	42.8	82.5	62.2	62.7
BERT+Skip-gram	64.1	43.8	77.5	66.6	63.0
Ours(preliminary)	65.7	44.0	85.0	70.4	66.3

Table 3: Results on extrinsic tasks. The best results are bolded, and the second-best underlined.

4.3 Quantitative Comparison

Word Similarity and Analogy. Table 1 shows the experimental results of intrinsic tasks. Overall, the models that integrate contextualized information into static embeddings (*Context-to-Vec*) perform better than other types (*Contextualized / Satic*). Our results outperform baselines across the board. To be fair, the backbone of our model here is BERT as that in the main baseline (*BERT+Skip-gram*) (Wang et al., 2021).

Within the *Context-to-Vec* category, our models perform best on all word similarity datasets. Our base model without post-processing obtains an average absolute improvement of about +23.8%(+13.2) and related improvement of +4.4%(+2.9) compared with the main baseline. The performance is further enhanced using post-processing with a +25.6%(+14.2) absolute increase, and a +5.8%(+3.8) relative increase compared with the main baseline, and a +1.4%(+1.0) relative increase compared with our base model (w/o post-processing). It is worth mentioning that the main baseline does not perform better than BERT$_{avg}$ in *Contextualized* group on the RG65 dataset, but our model does make up for their regrets, which indicates that our model is better at understanding contextual correlates of synonymy.

For the word analogy task, our performances are basically equal to the baselines. Overall, we gain the best score (+0.5) on the Google dataset but without a significant improvement. Although we do not gain the best score across all baselines on the SemEval dataset, our model performs better than the main baseline.

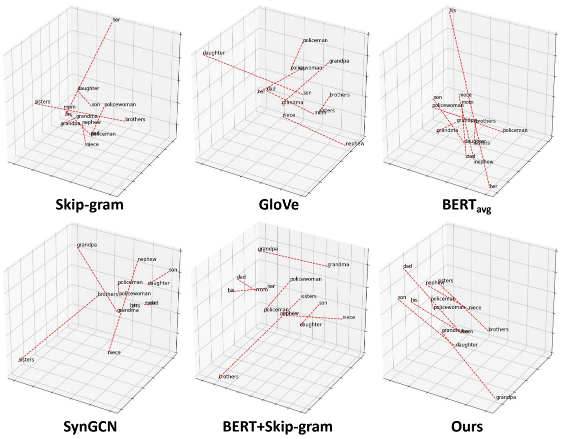

Figure 4: Visualization on word pairs of gender relationship.

For different datasets, especially in word similarity tasks, the improvement of our preliminary model on WS353, SimiLex, RG65 (+4.1, +5.5, and +5.7, respectively) is significantly better than other datasets. For example, the improvement of the main baseline on the WS353R (relatedness) subset and the WS353 set is far greater than that on the WS353S (similarity) subset. While our model bridges their gaps in the WS353 set and also ensures that the performance of WS353S and WS353R is further improved slightly.

Word Concept Categorization. Word concept categorization is another important intrinsic evaluation metric. We use 4 commonly used datasets as shown in Table 2. Overall, our model without post-processing outperforms the baselines by a large margin, giving the best performance and obtaining an average performance gain of +5.2%(+5.1) compared to the main baseline. In particular, the largest increases are observed on the ESSLI(N) (+7.5), ESSLI(V) (+3.8). And with post-processing, our model can obtain better improvements (+3.3 vs. +5.1). The experimental results show the advantage of integrating contextualized and word co-occurrence information, which can excel in grouping nominal concepts into natural categories.

Extrinsic Tasks. Extrinsic tasks reflect the effectiveness of embedded information through downstream tasks. We conduct extrinsic evaluation from chunking, NER, and POS tagging tasks as shown in

Methods	WS353	WS353S	WS353R	SimiLex	RW	MEN	RG65	Avg
w/o retrofitting	76.9	76.7	68.3	54.9	43.5	76.8	84.3	68.8
+Faruqui et al. (2014)	77.2	76.1	69.8	55.0	43.8	76.2	83.5	68.8
+Artetxe et al. (2018)	78.3	75.3	70.0	49.4	42.7	77.4	84.6	68.2

Table 4: Comparison on post-processing schemes.

Models	Nearest neighbors of *light*	Nearest neighbors of *while*
Skip-gram	uv, bioluminescence, fluorescent, glare, sunlight, illumination	whilst, recuperating, pursuing, preparing, attenmpting, fending
CBOW	stevenson, initimadation, earle, yellowing, row, kizer	whilst, when, still, although, and, but
GloVe	excluding, justify, orestes, generation, energy, frieze	both, taking, ',' , up, but, after
FASTTEXT	sculpts, baha'i, kinghorn, lick, inputs, minimize	whilst, still, and, meanwhile, instead, though
SynGCN	search, prostejov, preceding, forearms, freewheel, naxos	whilst, time, when, years, months, tenures
BERT+SkipGram	lights, dark, lighter, illumination, glow, illuminating	whilst, whereas, although, conversely, though, meanwhile
Ours	lumière, lumiere, licht, illumination, luminous, lights	whilst, whereas, although, though, despite, albeit

Table 5: Nearest neighbors of words "*light*" and "*while*".

Table 3. We select comparison representatives from the *Static* group, the *Contextualized* group, and the *Context-to-Vec* group, respectively. Although the improvement is not significant compared with the intrinsic evaluations, it can be seen that our performances are better than the baselines, which can prove the superiority of our model. The primary baseline *BERT+Skip-gram* obtains the second-best average score, but does not excel in the chunking task. In contrast, our model not only outperforms all baselines moderately on average, but also performs best in every individual task.

4.4 Ablation and Analysis

Post-processing Schemes. From Table 1, we can initially find that the post-processing method has a positive impact. To further quantitatively analyze, we compare more related methods as shown in Table 4. In this ablation experiment, the comparison baseline is our trained original word vectors (w/o retrofitting), and the other comparison methods include the singularity decomposition-based method (Artetxe et al., 2018), and the synonym-based constraint method (Faruqui et al., 2014). From the results, we can see that other post-processing schemes can improve the word vectors to some extent, but do not perform better in all datasets. However, our proposed post-processing scheme performs the best across the board here, which shows that converting the distance distribution into a probability distribution is more effective.

Nearest Neighbors. To further understand the results, we show the nearest neighbors of the words "*light*" and "*while*" based on the cosine similarity, as shown in Table 5. For the noun "*light*", other methods generate more noisy and irrelevant words, especially static embeddings. In contrast, the *Context-to-Vec* approaches (Ours & BERT+Skip-gram) can capture the key meaning and generate cleaner results, which are semantically directly related to "*light*" literally. For the word "*while*", the static approaches tend to co-occur with the word "*while*", while *Context-to-Vec* approaches return conjunctions with more similar meaning to "*while*", such as "*whilst*", "*whereas*" and "*although*", which demonstrates the advantage of using contextualization to resolve lexical ambiguity.

Word Pairs Visualization. Fig.4 shows the 3D visualization of the gender-related word pairs based on t-SNE (Van der Maaten and Hinton, 2008). These word pairs differ only by gender, e.g., "*nephew* vs. *niece*" and "*policeman* vs. *policewoman*". From the topology of the visualized vectors, the spatial connectivity of the word pairs in Skip-gram and GloVe is rather inconsistent, which means that static word vectors are less capable of capturing gender analogies. In contrast, for vectors based on contextualized embeddings, such as BERT_{avg}, SynGCN, BERT+Skip-gram, and our model, the outputs are more consistent. In particular, our outputs are highly consistent in these instances, which illustrates the ability of our model to capture relational analogies better than baselines and the importance of contextualized information based on semantic knowledge.

5 Conclusion

We considered improving word embeddings by integrating more contextual information from existing pre-trained models into the Skip-gram framework. In addition, based on inherent properties of static embeddings, we proposed a graph-based post-retrofitting method by employing priori synonym knowledge and a weighted distribution probability.

The experimental results show the superiority of our proposed methods, which gives the best results on a range of intrinsic and extrinsic tasks compared to baselines. In future work, we will consider prior knowledge directly during training to avoid a multi-stage process.

Abstract

Sarcasm is important to sentiment analysis on social media. Sarcasm Target Identification (STI) deserves further study to understand sarcasm in depth. However, text lacking context or missing sarcasm target makes target identification very difficult. In this paper, we introduce multimodality to STI and present Multimodal Sarcasm Target Identification (MSTI) task. We propose a novel multi-scale cross-modality model that can simultaneously perform textual target labeling and visual target detection. In the model, we extract multi-scale visual features to enrich spatial information for different sized visual sarcasm targets. We design a set of convolution networks to unify multi-scale visual features with textual features for cross-modal attention learning, and correspondingly a set of transposed convolution networks to restore multi-scale visual information. The results show that visual clues can improve the performance of TSTI by a large margin, and VSTI achieves good accuracy.

1 Introduction

Sarcasm is a type of sentiment in which people express their negative feelings using positive or intensified positive words. It has the power to disguise the hostility of the speaker (Dews and Winner, 1995), thereby enhancing the effect of mockery or humor on the listener. Sarcasm is prevalent on today's social media platforms such as Twitter, and automatic Sarcasm Target Identification (STI) bears great significance in customer service, opinion mining, and online harassment detection. Previous works about STI have focused on text modality and proposed some methods such as rule-based, statistical classifier-based (Joshi et al., 2018), and deep learning models with socio-linguistic features (Patro et al., 2019).

[ST This guy] definitely deserves $15 an hour!

(a)

bombay dyeing just found an accessory for their 6×6 bedsheets collection

(b)

Figure 1: Two examples of MSTI. (a) "This guy" and the blue bounding box denote textual and visual STs, respectively; (b) No textual ST and the blue bounding box denotes visual ST.

However, detecting a sarcasm target with only text modality is not sufficient and complete. For example, in Figure 1(a), we are not sure whether the context conveys positive or negative emotions if we only see the text "This guy definitely deserves $15 an hour!". However, the negative information comes from the image. When observing a lazy guy in the picture lying on the chair, we can easily determine that the lazy guy is a sarcasm target and label the text "This guy" as a sarcasm target (ST). Moreover, the sarcasm target sometimes does not appear explicitly in the text, which is marked as '*OUTSIDE*'. In ALTA Shared Task (Molla and Joshi, 2019), '*OUTSIDE*' cases account for over 30% of the data. For example, in the tweet of Figure 1(b), the author teased that the skirt was too long, similar to a bed sheet; therefore, the sarcasm target should be the long skirt. However, no sarcasm target appears in the text but we can label the long skirt as an ST with a blue bounding box in the picture. The above examples illustrate the necessity of combining images for STI.

In this paper, we introduce a novel task called Multimodal Sarcasm Target Identification (MSTI) on social media data. The MSTI task is to extract sarcasm targets (STs) from both texts and images

in tweets. The textual ST is a word or a phrase, and the visual ST is an object labeled by a bounding box, as shown in Figure 1. The challenge of the MSTI task is not only to extract both textual and visual features but also to leverage cross-modality interaction and semantic learning to improve the performance of STI. The contributions of this paper can be summarized as follows:

- To the best of our knowledge, this is the first attempt to perform the MSTI task. We build an MSTI dataset and propose a novel cross-modality MSTI framework. Textual and multi-scale visual features are fused in a cross-modality encoder via convolution and transposed convolution. Our model performs textual and visual tasks simultaneously in an end-to-end manner, and it can leverage textual and visual contexts to enhance textual and visual representations for MSTI.

- We design a cross-modality attention visualization method in terms of text-to-image and image-to-text to illustrate the mutual effects between textual and visual modalities. These results show the image regions and words extracted through cross-modality attention are the keys to sarcasm and explain the improved performance of TSTI and VSTI by cross-modality learning.

- The comprehensive experimental results are presented. The results indicate that the images in tweets improve the performance of TSTI by a large margin. Comparisons with textual, object detection, and pretrained multimodal baselines show the advanced performance of our model.

2 Related Work

The existing research on sarcasm analysis mainly focuses on sarcasm detection (SD) and sarcasm target identification (STI). We begin the literature review with textual sarcasm.

Textual Sarcasm Detection. Traditional sarcasm detection is defined as a binary classification of sarcastic or non-sarcastic sentiments in text (Guo et al., 2021). Earlier approaches (Joshi et al., 2017) were based on sarcastic pattern rules (Riloff et al., 2013) or statistical models such as SVM (Joshi et al., 2015) or logistic regression (Bamman and Smith, 2015). Recently, deep learning techniques have gained popularity. Word embeddings and LSTM/CNN model were employed in Joshi et al. (2016); Zhang et al. (2016). Furthermore, Peled and Reichart (2017) presented a neural machine translation framework and Tay et al. (2018) proposed an attention-based neural model to interpret and reason with sarcasm. Xiong et al. (2019) proposed a self-matching network to capture incongruity information by exploring word-to-word interactions. Agrawal et al. (2020) formulated sarcasm detection as a sequence classification problem by leveraging the natural shifts in various emotions over the course of a piece of text. Babanejad et al. (2020) extended the architecture of BERT by incorporating both affective and contextual feature embeddings. Guo et al. (2021) proposed a latent-optimized adversarial neural transfer model for cross-domain sarcasm detection.

Textual Sarcasm Target Identification. To deepen the field of sarcasm analysis, STI has been well studied recently (Patro et al., 2019; Parameswaran et al., 2021). The goal of STI is to label the subject of mockery or ridicule within sarcastic texts. Patro et al. (2019) showed that the Exact Match (EM) accuracy on tweets is approximately 30%.

Joshi et al. (2018) introduced the STI problem and summarized the 2019 ALTA shared task regarding STI (Molla and Joshi, 2019). The evaluation metrics such as EM accuracy and F1 score were presented. Patro et al. (2019) presented a deep learning framework augmented with socio-linguistic features to detect sarcasm targets. Parameswaran et al. (2019) employed an ensemble of classifiers such as SVM, logistic and linear classifiers to classify '*OUTSIDE*' and '*NOT OUTSIDE*', then used a rule-based approach to extract the target sarcasm words from the '*NOT OUTSIDE*' samples.

Multimodal Sarcasm Detection. Benefiting from images, multimodal sarcasm detection (MSD) has gained increasing research attention. Schifanella et al. (2016) first tackled this task as a multimodal classification problem. They concatenated the visual and textual features and employed SVM or a neural network consisting of fully connected and softmax layers, to detect sarcasm. Cai et al. (2019) extended the input modalities to a triplet of text, image, and image attributes, and they proposed a hierarchical fusion model for sarcasm detection. Castro et al. (2019) proposed a video-level multimodal sarcasm detection task. Features were ob-

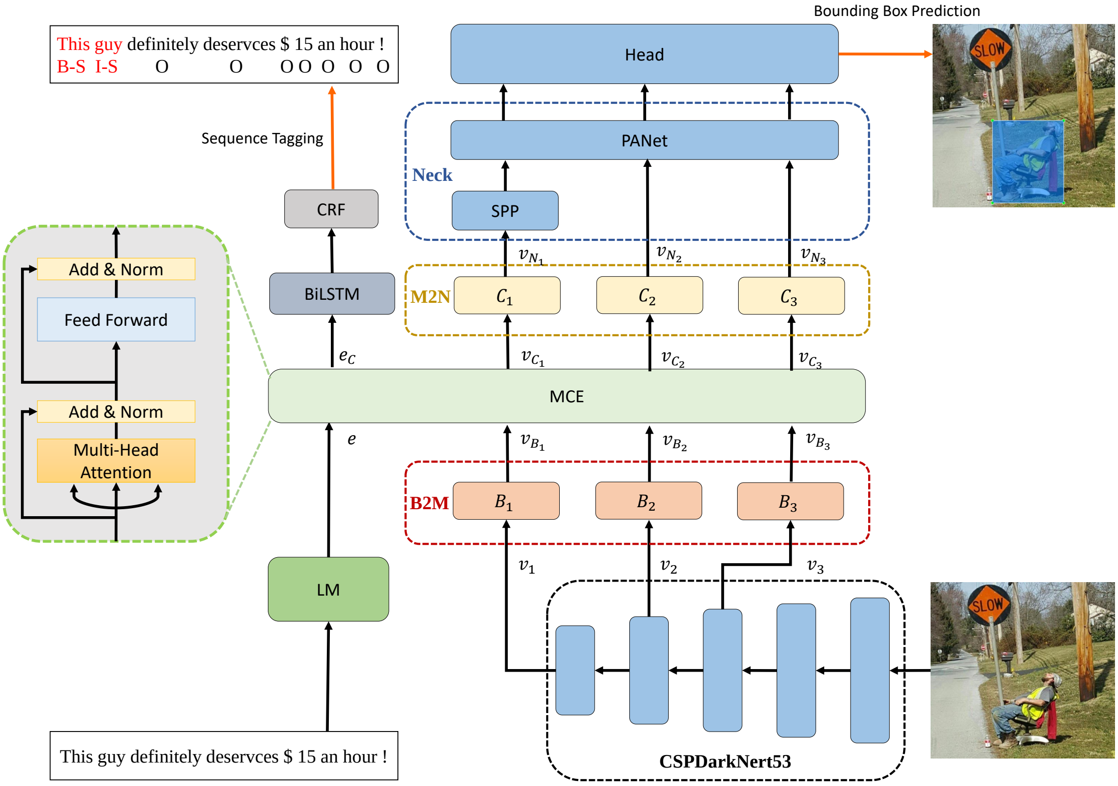

Figure 2: Our MSTI architecture overview.

tained from three modalities, i.e., text, speech, and video, and an SVM classifier with RBF kernel was employed. Sangwan et al. (2020) presented an RNN-based model and gating mechanism, which attempted to decide the weight of image modality regarding textual modality. Pan et al. (2020) proposed a BERT-based model that concentrated on both intra- and inter-modality incongruity for multimodal sarcasm detection. Xu et al. (2020) constructed the decomposition network to model the discrepancy between image and text and the relation network to model the semantic association in cross-modality context.

3 The Proposed Approach

In this section, we introduce a novel neural architecture for MSTI, as shown in Figure 2.

3.1 Neural Architecture

Figure 2 illustrates the overall architecture of our MSTI model. The model mainly consists of five components: (1) Backbone to MCE converter (B2M), (2) Multi-scale Cross-modality Encoder (MCE), (3) MCE to Neck network converter (M2N), (4) Textual Sarcasm Target Identification (TSTI), and (5) Visual Sarcasm Target Identification (VSTI). We first extract textual and visual features separately. The multi-scale visual features of the last three blocks of the pretrained backbone network are unified to the same dimension by B2M and input to the MCE together with textual features. The MCE outputs cross-modality representations, where the parts corresponding to textual features are fed into BiLSTM-CRF to label the sequence for TSTI and the parts corresponding to multi-scale visual features restored by M2N are connected to the neck and head networks to predict bounding boxes for VSTI.

3.2 Textual and Visual Representations

Textual Representation: We obtain contextual word embeddings from pretrained language models (LM) such as BERT (Devlin et al., 2019) to extract linguistic features. Let $S = ([\texttt{CLS}], t_1, ..., t_n, [\texttt{SEP}])$ be the token sequence and $e = (e_1, ..., e_n)$ be the contextual word embeddings generated by a pretrained LM, where $e_i \in \mathbb{R}^d$. As shown in Figure 2, the contextual word embeddings e represent the textual input of the next module MCE.

Visual Representation: We extract visual features from an image with pretrained backbone networks such as ResNet (He et al., 2016), VGG (Simonyan and Zisserman, 2014), and CSPDarkNet (Wang et al., 2020). To improve the detection performance of sarcasm targets with various sizes, our model performs VSTI using multi-scale visual features. The multi-scale outputs at the last three blocks of the backbone are denoted as v_1, v_2, and v_3, shown in Figure 2, for the later use of the Neck network. The dimensions of v_1, v_2, and v_3 are $d_{s_1} \times d_{s_1} \times d_1$, $d_{s_2} \times d_{s_2} \times d_2$, and $d_{s_3} \times d_{s_3} \times d_3$, respectively, where $d_{s_i} \times d_{s_i}$ represents image scale and d_i represents feature map, $i = \{1, 2, 3\}$.

3.3 B2M Converter

The B2M converter aims to unify the dimensions of three visual features with the dimension d of textual feature and lower the scales of three visual features to reduce the computation of the MCE. The B2M has three parts B_1, B_2, and B_3 corresponding to the visual features v_1, v_2, and v_3. Each part consists of convolutional layers followed by Rectified Linear Unit (ReLU) and max pooling layer.

Table 1 shows the architecture of B2M. The input dimensions of B_1, B_2, and B_3 are $19 \times 19 \times 1024$, $38 \times 38 \times 512$, and $76 \times 76 \times 256$, respectively, when the backbone is set to CSPDarkNet53 (Bochkovskiy et al., 2020). We denote the outputs of B_1, B_2, and B_3 as v_{B_1}, v_{B_2}, and v_{B_3}, respectively. According to the computation of the convolutional layer, the output scale is $\lfloor \frac{I+2P-K}{S} \rfloor + 1$, where I is the dimension of input scale, P is padding, S is stride, and K is kernel. The Conv generates feature maps of d, which is the same as the dimension of the word embeddings. Then, we can obtain all v_{B_1}, v_{B_2}, and v_{B_3} with size $5 \times 5 \times d$. Finally, we flatten the shape size 5×5 to 25 visual tokens $\{v_{B_i}^{p,q}\}$ $(1 \leq p, q \leq 5)$ to generate the visual inputs of the MCE.

3.4 Multi-scale Cross-modality Encoder

The MCE is based on the Transformer encoder architecture presented in Vaswani et al. (2017) and shown in the left of Figure 2. The Transformer encoder has a multi-head self-attention sub-layer and a fully connected feed-forward sub-layer. A residual connection and layer normalization are employed around two sub-layers. The Transformer encoder adopts scaled dot-product attention, which is defined as follows:

$$Attention(Q, K, V) = softmax(\frac{QK^T}{\sqrt{d_k}})V, \tag{1}$$

where matrices Q, K, and V consist of queries, keys, and values, respectively, and d_k is the dimension of keys. In our model, we concatenate the textual and visual features into a sequence G,

$$G = (\underbrace{e_1, ..., e_n}_{n}, \underbrace{v_{B_1}^{1,1}, \ldots, v_{B_1}^{5,5}}_{25=5\times5}, \underbrace{v_{B_2}^{1,1}, ..., v_{B_2}^{5,5}}_{25=5\times5}, \underbrace{v_{B_3}^{1,1}, ..., v_{B_3}^{5,5}}_{25=5\times5}). \tag{2}$$

We feed G into the MCE, and therefore $Q = K = V = G^\top$.

The outputs of the MCE are divided into two parts: the corresponding textual part e_C is used for TSTI, and the corresponding multi-scale visual parts v_{C_1}, v_{C_2}, and v_{C_3} are used for VSTI.

B2M	B_1	Conv	$[K = 3 \times 3, P = 1, S = 2]$
		MaxPooling	$[2 \times 2]$
	B_2	Conv	$\begin{bmatrix} K = 3 \times 3, P = 1, S = 2 \\ K = 3 \times 3, P = 1, S = 2 \end{bmatrix}$
		MaxPooling	$[2 \times 2]$
	B_3	Conv	$\begin{bmatrix} K = 5 \times 5, P = 2, S = 4 \\ K = 3 \times 3, P = 1, S = 2 \end{bmatrix}$
		MaxPooling	$[2 \times 2]$
M2N	C_1	UpSampling	$[2 \times 2]$
		ConvT	$[K = 3 \times 3, P = 1, S = 2]$
	C_2	UpSampling	$[2 \times 2]$
		ConvT	$\begin{bmatrix} K = 3 \times 3, P = 1, S = 2 \\ K = 3 \times 3, P = 1, S = 2 \end{bmatrix}$
	C_3	UpSampling	$[2 \times 2]$
		ConvT	$\begin{bmatrix} K = 3 \times 3, P = 1, S = 2 \\ K = 5 \times 5, P = 2, S = 4 \end{bmatrix}$

Table 1: Architecture of B2M and M2N converters.

3.5 M2N Converter

The M2N converter is an inverse procedure of the B2M converter. The dimensions of the output v_{N_i} of the M2N converter are the same as those of the input v_i of the B2M converter, where $i = \{1, 2, 3\}$. The M2N converter has three parts C_1, C_2, and C_3, corresponding to B_1, B_2, and B_3 of the B2M converter, respectively. The architecture of M2N is shown in Table 1. Each part consists of transposed convolution (ConvT) (Dumoulin and Visin, 2016) followed by ReLU and upsampling layer. The ConvT is considered as the reverse operation of convolution. If the ConvT's kernel size, padding size, and stride are the same as those carried out on the Conv layer, then the ConvT generates the same spatial dimension as that of the Conv's input. Upsampling reverses the pooling operation by the nearest-neighbor interpolation algorithm.

3.6 Textual Sarcasm Target Identification

We use the BIO (short for Beginning, Inside, and Outside) schema (Ramshaw and Marcus, 1995) to label textual sarcasm targets. The ‘B-ST’ tag indicates the beginning of an ST and the ‘I-ST’ tag indicates the inside of an ST. The ‘O’ tag indicates that a token does not belong to any ST.

We employ a classical sequence tagging model, i.e., BiLSTM-CRF (Huang et al., 2015), to label the textual STs. The bidirectional LSTM (BiLSTM) first processes each sentence token-by-token and produces forward and backward hidden vectors for each token. Then the concatenation of the two hidden vectors is input to a Conditional Random Fields (CRFs) layer (Lafferty et al., 2001). For a sequence of tags $y = \{y_1, \ldots, y_n\}$, the probability of the label sequence y is defined as follows:

$$p(y|x) = \frac{e^{s(x,y)}}{\sum_{y' \in Y} e^{s(x,y')}}, \tag{3}$$

where Y is all possible tag sequences for the sentence x and $s(x, y)$ are feature functions modeling transitions and emissions. The computation details can be found in Lample et al. (2016). The objective of labeling ST is to minimize the negative log-likelihood over the training data $\mathcal{D}_t = \{(x^{(i)}, y^{(i)})\}_{i=1}^{M}$:

$$\mathcal{L}_{TSTI} = -\sum_{i=1}^{M} log(p(y^{(i)}|x^{(i)})). \tag{4}$$

3.7 Visual Sarcasm Target Identification

There are two kinds of object detectors, one-stage and two-stage. One-stage object detector such as YOLO (Redmon et al., 2016) is faster and simpler. In this paper, we adopt YOLOv4’s Neck and Head networks (Bochkovskiy et al., 2020) to perform VSTI. The multi-scale cross-modality features v_{N_1}, v_{N_2}, and v_{N_3} are connected to the Neck network, which consists of Spatial Pyramid Pooling (SPP) (He et al., 2015) and Path Aggregation Network (PANet) (Liu et al., 2018). The Neck network is to increase the receptive field and preserve spatial information. The Head network is used for predicting bounding boxes at 3 different scales. The output tensor of the Head network of YOLOv4 is $d_{s_i} \times d_{s_i} \times [3 * (4 + 1 + C)]$ at each scale, predicting 3 boxes per grid cell where each box has 4 bounding offsets (t_x, t_y, t_w, t_h), 1 objectness score, and C class scores. The detailed computation of bounding offsets can be found in Redmon and Farhadi (2018). Each grid cell predicts the object probability and C class probabilities. In our model, since there is 1 sarcasm object class, we ablate C class scores.

Donald Trump has been asked to make a ‘dummy’ State visit to Britain this year to show he can avoid embarrassing the Queen.

this is the your <user> well done usa.

(c)

Figure 3: Examples of the MSTI dataset. (a) STs are both in text and image, (b) ST is only in text, and (c) ST is only in image. The green bounding box indicates a visual ST.

The objective function of VSTI consists of bounding box regression loss $\mathcal{L}_b$ and objectness score loss $\mathcal{L}_o$:

$$\mathcal{L}_{VSTI} = \mathcal{L}_b + \mathcal{L}_o. \tag{5}$$

As in YOLO, $\mathcal{L}_b$ is based on the bounding box priors that are assigned to ground truth objects and computed by mean squared error (MSE). $\mathcal{L}_o$ is computed by binary cross-entropy (BCE) for classifying the bounding box priors as object or non-object.

Finally, combining the TSTI and VSTI tasks, the objective function for MSTI is as follows:

$$\mathcal{L}_{MSTI} = \mathcal{L}_{TSTI} + \mathcal{L}_{VSTI}. \tag{6}$$

4 Experiments

4.1 Dataset

In this paper, we build an MSTI dataset for public research[1]. We label textual and visual STs on the dataset collected by Cai et al. (2019) for multimodal sarcasm detection. Each sample is manually annotated by three persons based on their common sense. The agreement between the annotators is measured using a percentage of overlapping choices between the annotators, i.e., above one word overlapping for text phrases and above 50% intersection-over-union (IoU) overlapping for image regions. We ensure the quality of ground truth by keeping the consistency of all annotator’s

Table 4: Number (percentage) of different sized visual STs.

opinions. The samples with annotations that the three annotators agree on are put into the dataset otherwise removed, making the annotations valid. Figure 3 shows three examples.

The statistics of the MSTI dataset are shown in Table 2. The MSTI dataset is split into 3,546/727/742 as Train/Dev/Test in experiments. The number of textual and visual sarcasm targets are also listed. Table 3 shows the proportion of multimodal sarcasm target types, i.e., STs appear both in the text and image, ST only appears in the text, and ST only appears in the image. Table 4 shows the number and percentage of different sized visual STs. We categorize the size of ST as small (area occupation<1.5%), medium (1.5%<area occupation<10%), and large (area occupation>10%).

4.2 Settings

We use CSPDarkNet53 as backbone and BERT-Base (d=768) or BERT-Large (d=1024) as LM. All images are shaped to a size of 608 × 608. In the VSTI, we use the default settings of YOLOv4, e.g., IoU threshold and object confidence threshold. The weights of neural network are randomly initialized except the pretrained BERT, backbone and Neck networks. We train the model using the Adam (Kingma and Ba, 2014) optimizer with default settings and the learning rate is set to 1e-4. All pretrained models are finetuned with a learning rate of 1e-5. The mini-batch size is set to 8 and dropout rate is 0.5. We use two-layer BiLSTM with 768 hidden states and Transformer encoder with 12 heads.

We use Exact Match (EM) accuracy (Joshi et al., 2018) and F1 score (Molla and Joshi, 2019) as evaluation metrics for TSTI. The EM accuracy is computed as the number of samples that strictly match the boundaries of gold annotations divided by the total number of samples. The F1 score = 2/(1/P+1/R) is calculated from precision P = TP/(TP+FP) and recall R = TP/(TP+FN), where TP is correctly predicted target word, FP is incorrectly predicted target word, and FN is target word but not predicted. Average Precision (AP) is widely used to evaluate object detection (Lin et al., 2014). The COCO-style AP, AP_{50}, and AP_{75} are evaluated for VSTI. The COCO-style AP averages AP at IoU=[0.5:0.05:0.95]. AP_{50} corresponds to AP at IoU=0.5 and AP_{75} corresponds to AP at IoU=0.75. IoU measures the amount of overlap between two bounding boxes and here is used as a criterion that determines if a prediction matches ground truth.

We train the model on one machine with an NVIDIA RTX 3090 (GPU) and Intel Core i9 10900K (CPU). Our model takes approximately 10 hours for 60 epochs in training.

4.3 Baselines

Our model is compared with text baselines such as rule-based & statistical extractors, socio-linguistic features, and BERT, object detection baselines such as Mask R-CNN (He et al., 2020) and YOLOv4, and pretrained multimodal baselines such as VL-BERT (Su et al., 2019) and Unicoder-VL (Li et al., 2020).

Rule-based & Statistical Extractors. Joshi et al. (2018) introduced STI and proposed a method based on rules and statistical classification extractors. The sarcasm target was determined based on the results of two extractors. The configuration of R2 and 'Hybrid AND' performs the best on the MSTI dataset. We test the source code[2] as a baseline of TSTI.

Socio-linguistic Features. Patro et al. (2019) presented a deep learning framework augmented with socio-linguistic features to detect textual ST. Socio-linguistic features include the distribution of location (LOC) and organization (ORG) named entities, the distribution of POS tags, and the distribution of LIWC and Empath (Fast et al., 2016) categories. We test the source code[3] as a baseline of TSTI.

BERT. We follow the sequence tagging task of Devlin et al. (2019) as a baseline to perform TSTI. The BERT-based model followed by linear and softmax layers is tested to tag textual ST.

Object Detection Models. We treat VSTI as a single object detection problem and test two state-of-the-art models, i.e., Mask R-CNN[4] and YOLOv4[5]. We train the models on the MSTI dataset with the default values of parameters in the repository.

Pretrained Multimodal Models. Recently, pretrained multimodal models such as VL-BERT, Unicoder-VL, and UNITER (Chen et al., 2020), have been proposed. These models use regions-of-interest (RoIs) produced by object detectors such as Faster R-CNN (Ren et al., 2016) as visual tokens. The inputs of pretrained multimodal models are RoI features and token embeddings; In this paper, we design an MSTI baseline approach based on pretrained multimodal models as follows: Labeling of the textual STs is based on the outputs of token embeddings, the same as in our TSTI method; The VSTI is performed by a binary classification on the outputs of RoI features followed by linear+softmax layers, and it is trained by the RoIs, which are considered as visual STs when the IoU with gold ST is larger than an optimal value of 0.7, otherwise they are considered as non-STs. We finetune the IoU threshold for non-maximum suppression (NMS) to ignore overlapping RoIs and find that $\text{IoU}_{NMS} = 0.2$ is optimal.

4.4 Results

Table 5 shows the performance of our model compared with text, object detection, and pretrained multimodal baselines on the Dev and Test sets. The results show that the BERT-based sequence tagging models are better than the previous works of STI (Joshi et al., 2018; Patro et al., 2019). Fusing visual clues, our model outperforms BERT-based textual models on average 5.3% in F1 score and 4.4% in EM accuracy. The object detection baselines such as Mask R-CNN and YOLOv4 which are directly trained by sarcastic objects are better than the pretrained multimodal baselines with RoIs detected by a traditional object detector, obtaining an increase of approximately 2% in AP metrics.

We test state-of-the-art backbones such as ResNet151 and VGG19, in which scale dimensions of the last three blocks are 19 × 19, 38 × 38, and 76 × 76, respectively, the same as in CSPDarkNet53. Therefore, the B2M in Table 1 can be directly used for ResNet151 and VGG19, and the M2N works if the dimensions of the output feature maps of $\{C_1, C_2, C_3\}$ are set to {2048, 1024, 512} for ResNet151 and {512, 512, 256} for VGG19, respectively. The results show that CSPDarkNet53 achieves the best performance. In addition, Table 6 reports APs (namely, AP_S, AP_M, and AP_L) by our best model based on small, medium, and large

sarcasm targets, respectively.

4.5 Ablation Study

We ablate text (w/o text) or image (w/o image) from our multimodal model. Table 7 shows the results of our model (backbone=CSPDarkNet53, LM=BERT-Large). The performance drops by 5.1% in F1 score and 4.1% in EM accuracy when ablating images, indicating that visual clues are very useful for STI.

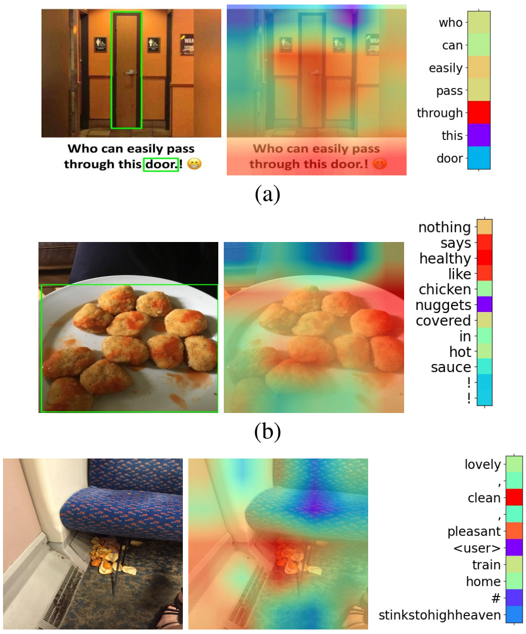
In addition, we ablate TSTI training (w/ text and w/o TSTI loss) or VSTI training (w/ image and w/o VSTI loss). We observe that by only adding text but not training the textual task, our model can greatly improve the VSTI performance, i.e., from 44.6% to 49.1% in AP_{50}. However, by only adding image but not training the image task, our model obtains a small increase of 1.5% EM accuracy and 1.1% F1 score for TSTI. These results indicate that texts has more explicit sarcasm information than images and sarcastic message likely comes more from texts, which are consistent with common sense.

4.6 Cross-modality Attention Visualization

We visualize the attentions of the MCE in terms of image-to-text and text-to-image in order to illustrate the sarcasm information added from anther modality. The input of the MCE is composed of textual and multi-scale visual embeddings. We abbreviate G, previously defined in Eq. (2), as $G = (e, v_B)$ where $e = (e_1, ..., e_n)$ and $v_B = (v_{B_1}^{1,1}, \ldots, v_{B_1}^{5,5}, v_{B_2}^{1,1}, ..., v_{B_2}^{5,5}, v_{B_3}^{1,1}, ..., v_{B_3}^{5,5})$. The attention weight matrix of the h-th head can be divided to four submatrics and denoted as follows:

$$A^h = \begin{pmatrix} A^h(e,e) & A^h(e,v_B) \\ A^h(v_B,e) & A^h(v_B,v_B) \end{pmatrix}. \tag{7}$$

Thus, the scaled dot-product attention of Eq. (1) also can be written as $A^h G^\top$. We define the computation of image-to-text and text-to-image attentions as follows:



(a)

(b)

(c)

Figure 4: Examples of cross-modality attention visualization. The left, middle, and right columns are images, text-to-image attentions, and image-to-text attentions, respectively. The figures are best viewed in color.

Text-to-image Attentions. The goal of text-to-image attention is to quantify the effect of text on each image block. We compute the average sum of $A^h(v_B, e)$ across all words, H heads, and 3 scales, then obtain the text-to-image attention weights on the image block with the coordinate (p, q) as follows:

$$w_{v^{p,q}} = \frac{1}{3H} \sum_{i=1}^{3} \sum_{h=1}^{H} \sum_{k=1}^{n} A^h(v_{B_i}^{p,q}, e_k). \tag{8}$$

Image-to-text Attentions. The text-to-image attention aims to quantify the effect of image on each word. We compute the average sum of $A^h(e, v_B)$ across 25 image blocks with 3 scales and H heads, then obtain the image-to-text attention weights as follows:

$$w_{e_k} = \frac{1}{3H} \sum_{i=1}^{3} \sum_{h=1}^{H} \sum_{p=1}^{5} \sum_{q=1}^{5} A^h(e_k, v_{B_i}^{p,q}), \tag{9}$$

where $k = 1, \ldots, n$.

Figure 4 shows the examples of text-to-image attentions in Eq. (8) and image-to-text attentions in

Eq. (9). The attention maps show some meaningful cues discovered by the MCE regarding sarcasm. The red color denotes the highest weights. We scale up the text-to-image attention map to image size using interpolation. As expected, the text-to-image attentions in the middle columns of Figure 4 focus on the regions that are highly relevant to sarcasm targets, such as door in (a), chicken nuggets in (b), and orange peel in (c). Surprisingly, the image-to-text attentions in the right columns of Figure 4 point out the key words to well understand sarcasm. Using these red colored words, the tweet authors express their opinions: (a) Can the door 'through'? (b) Are the chicken nuggets 'healthy'? (c) Is the train 'clean' or is train home 'pleasant'?

5 Conclusions

In this paper, we introduce a new task for identifying both textual and visual sarcasm targets. This work provides a good attempt to detect sarcasm targets on images. Our model integrates multiple components such as sequence labeling, multi-scale cross-modality learning, and object detection. The experimental results not only illustrate that visual clues can improve the performance of TSTI by a large margin, approximately 5% in F1 score, but also prove that it is feasible to detect sarcasm targets in images, obtaining a good accuracy of 51.9% in AP_{50}.

A Appendix

A.1 Case Study

Table 8 shows the examples of ground truth, BERT-large, VL-BERT, and our model in the MSTI dataset. The textual ST results are incorrect in all examples for the BERT baseline, but they are correct for our model with visual clues. The detected visual STs are correct for our model; however, there are a few noisy RoIs, such as a child in Example 2, Theresa Mary and tie in Example 3, for the VL-BERT baseline. Examples 3 and 4 show differences between sarcasm targets and traditional object classes, such as strings "Donald Trump" and a scene of a person carrying bags. These cases also show that our model can detect visual STs with various sizes. The small size strings 'door' in Example 1 and "Donald Trump" in the middle of Example 3, the medium size string "Donald Trump" at the upper left corner and person "Donald Trump" in Example 3, and the large size objects in Examples 2 and 4, illustrate that the multi-scale features enrich spatial information for visual ST detection.

Table 9 shows the failure cases by our model. Our model fails in detecting the textual ST "chicken nuggets" in Example 1, probably because the linguistic representations do not perform well although the cross-modality attention contributes the sarcastic word 'healthy' shown in Figure 4(c). The visual STs such as the innovation object in Example 2 and string "SUNDAY FUNDAY" in Example 4 are not detected. In Examples 3 and 5, our model detects the highly related negative visual clues in images, i.e., crowded train and orange peel trash, although it fails in detecting textual STs.

Flexible Generation from Fragmentary Linguistic Input

Peng Qian **Roger P. Levy**

Abstract

The dominant paradigm for high-performance models in novel NLP tasks today is direct specialization for the task via training from scratch or fine-tuning large pre-trained models. But does direct specialization capture how humans approach novel language tasks? We hypothesize that human performance is better characterized by flexible inference through composition of basic computational motifs available to the human language user. To test this hypothesis, we formulate a set of novel *fragmentary text completion* tasks, and compare the behavior of three direct-specialization models against a new model we introduce, GibbsComplete, which composes two basic computational motifs central to contemporary models: masked and autoregressive word prediction. We conduct three types of evaluation: human judgments of completion quality, satisfaction of syntactic constraints imposed by the input fragment, and similarity to human behavior in the structural statistics of the completions. With no task-specific parameter tuning, GibbsComplete performs comparably to direct-specialization models in the first two evaluations, and outperforms all direct-specialization models in the third evaluation. These results support our hypothesis that human behavior in novel language tasks and environments may be better characterized by flexible composition of basic computational motifs rather than by direct specialization.

1 Introduction

Representation learning has tremendously benefited engineering for language comprehension and generation systems. General frameworks such as encoder-decoder or auto-regressive model can be flexibly applied to a diverse range of problems. With scaled models, enormous data, and well-chosen training objective functions, generative pre-training extracts useful and transferable information from unlabeled text data (Howard and Ruder, 2018; Liu et al., 2019b). These generic representations can then be finetuned to quickly yield performant models directly specialized for downstream tasks (Howard and Ruder, 2018; Radford et al., 2019; Devlin et al., 2019, *inter alia*). While the broad idea of exploiting rich statistical information in general-purpose representations has proven practically effective for deep learning models since a decade ago (Erhan et al., 2010; Collobert et al., 2011), it remains an open question how well this "direct specialization" approach yields models that behave similarly to humans in flexible linguistic behavior in novel situations.

Here we take this "direct specialization" approach as a scientific hypothesis regarding the nature of linguistic knowledge and its flexible deployment in the human mind: that the human capacity of processing linguistic information in novel tasks arises from directly specializing and reshaping a generic yet versatile representation. We contrast it with an alternative hypothesis: that flexible knowledge deployment reflects algorithmic composition of a constrained repertoire of simple, reusable inference motifs. We depict these competing hypotheses in Figure 1. In the "compositional inference" hypothesis, the basic motifs arise from learning processes and could potentially involve distinct internal representations, but can be recombined into new inference routines guided by the principles of approximate probabilistic inference. In this hypothesis, the computational-level specifications (Marr, 1982) of motif functional forms play a crucial role. As a theory of how the human mind approaches new and potentially complex problems, the "direct specialization" hypothesis entails generic starting representations, task-specific supervision, and specialization. The "compositional inference" hypothesis, in contrast, entails novel combinations of solutions to old problems.

Directly testing these two hypotheses would require a comprehensive set of experimental stud-

ies of human behaviors involving various tasks, which goes beyond the scope of this work. However, as an initial step, we consider these two hypotheses as computational paradigms that inform and inspire the architecture of models that flexibly perform novel language tasks, and ask which paradigm gives rise to more human-like behaviors. Here we ground the general question in a specific setting: a novel set of fragmentary input completion challenges, inspired by the classic cloze task (Ebbinghaus, 1897) and its contemporary variants. Taking a reverse-engineering approach, we instantiate the "direct specialization" and "compositional inference" hypotheses as explicit computational models and compared the models' behaviors to that of humans in a behavioral task of fragmentary input completion. Our fragmentary input designs highlight various aspects of abstract reasoning involving subtle features of grammar and semantics. We find that the model of the compositional inference approach generates high-quality completions without direct training on the target task, achieves comparable performance to the models from the direct specialization approach in reasoning about constrained syntactic contexts, and better matches the fine-grained structural statistics of completions written by human subjects.

2 The Fragment Completion Challenge

For purposes of this paper, we define a *fragmentary linguistic input*, or simply a *fragment*, as a sequence of word strings. *Completing* a fragment involves adding a word string of any length between adjacent strings in the input to yield a single overall well-formed sentence. The fragment completion problem is formally equivalent to the text infilling problem studied in a number of recent papers (Fedus et al., 2018; Zhu et al., 2019; Liu et al., 2019a; Donahue et al., 2020; Shen et al., 2020; Huang et al., 2020), but here we study considerably more open-ended completion problems from potentially much briefer input than has been studied before. For example, many native English speakers find the simple fragmentary input

____ published won ____ .

initially challenging yet solvable.[1] We find that carefully chosen simple fragmentary inputs can

---

[1] The input requires building a nested center-embedding context such as "*The most recent book she* published *won a prize*".

offer insight into the abilities of "direct specialization" and "compositional inference" models, and the similarity of model and human behavior.

2.1 Computational Models

Formally, fragment completion involves generating, given input comprised of a sequence of k word strings $C = \{C_1, \dots, C_k\}$, a sequence of $k-1$ word strings $B = \{B_1, \dots, B_{k-1}\}$, such that the resulting completion is $C_1 \circ B_1 \circ \cdots \circ C_{k-1} \circ B_{k-1} \circ C_k$.[2] In general, exact inference over the full conditional distribution $P(B|C)$ will be intractable. The "direct specialization" and "compositional inference" paradigms offer differing model specifications and algorithmic options.

2.1.1 Direct Specialization

With direct specialization, we learn or fine-tune representations under supervision for the task. We take the learning objective to be maximizing the likelihood $p(B|C)$ for some sampled (B, C) pairs generated from a training corpus (see Section 2.2):

$$p(B|C) = \prod_{i=1}^{|B|} p(B_i \mid B_{<i}, C)$$

We ground this approach into two learning procedures: (a) fine-tuning pretrained language model to solve the target task, and (b) training on the target task from scratch. The fine-tuning procedure takes advantage of transferring knowledge from large pretrained models, while the training from scratch procedure allows us to further control the effect of pretrained representation. For both learning procedures, we use three existing models trained or fine-tuned for infilling: T5 (Raffel et al., 2019; InfillT5), BART (Lewis et al., 2020; InfillBART), and GPT-2 (Radford et al., 2019) fine-tuned for text infilling, which was previously explored in Donahue et al. (2020) and which we will follow them in calling the Infilling Language Model (ILM) for short. Implementation details can be found in Section 2.2.

2.1.2 Compositional Inference Approach

For the compositional inference approach, we propose **GibbsComplete**, a neurally-guided approximate inference algorithm that combines two canonical computational motifs: masked word prediction and autoregressive word prediction. Consider a candidate for the i-th completion string B_i to consist of $b_{i,<j} \circ b_{i,j} \circ b_{i,j<}$. GibbsComplete takes a masked language modelling motif as a proposal distribution $p(b_{i,j}|B_{\setminus i}, b_{i,<j}, b_{i,j<}, C)$ and composes it with a global scoring function $\phi(B, C)$ given by a unidirectional language modelling motif, in line with previous work on applying sampling-based methods to generative neural sequence models (Berglund et al., 2015; Su et al., 2018; Miao et al., 2019; Wang and Cho, 2019; He and Li, 2021). GibbsComplete can also be broadly viewed as an example of unsupervised language generation, among many other alternatives (Liu et al., 2019a; Qin et al., 2020; West et al., 2021).

Algorithm 1: GibbsComplete

```
Data: An incomplete sentence with blanks.
Result: $M$ completions
initialize $N$; // Number of candidates
initialize $T$; // Number of iterations
completions ← [];
for $n = 0$; $n < N$; $n = n + 1$ do
    propose a blank configuration;
    for $i = 0$; $i < T$; $i = i + 1$ do
        randomly choose a token in the blanks;
        sample a replacement from MASKED
          LANGUAGE MODEL;
    add the final sample to completions;
rerank $N$ completions to top-$M$ based on average
  word surprisal estimated by FORWARD LANGUAGE
  MODEL;
```

Our GibbsComplete algorithm first proposes a random uniform guess on $[1, 10]$ about the length of each $\{B_i\}$, and initializes them as "`[MASK]`" sequences of the guessed lengths. It then proposes an edit to a randomly chosen position $b_{i,j}$ within the blanks by sampling from the sorted list of likely replacements according to the conditional probability $p(b_{i,j}|B_{\setminus i}, b_{i,<j}, b_{i,j<}, C)$ given by a masked language model. We take 500 stochastic editing steps: for the first 250 steps as a burn-in period, the replacement is sampled from the top 50 likely words; for the remaining iterations, the most likely word is picked as the replacement, following the common practice of annealing temperature for better generation quality (Wang and Cho, 2019). The final output of the editing process is a candidate completion. We sample 1000 such candidates, and then rerank them with an autoregressive forward language model, using mean per-word conditional log-probability as a scoring function to promote fluency.

Note that neither the masked language model nor the autoregressive language model is fine-tuned

---

[2] We represent cases where material can be added at the beginning or the end of the input as c_1 or c_k being the empty string, ϵ.

or retrained on the target infilling task: we take them as basic computational motifs that are immediately available to a language-using agent for use in sampling-based probabilistic inference to facilitate novel behaviors. Completing fragmentary inputs of the type studied here is not a major form of everyday language use, yet as our experiments show, native speakers can perform even challenging fragment completions fairly well with little practice.

Like the two learning settings considered in the "direct specialization" approach, we implement instances of GibbsComplete algorithm with (a) pretrained language models as the computational motifs, and (b) computational motifs of the same architecture as the pretrained counterparts but learned from the same corpus as those trained-from-scratch models from the "direct optimization" approach.

2.2 Model Implementations and Training Datasets

We implement instances of the models under two learning settings: (a) transferring knowledge from pretrained models, and (b) training from scratch. Implementations are based on the Huggingface `transformers` package (Wolf et al., 2020).

In the case of knowledge transfer with pretrained models, no fine-tuning or learning is needed for GibbsComplete. We simply use the small version of pretrained GPT-2 (Radford et al., 2019) and the base cased version of pretrained BERT (Devlin et al., 2019) as the corresponding computational motifs. For direct specialization models, we fine-tune pretrained GPT-2 small, T5 base, and BART large[3] to get ILM, InfillT5 and InfillBART respectively. The total number of parameters of these model architectures is listed in Table 1. All models were fine-tuned on a 10 million token subset of New York Times Corpus 2007 portion (Sandhaus, 2008), with a batch size of 32 and learning rate of 10^{-5}. The supervision signal is generated by randomly cropping some spans of words in a sentence to get the fragmentary context C and a plausible completion B (see Appendix C.2 for details). We stopped fine-tuning when the validation loss increases for two epochs in a row. To generate completions from ILM, InfillT5, and InfillBART, we apply ancestral sampling from a list of top 50 mostly likely tokens at each time step. In experimenting with the fine-tuned models, we noticed lower diversity in InfillBART samples compared to the other models. Hence we set the sampling temperature as 1 for other models but 1.8 for the fine-tuned InfillBART to ensure that all models generate a good variety of completions.

When training from scratch, we train all components to be learned in all models on two separate 42-million-token datasets: (1) part of the 2006 year portion of New York Times Corpus (Sandhaus, 2008; `NYT`), and (2) part of the `BLLIP` corpus (Charniak et al., 2000) previously prepared by Hu et al. (2020). For GibbsComplete, we train an auto-regressive Transformer decoder language model of the same size as pretrained GPT-2 small and a masked language model of the same size as pretrained base cased BERT. For ILM, InfillT5, and InfillBART, we initialize the same architecture and tokenizer as their fine-tuned counterparts and train each model from scratch. We use a batch size of 16 for the masked language model in GibbsComplete and 32 for all the other models. The learning rate is set as 10^{-5} across all the models. Training is early stopped if either the validation loss increases for two epochs in a row or the total number of training epochs exceeds 100.

2.3 Collecting Human Completions

We also collect human completions of our fragments on Mechanical Turk, to evaluate performance and for fine-grained comparison of human and model behavior. The visual layout of these experiments is shown in Appendix A. Participants were instructed to use as many or little words as they see appropriate to fill in the blanks in the fragmentary input, so that each completed sentence is coherent, grammatical, and meaningful. The interface required each blank to be filled in with at least one word. We imposed no time constraints.

3 Experiments

To address the question of whether the "direct specialization" or "compositional inference" paradigm gives rise to more humanlike behaviors, we focus on designing a series of linguistically-motivated experiments[4].

---

[3] Although the pretraining tasks of T5 and BART do include modified versions of the sentence infilling problem or related text denoising tasks, our initial experimentation suggested that pretrained T5 and BART could not fully support the flexible generalization required in our studies, hence we fine-tuned them as above.

[4] Code and stimuli available at `https://github.com/pqian11/fragment-completion`

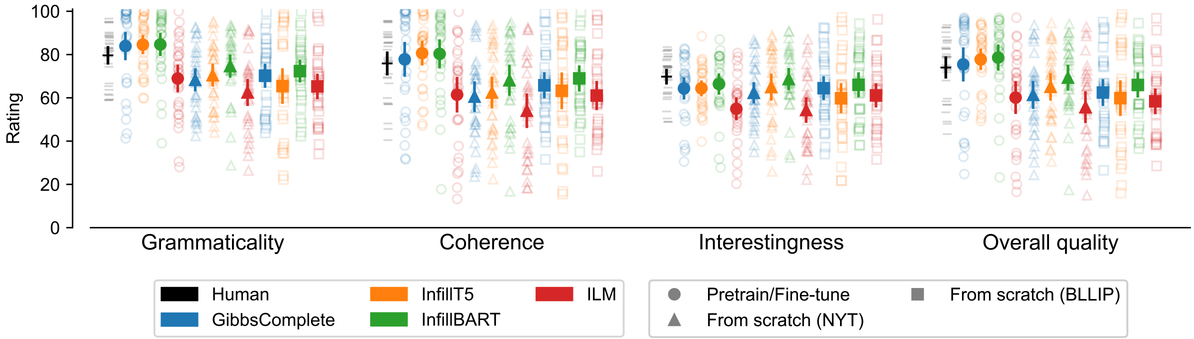

Figure 2: Human evaluation of completion quality for human participants and models in Experiment I. Semi-transparent hollow markers indicate the average rating for a particular item. Solid markers indicate the mean score, with error bar representing asymptotic 95% confidence interval of the population mean score.

3.1 Evaluation I: Completion Quality Given Bi-directional Context

Our first experiment qualitatively confirms that each model respects basic bidirectional constraints, and quantitatively evaluates the fluency of each model's completions using human judgments. We design 30 two-fragment stimuli of the form

$$\alpha \_\_\_\_ \beta$$

by adapting sentences from the Brown Corpus (Francis and Kucera, 1979) and British National Corpus (2001), choosing spans to crop out such that successful completion does not require outside-of-sentence information or much factual world knowledge, but does require non-trivial respect of grammatical constraints: we require that both α and β are multi-word fragments that cross conventional constituent boundaries.

Table 4 in Appendix G.1 lists one randomly-generated completion from different models to a subset of the stimuli. Qualitatively, all models generate high-quality completions that fit the context and sound fluent, although coherence is sometimes lacking. For quantitative evaluation, we recruit human raters on Prolific to evaluate the quality of the completed sentences written by models as well as human writers previously recruited on Mechanical Turk. Human raters were presented with the fragmentary input together with a completion and asked to judge the grammaticality, coherence, interestingness, and overall quality of the presented completion. Ratings range from 1 to 100, with 1 the lowest score and 100 the highest. Each human rater judged 150 completions in total, with 30 completions from a human writer or each of the models. Raters did not know whether a completion comes from a human or a model. The results of these ratings are shown in Figure 2: GibbsComplete, InfillT5, and InfillBART achieve similar performance on grammaticality judgment on this set of stimuli. The same human evaluation procedure is also applied to the set of models trained from scratch on the `NYT` and `BLLIP` data; results are given in Figure 2. Overall performance is worse than with the pre-trained models, but the relative patterns from model to model are similar. Overall, the results of Evaluation 1 suggest that when extensive bidirectional context is given, *all* models are able to generate structurally well-formed completions. This success motivates our next experiment, which involves briefer input in syntactically constrained configurations that more strongly challenge models' grammatical abilities.

3.2 Evaluation II: Satisfying Syntactic Constraints

To illustrate our syntactic constraint satisfaction tests, consider this example:

The paintings that the artist gave to _____ is _____ .

The first fragment consists of a plural noun phrase with an incomplete relative clause postmodifier; the second fragment is a singular verb, "is". The plural noun in the first fragment cannot be the subject of "is" due to number agreement in English, which forces a syntactically complex completion, such as "The paintings that the artist gave to *the museum are gorgeous and one of them* is *absolutely a masterpiece*.".

We design 26 novel fragment configurations to test models' syntactic behavior, ranging broadly across subject-predicate agreement, clausal structure, coordination, and filler-gap dependencies. For

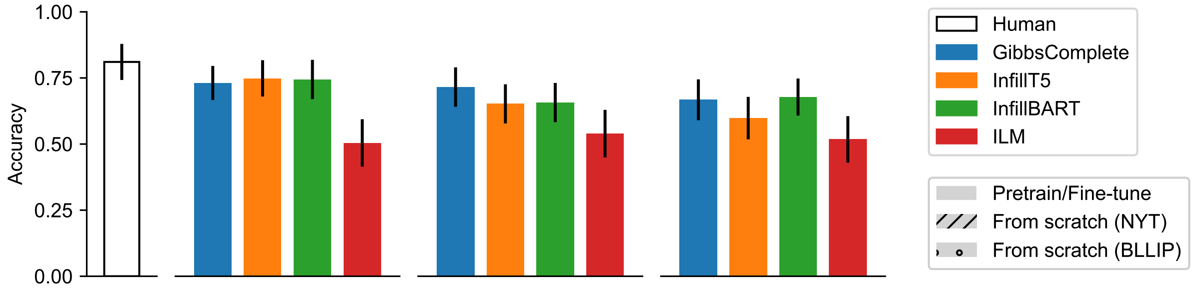

Figure 3: Aggregated results on syntactic reasoning tests. Error bars represent 95% confidence intervals.

each configuration we construct a set of semantically diverse fragmentary inputs that share the critical high-level syntactic structure for inducing similar grammatical constraints. The semantic diversity of the items facilitates more reliable estimation of the models' syntactic reasoning abilities. We provide descriptions and examples of each syntactic reasoning test in Appendix E.

With each model we generated 35 completions for each stimulus in each of the 26 tests. To collect human judgments for every single completion would be laborious and difficult to scale, in particular because evaluating whether the syntactic constraint is satisfied often requires some linguistic expertise. Instead, we represent the key syntactic constraints imposed by the fragments as tree patterns to be expected in the constituency parse of a completed stimulus. For example, given a stimulus "____ published won ____ ." from the test (6) as shown in Appendix E, the linguistic intuition is that "published" should be part of a Verb Phrase embedded in a relative clause that modifies the subject of the predicate "won", despite other possible structural variations. We express these tree patterns using the Tregex tool (Levy and Andrew, 2006), compute the average rate of hitting the desired syntactic patterns out of the 35 completions which are annotated with syntactic parses by an off-the-shelf neural constituency parser `benepar` (Kitaev and Klein, 2018), and average across all the stimuli in a test as the final accuracy score for that test.[5]

Figure 3 shows the performance of humans and each model; Figure 8 in Appendix G.2 breaks down accuracy scores by each test separately. Human performance[6] is as good as or superior to all models ($p < 0.05$ for all models except fine-tuned InfillT5 and InfillBART, two-sided paired t-test). For the pretrained models, ILM performs the worst; the other three models' performance is comparable. When training from scratch, GibbsComplete outperforms all other models except on `BLLIP`, where its performance is matched by InfillBART. To address a potential concern about the ensembling effect of the reranking process in GibbsComplete, we also examine the performance obtained when composing the outputs of the directly-specialized models with the reranking process of GibbsComplete, generating 1000 candidate completions per fragment and selecting the top-ranked 35 completions using the same reranker as in GibbsComplete. Figure 10 in Appendix G.2 shows the results: InfillT5 and InfillBART now perform the best and even match human performance, further underscoring the value of a compositional approach even when dedicated training for direct specialization is available.

3.3 Evaluation III: Structural Similarity to Human Behavior

Evaluation II showed that models can perform very well even on more grammatically challenging fragment completion tasks, in some cases matching human performance. But do these models complete fragments *in a similar way* as humans do? Evaluation III turns to this question, using still more open-ended fragments and fine-grained analysis of the structural similarity of human and model completions.

To evaluate fine-grained similarity of human and model behavior, we define summary statistics of features of completions and assess the similarity of the summary statistics seen in human and model completions. We designed 120 stimuli in the form

---

[5] We also conducted manual evaluation of a sample of the pattern-matching results, which confirmed high accuracy of this automated evaluation procedure; see Appendix F for details.

[6] We collected human completions from Mechanical Turk for two stimulus items of each test, with 5–6 responses for each item. Human completions were evaluated with the same tree pattern-based method as model-generated completions.

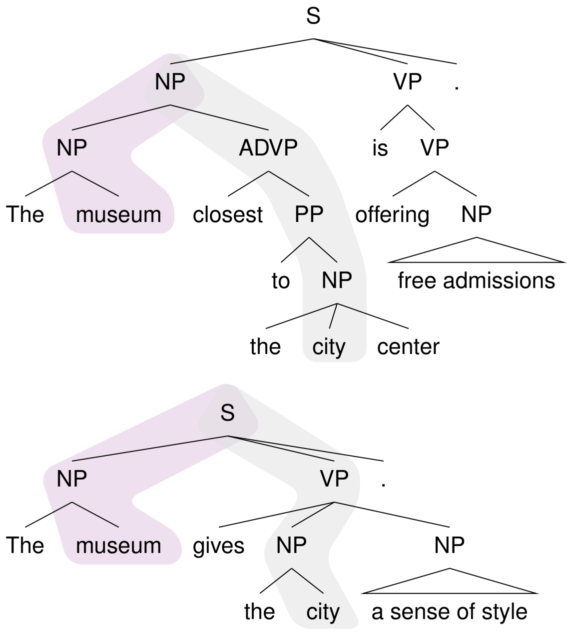

Figure 4: Lowest common ancestor of the fragments "museum" and "city" in constituency parses.

of "____ w_1 ____ w_2 ____ .", where w_1 and w_2 are single-word fragments, allowing for a diverse range of plausible syntactic choices of the global context. For example,

____ museum ____ city ____ .

may be completed using a variety of different structural configurations, as shown in Figure 4. We parse each completion with `benepar` (Kitaev and Klein, 2018) and use the syntactic category of the lowest common ancestor (LCA) of w_1 and w_2 in the parse tree as a feature of the completion. We choose 40 Noun-Noun, 40 Adjective-Adjective, and 40 Adjective-Noun combination as w_1 and w_2 respectively, once again with diverse semantic content. We recruited human subjects from Mechanical Turk, with 18 subjects for Noun-Noun condition, 18 subjects for Adjective-Adjective, and 18 subjects for Adjective-Noun. Each subject wrote one completion for every item in the assigned condition. For an item, the completions from the subjects provide the human data from which we estimate the summary statistics of interest. We estimate the LCA frequency distribution across five syntactic category types: S, NP, VP, ADJP, and Other (everything else). For models, we sample and parse 35 completions for each stimulus to estimate the LCA frequency distribution.

We evaluate the performance of a model by its mean squared error (MSE) against human relative frequencies of the five syntactic category types for each item. Statistical significance of difference between model performances is tested with two-sided paired t-test. Figure 5 shows quantitative results for each model+training condition. Overall, GibbsComplete is the best-performing model. With pretrained models, GibbsComplete has significantly lower aggregated MSE than fine-tuned InfillT5 ($p = 0.012$) and fine-tuned ILM ($p = 0.010$), and is numerically lower than that of fine-tuned InfillBART ($p = 0.108$). When training from scratch, GibbsComplete is not significantly better. The MSE of GibbsComplete with motifs trained from scratch is not significantly better than other models trained from scratch on `NYT`, but when training on `BLLIP` it significantly outperforms InfillT5 ($p = 0.017$) and InfillBART ($p = 0.048$) trained from scratch on `BLLIP`. Looking at specific LCA categories, we find that GibbsComplete outperforms all the other models ($p < 0.005$) in matching the frequency of NP in human completions. Except when comparing ILM trained on `NYT` to GibbsComplete on VP ($p = 0.041$), no other directly-specialized models significantly performs better than GibbsComplete for category S, VP, and ADJP. Overall, these results suggest that the statistics of LCA categories in the parsed completions by GibbsComplete with pretrained models better match those of humans than those fine-tuned models, and that the advantage of GibbsComplete may also extend to low-resource setting.

4 Discussion

In this paper we have considered the direct-specialization approach to novel tasks dominant in contemporary NLP today as a cognitive hypothesis: that the knowledge structures and processes humans deploy for novel language tasks are best captured by the end result of fine-tuning or from-scratch training on the novel task itself. We have contrasted this with a competing hypothesis, namely that human behavior in novel tasks is better captured by inferences resulting from flexibly composing existing basic computational motifs, which relates to the idea explored in compositional use of neural modules (Andreas et al., 2016). To compare these hypotheses, we have developed and tested new, more challenging, and more open-ended versions of the text infilling task, which we term fragmentary input completion, and evaluated the performance of different models instantiating the two

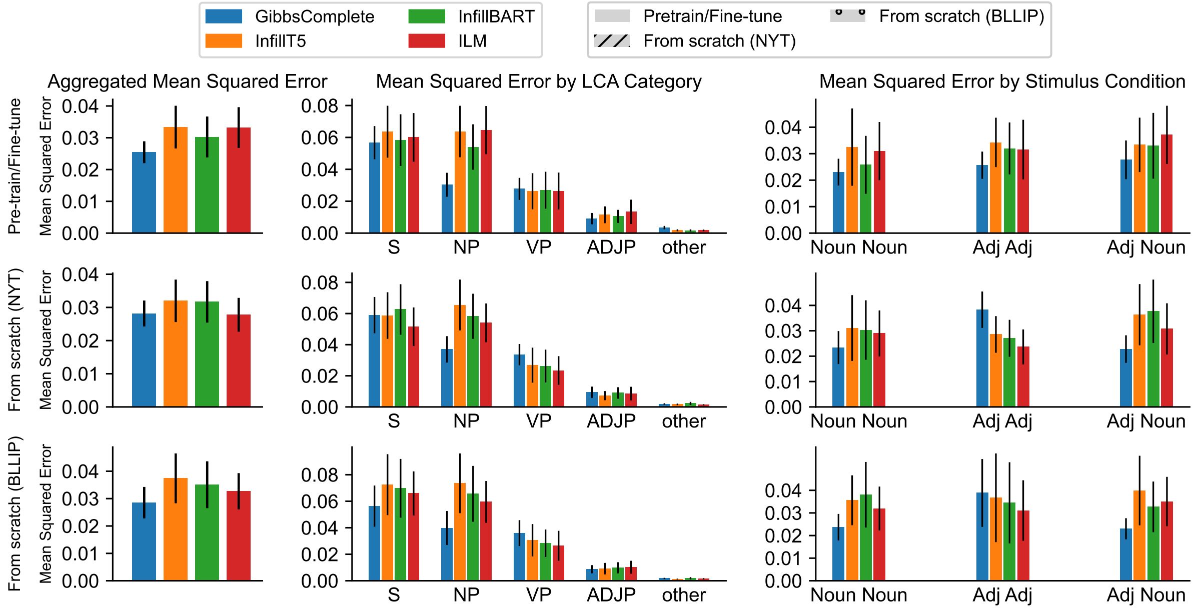

Figure 5: Comparing structural statistics in model's completions with that of the human-written completions. Error bars represent asymptotic 95% confidence intervals.

hypotheses against subjective human judgments, fixed success criteria, and fine-grained comparisons with human task performance. In the future this approach could be extended further for more comprehensive evaluation of conditioned language generation systems.

Our results are generally favorable for the compositional inference hypothesis as exemplified by our novel GibbsComplete algorithm, which composes the two fundamental language modelling motifs central to today's language models, masked word prediction and autoregressive modeling. The motifs themselves need to be learned in the first place, but there is a strong case that these motifs reflect tasks fundamental to everyday language use: identifying an uncertain word using bidirectional context (Connine et al., 1991; Dilley and Pitt, 2010; Levy, 2008b) and predicting upcoming input (Hale, 2001; Levy, 2008a; Kutas et al., 2011; Kuperberg and Jaeger, 2016). The idea we advance here, that these fundamental motifs are pre-existing and flexibly deployed for novel tasks, echoes a long-standing perspective in cognitive science well-summarized by Bruner et al. (1986), that "*Thinking is not the acquisition of knowledge, but the use of knowledge in the interest of solving problems*".

Of course, we do not interpret these results as suggesting that the human mind is literally a Gibbs sampler. But there are broader arguments that sampling-based approaches may capture important general features of human inferential patterns (Vul et al., 2014). Furthermore, the compositional inference approach to modelling flexible language generation by no means diminishes the value of learning or fine-tuning—indeed, fine-tuned models can themselves be composed (see also our exploratory work in Appendix G.2). Rather, we hope that this work may help widen the perspective on the relationship between learning and inference in novel language tasks and contexts.

5 Conclusion

Scaled learning and quick adaptation of linguistic representation have enabled huge progress in the engineering of high-performance NLP systems, but our results suggest that flexible redeployment of basic computational motifs may have advantages for capturing how humans flexibly use language in novel circumstances where they do not have extensive experience. Our studies offer systematic model comparisons with materials designed to highlight subtle features of grammatical knowledge and featural statistics of human completion preferences, and point to the need for longer-term efforts in understanding and modeling human cognitive flexibility in computational terms. As an initial step, we explored the "compositional inference" hypothesis by sketching out an inference algorithm based on the principles of approximate Bayesian inference. The results suggest certain advantages of an inference-oriented view of human language generation, and an alternative path towards building models that process linguistic information as flexibly as humans do.

Acknowledgments

We thank the anonymous reviewers and members of the MIT Computational Psycholinguistics Lab for their helpful comments, and members of the Goals, Problems and Stories working group for discussions on early idea of the project. This work was supported by the MIT-IBM Watson AI Lab and by NSF award BCS-2121074.

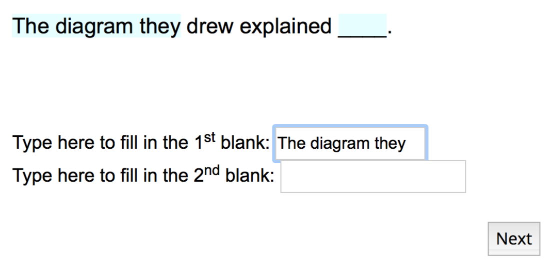
A Behavioral Experiment

Figure 6 shows the screenshot of one trial in the behavioral experiment, through which we collected human-written completions to the fragmentary linguistic stimuli. In our implementation, we depict the blanks in the fragmentary input as a short underline placeholder. As soon as one starts typing words in the text input box, the typed content will be rendered immediately as replacement of the corresponding blank.



The diagram they drew explained ____.

Type here to fill in the 1st blank: The diagram they

Type here to fill in the 2nd blank:

Figure 6: Screenshot of an experimental trial of the fragment completion task for human participants.

B Human Evaluation of Completion Quality

We collected human rating of completion quality for Evaluation I. Figure 7 shows the screenshot of one trial in the completion quality judgment task for human raters.

C Model Implementation

C.1 Model Size

Table 1 lists the number of parameters in each model. Notice that the count of total parameters for GibbsComplete includes the autoregressive language modeling motif (124M) and the masked language modeling motif (109M), both of which has 12 layers.

	# of layers	# of parameters
GibbsComplete	12	233M
InfillT5	12	223M
InfillBART	24	406M
ILM	12	124M

Table 1: Model size comparison.

C.2 Sampling Infilling Pairs for Model Training

To train InfillT5, InfillBART, and ILM directly on the text infilling task, we employ a data generation process to randomly sample training data and prepare validation data. Given a sentence, we randomly replace spans of the sentence with `[BLANK]` symbol and append the original contents of the blanks in order separated by `[FILLER]` symbol. The total number of spans is uniformly sampled between 2 and 9. For a sentence, the maximal number of spans to be sampled is capped at the sentence length if the total number of words in the sentence is less than 9. This process gives us a fragmentary context C and one of its plausible completion B. The paired C and B sampled from a corpus are used to provide task supervision signal.

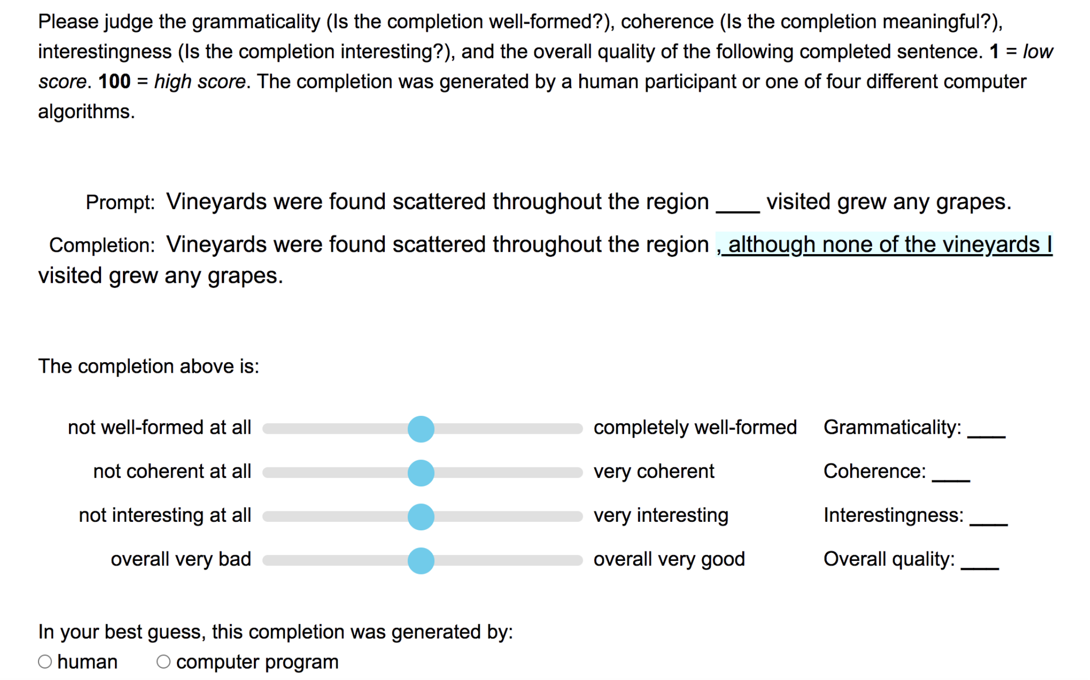
For example, given the original sentence in the corpus: "The camera had been operating on its backup electrical system since last summer, however, when electrical problems in its main system caused it to shut down for a while.", a training instance after randomly cropping the sentence may consist of C as "The camera had been `[BLANK]` backup electrical `[BLANK]` electrical problems in its main system caused it to shut `[BLANK]` while." and B as "operating on its `[FILLER]` system since last summer, however, when `[FILLER]` down for a `[FILLER]`", where the cropped spans of words to be filled in are simply concatenated with `[FILLER]` marking the end of each span.

Notice that pretrained T5 uses a numbered list of tokens (e.g. `<extra_id_0>`, `<extra_id_1>`, etc) as delimiters of the spans to be filled into the blanks. Hence we follow the same convention when generating infilling pair data for fine-tuning pretrained T5 or training InfillT5 from scratch.

D Test Items in Evaluation I

Here we list the 30 items of the form "α _____ β" used in Evaluation I:

(1) He is one of _____ jazz on a violin.
(2) It is unclear _____ will have on the elections.
(3) The prices - even the special offers - _____ thought reasonable.
(4) Giving up the violin _____ had predicted would have a promising career on the concert stage.
(5) A difference of opinion arose between _____ the vote is handled.
(6) He was quiet, polite, _____ he met.
(7) The local authority _____ applied refused to provide the necessary grant.
(8) They argued _____ proposed implies a competitive outcome.
(9) Vineyards were found scattered throughout the region _____ visited grew any grapes.
(10) She knew the rents _____ find any good, affordable space in town.
(11) Due to the fact that building codes _____ what they are.



Please judge the grammaticality (Is the completion well-formed?), coherence (Is the completion meaningful?), interestingness (Is the completion interesting?), and the overall quality of the following completed sentence. **1** = *low score*. **100** = *high score*. The completion was generated by a human participant or one of four different computer algorithms.

Prompt: Vineyards were found scattered throughout the region ____ visited grew any grapes.

Completion: Vineyards were found scattered throughout the region , although none of the vineyards I visited grew any grapes.

The completion above is:

not well-formed at all	●	completely well-formed	Grammaticality: ____
not coherent at all	●	very coherent	Coherence: ____
not interesting at all	●	very interesting	Interestingness: ____
overall very bad	●	overall very good	Overall quality: ____

In your best guess, this completion was generated by:
○ human ○ computer program

Figure 7: Screenshot of a trial of the completion quality evaluation task for human raters.

(12) The fact that _____ but no less important in the long run.
(13) It is _____ ever existed outside the imaginations of historians.
(14) He _____ any of the Beatles songs.
(15) Even _____ say the findings should be taken with caution.
(16) The manager put _____ table.
(17) Each of the children invited to _____ marked with a red, white and blue ribbon.
(18) A sports club located _____ to keep up with the rent.
(19) A man believed involved _____ yesterday.
(20) The famous writer _____ a publisher to write two more books.
(21) If these services are _____ revenues to make them possible.
(22) It does indeed _____ through no fault of their own shoulder the cost.
(23) Although they emphasizes that the opportunities _____ them worth considering.
(24) This building has been consistently _____ and businesses for ten years.
(25) The team admitted it _____ a tough year.
(26) The performance marked _____ most promising young conductor.
(27) Previous experience _____ the best equipment possible.
(28) There appears to be enough _____ the interest deficiency for eight more years.
(29) They do not _____ not open to debate.
(30) The government _____ not addressing the poverty.

E Syntactic Reasoning Tests

Here we briefly introduce the 26 sets of tests, using one stimulus from each test to illustrate the syntactic constraints imposed by the fragments. Tests (1–5) target SUBJECT–PREDICATE AGREEMENT in English. These tests target the number mismatch of a noun phrase and a predicate, with the noun phrase embedded in various local syntactic structures, including (1) a bare noun phrase, (2) a noun phrase with a relative clause, (3) a noun phrase in complement clause, (4) a noun phrase in a coordinate structure, and (5) a noun phrase with a partially complete prepositional-phrase modifier.

(1) The reporter _____ are _____ .
(2) The paintings that the artist gave to _____ is _____ .
(3) _____ insist that the jury _____ have _____ .
(4) The bike and _____ has _____ .
(5) The museums in _____ is _____ .

Tests (6–15) target a variety of CLAUSAL STRUCTURE. Tests (6–11) require that the completion place the first verb inside an embedded clause that ends where the second verb's VP begins. Tests (12–13) feature a sentence-final verbal phrase with a missing obligatory object, requiring a completion in which that object has been extracted. Tests (14–15) target resultative structure.

(6) _____ published won _____ .
(7) _____ introduced into the classroom has _____ .
(8) _____ visited during the trip to the beautiful valley grew _____ .
(9) _____ owned the trademark began _____ .
(10) _____ brought out the plan for protecting the habitat of the endangered birds argued _____ .
(11) Giving up the violin _____ predicted would _____ .
(12) _____ relied on.

(13) _____ the founder of the research institute has never dreamed of.
(14) _____ growth steady.
(15) _____ decision of selling the old car unwise.

Tests (16–22) target COORDINATION of different phrasal categories, including (16) coordinated clauses, (17) coordinated VPs, (18) coordinated NPs in an embedded clause, (19) coordinated VPs in an embedded clause, and (22) coordinated subjects in a complement clause. Tests (20) and (21) feature collocations "either ... or ..." and "neither ... nor ... ". The intuition behind (20–21) is that the "either" or "neither", if used as conjunction words, requires an "or" or "nor" to follow respectively.

(16) _____ problem but no one took _____ .
(17) _____ standards and improved the _____ .
(18) _____ the symbols and the patterns carved on the surface of the clay bowl stood for.
(19) _____ studied the formation of galaxies and explored the mystery of the universe was _____ .
(20) _____ either book a ticket from the official website of _____ .
(21) _____ neither give up too quickly simply because of the failures encountered at the initial _____ .
(22) _____ what the senator and those who supported _____ steps moving forward.

Tests (23–26) target FILLER-GAP DEPENDENCIES. The basic idea is that the wh-word requires a gap to appear at an appropriate position.

(23) _____ how the _____ has ever thought about.
(24) _____ what the _____ the sculpture.
(25) _____ who _____ bake different kinds of bread.
(26) _____ why _____ benefited from.

F Comparing Automated Tree-Search Evaluation with Human Judgment

	Precision	Recall	Accuracy
Human	0.938	0.894	0.865
GibbsComplete	0.974	0.841	0.846
InfillT5	0.978	0.889	0.875
InfillBART	0.966	0.934	0.913
ILM	0.928	0.842	0.837

Table 2: Performance of tree search pattern-based evaluation by model types.

To show the effectiveness of Tregex-based automatic evaluation with hand-designed tree search pattern, we conduct a small-scale comparison of human evaluation of the targeted structure in a completion to an item of the syntactic reasoning test. We select a subset of completions generated by humans and models. For each model along with humans, we randomly choose two items out of each test and randomly select two completions to each of the item. There are 520 completions in total for us to annotate human judgment.

For each of the 520 completions, we evaluate whether it resolves the challenge associated with the particular test and annotate human judgment as binary outcome, with 1 indicating success and 0 indicating failure. During the annotation process, the human annotator was blind to the judgment of Tregex-based evaluation as well as which model the completion came from. Completions were also shuffled before the annotation. Table 2 shows that the tree search pattern-based evaluation generally aligns with human judgment with high accuracy for all models. Table 3 shows that tree search pattern-based automated evaluation result aligns with that of human judgments for most tests.

G Additional Results

G.1 Evaluation I

Table 4, 5, and 6 list one sampled completion for four selected items from the 30 stimuli used in Evaluation I. Completions in Table 4 are generated by pretrained/fine-tuned models. Completions in Table 5 are generated by models trained from scratch on `NYT`. Completionns in Table 6 are generated by models trained from scratch on `BLLIP`.

G.2 Evaluation II

Figure 8 shows model performance on each syntactic reasoning test. Figure 9 and Figure 10 show accuracies on each syntactic reasoning test and the aggregated performance respectively, based on results where the outputs of the directly-specialized models are composed with the reranking process of GibbsComplete with the same reranker.

G.3 Evaluation III

Figure 11 shows the comparison among GibbsComplete and other models with similar reranking process applied. The qualitative pattern is similar to those reported in Section 3.3. Figure 12, 13, and 14 plot the relative frequency of specific LCA category in human-written completions against that of model-generated completions, which are estimated from pretrained/fine-tuned models, models trained from scratch on `NYT`, and models trained from scratch on `BLLIP` respectively.

Test Index	Test Name	Precision	Recall	Accuracy
(1)	Number Agreement	0.875	0.875	0.800
(2)	Number Agreement (Long Subject)	0.938	0.882	0.850
(3)	Number Agreement (Embedded Clause)	1.000	0.900	0.900
(4)	Number Agreement (Coordination)	1.000	0.727	0.850
(5)	Number Agreement (with PP)	0.938	1.000	0.950
(6)	Clausal Structure	1.000	0.882	0.900
(7)	Clausal Structure (PP Adjunct)	0.950	1.000	0.950
(8)	Clausal Structure (Long Adjunct)	0.938	0.833	0.800
(9)	Clausal Structure (Complement)	1.000	0.944	0.950
(10)	Clausal Structure (Long Complement)	1.000	0.944	0.950
(11)	Gerund	0.846	0.733	0.700
(12)	Phrasal Verb	0.938	0.789	0.750
(13)	Phrasal Verb (with NP)	1.000	0.875	0.900
(14)	Resultative	1.000	0.938	0.950
(15)	Resultative (Long NP)	1.000	0.867	0.900
(16)	S Coordiation	1.000	0.789	0.800
(17)	VP Coordination	1.000	1.000	1.000
(18)	Embedded NP Coordination	1.000	0.500	0.700
(19)	Embedded VP Coordination	0.947	1.000	0.950
(20)	Coordination (either)	1.000	0.833	0.850
(21)	Coordination (neither)	0.727	0.667	0.650
(22)	Coordination in wh-clause	1.000	0.842	0.850
(23)	Filler-Gap (Adjunct)	0.941	0.889	0.850
(24)	Filler-Gap (Object)	1.000	1.000	1.000
(25)	Filler-Gap (Subject)	0.947	0.947	0.900
(26)	Filler-Gap (Phrasal Verb)	0.882	1.000	0.900

Table 3: Performance of tree search pattern-based evaluation by individual test.

	He is one of _____ jazz on a violin.
GibbsComplete	He is one of the few jazz musicians to have played jazz on a violin.
InfillT5	He is one of the first to play jazz on a violin.
InfillBART	He is one of the few people in the country with a master of jazz on a violin.
ILM	He is one of only three players to have taught jazz on a violin.
	Vineyards were found scattered throughout the region _____ visited grew any grapes.
GibbsComplete	Vineyards were found scattered throughout the region, but none of the vineyards she had visited grew any grapes.
InfillT5	Vineyards were found scattered throughout the region but no one ever visited grew any grapes.
InfillBART	Vineyards were found scattered throughout the region, but none of the farms I visited grew any grapes.
ILM	Vineyards were found scattered throughout the region, and once they had visited grew any grapes.
	The famous writer _____ a publisher to write two more books.
GibbsComplete	The famous writer, however, moved on and finally found a publisher to write two more books.
InfillT5	The famous writer, he said he is considering a bid from a publisher to write two more books.
InfillBART	The famous writer Ivanov has just been hired by a publisher to write two more books.
ILM	The famous writer Samuel Beckett became a publisher to write two more books.
	Giving up the violin _____ had predicted would have a promising career on the concert stage.
GibbsComplete	Giving up the violin, she asked her brother, Francis, who she had predicted would have a promising career on the concert stage.
InfillT5	Giving up the violin to pursue a more eminent musical career, he made Mr. Orbach a friend and friend who he had predicted would have a promising career on the concert stage.
InfillBART	Giving up the violin, she gave up her training to concentrate on her son's music studies, which she had predicted would have a promising career on the concert stage.
ILM	Giving up the violin he had predicted would have a promising career on the concert stage.

Table 4: Completions generated by pretrained/fine-tuned models for selected stimuli in Evaluation I.

	He is one of _____ jazz on a violin.
GibbsComplete	He is one of some of the most popular musicians in the history of jazz on a violin.
InfillT5	He is one of the best and brightest young singers, though the music is a bit of a sardonic evocation of jazz on a violin.
InfillBART	He is one of several young singers nominated for the prize, whether with a soloist or with the jazz on a violin.
ILM	He is one of four music students competing with jazz on a violin.
	Vineyards were found scattered throughout the region _____ visited grew any grapes.
GibbsComplete	Vineyards were found scattered throughout the region by people who pointed out that no one they visited grew any grapes.
InfillT5	Vineyards were found scattered throughout the region, and none of the pigs he visited grew any grapes.
InfillBART	Vineyards were found scattered throughout the region, and no one in the group of counties we visited grew any grapes.
ILM	Vineyards were found scattered throughout the region and not in as far north as the New Hampshire border, but the discovery of more vines than anyone else hasd visited grew any grapes.
	The famous writer _____ a publisher to write two more books.
GibbsComplete	The famous writer then told us that it would be a mistake for a publisher to write two more books.
InfillT5	The famous writer in the novel–"Fountains and Mysteries"–really was looking for a publisher to write two more books.
InfillBART	The famous writer who helped write "Municipal Bondage," she also said she had a intention of waiting for a publisher to write two more books.
ILM	The famous writer for The Times has a publisher to write two more books.
	Giving up the violin _____ had predicted would have a promising career on the concert stage.
GibbsComplete	Giving up the violin was a good example of what some critics had predicted would have a promising career on the concert stage.
InfillT5	Giving up the violin in his youth, he wore a long jacket and tie and was a fixture of a young man that he had predicted would have a promising career on the concert stage.
InfillBART	Giving up the violin part of the album, Mr. Carter, 61, earned a reputation as a musician who he had predicted would have a promising career on the concert stage.
ILM	Giving up the violin is the only kind of performance Mr. Levine had predicted would have a promising career on the concert stage.

Table 5: Completions generated by models trained from scratch on `NYT` for selected stimuli in Evaluation I.

	He is one of _____ jazz on a violin.
GibbsComplete	He is one of the few who think the big players are playing jazz on a violin.
InfillT5	He is one of the leading characters of jazz on a violin.
InfillBART	He is one of the few players to play jazz on a violin.
ILM	He is one of the most popular jazz on a violin.
	Vineyards were found scattered throughout the region _____ visited grew any grapes.
GibbsComplete	Vineyards were found scattered throughout the region and almost a third of the homes he had visited grew any grapes.
InfillT5	Vineyards were found scattered throughout the region, but the food I visited grew any grapes.
InfillBART	Vineyards were found scattered throughout the region, but neither those they visited grew any grapes.
ILM	Vineyards were found scattered throughout the region as soon as the trees visited grew any grapes.
	The famous writer _____ a publisher to write two more books.
GibbsComplete	The famous writer lives in Beverly Hills and is trying to persuade a publisher to write two more books.
InfillT5	The famous writer wants a publisher to write two more books.
InfillBART	The famous writer is a woman who has to get a book to get a publisher to write two more books.

Abstract

Non-autoregressive text to speech (NAR-TTS) models have attracted much attention from both academia and industry due to their fast generation speed. One limitation of NAR-TTS models is that they ignore the correlation in time and frequency domains while generating speech mel-spectrograms, and thus cause blurry and over-smoothed results. In this work, we revisit this over-smoothing problem from a novel perspective: the degree of over-smoothness is determined by the gap between the complexity of data distributions and the capability of modeling methods. Both simplifying data distributions and improving modeling methods can alleviate the problem. Accordingly, we first study methods reducing the complexity of data distributions. Then we conduct a comprehensive study on NAR-TTS models that use some advanced modeling methods. Based on these studies, we find that 1) methods that provide additional condition inputs reduce the complexity of data distributions to model, thus alleviating the over-smoothing problem and achieving better voice quality. 2) Among advanced modeling methods, Laplacian mixture loss performs well at modeling multimodal distributions and enjoys its simplicity, while GAN and Glow achieve the best voice quality while suffering from increased training or model complexity. 3) The two categories of methods can be combined to further alleviate the over-smoothness and improve the voice quality. 4) Our experiments on the multi-speaker dataset lead to similar conclusions as above and providing more variance information can reduce the difficulty of modeling the target data distribution and alleviate the requirements for model capacity.

1 Introduction

Non-autoregressive text to speech (NAR-TTS) models (Ren et al., 2019, 2020; Peng et al., 2020; Vainer and Dušek, 2020; Łańcucki, 2020; Kim et al., 2020; Miao et al., 2020) have shown much faster inference speed than their autoregressive counterparts (Wang et al., 2017; Shen et al., 2018; Ping et al., 2018), while achieving comparable or even better voice quality (Ren et al., 2019, 2020). The text-to-speech mapping can be formulated as a conditional distribution $P(y|x)$ where x and y are the text and speech sequences, respectively. Text-to-speech mapping is a one-to-many mapping problem (Wang et al., 2017), since multiple possible speech sequences correspond to a text sequence due to speech variations such as pitch, duration and prosody. Furthermore, speech mel-spectrograms are strongly correlated in time and frequency dimensions (see Section 2.1 for detailed analyses). Therefore, $P(y|x)$ is actually a dependent and multimodal distribution (Ling et al., 2013; Zen and Senior, 2014)[1].

Early non-autoregressive TTS models (Ren et al., 2019; Peng et al., 2020) use mean absolute error (MAE) or mean square error (MSE) as loss function to model speech mel-spectrograms, implicitly assuming that data points in mel-spectrograms are independent to each other and follow a unimodal distribution[2]. Consequently, the mel-spectrograms following dependent and multimodal distributions cannot be well modeled by the MAE or MSE loss, which presents great challenges in non-autoregressive TTS modeling and causes over-smoothed (blurred) predictions in mel-spectrograms (Vasquez and Lewis, 2019; Sheng and Pavlovskiy, 2019).

In this work, we conduct a comprehensive study on the over-smoothing problem in TTS. We find that the over-smoothness is closely related to the mismatch between the complexity of data distri-

butions (*e.g.*, dependent and multimodal distributions are more complex than independent and unimodal distributions) and the power of modeling methods (*e.g.*, simple losses such as MAE and MSE are less powerful than GAN or Glow-based methods). Both simplifying data distributions and enhancing modeling methods can alleviate the over-smoothing problem. From this perspective, we categorize recent methods combating over-smoothness into two classes: **1. Simplifying data distributions**: The data distribution $P(y|x)$ can be simplified by providing more conditional input information. We review two main methods: 1) Providing the previous mel-spectrogram frames $y_{<t}$ to predict current frame y_t, i.e., factorizing the complex dependent distribution $P(y|x)$ into a simpler conditional distribution $\prod_t P(y_t|y_{<t}, x)$, as used in autoregressive TTS models (Wang et al., 2017; Li et al., 2019). 2) Providing more variance information v^{3} such as pitch, duration, and energy to predict mel-spectrogram in parallel, i.e., modeling $P(y|x, v)$ rather than $P(y|x)$, as done in some non-autoregressive TTS models (Ren et al., 2020; Łańcucki, 2020). **2. Enhancing modeling methods**: Generally speaking, the modeling method should be powerful enough to fit complex data distributions. We review methods based on different distribution assumptions, including Laplacian mixture loss, structural similarity index (SSIM) (Wang et al., 2004) loss, generative adversarial network (GAN) (Lee et al., 2020) and Glow (Kim et al., 2020).

By studying those methods, we have the following findings. We hope that our studies and findings can inspire the community to design better models for TTS.

- By either autoregressive factorization or providing more variance information as input, complex distributions can be simplified to be less dependent and multimodal, which clearly alleviates the over-smoothing problem and improves the generated voice quality. Among them, providing more variance information such as FastSpeech 2 enjoys the advantages of fast generation due to its non-autoregressive nature.

- Enhanced modeling methods outperform MAE in synthesized voice quality. Laplacian mixture loss significantly improves the quality of generated mel-spectrograms and enjoys the simplicity of modeling. GAN and Glow achieve the best quality under both subjective and objective evaluations (since they make no assumptions about output distributions), but at the cost of increased training or model complexity.

- To further analyze the effectiveness of combining the basic ideas of the above two categories, we enhance FastSpeech 2 (considering its fast inference speed and good quality in the first category) with Laplacian mixture loss, SSIM, GAN and Glow, respectively. We find that the enhanced FastSpeech 2 generates speech with even better quality and the over-smoothing problem is further alleviated, which shows that the methods in the two categories are complementary to each other.

- We also extend our experiments to multi-speaker TTS task and obtain similar conclusions as above. Besides, we find that Glow has poor modeling ability in multi-speaker scenarios due to limited model capacity and more complex target data distributions compared with the single-speaker scenario, while it can be greatly alleviated by simplifying data distributions (introducing more variance information).

2 Preliminary Study

Text-to-speech mapping is a one-to-many mapping since multiple speech sequences can possibly correspond to a text sequence with different pitch, duration and prosody, making the mel-spectrograms distribution $P(y|x)$ multimodal. And due to the continuous nature of the mel-spectrograms, adjacent data points are dependent to each other. In this section, we first empirically characterize the distribution of $P(y|x)$ in TTS[4] through visualization (Section 2.1), and then provide a novel perspective to study the over-smoothing problem in TTS (Section 2.2).

2.1 Visualizations

We first visualize the distribution of $P(y|x)$ to see whether it is dependent and multimodal[5]. Denote

---

[3] The term "variance information" is first mentioned in FastSpeech 2 (Ren et al., 2020), which refers some speech-related conditional information

[4] In this work, we mainly focus on text (phoneme) to mel-spectrogram mapping, and leave mel-spectrogram to waveform mapping and text to waveform mapping to future work.

[5] We approximate the mel-spectrogram distribution on LJSpeech dataset. The detailed data processing procedure is the same as that in Section 3.2.

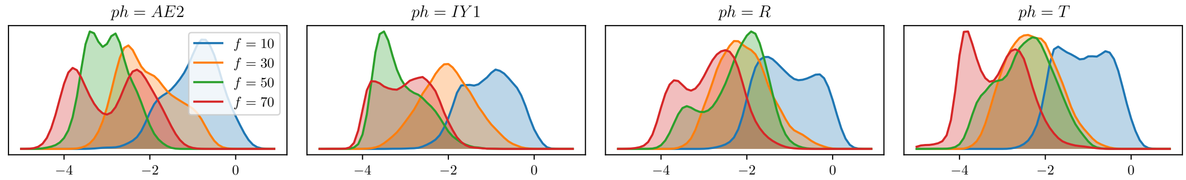

Figure 1: The marginal distributions $P(y(t, f)|x = ph)$ for several different phonemes. We choose 4 different phonemes ($ph = AE2, IY1, R, T$) and 4 frequency bins ($f = 10, 20, 50, 70$) in this case study. More marginal distributions are added in Appendix D.1.

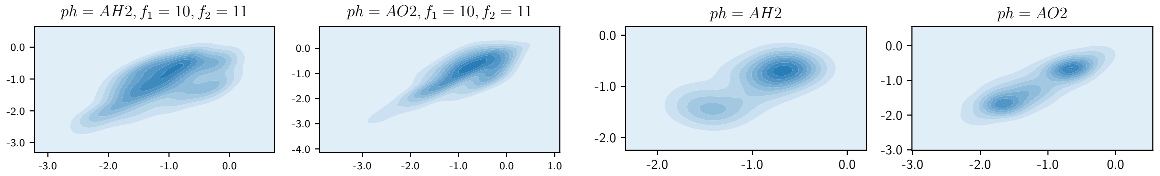

(a) (b)

Figure 2: Joint distributions of two data points in mel-spectrogram. (a) Along the frequency axis $P(y(t, f_1), y(t, f_2)|x = ph)$, where $f_1 = 10$ and $f_2 = 11$. (b) Along the time axis $P(y(t_1, f), y(t_2, f)|x = ph)$. We choose 2 phonemes ($ph = AO2, AH2$) in this visualization. More visualizations are included in Appendix D.1.

the data point in the t-th frame and the f-th frequency bin in the ground-truth mel-spectrogram as $y(t, f)$, where $t \in [1, T]$, $f \in [1, F]$, and T, F represent the total length and the number of frequency bins of mel-spectrograms respectively. Since different phonemes have different mel-spectrograms, we analyze the distribution of each phoneme separately. Specifically, for all the mel-spectrogram frames corresponding to each phoneme ph, we calculate three distributions: 1) marginal distribution $P(y(t, f)|x = ph)$; 2) joint distribution between two different frequency bins $P(y(t, f_1), y(t, f_2)|x = ph)$; 3) joint distribution between two different time frames $P(y(t_1, f), y(t_2, f)|x = ph)^6$. For each distribution, we first compute the histograms and smooth into probability density functions with kernel density estimation (Dehnad, 1987) for better visualization.

The marginal distributions $P(y(t, f)|x = ph)$ for several different phonemes are shown in Figure 1. It can be seen that the shape of the marginal distribution of each data point $y(t, f)$ in mel-sepctrogram is multimodal, especially for data points in high-frequency bins. The joint distribution $P(y(t, f_1), y(t, f_2)|x = ph)$ and $P(y(t_1, f), y(t_2, f)|x = ph)$ are shown in Figure 2a and Figure 2b, respectively. Obviously, those joint distributions are also multimodal and neighboring points in mel-spectrograms are strongly correlated. From these observations, we can see that the distribution $P(y|x)$ of mel-sepctrograms is multimodal and dependent across time and frequency.

2.2 A Novel Perspective

Table 1: The two categories of methods to combat over-smoothness in TTS.

Categories	Methods
Simplifying data distributions	AR modeling (Li et al., 2019), FastSpeech 2 (Ren et al., 2020), FastPitch (Łańcucki, 2020)
Enhancing modeling methods	SSIM (Wang et al., 2004), Laplacian mixture, GAN (Lee et al., 2020), Glow (Kim et al., 2020)

The dependent and multimodal distribution of $P(y|x)$ increases the difficulty of TTS modeling and causes over-smoothing problem if it is not correctly handled. We provide a novel perspective to depict this problem: the degree of over-smoothness is closely related to the gap between the complexity of data distributions and the power of modeling methods. A larger gap between the power of a modeling method and the complexity of a data distribution results in more severe over-smoothing problem. Consequently, simplifying data distributions and enhancing modeling methods can alleviate the over-smoothing problem. From this perspective,

---

[6] We denote one of the frame index among all mel-spectrograms corresponding to the phoneme x as t_1 and set $t_2 = t_1 + 1$.

we list the methods to combat over-smoothness in two categories in Table 1.

In the following sections, we first explore the effectiveness of simplifying data distributions (Section 3) and then that of enhancing modeling methods (Section 4). Finally, we combine the basic ideas of these two categories to improve an existing model (Section 5.1) and conduct further exploration on the multi-speaker dataset (Section 5.2).

3 Simplifying Data Distributions $P(y|x)$

Simplifying data distributions $P(y|x)$ is usually achieved by providing more conditional input information in the TTS literature (Wang et al., 2017; Li et al., 2019; Ren et al., 2020)[7]. In this way, more conditional information in input can alleviate the one-to-many mapping issue, and thus the distribution becomes less multimodal and the correlation along time and frequency is reduced given more condition. There are mainly two methods to provide more conditional input information: 1) autoregressive factorization along the time (Wang et al., 2017; Li et al., 2019) or frequency axis; 2) providing more variance information to predict mel-spectrogram in parallel, as used in some non-autoregressive TTS models (Ren et al., 2020; Łańcucki, 2020). In this section, we first overview these two kinds of methods in detail and conduct the experiment analyses to measure their effectiveness in solving the over-smoothing problem.

3.1 Methods

In this subsection, we overview the two kinds of methods to simplify data distributions, including autoregressive factorization and providing more variance information as input.

Autoregressive Factorization The joint probability $P(y|x)$ can be factorized according to the chain rule in two ways along time and frequency dimensions respectively:

- $P(y|x) = \prod_{t=1}^{T} P(y_t|y_{<t}, x)$, where $y_{<t}$ is the proceeding frames before the t-th frame and T is the total frames.
- $P(y|x) = \prod_{f=1}^{F} P(y_f|y_{<f}, x)$, where $y_{<f}$ is the proceeding frequency bins before the f-th frequency bin and F is the total number of frequency bins (*e.g.*, 80).

More Variance Information Another way to simplify data distributions $P(y|x)$ is to provide more variance information v such as pitch, duration, and energy, to convert $P(y|x)$ into $P(y|x, v)$, as used in previous works (Ren et al., 2020; Łańcucki, 2020). In this way, the distribution becomes less multimodal and the correlation along time and frequency is reduced.

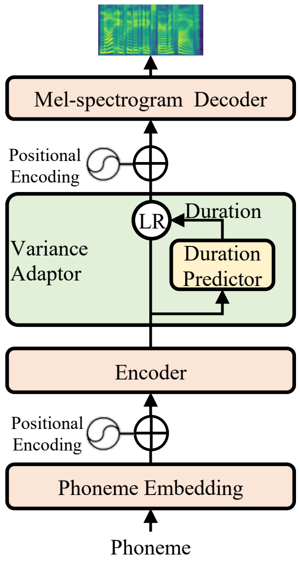

Figure 3: The overall architecture for our baseline model.

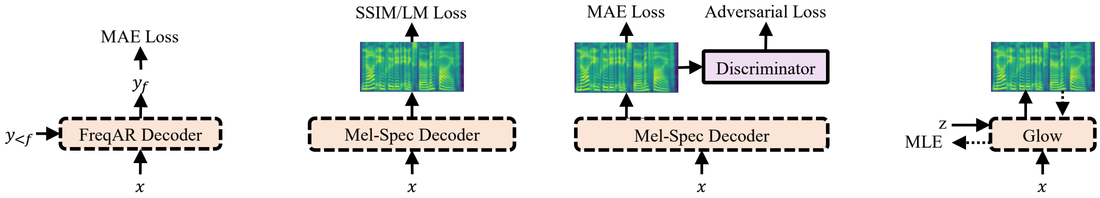
3.2 Experiments and Analyses

Experimental Settings We conduct all experiments[8] on LJSpeech dataset (Ito, 2017). We use ParallelWaveGAN (PWG) (Yamamoto et al., 2020) as the vocoder to convert mel-spectrograms to waveforms. To evaluate the voice quality of the synthesized speech subjectively, we conduct the MOS (Loizou, 2011) tests. To measure the degree of over-smoothness of mel-spectrograms objectively, we calculate the variation of the Laplacian (Pech-Pacheco et al., 2000) ($\mathrm{Var_L}$) on the generated mel-spectrograms and compare with that on the ground-truth mel-spectrograms. We use FastSpeech (Ren et al., 2019) trained with MAE loss as the baseline model as shown in Figure 3. For autoregressive modeling along time, we directly use TransformerTTS (Li et al., 2019). For

---

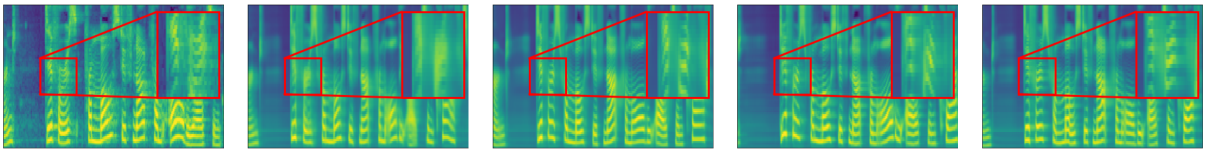
[7] Ren et al. (2019) use knowledge distillation to simplify the target mel-spectrogram itself, which also simplifies the data distribution but affects data quality as analyzed in Ren et al. (2020). Thus, we do not consider this method in our study.

[8] The corresponding audio samples are available at `https://revisittts.github.io/revisittts/`.



(a) Frequency-AR. (b) Simple losses. (c) GAN-based. (d) Glow-based.

Figure 4: The architecture of mel-spectorgram decoder used in each mel-spectrogram modeling method. All these methods use the same architectures of phoneme embedding, encoder and variance adaptor as the baseline model in Figure 3. x denotes the output hidden of the encoder.



(a) *GT* (b) *MAE* (c) *FreqAR* (d) *TimeAR* (e) *FastSpeech 2*

Figure 5: Visualizations of the ground-truth and generated mel-spectrograms by different methods for simplifying data distributions.

autoregressive modeling along frequency, we modify the vanilla mel-spectrogram decoder in baseline model to support autoregressive generation along frequency (which is called FreqAR decoder) and feed $y_{<f}$ to the FreqAR decoder to model $P(y_f|y_{<f})$ as shown in Figure 4a. For the method providing more variance information, we use FastSpeech 2 (Ren et al., 2020), which adds pitch, duration and energy information to the variance adaptor of the baseline model. We put more detailed model descriptions in Appendix A and experimental settings in Appendix B.

Table 2: Results for different methods for simplifying data distributions for TTS. The best scores are in bold.

Methods	MOS	Var_L
GT	4.18±0.08	0.367
GT (PWG)	3.90±0.08	/
MAE	3.64±0.10	0.072
FreqAR	3.80±0.09	0.175
TimeAR	3.81±0.08	**0.186**
FastSpeech 2	**3.83±0.09**	0.184

Results and Analyses We conduct MOS evaluation and compute Var_L to compare methods including the baseline model (denoted as *MAE*), autoregressive modeling along frequency (denoted as *FreqAR*) and along time (denoted as *TimeAR*) and *FastSpeech 2*. The results are shown in Table 2. We also visualize the mel-spectrograms generated by all modeling methods in Figure 5. From the results, we have some observations: 1) Autoregressive modeling along frequency (*FreqAR*) and time (*TimeAR*) dimensions both outperform *MAE* in terms of MOS and Var_L, which shows that simplifying data distributions using frequency or time dimension factorization can ease the over-smoothing problem. However, the autoregressive models suffer from slow inference. 2) FastSpeech 2 also greatly outperforms the baseline model, further indicating that simplifying data distributions by providing more variance information is another way to alleviate the over-smoothing problem. In conclusion, autoregressive modeling and providing more variance information can both simplify the complex distribution to be less dependent and multimodal and thus alleviate the over-smoothing problem. Besides, methods that provide more variance information such as FastSpeech 2 also enjoy the fast inference speed.

4 Enhancing Modeling Methods

Most previous non-autoregressive TTS models (Ren et al., 2019; Wang et al., 2019; Ren et al., 2020) use mean absolute error (MAE) or mean square error (MSE) as training loss. However, they fail to capture dependent and multimodal distributions. MAE loss is derived from the Laplace distribution and MSE from the Gaussian distribution (Chai and Draxler, 2014), which means minimizing MAE/MSE will maximize the data log-likelihood under a Laplace/Gaussian distribution. Both of these distributions are unimodal and thus encourage the model to predict a single mode in each data point. As a result, the model just learns an average of all modes, which leads to over-smoothed results. Another problem brought by MAE and MSE is that they are independent across time and frequency for mel-spectrogram output, which ignores the correlation across time and frequency axes in mel-spectrogram.

In this section, we first introduce several enhanced modeling methods to directly model the dependent and multimodal distribution $P(y|x)$ (Section 4.1), and then conduct experiments to compare and analyze these methods (Section 4.2).

4.1 Methods

We list the enhanced methods, including SSIM loss, Laplacian mixture loss, GAN[9] and Glow-based method and their distribution assumptions in Table 3. We put the details of each method in Appendix A.

Table 3: The distribution assumptions of different methods.

Assumptions	Modeling Methods
Independent & unimodal	Mean absolute error
Independent & multimodal	Laplacian mixture
No assumption	SSIM (Wang et al., 2004), GAN (Goodfellow et al., 2014), Glow (Kingma and Dhariwal, 2018)

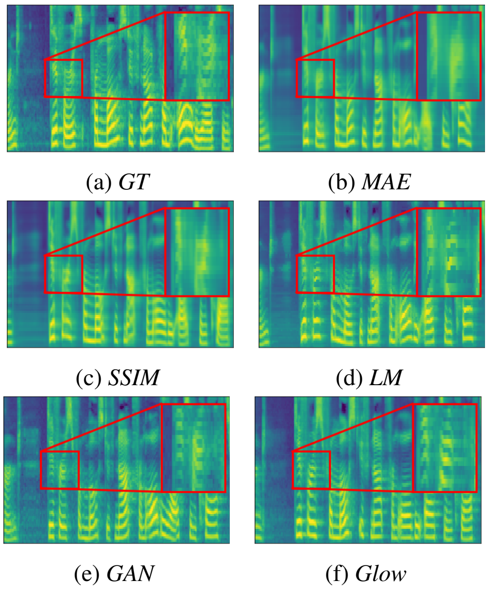
Structural Similarity Index (SSIM) Structural Similarity Index (SSIM) (Wang et al., 2004) is one of the state-of-the-art perceptual metrics to measure image quality, which can capture structural information and texture. The value of SSIM is between 0 and 1, where 1 indicates perfect perceptual quality relative to the ground truth. The model architecture of SSIM loss follows the baseline model in Figure 3 and we directly replace the MAE loss in the baseline model with SSIM loss as shown in Figure 4b.

Laplacian Mixture (LM) Loss Laplacian mixture loss[10] can model samples independently with multimodal distribution. As shown in Figure 4b, the basic architecture of mel-spectrogram decoder follows baseline model and we modify the output layer of the baseline model to predict the multimodal distribution of each mel-spectrogram bin.

Generative Adversarial Network (GAN) We introduce adversarial training to better model the dependent and multimodal distribution. Inspired by Wu and Luan (2020); Binkowski et al. (2020), we adopt multiple random window discriminators. We use the LSGAN (Mao et al., 2017) loss to train the TTS model and multi-window discriminators.

Glow Glow (Kingma and Dhariwal, 2018) is a kind of normalizing flow, which maps data into a known and simple prior (*e.g.*, spherical multivariate Gaussian distribution). As shown in Figure 4d, our Glow-based decoder models the distribution of mel-spectrograms conditioned on the encoder output hidden states x.

4.2 Experiments and Analyses



(a) *GT* (b) *MAE*
(c) *SSIM* (d) *LM*
(e) *GAN* (f) *Glow*

Figure 6: Visualizations of the ground-truth and generated mel-spectrograms by different modeling methods.

---

[9] Although GAN is well-known to suffer from the mode collapse issue, practically it performs very well in modeling the multi-modal distribution through well-tuning (Mao et al., 2017). GAN can avoid the average frame prediction in MAE loss that has a strong unimodal assumption, and can generate high-quality and reasonable results when the data distribution is multimodal. Therefore, we regard GAN as "no distribution assumption" method.

[10] We choose Laplace distribution as the mixture distribution since the distribution of the magnitude of spectrogram is Laplacian (Tits et al., 2019; Usman et al., 2018; Gazor and Zhang, 2003). We have also tried other mixture distributions (*e.g.*, mixture of logistic and mixture of Gaussian) and have similar findings.

The dataset, baseline model and evaluation metrics are the same as Section 3.2. We conduct MOS evaluation and compute $\mathrm{Var_L}$ to compare different modeling methods including MAE (denoted as *MAE*), Laplacian mixture loss (denoted as *LM*), structural similarity index (denoted as *SSIM*), generative adversarial network (denoted as *GAN*), Glow (denoted as *Glow*). The results are shown in Table 4. We also visualize mel-spectrograms generated by all modeling methods in Figure 6. From the results, we can find that:

Table 4: Results for different modeling methods for TTS. The best scores are in bold.

Methods	MOS	$\mathrm{Var_L}$
GT	4.18±0.08	0.367
GT (PWG)	3.90±0.08	/
MAE	3.64±0.10	0.072
SSIM	3.68±0.10	0.201
LM	3.72±0.08	0.296
GAN	3.76±0.08	**0.326**
Glow	**3.78±0.08**	0.310

1) *LM* and *SSIM* outperform *MAE* in terms of voice quality according to MOS evaluation and the mel-spectrogram visualizations, which shows that even simply replacing the loss function with those without strong unimodal and independent assumptions can significantly alleviate the over-smoothing problem and improve the generated mel-spectrograms. Among simple loss functions, *LM* performs the best and generates sharper and clearer mel-spectrograms since its $\mathrm{Var_L}$ is closer to *GT*, which demonstrates that Laplacian mixture loss can model the multimodal distribution well.

2) *GAN* and *Glow* show more superior performances compared with other modeling methods, indicating that modeling mel-spectrogram with both dependent and multimodal distribution can significantly ease the over-smoothing problem and improve the generated speech. From the visualizations, we can see that *GAN* and *Glow* generate formants with rich details in the middle/high-frequency region. However, GAN-based and Glow-based methods suffer from training complexity and large model footprint respectively: GAN relies on the discriminator to fit the distribution, which causes unstable training and difficult hyper-parameters tuning; Glow imposes strong architectural constraints and requires a large model footprint (about 2x model parameters) to keep the bijection between the simple independent latent distribution (*e.g.*, spherical multivariate Gaussian distribution) and the complex and dependent data distribution.

5 Further Explorations and Extensions

In this section, we first explore the advantages of combining methods from two categories and then perform extensional analyses on multi-speaker dataset.

5.1 Combining Methods from Two Categories

Table 5: Results of different models that combine the basic ideas of two categories. The best scores are in bold.

Methods	MOS	$\mathrm{Var_L}$
GT	4.27±0.10	0.367
GT (PWG)	4.00±0.10	/
FastSpeech 2	3.81±0.10	0.184
FastSpeech 2 + SSIM	3.84±0.09	0.205
FastSpeech 2 + LM	3.90±0.10	0.306
FastSpeech 2 + GAN	3.86±0.10	**0.341**
FastSpeech 2 + Glow	**3.92±0.10**	0.315

After studying the two categories to combat over-smoothing problems, we have demonstrated that both simplifying data distributions and enhancing modeling methods can alleviate this problem and improve the voice quality of TTS. A natural thought is to combine the methods from two categories, which may integrate the advantages of both aspects to reduce the gap between the complexity of data distribution and the power of the modeling method, resulting in better voice quality and further alleviating the over-smoothing problem. To demonstrate this idea, we choose the FastSpeech 2 as the model from the first category since it achieves better perceptual voice quality than autoregressive modeling models according to Table 2 and importantly, it enjoys the fast and robust inference advantages due to its non-autoregressive nature. Then we combine two categories by applying enhanced modeling methods to FastSpeech 2 and obtain the following systems: 1) *FastSpeech 2 + SSIM*, which replaces MAE loss with SSIM loss; 2) *FastSpeech 2 + LM*, which predicts the k-component mixture of Laplace distribution and uses LM loss for training; 3) *FastSpeech 2 + GAN*, which adds the adversarial loss to FastSpeech 2; and 4) *FastSpeech 2 + Glow*, which replaces the mel-spectrogram decoder with Glow. We conduct subjective and objective eval-

Table 6: Results for of different multi-speaker TTS models on multi-speaker dataset. The best scores are in bold.

Methods	MOS	$\mathrm{Var}_{\mathrm{L}}$
GT	3.97±0.13	0.338
GT (PWG)	3.67±0.10	/
FastSpeech	2.96±0.10	0.050
FastSpeech + GAN	3.14±0.15	0.251
FastSpeech + Glow	2.94±0.10	0.232
FastSpeech 2	3.18±0.16	0.132
FastSpeech 2 + GAN	**3.35±0.13**	0.257
FastSpeech 2 + Glow	3.30±0.12	**0.264**

uations to compare these combined systems with *FastSpeech 2*.

The results are shown in Table 5. We can see that combining FastSpeech 2 with more powerful modeling methods can further alleviate the over-smoothing problem in terms of $\mathrm{Var}_{\mathrm{L}}$ and improve the generated speech quality in terms of MOS, which demonstrate our idea that simplifying data distributions and enhancing modeling methods can be used together and it is complementary to each other to further improve TTS performance. Among these methods, *GAN* performs best in alleviating the over-smoothing problem and *Glow* achieves the best perceptual voice quality, while they suffer from the cost of increased training or model complexity as we described in Section 4.2; compared with *GAN* and *Glow*, *LM* can generate mel-spectrograms with comparable clearness and quality while enjoying its simplicity.

5.2 Analyses on Multi-Speaker Dataset

To demonstrate the generalization of our findings and provide more insights, we conduct experiments on a multi-speaker LibriTTS (Zen et al., 2019) dataset. We modify our models to support multiple speakers by adding speaker embeddings to the encoder outputs to indicate the speaker identity. We put more details of our multi-speaker TTS models and the dataset in Appendix C. We compare the following systems: 1) *FastSpeech*; 2) *FastSpeech + GAN*; 3) *FastSpeech + Glow*; 4) *FastSpeech 2*; 5) *FastSpeech 2 + GAN*; and 6) *FastSpeech 2 + Glow*. The results are shown in Table 6. We can see that 1) simplifying data distributions by providing more variance information and enhancing modeling method can alleviate the over-smoothing problem and improve the generated mel-spectrogram, and combining them together can achieve further better audio quality, which are consistent with the findings on single-speaker dataset. 2) *FastSpeech + Glow* leads to inferior performance compared with the baseline model (*FastSpeech*), because the multi-speaker dataset has more complex target data distributions and Glow requires a large model footprint to capture them as described in Section 4.2. When providing more variance information, *FastSpeech 2 + Glow* achieves much better performance, which can reduce the difficulty of modeling the target data distribution and thus alleviate the requirements for model capacity.

6 Related Works

Non-autoregressive Text to Speech Previous TTS systems such as Tacotron (Wang et al., 2017), Tacotron 2 (Shen et al., 2018), Deep Voice 3 (Ping et al., 2018) and TransformerTTS (Li et al., 2019) synthesize speech sequentially, which suffer from slow inference speed. To solve these shortcomings, various non-autoregressive TTS models are proposed to synthesize spectrogram frames in parallel. FastSpeech (Ren et al., 2019) and ParaNet (Peng et al., 2020) are early non-autoregressive TTS model which both adopt a fully parallel model architecture and rely on an autoregressive teacher model to provide the alignment between phonemes and mel-spectrograms. FastSpeech introduces knowledge distillation for mel-spectrograms to simplify data distributions. FastSpeech 2 (Ren et al., 2020) and FastPitch (Łańcucki, 2020) introduce more variance information as input to further reduce the output uncertainty and ease the one-to-many mapping problem. However, they are trained with MAE loss, which fits independent and unimodal Laplace distribution and results in blurry and over-smoothed mel-spectrograms in inference. SpeedySpeech (Vainer and Dušek, 2020) use the combination of MAE and structural similarity index (SSIM) losses to avoid blurry mel-spectrograms. Glow-TTS (Kim et al., 2020) and Flow-TTS (Miao et al., 2020) both use flow-based decoder to apply some invertible transforms between mel-spectrograms and noise data sampled from simple distribution. Sheng and Pavlovskiy (2019) employ a cascaded Tacotron 2 and GAN pipeline to reduce the over-smoothness of synthesized speech. Multi-SpectroGAN (Lee et al., 2020) introduces generative adversarial network (GAN) and a multi-scale discriminator and is trained with only the adversarial feedback by conditioning hidden states with variance information (*e.g.*, duration, pitch and energy) to a discriminator. GAN and Flow-based methods can model dependent and multimodal distribution well, while they suffer from training or model complexity. In this work, we conduct systematic studies on several modeling methods in both NAR-TTS and AR-TTS from a novel perspective.

Handling Dependent and Multimodal Distributions Dependent and multimodal distributions increase the uncertainty for model training and lead to blurry results, which is observed in many generation tasks (Gu et al., 2018; Isola et al., 2017; Mathieu et al., 2016). There are some common ways to handle dependent and multimodal distributions: 1) using loss functions or modeling methods that can well fit the distributions; and 2) introducing some input variables or transforming the target data to simplify data distributions. In neural machine translation, Gu et al. (2018) tackle this problem by introducing knowledge distillation to simplify target data distributions and using fertilities extracted by an external aligner to directly model the nondeterminism in the translation process. In image translation task, Isola et al. (2017) compare the generated images by their proposed adversarial generative method with those generated by using MAE and MSE losses and conclude that adversarial loss can help avoid blurry results. In video prediction task, Mathieu et al. (2016) propose a multi-scale architecture, an adversarial training method, and an image gradient difference loss function to deal with the inherently blurry predictions obtained from the MSE loss function. However, there is no systematic analysis on multimodal and dependent distributions in TTS task as far as we know. In this paper, we conduct comprehensive analyses and studies on handling dependent and multimodal distributions in TTS from a novel perspective.

7 Conclusion

In this paper, we revisited the over-smoothing problem in TTS with a novel perspective: the degree of over-smoothness is determined by the gap between the complexity of data distribution and the capability of the modeling method. Under this perspective, we classified existing methods combating over-smoothness into two categories: simplifying data distributions and enhancing modeling methods, and conducted comprehensive analyses and studies on these methods. For simplifying data distributions, we found that both AR factorization and providing more variance information as input (*e.g.*, FastSpeech 2) can alleviate the over-smoothing problem, and FastSpeech 2 enjoys the advantage of fast generation over AR factorization. For enhancing modeling methods, we found that Laplacian mixture loss can improve the generation quality and enjoy its simplicity, while GAN and Glow can further achieve better quality at the cost of increased training or model complexity. Based on the above findings, we further combined these two categories of methods and found that the over-smoothing problem is further alleviated, and the generated speech quality is further improved, which shows that these two categories are complementary to each other. When performing our analyses on the multi-speaker dataset, we drew similar conclusions and found that providing more variance information can reduce the difficulty of modeling the target data distribution and alleviate the requirements for model capacity.

We hope that our studies can inspire the community and industry to develop more powerful TTS models. Besides, since we are the first to discuss the over-smoothing problem systematically in the speech domain. We hope our analysis methodology as well as the findings can be extended to other tasks and inspire other domains.

A Details in Modeling Methods

A.1 Baseline Model

Our baseline model is based on FastSpeech (Ren et al., 2019). The dimension of phoneme embeddings and the hidden size of the self-attention are set to 256; the number of attention heads is set to 2 and the kernel sizes of the 1D-convolution in the 2-layer convolutional network after the self-attention layer are set to 9 and 1, with input/output size of 256/1024 for the first layer and 1024/256 in the second layer; the output linear layer converts the 256-dimensional hidden states into 80-dimensional mel-spectrograms. The size of the phoneme vocabulary is 76, including punctuations. In the duration predictor, the kernel sizes of the 1D-convolution are set to 3, with input/output sizes of 256/256 for both layers and the dropout rate is set to 0.5.

A.2 Autoregressive Modeling along Frequency

Autoregressive modeling along frequency (denoted as FreqAR) factorizes $P(y|x)$ to $\prod_{f=1}^{F} P(y_f|y_{<f}, x)$, where $y_{<f}$ is the proceeding frequency bins before the f-th frequency bin and F is the total number of frequency bins (*e.g.*, 80). We implement FreqAR by adding an extra small LSTM to the top of the four feedforward Transformer blocks[11] as shown in Figure 7. For timestep $f = 1$, we set the input hidden h_0 of LSTM to the output hidden of the mel-spectrogram decoder q, which has a size of $T \times H$, where T is the total number of the frames, and H is the hidden size of the LSTM. For $1 < f < F$, we concatenate the previous output frequency bins y_{f-1} with the size of $T \times 1$ and q with the size of $T \times H$ along the channel axis and project the channel to H with a linear layer as the input hidden h_f of LSTM. The output hidden of LSTM is projected to o_f using another linear layer. Finally, we concatenate $y_1, y_2, ..., y_{80}$ along the channel axis and obtain the output mel-spectrogram. We train the FreqAR model with teacher forcing. In this work, we set H to 32.

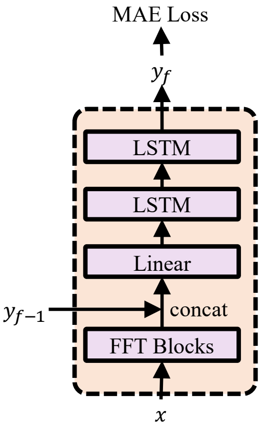

Figure 7: The architecture of the decoder for autoregressive modeling along frequency. “FFT blocks" denotes the feedforward Transformer Blocks (Ren et al., 2019).

A.3 Structural Similarity Index (SSIM)

Structural Similarity Index (SSIM) (Wang et al., 2004) is one of the state-of-the-art perceptual metrics to measure image quality, which can capture structural information and texture. The value of SSIM is between 0 and 1, where 1 indicates perfect perceptual quality relative to the ground truth. For each data point in predicted and ground-truth mel-spectrograms ($\hat{s} = \hat{y}(t, f)$ and $s = y(t, f)$), the SSIM value is computed as: $\mathrm{SSIM}(s, \hat{s}) = \frac{2\mu_s\mu_{\hat{s}}+C_1}{\mu_s^2+\mu_{\hat{s}}^2+C_1} \cdot \frac{2\sigma_{s\hat{s}}+C_2}{\sigma_s^2+\sigma_{\hat{s}}^2+C_2}$, where μ_s and $\mu_{\hat{s}}$ denote the means for two regions, which are centered in s and $\hat{s}$ within a 2D-window with size (W, W) respectively, and we set W to 11; σ_s and $\sigma_{\hat{s}}$ are standard deviation for regions s and $\hat{s}$; $\sigma_{s\hat{s}}$ is the covariance of regions s and $\hat{s}$ and $C_1 = 0.0001$ and $C_2 = 0.0009$ are constant values for stabilizing the denominator. The SSIM loss for all mel-spectrogram data points $y(t, f)$ and $\hat{y}(t, f)$ is expressed as: $\mathcal{L}_{SSIM} = \frac{1}{TF} \sum_{t=1}^{T} \sum_{f=1}^{F} (1 - SSIM(y(t, f), \hat{y}(t, f)))$. The model architecture of SSIM loss follows the baseline model and we directly replace the MAE loss in the baseline model with SSIM loss as shown in Figure 4b.

A.4 Laplacian Mixture (LM) Loss

Laplacian mixture loss[12] can model samples independently with multimodal distribution. Let $\mathrm{La}(y; \mu, \beta)$ denotes the probability distribution function for a Laplace random variable y, where μ and β are the mean and average absolute deviation (MAD) of the Laplace distribution. The k-component mixture of Laplace distribution is defined as follows:

$$P(y(t, f)) = \sum_{k=1}^{K} \pi_k(t, f) \times \\ \mathrm{La}(y(t, f); \mu_k(t, f), \beta_k(t, f)),$$

where $\mu_k(t, f)$ and $\beta_k(t, f)$ are the mean and MAD of the distribution of the k-th Laplacian component. The log-likelihood loss under mixture of Laplace distribution is:

$$L_{LM} = -\frac{1}{TF} \sum_{t=1}^{T} \sum_{f=1}^{F} \log \left\{ \sum_{k=1}^{K} \pi_k \, \mathrm{La}(y(t, f); \mu_k, \beta_k) \right\}.$$

As shown in Figure 4b, the basic architecture of mel-spectrogram decoder follows baseline model and we modify the output layer of the baseline

---

[11] Since the time axis of mel-spectrogram has a variable length, we cannot model the autoregressive along frequency by regarding the time axis as the channel dimension and directly feeding the transposed mel-spectrogram into a causal decoder similar to that in TransformerTTS.

[12] We choose Laplace distribution as the mixture distribution since the distribution of the magnitude of spectrogram is Laplacian (Tits et al., 2019; Usman et al., 2018; Gazor and Zhang, 2003). We have also tried other mixture distributions (*e.g.*, mixture of logistic and mixture of Gaussian) and have similar findings.

model to predict $\mu_k(t,k), \sigma_k(t,k)$ and $\pi_k(t,k)$ for each component k in each mel-spectrogram bin located in (t,k). Then the model is optimized with L_{LM} loss only and we set $k = 5$. In inference, for each data point in the mel-spectrogram, we first choice the Laplacian component k according to the probability $\pi_1, ..., \pi_K$ and then sample it from the Laplacian distribution $\text{La}(y(t,f); \mu_k(t,f), \beta_k(t,f))$.

A.5 Generative Adversarial Network (GAN)

We introduce adversarial training to better model the dependent and multimodal distribution. Inspired by Wu and Luan (2020); Binkowski et al. (2020), we adopt multiple random window discriminators where the input mel-spectrogram is randomly clipped into 3 clips with different window lengths, and each clip is fed into one discriminator. The discriminator consists of a 3-layer 2D-convolutional network[13] with LeakyReLU activation, each followed by the batch normalization and dropout layer, and finally, an extra linear layer is added to project the hidden states to a probability to measure whether the input is a real mel-spectrogram sample. We use the LS-GAN (Mao et al., 2017) loss to train the TTS model G and multi-window discriminators D_1, D_2 and D_3: $L_{adv_D} = \sum_{i=1}^{3} \mathbb{E}_y(D_i(y) - 1)^2 + \mathbb{E}_{\hat{y}} D_i(\hat{y})^2, L_{adv_G} = \frac{1}{3}\sum_{i=1}^{3} \mathbb{E}_{\hat{y}}(D_i(\hat{y}) - 1)^2$, where $\hat{y}$ and y are the generated and ground-truth mel-spectrograms.

We use multiple random window discriminators to implement the generative adversarial network. The architecture of multiple random window discriminators is shown in Figure 8.

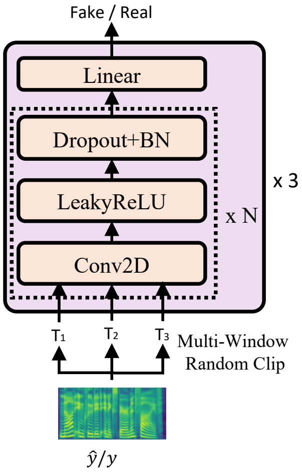

Figure 8: The architecture of multiple random window discriminators. $\hat{y}$ and y denote the predicted and the ground-truth mel-spectrogram respectively.

A.6 Glow

Glow (Kingma and Dhariwal, 2018) is a kind of normalizing flow, which maps data into a known and simple prior (*e.g.*, spherical multivariate Gaussian distribution). Glow is optimized with the exact log-likelihood of the data and as a generative model, it is very good at modeling all dependencies within very high-dimensional input data, which is usually specified in the form of a dependent and multimodal probability distribution. To make a fair comparison with other modeling methods, we only take the output hidden states of the encoder as the condition to each step of flows and use spherical Gaussian as the prior distribution like in the vanilla Glow (Kingma and Dhariwal, 2018). As shown in Figure 4d, our Glow-based decoder models the distribution of mel-spectrograms conditioned on the encoder output hidden states x. The Glow-based decoder is composed of k flow steps $\boldsymbol{f}_1, ..., \boldsymbol{f}_k$, each of which consists of an affine coupling layer, an invertible 1x1 convolution, and an activation normalization layer. Glow-based decoder maps the spherical Gaussian random variables $\boldsymbol{z}$ to the mel-spectrograms as

$$\boldsymbol{z} \sim \mathcal{N}(\boldsymbol{z}; 0, \boldsymbol{I}),\ y = \boldsymbol{f}_0 \circ \boldsymbol{f}_1 \circ \ldots \boldsymbol{f}_k(\boldsymbol{z}, x). \tag{1}$$

In training (dotted line in Figure 4d), we directly minimize the negative log-likelihood of the data, which can be calculated using a change of variables:

$$\boldsymbol{z} = \boldsymbol{f}_k^{-1} \circ \boldsymbol{f}_{k-1}^{-1} \circ \ldots \boldsymbol{f}_0^{-1}(y), \tag{2}$$

$$\log p_\theta(y|x) = \log p_\theta(\boldsymbol{z}) + \sum_{i=1}^{k} \log|\det(\boldsymbol{J}(\boldsymbol{f}_i^{-1}(y, x)))|, \tag{3}$$

where the first term in Eq. (3) is the log-likelihood of the spherical Gaussian, $\boldsymbol{J}$ is the Jacobian and θ is the parameters of the Glow-based mel-spectrogram decoder. In inference (solid line in Figure 4d), we sample $\boldsymbol{z}$ from the spherical multivariate Gaussian distribution and generate mel-spectrogram using Eq. (1).

---

[13] Through experiments, we find that the 2D-CNN-based network performs better than 1D-CNN in discriminator, especially for the reconstruction of high-frequency details.

The architecture of Glow-based modeling method is shown in Figure 9. We choose non-causal WaveNet (Van Den Oord et al., 2016) as the network in the affine coupling layers following Kim et al. (2020). We set the number of flow steps K to 24 and the layers of WaveNet to 4[14]. We also set the dilation of WaveNet to 1 since we do not need very large receptive fields as that used in vocoder.

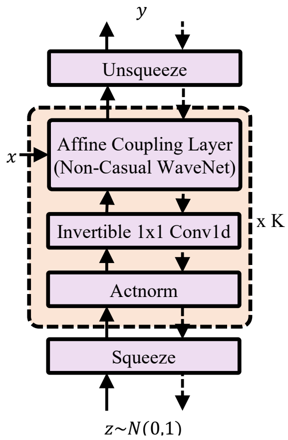

Figure 9: The architecture for Glow-based modeling method. The training and inference directions are represented with dotted and solid lines respectively.

B Experimental Settings

In this section, we describe detailed experimental settings including datasets, training and inference details and evaluation criterion.

Datasets We conduct all experiments on LJSpeech dataset (Ito, 2017), which contains 13,100 English audio clips (about 24 hours) of a single speaker and corresponding text transcripts. We split the dataset into three sets: 12,228 samples for training, 349 samples (with document title LJ003) for validation and 523 samples (with document title LJ001 and LJ002) for testing following Ren et al. (2020). We convert the text sequence into the phoneme sequence (Arik et al., 2017; Wang et al., 2017; Shen et al., 2018) with an open-source grapheme-to-phoneme tool[15] to alleviate the mispronunciation problem. The raw waveform is transformed into mel-spectrograms following Shen et al. (2018) and we set frame size and hop size to 1024 and 256 with respect to the sample rate 22050.

Training and Inference We train the model on 1 NVIDIA 2080Ti GPU, with batch size of 48 sentences. We use the Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.5$, $\beta_2 = 0.998$ and $\varepsilon = 10^{-9}$ which can stabilize the adversarial training. We follow the same learning rate schedule in Vaswani et al. (2017). It takes 160k steps for training until convergence, except Glow-based model, which needs 480k steps. In the inference process, the output mel-spectrograms are transformed into audio samples using pre-trained Parallel WaveGAN (Yamamoto et al., 2020)[16].

Subjective Evaluation To evaluate the perceptual quality, we conduct the MOS and CMOS (Loizou, 2011) tests. We randomly choose 30 samples from the test set for subjective evaluation. Twenty native English speakers are asked to make quality judgments about the synthesized speech samples. The text content keeps consistent among different systems so that all testers only examine the audio quality without other interference factors. For MOS, each evaluator is asked to mark the subjective naturalness of a sentence on a 1-5 Likert scale. For CMOS, listeners are asked to compare pairs of audio generated by systems A and B and indicate which of the two audio they prefer and choose one of the following scores: 0 indicating no difference, 1 indicating small difference, 2 indicating a large difference and 3 indicating a very large difference. The estimated hourly wage paid to participants is about $10 and we totally spent about $900 on participant compensation.

Objective Evaluation Pech-Pacheco et al. (2000) propose the variation of the Laplacian as a “blurriness metric" for images since the Laplacian filter can define edges well and blurry images barely have any edges while a well-focused (clear) image is expected to have a high variation of the Laplacian in grey levels. Inspired by their work, we introduce the variation of the Laplacian to mel-spectrograms and analyze its correlation with the smoothness. Specifically, the variation of the Laplacian $\mathrm{Var_L}$ is given by:

$$\mathrm{Var_L}(\bar{y}) = \sum_{t}^{T}\sum_{f}^{F}\left(|L(t,f)| - \frac{1}{NM}\sum_{m}^{M}\sum_{n}^{N}|L(m,n)|\right)^2$$

---

[14] The total number of parameters of Glow-based method (43M) is about twice that of other modeling methods (26M) and we find that the performance degrades when using the smaller model, indicating that the Glow-based modeling method requires a large model footprint to keep the bijection.

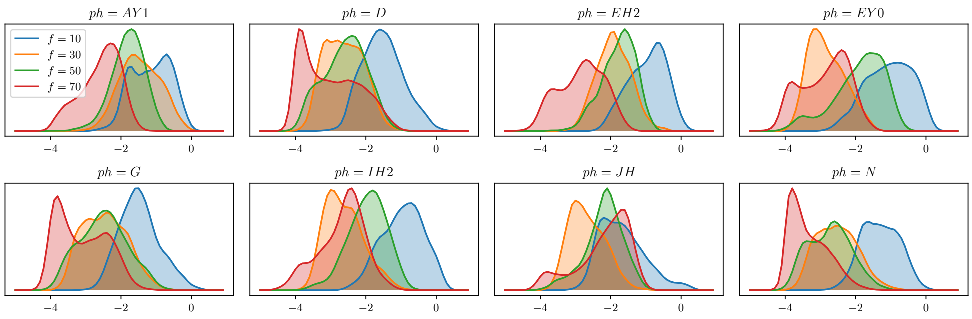

Figure 10: More marginal distributions mel-spectrogram $P(y(t, f)|x = ph)$ for several different phonemes ph.

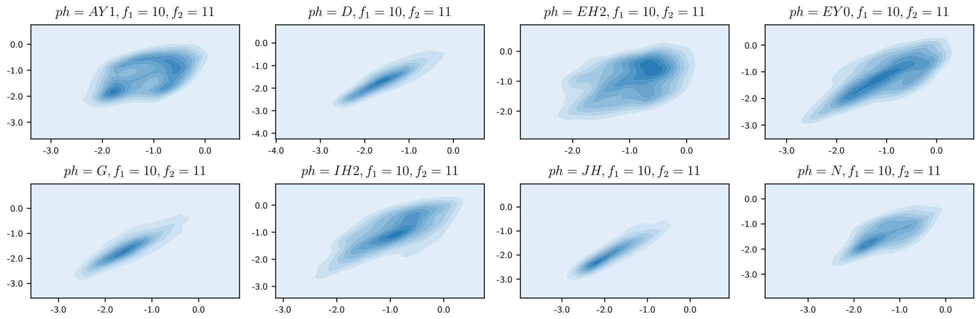

Figure 11: More joint distributions $P(y(t, f_1), y(t, f_2)|x)$ of two data points in mel-spectrogram along the frequency axis ($f_1 = 10$ and $f_2 = 11$).

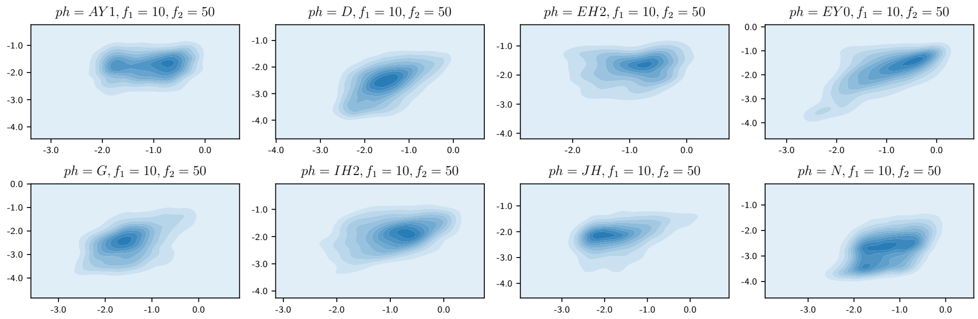

Figure 12: More joint distributions $P(y(t, f_1), y(t, f_2)|x)$ of two data points in mel-spectrogram along the frequency axis ($f_1 = 10$ and $f_2 = 50$).

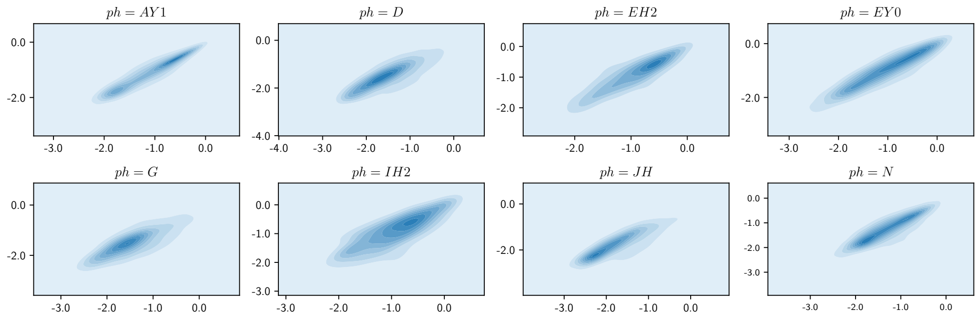

Figure 13: More joint distributions $P(y(t, f), y(t + 1, f)|x)$ of two data points in mel-spectrogram along the time axis.

where $L(t, f)$ is the convolution of the (predicted or ground-truth) mel-spectrogram $\bar{y}(t, f)$ with the Laplacian operation mask L defined as:

$$L = \frac{1}{6}\begin{pmatrix} 0 & -1 & 0 \\ -1 & 4 & -1 \\ 0 & -1 & 0 \end{pmatrix}.$$

The variation of the Laplacian increases with decreased smoothness of mel-spectrograms. We calculate the variation of the Laplacian $\mathrm{Var}_{\mathrm{L}}$ of the predicted mel-spectrogram and that of the ground-truth mel-spectrogram to see how close they are. We use an open-source tool[17] to compute $\mathrm{Var}_{\mathrm{L}}$.

C Experimental Settings for Multi-Speaker TTS

In this section, we describe the experimental settings for multi-speaker TTS (Section 5.2). We first introduce the dataset, and then describe the model details.

Dataset We conduct our experiments on the *train-clean-100* subset in LibriTTS (Zen et al., 2019), which contains about 54 hours speech audio samples and their corresponding text transcriptions. We choose the *train-clean-100* subset since the data in this subset is clean and the total time of speech audio in this subset is comparable with that in LJSpeech, which help us analyze the influence of multi-speaker setting while excluding the influence of training data size and noisy audio. These audio samples are recorded by 123 female speakers and 124 male speakers. We randomly choose 200 audio samples as the validation set, 200 of them as the test set and the rest of them as the training set.

Model Details Based on the single-speaker baseline model described in Section 3.2, to introduce the speaker identity information into our model, we add an extra speaker embedding module. We look up the speaker embedding from this module and add it to the encoder outputs. The hidden size of the speaker embedding module is the same as the encoder hidden size.

D More Analyses on Mel-Spectrogram Distributions

D.1 More Visualizations

We plot more marginal and joint distributions (along time and frequency) of mel-spectrogram in Figure 10, 11, 12 and 13.

D.2 Multimodality Evaluation on the Marginal Distributions

To further demonstrate that combination of the methods from two categories (FastSpeech 2 and other enhanced modeling methods) can alleviate the over-smoothing problem, we conduct Hartigan's dip test (Hartigan et al., 1985) on the marginal distributions $P(y(t,f)|x=ph)$ given f and ph to measure the degree of multimodality of each method. Specifically, we denote the dip test value given the distribution P as $\mathcal{D}(P)$ and a lower value means more multimodal. we calculate the $\mathcal{D}(\mathcal{P})$ under the marginal distributions $P(\bar{y}(t,f)|x=ph)$ and average $\mathcal{D}(\mathcal{P})$ under different ph and f to obtain the averaged dip test value $\bar{\mathcal{D}}$. We compute $\bar{\mathcal{D}}$ on the following systems: 1) *GT*, the ground-truth mel-spectrogram; 2) *MAE*, which is the baseline model as described in Section 3.2; 3) *FastSpeech 2* as described in Section 3.1; 4) *FastSpeech 2 + SSIM*, which replaces MAE loss with SSIM loss; 5) *FastSpeech 2 + LM*, which predicts the k-component mixture of Laplace distribution and is trained with LM loss; 6) *FastSpeech 2 + GAN*, which adds the adversarial loss to FastSpeech 2; and 7) *FastSpeech 2 + Glow*, which replaces the mel-spectrogram decoder with Glow.

Table 7: Results of different models combining the basic ideas of two categories. The best scores are in bold.

Methods	$\bar{\mathcal{D}}$
GT	0.049
MAE	0.064
FastSpeech 2	0.060
FastSpeech 2 + SSIM	0.058
FastSpeech 2 + LM	0.060
FastSpeech 2 + GAN	**0.054**
FastSpeech 2 + Glow	0.056

The results are shown in Table 7. We can see that all of these combined methods can increase the degree of multimodality of the marginal distributions $P(y(t,f)|x=ph)$ and GAN achieves the best $\bar{\mathcal{D}}$ among these methods, which is consistent with our findings in Section 5 that all the combined methods can alleviate the over-smoothing problem and GAN performs the best.

E Potential Negative Societal Impacts and Limitations

Although our analyses can inspire the community and industry to develop more powerful TTS models, it may result in unemployment for people with related occupations such as broadcaster and radio host. Besides, powerful TTS systems may be used in non-consensual voice cloning and fake media

---

[17] `https://github.com/petronav/Blur_Detection/blob/master/Variance_of_Laplacian/blur_check_vol.py`

generation, which might be harmful to society. As for the limitation, we combine existing methods to build a better TTS system rather than proposing a brand new text-to-speech model.

F Ethics Statement

F.1 For every submission

F.1.1 Did you discuss the *limitations* of your work?

Yes. See Appendix E.

F.1.2 Did you discuss any potential *risks* of your work?

Yes. See Appendix E.

F.1.3 Do the abstract and introduction summarize the paper's main claims?

Yes. See abstract and Section 1.

F.2 Did you use or create *scientific artifacts*?

No.

F.3 Did you run *computational experiments*?

Yes.

If yes:

F.3.1 Did you report the *number of parameters* in the models used, the *total computational budget* (e.g., GPU hours), and *computing infrastructure* used?

Yes. See Section 3.2 and Appendix B.

F.3.2 Did you discuss the experimental setup, including *hyperparameter search* and *best-found hyperparameter* values?

Yes. See Section 3.2 and Appendix B.

F.3.3 Did you report *descriptive statistics* about your results (e.g., error bars around results, summary statistics from sets of experiments), and is it transparent whether you are reporting the max, mean, etc. or just a single run?

Yes. See Section 3.2, 4.2 and 5.1.

F.3.4 If you used existing packages (e.g., for preprocessing, for normalization, or for evaluation), did you report the implementation, model, and parameter settings used (e.g., NLTK, Spacy, ROUGE, etc.)?

Yes. See Appendix B.

F.4 Did you use *human annotators* (e.g., crowdworkers) or *research with human subjects*?

Yes.

If yes:

F.4.1 Did you report the full text of instructions given to participants, including e.g., screenshots, disclaimers of any risks to participants or annotators, etc.?

Yes. See Appendix B.

F.4.2 Did you report information about how you recruited (e.g., crowdsourcing platform, students) and paid participants, and discuss if such *payment is adequate* given the participants' demographic (e.g., country of residence)?

Yes. See Appendix B.

F.4.3 Did you discuss whether and how *consent* was obtained from people whose data you're using/curating (e.g., did your instructions explain how the data would be used)?

Yes. See Appendix B.

F.4.4 Was the data collection protocol *approved (or determined exempt)* by an ethics review board?

N/A.

F.4.5 Did you report the basic demographic and geographic characteristics of the *annotator* population that is the source of the data?

Yes, they are all native English speakers. See Appendix B.

Coherence boosting:
When your pretrained language model is not paying enough attention

Abstract

Long-range semantic coherence remains a challenge in automatic language generation and understanding. We demonstrate that large language models have insufficiently learned the effect of distant words on next-token prediction. We present *coherence boosting*, an inference procedure that increases a LM's focus on a long context. We show the benefits of coherence boosting with pretrained models by distributional analyses of generated ordinary text and dialog responses. It is also found that coherence boosting with state-of-the-art models for various zero-shot NLP tasks yields performance gains with no additional training.

1 Introduction

Language models (LMs) are commonly evaluated for their ability to generate, rank, or classify coherent spans of text. **Long-range semantic coherence** is a unifying feature of modern NLP benchmarks and applications, whether they are about producing short answers to questions, ranking answer choices by their consistency with world knowledge, or generating long responses.

Large nonspecialized LMs, such as GPT-2 and -3 (Radford et al., 2019; Brown et al., 2020), sometimes fail to understand or use the semantic link between a text and its prompt or long-range context (Fig. 1). Samples from these LMs have an unnaturally low density of words that require many tokens of context to predict (§4.1), and the scores that the models give to completions of prompts indicate that they are oversensitive to recent context (§5).

We hypothesize that these failures arise from modeling choices and distribution shift. Specifically, autoregressive LMs are typically fit to a multi-objective problem: simultaneously maximizing token likelihoods conditioned on many lengths of truncated context (§2.1). Yet, at generation or scoring time, likelihoods are conditioned on the entire prompt or previously generated string, specifically selected to be coherent or even guaranteed to influence the output. The two common solutions – finetuning models on one or multiple tasks (Khashabi et al., 2020; Sanh et al., 2022) and improving models or prompts to facilitate in-context learning (Brown et al., 2020; Schick and Schütze, 2021) – do not directly target the problem of long-range coherence.

This paper proposes **coherence boosting**, a simple inference-time procedure that increases the effect of distant words on predicted token distributions and is applicable in both generation and ranking settings. A pretrained model is viewed as an *ensemble* of experts that produce token distributions conditioned on varying lengths of context. These experts are log-linearly mixed to form a predictor that is superior to the base model (§2).

Coherence boosting greatly improves prediction of words that depend on a long context, as evidenced by state-of-the-art results on tasks specially meant to assess models' attention to distant words (§3). In generation of generic text and dialog responses, we show that coherence boosting brings the frequency of occurrence of such words close to that seen in natural text (§4). Beyond generation, we study diverse multiple-choice tasks (§5), in which examples are known to be highly coherent. Coherence boosting does not modify the base model and depends on a single parameter than can be estimated in one pass through a validation set, yet is a competitive adaptation algorithm.

1.1 Background and related work

Balance between satisfaction of short-range statistical constraints and maintenance of long-range structure was a central question of language generation long before neural language modeling. To compensate for the sparsity of the learning signal for long-range influences, n-gram models and

Figure 1: Next-token probabilities given by LMs (DialoGPT and GPT-2) conditioned on a long context and on a partial context. The top words in both distributions are incorrect, but a log-linear mixture of the distributions makes the correct word most likely. Sampling from such a mixture at each generation step (*coherence boosting*) improves the quality of output text (§4). (Dialog example constructed by the authors; other examples from OpenWebText.)

early neural language models used 'backing-off' schemes that interpolate between predictors with different context lengths (Chen and Goodman, 1996; Bengio et al., 2003). Neural language modeling brought a need for recurrent units with better numerical properties for propagating information over long distances (Hochreiter and Schmidhuber, 1997; Cho et al., 2014) and eventually saw the reintroduction of alignment variables (Brown et al., 1993) into generation in the form of attention (Bahdanau et al., 2015; Vaswani et al., 2017). Attention is at the core of Transformer LMs, including GPT.

Language models are being trained on and adapted to ever-longer input sequences (Beltagy et al., 2020; Zaheer et al., 2020; Roy et al., 2021; Press et al., 2022), but they remain undersensitive to distant content or syntax (Khandelwal et al., 2018; Sun et al., 2021) and are easily fooled by recency bias in few-shot prompts (Zhao et al., 2021) or multi-turn conversations (Sankar et al., 2019).

Recent work has continued to study inference-time procedures that prevent text sampled from LMs from degenerating into nonsense. Most of these procedures, such as tempered sampling and top-k/top-p truncation (Fan et al., 2018; Holtzman et al., 2019), independently modify the output distribution at each generation step to decrease its entropy and diminish its low-likelihood tail. Holtzman et al. (2019) and Meister and Cotterell (2021) found that such local modifications increase the quality of long generated sequences; we adopt and extend their methodology in §4.1.

For dialog systems, Li et al. (2016) propose a decoding scheme that maximizes a mutual information criterion, which explicitly optimizes for dependence of generated text on prompts – a special case of coherence boosting. In multiple-choice tasks, where a model must choose one of several given completions of a prompt, Brown et al. (2020) observe that selecting the completion that maximizes the conditional likelihood of the completion following the prompt often favors completions having high *unconditional* likelihood (likelihood following an empty or dummy prompt) and, for some tasks, chooses to divide the scores of candidate answers by their unconditional likelihoods. This is also a special case of coherence boosting.

Such scoring modifications are more thoroughly studied by Zhao et al. (2021); Holtzman et al. (2021). The latter attributes the problem to 'surface form competition': there are many variants of the correct completion that together may capture a large part of probability mass, but the form of the given answer choice alone is not the most likely. However, we show that other causes are at play: surface form competition is impossible when the completion is known to be a single token and the range of choices is the whole vocabulary (§3), and it is not applicable to open-ended generation (§4).

2 Coherence boosting

In this section, f is an autoregressive LM over a vocabulary V with learnable parameters θ, taking as input a variable number of tokens (up to a maximum context length M) and producing a vector of next-token likelihoods:

$$f(w_1, \ldots, w_n; \theta) \in \Delta(V), \quad w_1, \ldots, w_n \in V,$$

where $\Delta(V)$ is the probability simplex over V. We will write the w-th component of this output vector as a conditional likelihood, $f(w \mid w_1, \ldots, w_n; \theta)$.

We denote by f_k the model evaluated on only the *last* k input tokens, ignoring earlier tokens:

$$f_k(w_1, \ldots, w_n; \theta) := f(w_{n-k+1}, \ldots, w_n; \theta).$$

Coherence boosting for next-token prediction. *Coherence boosting* for a model f selects real-valued weights $\boldsymbol{\alpha} = (\alpha_1, \alpha_2, \ldots, \alpha_M)$ and produces a new language model f_{α}, defined by

$$\begin{aligned} &f_{\alpha}(w_1, \ldots, w_n; \theta) \\ &:= \operatorname{softmax}\left(\sum_{k=1}^{M} \alpha_k \log f_k(w_1, \ldots, w_n; \theta)\right), \quad (1) \end{aligned}$$

where log is taken element-wise, or, equivalently,

$$f_{\alpha}(w|w_1, \ldots, w_n; \theta) \propto \prod_{k=1}^{M} f_k(w|w_1, \ldots, w_n; \theta)^{\alpha_k}.$$

This is a weighted product-of-experts model, where the 'experts' are copies of the base model f evaluated on different context lengths.

Because evaluating f is expensive, we use sparse weights $\boldsymbol{\alpha}$, as the expression (1) depends only on those f_k for which $\alpha_k \neq 0$. In Fig. 1 and in the experiments, we allow $\boldsymbol{\alpha}$ to have only two nonzero entries: when computing likelihoods of words following a sequence of length n, we consider weighted products of $f_{\max} := f_n$ (the full context) and an f_k with $k \leq n$ (a short context, either of fixed length or decided by prompt structure as in §4.2).

As its name suggests, the form of coherence boosting in (1) bears a resemblance to log-linear boosting for multiclass classification (Friedman et al., 2000). However, our weak classifiers are pretrained and share all of their parameters, not obtained by an iterative procedure of training on reweighted data, and we permit negative weights.[1]

Coherence boosting for answer selection. In multiple-choice problems, a LM must choose the best answer following a context, which consists of a premise or passage followed by a shorter *premise-free context* (either a short phrase, such as "Answer:", that incites the LM to generate an answer in the right format, or a hypothesis that depends on the premise). The full context is the concatenation of the premise and the premise-free context (§E).

By the autoregressive factorization, the model f assigns conditional likelihoods to *sequences* of tokens following context. A typical model for answer selection ranks the candidate answers a_i (sequences of tokens) by $f(a_i \mid \text{full context}; \theta)$ and outputs the highest-ranked a_i. *Coherence boosting* chooses a parameter α and ranks the choices by:

$$\begin{aligned} &\log f(a_i \mid \text{full context}; \theta) + \\ &+ \alpha \log f(a_i \mid \text{premise-free context}; \theta). \quad (2) \end{aligned}$$

This is a log-linear combination of two models: f evaluated with full context and with a partial context. When $\alpha = 0$, ranking by (2) is equivalent to ranking by the base model. When $\alpha = -1$, it is equivalent to dividing the base model's score by the score of each answer conditioned on the prompt (short context), and thus to maximizing pointwise mutual information between the premise and the answer conditional on the premise-free context. Unlike Brown et al. (2020); Holtzman et al. (2021), our formulation allows the premise-free context to include information specific to the example, not only a domain-specific dummy prompt.

We expect coherence boosting to correct for an oversensitivity to the premise-free context, and thus the optimal α will typically be negative (see §5).

2.1 Why should boosting models be better than full-length predictors?

Multi-objective training. As we will now see, the training of the model f simultaneously fits all of

---

[1] As for the first half of the term 'coherence boosting', Howcroft et al. (2020); Belz et al. (2020) found that very incoherent definitions of the word 'coherence' abound in the natural language evaluation literature. The reader is asked to forgive us for the loose definition of 'long-range semantic coherence' adopted in this paper.

the predictors f_k, which share parameters θ. Each training iteration samples a sequence (or batch of sequences) of a chosen maximum length $M + 1$ from the data distribution $\mathcal{D}$ and minimizes the average negative log-likelihood (NLL) of *all* words following the parts of the sequence that precede them: the optimization criterion is:

$$\mathbb{E}_{w_1 \dots w_{M+1} \sim \mathcal{D}} \frac{1}{M} \sum_{k=1}^{M} -\log f(w_{k+1}|w_1, \dots, w_k; \theta).$$

If $\mathcal{D}$ is uniform over all length-$(M + 1)$ subsequences of a training corpus, any given word is equally to likely to appear in all positions within a sampled sequence[2], and the criterion is equal to

$$\sum_{k=1}^{M} \frac{1}{M} \underbrace{\mathbb{E}\left[-\log f_k(w_{M+1}|w_1, \dots, w_M; \theta)\right]}_{\mathcal{L}_k(\theta)}, \quad (3)$$

This is a uniform scalarization of an M-task problem: the k-th objective $\mathcal{L}_k(\theta)$ is the expected NLL of a word in the corpus following k context words.

This situation is different from that seen at *generation* time. If the text generated so far is $w_1 w_2 \dots w_n$, the distribution from which the next word w_{n+1} is sampled is $f_n(w_1, \dots, w_n; \theta)$ – only the ensemble member using full context is used. However, if the string $w_1 \dots w_n w_{n+1}$ had been seen in training, f would have been trained to predict w_{n+1} given *all partial contexts*, with equal weight given to all prediction losses. Thus, f is trained to make predictions on data it never sees in evaluation, and may be prevented from optimally learning to use long context: parameters that locally optimize (3) are locally Pareto-optimal for the *set* of prediction losses $\mathcal{L}_1, \dots, \mathcal{L}_M$, but not necessarily optimal for any individual $\mathcal{L}_k$. An ensemble of the f_k ($k \le n$) may be a better predictor than f_n alone. (See §A for further analysis of when this occurs.)

Undertraining. The parameters θ are shared by the predictors f_k, and modeling power must be spread among the losses $\mathcal{L}_k(\theta)$. The short-context predictors are easier to fit, while sequences in which long context affects the prediction are rare. We expect sensitivity to long context, and precision in modeling its effect, to be especially diminished if the model is undertrained.

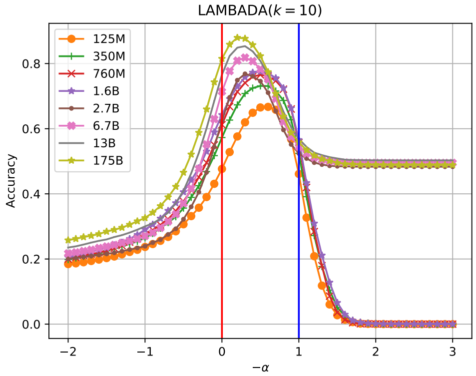

Figure 2: Model comparison on LAMBADA with $k = 10$ and varying α_k. The red line ($\alpha = 0$) is the base LM $f_{\max}$. (The different right tails of GPT-3 models are due to top-100 truncation of logits returned by the API.)

Distribution shift. While the training procedure causes a bias against the influence of longer contexts on generation, we see the opposite bias in downstream tasks (question answering, natural language inference, adversarial probes for common sense): Many modern NLP benchmarks try to challenge models to use long context (§3, §5).

3 Experiments: LAMBADA

The LAMBADA dataset (Paperno et al., 2016) tests LMs' understanding of long-range dependencies by measuring the prediction of the final words in passages of several sentences. The task explicitly requires reasoning over a broad context: humans can reliably guess the last word when given a whole passage, but not when given only the last sentence.

We perform experiments with the GPT family of models, closely replicating the evaluation setting of Radford et al. (2019).[3] We predict the final word as the top-ranked token under the boosted model $f_{\max} f_k^{\alpha_k}$, where $f_{\max}$ is the model taking the full available context and k, α_k are the chosen length and coefficient of the short context. To choose k and α_k, we do a grid search on the validation set and apply the best values to the testing set.

Results. Table 1 shows the accuracies and optimal parameter values k^*, α_k^*. Coherence boosting vastly reduces prediction error for all models. In particular, the boosted GPT-2 Small performs better than the original GPT-3 2.7B. The boosted GPT-3 175B achieves a new state of the art.

---

[2] Many authors leave unspecified the way in which training batches are formed from a corpus of input documents. Here we assume that all training documents are concatenated into one (very long) document separated by end-of-text tokens and ignore minute effects near the start and end of this document.

[3] Certain details are omitted by Radford et al. (2019). Based on `https://github.com/openai/gpt-2/issues/131`, we nearly match baseline accuracy by predicting the last subword token, rather than the last word.

	GPT-2				GPT-3			
	125M	350M	760M	1.6B	2.7B	6.7B	13B	175B
$f_{\max}$	47.66	57.29	61.23	64.25	62.39	71.40	76.58	81.51
CB ($\alpha_k = \alpha_k^*$)	66.70	73.53	76.54	77.53	77.00	81.84	86.36	88.61
α_k^*	−0.6	−0.5	−0.5	−0.5	−0.3	−0.3	−0.3	−0.2
k^*	10	11	10	9	9	10	3	3

Table 1: Accuracy (%) and optimal boosting parameters on LAMBADA: $f_{\max}$ is the full-context model without boosting; CB is our model with the optimal boosting parameters (last two rows).

Other than the impressive performance gain, we highlight two observations. **(1)** The optimal α_k is always negative, indicating that the optimal mixture of models penalizes the influence of short-range context relative to long-range context. **(2)** With increasing model size, the optimal α_k and k become closer to 0. This means that bigger models capture long-range coherence better than small models, as they have less need to penalize the effect of short context. (Fig. 2 shows the accuracy curves for all models by sweeping α_k with a fixed k. The peak clearly moves to the left as model size grows.)

4 Experiments: Language generation

4.1 Generic text

The experiment in this section extends that of Holtzman et al. (2019). A selection of 5000 articles from WebText (Radford et al., 2019) is taken as a reference corpus of human-written text. A language model (for us, GPT-2 Large) is prompted to generate text conditioned only on the *first sentence* of each of these articles, up to a maximum of 200 tokens, yielding 5000 machine-generated texts.

The human-written and machine-generated texts are compared by four automatic metrics: **perplexity** under the base LM, **self-BLEU-4** (Zhu et al. (2018); the mean BLEU-4 score of a generated text with respect to all other generated texts as references), **Zipf coefficient** (the linear regression coefficient between log-rank and log-frequency of generated tokens) and **repetition** (the fraction of generated texts that end in a repeating sequence of tokens). It is desirable for a model and inference procedure to produce text that is as close as possible in these metrics to the human-written reference.

To measure long-range semantic coherence in the generated text, we define three new metrics:

Long-range repetition (LR$_n$): For a whole number n and document D, let $S(D)$ be the number of distinct tokens in D, and let $R_n(D)$ be the number of distinct tokens for which the distance between their first and last occurrence in D is at least n positions. The long-range repetition score LR$_n$ of a corpus $\{D_1, \ldots, D_{5000}\}$ is a macro-average:

$$\mathrm{LR}_n := \frac{\sum_{i=1}^{5000} R_n(D_i)}{\sum_{i=1}^{5000} S(D_i)}.$$

This simple measure of lexical coherence favors repetition of words long after they are first used, but gives lower weight to documents that degenerate into repetition of a short span.

Long-dependent token frequency (LTF): A *long-dependent token* is one to which the base LM assigns a likelihood of at least 20% given its full context, but a likelihood of less than 5% given only the 20 tokens of context preceding it. We compute the frequency of long-dependent tokens among all generated tokens.

Long-short likelihood difference (δ): The mean difference in likelihoods assigned to tokens by the base LM conditioned on full context and conditioned on 20 tokens of context.

Although some choices of constants are needed to define **LTF** and δ, we intend them to be intuitive summaries of long-range coherence in the absence of established metrics. In particular, 20 tokens is close to the length of one sentence in typical English text.

We sample 5000 document completions from GPT-2 Large following sampling procedures with a range of boosting schemes. We consider models of the form $f_k^{\alpha_k} f_{\max}^{1-\alpha_k}$, for $k \in \{8, 16, 32, 64\}$ and $\alpha_k \in \{-0.4, -0.2, -0.1, -0.05, -0.025, 0\}$. (Such a parametrization of boosting parameters was chosen to ensure that when the context has length less than k – or the distant context has very little effect on the next word – the boosted model becomes equivalent to the untempered $f_{\max}$.) Top-p truncation with $p = 0.95$ is applied to all models.

	from Holtzman et al. (2019)				lex coherence		long-dep tokens

Human	13.19	0.31	0.93	0.28	15.95	9.51	6.54	4.03

Table 2: Distributional metrics of WebText completions. The last four columns are measures of long-range coherence (§4.1). (Nearest-to-human values in **bold**, boosting models better than top-p sampling alone in *italics*.)

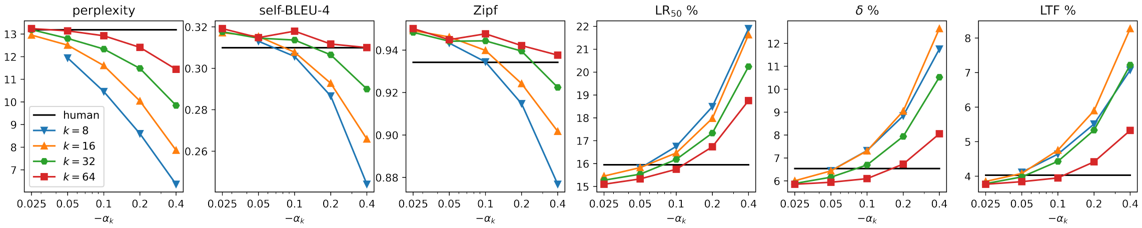

Figure 3: Effect of k and α_k on metrics from Table 2. The horizontal line marks the score of the human reference.

Results. Metrics of two of the best models, with $k = 32, \alpha_k = -0.05$ and $k = 64, \alpha_k = -0.1$, are shown in Table 2. In particular, the latter model generates text that is closer to the human reference, or equally close, to the pure top-p sampling ($\alpha_k = 0$) baseline in all metrics, with the greatest improvement seen in the coherence measures.

Fig. 3 shows the dependence of selected metrics on k and α_k. Coherence boosting brings all metrics closer to those of human text. As k increases, the optimal α_k grows in magnitude. This is expected: the predictive effect of tokens more than k positions away decreases with k (f_k approaches $f_{\max}$).

We also note that a simple sampling with temperature 0.9 performs better than top-p sampling in most of the coherence metrics. This suggests that the improvements accomplished by top-p truncation come at the cost of introducing a bias towards tokens that are predictable from a short context. Coherence boosting corrects this bias without sacrificing the gains in other measures.

An example of human, top-p, and coherence boosting outputs is shown in Table D.1.

4.2 Dialog systems

This experiment is based on the Dialog System Technology Challenge 7 (DSTC7) (Galley et al., 2019), which benchmarks generation of dialog responses conditioned on one or more turns of conversation context. As a base model, we use DialoGPT (Zhang et al., 2020c), a GPT-2 Small variant that demonstrated strong results on this task.

Dialog systems' responses to the 2208 conversation prompts[4] are scored against human-written reference responses (five for each example). Following Zhang et al. (2020c), we use the n-gram overlap metrics **NIST** (Doddington, 2002), **BLEU** (Papineni et al., 2002), and **METEOR** (Lavie and Agarwal, 2007), as well as two intrinsic measures of n-gram diversity from Li et al. (2016); Zhang et al. (2018): **Distinct-n** and **Entropy-n**. It is desirable for a dialog system to reach scores close to those of the human responses in all metrics.

In addition to the decoding algorithms considered by (Zhang et al., 2020c) – beam search and greedy decoding – we consider greedy decoding with a coherence boosting model. As long and short predictors, we use DialoGPT conditioned on the full conversation context and on *only the (context-free) response generated so far*. That is, if the conversation context is S and the text generated so far is $w_1 \dots w_k$, then w_{k+1} is predicted using the model $f_{\max} f_{k+1}^{\alpha}$, evaluated on the string S ⟨sep⟩ $w_1 \dots w_k$, where ⟨sep⟩ is the turn separa-

---

[4] The DSTC7 evaluation data, scraped from Reddit, is undisclosed; we reacquire it using officially released code.

	NIST		BLEU			diversity metrics

Table 3: Metrics of DialoGPT responses on DSTC7. Nearest-to-human values in each column are **bolded**.

tor token. We consider $\alpha \in \{0, -0.1, \ldots, -0.8\}$.

Results. Table 3 shows the metrics of the boosting models that reach the peak average NIST and BLEU scores ($\alpha = -0.3$ and $\alpha = -0.7$). Increasing the magnitude of α leads to responses that are more relevant to the prompt (higher BLEU and NIST) and more diverse than those from greedy decoding. As $-\alpha$ grows large, the boosting model favors creative responses that are relevant to the prompt (high NIST), but simple responses that are common in the reference data become unlikely (low BLEU).[5]

We observed that the responses with $\alpha = -0.7$, despite the superior metrics, are more likely to be ungrammatical and innovate words in an effort to use tokens relevant to the prompt. In practice, improving dialog systems with coherence boosting may require techniques to prevent these side effects, such as repetition penalties or relaxation of greedy decoding to low-temperature sampling.

Finally, we note that the learning of DialoGPT was initialized with a pretrained GPT-2 and uses GPT-2's end-of-text token as the turn separator. This choice may reduce DialoGPT's attention to past turns, as tokens *preceding* the end-of-text token are never informative in GPT-2's training data.

5 Experiments: Language understanding

We evaluate coherence boosting on zero-shot language understanding and inference tasks, where examples are expected to be highly coherent.

We study 15 datasets in 5 categories of tasks. **(1) Cloze tasks**: *StoryCloze* (Mostafazadeh et al., 2016), *HellaSwag* (Zellers et al., 2019), and *COPA* (Roemmele et al., 2011). **(2) Question answering**: *CommonsenseQA* (CsQA) (Talmor et al., 2019), *OpenBookQA* (OBQA) (Mihaylov et al., 2018), *ARC Easy / Challenge* (ARC-E/C) (Clark et al., 2018), and *PIQA* (Bisk et al., 2020). **(3) Text classification**: *SST-2/5* (Socher et al., 2013), *TREC* (Voorhees and Tice, 2000), *AGNews* (Zhang et al., 2015). **(4) Natural language inference**: *RTE* (Dagan et al., 2005), *CB* (De Marneffe et al., 2019), and *BoolQ* (Clark et al., 2019). (5) **Fact knowledge retrieval**: *LAMA* (Petroni et al., 2019).

All tasks except LAMA are formulated as multiple-choice problems. We convert text classification and inference tasks to multiple-choice tasks by choosing meaningful answer words, e.g., "True"/"False". The prediction is made by selecting the choice with the highest LM likelihood.

For in-context learning of GPT models, prompt formats greatly impact performance. We follow previous work (Brown et al., 2020; Zhao et al., 2021; Holtzman et al., 2021) to create natural prompts to enlarge the effectiveness of in-context learning, but we do not aim to optimize the full and context-free prompt format: our goal is to evaluate coherence boosting models with a fixed prompt. The prompt formats we use are listed in Table E.1. As described in §2, within each prompt we identify a *premise-free context*, which is used as the context for the short-range model in coherence boosting.

For each dataset, we pick the optimal value α^* of the parameter α on the validation set and report the accuracy on testing set. (If no testing set is publicly available, we choose α on a subset of the training set and report the final number on the validation set.) Across all experiments, we do not put any few-shot examples in the prompt.

For the knowledge retrieval task, we follow Zhao et al. (2021)'s data split of LAMA and evaluate GPT models on facts whose missing answers are at the end of the sentence (to fit the nature of autoregressive language models). We limit the prompt length to be larger than 5 tokens and rerun the model from Zhao et al. (2021) on the new data.

---

[5] Galley et al. (2019) argue that NIST and diversity metrics are more informative measures than BLEU for multi-reference scoring, since BLEU favors systems that often produce responses with little relation to the prompt (e.g., "I don't know").

Table 4: Testing accuracy (%) of three representative GPT models on multiple-choice tasks. The first column for each model is the full-context model, the second is our model only when $\alpha = -1$ (a baseline), and the third column is our model with the optimal α chosen on a validation set. The fourth column shows this optimal value of α.

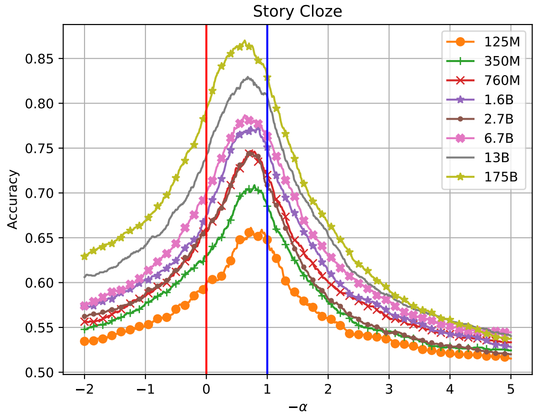

Figure 4: Model comparison for the StoryCloze task. The red line $\alpha = 0$ indicates the base model, and the blue line $\alpha = -1$ is an unconditional normalization. See Figs. F.1 and F.2 for plots for other tasks, and note that they do not all have the same shape.

Results: Multiple-choice tasks. Results of three representative base models on all multiple-choice tasks are presented in Table 4. (Results for all models are in Tables F.1 and F.2.) We compare our best model with two baselines, $\alpha = 0$ ($f_{\max}$) and $\alpha = -1$. The former one is the original full-context model, while the latter is, for most tasks, a form of unconditional probability normalization as performed by Brown et al. (2020); Holtzman et al. (2021). We also compare our best model with other inference methods (Holtzman et al., 2021; Min et al., 2021) in Tables F.3 and F.4.

By comparing the third column with the first two columns within each model in Table 4, we can see that our method with the selected α generally improves the accuracy on all tasks. Some of the improvements are dramatic, where boosted GPT-2 Small outperforms GPT-2 XL's base model (e.g., CsQA, OBQA, ARC-C) and is even comparable with GPT-3 175B's base model (e.g., SST-2, SST-5, RTE). We make similar conclusions when comparing coherence boosting with other inference methods in Tables F.3 and F.4.

We observe that the optimal α depends on tasks and models (fourth column within each model), which means that α cannot be heuristically set to 0 or −1 as in past work. This finding suggests the necessity of searching for an optimal α. We visualize the accuracy curve by varying α in the testing set of all datasets. We show the curve for StoryCloze in Fig. 4 and present similar figures for all tasks in Figs. F.1 and F.2.

Consistent with the results on LAMBADA (§3), the optimal α is usually negative, and its absolute value tends to decrease with the model size. We selected the optimal α by the validation set, but future work may explore automatic and adaptive methods for setting this parameter. Notice that all experiments required only a *single pass* through the data to compute answer likelihoods conditioned

	GPT-2				GPT-3

CB ($\alpha_k = \alpha_k^*$)	19.85	22.87	25.74	25.43	28.75	32.25	35.02	37.57
α_k^*	−0.5	−0.5	−0.5	−0.5	−0.5	−0.5	−0.5	−0.4
k^*	1	2	3	3	1	1	1	2

Table 5: Accuracies (%) of GPT models on LAMA.

on full and premise-free contexts – no iterative gradient-based finetuning was applied.

Results: Knowledge retrieval. Unlike LAMBADA, where long contexts are required for inferring the last word, LAMA contains much shorter sentences for knowledge facts, i.e., (subject, relation, object). A recent study (Cao et al., 2021) shows that the prediction is biased by the relation in the short context, i.e., the answer to a prompt (e.g., "Dante was born in ___") can be induced by the relation ("was born in") without the subject. Coherence boosting mitigates the influence of those short contexts by making the prediction dependent on a longer context containing the subject.

We present results for all models on LAMA in Table 5. We also compare our model with contextual calibration (CC) (Zhao et al., 2021), which processes the LM's output probabilities with a log-linear model.[6] Coherence boosting with the selected α and k outperforms both the base model and CC by significant margins.

6 Extensions and future work

We suggest three promising research directions:

Coherence tuning. The need to evaluate the base LM with multiple contexts in coherence boosting introduces cost and complexity at inference time. It may be desirable instead to modify the weights of the base model to improve long-range coherence properties. In §B, we describe a 'self-tuning' algorithm that achieves this *without training on any data created for this purpose*.

New domains and architectures. In this paper, we mainly considered coherence boosting with decoder-only Transformer LMs trained on generic text, but future work should consider other architectures and target domains. In §C, we give preliminary results on the *text summarization* domain.

Although we expect recency bias to be less pronounced in LMs that use separate attention modules to process the prompt and the output – such as encoder-decoder models for translation or summarization – procedures inspired by coherence boosting may prove effective in domains where a strong causal link between prompt and output is known to exist. Such domains include language generation conditioned on structured data (Yao et al., 2020; Mager et al., 2020; Moosavi et al., 2021) and model-guided reasoning in formal languages, such as proof or program synthesis (Polu and Sutskever, 2020; Chen et al., 2021; Li et al., 2022).

Efficient search proposals. Procedures that force LMs to be more focused on a prompt, or a specific part of it, when generating or ranking tokens can benefit algorithms that search for combinations of words through sampling. It would be interesting to use coherence boosting in non-autoregressive text generation algorithms, such as to accelerate the mixing of MCMC methods for constrained text generation (Miao et al., 2019; Zhang et al., 2020b; Malkin et al., 2021).

7 Conclusion

We have illustrated the hyposensitivity of pretrained language models to long-range context and proposed a simple inference-time remedy. We hope to see coherence boosting used as a simple alternative or complement to finetuning procedures in zero-shot applications of pretrained LMs.

Acknowledgments

The authors are grateful to Sudha Rao, Matt Richardson, and Huan Sun for valuable discussions about this project. We thank the anonymous reviewers for their comments and suggestions.

---

[6] Note that CC applies a log-linear model to the *probability* domain, not the logit domain, which does not have an information-theoretic interpretation.

Ethics statement

We hope and expect to see a nonnegative net societal impact from better text generation and ranking algorithms in general and from this work in particular. As we have shown, there is room to improve the inference procedures used with small language models, which incur lower costs than training and evaluation of large models. However, researchers should bear in mind the risks and potential misuse of automatic generation of long-form text.

A On multi-objective training and log-linear weights

The section extends the discussion in §2.1.

Recall that the language model f is trained on the multi-objective loss (3):

$$\sum_{k=1}^{M} \lambda_k \underbrace{\mathbb{E}_{w_1 \ldots w_{M+1} \in \mathcal{D}} \left[-\log f_k(w_{M+1} | w_1, \ldots, w_M; \theta) \right]}_{\mathcal{L}_k(\theta)}, \quad \lambda_k = \frac{1}{M}.$$

As we saw in the main text, the scalarization weights λ_k are uniform as a consequence of the training regime. However, evaluation procedures effectively give nonuniform weight to the M prediction losses.

Some vector calculus. Denote by $\hat{\theta}(\boldsymbol{\lambda})$ a local optimum of the above optimization problem for general linear combination weights $\boldsymbol{\lambda} = (\lambda_1, \ldots, \lambda_M)$. Under suitable regularity conditions, the gradient of the combined loss vanishes:

$$\sum_k \lambda_k \left. \frac{\partial \mathcal{L}_k(\theta)}{\partial \theta} \right|_{\theta = \hat{\theta}(\lambda)} = \mathbf{0}. \tag{4}$$

Assuming the Hessian $\mathbf{A}$ of the optimization criterion $\sum_k \lambda_k \mathcal{L}_k(\theta)$ is nonsingular, we can implicitly differentiate (4) with respect to $\boldsymbol{\lambda}$ to obtain the matrix derivative

$$\frac{\partial \hat{\theta}(\boldsymbol{\lambda})}{\partial \boldsymbol{\lambda}} = -\mathbf{A}^{-1} \left. \frac{\partial \left(\mathcal{L}_1(\theta), \ldots, \mathcal{L}_M(\theta) \right)}{\partial \theta^T} \right|_{\theta = \hat{\theta}(\lambda)}. \tag{5}$$

The local dependence of the losses on the scalarization weights can be expressed as a bilinear form evaluated on $\frac{\partial \mathcal{L}_i}{\partial \theta}$ and $\frac{\partial \mathcal{L}_j}{\partial \theta}$:

$$\frac{\partial \mathcal{L}_i(\hat{\theta}(\boldsymbol{\lambda}))}{\partial \lambda_j} = \left. \frac{\partial \mathcal{L}_i}{\partial \theta} \right|_{\theta = \hat{\theta}(\lambda)} \frac{\partial \hat{\theta}(\boldsymbol{\lambda})}{\partial \lambda_j} = - \left. \frac{\partial \mathcal{L}_i}{\partial \theta} \mathbf{A}^{-1} \frac{\partial \mathcal{L}_j}{\partial \theta^T} \right|_{\theta = \hat{\theta}(\lambda)}. \tag{6}$$

Because $\hat{\theta}$ is a local minimizer, $-\mathbf{A}^{-1}$ is negative definite. In particular, any $\frac{\partial \mathcal{L}_i(\hat{\theta}(\lambda))}{\partial \lambda_i}$ is negative. This expresses the intuitive fact that if an infinitesimally higher weight is given to some prediction loss in optimization, the value of this loss at the optimum will be infinitesimally lower.

For concreteness, consider how the highest-length prediction loss $\mathcal{L}_M(\hat{\theta}(\boldsymbol{\lambda}))$ changes when λ_M is increased and the λ_j ($j \neq i$) are decreased with rate proportional to λ_j, while $\sum \lambda_j$ is kept constant. That is, let $\boldsymbol{\beta} = \left(-\lambda_1, \ldots, -\lambda_{i-1}, \sum_{j \neq i} \lambda_j, -\lambda_{i+1}, \ldots, -\lambda_M \right)$. Then

$$\frac{d \mathcal{L}_i(\hat{\theta}(\boldsymbol{\lambda} + t\boldsymbol{\beta}))}{dt} = \sum_j \frac{\partial \mathcal{L}_i}{\partial \lambda_j} \beta_j = -\frac{\partial \mathcal{L}_i}{\partial \theta} \mathbf{A}^{-1} \sum_j \frac{\partial \mathcal{L}_j}{\partial \theta^T} \beta_j = -\frac{\partial \mathcal{L}_i}{\partial \theta} \mathbf{A}^{-1} \frac{\partial \mathcal{L}_i}{\partial \theta^T} \sum_j \lambda_j \leq 0, \tag{7}$$

where the last two equalities follow from (6) and (4), respectively, and the inequality holds because $\mathbf{A}^{-1}$ is positive definite. So we have shown that, in nondegenerate cases, the $\mathcal{L}_M(\theta)$ term of the optimization criterion decreases under the locally optimal weights θ when λ_M is infinitesimally increased in this way.

Log-linear mixture of predictors. Returning to coherence boosting, suppose that we aim to build out of the predictors $f_k(-; \widehat{\theta(\boldsymbol{\lambda})})$ a new predictor g that would have lower negative log-likelihood on prediction of a word given the maximum-length context:

$$\mathbb{E}_{w_1 \ldots w_{M+1} \in \mathcal{D}} \left[-\log g(w_{M+1} \mid w_1, \ldots, w_M) \right] < \mathbb{E} \left[-\log f_M(w_{M+1} \mid w_1, \ldots, w_M; \hat{\theta}(\boldsymbol{\lambda})) \right].$$

As we just saw, using this predictor in place of f_M achieves the same direction of movement in the prediction loss as optimizing with higher weight λ_M.

A naïve guess – not a proper predictor, as its outputs do not sum to 1 – would lightly perturb f_M by log-linearly mixing small multiples of the f_k weight weights β_k summing to 0:

$$g^{(t)}_{\text{naïve}}(w_1,\dots,w_M) = \exp\left(\log f_M(w_1,\dots,w_M;\hat{\theta}(\boldsymbol{\lambda})) + t\sum_k \beta_k \log f_k(-,\hat{\theta}(\boldsymbol{\lambda}))\right).$$

Then, by linearity of expectation,

$$\begin{aligned}\left.\frac{d}{dt}\right|_{t=0} \mathbb{E}\left[-\log g^{(t)}_{\text{naïve}}(w_{M+1}\mid w_1,\dots,w_M)\right] &= \sum_k \beta_k \mathbb{E}\left[-\log f_k(w_{M+1}\mid w_1,\dots,w_M;\hat{\theta}(\boldsymbol{\lambda}))\right]\\ &= \sum_k \beta_k \mathcal{L}_k(\hat{\theta}(\boldsymbol{\lambda})). \qquad (8)\end{aligned}$$

This quantity is negative if, for example, $\mathcal{L}_M(\hat{\theta}(\boldsymbol{\lambda}))$ is minimal among the $\mathcal{L}_k(\hat{\theta}(\boldsymbol{\lambda}))$.

Reintroducing the normalization condition, we define a candidate function $g^{(t)}$ as the normalization of $g^{(t)}_{\text{naïve}}$ over w_{M+1} and compute, with the aid of (8) and using that the g_k are normalized to simplify the derivative of $\log\sum\exp$:

$$\begin{aligned}&\left.\frac{d}{dt}\right|_{t=0} \mathbb{E}\left[-\log g^{(t)}(w_{M+1}\mid w_1,\dots,w_M)\right]\\ &= \sum_k \beta_k \mathcal{L}_k(\hat{\theta}(\boldsymbol{\lambda})) + \left.\frac{d}{dt}\right|_{t=0} \mathbb{E}\log\sum_w g^{(t)}_{\text{naïve}}(w\mid w_1,\dots,w_M)\\ &= \sum_k \beta_k \mathcal{L}_k(\hat{\theta}(\boldsymbol{\lambda})) + \mathbb{E}\sum_w \left\langle \sum_k \beta_k \log f_k(w_1,\dots,w_M;\hat{\theta}(\boldsymbol{\lambda})), f_M(w_1,\dots,w_M;\hat{\theta}(\boldsymbol{\lambda}))\right\rangle\\ &= \sum_k \beta_k \mathcal{L}_k(\hat{\theta}(\boldsymbol{\lambda})) - \sum_k \beta_k \mathbb{E}\left[D_{\text{KL}}\left(f_M(w_1,\dots,w_M;\hat{\theta}(\boldsymbol{\lambda})) \,\|\, f_k(w_1,\dots,w_M;\hat{\theta}(\boldsymbol{\lambda}))\right)\right], \qquad (9)\end{aligned}$$

where the last line used that $\sum\beta_k = 0$.

In practice, we are interested in sparse log-linear mixtures. Taking $\beta_M = 1, \beta_k = -1$ for a single k, and all other $\beta_i = 0$, we conclude that the boosted model proportional to $f_M^{1+t} f_k^{-t}$ is a better predictor than f_M alone if the difference between prediction losses $\mathcal{L}_M$ and $\mathcal{L}_k$ is greater than the average KL divergence between the predictions f_M and f_k.

B From coherence boosting to coherence tuning

As mentioned in the main text, algorithms that modify the weights of a pretrained LM to increase effect of distant words, mimicking coherence boosting, are an interesting direction for future work. Here we propose an algorithm, **coherence tuning**, that achieves this without training on any specialized data.

Initializing with the pretrained model $f(-|-;\theta)$, the algorithm iterates the following training steps to bring the LM closer to its coherence-boosted version f_α:

(1) Generate a sequence $w_1 \dots w_n$ from the current model $f(-|-;\theta)$.

(2) Compute all next-token distributions under the coherence-boosted version of the current model ($f_\alpha(w_1 \dots w_k;\theta)$) and under the current model without boosting ($f(w_1 \dots w_k;\theta)$).

(3) Gradient step on $\text{KL}(f_\alpha(w_1 \dots w_k;\theta) \| f(w_1 \dots w_k;\theta))$, where the first distribution f_α is treated as constant. This step may be restricted only to k near the end of the sequence.

We provide a batched implementation in Fig. B.1 in lieu of pseudocode. This coherence tuning code, which performs 32 gradient steps on batches of 32 sequences of length 32, runs in a few minutes on modern hardware, amortizing the overhead cost of coherence boosting while achieving comparable results on the WebText article completion task (second-to-last row of Table 2).

```python
from transformers import GPT2LMHeadModel
import torch

model = GPT2LMHeadModel.from_pretrained('gpt2-large')
model.eval()

batch_size = 32
max_length, k = 32, 16
alpha = -0.1
num_steps = 32

opt = torch.optim.SGD(model.parameters(), 1e-2)

for _ in range(num_steps):
    with torch.no_grad():
        x = model.generate(None, max_length=max_length,
                                 early_stopping=False,
                                 do_sample=True,
                                 num_return_sequences=batch_size,
                                 pad_token_id=50256)

    logits = model(x).logits[:, k:].log_softmax(2)
    logits_short = model(x[:, k:]).logits
    logits_cb = ((1-alpha)*logits + alpha*logits_short).log_softmax(2).detach()

    kl = -((logits-logits_cb) * logits_cb.exp()).sum(2).mean()

    opt.zero_grad()
    kl.backward()
    opt.step()
```

Figure B.1: Coherence tuning in PyTorch.

C GPT-2 summarization experiments

In §4 of the main text, we applied coherence boosting to generic text and dialogue response generation. Another interesting task that also requires long-range coherence is text summarization, in which the model is often expected to attend to the first few sentences to summarize a long article. Thus, we provide preliminary experiments for zero-shot abstractive summarization by applying our proposed method to GPT-2 models.

Experiment details. We take the two most popular summarization datasets, CNN/DM (See et al., 2017) and XSum (Narayan et al., 2018), where both contain recent articles and the summaries for the latter are more abstractive than the former. Following standard design (Radford et al., 2019), we append the tokens "TL;DR:" at the end of each article to induce summarization behavior of GPT models. We leverage the GPT-2 XL model and let it continue generating 100 tokens with greedy decoding. We take the first three sentences for CNN/DM articles and the first two sentences for XSum articles as their summaries. We use the preprocessed data and metric calculation from Zhong et al. (2020) and report the standard ROUGE scores in Table C.1.

To apply our proposed coherence boosting method, similarly to the method used for dialogue response generation, we define the short context as the newly generated text after the "TL;DR:" tokens. That is, at any time step during the summarization, the long context is the full article with the so-far generated summary, and the short context is only the generated summary.

Results. As we can see from Table C.1, our proposed CB method improves most of the metrics on both datasets. On the CNN/DM dataset, CB yields improvements of up to ~3 ROUGE points. We believe such a significant improvement is due to the article structure of the CNN/DM dataset. Specifically, the first three sentences in CNN/DM articles can provide pretty good summaries for a large portion of articles and have been considered as a very strong baseline for summarization models (Zhong et al., 2020). This

	CNN/DM			XSum		
	ROUGE-1	ROUGE-2	ROUGE-L	ROUGE-1	ROUGE-2	ROUGE-L
GPT-2 XL	26.671	7.792	23.926	21.346	**4.360**	16.880
CB, $\alpha = -0.1$	28.027	8.658	25.179	**21.580**	4.265	17.025

CB, $\alpha = -0.9$	29.481	9.109	25.990	19.387	3.195	15.256

Table C.1: Abstractive summarization performance with the GPT-2 XL model. The best performance is bolded and the second-best is underlined.

long-range information in the first few sentences is hard to capture for GPT models, and this difficulty can be alleviated by coherence boosting.

Such structure might be less pronounced in the XSum dataset, thus leading to a smaller improvement from coherence boosting. The difference between the datasets is also reflected in the best value of α. The optimal α for the CNN/DM dataset is around −0.5, while the best α for XSum is around −0.2, which indicates that boosting has less effect on XSum.

Finally, we note that the performance with GPT models presented here is far lower than that of state-of-the-art summarization-specific models, such as finetuned BART models (Lewis et al., 2020; Zhang et al., 2020a). We leave the use of coherence boosting with such encoder-decoder models to future work.

D Example WebText completion

An example of human, top-p, and coherence boosting outputs is shown in Table D.1. All outputs for all boosting schemes are included in the code repository.

Prompt	University of Alberta doctoral candidate Scott Persons measured the limb length for 53 different species of carnivorous dinosaurs to create an equation to score how much each was built for speed.
Human	A new study published out of the University of Alberta has found that carnivorous dinosaurs evolved to become faster and faster over time — and the proof is in the leg length. As part of his doctoral research, lead author Scott Persons travelled the world measuring the limb lengths for 53 different species of carnivorous bipedal dinosaurs, including the Velociraptor, Allosaurus and Tyrannosaurus rex. In particular, Persons looked at the length of the dinosaurs' legs below the knee. As a rule, he said, the longer the lower leg is in comparison to the upper leg, the faster the animal is. Modern-day cheetahs have proportionately longer legs than hyenas. That relationship is mirrored in the animals' speeds, Persons said. "That's true for modern carnivores, and must have been true for dinosaurs," Persons said in a statement released Wednesday.
Nucleus ($p = 0.95$)	"In a lot of areas of the world, dinosaurs at the time didn't have legs, they had weapons," said Persons. So he used his scientific skill, titled "Toill's Law of Tragedy," to give the dinosaurs an on-the-ground estimate of what their internal organs weighed. For example, wood-eating reptiles, such as the dinosaur Lufengosaurus and the ceratopsian Tyrannosaurus rex, would have weighed up to 52 kg (115 lbs) each. And as many as 50 plates should have been available to hunt, Persons said. But what's important is that a dinosaur's pack or herd probably wouldn't have been able to feed all three in one sitting. Dinosaurs were extremely resilient, as very few of them survived from one kill to the next and later on would start a "phased trip" back to where they'd been killed, Persons said.
+ boost ($k = 64$, $\alpha_k = -0.1$)	"In a lot of areas of the world, dinosaurs at the time didn't have legs, they had weapons," said Persons. So he used his undergraduate course to work on a formula to calculate a specific height for each carnivore based on the evolutionary requirements of different dinosaurs and when it would have been optimal for meat eating. He then moved that formula into his doctoral thesis project, which is looking at limb lengths for medium-sized, fearsome carnivores. "His thesis is about how to measure the shape of different places, plant diversity and evolutionary biology and kind of how we see dinosaurs and the relationships between species," said Susanne Dufoot, an associate professor of paleontology at McMaster University who recently returned from attending Persons' research. "It's interesting because he's basically done the legwork, developed this model that can give us information about plant species." 'He was an amazing creature'

Table D.1: Completions of an article: written by a human (original WebText) and sampled from GPT-2 Large with top-p sampling, with and without coherence boosting. While top-p sampling produces text that is coherent at first glance – it is free of repetition and nonce words – the topic of the article meanders from limb length to internal organs and killing, and nonsensical comments appear ('Toill's Law of Tragedy', herbivorous ceratopsian T-Rex, etc.). The output with coherence boosting is largely free of these issues, maintaining focus on limb length and diet.

E Prompt formats for multiple-choice tasks

Task	Prompt format
Story Cloze	[Context] [Completion]
HellaSwag	[Context] he/she/they/... [Completion]
COPA	[Premise] because/so [Hypothesis]
CommonsenseQA	[Question] the answer is: [Answer]
OpenBookQA	[Question] the answer is: [Answer]
ARC Easy	Question: [Question] Answer: [Answer]
ARC Challenge	Question: [Question] Answer: [Answer]
PIQA	Question: [Question] Answer: [Answer]
SST-2	[Context] This quote has a tone that is: [Label]
SST-5	[Context] This quote has a tone that is: [Label]
AGNews	Title: [Title] Summary: [Context] Topic: [Label]
TREC	[Question] The answer to this question will be [Label]
BoolQ	[Passage]\n Question: [Hypothesis] True or False? Answer: [Label]
RTE	[Premise]\n question: [Hypothesis] true or false?\n answer: [Label]
CB	Given question: [Premise] Is [Hypothesis] true, false or neither?\n The answer is: [Label]

Table E.1: Prompt formats used in our experiments. The full context is underlined in blue; the premise-free context is also underlined in red. We mainly draw inspiration from (Brown et al., 2020; Holtzman et al., 2021; Zhao et al., 2021) to make our prompts more natural to facilitate boosting the coherence of the completion.

Abstract

Uncertainty estimation (UE) of model predictions is a crucial step for a variety of tasks such as active learning, misclassification detection, adversarial attack detection, out-of-distribution detection, etc. Most of the works on modeling the uncertainty of deep neural networks evaluate these methods on image classification tasks. Little attention has been paid to UE in natural language processing. To fill this gap, we perform a vast empirical investigation of state-of-the-art UE methods for Transformer models on misclassification detection in named entity recognition and text classification tasks and propose two computationally efficient modifications, one of which approaches or even outperforms computationally intensive methods[1].

1 Introduction

Machine learning methods are naturally prone to errors as they typically have to deal with ambiguous and incomplete data during both training and inference. Unreliable predictions hinder the application of these methods in domains, where the price of mistakes is very high, such as clinical medicine. Even in more error-tolerant domains and tasks, such as intent recognition in general-purpose chatbots, one would like to achieve a better trade-off between expressiveness of a model and its computational performance during inference.

Since mistakes are inevitable, it is crucial to understand whether model predictions can be trusted or not and abstain from unreliable decisions. Uncertainty estimation (UE) of model predictions aims to solve this task. Ideally, uncertain instances should correspond to erroneous objects and help in *misclassification detection*. Besides misclassification detection, UE is a crucial component for active learning (Settles, 2009), adversarial attack detection (Lee et al., 2018), detection of out-of-distribution (OOD) instances (Van Amersfoort et al., 2020), etc.

Some classical machine learning models, e.g. Gaussian processes (Rasmussen, 2003), have built-in UE capabilities. Modern deep neural networks (DNNs) usually take advantage of a softmax layer, which output can be considered as a prediction probability and be used for UE. However, the softmax probabilities are usually unreliable and produce overconfident predictions (Guo et al., 2017). Some previously proposed techniques such as deep ensemble (Lakshminarayanan et al., 2017) are known for producing good UE scores but require a large additional memory footprint for storing several versions of weights and multiply an amount of computation for conducting several forward passes. Reliable UE of DNN predictions that does not introduce high computational overhead is an open research question (Van Amersfoort et al., 2020).

In this work, we investigate methods for UE of DNNs based on the Transformer architecture (Vaswani et al., 2017) in misclassification detection. We consider two of the most common NLP tasks: text classification and named entity recognition (NER). The latter has been overlooked in the literature on UE. To our knowledge, this work is the first to consider UE for NER.

We propose two novel computationally cheap methods for UE of Transformer predictions. The first method is the modification of the Monte Carlo dropout with determinantal point process sampling of dropout masks (Shelmanov et al., 2021). We introduce an additional step for making masks more diverse, which helps to

---

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 8237 - 8252

achieve substantial improvements and approach the performance of computationally-intensive methods on NER. The second method leverages Mahalanobis distance (Lee et al., 2018) but also adds a spectral normalization of the weight matrix in the classification layer (Liu et al., 2020). This method achieves the best results on most of the datasets and even outperforms computationally-intensive methods. We also investigate recently proposed regularization techniques in combination with other UE methods. The contributions of this paper are the following:

- We propose two novel computationally cheap modifications of UE methods for Transformer models. The method based on Mahalanobis distance with spectral normalization approaches or even outperforms strong computationally intensive counterparts.
- This work is the first to investigate UE methods on the NER task.
- We conduct an extensive empirical evaluation, in which we investigate recently proposed regularization techniques in combination with other UE methods.

2 Related Work

It is well known that reliable uncertainty scores can be obtained simply by constructing an ensemble of decorrelated neural networks (*deep ensemble*) (Lakshminarayanan et al., 2017). However, such a straightforward approach is coupled with substantial computational and memory overhead during training an ensemble, performing inference of all its components, and storing multiple versions of weights. This overhead is a serious obstacle to deploying ensemble-based uncertainty estimation methods in practice.

Uncertainty estimation is a built-in capability of Bayesian neural networks (Blundell et al., 2015). However, such models have similar issues as ensembles and also require special training procedures. Recently, it was shown by Gal and Ghahramani (2016) that dropout, a well-known regularization technique, is formally equivalent to approximate variational inference in a deep Gaussian process if it is activated during prediction. This method, known as Monte Carlo (MC) dropout, uses the approximating variational distribution with Bernoulli variables related to network units. MC dropout does not impose any overhead during training, introduces no additional parameters, and thus does not require any additional memory. The main disadvantage of this method is that it usually requires many forward-pass samplings for approximating predictive posterior, which makes it also computationally expensive.

Recently, many works have investigated the approximate Bayesian inference for neural networks using deterministic approaches: Lee et al. (2018); Liu et al. (2020); Van Amersfoort et al. (2020); Mukhoti et al. (2021); Shen et al. (2021), etc. These methods do not introduce notable overhead for inference, storing weights, and usually require compatible training time. However, most of the research in this area is accomplished for computer vision tasks.

For text classification, a series of works investigates UE methods for the OOD detection task (Liu et al., 2020; Podolskiy et al., 2021; Zeng et al., 2021; Hu and Khan, 2021). In this work, we focus on a more challenging task – misclassification detection. While OOD detection requires to model only the epistemic uncertainty inherent to the model and caused by a lack of training data, misclassification detection also requires to model aleatoric uncertainty caused by noise and ambiguity in data (Mukhoti et al., 2021). We consider recently proposed methods in this area that are evaluated in text processing.

Three recent works propose techniques for misclassification detection based on an additive regularization of a training loss function. Zhang et al. (2019) suggest adding a penalty that reduces the Euclidean distance between training instances of the same class and increases the distance between instances of different classes. He et al. (2020) suggest using two components in the loss function that reduce the difference between outputs from two versions of a model initialized with different weights. They also use mix-up (Thulasidasan et al., 2019) to generate additional training instance representations that help to capture aleatoric uncertainty, self-ensembling, MC dropout, and a distinctiveness score to measure the epistemic uncertainty. Xin et al. (2021) introduce a regularizer that penalizes overconfident instances with high loss. In another recent work, Shelmanov et al. (2021) propose to combine MC dropout with a Determinantal Point Process (DPP) to improve the diversity of predictions by considering the correlations between neurons and sampling the diverse neurons for activation in a dropout layer.

In this work, we conduct a systematic empirical investigation of UE methods on NLP tasks. We evaluate combinations of methods that have not been tested before and propose two modifications, one of which achieves the best results among computationally cheap methods. The previous work focuses on text classification tasks, while this work is the first to investigate UE also for NER.

3 Background and Methods

In this section, we describe the baselines and propose novel uncertainty estimation techniques.

3.1 Softmax Response

Softmax Response (SR) (Geifman and El-Yaniv, 2017) is a trivial baseline for UE that uses the probabilities generated via the output softmax layer of the neural network. SR is based on the maximum probability $p(y|x)$ over classes $y = c \in C$. The smaller this probability is, the more uncertain model is:

$$u_{\text{SR}}(x) = 1 - \max_{c \in C} p(y = c|x). \tag{1}$$

3.2 Monte Carlo Dropout

Standard Monte Carlo Dropout (MC Dropout) Consider we have conducted T stochastic forward passes with activated dropout. In this work, we use the following ways to quantify uncertainty with methods based on MC dropout:

- Sampled maximum probability (SMP) is:

$$u_{\text{SMP}} = 1 - \max_{c \in C} \frac{1}{T} \sum_{t=1}^{T} p_t^c, \tag{2}$$

  where p_t^c is the probability of the class c for the t-th stochastic forward pass.

- Probability variance (PV; Gal et al. (2017); Smith and Gal (2018)) is:

$$u_{\text{PV}} = \frac{1}{C} \sum_{c=1}^{C} \left(\frac{1}{T} \sum_{t=1}^{T} (p_t^c - \overline{p^c})^2 \right), \tag{3}$$

  where $\overline{p^c} = \frac{1}{T} \sum_t p_t^c$ is the probability for a class c averaged across T stochastic forward passes.

- Bayesian active learning by disagreement (BALD; Houlsby et al. (2011)) is:

$$u_{\text{BALD}} = - \sum_{c=1}^{C} \overline{p^c} \log \overline{p^c} + \frac{1}{T} \sum_{c,t} p_t^c \log p_t^c. \tag{4}$$

The two former techniques are specifically designed for estimation of the epistemic (model) uncertainty arising from the lack of knowledge and ignore the aleatoric uncertainty related to ambiguity and noise in the data, while the latter method can be seen as a measure of total uncertainty (Malinin and Gales, 2018).

Transformers contain multiple dropout layers (after the embedding layer, in each attention head, and before the last classification layer). It is shown in previous work that the standard MC dropout outperforms the baseline SR only when all dropout layers are activated in a model (Shelmanov et al., 2021). Therefore, we follow this setting for experiments in this work. We note that due to activating all dropout layers, multiple stochastic predictions are required for the whole network, which introduces a large computational overhead.

Similar UE scores are used in deep ensemble (Lakshminarayanan et al., 2017), where instead of multiple stochastic predictions we train and infer several model versions with different sets of weights.

Diverse Determinantal Point Process Monte Carlo Dropout (DDPP MC dropout) (Ours) Determinantal point processes (DPPs; Kulesza and Taskar (2012)) are used for sampling a subset of diverse objects from a given set. Recently, Shelmanov et al. (2021) have combined the MC dropout with a determinantal point process (DPP) for sampling neurons in a dropout layer and demonstrated that using stochasticity in the last dropout layer (in a classification head of Transformer) only is enough to improve upon SR in misclassification detection. This method is less computationally expensive than the standard MC dropout since it requires multiple stochastic predictions only for the top classification layer of the network with a small number of parameters, while all other layers are inferred only once.

Consider the similarity matrix C_h between neurons of the h-th hidden layer (in particular, we use a correlation matrix between output values of neurons on the training set). Then one can construct the DPP-based dropout masks M_h^{DPP} using C_h as a likelihood kernel for the DPP: $M_h^{DPP} \sim DPP(C_h)$. That gives the following probability to select a set S of activations on the layer h:

$$P\left[M_h^{DPP} = S\right] = \frac{\det(C_h^S)}{\det(C_h + I)}, \tag{5}$$

where C_h^S is the square submatrix of C_h obtained by keeping only rows and columns indexed by the sample S.

In this work, we improve this method by increasing the diversity of the sampled DPP masks. After multiple dropout masks are pre-generated via DPP in the inference step as in the original DPP MC dropout, we make an additional step, in which we select a diverse set of masks from this pre-generated pool using one of two strategies:

- **DDPP (+DPP)**: We sample a set of "diverse" masks that activate different sets of neurons. For this purpose, we apply DPP sampling again to the pool of pre-generated masks. As a similarity kernel in this step, we use an RBF-similarity matrix of mask vectors.
- **DDPP (+OOD)**: We sample a set of masks that generate diverse predictions. For this purpose, we select the masks that yield the highest PV scores on the given OOD dataset.

After a new set of T masks is selected, we use them as in the standard MC dropout to obtain stochastic predictions. Increasing the diversity of masks in the proposed modification is motivated by the finding of Jain et al. (2020) that improving the diversity of elements in an ensemble leads to better uncertainty estimates.

We note that in masks generated with DPP, usually, less than 50% of neurons are activated, which makes predictions poorly calibrated. To mitigate this problem, for each constructed mask, we perform a temperature-scaling calibration (Guo et al., 2017) using a held-out dataset.

3.3 Deterministic Uncertainty Estimation

Spectral-normalized Neural Gaussian Process (SNGP) Liu et al. (2020) suggest replacing the typical dense output layer of a network with a layer that implements a Gaussian process with an RBF kernel, whose posterior variance at a given instance is characterized by its L_2 distance from the training data in the hidden vector space constructed by underlying layers of a network. The authors propose an approximation based on random Fourier feature expansion, which enables end-to-end training and makes the inference feasible.

However, this method requires hidden representations to be distance-preserving in order to make it work. While the distance between instances in the hidden space does not always have a meaningful correspondence to the distance in the input space, authors prove that to keep hidden representations distance-preserving, the transformation should satisfy the bi-Lipschitz condition. For ResNets (He et al., 2016), this requirement is satisfied if weight matrices for the nonlinear residual blocks have a spectral norm (i.e., the largest singular value) bounded from above by a constant. Therefore, to enforce the aforementioned Lipschitz constraint, they apply a spectral normalization (SN) on weight matrices. For Transformers, they normalize the matrix of the penultimate classification layer only.

Mahalanobis Distance (MD) Mahalanobis distance is a generalisation of the Euclidean distance, which takes into account the spreading of instances in the training set along various directions in a feature space. Lee et al. (2018) suggest estimating uncertainty by measuring the Mahalanobis distance between a test instance and the closest class-conditional Gaussian distribution:

$$u_{\text{MD}} = \min_{c \in C} (h_i - \mu_c)^T \Sigma^{-1} (h_i - \mu_c), \quad (6)$$

where h_i is a hidden representation of a i-th instance, μ_c is a centroid of a class c, and Σ is a covariance matrix for hidden representations of training instances.

Recently, the Mahalanobis distance has been adopted for out-of-distribution detection with Transformer networks by Podolskiy et al. (2021).

Mahalanobis Distance with Spectral-normalized Network (MD SN) (Ours) Since the UE method based on the Mahalanobis distance utilizes the idea of a proximity of a tested instance hidden representation to the training distribution, we expect this method to benefit from distance-preserving representations. Therefore, we propose the modification of the method of Lee et al. (2018) and Podolskiy et al. (2021) that enforces the bi-Lipschitz constraints on transformation implemented by the network. We perform spectral normalization of the weight matrix of the linear layer in the classification head of Transformer as it is suggested in SNGP (Liu et al., 2020). At each training step, a spectral norm ν is estimated using the power iteration method $\nu = \|W\|_2$, and a normalized weight matrix is obtained: $\hat{W} = \frac{W}{\nu}$. At the inference step, hidden representations are calculated using the normalized matrix $\tilde{h}(x) = \tilde{W}x + b$ and are used for computing the Mahalanobis distance.

3.4 Training Loss Regularization

Additive regularization is another approach to improving UE of neural network predictions. Usually, the training loss combines the original task-specific loss L_{task} (e.g. cross-entropy) and a regularization component L_{reg} that facilitates producing better calibrated UEs:

$$L = L_{task} + \lambda L_{reg}, \tag{7}$$

where λ is a hyperparameter that controls the regularization strength.

The positive side of such techniques is that, besides SR, they can be used to improve other methods like MC dropout and deterministic methods. The drawback is that regularization affects the training procedure and can decrease the model quality.

Confident Error Regularizer (CER) Xin et al. (2021) propose a regularizer that adds a penalty for an instance with a bigger loss than other instances and, at the same time, bigger confidence:

$$L_{reg} = \sum_{i,j=1}^{k} \Delta_{i,j} \mathbb{1}[e_i > e_j], \tag{8}$$

$$\Delta_{i,j} = \max\{0, \max_c p_i^c - \max_c p_j^c\}^2, \tag{9}$$

where k is the number of instances in a batch and e_i is an error of the i-th instance: e_i is 1 if the prediction of the classifier matches the true label, and e_i is 0 otherwise. The authors evaluate this type of regularization only in conjunction with the SR baseline.

Metric Regularizer Zhang et al. (2019) propose a regularizer that aims to shorten the intra-class distance and enlarge the inter-class distance:

$$L_{reg} = \sum_{c=1}^{C} \Big\{ L_{intra}(c) + \varepsilon \sum_{k \neq c} L_{inter}(c,k) \Big\}, \tag{10}$$

$$L_{intra}(c) = \frac{2}{|S_c|^2 - |S_c|} \sum_{i,j \in S_c, i<j} D(h_i, h_j), \tag{11}$$

$$L_{inter}(c,k) = \frac{1}{|S_c| \cdot |S_k|} \sum_{i \in S_c, j \in S_k} [\gamma - D(h_i, h_j)]_+, \tag{12}$$

$$D(r_i, r_j) = \frac{1}{d} ||h_i - h_j||_2^2, \tag{13}$$

where h_i is a feature representation of an instance i from a penultimate layer of a model with a dimension d, S_c is the set of instances from class c, $|S_c|$ is the number of elements in S_c, ε and γ are positive hyperparameters, $[x]_+ = max(0, x)$.

4 Experimental Setup

In the experiments, we train a model on a given dataset and perform inference on a separate test set to compute both predictions and UE scores u. We are interested in how the scores correlate with the mistakes $\tilde{e}$ of the model on the test set. For text classification, mistakes are computed in the following way:

$$\tilde{e}_i = \begin{cases} 1, & y_i \neq \hat{y}_i, \\ 0, & y_i = \hat{y}_i, \end{cases} \tag{14}$$

where y_i is a true label, $\hat{y}_i$ is a predicted label.

For NER, we use two evaluation options: token-level and sequence-level. For the token-level evaluation, individual tokens are considered as separate instances as in the text classification. For the sequence-level evaluation, mistakes are computed in the following way:

$$\tilde{e}_i = \begin{cases} 1, & \exists j \in \{1, \ldots, n\}, \ y_{ij} \neq \hat{y}_{ij}, \\ 0, & \forall j \in \{1, \ldots, n\}, \ y_{ij} = \hat{y}_{ij}, \end{cases} \tag{15}$$

where n is a sequence length, y_{ij} is a true label, $\hat{y}_{ij}$ is a predicted label of a j-th token in a sequence. In the sequence-level evaluation, UE of a sequence is aggregated from UEs of tokens by taking maximum (for MD methods) or by summation (for others).

4.1 Metrics

El-Yaniv and Wiener (2010) suggest evaluating the quality of UE using the **area under the risk coverage curve (RCC-AUC)**. The risk coverage curve demonstrates the cumulative sum of loss due to misclassification (cumulative risk) depending on the uncertainty level used for rejection of predictions. The lower area under this curve indicates better quality of the UE method.

Xin et al. (2021) propose a **reversed pair proportion (RPP)** metric. They note that instances with higher confidence should have a lower loss l. RPP measures how far the uncertainty estimator $\tilde{u}$ is to ideal, given the labeled dataset of size n:

$$RPP = \frac{1}{n^2} \sum_{i,j=1}^{n} \mathbb{1}[\tilde{u}(x_i) > \tilde{u}(x_j), l_i < l_j]. \tag{16}$$

Table 1: Results for methods based on MC dropout and regularization techniques (ELECTRA model). The best results are shown in bold, the best results for each method are underlined.

This metric has an upper bound of 1; for convenience, the reported values are multiplied by 100. Similar to Xin et al. (2021), for both metrics, l is an indicator loss function.

We conduct each experiment six times with different random seeds, obtaining the corresponding metric values, and report their mean and standard deviation.

We also present the results using the **accuracy rejection curve**. This curve is drawn by varying the rejection uncertainty level (horizontal axis) and presenting the corresponding accuracy obtained when all rejected instances are labeled with an oracle (vertical axis). This emulates the work of a human expert in conjunction with a machine learning system. The higher the curve, the smaller amount of labor is needed to achieve a certain level of performance and the better is the UE method. A similar evaluation approach in a table form is used in (Zhang et al., 2019). A similar curve but without oracle labeling is used in (Lakshminarayanan et al., 2017; Filos et al., 2019).

4.2 Datasets

For experiments with text classification, we use three datasets from the GLUE benchmark (Wang et al., 2018) that were previously leveraged by Shelmanov et al. (2021) and Xin et al. (2021) for the same purpose: Microsoft Research Paraphrase Corpus (MRPC) (Dolan and Brockett, 2005), Corpus of Linguistic Acceptability (CoLA) (Warstadt et al., 2019), and Stanford Sentiment Treebank (SST-2) (Socher et al., 2013). Similar to (Shelmanov et al., 2021), we randomly subsample SST-2 to 10% to emulate a low-resource setting.

The experiments with NER were performed on the widely-used CoNLL-2003 task (Tjong Kim Sang and De Meulder, 2003). For this dataset, we also subsample the training part to 10%.

As an out-of-domain dataset for DDPP MC dropout, we use the IMDB binary sentiment classification dataset (Maas et al., 2011). We randomly select 5,000 instances from its test part and use them to select DPP-generated masks.

The dataset statistics are provided in Table 4 in Appendix A.

4.3 Model Choice and Hyperparameter Selection

For experiments, we use two modern Transformers: the pre-trained ELECTRA model (Clark et al., 2020) with 110 million parameters and DeBERTa (He et al., 2021) with 138 million parameters. They achieve higher performance on the GLUE benchmark in comparison with previous models, such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019).

The optimal hyperparameter values for each triple <Dataset, Regularization Type, Spectral Normalization Usage> are presented in Table 6

Table 2: Results of deterministic methods with different types of regularization (ELECTRA model). The best results are highlighted with the bold font, the best results for each method are underlined.

in Appendix A. For the optimal hyperparameter search, we split the original training data into training and validation subsets in a ratio of 80 to 20 and apply Bayesian optimization with early stopping. For text classification, we use *accuracy* as an objective metric, and for sequence tagging, we use *span-based F1-score* (Tjong Kim Sang and De Meulder, 2003). Sets of pre-defined values for each hyperparameter are given in the caption of Table 6. After the hyperparameter search is completed, we train the model on the original training set using the optimal values.

The hyperparameters for UE methods are presented in Table 9 in Appendix A. The values for the DDPP MC dropout and MD SN are chosen using a grid search, while validating on the held-out validation dataset with RCC-AUC as an objective. For deep ensemble, we use random subsampling of the training set with a fixed ratio of 90%.

The hardware configuration for experiments is provided in Table 5 in Appendix A.

5 Results and Discussion

5.1 Monte Carlo Dropout and Regularization

The results of methods based on MC dropout and loss regularization are presented in Table 1 (for ELECTRA). The standard computationally intensive MC dropout achieves big improvements over the SR baseline on all text classification datasets and the sequence-level CoNLL-2003 benchmark. For token-level CoNLL-2003, none of the considered methods substantially outperform the baseline. Uncertainty estimation scores BALD and PV have similar results, outperforming SMP on SST-2, while SMP has a slight advantage over them on CoLA and CoNLL-2003.

The DDPP MC dropout method does not outperform the MC dropout. However, DDPP (+DDPP) demonstrates a notable advantage over the SR baseline on text classification datasets SST-2 and CoLA, while both DDPP (+DDPP) and DDPP (+OOD) outperform the baseline on the sequence-level CoNLL-2003 benchmark. The main advantage of the proposed DDPP MC dropout method consists in its much faster inference compared to the computationally expensive standard MC dropout. The DDPP MC dropout has the same computational overhead during inference as the original DPP MC dropout, which is only less than 0.5% of the overhead introduced by the standard MC dropout (Shelmanov et al., 2021).

We conduct an ablation study of the proposed modifications for the original DPP MC dropout. The experimental results of this study presented in Table 12 in Appendix C demonstrate the benefits of using calibration and introducing diversity in mask generation.

Both metric regularization and CER achieve a substantial advantage over the baseline on text classification datasets SST-2 and MRPC. However, regularization appears to be malignant for NER. Adding loss regularization to MC dropout usually helps to achieve better results on text classification. The best results on SST-2 and CoLA are achieved using metric regularization, while the best result for MRPC is obtained using CER. Regularization and DDPP MC dropout usually complement each other, the results of their combination are slightly better than when they are applied individually for all datasets except CoNLL-2003.

5.2 Deterministic Methods

The results for deterministic methods are presented in Table 2 (for ELECTRA). SNGP gives substantial improvements on the text classification datasets MRPC and SST-2 but significantly falls behind the trivial baseline on CoNLL-2003. The low performance of SNGP for NER can be attributed to the fact that it is initially designed for classification

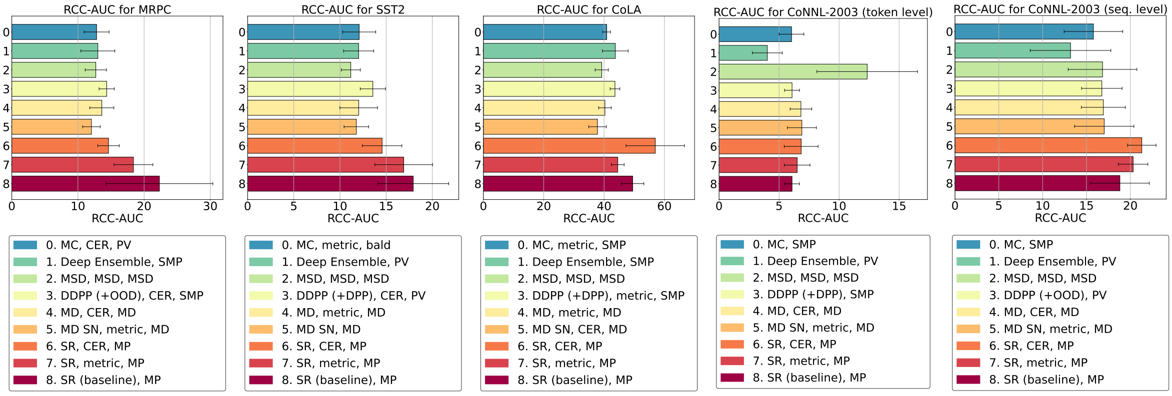
Table 3: Comparison of the best results for all methods (ELECTRA model). The computationally intensive methods are at the top of the table; the computationally cheap methods are at the bottom. The best results overall are highlighted with the bold font, the best results for computationally cheap methods are underlined.



a) MRPC b) SST2 c) CoLA d) CoNLL token. level e) CoNLL seq. level

Figure 1: RCC-AUC↓ of the best UE methods for the ELECTRA model.

tasks rather than sequence tagging. MD yields much bigger improvements over the SR baseline on all datasets and significantly outperforms SNGP. MD SN is able to improve the misclassification detection performance even further for MRPC, SST-2, and CoLA.

We also conduct an ablation study (Table 2), in which we use the spectral normalization without MD. We see that SN on its own, as expected, mostly does not improve the UE performance; the results usually are even slightly worse than the baseline.

Regularization also helps to improve the results of methods based on the Mahalanobis distance. For both MD and MD SN, regularization helps on CoLA and CoNLL-2003. For MD, it also helps on SST-2, while for MD SN, regularization improves the results on MRPC. We note that regularization reduces the gap between MD and MD SN on text classification datasets and even gives a slight advantage to MD over MD SN on CoNLL-2003.

The best results across all deterministic methods for text classification datasets are achieved by MD SN. The biggest improvements are obtained on MRPC, where regularized MD SN reduces RCC-AUC by more than 46% compared to the baseline.

5.3 Best Results

Table 3 and Figure 1 compare results of the best methods in each group for ELECTRA. Table 11 and Figure 3 in Appendix B show the best results for DeBERTa. In these tables and figures, we also present the results of deep ensemble (Lakshminarayanan et al., 2017), which is a strong yet computationally intensive baseline (Ashukha et al., 2020), and results of another recently proposed computationally intensive method called MSD (He et al., 2020) that leverage "mix-up" (Thulasidasan et al., 2019), "self-ensembling", MD,

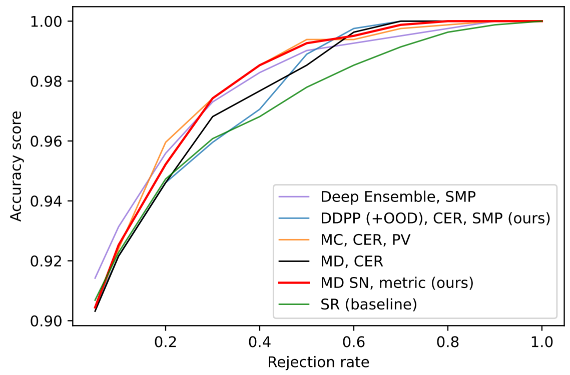


Figure 2: Median values of accuracy rejection curves for selected methods on MRPC (ELECTRA model).

and the MC dropout (all layers are activated).

We can see that it is possible to substantially improve misclassification detection performance and achieve even better results than MC dropout, deep ensemble, or MSD almost with no overhead in terms of memory consumption and amount of computation. For text classification and for both models, computationally cheap methods are either better or on par with the expensive counterparts. However, for NER, we see that the latter methods seriously fall behind deep ensemble and MC dropout. On the token-level CoNLL-2003 benchmark, only deep ensemble substantially outperforms the SR baseline. On the sequence-level CoNLL-2003 benchmark, MD with CER, DDPP (+DDP) PV, and DDPP (+OOD) PV improve upon SR, but only approach the performance of computationally intensive methods.

The proposed in this work MD SN method outperforms all other computationally efficient alternatives on text classification datasets. For both models, it even substantially outperforms all computationally expensive methods on the CoLA dataset, while on other text classification datasets it is on par with them. Another method proposed in this work, DDPP MC dropout, empowered with regularization techniques, is able to substantially reduce the gap between the SR baseline and computationally intensive UE methods, while introducing only a fraction of their overhead.

Figure 2 also presents accuracy rejection curves for selected methods on MRPC. The figure shows that if we reject 20% of instances using UE obtained with MC dropout and ask human experts to label these uncertain objects, the accuracy score of such a human-machine hybrid system will increase from 88.4% to 96.0%, which is 1.3% better than the SR baseline. Such an additional gain over the SR baseline can be crucial for safe-critical applications. Deep ensemble and MD SN are close to each other and achieve 95.6% and 95.2% of accuracy correspondingly. Rejecting 40% of most uncertain instances gives 98.2% of accuracy for the computationally-intensive deep ensemble, while the proposed cheap MD SN method yields even better result with 98.5% of accuracy, which is 1.7% higher than the result of the SR baseline.

6 Conclusion

Our extensive empirical investigation on text classification and NER tasks shows that computationally cheap UE methods are able to substantially improve misclassification detection for Transformers, performing on par or even better than computationally intensive MC dropout and deep ensemble. The proposed in this work method based on the Mahalanobis distance and spectral normalization of a weight matrix (MD SN) achieves the best results among other computationally cheap methods on text classification datasets and is on par with expensive methods. This method does not require seriously modifying a model architecture, extra memory storage, and introduces only a little amount of additional computation during inference.

We also show that our modification of DPP MC dropout that leverages the diversity of generated dropout masks, which is also a computationally cheap method, is able to outperform the softmax response baseline and approach the computationally intensive methods on NER. Finally, we find that regularization can slightly improve the results of methods based on MC dropout and the Mahalanobis distance in text classification.

The spectral normalization is theoretically proven to ensure bi-Lipschitz constraint on the transformation defined by the standard residual connection network (Liu et al., 2020). However, the self-attention blocks in Transformers have a more complicated architecture than the layers of standard ResNets, which means that the theoretical guarantees for them do not hold in general. In future work, we are looking forward to investigating other techniques to ensure bi-Lipschitz constraint on self-attention blocks, which might further improve deterministic methods for uncertainty estimation of Transformers.

A Dataset Statistics, Hyperparameter Values, and Hardware Configuration

Datasets	Train	Test	# Labels
MRPC	3.7K	0.4K	2
CoLA	8.6K	1.0K	2
SST-2	67.3K	0.9K	2
CoNLL-2003	14.0K/203.6K	3.5K/46.4K	9

Table 4: Dataset statistics. The table presents the number of sequences for the training and test parts of the datasets. For CoNLL-2003, the table presents both the number of sequences and tokens because for NER, we evaluate both sequence-level and token-level UE scores. For the datasets from the GLUE benchmark (MRPC, CoLA, SST-2), we used the available validation set as the test set.

CPU	2 Intel Xeon Platinum 8168, 2.7 GHz
CPU Cores	24
GPU	NVIDIA Tesla v100 GPU
GPU Memory	32 GB

Table 5: Hardware configuration used in experiments.

Dataset	Reg. Type	Spect. Norm.	Objective Score	Reg. Lambda	Margin	Learning Rate	Num. Epochs	Batch Size	Weight Decay

Table 6: Optimal hyperparameters for the experiments with ELECTRA except SNGP. "Objective score" refers to the accuracy score for classification / F1-score for sequence tagging on the validation sample. For the metric regularization the reg. lambda column contains λ and $\varepsilon\lambda$ parameters. For the MSD method, the reg. lambda column contains λ_1 and λ_2 parameters and the margin column contains Ω parameter. We select hyperparameter values from the following pre-defined list:

Reg. lambda (λ) (and also ($\boldsymbol{\lambda_1}$) and ($\boldsymbol{\lambda_2}$)): [1e-3, 2e-3, 3e-3, 5e-3, 6e-3, 8e-3, 1e-2, 2e-2, 5e-2, 1e-1, 2e-1, 1];
Reg. lambda (for metric regularization): [1e-2, 2.5e-2, 5e-2, 1e-1, 2.5e-1, 5e-1, 1.0, 2.5, 5.0, 10.0];
Reg. $\varepsilon\lambda$: [1e-3, 2e-3, 3e-3, 5e-3, 6e-3, 8e-3, 1e-2, 2e-2, 5e-2, 1e-1, 2e-1, 1];
Margin (γ): [1e-2, 2.5e-2, 5e-2, 1e-1, 2.5e-1, 5e-1, 1.0, 2.5, 5.0, 10.0];
Omega (Ω): [0.5, 0.55, 0.6, 0.65, 0.7, 0.75, 0.8, 0.85, 0.9, 0.95, 1.0];
Spect. Norm.: [0.4, 0.6, 0.8, 1.0, 2.0, 3.0];
Learning rate: [5e-6, 6e-6, 7e-6, 9e-6, 1e-5, 2e-5, 3e-5, 5e-5, 7e-5, 1e-4];
Num. of epochs: $\{n \in \mathbb{N} | 2 \leq n \leq 15\}$;
Batch size: [4, 8, 16, 32, 64];
Weight decay: [0, 1e-2, 1e-1].

Dataset	Objective Score	Learning Rate	Num. Epochs	Batch Size	Weight Decay
CoLA	0.879	6e-6	10	16	0
MRPC	0.867	3e-5	9	16	0
SST-2	0.917	2e-5	6	8	1e-1
CoNLL-2003	0.887	3e-5	85	4	1e-1

Table 7: Optimal hyperparameters for the experiments with SNGP and ELECTRA. For text classification datasets, we use the same pre-defined list of possible values for each hyperparameter. For CoNLL-2003, the following value ranges are used for the *number of epochs* and *learning rate*:
Learning rate: [9e-6, 1e-5, 2e-5, 3e-5, 5e-5, 7e-5, 1e-4];
Num. of epochs: $\{n \in \mathbb{N} | 10 \leq n \leq 100\}$.

Dataset	Reg. Type	Spect. Norm.	Objective Score	Reg. Lambda	Margin	Learning Rate	Num. Epochs	Batch Size	Weight Decay
CoLA	–	0.4	0.854	-	-	7e-6	8	4	1e-1
CoLA	–	-	0.86	-	-	7e-6	13	4	0

Table 9: Optimal hyperparameter values for UE methods based on MC dropout and deep ensemble with the ELECTRA model. These parameters denote the following:
Dropout Ratio – probability of a neuron to be zeroed during inference in a dropout layer;
Committee Size – a number of ensemble elements or stochastic forward passes in the MC dropout;
Max. Frac. – a maximum number of active neurons in a DPP mask;
Kernel Type – type of a kernel in a DPP mask;
DDPP Mask Pool Size – a number of masks in a pool, from which DDPP selects a diverse set of masks;
DDPP Kernel Type – a type of a kernel for a DDPP mask.

Dataset	Method	Dropout Ratio	Committee Size	Max. Frac.	Kernel Type	DDPP Mask Pool Size	DDPP Kernel Type

Abstract

We propose VALSE (**V**ision **A**nd **L**anguage **S**tructured **E**valuation), a novel benchmark designed for testing general-purpose pretrained vision and language (V&L) models for their *visio-linguistic grounding* capabilities on *specific linguistic phenomena*. VALSE offers a suite of six tests covering various linguistic constructs. Solving these requires models to ground linguistic phenomena in the visual modality, allowing more fine-grained evaluations than hitherto possible. We build VALSE using methods that support the construction of *valid* foils, and report results from evaluating five widely-used V&L models. Our experiments suggest that current models have considerable difficulty addressing most phenomena. Hence, we expect VALSE to serve as an important benchmark to measure future progress of pretrained V&L models from a *linguistic perspective*, complementing the canonical task-centred V&L evaluations.

1 Introduction

General-purpose pretrained vision and language (V&L) models have gained notable performance on many V&L tasks (Lu et al., 2019; Tan and Bansal, 2019; Li et al., 2019; Chen et al., 2020; Li et al., 2020a; Su et al., 2020). As a result, V&L research has changed its focus from task-specific architectures to fine-tuning large V&L models.

Current benchmarks give a good perspective on model performance on a wide range of V&L tasks (Cao et al., 2020; Lourie et al., 2021; Li et al., 2021), but the field is only starting to assess *why* models perform so well and whether models learn *specific capabilities that span multiple V&L tasks*. Specifically, we lack detailed understanding of the extent to which such models are able to ground linguistic phenomena—from morphosyntax to semantics—in the visual modality (Bernardi and Pezzelle, 2021). For example, recent evidence suggests that models are insensitive to linguistic distinctions of verb-argument structure (Hendricks and Nematzadeh, 2021) and word order (Cirik et al., 2018; Akula et al., 2020).

Our work addresses this gap with VALSE (Vision And Language Structured Evaluation), a benchmark for V&L model evaluation comprising six tasks, or ‘pieces’, where each piece has the same structure: given a visual input, a model is asked to distinguish real captions from *foils*, where a foil is constructed from a caption by altering a word or phrase that realizes a *specific linguistic phenomenon*, e.g., semantic number of nouns, verb argument structure, or coreference. VALSE uses a resource-lean diagnostic setup that dispenses with large-scale annotation (e.g., of bounding boxes), and builds on existing high-quality image captioning and VQA data. VALSE is designed to leverage the existing prediction heads in pretrained (or finetuned) V&L models; for that reason, our benchmark does not include any re-training and can be interpreted as a *zero-shot* evaluation. We build *test* data for each piece so as to safeguard against the possibility of models exploiting artefacts or statistical biases in the data, a well-known issue with highly parameterised neural models pretrained on large amounts of data (Goyal et al., 2017; Madhyastha et al., 2018; Kafle et al., 2019). With this in view, we propose novel methods to guard against the emergence of *artefacts* during foiling.

Our main contributions are:

i) We introduce VALSE, a novel benchmark aimed at gauging the sensitivity of pre-trained V&L models to *foiled* instances.
ii) We cover a wide spectrum of basic linguistic phenomena affecting the linguistic *and* visual modalities: existence, plurality, counting, spatial relations, actions, and entity coreference.
iii) We investigate novel strategies to build *valid* foils that include automatic *and* human valida-

tion. We balance *word frequency distributions* between captions and foils, and test against pretrained models solving the benchmark *unimodally* by relying only on text. We employ *masked language modeling* (MLM) in foil creation and *semantic inference* for validating foils, and finally collect *human annotations* for the entire benchmark.

iv) We establish initial experimental results for pretrained V&L models of diverse architectures on VALSE. The overall weak performance of these models indicates that the time is ripe for a novel, reliable foiling dataset targeting the visual grounding capabilities of V&L models through the lens of linguistic constructs.[1]

2 Background and Related work

Pretrained V&L models learn to combine vision and language through self-supervised multitask learning. Tasks include *multimodal masked modeling*—where words in the text and object labels or regions in the image are masked out, then predicted—and *image-sentence alignment*, whereby a model learns to predict whether an image and a text correspond. Major architectures are single- and dual-stream multimodal transformers: *single-stream models* concatenate word and image features, and encode the resulting sequence with a single transformer stack; *dual-stream models* use distinct transformer stacks to handle visual and textual inputs, and additional layers (e.g. co-attention) to fuse these into multimodal features.

Benchmarking V&L models V&L models (Li et al., 2019; Lu et al., 2019; Tan and Bansal, 2019; Lu et al., 2020; Li et al., 2020b; Kim et al., 2021) are commonly evaluated on V&L *tasks* such as VQA (Goyal et al., 2017), visual reasoning (Suhr et al., 2019), or image retrieval (Lin et al., 2014; Plummer et al., 2015).

Given how well transformer-based models perform across unimodal and multimodal tasks, research efforts have recently started to address what makes them so effective, and to what extent they learn generalisable representations. Techniques to address these questions in unimodal and multimodal V&L contexts include: adversarial examples (Jia and Liang, 2017; Jia et al., 2019); investigation of the impact of bias, be it linguistic (Gururangan et al., 2018), visual semantic (Agarwal et al., 2020), or socio-economic (Garg et al., 2019); and the use of linguistically-informed counterfactual and minimally-edited examples (Levesque et al., 2012; Gardner et al., 2020). A trend within the latter research line that is specific to V&L models is *vision-and-language foiling* (Shekhar et al., 2017b; Gokhale et al., 2020; Bitton et al., 2021; Parcalabescu et al., 2021; Rosenberg et al., 2021), where the idea is to create counterfactual (i.e., *foiled*) and/or minimally edited examples by performing data augmentation on captions (Shekhar et al., 2017b,a) or images (Rosenberg et al., 2021).

Since most V&L models are pretrained on some version of the image-text alignment task, it is possible to test their ability to distinguish correct from foiled captions (in relation to an image) in a zero-shot setting. The construction of foils can serve many investigation purposes. With VALSE, we target the *linguistic grounding capabilities of V&L models*, focusing on pervasive linguistic phenomena that span *multiple tokens*, described in §3.1–§3.6. At the same time, we ensure that our data is robust to perturbations and artefacts by i) controlling for word frequency biases between captions and foils, and ii) testing against *unimodal collapse*, a known issue of V&L models (Goyal et al., 2017; Madhyastha et al., 2018), thereby preventing models from solving the task using a single input modality. The issue of neural models exploiting data artefacts is well-known (Gururangan et al., 2018; Jia et al., 2019; Wang et al., 2020b; He et al., 2021) and methods have been proposed to uncover such effects, including gradient-based, adversarial perturbations or input reduction techniques (cf. Wallace et al., 2020). Yet, these methods are still not fully understood (He et al., 2021) and can be unreliable (Wang et al., 2020b).

Our work is related to Gardner et al. (2020), who construct *task-specific contrast sets* for NLU. However, our focus is on modelling *linguistic phenomena* instead of tasks, and we construct carefully curated, balanced, single foils from valid instances that we select from multiple multimodal datasets.

3 Constructing the VALSE benchmark

We resort to a musical analogy to describe VALSE: Vision And Language Structured Evaluation is composed of 6 *pieces*, each corresponding to a specific linguistic phenomenon (see Table 1 for an

Table 1: Overview of pieces and instruments in VALSE, with number of examples per piece; the foil generation method used; whether masked language modelling (MLM), GRUEN, and NLI filtering are used; dataset and image sources; and image-caption-foil examples. [†]The number of examples is the sum of the examples available for each instrument in the piece. In Table 5 (in the Appendix) we list the number of examples in each individual instrument.

overview). Each piece consists of one or more *instruments* designed to evaluate a model's ability to ground that specific linguistic phenomenon.

All instruments are built by applying *foiling functions* (FFs) specific to the linguistic phenomenon under study. FFs take a *correct caption* as input and change a specific part to produce a *foiled caption* (or *foil*). We design FFs such that the sentences they produce fail to describe the image, while still being grammatical and otherwise valid sentences.

Of course, a *foiled* caption may be less likely than the original caption from which it was produced, and such unwarranted biases can be easily picked up by overparameterised V&L models. Moreover, an automatic FF may fail to produce a foil that contradicts the image, for example by altering the original caption to yield a near-synonymous one, or one that is entailed by the original caption. For phenomena that make it difficult to control these crucial properties of foils, we apply additional filters: i) some FFs make use of strong LMs to propose changes to captions, so that the generated foils are still high-probability sentences; ii) we use state-of-the-art natural language inference (NLI) methods to detect cases where there is an *entailment* between caption and foil, and filter out such foils from the dataset (see §4 for discussion). As a final measure, we employ human annotators to validate all generated testing data in VALSE.

VALSE data is sourced from existing V&L datasets. Below, we describe each piece and its instruments, and the corresponding task setup in VALSE. For each instrument, we follow the same procedure: i) we identify captions that contain instances of the targeted linguistic phenomenon; ii) we apply a FF that automatically replaces the expression with a variant that contradicts the original expression's visual content, thereby constructing one or more foils from each target instance in the original caption, as discussed in §4; we then iii) subject the obtained foils to various filters, with the aim of distilling a subset of *valid* and *reliable* foils that cannot be easily tricked by a new generation of highly parameterised pretrained V&L models.

3.1 Existence

The **existence** piece has a single instrument and targets instances with **existential quantifiers**. Models need to differentiate between examples i) where *there is no entity* of a certain type or ii) where *one or more of these entities* are visible in an image.

We use the Visual7W visual question answering dataset (Zhu et al., 2016) and source its 'how many' examples, building a pool of those whose answers are numerals (0, 1, 2, etc.). We use templates to transform question and answer fields into a declarative statement that correctly describes what can be seen in the image, e.g. 'Q: How many animals are shown? A: 0' → 'There are 0 animals shown'. We then transform these statements into an existential statement. In the example above, we replace the numeral by the word ‘no’ to create a correct caption (‘There are no animals shown’) and remove the numeral altogether to create a foil (‘There are animals shown’). The existence piece has 505 image–caption–foil tuples after manual validation, out of 534 candidates (cf. §4), and captions/foils are balanced: 50% of the (correct) captions originally have answer 0, and the remaining have answer 1 or greater. Full details are provided in A.1.

3.2 Plurality

The **plurality** piece has a single instrument, concerned with **semantic number**. It is intended to test whether a model is able to distinguish between noun phrases denoting a single entity in an image (‘exactly one flower’), versus multiple entities (‘some flowers’). The dataset consists of 851 validated instances out of 1000 generated candidates (cf. §4), evenly divided between cases where the caption contains a plural NP, foiled by replacing it with a singular (`pl2sg`: ‘some flowers’ → ‘exactly one flower’), or conversely, the caption contains a singular which is foiled by replacing it with a plural (`sg2pl`). Foil candidates were generated from the COCO 2017 validation set (Chen et al., 2015). Full details about the foil construction and our measures against introducing biases with quantifiers such as ‘exactly one’, are provided in A.2.

3.3 Counting

The **counting** piece has three instruments: **balanced**, **adversarial** and **small numbers**. All instances are *statements about the number of entities visible in an image*. The model needs to differentiate between examples where *the specific number of entities in the associated image* is correct or incorrect, given the statement. Similarly to the existence piece, we use the Visual7W VQA dataset (Zhu et al., 2016) and source its ‘how many’ examples whose answers are numerals (0, 1, 2, etc.). We use templates to transform question and answer fields into a declarative statement describing the image and create foils by replacing the numeral in the correct statement by another numeral.

All three instruments are designed to show whether models learn strategies that generalize beyond the training distribution, and to what extent a model exploits class frequency bias.[2] In **counting balanced** we cap the number of examples to a maximum per class and make sure correct and foil classes are balanced, so that models that exploit class frequency bias are penalized. In **counting adversarial** we ensure that all foils take class $n \in \{0, 1, 2, 3\}$, whereas all correct captions take class $m \in \{m \mid m \geq 4\}$. Biased models are expected to favour more frequent classes. Since small numbers are naturally the most frequent, models that resort to such biases should perform poorly on this adversarial test set. **Counting small numbers** is a sanity check where all correct captions and foils have class $n \in \{0, 1, 2, 3\}$, and caption/foil classes are balanced. Since models likely have been exposed to many examples in this class set and all such classes are high-frequency, with this instrument we disentangle model performance from class exposure. Counting balanced, adversarial, and small numbers have 868 (1000), 691 (756), and 900 (1000) instances after (before) manual validation, respectively (cf. §4). For details, see A.3.

3.4 Spatial relations

The **relations** piece has a single instrument and focuses on the ability of models to distinguish between different spatial relations. Foils differ from the original caption only by the replacement of a spatial preposition. As with plurals, the data was sourced from the COCO 2017 validation split. To create foils, we first identified all preposition sequences in captions (e.g., ‘in’, ‘out of’). Foils were created by masking the prepositions and using SpanBERT (Joshi et al., 2020) to generate candidates of between 1–3 words in length. We keep SpanBERT candidates, which are spans whose lengths vary from 1 to 3, if they differ from the original preposition sequence, but exist in the dataset. There are 535 instances after manual validation out of 614 proposed instances (cf. §4), and we ensure that prepositions are similarly distributed among captions and foils. Full details are provided in A.4.

3.5 Actions

The **actions** piece has two instruments: i) **action replacement** and ii) **actant swap**. They test a V&L model’s capability to i) identify whether an *action* mentioned in the text matches the action seen in the image (e.g., ‘a man shouts / smiles at a woman’), and ii) correctly identify the *participants* of an action and the *roles* they play (e.g., is it the man who is shouting or is it the woman, given the picture in Table 1?).

The SWiG dataset (Pratt et al., 2020) contains

---

[2] We take the original answer in Visual7W as the example class: e.g., in ‘There are 0 animals shown’, the class is 0.

504 action verbs, and we generate captions and foils from SWiG annotations of semantic roles and their fillers. For the action replacement piece, we exchange action verbs with other verbs from SWiG that fit the linguistic context as suggested by BERT. For the actant swap, we swap role fillers in the role annotations, hence generating action descriptions with inverted roles. Action replacement and actant swap have 648 (779) and 949 (1042) instances after (before) manual validation, respectively (cf. §4). See A.5 for full details.

3.6 Coreference

The **coreference** piece aims to uncover whether V&L models are able to perform pronominal coreference resolution. It encompasses cases where i) the pronoun has a noun (phrase) antecedent and pronoun and (noun) phrase are both grounded in the visual modality ('A woman is driving a motorcycle. Is she wearing a helmet?'), and cases where ii) the pronoun refers to a region in the image or even to the entire image ('Is this outside?').

We create foils based on VisDial v1.0 (Das et al., 2017) with images from MSCOCO (Lin et al., 2014). VisDial captions and dialogues are Q&A sequences. We select image descriptions of the form [*Caption. Question? Yes/No.*] where the question contains at least one pronoun. When foiling, we exchange the answer from *yes* to *no* and vice-versa (see Table 1). We ensure a 50-50% balance between yes / no answers.

The coreference piece consists of two instruments: **coreference standard** originating from the VisDial train set and a small **coreference clean** set from the validation set, containing 708 (916) and 104 (141) examples after (before) manual validation, respectively (cf. §4).[3] See A.6 for full details.

4 *Reliable* construction of *valid* foils

In VALSE, an instance consisting of an image-caption-foil triple is considered *valid* if: the foil minimally differs from the original caption; the foil does not accurately describe the image; and independent judges agree that the caption, but not the foil, is an accurate description of the image. We consider a *foiling method* to be more *reliable* the more it ensures that a generated foil does not substantially differ from a human caption regarding distributional and plausibility bias, and cannot be easily solved unimodally.

In this section, we discuss automatic and manual means to reliably construct valid foils. In this context, two types of bias are especially worthy of note: distributional bias (§4.1) and plausibility bias (§4.2). In §4.3 we discuss how we apply a natural language inference model to filter examples in our data pipeline, and §4.4 show how we manually validate *all examples* in our benchmark. Random samples from the final version of each instrument are shown in Tab. 6–11.

4.1 Mitigating distributional bias

A first form of bias is related to distributional imbalance between captions and foils (e.g., certain words or phrases having a high probability only in foils). Previous foiling datasets exhibit such imbalance, enabling models to solve the task disregarding the image (Madhyastha et al., 2019). To mitigate this problem, for each phenomenon and throughout our data creation process, we ensure that the token *frequency distributions* in correct and foiled captions are approximately the same (cf. App. A and E).

4.2 Countering plausibility bias

A second form of bias may arise from automatic procedures yielding foils that are implausible or unnatural, which can facilitate their detection. Often, VALSE pieces can be safely foiled by simple rules (e.g., switching from existence to non-existence, or from singular to plural or vice versa). However, with *spatial relations* and *actions*, a foil could be deemed unlikely given only the textual modality and independently of the image, e.g., 'a man stands under / on a chair'. Such **plausibility biases** may be detected by large language models that incorporate commonsense knowledge (Petroni et al., 2019; Wang et al., 2020a), and we expect future V&L models to exhibit similar capabilities.

To ensure that foiled and correct captions are similarly plausible, we use language models such as BERT (Devlin et al., 2019) and SpanBERT (Joshi et al., 2020) to suggest replacements in our foiling functions. Additionally, in the case of spatial relations and plurals, we also apply a grammaticality filter using GRUEN (Zhu and Bhat, 2020). GRUEN was originally proposed to automatically score generated sentences based on discourse-level and grammatical properties. We use only the grammaticality component of GRUEN, and retain only foil candidates with a grammaticality score ≥ 0.8.

Furthermore, we evaluate unimodal, language-only models on VALSE to verify whether our

---

[3] VisDial annotations are not available for the test set.

benchmark could be solved by a multimodal model with strong linguistic capacities in **unimodal collapse**, whereby a model silently relies on a single modality within which biases are easier to exploit (Goyal et al., 2017; Shekhar et al., 2019a). By evaluating VALSE with unimodal models, we establish a baseline that V&L models should exceed if we are to expect true multimodal integration.

4.3 Filtering foils with NL Inference

When constructing foils, we need to ensure that they *fail* to describe the image. To test this automatically, we apply natural language inference (NLI) with the following rationale: We consider an image and its caption as a premise and its entailed hypothesis, respectively (a similar rationale is applied in the visual entailment task; Xie et al., 2019). In addition, we consider the *caption as premise* and the *foil as its hypothesis*. If a NLI model predicts the foil to be entailed (E) by the caption, it cannot be a good foil since by transitivity it will give a truthful description of the image. By contrast, if the foil is predicted to contradict (C) or to be neutral (N) with respect to the caption, we take this as an indicator of a valid (C) or a plausible (N) foil.[4]

We use the NLI model ALBERT (Lan et al., 2020) finetuned on the task (see Appendix C for details). Filtering with NLI was initially applied to *relations, plurals* and *actions*, on the grounds that foils in these pieces may induce substantive changes to lexical content.[5] Following automatic labelling of caption-foil pairs, we manually validated a sample labelled as E, C or N. For *relations* ($N = 30$), labels were found to be near 100% accurate with only 2 (0.06%) errors overall. For *plurals* ($N = 60$, 50% `sg2pl` and 50% `pl2sg`), the error rate was also low, with 0 errors for C, 33% errors for E and 11% errors for N. Here, a number of entailment errors were due to odd formulations arising from the automatic foiling process, whereas no such oddities were observed for C. We therefore include only foils labelled C in the final relations and plurals pieces. For *actions*, the model labelled contradictions very accurately (0% error) but was erroneous up to 97.1% for E, meaning that a large number of valid foils would be spuriously excluded. To avoid reducing the dataset too much, we did not use NLI filtering for actions, but relied on human annotation as a final validity check.

4.4 Manual evaluation of generated foils

As a final step, the data for each instrument was submitted to a manual validation. For each instance, annotators were shown the image, the caption and the foil. Caption and foil were numbered and displayed above each other to make differences more apparent, with differing elements highlighted in boldface (Fig. 2, App. E). Annotators were not informed which text was the caption and which was the foil, and captions appeared first (numbered *1*) 50% of the time. The task was to determine which of the two texts accurately described what could be seen in the image. In each case, annotators had a forced choice between five options: a) the first, but not the second; b) the second, but not the first; c) both of them; d) neither of the two; and e) I cannot tell.

Each item was annotated by three individuals. The validation was conducted on Amazon Mechanical Turk with a fixed set of annotators who had qualified for the task. For details see App. E. For the final version of VALSE, we include instances which passed the following validation test: at least two out of three annotators identified the caption, but not the foil, as the text which accurately describes the image. Across all instruments, 87.7% of the instances satisfied this criterion (min 77.3%; max 94.6%), with 73.6% of instances overall having a unanimous (3/3) decision that the caption, but not the foil, was an accurate description. We consider these figures high, suggesting that the automatic construction and filtering procedures yield foils which are likely to be valid, in the sense discussed in §4 above.

We compute inter-annotator agreement for each instrument (Tab. 5). On the valid subset, agreement is low to medium (Krippendorff's α: min=0.23, max=0.64, mean=0.42, sd=0.12). We note that there is considerable variation in the number of annotations made by individuals, and α is computed over 5 categories. Hence, this result cannot be straightforwardly interpreted as a ceiling of human performance for VALSE. However, α is higher for pieces on which models also perform better (e.g.

---

[4] See the following examples from action replacement:
P: *A mother scolds her son.*
H1: *A mother encourages her son.* (C; good foil);
H2: *A mother camps with her son.* (N; needs image control);
H3: *A mother talks to her son.* (E; not a suitable foil)

If the NLI prediction is N, we still need to check the image, since the description might happen to fit the image content.

[5] By contrast, existence and counting foils involve a more straightforward swap (e.g., between numerical quantities); similarly, coreference foils simply involve the replacement of a positive with a negative answer.

existence, Foil-It!; cf. §5).

5 Benchmarking with VALSE

We propose VALSE as a task-independent, *zero-shot* benchmark to assess the extent to which models learn to ground specific linguistic phenomena as a consequence of their pretraining (or fine-tuning). VALSE is built in the spirit of approaches such as Checklist (Ribeiro et al., 2020), including pairs consisting of captions and minimally edited foils.

The only requirement to evaluate a model on our benchmark is: *i)* to have a binary classification head to predict whether an image-sentence pair is foiled, or *ii)* to predict an image-sentence matching score between the image and the caption vs. the foil, returning the pair with the highest score. Systems reporting results on VALSE are expected to report any data used in model training prior to testing on VALSE, for comparability.

5.1 Benchmark Metrics

We employ five metrics[6] for evaluation: overall **accuracy** (acc) on all classes (foil and correct); **precision** (p_c) measuring how well models identify the *correct* examples; **foil precision** (p_f) measuring how well *foiled* cases are identified; **pairwise ranking accuracy** (acc_r), which measures whether the image-sentence alignment score is greater for a correct image-text pair than for its foiled pair; and **area under the receiver operating characteristic curve** (AUROC), which measures how well models distinguish correct vs. foiled examples across different prediction thresholds. acc_r is more permissive than acc as it accepts model predictions if the score for a foil is lower than the caption's score. Our main metrics are AUROC and acc_r. acc_r gives results for a pair $\langle$*image, caption*$\rangle$ and $\langle$*image, foil*$\rangle$. Both AUROC and acc_r are well suited to evaluate minimally-edited pairs as neither uses a classification threshold. As for p_c and p_f, since these are competing metrics where naively increasing one can decrease the other, we report the smaller of the two as an indicator of how informed model predictions are. Since all instruments are implemented as a balanced binary classification, the random baseline is always 50%.

5.2 V&L models

We benchmark five V&L models on VALSE: CLIP (Radford et al., 2021), LXMERT (Tan and Bansal, 2019), ViLBERT (Lu et al., 2019), ViLBERT 12-in-1 (Lu et al., 2020), and VisualBERT (Li et al., 2019). These models have different architectures and are pretrained on a variety of tasks with different training data. We also benchmark two unimodal text-only models, GPT1 (Radford et al., 2018) and GPT2 (Radford et al., 2019). See Appendix D for details on all these models used in our evaluation.

Unimodal models GPT1 and GPT2 are autoregressive language models pretrained on English text. We test whether VALSE is solvable by these unimodal models by computing the perplexity of the correct and foiled caption and *predicting the entry with the lowest perplexity*. If the perplexity is higher for the foil, we take this as an indication that the foiled caption may suffer from **plausibility bias** or other linguistic biases (cf. §4.2).

5.3 Experiments and Results

We test V&L and unimodal models on VALSE in a zero-shot setting, and also evaluate on a number of correct captions and foils from the *FOIL it!* dataset (Shekhar et al., 2017b) (cf. App. A.7 for details). All results are listed in Table 2.

Unimodal results For most instruments, unimodal results are close to random and hence do not signal strong linguistic or plausibility biases. One exception is the original *FOIL it!* dataset, in line with Madhyastha et al. (2019)'s findings. Also the spatial relations (77.2%), action replacement (66.8%) and actant swap (76.9%) instruments suggest plausibility biases in foils. Such biases are hard to avoid in automatic foil generation for actions due to the verb arguments' selectional restrictions, which are easily violated when flipping role fillers, or replacing the verb. Similar considerations hold for relations: though SpanBERT proposals are intended to aid selection of likely replacements for prepositions, plausibility issues arise with relatively rare argument-preposition combinations.

While these might be the first instruments in VALSE to be solved in the future, current V&L models struggle to detect even blatant mismatches of actant swap, e.g., 'A ball throws a tennis player.' For VALSE, the unimodal scores will serve as a baseline for the pairwise accuracy of V&L models.

Multimodal results The best zero-shot results are achieved by ViLBERT 12-in-1 with the highest scores across the board, followed by ViLBERT,

---

Table 2: Performance of unimodal and multimodal models on the VALSE benchmark according to different metrics. We bold-face the best overall result per metric, and underscore all results below (or at) the random baseline. acc_r is a pairwise ranking accuracy where a prediction is considered correct if $p(caption, img) > p(foil, img)$. Precision p_c and foil precision p_f are *competing* metrics where naïvely increasing one can decrease the other: therefore *looking at the smaller number among the two gives a good intuition of how informed is a model prediction.* †**sns.** Counting small numbers. **adv.** Counting adversarial. **repl.** Action replacement. ‡ **Sp.rel.** Spatial relations. *Unimodal text-only models that do not use images as input. CLIP is only tested in pairwise ranking mode (fn. 6).

LXMERT, CLIP,[7] and finally VisualBERT. The latter obtains high p_f but very low p_c values—reflected in the $\min(p_c, p_f)$ scores—indicating that VisualBERT learned a heuristic that does not generalise (see Hendricks and Nematzadeh, 2021, for similar observations with other models). We hypothesise that this is due to the way image-sentence alignment is framed in VisualBERT's pretraining: the model expects an image and a correct sentence c_1, and predicts whether a second sentence c_2 is a match.[8] During pretraining c_1 and c_2 are likely to differ in many ways, whereas in our setting, they are nearly identical. This may bias the model against predicting foils, which would raise the value p_f.

Instruments centered on individual objects like existence and the *FOIL it!* dataset are almost solved by ViLBERT 12-in-1, highlighting that models are capable of identifying named objects and their presence in images. However, none of the remaining pieces can be reliably solved in our adversarial foiling settings: i) distinguishing references to single vs. multiple objects or counting them in an image (plurality and counting); ii) correctly classifying a named spatial relation between objects in an image (relations); iii) distinguishing actions and identifying their participants, even if supported by preference biases (actions); or, iv) tracing multiple references to the same object in an image through the use of pronouns (coreference).

Correct vs. foil precision p_c and p_f show that V&L models struggle to solve the phenomena in VALSE. When a model achieves high precision on correct captions p_c this is often at the expense of very low precision on foiled captions p_f (cf. ViLBERT), or vice-versa (cf. VisualBERT). This suggests that such models are insensitive to VALSE's inputs: models that almost always predict a match will inflate p_f at the expense of p_c. $\min(p_c, p_f)$ reveals that VisualBERT and ViLBERT perform poorly and below random baseline, and LXMERT close to or below it. ViLBERT 12-in-1 performs strongly on existence, well on counting, but struggles on plurality, spatial relations, coreference, and actions. These tendencies we see reflected in our main metrics, acc_r and AUROC.

6 Conclusions and Future Work

We present the VALSE benchmark to help the community improve V&L models by hard-testing their visual grounding capabilities through the lens of lin-

---

[7] CLIP works in a contrastive fashion, therefore we report only acc_r (cf. Appendix D for details).

[8] c_1 is one of the 5 captions describing the relevant image in MSCOCO. During VisualBERT's pretraining, c_2 can be an alternative caption out of these 5, or a randomly drawn caption which does not describe the image. The pretraining task is to determine if c_2 correctly describes the image or not.

guistic constructs. Our experiments show that V&L models identify named objects and their presence in images well (as shown by the existence piece), but struggle to ground their interdependence and relationships in visual scenes when forced to respect linguistic indicators. We encourage the community to use VALSE for measuring progress towards V&L models capable of true language grounding. Furthermore, VALSE could be used as an indirect assessment of datasets, as models could be evaluated before and after training or fine-tuning to see if a dataset helps models improve on any of the aspects tested by VALSE.

VALSE is designed as a living benchmark. As future work we plan to extend it to further linguistic phenomena, and to source data from diverse V&L datasets to cover more linguistic variability and image distributions.

A Benchmark creation

A.1 Existence

The **existence** piece has a single instrument and targets instances with **existential quantifiers**. Models need to differentiate between examples i) where *there is no entity* of a certain type or ii) where *there is one or more of these entities* visible in an image.

Data sources We use the Visual7W visual question answering dataset (Zhu et al., 2016) to source examples, starting with the 'how many' questions in Visual7W and building a pool of those whose answers are numerals (e.g., 0, 1, 2, etc.). We use the templates from Parcalabescu et al. (2021) to transform question and answer fields into a declarative statement that correctly describes what can be seen in the image, e.g., 'Q: How many animals are shown? A: 0' → 'There are 0 animals shown'.

Foiling method Let us use x = 'There are N animals shown' as a running example for a correct caption, where N is a number. If $N > 0$, we simply remove N from the sentence, effectively creating the statement $\exists x$ or 'There are animals shown'. If $N = 0$, we replace N by 'no', creating the statement $\neg\exists x$ or 'There are no animals shown'. If necessary, we fix singular–plural agreement. To create data with balanced correct and foil classes, we select 50% of our examples from those where the correct answer is originally 0, and the remaining 50% from those where the correct answer is any other number (e.g., 1, 2, etc.). To create foils, we then simply convert the statement from $\exists x$ to $\neg\exists x$, and vice-versa.

A.2 Plurality

The **plurality** piece has a single instrument, concerned with **semantic number**, that is, the distinction between single entities in an image ('exactly one flower') and multiple instances of the same type ('some flowers'). In this piece, foil candidates are created either by converting a singular NP and its coreferents to a plural, or vice versa.

Data sources The data was sourced from the validation split of the COCO 2017 dataset (Chen et al., 2015). Captions are only foiled if their length after tokenization with the pretrained BERT tokenizer[9] is of 80 tokens or less. This is done to minimise the risk that captions and foils need to be truncated to accommodate the input specifications of current pretrained V&L models.

Foiling method Foiling is done in two directions: singular-to-plural (`sg2pl`) or plural-to-singular (`pl2sg`). Given a caption, NP chunking is applied to identify all non-pronominal NPs. In the `sg2pl` case, a foiled version of a caption containing a singular NP is created by pluralising the head noun. We automatically identify anaphoric expressions coreferring to the singular NP within the caption and pluralise them in the same way. For NPs which are subjects of copular VPs or VPs with an auxiliary requiring subject-verb number agreement (e.g. 'N is V'), we also pluralise the verb. Note that this procedure creates a potential foil for every singular NP in the caption; thus, more than one foil candidate can be created for each instance in the source dataset.[10] In the `pl2sg` case, the same procedure is carried out, but turning a plural NP, as well as its coreferents, into a singular. We generate all foil candidates using the Checklist framework (Ribeiro et al., 2020), within which we implement our procedures for data perturbation.

An important consideration, especially in the `pl2sg` case, is that singularising an NP in a foil can still be truth-preserving. Specifically, a caption with a plural NP, such as 'A small copper vase with some flowers in it', arguably still entails the version with the singular '(. . .) a flower'. As a result, the singular version may still correctly be judged to match the image. One way around this problem is to insert a quantifier in the singular NP which makes it explicit that exactly one instance and no more is intended (e.g. 'exactly one flower'). This may however result in a biased dataset, with such singular quantifiers acting as signals for singular foils and enabling models to solve the task with no grounding in the visual information. We avoid this by adopting a uniform strategy for both `sg2pl` and `pl2sg`. We determine two singular quantifiers ('exactly one N' and 'a single N') and two plural quantifiers ('some N', 'a number of N'). When a foil candidate is generated, we alter the *original* NP by inserting one of the two quantifiers matching its semantic number, and generate a foil with one

---

[9] We use the `bert-large-cased` pretrained tokenizer distributed as part of the `transformers` python library.

[10] NP chunking is performed using the Spacy v.3 pipeline for English using the `en_core_web_md` pretrained models. Coreference chains are detected using the pretrained English model for Coreferee (`github.com/msg-systems/coreferee`). Pluralisation of head nouns is carried out using the `inflect` engine (`github.com/jaraco/inflect/`).

of the two quantifiers for the other number. In the foregoing example, we end up with 'A small copper vase with some flowers / exactly one flower in it.'

After generating all candidate foils, in both directions, we use the GRUEN pretrained model (Zhu and Bhat, 2020) to score the foils for grammaticality. We only keep foils with a score $\geq$ 0.8, and run each foil-caption pair through the NLI model described in Section 4.3, keeping only pairs whose predicted label is *contradiction*, for an initial candidate set of 1000 cases (500 `sg2pl` and 500 `pl2sg`), of which 851 (85.1%) are considered valid following manual validation (see §4.4). Figure 4 shows the distribution of nouns in captions and foils, before and after the validation. Note that the validation process does not result in significant change to the distributions.

A.3 Counting

The **counting** piece comes in three instruments: **balanced**, **adversarial** and **small numbers**. All three instruments include instances with *statements about the number of entities visible in an image*. The model needs to differentiate between examples where *the specific number of entities in the associated image* is correct or incorrect, given the statement.

All three instruments are designed to show whether models learn strategies that generalize beyond the training distribution, and to what extent a model exploits class frequency bias.[11] In **counting balanced** we cap the number of examples to a maximum per class and make sure correct/foil classes are balanced, so that models that exploit class frequency bias are penalized. In **counting adversarial** we make sure that all foils take class $n \in \{0, 1, 2, 3\}$, whereas all correct captions take class $n \in \{n \mid n \geq 4\}$. Biased models are expected to favour more frequent classes and these correspond to smaller numbers, therefore models that resort to such biases should perform poorly on this adversarially built test. Instrument **counting small numbers** is a sanity check where all correct captions and foils have class $n \in \{0, 1, 2, 3\}$, and caption/foil classes are balanced. Models likely have been exposed to many examples in this class set, so with this instrument we assess model performance certain it does not suffer from (class) exposure bias.

Data sources We use the Visual7W visual question answering dataset (Zhu et al., 2016) and source its 'how many' examples, building a pool of those whose answers are numerals (e.g., 0, 1, 2, etc.). We use the templates from Parcalabescu et al. (2021) to transform question and answer fields into a declarative statement that correctly describes what can be seen in the image.

Foiling method We create foils by directly replacing the numeral in the correct caption by another numeral. When creating foils we make sure that the class distribution for correct and foiled captions are approximately the same, i.e., there are a similar number of correct and foiled examples in each class in each instrument. The only exception is the counting adversarial instrument, where the classes used in correct and foiled captions are disjoint, i.e., $n \in \{0, 1, 2, 3\}$ and $n \in \{n \mid n \geq 4\}$, respectively. See Figure 3 for a visualisation of these distributions.

A.4 Spatial relations

The **relations** piece has one instrument and focuses on the ability of models to distinguish between different spatial relations, as expressed by prepositions. Foils therefore consist of captions identical to the original except for the replacement of a spatial preposition.

Data sources Data was sourced from the COCO 2017 validation split (Chen et al., 2015). To generate foil candidates, we first extracted from the original COCO captions all the sequences consisting of one or more consecutive prepositions (e.g., 'on' or 'out of'). Foils are generated by detecting these preposition spans, and replacing them with another preposition span attested in the list.

Foiling method To generate foils, we mask the preposition span in an original caption, and use SpanBERT (Joshi et al., 2020), a pretraining method based on BERT (Devlin et al., 2019).[12] The advantage of SpanBERT over BERT is that in a masked language modelling context, with masks spanning more than a single word, SpanBERT predicts sequences and takes into account their joint probability, whereas BERT trained with standard Masked Language Modelling can only predict single tokens independently. With SpanBERT, we

---

[11] We take the original answer in Visual7W as the example class. E.g., in *There are four zebras*, the class is 4.

[12] We use SpanBERT with the pretrained `bert-large-cased` model distributed as part of the `transformers` Python library.

generate replacements of between 1 and 3 tokens in length, in each case retaining only the best prediction out of the top k which matches one of the preposition sequences in the pre-extracted list.

After all candidates are generated, we apply GRUEN (Zhu and Bhat, 2020) to score the foils for grammaticality, and further apply the NLI model descibed in Section 4.3 to label the entailment relationship between caption and foil pairs. From the resulting data, we sample as follows: i) we keep only caption-foil pairs labelled as *contradiction*, where the GRUEN grammaticality score is ≥ 0.8; ii) for every caption-foil pair sampled where p is replaced with q, we search for another caption-foil pair where q is replaced with p, if present. This strategy yields a roughly balanced dataset, where no single preposition or preposition sequence is over-represented in captions or foils.

These processes result in an initial set of 614 cases, of which 535 (87.1%) are selected following manual validation described in §4.4.

Figure 3 shows proportions in captions and foils of the prepositions. E.g.: 'A cat plays with a pocket knife on / underneath a table.'

As with plurals, we implement procedures for foil candidate generation by extending the `perturb` functionality in Checklist (Ribeiro et al., 2020).

A.5 Actions

The **action** piece consists of two instruments: i) **action replacement** and ii) **actant swap**. They are testing a V&L model's capability of i) identifying whether an *action* mentioned in the textual modality matches the action seen in the image or not (e.g. 'a man shouts / smiles at a woman') and ii) correctly identifying the *participants* of an action and the *roles* they are playing in it (e.g., given the picture in Table 1: is it the man or the woman who shouts?).

Data source For creating interesting foils with *diverse* actions, we focus on the SWiG dataset (Pratt et al., 2020) that comprises 504 action verbs annotated with semantic roles and their fillers, which are grounded in images of the *imSitu* dataset (Yatskar et al., 2016). We generate English captions for the images using SimpleNLG (Gatt and Reiter, 2009)[13]. For generation we use the specified *action verb*, the realized FrameNet semantic roles and their annotated filler categories (see Table 1 for *shout*: AGENT: man, ADDRESSEE: woman), and generate short captions, with realization of two roles in active form. We apply various filters to ensure high quality of the generated captions using diverse metrics[14] and manual checks through AMT crowdsourcing.

Foiling method When creating the **action replacement** instrument, we need to make sure that the action replacement suits the context. We propose action replacements with BERT (Devlin et al., 2019) that need to satisfy three conditions: 1) the proposed action verbs originate from the SWiG dataset – otherwise new verbs are introduced on the foil side only, which may induce biases; 2) the frequency distribution of action verbs on the caption and on the foil side is approximately the same (cf. Figure 4); 3) we constrain the replacement verbs to be either antonyms of the original verb or at least not synonyms, hyponyms or hypernyms to the original, according to WordNet (Fellbaum, 1998) in order to avoid situations where replacements are almost synonymous to the original action. The **actant swap** instrument is based on the original image annotations, but swaps the two role fillers (e.g., 'A woman shouts at the man.' for the image in Table 1). To avoid agreement mistakes, we *generate* these foils using the inverted role fillers as input.

We plot caption and foil word frequency distributions for action replacement in Figure 4. We do not plot statistics for the actant swap instrument since by construction it cannot suffer from distributional bias since caption and foil contain the same words up to a *permutation*.

A.6 Coreference

The **coreference** piece consists of two pieces: **coreference standard** and **coreference clean**. It aims to uncover whether V&L models are able to perform pronoun coreference resolution. The coreference phenomenon encompasses both cases where i) the pronoun refers to a noun (phrase) and both the pronoun and the (noun) phrase are grounded

---

[13] SimpleNLG is a surface realization engine that – given some content and crucial syntactic specifications – performs surface generation including morphological adjustments.

[14] We use the GRUEN metric (Zhu and Bhat, 2020) that scores grammaticality, naturalness and coherence of generations and compute perplexity with GPT-2 to rank alternative outputs. We determined appropriate thresholds based on manual judgements of acceptability and chose the highest-ranked candidates. The final data quality is controlled by crowdsourced annotation with AMT.

in the visual modality (e.g. 'A woman is driving a motorcycle. Is she wearing a helmet?'), and cases where ii) the pronoun refers directly to a region in the image or even to the whole image (e.g. 'A man is sitting on a bench. Is this outside?').

Data source We source the data from VisDial v1.0 (Das et al., 2017), which contains images from MSCOCO (Lin et al., 2014), their captions and dialogues about the images in form of Q&A sequences. To ensure that the coreference phenomenon is present in the [*Caption. Question? Yes/No.*] formulations, we check whether pronouns are present in the *question*. The list of pronouns and their frequencies in our train-val-test splits are represented in Figure 1.

The **coreference standard** instrument contains 916 data samples (708 are valid[15]) from the VisDial's training set. The data of **coreference clean** instrument consisting of 141 samples (104 are valid), originates from VisDial's validation set. With models that have been trained on VisDial, we would be in the situation where models are tested on their training data. Therefore we also have the *coreference clean instrument* based on the validation set of VisDial to test models safely. Unfortunately, we cannot use VisDial's test set because the required question-answers annotations necessary for foiling are withheld.

Foiling method When foiling, we take the image description of the form [*Caption. Question? Yes/No.*] and exchange the answer: *yes* →*no* and vice-versa (see example in Table 1). This way, we keep the full textual description including pronoun and noun (phrase) intact, hence ensuring that the coreference phenomenon is present and valid in the foil too, and rely on the model to interpret affirmation and negation correctly. Note that we rely on the capability of models to correctly interpret negation also in the existence piece (cf. §3.1).

Arguably, coreference is the most difficult phenomenon to foil in VALSE. Especially in cases where pronouns refer to a noun (phrase) (e.g., 'A woman is driving a motorcycle. Is she wearing a helmet? Yes.'), exchanging the pronoun with another pronoun would generate incoherent and unlikely sequences[16] (e.g., 'A woman is driving a motorcycle. Is he wearing a helmet?'), and exchanging it with a noun phrase would furthermore break the pronoun coreference phenomenon because there would be no pronoun anymore (e.g., 'A woman is driving a motorcycle. Is the man wearing a helmet?'). Therefore when foiling the coreference piece, we aim to keep the original description intact for ensuring the preservation of the coreference phenomenon. Hence we rely on the answers containing *yes* or *no*[17] and exchange affirmative to negative answers and vice-versa.

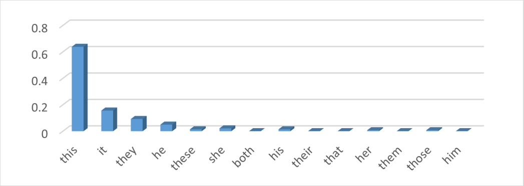

Figure 1: Normalized pronoun frequencies in the coreference subset.

A.7 FOIL it! data

We include an additional piece in VALSE consisting of 1000 randomly sampled entries from the *FOIL it!* dataset (Shekhar et al., 2017b). Each entry in *FOIL it!* consists of an MSCOCO (Lin et al., 2014) image and a foiled caption where a noun phrase depicting an object visible in the image was replaced by a semantically related noun phrase. Since examples in the *FOIL it!* dataset are linked to MSCOCO, we use these links to retrieve one correct caption from the five captions available for the image, and create an image–caption–foil triple. From the original 1000 entries, 943 have been validated by our manual annotation procedure (in Appendix E). Please refer to Shekhar et al. (2017b) for more details.

B Evaluation metrics

We evaluate pretrained V&L models on VALSE using **accuracy** (acc), the overall accuracy on all classes; **precision** or *positive predictive value* (p_c), which measures the proportion of correctly identified *correct captions*; and **foil precision** or *negative predictive value* (p_f), which measures the proportion of correctly identified *foiled* examples; **pairwise ranking accuracy** acc_r, computed using the image-sentence alignment score ϕ that the model assigns to correct and foiled image-text pairs; and

---

[15] The majority of manual annotators validated that the caption describes the image but the foil does not.

[16] Even more, the possibilities of exchanging pronouns with pronouns in grammatical ways are very limited: *she* – *he* but not *she* – *they* / *her* / *their*.

[17] If the answer is longer than just *yes/no* (e.g., 'Yes, she is') we shorten it to *yes/no*.

area under the receiver operating characteristic curve (AUROC)—a classic metric used in machine learning classification problems—which in our case measures how well models distinguish correct vs. foiled examples across different prediction thresholds. The AUROC has a probabilistic interpretation and can be understood as the probability that a model will assign a higher score to a randomly chosen correct example relative to a randomly chosen foil.

With acc_r, a prediction is considered successful, if given an image (i) paired with a correct (c) versus a foil (f) text, the score of the positive/correct pair is greater than that of the foiled pair.

$$acc_r = \frac{\sum_{(i,c)\in C} \sum_{f\in F} s(i,c,f)}{|C| + |F|},$$
$$s(i,c,f) = \begin{cases} 1, & \text{if } \phi(i,f) \leq \phi(i,c), \\ 0, & \text{otherwise,} \end{cases}$$

where C is the set of correct image-caption pairs (i, c), and F is the set of foils for the pair (i, c).

The **pairwise accuracy** acc_r is important for two reasons: First, it enables V&L models to be evaluated on VALSE without a binary classification head for classifying image-sentence pairs as correct or foiled. For example, CLIP (Radford et al., 2021) is a model that computes a score given an image-sentence pair. This score can be used to compare the scores of a correct image-sentence pair and the corresponding foiled pair. By contrast, a model like LXMERT (Tan and Bansal, 2019) has a binary image-sentence classification head and can predict a correct pair independently of the foiled pair (and vice-versa). Second, acc_r enables the evaluation of unimodal models on VALSE, as motivated in §4.2. In Table 4, we show results for all models investigated according to all above-mentioned metrics.

C Filtering methods

NLI filtering For NLI filtering we make use of the *HuggingFace* (Wolf et al., 2020) implementation of ALBERT (xxlarge-v2) that was already finetuned on the concatenation of SNLI (Bowman et al., 2015), MultiNLI (Williams et al., 2018), FEVER-NLI (Nie et al., 2019) and ANLI datasets (Nie et al., 2020). The model is the best performing on the ANLI benchmark leaderboard[18] and it achieves 90% accuracy on MultiNLI devset.

D Vision & Language and Unimodal Models

In Table 3 we summarise the five V&L models used in our experiments, their architecture, pretraining tasks and data, and fine-tuning tasks (if any).

CLIP CLIP (Radford et al., 2021) is composed of two transformer-based text and an image encoders. These are jointly trained on 400M image-text pairs through contrastive learning for predicting high scores for paired image-text examples and low scores when image-text samples are not paired in the dataset. CLIP has shown zero-shot capabilities in e.g. object classification, OCR, activity recognition (Radford et al., 2021). Goh et al. (2021) have shown the existence of multimodal neurons in CLIP, responding to the same topic regardless of whether it is represented in an image, drawing or handwritten text. We use CLIP's image-text alignment scores for benchmarking on VALSE: Given an image, we compare whether CLIP[19] predicts higher image-text similarity for the correct or for the foiled caption.

LXMERT LXMERT (Tan and Bansal, 2019) is a dual-stream transformer model combining V&L through cross-modal layers. It is pretrained on MSCOCO (Lin et al., 2014) and on multiple VQA datasets for (i) multimodal masked word and object prediction, (ii) image-sentence alignment, i.e., determining whether a text corresponds to an image or not, and (iii) question-answering. For benchmarking on VALSE, we use LXMERT's[20] image-sentence alignment head.

ViLBERT and ViLBERT 12-in-1 ViLBERT (Lu et al., 2019) is a BERT-based transformer architecture that combines V&L on two separate streams by co-attention layers. It is pretrained on Google Conceptual Captions (Sharma et al., 2018) on (i) multimodal masked word and object prediction; and (ii) image-sentence alignment. ViLBERT 12-in-1 (Lu et al., 2020) further finetuned a ViLBERT model checkpoint on 12 different tasks including VQA, image retrieval, phrase grounding and others.[21] We use the image-sentence alignment head of the publicly available model checkpoints for

Table 4: Performance of unimodal and multimodal models on the VALSE benchmark according to different metrics. We bold-face the best overall result per metric, and underscore all results below (or at) the random baseline. acc_r is a pairwise ranking accuracy where a prediction is considered correct if $p(caption, img) > p(foil, img)$. Precision p_c and foil precision p_f are *competing* metrics where naïvely increasing one can decrease the other: therefore *looking at the smaller number among the two gives a good intuition of how informed is a model prediction.* †**sns.** Counting small numbers. **adv.** Counting adversarial. **repl.** Action replacement. ‡ **Sp.rel.** Spatial relations. *Unimodal text-only models that do not use images as input. CLIP is only tested in pairwise ranking mode (fn. 6).

ViLBERT[22] and ViLBERT 12-in-1[23].

VisualBERT VisualBERT (Li et al., 2019) is also a BERT-based transformer. Its single-stream architecture encodes image regions and linguistic features via a transformer stack, using self-attention to discover the alignments between the two modalities. VisualBERT is pretrained on MSCOCO captions (Chen et al., 2015) on two tasks: (i) masked language modelling, and (ii) sentence-image prediction. The latter is framed as an extension of the next sentence prediction task used with BERT. Inputs consist of an image and a caption, with a second caption which has a 50% probability of being random. The goal is to determine if the second caption is also aligned to the image. In our experiments, we use the publicly available implementation of VisualBERT[24].

2019) are transformer-based autoregressive language models pretrained on English data through self-supervision. We test whether our benchmark is solvable by these unimodal models by computing the perplexity of the correct sentence and compare it to the perplexity of the foiled sentence. In case the computed perplexity is higher for the foil than for the correct sentence, we assume that the correctly detected foiled caption may possibly suffer from a **plausibility bias** (as described in section 4.2) or from other biases (e.g. a model's preference towards affirmative or negative sentences).

E Mechanical Turk Annotation and Evaluation

Setup The validation study was conducted on all the data for each instrument in VALSE, as well as for the FOIL it! data (Shekhar et al., 2019b). Each instance consisted of an image, a caption and a foiled version of the caption, as shown in Figure 2. Annotators received the following general instructions:

> *You will see a series of images, each accompanied by two short texts. Your task is to judge which of the two texts accurately describes what can be seen in the image.*

Each instance was accompanied by the caption and the foil, with the ordering balanced so that the caption appeared first 50% of the time. In each instance, the caption and foil were placed above each other, with the differing parts highlighted in bold. Annotators were asked to determine *which of the two sentences accurately describes what can be seen in the image?* In each case, they had to choose between five options: (a) the first, but not the second; (b) the second, but not the first; (c) both of them; (d) neither of the two; and (e) I cannot tell. We collected three annotations for each instance, from three independent workers.

Annotator selection We recruited annotators who had an approval rating of 90% or higher on Amazon Mechanical Turk. We ran an initial, pre-selection study with 10 batches of 100 instances each, in order to identify annotators who understood the instructions and performed the task adequately. The pre-selection batches were first manually annotated by the authors, and we identified 'good' annotators based on the criterion that they preferred the caption to the foil at least 70% of the time. Based on this, we selected a total of 63 annotators. Annotators were paid $0.05 per item (i.e. per HIT on Mechanical Turk).

Results Table 5 shows, for each instrument, the number of instances in total, as well as the proportion of instances which we consider *valid*, that is, those for which at least two out of three annotators chose the caption, *but not the foil*, as the

text which accurately describes the image. We also show the number of instances for which annotators unanimously (3/3) chose the caption.

Annotator agreement As shown in Table 5, the proportion of *valid* instances in each instrument was high, ranging from 73.8% to 94.6%, with most instruments having annotators choose the caption well over 80% of the time. The table also shows two inter-annotator agreement statistics, both computed using Krippendorff's α: over all the data in a given instrument, and over the valid subset only. On the valid subset, agreement is higher, and ranges from 0.3 to 0.6 (mean = 0.42; sd=0.12). There is a significant positive correlation between the percentage of valid instances per instrument and the α value (Spearman's $\rho = 0.75; p < .05$). The low to medium agreement suggested by the α range is due to two factors: first, the statistic is computed over the entire pool of annotators, of whom there were significant diversions in the amount of annotations they computed (e.g. some workers annotated fewer than 5 HITs); furthermore, the agreement is computed over 5 categories (see above). Given these factors, the inter-annotator agreement results should be treated with caution, and are not straightforwardly interpretable as an index of human performance on VALSE - in particular, the validation task (with 5 categories) was framed differently from the benchmark (which is binary).

Bias check While measures were taken to control for distributional bias between captions and foils in the different pieces of VALSE (cf. §4.1), it is possible that sub-sampling after manual validation could reintroduce such biases. To check that this is not the case, we compare the *word frequency distributions between captions and foils* in the original pieces, and the word frequency distribution of the manually validated set. We report the Jensen-Shannon divergence and the number of words that differ between caption and foil in Table 5. The foil-caption word frequency distributions can be inspected in Figures 3 and 4. The Jensen-Shannon (JS) divergence is defined as:

$$JS(f \parallel c) = \sqrt{\frac{KL(f \parallel m) + KL(c \parallel m)}{2}}$$

where f is the normalized word frequency for foils, c the normalized word frequency for captions, m is the point-wise mean of f and c, and KL is the Kullback-Leibler divergence.

As Table 5 shows, the JS-divergence between caption and foil distributions remains the same, or changes only marginally (compare columns *JS-div* and *Js-div valid*, where *#Lexical Items* indicates the number of lexical/phrasal categories in the relevant distributions). This indicates that no significant bias was introduced as a result of subsampling after manual validation.

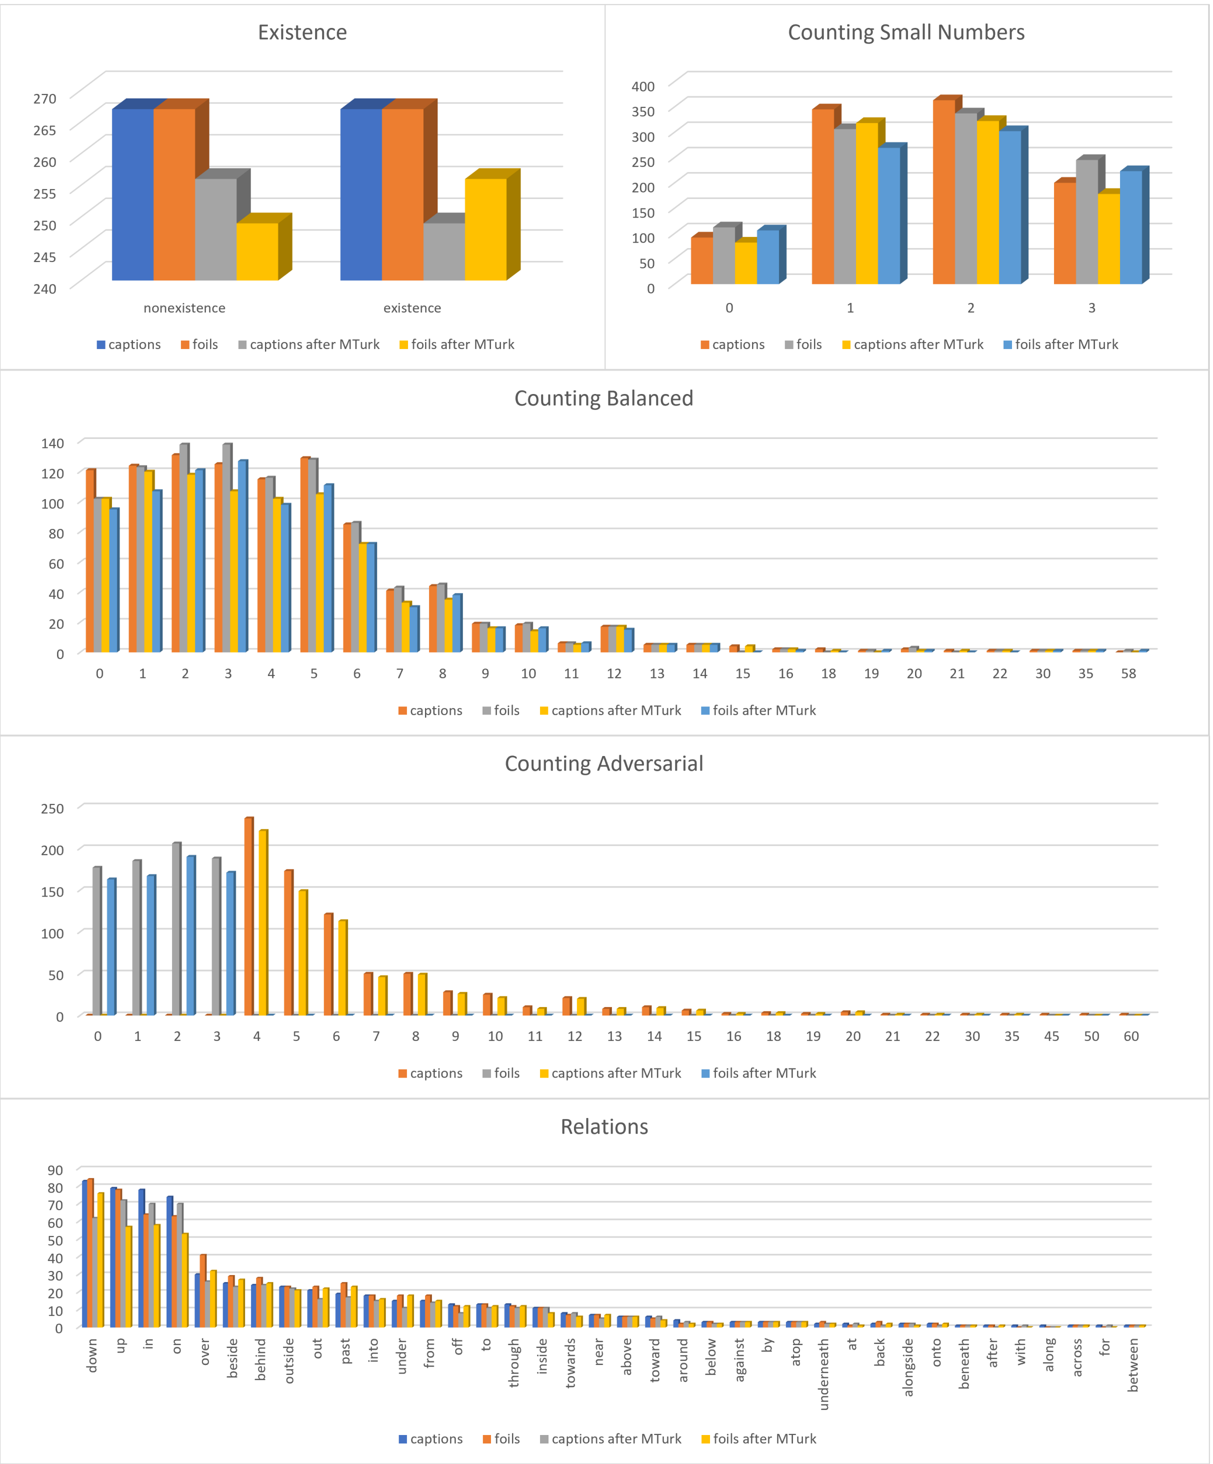

Figure 3: Word frequency distributions for captions and foils before and after the manual validation for existence, counting and relations.

Figure 4: Word frequency distributions for captions and foils before and after the manual validation for plurality, action replacement and FOIL it. The actant swap instrument is not visualised here: By construction, actant swap cannot suffer from distributional bias since caption and foil contain the same words up to a *permutation*.

Abstract

The learning trajectories of linguistic phenomena in humans provide insight into linguistic representation, beyond what can be gleaned from inspecting the behavior of an adult speaker. To apply a similar approach to analyze neural language models (NLM), it is first necessary to establish that different models are similar enough in the generalizations they make. In this paper, we show that NLMs with different initialization, architecture, and training data acquire linguistic phenomena in a similar order, despite their different end performance. These findings suggest that there is some mutual inductive bias that underlies these models' learning of linguistic phenomena. Taking inspiration from psycholinguistics, we argue that studying this inductive bias is an opportunity to study the linguistic representation implicit in NLMs.

Leveraging these findings, we compare the relative performance on different phenomena at varying learning stages with simpler reference models. Results suggest that NLMs exhibit consistent "developmental" stages. Moreover, we find the learning trajectory to be approximately one-dimensional: given an NLM with a certain overall performance, it is possible to predict what linguistic generalizations it has already acquired. Initial analysis of these stages presents phenomena clusters (notably morphological ones), whose performance progresses in unison, suggesting a potential link between the generalizations behind them.

1 Introduction

Children present remarkable consistency in their patterns of language acquisition. They often acquire linguistic phenomena in a similar order (Kuhl et al., 1992; Ingram, 1989), and make similar generalizations and over-generalizations (Kuczaj II, 1977; Pinker, 1995). This consistency provides an important starting point for linguistic study. For example, arguments in favor of single or dual system accounts of morphological representation are often backed by computational models of children learning trajectories (e.g., Rumelhart and McClelland, 1986; Pinker and Prince, 1988; Kirov and Cotterell, 2018). In this paper, we embrace this program for the study of computational language models, investigating learning trajectories. [1]

The representations that language models (LM) acquire have been studied extensively, including studying their learning dynamics to improve training (see §6). However, very little work aimed at drawing connections between the training dynamics and the learned representations. In this work we adopt a behavioral approach, thus revealing that NLMs share learning trajectories and generalize in similar ways during training. This implies that studying trajectories of NLMs is worthwhile, in the sense that results on one architecture or size are expected to be reproducible by others.

These findings call for a characterization of these trajectories, a new and promising territory for research. We take first steps to explore these directions, emphasizing their potential benefit to a better future understanding of what models learn.

Specifically, we train NLMs on next-word prediction, but evaluate and compare them by tracking their performance on grammar learning in English, using the BLIMP dataset (See 2.1). BLIMP is a dataset that consists of 67K minimal pairs, where each pair includes a grammatically correct and a grammatically erroneous sentence. NLMs are tested for their ability to assign higher probability to the correct one. See example in Table 1, and details of our experimental methodology in §2.

We begin (§3) by establishing that NLMs learn grammatical phenomena in a consistent order. We evaluate NLMs at different time points along their training, showing that the performance on linguis-

tic phenomena across initializations is highly correlated. We further find many similarities in the set of examples that they correctly classify.

Still, models of different architectures learn at a different pace, and hence cannot be directly compared at identical time points. In §3.3, we overcome this by re-scaling the timeline. We then show that despite architectural differences, NLMs present highly correlated performance trajectories. In §3.4, we further demonstrate that even the choice of training data has minor influence on the results. Finally, in §3.5 we show that the learning dynamics essentially follows a single dimension. Namely, where the average performance is similar, success on linguistic phenomena is also similar.

We proceed by analyzing the early stages of learning in §4. We find that, at first, NLMs rely mostly on local cues and not on word order. They thus resemble bag-of-words models over a window of the preceding tokens. Later stages seem to drift further away from bag-of-words models toward n-gram models, and with time seem to be more sensitive to structural cues. We also find evidence that some latent features that the model learns may not be related to linguistic phenomena.

Finally, in §5 we take the first steps in categorizing linguistic phenomena by their learning trajectories. We identify links between their representations by finding phenomena that progress in unison. For example, we find that morphological phenomena are mostly learned at similar stages. Of particular interest are cases where performance decreases with time, which may suggest either overgeneralization or biases in the BLIMP challenges.

2 Experimental Setup

2.1 The BLIMP Dataset

We use BLIMP (Warstadt et al., 2019) to assess the extent to which generalizations are made by the NLMs. BLIMP includes 67 grammatical *challenges* categorized into 13 *super-phenomena* (e.g., island-related or quantifiers) comprising of 4 broad *fields* (e.g., Syntax, Semantics). Each challenge consists of 1K minimal pairs of sentences. A minimal pair contains a sentence and a near-duplicate distractor that incorporates an error on a particular linguistic phenomenon, i.e., only the phenomenon in question is changed between the sentences in a pair (see Table 1). Each challenge includes pairs with the same linguistic phenomenon.

2.2 Training

LM details: as training multiple GPT2 instances (Radford et al., 2019) is computationally demanding, we train smaller NLMs. Following Turc et al. (2019), we trained 1 instance of GPT2$_{small}$ (width 768, 12 layers, 8 attention heads) and 4 instances of GPT2$_{tiny}$ (width 512, 4 layers, 4 attention heads), with different random seeds.

Similarly, we train a small TransformerXL (Dai et al., 2019), XL_{small} (width 512, 4 layers, 8 attention heads) and a full-sized one (width 4096, 18 layers, 16 attention heads). We stop the full model after 600K steps, while the perplexity remained high. We use it for comparison to the early stages of learning of TransformerXL. All models' hyperparameters can be found in App. §B. We also use the results of the fully trained GPT2, TransformerXL, LSTM and human performance reported in Warstadt et al. (2019).

In §4, we compare NLMs with simpler models. To this end, we create two GPT2$_{tiny}$ variations, denoted *BOW* and *Window-5*. BOW replicates GPT2$_{tiny}$, but relies only on bag of words. This is achieved by removing the positional weights, and replacing the attention weights with a simple average.[2] Window-5 similarly ignores the positions, and additionally only attends to the last 5 words. Note that both are unidirectional LMs and consider only previously predicted words at each step.

Unless explicitly stated otherwise (as in §3.4), all models were trained on the WikiBooks dataset (Zhu et al., 2015), which contains the English Wikipedia (2.1B words) and BookCorpus (854M words). This dataset resembles BERT's training data (Devlin et al., 2019), except that current Wikipedia is used. Additionally, we trained models on the following datasets: English openSubtitles (Lison and Tiedemann, 2016), newsCrawl (Barrault et al., 2019), GigaWord (Napoles et al., 2012), and

---

[2] Supposedly, removing the positional embeddings would suffice. Empirically, it has little effect. Presumably, as embeddings only attend to previous positions, the network manages to represent positions by the difference between them. This is in line with the finding that GPT2's positional embeddings are not meaning-bearing (Wang and Chen, 2020).

a sample of openWebText (3B words; Gokaslan and Cohen, 2019) – a replication of GPT2 dataset.

Throughout this paper, we report Pearson correlation. Using Spearman correlation leads to qualitatively similar conclusions. When multiple models are correlated against each other, their average pairwise correlation is reported.

3 The Learning Order of NLMs

In this section, we examine various aspects of NLMs, generally showing that their learning trajectories are similar.

We evaluate network similarity by adopting a behavioral approach. Accordingly, networks are viewed as functions, whose *latent features* manifest themselves only by their influence on the network's behavior. Latent features are the unobserved causes of the measured behavior. Consequently, parameters, activation patterns and representations can be completely different among *similar* models. This is unlike the approaches employed by Williams et al. (2018); Saphra and Lopez (2019); Liu et al. (2021), which analyze internal representations directly.

To formalize the above notion, let L_t denote a checkpoint, the language model L at time t. Let $pv(L_t)$ denote its *performance vector* – the accuracy obtained by L on each BLIMP challenge p:

$$pv(L_t) = [acc(L_t, p)]_{p \in BLIMP} \in \mathbb{R}^{67} \qquad (1)$$

Time t is measured in training steps or perplexity. The trajectory of the performance vector as a function of t reflects L's training dynamics.

Given this behavioral definition, we focus on comparing the relative strength of models. Similarity between models is thus measured as the correlation between their performance vectors. Hence, models are similar if they rank phenomena in the same way. On the other hand, models of the same average performance can be dissimilar: consider two models that agree on everything except nouns. One generates only feminine nouns and the other plural nouns. The models' average performance is similar, but due to their biases, they are correct on different challenges. This dissimilarity suggests that the models rely on different latent features.

3.1 Consistent Order of Learning

We begin by showing that models produced by different initializations learn the same phenomena, in the same order. In terms of our definitions above, this may imply that despite converging to different parameter values, the learned latent features and the generalization patterns made are similar.

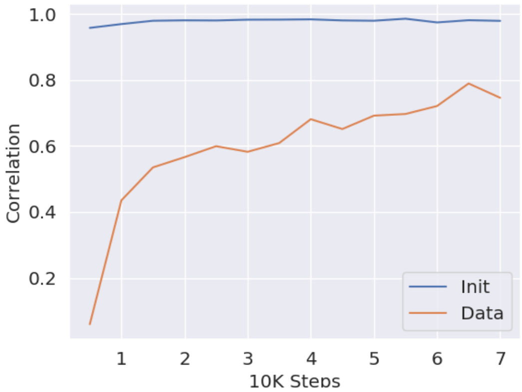

Figure 1: **High correlation** after warmup (5K steps). Correlation between the performance vectors (measured by steps) of GPT2$_{tiny}$ models with different initialization (blue) or training data (orange).

In order to examine the hypothesis empirically, we compute the correlation between 4 random initializations (Fig. 1). Results confirm the hypothesis, the correlation between GPT2$_{tiny}$ instances is extremely high. It is already high after 10K steps, and remains high throughout training. We note that the correlation at step 0 is 0 (not shown), and that after 10K warm-up steps the network's ability as a LM is still poor. For example, perplexity is 10.9 after 10K steps and 6.7 after 70K steps.

3.2 Effects of Architecture

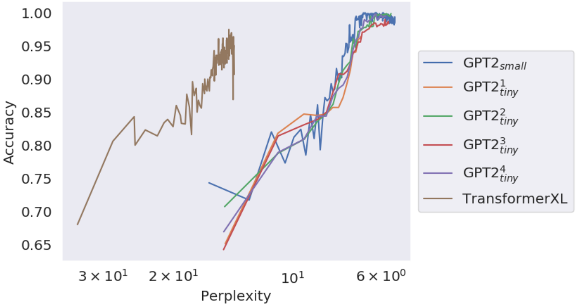

Figure 2: **Similar Accuracy** despite different initializations and sizes of the GPT2$_{small}$ models. TransformerXL perplexity is not computed on the same vocabulary, but still shows a (rescaled) similar trend. The graph depicts trajectories on an example phenomenon ("existential there"). y-axis is the accuracy during training and x-axis is the model's perplexity.

Next, we show that different architectures also present similar trajectories. As the learning pace is not comparable across models, computing correlation in fixed and identical intervals is not informative. Instead, we choose t to be the perplexity on the development set, comparing models at the same performance level. TransformerXL is not directly comparable as perplexity requires the vocabulary to be the same.

Following this paradigm, we see that GPT2$_{small}$ and GPT2$_{tiny}$ are highly correlated (>0.9), presenting similar learning order throughout training. Observing the trajectories per challenge qualitatively, we see that they align very well (cf. Fig. 2 and App. §A, §C). TransformerXL also seems to share the general tendencies of the GPT2 architectures.

Interestingly, we see that models behave similarly not only in terms of relative performance, but also at the example level (binary decision per minimal pair). We find that GPT2$_{small}$ and GPT2$_{tiny}$ have an average agreement of $\kappa = 0.83$ (Fleiss et al., 1969). This implies strong consistency in the order of learning of different examples also within phenomena. Henceforth, we focus on the phenomena-level as it is more interpretable, lending itself more easily to characterization. We discuss per-example similarity further in App. §D.

3.3 Comparison to Off-the-shelf Models

So far, we have observed the common trajectories presented by NLMs that are trained in parallel. We proceed to compare trajectories of one model to other models' performance vectors at a single point of interest in their learning, i.e. a checkpoint's performance vector. This allows us to analyze how similarities evolve, rather than whether two trajectories are synced. We compare fully trained off-the-shelf NLMs with the trajectory of GPT2$_{tiny}$ (Fig. 3a) and GPT2$_{small}$ (App. §E).

The observed similarity to off-the-shelf models is high (0.6-0.8), implying that NLMs in general share tendencies and biases. Moreover, similarity increases until the point of same performance and then (when relevant) decreases. This suggests that the small NLM approaches off-the-shelf tendencies as it improves and stops somewhere on the same trajectory of generalizations (cf. §3.5). Furthermore, we find considerable correlation with the performance levels of humans on the different challenges, but still, all NLMs correlate better with our model than humans correlate with it.

These results present a curious order imposed on the NLMs. Both GPT2$_{tiny}$ and GPT2$_{small}$ (App. §E) are more similar to the LSTM model than to TransformerXL, and even less similar to GPT2$_{large}$. Interestingly, our models are more similar to an RNN and a model with a different architecture, than to a larger model with the same architecture. Thus, it seems that the architecture type cannot explain the similarities in the relative order. We further examine this issue in the next section.

3.4 Effect of Training Data

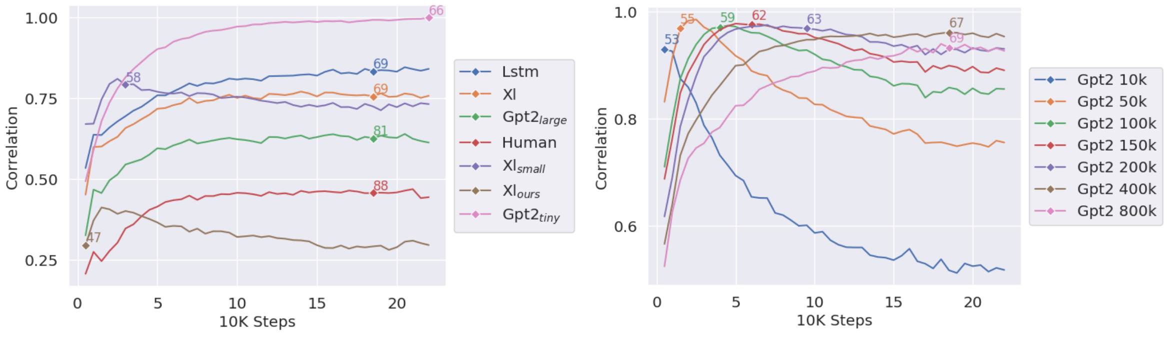
This section examines the possibility that the similarities reported in Fig. 3a can simply be explained by the similarity in the NLM's training data. More specifically, since the ranking by model similarity reported above fits the similarity between the training sets that the models were trained on, we view it as a potential confound and attempt to control for it. Our training data (WikiBooks) consists mostly of Wikipedia and so do the LSTM's and TransformerXL's training sets, which are trained on earlier versions of Wikipedia and WikiMatrix (Schwenk et al., 2019) respectively. GPT2, on the other hand, is trained on openWebText, which consists of scraped web pages.

To tease apart the effect of training data, we trained 3 additional GPT2$_{tiny}$ instances over the openWebText, openSubtitles and newsCrawl datasets. Results (Fig. 1) show that the dataset has more effect on the correlation than initialization. Hence, the choice of training data does affect the learning trajectory, but its effect decreases with training (correlation gets higher with more training steps). We also recompute the correlations from §3.3 after training GPT2$_{tiny}$ on the same data as GPT2$_{large}$ (App. §F), and find that the relative order between the NLMs remains the same, with GPT2$_{large}$ being the least similar.

We conclude that while the training data affects the learned generalizations, it only very partially explains the observed similarities between NLMs.

3.5 One Dimension of Learning

Based on the findings of the previous sub-sections, we hypothesize that current NLMs all learn in a similar order, where the effect of training data and architecture is secondary. In other words, training time, size and efficiency may affect what a model has learned, but not its learning order. This implies that stronger models may improve performance, but still follow a similar learning trajectory. If this hypothesis is correct, models should be most similar to models with the same performance; similarity should drop as the gap in performance widens.



(a) Off-the-shelf and human

(b) GPT2$_{small}$ checkpoint after X steps

Figure 3: Reference models **correlate** the most with GPT2$_{tiny}$ **when** they have the most **similar performance** (or near it). Correlation during GPT2$_{tiny}$ training compared to off-the-shelf LMs and human performance (left) or to mid-training GPT2$_{small}$ checkpoints (right). Curves correspond to fixed performance vectors. Where the X-axis follows the training trajectory of gpt, each line represents similarity to a different checkpoint, either of different fully trained models (left) or to checkpoint during the training of a larger model (right). Numbers are the average performance of the checkpoint, and are placed over the step where this average performance is the most similar to that of GPT2$_{tiny}$. The best score of GPT2$_{tiny}$ is 67.

Controlled comparison supports this hypothesis. Fig. 3b presents the correlation of GPT2$_{tiny}$ training trajectory with several static checkpoints taken during GPT2$_{small}$ training. We observe that at the point in which the average performance of GPT2$_{tiny}$ is closest to that of the checkpoint, the correlation peaks, and then decreases again as GPT2$_{tiny}$ surpasses the checkpoint in average performance. So overall correlation peaks when average performance is most similar. Note that despite the different network sizes and convergence rates, the correlation's maximal value is very high (higher than 0.9).

Further experiments show similar trends. Fig. 3a presents a similar investigation, albeit with more varied architectures and training datasets. Here too the maximum correlation is obtained around the point of most similar performance.

3.6 Comparison to 5-gram

NLMs are most similar to other NLMs with the same performance. However, when compared to non-neural LMs, this is no longer the case.

More specifically, we compare GPT2$_{tiny}$ to two 5-gram LMs trained on the same dataset as the NLMs (WikiBooks) and another (GigaWord) dataset. Results are shown in Fig. 4, which is qualitatively different from Fig. 3a. Here, similarity in performance implies neither high correlation, nor the point of highest similarity. This serves both as a sanity check to our methodology, and as a reminder of model biases: In general, models may have different biases and tendencies, regardless of overall performance. In our case, it seems that NLMs share biases between them that are not necessarily shared with other LMs.

While not the main purpose of the analysis, our comparison reveals other noteworthy trends. For example, 5-gram LMs trained on different corpora have different correlations to the GPT2$_{tiny}$ trajectory. This is further discussed in App. §G.

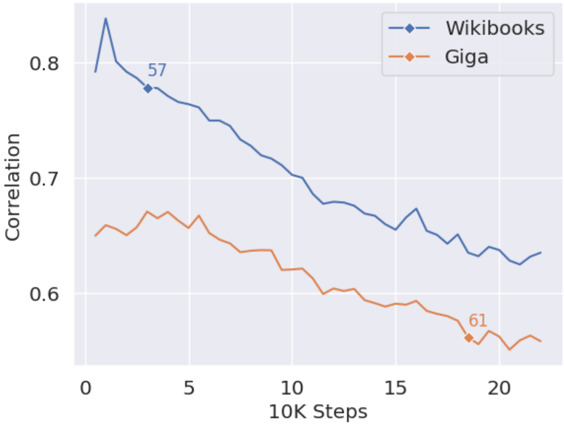


Figure 4: Correlation during training of GPT2$_{tiny}$ compared to a **5-gram** model trained on the same data (WikiBooks) and on GigaWord. On each curve, we mark the point at which the accuracy is most similar to GPT2$_{tiny}$, and additionally indicate the corresponding overall average accuracy of the reference models.

3.7 Discussion

We find that the order of learning is surprisingly stable across architectures, model sizes and training sets. Therefore, given a new NLM, the order in which it will learn linguistic phenomena can be predicted by another model that achieves a similar average accuracy. When considering non-neural LMs, this observation does not always hold: inherently different architectures (such as 5-grams) have very different trajectories. Hence, future models with very different induced biases may present different orders.

4 Phases of Learning

Having established that different NLMs learn in a consistent order, we investigate the emerging learning trajectory by comparing it with simpler reference models. Our goal is to identify distinct learning phases that characterize NLM's training.

Setup. We compare GPT2$_{tiny}$ to fully trained LMs (same as §3.3), as well as to a variety of metrics. For each metric m we compute the average score over each example for each of the 67 sets $\mathbb{E}_{p_i \in p}\left[m\left(p_i\right)\right] \in \mathbb{R}^{67}$. The results are replicated with GPT2$_{small}$ and TransformerXL and lead to similar conclusions (see App. §E).

Sentence-level Metrics. First, we consider two sentence-level metrics: sentence length (in tokens) and syntactic depth. Assuming a sentence parse tree, the depth is the longest path from a word to the root. Sentence length is often considered to be a source of challenge for infants (Brown, 1973) and networks (Neishi and Yoshinaga, 2019), regardless of the sentence's complexity. Syntactic depth (Yngve, 1960) is a measure used to assess how cognitively complex a sentence is. We leave the question of which measure of linguistic complexity (Szmrecsányi, 2004) correlates best with the trajectory exhibited by NLMs to future work.

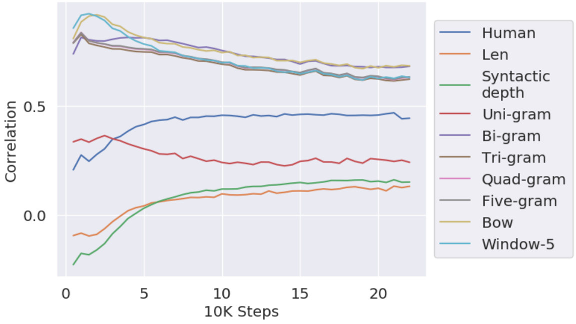

Figure 5: Correlation between the performance vectors of different **metrics** and **models** against the vector of GPT2$_{tiny}$ at different stages of learning.

Our results (Fig. 5) show that neither sentence-level metric (length and syntactic depth) can predict well what is difficult for the model. This is not surprising, as both measures only capture sentence complexity at a general level, and are not directly related to the linguistic phenomenon that is being tested. We do see that the syntactic depth starts off as a worse predictor of the NLM performance and ends as a better one. We provide a different perspective on this initial learning phase, before and after that switch, later in this section.

Next, we compare the performance vector with task difficulty for humans, as reported in the original BLIMP paper. We observe that correlation is fairly high after a sufficient number of steps. In fact, the network becomes more similar to humans as it improves: at the beginning, the network relies on different features than humans, but with time more of the hurdles are shared. However, correlation saturates at a mid-range correlation of under 0.5. This suggests that the network (partially) relies on features that are not used by human annotators. These may be valid generalizations not tested by BLIMP, or erroneous ones that are still beneficial to reduce the score on the task it was trained on (cf. McCoy et al., 2019). We revisit this issue in §5.

Comparison with Limited Context and Locality. Our methodology opens the door to examine other potential biases of LMs. We now do so, starting with context and locality.

We consider models that take into account different scopes of context: unigram, and 2-5 gram LMs that can exploit the order of preceding words. We argue that the correlation between NLMs and n-gram LMs may indicate that features based on limited context are also employed by NLMs.

Surprisingly, the unigram model, which doesn't use context, perfectly classifies 7 phenomena, achieves 98.1% accuracy on 1, and completely fails (0% accuracy) on 8. This suggests that high accuracy on some syntactic and semantic challenges (as defined by BLIMP) can be achieved by simple heuristics. Note, however, that the NLMs we test are not trained towards any specific phenomena and are not fine-tuned in any way. Hence, NLMs can only attain heuristics or biases (generalization errors) which are beneficial in general, not ones specific to our test challenges.

While NLMs initially present a strong correlation with the unigram model, this correlation quickly drops (see Fig. 5). From the outset, GPT2$_{tiny}$ succeeds on 6 of the 8 phenomena that are classified well by unigrams, and 4 of the 8 that the unigram model utterly fails on. Interestingly, for 3 of the other phenomena on which the unigram failed, GPT2$_{tiny}$ initially achieves 0% accuracy (chance level is 50%), but its accuracy does climb during training (e.g., see App. §A). We conclude that, as expected, the NLM acquires a bias towards predicting frequent words early in training, but that this bias is weighed in against other (contextual) considerations later on in training.

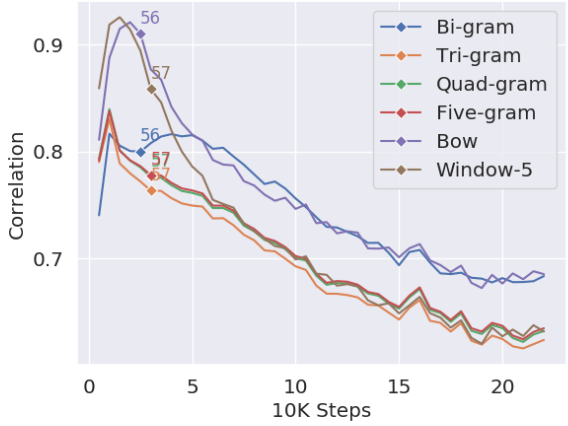

Figure 6: Correlation between the performance vectors of GPT2$_{tiny}$ throughout learning with simple LMs. The figure focuses on LMs found also on Fig. 5.

Comparing different scopes of context, our results (Fig. 6 and App. §E) show that throughout training, the network presents high correlation with n-gram models. From a certain point onward, the network becomes more similar to the bi-gram model than to the other n-gram LMs. We also note that similarity peaks early on, but with time the correlation decreases. This may suggest that initially, the NLMs acquire grammatical behavior that resembles a Markov model, or even a bi-gram model. Only later does the network rely more on global features. This is in line with our earlier findings, which show an increasing correlation with syntactic depth as compared to sentence length.

At the very beginning, NLMs often generate one word repetitions (e.g., "the" Fu et al., 2020). This seems to be at odds with our finding that grammar learning already begins at this early stage. However, while frequency may dictate the most probable predictions, comparing two options that differ only slightly may prove to depend more on context, as our results indicate.

Limited Context and Word Order. By comparing NLMs to n-grams, we examined the effect of context within a fixed window size. Now we examine the effect of word order, within a window and in general. To this end, we create two ablated GPT2$_{tiny}$ models. BOW is agnostic to the order between preceding tokens, while Window-5 is similar but relies only on 5 tokens (details in §2).

Our results suggest that initially, the identity of the preceding words is more important than their order. Both BOW and Window-5 better correlate with our NLM than the n-gram models. Later on, this trend reverses and the n-grams, that do exploit word order, become better correlated. Furthermore, the correlation with Window-5 is significantly smaller than with BOW at later stages of learning, suggesting that the network gradually learns to rely on more context (cf. Saphra and Lopez, 2019).

5 Classifying the Learning Trajectories

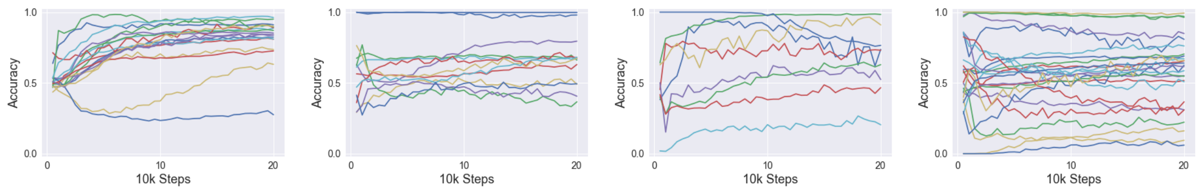
To understand the latent features learned by NLMs, we categorize linguistic phenomena through the lens of their learning trajectories. We ask whether linguistically similar phenomena are learned in a similar fashion, and whether what is learned similarly is defined by linguistic terms.

We inspect linguistic categories by comparing the learning trajectories of their phenomena. In the Morphology field, we find that they display similar gradual curves, ultimately reaching high performance (median accuracy 0.85, see Fig. 7a). This may indicate that some latent features learned are morphological, and affect performance on almost all ’Morphology’ phenomena.

Syntax-semantics phenomena also present unique behavior: their scores plateau near chance performance (see Fig 7b), suggesting that the learned features are insufficient to correctly represent phenomena in this field. The other fields, "semantics" and "syntax" (Figs 7c,7d), do not present prototypical learning curves, suggesting that they are too broad to correspond to a single learning pattern. This, in turn, may suggest that they do not all correspond to a well-defined set of latent features.

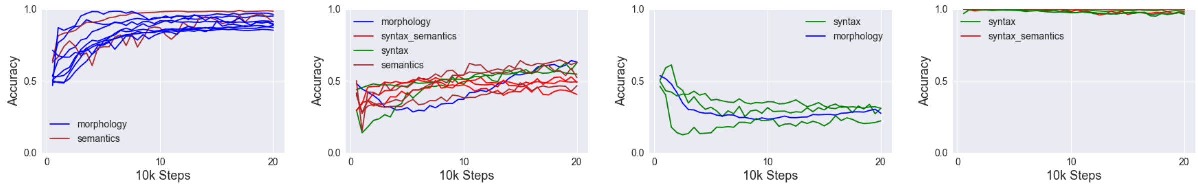
Next, we follow the reverse direction and cluster the learning curves of GPT2$_{tiny}$. We use spectral clustering with 10 clusters and sklearn default parameters, by projecting the learning curves into a normalized Laplacian and applying k-means. Intuitively, learning curves with similar values along the principal directions, are clustered together. Other clustering methods show similar results.

The clusters (Fig. 8 and App. §H) reflect several



(a) Morphology (b) Syntax-Semantics (c) Semantics (d) Syntax

Figure 7: Morphology and Syntax-Semantics (left) characterize NLM learning well, while semantics and syntactic phenomena show little similarity (between lines). Learning curves of GPT2$_{tiny}$ per challenge (lines), clustered according to different fields (graphs) and colored by super-phenomena.



(a) (b) (c) (d)

Figure 8: Some phenomena are learned, others (c) deteriorate, implying the network (that learns language modelling, not phenomena) learns orthogonal features. Learning curves of GPT2$_{tiny}$ on BLIMP challenges, obtained by spectral clustering and colored by fields.

learning profiles, some more expected than others. For some, accuracy improves as learning progresses (see Fig. 8a). Some are barely learned, and accuracy remains at near-chance level (see Fig. 8b). Perhaps more surprisingly, some clusters deteriorate, and accuracy drops to nearly 0 as learning progresses (see Fig. 8c). Notably, some challenges are quite easy – NLMs instantly reach perfect accuracy (see Fig. 8d), while some are confusing – NLMs performance is worse than chance (see Fig. 8c). In the latter cases, the NLMs presumably learn unrelated, harmful generalizations.

When inspecting the emerging clusters, many (but not all, see Fig. 8b) contain a shared prominent field, but often varied super-phenomena (see Fig. 8a). Thus, while the categorization in BLIMP reflects a common linguistic organization of grammatical phenomena, from the perspective of learning trajectories only few of the super-phenomena in BLIMP show consistent behavior. We cautiously conclude that there is some discrepancy between the common linguistic categorization of grammatical phenomena and the categorization induced by the learning trajectories of NLMs. An interesting direction for future work would therefore be the development of a theory that can account for the patterns presented by NLMs' learning trajectories.

We manually inspect a few phenomena with strong initial performance that then deteriorates. We find that some of these challenges are solvable by a simple rule, easily learnable by an n-gram model. For example, in "principle A case 1", always preferring subjective pronouns (e.g., "she" or "he") over reflexive ones (e.g., "himself", "herself") is sufficient to obtain a perfect score, and preferring "not ever" over "probably/fortunately ever" solves "sentential negation NPI licensor present". The fact that NLM performance deteriorates, fits our finding that nascent NLMs resemble an n-gram model.

6 Related Work

Characterizing what networks learn is a longstanding challenge. Recently, studies suggested methods to analyze trained models such as probing (Tenney et al., 2019; Slobodkin et al., 2021), analyzing attention heads (Voita et al., 2019; Abnar and Zuidema, 2020) and neurons (finding also correlations across epochs; Bau et al., 2018) and assessing the extent to which LMs represent syntax (van Schijndel et al., 2019). Other works compare outputs, like us, to assess network generalizations (Choshen and Abend, 2019; Ontan'on et al., 2021), look for systematic biases (Choshen and Abend, 2018; Stanovsky et al., 2019) or evaluate characteristics of outputs (Gehrmann et al., 2021; Choshen et al., 2020). McCoy et al. (2020) fine-tuned BERT and tested generalizations on the adversarial dataset HANS (McCoy et al., 2019), finding models to make inconsistent generalizations. Their results differ from ours, but so is their setup, which involves fine-tuning for inference.

Characterizing the features learned by networks according to the order in which examples and phenomena are learned is a relatively new topic. Recently, Hacohen et al. (2020); Hacohen and Weinshall (2021); Pliushch et al. (2021) showed that classifiers learn to label examples in the same order. While their focus was on computer vision, it provided motivation for this work. Other studies use learning dynamics as a tool, rather than a topic of study. They choose training examples (Toneva et al., 2018), categorize examples (Swayamdipta et al., 2020) or characterize the loss-space (Xing et al., 2018). Little research on NLM learning dynamics and generalization types was previously conducted.

Perhaps the closest to this work is Saphra and Lopez (2019), which compared LSTM representations with 3 types of linguistic tagger outputs, finding that correlation is low and that later in training, more context is used. The latter is reminiscent of our findings in §4.

In parallel work, Liu et al. (2021) probe models during training. They show that, early in training, information required for linguistic classifications is found somewhere in the layers of the model. Our work supports their findings by showing that grammar learning experiments conducted with one model are likely to replicate on another. Our methodology differs from theirs in requiring the information the model learnt to manifest itself in behavior rather than to be extractable with a dedicated classifier.

Studying the trajectories of language learning is a mostly untapped area in NLP, but is a long-established field of research in linguistics and psychology. Such lines of research study topics such as acquisition of phonemes (Kuhl et al., 1992), morphology (Marcus et al., 1992), complex constructions (Gropen et al., 1991; Qing-mei, 2007) and innate learning abilities (Tomasello, 2003). Considerable computational work was also done on constructing models that present similar learning trajectories to those of infants (McClelland and Rumelhart, 1981; Perfors et al., 2010; Abend et al., 2017, among many others).

Our work suggests that the generalizations NLMs make are coupled with the bottom-line performance. This gives a new angle and opens avenues of research when combined with previous work about bottom-line performance. For example, the bottom-line performance of small models could predict the performance of larger models (Ivgi et al., 2022). In such cases, the type of generalizations made might also be predicted from the smaller models.

Our work is also closely related to fields such as curriculum learning (Bengio et al., 2009; Hacohen and Weinshall, 2019), self-paced learning (Kumar et al., 2010; Tullis and Benjamin, 2011), hard data mining (Fu and Menzies, 2017), and active learning (Krogh and Vedelsby, 1994; Hacohen et al., 2022; Ein-Dor et al., 2020). In these fields, the order in which data should be presented to the learner is investigated. On the other hand, in our work, we study the order of the data in which the learner is learning – which may shed some light on the advancement of such fields.

7 Summary and Conclusions

We showed that NLMs learn English grammatical phenomena in a consistent order, and subsequently investigated the emerging trajectory. Our findings suggest that NLMs present consistent and informative trends. This finding suggests a path for studying NLMs' acquired behavior through their learning dynamics, as a useful complementary perspective to the study of final representations.

Future work will consider the impact of additional factors, architectures and learning phases that appear only later in training. We hope that this work will increase the affinity between the knowledge and methodologies employed in developmental studies, and those used for studying NLMs. Our goal is to obtain a better understanding of what makes linguistic generalization complex or simple to learn, for both humans and NLMs.

Acknowledgments

We thank Prof. Inbal Arnon for her helpful discussions. This work was supported in part by the Israel Science Foundation (grant no. 2424/21), by a grant from the Israeli Ministry of Science and Technology, and by the Gatsby Charitable Foundations.

A Per challenge Graphs

We include behaviours of each model trained over the main dataset used (Wikipedia and books) on each BLIMP challenge by perplexity. In general, accuracy is similar despite different initialization and size of the GPT2 models. TransformerXL shows a similar trend, despite the uncomparable Perplexity. We supply several examples here and leave the rest to the data accompanying this paper.

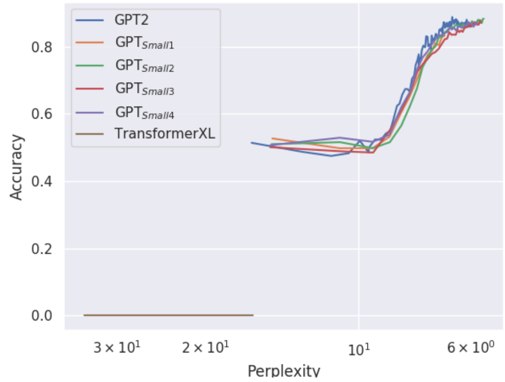

Figure 9: The accuracy on determiner noun agreement during training. Accuracy is similar despite different initialization and size of the GPT2 models. TransformerXL shows a similar trend, despite the uncomparable Perplexity.

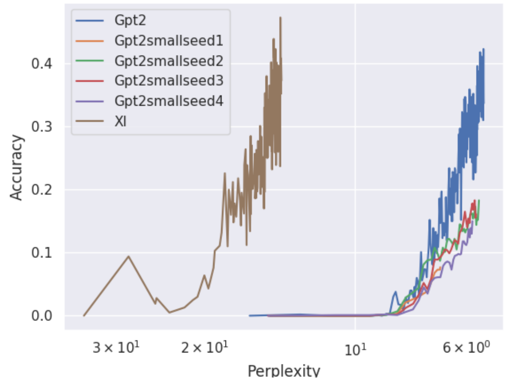

Figure 10: The accuracy on wh vs that with gap during training.

B Details on experimental settings

We include further settings to ensure reproduciblity of the results. Parameters shared by all the trained NLMs include $32K$ tokens in the vocabulary, $5 \cdot 10^{-5}$ learning rate, max gradient norm of 1, Adam optimizer (Kingma and Ba, 2015), and $10K$ warm-up steps. TransformerXl vocabulary is kept to its default. All other parameters, including GPT2$_{small}$ size parameters, are the defaults according to the HuggingFace transformers library.

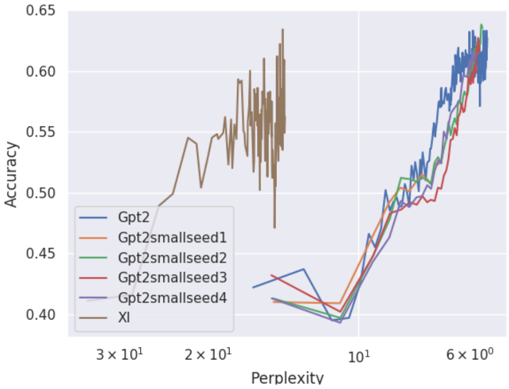

Figure 11: The accuracy on causative during training.

Our 2-5 grams are KenLM (Heafield, 2011) trained on WikiBooks. A second 5-gram model trained on GigaWord corpus (Graff et al., 2003), as reported by BLIMP. The Uni-gram LM is defined according to the frequency of a word in WikiBooks. Sentence probability is normalized by the number of words, which is helpful for the rare cases where the minimal pairs are of different lengths.

C Correlation during training

We see that tendencies during training are not only similar between instances of the same architecture but also between different architectures. On comparable stages of learning, the GPT2$_{tiny}$ and GPT2$_{small}$ correlate well (>0.9) with respect to their performance vectors. We present the correlations of GPT2$_{tiny}$ compared to GPT2$_{small}$ in Fig. 12. We find the two learn in a similar order throughout their training.

We manually compare the results to TransformerXL. Qualitatively, observing the trajectories per challenge (Trajectories are found in Supp. §A and the supplied data) of TransformerXL, it seems to share the general tendencies of the GPT2 architectures. However, reaching a lower stage of training, it never improves on some challenges (e.g., determiner-noun agreement).

D Models are consistent on per example level

We compute the binary score of every example by each model. We reframe the question as an annotator agreement problem and ask whether the models agree on the right answer for each example.

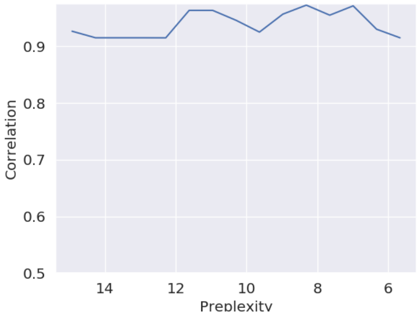

Figure 12: Correlation between the performance vectors of GPT2$_{tiny}$ and GPT2$_{small}$, aligned by perplexity.

Framed this way, the methodology is clear. We compute Fleiss kappa (Fleiss et al., 1969) and find the per example correlation. The full results per step and challenge are added as a supplemental file. The average overall kappa is 0.83, models not only agree on the order of learning phenomena but also on the order of learning examples within each per-phenomenon (if learnt at all). While there are phenomena with lower and higher agreement, there are only two phenomena in the range of 0.5-0.6 agreement. Meaning even the most different ones have high example correlation and there is little variance between models to explain.

Our main aim in this work is to compare models acquisition. However, we see the per example order of acquisition as less informative, unless we can cluster or name the examples learnt. The reason to choose the phenomena was to extract such names, and we hence focus in our work on them.

Note, that consistency per example was shown before in the scope of computer vision (Hacohen et al., 2020). However, a critical difference is that they deal with classification and check whether which examples are learnt first. We however, aim to ask about generalization, given that you learn one task (language modelling), what type of generalizations do you make, tested on another. For example, while learning to predict the next word, the network understands after X steps that the verb should be in agreement with the subject.

E Reproducing with other models

We provide the GPT2$_{small}$ correlation with other models and with various metrics and models in Fig. 13 and 14 respectively. We also supply the average BLIMP accuracies of the models we trained in Fig. 15.

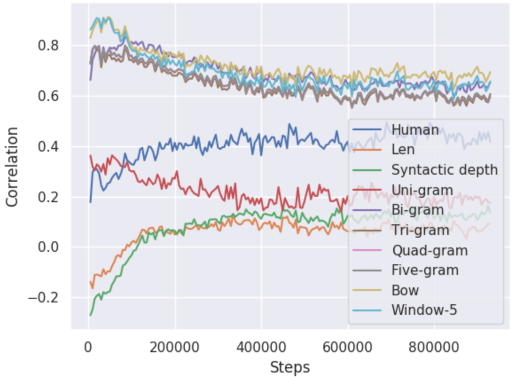

Figure 13: Correlation between the difficulty of GPT2 and of other models for each phenomena in each training step.

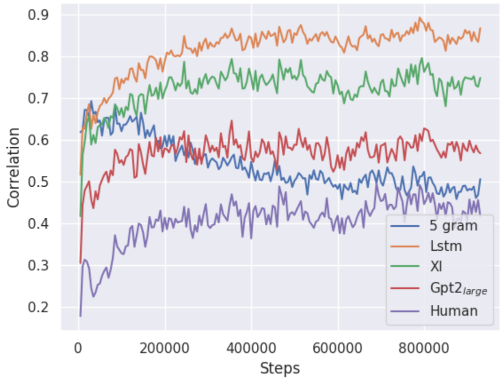

Figure 14: Correlation between the difficulty predicted by BLIMP models and the difficulties for the model for each phenomena in each training step.

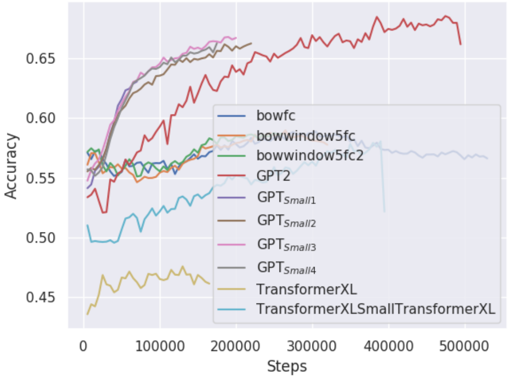

Figure 15: Overall BLIMP accuracy by step.

E.1 Results mainly replicate in TransformerXL

We replicate the same experiment over the training of the TransformerXL instance. The TransformerXL seems to reach a lower stage of learning, probably due to the vast vocabulary and model.

The model replicates some of the general notions seen on GPT2$_{small}$. It correlates most with simpler models, then with humans and then with global features. At first, sentence length makes a sentence more challenging than its actual structure, 5 window BOW starts as more relevant than BOW over all the sentence.

We do see that the overall graph is quite straight. With that, the increase in correlation with humans is quite small, the BOW models don't drop and the evidence of relying on more abstract knowledge in late stages is less apparent. This might be expected, as we know the network reached an early step on the performance scale.

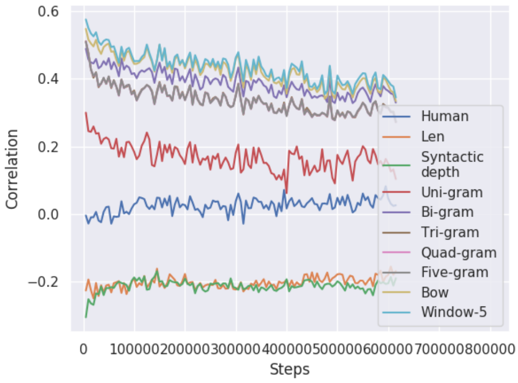

Figure 16: Correlation between the difficulty predicted by metrics and the difficulties for the model for each phenomena in each time step.

F Reproducing with other data

As comparison to the correlations with our main model, we provide the correlations of GPT2$_{tiny}$ trained on OpenWebText with the two 5-gram models, one on WikiBooks and one on Giga word (Fig. 17). We see that the higher resemblence to WikiBook trained model is kept despite being trained on the same data, but the difference is lower at the beginning and more stable. It might be the case that over reliance on the specific data is shown at those first steps where the difference is large, but it would require further evidence.

We also compare the model to several other trained models in Fig. 18.

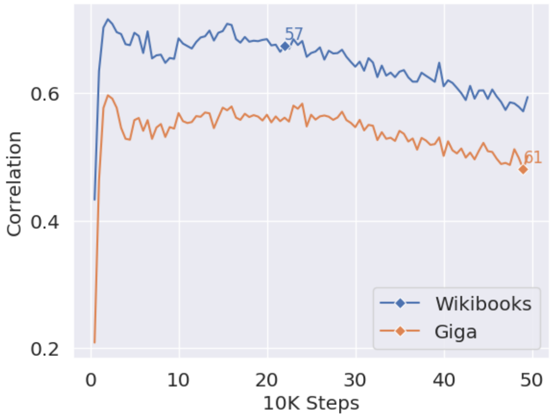

Figure 17: Correlation during training of GPT2$_{tiny}$ on OpenWebText compared to 5-gram model trained on WikiBooks and on GigaWord. Correlation is over BLIMP challenges. Numbers indicate the overall average of the reference models over BLIMP and are found over the step with most similar accuracy on GPT2$_{tiny}$. GPT2$_{tiny}$ best score is 67.

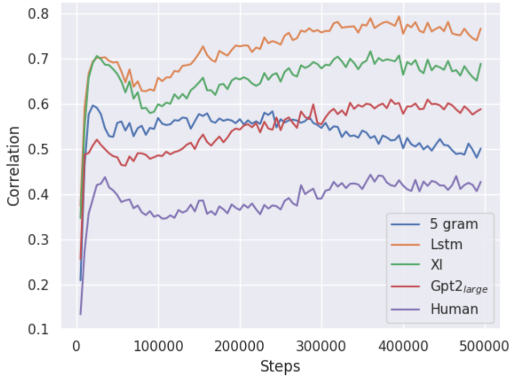

Figure 18: Correlation during training of GPT2$_{tiny}$ trained on OpenWebText data compared to Off-the-shelve models and XL smaller models. The correlation with itself during training is shown in gray. Correlation is over BLIMP challenges. Numbers indicate the overall average of the reference models over BLIMP and are found over the step with most similar accuracy on GPT2$_{tiny}$.

G 5-grams notes

The gap between the correlation with the two 5-grams decreases during the first 50K steps or so, and then remains constant. This suggests that the choice of a dataset is more important during early NLM training. Because, at the beginning the network learn generalizations which are more common to counts of one (huge, general domain) dataset than another, and this effect diminishes. Possibly, this is because at this point NLMs rely more on word identity, rather than on abstract generalizations, that are shared to a greater extent across corpora (see §4). We observe that the 5-gram trained on WikiBooks correlates better with GPT2$_{tiny}$, even when GPT2$_{tiny}$ is not trained on it (not reported). We cannot offer a simple explanation for this trend.

H Clustering BLIMP

We include the learning curves of GPT2$_{tiny}$ on BLIMP dataset, clustered according to fields (Fig. 19),, super-phenomena (Fig. 20), and the spectral clustering (Fig. 21). Due to restrictions on appendix files the figures are found in corresponding folders in the supplied data.

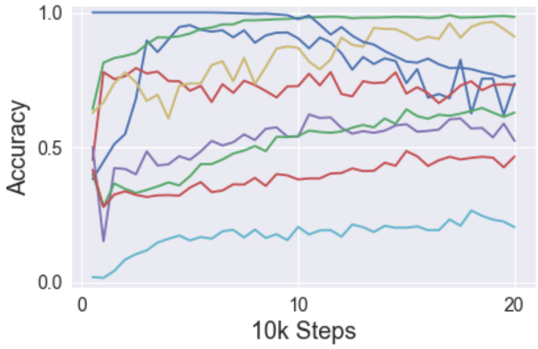

Figure 19: Cluster of semantic phenomena, each line is the trajectory of learning of a phenomenon.

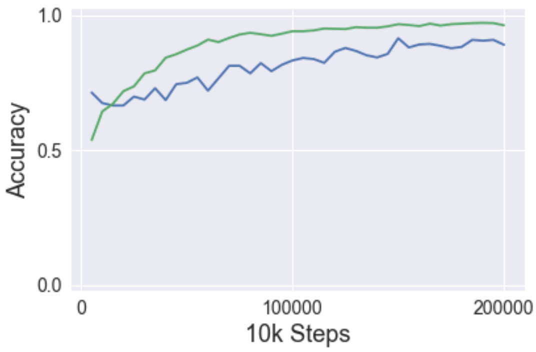

Figure 20: Anaphor agreement super phenomena trajectories.

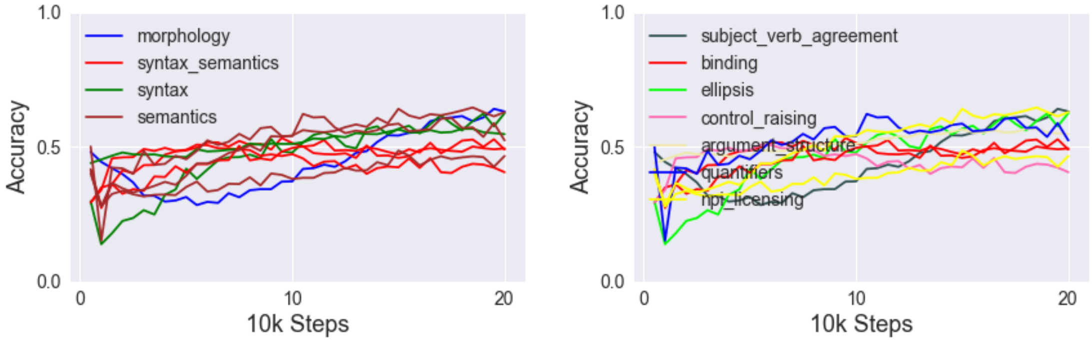

Figure 21: Cluster of phenomebna chosen by spectral clustering. The phenomena behave similarly but do not follow the same linguistic categorizations.

Generating Scientific Definitions with Controllable Complexity

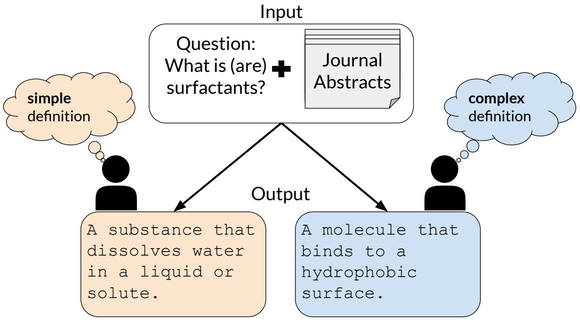
Abstract

Unfamiliar terminology and complex language can present barriers to understanding science. Natural language processing stands to help address these issues by automatically defining unfamiliar terms. We introduce a new task and dataset for defining scientific terms and *controlling* the complexity of generated definitions as a way of adapting to a specific reader's background knowledge. We test four definition generation methods for this new task, finding that a sequence-to-sequence approach is most successful. We then explore the version of the task in which definitions are generated at a target complexity level. We introduce a novel reranking approach and find in human evaluations that it offers superior fluency while also controlling complexity, compared to several controllable generation baselines.



`A substance that dissolves water in a liquid or solute.`

`A molecule that binds to a hydrophobic surface.`

Figure 1: Example of our task. Definitions are generated with a controlled amount of complexity based on the question, "What is (are) X?"

1 Introduction

Unfamiliar concepts and complex language can make understanding scientific information difficult for readers (Brossard and Shanahan, 2006; Shea, 2015; Martínez and Mammola, 2021), especially because understanding such terms is highly dependent on their domain knowledge. Given the wide variation in such knowledge, providing a one-size-fits-all definition may not be sufficiently understandable for all readers.

We envision a software tool designed to aid readers with varying domain knowledge by automatically defining scientific terms. Such a tool would afford readers control over generated definitions, including their complexity. This hypothetical system motivates research on automated generation of scientific definitions and generation-time control of definition complexity.

Prior work in generating definitions and personalizing generations to a reader falls short of these goals. Most definition generation has focused on common, general-usage words in English (Noraset et al., 2017; Balachandran et al., 2018); however, these approaches and models may not be suitable for generating scientific definitions (Beltagy et al., 2019). Scientific terms rarely reach common usage (Shea, 2015; Britt et al., 2014) and the contexts in which their definitions might appear (e.g., a research paper) are often much more complex than general-purpose resources for definitions (e.g., dictionaries or standard word embeddings). Previous methods focused on reader personalization have aimed at generating based on a reader's prior knowledge and interests (Acharya et al., 2018; Murthy et al., 2021). These approaches work well when models can leverage a reader profile (Murthy et al., 2021) or incorporate reader feedback over time. However, in many cases a model might not have access to this additional information, such as for newcomers in an online forum discussing scientific findings (August et al., 2020a). We are interested instead in providing readers the ability to explicitly set definition complexity suited to their technical comfort (McNamara and Kintsch, 1996; Kintsch, 1994; Kim et al., 2016).

We introduce a new task for generating definitions of scientific and medical terms with varying complexity (§2; Joshi et al., 2017; Fan et al., 2019).

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 8298 - 8317
May 22-27, 2022

Our dataset (§3) is constructed from consumer medical questions and science glossaries containing words that vary in their complexity and frequency.

We start by evaluating four modeling approaches for generating definitions, finding that, among them, a finetuned BART model is most successful at this new task (§4). As a first step to adjusting definition complexity, we introduce methods to explicitly set definition complexity as either high or low at generation time.

To our knowledge, this is the first paper using decoding-time controllable generation techniques on text complexity. We operationalize complexity based on readability and science communication research (Pitler and Nenkova, 2008; Gardner and Davies, 2013; Leroy et al., 2010) and evaluate several state-of-the-art controllable generation methods on this task (§5). We also develop a new, lightweight method for controlling generation based on discriminator ranking.

Our automatic and human evaluations show that our lightweight method is effective at varying complexity while maintaining high fluency and reducing factual errors. We release our dataset and code to encourage future work on this task.[1]

2 Definition Tasks

Generating definitions has been approached as a word-to-sequence task, where language models used a word's embedding to generate its definition (Noraset et al., 2017). Recent work used a sequence-to-sequence setup for generating definitions instead, where the defined word was a highlighted token in a sequence (Mickus et al., 2019).

This conceptualization of definition modeling is an important starting point for addressing our task. However, new scientific terms are introduced regularly and many never appear in dictionaries or reach common usage (Shea, 2015; Britt et al., 2014), making it difficult to rely on general-purpose dictionaries (Kim et al., 2016). Scientific terms are also notoriously esoteric (e.g., *hidden Markov model*) or else overload definitions of common words (e.g., *transformer* the model architecture versus *transformer* the electrical device), both of which complicate the use of standard word representations from pretrained models (Beltagy et al., 2019).

We address these issues by drawing inspiration from abstractive question answering (QA). Specifically, we frame our task as generating an answer to the question "What is (are) X?" This reframing allows us to leverage scientific definitions from more diverse sources (e.g., QA datasets) and to incorporate domain-specific knowledge into definition generation by including supporting information (§3.2; Chen et al., 2017; Joshi et al., 2017).

3 Dataset Collection

We collect a new dataset of definitions that are answers to the question "What is (are) X?" where X is a scientific term or concept (e.g., *carbon nanotubes*). These questions are drawn roughly equally from an existing QA dataset or templated from scientific glossaries.

3.1 Sources

We draw definitions from two sources.

Medical consumer questions Ben Abacha and Demner-Fushman (2019) collected 47,457 medical questions from 12 National Institutes of Health (NIH) websites and collected them into the MedQuAD dataset. The dataset covers 37 different question types. Three question categories are focused on defining and providing information on medical terms: "Information," "How can I learn more," and "Other information."

Manual inspection of these question categories shows that all questions are of the form "What is (are) X?" or "Do you have more information on X?" Responses to the these questions begin with a brief definition of X. After filtering for this question type and removing questions with no answer due to copyright restrictions, we had 4,525 definitions.

Wikipedia The MedQuAD questions are an excellent source of definitions, but only cover medical terms. Because we are interested in tackling scientific terms more broadly, we augment this set with terms drawn from Wikipedia science glossaries.[2] We extract all science-related terms and their definitions, yielding another 3,738 terms for a total dataset of 8,263 terms.

We also explored using other QA datasets that included scientific information to expand our coverage of scientific domains outside of medicine, such as the Explain Like I am Five (Fan et al., 2019) and ARC science exam question

Source	Count	Example Questions	Example Definitions
MedQuAD	4,525	What is (are) complement component 2 deficiency?	Complement component 2 deficiency is a disorder that causes the immune system to malfunction, resulting in a form of immunodeficiency.
		What is (are) Progressive Supranuclear Palsy?	Progressive supranuclear palsy (PSP) is a rare brain disorder that causes serious and progressive problems with control of gait and balance, along with complex eye movement and thinking problems.
Wikipedia	3,738	What is (are) rotation period?	The time that an object takes to complete a single revolution about its own axis of rotation relative to the background stars.
		What is (are) glaciation?	Process or state of being covered with a glacier.
Total	8,263		

Table 1: Dataset statistics and examples.

datasets (Clark et al., 2018). We found these questions to be less focused on definitions, though future work might find ways to make use of them.

We split our dataset into training, development, and test sets (8/1/1). Examples of terms in this dataset are in Table 1.

3.2 Support Documents

We next collect scientific abstracts related to each term to allow models to incorporate related scientific knowledge (Fan et al., 2019; Clark et al., 2018). Specifically, given a term question (i.e., "What is (are) X?"), we query S2ORC (Lo et al., 2020), a corpus of over 81 million scientific articles, for the top 10 related abstracts. Query scoring and retrieval is done with Elasticsearch.[3] These abstracts are concatenated together and form the input along with the term question for our models (§4).

We use scientific abstracts, rather than general audience text like Wikipedia or the Common Crawl, for two reasons. First, scientific terms are originally introduced and most commonly used in research papers, making them the most reliable source for these terms. Second, terms can be contextual, having different meanings in common usage. Additional details for collecting the dataset and creating the support documents are in Appendices A.1 and A.2.

3.3 Why Not Standard Dictionaries?

Our goal is to create a definition dataset with (i) coverage of scientific and medical terminology and (ii) diverse levels of complexity, to support the application envisioned in §1. We conjecture that general-purpose dictionaries will lack coverage of such terms and tend to have complex definitions for those terms that they do include. Indeed, we found that less than 20% (191) of a sample of 1,000 terms in the medical consumer portion of our dataset have entries in the Merriam Webster Dictionary (MW).[4] The dictionary definitions also use substantially more academic vocabulary: an average of 39% (s.d. 12%) of words in those dictionary definitions were in the Academic Vocabulary List (Gardner and Davies, 2013)—a list of words that occur more frequently in academic writing than common usage—compared to 29% (s.d. 12%) in the medical consumer definitions. Examples of definitions from our dataset and from MW are in Table 2.

While complex definitions are not necessarily bad, we want diverse complexity levels in our input. While medical consumer questions tend to use fewer specialized terms than a dictionary, we also find that a random sample of 1,000 Wikipedia terms in our dataset use close to as much specialized terminology as a dictionary (37%, s.d. 12%). This provides us with a wider range of complexity levels than were we to use a single source of scientific definitions. We later explore how this exposure to different complexity levels in the input makes it possible to control the complexity of generated definitions (§5.2).

4 Definition Generation: Basic Models

Our first goal is to generate fluent definitions that include relevant and accurate information about the term being defined. Because this is a new task and there are multiple reasonable approaches to generating fluent text (Prabhumoye et al., 2020), we experiment with four methods that have performed strongly in question answering and general-purpose definition generation and evaluate their effectiveness in this novel domain. For additional details on

---

[3] `https://www.elastic.co/`

[4] For this analysis, we exclude the Wikipedia science glossary terms since Wikipedia is also often used as a general-purpose resource of definitions, and the Merriam Webster API restricts us to 1,000 queries.

Term	Dictionary definition	Dataset definition
neuroblastoma	A malignant tumor formed of embryonic ganglion cells	Neuroblastoma is a type of cancer that most often affects children.
cirrhosis	Widespread disruption of normal liver structure by fibrosis and the formation of regenerative nodules that is caused by any of various chronic progressive conditions affecting the liver	Cirrhosis is scarring of the liver.
antibiotics	A substance able to inhibit or kill microorganisms; specifically : an antibacterial substance (such as penicillin, cephalosporin, and ciprofloxacin) that is used to treat or prevent infections by killing or inhibiting the growth of bacteria in or on the body	Summary: Antibiotics are powerful medicines that fight bacterial infections.

the training setups and hyperparameter tuning for the models described below, see Appendix A.3.

4.1 Methods

Sequence-to-Sequence: BART (BART SD and BART NO SD) BART (Lewis et al., 2020) has been used to define general English terms in context (Bevilacqua et al., 2020) and reached state-of-the-art results on the Explain Like I am Five (ELI5; Lewis et al., 2020) QA dataset, which includes some questions requiring scientific knowledge (e.g., “What is a Turing Machine and why is it so important?”).

We experiment with finetuning the BART pretrained model on our task and dataset in two ways. In the first, BART is trained with the term question concatenated with the supporting document (referred to as BART SD). In the second, we train a BART model with just the term question and definition answer, without the support documents (BART NO SD). This second version is included to assess how important the support documents are for generating definitions of scientific terms. We use BART-large as our base model for both versions.[5]

Out-of-the-Box Causal Language Modeling (OOTB GPT-2 and OOTB GPT-3) Recent work has also shown that large pretrained causal language models, such as GPT-2 and GPT-3, can generate fluent answers to factual questions without finetuning (Brown et al., 2020).

We experiment with using both GPT-2 and GPT-3 out-of-the-box (OOTB GPT-2 and OOTB GPT-3). We use GPT-2 medium[6] and GPT-3 davinci[7] for these experiments. For OOTB GPT-3, we evaluate with 100 terms due to OpenAI API limits. For generation, we follow the few-shot setting proposed in Brown et al. (2020) and prepend two held-out question term and definition pairs before each generation.

We do not include the support documents in this few shot setting since doing so extends beyond GPT-2's context window of 1024 tokens and preliminary results showed that the additional text led to fewer definitions and more repetition from the abstracts.

Finetuning GPT-2 (FT GPT-2): Because OOTB GPT-2 and OOTB GPT-3 involve no finetuning or use of the support documents, we suspect that they will underperform BART SD. We experiment with finetuning the GPT-2 medium model (FT GPT-2) with the question and support document, separated by new special tokens.

Information Retrieval (OOTB BIDAF): Information retrieval (IR) methods are an important part of many open-domain QA systems and have presented a strong baseline in scientific question answering (Clark et al., 2018). We experiment using a pretrained BiDAF model (Seo et al., 2018) to extract the highest scoring span in the support document based on the term question (OOTB BIDAF). We use AllenNLP's implementation of BiDAF trained on SQuAD.[8]

4.2 Results

Model	Response
BART SD	Acanthoma is a skin lesion that develops from cells in the skin.
BART NO SD	Aanthoma is a type of **skin cancer**.
FT GPT-2	Acanthoma **(cancer) is a type of cancer**.
OOTB GPT-2	Acanthoma is a **type of skin cancer** that is caused by **the fungus Acanthamoeba histolytica**. **It is a common skin cancer in the United States, and it is also found in other parts of the world, such as the United Kingdom, Australia, and New Zealand**.
OOTB GPT-3	An Acanthoma is a **form of skin cancer** which can also be termed as a skin tumor that arises from the cells of the epidermis, is usually pinkish in color and may or may not be itchy. Acanthomas are classified in various ways based on their histological appearance, such as:
OOTB BIDAF	**Broad Line Region**

Table 3: Generated definitions from each modeling approach for the question: "What is (are) Acanthoma?" Factually incorrect information is labelled in **bold red**.

Model	ROUGE (↑)			BERT (↑)
	1	2	L	
BART SD	**0.33**	**0.16**	**0.30**	**0.89**
BART NO SD	0.32	0.15	0.29	0.89
FT GPT-2	0.27	0.08	0.24	0.87
OOTB GPT-2	0.20	0.05	0.16	0.85
OOTB GPT-3	0.30	0.14	0.27	0.87
OOTB BIDAF	0.03	0.00	0.03	0.80

Table 4: ROUGE and BERT scores for basic definition generation methods..

models. OOTB GPT-3 performs surprisingly well, outperforming even FT GPT-2. BART NO SD also performs closely to BART SD, suggesting that while the support documents can boost performance in this task, the effect can be small. OOTB BIDAF extracts spans that don't answer the question.

Table 3 provides examples of the generated definitions for each modeling approach. BART SD provides the most concise answer while also remaining informative, compared to FT GPT-2's definition, which is circular (e.g., "Acanthoma (cancer) is a type of cancer"). While most models show impressive background knowledge, there is evidence of incorrect or hallucinated information, such as acanthoma being a type of skin cancer (OOTB GPT-2 and BART NO SD), these hallucinations are marked in Table 3. We explore the amount of hallucinated information further in §7.2. For the rest of the paper we use the BART SD model since it outperforms other methods.

5 Controlling Definition Complexity

Automatically generating definitions is an important first step in supporting readers who come across unfamiliar scientific terms, but individuals can have different tolerances for the complexity of a definition depending on their domain knowledge (Britt et al., 2014). The models we tested in §4 were not trained to vary the complexity of definitions; they do not adapt definitions to different readers. Here we explore how to control the complexity of generated definitions.

Controlling or guiding text generation is an active research area with important applications like toxicity control (Gehman et al., 2020) and language debiasing (Ma et al., 2020). For a review, see Prabhumoye et al., 2020. To the best of our knowledge, ours is the first work to evaluate decoding-time controllable generation methods for text complexity.

One task that has considered changing text complexity is text simplification. Work on text simplification has mostly used a machine translation setup based on parallel corpora (Zhu et al., 2010; Cao et al., 2020) to translate complex sentences into simple ones. These parallel corpora are rare and often expensive to create (Xu et al., 2015). This setup also assumes an input text to be simplified (Surya et al., 2019), whereas our task expects that the text will be generated with varying complexity.

5.1 Baseline Generation Control Methods

Below we describe prior methods, used as baseline generation control methods. In each case, we focus on a binary distinction between "low complexity" and "high complexity" definitions, leaving more fine-grained distinctions to future work. We also introduce a novel lightweight approach based on reranking candidate generations in §5.2. Additional details for training are in Appendix A.4.

Plug-and-play language models PPLM (Dathathri et al., 2020) is a technique to guide generation using the gradients of a classifier for a

---

are later evaluated on. Hyperparameter tuning and finetuning were done on split subsets of the training data.

particular desired text attribute. At each generation step, the classifier's gradients are used to update the language model's hidden representations. Due to the computational expense of PPLM, we evaluate with 100 randomly sampled test set terms.

We train our attribute classifier on sentences from scientific journal abstracts and scientific news articles. Journal abstracts are sampled from the ArXiv dataset (Clement et al., 2019) and used to guide to more complex language. Scientific news articles are sampled from a corpus of science news articles (August et al., 2020b) and used to guide towards less complex language.

Generative discriminators The GeDi method (Krause et al., 2021) uses a class-conditioned language model trained on text with a certain desired (or undesired) feature (e.g., toxicity) to guide generation. At each generation step, the model provides next token probabilities to the generator via Bayes' rule. We train a new GeDi on the same dataset of science news and journal articles as for PPLM.

Ensemble of language models DExperts (Liu et al., 2021) combines multiple pretrained language models in an ensemble of "experts" and "anti-experts." Specifically, a base language model is combined with a language model trained on text with desirable attributes (expert) and text with undesirable attributes (anti-expert). At generation time, the base model's logits are combined with the difference of the expert's and anti-expert's logits.

Our expert and anti-expert are pretrained BART-large models that we continue to pretrain on the data used to train the PPLM discriminator. One model is pretrained on the journal abstracts and one on the science news articles. To generate more complex definitions, the expert is the model trained on journal abstracts while the anti-expert is the model trained on science news. To generate less complex definitions, the roles are reversed.

5.2 Novel Approach: Reranking

We introduce a new, lightweight method to generate definitions with different complexity via reranking. Past work has explored selecting candidate generations based discriminator scores to control for specific topics or discourse structure but found that it did not provide strong control (Dathathri et al., 2020; Gabriel et al., 2021). Because our generation task does not require topic shifts and our input has naturally varying complexity (§3.3), we adapt this method by scoring and selecting candidates based on complexity discriminators.

Specifically, at test time we use our BART model (BART SD) to generate 100 candidate definitions for each definition. We then rerank these candidate generations based on logits from a discriminator trained to distinguish scientific journal text from science news text. While this method requires regenerating the definition many times, it does not require gradient or probability distribution updating during generation or any prior pretraining, allowing for much greater flexibility during generation (e.g., generating from a language model without access to vocabulary logits during generation). We consider two discriminators. Both are trained on the same dataset of science news and journal articles as PPLM.

BERT We use the SciBERT uncased pretrained model (Beltagy et al., 2019). For more complex definitions we select definitions with high predicted probability for journal text, and for less complex definitions we select definitions with high prediction probability for science news text.

Linear We also experiment with using a linear SVM classifier. The SVM's features are complexity measures drawn from science communication and readability literature, discussed in §5.3.

5.3 Complexity Measures

The complexity of scientific writing is affected by many factors and it is difficult to operationalize it into a single dimension. We therefore use multiple measures of scientific writing complexity based on prior work in science communication and readability. These measures are not meant to be an exhaustive list (for a review, see Pitler and Nenkova, 2008), but a selection of measures that capture different elements of complexity important to definitions. Table 17 in the Appendix has examples of model outputs that scored either very high or very low for each measure.

Scientific language is often associated with language formality (Lahiri, 2016; Heylighen et al., 1999). This might lead to some methods introduced in §5.1 to generate definition with higher formality when guided towards higher complexity. We therefore focus our measures on aspects of complexity important for reader comprehension (e.g., unfamiliar terminology or dense text) rather than the formality of the definition.

We use most of these measures in two different

Model	AVL ↑	TE ↑	Function Words ↓	GPT ppl. ↑	Sent. Length ↓	Flesch-Kincaid ↑
Rerank-SVM	**0.10**	**0.12**	**–0.04**	**128.71**	**–0.53**	1.60
Rerank-BERT	**0.01**	**0.04**	**–0.01**	–4.36	0.20	0.68
DExperts	–0.06	**0.05**	0.01	**1130.29**	**–3.23**	–4.01
GeDi	–0.01	**0.01**	–0.01	–40.45	**–1.14**	–0.48
PPLM (100)	–0.02	**0.03**	**–0.01**	123.16	–0.67	–0.04
Journal - News	**0.10**	**0.08**	**–0.04**	**238.07**	2.94	2.68

Table 5: Differences between high and low complexity generations. **Bolded** values are statistically significant in the correct direction using independent samples t-test corrected with the Bonferroni-Holm correction for multiple hypothesis testing (Holm, 1979). Flesch-Kincaid is a single score and so not tested for significance.

ways. Five of them are the features in our linear SVM reranker. We also use them as a preliminary automatic evaluation of the various controllable generation approaches in §5.1 and §5.2. Obviously, we expect the linear SVM reranker to outperform the other approaches in this automatic evaluation since it was trained with these complexity features; it should be considered something like an upper bound for these complexity measures. Our human evaluations (§6.2 and §7) provide a more complete picture of the systems' performance.

Academic Vocabulary List (AVL) occurrences The AVL is a list of academic vocabulary drawn from corpora spanning many scientific disciplines (Gardner and Davies, 2013). We measure the fraction of AVL words in a generated definition.

***Thing Explainer* out-of-vocabulary** The popular book *Thing Explainer* explains scientific concepts using only the 1,000 most frequent words in English (measured by Wiktionary's contemporary fiction frequency list; Munroe, 2017).[10] We measure the fraction of words in the definition outside of the top 1,000 used in *Thing Explainer*.

Function words In health communication, function words (e.g., prepositions, auxiliary verbs, or question words) positively correlate with perceived and actual readability (Leroy et al., 2008, 2010).

Sentence length Sentence length is a commonly used metric for document level complexity and is part of many classic readability measures (Pitler and Nenkova, 2008; Feng et al., 2010). While we set a maximum generation length for our definitions (64 tokens), we enable early stopping. While longer sentences are often considered more complex, we hypothesize that in our dataset longer definitions will be associated with less complex language due to elaborative simplification, where complex terms are explained as a way of simplifying them (Srikanth and Li, 2021).

Language model perplexity Language model perplexity has been found to correlate with perceived and actual reading difficulty (Pitler and Nenkova, 2008; Collins-Thompson, 2014). We use the GPT model to measure language model perplexity, as it was trained on common English (as opposed to scientific text).

Flesch-Kincaid grade level This score (FK) uses simple calculations based on sentence length, word length, and syllable counts (Kincaid et al., 1975). Although findings are mixed on how well the FK predicts readability in science or medical documents (Leroy et al., 2008), it is a standard, widely used measure of text complexity (Redmiles et al., 2019). The FK expects a document with multiple sentences, but our definitions are a single sentence. To address this, we calculate the FK based on the concatenation of all definitions generated by a particular method. For the same reason, we do not include the FK score as a feature in our SVM reranker (§5.1).

5.4 Complexity in Journal Abstracts and News Articles

As a preliminary analysis of complexity using our measures, we evaluate how the journal abstracts and science news articles used for guiding complexity generation (described in §5.1) vary across our measures. Table 5 includes a row representing the difference in each measure between the training set of journal abstracts and science news articles (Journal - News). We see that all the measure behave in the expected direction except sentence length, which goes in the opposite direction. This might signify that journal abstracts still use longer sentences even if science news articles are explaining complex topics to simplify them (Srikanth and Li, 2021).

Control Method	Direction	
	Low (News)	High (Journal)
SVM-Rerank	A type of computing in which there are many computers running at the same time in different parts of the world.	In computer science, distributed computing is the process of computing on a large scale **without a single centralized data center**.
BERT-Rerank	A type of computer system in which there are more than a few computers working together.	In computer science, distributed computing is the process of computing on a large scale **without a single centralized data center**.
GeDi	Is the implementation of computer programs across multiple computers on similar hardware and/or software resources.	In computer science, **a concept that states that data must be shared across computing resources**.
DExpert	An **Internet-driven by-computing** that portion of different computers from start to finish.	In computer science and communication between-Consequently-integrates.
PPLM	**Easeless, self-organized, and often self-organizing** networked computer systems intended for the purposes of optimization.	Multi-purpose, distributed **system software** with or without a single datum storage system.

Table 6: Generated definitions from each complexity control method for the question: **What is (are) distributed computing?** Factually incorrect information is labelled in **bolded red**.

6 Evaluating Complexity

Here we evaluate how well our baseline and novel generation control methods can vary the complexity of definitions. For each generation method, we generate and evaluate 10 definitions for each term.

6.1 Automatic Evaluation

We automatically evaluate each control method by calculating the difference in each complexity measure (§5.3) for the high and low complexity generations. Table 5 details these differences. While each measure captures a different element of complexity, counting the number of words outside of the top 1,000 most common English words (TE) seems to be one of the most consistent measures, with all higher complexity generations having differences in the expected direction. DExperts and the BERT reranker have the largest differences, with 5% and 4% more words per sentence. Higher complexity generations also have higher GPT perplexity, with DExperts having the largest difference.

The two rerankers (BERT and SVM) perform better than other models on most measures. This is unsurprising for the SVM since it was trained with these complexity features, but it is interesting that reranking with the BERT classifier also provides effective control over complexity. Table 6 provides example generations based on each approach.

6.2 Human Evaluation

Automatic classification of text complexity is difficult and domain-specific (Collins-Thompson, 2014; Redmiles et al., 2019); even in combination, we believe the measures in §5.3 are insufficient for a full evaluation of our approaches. We therefore carry out a human evaluation to assess how each method influences perceived definition complexity.

We select the models that performed best overall in our automatic evaluation: DExperts, GeDi, and the SVM reranker.[11] We randomly sample 50 terms from our test split to evaluate. We use a high and low complexity generation from each model, leaving us with $50 \times 2 \times 3 = 300$ definitions.

We broke down complexity into two ratings: how complicated a definition was and how difficult to understand the definition was. For each, participants rated definitions on a 1–4 Likert scale. We recruited participants on Amazon Mechanical Turk. Each participant was payed US$0.50 cents based on US$10 dollars/hour. This study was approved by our institution's internal review board.

Participants 233 participants took part in our evaluation (mean age 35 years, s.d. 11). Table 18 in the Appendix provides more details on their demographics. We removed 4 participants due to low effort responses (i.e., responding to all prompts with the same rating within 15 seconds).

Results Figure 2 shows the average ratings for each model type. DExperts generations differentiate most between high and low complexity. GeDi definitions behave in a way that is the opposite of what we expected, with the low complexity generations rated as more complicated and difficult to understand than the high complexity generations. The SVM-reranked definitions perform in the expected direction, with high complexity generations

---

[11] We do not include PPLM in this analysis due to its computational cost and similar performance to GeDi.

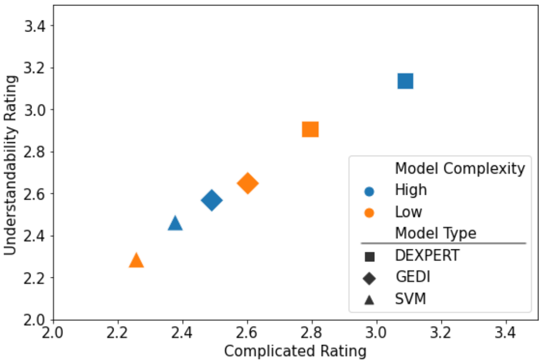

Figure 2: Average ratings for how complicated ("How complicated is the definition's text?") and difficult to understand ("Imagine you are looking up this term, how hard is it for you to understand this definition?") definitions are for each model on each complexity level. Range is from 1 = "Not at all" to 4 = "Very". No differences are statistically significant.

being rated as more complicated and difficult to understand. Examples of ratings and raw counts are in Table 19 and Figure 4 in the Appendix.

7 Evaluating Fluency, Relevance, and Factuality

Our results suggest that our reranking method is a simple intervention that can control complexity with similar performance as other state-of-the-art methods. However, definitions of scientific terms also must be fluent, relevant, and factual. Factuality can be especially difficult to achieve in generations (Maynez et al., 2020). In science communication such failures could spread misinformation with fluent but incorrect definitions (Britt et al., 2019).

We do two additional human evaluations for fluency and relevance (§7.1), and factuality (§7.2). We used two trained annotators, one of them an author, to rate the same 300 definitions used in the complexity evaluation (§6.2). Neither annotator saw the model generations before evaluation or knew which method had generated each definition.

7.1 Fluency & Relevance

Annotators rated definitions for fluency and relevance using 1–4 Likert scales (1 = "Not at all" to 4 = "Very"). Table 7 shows the average fluency and relevance ratings. The SVM-reranked definitions were rated close to "Very" fluent and relevant (both above 3.5 on a 4 point scale), and significantly more fluent compared to GeDi ($t_{198} = 5.99$ $p < 0.001$, Cohen's $d = 0.60$) and DExperts ($t_{198} = 18.85$ $p < 0.001$, $d = 1.88$).

Model	**Fluency (s.d.)↑**	**Relevence (s.d.)↑**	**Factuality (s.d.)↓**
SVM	3.71 (0.59)	3.51 (0.78)	1.81 (0.81)
GeDi	3.20 (1.06)*	2.86 (1.22)*	2.38 (1.12)*
DExpert	2.33 (0.85)*	2.80 (0.91)*	2.59 (0.97)*

Table 7: Fluency, relevance, and factuality ratings from our human evaluation. More details are in Appendices A.7.2 and A.7.3. * =Significant compared to SVM ratings using independent t-tests corrected for multiple hypothesis testing using the Bonferroni-Holm correction.

7.2 Factuality

For each definition, annotators identified if there was any factually incorrect information in the definition (a binary label) and if so, rated how extensive these errors were on the same 1–4 scale. Table 7 reports on the average rating for how extensive these errors were. Below we report on the binary label.

Overall 60% of our generations were labeled as factually incorrect by at least one annotator (40% by both). The SVM had significantly fewer factual errors (38% by one annotator, 16% by both), compared to GeDi (52% and 33%, $t_{198} = 4.71$ $p < 0.001$, Cohen's $d = 0.47$) and DExperts (86% and 67%, $t_{198} = 12.29$ $p < 0.001$, $d = 1.24$).

8 Conclusion

We introduce a new task and dataset for generating definitions of scientific terms with controllable complexity as a way of adapting to different readers' scientific background. We evaluate conventional generation methods and introduce a lightweight approach of reranking candidate generations based on a discriminator to control complexity. We find that this reranking is effective at controlling text complexity while also maintaining fluency and factuality. We release our dataset and code to encourage more work on making scientific terms more accessible to readers of diverse background knowledge.[12]

9 Ethical Considerations

The goal of this paper is to enable a wider audience of readers to understand and engage with scientific writing. A risk, though, is that such attempts might instead widen the gap to accessing scientific information. The texts in the datasets we train our models on are in General or Academic American

---

[12] `https://github.com/talaugust/definition-complexity`

English. Many people, especially those who have been historically underrepresented in STEM disciplines and medicine, may not be comfortable with this dialect of English. This risks further alienating the readers we hope to serve. This is a common issue in NLP systems (Sap et al., 2019), since the majority of datasets are in General American English. An important and exciting direction in NLP is making models more flexible to dialects and low-resource languages (e.g., the ACL 2022 special theme being "Language Diversity").

While our results suggest that the lighter control of reranking generations leads to less hallucinated information, strong supervision of definition factuality is important for any future deployment of such a system. While hallucinated information can be damaging in any generation context, incorrect scientific definitions could mislead readers and potentially contribute to broader scientific misinformation. Furthermore, a bad actor could use these models to generate fluent but incorrect definitions at scale, potentially contributing to misinformation campaigns with a veneer of scientific language (Britt et al., 2019). We trained our models on data we believe is trustworthy (e.g., questions and answers from NIH websites); and we release our training data and models to allow for further work on encouraging factuality in these model generations.

Acknowledgements

We thank Anita Silva for her help annotating definitions and the Mechanical Turk annotators for their work on the project. We also thank the anonymous reviewers and members of the UWNLP and DUB community for their helpful feedback. A Appendix

A.1 Data Collection

We downloaded all terms from the Wikipedia science glossaries.[13] We included the first definition for each term, and cleaned Wikipedia text of URL and image references. Note that since the glossaries provide definitions of all terms on a single page, we did not use the full Wikipedia articles for each term. For each Wikipedia term, X, we format the term as the question "What is (are) X?".

Because our definitions often include additional information beyond a definition (e.g., recommendations for checking if you have the disease being defined), we use the first sentence of each response, which is commonly used in constructing definition datasets (Fahmi and Bouma, 2006).

A.2 Support Documents

Following Fan et al. (2019), we concatenate the abstracts together using a <*P*> token to create a support document for each term question. We filter all retrieved journal abstracts for each question to make sure that none of the same abstracts occur across the train, development, and test splits in our data.

We analyze how often definitions occur in our support documents by searching the documents for the phrase "X is a/an." We find that around 20% of the support documents contain at least one sentence with this phrase. Manual inspection of these sentences revealed that many of them are heavily jargoned, usually containing very few of the same words as our gold definitions. When removing these examples from our test and development set we see no drop in performance. We view these embedded definitions as an additional source of complexity that our models can leverage to vary the generated definitions' complexity.

A.3 Definition Generation Finetuning

All training and finetuning was done on a NVIDIA Titan X 12GB GPU. We select 1,000 examples from our training dataset and seperate them into a 75/25 split for training and testing each hyperparameter setting. For our model evaluations in §4, we train on a 75/25 split of the full training data and reserve the original development split for testing.

Finetuning BART (BART SD and BART NO SD) For finetuning the BART model on our dataset, we do a random search for hyperparameter tuning with a subset of our training data. We ran a total of 10 search trials. During training and generation we concatenate the template question with the support document in the format "question: What is (are) X? context: <SUPPORT DOC>" for BART SD. For BART NO SD, we instead use only the question.

Table 8 details the final hyperparameters. We use the training code provided by HuggingFace for sequence-to-sequence summarization finetuning.[14]

Out-of-the-Box (OOTB) Language Modeling (OOTB GPT-2 and OOTB GPT-3) For generation, we follow the few-shot setting proposed in Brown et al. (2020). We prepend two held-out question term and definition pairs, shown in Table 9. The two examples are separated by two newlines and a separator token used during generation as the stop symbol (i.e., *###*). At generation time we append the question for the term. Some GPT-3 outputs were empty, which we ignore for evaluation.

Finetuning GPT-2 (FT GPT-2) Each part of the input (supporting document, question, definition) is prepended with a new special symbol (i.e., <*context*>, <*question*>, <*definition*>) and the model is trained in the standard causal language model loss. At generation time, the model is conditioned on the support document, question, and the <*definition*> tag.

We do the same random search for hyperparameter tuning for the GPT-2 model as for BART with the same subset of data. One difference is that we finetune on the standard causal language modeling objective for GPT-2 rather than the sequence-to-sequence summarization task. We use the training code provided by HuggingFace for causal language model training.[15] Table 8 details the final hyperparameters for our GPT-2 model.

A.4 Discriminator Training

We filter out all sentences sampled from the journal abstracts and scientific news articles that are less than 5 words, as these sentences are usually bylines

Table 8: Final hyperparameters for finetuning the BART and GPT-2 models on definition generation and bounds for hyperparameter tuning random search.

Hyperparameter	BART Assignment	GPT-2 Assignment	Bounds
Number of epochs	3	3	[3, 5]
Effective batch size	8	16	[4, 8, 16]
Learning rate	5e-05	4e-04	[4e-3, 4e-4, 4e-5, 5e-05, 4e-6]
Adam Epsilon	1e-08	1e-07	[1e-7, 1e-8, 1e-9]
Source length/Block size	1024	1024	[1024]
Target length	64	NA	[64]

Table 9: Held out QA pairs for OOTB GPT-2 and OOTB GPT-3.

Question	Answer
What is (are) complement component 2 deficiency?	Complement component 2 deficiency is a disorder that causes the immune system to malfunction, resulting in a form of immunodeficiency.
What is (are) entrepreneurship?	The efforts by a person, known as an 'entrepreneur,' in organizing resources for the creation of something new or taking risks to create new innovations and production.

or headers, and randomly sample 50k sentences from each set (100k total) for training, and another 5k each for the development and testing splits.

Even some science news articles require background knowledge not shared among all possible readers (Shea, 2015). We try to address this issue by sampling sentences from science venues that reach a broader audience (e.g., magazines) and have been shown to have lower jargon levels (August et al., 2020b).

PPLM For training the PPLM attribute classifier, we adapt the HuggingFace training code[16] to work with the sequence-to-sequence architecture of BART. Our attribute classifier is trained from the BART-large pretrained model. We use the default training hyperparameters, shown in Table 10.

GeDi For training the GeDi discriminator we adapt the authors' original training code[17] to work with the sequence-to-sequence architecture of BART. Our GeDi is trained from the BART-large pretrained model. We use the default training hyperparameters, shown in Table 11.

Table 10: Hyperparameters for BART-large PPLM training.

Hyperparameter	Assignment
Batch size	64
Embedding size	1024
Number of steps	10 epochs
Learning rate	1e-4

Table 11: Hyperparameters for BART-large GeDi training.

Hyperparameter	Assignment
Number of epochs	1
Max length	192
Effective batch size	4
Learning rate	2e-5
Lambda	0.80

Table 12: Hyperparameters for additional BART-large pretraining for DExperts.

Hyperparameter	Assignment
Number of epochs	3
Source length	512
Target length	512
Effective batch size	8
Learning rate	5e-05
Learning rate optimizer	Adam
Adam epsilon	1e-08
learning rate scheduler	linear
weight decay	0

DExperts For the expert and anti-expert models, we continue to pretrain the BART-large model on science journal text or science news text. Because there is no official script for BART's pretraining, we re-implement the text corruption described in the original paper (Lewis et al., 2020). We specifically create a text-infilling approach, where a number of tokens are masked from each sentence. The number of tokens is drawn from a Poisson distribution ($\lambda = 3$), and they are replaced with a single [MASK] token. We use one mask per sentence in the dataset. We use the default pretraining hyperparameters from HuggingFace's sequence-to-sequence summarization script, detailed in Table 12. We again start from the BART-large pretrained language model.

BERT Reranker We use the SciBERT model (Beltagy et al., 2019) to train our BERT reranker. The training data is identical for training our other discriminators. Table 13 details hyperparameter settings.

SVM Reranker We train our SVM with complexity features from Section 5.3 to classify sentences from academic journal abstracts and science news text using the same dataset for training our discriminators. The SVM reaches 79% accuracy on held out data, showing that these features can be strong differentiators of scientific text.

Table 13: Hyperparameters for BERT reranker training.

Hyperparameter	Assignment
Number of epochs	3
Max input length	1024
Effective batch size	16
Learning rate	5e-05
Learning rate optimizer	Adam
Adam epsilon	1e-08
Learning rate scheduler	linear
Weight decay	0.01
Warmup steps	500

Table 14: Hyperparameters shared among all models for generation. For reranking, the top 10 samples are taken out of 100 total returned sequences.

Hyperparameter	Assignment
Number of samples	10
Number of beams	5
Top-p (sampling)	0.9
Top-k	50
Temperature	1
Max length	64
Min length	8

A.5 Complexity Generation Hyperparameters

We use the same generation hyperparameters across all models where possible. Shared generation hyperparameters are detailed in Table 14, while those specific to PPLM and GeDi are in Table 15, and Table 16, respectively. For DExperts, there is one additional hyperparameter, α, which we set to $\alpha = 2.0$ based on the authors original experiments (Liu et al., 2021). For reranking, the top 10 samples are taken out of 100 total returned sequences.

A.6 Complexity Features

To calculate complexity features, we tokenized and lemmatized all generated definitions using Spacy.[18] We lemmatized all words in the AVL and *Thing*

---

[18] `https://spacy.io/`

Table 15: Hyperparameters specific to PPLM for generation. Details of each hyperparameters can be found in (Dathathri et al., 2020).

Hyperparameter	Assignment
Number of samples	10
Stepsize	0.06
Gamma	1
GM-scale	0.9
KL-scale	0.01
Repetition penalty	1.0
Grad length	10,000
Horizon length	1
Window length	0

Table 16: Hyperparameters specific to GeDi for generation. Details of each hyperparameters can be found in (Krause et al., 2021).

Hyperparameter	Assignment
Posterior weighting exponent	30
Filter p (1 - p)	0.8
Target p (τ)	0.8
Repetition penalty scale	10
Repetition penalty	1.2

Explainer list to search for AVL word occurances and *Thing Explainer* out-of-vocabulary words.

For function words, we used Spacy's POS tags. The following tags we considered function words: ['DET', 'ADP', 'PRON', 'CONJ', 'SCONJ', 'AUX', 'PART', 'INTJ']. For the Flesch-Kincaid grade level, we use the py-readability-metrics package.[19]

Table 17 provides examples of definitions that scored high and low for each complexity feature.

A.7 Human Evaluations

We select our number of samples (50) based on a power analysis with an expected medium effect and power $\beta = 0.8$ (for more information on power and statistical tests in NLP, see Card et al., 2020).

A.7.1 Complexity & Understandability

The participant demographics for the complexity evaluation (§6.2) are shown in Table 18.

Before beginning, participants filled out a short demographics questionnaire detailing their age, highest degree attained, and STEM (Science, Technology, Engineering, and Math) education. They then reviewed instructions that provided examples of very complex and not at all complex definitions (Figure 5). Each participant rated 3 definitions randomly drawn from different terms. Figure 3 provides an example of the interface for the complexity evaluation. Raw counts of complexity and understandability ratings are provided in Figure 4.

Interrater agreement was relatively low for complexity (Krippendorff's $\alpha = 0.14$) and understandability ($\alpha = 0.14$). This is unsurprising given that we used untrained annotators and perceived complexity and understandability are often based on a reader's domain knowledge (Kintsch, 1994).

A.7.2 Fluency and Relevance

Annotators were given examples of very fluent and relevant definitions, and not at all fluent and relevant definitions before starting the task. For fluency, annotators were asked, "How fluent is this definition?" and for relevance, they were asked, "How relevant is this definition for the term?" Interrater agreement was high for both fluency (Krippendorff's $\alpha = 0.63$) and relevance ($\alpha = 0.58$).

A.7.3 Factuality

Annotators were given examples of very extensive factual errors and and not at all extensive factual errors before starting the task. For each definition, annotators checked a box if there was any factually incorrect information in the definition based on the question, "Does this definition contain factually incorrect information?" and if so, rated how extensive these errors were based on the question, "If the definition contains factually incorrect information, how extensive are these errors?" Annotators were encouraged to use the internet if they did not know if a definition was correct.

Interrater agreement was high for both whether a definition contained factually incorrect information (Krippendorff's $\alpha = 0.59$) and how extensive these errors were ($\alpha = 0.55$).

---

[19] `https://pypi.org/project/py-readability-metrics/`

Table 17: Examples of sentences with high or low values of each complexity feature. The Flesch-Kincaid reading level score is not included since it is calculated over all responses for a model.

Feature	**High**	**Low**
AVL Occurances	The process by which organic material dissolves in soil.	Your gallbladder is part of your liver.
Thing Explainer OOV	Rock composed mostly yellow tolukalaceous organic material composed mostly marine calcite.	Your brain changes as you age.
Function Words	A place to shelter from the elements of a storm.	See kin genealogy.
GPT Perplexity	A metamorphism consisting mainly pyroxenesiloclinic pyroxene.	Your body is made up of many types of muscles.
Sentence Length	An area of machine-readable digital forerunners or virtual reality-generally enhanced with the goal of gathering, organizing artificial intelligence and guiding artificial neural networks in-depth (machine learning from artificial neural network technology, machine learning and/machine learning and machine learning.	See asteroid impact.

Table 18: Participant demographics for the complexity evaluation.

Age	0-19	0
	20-29	74
	30-39	106

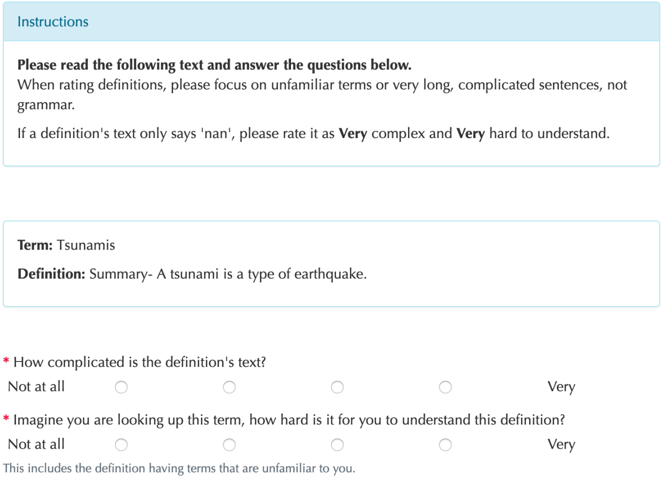
	10+	32



Instructions

Please read the following text and answer the questions below.
When rating definitions, please focus on unfamiliar terms or very long, complicated sentences, not grammar.

If a definition's text only says 'nan', please rate it as **Very** complex and **Very** hard to understand.

Term: Tsunamis

Definition: Summary- A tsunami is a type of earthquake.

* How complicated is the definition's text?
Not at all ○ ○ ○ ○ Very

* Imagine you are looking up this term, how hard is it for you to understand this definition?
Not at all ○ ○ ○ ○ Very
This includes the definition having terms that are unfamiliar to you.

Figure 3: Human evaluation interface for definition complexity. The fluency and factuality evaluations had the same interface.

Table 19: Example generations and their ratings. Examples are selected to show a range of ratings.

Model	Term	Definition	Complexity	Understandability
DEXPERT High	Bayesian Programming	A formalism for problem-solving in computer programming.	1	4
DEXPERT Low	Zirconium	A rock mineral that crystallises on rock beds or minerals silicate beds.	3	1
GeDi Low	Sexually Transmitted Diseases	There are a number of sexually transmitted diseases.	1	1
GeDi High	Tsunamis	Summary : Tsunamis are oceanic tsunamis.	2	4
SVM Low	Paroxysmal extreme pain disorder	Paroxysmal extreme pain disorder (PEPD) is a rare form of erythromelalgia.	4	2
SVM High	Kelvin–Helmholtz instability	A condition in which the flow of charged particles in a fluid is unstable.	4	4

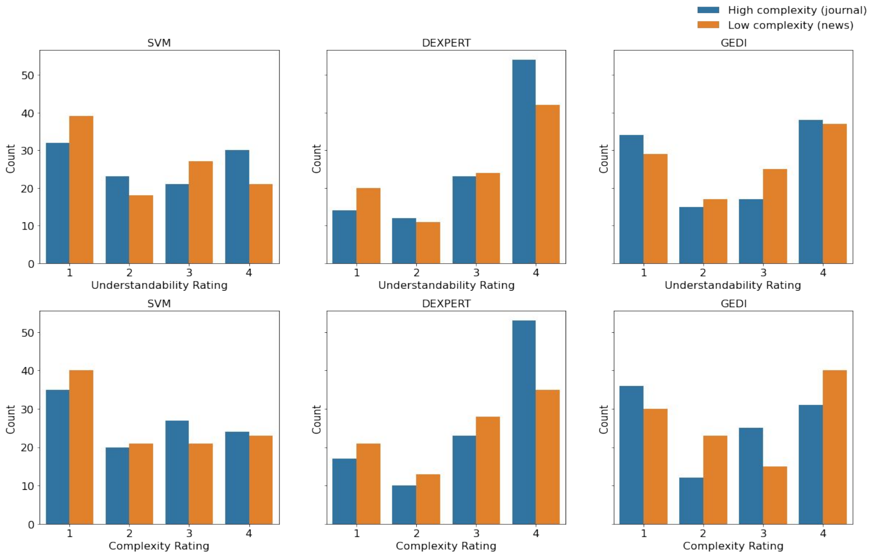


Figure 4: Counts of complexity and understandability ratings for each controllable generation method. 1 = Not at all and 4 = Very.

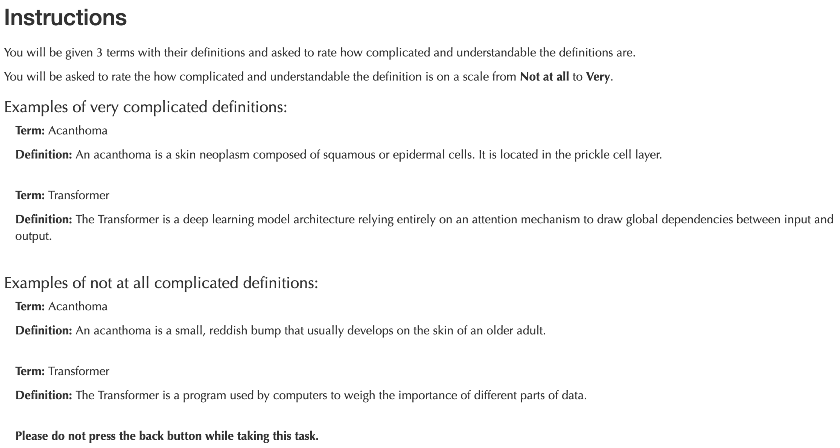

Instructions

You will be given 3 terms with their definitions and asked to rate how complicated and understandable the definitions are.

You will be asked to rate the how complicated and understandable the definition is on a scale from **Not at all** to **Very**.

Examples of very complicated definitions:

Term: Acanthoma

Definition: An acanthoma is a skin neoplasm composed of squamous or epidermal cells. It is located in the prickle cell layer.

Term: Transformer

Definition: The Transformer is a deep learning model architecture relying entirely on an attention mechanism to draw global dependencies between input and output.

Examples of not at all complicated definitions:

Term: Acanthoma

Definition: An acanthoma is a small, reddish bump that usually develops on the skin of an older adult.

Term: Transformer

Definition: The Transformer is a program used by computers to weigh the importance of different parts of data.

Abstract

In text classification tasks, useful information is encoded in the label names. Label semantic aware systems have leveraged this information for improved text classification performance during fine-tuning and prediction. However, use of label-semantics during pre-training has not been extensively explored. We therefore propose **L**abel **S**emantic **A**ware **P**re-training (LSAP) to improve the generalization and data efficiency of text classification systems. LSAP incorporates label semantics into pre-trained generative models (T5 in our case) by performing secondary pre-training on labeled sentences from a variety of domains. As domain-general pre-training requires large amounts of data, we develop a filtering and labeling pipeline to automatically create sentence-label pairs from unlabeled text. We perform experiments on intent (ATIS, Snips, TOPv2) and topic classification (AG News, Yahoo! Answers). LSAP obtains significant accuracy improvements over state-of-the-art models for few-shot text classification while maintaining performance comparable to state of the art in high-resource settings.

1 Introduction

Large pre-trained language models have enabled better performance on many NLP tasks—especially in few-shot settings (Brown et al., 2020; Schick and Schütze, 2021a; Wu and Dredze, 2020). More informative representations of textual inputs often leads to much higher downstream performance on NLP applications, which explains the rapid and general adoption of models such as (Ro)BERT(a) (Devlin et al., 2019; Liu et al., 2019), GPT-2 (Radford et al., 2019), and T5 (Raffel et al., 2020). However, while these models are often used to effectively encode inputs, fewer works have attempted to give models access to informative representations of *labels* as well.

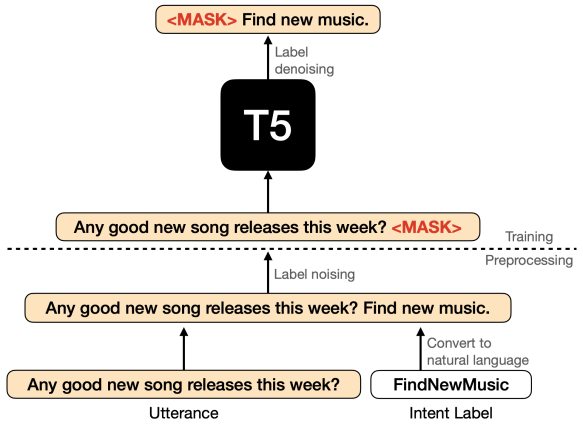

Figure 1: Overview of our approach, label semantic aware pre-training (LSAP). We collect utterance-intent pairs and create new pairs from unlabeled Reddit and Twitter data, convert the intents to natural language, concatenate the utterance and intent, noise the concatenated sequence, and train a sequence-to-sequence model to denoise the sequence.

Most discriminative approaches to text classification only give the model access to label indices. A recent stream of work has obtained significant improvements in structured prediction tasks by using sequence-to-sequence (seq2seq) models to generate labels (Athiwaratkun et al., 2020; Paolini et al., 2021). Yet these generative approaches make use of label semantics—the meaning of class label names—only during fine-tuning and prediction. Thus, we propose **L**abel **S**emantic **A**ware **P**re-training (LSAP) to incorporate label semantics as well as input-label associations into the pre-training step (Figure 1). Our experiments show that LSAP yields higher performance with fewer fine-tuning examples in a variety of domains.

Our contributions include the following:

1. A method to incorporate label semantics into generative models during pre-training.
2. A method for creating utterance-intent pairs for label semantic aware pre-training from unlabeled noisy data.

3. State-of-the-art few-shot performance on intent and topic classification datasets.

Our code is publicly available.[1]

2 Related Work

Label semantics has been leveraged in many settings and tasks to improve performance and robustness, even before dense embedding representations became standard: Chang et al. (2008) achieve over 80% accuracy on binary text classification tasks without any labeled training examples by giving naïve Bayes classifiers rich semantic representations (Gabrilovich and Markovitch, 2007) of labels. Song and Roth (2014) use a similar approach for hierarchical and multinomial classification, finding that dataless procedures approached the performance of (and sometimes outperformed) supervised approaches.

More recently, label semantics based on dense embedding representations have become popular—especially with the rise of contextualized word embeddings (Peters et al., 2018). One stream of work integrates label representations using label vectors and label attention: label-wise attention networks (LWAN; Mullenbach et al., 2018) are designed for datasets with very large structured label spaces, and where multiple labels can apply to a potentially very long document. Mullenbach et al. (2018) generate label feature vectors and use an LWAN based on convolutional neural networks (CNNs); Rios and Kavuluru (2018) extend the attention mechanism for zero-shot settings. Chalkidis et al. (2020) use BERT to embed the labels for an LWAN.[2] In contrast, our label space is flatter and much smaller, and the input texts are much shorter on average.

Another label-semantic-aware approach for massively multi-label text classification is CLESS (Rethmeier and Augenstein, 2022). CLESS performs contrastive pre-training from scratch on a question-answering dataset with a large and sparse label space. Using contrasts between positive and negative answer embeddings, they obtain performance comparable to or better than RoBERTa using only in-domain data. However, CLESS pre-trains and classifies on the same data, and is meant for classification in one domain with a very large label space; our setting contains a larger mismatch between pre-training (where we have domain-general data and a large label space) and fine-tuning (where we have domain-specific data and a small label space). We want our approach to be more domain-general and to leverage the simplicity and effectiveness of token and span reconstruction objectives—for example, masked language modeling (Devlin et al., 2019) and span denoising (Raffel et al., 2020). Thus, we opt to perform secondary pre-training on data from a variety of domains using an existing model.

Other work integrates label embeddings into short-text intent and topic classification systems, more similarly to our task. Gaonkar et al. (2020) use label embeddings from BERT and a label attention mechanism to improve emotion classification accuracy. Generative approaches like those of Rongali et al. (2020); Athiwaratkun et al. (2020); Paolini et al. (2021) implicitly make use of label semantics for text and token classification tasks by generating the labels at prediction time. Rastogi et al. (2019) use embeddings of human-defined schema which guide a dialogue state tracking system.

Few-shot text classification entails performing classification after training or tuning a model on only a few examples from the training split of an evaluation set. Recent approaches to this include (Ro)BERT(a)-based (Chen et al., 2020) and especially XLNet-based (Yang et al., 2019) classifiers, prototypical networks (Snell et al., 2017), dynamic memory induction networks (Geng et al., 2020), and generative classification (discussion follows).

Text classification contains more specific subtasks. Here, we evaluate on topic classification (TC; labeling text with its general domain, e.g. "world news") and intent classification (IC; labeling intentful text with what it is trying to accomplish, e.g. "book flight"). The scarcity of IC data in many domains prevents the use of many neural text classification methods (Krone et al., 2020). In IC, the input is a conversational utterance and the output is a label describing what the user intends to do; for example, given a set of intents {`BookHotel`, `BookFlight`, `CheckAccount`} and an input utterance "I would like a flight to NYC next month", the model should classify the utterance as `BookFlight`. Recent approaches to few-shot IC include dual encoders (Cer et al., 2018; Henderson et al., 2020;

---

[1] `https://github.com/amazon-research/label-aware-pretrain`

[2] Note that BERT-Base often performs similarly to or better than BERT-LWAN, and XLNet performs significantly better than BERT-Base in text classification settings that more closely resemble our setting (Yang et al., 2019). We therefore opt to compare to XLNet.

Casanueva et al., 2020), combining prototypical networks with meta-learning (Krone et al., 2020), a nearest-neighbor discriminative method (Zhang et al., 2020a), and span-level contextualized embedding retrieval (Yu et al., 2021).

Generative text classification has become more feasible with the advent of large pre-trained language models (Radford et al., 2019; Brown et al., 2020). Here, one tunes a model to generate a natural language label given an input sequence, which reduces the train-test gap and does not require architectural changes.

Pattern-exploiting training (PET; Schick and Schütze, 2021a,b) entails formatting train and test examples as cloze-style prompts, where the label is generally one word. Here, a language model can see the inputs and the embeddings of the output classes during tuning and prediction, though unlike our approach, there is no domain-general training step. Prompt tuning (Lester et al., 2021; Gao et al., 2021) improves PET by automatically optimizing the prompt design. Our approach is even more widely applicable in that we give the model concatenated utterances and labels and allow it to transduce to variable-length label sequences, rather than reformatting the evaluation data into a cloze format where the label must be one word/token.

Sequence-to-sequence (seq2seq) approaches based on pointer/copy mechanisms (Rongali et al., 2020) or T5 (Raffel et al., 2020) tend to be effective and more data-efficient for text and token classification in semantic parsing tasks, including slot labeling (Athiwaratkun et al., 2020) and entity-relation extraction (Paolini et al., 2021). In this method, one trains or fine-tunes a seq2seq model to transduce from an unlabeled text sequence to a sequence with labeled spans (or to just the label). Our approach is based on T5, but unlike prior work, we perform a *label semantic aware* secondary pre-training step on a variety of datasets before fine-tuning.

3 Approach

Our approach, LSAP, performs a secondary pre-training step with T5 on a large scale collection of (pseudo-)labeled examples; see Figure 1 for an overview. In addition to training on existing labeled datasets (§3.1), we (1) filter unlabeled data using a **dialogue act classifier** (§3.1.1); (2) pseudo-label the utterances that pass the filter using an **intent generator** (§3.1.1); and (3) perform secondary pre-training on the labeled and pseudo-labeled data using T5 (§3.2). §3.1 details how we collect, select, and label pre-training data. §3.2 describes the pre-training formats we test in our experiments.

3.1 Data

Our pre-training data (Table 1) consists of utterances with intent labels. We use intentful utterances for pre-training because intent labels are often more specific, informative, and varied than sentiment or topic labels. For example, consider the intents `BookFlight` and `ViewAirfare` versus the topic `AirTravel`. Our pre-training corpus combines gold (human-labeled), silver (heuristically labeled), and bronze (pseudo-labeled) data.

We first collect gold datasets: here, we use a set of non-public benchmark datasets as well as PolyAI Banking (Coope et al., 2020), which yields approximately 130K training examples containing over 1,200 unique intents.[3]

To supplement this data, we add the silver WikiHow intents (Zhang et al., 2020b) dataset, which is heuristically labeled. Each WikiHow example consists of an utterance, the longest step in a WikiHow article, and an intent label (the article title with "How To" removed). Training on this dataset has been shown to improve few-shot IC performance in a variety of domains (Zhang et al., 2020b).

3.1.1 Pseudo-labeling Noisy Data

Gold and silver conversational datasets are scarce and tend to focus on one or a few narrow domains. To obtain more data from a larger variety of domains, we propose a filtering and labeling pipeline for converting unlabeled conversational data into pseudo-labeled "bronze" pre-training data. See Figure 2 for an overview.

We start by collecting conversational utterances. We first use the Customer Support on Twitter (CSTwitter) dataset;[4] this consists of over 2.81M tweets to and from company customer support agents. We also use the Reddit PushShift dataset;[5] this dataset is large, so we only download most recent comment dumps by date until reaching 100M comments.

Dialogue act classifier. In a conversational dataset, many utterances will not be intentful, and thus will not lend themselves to informative labels. For example, the statement "Hiking is an

[5] `https://files.pushshift.io/reddit/comments/`

Dataset	Quality	Description	Training Examples		Intents
Internal benchmark data	Gold	Benchmark datasets. 15+ domains from English locales.		119,920	1,172
PolyAI Banking	Gold	Online banking queries.		10,016	77
WikiHow Intent Classification	Silver	Automatically labeled intent classification dataset. Intent is article title with ”How to” removed, and utterance is the longest step in the article.		110,573	110,573
			Pre-filter	**Post-filter**	
Customer Support on Twitter	Bronze	Conversations (tweets) between consumers and customer support agents on Twitter.	2,811,774	446,309	122,909
Reddit PushShift	Bronze	Comments scraped from Reddit.	100,000,000	680,000	220,786

Table 1: Pre-training datasets. “Quality” refers to the source of the labels (human-labeled is gold, deterministically labeled is silver, probabilistically labeled is bronze). “Pre-filter” and “Post-filter” refer to the number of training examples before and after using the dialogue act classifier described in §3.1.1.

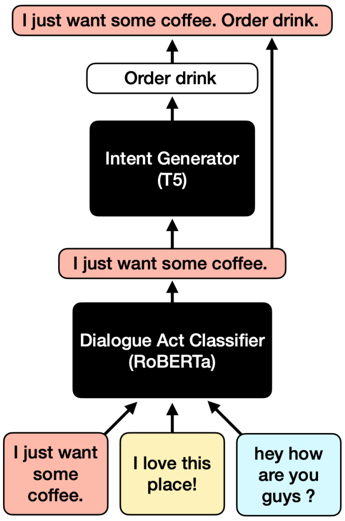

Figure 2: Our pipeline for creating utterance-intent pairs from unlabeled conversational data. We automatically filter data for intentful utterances using a dialogue act classifier, and then run filtered utterances through a T5-based intent generator. Each filtered utterance and its respective intent is concatenated to create a pre-training example.

outdoor activity” does not express a clear goal out-of-context (i.e., it is non-intentful), whereas “Buy a plane ticket to NYC for next month” is a command with a clear goal. Applying an intent label to a non-intentful utterance may lead to supervision that is harmful to downstream performance. To filter for intentful utterances, we tune a RoBERTa-based binary classifier (intentful vs. non-intentful) using Multi-Domain Goal-Oriented Dialogue (MultiDoGO; Peskov et al., 2019) and Schema-guided Dialogue (SGD; Rastogi et al., 2019; Kale and Rastogi, 2020). For MultiDoGO, we treat greetings/goodbyes, thank yous, and other generic intents as non-intentful/negative examples; we treat all other intents that are not out-of-domain as intentful/positive examples. For SGD, we treat any utterance tagged with INFORM intents as non-intentful; utterances with intents tagged as REQUEST are treated as intentful. When evaluating on a held-out set of MultiDoGO and SGD, the classifier achieves 98% precision.

To evaluate the precision of the classifier on our newly filtered data, we randomly sample 150 utterances (per dataset) tagged as intentful by the classifier and calculate the proportion that are actually intentful, as judged by human evaluation. For CSTwitter, we obtain 91% precision; this high precision may be due to the dataset being composed primarily of intentful customer-service-focused queries. For Reddit, we initially obtained 54% precision. We qualitatively find that the probability assigned by the classifier to the positive label correlates well with intentfulness, so for Reddit, we exclude all examples to which our classifier assigned a positive-label probability lower than the median for all utterances tagged as positive examples. After probability thresholding, we obtain 76% precision on Reddit.

Intent generator. To label the intentful utterances, we train a T5-based generative intent labeler. We fine-tune T5 on the gold and silver data to transduce from utterances to intents (e.g., “intent classification: Find me a hotel in NYC” → “Book hotel”), and then apply this tuned model to the filtered utterances. We find that this model gen-

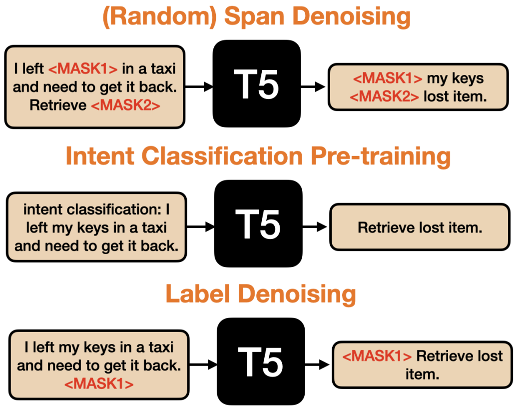

Figure 3: Pre-training formats that we test in our experiments. We find that label denoising is best.

erates intents not seen in the training set for 37% of the utterances. These novel intents often but do not always demonstrate lexical overlap with the utterance (e.g., "i'm wondering if there's fireworks for sale there?" → "Fireworks for sale") or add specific descriptors to intents from the training set (e.g., "Find a job" appears in the training set, but our model generates "Find a job in the UK" which does not).

3.2 Pre-training Formats

We experiment with different pre-training formats, all but one of which are based on T5's span denoising objective. See Figure 3 for an overview of our formats and an example of each.

First, we try *random span denoising*. In this approach, we concatenate each intent label (in natural language format) to its associated utterance. Then, we randomly noise 15% of the tokens[6] in the utterance-intent input sequence, reconstructing the contiguous noised spans in the output sequence. This is the same objective that T5 uses.[7]

Our second approach is *intent classification (IC) pre-training*, where we supervise T5 with utterances and intents in the same format used for downstream supervised fine-tuning. Here, the input sequence is "intent classification: " followed by the utterance. The output sequence is the intent.

Finally, we implement *label denoising*, where we train on utterances and their respective intents as before; however, instead of noising random spans, we deterministically noise the entire label sequence in the input sequence and reconstruct it in the output sequence. This is a way of framing the intent classification task as an unsupervised denoising task. This format is formally equivalent to IC pre-training in that we must transduce from utterances to intents, though we empirically show that the unsupervised denoising format matters a great deal for downstream IC performance.

3.3 Evaluation Label Overlap is Rare

We search for non-case-sensitive intent matches with Snips and ATIS in our pre-training dataset, finding that exact intent matches (or intents with Snips/ATIS intents as substrings) are very rare in our data: 682 examples (0.005%) featured exact or substring overlap. We also search for the presence of *any* lexical overlap between the intents in ATIS/Snips and the intents in our pre-training examples (i.e., if any word in an ATIS or Snips intent appears in a pre-training example's intent, we count it): less than 8,000 examples (0.6%) in our pre-training dataset featured lexical overlap. Utterances tagged with exact intent matches were often not similar to the kinds of utterances seen in the evaluation sets; for example, `PlayMusic` is a label in Snips that typically refers to playing specific songs or artists, while the same label in our pre-training set often referred to requests to buy or play an instrument.

To check whether there was semantic overlap more broadly between the utterances in our pre-training set and those in Snips/ATIS, we obtain sentence embeddings for 5 randomly sampled utterances from each intent in Snips and ATIS, and for each utterance in our pre-training dataset. Sentence embeddings are obtained using a sentence-BERT model (Reimers and Gurevych, 2019); we use `all-MiniLM-L6-v2`, as it is both fast and performs best on semantic similarity tasks. We then calculate pairwise semantic similarity between the utterances in our pre-training set and the Snips/ATIS utterances by calculating the cosine similarity between sentence embedding pairs. When observing the most similar utterances, we do not often see much semantic overlap. For example, "Play some Mf Doom from the sixties on pandora" (in Snips) has the greatest sentence embeddings similarity to "I love doom and won't let some launcher protest stop me from playing it" (in our dataset); there is

---

[6] 15% is the proportion of tokens that are noised in the original pre-training setup (Raffel et al., 2020).

[7] Unlike T5, we do not pack multiple sequences into single training examples. When we pack multiple utterance-intent pairs into training examples of length ≈ 512, we find that performance drops sharply compared to training on individual utterance-intent pairs.

lexical overlap in the utterance, but the sentence in our dataset refers to playing a video game rather than a song. However, there were rare instances where semantic overlap was significant: for example, “Add this tune to the Rock Save the Queen playlist” (in Snips) was similar to “Please add the Fresh Prince of Bel-Air song to this” in our dataset.

4 Experimental Setup

We aim to understand whether LSAP can improve text classification performance over a variety of state-of-the-art (SOTA) baselines.

Dataset	Train	Test	Classes	Balanced?
Snips	13,784	700	7	✓
ATIS	4,978	700	20	
TOPv2 (reminder)	494	338	9	
TOPv2 (weather)	177	148	4	
Yahoo! Answers	1.4M	60,000	10	✓
AG News	120,000	7,600	4	✓

Table 2: Evaluation datasets for intent classification (top) and topic classification (bottom). For TOPv2, we use the two provided low-resource domains as separate evaluation sets; we use the 25 Samples per Intent and Slot (SPIS) splits from Chen et al. (2020) as the maximum split size.

We evaluate LSAP on two text classification tasks: intent classification (IC) and topic classification (TC). IC is the most similar task to our pre-training objective. Our IC evaluation datasets include Snips (Coucke et al., 2018), ATIS (Price, 1990), and the low-resource *reminder* and *weather* domains provided in TOPv2 (Chen et al., 2020). Snips’ intents are each from different domains. ATIS focuses on the flight domain; some intents appear only once or not at all in the training set, and some utterances are tagged with multiple intents (we count these as separate intents). For multi-class examples, we separate intents with the character “#” (e.g., “book flight # airfare”). TOPv2 (*reminder*) focuses on the creation and modification of personal reminders, while TOPv2 (*weather*) focuses on queries regarding the weather and time of sunrise/sunset.

For TC, we evaluate on Yahoo! Answers (YA)[8] and AG News.[9] YA consists of conversational user questions labeled with the general category of the question (e.g., “Health”, “Sports”). AG News consists of formal-register news articles labeled with their category (e.g., “Business”, “World”).

4.1 Fine-tuning

When fine-tuning our T5-based models, the input sequence consists of an “intent classification:” prefix followed by the utterance. The output sequence is the intent in a natural language format. For example: “intent classification: Find me a flight from NYC to Baltimore.” → “Book flight”.[10]

We create few-shot splits of size k for each evaluation set, where we sample $\leq k$ examples for each class i from the set of labeled training examples T. More specifically, $\forall k \in \{1, 2, 4, 8, 16, 32\}$,$\forall i \in T$, if $|T_i| \geq k$, we randomly sample k training examples from T_i *without replacement*; if $|T_i| < k$, we simply use T_i. We ensure that smaller splits are subsets of larger splits such that we may perform more principled comparisons across split sizes. In low-resource settings, the random seed can have a large impact on performance. We therefore average all accuracies over 5 random fine-tuning seeds.

See Appendix G for hyperparameters.

4.2 Baselines

XLNet (Yang et al., 2019) is an autoregressive Transformer-based (Vaswani et al., 2017) language model which sees various word order permutations of the inputs during pre-training. We append a linear layer to the mean-pooled output of XLNet to obtain an XLNet-based classifier. This model has achieved SOTA performance on many text classification datasets, including AG News.

SEQ2SEQ-PTR (Rongali et al., 2020) is based on sequence-to-sequence (Sutskever et al., 2014) and pointer generator networks (Vinyals et al., 2015; See et al., 2017); it achieves SOTA IC/SL performance on Snips, ATIS, and TOPv2. It transduces from an unlabeled utterance to a sequence with labeled spans (including the intent label, where the span is the entire sentence).

LM-BFF (Gao et al., 2021) is a prompt-tuning-based model for few-shot text classification. It uses automatically generated and optimized prompts (from T5) to perform generative classification (with RoBERTa) by predicting a masked token after the

---

[8] https://www.kaggle.com/soumikrakshit/yahoo-answers-dataset

[9] http://groups.di.unipi.it/~gulli/AG_corpus_of_news_articles.html

[10] We also try label denoising fine-tuning to reduce the mismatch between pre-training and fine-tuning, but we find that this is not as effective as the traditional T5 fine-tuning setup. See Appendix F for scores.

	Snips			ATIS			TOPv2 (reminder)			TOPv2 (weather)		
Format	1-shot	4-shot	Full	1-shot	4-shot	Full	1-shot	4-shot	Full	1-shot	4-shot	Full
Span denoising	80.9	92.0	**99.1**	67.0	85.4	**97.8**	60.9	80.0	**92.0**	61.5	77.1	86.4
IC pre-training	67.1	90.9	99.0	67.0	86.9	97.4	68.2	77.4	87.1	70.5	80.1	87.1
Label denoising	**88.7**	**93.5**	99.0	**68.7**	**87.8**	97.6	**69.0**	**80.6**	91.4	**72.7**	**81.4**	**89.1**

Table 3: 1-shot, 4-shot, and full-resource accuracies across LSAP pre-training formats on each IC evaluation set. Label denoising is consistently best in few-shot settings while obtaining similar performance to other formats in full-resource settings. Subsequent tables refer to the label denoising variant as LSAP for brevity. Results for all models and split sizes in Appendix C.

input. It achieves SOTA scores on few-shot binary/trinary sentiment classification and NLI tasks. We employ the best-performing *prompt-tuning with demonstrations* approach, adapting it for IC by reducing the intent labels to single words.

T5 is the closest baseline to LSAP: our model differs only in the addition of the label aware pre-training step. We thus compare LSAP against T5 to understand the contribution of our label aware pre-training approach to downstream performance. T5 is comparable to TANL (Paolini et al., 2021), which is based on vanilla T5; TANL's SOTA performance on a variety of structured prediction tasks indicates that T5 as-is can be a strong baseline.

To test whether performance improvements with LSAP can be attributed to label semantics or domain adaptation on the utterances, we also present results for T5 adapted (with random span denoising) on only on the utterances and *not* the intents in our pre-training data. This is equivalent to LSAP with random span denoising, but without the intent labels. We refer to this as "T5 (adapted)".

5 Results

Which pre-training format is best? We present 1-shot, 4-shot, and full-resource IC accuracies on each evaluation set in Table 3. **Label denoising is the best-performing pre-training format in few-shot settings across all evaluation sets**. Differences in performance between LSAP formats decrease as we increase the fine-tuning set size; in full-resource settings, the difference between span denoising and label denoising is not significant. This suggests that explicitly demarcating intents from utterances during pre-training may help T5 better leverage the pre-training examples.[11] As "label denoising" performs best, we focus on that variant of LSAP from here on, though note that all LSAP formats outperform T5 and T5 (adapted).

Table 4 displays IC accuracies across models. Compared to T5, the T5 (adapted) baseline achieves consistently higher IC accuracies. However, T5 (adapted) is vastly outperformed by LSAP (by up to 18% on Snips and 3% on ATIS in 1-shot settings), even though the utterances are the same across these settings; this indicates that **much of the improvements may be attributed to label semantics**, and that domain adaptation is only responsible for a small portion of the improvement.

	Snips: **Examples per Label**						
Model	1	2	4	8	16	32	Full
XLNet	70.0	77.6	88.1	92.9	96.2	96.9	99.0

Table 4: Mean intent classification accuracies across 5 seeds on Snips and ATIS at various few-shot split sizes. Smaller splits are subsets of larger splits. LSAP is consistently best in lower-resource settings while maintaining comparable performance to other models in higher-resource settings. Standard deviations and results for TOPv2 are in Appendix C.

We next observe that **generative approaches are generally more effective than discriminative approaches, especially in lower-resource settings.** The XLNet classifier does not have access to label semantics during fine-tuning, instead observing class indices and utterances only; all other approaches hence have access to more information during fine-tuning and prediction.

---

[11] These results are stable across random samples of the few-shot splits. See Appendix B.

	Yahoo! Answers: **Examples per Label**						
Model	1	2	4	8	16	32	Full
XLNet	23.9	42.4	44.0	52.8	62.3	65.9	77.6
T5	41.9	54.0	59.3	61.3	64.6	65.6	**77.8**
LSAP	**49.2**	**58.8**	**60.7**	**63.3**	**64.7**	**66.4**	77.7

	AG News: **Examples per Label**						
Model	1	2	4	8	16	32	Full
XLNet	55.3	63.5	69.7	79.4	**85.4**	**86.8**	**95.6**
T5	62.0	74.4	77.2	81.1	84.6	85.9	94.8
LSAP	**74.8**	**77.2**	**80.7**	**82.3**	**85.4**	86.5	94.8

Table 5: Few-shot text classification accuracies on Yahoo! Answers (top) and AG News (bottom). Smaller splits are subsets of larger splits. Our LSAP approach yields improvements over the SOTA XLNet model. LSAP also improves up over vanilla T5, indicating that our approach generalizes to topic classification.

	Snips: **Examples per Label**					
Pre-training Data	1	2	4	8	16	32
None	71.2	79.5	89.5	92.9	95.2	96.5
gold	82.2	86.9	91.7	94.0	95.9	96.5
+silver	81.6	85.3	92.0	95.0	96.0	96.8
+CSTwitter	82.9	88.4	92.7	94.4	**96.7**	97.1
+Reddit	**88.7**	**90.5**	93.5	94.8	**96.7**	97.3
CSTwitter+Reddit	80.9	90.1	**93.7**	**95.2**	96.6	**97.6**
C4	82.4	87.1	92.8	94.9	96.2	97.3

Table 6: Pre-training dataset ablation using LSAP (with label denoising). We display intent classification accuracies on Snips. Each pre-training dataset improves performance, but we can recover most of the performance from our best dataset when using *only* our bronze data.

LSAP induces better performance than LM-BFF and SEQ2SEQ-PTR in very low-resource settings, though LM-BFF and SEQ2SEQ-PTR perform better than T5. Note that for ATIS, LM-BFF does not effectively handle the multi-class examples due to the single-word cloze format, nor the high number of similar labels due to the intended contrastive word use case; we thus do not compare to LM-BFF here.

As we increase the size of the fine-tuning splits, performance increases and converges across methods. Thus, the primary contribution of LSAP is inducing quicker generalization across domains.

Finally, we present topic classification accuracies for YA and AG News (Table 5). Our LSAP approach yields up to 35% improvements on AG News over the SOTA XLNet model in 1-shot settings, and over 100% on YA; we also maintain comparable performance to the SOTA XLNet baseline in full-resource settings. LSAP also improves up to 21% on AG News and 18% on YA over vanilla T5; this is evidence that **our pre-training procedure is not just tuning T5 to recognize utterance-intent associations: it is also teaching T5 how to be a better text classifier in general.** This also indicates that our procedure generalizes to labels that have not been seen during pre-training: topic labels are not present in the pre-training data, though some of these labels do appear as substrings of more specific intent labels (e.g., while "Health" does not appear as a label in our pre-training data, "Get health information" does appear).

Our model also generalizes well to joint IC/SL. See Appendix A.

5.1 Dataset Ablation

Using LSAP with label denoising, we ablate over each pre-training dataset and observe the effect on downstream IC performance (Table 6).

The gold data improves few-shot IC performance over T5 by over 10%. Adding the silver data does not significantly change performance. Adding CSTwitter improves performance in few-shot settings, though it also increases variance across random seeds. The best accuracies and lowest variances are achieved after adding the Reddit data.

Notably, we find that **pre-training on only automatically filtered and labeled examples still improves performance over T5.** To test whether this is due to CSTwitter and Reddit simply being well-suited to our evaluation sets, we try automatically filtering and labeling a less conversational dataset: Colossal Cleaned Common Crawl (C4; Raffel et al., 2020), the same dataset used for pre-training T5. We use the same number of training examples as in our combined CSTwitter+Reddit data for comparability (1,126,309 examples). We still observe performance improvements when pre-training on this dataset, and the difference between pre-training on this versus CSTwitter+Reddit is only significant at 2 examples per label. This is evidence that **our method for creating new pre-training examples is effective with different types of data, including non-conversational data**. Note that adding C4 to the gold+silver+CSTwitter+Reddit data does not significantly improve performance; we therefore do not include it in our final pre-training dataset.

			Snips: **Examples per Label**					
Model	Shuffled pre-train labels?	Remapped eval labels?	1	2	4	8	16	32

LSAP	✓	✓	-41.8	-30.4	-36.0	-28.0	-21.7	-16.7

Table 7: Absolute difference in intent classification accuracy relative to LSAP on Snips and ATIS at all few-shot split sizes after shuffling labels assigned to utterances in the pre-training set (random label semantics), remapping labels in the evaluation set (misleading label semantics), or both.

5.2 The Importance of Meaningful Labels

Including label sequences in the pre-training data results in large performance increases. Is this due solely to intent sequences being helpful independent information, or is the model learning useful associations between the inputs and labels? To investigate this, we experiment with misleading and random label semantics. For "misleading label semantics," we remap the labels in an evaluation dataset by defining a bijective function from each intent to a randomly selected different intent, ensuring that identity mappings do not occur. In other words, if label i is replaced with label j, all instances of i are systematically converted to j in the training *and* test sets. We then fine-tune our models on these remapped-intent datasets and observe whether performance decreases, and by how much. Significant performance decreases indicate reliance on input-label associations.

We also define a "random label semantics" variant of LSAP, where we randomly shuffle the intents with respect to the utterances in the *pre-training data* and then pre-train with label denoising on the shuffled data. Unlike the evaluation label remapping, this shuffling procedure preserves the number of instances of each intent such that our pre-training set is technically the same—the intents and utterances are simply mismatched.

Performance with misleading and/or random label semantics (Table 7)[12] decreases considerably across datasets, and this is especially apparent in the low-resource case. Label denoising seems the most sensitive to utterance-label associations. Performance drops decrease with increasing few-shot split sizes. This suggests that **our models do rely on utterance-intent associations to achieve high IC performance, and that these associations are more important in lower-resource settings than higher-resource settings.**

6 Conclusions

We have proposed a pre-training approach for leveraging the semantic information inherent in labels. Our method improves few-shot text classification performance across domains while maintaining high performance in full-resource settings. This approach is fairly general and could potentially be extended to more structured semantic parsing tasks by annotating some of the pre-training examples, or perhaps by simply including diverse labeled examples from a variety of tasks in the pre-training step. Future work could investigate extending this method to pre-training from scratch, as well as tuning the utterance and label formats. One could also use demonstrations to achieve better performance with fewer gradient updates.

Acknowledgments

We thank Giovanni Paolini, Ben Athiwaratkun, and the reviewers for their thoughtful feedback on earlier versions of this work.

A Joint Intent Classification and Slot Labeling

Intent classification (IC) and slot labeling (SL) are often performed simultaneously. For sequence-to-sequence models, this can be done by transducing from an unlabeled utterance to a labeled utterance, as in Athiwaratkun et al. (2020). To evaluate whether our model can be used as an effective IC/SL system, we use the same approach, substituting our model for TANL. This tuning setup is more distinct from our pre-training task than the IC setup, so we hypothesize that performance gains over TANL will be slightly smaller here on IC than in the approach in the main paper. We also hypothesize that we will see similar SL scores as for TANL.

Our results (Table 8) indicate that in this setting, our pre-training approach still results in increased intent classification accuracy over TANL. As found before, the performance improvements are most noticeable in the few-shot setting. We also find that slot labeling performance is mostly maintained after pre-training, including in the 1-shot setting. Future work could investigate ways to integrate slot labeling supervision into pre-training for improving performance on both IC and SL.

		Intent Class.		Slot Labeling	
	Model	**ATIS**	**Snips**	**ATIS**	**Snips**
Full	Joint BERT	98.6	97.5	**97.0**	**96.1**
	ELMO+BiLSTM	**99.3**	97.4	93.9	95.6
	TANL	99.0	97.0	96.9	**96.1**
	LSAP (label denoising)	99.1	**97.6**	96.8	**96.1**
1-shot	TANL	78.8	88.5	**36.0**	**81.7**
	LSAP (label denoising)	**82.3**	**89.3**	35.8	80.8

Table 8: Intent classification accuracy and slot labeling F1 on ATIS and Snips.

B Stability Across Random Samples of the Few-shot Splits

In few-shot settings, the selection of fine-tuning examples can make a large difference in downstream performance. Here, we present IC accuracy distributions across 5 random samples of the 1-shot results (Figure 4) to understand whether the relative performance of each approach is stable given different fine-tuning set samples. Specifically, we present macroaverages across random fine-tuning set samples after averaging performance across random seeds; this is so that we average over more stable estimates of performance within each fine-tuning set.

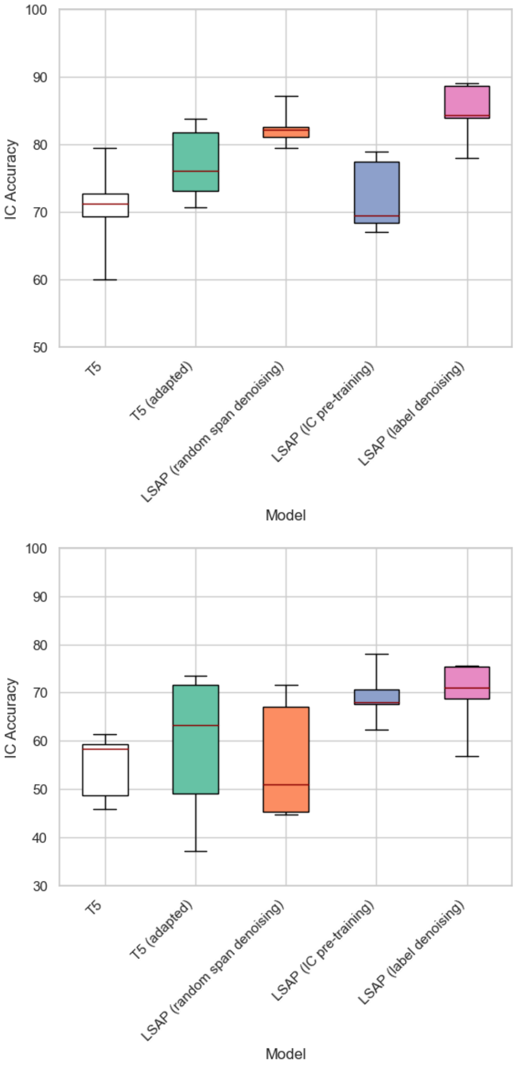

Figure 4: Intent classification accuracy distribution across 5 random samples of the 1-shot fine-tuning set for Snips (top) and ATIS (bottom).

Performance on Snips across random 1-shot fine-tuning samples is largely stable. All of our original conclusions regarding which models are better than others still hold: label denoising is best among our label semantic aware methods, and each label semantic aware approach (except IC pre-training) beats the non-label semantic aware baselines. Performance on ATIS is more variable across random 1-shot samples, but the relative performance of models is still largely the same: IC pre-training is more competitive on this evaluation set and random span denoising does not beat the T5 (adapted) baseline, but label denoising is still best.

C Pre-training Method Comparison: Full Results

Here, we present intent classification accuracies for ATIS (Table 10) the low-resource domains of TOPv2 (Tables 11,12) using each of our pre-training approaches. Our results here indicate that the relative performance of each method is stable across evaluation sets: **label denoising is consistently the best approach in the lowest-resource setting.** Intent classification pre-training is often second-best, while random span denoising is consistently least effective among our pre-training formats (but still improves performance over vanilla T5 and the T5 (adapted) baseline for *all* evaluation datasets).

D The Importance of Meaningful Labels: Full Results

Here, we present intent classification performance with misleading label semantics (after the random label remapping procedure described in §5.2) for the low-resource domains of TOPv2 (Tables 13,14). We present accuracy *differences* after remapping labels in order to observe how performance changes when using intent names that are not semantically related to the utterances they classify.

We find that our results are mostly consistent across evaluation sets: our best models rely more on utterance-intent associations and are thus more sensitive to label remapping, as evidenced by higher performance drops after label remapping. However, there appears to be variance across datasets with respect to reliance on intent labels: the performance drops for TOPv2 in both domains are much larger than for ATIS and Snips, providing evidence that **utterance-label associative information is much more important for some datasets than others**. We also find larger performance drops for our model pre-trained with the IC pre-training format than for our best model pre-trained with label denoising. Thus, **the best model is not necessarily the most reliant on utterance-label associations**.

The "random label semantics" baselines are sensitive to misleading label semantics for TOPv2 (reminder) and ATIS, as indicated by consistently large accuracy drops after label remapping. This is not the case for TOPv2 (weather) nor Snips in low-resource settings, where performance differences tend to be positive or closer to 0. The performance drop is much smaller for this baseline than for other models (indicating lower associative sensitivity), but it is still notable that the model was still able to rely on associations between utterances and intents after shuffling; perhaps this is due to the similarity of each intent label in these highly domain-specific datasets, though this would not explain the lack of sensitivity to utterance-label associations in TOPv2 (weather) since this is also highly domain-specific. Future work could more specifically investigate the source of these label sensitivity differences across datasets.

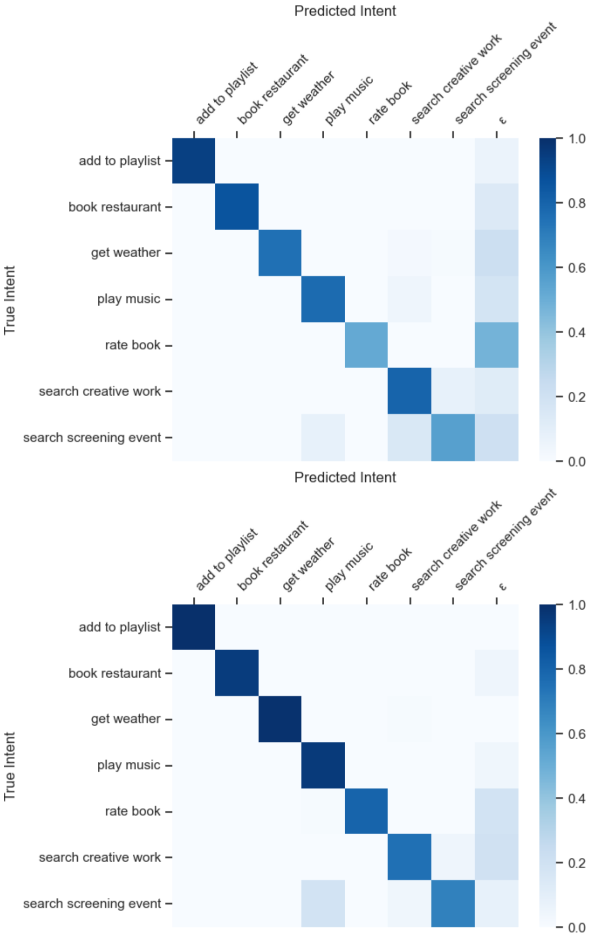

Figure 5: Confusion matrices displaying 1-shot results on Snips using vanilla T5 (top) and LSAP with label denoising (bottom). The fine-tuning setups are identical. "ϵ" refers to generated labels outside the set of labels in Snips.

E Error Analysis

What kinds of errors does T5 make before and after pre-training? We present confusion matrices before and after our best label semantic aware pre-training approach (Figure 5). When using the same fine-tuning setup and hyperparameters, vanilla T5 tends to generate more out-of-domain intent labels

	Snips: **Examples per Label**

Table 10: Pre-training method comparison. Intent classification accuracy on ATIS at various few-shot split sizes. Smaller splits are subsets of larger splits. Each score is averaged over 5 fine-tuning runs. Note that the high standard deviation for T5 (label denoising) in the 1-shot setting is because the accuracies skew high; three seeds yield accuracies over 80%, one at 76.9%, and one at 60%.

than our best model. These out-of-domain generations are typically mergers between two intents: Snips contains `PlayMusic` and `RateBook` intents, and vanilla T5 often generates `RateMusic`. After pre-training, this is much less frequent.

Vanilla T5 also seems to assign higher prior probabilities to specific intents, despite seeing class-balanced tuning data; for example, `SearchCreativeWork` is generated for utterances from a variety of intents, as indicated by the slight vertical stripe in Figure 5. After pre-training, this problem is almost non-existent.

F Label Denoising Fine-tuning

Here, we compare the performance of LSAP (label denoising pre-training) when fine-tuned using the traditional T5 format (task prefix, no masking) and when using the label denoising format (concatenate the document and its label in the source sequence, mask the label sequence, and reconstruct the label in the output sequence). See Tables 15 and 16.

In lower-resource settings, regular fine-tuning significantly outperforms label denoising fine-tuning across evaluation sets; an exception is TOPv2 (*weather*) at 2 examples per label, but the difference in performance is not large here. In higher-resource settings, label denoising fine-tuning begins to achieve comparable performance to regular fine-tuning (and sometimes outperforms regular fine-tuning). Nonetheless, accuracy differences in higher-resource settings are not large, and regular fine-tuning performs significantly better on average. We therefore opt to use regular fine-tuning when comparing to baselines.

G Hyperparameters

Our experiments are based on the huggingface implementation (Wolf et al., 2020) of T5.

For secondary pre-training, we use initial learning rate 5×10^{-4} and batch size 128. We tune over the number of training epochs $\in [1, 8]$, finding 3 epochs to generally be best.

During fine-tuning, we use init. LR 5×10^{-4} and batch size 1.[13] We tune over the number of fine-tuning epochs $\in [1, 16]$ for the largest few-shot split, typically finding 2 epochs to be best. Once we have the best setting for the largest split, we double the number of tuning epochs for each halving of the split size such that the number of tuning steps is similar for all split sizes. All other hyperparameters are huggingface defaults.

Abstract

Residual networks are an Euler discretization of solutions to Ordinary Differential Equations (ODE). This paper explores a deeper relationship between Transformer and numerical ODE methods. We first show that a residual block of layers in Transformer can be described as a higher-order solution to ODE. Inspired by this, we design a new architecture, *ODE Transformer*, which is analogous to the Runge-Kutta method that is well motivated in ODE. As a natural extension to Transformer, ODE Transformer is easy to implement and efficient to use. Experimental results on the large-scale machine translation, abstractive summarization, and grammar error correction tasks demonstrate the high genericity of ODE Transformer. It can gain large improvements in model performance over strong baselines (e.g., 30.77 and 44.11 BLEU scores on the WMT'14 English-German and English-French benchmarks) at a slight cost in inference efficiency.

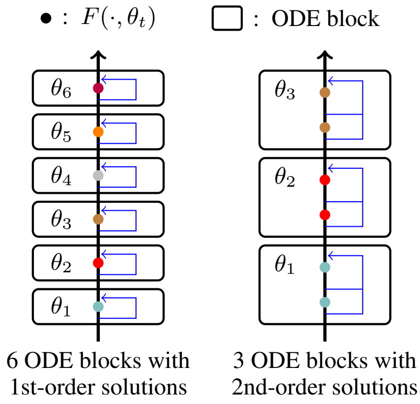
1 Introduction

Residual networks have been used with a great success as a standard method of easing information flow in multi-layer neural models (He et al., 2016; Vaswani et al., 2017). Given an input y_t, models of this kind define the output of a layer t to be:

$$y_{t+1} = y_t + F(y_t, \theta_t) \tag{1}$$

where $F(\cdot,\cdot)$ is the function of the layer and θ_t is its parameter. Interestingly, recent work in machine learning (Weinan, 2017; Lu et al., 2018; Haber et al., 2018; Chang et al., 2018; Ruthotto and Haber, 2019) points out that Eq. (1) is an Euler discretization of the Ordinary Differential Equation (ODE), like this:

$$\frac{\mathrm{d}y(t)}{\mathrm{d}t} = F(y(t), \theta(t)) \tag{2}$$



6 ODE blocks with 1st-order solutions

3 ODE blocks with 2nd-order solutions

Figure 1: Models with different ODE blocks.

where $y(t)$ and $\theta(t)$ are continuous with respect to t. In this way, we can call Eq. (1) an *ODE block*. This finding offers a new way of explaining residual networks in the view of numerical algorithms. Then, one can think of a multi-layer network as applying the Euler method (i.e., Eq. (1)) to solve Eq. (2) subject to the initial conditions $y(0) = y_0$ and $\theta(0) = \theta_0$.

The solution of Eq. (2) has a sufficiently low error bound (call it a *stable solution*) only if $\theta(t)$ changes slow along t (Haber and Ruthotto, 2017; Chen et al., 2018). But this assumption does not always hold for state-of-the-art natural language processing (NLP) systems, in which models are non-linear and over-parameterized. For example, language modeling and machine translation systems learn quite different parameters for different layers, especially when the layers are close to the model input (Vaswani et al., 2017; Dai et al., 2019). Also, truncation errors are nonnegligible for the Euler method because it is a first-order approximation to the true solution (He et al., 2019). These problems make the situation worse, when more layers are stacked and errors are propagated through the neural network. It might explain why recent

Machine Translation (MT) systems cannot benefit from extremely deep models (Wang et al., 2019; Liu et al., 2020a; Wei et al., 2020; Li et al., 2020).

This paper continues the line of research on the ODE-inspired method. The basic idea is to use a high-order method for more accurate numerical solutions to the ODE. This leads to a larger ODE block that generates a sequence of intermediate approximations to the solution. We find that the larger ODE block is sufficient to take the role of several ODE blocks with first-order solutions. The benefit is obvious: the use of fewer ODE blocks lowers the risk of introducing errors in block switching, and the high-order method reduces the approximation error in each ODE block. See Figure 1 for a comparison of different models.

Our method is parameter-efficient because $\theta(t)$ is re-used within the same ODE block. As another "bonus", the model can be improved by learning coefficients of different intermediate approximations in a block. We evaluate our method in strong Transformer systems, covering both the wide (and big) model and the deep model. For machine translation tasks, ODE Transformer achieves 30.77 and 44.11 BLEU scores on the WMT'14 En-De and En-Fr test sets, setting a new state-of-the-art on the WMT'14 En-Fr task. It also significantly outperforms baselines on abstractive summarization and grammar error correction tasks.

2 Transformer and ODEs

We start with a description of Transformer, followed by its relationship with ODEs. We choose Transformer for our discussion and experiments because it is one of the state-of-the-art models in recent sentence generation tasks.

2.1 Transformer

Transformer is an example of the encoder-decoder paradigm (Vaswani et al., 2017). The encoder is a stack of identical layers. Each layer consists of a self-attention block and a feedforward network (FFN) block. Both of them equip with a residual connection and a layer normalization unit. Note that the term "block" is used in many different ways. In this paper, the term refers to any neural network that is enhanced by the residual connection (occasionally call it a *residual block*). Following the Pre-norm architecture (Wang et al., 2019), we define a block as

$$y_{t+1} = y_t + G(\mathrm{LN}(y_t), \theta_t) \quad (3)$$

where $\mathrm{LN}(\cdot)$ is the layer normalization function,[1] and $G(\cdot)$ is either the self-attention or feedforward network. The decoder shares a similar architecture, having an additional encoder-decoder attention block sandwiched between the self-attention and FFN blocks.

2.2 Ordinary Differential Equations

An ordinary differential equation is an equation involving a function $y(t)$ of a variable t and its derivatives. A simple form of ODE is an equation that defines the first-order derivative of $y(t)$, like

$$\frac{\mathrm{d}y(t)}{\mathrm{d}t} = f(y(t), t) \quad (4)$$

where $f(y(t), t)$ defines a time-dependent vector field if we know its value at all points of y and all instants of time t. Eq. (4) covers a broad range of problems, in that the change of a variable is determined by its current value and a time variable t. This formulation also works with Pre-norm Transformer blocks. For notational simplicity, we redefine $G(\mathrm{LN}(y_t), \theta_t)$ as a new function $F(y_t, \theta_t)$:

$$F(y_t, \theta_t) = G(\mathrm{LN}(y_t), \theta_t)) \quad (5)$$

We then relax y_t and θ_t to continuous functions $y(t)$ and $\theta(t)$, and rewrite Eq. (3) to be:

$$y(t + \Delta t) = y(t) + \Delta t \cdot F(y(t), \theta(t)) \quad (6)$$

where Δt is the change of t, and is general called *step size*. Obviously, we have $\Delta t = 1$ in Transformer. But we can adjust step size Δt using a limit, and have

$$\lim_{\Delta t \to 0} \frac{y(t + \Delta t) - y(t)}{\Delta t} = F(y(t), \theta(t)) \quad (7)$$

Given the fact that $\lim_{\Delta t \to 0} \frac{y(t+\Delta t) - y(t)}{\Delta t} = \frac{\mathrm{d}y(t)}{\mathrm{d}t}$, Eq. (7) is an instance of Eq. (4). The only difference lies in that we introduce $\theta(t)$ into the right-hand side of Eq. (4). Then, we say that a Pre-norm Transformer block describes an ODE. It has been found that Eq. (3) shares the same form as the Euler method of solving the ODE described in Eq. (7) (Haber and Ruthotto, 2017). This establishes a relationship between Transformer and ODEs, in that, given $F(\cdot, \cdot)$ and learned parameters $\{\theta_t\}$, the forward pass of a multi-block Transformer is a process of running the Euler method for several steps.

---

[1] We drop the parameter of $\mathrm{LN}(\cdot)$ for simplicity.

3 The ODE Transformer

In numerical methods of ODEs, we want to ensure the precise solutions to the ODEs in a minimum number of computation steps. But the Euler method is not "precise" because it is a first-order method, and naturally with local truncation errors. The global error might be larger if we run it for a number of times.[2] This is obviously the case for Transformer, especially when the multi-layer neural network arises a higher risk of instability in solving the ODEs (Haber and Ruthotto, 2017).

3.1 High-Order ODE Solvers

Here we use the Runge-Kutta methods for a higher order solution to ODEs (Runge, 1895; Kutta, 1901; Butcher, 1996; Ascher and Petzold, 1998). They are a classic family of iterative methods with different orders of precision.[3] More formally, the explicit Runge-Kutta methods of an n-step solution is defined to be:

$$\begin{aligned} y_{t+1} &= y_t + \sum_{i=1}^{n} \gamma_i F_i && (8) \\ F_1 &= hf(y_t, t) && (9) \\ F_i &= hf(y_t + \sum_{j=1}^{i-1} \beta_{ij} F_j, t + \alpha_i h) && (10) \end{aligned}$$

where h is the step size and could be simply 1 in most cases. F_i is an intermediate approximation to the solution at step $t + \alpha_i h$. α, β and γ are coefficients which can be determined by the Taylor series of y_{t+1} (Butcher, 1963). Eq. (10) describes a sequence of solution approximations $\{F_1, ..., F_n\}$ over n steps $\{t + \alpha_1 h, ..., t + \alpha_n h\}$. These approximations are then interpolated to form the final solution, as in Eq. (8).

The Runge-Kutta methods are straightforwardly applicable to the design of a Transformer block. All we need is to replace the function f (see Eq. (10)) with the function F (see Eq. (5)). The advantage is that the function F is re-used in a block. Also, the model parameter θ_t can be shared within the block.[4] In this way, one can omit $t + \alpha_i h$ in Eq. (10), and compute F_i by

$$F_i = F(y_t + \sum_{j=1}^{i-1} \beta_{ij} F_j, \theta_t) \quad (11)$$

This makes the system more parameter-efficient. As would be shown in our experiments, the high-order Runge-Kutta methods can learn strong NMT systems with significantly smaller models.

The Runge-Kutta methods are general. For example, the Euler method is a first-order instance of them. For a second-order Runge-Kutta (RK2) block, we have

$$\begin{aligned} y_{t+1} &= y_t + \frac{1}{2}(F_1 + F_2) && (12) \\ F_1 &= F(y_t, \theta_t) && (13) \\ F_2 &= F(y_t + F_1, \theta_t) && (14) \end{aligned}$$

This is also known as the improved Euler method. Likewise, we can define a fourth-order Runge-Kutta (RK4) block to be:

$$\begin{aligned} y_{t+1} &= y_t + \\ & \quad \frac{1}{6}(F_1 + 2F_2 + 2F_3 + F_4) && (15) \\ F_1 &= F(y_t, \theta_t) && (16) \\ F_2 &= F(y_t + \frac{1}{2}F_1, \theta_t) && (17) \\ F_3 &= F(y_t + \frac{1}{2}F_2, \theta_t) && (18) \\ F_4 &= F(y_t + F_3, \theta_t) && (19) \end{aligned}$$

See Figure 2 for a comparison of different Runge-Kutta blocks. It should be noted that the method presented here can be interpreted from the perspective of representation refinement (Greff et al., 2017). It provides a way for a function to update the function itself. For example, Universal Transformer refines the representation of the input sequence using the same function and the same parameters in a block-wise manner (Dehghani et al., 2019). Here we show that inner block refinements can be modeled with good theoretical support.

3.2 Coefficient Learning

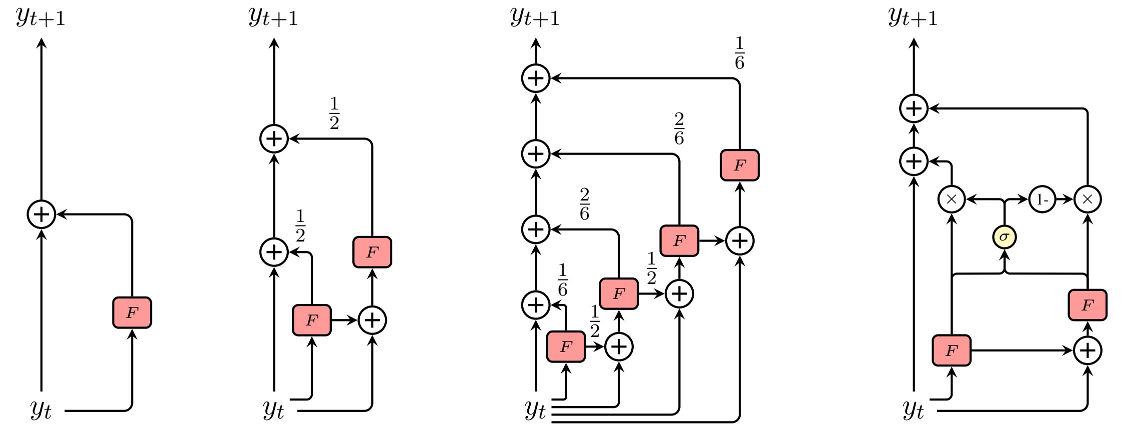
In our preliminary experiments, the RK2 and RK4 methods yielded promising BLEU improvements when the model was shallow. But it was found that the improvements did not persist for deeper models. To figure out why this happened, let us review the Runge-Kutta methods from the angle of training.

---

[2] The global error is what we would ordinarily call the error: the difference between $y(t)$ and the true solution. The local error is the error introduced in a single step: the difference between $y(t)$ and the solution obtained by assuming that $y(t-1)$ is the true solution

[3] A p-order numerical method means that the global truncation error is proportional to p power of the step size.

[4] Although we could distinguish the parameters at different steps in a block, we found that it did not help and made the model difficult to learn.



(a) Residual block (b) RK2-block (c) RK4-block (d) RK2-block (learnable γ_i)

Figure 2: Architectures of ODE Transformer blocks.

Take the RK2 method as an example. We rewrite Eq. (12) by substituting F_1 and F_2, as follow

$$\begin{aligned} y_{t+1} &= y_t + \frac{1}{2}F(y_t, \theta_t) + \\ &\quad \frac{1}{2}F(y_t + F(y_t, \theta_t), \theta_t) \end{aligned} \tag{20}$$

Let $\mathcal{E}$ be the loss of training, L be the number blocks of the model, and y_L be the model output. The gradient of $\mathcal{E}$ at y_t is

$$\frac{\partial \mathcal{E}}{\partial y_t} = \frac{\partial \mathcal{E}}{\partial y_L} \cdot \frac{1}{2^{L-t}} \cdot \prod_{k=t}^{L-1} (1 + g_k) \tag{21}$$

where

$$\begin{aligned} g_k &= \left(1 + \frac{\partial F(y_k, \theta_k)}{\partial y_k}\right) \cdot \\ &\quad \left(1 + \frac{\partial F(y_k + F(y_k, \theta_k), \theta_k)}{\partial y_k + F(y_k, \theta_k)}\right) \end{aligned} \tag{22}$$

Seen from Eq. (21), $\frac{\partial \mathcal{E}}{\partial y_t}$ is proportional to the factor $\frac{1}{2^{L-t}}$. This leads to a higher risk of gradient vanishing when L is larger.

The problem somehow attributes to the small coefficients of F_i, that is, $\gamma_1 = \gamma_2 = \frac{1}{2}$. A natural idea is to empirically set $\gamma_i = 1$ to eliminate the product factor of less than 1 in gradient computation, although this is not theoretically grounded in standard Runge-Kutta methods. We rewrite Eq. (20) with the new coefficients, as follows

$$\begin{aligned} y_{t+1} &= y_t + F(y_t, \theta_t) + \\ &\quad F(y_t + F(y_t, \theta_t), \theta_t) \end{aligned} \tag{23}$$

Then, we have the gradient, like this

$$\frac{\partial \mathcal{E}}{\partial y_t} = \frac{\partial \mathcal{E}}{\partial y_L} \cdot \prod_{k=t}^{L-1} g_k \tag{24}$$

This model is easy to optimize because $\frac{\partial \mathcal{E}}{\partial y_L}$ can be passed to lower-level blocks with no scales. Note that, the methods here are instances of parameter sharing (Dehghani et al., 2019; Lan et al., 2020). For example, in each ODE block, we use the same function F with the same parameter θ_t for all intermediate steps. Setting $\gamma_i = 1$ is a further step towards this because F_i is passed to the following computations with the same scale. Here we call it implicit parameter sharing.

Another way of scaling F_i to further improve ODE functions is to learn the coefficients automatically on the training data. The simplest method is to initialize $\gamma_i = 1$ and independently optimize each scale. It helps the system learn the way of flowing F_i in a block. Based on it, scaling F_i by a weighted gate mechanism (Srivastava et al., 2015) empirically achieves the best performance (see Section 4). Take RK2-block as an instance, the concatenation of F_1 and F_2 is transformed to a scalar $(0, 1)$ through a sigmoid gate, then the block output y_{t+1} is

$$y_{t+1} = y_t + g \cdot F_1 + (1 - g) \cdot F_2 \tag{25}$$

$$g = \text{sigmoid}([F_1, F_2] \cdot W + b) \tag{26}$$

where $[,]$ denotes the concatenation operation and W, b are learnable parameters. We call it RK2-block (learnable γ_i), and the architecture is shown in Figure 2 (d). This kind of formulation offers a more flexible way to decide which part contributes more and is also easy to be optimized. Moreover, we also summarize the comparison of various scaling functions in Appendix C.

3.3 Efficiency Discussion

ODE Transformer is efficient to use. As we only apply the ODE design schema to the encoder side, it only brings minor impacts on the inference speed due to the autoregressive decoding schema. Another concern here is memory consumption. ODE Transformer consumes more memory than the baseline in the same depth since we need to store the intermediate approximations in the forward pass. But the additional consumption is less than that of the baseline who has the same computation cost, which is acceptable for most scenarios. We give a quantitative analysis in Section 5.

4 Experiments

We evaluated the ODE Transformer on three sequence generation tasks: machine translation, abstractive summarization and grammar error correction. The datasets we used are elaborated in the following section, and more details of experimental setups could be found in Appendix A and B.

4.1 Datasets

Machine Translation We report results on three WMT benchmarks. For the WMT'14 English-German (En-De) task, the training data consisted of approximately 4.5M tokenized sentence pairs, as in (Vaswani et al., 2017). All sentences were segmented into sequences of sub-word units (Sennrich et al., 2016) with 32K merge operations using a shared vocabulary. We selected *newstest2013* as the validation data and *newstest2014* as the test data. For the WMT'14 English-French (En-Fr) task, we used the dataset provided within Fairseq, i.e., 36M training sentence pairs from WMT'14. *newstest2012+newstest2013* was the validation data and *newstest2014* was the test data. For the WMT'16 English-Romanian (En-Ro) task, we replicated the setup of (Mehta et al., 2020), which used 600K/2K/2K sentence pairs for training, evaluation and inference, respectively.

Abstractive Summarization We also tested the models' ability to process long sequences on the CNN-DailyMail summarization task (Nallapati et al., 2016; Hermann et al., 2015). The prepro-

Model	**Params**	**Epochs**	**BLEU**

RK2-block (learnable γ_i, H=256, L=18)	29M	27.84

Table 3: The comparison of model efficiency on the WMT En-De task.

cessed method was the same as in (Ott et al., 2019). We used a shared BPE with 30K operations, resulting in a vocabulary of $32,580$ entries. The evaluation metric was F1-Rouge (Lin, 2004) (Rouge-1, Rouge-2 and Rouge-L).

Grammar Error Correction We used the following datasets as the training data, including National University of Singapore Corpus of Learner English (NUCLE) (Dahlmeier et al., 2013), Lang-8 Corpus of Learner English (Lang-8) (Tajiri et al., 2012), FCE dataset (Yannakoudakis et al., 2011), and Write & Improve + LOCNESS Corpus (Bryant et al., 2019). We borrowed the setup from Chollampatt and Ng (2018) and used the provided preprocessed script. The word-level dropout technique was also applied to prevent the overfitting problem.

Language Modeling The truncation error analysis is conducted on the Penn Treebank (Mikolov et al., 2011), which is a widely-used language model dataset. It contains 88K, $3,370$ and $3,761$ sentences for training, validation and test. The vocabulary size was 10K. We set the layer depth of the language model to 1 or 2 to make a fair comparison. Assume the layer depth is 1, then the loss between the block output and the ground-truth could be regarded as the truncation error. It alleviates the influence of the error accumulation across different layers.

4.2 Experimental Results

Results of En-De and En-Fr Table 1 compares ODE Transformer with several state-of-the-art systems. Both RK2-block and RK4-block outperform the baselines by a large margin with different model capacities. For example, RK2-block obtains a $+1.00$ BLEU improvement with the base configuration when the depth is 6. RK4-block yields a gain of 0.17 BLEU points on top of RK2-block. This observation empirically validates the conjecture that high-order ODE functions are more efficient. When we switch to deep models, our method is more parameter efficient. E.g., RK2-block is comparable with a strong 48-layer system (Li et al., 2020) with half of the encoder depth. Similarly, wide models can also benefit from the enlarging layer depth (Wei et al., 2020; Li et al., 2020). RK2-block achieves BLEU scores of 30.77 and 44.11 on the En-De and the En-Fr tasks, significantly surpassing the standard Big model by 1.32 and 0.70 BLEU points. This sets a new state-of-the-art on these tasks with fewer parameters.

Results of En-Ro Table 2 exhibits model parameters, total training steps and BLEU scores of several strong systems on the En-Ro task. Again, ODE Transformer outperforms these baselines. As stated in (Mehta et al., 2020), they trained the model up to 170 epochs and obtained a BLEU score of 34.70 through the `DeLight` model. However, the observation here is quite different. The validation PPL begins to increase after 20 epochs. Thus, our baseline is slightly inferior to theirs, but matches the result reported in Lin et al. (2020). ODE blocks achieve even better performance with `DeLight` within much less training cost. For a bigger model (line 6), it obtains a BLEU score of 35.28.

Parameter Efficiency Table 3 summaries the results of several efficient Transformer variants, including Lite Transformer (Wu et al., 2020), DeLight (Mehta et al., 2020) and a light version of the Evolved Transformer (So et al., 2019). As expected, ODE Transformer is promising for smaller models. It is comparable in BLEU with `DeLight` but having 9M fewer parameters. Under the same model capacity, it outperforms `DeLight` by 0.64 BLEU points. It may offer a new choice for deploying NMT systems on edge devices.

Results of Summarization and Correction We also evaluated the ODE Transformer on another two sequence generation tasks. Table 4 shows that both RK2-block and RK4-block outperform the

Model	Summarization			Correction		
	RG-1	RG-2	RG-L	Prec.	Recall	$F_{0.5}$
Liu et al. (2020b)	41.00	18.30	37.90	66.80	35.00	56.60
Residual-block	40.47	17.73	37.29	67.97	32.17	55.61
RK2-block	41.58	18.57	38.41	**68.21**	35.30	57.49

RK4-Block	6	124.8	87.1	9.7	18.2

Table 6: Comparison of inference speed (sentences/s) and memory consumption (G).

baselines by a margin. Similarly, RK4-block is superior to RK2-block when the model is shallow. More results and case studies could be found in Appendix C.

5 Analysis

Here we investigate some interesting issues. For simplicity, we call RK2-block with coefficients initialized by 1 as RK2-block-v1, and learnable coefficients (Eq. (25)) as RK2-block-v2.
