Table 13 shows example QA-pairs for different annotations in FairytaleQA dataset. There is one example QA-pair for each narrative element as well as for implicit and explicit.

E Fine-tuning Parameters

For the QA task, we keep the following fine-tuning parameters consistent over different datasets: *learning rate* = $5e^{-6}$; *batch size* = 1; *epoch* = 1.
For the QG task, we keep the following fine-tuning parameters consistent over different datasets: *learning rate* = $5e^{-6}$; *batch size* = 1; *epoch* = 3.

F Proportion of Each Question Type

Figure 3 shows the percentage of each question type by coder.

KaFSP: Knowledge-Aware Fuzzy Semantic Parsing for Conversational Question Answering over a Large-Scale Knowledge Base

Abstract

In this paper, we study two issues of semantic parsing approaches to conversational question answering over a large-scale knowledge base: (1) The actions defined in grammar are not sufficient to handle uncertain reasoning common in real-world scenarios. (2) Knowledge base information is not well exploited and incorporated into semantic parsing. To mitigate the two issues, we propose a knowledge-aware fuzzy semantic parsing framework (KaFSP). It defines fuzzy comparison operations in the grammar system for uncertain reasoning based on the fuzzy set theory. In order to enhance the interaction between semantic parsing and knowledge base, we incorporate entity triples from the knowledge base into a knowledge-aware entity disambiguation module. Additionally, we propose a multi-label classification framework to not only capture correlations between entity types and relations but also detect knowledge base information relevant to the current utterance. Both enhancements are based on pre-trained language models. Experiments on a large-scale conversational question answering benchmark demonstrate that the proposed KaFSP achieves significant improvements over previous state-of-the-art models, setting new SOTA results on 8 out of 10 question types, gaining improvements of over 10% F1 or accuracy on 3 question types, and improving overall F1 from 83.01% to 85.33%. The source code of KaFSP is available at `https://github.com/tjunlp-lab/KaFSP`.

1 Introduction

With the growing popularity of intelligent virtual assistants (e.g., Alexa, Siri, Cortana) and the availability of large-scale knowledge bases (e.g., DBPedia (Auer et al., 2007), Wikidata (Vrandečić and Krötzsch, 2014), YAGO (Rebele et al., 2016)), conversational question answering (QA) over knowledge bases (KB) has attracted broad interests. It aims to satisfy users' information needs by retrieving answers from a given knowledge graph to users' questions in a multi-turn conversational setting with a wide range of discourse phenomena (e.g., ellipsis, coreference, lexical cohesion).

While conversational QA over large-scale KBs can be realized without explicit semantic parsing (e.g., HRED-KVM (Kacupaj et al., 2021)), the majority of effort is dedicated to the exploration of contextual semantic parsers (Guo et al., 2018; Shen et al., 2019; Thirukovalluru et al., 2021; Kacupaj et al., 2021; Lan and Jiang, 2021). The semantic parsing based approaches usually project an utterance into a logical form that can be executed on a given knowledge base. Early semantic parsing method D2A (Guo et al., 2018) suffers from the stepwise error propagation issue, which is improved by MaSP (Shen et al., 2019) that jointly learns pointer-equipped semantic parsing and type-aware entity detection in a multi-task learning framework. The very recent work LASAGNE (Kacupaj et al., 2021) further enhances MaSP via a graph attention network that exploits the correlation (missing in MaSP) between entity types and relations and achieves the state-of-the-art results on the CSQA benchmark (Saha et al., 2018).

Despite the aforementioned progress, we argue that current semantic parsing approaches to conversational QA over large-scale KBs still suffer from two critical issues. First, grammar rules that form the base for the mapping of questions to logical forms, although being constantly updated in D2A, MaSP, and LASAGNE, are still not sufficient to cover all real-world situations, e.g., fuzzy inference on numbers. Consider the question "*Which nutrients can interact with approximately 89 chemical substances and drugs?*". It is difficult for existing grammar to represent "*approximately 89*". Second, the interaction between questions and knowledge base is not adequate for entity disambiguation and redundancy detection in semantic parsing. For the

question "*Which educational institution is the alma mater of Pierre Lefebvre?*", without using relevant information from KB, it is difficult for semantic parsing to distinguish whether "*Pierre Lefebvre*" is a French military physician or a French politician as more than one persons named "*Pierre Lefebvre*" are in the knowledge base.

To address these two issues, we propose a **K**nowledge-**a**ware **F**uzzy **S**emantic **P**arsing (KaFSP) model to enhance both grammar rules and the interaction between KB and semantic parsing. Particularly, we introduce fuzzy operations into the grammar system used in previous work, enabling the system to perform uncertainty reasoning on numbers. Such updates have a significant impact on answering quantitative and comparative questions. In order to make the knowledge base well facilitate semantic parsing, we incorporate deep entity knowledge in the given knowledge base into different modules in the proposed semantic parsing framework. In the entity disambiguation module, entity triples from the knowledge base are exploited to disambiguate candidate entities. In the entity type and relation prediction module, a multi-label classification framework is proposed to capture correlations between entity types and relations and to pinpoint KB information relevant to the current utterance.

Contributions Our main contributions are as follows:

- We propose a knowledge-aware fuzzy semantic parsing framework for conversational QA over large-scale KBs, which enables the grammar system to model uncertainty reasoning based on the fuzzy set theory, and enhances the interaction between KB and semantic parsing with two knowledge-aware modules.
- Experiment results demonstrate that our proposed model achieves new state-of-the-art results on 8 out of 10 question types on the CSQA dataset (Saha et al., 2018), which is to date the largest dataset for complex conversational question answering over a large-scale knowledge base.

2 Related Work

Semantic parsing approaches have conventionally been used for knowledge base question answering (KBQA). Early efforts parse natural language questions into logical forms typically via dictionary-based parsers or similarity models (Wong and Mooney, 2007; Zettlemoyer and Collins, 2007, 2009; Kwiatkowski et al., 2011; Andreas et al., 2013; Artzi and Zettlemoyer, 2013; Reddy et al., 2014; Zhao and Huang, 2015; Dubey et al., 2016; Long et al., 2016).

Recent years have witnessed that semantic parsing has been shifted from traditional statistical models with feature engineering to neural approaches that learn continuous representations for generating logical forms (Yih et al., 2014; Jia and Liang, 2016; Xiao et al., 2016; Bao et al., 2016; Dong and Lapata, 2018, 2016; Bhutani et al., 2020; Lan and Jiang, 2020, 2021). For example, Dong and Lapata (2016) use the encoder-decoder framework equipped with a neural attention mechanism to cast semantic parsing into Seq2Seq generation.

As knowledge bases are becoming large, semantic parsing for KBQA is usually performed in a stepwise, modular framework. Guo et al. (2018) recognize entities in questions and link them to the given large-scale knowledge graph at the first stage and then learn to map the entity-linked questions into logical forms. Dong and Lapata (2018) propose a coarse-to-fine two-stage decoding method for semantic parsing, which generates a coarse sketch for a question with low-level features at the first stage and then continues to decode the final logical form based on the output of the first stage as well as the question itself.

As mentioned in Section 1, such stepwise methods are confronted with error propagation across stages (e.g., from entity linking to mapping, from coarse parse to fine parse). In order to alleviate such problem, Shen et al. (2019) and Kacupaj et al. (2021) use a multi-task learning framework to jointly learn entity detection, linking, and semantic parsing in a single model. Kacupaj et al. (2021) also use a graph attention network (Veličković et al., 2018) to explore entity type and relation information in the knowledge base.

Due to the superiority of multi-task learning for semantic parsing tailored for KBQA, our work is also based on the multi-task learning framework. However, our model is significantly different from existing works in both fuzzy grammar rules and knowledge-aware entity disambiguation together with entity type and relation prediction.

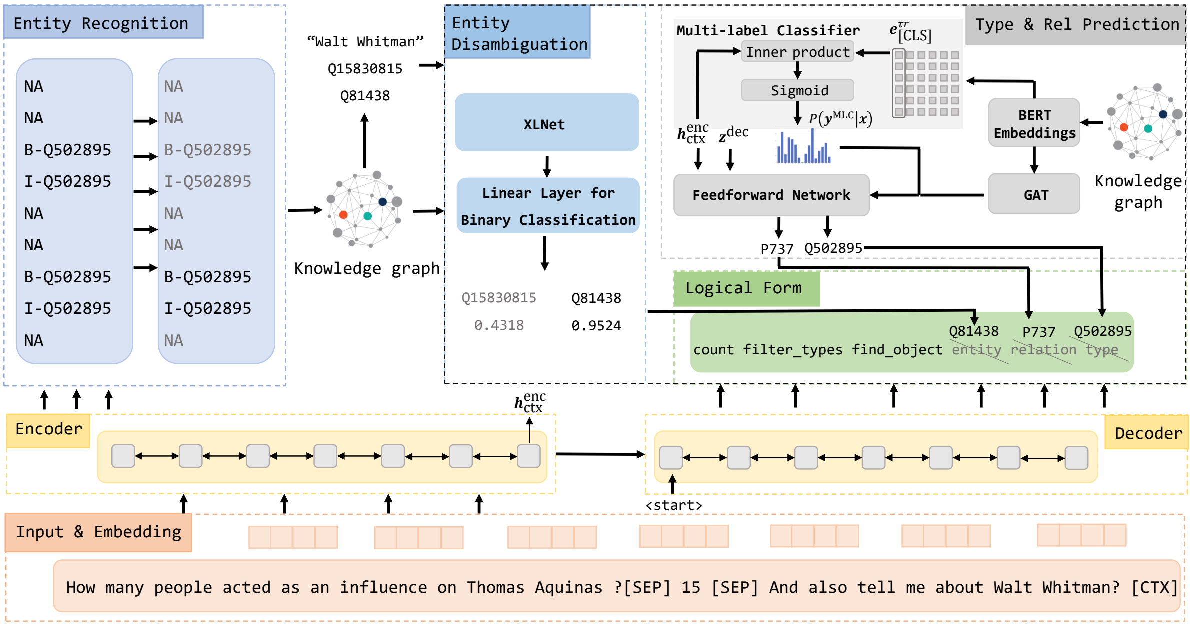

Figure 1: The diagram of KaFSP. Note that Q* and P* are entity and relation IDs defined in Wikidata where an entity type is also regarded as an entity.

3 KaFSP

We use a multi-task learning framework to map an input (current question concatenated with context) into a logical form where entities are detected and linked to the given knowledge base. Figure 1 shows the architecture of KaFSP. The backbone network of KaFSP follows LASAGNE (Kacupaj et al., 2021) consisting of a seq2seq network, an entity recognition module and a graph attention network module (Section 3.2). Our contributions lie in the fuzzy grammar (Section 3.1), the knowledge-aware entity disambiguation module (Section 3.3), and the entity type and relation prediction module (Section 3.4). The two knowledge-aware modules are shown in the black dashed box in Figure 1.

3.1 Fuzzy Grammar

In semantic parsing approaches tailored for conversational KBQA, a grammar with the minimum number of actions is usually defined to construct KB-executable logical forms (i.e., semantic parse trees). The actions defined in the previous grammar system (Guo et al., 2018; Kacupaj et al., 2021) are all deterministic operations. However, vague and fuzzy questions are common in real-world scenarios, e.g., "*How many works of art did approximately the same number of people do the dubbing for as Another ?*", which cannot be answered by previous deterministic grammars. The grammar of LASAGNE includes an action termed "approx", which aims to perform the operation of "approximately equal to". However, how two numbers are measured to be roughly equal to each other is not defined. Therefore, we take the grammar of LASAGNE as a starting point for building our own grammar and add fuzzy actions to the grammar to make it to adapt to real-world vague questions mentioned above. The new grammar is briefly summarized in Table 1.

We further give a "precise" (measurable) definition for these added fuzzy actions based on the fuzzy set theory (Zadeh, 1965). For a number a, we define its fuzzy set as $A = \{x, \mu(x)|x \in \mathbb{R}\}$. $\mu(x)$ is the membership function of set A, which indicates the degree of similarity between x and a, and is defined based on a generalized bell-shaped membership function as:

$$\mu(x) = \frac{1}{1 + |\frac{x-a}{c}|^{2b}}, \tag{1}$$

where $c \in \mathbb{R}$ and $b \in \mathbb{N}^{+}$. When $\mu(x) = 1$, x and a are strictly equal; and when $\mu(x) = 0$, x and a are strictly not equal.

A threshold $\lambda \in (0, 1]$ can be defined to get three

Category	Action	Description
find	set→subject(e, r)	set of subjects part of the triples with object e and relation r
	set→object(e, r)	set of objects part of the triples with subject e and relation r
	boolean→in(e, set)	check if the entity e is part of the set
filter	set→types(set$_e$, set$_t$)	filter the entity set set$_e$ based on type set set$_t$
count	num→count(set)	count the number of elements in the set
	dict→sub_triples(r, τ_1, τ_2)	extracts a dictionary, where keys are entities of type τ_1 and values are the number of objects of type τ_2 related with r
	dict→ob_ triples(r, τ_1, τ_2)	extracts a dictionary, where keys are entities of type τ_1 and values are the number of subjects of type τ_2 related with r
strict comparison	set→greater (dict, num)	set of those entities that have greater count than num
	set→lesser(dict, num)	set of those entities that have lesser count than num
	set→equal(dict, num)	set of those entities that have equal count with num
	set→atmost(dict, num)	set of those entities that have at most same count with num
	set→atleast(dict, num)	set of those entities that have at least same count with num
	set→argmax(dict, num)	set of those entities that have the most count
	set→argmin(dict, num)	set of those entities that have the least count
fuzzy comparison	set→equal(dict, num)	set of those entities that are in the fuzzy set $A_\lambda^{\approxeq}$ of num
	set→greater(dict, num)	set of those entities that are in the fuzzy set $A_\lambda^{\gtrsim}$ of num
	set→lesser(dict, num)	set of those entities that are in the fuzzy set $A_\lambda^{\lesssim}$ of num
set operation	set→intersection(set$_1$, set$_2$)	interesection of set$_1$ and set$_2$
	set→union(set$_1$, set$_2$)	union of set$_1$ and set$_2$
	set→difference(set$_1$, set$_2$)	difference of set$_1$ and set$_2$

Table 1: Fuzzy grammar defined for KaFSP.

fuzzy sets:

$$\begin{aligned} A_\lambda^{\approxeq} &= \{\mu(x) > \lambda | x \in \mathbb{R}\}, \\ A_\lambda^{\gtrsim} &= \{x > a | x \in \mathbb{R}\} \cup A_\lambda^{\approxeq}, \\ A_\lambda^{\lesssim} &= \{x < a | x \in \mathbb{R}\} \cup A_\lambda^{\approxeq}. \end{aligned} \tag{2}$$

When $\mu(x) > \lambda$, then $x \in A_\lambda^{\approxeq}$, which denotes that x and a is approximately equal to each other. When $x \in A_\lambda^{\gtrsim}$, x is considered to be greater than or approximately equal to a. When $x \in A_\lambda^{\lesssim}$, x is considered to be less than or approximately equal to a.

It is worth noting that all the parameters in Eq. (1) and the threshold λ can be flexibly predefined, which makes our grammar adjustable to different fuzzy scenarios.

3.2 Backbone Network

We follow the multi-task learning framework of LASAGNE (Kacupaj et al., 2021) to build the backbone network for our KaFSP.

Encoder and Decoder The skeleton of the entire model is a Transformer-based encoder-decoder network. The input $\boldsymbol{x}$ fed into the encoder is formed in a way similar to LASAGNE, which is composed of the previous question, the answer to the previous question, and the current question separated by a symbol "[SEP]". A special token "[CTX]" is appended to the input for encoding the input representation $\boldsymbol{h}_{\text{ctx}}^{\text{enc}}$, as shown in Figure 1. Both the encoder and decoder use a two-layer multi-head attention Transformer block, which can be formulated as:

$$\begin{aligned} \boldsymbol{h}^{\text{enc}} &= \text{encoder}(\boldsymbol{x}; \boldsymbol{\theta}^{\text{enc}}), \\ \boldsymbol{z}^{\text{dec}} &= \text{decoder}(\boldsymbol{h}^{\text{enc}}; \boldsymbol{\theta}^{\text{dec}}), \\ P(\boldsymbol{y}^{\text{dec}} | \boldsymbol{x}) &= \prod_t \text{softmax}(\boldsymbol{W}^{\text{dec}} \boldsymbol{z}_t^{\text{dec}}), \end{aligned} \tag{3}$$

where $\boldsymbol{z}_t^{\text{dec}} \in \mathbb{R}^{|\mathbb{V}^{\text{dec}}|}$ is the hidden state of the decoder at time step t, and $\boldsymbol{W}^{\text{dec}}$ is the linear projection matrix at the targe side. The key task of the decoder is to generate an action (listed in Table 1) at each time step to obtain the logical form $\boldsymbol{y}^{\text{dec}}$ corresponding to the input $\boldsymbol{x}$.

Entity Recognition Inspired by Shen et al. (2019), we jointly detect entities and their types in a BIO sequence labeling way. The labels for the input sequence $\boldsymbol{x}$ are in $\{O, \{B, I\} \times \{T_i\}_1^{N_{\text{tp}}}\}$. T_i stands for the i-th entity type label, and N_{tp} denotes the number of the distinct entity types in the knowledge base. An LSTM network, stacked over the encoder, is used to perform the sequence labeling task. To make the outputs of the sequence labeling task compatible with logical forms, we follow LASAGNE to use a feedforward layer stacked over the LSTM layer. The entire module of entity recognition is hence formulated as follows:

$$\begin{aligned} &\boldsymbol{h}^{\text{LSTM}} = \text{LSTM}(\boldsymbol{h}^{\text{enc}}; \boldsymbol{\theta}^{\text{LSTM}}), \\ &\boldsymbol{h}^{\text{FFN}} = \text{LeakyReLU}(\boldsymbol{W}^{\text{FFN}_1}[\boldsymbol{h}^{\text{enc}}; \boldsymbol{h}^{\text{LSTM}}]), \\ &P(\boldsymbol{y}^{\text{ER}}|\boldsymbol{x}) = \prod_t \text{softmax}(\boldsymbol{W}^{\text{FFN}_2}\boldsymbol{h}_t^{\text{FFN}}), \end{aligned} \tag{4}$$

where $\boldsymbol{h}^{\text{LSTM}}$ is the LSTM hidden state at time step t, $\boldsymbol{h}^{\text{FFN}}$ is the FFN-transformed version of $\boldsymbol{h}^{\text{LSTM}}$, and $P(\boldsymbol{y}^{\text{ER}}|\boldsymbol{x})$ denotes the probability distribution over entity tags.

Graph Attention Network (GAT) We follow LASAGNE to use the GAT module to learn the correlations between entity types and their relations in the knowledge base. It can be defined as:

$$\boldsymbol{h}^{\text{GAT}} = \text{GAT}(\boldsymbol{e}^{\text{node}}; \boldsymbol{\theta}^{\text{GAT}}), \tag{5}$$

where $\boldsymbol{e}^{\text{node}}$ are the embeddings of nodes in the type-relation graph constructed from the knowledge base. Please refer to Kacupaj et al. (2021) for more details on the GAT module.

3.3 Entity Disambiguation

In a large-scale knowledge base, it is common that entities with different meanings share the same surface forms. Predicting entity types could help differentiate them. However, when candidates have both the same type and surface form, it is difficult for entity type prediction to distinguish them again. In order to address this issue, we incorporate more information about these ambiguous entities from the knowledge base to disambiguate them.

We model the entity disambiguation problem as a binary classification problem:

$$y = f(\boldsymbol{c}, s, \mathcal{K}(e)), \tag{6}$$

where s is the surface form of a candidate entity e, $\boldsymbol{c}$ is the context where e occurs, and $\mathcal{K}(e)$ denotes relevant information of the candidate entity e from the knowledge base. If $y = 1$ the entity e is disambiguated and linked to the true entity in the knowledge base defined by $\mathcal{K}(e)$. The purpose of this is to maximize both the true positive and true negative.

We define the context of e as the entire input $\boldsymbol{x}$. To define $\mathcal{K}(e)$, we use all triples that are relevant to e in the knowledge base, regardless of whether the entity is a subject or an object in triples. That is, $\mathcal{K}(e)$ is an ordered set of KB triples. Each triple in $\mathcal{K}(e)$ can be formulated as (e_h, r, e_t), where the candidate entity e is either the head entity (e_h) or tail entity (e_t).

In Eq. (6), f is the classifier to disambiguate candidate entities. We use a pre-trained language model XLNet (Yang et al., 2019) fine-tuned in the training dataset as the classifier.

In order to feed s, $\boldsymbol{c}$, and $\mathcal{K}(e)$ into the pre-trained and fine-tuned classifier, we reorganize them into a concatenated textual sequence, with components be separated by the token "[SEP]". KB triples are all instantiated with corresponding words in the knowledge base, where e_h, r, and e_t are separated by blanks. We use the top 3 triples in $\mathcal{K}(e)$ and feed them into the classifier, where the triples are sorted by their IDs. Such a choice is a trade-off between knowledge graph coverage and memory consumption in practice. If the number of relevant triples retrieved from the knowledge base is less than 3, we use the candidate entity itself to fill in the empty triples.

3.4 Type and Relation Prediction

This module mainly performs two subtasks: the unified recognition of entity types and relations, and the KB-guided prediction of correct entity types and relations stacked over the first subtask, as shown in the Type & Relation Prediction module in Figure 1.

Let $\mathcal{G} \subseteq \mathcal{E} \times \mathcal{R} \times \mathcal{E}$ denote the knowledge base, where $\mathcal{E}$ is the entity set and $\mathcal{R}$ is the relation set. Each entity $e \in \mathcal{E}$ has an entity type $\tau \in \mathcal{T}$ (entity type set).

We model the type and relation recognition subtask as a multi-label classification task and use a classifier to predict the probability of an output sequence from a given input sequence.

To obtain neural representations of both entity types and entity relations for the recognition subtask, we use a pre-trained language model BERT (Devlin et al., 2019). The input fed into BERT is formed in a way similar to the entity disambiguation module. The difference is that we replace the entity with its entity type. Formally, the neural representation $\boldsymbol{e}^{\tau}$ of an entity type is computed as follows:

$$\boldsymbol{e}^{\tau} = \text{BERT}_{[\text{CLS}]}([\text{CLS}]s(\tau)[\text{SEP}]\mathcal{K}(\tau)[\text{SEP}]),$$

where [CLS] indicates that we use the representation of the prepended artificial [CLS] token as the representation of the entity type τ, $s(\tau)$ and $\mathcal{K}(\tau)$ represent the surface form and triples of τ, respectively. Similarly, the neural representation e^r of a relation is formulated as:

$$\boldsymbol{e}^r = \mathrm{BERT}_{\mathrm{[CLS]}}([\mathrm{CLS}]s(r)[\mathrm{SEP}]\mathcal{K}(r)[\mathrm{SEP}]).$$

Kacupaj et al. (2021) find that modeling the correlations between entity types and relations is crucial for semantic parsing. In our KaFSP, we use a single classifier to predict both entity types and relations, instead of using two separate classifiers that share no common information (Shen et al., 2019; Kacupaj et al., 2021). Hence, the prediction space of our classifier is $\mathcal{T} \cup \mathcal{R}$, and the correlations between types and relations are naturally captured in the same single classifier. We use a sigmoid function to output probabilities as follows:

$$P(\boldsymbol{y}^{\mathrm{MLC}}|\boldsymbol{x}) = \mathrm{Sigmoid}(\boldsymbol{h}^{\mathrm{enc}}_{\mathrm{ctx}} \times \boldsymbol{W}^{\mathrm{MLC}}(\boldsymbol{e}^{\tau r})^\top), \tag{7}$$

where $\boldsymbol{W}^{\mathrm{MLC}} \in \mathbb{R}^{|\mathcal{T}\cup\mathcal{R}|\times d}$ is a linear projection matrix, and $\boldsymbol{e}^{\tau r}$ are the concatenation of the embeddings of $\tau \in \mathcal{T}$ and $r \in \mathcal{R}$.

The KB-guided prediction of entity types and relations is actually to make final decisions on them with relevant information from the knowledge base. Since KB contains a lot of triples irrelevant to the current utterance u, in order to make the knowledge graph embedding provide the information related to u, we use the output probabilities from the proposed multi-label classifier to pinpoint relevant information from the knowledge base encoded by GAT. Particularly, we calculate the Hadamard product of $P(\boldsymbol{y}^{\mathrm{MLC}}|\boldsymbol{x})$ and $\boldsymbol{h}^{\mathrm{GAT}}$:

$$\boldsymbol{h}^{\mathrm{MLC}} = \boldsymbol{W}^{\mathrm{TRP}}(\boldsymbol{h}^{\mathrm{GAT}} \odot P(\boldsymbol{y}^{\mathrm{MLC}}|\boldsymbol{x})), \tag{8}$$

where $\boldsymbol{W}^{\mathrm{TRP}} \in \mathbb{R}^{2d\times d}$ is a linear projection matrix.

Given the hidden states of the decoder $\boldsymbol{z}^{\mathrm{dec}}$ and last hidden state of the encoder $\boldsymbol{h}^{\mathrm{enc}}_{\mathrm{ctx}}$, we use a feedforward network to predict the sequence of types and relations:

$$P(\boldsymbol{y}^{\mathrm{TRP}}|\boldsymbol{x}) = \prod_t \mathrm{softmax}((\boldsymbol{h}^{\mathrm{MLC}})^\top \mathrm{FFN}(\boldsymbol{h}^{\mathrm{enc}}_{\mathrm{ctx}}; \boldsymbol{z}^{\mathrm{dec}}_t)), \tag{9}$$

where $\mathrm{FFN}(\boldsymbol{h}^{\mathrm{enc}}_{\mathrm{ctx}}; \boldsymbol{z}^{\mathrm{dec}}_t)$ is the projection of the concatenation of the context representation and the hidden state of the decoder at time step t.

4 Learning and Inference

4.1 KaFSP Training

Before training KaFSP, we use weak supervisions (only the final answers) to obtain golden standard logical forms of questions in the training set through BFS, following Guo et al. (2018).

In KaFSP, we have 6 subtasks: the encoder-decoder subtask (DEC), the entity recognition subtask (ER), the filtering and permutation subtask from LASAGNE (FP), the multi-label classification subtask (MLC) described in Section 3.4, the type and relation prediction subtask (TRP) and the entity disambiguation subtask (ED). We a mixed training strategy to train these subtasks. The first 5 subtasks are jointly trained in a multi-task learning way while the last subtask is separately trained. Reasons for this strategy are twofold: 1) Entity disambiguation is a relatively independent subtask compared with other subtasks. 2) We fine-tune a huge pre-trained language model XLNet (Yang et al., 2019) on this subtask. Direct incorporation of the fine-tuning procedure into multi-task learning may make it difficult for the entire model to converge.

The joint loss $\mathcal{J}$ for the multi-task learning training is formulated as:

$$\mathcal{J} = \sum_{m\in\mathcal{M}} \gamma^m \mathcal{L}^m, \tag{10}$$

where $\mathcal{M} = \{\mathrm{DEC}, \mathrm{ER}, \mathrm{FP}, \mathrm{MLC}, \mathrm{TRP}\}$ is the set of subtasks and γs are the weights of these subtasks, which are learned during training. In learning these weights, we take into account the difference in magnitude among the 5 losses according to the log standard deviation (Kendall et al., 2018). $\mathcal{L}^{\mathrm{DEC}}$, $\mathcal{L}^{\mathrm{ER}}$, $\mathcal{L}^{\mathrm{FP}}$ and $\mathcal{L}^{\mathrm{TRP}}$ are the negative log-likelihood losses of 4 subtasks, which are defined as follows:

$$\begin{aligned}
\mathcal{L}^{\mathrm{DEC}} &= -\sum_{k=1}^{m} \log P(\boldsymbol{y}^{\mathrm{DEC}}_k|\boldsymbol{x}),\\
\mathcal{L}^{\mathrm{ER}} &= -\sum_{j=1}^{n} \log P(\boldsymbol{y}^{\mathrm{ER}}_j|\boldsymbol{x}),\\
\mathcal{L}^{\mathrm{FP}} &= -\sum_{j=1}^{n} \log P(\boldsymbol{y}^{\mathrm{FP}}_j|\boldsymbol{x}),\\
\mathcal{L}^{\mathrm{TRP}} &= -\sum_{k=1,\boldsymbol{y}^{\mathrm{dec}}_k\in\mathbb{P}}^{m} \log P(\boldsymbol{y}^{\mathrm{TRP}}_k|\boldsymbol{x}),
\end{aligned} \tag{11}$$

where n and m are the length of the input utterance $\boldsymbol{x}$ and the golden standard logical form, respectively. $\mathbb{P}$ is the set of placeholders for relations and types. $\boldsymbol{y}^*$ are ground-truth labels for corresponding subtasks.

The loss for the multi-label classification $\mathcal{L}^{\text{MLC}}$ is a binary cross-entropy loss, defined as:

$$\begin{aligned}\mathcal{L}^{\text{MLC}} = -\frac{1}{l}\sum_{i=1}^{l} &\boldsymbol{y}_i^{\text{MLC}} \log(P(\boldsymbol{y}_i^{\text{MLC}}|\boldsymbol{x})) \\ &+ \bar{\boldsymbol{y}}_i^{\text{MLC}} \log(P(\bar{\boldsymbol{y}}_i^{\text{MLC}}|\boldsymbol{x})),\end{aligned} \tag{12}$$

where l is the size of $\mathcal{T} \cup \mathcal{R}$, $\bar{\boldsymbol{y}}^{\text{MLC}} = 1 - \boldsymbol{y}^{\text{MLC}}$, $\boldsymbol{y}^{\text{MLC}}$ is defined in Eq. (7).

The entity disambiguation is trained separately, and its loss function is defined as:

$$\begin{aligned}\mathcal{L}^{\text{ED}} = \sum_{e \in \mathcal{E}_{\boldsymbol{x}}} &\boldsymbol{y}_i^{\text{ED}} \log(P(\boldsymbol{y}_i^{\text{ED}}|\boldsymbol{x})) \\ &+ \bar{\boldsymbol{y}}_i^{\text{ED}} \log(P(\bar{\boldsymbol{y}}_i^{\text{ED}}|\boldsymbol{x})),\end{aligned} \tag{13}$$

where $\mathcal{E}_{\boldsymbol{x}}$ is the set of entities that appear in $\boldsymbol{x}$ and $\boldsymbol{y}^{\text{ED}}$ is defined in Eq. (6).

To train this subtask, we retrieve all entities that are present in the current input from the knowledge base. Note that we only construct 500,000 and 40,000 samples respectively for training and validation of the entity disambiguation module.

4.2 Grammar-Guided Inference

The grammar defined in Table 1 is used to guide the decoding step. The decoder generates a sequence mixed with actions and placeholders. Placeholders are instantiated with specific entities, types, relations, and numbers. The decoding process for a logical form terminates when no nonterminals remain. After decoding, we use a shift-reduce method to check the logical form sequence and delete or correct wrong placeholders.

Once the BIO tags and entity types are identified, entity spans can be located from the input utterance. We search from the inverted index constructed for the knowledge base for each predicted entity span to obtain an entity candidate list. After filtering the retrieved entity candidate list according to the corresponding entity type, if there are still multiple candidate entities, the entity disambiguation module is activated to calculate the conditional probability of each candidate entity. The candidate entity with the highest probability is selected.

Finally, we use the relation and type prediction results and disambiguated entities to instantiate the placeholders to get final logical forms.

5 Experiments

We carried out experiments and analyses to validate the effectiveness of the proposed KaFSP.

5.1 Experimental Settings

Dataset We evaluated the proposed model on the CSQA dataset (Saha et al., 2018), a standard dataset for complex sequential question answering. The dataset is composed of 200K dialogues with 1.6M turns, and over 12.8M entities from Wikidata, where 153K, 16K, and 28K dialogues are used for training, verification, and test, respectively. The questions cover a wide range of linguistic phenomena, such as co-reference, ellipsis, and reasoning.

Evaluation Metrics We used the same evaluation metrics as Saha et al. (2018). When answers are composed of one or more entities, F1 score is used as the evaluation metric. When answers are a Boolean value or number, accuracy is used as the metric. Following previous works (Guo et al., 2018; Shen et al., 2019; Kacupaj et al., 2021), we also calculated overall scores for all types of questions under each evaluation metric.

Baselines We compared KaFSP against 5 state-of-the-art baselines on the CSQA. The first baseline is HRED+KVM (Saha et al., 2018), which combines the HRED model with the key-value memory network. The other four baselines are D2A (Guo et al., 2018), MaSP (Shen et al., 2019), KISP (Thirukovalluru et al., 2021), LASAGNE (Kacupaj et al., 2021), which achieve state-of-the-art results on different types of questions on the CSQA dataset. More details for model settings can be found in Appendix A.

5.2 Results

Table 2 shows experiment results on the CSQA dataset. Our model outperforms LASAGNE on all types of questions and achieves new SOTA results in 8 out of 10 question types. Additionally, our model outperforms all previous baselines in terms of "overall" results.

For question types that involve one or more entities, namely *Logical Reasoning (All)*, *Simple Question (Direct)*, and *Verification (Boolean)*, the improvements over LASAGNE on these question types are 3.14%, 2.78%, and 1.29% respectively. This is mainly because we have added a knowledge-aware entity disambiguation module to improve the accuracy of entity linking.

Method	HRED-KVM	D2A	MaSP	KISP	LASAGNE	KaFSP	Δ
# Params	-	-	15M	160M	14.7M	133.7M	
Question Type	F1 score						
Overall	9.39%	66.70%	79.26%	83.01%	82.91%	**85.33%**	+2.42%
Clarification	16.35%	35.53%	80.79%	76.33%	69.46%	**81.37%**	+11.91%
Comparative Reasoning (All)	2.96%	45.85%	68.90%	67.83%	69.77%	**86.00%**	+16.23%
Logical Reasoning (All)	8.33%	67.31%	69.04%	87.14%	89.83%	**92.97%**	+3.14%
Quantitative Reasoning (All)	0.96%	56.41%	73.75%	77.52%	86.67%	**93.74%**	+7.07%
Simple Question (Co-referenced)	7.26%	57.69%	76.47%	**79.66%**	79.06%	79.61%	+0.55%
Simple Question (Direct)	13.64%	78.42%	85.18%	87.68%	87.95%	**90.73%**	+2.78%
Simple Question (Ellipsis)	9.95%	81.14%	83.73%	**86.06%**	80.09%	81.75%	+1.66%
Question Type	Accuracy						
Overall	14.95%	37.33%	45.56%	46.22%	64.34%	**69.32%**	+4.98%
Verification (Boolean)	21.04%	45.05%	60.63%	72.72%	78.86%	**80.15%**	+1.29%
Quantitative Reasoning (Count)	12.13%	40.94%	43.39%	50.92%	55.18%	**61.23%**	+6.05%
Comparative Reasoning (Count)	8.67%	17.78%	22.26%	27.32%	53.34%	**72.79%**	+19.45%

Table 2: Comparison results against 5 baselines on CSQA. The last column shows the absolute improvements of our model over LASAGNE.

For question types *Clarification*, *Comparative Reasoning (All)*, and *Comparative Reasoning (Count)*, they usually involve multiple entity types and relations. KaFSP achieves huge improvements of 11.91%, 16.23%, and 19.45% on these question types over LASAGNE. This is mainly due to fuzzy comparison rules in the new grammar system and the proposed knowledge-aware type and relation prediction module. The module benefits from the multi-label classification with a single classifier that not only helps to capture correlations between entity types and relations but also pinpoints and incorporates only relevant information from the knowledge base into relation and type prediction, which makes the predictions of types and relations more accurate.

Our model does not outperform previous SOTA results on only 2 question types, i.e., *Simple Question (Co-referenced)* and *Simple Question (Ellipsis)*. Although KaFSP is lower than KISP on these two question types, it is 0.55% and 1.66% higher than LASAGNE. We conjecture that the reasons for being not superior to KISP on these question types are twofold. First, spurious logical forms may have a negative impact on the decoder when it is trained on data indeed with false logical forms. Second, in conversational QA, not only entities but also entity relations can be omitted in questions. For example, "*How many people acted as an influence on Thomas Aquinas? And also tell me about Walt Whitman?*". In KaFSP, we replace the real ID of an omitted entity with "previous-entity". However, this strategy is not used for omitted relations when producing logic forms, which may have negative impacts on the two question types mentioned above.

Methods	KaFSP	w/o Fuzzy	w/o ED	w/o MLC
Question Type	F1 score			
Clarification	81.37%	69.96%	79.44%	79.17%
Comparative	86.00%	70.55%	85.88%	85.65%
Logical	92.97%	-	90.03%	89.60%
Quantitative	93.74%	86.64%	-	93.32%
Simple(Coref)	79.61%	-	77.94%	77.28%
Simple(Direct)	90.73%	-	88.13%	88.19%
Simple(Ellipsis)	81.75%	-	80.34%	79.05%
Question Type	Accuracy			
Verification	80.15%	-	78.15%	79.02%
Quantitative	61.23%	57.74%	59.36%	59.46%
Comparative	72.79%	54.55%	72.39%	71.93%

Table 3: Ablation Study. "-" means the result is the same as KaFSP.

Furthermore, although KaFSP increases the number of parameters, most added parameters are from the pretrained XLNet (base) model included for entity disambiguation. This does not have a big impact on the inference speed of KaFSP compared to LASAGNE.

5.3 Ablation Study

Table 3 summarizes experiment results of ablation study on our major contributions: fuzzy grammar, the knowledge-aware entity disambiguation module, and the multi-label classification framework. We observe that all three key components make substantial contributions to our proposed model.

For the ablation study on the entity disambiguation module, we compared KaFSP against "w/o ED" that directly selects the first entity from the ordered candidate list retrieved from the knowledge

Question Type	Disamb.	Total	Perc.
Total	38, 023	272, 060	13.98%
Clarification	1, 403	12, 121	11.57%
Comparative	1, 540	15, 284	10.08%
Logical	4, 982	22, 466	22.18%
Quantitative	0	9, 253	0%
Simple (Coref)	5, 061	54, 854	9.23%
Simple (Direct)	11, 570	81, 994	14.11%
Simple (Ellipsis)	1, 466	10, 045	14.59%
Verification	5, 961	26, 728	22.30%
Quantitative (Cnt)	4, 495	24, 281	18.51%
Comparative (Cnt)	1, 545	15, 034	10.28%

Table 4: The number of entities in different types of questions, the number and percentage of entities disambiguated by the proposed entity disambiguation module.

base as the disambiguated entity. When ED module isn't used, candidate entities are sorted lexicographically by their IDs. This was done to be consistent with previous approaches in our baselines. We find that for all types of questions, the application of the proposed knowledge-aware ED improves the results to various degrees. This is because entity ambiguity is present in a wide range of questions. For *Simple Question (Direct)* questions, our further analysis shows that 14.11% of entities are updated by our knowledge-aware ED, which leads to an improvement of 2.60%. Both natural language questions and the knowledge base contain information that can be used to disambiguate entities. The proposed knowledge-aware ED incorporates both types of information for disambiguation.

Table 4 shows the total number of entities, the total number of disambiguated entities, and their proportions in the logical forms of different types of questions. It can be seen that overall, the disambiguated entities account for 13.98%. For *Logical Reasoning* and *Verification* questions where the proportion of disambiguated entities is relatively high, correspondingly, the improvements achieved by adding the entity disambiguation module is high. This further validates the effectiveness of the proposed entity disambiguation module.

Similarly, our ablation study validates the effectiveness of both the fuzzy grammar and the knowledge-aware multi-label classification (case study on the multi-label classification can be found in Appendix B).

5.4 Error Analysis

For error analysis, we randomly sampled 100 incorrect predictions and summarized the following two types of typical errors:

Entity Ambiguity (54%) Although our entity disambiguation model can achieve a prediction accuracy of 95.16%, ambiguous entities still exist in some questions. Take the question *"What lead to the death of Jerry Stephenson?"* as an example. Both entity Q6184489 and Q100927364 are found in the knowledge base, which matches the surface form "*Jerry Stephenson*". However, it is difficult to determine whether the real entity in the question is Q100927364 (college basketball player (1971–1971) Austin Peay) or Q6184489 (American baseball player) with only information of three triples and insufficient context.

Spurious Logical Forms (6%) Similar to previous works (Shen et al., 2019; Kacupaj et al., 2021), we find that our model can infer correct answers even with wrong "ground-truth" logical forms generated with the algorithm taken from previous work (Guo et al., 2018). This will affect the overall performance of the model. Such a phenomenon is especially common in complex reasoning questions.

6 Conclusion

In this paper, we have presented a knowledge-aware fuzzy semantic parsing framework KaFSP for conversational question answering over a large-scale knowledge base. KaFSP defines fuzzy comparison actions in grammar based on the fuzzy set theory to cover approximately comparative reasoning. In addition to this, we propose two knowledge-aware components in KaFSP to incorporate information from the knowledge base for entity disambiguation and entity type & relation prediction. Experiment results demonstrate that KaFSP is substantially better than all previous state-of-the-art models, setting new SOTA results on 8 out of 10 question types on the CSQA dataset and achieving over 90% F1 or accuracy in 3 question types for the first time.

Table 5: Hyper-parameters for KaFSP.

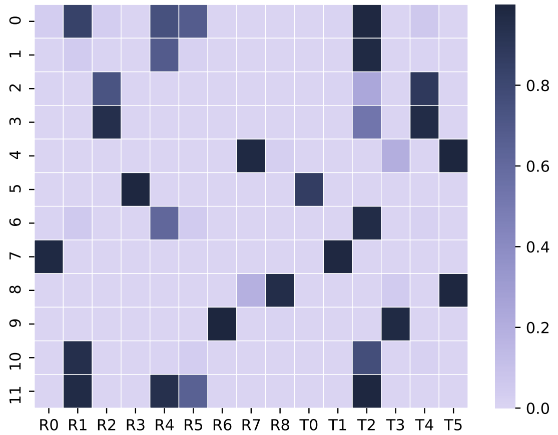

Figure 2: MLC probabilities of entity types and relations on sampled 12 questions. We represent questions with their IDs, and use T* and R* to represent Q* and P* which are the real IDs of the entity types and the relations in the Wikidata. Original questions with ground-truth entity types and relations are shown in Table 6.

A Hyperparamters and Module Configurations

Table 5 summarizes the hyperparameters used in the KaFSP framework. For the Transformer module, we used the standard configurations from Vaswani et al. (2017). Following the setting for Transformer base, we used residual dropout (Srivastava et al., 2014) in the summation of word embeddings and positional encodings in both the encoder and decoder with a rate of 0.1.

B Case Study on the Multi-Label Classification

We sample 12 questions and list the ground-truth labels (i.e., entity types and relations) corresponding to each question in Table 6. Through the proposed knowledge-aware multi-label classification module, we get the probabilities of different labels for each question, which are visualized in Figure 2.

We observe that the knowledge-aware multi-label classification module can effectively recognize entity types and relations in the questions. Take Question 10 and 11 as examples. Both questions contain type T2 and relation R1, while Question 11 has another relation R4. In Figure 2, we observe that this module can recognize these types and relations correctly. Applying the proposed multi-label classification module to the type and relation prediction module will hence effectively filter information irrelevant to the current question and help the model make better predictions.

We also find that some questions have a higher probability on a very small number of irrelevant labels. However, as the number of labels in KBs is large, having a high probability of only a few irrelevant labels will not greatly affect the results of the entire model.

ID	Question	Ground-truth Labels
0	Which administrative territories have diplomatic relationships with Greece and do Eliyahu Sasson belong to ?	P27 (R4), P530 (R5), Q15617994 (T2)
1	Which administrative territories are the countries of citizenship of Alfred Haighton or Thom Vink ?	P27 (R4), Q15617994 (T2)
2	Which administrative territories are the places of birth of Alfred Haighton or Dougie Bell ?	P19 (R2), Q56061 (T4)
3	Which administrative territories were Argo Arbeiter or Vera Hrochova born ?	P19 (R2), Q56061 (T4)
4	Which nucleic acid sequences are the species that have Pusl1 or SGCZ as their orthologous gene ?	P684 (R7), Q863908 (T5)
5	Which special fields are the medical specalities concerned with infectious disease or Borderline tuberculoid leprosy ?	P1995 (R3), Q1047113 (T0)
6	Which administrative territories are the countries of citizenship of Dinei or Jurgen Beck ?	P27 (R4), Q15617994 (T2)
7	Which occupations do Margaret Cavendish, Duchess of Newcastle-upon-Tyne and Jonathan Mayhew do for a living ?	P106 (R0), Q12737077 (T1)
8	Which nucleic acid sequences genes encode inorganic polyphosphate/ATP-NAD kinase CBU_1296 or formate dehydrogenase-specific chaperone VP1511 ?	P702 (R8), Q863908 (T5)
9	Which nutrients are involved in metabolic process and phosphorylation ?	P682 (R6), Q181394 (T3)
10	Which administrative territories are 1980 Winter Olympics or Ha Tien, Kien Giang present in ?	P17 (R1), Q15617994 (T2)
11	Which administrative territories are 1980 Winter Olympics a part of or are the native countriesof Dale M. Cochran ?	P17 (R1), P27 (R4), Q15617994 (T2)

Abstract

Predicting missing facts in a knowledge graph (KG) is crucial as modern KGs are far from complete. Due to labor-intensive human labeling, this phenomenon deteriorates when handling knowledge represented in various languages. In this paper, we explore multilingual KG completion, which leverages limited seed alignment as a bridge, to embrace the collective knowledge from multiple languages. However, language alignment used in prior works is still not fully exploited: (1) alignment pairs are treated equally to maximally push parallel entities to be close, which ignores KG capacity inconsistency; (2) seed alignment is scarce and new alignment identification is usually in a noisily unsupervised manner. To tackle these issues, we propose a novel self-supervised adaptive graph alignment (SS-AGA) method. Specifically, SS-AGA fuses all KGs as a whole graph by regarding alignment as a new edge type. As such, information propagation and noise influence across KGs can be adaptively controlled via relation-aware attention weights. Meanwhile, SS-AGA features a new pair generator that dynamically captures potential alignment pairs in a self-supervised paradigm. Extensive experiments on both the public multilingual DBPedia KG and newly-created industrial multilingual E-commerce KG empirically demonstrate the effectiveness of SS-AGA[1].

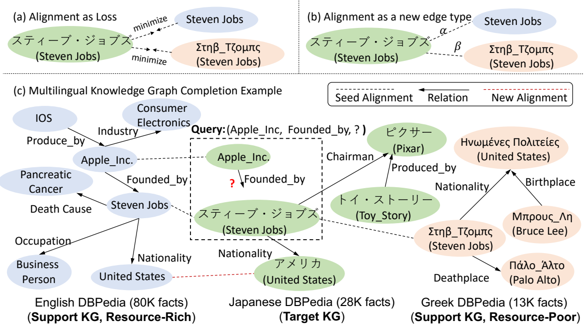

Figure 1: (a) Existing methods treat alignment pairs equally as a loss, which maximally ensures the same entity from different languages to be as similar as possible. (b) Our method differentiates alignment pairs as a new type edge with dynamic attention weights such as α and β, which control the influence and information propagation from other support KGs. (c) An example of MKGC task answering the query in the Japanese KG.

1 Introduction

Knowledge graphs (KGs) like Freebase (Bollacker et al., 2008) and DBPedia (Lehmann et al., 2015) are essential for various knowledge-driven applications such as question answering (Yasunaga et al., 2021) and commonsense reasoning (Lin et al., 2021). A KG contains structured and semantic information among entities and relations, where prior knowledge can be instantiated as factual triples (head entity, relation, tail entity), e.g., (*Apple Inc.*, *Founded by*, *Steven Jobs*). As new facts are continually emerging, modern KGs are still far from being complete due to the high cost of human annotation, which spurs on the Knowledge Graph Completion (KGC) task to automatically predict missing triples to complete the knowledge graph.

The KG incompletion circumstance is exacerbated in the multilingual setting, as human annotations are rare and difficult to gather, especially for low-resource languages. Unfortunately, most efforts for KGC have been devoted to learning each monolingual KG separately (Peng et al., 2021; Xu et al., 2021; Liang et al., 2021; Cao et al., 2021; Lovelace et al., 2021), which usually underperform in low-resource language KGs that suffer from the sparseness (Chen et al., 2017, 2020; Sun et al., 2020). In contrast, KGs from multiple languages are not naturally isolated, which usually share some real-world entities and relations. The transferable knowledge can be treated as a bridge to align different KGs, which not only facilitates the knowledge propagation to low-resource KGs but also alleviates

costly manual labeling for all languages.

In this paper, we explore multilingual KG completion (MKGC) (Chen et al., 2020) with limited seed alignment across languages. To mitigate language gaps, some efforts have been initiated on multilingual KG embedding methods, which leverage a KG embedding module (e.g., TransE (Bordes et al., 2013)) to encode each language-specific KG independently and then employ an alignment loss to force pairs of aligned entities to be close maximally (Chen et al., 2020; Zhang et al., 2019; Sun et al., 2020). However, such approaches mainly involve two limitations: (1) the KG inconsistency issue among different languages is neglected due to the equal treatment for parallel entities; (2) the scarcity of seed alignment hinders the efficient knowledge transfer across languages.

Concretely, prior methods treat all alignment pairs equally by forcing all parallel entities to be maximally close to each other (Chen et al., 2018; Sun et al., 2018; Chen et al., 2017). This ignores potentially negative effects from the KG inconsistency due to the language diversity. For example, as shown in Figure 1, the support English KG in DBP-5L (Chen et al., 2020) has much more enriched knowledge (80K facts) than the Greek one (13K facts). In order to complete the query (*Apple Inc.*, *Founded by*, ?) in the resource-poor Japanese KG (28K facts), we can transfer more knowledge from resource-rich English KG through the alignment link of *Steven Jobs* than that of the low-data Greek. However, if roughly pushing *Steven Jobs* to be equally close to that English KG and Greek KG, the learned embeddings for *Steven Jobs* will be similar even though they have different structures, KG capacity, coverage and quality. As such, it will bring in irrelevant information regarding this query and may cause the model to get the wrong answer. Thus, we encourage the model to automatically distinguish the underlying inconsistency and transfer knowledge from suitable support KGs[2] for better language-specific KGC performance.

One the other hand, seed alignment is critical for cross-lingual transfer (Chen et al., 2020; Sun et al., 2020), while acquisition of such parallel entities across languages is costly and often noisy. To mitigate such issue, some recent works (Chen et al., 2018, 2020) propose to generate new alignment pairs based on the entity embedding similarity during the training process. The generated new pairs can increase the inter-connectivity between KGs to facilitate knowledge transfer. However, simple usage of correlations between entities without any supervision may increase the noise during training, and inhibit the effectiveness of realistic language alignment in KGs (Sun et al., 2020).

Motivated by these observations, we propose a **S**elf-**S**upervised **A**daptive **G**raph **A**lignment (**SS-AGA**) framework for MKGC. To tackle the knowledge inconsistency issue, SS-AGA regards alignment as a new edge type between parallel entities instead of a loss constrain, which fuses KGs from different languages as a whole graph. Based on such unified modeling, we propose a novel GNN encoder with a relation-aware attention mechanism, which aggregates local neighborhood information with learnable attention weights and differs the influence received from multiple alignment pairs for the same entity as shown in Figure 1(b). To alleviate the scarcity of seed alignment, SS-AGA exploits a new pair generator that iteratively identifies new alignment pairs in a self-supervised manner. This is achieved by masking some seed alignment in the fused KG before GNN encoding and teaching the generation module to recover them. Empirically, SS-AGA outperforms popular baselines in both public and industrial datasets. For the public dataset, we use the multilingual DBPedia KG (Chen et al., 2020) and for the industrial dataset, we create a multilingual E-commerce Product KG called E-PKG.

Our contributions are as follows: (1) We handle the knowledge inconsistency issue for MKGC by treating entity alignment as a new edge type and introducing a relation-aware attention mechanism to control the knowledge propagation; (2) We propose a new alignment pair generation mechanism with self-supervision to alleviate the scarcity of seed alignment; (3) We constructed a new industrial-level multilingual E-commerce KG dataset; (4) Extensive experiments verify the effectiveness of SS-AGA in both public and industrial datasets.

2 Preliminaries

2.1 Knowledge Graph Completion

A knowledge graph $G = (\mathcal{E}, \mathcal{R}, \mathcal{T})$ consists of a set of entities $\mathcal{E}$, relations $\mathcal{R}$, and relational facts $\mathcal{T} = \{(e_h, r, e_t)\}$, where $e_h, e_t \in \mathcal{E}$ are head and tail entities, and $r \in \mathcal{R}$ is a relation. Entities and relations are represented by their text descriptions. The

---

[2] We regard the remaining KGs as the support KGs when conducting the KGC task in the target one.

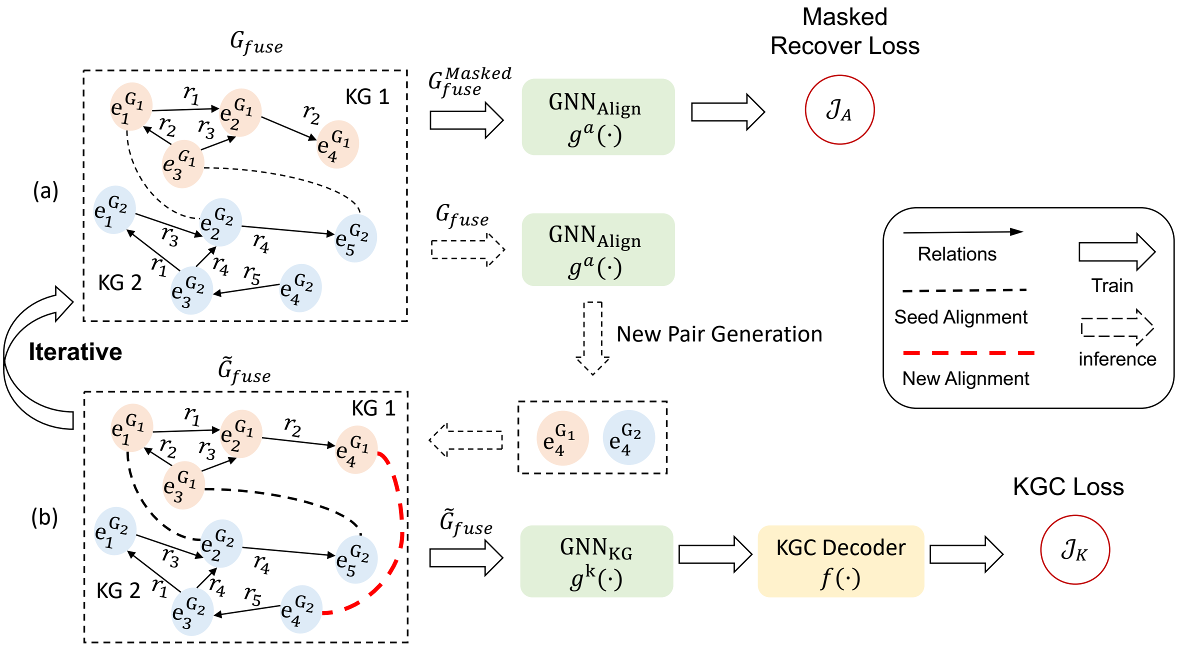

Figure 2: The overall framework of the Self-Supervised Adaptive Graph Alignment (SS-AGA).

KG completion task seeks to impute the missing head or tail entity of a triple given the relation and the other entity. Without loss of generality, we hereafter discuss the case of predicting missing tails, which we also refer to as a query $q = (e_h, r, ?e_t)$.

Multilingual KG completion (MKGC) utilizes KGs across multiple languages to achieve more accurate KG completion task on each individual KG (Chen et al., 2020). Formally, we are given M different language-specific KGs as $G_1, G_2, \cdots, G_M$, and only limited entity alignment pairs $\Gamma_{G_i \leftrightarrow G_j} \subseteq \{(e_i, e_j) : e_i \in \mathcal{E}_i, e_j \in \mathcal{E}_j\}$ between G_i and G_j. We also call $\Gamma_{G_i \leftrightarrow G_j}$ the *seed* alignment pairs to distinguish it from the new or pseudo alignment. Each KG G_i has their own relation set $\mathcal{R}_i$. We denote the union of relation sets from all KGs as a unified relation set $\mathcal{R} = \mathcal{R}_1 \cup \mathcal{R}_2 \cup \cdots \mathcal{R}_M$. MKGC is related to but different from the entity alignment (EA) task (Cao et al., 2019; Sun et al., 2020). In MKGC, seed alignment is not direct supervision while the auxiliary input features, all used in the training stage for cross-lingual transfer to boost the KGC results.

2.2 KG Embedding Models

KG embedding models aim to learn latent low-dimensional representations for entities $\{\boldsymbol{e}\}_{e\in\mathcal{E}}$ and relations $\{\boldsymbol{r}\}_{r\in\mathcal{R}}$. A naive implementation is an embedding lookup table (Bordes et al., 2013; Sun et al., 2019). Recently, Graph Neural Networks (GNN) have been explored to aggregate neighborhood information in KGs, where each triple is no longer considered independent of each other (Hao et al., 2019). Mathematically, these methods employ a GNN-based encoder g that embeds entities considering the neighborhood information,

$$\{\boldsymbol{e}\}_{e\in\mathcal{E}} = g(G).$$

Then, the plausibility of a relational fact (e_h, r, e_t) can be measured by the triple score:

$$f(\boldsymbol{e}_h, \boldsymbol{r}, \boldsymbol{e}_t),$$

where f can be any scoring function such as TransE (Bordes et al., 2013), RotatE (Sun et al., 2019). We also refer it to as the KGC decoder.

3 Method

We introduce SS-AGA for MKGC, consisting of two alternating training components (a) and (b) in Figure 2: (a) A new alignment pair generation module for alleviating the limited seed alignment in G_{fuse}. Specifically, we mask some seed alignment in the fuse KG to obtain $G_{\text{fuse}}^{\text{Masked}}$ and train the generator $g^a(\cdot)$ to recover them. Then, the trained generator will propose new edges based on the learned entity embeddings, which will be incorporated to G_{fuse} as $\widetilde{G}_{\text{fuse}}$ for MKG embedding model $g^k(\cdot)$ in the next iteration; (b) A novel relation-aware MKG embedding model $g^k(\cdot)$ for addressing the knowledge inconsistency across multilingual KGs. Specifically, we fuse different KGs as a whole graph G_{fuse} by treating alignment as a new edge type. Then $g^k(\cdot)$ computes the contextualized embeddings for each node with learnable relation-aware attention weights that differ the influence received from multiple alignment pairs. Finally, a KGC decoder $f(\cdot)$ computes the triple scores.

3.1 Relation-aware MKG Embedding

As mentioned before, the knowledge transfer is inefficient in existing MKGC methods, as they encode each KG separately and transfer knowledge by forcing aligned entities to share the same embedding. To handle the knowledge inconsistency, we first fuse all KGs as a whole, which relaxes the entity alignment to relational facts. We then design an attention-based relation-aware GNN to learn the contextualized MKG embeddings for entities, which can differ the influence from multiple alignment sources with learnable attention weights. Afterwards, we apply a KGC decoder on the contextualized embedding to get the triple scores for relational facts.

More specifically, we create the fused KG by preserving triples within each KG and converting each cross-KG alignment pair (e_i, e_j) to two relational facts $(e_i, r_{\text{align}}, e_j)$ and $(e_j, r_{\text{align}}, e_i)$ with the alignment edge as a newly introduced relation r_{align}. In this way, we enable direct message passing among entities from different KGs, where the attention weight can be learned automatically from data to differ the influence from multiple alignment pairs. We denote the fused knowledge graph as $G_{\text{fuse}} = (\mathcal{E}_{\text{fuse}}, \mathcal{R}_{\text{fuse}}, \mathcal{T}_{\text{fuse}})$, where $\mathcal{E}_{\text{fuse}} = \bigcup_{i=1}^{M} \mathcal{E}_i$, $\mathcal{R}_{\text{fuse}}! = (\bigcup_{i=1}^{M} \mathcal{R}_i) \cup \{r_{\text{align}}\}$ and $\mathcal{T}_{\text{fuse}} = (\bigcup_{i=1}^{M} \mathcal{T}_i) \cup (\bigcup_{i,j}\{(e_h, r_{\text{align}}, e_t) : (e_h, e_t) \text{ or } (e_t, e_h) \in \Gamma_{G_i \leftrightarrow G_j}\})$.

Given the fused KG G_{fuse}, we propose an attention-based relation-aware GNN encoder $g^k(\cdot)$ to learn contextualized embeddings for entities following a multi-layer message passing architecture.

At the l-th layer of GNN, we first compute the relation-aware message delivered by the entity e_i in a relational fact (e_i, r, e_j) as follows:

$$\boldsymbol{h}_{i(r)}^{l} = \mathrm{Msg}\left(\boldsymbol{h}_i^l, r\right) := \boldsymbol{W}_v^l \mathrm{Concat}(\boldsymbol{h}_i^l, \boldsymbol{r}),$$

where $\boldsymbol{h}_i^l$ is the latent representation of e_i at the l-th layer, $\mathrm{Concat}(\cdot,\cdot)$ is the vector concatenation function, and $\boldsymbol{W}_v^l$ is a transformation matrix. Then, we propose a relation-aware scaled dot product attention mechanism to characterize the importance of each entity's neighbor e_i to itself e_j, which is computed as follows:

$$\mathrm{Att}\left(\boldsymbol{h}_{i(r)}^l, \boldsymbol{h}_j^l\right) = \frac{\exp(\alpha_{ij}^r)}{\sum_{(e_{i'}, r) \in \mathcal{N}(e_j)} \exp\left(\alpha_{i'j}^r\right)}$$

$$\alpha_{ij}^r = \left(\boldsymbol{W}_k^l \boldsymbol{h}_{i(r)}^l\right)^T \cdot \left(\boldsymbol{W}_q^l \boldsymbol{h}_j^l\right) \cdot \frac{1}{\sqrt{d}} \cdot \beta_r, \qquad (1)$$

where d is the dimension of the entity embeddings, $\boldsymbol{W}_k^l, \boldsymbol{W}_q^l$ are two transformation matrices, and β_r is a learnable relation factor. Different from the traditional attention mechanism (Veličković et al., 2018; Bai et al., 2019), we introduce β_r to characterize the general significance of each relation r. It is essential as not all the relationships contribute equally to the query entity. We also remark that the neighborhood is bidirectional, i.e. $\mathcal{N}(e_j) := \{(e_{i'}, r) : (e_{i'}, r, e_j) \in \mathcal{T}_{\text{fuse}} \text{ or } (e_j, r, e_{i'}) \in \mathcal{T}_{\text{fuse}}\}$ as the tail entity will also influence the head entity.

We then update the hidden representation of entities by aggregating the message from their neighborhoods based on the attention score:

$$\boldsymbol{h}_j^{l+1} = \boldsymbol{h}_j^l + \sigma\left(\sum_{(e_{i'}, r) \in \mathcal{N}(e_j)} \mathrm{Att}\left(\boldsymbol{h}_{i'(r)}^l, \boldsymbol{h}_j^l\right) \cdot \boldsymbol{h}_{i'(r)}^l\right),$$

where $\sigma(\cdot)$ is a non-linear activation function, and the residual connection is used to improve the stability of GNN (He et al., 2015).

Finally, we stack L layers to aggregate information from multi-hop neighbors and obtain the contextualized embedding for each entity e_j as: $\boldsymbol{e}_j = \boldsymbol{h}_j^L$. Given the contextualized entity embeddings, the KGC decoder computes the triple score for each relational fact: $f(\boldsymbol{e}_h, \boldsymbol{r}, \boldsymbol{e}_t)$. The learning object is to minimize the following hinge loss:

$$\mathcal{J}_K = \sum_{\substack{(e_h, r, e_t) \in \mathcal{T}_m \\ (e_{h'}, r, e_{t'}) \notin \mathcal{T}_m \\ m=1,\dots,M}} \left[f\left(\boldsymbol{e}_h{'}, \boldsymbol{r}, \boldsymbol{e}_t'\right) - f\left(\boldsymbol{e}_h, \boldsymbol{r}, \boldsymbol{e}_t\right) + \gamma\right]_+, \qquad (2)$$

where $\gamma > 0$ is a positive margin, f is the KGC decoder, $(e_{h'}, r, e_{t'})$ is a negative sampled triple obtained by replacing either head or tail entity of the true triple (e_h, r, e_t) randomly by other entities in the same language-specific KG.

Remark 1. Our method views cross-KG alignment as a relation r_{align} in the fused KG. The knowledge transfer cross KGs is essentially conducted via the learnable attention weight $\alpha_{ij}^{r_{\text{align}}}$, where e_i and e_j are connected through the relation r_{align}. Thanks to the power of GNN, $\alpha_{ij}^{r_{\text{align}}}$ differs the influence from multiple alignment sources, as opposed to some existing models that simply force pairs of entities to be close to each other through a pre-defined alignment loss. In this way, we properly conduct knowledge transfer among KGs with aware of their knowledge inconsistency.

Scalability issue. Since we fuse all the M KGs as a whole, and duplicate edges for head entities, the scale of the graph G_{fuse} would become very large. We therefore employ a k-hop graph sampler that samples the k-hop neighbors for each node and compute their contextualized embeddings.

3.2 Self-supervised New Pair Generation

In multilingual KGs, we are only provided with limited seed alignment pairs to facilitate knowledge transfer, as they are expensive to obtain and even sometimes noisy (Sun et al., 2020). To tackle such challenge, we propose a self-supervised new alignment pair generator. In each iteration, the generator identifies new alignment pairs which will be fed into the GNN encoder $g^k(\cdot)$ to produce the contextualized entity embeddings in the next iteration. The training of the generator is conducted in a self-supervised manner, where the generator is required to recover masked alignment pairs.

New Pair Generation (NPG) relies on two sets of entity embeddings: the structural embeddings and the textual embeddings. The structural embeddings are obtained by another GNN encoder g^a: $\{\boldsymbol{e}^a\}_{e\in\mathcal{E}_{\text{fuse}}} = g^a(G_{\text{fuse}})$, which shares the same architecture with $g^k(\cdot)$ in the relation-aware MKG Embedding model (Section 3.1). The reason we employ two GNN encoders is that the set of embeddings that generate the best alignment results may differ from those that can best achieve the KG completion task.

The textual embeddings are obtained by entities' text description and mBERT: $\boldsymbol{e}^{\text{text}} = \text{mBERT}(e)$. mBERT is a multilingual pre-trained language model (Devlin et al., 2019) and is particularly attractive to the new alignment pair generation due to the following merits: (1) it captures rich semantic information of the text; (2) the pre-trained BERT embeddings are also aligned across different languages (Devlin et al., 2019; Sun et al., 2020).

We then model the pairwise similarity score between entity e_i and e_j as the maximum of the cosine similarities of their structural embeddings and textual embeddings:

$$\text{sim}(e_i, e_j) = \max\left(\cos\left(\boldsymbol{e}_i^a, \boldsymbol{e}_j^a\right), \cos\left(\boldsymbol{e}_i^{\text{text}}, \boldsymbol{e}_j^{\text{text}}\right)\right).$$

Then we introduce new alignment pairs if a pair of unaligned entities in two KGs are mutual nearest neighbors according to the cross-domain similarity local scaling (CSLS) measure (Conneau et al., 2018) as shown below,

$$\begin{aligned}
&\text{CSLS}(e_i, e_j) = 2\text{sim}(e_i, e_j) - s(e_i) - s(e_j) \\
&\text{subject to } s\left(e_i\right) = \frac{1}{K}\sum_{e_{i'}\in\mathcal{N}(e_i)} \text{sim}\left(e_i, e_{i'}\right),
\end{aligned}$$

where K is the number of each node's k-nearest neighbors. CSLS is able to capture the sturctural similarity between pairs of entities. The generated pairs are then utilized to update the graph structure of G_{fuse} to $\widetilde{G}_{\text{fuse}}$ in the next iteration, to alleviate the challenge of limited seed alignment.

Self-Supervised Learning (SSL) Similar to many existing works (Chen et al., 2020; Sun et al., 2020), the aforementioned NPG paradigm is unsupervised and may bring in unexpected noises. Inspired by masked language modeling (Devlin et al., 2019) which captures contextual dependencies between tokens, we propose a self-supervised learning procedure to guide and denoise the new pair generation. Specifically, we randomly mask out some alignment relational facts, $\mathcal{T}_{\text{masked}} \subseteq \{(e_h, r, e_t) \in \mathcal{T}_{\text{fuse}} : r = r_{\text{align}}\}$, and let the generator to recover them. Such masked alignment recovery in KGs can automatically identify the underlying correlations for alignment neighbors and encourage the NPG to generate high-quality alignment pairs that are real existences but hide due to the limited seed alignment.

Given the fused KG with masked alignment $G_{\text{fuse}}^{\text{Masked}} = \{\mathcal{E}_{\text{fuse}}, \mathcal{R}_{\text{fuse}}, \mathcal{T}_{\text{fuse}}/\mathcal{T}_{\text{masked}}\}$, the GNN encoder g^a embeds the entities as

$$\{\widetilde{\boldsymbol{e}}\}_{e\in\mathcal{E}_{\text{fuse}}} = g^a(G_{\text{fuse}}^{\text{Masked}}).$$

The GNN g^a is then trained via minimizing the following hinge loss $\mathcal{J}_A$,

$$\begin{aligned}
\mathcal{J}_A^{G_i\leftrightarrow G_j} &= \sum_{\substack{(e_h, e_t)\in\Gamma_{ij}^p \\ \left(e_{h'}, e_{t'}\right)\in\Gamma_{ij}^n}} \left[\|\widetilde{\boldsymbol{e}}_h^a - \widetilde{\boldsymbol{e}}_t^a\|_2 - \|\widetilde{\boldsymbol{e}}_{h'}^a - \widetilde{\boldsymbol{e}}_{t'}^a\|_2 + \gamma_a\right]_+ \\
\mathcal{J}_A &= \sum_{1\leq i<j\leq M} \mathcal{J}_A^{G_i\leftrightarrow G_j}, \qquad (3)
\end{aligned}$$

where $\Gamma_{ij}^p = \{(e_h \in \mathcal{E}_i, e_t \in \mathcal{E}_j) : (e_h, r_{\text{align}}, e_t) \in \mathcal{T}_{\text{masked}}\}$ is the masked alignment set, $\Gamma_{ij}^n = \{(e_h \in \mathcal{E}_i, e_t \in \mathcal{E}_j) : (e_h, e_t) \notin \Gamma_{G_i\leftrightarrow G_j}\}$ is the unaligned entity pair set, and $\gamma_a > 0$ is a positive margin. $(e_{h'}, e_{t'})$ is randomly sampled by replacing one of the entities in the positive entity pairs.

3.3 Training

The overall loss function is the combination of the KG completion loss Eq. (2) and the self-supervised alignment loss Eq. (3) as shown below

$$\mathcal{J} = \mathcal{J}_K + \lambda \mathcal{J}_A, \tag{4}$$

where $\lambda > 0$ is a positive hyperparameter to balance between the two losses. We summarize the training process in Algorithm 1 of the Appendix.

4 Experiments

4.1 Dataset

We conduct experiments over two real-world datasets. (i) **DBP-5L** (Chen et al., 2020) contains five language-specific KGs from DBpedia (Lehmann et al., 2015), i.e., English (EN), French (FR), Spanish (ES), Japanese (JA), Greek (EL). As the original dataset only contains structural information, we additionally crawled the text information for these entities and relations based on the given URLs. (ii) **E-PKG** is a new industrial multilingual E-commerce product KG dataset, which describes phone-related product information from an E-commerce platform across six different languages: English (EN), German (DE), French (FR), Japanese (JA), Spanish (ES), Italian (IT). The statistics are shown in Table 1. The # Aligned Links for a specific KG G_i denotes the number of alignment pairs where one of the aligned entities belong to that KG. It is possible for an entity to have multiple alignment pairs across different KG sources. For both datasets, we randomly split the facts in each KG into three parts: 60% for training, 30% for validation, and 10% for testing. Please refer to *Appendix A* for the details of E-PKG construction.

4.2 Evaluation Protocol

In the testing phase, given each query $(e_h, r, ?e_t)$, we compute the plausibility scores $f(e_h, r, \widetilde{e}_t)$ for triples formed by each possible tail entity $\widetilde{e}_t$ in the test candidate set and rank them. We report the mean reciprocal ranks (MRR), accuracy (Hits@1) and the proportion of correct answers ranked within the top 10 (Hits@10) for testing. We also adopt the filtered setting following previous works based on the premise that the candidate space has excluded the triples that have been seen in the training set (Wang et al., 2014a; Yang et al., 2015a).

4.3 Baselines

- **Monolingual Baselines.** (i) **TransE** (Bordes et al., 2013) models relations as translations in the Euclidean space; (ii) **RotatE** (Sun et al., 2019) models relations as rotations in the complex space; (iii) **DisMult** (Yang et al., 2015b) uses a simple bilinear formulation; (iv) **KG-BERT** (Yao et al., 2020) employs pre-trained language models for knowledge graph completion based on text information of relations and entities.
- **Multilingual Baselines.** (i) **KEnS** (Chen et al., 2020) embeds all KGs in a unified space and exploits an ensemble technique to conduct knowledge transfer; (ii) **CG-MuA** (Zhu et al., 2020) is a GNN-based KG alignment model with collective aggregation. We revise its loss function to conduct MKGC. (iii) **AlignKGC** (Singh et al., 2021) jointly trains the KGC loss with entity and relation alignment losses. For fair comparison, we use mBERT (Devlin et al., 2019) to obtain initial embeddings of entities and relations from their text for all methods. We do not employ any pretrained tasks such as EA to obtain these initial text embeddings as in (Singh et al., 2021).

4.4 Main Results

The main results are shown in Table 2 and Table 3. Firstly, by comparing multilingual and monolingual KG models, we can observe that multilingual methods can achieve better performance. This indicates that the intuition behind utilizing multiple KG sources to conduct KG completion is indeed beneficial, compared with inferring each KG independently. Notably, multilingual models tend

to bring larger performance gains for those low-resource KGs such as Greek in DBP-5L, which is expected as low-resource KGs are far from complete and efficient external knowledge transfer can bring in potential benefits. Among multilingual models, our proposed method SS-AGA can achieve better performance in most cases across different metrics, languages, and datasets, which verifies the effectiveness of SS-AGA.

4.5 Ablation Study

To evaluate the effectiveness of our model design, we conduct ablation study by proposing the following model variants: (i) **GNN** applies the GNN encoder without relation modeling to each KG independently, and directly forces all alignment pairs to be close to each other as in prior works (Chen et al., 2020; Zhu et al., 2020); (ii) **R-GNN** is the proposed relation-aware MKG embedding model (Section 3.1), which utilizes all seed alignment to construct G_{fused} and differs the influence from other KGs by the relation-aware attention mechanism; (iii) **R-GNN + NPG** conducts additional new pair generation for R-GNN; (iv) **R-GNN + NPG + SSL** is our proposed full model SS-AGA, which leverages SSL to guide the NPG process. We also investigate the effect of whether to share or not share the encoders $g^a(\cdot), g^k(\cdot)$ that generate the embeddings for the SSL and KGC loss, respectively.

We report the average Hits@1, Hits@10 and MRR over DBP-5L as shown in Table 4. As we can see, applying a GNN encoder to each KG independently would cause the performance drop as all aligned entities are being equally forced to be close to each other. Removing the new pair generation process would also cause a performance degradation due to the sparsity of seed alignment, which shows that iteratively proposing new alignment is indeed helpful. If the generation process is further equipped with supervision, the performance would be enhanced, which verifies the effectiveness of the self-supervised alignment loss. Finally, sharing the parameters of two GNN encoders would harm the performance. Though MKGC and entity alignment are two close-related tasks that can potentially benefit each other, the set of embeddings that produce the best alignment result do not necessarily yield the best performance on the MKGC task.

4.6 Impact of Seed Alignment

We next study the effect of seed alignment number as depicted in Figure 3. Firstly, we can observe that SS-AGA consistently outperforms other multilingual models on varying alignment ratios. Secondly,

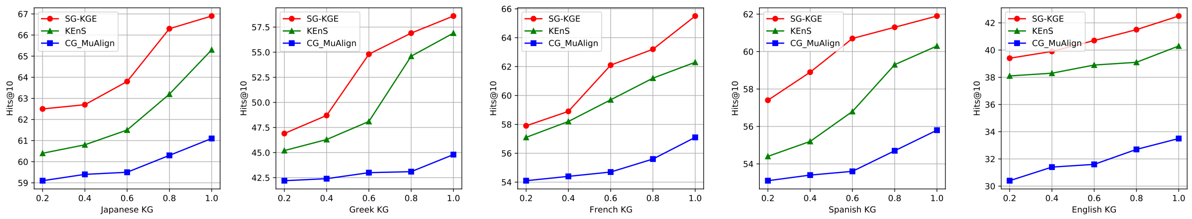

Figure 3: Hits@10 with respect to different sampling ratio of seed alignment pairs.

Method	Avg H@1	Avg H@10	Avg MRR
GNN	24.1	56.3	33.2
R-GNN	25.7	57.9	34.4
R-GNN + NPG	26.2	58.3	34.9
R-GNN + NPG + SSL (SS-AGA)			
- encoder (shared)	25.8	57.7	34.1
- encoder (no shared)	**26.9**	**58.7**	**35.3**

Table 4: Ablation results on DBP-5L.

for low-resources KGs such as Japanese and Greek KGs, we can observe a sharp performance drop when decreasing the alignment ratio compared with those popular KGs such as English KG. This indicates that the knowledge transfer among different KGs is especially beneficial for those low-resources KGs, as popular KGs already contain relatively rich knowledge. However, such transfer process is heavily dependent on the seed alignment, which yields the necessity of new alignment generation process.

4.7 Case Study

To interpret the knowledge transfer across different KGs, we visualize the normalized average attention weight for each KG w.r.t. the attention score computed in Eq. (1) from different KG sources. We can see that for those popular KGs, they will receive the highest attention score from themselves such as English and French KGs. Although Japanese KG is low-resource, from the main results table 2, we can see that the gap improvement brought by multilingual methods is relatively small compared to another low-resource Greek KG. This indicates that Japanese KG may contain more reliable facts to facilitate missing triple predictions. However, for Greek KG, we can observe that the attention weights from other languages take the majority, which means that the performance boost in Greek KG is largely attributed to the efficient knowledge transfer from other KG sources.

5 Related Work

5.1 Monolingual KG Embeddings

Knowledge graph embeddings (Bordes et al., 2013; Sun et al., 2019; Con, 2018) achieve the state-of-the-art performance for KGC, which learn the latent low-dimensional representations of entities and relations. They measure triple plausibility based on varying score functions such as translation-based TransE (Bordes et al., 2013), TransH (Wang et al., 2014b); rotation-based RotatE (Sun et al., 2019) and language-model-based KG-BERT (Yao et al., 2020). Recently, GNN-based methods (Li et al., 2019; Zhang et al., 2020; Javari et al., 2020) have been proposed to capture node neighborhood information for the KGC tasks. GNN is a class of neural networks that operate on graph-structured data by passing local messages (Kipf and Welling, 2017; Veličković et al., 2018; Xu et al., 2019; Bai et al., 2019; Huang et al., 2020, 2021; Wang et al., 2021). Specifically, they use GNN as an encoder to generate contextualized representation of entities by passing local messages (Kipf and Welling, 2017; Veličković et al., 2018; Xu et al., 2019; Bai et al., 2019; Huang et al., 2020, 2021). Then, existing score functions are employed to generate triple scores which outperform the aforementioned methods that treat each triple independently only with the scoring function.

5.2 Multilingual KG Embeddings

Multilingual KG embeddings are extensions of monolingual KG embeddings that consider knowledge transfer across KGs with the use of limited seed alignment (Sun et al., 2020; Singh et al., 2021). Earlier work proposes different ways to reconcile KG embeddings for the **entity alignment (EA)** task: MTransE (Chen et al., 2017) learns a transformation matrix between pairs of KGs. MuGNN (Cao et al., 2019) reconciles structural differences via rule grounding. CG-MuA utilizes collective aggregation of confident neighborhood (Zhu et al., 2020). Others incorporate attribute information such as entity text (Zhang et al., 2019; Chen et al., 2018). To tackle the sparsity of seed alignment, BootEA (Sun et al., 2018) iteratively proposes new aligned pairs via bootstrapping. Zhu et al. (2017) utilizes parameter sharing to improve alignment performance. While they focus

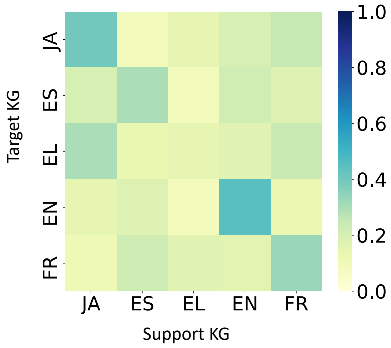

Figure 4: Average attention weight learned in DBP-5L.

on the EA task rather than the MKGC task that we tackle here, such techniques can be leveraged to conduct knowledge transfer among KGs. Recently, Chen et al. (2020) propose an ensemble-based approach for the MKGC task. In this paper, we view alignment as a new edge type and employ a relation-aware GNN to get the contextualized representation of entities. As such, the influence of the aligned entities is captured by the learnable attention weight, instead of assuming each alignment pair to have the same impact. We also propose a self-supervised learning task to propose new alignment pairs during each training epoch to overcome the sparsity issue of seed alignment pairs.

6 Discussion and Conclusion

In this paper, we propose SS-AGA for multilingual knowledge graph completion (MKGC). It addresses the knowledge inconsistency issue by fusing all KGs and utilizing a GNN encoder to learn entity embeddings with learnable attention weights that differs the influence from multiple alignment sources. It features a new pair generation conducted in a self-supervised learning manner to tackle the limited seed alignment issue. Extensive results on two real-world datasets including a newly-created E-commerce dataset verified the effectiveness of SS-AGA. Our current approach may fail to fully exploit the benefit of entity and relation texts. In the future, we plan to study more effective ways to combine text data with graph data for better model performance. We are also interested in studying MKGC where there no alignment pairs are given, which is a very practical setting and our current model is not able to deal with.

7 Ethical Impact

Our paper proposed SS-AGA, a novel multilingual knowledge graph completion model for predicting missing triples in KGs considering their knowledge transfer. SS-AGA neither introduces any social/ethical bias to the model nor amplifies any bias in the data. We the created multilingual E-commerce product KG dataset by masking all customers'/sellers' identity and privacy. We only collect information related to products without any personal information leakage. Our model is built upon public libraries in Pytorch. We do not foresee any direct social consequences or ethical issues.

A Data Construction

We introduce the generation process of the multilingual E-commerce KG dataset (E-PKG). E-PKG is a phone-related multilingual product KG across six different languages: English (EN), German (DE), French (FR), Japanese (JA), Spanish (ES), Italian (IT). The statistics are shown in Table 5.

	EN	DE	FR	JA	ES	IT
#Triple_between	90,318	65,077	69,451	14,814	23,671	60,998
#Triple_attributes	5,013	7,345	6,017	946	5,396	6,016
#Triple_products	5,220	3,448	4,547	943	1,096	4,278
#Triples	100,531	75,870	80,015	16,703	30,163	71,292
#Aligned Pairs	21,382	24,696	24,812	5,175	20,184	23,827
#Entities	16,544	17,223	17,068	2,642	9,595	15,670
#Relations	21	21	21	21	21	21

Table 5: Statistics of E-PKG.

Specifically, each KG consists of two types of entities, which are products such as iPhone 12 and attributes such as style and brand. There are three types of triples grouped by their relation types: 1.) The triples that describe relations between a product and an attribute (Triple_between), such as product-belong-to-brand; 2.) The triples that denote relations between a product and a product, such as product-co-buy-with-product (Triple_products); 3.) The triples that refer to relations between an attribute and an attribute, such as manufacturer-has-brand (Triple_attributes). All relations are described in English and entities are in their own languages. The entity type distributions and seed alignment pairs distributions are illustrated in Figure 5 and Figure 6, respectively.

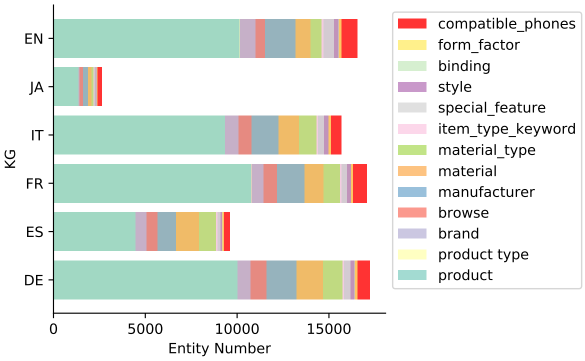

Figure 5: Entity distribution for E-PKG.

B Implementation Details

We use Adam (Kingma and Ba, 2014) as the optimizer to train our model and use TransE (Bordes et al., 2013) as the KG decoder whose margin γ is set to be 0.3. For the two GNN encoders $g^k(\cdot)$ and $g^a(\cdot)$, we set the latent dimension as 256 with 2 layers, and the dimensions of entity and relation embeddings are also set as 256. We use batch size of 512 and learning rate $lr = 0.005$ during training. The detailed training procedure is illustrated in Algo 1. Instead of directly opmizing $\mathcal{J}$ as in Eqn 4, we alternately update $\mathcal{J}_K$ and $\mathcal{J}_A$ with different learning rate. Specifically, in our implementation, we optimize with $\theta_{new} \leftarrow \theta_{old} - \eta\nabla\mathcal{J}_K$, $\theta_{new} \leftarrow \theta_{old} - (\lambda\eta)\nabla\mathcal{J}_A$ in consecutive steps within one epoch, where θ_{new} denotes our model parameters and ∇ is the training step.

Abstract

Automatic code summarization, which aims to describe the source code in natural language, has become an essential task in software maintenance. Our fellow researchers have attempted to achieve such a purpose through various machine learning-based approaches. One key challenge keeping these approaches from being practical lies in the lacking of retaining the semantic structure of source code, which has unfortunately been overlooked by the state-of-the-art methods. Existing approaches resort to representing the syntax structure of code by modeling the Abstract Syntax Trees (ASTs). However, the hierarchical structures of ASTs have not been well explored. In this paper, we propose CODESCRIBE to model the hierarchical syntax structure of code by introducing a novel triplet position for code summarization. Specifically, CODESCRIBE leverages the graph neural network and Transformer to preserve the structural and sequential information of code, respectively. In addition, we propose a pointer-generator network that pays attention to both the structure and sequential tokens of code for a better summary generation. Experiments on two real-world datasets in Java and Python demonstrate the effectiveness of our proposed approach when compared with several state-of-the-art baselines[1].

1 Introduction

Code documentation in the form of code comments has been an integral component of software development, benefiting software maintenance (Iyer et al., 2016), code categorization (Nguyen and Nguyen, 2017) and retrieval (Gu et al., 2018). However, few real-world software projects are well-documented with high-quality comments. Many projects are either inadequately documented due to missing important code comments or inconsistently documented due to different naming conventions by developers, e.g., when programming in legacy code bases, resulting in high maintenance costs (de Souza et al., 2005; Kajko-Mattsson, 2005). Therefore, automatic code summarization, which aims to generate natural language texts (i.e., a short paragraph) to describe a code fragment by extracting its semantics, becomes critically important for program understanding and software maintenance.

Recently, various works have been proposed for code summarization based on the encoder-decoder paradigm, which first encodes the code into a distributed vector, and then decodes it into natural-language summary. Similarly, several works (Iyer et al., 2016; Allamanis et al., 2016) proposed to tokenize the source code into sequential tokens, and design RNN and CNN to represent them. One limitation of these approaches is that they only consider the sequential lexical information of code. To represent the syntax of code, several structural neural networks are designed to represent the Abstract Syntax Trees (AST) of code, e.g., TreeLSTM (Wan et al., 2018), TBCNN (Mou et al., 2016), and Graph Neural Networks (GNNs) (LeClair et al., 2020). To further improve the efficiency on AST representation, various works (Hu et al., 2018a; Alon et al., 2019) proposed to linearize the ASTs into a sequence of nodes or paths.

Despite much progress on code summarization, there are still some limitations in code comprehension for generating high-quality comments. Particularly, when linearizing the ASTs of code into sequential nodes or paths, the relationships between connected nodes are generally discarded. Although the GNN-based approaches can well preserve the syntax structure of code, they are insensitive to the order of nodes in AST. For example, given the expressions `a=b/c` and `a=c/b`, current approaches cannot capture the orders of variables `b` and `c`. However, these orders are critical to accurately preserve the semantics of code.

To address the aforementioned limitation, this

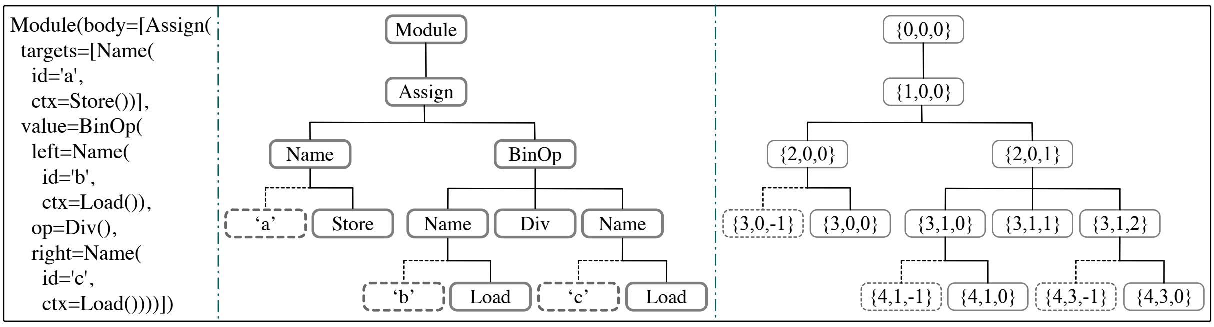

Figure 1: The AST of Python code snippet "`a = b / c`". The left is the text form of AST, the middle shows the tree structure of AST, and the right specifies triplet positions for all nodes of AST structure.

paper proposes to model the hierarchical syntax structure of code using triplet position, inspired by the positional encoding used in sequence modeling (Gehring et al., 2017; Vaswani et al., 2017), and incorporates the triplet position into current GNNs for better code summarization. The triplet position records the depth, width position of its parent, and width position among its siblings for each node.

To utilize the triplet position in AST, this paper proposes CODESCRIBE, an encoder-decoder-based neural network for source code summarization. Specially, we initialize the embedding of each AST node by incorporating the triplet positional embeddings, and then feed them into an improved GNN, i.e., GraphSAGE (Hamilton et al., 2017) to represent the syntax of code. In addition, we also account for the sequential information of code by using a Transformer encoder (Vaswani et al., 2017). In such a case, the decoding process is performed over the learned structural features of AST and sequential features of code tokens with two multi-head attention modules. To generate summaries with higher quality, we further design a pointer-generator network based on multi-head attention (Vaswani et al., 2017), which allows the summary tokens to be generated from the vocabulary or copied from the input source code tokens and ASTs. To validate the effectiveness of our proposed CODESCRIBE, we conduct experiments on two real-world datasets in Java and Python.

Overall, the primary contributions of this paper are as follows.

- It is the first time that we put forward a simple yet effective approach of triplet position to preserve the hierarchical syntax structure of source code accurately. We also incorporate the triplet position into an adapted GNN (i.e., GraphSAGE) for source code summarization.
- We conduct comprehensive experiments on two real-world datasets in Java and Python to evaluate the effectiveness of our proposed CODESCRIBE. Experimental results on both datasets demonstrate the superiority of CODESCRIBE when comparing with several state-of-the-art baselines. For example, we get 3.70/5.10/4.77% absolute gain on BLEU/METEOR/ROUGE-L metrics on the Java dataset, when comparing with the most recent mAST+GCN (Choi et al., 2021).

2 Hierarchical Syntax in Triplet Position

Recent studies have showed promising results by using AST context for tasks based on code representation learning (Yao et al., 2019; Zhang et al., 2019; Choi et al., 2021). Therefore, our work also relies on AST information besides source code tokens. As a type of intermediate representation, AST represents the hierarchical syntactic structure for source code, which is an ordered tree with labeled nodes (cf. Figure 1). In this work, we divide the nodes into two categories: (1) *function node* that controls the structure of AST and function realization, e.g., `Module` and `Assign` in Figure 1, and (2) *attribute node* that provides the value or name of its parent function node, which is always visualized as leaf node, such as '`a`' and '`b`' in dotted boxes of Figure 1.

Due to the strict construction rules of AST, positions are crucial for AST nodes. For example in Figure 1, the node `BinOp` has two children with the same label `Name`. If the positions of the two siblings are swapped, the source code will become `a=c/b`, which is totally different from the intent of the code `a=b/c`. However, GNNs are insensitive to the positions of neighbouring nodes when encoding such tree structures. Based on this obser-

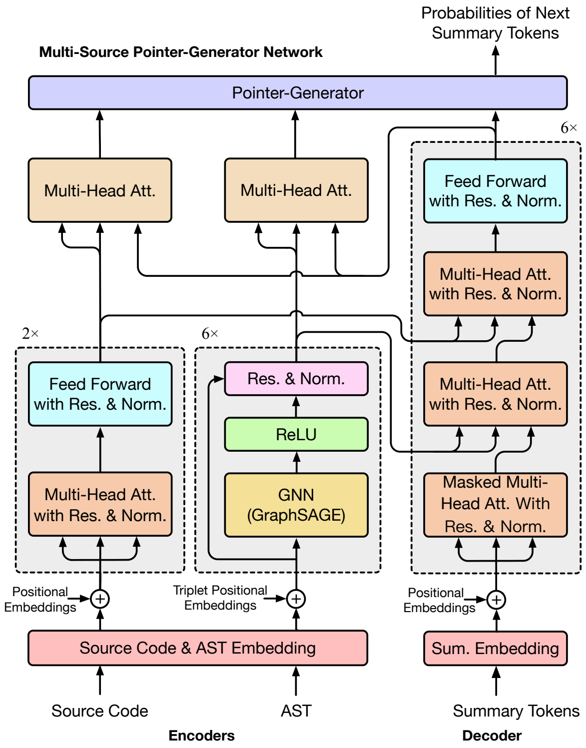

Figure 2: The architecture of CodeScribe model. Att., Res., and Norm. denote attention, residual connection, and layer normalization, respectively.

vation, we specify triplet positions for AST nodes to retain accurate structural information in AST learning. The triplet position of a node includes: (1) the depth of the node in the AST, (2) the width position of its parent node in the layer, and (3) the node's width position among its siblings, which can also distinguish function node from attribute node. That is, the width position of a function node is a non-negative integer starting from 0, while the width position of an attribute node is a negative integer counting from -1. Note that, width positions are estimated in a breadth traversal from left to right. With such triplet indices specified, all nodes can be marked with unique positions in a given AST.

Taking a Python code snippet `a=b/c` as an example, Figure 1 illustrates its AST structure with triplet positions of nodes. Specifically, by traversing the tree, we can represent the function node `(Name,{2,0,0})` as the first child node of node `(Assign,{1,0,0})`: the depth position `2` means the third level (counting from the top to bottom starting with 0); the second width position `0` means that the parent node `Assign` is the first function node at this level (counting from the left to right); and the third position `0` indicates that the node is the first (counting from left to right) among its siblings (i.e., all children nodes of node `Assign`). Another example is the node `('a',{3,0,-1})`. The difference lies in the third position that represents it is an attribute node and it is the first among the siblings. In particular, we set the position of root node `Module` to `{0,0,0}` as it has no parent node. This triplet positioning is very precise and unique, allowing to track and discriminate among the `Name` nodes which also include `(Name,{3,1,0})` and `(Name,{3,1,2})`.

3 CodeScribe Approach

3.1 Notations and Framework Overview

Given a code snippet with l_c tokens $\mathbf{T}_c = (c_1, c_2, \ldots, c_{l_c})$ and sequential positions $\mathbf{P}_c = (1, 2, \ldots, l_c)$, and its AST with l_n nodes $\mathbf{T}_n = (n_1, n_2, \ldots, n_{l_n})$ and triplet positions $\mathbf{P}_n = (\{x_1, y_1, z_1\}, \{x_2, y_2, z_2\}, \ldots, \{x_{l_n}, y_{l_n}, z_{l_n}\})$, CodeScribe predicts the next summary token s_m based on the existing tokens $\mathbf{T}_s = (\texttt{</s>}, s_1, s_2, \ldots, s_{m-1}, \ldots)$ with the sequential positions $\mathbf{P}_s = (1, 2, \ldots, l_s)$, where `</s>` is a special starting tag for summary input. Note that $\mathbf{T}_s$ is padded to a maximum length of l_s with special padding tags (e.g., `<pad>`s).

Figure 2 illustrates the architecture of CodeScribe model, which is mainly composed of four modules: source code encoder, AST encoder, summary decoder and multi-source pointer-generator network (MPG) for output. As shown in Figure 2, the source code, AST, and summary tokens are firstly mapped into embedding vectors $\mathbf{E}_c^0 \in \mathbb{R}^{l_c \times d}$, $\mathbf{E}_n^0 \in \mathbb{R}^{l_n \times d}$, and $\mathbf{E}_s^0 \in \mathbb{R}^{l_s \times d}$ where d is the embedding size. In the encoding process, the embedded code and AST are fed into Transformer encoder (Vaswani et al., 2017) and GNN layers respectively for learning the source code representation $\mathbf{E}_c' \in \mathbb{R}^{l_c \times d}$ and the AST representation $\mathbf{E}_n' \in \mathbb{R}^{l_n \times d}$. Then, the decoding process is performed to yield the decoded vector $\mathbf{e}_s' \in \mathbb{R}^d$ for the predicted summary token by fusing the learned source code and AST features (i.e., $\mathbf{E}_c'$ and $\mathbf{E}_n'$) as an initial state for decoding $\mathbf{E}_s^0$. At the decoding stage, we build MPG stacked on the decoder and encoders to predict the next summary token s_m by selecting from summary vocabulary or copying from the input source code and AST tokens. The detailed process will be further described in the following sub-sections.

3.2 Initial Embeddings

Before feeding code tokens, AST nodes, and summary tokens into neural networks, it is essential to embed them into dense numerical vectors. In this work, the source code tokens $\mathbf{T}_c$, AST nodes $\mathbf{T}_n$, and summary tokens $\mathbf{T}_s$ are all embedded into numeric vectors with their related positions $\mathbf{P}_c$, $\mathbf{P}_n$, and $\mathbf{P}_s$ incorporated through learnable positional embeddings (Gehring et al., 2017). In particular for AST, we take each triplet position $\{x_i, y_i, z_i\}$ in $\mathbf{P}_n$ as an individual tuple, and directly map it into a positional embedding vector $\mathbf{e}_i \in \mathbb{R}^d$. The embedded triplet positional information is then added to the node embeddings for initializing the AST representation. The embedding processes are formulated as follows:

$$\begin{aligned}
\mathbf{E}_c^0 &= \mathit{CNEmb}(\mathbf{T}_c) * \sqrt{d} + \mathit{CPEmb}(\mathbf{P}_c)\,, \\
\mathbf{E}_n^0 &= \mathit{CNEmb}(\mathbf{T}_n) * \sqrt{d} + \mathit{NPEmb}(\mathbf{P}_n)\,, \\
\mathbf{E}_s^0 &= \mathit{SEmb}(\mathbf{T}_s) * \sqrt{d} + \mathit{SPEmb}(\mathbf{P}_s)\,,
\end{aligned} \tag{1}$$

where *CNEmb* denotes the shared embedding operation for source code tokens and AST nodes; *SEmb* means the token embedding operation for summary text; *CPEmb*, *NPEmb*, and *SPEmb* are the corresponding positional embedding operations. Afterwards, the initialized representations $\mathbf{E}_c^0$, $\mathbf{E}_n^0$, and $\mathbf{E}_s^0$ are fed into the encoders and decoder of CODESCRIBE for in-depth processing.

3.3 Code Representation

Source Code Encoder. As shown in Figure 2, the code encoder is composed of two identical layers. And each layer consists of two sub-layers: multi-head attention mechanism and fully connected position-wise feed-forward network (FFN). In addition, residual connection (He et al., 2016) and layer normalization (Ba et al., 2016) are performed in the two sub-layers for the sake of vanishing gradient problem in multi-layer processing and high offset of vectors in residual connection. For the k-th layer, the process can be formulated as:

$$\begin{aligned}
\mathbf{H}_c^k &= \mathit{LayerNorm}(\mathbf{E}_c^{k-1} + \mathit{Att}(\mathbf{E}_c^{k-1}, \mathbf{E}_c^{k-1}, \mathbf{E}_c^{k-1}))\,, \\
\mathbf{E}_c^k &= \mathit{LayerNorm}(\mathbf{H}_c^k + \mathit{FFN}(\mathbf{H}_c^k))\,,
\end{aligned} \tag{2}$$

where $\mathbf{E}_c^{k-1} \in \mathbb{R}^{l_c \times d}$ is the output vectors from the $(k-1)$-th layer ; *LayerNorm* denotes layer normalization; and *Att* means the multi-head attention (Vaswani et al., 2017) that takes query, key, and value vectors as inputs.

AST Encoder. Considering that AST is a kind of graph, it can be learned by GNNs. Since GraphSAGE (Hamilton et al., 2017) shows high efficiency and performance dealing with graphs, we introduce the idea of GraphSAGE and improve it by adding residual connection for AST encoding, as shown in Figure 2. The encoding layer processes the AST by firstly aggregating the neighbors of the nodes with edge information and then updating the nodes with their aggregated neighborhood information. For a node i and its neighbors in the k-th layer, the process can be formulated as follows:

$$\mathbf{h}_i^k = \mathbf{W}_1 \cdot \mathbf{e}_i^{k-1} + \mathbf{W}_2 \cdot \mathit{Aggr}(\{\mathbf{e}_j^{k-1}, \forall j \in \mathcal{N}(i)\})\,, \tag{3}$$

where $\mathbf{e}_i^{k-1} \in \mathbb{R}^d$ means the vector representation of i-th node from the $(k-1)$-th layer; $\mathcal{N}(i)$ is the neighbors of the node i; $\mathbf{e}_j^{k-1} \in \mathbb{R}^d$ denotes the j-th neighbor vector for node i; $\mathbf{W}_1, \mathbf{W}_2 \in \mathbb{R}^{d \times d}$ are learnable weight matrices; *Aggr* represents aggregation function.

After updating the node information, the node vectors are put together into a *ReLU* activation for non-linear transformation:

$$\mathbf{H}_n^k = \mathit{ReLU}([\mathbf{h}_1^k, \mathbf{h}_2^k, \ldots, \mathbf{h}_i^k, \ldots])\,. \tag{4}$$

With the increase of the number of layers, a node aggregates the neighborhood information from a deeper depth. In order to achieve strong capability of aggregation, the AST encoder is composed of six layers. And to mitigate gradient vanishing and high offset caused by multi-layer processing, we adopt residual connection (He et al., 2016) and layer normalization (Ba et al., 2016) in each layer for improvement, which is formulated as follows:

$$\mathbf{E}_n^k = \mathit{LayerNorm}(\mathbf{H}_n^k + \mathbf{E}_n^{k-1})\,. \tag{5}$$

Note that, $\mathbf{E}_n^{k-1} \in \mathbb{R}^{l_n \times d}$ in this formula denotes the output vectors of nodes from the $(k-1)$-th layer.

3.4 Summary Decoder

The decoder of CODESCRIBE is designed with six stacks of modified Transformer decoding blocks. Given the existing summary tokens, the k-th decoding block firstly encodes them by masked multi-head attention with residual connection and layer normalization, which is formalized as:

$$\mathbf{H}_s^k = \mathit{LayerNorm}(\mathbf{E}_s^{k-1} + \mathit{MaskAtt}(\mathbf{E}_s^{k-1}, \mathbf{E}_s^{k-1}, \mathbf{E}_s^{k-1}))\,, \tag{6}$$

where $\mathbf{E}_s^{k-1} \in \mathbb{R}^{l_s \times d}$ is the output vectors from the $(k-1)$-th layer and *MaskAtt* denotes the masked multi-head attention (Vaswani et al., 2017).

After that, we expand the Transformer block by leveraging two multi-head attention modules to interact with the two encoders for summary decoding. One multi-head attention module is performed over the AST features to get the first-stage decoded information, which will then be fed into the other over the learned source code for the second-stage decoding. Then the decoded summary vectors are put into FFN for non-linear transformation. The process can be formalized as follows:

$$\begin{aligned}
&\mathbf{H}^k_{s,n} = \mathit{LayerNorm}(\mathbf{H}^k_s + \mathit{Att}(\mathbf{H}^k_s, \mathbf{E}'_n, \mathbf{E}'_n))\,, \\
&\mathbf{H}^k_{s,c} = \mathit{LayerNorm}(\mathbf{H}^k_{s,n} + \mathit{Att}(\mathbf{H}^k_{s,n}, \mathbf{E}'_c, \mathbf{E}'_c))\,, \\
&\mathbf{E}^k_s = \mathit{LayerNorm}(\mathbf{H}^k_{s,c} + \mathit{FFN}(\mathbf{H}^k_{s,c}))\,,
\end{aligned} \tag{7}$$

where $\mathbf{E}'_n$ and $\mathbf{E}'_c$ are the learned features of AST nodes and code tokens, respectively.

3.5 Multi-Source Pointer-Generator Network

We present a multi-source pointer-generator network (MPG) on top of the decoder and encoders to yield the final probability of the next summary token. Considering that tokens such as function names and variable names appear both in code and summary text (Ahmad et al., 2020), MPG is designed to allow CODESCRIBE to generate summary tokens both from the summary vocabulary and from the AST and source code.

Taking the m-th output token as an example, three probability distributions $\mathbf{p}_v$, $\mathbf{p}_c$, and $\mathbf{p}_n$ will be calculated from decoded summary, code, and AST and determine the probabilities for the token. To get the first probability distribution $\mathbf{p}_v$, a *Linear* sub-layer with *Softmax* is applied over the decoded summary token vector $\mathbf{e}'_s \in \mathbb{R}^d$, as follows:

$$\mathbf{p}_v = \mathit{Softmax}(\mathit{Linear}(\mathbf{e}'_s))\,. \tag{8}$$

For a token w, $\mathbf{p}_v(w) = 0$ if w is an out-of-vocabulary word to the summary vocabulary.

As for the distributions $\mathbf{p}_c$ and $\mathbf{p}_n$, we only describe $\mathbf{p}_c$ since the two have the similar calculation process. In detail, our model applies an additional multi-head attention layer stacked on the last code encoding block and summary decoding block. It takes the decoded summary token vector $\mathbf{e}'_s \in \mathbb{R}^d$ as query and the encoded code information $\mathbf{E}'_c \in \mathbb{R}^{l_c \times d}$ as key and value:

$$\begin{aligned}
&\boldsymbol{\delta}_c = \mathit{Att}(\mathbf{e}'_s, \mathbf{E}'_c, \mathbf{E}'_c)\,, \\
&\boldsymbol{\alpha}_c = \mathit{Softmax}(\mathit{Mean}(\mathbf{a}_1, \mathbf{a}_2, \ldots, \mathbf{a}_i, \ldots))\,, \\
&\mathbf{a}_i = \mathit{Softmax}\left(\frac{\mathbf{e}'_s\mathbf{W}^Q_i(\mathbf{E}'_c\mathbf{W}^K_i)^T}{\sqrt{d}}\right)(\mathbf{E}'_c\mathbf{W}^V_i)\,,
\end{aligned} \tag{9}$$

where $\mathbf{W}^Q_i$, $\mathbf{W}^K_i$, and $\mathbf{W}^V_i$ are learnable parameters. The context vector $\boldsymbol{\delta}_c \in \mathbb{R}^d$ will be used for the final distribution. Through the function *Mean* and *Softmax*, the attention vectors $(\mathbf{a}_1, \mathbf{a}_2, \ldots, \mathbf{a}_i, \ldots)$ of all heads are averaged as $\boldsymbol{\alpha}_c \in \mathbb{R}^{l_c}$. For the token w, its probability $\mathbf{p}_c(w)$ is formulated as follows:

$$\mathbf{p}_c(w) = \textstyle\sum_{i:w_i=w} \boldsymbol{\alpha}_{ci}\,, \tag{10}$$

where w_i means the i-th token in the source code.

Similarly, we can get $\boldsymbol{\delta}_n$ and $\mathbf{p}_n$ corresponding to the AST. After that, the final probability $p_s(w)$ of the token w is defined as a mixture of the three probabilities:

$$\begin{aligned}
&\mathbf{p}_s(w) = \lambda_v \cdot \mathbf{p}_v(w) + \lambda_c \cdot \mathbf{p}_c(w) + \lambda_n \cdot \mathbf{p}_n(w)\,, \\
&[\lambda_v, \lambda_c, \lambda_n] = \mathit{Softmax}(\mathit{Linear}([\mathbf{e}'_s, \boldsymbol{\delta}_c, \boldsymbol{\delta}_n]))\,,
\end{aligned} \tag{11}$$

where λ_v, λ_c, and λ_n are the weight values for $\mathbf{p}_v(w)$, $\mathbf{p}_c(w)$, and $\mathbf{p}_n(w)$. The higher the probability $\mathbf{p}_s(w)$ is, the more likely the token w is considered as the next summary token.

4 Experiments

We conduct experiments to answer the following research questions: *(1) How effective is* CODESCRIBE *compared with the state-of-the-art baselines? (2) How effective is the structure design of* CODESCRIBE*? (3) What is the impact of model size on the performance of* CODESCRIBE*?* We also perform a qualitative analysis of two detailed examples.

4.1 Datasets

The experiments are conducted based on two benchmarks: (1) Java dataset (Hu et al., 2018b) and (2) Python dataset (Wan et al., 2018). The two datasets are split into *train/valid/test* sets with *69,708/8,714/8,714* and *55,538/18,505/18,502*, respectively. In the experiments, we follow the divisions for the fairness of the results.

In the data preprocessing, *NLTK* package (Bird, 2006) is utilized for the tokenization of source code and summary text. And we apply *javalang* [2] and *ast* [3] packages to parsing Java and Python code into ASTs. In addition, the tokens in forms of "*CammelCase*", "*snake_case*", and "*concatenatecase*" are split into sub-tokens as "*Cammel Case*", "*snake case*", and "*concatenate case*".

Table 1: Comparison with the baselines on the Java and Python datasets.

4.2 Implementation Details

We leverage PyTorch 1.9 for CODESCRIBE implementation. The model runs under the development environment of Python 3.9 with NVIDIA 2080 Ti GPUs and CUDA 10.2 supported.

We follow the previous works (Ahmad et al., 2020; Choi et al., 2021) and set all the embedding sizes of code tokens, AST nodes, and summary tokens to 512, and the number of attention headers to 8. As described in Section 3, the numbers of layers of code encoder, AST encoder, and summary decoder are 2, 6, and 6, respectively.

The model is trained with Adam optimizer (Kingma and Ba, 2015). We initialize the learning rate as $5e^{-4}$ that will be decreased by 5% after each training epoch until to $2.5e^{-5}$. The dropout rate is set to 0.2. We set the batch size to 96 and 160 for the Java and Python datasets, respectively. The training process will terminate after 100 epochs or stop early if the performance does not improve for 10 epochs. In addition, we leverage beam search (Koehn, 2004) during the model inference and set the beam width to 5.

4.3 Baselines

We introduce eight state-of-the-art works as baselines for comparison, including six RNN-based models and two Transformer-based models.

RNN-based Models. Among these baselines, CODE-NN (Iyer et al., 2016), API+CODE (Hu et al., 2018b), and Dual Model (Wei et al., 2019) learn source code for summarization. Tree2Seq (Eriguchi et al., 2016) and DeepCom (Hu et al., 2018a) generate summaries from AST features. RL+Hybrid2Seq (Wan et al., 2018) combines source code and AST based on LSTM.

Transformer-based Models. The two baselines include CopyTrans (Ahmad et al., 2020) and mAST+GCN (Choi et al., 2021), both of which leverage Transformer for code summary generation. The main difference is that CopyTrans learns sequential source code, and mAST+GCN is built based on AST.

For the model evaluation, three metrics are introduced: BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), and ROUGE (Lin, 2004). All the scores are presented in percentage.

4.4 Comparison with the Baselines (RQ1)

We first evaluate the performance of CODESCRIBE by comparing it with eight state-of-the-art baselines. The results of baselines are all from Choi et al. (2021) and are shown in Table 1.

The overall results in Table 1 illustrate that the recent Transformer-based models (Ahmad et al., 2020; Choi et al., 2021) are superior to the previous works based on RNNs (Iyer et al., 2016; Eriguchi et al., 2016; Wan et al., 2018; Hu et al., 2018a,b; Wei et al., 2019). Although the two models CopyTrans and mAST+GCN have high performance in code summarization, our approach CODESCRIBE performs much better than them both on the two datasets. Intuitively, CODESCRIBE improves the performance (i.e., BLEU/METEOR/ROUGE-L) by 4.46/5.84/4.83% on the Java dataset and 2.59/3.71/3.73% on the Python dataset compared to CopyTrans. In comparison with mAST+GCN, the performance of CODESCRIBE improves by 3.70/5.10/4.77% on the Java dataset and 2.29/3.36/3.65% on the Python dataset.

The comparison demonstrates the outperformance of CODESCRIBE. It indicates that: (1) Transformer-like models are more effective than

RNN-based models in code summarization task; (2) AST information contributes significantly to code comprehension; and (3) by incorporating both AST and source code into CODESCRIBE based on GraphSAGE and Transformer, the performance can be greatly improved due to its more comprehensive learning capacity for code and better decoding for summary generation.

4.5 Ablation Study (RQ2)

This section validates the effectiveness of CODESCRIBE's structure to by performing an ablation study on the Java dataset. We firstly design five models for comparison that remove one of important components in CODESCRIBE including: (1) the AST encoder (R-AST), (2) the source code encoder (R-Code), (3) the triplet positions (R-ASTPos), (4) the MPG (R-Copy), and (5) the residual connection in the AST encoder (R-ASTRes). We further investigate the rationality of CODESCRIBE's structure by comparison with five variants: (1) V-Copy that replaces MPG with the copying mechanism (See et al., 2017) used in Ahmad et al. (2020), (2) V-GCN that replaces GraphSAGE with GCN (Kipf and Welling, 2017), (3) V-GAT that replaces GraphSAGE with GAT (Kipf and Welling, 2017), (4) V-Emb that replaces the shared embedding layer for code tokens and AST nodes with two independent embedding layers, and (5) V-Dec that reverses the decoding order for the source code and AST features.

Model	BLEU	METEOR	ROUGE-L
R-AST	46.45	29.37	56.42
R-Code	47.06	30.06	57.03
R-ASTPos	48.53	31.62	58.84
R-Copy	48.64	31.71	58.68
R-ASTRes	13.03	2.59	5.89
V-Copy	48.59	31.82	58.73
V-GCN	48.84	31.96	58.95
V-GAT	48.84	32.03	59.23
V-Emb	49.05	31.93	58.95
V-Dec	48.99	32.11	59.31
CODESCRIBE	**49.19**	**32.27**	**59.59**

Table 2: Ablation study on the Java dataset.

As shown in Table 2, the performance of CODESCRIBE is affected if the components are removed. The results of R-AST and R-Code show that the two encoders are the most significant learning components to CODESCRIBE. Moreover, the AST encoder is more important than the code encoder as R-Code performs better than R-AST. The performances of R-ASTPos and R-Copy indicate that the triplet positions for nodes and copying mechanism (MPG) we proposed are effective for CODESCRIBE in code summarization. In addition, we find that R-ASTRes suffers from under-fitting on the Java dataset, which indicates that the residual connection in AST encoder has a powerful influence on CODESCRIBE.

As illustrated in Table 2, CODESCRIBE improves the performance by 0.26/0.22/0.30% on the Java dataset compared with V-Copy. It indicates that our proposed MPG is more effective than the copying mechanism in Ahmad et al. (2020). As for the GNN module in AST encoding, it can be observed that CODESCRIBE still has the higher performance than V-GCN and V-GAT. This demonstrates the superiority of GrahpSAGE for the architecture of CODESCRIBE compared to GCN and GAT. Compared with V-Emb, it shows that the shared embedding layer works better than two separated embedding layers for AST and source code. The result of V-Dec turns out that the performance will not be affected sinificantly if the order of decoding over AST and code features is reversed. The results on the Python dataset are presented in Table 7 in Appendix A.

4.6 Study on the Model Size (RQ3)

This section studies the performance of CODESCRIBE with the change of model size [4] on the Java dataset. To that end, we modify the number of layers of the encoders and the decoder respectively for performance observation and comparison.

AST Layers	Model Size($\times 10^6$)	BLEU	METEOR	ROUGE-L
2	38.89	48.68	31.76	58.77
4	39.94	48.76	31.99	59.10
6	*40.99*	***49.19***	***32.27***	***59.59***
8	42.05	49.11	32.20	59.49
10	43.10	48.97	32.12	59.23
12	44.15	48.84	32.06	59.10

Table 3: Performance of CODESCRIBE with different numbers of AST encoding layers on the Java dataset.

Table 3 presents the performance of CODESCRIBE when the number of AST encoding layers

---

[4] This work considers the number of trainable parameters in the encoders and decoder of CODESCRIBE as the model size to facilitate observation.

varies from 2 to 12. The results show that the performance improves as the number of AST encoding layers increases from 2 to 6. With the increase of the number from 6 to 12, the performance does not improve any more and is even impacted slightly. As illustrated in Table 4, CodeScribe has the best performance with 2 code encoding layers. With the number of code layers growing from 4 to 12, there is a trend of gradual decrease of the performance. For the model size concerned with summary decoding layers, as shown in Table 5, the performance is getting better when the number of layers ranges from 2 to 6, and can not be improved as the number continues to increase. The overall results show that it the performance of CodeScribe will not be improved if the encoders and the decoder become too deep (i.e. with more layers), especially for the source code encoder. More experimental results are provided in Table 8 - 11 in Appendix B.

4.7 Case Study

Table 6 shows the qualitative examples of R-AST, R-Copy, V-GCN, V-Dec, and CodeScribe on the two datasets. From the table, it can be observed that CodeScribe with the whole architecture generates better code summaries compared with the four variants. In the case on the Java dataset, only R-Copy and CodeScribe get the right intent of the code. The other variants miss out the key word "*history*". In the case on the Python dataset, CodeScribe generates the most accurate summary compared to the other variants. In contrast, although the four variants output the first half of the summary (i.e., "*create an image*"), the rest information "*from the value dictionary* ." can not be generated correctly. More qualitative examples are referred to Table 12 and 13 in Appendix C.

Code Layers	Model Size($\times 10^6$)	BLEU	METEOR	ROUGE-L
2	*40.99*	***49.19***	***32.27***	***59.59***

5 Related Work

With the development of deep learning, most works have considered code summarization as a sequence generation task. In many of the recent approaches, source code snippets are modeled as plain texts based on RNNs (Iyer et al., 2016; Hu et al., 2018b; Wei et al., 2019; Ye et al., 2020). For example, Hu et al. (2018b) proposed an RNN-based model that learns API knowledge from a different but related task and incorporates the knowledge into code summarization. Wei et al. (2019) presented a dual learning framework based on LSTMs to train code generation and code summarization and improve the performances of both tasks. Ye et al. (2020) combined code summarization and code generation to train the code retrieval task via multi-task learning, which achieved competitive performance for the code summarization task. Most recently, Ahmad et al. (2020) applied Transformer to encoding the source code sequence to improve the summarization performance.

Since considering source code as plain text ignores the structural information in code, recent works have explored the AST of code and modeled the tree-based structure for code summarization. Typically, Hu et al. (2018a) proposed a structure-based traversal (SBT) method to traverse ASTs into node sequences and used a sequence-to-sequence model based on LSTMs to generate code comments. Alon et al. (2019) represented a code snippet as a set of compositional paths in its AST and used LSTMs to encode these paths. Shido et al. (2019) extended Tree-LSTM (Tai et al., 2015) to Multi-way Tree-LSTM to learn the representation of AST for code summary generation. Liu et al. (2020) built code property graph (CPG) (Yamaguchi et al., 2014) based on AST and combined retrieval method and GNNs for describing *C* programming language. The latest work (Choi et al., 2021) performed graph convolutional networks (GCNs) (Kipf and Welling, 2017) before Transformer framework to learn AST representation for summary generation.

Code

Java

```
public void addMessage(String
↪  message){
  messages.addLast(message);
  if (messages.size() >
  ↪  MAX_HISTORY) {
    messages.removeFirst();}
  pointer=messages.size();}
```

Python

```
@_get_client
def image_create(client, values,
↪  v1_mode=False):
 return client.image_create(values=values,
 ↪  v1_mode=v1_mode)
```

	Java	Python
Summary	Gold: add a message to the history R-AST: add a message to the end of the list R-Copy: add a message to the history . V-GCN: add a message to the list V-Dec: add a message to the list CODESCRIBE: add a message to the history .	Gold: create an image from the value dictionary . R-AST: create an image cli example : . R-Copy: create an image mode that can exist from the give value . V-GCN: create an image from a v <number> image . V-Dec: create an image object . CODESCRIBE: create an image from the value dictionary .

Table 6: Qualitative examples on the Java and Python datasets.

To represent the code comprehensively, more and more works have paid attention to both the source code and the AST for code summarization. For example, Hu et al. (2020) integrated both AST node sequence and source code into a hybrid learning framework based on GRUs. Wei et al. (2020) and Zhang et al. (2020) both utilized the information retrieval techniques to improve the quality of code summaries that are generated from the code snippets and ASTs. Wan et al. (2018) incorporated AST as well as sequential content of code snippet into a deep reinforcement learning framework based on LSTM and AST-based LSTM. LeClair et al. (2020) proposed a graph-based neural architecture for code summarization, which uses GRUs and GCN to encode AST and GRUs to learn source code sequence. Wang et al. (2022) presented the first hierarchical-attention based learning approach for code summarization by integrating source code, type-augmented AST, and control-flow graphs.

Recently, several pre-trained models, e.g., CodeBERT (Feng et al., 2020), CodeT5 (Wang et al., 2021), PLBART (Ahmad et al., 2021) and CoTexT (Phan et al., 2021), have been proposed to better represent the source code, and verified on code summarization. For example, CodeBERT (Feng et al., 2020) is a pre-trained model based on ELECTRA (Clark et al., 2020), which has achieved promising performance on downstream tasks including code summarization. CodeT5 (Wang et al., 2021) considers the token type information in code and builds on the T5 architecture (Raffel et al., 2020) that utilizes denoising sequence-to-sequence pre-training. PLBART (Ahmad et al., 2021) is another start-of-the-art pre-trained model on an extensive collection of Python and Java functions, as well as their natural language summaries via denoising auto-encoding. Note that, our work is aim to introduce an encoder network with a novel triplet position to better represent the hierarchical structure of programs, rather than pre-training a language model for source code. We think that our introduced encoder can be easily incorporated into the pre-training models through masking and predicting code tokens or code graphs. We leave the comparison between our model and those mentioned pre-trained code models to future work.

6 Conclusion

This paper has presented CODESCRIBE, an encoder-decoder-based neural network for source code summarization. CODESCRIBE designs a triplet position to model the hierarchical syntax structure of code, which is then incorporated into the Transformer and GNN based framework for better representation of lexical and syntax information of code, respectively. The performance of CODESCRIBE is further enhanced by the introduced multi-source pointer generator in decoding. Experiments on two benchmarks reveal that the summaries generated by CODESCRIBE are of higher quality when compared with several recent state-of-the-art works.

A Results of Ablation Study

Table 7 shows the results of ablation study on the Python dataset. It can be observed that CodeScribe has the best performance in contrast with all the variants except V-Dec. Although there is no under-fitting for R-ASTRes on the Python dataset, we can find that the performance (i.e., BLEU/METEOR/ROUGE-L) is reduced by 1.02/0.89/1.51 if the residual connection in AST encoder is excluded. So it also demonstrates the effectiveness of this component to the AST encoder. In addition, the result of V-Dec still confirms the conclusion that the order of decoding over AST and source code features won't impact the performance of CodeScribe.

Model	**BLEU**	**METEOR**	**ROUGE-L**
R-AST	32.97	21.24	47.70
R-Code	33.54	21.91	48.61
R-ASTPos	34.50	22.91	49.79
R-Copy	34.55	23.16	49.88
R-ASTRes	34.09	22.59	48.95
V-Copy	34.85	23.26	50.16
V-GCN	34.73	23.24	50.11
V-GAT	34.88	23.27	50.25
V-Emb	34.55	22.80	49.16
V-Dec	35.04	23.41	50.40
CodeScribe	**35.11**	**23.48**	**50.46**

Table 7: Ablation study on the Python dataset.

B Results of Study on the Model Size

The additional results of study on the model size on the Python dataset are described in the Table 8, 9, and 10. The performances show the similar change trends with that on the Java dataset. For example, Table 9 shows that the performance of CodeScribe does not improve with the number increasing from 2 to 12.

AST Layers	**Model Size**($\times 10^6$)	**BLEU**	**METEOR**	**ROUGE-L**
2	38.89	34.81	23.27	50.12
4	39.94	34.76	23.26	50.25
6	*40.99*	***35.11***	***23.48***	***50.46***
8	42.05	35.02	23.38	50.34
10	43.10	34.88	23.35	50.22
12	44.15	34.97	23.26	50.14

Table 8: Performance of CodeScribe with different numbers of AST encoding layers on the Python dataset.

Code Layers	**Model Size**($\times 10^6$)	**BLEU**	**METEOR**	**ROUGE-L**
2	*40.99*	*35.11*	*23.48*	*50.46*
4	47.30	34.99	23.43	50.37
6	53.60	34.86	23.32	50.33
8	59.91	35.08	**23.58**	**50.61**
10	66.21	**35.16**	23.41	50.18
12	72.52	34.94	23.21	49.87

Table 9: Performance of CodeScribe with different numbers of code encoding layers on the Python dataset.

Summary Layers	**Model Size**($\times 10^6$)	**BLEU**	**METEOR**	**ROUGE-L**
2	19.97	34.16	22.92	49.70
4	30.48	34.75	23.32	50.29
6	*40.99*	*35.11*	*23.48*	*50.46*
8	51.51	34.90	23.43	50.37
10	62.02	35.08	23.49	50.56
12	72.53	**35.19**	**23.59**	**50.58**

Table 10: Performance of CodeScribe with different numbers of summary decoding layers on the Python dataset.

We further provide the results of CodeScribe by varying the embedding size from 128 to 1024 with the interval of 128. As depicted in Table 11, CodeScribe has the worst performance with the embedding size 128, and performs much better when the size becomes 256. Then the performance improves steadily as the embedding size increases until to 512. After that, although CodeScribe can be boosted with the growth of embedding size (from 512 to 1024), the improvement is not so obvious. These observations suggest that expanding the embedding size properly is indeed effective to CodeScribe. However, excessive expansion will not help much for the improvement.

Emb. Size	Model Size($\times 10^6$)	Java			Python		
		S-BLEU	METEOR	ROUGE-L	S-BLEU	METEOR	ROUGE-L
128	2.58	33.55	22.31	47.89	26.83	18.53	43.68
256	10.27	44.24	28.62	55.36	32.19	21.50	47.54
384	23.08	48.16	31.56	58.67	34.34	22.99	49.73
512	*40.99*	*49.19*	*32.27*	***59.59***	*35.11*	*23.48*	*50.46*
640	64.02	49.17	32.29	59.45	35.31	23.62	**50.59**
768	92.16	49.20	**32.32**	59.28	**35.35**	23.69	50.59
896	125.41	49.19	32.26	59.34	35.55	23.75	50.56
1024	163.78	**49.32**	32.29	59.35	35.20	23.56	50.29

Table 11: Performance of CODESCRIBE with different embedding sizes on the Java and Python datasets.

C Qualitative Examples

Table 12 and 13 provide qualitative examples of R-AST, R-Copy, V-GCN, V-Dec, and our CODESCRIBE on the Java and Python datasets for case study. The overall results show that CODESCRIBE generates better summaries for the given code snippets. For instance, in the first case in Table 12, only R-Copy and CODESCRIBE get the right intent of the code. In the third case in Table 12, only CODESCRIBE grasps the key information, i.e., “status panel”. In the first case in Table 13, CODESCRIBE generates the most accurate summary compared to the other variants, which is the same in the second case.

Code

```java
public void addMessage(String message){
  messages.addLast(message);
  if (messages.size() > MAX_HISTORY) {
    messages.removeFirst();
  }
  pointer=messages.size();
}
```

Summary

Gold: add a message to the history
R-AST: add a message to the end of the list
R-Copy: add a message to the history .
V-GCN: add a message to the list
V-Dec: add a message to the list
CodeScribe: add a message to the history .

Code

```java
public void hspan(double start,double end,Paint color,String legend){
  LegendText legendText=new LegendText(color,legend);
  comments.add(legendText);
  plotElements.add(new HSpan(start,end,color,legendText));
}
```

Summary

Gold: draw a horizontal span into the graph and optionally add a legend .
R-AST: plot request data a a vertical and optionally add a legend .
R-Copy: draw a vertical span into the graph and optionally add a legend .
V-GCN: draw the current legend .
V-Dec: plot request data a a line , use the color and the line width specify .
CodeScribe: draw a vertical span into the graph and optionally add a legend .

Code

```java
public CStatusPanel(final BackEndDebuggerProvider debuggerProvider){
  super(new BorderLayout());
  Preconditions.checkNotNull(debuggerProvider,"IE1094: Debugger provider argument can not be
  ↪   null");
  m_label.setForeground(Color.BLACK);
  add(m_label);
  m_synchronizer=new CStatusLabelSynchronizer(m_label,debuggerProvider);
}
```

Summary

Gold: create a new status panel .
R-AST: create a new panel .
R-Copy: create a new panel object .
V-GCN: create a new debugger panel .
V-Dec: create a new panel object .
CodeScribe: create a new status panel object .

Code

```java
private Spannable highlightHashtags(Spannable text){
  if (text == null) {
    return null;
  }
  final Matcher matcher=PATTERN_HASHTAGS.matcher(text);
  while (matcher.find()) {
    final int start=matcher.start(1);
    final int end=matcher.end(1);
    text.setSpan(new
    ↪   ForegroundColorSpan(mHighlightColor),start,end,Spanned.SPAN_EXCLUSIVE_EXCLUSIVE);
    text.setSpan(new
    ↪   StyleSpan(android.graphics.Typeface.BOLD),start,end,Spanned.SPAN_EXCLUSIVE_EXCLUSIVE);
  }
  return text;
}
```

Summary

Gold: highlight all the hash tag in the pass text .
R-AST: highlight all the text in the pass text .
R-Copy: highlight all the hash text in the pass text .
V-GCN: highlight all the span of the text .
V-Dec: highlight all the occurrence of a match tag in the pass text .
CodeScribe: highlight all the hash line in the pass text .

Table 12: Qualitative examples on the Java dataset.

Code

```
@_get_client
def image_create(client, values, v1_mode=False):
 return client.image_create(values=values, v1_mode=v1_mode)
```

Summary

Gold: create an image from the value dictionary .
R-AST: create an image cli example : .
R-Copy: create an image mode that can exist from the give value .
V-GCN: create an image from a v <number> image .
V-Dec: create an image object .
CODESCRIBE: create an image from the value dictionary .

Code

```
def test_help_command_should_exit_status_ok_when_no_cmd_is_specified(script):
 result = script.pip('help')
 assert (result.returncode == SUCCESS)
```

Summary

Gold: test help command for no command .
R-AST: test help command for exist command .
R-Copy: test help command for exist command .
V-GCN: test help command for exist command .
V-Dec: test help command for exist command .
CODESCRIBE: test help command for no command .

Code

```
def all_editable_exts():
 exts = []
 for (language, extensions) in sourcecode.ALL_LANGUAGES.items():
  exts.extend(list(extensions))
 return [('.' + ext) for ext in exts])
```

Summary

Gold: return a list of all editable extension .
R-AST: return a list of all python extension .
R-Copy: return a list of tuples extension for all editable s .
V-GCN: return a list of all file extension that be editable by the extension .
V-Dec: return a list of all available extension .
CODESCRIBE: return a list of all editable s extension .

Code

```
def update_featured_activity_references(featured_activity_references):
 for activity_reference in featured_activity_references:
  activity_reference.validate()
 activity_hashes = [reference.get_hash() for reference in featured_activity_references]
 if (len(activity_hashes) != len(set(activity_hashes))):

Abstract

The few-shot natural language understanding (NLU) task has attracted much recent attention. However, prior methods have been evaluated under a disparate set of protocols, which hinders fair comparison and measuring progress of the field. To address this issue, we introduce an evaluation framework that improves previous evaluation procedures in three key aspects, i.e., test performance, dev-test correlation, and stability. Under this new evaluation framework, we re-evaluate several state-of-the-art few-shot methods for NLU tasks. Our framework reveals new insights: (1) both the absolute performance and relative gap of the methods were not accurately estimated in prior literature; (2) no single method dominates most tasks with consistent performance; (3) improvements of some methods diminish with a larger pretrained model; and (4) gains from different methods are often complementary and the best combined model performs close to a strong fully-supervised baseline. We open-source our toolkit, FewNLU, that implements our evaluation framework along with a number of state-of-the-art methods. [1] [2]

1 Introduction

Few-shot learning for natural language understanding (NLU) has been significantly advanced by pretrained language models (PLMs; Brown et al., 2020; Schick and Schütze, 2021a,b). With the goal of learning a new task with very few (usually less than a hundred) samples, few-shot learning benefits from the prior knowledge stored in PLMs. Various few-shot methods based on PLMs and prompting have been proposed (Liu et al., 2021b; Menon et al., 2021; Gao et al., 2020).

Although the research of few-shot NLU is developing rapidly, the lack of a standard evaluation protocol has become an obstacle hindering fair comparison between various methods on a common ground and measuring progress of the field. While some works (Schick and Schütze, 2021b; Menon et al., 2021) experimented with a fixed set of hyper-parameters, prior work (Perez et al., 2021; Zhang et al., 2020) noted that such a setting might be exposed to the risk of overestimation .[3] Other works (Liu et al., 2021b; Gao et al., 2020; Perez et al., 2021) proposed to use a small development set to select hyper-parameters, but their evaluation protocols vary in a few key aspects (e.g., how to construct data splits), which in fact lead to large differences as we will show (in Section 4.2). The above phenomena highlight the need for a common protocol for the evaluation of few-shot NLU methods. However, the fact that few-shot learning is extremely sensitive to subtle variations of many factors (Dodge et al., 2020; Gao et al., 2020) poses challenges for designing a solid evaluation protocol.

In this work, aiming at addressing the aforementioned challenge, we propose an evaluation framework for few-shot NLU. The evaluation framework consists of a repeated procedure—selecting a hyper-parameter, selecting a data split, training and evaluating the model. To set up a solid evaluation framework, it is crucial to specify a key design choice—how to construct data splits for model selection. We conduct a comprehensive set of experiments to answer the question. Specifically, we propose a "Multi-Splits" strategy, which randomly splits the available labeled samples into training and development sets multiple times, followed by aggregating the results from each data split. We show that this simple strategy outperforms several

[3] This is because the fixed hyper-parameters are selected according to practical considerations, which are informed by the test set performance from previous evaluations.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 501 - 516
May 22-27, 2022

baseline strategies in three dimensions: (1) the test set performance of the selected hyper-parameters; (2) correlation between development set and true test set performance; and (3) robustness to hyper-parameter settings.

We then take a step further to re-evaluate recent state-of-the-art few-shot NLU methods under this common evaluation framework. Our re-evaluation leads to several key findings summarized in Section 2.

To aid reproducing our results and benchmarking few-shot NLU methods, we open-source FewNLU, a toolkit that contains implementations of a number of state-of-the-art methods, data processing utilities, as well as our proposed evaluation framework.

To sum up, our contributions are as follows.

1. We introduce a new evaluation framework of few-shot NLU. We propose three desiderata of few-shot evaluation and show that our framework outperforms previous ones in these aspects. Thus our framework allows for more reliable comparison of few-shot NLU methods.
2. Under the new evaluation framework, we benchmark the performance of recent methods individually as well as the best performance with a combined approach. These benchmarks reflect the current state of the art and will serve as important baselines for future research.
3. Throughout our exploration, we arrive at several key findings summarized in Section 2.
4. We open-source a toolkit, FewNLU, to facilitate future research with our framework.

2 Summary of Findings

For reference, we collect our key findings here and discuss each of them throughout the paper.

Finding 1. Our proposed Multi-Splits is a more reliable data-split strategy than several baselines with improvements in (1) test performance, (2) correlation between development and test sets, and (3) stability w.r.t. the number of runs.

Finding 2. The absolute performance and the relative gap of few-shot methods were in general not accurately estimated in prior literature. It highlights the importance of evaluation for obtaining reliable conclusions. Moreover, the benefits of some few-shot methods (e.g., ADAPET) decrease on larger pretrained models.

Finding 3. Gains of different methods are largely complementary. A combination of methods largely outperforms individual ones, performing close to a strong fully-supervised baseline with RoBERTa.

Finding 4. No single few-shot method dominates most NLU tasks. This highlights the need for the development of few-shot methods with more consistent and robust performance across tasks.

3 Related Work

The pretraining-finetuning paradigm (Howard and Ruder, 2018) shows tremendous success in few-shot NLU tasks. Various methods have been developed such as [CLS] classification (Devlin et al., 2018), prompting-based methods with discrete prompts (Schick and Schütze, 2021b; Gao et al., 2020) or continuous prompts (Liu et al., 2021b; Shin et al., 2020; Li and Liang, 2021; Lester et al., 2021), and methods that calibrate the output distribution (Yang et al., 2021; Zhao et al., 2021).

The fact that few-shot learning is sensitive to many factors and thus is extremely unstable (Liu et al., 2021a; Lu et al., 2021; Zhang et al., 2020; Dodge et al., 2020) increases the difficulty of few-shot evaluation. Several works address evaluation protocols to mitigate the effects of instability: Gao et al. (2020) and Liu et al. (2021b) adopt a held-out set to select models. Perez et al. (2021) proposed K-fold cross-validation and minimum description length evaluation strategies. Our work differs from these works on few-shot evaluation in several aspects: (1) we propose three metrics to evaluate data split strategies; (2) while most prior work proposed evaluation protocols without justification, we conduct comprehensive experiments to support our key design choice; (3) we formulate a general evaluation framework; (4) our re-evaluation under the proposed framework leads to several key findings.

Though there have been a few existing few-shot NLP benchmarks, our work is quite different in terms of the key issues addressed. FLEX (Bragg et al., 2021) and CrossFit (Ye et al., 2021) studied principles of designing tasks, datasets, and metrics. FewGLUE (Schick and Schütze, 2021b) is a dataset proposed for benchmarking few-shot NLU. CLUES (Mukherjee et al., 2021) pays attention to the unified format, metric, and the gap between human and machine performance. While the aforementioned benchmarks focus on “what data to use” and “how to define the task”, our work discussed “how to evaluate” which aims at establishing a proper evaluation protocol for few-shot NLU methods. Since FewNLU is orthogonal to the aforementioned prior work, it can also be employed on the data and tasks proposed in previous work.

4 Evaluation Framework

Formally, for a few-shot NLU task, we have a small labeled set $\mathcal{D}_{\text{label}} = \{(x_i, y_i)\}_i^N$ and a large test set $\mathcal{D}_{\text{test}} = \{(x_i^{\text{test}}, y_i^{\text{test}})\}_i$ where N is the number of labeled samples, x_i is a text input (consisting of one or multiple pieces), and $y_i \in \mathcal{Y}$ is a label. The goal is to finetune a pretrained model with $\mathcal{D}_{\text{label}}$ to obtain the best performance on $\mathcal{D}_{\text{test}}$. An unlabeled set $\mathcal{D}_{\text{unlab}} = \{x_i^{\text{unlab}}\}_i$ may additionally be used by semi-supervised few-shot methods (§5.1).

4.1 Formulation of Evaluation Framework

Our preliminary results (in Appendix §A.1) show that using a fixed set of hyper-parameters (Schick and Schütze, 2021a,b) is sub-optimal, and model selection is required. It motivates us to study a more robust evaluation framework for few-shot NLU. The goal of an evaluation framework is twofold: (1) benchmarking few-shot methods for NLU tasks such that they can be fairly compared and evaluated; and (2) obtaining the best few-shot performance in practice. In light of the two aspects, we propose the few-shot evaluation framework in Algorithm 1.

The framework searches over a hyper-parameter space $\mathcal{H}$ to evaluate a given few-shot method M, obtaining the best hyper-parameter setting $h^\star$ and its test set results. [4] The measurement for each h is estimated by performing training and evaluation on multiple data splits (obtained by splitting $\mathcal{D}_{\text{label}}$ according to a strategy) and reporting their average dev set results. Finally, the method is evaluated on $\mathcal{D}_{\text{test}}$ using the checkpoints corresponding to $h^\star$. For benchmarking, we report the average and standard deviation over multiple test set results. Otherwise, that is, to achieve a model with the best practical performance, we re-run on the entire $\mathcal{D}_{\text{label}}$ with $h^\star$.

The framework requires specifying a key design choice—how to construct the data splits, which we will discuss in §4.2.

Algorithm 1: A Few-Shot Evaluation Framework

```
Data: $\mathcal{D}_{\text{label}}$, $\mathcal{D}_{\text{test}}$, a hyper-parameter space $\mathcal{H}$, a
      few-shot method $M$, the number of runs $K$.
Result: test performance; best hyper-parameter $h^\star$.
for $k \leftarrow 1 \cdots K$ do
    Divide $\mathcal{D}_{\text{label}}$ into $\mathcal{D}_{\text{train}}^k$ and $\mathcal{D}_{\text{dev}}^k$ according to a
      data-split strategy;
end
for $h \in \mathcal{H}$ do
    for $k \leftarrow 1 \cdots K$ do
        Run the method $M$ by training on $\mathcal{D}_{\text{train}}^k$ and
          evaluating on $\mathcal{D}_{\text{dev}}^k$;
        Report the dev-set performance $\mathcal{P}_{\text{dev}}^{h,k}$.
    end
    Compute the mean and standard deviation over
      $K$ dev-set results, $\mathcal{P}_{\text{dev}}^h \pm \mathcal{S}_{\text{dev}}^h$;
end
Select $h^\star$ with the best $\mathcal{P}_{\text{dev}}^h$.;
if the goal is to evaluate a method then
    Evaluate on the test set $\mathcal{D}_{\text{test}}$ with the $K$
      checkpoints that correspond to $h^\star$;
    Report the mean and standard deviation over the
      $K$ test results $\mathcal{P}_{\text{test}}^{h\star} \pm \mathcal{S}_{\text{test}}^{h\star}$.
else if the goal is to obtain the best performance then
    Re-run on the entire $\mathcal{D}_{\text{label}}$ using fixed $h^\star$ with $L$
      different random seeds;
    Evaluate on the test set with the $L$ checkpoints;
    Report the mean and stddev over $L$ test results.
end
```

4.2 How to Construct Data Splits

4.2.1 Desiderata: Performance, Correlation, and Stability

We first propose the following three key desiderata for the evaluation of different data split strategies.

1. **Performance of selected hyper-parameter.** A good data split strategy should select a hyper-parameter that can achieve a good test set performance. We use the same metrics as (Schick and Schütze, 2021b), along with standard deviations.
2. **Correlation between dev and test sets (over a hyper-parameter distribution)**. Since a small dev set is used for model selection, it is important for a good strategy to obtain a high correlation between the performances on the small dev set and test set over a distribution of hyper-parameters. We report the Spearman's rank correlation coefficient for measurement.
3. **Stability w.r.t. number of runs K.** The choice of the hyper-parameter K should have small impacts on the above two metrics (i.e., performance and correlation). To analyze the stability w.r.t K, we report the standard deviation over multiple different values of K. Besides, it is desirable to have reduced variance when K increases. Thus we report the above two metrics with different

---

[4] For simplicity and ease of use, we use grid search for searching the hyper-parameter space $\mathcal{H}$ and identify critical hyper-parameters to limit its size. More complex search methods such as Bayesian Optimization (Snoek et al., 2012) could be used to search over larger hyper-parameter spaces.

values of K and the standard deviation of test scores over K runs.

4.2.2 Data Split Strategies

We consider several data split strategies. Some are proposed by previous work, including K-fold cross validation (CV) (Perez et al., 2021), minimum description length (MDL) (Perez et al., 2021), and bagging (BAG) (Breiman, 1996). We also consider two simple strategies worth exploring, including random sampling (RAND) and model-informed splitting (MI). And we propose a new data split strategy, Multi-Splits (MS). Besides, we also experiment a special case of CV when K equals the number of labeled sample, which is leave-of-out cross validation (LOOCV). Since LOOCV takes much longer time and suffers from efficiency problem, we only experimented on several tasks and left the results in Appendix A.2.4. They all fit into the pipeline of the proposed framework in §4.1:

1. **K-fold CV** equally partitions $\mathcal{D}_{\text{label}}$ into K folds. Each time, it uses the k^{th} fold for validation and the other $K-1$ folds for training.
2. **MDL** assigns half of $\mathcal{D}_{\text{label}}$ as the joint training data and equally partitions the other half into K folds. Each time, it uses the k^{th} fold for validation, and all its previous $k-1$ folds together with the joint training data for training.
3. **Bagging** samples $N \times r$ ($r \in (0, 1]$ is a fixed ratio) examples with replacement from the labeled sample as the training set, leaving samples that do not appear in the train set for validation.
4. **Random Sampling** performs random sampling without replacement from $\mathcal{D}_{\text{label}}$ twice, respectively sampling $N \times r$ and $N \times (1-r)$ data as the training and development sets.
5. **Model-Informed Splitting** computes representations of each labeled example using a model, and clusters them into two distinct sets, respectively as the training and development sets. [5]
6. **Multi-Splits** randomly splits $\mathcal{D}_{\text{label}}$ into training and development sets using a fixed split ratio r.

Essentially, these data split strategies differ in several key aspects.

1. For CV and MDL, K controls the number of runs and the split ratio. For Multi-Splits, BAG and RAND, the split ratio is decoupled from K and is controlled by r. For MI, the split ratio and number of runs depend on $\mathcal{D}_{\text{label}}$.

	#Train	#Dev
CV	$(K-1) \times N/K$	N/K
MDL	$N/2 + N(k-1)/(2K)$	$N/(2K)$
BAG	$N \times r$	$> (N \times (1-r))$
RAND	$N \times r$	$N \times (1-r)$
Multi-Splits	$N \times r$	$N \times (1-r)$

Table 1: Number of examples of training and development sets for different strategies. N: number of labeled data, K: number of runs, k: the k^{th} split for MDL; r: split ratio. MI is omitted since its number of examples depends on the dataset.

2. They use a different amount of data for training and development sets as Table 1 shows.
3. There are cases when CV and MS share the same split ratio. The difference is that MS allows overlap between splits while CV does not.
4. BAG allows duplicated training data, while RAND and Multi-Splits do not. The training and development sets do not overlap for BAG and Multi-Splits but overlap for RAND.

In the limit, our Multi-Splits is similar to leave-P-out cross-validation (LPOCV; Celisse, 2014)[6] where LPOCV runs $\binom{N}{P}$ times (P is the number of dev set examples) while Multi-Splits runs K times. As K increases, Multi-Splits gradually approaches LPOCV. Since it is impossible to enumerate the large number of possible splits in practice, Multi-Splits can be viewed as a practical version of LPOCV. Compared to the strategy of (Gao et al., 2020) that uses multiple datasets, our Multi-Splits uses multiple data splits for a single dataset. It is thus more practical as in real-world scenarios, it is hard to obtain multiple labeled datasets for a true few-shot problem; otherwise, it could be formulated as a fully-supervised learning problem. The strategy in (Liu et al., 2021b) is a special case of Multi-Splits when $K = 1$, which suffers from higher variance.

4.2.3 Experimental Setup

To evaluate different data split strategies, we experiment on the FewGLUE benchmark (Schick and Schütze, 2021b). We evaluate strategies based on the widely used prompt-based few-shot method PET (Schick and Schütze, 2021b) with DeBERTa as the base model.[7] We run experiments on the same tasks with the same hyper-parameter space

---

[5] Specifically, we used a BERT-Base model to encode data and take the [CLS] representations.

[6] Leave-P-out cross-validation uses P data examples as the development set and the remaining data examples as the training set. This is repeated on all ways to cut the labeled dataset in a development set and a training set.

[7] We fixed the parameters of DeBERTa's bottom one-third layers due to GPU memory limitations, which did not affect the performance much in our preliminary experiments.

to ensure a fair comparison; in this experiment we search learning rate, evaluation ratio, prompt pattern and maximum training step. More experimental details are in Appendix A.2.

4.2.4 Main Results and Analysis

Table 2, Table 3 and Figure 1 show the main results with 64 labeled samples.

It is noteworthy that we also experimented with 32 labeled samples and have observed that varying the number of labeled examples does not affect the following conclusion (see Appendix A.2).

Test Performance and Correlation. From both Table 2 and Table 3, we find that Multi-Splits achieves the best average test set performance as well as the best average correlation among all strategies. We analyze them as follows:[8]

1. Multi-Splits uses fewer labeled samples for training (i.e., 128) while CV and MDL use more (i.e., 192 and 176). Despite using more training data, both CV and MDL do not perform better. This indicates few-shot performance is limited by not being able to select the best model rather than not having sufficient training data. Both CV and MDL use fewer data for validation (i.e., 64 and 32) than Multi-Splits (i.e., 128), thus leading to poor correlation.
2. Although Multi-Splits and BAG use the same number of training data (i.e., 128), there could be duplication in the training set of BAG, making it poor in diversity and further leading to lower test performance, compared to Multi-Splits. This indicates diversity of training sets is crucial when constructing few-shot data splits.
3. RAND uses similar-sized dev and train sets to BAG and MS but performs worse in test performance. Since there could be overlap between train and dev sets, the model may have memorized data, leading to poor test performance.
4. MI constructs very different train and dev sets. Overfitting on one of them and validating on the other pose more challenges for the few-shot method on out-of-distribution tasks.

Stability w.r.t. the number of runs K. Figure 1 shows the results on stability. In light of limited computation resources, we only experiment with

---

[8] In the following explanation, the numbers refer to the total training/development data covering K=4 runs.

some representative strategies. Both CV and MDL represent strategies whose number of runs are coupled with the size of data split, while Multi-Splits represents strategies that have a fixed ratio and independent K. We observe: (1) Multi-Splits (blue lines) is the most stable in correlation and performance, while other strategies CV and MDL are more sensitive to the choice of K. (2) Multi-Splits shows the smallest variance over multiple runs on both BoolQ and RTE. For COPA, though Multi-Splits shows high variance when $K = 2$, the variance becomes smaller with larger K, while CV and MDL suffer from increasing or unstable variance.

A possible explanation is that increasing K does not affect the number of training and development examples for Multi-Splits; instead, it increases the confidence of results. An important practical benefit of Multi-Splits is that one can always choose to increase K for lower variance. However, for CV and MDL, the sizes of training and development sets are affected by K, where extremely large K value leads to a failure mode and extremely small K leads to unstable results. In practice, it is hard to know which value of K to use a priori.

To sum up, based on the aforementioned results and analysis, we arrive at the following finding.

Finding 1. Our proposed Multi-Splits is a more reliable data-split strategy than several baselines with improvements in (1) test performance, (2) correlation between development and test sets, and (3) stability w.r.t. number of runs.

Remark Our evaluation framework is better in terms of test performance, dev-test correlation, and stability, which proves it can achieve possible peak performance, reliably select the corresponding hyperparameters according to dev results without overfitting, and mitigate the effects of randomness to the maximum extent. Therefore, the estimation of our evaluation framework for model performance is more reliable than previous evaluations.

5 Re-Evaluation of State-of-the-Art Methods

5.1 Few-Shot Methods

We now proceed to re-evaluate state-of-the-art few-shot methods under our evaluation framework with the Multi-Splits strategy. We consider two types: *minimal few-shot methods*, which only assume access to a small labeled dataset, including Classification (CLS; Devlin et al., 2018), PET (Schick and Schütze, 2021b), ADAPET (Menon et al., 2021), P-tuning (Liu et al., 2021b) and FlipDA (Zhou et al., 2021); and *semi-supervised few-shot methods*, which allow accessing an additional unlabeled dataset, including PET+MLM (Schick and Schütze, 2021a), iPET (Schick and Schütze, 2021b) and Noisy Student (Xie et al., 2020).

5.2 Experimental Setup

The same benchmark datasets, metrics, and hyperparameter space as in §4.2.3 are used. We use 32 labeled samples for training. We consider two labeling strategies to obtain the pseudo-labels on unlabeled samples used by the semi-supervised methods for self-training, including *single-split labeling* and *cross-split labeling*. In the single-split setting (Schick and Schütze, 2021b), pseudo-labels are generated by the models trained on the same data split. In the cross-split setting in our evaluation framework, the pseudo-labels are generated by the models trained on multiple different data splits. More configuration details are in Appendix A.4.

5.3 Main Results and Analysis

Re-Evaluation Results Table 4 shows our re-evaluation results. The prompt-based fine-tuning paradigm significantly outperforms the classification fine-tuning on all tasks and on both pretrained models (with an advantage of more than 15 points on average). DeBERTa outperforms ALBERT consistently. We observe significant differences in performance between different prompt-based minimal few-shot methods with ALBERT (e.g., ADAPET and FlipDA outperform PET respectively by about 4 points and 2 points on average) while differences with DeBERTa are slight (e.g., PET, ADAPET, P-tuning, and FlipDA have a performance gap of only about 1.0 points on average). In contrast, semi-supervised few-shot methods (i.e., iPET and Noisy) generally improve 1–2 points on average compared to minimal few-shot methods on both models.

Comparison to Prior Evaluations Since we have proved that our evaluation framework is more reliable in estimating method performance as shown in Section 4.2.4, we conduct experiments to compare the estimates by our evaluation framework and prior evaluations to study whether model performance was accurately estimated in prior work.

Table 6 lists the absolute performance from prior evaluations and our evaluation. Results show the absolute performance of few-shot methods in prior evaluations was generally overestimated on RTE

Base Models	Few-Shot Methods	BoolQ	RTE	WiC	CB		MultiRC		WSC	COPA	Avg.

DeBERTa	Our Best[3,4] (few-shot)	**84.0** ±0.55	**85.7** ±0.63	**69.6** ±2.15	**95.1** ±2.68	**93.6** ±2.62	**81.5** ±0.76	**48.0** ±0.99	**88.4** ±2.82	**93.8** ±2.99	**85.44**[1]
RoBERTa	RoBERTa [5] (fully sup.)	86.9	86.6	75.6	98.2	-	85.7	-	91.3	94.0	88.33
DeBERTa	DeBERTa [2] (fully sup.)	88.3	93.5	-	-	-	87.8	63.6	-	97.0	-

[1] For comparison with RoBERTa (fully sup.), the average of Our Best (few-shot) 85.17 excludes MultiRC-EM and CB-F1.
[2] The fully-supervised results on DeBERTa are reported in `https://github.com/THUDM/GLM`.
[3] Unlabeled data are used.
[4] The ensemble technique is used.
[5] The RoBERTa (fully-sup.) results by (Liu et al., 2019). RoBERTa-large has less parameters than DeBERTa-xxlarge-v2.

Table 4: Re-evaluation of few-shot methods on ALBERT and DeBERTa under our evaluation framework with Multi-Splits strategy on test set of our setup. For iPET and Noisy Student, (cross) and (single) respectively means cross-split labeling and single-split labeling strategies as introduced in §5.2. "Our Best (few-shot)" is the results achieved by a combination method as introduced in §5.4. **Globally best results** for each task are in bold. Best results for minimal few-shot methods are underlined. Best results for semi-supervised few-shot methods are marked with wavelines.

	BoolQ	RTE	WiC	CB	MultiRC	WSC	COPA
Minimal Few-Shot Methods	PET	ADAPET	PET	FlipDA	ADAPET	ADAPET	PET
Training Paradigm	iPET(cross)	Noisy(cross)	iPET(cross)	single	Noisy(cross)	Noisy(single)	iPET(cross)
+ MLM	✓	-	-	-	-	-	-

Table 5: The combination of methods that achieves the best few-shot performance for each task. There are five minimal few-shot methods and five training paradigms as combined options, as §5.4 illustrates. "+MLM" means adding an additional MLM loss.

Methods	RTE		WiC		COPA	
	Prev.	Ours	Prev.	Ours	Prev.	Ours
PET	69.80	72.83	52.40	53.87	95.00	81.75
ADAPET	76.50	74.28	54.40	58.07	89.00	81.75
P-tuning	76.50	63.27	56.30	55.49	87.00	85.25
FlipDA	70.67	70.85	54.08	57.17	89.17	87.50
+MLM	62.20	71.48	51.30	52.39	86.70	85.75
iPET	74.00	72.35	52.20	54.78	95.00	84.00

Table 6: Comparison of prior evaluations and our evaluation. We report the absolute performance of different methods respectively from previous evaluation (Prev.) and our evaluation framework (Ours.) on RTE, WiC and COPA tasks. The results are based on ALBERT. Results of previous evaluation are taken from the original papers, including ADAPET (Menon et al., 2021), P-tuning (Liu et al., 2021b), FlipDA (Zhou et al., 2021) and iPET (Schick and Schütze, 2021b). Since (Schick and Schütze, 2021a) reported results of PET+MLM on different tasks, we re-experimented on the same tasks under the same setting as (Schick and Schütze, 2021a). Wave lines and underlines indicate examples of inaccurate estimates of relative gaps in prior works (see text for details).

and COPA. Similar findings have been highlighted in prior works (Perez et al., 2021; Zhang et al., 2020), and our evaluation framework confirms the findings under a more reliable setup. This results from a more reliable evaluation procedure that emphasizes dev-test correlation to prevent overfitting (discussed in Section 4.2).

Besides, the relative gaps between different methods were not accurately estimated by the prior reported numbers. For example, according to the reported results in prior works, ADAPET outperforms P-Tuning on COPA and P-Tuning beats ADAPET on WiC, while our evaluation reveals the opposite. On one hand, this is because prior results were obtained under a less reliable evaluation procedure (discussed in Section 4.2). Deviation in the estimates of absolute performance contributes to inaccuracy in the estimates of relative performance. On the other, prior experiments were not conducted under a shared evaluation procedure. These two factors are corrected by our re-evaluation under the more reliable proposed framework.

To sum up, our re-evaluation compares all methods on a common ground, revealing the following:

Finding 2. The absolute performance and the relative gap of few-shot methods were in general not accurately estimated in prior literature. This is corrected by our new evaluation framework with improved reliability. It highlights the importance of evaluation for obtaining reliable conclusions. Moreover, the benefits of some few-shot methods (e.g., ADAPET) decrease on larger pretrained models like DeBERTa.

5.4 What is the Best Performance Few-Shot Learning can Achieve?

We further explore the best few-shot performance by combining various methods, and evaluating under our evaluation framework. For combined options, we consider five minimal few-shot methods (i.e., CLS, PET, ADAPET, P-tuning, and FlipDA), five training paradigms (i.e., single-run, iPET (single/cross), and Noisy Student (single/cross)), and the addition of a regularized loss (+MLM). We experiment with all possible combinations and report the best for each task.

"Best (few-shot)" in Table 4 achieves the best results on all tasks among all methods. Existing few-shot methods can be practically used in combination. Compared to RoBERTa (fully-sup) (Liu et al., 2019), the performance gap has been further narrowed to 2.89 points on average.[9] Compared to DeBERTa (fully-sup), there is still a sizeable gap between few-shot and fully-supervised systems.

We list the best-performing combination for each task in Table 5. The best combinations are very different across tasks, and there is no single method that dominates most tasks. PET and ADAPET as well as iPET and Noisy Student are about equally preferred while cross-split labeling and no regularization term perform better. We thus recommend future work to focus on the development of methods that achieve consistent and robust performance across tasks. We summarize the following findings:

Finding 3. Gains of different methods are largely complementary. A combination of methods largely outperforms individual methods, performing close to a strong fully-supervised baseline on RoBERTa. However, there is still a sizeable gap between the best few-shot and the fully-supervised system.

Finding 4. No single few-shot method dominates most NLU tasks. This highlights the need for the development of few-shot methods with more consistent and robust performance across tasks.

6 FewNLU Toolkit

We open-source FewNLU, an integrated toolkit designed for few-shot NLU. It contains implemen-

---

[9] Note that the gap could be larger since RoBERTa-Large has a smaller number of parameters than DeBERTa, and RoBERTa (fully-sup) does not incorporate additional beneficial techniques such as ensembling or self-training.

tations of state-of-the-art methods, data processing utilities, a standardized few-shot training framework, and most importantly, our proposed evaluation framework. Figure 2 shows the architecture. We hope FewNLU could facilitate benchmarking few-shot learning methods for NLU tasks and expendit the research in this field.

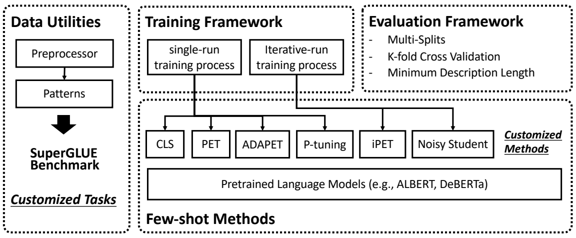

Figure 2: Architecture of FewNLU.

7 Conclusions

We introduce an evaluation framework, re-evaluate a number of few-shot learning methods under the evaluation framework with a novel Multi-Splits strategy, and release a few-shot toolkit. Apart from this, we also aim at advancing the development of few-shot learning by sharing several new experimental findings. We identify several new directions for future work: (1) In practice, how to define the hyper-parameter search space a priori is a challenge. (2) It is critical for the community to iterate and converge on a common evaluation framework. (3) Few-shot natural language generation might also be studied in a similar framework.

A Appendix

A.1 Fixed Hyper-Parameters are not Optimal

Some prior works (Schick and Schütze, 2021a,b; Menon et al., 2021) perform few-shot learning with a fixed set of hyper-parameters (determined by practical considerations and experiences) without early stopping and any model selection.

	Hyper-Parameters				Test Acc.	Avg.
	P	LR	Step	WR		
Fixed	0	1e-5	250	0	69.31 ±4.39	67.36
	1				61.13 ±0.91	
	2				63.06 ±1.50	
	3				63.06 ±1.82	
	4				80.26 ±1.85	
Optimal	0	1e-5	300	0.05	72.44 ±1.85	70.42
	1	5e-6	300	0.05	63.78 ±1.37	
	2	5e-6	300	0	69.07 ±5.55	
	3	5e-6	300	0	65.70 ±1.25	
	4	5e-6	300	0	81.11 ±1.37	

Table 7: Performance of PET on RTE task with different hyper-parameters. The patterns and fixed hyper-parameters are reported by (Schick and Schütze, 2021b). Base model: DeBERTa-xxLarge, "P": pattern ID, "LR": learning rate, "Step": number of training steps, "WR": warmup ratio.

We first study how well fixed hyper-parameters transfer to a new scenario, e.g. switching to another base pretrained model. We perform preliminary experiments on FewGLUE with 64 labeled sample based on DeBERTa. Firstly, we experiment with the fixed hyper-parameters used for ALBERT in (Schick and Schütze, 2021b). Secondly, we manually try other hyper-parameters to find out whether there are better configurations. From Table 7, we observe:

1. Certain factors, especially the patterns, impact the performance a lot (best 80.26%, and worst 61.13%). However, we cannot differentiate between them without a development set.
2. There exists a hyper-parameter ("Optimal" in Table 7) that performs much better than the fixed one. A mechanism to identify the best hyper-parameter setting is thus necessary.
3. Results show a good hyper-parameter on ALBERT does not work well on DeBERTa. Fixed hyper-parameters are not optimal and we need to re-select them given new conditions.

A.2 Details of How to Construct Data Splits

A.2.1 Datasets

To justify the proposed evaluation framework, we perform experiments on the few-shot SuperGLUE benchmark, which was constructed to include some of the most difficult language understanding tasks for current NLP approaches (Wang et al., 2019a). Unlike other NLU benchmarks (e.g., GLUE (Wang et al., 2019b)) that contain single-sentence tasks, SuperGLUE consists of complicated ones that are sentence-pair or sentence-triple tasks, which demand advanced understanding capabilities. Seven SuperGLUE tasks are considered, including question answering (BoolQ (Clark et al., 2019) & MultiRC (Khashabi et al., 2018)), textual entailment (CB (De Marneffe et al., 2019) & RTE (Dagan et al., 2005)), word sense disambiguation (WiC (Pilehvar and Camacho-Collados, 2018)), causal reasoning (COPA (Roemmele et al., 2011)), and co-reference resolution (WSC (Levesque et al., 2012)).

A.2.2 Hyper-parameters

To quantitatively evaluate different data-split strategies, we perform extensive experiments with the following hyper-parameter search space. Data-split experiments are based on DeBERTa-xxLarge. The hyper-parameter search space is shown in Table 8. We use the same prompt patterns as in (Schick and Schütze, 2021b). To observe the changes of performance and correlation metrics w.r.t different K values, we also experimented with $K = \{2, 4, 8, 16\}$ over three tasks (i.e., BoolQ, RTE and COPA).

Hyper-parameter	Value
Learning Rate	$\{5e-6, 1e-5\}$
Maximum Training Step	$\{250, 500\}$
Evaluation Frequency	$\{0.02, 0.04\}$
Number of Runs K	4
Split Ratio r for Multi-Splits	1:1

Table 8: Hyper-parameter Search Space for Data-Split Strategy Evaluation

A.2.3 Evaluation Results with 32 Labeled Data

In the data-split strategy evaluation, in addition to the 64-data-setting results in the main text, we also experimented with 32 labeled data as (Schick and Schütze, 2021b,a; Menon et al., 2021). The 32-data-setting results are also provided in Table 10.

A.2.4 Leave-One-Out Cross Validation Results

We also experiment with another useful data split strategy, leave-one-out cross validation (LOOCV). In fact, LOOCV is a special case of K-fold cross validation when K equals the number of labeled data. Since LOOCV takes even longer time than any other data split strategies, we only experi-

		BoolQ	RTE	WiC
Multi-Splits	Perf.	82.67 ±0.78	79.42 ±2.41	67.20 ±1.34
	Corr.	0.7079	0.8266	0.9464
CV	Perf.	82.71 ±1.29	77.80 ±2.25	64.42 ±1.63
	Corr.	-0.0497	0.8561	0.8184
LOOCV	Perf.	80.20 ±5.63	63.91 ±5.37	62.40 ±4.70
	Corr.	-0.8001	-0.5070	0.1998

Table 9: Test performance and correlation results of leave-one-out cross validation on BoolQ, RTE and WiC tasks with 64 labeled examples.

mented on three tasks, including BoolQ, RTE and WiC tasks. Both performance and correlation results are shown in Table 9. Our results show that compared to other strategies, LOOCV achieved worse test performance as well as correlation. LOOCV only uses a single instance for validation each time, and thus leads to poor correlation and random model selection. As a result, the performance estimation is subject to much randomness.

A.3 How to Define the Hyper-parameter Search Space

Aside from how to construct the data splits, another important question for the evaluation framework is how to define the hyper-parameter search space. We left this question in the future work. However, we did several preliminary experiments that could reveal certain insights into the problem.

A.3.1 Should We Search Random Seeds?

We focus on two types of factors that affect few-shot evaluation, hyper-parameters and randomness. Randomness could cause different weight initialization, data splits, and data order during training. Empirically, how randomness is dealt with differs depending on the use case. In order to obtain the best possible performance, one could search over sensitive random factors such as random seeds. However, as we focus on benchmarking few-shot NLU methods, we report mean results (along with the standard deviation) in our experiments in order to rule out the effects of randomness and reflect the average performance of a method for fair comparison and measurement.

A.3.2 Experiments

Experimental Setup To examine how a certain factor affects few-shot performance, we assign multiple different values to a target factor while fixing other hyper-parameters. We report the standard deviation over the multiple results. Larger values indicate that a perturbation of the target factor would largely influence the few-shot performance and the factor thus is crucial for searching. We experiment on BoolQ, RTE, CB, and COPA tasks. Considered factors include: sample order during training, prompt pattern, training batch size, learning rate, evaluation frequency, and maximum train steps.

Results and Analysis Results are in Table 11. We mark values larger than a threshold of 2.0 in bold. We can see that the prompt pattern is the most influential factor among all, indicating the design or selection of prompt patterns is crucial. Training example order also significantly affects the performance. The evaluation frequency affects the score on the small development but not on the test set. We speculate that a lower frequency selects a model with better performance on the small development set, but the gains do not transfer to the test set because of partial overfitting. To conclude:

Finding 5. We recommend to at least search over prompt patterns during hyper-parameter tuning, and it is also beneficial to search others. All comparison methods should be searched and compared under the same set of hyper-parameters.

A.3.3 Detailed Configuration

For a given task and a target factor, we fixed the hyper-parameters to be the best-performing ones obtained in Section 4.2, and assigned multiple values for the target factor. For the prompt pattern, we assigned it with the same values as (Schick and Schütze, 2021b). Possible values for other hyper-parameters are in Table 12.

A.4 Details of Re-Evaluation

A.4.1 Methods

The five considered minimal few-shot methods are introduced as follows.

1. **Classification** is a conventional finetuning algorithm, which uses the hidden states of a special [CLS] token for classification.
2. **PET** is a prompt-based finetuning algorithm. It transforms NLU problems into cloze problems with prompts, and then converts the cloze outputs into the predicted class.
3. **ADAPET** is based on PET and decouples the losses for the label tokens. It proposes a label-conditioned masked language modeling (MLM) objective as a regularization term.

Hyper-parameters are set the best-performing ones obtained in §5 while the target factor is assigned with multiple values. "Train Order": training sample order; "Train Batch": total train batch size; "Eval Freq": evaluation frequency.

Hyper-parameter	Value
Learning Rate	$\{6e-6, 8e-6, 1e-5\}$
Evaluation Frequency	$\{0.02, 0.04, 0.08\}$
Training Batch Size	$\{8, 16, 32, 64\}$
Sample Order Seed	$\{10, 20, 30, 40, 50, 60, 70, 80\}$

Table 12: Hyper-parameter Search Space for Crucial Factor Evaluation

4. **P-tuning** is also based on PET and automatically learns continuous vectors as prompts via gradient update.
5. **FlipDA** is similar to PET but uses both labeled data and augmented data for training. The augmented data are automatically generated by taking labeled data as inputs. [10]

The three semi-supervised few-shot methods are introduced as follows.

1. **PET+MLM** is based on PET and additionally adds an auxiliary language modeling task performed on unlabeled dataset. It was first proposed by (Schick and Schütze, 2021a) to resolve catastrophic forgetting.
2. **iPET** is a self-training method. It iteratively performs PET for multiple generations. At the end of each generation, unlabeled data are assigned with pseudo-labels by the fully-trained model, and will be used for training along with train data in the next generation.
3. **Noisy Student** is similar to iPET with the difference that Noisy Student injects noises into the input embeddings of the model.

A.4.2 Hyper-parameter Search Space

The hyper-parameter search space for other few-shot methods are shown in Table 17.

A.4.3 The Searched Best Hyper-parameters

We list the searched best hyper-parameter configuration for different tasks and methods in Table 13, Table 14, Table 15, Table 16.

A.4.4 More Discussion on ADAPET

Since it is observed ADAPET shows less improvement on DeBERTa than it has achieved on ALBERT, we further discuss the phenomena by raising the question what other differences it has made. We respectively visualize the few-shot performance distribution over the same hyper-parameter space of PET and ADAPET in Figure 3. We observe that PET is more likely to obtain extremely bad

---

[10] In our experiments, we use the best checkpoints searched with PET as the classifier for data selection.

[11] As recommended in (Zhou et al., 2021), we fix one mask ratio for each dataset, i.e., 0.3 for BoolQ, MultiRC, and WSC, 0.5 for RTE and CB, and 0.8 for COPA and WiC. We fix one fill-in strategy for each dataset, i.e., "default" for BoolQ, RTE, WiC, CB, and WSC, "rand_iter_10" for MultiRC, and "rand_iter_1" for COPA.

	BoolQ	RTE	WiC	CB	MultiRC	WSC	COPA
Learning Rate	1e-5	5e-6	5e-6	1e-5	1e-5	1e-5	1e-5

	Drop Inconsistant Data	{yes, no}
	Mask Ratio	Fixed [11]
	Fill-in Strategy	Fixed [9]
iPET/ Noisy	Unlabeled Data Number	500
	Increasing Factor	3.0
	Sample Ratio (single-split)	1.0
	Sample Ratio (cross-split)	2/3
	Dropout Rate for Noisy	0.05

Table 17: Hyper-parameter Space for Re-Evaluation

task	method	g1	g2	g3
WiC	Multi-Patterns	60.11 ±5.64	60.19 ±4.12	59.66 ±4.27
	Best-Pattern	64.21 ±2.58	64.18 ±4.61	63.37 ±6.29
RTE	Multi-Patterns	65.08 ±10.07	69.20 ±7.13	71.46 ±5.59
	Best-Pattern	79.39 ±2.75	81.95 ±1.04	83.12 ±1.42

Table 18: The performance results of iPET on both WiC and RTE at every generation (g1, g2, and g3). Each experiment uses either ensemble over all patterns (Multi-Patterns) or ensemble over the only best pattern (Best-Pattern). This experiment is conducted with 1000 unlabeled data and an increasing factor 5.

results on BoolQ and RTE, while ADAPET shows stable results. It suggests that ADAPET appears to be more robust to the hyper-parameters, and overall achieves good performance regardless of hyper-parameter selection. However, ADAPET is less inclined to produce better peak results. To sum up, we can conclude: Loss regularization (e.g., ADAPET (Menon et al., 2021)) enhances stability w.r.t. hyper-parameters.

A.4.5 More Discussion on Semi-supervised Few-shot Methods

We focus on semi-supervised methods that iteratively augment data (i.e., iPET and Noisy Student), which have demonstrated promising results on both models in Table 4. Several key points for their success are especially discussed.

1. For semi-supervised methods such as iPET and Noisy Student, it is time-consuming when searching over a large hyper-parameter space for each generation. We directly use the searched best hyper-parameters for PET in each generation. From Table 4, we can see that their results show advantages over PET (by more than 1 points). It suggests that the best hyper-parameters can be transferred to such methods, to reduce the cost of time and computational resources. If we search for each generation, results might be even better.
2. Comparing the single-split labeling strategy, the cross-split labeling strategy works better. As the results show, both iPET (cross) and Noisy (cross) outperform iPET (single) and Noisy (single) in most tasks on both models.
3. Another simple and effective technique is our proposed ensemble labeling strategies. (Schick and Schütze, 2021b) utilizes the ensemble results over all patterns to label unlabeled data, since it is hard to select patterns. Under the Multi-Splits strategy, self-training methods can recognize the best pattern, and only ensemble trained models for the best pattern when labeling unlabeled data. Table 18 shows the results of iPET on WiC and RTE tasks, respectively ensemble over multiple patterns or ensemble over the only best pattern. We can see that results of ensemble with the best pattern significantly outperform results of ensemble with all patterns at every generation.

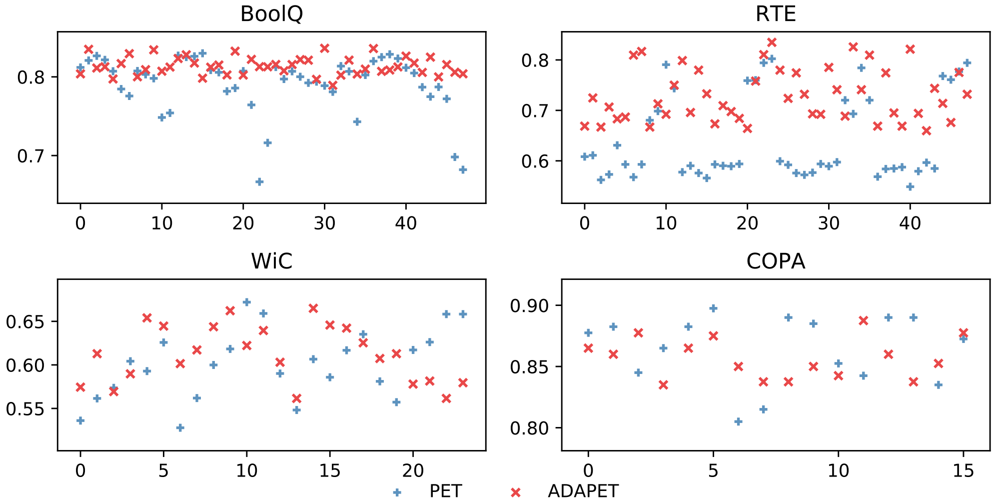

Figure 3: Visualization of few-shot performance over the same hyper-parameter space of ADAPET and PET based on DeBERTa and Multi-Splits. The x-axis is the index of the hyper-parameter combination. We search each task with a learning rate of 1e-5 or 5e-6, max steps of 250 or 500, evaluation ratio of 0.02 or 0.04, and all the available prompt patterns. Therefore, each task has $8N$ hyper-parameter combinations, where N is the number of available prompt patterns, i.e., 6 for BoolQ and RTE, 3 for WiC, and 2 for COPA. The y-axis is the score of each task given a certain hyper-parameter combination.

Learn to Adapt for Generalized Zero-Shot Text Classification

Beijing University of Posts and Telecommunications
{garyzhang, yuancx, xjwang, bestbzw, liuyb}@bupt.edu.cn

Abstract

Generalized zero-shot text classification aims to classify textual instances from both previously seen classes and incrementally emerging unseen classes. Most existing methods generalize poorly since the learned parameters are only optimal for seen classes rather than for both classes, and the parameters keep stationary in predicting procedures. To address these challenges, we propose a novel *Learn to Adapt* (LTA) network using a variant meta-learning framework. Specifically, LTA trains an adaptive classifier by using both seen and virtual unseen classes to simulate a generalized zero-shot learning (GZSL) scenario in accordance with the test time, and simultaneously learns to calibrate the class prototypes and sample representations to make the learned parameters adaptive to incoming unseen classes. We claim that the proposed model is capable of representing all prototypes and samples from both classes to a more consistent distribution in a global space. Extensive experiments on five text classification datasets show that our model outperforms several competitive previous approaches by large margins. The code and the whole datasets are available at `https://github.com/Quareia/LTA`.

1 Introduction

Text classification plays an important role in many natural language processing (NLP) applications, such as question classification, news categorization, user intent classification and so on (Minaee et al., 2021). Although a wide variety of methods have been proved successful in supervised text classification, they often break down when applied to make predictions for incrementally emerging classes without labeled training data (Pourpanah et al., 2020). Unlike zero-shot learning (ZSL) that aims to classify unseen class instances at test time (Romera-Paredes and Torr, 2015; Wang et al., 2019), generalized zero-shot learning (GZSL), which we focus on in this work, aims to classify text samples from both previous seen and emerging novel classes. Since there is a strong bias towards seen classes (Xian et al., 2019a), GZSL is a more challenging yet critical problem.

Previously methods mainly focus on transductive approaches for generalized zero-shot text classification. Rios and Kavuluru (2018) use a graph convolution network to enhance the unseen class label embeddings. Zhang et al. (2019) and Song et al. (2020) generate illusion feature embeddings for unseen classes based on side information, *i.e.*, class-level attributes or text description. More recently, Ye et al. (2020) use reinforced self-training methods to leverage unlabeled data during training.

With the assumption that no knowledge about unseen categories is available during the model learning phase, researchers resort to inductive approaches to handle generalized zero-shot text classification. ReCapsNet (Liu et al., 2019) uses a dimensional attention-based intent capsule network and constructs zero-shot class prototypes by similarity matrix transformation. SEG (Yan et al., 2020) exploits an outlier detection approach that can be directly applied on ReCapsNet, which discriminates the domain first, then outputs the final class label.

However, the existing methods still have two key limitations. Firstly, while the goal of these methods is to transfer beneficial knowledge for unseen classes, these models merely learn optimal parameters by minimizing the loss of instances from seen classes, regardless of explicitly calibrating the predictions on unseen classes. Therefore, domain bias problem (Xian et al., 2019a) towards seen classes is not fairly resolved. Secondly, although some of them take into account the inter-class relationship when constructing prototypes for unseen classes (Liu et al., 2019), the models keep static no matter what different new classes emerge in future applications. As a result, these models show a large quality gap between instances from seen classes

May 22-27, 2022

and from emerging unseen classes.

To address these problems, motivated by the success of meta-learning in the few-shot learning task (Vinyals et al., 2016; Snell et al., 2017; Sung et al., 2018; Finn et al., 2017), we present a novel *Learn to Adapt* (LTA) network for generalized zero-shot text classification. Concretely, the proposed LTA learns over multiple learning episodes that mimic GZSL setting explicitly during training, making the learning setting consistent with the test environment and thereby improving generalization. The model notably extends its ability from two views: prototype adaptation and sample adaptation. In each episode, the LTA adjusts the representative prototypes of both seen classes and "fake" unseen classes, with the assumption that unseen classes will help in calibrating representation of seen ones and thereby enable the model to learn the class-sensitive representations. The updating for all prototypes is then used to generate a set of calibration parameters, called semantic components, to guide the adaptation of sample embeddings, which is designed to compensate for the shrinking features (Chen et al., 2018) that are ignored during training if they are not discriminating for seen classes, but could be critical for recognizing unseen classes. The refined sample embeddings are then classified based on similarity scores with all adapted class prototypes. The same setting can be directly applied in testing, where the LTA executes class prediction and adapts the learned model rationally in an on-the-fly manner.

In summary, our contributions include: (i) We propose a novel *Learn to Adapt* (LTA) network for generalized zero-shot text classification which is capable of adapting incrementally between seen classes and emerging unseen classes at test time. (ii) We propose a methodology for calibrating both prototypes and sample embeddings to deduce a global representation space, efficiently avoiding over-fitting on seen classes. (iii) Experimental results on five generalized zero-shot text classification datasets show that our method outperforms previous methods with a large margin.

2 Related Work

Generalized Zero-Shot Learning The challenge of zero-shot learning (ZSL) has been the focus of attention in recent years, especially in the applications of image classification (Socher et al., 2013; Xian et al., 2019a; Wang et al., 2019), intent detection (Xia et al., 2018; Liu et al., 2019; Yan et al., 2020), and question classification (Fu et al., 2018). Different from ZSL, generalized zero-shot learning (GZSL) that attempts to categorize instances from both seen and unseen classes is a more realistic condition that matches with practical applications. For example, a question classifier for a question answering system has to classify not only the questions ever asked but also new questions incrementally emerging from the users.

There are two key issues that GZSL has to address: (1) how to incrementally learn beneficial knowledge for unseen classes from seen ones, and (2) how to tackle the domain bias caused by the extremely imbalanced data of seen and unseen domains.

To alleviate the first issue, some of the earliest works on ZSL attempt to learn a matching model between instance embedding and class prototype embeddings represented by extra information including class-level attribute, text description, or their combinations (Frome et al., 2013; Nam et al., 2016; Zhu et al., 2019; Xia et al., 2018). In a similar vein, other methods (Wang et al., 2018; Rios and Kavuluru, 2018; Si et al., 2021) also investigate the semantic relationship between the side information for obtaining better prototype representation. Nevertheless, these models are trained using data from seen classes and fail to incrementally adapt to emerging new classes.

The key problem of the second issue is that the model is trained with data from the seen classes and the parameters are actually optimized on the seen domain, thus they are not aware of unseen classes. Assuming the extra information about unseen classes is available, another prominent approach attempts to use generative models to generate virtual samples or features for unseen domains (Xian et al., 2018; Schönfeld et al., 2019; Zhang et al., 2019; Song et al., 2020). By using synthesized samples, the generative approaches can convert GZSL problem to the conventional supervised learning problem where biases towards seen classes are largely alleviated. Additionally, studies also extend to exploit the unlabeled data for unseen classes (Xian et al., 2019b; Rahman et al., 2019; Ye et al., 2020). However, these models assume that they have access to the extra information about the unseen classes, which is not very realistic since often neither the test data nor their label descriptions is available at the training phase (as supposed in this work). In contrast, our model can involve all classes (seen and unseen) jointly during inference, essentially it is trained towards continuous generalization for new classes, hence it is capable to adapt to incoming new classes dynamically.

Episode-Based Training in GZSL Our approach is primarily based on the episodic training paradigm that has been widely used in few-shot learning (FSL) (Vinyals et al., 2016; Snell et al., 2017; Sung et al., 2018). The primitive goal of episodic training is to quickly learn a meta-task from sampled classes. A particular advantage of episodic training is that, by constructing meta-tasks, the setting of training is consistent with that of testing, which is essential for classification problems.

Studies extend to exploit episodic training in the "generalized" settings. Verma et al. (2020) constructs model-agnostic meta-tasks to train generative models on GZSL. In addition, Gidaris and Komodakis (2018) utilizes weight generators to update unseen prototypes in generalized FSL(GFSL). Subsequently, to update both seen and unseen prototypes, Ye et al. (2021) exploits attention mechanism while Shi et al. (2020) takes advantage of graph neural networks in GFSL. Yu et al. (2020) use a generative network to generate unseen prototypes in GZSL. These methods only consider the prototype adaptation while the sample embeddings are still static whatever the unseen classes are. Additionally, Bao et al. (2020) uses distributional signatures to update sample embeddings in GFSL. Considering that distributional signatures can be equal for two different tasks, our method uses a novel semantic update extractor to update samples following the prototype adaptation rather than statistical information.

A compelling property of our method is that it tackles knowledge transferring and domain bias simultaneously in an episodic training framework by adapting both prototypes and sample embeddings, and draws a fast adaptation to the novel classes without the cost of dramatic damage in discriminating the seen classes.

3 Methodology

3.1 Problem Definition

Formally, let $\mathcal{Y}^s = \{y_1^s, ..., y_{C^s}^s\}$ and $\mathcal{Y}^u = \{y_1^u, ..., y_{C^u}^u\}$ denote C^s seen classes and C^u unseen classes respectively, and $\mathcal{Y} = \mathcal{Y}^s \cup \mathcal{Y}^u$ denote the global label space with $\mathcal{Y}^s \cap \mathcal{Y}^u = \emptyset$. Suppose we have a collection of training samples $\mathcal{D}^s = \{(x_j^s, y_j^s, a_j^s)\}_{j=1}^{M}$, that consists of M samples from C^s seen classes, where $x_j^s \in \mathcal{X}^s$ represents j-th text utterance, y_j^s and a_j^s are its one-hot class label and corresponding class-level textual description, respectively. At the test time, provided with a class description set $\mathcal{A}^u = \{a_j^u\}_{j=1}^{C^u}$ for unseen classes, the GZSL task is to classify the test instance into either a seen or an unseen class.

3.2 Overview

Encoder An textual input x with T words is encoded by a BERT (Devlin et al., 2019) (or any other textual encoder) into a sequence of hidden vectors $\mathbf{H} = [\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_T] \in \mathbb{R}^{T \times d_h}$, where d_h is the dimension of the hidden vectors. The text embedding $f(x) \in \mathbb{R}^{d_h}$ is then obtained by averaging over the T hidden vectors.

Training In the training stage, we apply an episodic learning paradigm, which trains the model by simulating multiple generalized zero-shot text classification tasks on seen classes. Following the principle that train and test conditions must match (Vinyals et al., 2016) and recent studies on "generalized" setting (Gidaris and Komodakis, 2018; Shi et al., 2020; Ye et al., 2021; Bao et al., 2020; Verma et al., 2020; Yu et al., 2020), the i-th episode involves an N^s-way K-shot learning task for seen classes, denoted as $\mathcal{D}_i^s = \{(x_j^s, y_j^s, a_j^s)\}_{j=1}^{N^s \times K}$ with K labelled instances for each of the N^s classes, which are randomly sampled from the seen data $\mathcal{D}^s$, and a N^u-way K-shot learning task for "fake" unseen classes, denoted as $\mathcal{D}_i^u = \{(x_j^u, y_j^u, a_j^u)\}_{j=1}^{N^u \times K}$ which is also from $\mathcal{D}^s$, with $N^s + N^u \leq C^s$. More precisely, let $\mathcal{Y}_i^s$ and $\mathcal{Y}_i^u$ denote the sampled seen class space and sampled "fake" unseen class space respectively, with $\mathcal{Y}_i^s \subset \mathcal{Y}^s$, $\mathcal{Y}_i^u \subset \mathcal{Y}^s$, and $\mathcal{Y}_i^s \cap \mathcal{Y}_i^u = \emptyset$. For a new query instance x, the generalized zero-shot learning model performs:

$$\hat{y} = \arg\max_{y \in \{\mathcal{Y}_i^s \cup \mathcal{Y}_i^u\}} p(y|x, \mathcal{D}_i^s, \mathcal{D}_i^u) \quad (1)$$

The model has to maintain a globally consistent joint class prototype space as well as dynamic adaptation to unseen classes with zero labeled instances. In this end, we design a *Learn to Adapt* (LTA) network which first introduces a pre-trained and learnable look-up table $\mathbf{S}$ to store embeddings of the seen prototypes, and obtain the "fake" seen classes $\mathbf{S}_i$ from $\mathbf{S}$. The "fake" unseen prototypes

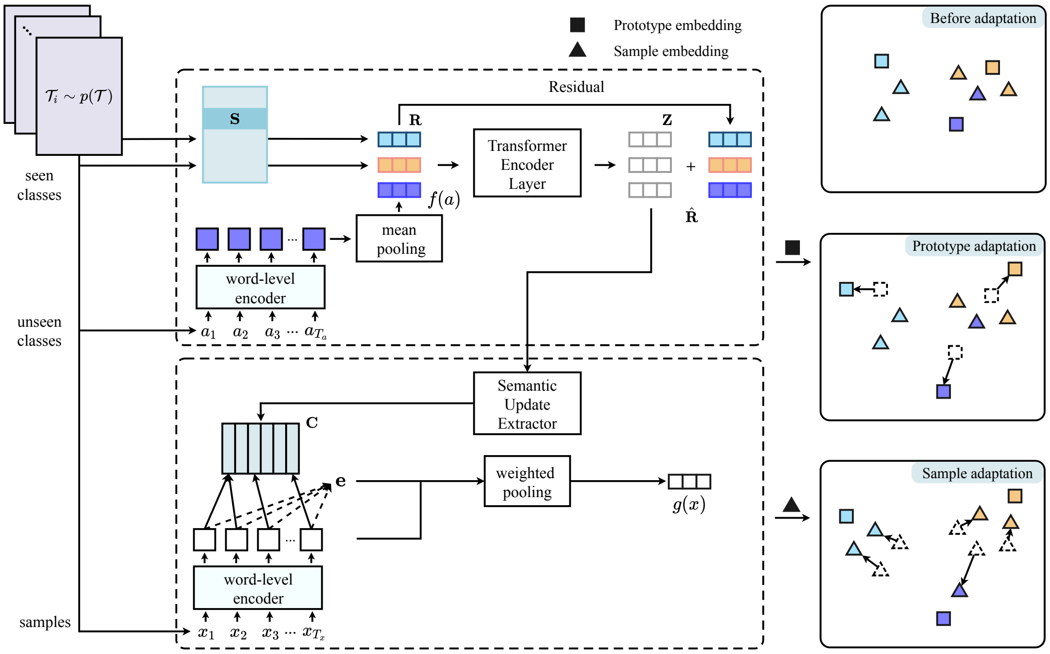

Figure 1: Illustration of the proposed LTA framework. The right part demonstrates the prototype adaptation and sample adaptation, in which ■ and ▲ respectively denote prototypes and samples, dotted border and solid border represent before and after adaptation, respectively.

are encoded into a matrix $\mathbf{U}_i$ with a BERT encoder using "fake" unseen class descriptions. Then the $\mathbf{S}_i$ and the $\mathbf{U}_i$ are concatenated and fed into a transformer encoder layer to explicitly calibrate the seen prototype space and unseen prototype space. Meanwhile, a matrix of semantic components $\mathbf{C}$ is generated conditioned on the updating of the prototypes. With the belief that the instance feature space should be also calibrated according to the prototypes in an on-the-fly manner, $\mathbf{C}$ is further used for updating the feature embedding output by the same encoder.

3.3 Prototype adaptation

The proposed LTA network first introduces a learnable look-up table $\mathbf{S} \in \mathbb{R}^{C^s \times d_h}$ from which to extract the "fake" seen prototypes $\mathbf{S}_i \in \mathbb{R}^{(C^s - N^u) \times d_h}$ on demand. Following Gidaris and Komodakis (2018); Ye et al. (2021); Shi et al. (2020), the $\mathbf{S}$ is firstly initialized by the prototypes trained using a supervised metric learning classifier on seen classes. The detail of the supervised metric learning classifier will be described in the experiment section. We claim that this initialization step will reduce the variance caused by the sampling episode sequences. The "fake" unseen prototypes $\mathbf{U}_i$ is produced by the BERT encoder $f(\cdot)$ using their corresponding class descriptions: $\mathbf{U}_i = [f(a_y)]_{y \in \mathcal{Y}_i^u} \in \mathbb{R}^{N^u \times d_h}$.

Then the joint prototype matrix $\boldsymbol{R}$ is obtained by concatenating $\mathbf{S}_i$ and $\mathbf{U}_i$, $\mathbf{R} = [\mathbf{S}_i, \mathbf{U}_i] \in \mathbb{R}^{C^s \times d_h}$, with $\mathbf{r}_k$ as the k-th prototype. Then $\boldsymbol{R}$ is fed into a single Transformer encoder layer (Vaswani et al., 2017) to explicitly model the updates for both seen prototypes and novel prototypes:

$$\begin{aligned} \mathbf{Z} &= \text{TransformerEncoder}(\mathbf{R}) \\ &= \text{Concat}(\text{head}_1, ..., \text{head}_h)\mathbf{W_o} \\ \text{where head}_i &= \text{Softmax}(\frac{\mathbf{R}\mathbf{W_q}\mathbf{W_k}\mathbf{R}}{d_h})\mathbf{R}\mathbf{W_v} \end{aligned} \tag{2}$$

$$\hat{\mathbf{R}} = \mathbf{R} + \mathbf{Z} \tag{3}$$

where $\mathbf{Z} \in \mathbb{R}^{C^s \times d_h}$ highlights the adjustment after mutual reflections, $\mathbf{W_o}, \mathbf{W_q}, \mathbf{W_k}, \mathbf{W_v} \in \mathbb{R}^{d_h \times d_h}$ are trainable parameters, and the updated prototypes $\hat{\mathbf{R}} \in \mathbb{R}^{C^s \times d_h}$ is regarded as the calibrated representative prototypes of both seen and unseen categories, with $\hat{\mathbf{r}}_k$ as the adjusted k-th prototype. The self-attentions used in Transformer is agile to capture the inter-class relationship of seen and unseen classes and thereby it is beneficial to derive globally discriminative prototypes. The prototype adaptations simultaneously update both seen and unseen classes, which enables the model to represent and discriminate the newly incoming categories in an on-the-fly manner.

3.4 Sample adaptation

As been discussed in (Chen et al., 2018), the zero-shot learning tasks are prone to produce semantics loss, where some features would be discarded during training if they are not discriminating for seen classes, but critical for recognizing unseen classes. We observe that the similar problem is exacerbated in GZSL task due to the extreme unbalance between seen and unseen classes. We tackle this problem by introducing sample adaptation following the trajectories of prototypes adaptation. In concrete, we apply a semantic update extractor via attention mechanism to capture synchronous updating of the prototypes:

$$\mathbf{F} = \mathbf{Z}\mathbf{W_1} \tag{4}$$

$$\mathbf{A} = \text{Softmax}(\mathbf{W_3}\text{ReLU}(\mathbf{W_2}\mathbf{F}^T)) \tag{5}$$

$$\mathbf{C} = \mathbf{A}\mathbf{F} \tag{6}$$

where $\mathbf{W_1} \in \mathbb{R}^{d_h \times d_h}, \mathbf{W_2} \in \mathbb{R}^{d_a \times d_h}, \mathbf{W_3} \in \mathbb{R}^{d_r \times d_a}$ are trainable parameters, $\mathbf{A}$ denotes the attention weight matrix and $\mathbf{C} \in \mathbb{R}^{d_r \times d_h}$ extracts different semantic components with $\mathbf{c}_l$ as its l-th semantic components. To offset the semantic loss mentioned above, we use these semantic components to guide the adaptation of sample embeddings. Concretely, we compare the attention score for each $\mathbf{h}_t$ to get the most related semantic adjustment and reconstruct the contribution of each word-level feature:

$$e_t = \text{Softmax}(\alpha \max_l(\frac{\mathbf{h}_t \mathbf{c}_l}{\|\mathbf{h}_t\| \|\mathbf{c}_l\|})) \tag{7}$$

$$g(x) = \sum_{t=1}^{T} e_t \mathbf{h}_t \tag{8}$$

where the self-attention weight e_t is used to reweight the t-th word of sample x to be classified, and α is a learnable temperature scalar to control the differentiation of Softmax scores (Gidaris and Komodakis, 2018). In this way, the different attention weights discriminate the importance of words rather than averaging them.

One notable reason of choosing of the above feature-level calibration is that, in classification task, the encoder is trained to produce feature embedding that collapses to its ground-truth prototype, therefore the adjustment of feature embedding should cater to the adjustment of a reliable global prototype space. In addition, since this calibration is applied after the encoding, it reduces the complicated parameter tuning for a massive encoder (*e.g.*, BERT), which elegantly helps the GZSL task to fast adapt to the incoming test instances.

3.5 Loss function

With the adapted prototypes $\hat{\mathbf{R}}$ and the adapted sample $g(x)$, a Softmax classifier is used:

$$p(\hat{y} = y \mid x) = \frac{\exp(s(g(x), \hat{\mathbf{r}}_y))}{\sum_{\hat{y}} \exp(s(g(x), \hat{\mathbf{r}}_{\hat{y}}))} \tag{9}$$

where $s(a, b) = \frac{\gamma \cdot ab}{\|a\| \|b\|}$ is cosine similarity with a learnable temperature scalar γ. Finally the model is trained by minimizing the losses across N episodes:

$$\mathcal{L} = \frac{1}{N} \sum_i \mathcal{L}_i \tag{10}$$

where $\mathcal{L}_i$ is the loss of the i-th episode:

$$\mathcal{L}_i = -\frac{1}{(N^s + N^u)K} \sum_{(x,y,a) \in \mathcal{D}_i^s \cup \mathcal{D}_i^u} \log p(\hat{y} = y \mid x) \tag{11}$$

The training process is summarized in Algorithm 1.

Algorithm 1: LTA training algorithm.

```
Input: distribution over tasks $p(\mathcal{T})$, class set $\mathcal{Y}^s$
Output: learned model parameters
while not done do
    Randomly sample a meta GZSL task $\mathcal{T}_i \sim p(\mathcal{T})$ with seen meta-test $\mathcal{D}_i^s$ and unseen meta-test $\mathcal{D}_i^u$.
    Get adapted prototypes $\hat{\mathbf{R}}$ by Eq 2~3.
    Get semantic components $\mathbf{C}$ by Eq 4~6.
    for all $\mathcal{D}_i^s \cup \mathcal{D}_i^u$ do
        Get adapted sample embeddings by Eq 7~8.
    end
    Update model by Eq 9~11.
end
```

4 Experiments

4.1 Datasets

Intent Classification Datasets. We collect four intent classification datasets. (1) **SNIPS-SLU** (Coucke et al., 2018), a widely used benchmark for English GZSL intent detection with 5 seen intents and 2 unseen intents. (2) **SMP-18** (Zhang et al., 2017), a Chinese dialogue corpus for user intent detection with 24 seen intents and 6 unseen intents. (3) **ATIS** (Hemphill et al., 1990), an English airline travel domain dataset, from which we extract 17 intents with at least 5 samples, and split them into 12 seen intents and 5 unseen intents. (4) **CLINC** (Larson et al., 2019) is a recently published intent detection dataset includes 22,500 in-scope queries covering 150 intent classes from 10 domains. We randomly split them into 120 seen intents and 30 unseen intents.

Question Classification Dataset. In order to draw a comprehensive analysis of the proposed method, we construct a question classification task from the Quora Question Pairs dataset [1], which is aimed to identify duplicate questions. We collect questions with at least 5 duplicate samples into classes. In each class, we choose the question with minimum words as the label description, called the standard question, which is widely used in real-world question-answering systems (Sakata et al., 2019). Table 1 summarizes all datasets statistics. It is worth to note that intents in ATIS are highly unbalanced with *flight* accounts for about 87% of training data.

Table 1: Dataset statistics. "FS" indicates "few-shot", "BAL" indicates "balance", "IBAL" indicates "imbalance". The "avg #samples" indicates the average number of samples per class.

Dataset	#classes		#samples		sent	type
	seen	unseen	total	avg	len	
SNIPS	5	2	13802	1384	9.10	BAL
SMP	24	6	2460	60	4.83	FS
ATIS	12	5	4972	245	11.44	IBAL
Clinc	120	30	22500	105	8.23	BAL
Quora	1360	340	17394	7	10.46	FS

Dataset Settings. Following (Siddique et al., 2021), we randomly sample seen and unseen classes for 10 runs instead of manual selection used in (Yan et al., 2020), which leads to more fair results because every class could be unseen class. We randomly take 70% samples of each seen class as the training set and the remaining 30% as the seen test, and take all the samples of unseen classes as the unseen test. All the textual labels of the same class are regarded as the description for this class.

4.2 Baseline Methods

To validate the benefits of the proposed LTA, we compare against with other approaches in three aspects:

Supervised Learning Methods. To show the performances on seen classes with supervised learning instead of GZSL setting, we use (1) **BiLSTM** (Schuster and Paliwal, 1997) and (2) **BERT** (Devlin et al., 2019) as the encoder with a linear Softmax classifier, which only requires samples and one-hot label.

Metric Learning Methods. Metric-based embedding methods are commonly used as baselines for GZSL. Thus we introduce three different metric learning methods: (1) **EucSoftmax**: We adapt (Snell et al., 2017) that uses squared Euclidean distance as the metric and Softmax classifies; (2) **Zero-shot DNN**: We adapt (Kumar et al., 2017) that uses squared Euclidean distance and triplet loss to maintain a margin for different classes. We choose the label embedding (prototype) as the anchor and the closest sample as negative sample in each triplet tuple; (3) **CosT**: We adapt (Gidaris and Komodakis, 2018) which uses cosine distance as the metric with a learnable temperature scalar.

SOTA Methods. We also compare our model with two recent state-of-the-art (SOTA) methods: (1) **ReCapsNet** (Liu et al., 2019) uses a dimensional attention-based intent capsule network and a matrix transformation method for GZSL. (2) **SEG** (Yan et al., 2020) is an outlier detection approach that can be directly applied on ReCapsNet. SEG acts as a domain discriminator which first determines whether a test sample belongs to seen classes or unseen classes and then classifies in their own domain. RIDE (Siddique et al., 2021) is not considered because they use outer knowledge that is not available in our settings, and they limit the intent labels to only two components "Action" and "Object".

4.3 Experimental Setup

Evaluation Metrics. We basically use accuracy (Acc) to estimate the performances on seen and unseen test sets. Besides, we adopt Macro-F1 (F1) rather than Micro-F1 to better evaluate the performances on imbalanced and few-shot datasets, because Macro-F1 gives the average weight of F1 scores for each class. For overall assessments, we adopt the widely used Harmonic Mean (HM) of

Acc and F1 on seen and unseen test sets rather than the overall metrics on the whole test set, because the overall metrics are disturbed by the ratio of seen and unseen test set sizes.

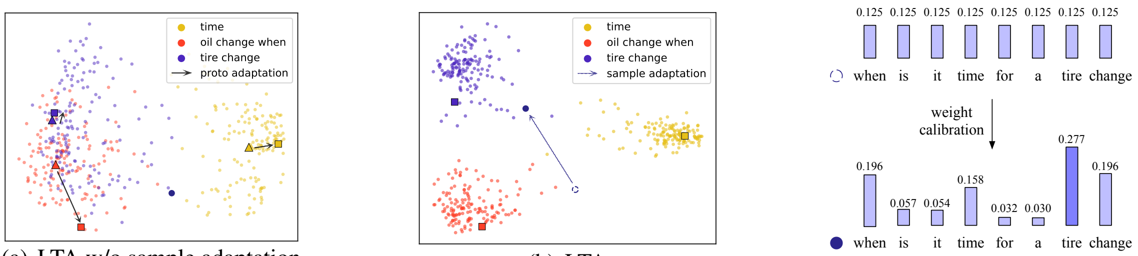
Implementation Details. We use the pretrained BERT-base encoder with $d_h = 768$ on intent classification datasets and BiLSTM with $d_h = 128$ hidden vector size each direction on Quora dataset. The scalars of our model is set to be $\alpha = 10.0, \tau = 10.0, d_a = d_h$, which is trained via Adam (Kingma and Ba, 2015) optimizer, with learning rates 10^{-5} for BERT encoder, 10^{-4} for BiLSTM encoder and 10^{-3} for the other parameters. We use $h = 4$ heads Transformer encoder layer in prototype adaptation. During training, in order to treat seen classes and unseen classes as equal, we set $N^{s_i} = N^{u_i}$ in every meta-test set, and we set $K = 5$ and $N^{s_i} = N^{u_i} = [2, 2, 2, 10, 20]$, $d_r = [4, 16, 32, 64, 64]$ for SNIPS-NLU, SMP-18, ATIS, CLINC and Quora datasets, respectively.

We also conduct an ablation study to investigate the effectiveness of each proposed component. As depicted in Table 2 and Table 3, "w / o Init" refers to the model that randomly initializes $\mathbf{R}$ rather than pretrained prototypes. "w / o SA" refers to the model that only uses prototype adaptation without "sample adaptation". "w / o A" means none of the adaptation steps is applied.

4.4 Results

The results on four intent datasets and Quora dataset are given in Table 2 and Table 3, respectively. It is observed that our proposed methods achieve the overall best performances compared to baselines.

Detailed and interesting observations can also be derived from the results: (1) The metric-learning methods as the basic baselines, achieve compa-

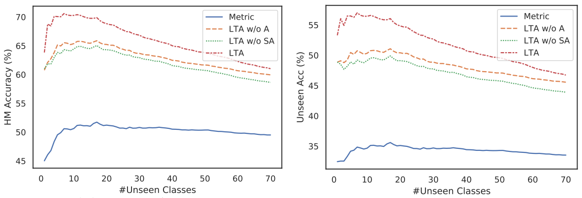


(a) LTA w/o sample adaptation (b) LTA (c) example

Figure 2: PCA plots of encoded unseen sample representations(·) and prototype representations(■) from (a) LTA w/o sample adaptation model and (b) full LTA model with sample adaptation (c) is an unseen example with sample-level raw attention and adapted attention. ▲ denotes the raw prototype before adaptation. ○ and ● respectively denote the example representations before and after sample adaptation.

rable results on *Seen Test* for all datasets. However, they all suffer from the domain bias problem and the performance drops with a large margin on *Unseen Test*, where the prediction is complicated due to zero-shot scenarios. (2) The performances on SNIPS-NLU and SMP-18 of ReCapsNet and SEG are worse than those in their original paper although we use the open-source codes in our experiments, that is because we randomly split the test unseen classes thus making it more challenging. Besides, these methods fail to recognize unseen samples well on datasets with a large scale of categories, yielding worse 0% Acc and F1 on Quora. The most likely reason is that ReCapsNet uses label embedding similarities to construct unseen prototypes in capsule network, which imposes a non-trivial computational and memory burden. (3) Our method shows its privilege for all datasets. In particular, with the help of continuous adapting ability, it observes a smaller gap between seen and unseen domains, which proves the adaptation on the testing phase effectively works. Although the performance on seen domain drops sightly, LTA outperforms the competitive metric-learning baselines by 9.54% HM Acc and 12.90% HM F1 averagely on the whole datasets, indicating that our model fairly balances the seen and unseen classes.

Ablation Study. To better understand the contribution of each component of our method, we explore three variants of LTA. We can observe that LTA with both prototype adaptation and sample adaptation outperforms those without any adaptation step in all cases. The "LTA w / o Init" has relatively stable performances. Note that "LTA w / o SA" with only prototype adaptation achieves worse performance compared to "LTA w / o A" on SNIPS-NLU, SMP-18 and CLINC. It indicates that the single prototype adaptation step may cause negative transfer, further illustrating the importance of the sample adaptation.



(a) HM Acc. (b) Unseen Acc.

Figure 3: The performance with increasing numbers of test unseen classes on CLINC dataset.

4.5 Results on Emerging Unseen Classes

As the partition of seen and unseen classes is fixed in previous experiments, to study the robustness of the proposed adaptation method, we conduct the experiment across unseen class sets of different scales on CLINC dataset. Specifically, we select 70 classes as seen classes and 10 classes as validating unseen classes. The number of testing unseen classes is varied from 1 to 70, which are randomly sampled from the remaining 70 classes. Each experiment is repeated 50 times with different sampling sets for a more stable result. Figure 3 (a) shows the HM accuracy on all classes as the number of the unseen classes increases. We can see that our LTA model outperforms the metric learning baseline and ablation models in all cases, where the improved performance is mainly attributed to the improvements on unseen classes as shown in Figure 3 (b). These results suggest that our adaptation method is robust and effective for adapting to increasing new classes as well as improving the overall performance of all classes.

4.6 Visualization

To demonstrate how our adaptation method works, we further visualize the encoded representation via PCA in Figure 2. When there is no unseen class, seen classes (yellow and red) is discriminative enough. But when the new class "tire change" (purple) comes, it is ambiguous with class "oil change when" (red). We observe that the seen and unseen class prototypes are updated to be far away from each other after prototype adaptation as shown in (a), which eases the domain bias problem. However, the performance is unsatisfactory since the sample representations are still not discriminative no matter how the prototype updates. As we can see, with the sample adaptation as shown in (b), the sample representations are independently clustered by the adapted prototypes and easy to be distinguished.

To further study how the sample adaptation works, we select a representative case "when is it time for a tire change" and show its attention weights used as calibration parameters in (c). The case is still misclassified after the prototype adaptation due that the common word "time" and "change" also appear in seen classes. After the sample adaptation, however, it can be seen that the word "tire" which is a keyword for classifying, gets the highest attention while the other confusing words do not. This result suggests that calibrating using attention weights helps acquire a prototype-aware representation that guides the sample adaptation.

5 Conclusion

This paper proposed a novel adaptive meta-learning network for generalized zero-shot text classification. The model was trained under a consistent setting with testing. In particular, it efficiently alleviated the bias towards seen classes by utilizing both prototype adaptation and sample adaptation. Experiments on five text classification datasets validated that our model achieved compelling results on both seen classes and unseen classes meanwhile was capable of fast adapting to new classes.

Abstract

Understanding tables is an important aspect of natural language understanding. Existing models for table understanding require linearization of the table structure, where row or column order is encoded as an *unwanted* bias. Such spurious biases make the model vulnerable to row and column order perturbations. Additionally, prior work has not thoroughly modeled the table structures or table-text alignments, hindering the table-text understanding ability. In this work, we propose a robust and structurally aware table-text encoding architecture TableFormer, where tabular structural biases are incorporated completely through learnable attention biases. TableFormer is (1) strictly invariant to row and column orders, and, (2) could understand tables better due to its tabular inductive biases. Our evaluations showed that TableFormer outperforms strong baselines in all settings on SQA, WTQ and TabFact table reasoning datasets, and achieves state-of-the-art performance on SQA, especially when facing answer-invariant row and column order perturbations (6% improvement over the best baseline), because previous SOTA models' performance drops by 4% - 6% when facing such perturbations while TableFormer is not affected.[1]

1 Introduction

Recently, semi-structured data (e.g. variable length tables without a fixed data schema) has attracted more attention because of its ubiquitous presence on the web. On a wide range of various table reasoning tasks, Transformer based architecture along with pretraining has shown to perform well (Eisenschlos et al., 2021; Liu et al., 2021).

In a nutshell, prior work used the Transformer architecture in a BERT like fashion by serializing tables or rows into word sequences (Yu et al., 2020; Liu et al., 2021), where original position ids are used as positional information. Due to the usage of row/column ids and global position ids, prior strategies to linearize table structures introduced spurious row and column order biases (Herzig et al., 2020; Eisenschlos et al., 2020, 2021; Zhang et al., 2020; Yin et al., 2020). Therefore, those models are vulnerable to row or column order perturbations. But, ideally, the model should make consistent predictions regardless of the row or column ordering for all practical purposes. For instance, in Figure 1, the predicted answer of Tapas model (Herzig et al., 2020) for Question (a) *"Of all song lengths, which one is the longest?"* based on the original table is *"5:00"*, which is incorrect. However, if the first row is adjusted to the end of the table during inference, the model gives the correct length *"5:02"* as an-

Title	Length
Screwed Up	**5:02**
Ghetto Queen	5:00

Question: Of all song lengths, which one is the longest?
Gold Answer: 5:02
TAPAS: 5:00
TAPAS after row order perturbation: 5:02
TableFormer: 5:02

(a) Tapas predicts incorrect answer based on the original table, while it gives the correct answer if the first row is moved to the end of the table.

Nation	Gold	Silver	Bronze
Great Britain	2	1	2
Spain	**1**	**2**	**0**
Ukraine	**0**	**2**	**0**

Question: Which nation received 2 silver medals?
Gold Answer: Spain, Ukraine
TAPAS: Spain
TableFormer: Spain, Ukraine
TableFormer w/o a proposed structural bias: Spain

(b) Tapas gives incomplete answer due to its limited cell grounding ability.

Figure 1: Examples showing the limitations of existing models (a) vulnerable to perturbations, and (b) lacking structural biases. In contrast, our proposed TableFormer predicts correct answers for both questions.

---

swer. This probing example shows that the model being aware of row order information is inclined to select length values to the end of the table due to spurious training data bias. In our experiments on the SQA dataset, TAPAS models exhibit a 4% - 6% (Section 5.2) absolute performance drop when facing such answer-invariant perturbations.

Besides, most prior work (Chen et al., 2020; Yin et al., 2020) did not incorporate enough structural biases to models to address the limitation of sequential Transformer architecture, while others inductive biases which are either too strict (Zhang et al., 2020; Eisenschlos et al., 2021) or computationally expensive (Yin et al., 2020).

To this end, we propose TABLEFORMER, a Transformer architecture that is robust to row and column order perturbations, by incorporating structural biases more naturally. TABLEFORMER relies on 13 types of task-independent table↔text attention biases that respect the table structure and table-text relations. For Question (a) in Figure 1, TABLEFORMER could predict the correct answer regardless of perturbation, because the model could identify the same row information with our *"same row"* bias, avoiding spurious biases introduced by row and global positional embeddings. For Question (b), TAPAS predicted only partially correct answer, while TABLEFORMER could correctly predict *"Spain, Ukraine"* as answers. That's because our *"cell to sentence"* bias could help table cells ground to the paired sentence. Detailed attention bias types are discussed in Section 5.2.

Experiments on 3 table reasoning datasets show that TABLEFORMER consistently outperforms original TAPAS in all pretraining and intermediate pretraining settings with fewer parameters. Also, TABLEFORMER's invariance to row and column perturbations, leads to even larger improvement over those strong baselines when tested on perturbations. Our contributions are as follows:

- We identified the limitation of current table-text encoding models when facing row or column perturbation.
- We propose TABLEFORMER, which is guaranteed to be invariant to row and column order perturbations, unlike current models.
- TABLEFORMER encodes table-text structures better, leading to SoTA performance on SQA dataset, and ablation studies show the effectiveness of the introduced inductive biases.

2 Preliminaries: TAPAS for Table Encoding

In this section, we discuss TAPAS which serves as the backbone of the recent state-of-the-art table-text encoding architectures. TAPAS (Herzig et al., 2020) uses Transformer architecture in a BERT like fashion to pretrain and finetune on tabular data for table-text understanding tasks. This is achieved by using linearized table and texts for masked language model pre-training. In the fine-tuning stage, texts in the linearized table and text pairs are queries or statements in table QA or table-text entailment tasks, respectively.

Specifically, TAPAS uses the tokenized and flattened text and table as input, separated by `[SEP]` token, and prefixed by `[CLS]`. Besides token, segment, and global positional embedding introduced in BERT (Devlin et al., 2019), it also uses rank embedding for better numerical understanding. Moreover, it uses column and row embedding to encode table structures.

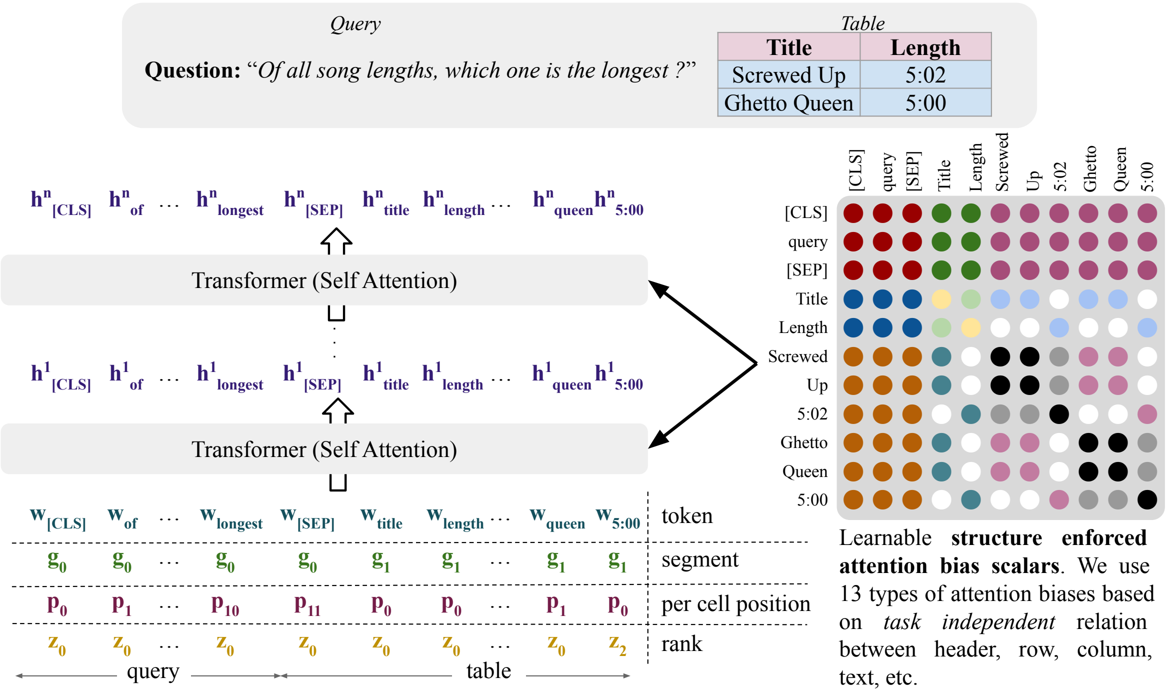
Concretely, for any table-text linearized sequence $S = \{v_1, v_2, \cdots, v_n\}$, where n is the length of table-text sequence, the input to TAPAS is summation of embedding of the following:

$$\begin{aligned}
\text{token ids } (W) &= \{w_{v_1}, w_{v_2}, \cdots, w_{v_n}\} \\
\text{positional ids } (B) &= \{b_1, b_2, \cdots, b_n\} \\
\text{segment ids } (G) &= \{g_{seg_1}, g_{seg_2}, \cdots, g_{seg_n}\} \\
\text{column ids } (C) &= \{c_{col_1}, c_{col_2}, \cdots, c_{col_n}\} \\
\text{row ids } (R) &= \{r_{row_1}, r_{row_2}, \cdots, r_{row_n}\} \\
\text{rank ids } (Z) &= \{z_{rank_1}, z_{rank_2}, \cdots, z_{rank_n}\}
\end{aligned}$$

where seg_i, col_i, row_i, $rank_i$ correspond to the segment, column, row, and rank id for the ith token, respectively.

As for the model, TAPAS uses BERT's self-attention architecture (Vaswani et al., 2017) off-the-shelf. Each Transformer layer includes a multi-head self-attention sub-layer, where each token attends to all the tokens. Let the layer input $H = [h_1, h_2, \cdots, h_n]^\top \in \mathbb{R}^{n \times d}$ corresponding to S, where d is the hidden dimension, and $h_i \in \mathbb{R}^{d \times 1}$ is the hidden representation at position i. For a single-head self-attention sub-layer, the input H is projected by three matrices $W^Q \in \mathbb{R}^{d \times d_K}$, $W^K \in \mathbb{R}^{d \times d_K}$, and $W^V \in \mathbb{R}^{d \times d_V}$ to the corresponding representations Q, K, and V:

$$Q = HW^Q, \quad V = HW^V, \quad K = HW^K \quad (1)$$



Learnable **structure enforced attention bias scalars**. We use 13 types of attention biases based on *task independent* relation between header, row, column, text, etc.

Figure 2: TableFormer input and attention biases in the self attention module. This example corresponds to table (a) in Figure 1 and its paired question "query". Different colors in the attention bias matrix denote different types of task independent biases derived based on the table structure and the associated text.

Then, the output of this single-head self-attention sub-layer is calculated as:

$$\mathrm{Attn}(H) = \mathrm{softmax}\left(\frac{QK^\top}{\sqrt{d_K}}\right)V \qquad (2)$$

3 TableFormer: Robust Structural Table Encoding

As shown in Figure 2, TableFormer encodes the general table structure along with the associated text by introducing task-independent relative attention biases for table-text encoding to facilitate the following: (a) structural inductive bias for better table understanding and table-text alignment, (b) robustness to table row/column perturbation.

Input of TableFormer. TableFormer uses the same token embeddings W, segment embeddings G, and rank embeddings Z as Tapas. However, we make 2 major modifications:

1) No row or column ids. We do not use row embeddings R or column embeddings C to avoid any potential spurious row and column order biases.

2) Per cell positional ids. To further remove any inter-cell order information, global positional embeddings B are replaced by per cell positional embeddings $P = \{p_{pos_1}, p_{pos_2}, \cdots, p_{pos_n}\}$, where we follow Eisenschlos et al. (2021) to reset the index of positional embeddings at the beginning of each cell, and pos_i correspond to the per cell positional id for the ith token.

Positional Encoding in TableFormer. Note that the Transformer model either needs to specify different positions in the input (i.e. absolute positional encoding of Vaswani et al. (2017)) or encode the positional dependency in the layers (i.e. relative positional encoding of Shaw et al. (2018)).

TableFormer does not consume any sort of column and row order information in the input. The main intuition is that, for cells in the table, the only useful positional information is whether two cells are in the same row or column and the column header of each cell, instead of the absolute order of the row and column containing them. Thus, inspired by relative positional encoding (Shaw et al., 2018) and graph encoding (Ying et al., 2021), we capture this with a same column/row relation as one kind of relative position between two linearized tokens. Similarly, we uses 12 such table-text structure relevant relations (including same cell, cell to header and so on) and one extra type representing all other relations not explicitly defined. All of them are introduced in the form of learnable attention bias scalars.

Formally, we consider a function $\phi(v_i, v_j) : V \times V \rightarrow \mathbb{N}$, which measures the relation between v_i and v_j in the sequence ($v_i, v_j \in S$). The function ϕ can be defined by any relations between the tokens in the table-text pair.

Attention Biases in TABLEFORMER. In our work, $\phi(v_i, v_j)$ is chosen from 13 bias types, corresponding to 13 table-text structural biases. The attention biases are applicable to any table-text pair and can be used for any downstream task:

- *"same row"* identifies the same row information without ordered row id embedding or global positional embedding, which help the model to be invariant to row perturbations,
- *"same column"*, *"header to column cell"*, and *"cell to column header"* incorporates the same column information without ordered column id embedding,
- *"cell to column header"* makes each cell aware of its column header without repeated column header as features,
- *"header to sentence"* and *"cell to sentence"* help column grounding and cell grounding of the paired text,
- *"sentence to header"*, *"sentence to cell"*, and *"sentence to sentence"* helps to understand the sentence with the table as context,
- *"header to same header"* and *"header to other header"* for better understanding of table schema, and *"same cell bias"* for cell content understanding.

Note that, each cell can still attend to other cells in the different columns or rows through *"others"* instead of masking them out strictly.

We assign each bias type a learnable scalar, which will serve as a bias term in the self-attention module. Specifically, each self-attention head in each layer have a set of learnable scalars $\{b_1, b_2, \cdots, b_{13}\}$ corresponding to all types of introduced biases. For one head in one self-attention sub-layer of TABLEFORMER, Equation 2 in the Transformer is replaced by:

$$\bar{A} = \frac{QK^\top}{\sqrt{d_K}}, \quad A = \bar{A} + \hat{A} \tag{3}$$

$$\text{Attn}(H) = \text{softmax}(A)V \tag{4}$$

where $\bar{A}$ is a matrix capturing the similarity between queries and keys, $\hat{A}$ is the Attention Bias Matrix, and $\hat{A}_{i,j} = b_{\phi(v_i,v_j)}$.

Relation between TABLEFORMER and ETC. ETC (Ainslie et al., 2020) uses vectors to represent relative position labels, although not directly applied to table-text pairs due to its large computational overhead (Eisenschlos et al., 2021). TABLEFORMER differs from ETC in the following aspects (1) ETC uses relative positional embeddings while TABLEFORMER uses attention bias scalars. In practice, we observed that using relative positional embeddings increases training time by more than 7x, (2) ETC uses global memory and local attention, while TABLEFORMER uses pairwise attention without any global memory overhead, (3) ETC uses local sparse attention with masking, limiting its ability to attend to all tokens, (4) ETC did not explore table-text attention bias types exhaustively. Another table encoding model MATE (Eisenschlos et al., 2021) is vulnerable to row and column perturbations, and shares limitation (3) and (4).

4 Experimental Setup

4.1 Datasets and Evaluation

We use the following datasets in our experiments.

Table Question Answering. For the table QA task, we conducted experiments on WikiTableQuestions (WTQ) (Pasupat and Liang, 2015) and Sequential QA (SQA) (Iyyer et al., 2017) datasets. WTQ was crowd-sourced based on complex questions on Wikipedia tables. SQA is composed of $6,066$ question sequences (2.9 question per sequence on average), constructed by decomposing a subset of highly compositional WTQ questions.

Table-Text Entailment. For the table-text entailment task, we used TABFACT dataset (Chen et al., 2020), where the tables were extracted from Wikipedia and the sentences were written by crowd workers. Among total $118,\ 000$ sentences, each one is a positive (entailed) or negative sentence.

Perturbation Evaluation Set. For SQA and TABFACT, we also created new test sets to measure models' robustness to answer-invariant row and column perturbations during inference. Specifically, row and column orders are randomly perturbed for all tables in the standard test sets.[2]

Pre-training All the models are first tuned on the *Wikipidia* text-table pretraining dataset (Herzig et al., 2020), optionally tuned on synthetic dataset at an intermediate stage ("inter") (Eisenschlos et al., 2020), and finally fine-tuned on the target dataset. To get better performance on WTQ, we follow Herzig et al. (2020) to further pretrain on SQA dataset after the intermediate pretraining stage in the "inter-sqa" setting.

Evaluation For SQA, we report the cell selection accuracy for all questions (ALL) using the official evaluation script, cell selection accuracy for all sequences (SEQ), and the denotation accuracy for all questions (ALL$_{\text{d}}$). To evaluate the models' robustness in the instance level after perturbations, we also report a lower bound of example prediction variation percentage:

$$VP = \frac{(\text{t2f} + \text{f2t})}{(\text{t2t} + \text{t2f} + \text{f2t} + \text{f2f})} \tag{5}$$

where t2t, t2f, f2t, and f2f represents how many example predictions turning from correct to correct, from correct to incorrect, from incorrect to correct and from incorrect to incorrect, respectively, after perturbation. We report denotation accuracy on WTQ and binary classification accuracy on TABFACT respectively.

4.2 Baselines

We use TAPAS$_{\text{BASE}}$ and TAPAS$_{\text{LARGE}}$ as baselines, where Transformer architectures are exactly same as BERT$_{\text{BASE}}$ and BERT$_{\text{LARGE}}$ (Devlin et al., 2019), and parameters are initialized from BERT$_{\text{BASE}}$ and BERT$_{\text{LARGE}}$ respectively. Correspondingly, we have our TABLEFORMER$_{\text{BASE}}$ and TABLEFORMER$_{\text{LARGE}}$, where attention bias scalars are initialized to zero, and all other parameters are initialized from BERT$_{\text{BASE}}$ and BERT$_{\text{LARGE}}$.

4.3 Perturbing Tables as Augmented Data

Could we alleviate the spurious ordering biases by data augmentation alone, without making any modeling changes? To answer this, we train another set of models by augmenting the training data for TAPAS through random row and column order perturbations.[3]

	Before Perturb			**After Perturb**	
	ALL	SEQ	ALL$_{\text{d}}$	ALL	VP
Herzig et al. (2020)	67.2	40.4	–	–	–
Eisenschlos et al. (2020)	71.0	44.8	–	–	–
Eisenschlos et al. (2021)	71.7	46.1	–	–	–
Liu et al. (2021)	–	–	74.5	–	–
TAPAS$_{\text{BASE}}$	61.1	31.3	–	57.4	14.0%
TABLEFORMER$_{\text{BASE}}$	**66.7**	**39.7**	–	**66.7**	**0.2%**
TAPAS$_{\text{LARGE}}$	66.8	39.9	–	60.5	15.1%

TAPAS$_{\text{BASE}}$ inter	67.5	38.8	–	61.0	14.3%
TABLEFORMER$_{\text{BASE}}$ inter	**69.4**	**43.5**	–	**69.3**	**0.1%**
TAPAS$_{\text{LARGE}}$ inter	70.6	43.9	–	66.1	10.8%
TABLEFORMER$_{\text{LARGE}}$ inter	**72.4**	**47.5**	**75.9**	**72.3**	**0.1%**

Table 1: Results on SQA test set before and after perturbation during inference (median of 5 runs). ALL is cell selection accuracy, SEQ is cell selection accuracy for all question sequences, ALL$_{\text{d}}$ is denotation accuracy for all questions (reported to compare with Liu et al. (2021)). VP is model prediction variation percentage after perturbation. Missing values are those not reported in the original paper.

For each table in the training set, we randomly shuffle all rows and columns (including corresponding column headers), creating a new table with the same content but different orders of rows and columns. Multiple perturbed versions of the same table were created by repeating this process $\{1, 2, 4, 8, 16\}$ times with different random seeds. For table QA tasks, selected cell positions are also adjusted as final answers according to the perturbed table. The perturbed table-text pairs are then used to augment the data used to train the model. During training, the model takes data created by one specific random seed in one epoch in a cyclic manner.

5 Experiments and Results

Besides standard testing results to compare TABLEFORMER and baselines, we also answer the following questions through experiments:

- How robust are existing (near) state-of-the-art table-text encoding models to semantic preserving perturbations in the input?
- How does TABLEFORMER compare with existing table-text encoding models when tested on similar perturbations, both in terms of performance and robustness?

---

[2] We fixed perturbation random seeds to make our results reproducible.

[3] By perturbation, we mean shuffling row and columns instead of changing/swapping content blindly.

- Can we use perturbation based data augmentation to achieve robustness at test time?

- Which attention biases in TABLEFORMER contribute the most to performance?

5.1 Main Results

Table 1, 2, and 3 shows TABLEFORMER performance on SQA, TABFACT, and WTQ, respectively. As can be seen, TABLEFORMER outperforms corresponding TAPAS baseline models in all settings on SQA and WTQ datasets, which shows the general effectiveness of TABLEFORMER's structural biases in Table QA datasets. Specifically, TABLEFORMER$_{\text{LARGE}}$ combined with intermediate pretraining achieves new state-of-the-art performance on SQA dataset.

Similarly, Table 2 shows that TABLEFORMER also outperforms TAPAS baseline models in all settings, which shows the effectiveness of TABLEFORMER in the table entailment task. Note that, Liu et al. (2021) is not comparable to our results, because they used different pretraining data, different pretraining objectives, and BART NLG model instead of BERT NLU model. But TABLEFORMER attention bias is compatible with BART model.

5.2 Perturbation Results

One of our major contributions is to systematically evaluate models' performance when facing row and column order perturbation in the testing stage.

Ideally, model predictions should be consistent on table QA and entailment tasks when facing such perturbation, because the table semantics remains the same after perturbation.

However, in Table 1 and 2, we can see that in our perturbed test set, performance of all TAPAS models drops significantly in both tasks. TAPAS models drops by at least 3.7% and up to 6.5% in all settings on SQA dataset in terms of ALL accuracy, while our TABLEFORMER being strictly invariant to such row and column order perturbation leads to no drop in performance.[4] Thus, in the perturbation setting, TABLEFORMER outperforms all TAPAS baselines even more significantly, with at least 6.2% and 2.4% improvements on SQA and TABFACT dataset, respectively. In the instance level, we can see that, with TAPAS, there are many example predictions changed due to high VP, while there is nearly no example predictions changed with TABLEFORMER (around zero VP).

---

[4] In SQA dataset, there is at most absolute 0.1% performance drop because of some bad data point issues. Specifically, some columns in certain tables are exactly the same, but the ground-truth selected cells are in only one of such columns. TABLEFORMER would select from one column randomly.

Model	Number of parameters
TAPAS$_{\text{BASE}}$	110 M
TABLEFORMER$_{\text{BASE}}$	110 M - 2*512*768 + 12*12*13 = 110 M - 0.8 M + 0.002 M
TAPAS$_{\text{LARGE}}$	340 M
TABLEFORMER$_{\text{LARGE}}$	340 M - 2*512*1024 + 24*16*13 = 340 M - 1.0 M + 0.005M

Table 4: Model size comparison.

5.3 Model Size Comparison

We compare the model sizes of TABLEFORMER and TAPAS in Table 4. We added only a few attention bias scalar parameters (13 parameters per head per layer) in TABLEFORMER, which is negligible compared with the BERT model size. Meanwhile, we delete two large embedding metrics (512 row ids and 512 column ids). Thus, TABLEFORMER outperforms TAPAS with fewer parameters.

5.4 Analysis of TABLEFORMER Submodules

In this section, we experiment with several variants of TABLEFORMER to understand the effectiveness of its submodules. The performance of all variants of TAPAS and TABLEFORMER that we tried on the SQA development set is shown in Table 5.

Learnable Attention Biases v/s Masking. Instead of adding learnable bias scalars, we mask out some attention scores to restrict attention to those tokens in the same columns and rows, as well as the paired sentence, similar to Zhang et al. (2020) (SAT). We can see that TAPAS$_{\text{BASE-SAT}}$ performs worse than TAPAS$_{\text{BASE}}$, which means that restricting attention to only same columns and rows by masking reduce the modeling capacity. This led to choosing soft bias addition over hard masking.

Attention Bias Scaling. Unlike TABLEFORMER, we also tried to add attention biases before the scaling operation in the self-attention module (SO). Specifically, we compute pair-wise attention score by:

$$A_{ij} = \frac{(h_i^\top W^Q)(h_j^\top W^K)^\top + \hat{A}_{ij}}{\sqrt{d_K}} \qquad (6)$$

instead of using:

$$A_{ij} = \frac{(h_i^\top W^Q)(h_j^\top W^K)^\top}{\sqrt{d_K}} + \hat{A}_{ij}, \qquad (7)$$

which is the element-wise version of Equation 1 and 3. However, Table 5 shows that TABLEFORMER$_{\text{BASE-SO}}$ performs worse than TABLEFORMER$_{\text{BASE}}$, showing the necessity of adding attention biases after the scaling operation. We think the reason is that the attention bias term does not require scaling, because attention bias scalar magnitude is independent of d_K, while the dot products grow large in magnitude for large values of d_K. Thus, such bias term could play an more important role without scaling, which helps each attention head know clearly what to pay more attention to according to stronger inductive biases.

	rc-gp	*c-gp*	*gp*	*pcp*
TAPAS$_{\text{BASE}}$	57.6	47.4	46.4	29.1
TAPAS$_{\text{BASE-SAT}}$	45.2	-	-	-
TABLEFORMER$_{\text{BASE-SO}}$	60.0	60.2	59.8	60.7
TABLEFORMER$_{\text{BASE}}$	62.2	61.5	61.7	61.9

Table 5: ALL questions' cell selection accuracy of TABLEFORMER variants on SQA development set. *rc-gp* represents the setting including row ids, column ids and global positional ids, *c-gp* represents column ids and global positional ids, *gp* represents global positional ids, and *pcp* represents per-cell positional ids. "SAT" represents masking out some attention scores. "SO" represents adding attention bias before scaling.

Row, Column, & Global Positional IDs. With TAPAS$_{\text{BASE}}$, TABLEFORMER$_{\text{BASE-SO}}$, and TABLEFORMER$_{\text{BASE}}$, we first tried the full-version where row ids, column ids, and global positional ids exist as input (*rc-gp*). Then, we deleted row ids (*c-gp*), and column ids (*gp*) sequentially. Finally, we changed global positional ids in *gp* to per-cell positional ids (*pcp*). Table 5 shows that TAPAS$_{\text{BASE}}$ performs significantly worse from *rc-gp* $\rightarrow$ *c-gp* $\rightarrow$ *gp* $\rightarrow$ *pcp*, because table structure information are deleted sequentially during such process. However, with TABLEFORMER$_{\text{BASE}}$, there is no obvious performance drop during the same process. That shows the structural inductive biases in TABLEFORMER can provide complete table structure information. Thus, row ids, column ids and global positional ids are not necessary in TABLEFORMER. We pick TABLEFORMER *pcp* setting as our final version to conduct all other experiments in this paper. In this way, TABLEFORMER is strictly invariant to row and column order perturbation by avoiding spurious biases in those original ids.

	Befor Perturb		**After Perturb**	
	ALL	SEQ	ALL	VP
TAPAS$_{\text{BASE}}$	61.1	31.3	57.4	14.0%
TAPAS$_{\text{BASE}}$ 1p	63.4	34.6	63.4	9.9%
TAPAS$_{\text{BASE}}$ 2p	64.6	35.6	64.5	8.4%
TAPAS$_{\text{BASE}}$ 4p	65.1	37.0	65.0	8.1%
TAPAS$_{\text{BASE}}$ 8p	65.1	37.3	64.3	7.2%
TAPAS$_{\text{BASE}}$ 16p	62.4	33.6	62.2	7.0%
TABLEFORMER$_{\text{BASE}}$	**66.7**	**39.7**	**66.7**	**0.1%**

Table 6: Comparison of TABLEFORMER and perturbed data augmentation on SQA test set, where VP represents model prediction variation percentage after perturbation. Median of 5 independent runs are reported.

5.5 Comparison of TABLEFORMER and Perturbed Data Augmentation

As stated in Section 4.3, perturbing row and column orders as augmented data during training can serve as another possible solution to alleviate the spurious row/column ids bias. Table 6 shows the performance of TABPAS$_{\text{BASE}}$ model trained with additional $\{1, 2, 4, 8, 16\}$ perturbed versions of each table as augmented data.

We can see that the performance of TAPAS$_{\text{BASE}}$ on SQA dataset improves with such augmentation. Also, as the number of perturbed versions of each table increases, model performance first increases and then decreases, reaching the best results with 8 perturbed versions. We suspect that too many versions of the same table confuse the model about different row and column ids for the same table, leading to decreased performance from 8p to 16p. Despite its usefulness, such data perturbation is still worse than TABLEFORMER, because it could not incorporate other relevant text-table structural inductive biases like TABLEFORMER.

Although, such data augmentation makes the model more robust to row and column order perturbation with smaller VP compared to standard TAPAS$_{\text{BASE}}$, there is still a significant prediction drift after perturbation. As shown in Table 6, VP decreases from 1p to 16p, however, the best VP (7.0%) is still much higher than (nearly) no variation (0.1%) of TABLEFORMER.

To sum up, TABLEFORMER is superior to row and column order perturbation augmentation, because of its additional structural biases and strictly consistent predictions after perturbation.

	ALL	SEQ
TABLEFORMER$_{\text{BASE}}$	**62.1**	**38.4**
- Same Row	32.1	2.8
- Same Column	**62.1**	37.7

- Sentence to Cell	60.8	36.2
- Sentence to Header	61.0	37.3
- Sentence to Sentence	60.0	35.3
- All Column Related (# 2, 4, 6)	54.5	29.3

Table 7: Ablation study of proposed attention biases.

5.6 Attention Bias Ablation Study

We conduct ablation study to demonstrate the utility of all 12 types of defined attention biases. For each ablation, we set the corresponding attention bias type id to *"others"* bias id. Table 7 shows TAPAS$_{\text{BASE}}$'s performance SQA dev set. Overall, all types of attention biases help the TABLEFORMER performance to some extent, due to certain performance drop after deleting each bias type.

Amongst all the attention biases, deleting *"same row"* bias leads to most significant performance drop, showing its crucial role for encoding table row structures. There is little performance drop after deleting *"same column"* bias, that's because TABLEFORMER could still infer the same column information through *"cell to its column header"* and *"header to its column cell"* biases. After deleting all same column information (*"same column"*, *"cell to column header"* and *"header to column cell"* biases), TABLEFORMER performs significantly worse without encoding column structures. Similarly, there is little performance drop after deleting *"same cell"* bias, because TABLEFORMER can still infer same cell information through *"same row"* and *"same column"* biases.

5.7 Limitations of TABLEFORMER

TABLEFORMER increases the training time by around 20%, which might not be ideal for very long tables and would require a scoped approach. Secondly, with the strict row and column order invariant property, TABLEFORMER cannot deal with questions based on absolute orders of rows in tables. This however is not a practical requirement based on the current dataset. Doing a manual study of 1800 questions in SQA dataset, we found that there are 4 questions[5] (0.2% percentage) whose answers depend on orders of rows. Three of them asked *"which one is at the top of the table"*, another asks *"which one is listed first"*. However, these questions could be potentially answered by adding back row and column order information based on TABLEFORMER.

6 Other Related Work

Transformers for Tabular Data. Yin et al. (2020) prepended corresponding column headers to cells contents, and Chen et al. (2020) used corresponding column headers as features for cells. However, such methods encode each table header multiple times, leading to duplicated computing overhead. Also, tabular structures (e.g. same row information) are not fully incorporated to such models. Meanwhile, Yin et al. (2020) leveraged row encoder and column encoder sequentially, which introduced much computational overhead, thus requiring retrieving some rows as a preprocessing step. Finally, SAT (Zhang et al., 2020), Deng et al. (2021) and Wang et al. (2021) restricted attention to same row or columns with attention mask, where such inductive bias is too strict that cells could not directly attend to those cells in different row and columns, hindering the modeling ability according to Table 5. Liu et al. (2021) used the seq2seq BART generation model with a standard Transformer encoder-decoder architecture. In all models mentioned above, spurious inter-cell order biases still exist due to global positional ids of Transformer, leading to the vulnerability to row or column order perturbations, while our TABLEFORMER could avoid such problem. Mueller et al. (2019) and Wang et al. (2020) also used relative positional encoding to encode table structures, but they modeled the relations as learnable relation vectors, whose large overhead prevented pretraining and led to poor performance without pretraining, similarly to ETC (Ainslie et al., 2020) explained in Section 3.

Structural and Relative Attention. Modified attention scores has been used to model relative positions (Shaw et al., 2018), long documents (Dai et al., 2019; Beltagy et al., 2020; Ainslie et al., 2020), and graphs (Ying et al., 2021). But adding learnable attention biases to model tabular structures has been under-explored.

7 Conclusion

In this paper, we identified the vulnerability of prior table encoding models along two axes: (a) capturing the structural bias, and (b) robustness to row and column perturbations. To tackle this, we propose TABLEFORMER, where learnable task-independent learnable structural attention biases are introduced, while making it invariant to row/column order at the same time. Experimental results showed that TABLEFORMER outperforms strong baselines in 3 table reasoning tasks, achieving state-of-the-art performance on SQA dataset, especially when facing row and column order perturbations, because of its invariance to row and column orders.

Abstract

Text-based games provide an interactive way to study natural language processing. While deep reinforcement learning has shown effectiveness in developing the game playing agent, the low sample efficiency and the large action space remain to be the two major challenges that hinder the DRL from being applied in the real world. In this paper, we address the challenges by introducing world-perceiving modules, which automatically decompose tasks and prune actions by answering questions about the environment. We then propose a two-phase training framework to decouple language learning from reinforcement learning, which further improves the sample efficiency. The experimental results show that the proposed method significantly improves the performance and sample efficiency. Besides, it shows robustness against compound error and limited pre-training data.

1 Introduction

Text-based games are simulated environments where the player observes textual descriptions, and acts using text commands (Hausknecht et al., 2020; Urbanek et al., 2019). These games provide a safe and interactive way to study natural language understanding, commonsense reasoning, and dialogue systems. Besides language processing techniques, Reinforcement Learning has become a quintessential methodology for solving text-based games. Some RL-based game agents have been developed recently and proven to be effective in handling challenges such as language representation learning and partial observability (Narasimhan et al., 2015; Fang et al., 2017; Ammanabrolu and Riedl, 2019).

Despite the effectiveness, there are two major challenges for RL-based agents, preventing them from being deployed in real world applications: the *low sample efficiency*, and the *large action space* (Dulac-Arnold et al., 2021). The low sample efficiency is a crucial limitation of RL which refers to the fact that it typically requires a huge amount of data to train an agent to achieve human-level performance (Tsividis et al., 2017). This is because human beings are usually armed with prior knowledge so that they don't have to learn from scratch (Dubey et al., 2018). In a language-informed RL system, in contrast, the agent is required to conduct both language learning and decision making regimes, where the former can be considered as prior knowledge and is much slower than the later (Hill et al., 2021). The sample efficiency could be improved through pre-training methods, which decouple the language learning from decision making (Su et al., 2017). The selection of pre-training methods thus plays an important role: if the pre-trained modules perform poorly on unseen data during RL training, the incurred compound error will severely affect the decision making process. Another challenge is the large discrete action space: the agent may waste both time and training data if attempting irrelevant or inferior actions (Dulac-Arnold et al., 2015; Zahavy et al., 2018).

In this paper, we aim to address these two challenges for reinforcement learning in solving text-based games. Since it is inefficient to train an agent to solve complicated tasks (games) from scratch, we consider decomposing a task into a sequence of subtasks as inspired by (Andreas et al., 2017). We design an RL agent that is capable of automatic task decomposition and subtask-conditioned action pruning, which brings two branches of benefits. First, the subtasks are easier to solve, as the involved temporal dependencies are usually short-term. Second, by acquiring the skills to solve subtasks, the agent will be able to learn to solve a new task more quickly by reusing the learnt skills (Barreto et al., 2020). The challenge of large action space can also be alleviated, if we can filter out the actions that are irrelevant to the current subtask.

Inspired by the observation that human be-

Figure 1: (a) An example of the observation, which can be textual, KG-based, or hybrid. (b) The decision making process. Through question answering, the agent is guided to first decompose the task as subtasks, then reduce the action space conditioned on the subtask.

ings can understand the environment conditions through question answering (Das et al., 2020; Ammanabrolu et al., 2020), we design world-perceiving modules to realize the aforementioned functionalities (i.e., task decomposition and action pruning) and name our method as **Q**uestion-guided **W**orld-perceiving **A**gent (QWA)*. Fig. 1 (b) shows an example of our decision making process. Being guided by some questions, the agent first decomposes the task to obtain a set of available subtasks, and selects one from them. Next, conditioned on the selected subtask, the agent conducts action pruning to obtain a refined set of actions. In order to decouple language learning from decision making, which further improves the sample efficiency, we propose to acquire the world-perceiving modules through supervised pre-training. We design a two-phase framework to train our agent. In the first phase, a dataset is built for the training of the world-perceiving modules. In the second phase, we deploy the agent in games with the pre-trained modules frozen, and train the agent through reinforcement learning.

We conduct experiments on a series of cooking games. We divide the games as simple games and complex games, and construct the pre-training dataset from simple games only. The experimental results show that QWA achieves high sample efficiency in solving complex games. We also show that our method enjoys robustness against compound error and limited pre-training data.

Our contributions are summarized as follows: Firstly, we develop an RL agent featured with question-guided task decomposition and action space reduction. Secondly, we design a two-phase framework to efficiently train the agent with limited data. Thirdly, we empirically validate our method's effectiveness and robustness in complex games.

2 Related work

2.1 RL agents for text-based games

The RL agents for text-based games can be divided as text-based agents and KG-based agents based on the form of observations. Compared with the text-based agents (Narasimhan et al., 2015; Yuan et al., 2018; Adolphs and Hofmann, 2020; Jain et al., 2020; Yin and May, 2019; Xu et al., 2020a; Guo et al., 2020), which take the raw textual observations as input to build state representations, the KG-based agents construct the knowledge graph and leverage it as the additional input (Ammanabrolu and Riedl, 2019; Xu et al., 2020b). By providing structural and historical information, the knowledge graph helps the agent to handle partial observability, reduce action space, and improve generalizability across games. Based on how actions are selected, the RL agents can also be divided as parser-based agents, choice-based agents, and template-based agents. The parser-based agents generate actions word by word, leading to a huge combinatorial action space (Kohita et al., 2021). The choice-based agents circumvent this challenge by assuming the access to a set of admissible actions at each game state (He et al., 2016). The template-based agents achieve a trade-off between the huge action space and the assumption of admissible action set by introducing the template-based action space, where the agent selects first a template, and then a verb-object pair either individually (Hausknecht et al., 2020) or conditioned on the selected template (Ammanabrolu and Hausknecht, 2020). In this work, we aim to improve the sam-

---

*Code is available at: `https://github.com/YunqiuXu/QWA` ple efficiency and reduce the action space through pre-training. Being agnostic about the form of observations and the action selecting methods, our work complements the existing RL agents.

2.2 Hierarchical RL

Our work is closely related to task decomposition (Oh et al., 2017; Shiarlis et al., 2018; Sohn et al., 2018) and hierarchical reinforcement learning (Dayan and Hinton, 1992; Kulkarni et al., 2016; Vezhnevets et al., 2017). Similar to our efforts, Jiang et al. (2019) and Xu et al. (2021) designed a meta-policy for task decomposition and subtask selection, and a sub-policy for goal-conditioned decision making. Typically, these works either assume the access to a set of available subtasks, or decompose a task through pre-defined rules, while we aim to achieve automatic task decomposition through pre-training, and remove the requirement for expert knowledge during reinforcement learning. Besides, existing work assumes that unlimited interaction data can be obtained to train the whole model through RL. In contrast, we consider the more practical situation where the interaction data is limited, and focus on improving the RL agent's data efficiency. Regarding the sub-policy, we do not assume the access to the termination states of the subtasks. We also do not require additional handcrafted operations in reward shaping (Bahdanau et al., 2019).

2.3 Pre-training methods for RL

There have been a wide range of work studying pre-training methods or incorporating pre-trained modules to facilitate reinforcement learning (Eysenbach et al., 2018; Hansen et al., 2019; Sharma et al., 2019; Gehring et al., 2021; Liu et al., 2021; Schwarzer et al., 2021). One major branch among them is Imitation Learning (IL), where the agent is trained to imitate human demonstrations before being deployed in RL (Hester et al., 2018; Zhu et al., 2018; Reddy et al., 2019). Although we also collect human labeled data for pre-training, we leverage the data to help the agent to perceive the environment instead of learning the solving strategies. Therefore, we do not require the demonstrations to be perfect to solve the game. Besides, our method prevails when pre-trained on simple tasks rather than complicated ones, making it more feasible for human to interact and annotate (Arumugam et al., 2017; Mirchandani et al., 2021). Further discussions to compare our method with IL are provided in subsequent sections.

In the domain of text-based games, some prior works have involved pre-training tasks such as state representation learning (Ammanabrolu et al., 2021; Singh et al., 2021), knowledge graph constructing (Murugesan et al., 2021) and action pruning (Hausknecht et al., 2019; Tao et al., 2018; Yao et al., 2020). For example, Ammanabrolu et al. (2020) designed a module to extract triplets from the textual observation by answering questions, and use these triplets to update the knowledge graph. As far as we know, we are the first to incorporate pre-training based task decompositon in this domain. Besides, instead of directly pruning the actions based on the observation, we introduce subtask-conditioned action pruning to further reduce the action space.

3 Background

POMDP Text-based games can be formulated as a Partially Observable Markov Decision Processes (POMDPs) (Côté et al., 2018). A POMDP can be described by a tuple $\mathcal{G} = \langle \mathcal{S}, \mathcal{A}, P, r, \Omega, O, \gamma \rangle$, with $\mathcal{S}$ representing the state set, $\mathcal{A}$ the action set, $P(s'|s,a) : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \mapsto \mathbb{R}^+$ the state transition probabilities, $r(s,a) : \mathcal{S} \times \mathcal{A} \mapsto \mathbb{R}$ the reward function, Ω the observation set, O the conditional observation probabilities, and $\gamma \in (0,1]$ the discount factor. At each time step, the agent receives an observation $o_t \in \Omega$ based on the probability $O(o_t|s_t, a_{t-1})$, and select an action $a_t \in \mathcal{A}$. The environment will transit into a new state based on the probability $T(s_{t+1}|s_t, a_t)$, and return a scalar reward r_{t+1}. The goal of the agent is to select the action to maximize the expected cumulative discounted rewards: $R_t = \mathbb{E}[\sum_{t=0}^{\infty} \gamma^k r_t]$.

Observation form In text-based games, the observation can be in the form of text, knowledge graph, or hybrid. Fig. 1 (a) shows an example of the textual observation and the corresponding KG-based observation. We do not make assumptions about the observation form and our method is compatible with any of those forms.

Problem setting We aim to design an RL-based agent that is able to conduct automatic task decomposition and action pruning in solving text-based games. We consider games sharing similar themes and tasks, but varying in their complexities (Adhikari et al., 2020; Chen et al., 2021). Taking the cooking games (Côté et al., 2018) as an example,

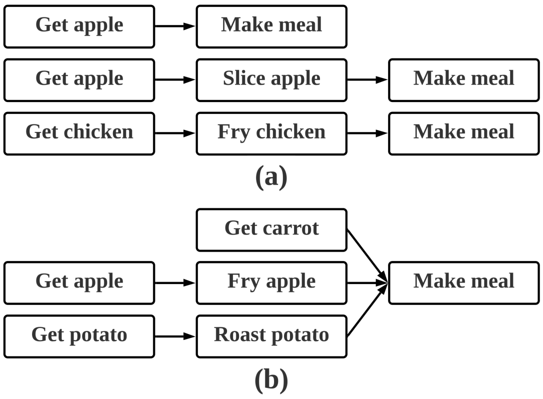

Figure 2: Subtasks for solving (a) 3 simple games and (b) 1 complex game.

the task is always "make the meal". To accomplish this task, the agent has to explore different rooms to collect all ingredients, prepare them in right ways, and make the meal. A game's complexity depends on the number of rooms, ingredients, and the required preparation steps. We define a subtask as a milestone towards completing the task (e.g., "get apple" if "apple" is included in the recipe), and a subtask requires a sequence of actions to accomplish (e.g., the agent has to explore the house to find the apple). A game is considered simple, if it consists of only a few subtasks, and complex if it consists of more subtasks. Fig. 2 gives examples of simple games and complex games. While being closer to real world applications, complex games are hard to solve by RL agents because: 1) it's expensive to collect sufficient human labeled data for pre-training; 2) it's unrealistic to train an RL agent from scratch. We therefore focus on agent's sample efficiency and performance on complex games. Our objective is to leverage the labeled data collected from simple games to speed up RL training in complex games, thus obtaining an agent capable of complex games. For more details and statistics of the simple / complex games used in our work, please refer to Sec. 5.1.

4 Methodology

4.1 Framework overview

Fig. 3 shows the overview of our QWA agent. We consider two world-perceiving modules: a task selector and an action validator. Given the observation o_t and the task candidate set $\mathcal{T}$, we use the task selector to first obtain a subset of currently available subtasks $\mathcal{T}_t \subseteq \mathcal{T}$, then select a subtask $T_t \in \mathcal{T}_t$. Given T_t and the action candidate set $\mathcal{A}$, we use the action validator to get an action subset $\mathcal{A}_t \subseteq \mathcal{A}$, which contains only those relevant to the subtask T_t. Finally, given o_t and T_t, we use an action selector to score each action $a \in \mathcal{A}_t$, and the action with the highest score will be selected as a_t.

The training of the world-perceiving modules can be regarded as the language learning regime, while the training of the action selector can be regarded as the decision making regime. We consider a two-phase training strategy to decouple these two regimes to further improve the sample efficiency (Hill et al., 2021). In the pre-training phase, we collect human interaction data from the simple games, and design QA datasets to train the world-perceiving modules through supervised learning. In the reinforcement learning phase, we freeze the pre-trained modules, and train the action selector in the complex games through reinforcement learning.

4.2 Task selector

Depending on the experiment settings, $\mathcal{T}$ and $\mathcal{A}$ can be either fixed vocabulary sets (parser-based), or changing over time (choice-based). We regard a subtask available if it is essential for solving the "global" task, and there's no prerequisite subtask. For example, the subtask "get apple" in Fig. 1, as the object "apple" is an ingredient which has not been collected. Although another subtask "dice apple" is also essential for making the meal, it is not available since there exists a prerequisite subtask (i.e., you should collect the apple before dicing it). The aim of the task selector is to identify a subset of available subtasks $\mathcal{T}_t \subseteq \mathcal{T}$, and then select one subtask $T_t \in \mathcal{T}_t$.

We formulate the mapping $f(o_t, \mathcal{T}) \rightarrow \mathcal{T}_t$ as a multi-label learning problem (Zhang and Zhou, 2013). For simplicity, we assume that the subtask candidates are independent with each other. Thus, the multi-label learning problem can be decomposed as $|\mathcal{T}|$ binary classification problems. Inspired by the recent progress of question-conditional probing (Das et al., 2020), language grounding (Hill et al., 2021), and QA-based graph construction (Ammanabrolu et al., 2020), we cast these binary classification problems as yes-or-no questions, making the task selector a world-perceiving module. For example, the corresponding question for the subtask candidate "get apple" could be "Whether 'get apple' is an available subtask?". This module can guide the agent to under-

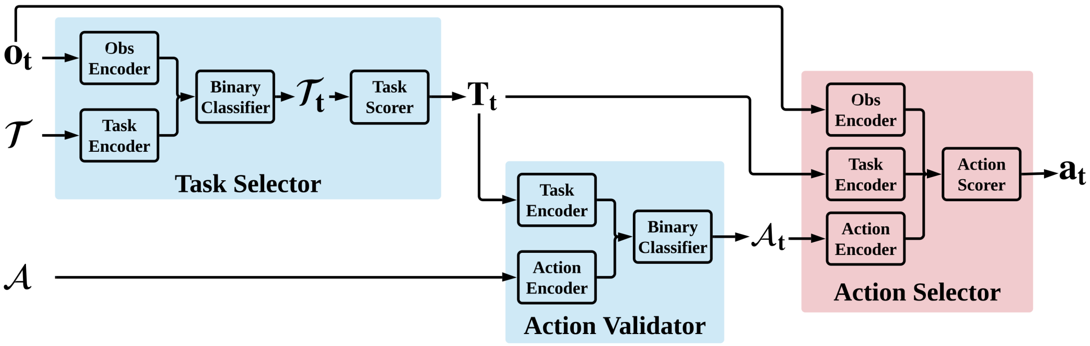

Figure 3: The overview of QWA. The blue modules will be trained in the pre-training phase, while the red module will be trained in the RL phase.

stand the environment conditions through answering questions, but will not directly lead the agent to a specific decision. We can obtain this module through supervised pre-training, and decouple it from reinforcement learning to yield better sample efficiency. Fig. 1 (b) shows some sample QAs, where a human answerer can be replaced by a pre-trained task selector.

Some previous work also considered task decomposition (Chen et al., 2021; Hu et al., 2019), but the related module is obtained through imitating human demonstrations, which is directly related to decision making instead of world perceiving. Compared with these work, our method has two folds of benefits. First, there may exist multiple available subtasks at a timestep. Imitating human demonstrations will specify only one of them, which may be insufficient and lead to information loss. Second, we do not require expert demonstrations which guarantee to solve the game. Instead, we can ask humans to annotate either imperfect demonstrations, or even demonstrations from a random agent. We will treat the IL-based method as a baseline and conduct comparisons in the experiments.

Given the set of available subtasks $\mathcal{T}_t$, arbitrary strategies can be used to select a subtask T_t from it. For example, we can employ a non-learnable task scorer to obtain T_t by random sampling, since each subtask $T \in \mathcal{T}_t$ is essential for accomplishing the task. We can also train a task scorer via a meta-policy for adaptive task selection (Xu et al., 2021).

4.3 Action validator

After obtaining the subtask T_t, we conduct action pruning conditioned on it (or on both T_t and o_t) to reduce the action space, tackling the challenge of large action space. Similar to the task selector, we formulate action pruning as $|\mathcal{A}|$ binary classification problems, and devise another world-perceiving module: the action validator. The action validator is designed to check the relevance of each action candidate $a \in \mathcal{A}$ with respect to T_t by answering questions like "Is the action candidate 'take beef' relevant to the subtask 'fry chicken'?", so as to obtain a subset of actions $\mathcal{A}_t \subseteq \mathcal{A}$ with irrelevant actions filtered. Fig. 3 shows the module architecture. Similar to the task selector, we pre-train this module through question answering. Sample QAs have been shown in Fig. 1 (b).

4.4 Action selector

After pre-training, we deploy the agent in the complex games, and train the action selector through RL. We freeze the pre-trained modules, as no human labeled data will be obtained in this phase. At each time step, we use the task selector and the action validator to produce $\mathcal{T}_t$ and $\mathcal{A}_t$, respectively. We keep using the same subtask T over time until it is not included in $\mathcal{T}_t$, as we do not want the agent to switch subtasks too frequently. The agent can simply treat T_t as the additional observation of o_t. If we do not limit the use of human knowledge in this phase, we can also treat T_t as a goal with either hand-crafted (Jiang et al., 2019) or learnt reward function (Colas et al., 2020). Arbitrary methods can be used for optimizing (Ammanabrolu and Hausknecht, 2020; Adhikari et al., 2020).

One issue we are concerned about is the compound error – the prediction error from imperfect pre-trained modules will adversely affect RL training (Talvitie, 2014; Racanière et al., 2017). For example, the false predictions made by the binary classifier in the task selector may lead to a wrong T_t, which affects $\mathcal{A}_t$ and a_t in turn. To alleviate the influence of the compound error, we assign time-awareness to subtasks. A subtask is bounded

Table 1: Game statistics. We use the simple games to provide human labeled data in the pre-training phase. We use the medium & hard games in the reinforcement learning phase.

Name	Traj.Length	#Triplets	#Rooms	#Objs	#Ings	#Reqs	#Acts	#Subtasks	#Avail.Subtasks
Simple	7.90	38.48	5.76	23.69	1.49	0.96	14.50	12.44	1.14
Medium	15.30	51.07	6.00	26.10	3.00	3.00	23.48	23.00	1.94
Hard	21.75	59.95	8.00	31.48	3.00	4.00	22.94	23.00	2.16

by a time limit $[0, \xi]$. If the current subtask T is not finished within its time limit, we force the agent to re-select a new subtask $T_t \in \mathcal{T}_t \setminus \{T\}$, regardless whether T is still available. Besides making the agent robust against errors, another benefit by introducing time-awareness to subtasks is that it improves the subtask selection diversity, which helps the agent to avoid getting stuck in local minima (Pong et al., 2020; Campero et al., 2020).

5 Experiments

5.1 Experiment settings

We conduct experiments on cooking games provided by the rl.0.2 game set[†] and the FTWP game set[‡], which share the vocabulary set. Based on the number of subtasks, which is highly correlated to the number of ingredients & preparing requirements, we design three game sets with varying complexities: 3488 simple games, 280 medium games and 420 hard games. Note that there is no overlapping games between the simple set and the medium / hard game sets. Table 1 shows the game statistics. Besides "Traj.Length", which denotes the average length of the expert demonstrations per game[§], other statistic metrics are averaged per time step per game (e.g., "#Subtasks" and "#Avail.Subtasks" denote the average number of subtask candidates $\mathcal{T}$, and the average number of available subtasks $\mathcal{T}_t$, respectively). We will collect human interaction data from the simple games for pre-training. We regard both medium & hard games as complex, and will conduct reinforcement learning on these two game sets without labeled data.

5.2 Baselines

We consider the following four models, and compare with more variants in ablation studies:

- **GATA** (Adhikari et al., 2020): a powerful KG-based RL agent, which is the benchmark model for cooking games.
- **IL** (Chen et al., 2021): a hierarchical agent which also uses two training phases. In the first phase, both the task selector and the action selector are pre-trained through imitation learning. Then in the second phase, the action selector is fine-tuned through reinforcement learning.
- **IL w/o FT**: a variant of the IL baseline, where only the imitation pre-training phase is conducted, and there's no RL fine-tuning.
- **QWA**: the proposed model with world-perceiving modules.

5.3 Implementation details

Model architecture All models are implemented based on GATA's released code[¶]. In particular, we use the version GATA-GTF, which takes only the KG-based observation, and denote it as GATA for simplicity. The observation encoder is implemented based on the Relational Graph Convolutional Networks (R-GCNs) (Schlichtkrull et al., 2018) by taking into account both nodes and edges. Both the task encoder and the action encoder are implemented based on a single transformer block with single head (Vaswani et al., 2017) to encode short texts. The binary classifier, the task scorer and the action scorer are linear layers. The GATA and IL models are equipped with similar modules. Please refer to Appendix C for details.

Pre-training We train the task selector and the action validator separately, as they use different types of QAs. We ask human players to play the simple games, and answer the yes-or-no questions based on the observations. The details of the dataset construction (interaction data collection, question generation, answer annotation, etc.) could be found at Appendix B. We train the task selector with a batch size of 256, and the action

[¶] `https://github.com/xingdi-eric-yuan/GATA-public`

Table 2: The testing performance at 20% / 100% of the reinforcement learning phase.

Model	Medium		Hard	
	20%	100%	20%	100%
QWA (ours)	**0.66**±0.02	**0.71**±0.04	**0.53**±0.04	**0.53**±0.02
GATA	0.31±0.02	0.57±0.18	0.25±0.02	0.48±0.01
IL	0.45±0.18	0.26±0.03	0.32±0.11	0.35±0.08
IL w/o FT	0.63±0.05	0.63±0.05	0.48±0.05	0.48±0.05

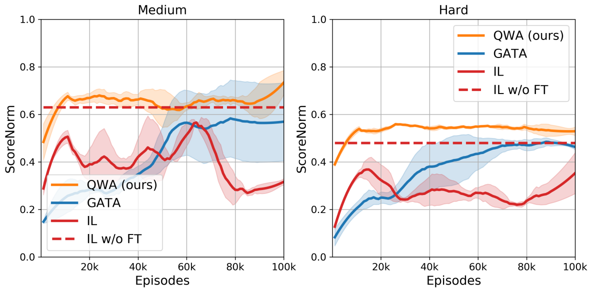

Figure 4: The RL testing performance w.r.t. training episodes. The red dashed line denotes the IL agent without fine-tuning.

validator with a batch size of 64. The modules are trained for 10-20 epochs using Focal loss and Adam optimizer with a learning rate of 0.001.

Reinforcement learning We consider the medium game set and hard game set as different experiments. We split the medium game set into 200 training games / 40 validation games / 40 testing games, and the hard game set into 300 / 60 / 60. We follow the default setting of (Adhikari et al., 2020) to conduct reinforcement learning. We set the step limit of an episode as 50 for training and 100 for validation / testing. We set the subtask time limit $\xi = 5$. For each episode, we sample a game from the training set to interact with. We train the models for 100,000 episodes. The models are optimized via Double DQN (epsilon decays from 1.0 to 0.1 in 20,000 episodes, Adam optimizer with a learning rate of 0.001) with Pritorized Experience Replay (replay buffer size 500,000). For every 1,000 training episodes, we validate the model and report the testing performance.

5.4 Evaluation metrics

We measure the models through their RL testing performance. We denote a game's score as the episodic sum of rewards without discount. As different games may have different maximum available scores, we report the normalized score, which is defined as the collected score normalized by the maximum score for a game.

6 Results and discussions

6.1 Main results

Fig. 4 shows the RL testing performance with respect to the training episodes. Table 2 shows the testing performance after 20,000 training episodes (20%) / at the end of RL training (100%). Compared with GATA, which needs to be "trained from scratch", the proposed QWA model achieves high sample efficiency: it reaches convergence with high performance before 20% of the training stage, saving 80% of the online interaction data in complex games. The effectiveness of pre-training can also be observed from the variant "IL w/o FT": even though it requires no further training on the medium / hard games, it achieves comparable performance to our model. However, the performance of QWA can be further improved through RL, while it does not work for the IL-based model, as we can observe the performance of "IL" becomes unstable and drops significantly during the RL fine-tuning. A possible reason is that there exists large domain gap between simple and medium (hard) games, and our model is more robust against such domain shifts. For example, our world-perceiving task selector performs better than IL-based task selector in handling more complex observations (according to Table 1, the observations in medium / hard games contain more triplets, rooms and objects), facilitating the training of the action selector. Besides the domain gap in terms of the observation space, there is also a gap between domains in terms of the number of available subtasks – while there's always one available subtask per time step in simple games, the model will face more available subtasks in the medium / hard games. Different from our task selector, which is trained to check the availability of every subtask candidate, the IL pre-trained task selector can not adapt well in this situation, as it is trained to find the unique subtask and ignore the other subtask candidates despite whether they are also available.

6.2 Performance on the simple games

We further investigate the generalization performance of our model on simple games, considering that simple games are not engaged in our RL training. To conduct the experiment, after RL training, we deploy all models on a set of 140 held-out sim-

Table 3: The RL testing performance on simple games.

Model	Medium 100%	Hard 100%
QWA (ours)	**0.80**±0.01	**0.82**±0.02
GATA	0.32±0.03	0.45±0.12
IL	0.44±0.02	0.29±0.03
IL w/o FT	0.76±0.06	0.76±0.06

ple games for RL interaction. Table 3 shows the results, where "Medium 100%" ("Hard 100%") denotes that the model is trained on medium (hard) games for the whole RL phase. The generalizability of GATA, which is trained purely with medium and hard games, is significantly low and cannot perform well on simple games. In contrast, our model performs very well and achieves over 80% of the scores. The world-perceiving modules, which are pre-trained with simple games, help to train a decision module that adapts well on unseen games. It is not surprising that the variant "IL w/o FT" also performs well on simple games, since they are only pre-trained with simple games. However, as indicated by the performance of "IL", after fine-tuning on medium/hard games (recalling Sec. 6.1), the action scorer "forgets" the experience/skills dealing with simple games and the model fails to generalize on unseen simple games. In summary, the best performance achieved by QWA demonstrates that our model can generalize well on games with different complexities.

6.3 Ablation study

We study the contribution of the subtask time-awareness by comparing our full model with the variant without this technique. Fig. 5 shows the result. Although the models perform similarly in the medium games, the full model shows better performance in the hard games, where there may exist more difficult subtasks (we regard a subtask more difficult if it requires more actions to be completed). Assigning each subtask a time limit prevents the agent from pursuing a too difficult subtask, and improves subtask diversity by encouraging the agent to try different subtasks. Besides, it prevents the agent from being stuck in a wrong subtask, making the agent more robust to the compound error.

We then investigate the performance upper bound of our method by comparing our model to variants with oracle world-perceiving modules. Fig. 6 shows the results, where "+expTS" ("+expAV") denotes that the model uses an expert task selector (action validator). There's still space to improve the pre-trained modules. The variant "QWA +expTS +expAV" solves all the medium games and achieves nearly 80% of the scores in hard games, showing the potential of introducing world-perceiving modules in facilitating RL. We also find that assigning either the expert task selector or the expert action validator helps to improve the performance. In light of these findings, we will consider more powerful pre-training methods as a future direction.

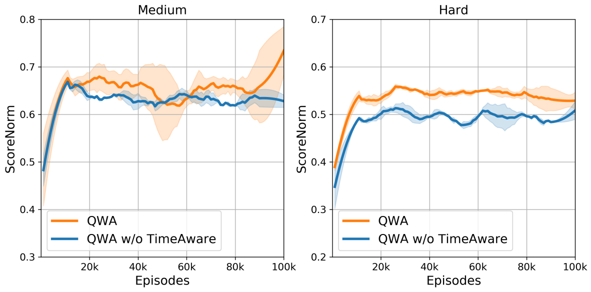

Figure 5: The performance of our model and the variant without time-awareness.

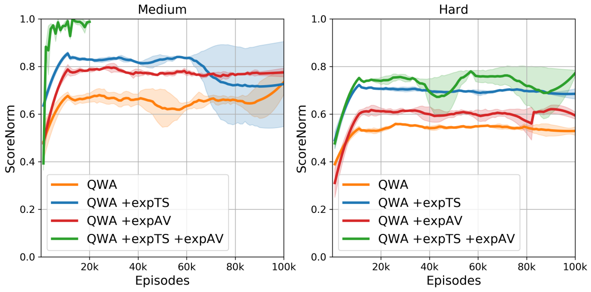

Figure 6: The performance of our model and the variants with expert modules.

6.4 Pre-training on the partial dataset

Although we only collect labeled data from the simple games, it is still burdensome for human players to go through the games and answer the questions. We are thus interested in investigating how the performance of our QWA (or world-perceiving modules) varies with respect to a reduced amount of pre-training data. Fig. 7 shows the results, where the pre-training dataset has been reduced to 75%, 50% and 25%, respectively. Our model still performs well when the pre-training data is reduced to 75% and 50%. When we only use 25% of the pre-training data, the model exhibits instability during the learning of hard games. Being pre-trained on a largely-reduced dataset, the world-perceiving modules might be more likely to make wrong predictions with the progress of RL training, leading to the performance fluctuation. However, the fi-

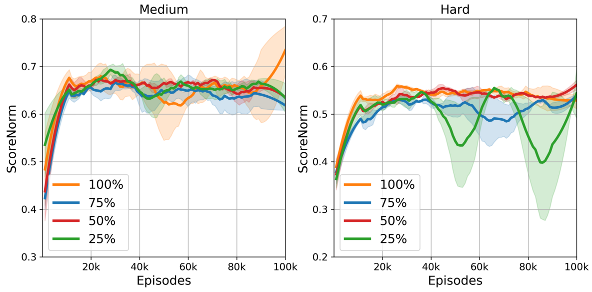

Figure 7: The performance of our model with varying amounts of pre-training data.

nal performance of this variant is still comparable. To summarize, our model is robust to limited pre-training data and largely alleviates the burden of human annotations.

7 Conclusion

In this paper, we addressed the challenges of low sample efficiency and large action space for deep reinforcement learning in solving text-based games. We introduced the world-perceiving modules, which are capable of automatic task decomposition and action pruning through answering questions about the environment. We proposed a two-phase training framework, which decouples the language learning from the reinforcement learning. Experimental results show that our method achieves improved performance with high sample efficiency. Besides, it shows robustness against compound error and limited pre-training data. Regarding the future work, we would like to further improve the pre-training performance by introducing contrastive learning objective (You et al., 2020) and KG-based data augmentation (Zhao et al., 2021).

Appendix

The appendix is organized as follows: Sec. A details the environment. Sec. B illustrates the process for constructing the pre-training datasets. Sec. C demonstrates the baselines' architecture and training details. Sec. D provides more experimental results.

A Game Environment

In the cooking game (Côté et al., 2018), the player is located in a house, which contains multiple rooms and interactable objects (food, tools, etc.). Her / his task is to follow the recipe to prepare the meal. Each game instance has a unique recipe, including different numbers of ingredients (food objects that are necessary for preparing the meal) and their corresponding preparation requirements (e.g., "slice", "fry"). Besides the textual observation, the KG-based observation can also be directly obtained from the environment. The game sets used in our work contains a task set $\mathcal{T}$ of 268 subtasks, and an action set $\mathcal{A}$ of 1304 actions. Following GATA's experiment setting (Adhikari et al., 2020), we simplify the game environment by making the action set changeable over time, which can be provided by the TextWorld platform. Note that although the action space is reduced, it still remains challenging as the agent may encounter unseen action candidates (Chandak et al., 2019, 2020). We then use a similar way to obtain a changeable task set, which is a combination of the verb set {chop, dice, slice, fry, make, get, grill, roast} and the ingredient set, where the construction details are provided in Appendix B. Table 4 and Table 5 show the KG-based observations o_t, corresponding subtask candidates $\mathcal{T}$ and action candidates $\mathcal{A}$. Table 6 and Table 7 show more examples of subtasks and actions, respectively. The underlined subtask candidates denote the available subtask set $\mathcal{T}_t$. The underlined action candidates in Table 7 denote the refined action set $\mathcal{A}_t$ after selecting the subtask "roast carrot". We still denote the subtask candidate set (action candidate set) as $\mathcal{T}$ ($\mathcal{A}$) to distinguish it from the available subtask set $\mathcal{T}_t$ (refined action set $\mathcal{A}_t$).

Table 4: The observations o_t, subtask candidates $\mathcal{T}$ and action candidates $\mathcal{A}$ of a simple game and a medium game. The underlined subtask candidates denote the available subtask set $\mathcal{T}_t$.

B Pre-training Datasets

We build separate datasets for each pre-training task (task decomposition, action pruning, and imitation learning). We first let the player to go through each simple game, then construct the datasets upon the interaction data. For each time step, the game environment provides the player with the action set $\mathcal{A}$ and the KG-based observation o_t, which is represented as a set of triplets. We use a simple method to build the subtask set $\mathcal{T}$ from o_t: As shown in Fig. 8, we first obtain the ingredients by extracting the nodes having the relation "part_of" with the node "cookbook". Then we build $\mathcal{T}$ as the Cartesian product of the ingredients and the verbs {chop, dice, slice, fry, get, grill, roast} plus two special subtasks "get knife" and "make meal". The player is required to select a subtask $T_t \in \mathcal{T}$, and select an action $a_t \in \mathcal{A}$. After executing a_t, the environment will transit to next state s_{t+1}, and the player will receive o_{t+1} and r_{t+1} to form a transition $\{o_t, \mathcal{T}, T_t, \mathcal{A}, a_t, o_{t+1}, r_{t+1}\}$, where $\{o_t, \mathcal{T}, T_t, \mathcal{A}, a_t\}$ will be used for imitation learning. Fig. 8 shows the construction process of the pre-training dataset for task decomposition. Each subtask candidate $T \in \mathcal{T}$ will formulate a question "Is T available?", whose answer is 1 (yes) if T is an available subtask for o_t, otherwise 0 (no). Fig. 9 shows the construction process of the pre-training dataset for action pruning. The action selector is made invariant of o_t, that we consider every subtask candidate $T \in \mathcal{T}$ during pre-training, regardless of whether T is a currently-available subtask. Each action candidate $a \in \mathcal{A}$ will be paired with T to formulate a question "Is a relevant to T", whose answer is 1 if a is relevant to T, otherwise 0.

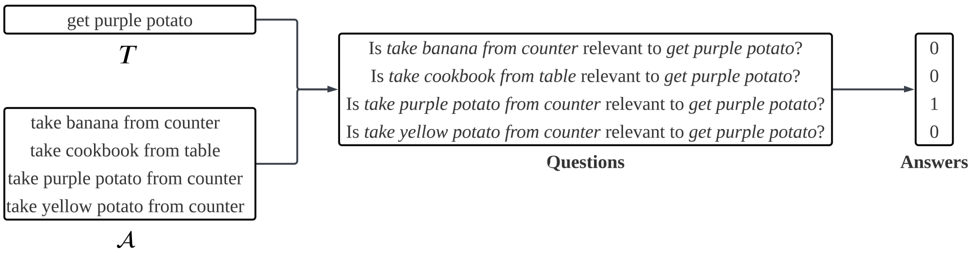

Figure 9: The construction process of the pre-training dataset for action pruning.

C Baseline details

C.1 GATA

Fig. 10 shows our backbone model GATA, which consists of an observation encoder, an action encoder and an action scorer. The observation encoder is a graph encoder for encoding the KG-based observation o_t, and the action encoder is a text encoder to encode the action set $\mathcal{A}$ as a stack of action candidate representations. The observation representation will be paired with each action candidate, and then fed into the action scorer, which consists of linear layers.

We train the GATA through reinforcement learning, the experiment setting is same with Sec. 5.3. Instead of initializing the word embedding, node embedding and edge embedding with fastText word vectors (Mikolov et al., 2017), we found that the action prediction task (AP), which is also included in GATA's work (Adhikari et al., 2020), could provide better initialization. In light of this, we could like to conduct such task, and apply the AP initialization to all encoders (observation encoder, task encoder, action encoder). Fig. 11 shows the action predicting process. Given the transition data, the task is to predict the action $a_t \in \mathcal{A}$ given the current observation o_t, and the next observation o_{t+1} after executing a_t. The transition data for AP task is collected from the FTWP game set and is provided by GATA's released code.

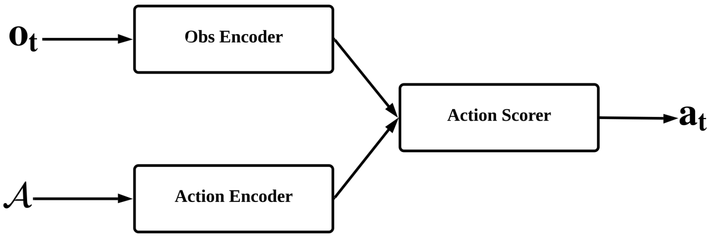

Figure 10: The architecture of GATA baseline.

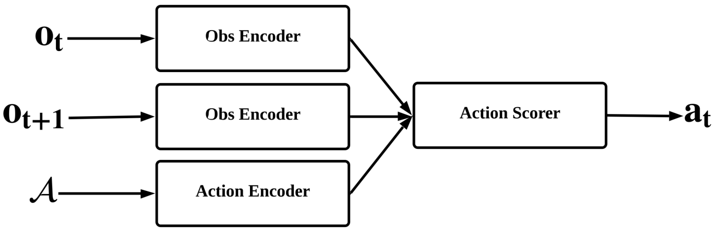

Figure 11: The architecture of GATA for action prediction.

C.2 IL

Fig. 12 shows the IL baseline. We follow (Chen et al., 2021) to conduct a two-phase training process: imitation pre-training and reinforcement fine-tuning. In the imitation pre-training phase, we use the transition data to train both the task selector ($f(o_t, \mathcal{T}) \rightarrow T_t$) and the action selector ($f(o_t, T_t, \mathcal{A}) \rightarrow a_t$) through supervised learning. The modules are optimized via cross entropy loss and Adam optimizer with learning rate 0.001. We train the modules with batch size 128 for up to 50 epochs. Then in the reinforcement fine-tuning phase, we freeze the task selector and fine-tune the action selector through reinforcement learning, where the experiment setting is same with QWA and GATA.

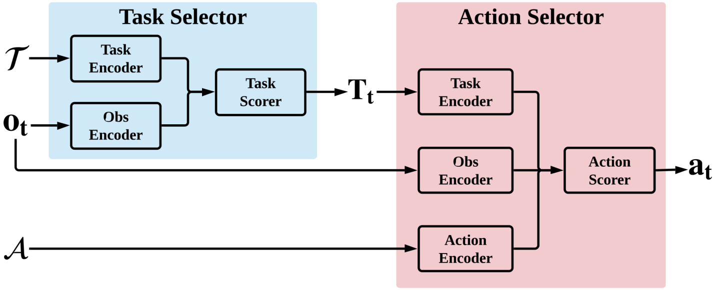

Figure 12: The architecture of IL baseline.

D More experimental results

In the pre-training phase, we conduct rough hyper-parameter tuning by varying batch sizes. Fig. 13 and Fig. 14 show the pre-training performance of QWA's task selector and action validator, respectively. Fig. 15 shows the pre-training performance of IL baseline.

Fig. 16 compares our GATA and the original GATA without the action prediction initialization. Fig. 17, Fig. 18, Fig. 19 and Fig. 20 show the full results of Fig. 4, Fig. 5, Fig. 6 and Fig. 7, respectively.

Abstract

In zero-shot multilingual extractive text summarization, a model is typically trained on English summarization dataset and then applied on summarization datasets of other languages. Given English gold summaries and documents, sentence-level labels for extractive summarization are usually generated using heuristics. However, these monolingual labels created on English datasets may not be optimal on datasets of other languages, for that there is the syntactic or semantic discrepancy between different languages. In this way, it is possible to translate the English dataset to other languages and obtain different sets of labels again using heuristics. To fully leverage the information of these different sets of labels, we propose NLSSum (**N**eural **L**abel **S**earch for **Sum**marization), which jointly learns hierarchical weights for these different sets of labels together with our summarization model. We conduct multilingual zero-shot summarization experiments on MLSUM and WikiLingua datasets, and we achieve state-of-the-art results using both human and automatic evaluations across these two datasets.

Sentence (English, Label 1): *He was never charged in* that Caribbean Nation. **Reference Summary (English):** *He was* arrested twice, but *never charged in* Natalee Holloway's disappearance.
Translated Sentence (German, Label 0): *Er* wurde jedoch *nie* in dieser karibischen Nation *angeklagt*. **Translated Reference Summary (German):** Beim Verschwinden von Natalee Holloway wurde *er* zweimal verhaftet, aber *nie angeklagt*.

Table 1: Monolingual Bias for Different Languages.

1 Introduction

The zero-shot multilingual tasks, which aim to transfer models learned on a high-resource language (e.g., English) to a relatively low-resource language (e.g., Turkish) without further training, are challenging (Ruder et al., 2019). Recently, large pre-trained multilingual transformers such as M-BERT (Devlin et al., 2019), XLM (Lample and Conneau, 2019), and XLM-R (Conneau et al., 2020) have shown remarkable performance on zero-shot multilingual natural language understanding tasks. During pre-training, these transformer models project representations of different languages into the same vector space, which makes the transfer learning across different languages easier during fine-tuning (Gong et al., 2021). In zero-shot extractive summarization, we train an extractive model (based on a pre-trained multilingual transformer) on English summarization dataset, which selects important sentences in English documents. Then, we apply this trained model to documents of a different language (i.e., extracting sentences of documents in another language). In this paper, we aim to enhance the zero-shot capabilities of multilingual sentence-level extractive summarization.

In text summarization, most datasets only contain human-written *abstractive* summaries as ground truth. We need to transform these datasets into *extractive* ones. Thus, a greedy heuristic algorithm (Nallapati et al., 2017) is employed to add one sentence at a time to the candidate extracted summary set, by maximizing the ROUGE (Lin, 2004) between candidate summary set and the gold summary. This process stops when none of the remaining sentences in the document can increase the ROUGE anymore. These selected sentences are labelled as one and all the other sentences labeled as zero. While the labels obtained from this greedy algorithm are monolingual-oriented and may not be suitable for multilingual transfer. For the example in Table 1, the English sentence is quite likely to be selected as a summary sentence, since it greatly overlaps with the English reference (high ROUGE). While when the document and the summary are translated into German, the ROUGE between the sentence and the summary is significantly lower

(fewer n-gram overlap). Then, another sentence will be selected as substitution. The greedy algorithm yields different labels on the English data and the translated data and these labels may complement for each other. We define this discrepancy as *monolingual label bias*, and it is the key to further improve the performance of zero-shot multilingual summarization.

To address the above problem, we design a method to create multiple sets of labels with different machine translation methods according to the English summarization dataset, and we employ NLSSum (**N**eural **L**abel **S**earch for **Sum**marization) to search suitable weights for these labels in different sets. Specically, in NLSSum, we try to search the hierarchical weights (sentence-level and set-level) for these labels with two neural weight predictors and these label weights are used to train our summarization model. During training, the two neural weight predictors are jointly trained with the summarization model. NLSSum is used only during training and during inference, we simply apply the trained summarization model to documents in another language.

Experimental results demonstrate the effectiveness of NLSSum, which significantly outperforms original XLMR by 2.25 ROUGE-L score on MLSUM (Scialom et al., 2020). The human evaluation also shows that our model is better compared to other models. To sum up, our contributions in this work are as follows:

- To the best of our knowledge, it is the first work that studies the *monolingual label bias* problem in zero-shot multilingual extractive summarization.
- We introduce the multilingual label generation algorithm (Section 3.5) to improve the performance of multilingual zero-shot models. Meanwhile, we propose the NLSSum architecture (Section 3.6) to search suitable weights for different label sets.
- Extensive experiments are conducted with detailed analysis, and the results across different datasets demonstrate the superior performance on multilingual datasets. In MLSUM, the zero-shot performance on Russian is even close to its supervised counterpart.

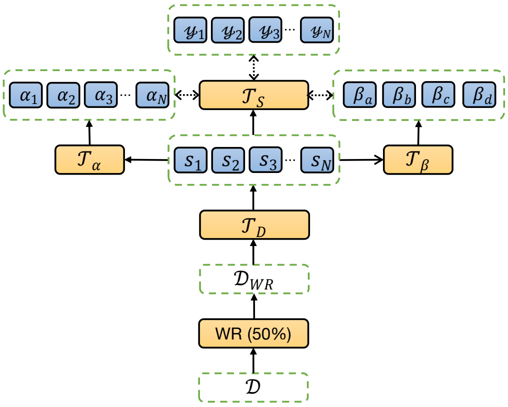

Figure 1: Overview of NLSSum. The input English document is argumented by 50% word replacement and the output is supervised by multilingual labels.

2 Related Work

There has been a surge of research on multilingual pretrained models, such as multilingual BERT (Devlin et al., 2019), XLM (Lample and Conneau, 2019) and XLM-RoBERTa (Conneau et al., 2020). For multilingual summarization, the summarize-then-translate and translate-then-summarize are widely used approaches in prior studies Lim et al. (2004). There is another effective multi-lingual data augmentation, a method that replaces a segment of the input text with its translation in another language (Singh et al., 2019). On the other hand, large-scale multilingual summarization datasets have been introduced (Scialom et al., 2020; Ladhak et al., 2020), which enable new research directions for the multilingual summarization. Nikolov and Hahnloser (2020) applies an alignment approach to collect large-scale parallel resources for low-resource domains and languages. In this paper, we aim to advance the multilingual zero-shot transferability, by training extractive summarization on English and inferring on other languages.

3 Methodology

3.1 Problem Definition

Let $\mathcal{D} = (s_1, s_2, ..., s_N)$ denotes a document with N sentences, where $s_i = (w_1^i, w_2^i, ..., w_{|s_i|}^i)$ is a sentence in $\mathcal{D}$ with $|s_i|$ words. $\mathcal{S}$ is the human-written summary. Extractive summarization can be considered as a sequence labeling task that assigns a label $y_i \in \{0, 1\}$ to each sentence s_i, where $y_i = 1$ indicates the i-th sentence should be included in the extracted summary. The gold labels of sentences in $\mathcal{D}$ are obtained from ($\mathcal{D}$, $\mathcal{S}$) by the

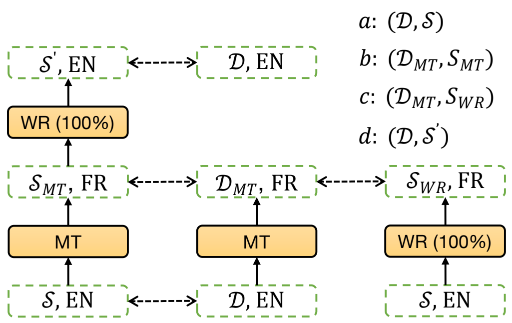

Figure 2: Four Sets of Multilingual Label. 'EN' is the symbol of English and 'FR' is for the foreign language.

greedy heuristic algorithm (Nallapati et al., 2017), which adds one sentence at a time to the extracted summary, skipping some sentences to maximize the ROUGE score of $\mathcal{S}$ and the extracted sentences. In multi-lingual zero-shot setting, the summarization model is trained on English dataset and is finally applied on documents of other languages.

3.2 Neural Extractive Summarizer

Our sentence encoder builds upon the recently proposed XLMR (Conneau et al., 2020) architecture, which is based on the deep bidirectional Transformer (Vaswani et al., 2017) and has achieved state-of-the-art performance in many multilingual zero-shot understanding tasks. Our extractive model is composed of a sentence-level Transformer $\mathcal{T}_S$ (initialized with XLMR) and a document-level Transformer $\mathcal{T}_D$ (a two-layer Transformer).

For each sentence s_i in the input document $\mathcal{D}$, $\mathcal{T}_S$ is applied to obtain a contextual representation for each word w_j^i:

$$[\mathbf{u}_1^1, \mathbf{u}_2^1, ..., \mathbf{u}_{|s_N|}^N] = \mathcal{T}_S([w_1^1, w_2^1, ..., w_{|s_N|}^N]) \quad (1)$$

Similar to Liu and Lapata (2019), the representation of a sentence s_i is acquired by taking the representation of the first token in the sentence $\mathbf{u}_1^i$. The document-level Transformer $\mathcal{T}_D$ (a two-layer inter-sentence Transformer), which is stacked to $\mathcal{T}_S$, takes s_i as input and yields a contextual representation $\mathbf{v}_i$ for each sentence. We intend this process to further captures the sentence-level features for extractive summarization:

$$[\mathbf{v}_1, \mathbf{v}_2, ..., \mathbf{v}_N] = \mathcal{T}_D([\mathbf{u}_1^1, \mathbf{u}_1^2, ..., \mathbf{u}_1^N]) \quad (2)$$

For sentence s_i, the final output prediction of the extractive model $\hat{y}_i$ (i.e., the probability of being selected as summary) is obtained through a linear and a sigmoid classifier layer:

$$\hat{y}_i = \sigma(\mathbf{W}_o \mathbf{v}_i + b_o) \quad (3)$$

where $\mathbf{W}_o$ and b_o are the weight matrix and bias term. Next we introduce how we obtain the neural labels for model training.

3.3 Overview of Neural Label Search

The training and inference of our NLSSum model includes five steps as follows.

(I) **Multilingual Data Augmentation**: This step aims to enhance the multilingual transfer capability of our extractive model and alleviate the discrepancy between training (on English) and inference (on unseen languages).

(II) **Multilingual Label Generation**: The extractive model is supervised by multilingual label, which consists of four sets of labels, according to different strategies.

(III) **Neural Label Search**: In this step, we design the hierarchical sentence-level and set-level weights for labels of different strategies. The final weights are calculated with a weighted average and assigned to corresponding sentences.

(IV) **Fine-Tuning**: We fine-tune our extractive model the augmented English document (generated in Step I) with supervision from the weighted multilingual labels (generated in Step III), as shown in Figure 1.

(V) **Zero-Shot**: We apply the model fine-tuned on English data (Step IV) to extract sentences on documents of the target language.

3.4 Multilingual Data Augmentation

In the training process, only the raw English documents and its paired summary labels are available. We use the following two methods for multilingual data argumentation of English documents, which we intend the model to align its English representations with representations in other languages.

Word Replacement (WR) Similar to Qin et al. (2020), we enhance multilingual transferability by constructing *Word Replacement* data in multiple languages *dynamically*. Let FR denote a foreign language. Specifically, a set of words are randomly chosen in raw English documents and replaced with words in FR using the bilingual dictionary MUSE (Conneau et al., 2018). This approach can in some degree align the replaced word representations in FR with their English counterpart by mixing with the English context.

Machine Translation (MT) The above augmentation method is applied *dynamically* during training, and *Machine Translation* yet is another offline strategy to augment data. First, we translate documents and their paired summaries from English into the target language FR using the MarianMT system[1] (Junczys-Dowmunt et al., 2018). Then, the labels are generated on the translated data with the same greedy algorithm as on English data. Finally, the extractive model is fine-tuned on the translated documents with the supervision of new labels, and inferred on the original FR document.

Unfortunately, the performance of machine translation is instable with the noise or error propagation (Wan et al., 2010). Therefore, we choose the word replacement method here to enhance the input document and the argumented document is served as the input of our extractive model. Note that we do use both the word replacement and machine translation methods to generate multilingual labels (see the next section).

3.5 Multilingual Labels

Given an English article $\mathcal{D}$ and its summary $\mathcal{S}$, we can obtain its extractive labels using the greedy algorithm introduced in Section 3.1.

Label Set U_a Let $U_a = \texttt{GetPosLabel}(\mathcal{D}, \mathcal{S})$ denote the indices of sentences with positive labels, where $\texttt{GetPosLabel}(\mathcal{D}, \mathcal{S})$ returns the indices of positive labeled sentences in the original English document $\mathcal{D}$ using the greedy algorithm. The labels created on English data $(\mathcal{D}, \mathcal{S})$ may not be optimal in multilingual settings (inference on a different language). As shown in Figure 2, we therefore create yet another three label sets using the WR and MT methods introduced earlier to simulate the multilingual scenario during inference time.

Label Set U_b To create labels based foreign language (FR) data, we translate both the English document $\mathcal{D}$ and its summary $\mathcal{S}$ to FR using the MT method in Section 3.4, resulting $\mathcal{D}_{MT}$ and $\mathcal{S}_{MT}$ (also see Figure 2). Again by using the greedy algorithm, we obtain the indices of sentences with positive labels $U_b = \texttt{GetPosLabel}(\mathcal{D}_{MT}, \mathcal{S}_{MT})$.

Label Set U_c Label set U_c is also based on FR data. To make label set U_c different from U_b, we translate $\mathcal{D}$ to $\mathcal{D}_{MT}$ using the MT method, while we translate $\mathcal{S}$ to $\mathcal{S}_{WR}$ using the WR method (we do 100% word replacement) with the EN-FR dictionary. The resulting label set $U_c = \texttt{GetPosLabel}(\mathcal{D}_{MT}, \mathcal{S}_{WR})$.

Label Set U_d Label set U_d is based on English data. The idea is to create a paraphrased English summary $\mathcal{S}'$ using the back translation technology. We first translate $\mathcal{S}$ to $\mathcal{S}_{MT}$ using MT method and translate $\mathcal{S}_{MT}$ back to English $\mathcal{S}'$ using the WR method (100% word replacement). We use different *translation* method for forward and backward translations to maximize the different between $\mathcal{S}$ and $\mathcal{S}'$. Finally, $U_d = \texttt{GetPosLabel}(\mathcal{D}, \mathcal{S}')$.

Note that there are also many other possible strategies for creating multilingual labels and we only use these four strategies above as examples to study the potential of multilingual labels. Intuitively, the contributions of these four label sets for multilingual transferability are different, and the MT and WR translation methods may introduce translation errors, which result noisy labels. Therefore, we introduce the *Neural Label Search* in the next section to find suitable weights for these multilingual labels.

3.6 Neural Label Search

In this section, we assign a weight for each sentence in a document and the weight will be used as the supervision to train our extractive model. Note that the weight is a multiplication of a sentence level weight and a label set level weight. Let $\mathcal{T}_\alpha$ denote the sentence level weight predictor and $\mathcal{T}_\beta$ the set level weight predictor. The implementation of $\mathcal{T}_\alpha(\cdot) = \sigma(g(\mathcal{T}'_\alpha(\cdot)))$ is a two-layer transformer model $\mathcal{T}'_\alpha(\cdot)$ followed by a linear layer $g(\cdot)$ and a sigmoid function. The implementation of $\mathcal{T}_\beta$ is the same as $\mathcal{T}_\alpha$, but with different parameters.

The predictor $\mathcal{T}_\alpha$ transforms sentence representations (see Equation (1) for obtaining $\mathbf{u}_j^i$) to probabilities $\alpha_i \in [0, 1]$ as follows:

$$[\hat{\alpha_1}, \hat{\alpha_2}, ..., \hat{\alpha_N}] = \mathcal{T}_\alpha([\mathbf{u}_1^1, \mathbf{u}_1^2, ..., \mathbf{u}_1^N])$$

$$\alpha_i = \begin{cases} \hat{\alpha_i}, & \text{if } i \in U \\ 0, & \text{otherwise} \end{cases} \tag{4}$$

---

[1] https://github.com/marian-nmt/marian

where $U = U_a \cup U_b \cup U_c \cup U_d$. Note that we only predict weights for sentences with non-zero labels, since we believe that these sentences, which are the minority, are more informative than zero-label sentences.

The computation of $\mathcal{T}_\beta$ is similar, but we first do a mean pooling over sentences in each label set.

$$[\beta_a, \beta_b, \beta_c, \beta_d] = \mathcal{T}_\beta([\frac{\sum_{i \in U_a} \mathbf{u}_1^i}{n_a}, \frac{\sum_{i \in U_b} \mathbf{u}_1^i}{n_b}, \frac{\sum_{i \in U_c} \mathbf{u}_1^i}{n_c}, \frac{\sum_{i \in U_d} \mathbf{u}_1^i}{n_d}])$$

where n_a, n_b, n_c, n_d are sizes of the four label sets.

The final weight l_i for sentence s_i is 0 when $i \notin U$ (i does not belong to any label set). Otherwise, the computation of l_i is as follows.

$$l_i = \alpha_i * \frac{\sum_{j \in \{a,b,c,d\}} \beta_j^i}{m_i} \tag{5}$$

where if $i \in U_j$, β_j^i is β_j, else β_j^i is 0 and m_i is the number of label sets containing i. Note that one sentence may belong to multiple label sets, so we normalize its β_j^i weights in Equation (5).

Weight Normalization In this paper, we only calculate the multilingual weights for multilingual labels, in which the corresponding sentences are all selected as summary sentences by different document-summary pairs, as shown in the Figure 2. The label weights l_i are used to train our summarization model, whose output $\hat{y}_i$ is through a sigmoid function (Equation 3). $\hat{y}_i > 0.5$ means sentence s_i could be selected as in summary. Therefore, when $i \in U$, we rescale l_i to $[0.5, 1.0]$:

$$l_i = \frac{l_i - l_{min}}{2 * (l_{max} - l_{min})} + 0.5 \tag{6}$$

where l_{max} and l_{min} are the maximum and minimum value of l_i, when $i \in U$.

3.7 Training and Zero-shot Inference

In this section, we present how we train our extractive model as well as the two weight predictors $\mathcal{T}_\alpha$ and $\mathcal{T}_\beta$. Note that we train the components above jointly. We train the extractive model using both the English labels y^a (created using the greedy algorithm) as well as the label weights generated in Section 3.6. To train $\mathcal{T}_\alpha$, we use binary labels y^α, where in one document, $y_i^\alpha = 1$ when $i \in U$, otherwise $y_i^\alpha = 0$. To train $\mathcal{T}_\beta$, we again use binary labels y^β, but these labels are on set level rather than sentence level. Defining positive examples for $\mathcal{T}_\beta$ is straight-forward and we set $y_q^\beta = 1$ when $q \in \{U_a, U_b, U_c, U_d\}$ (each label set corresponds to one positive example). For negative examples in one particular document, we randomly sample three sentence indices from sentences with zero labels as one negative example. We finally make the numbers of positive and negative examples for $\mathcal{T}_\beta$ close to 1:1.

Datasets	# Docs (Train / Val / Test)
CNN/DM, English	287,227 / 13,368 / 11,490
MLSUM, German	220,887 / 11,394 / 10,701
MLSUM, Spanish	266,367 / 10,358 / 13,920

WikiLingua, French	44,556 / 6,364 / 12,731

Table 2: Data Statistics: CNN/Daily Mail, MLSUM and WikiLingua.

The final loss is a sum of the four losses above:

$$\begin{aligned} \mathcal{L} = & CE(\hat{y}, y^a) + CE(\hat{y}, l) + \\ & CE(\alpha, y^\alpha) + CE(\beta, y^\beta) \end{aligned} \tag{7}$$

where CE is the cross entropy loss; l is the weighted multilingual label (Section 3.6); y^a, y^α, and y^β are the binary labels for the supervision of $\hat{y}$, α, and β. Specifically, $\alpha = [\alpha_1, \alpha_2, \ldots, \alpha_N]$ and $\beta = [\beta_a, \beta_b, \beta_c, \beta_d]$ (just as Equation 4 and 5).

During the zero-shot inference, we simply apply the model trained on the English dataset using the objectives above to other languages.

4 Experiments

4.1 Datasets

MLSUM & CNN/DM MLSUM is the first large-scale multilingual summarization dataset (Scialom et al., 2020), which is obtained from online newspapers and contains 1.5M+ document/summary pairs in five different languages, namely, French(Fr), German(De), Spanish(Es), Russian(Ru), and Turkish(Tr). The English dataset is the popular CNN/Daily mail (CNN/DM) dataset (Hermann et al., 2015). Our model is trained on CNN/DM.

WikiLingua A large-scale, cross-lingual dataset for abstractive summarization (Ladhak et al., 2020). The dataset includes 770K article and summary

pairs in 18 languages from WikiHow[2]. Our training setting is identical to that of MLSUM, our extractive model is trained on the English data and inferred on other three languages (French, German, Spanish). MLSUM and WikiLingua are described in detail in Table 2.

4.2 Evaluation

Similar to Liu and Lapata (2019), we also select the top three sentences as the summary, with Trigram Blocking to reduce redundancy. Following Scialom et al. (2020), we report the F1 ROUGE-L score of NLSSum with a full Python implemented ROUGE metric[3], which calculates the overlap lexical units between extracted sentences and ground-truth. Following Lin (2004), to assess the significance of the results, we applied bootstrap resampling technique (Davison and Hinkley, 1997) to estimate 95% confidence intervals for every correlation computation.

4.3 Implementation

Our implementation is based on Pytorch (Paszke et al., 2019) and transformers. The pre-trained model employed in NLSSum is `XLMR-Large`. We train NLSSum on one Tesla V100 GPU for 100,000 steps (2 days) with a batch size of 4 and gradient accumulation every two steps. Adam with $\beta_1 = 0.9, \beta_2 = 0.999$ is used as optimizer. The learning rate is linearly increased from 0 to $1e-4$ in the first 2,500 steps (warming-up) and linearly decreased thereafter. For the source document data augmentation, we use a 0.5 word replacement rate with a bilingual dictionary (Conneau et al., 2018).

4.4 Models in Comparison

Oracle sentences are extracted by the greedy algorithm introduced in Section 3.1. **Lead-K** is a simple baseline to choose the first k sentences in a document as its summary. We use $k = 2$ on MLSUM and $k = 3$ on WikiLingua, which lead to the best results. **Pointer-Generator** augments the standard Seq2Seq model with copy and coverage mechanisms (See et al., 2017). **mBERTSum-Gen** is based on the multilingual version BERT (mBERT; Devlin et al. 2019) and it is extended to do generation with a unified masking method in UniLM (Dong et al., 2019). **MARGE** is a pre-trained seq2seq model learned with an unsupervised multilingual paraphrasing objective (Lewis et al., 2020). **mBERTSum**, **XLMRSum**, **XLMRSum-MT** and **XLMRSum-WR** are all extractive models described in Section 3.2 and their sentence encoders are either initialized from `mBERT` or `XLMR-Large`. They are all trained on the Enlgish dataset. XLMRSum-MT is trained on the English training data argumented with machine translation. While XLMRSum-WR is trained on the English training data argumented with bilingual dictionary word replacement.

5 Result & Analysis

ROUGE Results on MLSUM Table 3 shows results on MLSUM. The first block presents the Oracle upper bound and the Lead-2 baseline, while the second block includes the supervised summarization results. Results of Pointer-Generator, mBERTSum-Gen are reported in Scialom et al. (2020), while results of MARGE are reported in Lewis et al. (2020). The results of MARGE training on all languages jointly (Train All) are slightly better than its counterpart when training on each language separately (Train One). While we see a different trend with other models. Comparing ex-

Table 6: Ablation Study, Zero-Shot ROUGE-L Results on Validation Dataset of MLSUM

tractive models against abstractive models in the supervised setting, the abstractive paradigm is still the better choice.

We present the zero-shot results in the third block. All models are trained on the Enlgish summarization dataset and infered on dataset of other languages. With a decent multi-lingual pre-trained model, the extractive XLMRSum performs better than the abstractive MARGE, which demonstrates the superiority of extractive approaches in zero-shot summarization. When applying machine translation based (XLMRSum-MT) and multi-lingual word replacement based (XLMRSum-WR) data argumentation method to XLMR (see Section 3.4), we obtain further improvements. With MT based argumentation method (XLMRSum-MT), we could re-generate extractive labels using the translated doucments and summaries (the U_b setting). We do observe that the re-generated labels could slightly improve the results, but the resulting XLMRSum-MT is still worse than XLMRSum and XLMRSum-WR. With the neural label search method, NLSSum-Sep outperforms all models in comparison. For faster feedback, we train a separate model for each language in XLMRSum-MT and XLMRSum-WR and NLSSum-Sep (models for different languages can be trained in parallel), which is to do data argumentation only to one target language. In our final model NLSSum, we train one model for all languages (we do data argumentation from English to all target languages) and we observe that the results of NLSSum-Sep and NLSSum are similar. Compared with the original XLMRSum, NLSSum achieves 2.27 improvements on the average R-L score, which is a remarkable margin in summarization. It indicates that our multilingual neural label search method significantly improves the multilingual zero-shot transferability. The differences between NLSSum and other models in comparison except NLSSum-Sep are significant ($p < 0.05$). Specifically, the performance XLMRSum-MT is worse than that of XLMRSum. For more in-depth analysis, we note that: 1) As the input of a model, the translation-based documents are prone to the error propagation, therefore, we should avoid to encode these noise documents. 2) Fortunately, our multilingual label only applies the translation method when converting document/summary pair into labels, instead of encoding.

ROUGE Results on WikiLingua To further evaluate the performance of NLSSum, we design additional zero-shot experiments for all our extractive models on WikiLingua. These models are trained on English and inferred on other three languages. The results are in Table 4. We observe that our NLSSum still performs better than all the other extractive models. Meanwhile, compared with the results on MLSUM, the improvement on WikiLingua is not remarkable. Probably because the documents and summaries in WikiLingua are a series of how-to steps, which are more platitudinous than news summarization.

5.1 Ablation Studies

To investigate the influence of each components in NLSSum, we conduct experiments on the validation set of MLSUM and the results are in Table 6. In neural label search, we have two weight predictors, the sentence level predictors $\mathcal{T}_\alpha$ and the label set level predictor $\mathcal{T}_\beta$ (Section 3.6). We can see from the first block of Table 6 that without $\mathcal{T}_\beta$, the result of NLSSum drops. NLSSum leverages four label sets (U_a, U_b, U_c and U_d) to train $\mathcal{T}_\alpha$ and $\mathcal{T}_\beta$. In the second block, we study the effect of each label set separately (note that XLMRSum-WR is the backbone of NLSSum and we therefore build label set baselines upon it). U_a works best overall. However, U_b is better on Russian compared to

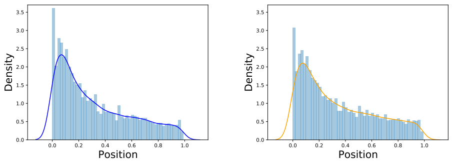
b	c \ d	0.7	0.8
0.7	0.7	32.46	32.51
	0.8	32.33	32.49
0.8	0.7	32.94	**33.03**
	0.8	32.62	32.86

Table 7: ROUGE-L Results for Different Weights

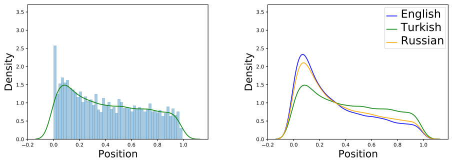
U_a, which indicates these different label sets can compensate for each other. Not surprisingly, using one label set performs worse than NLSSum. In the third block, we use all the label sets, but we use *fixed weights* instead of using weight predicted from neural label search[4]. We can see using multiple label sets can improve variants with only one label set, but there is still a gap to NLSSum, which learns these weights for each sentence automatically. It is also possible to use different weights for different label sets. To make the number of experiments tractable, we conduct experiments on German only and search weight around our optimal value (i.e., 0.8). Results are in Table 7. There is slight gain by using different weights, but the result is still worse than NLSSum. In the last block, we train NLSSum with different word replacement rates. We observe that 55% is the best choice for the bilingual dictionary word replacement and the word replacement rate is not sensitive. In practice, we set the rate to 50% directly instead of tuning it, in order to make the our experiments in *true* zero-shot settings (Perez et al., 2021).

5.2 Human Evaluation

The human evaluation is important for summarization tasks, since the ROUGE can only determine the textual representation overlapping. In this subsection, we design the ranking experiment (Cheng and Lapata, 2016) with system outputs of different systems on the German test set of MLSUM. First, we randomly select 20 samples from the test set of German. Then, we extract summary sentences from the original document with four mBERTSum, XLMRSum, NLSSum, and Oracle. Third, we translate the document and summaries into English by Machine Translation. Finally, the human participants are presented with one translated English document and a list of corresponding translated summaries produced by different approaches. Each example is reviewed by five different participants separately. Participants are requested to rank these summaries by taking the importance and redundancy into account. To measure the quality of MT System, we first translate the English document into German and then back-translate it into English. We observed that there are almost no changes in meanings between the original English documents and the back-translated English documents. We therefore conclude the German to English translation quality is acceptable. As shown in Table 5, NLSSum is ranked 1st 28% of the time and considered best in the extractive models except for Oracle.



(a) English (b) Russian



(c) Turkish (d) Comparison

Figure 3: Density of Summary Sentences in CNN/DM

5.3 Monolingual Label Bias

In Figure 3, we calculate the positions of oracle sentence and plot the kernel density[5]. Specically, we translate the test set of CNN/DM from English into Turkish and Russian, and re-calculate the oracle labels for each language. Then, we collect all of the oracle sentences and keep its relative positions. It is obvious that: 1) The oracle sentences of English are mainly located in the head of document, and the Russian takes the second place, and then the Turkish. That is why the Turkish achieves more improvement than Russian, by comparing the results of NLSSum and XLMRSum in the in Part III of Table 3. 2) Multilingual labels pay more attention to the latter sentences, which is more suitable in multilingual summarization.

6 Conclusion

We first study the monolingual label bias, that when translate the (document, summary) from English

---

[4] *Fixed weight* means a fixed weight for label sets U_b, U_c and U_d, instead of the label search in Section 3.6. Weight of original English labels U_a is set to 1.0, since the second block shows the quality of U_a is the highest.

[5] https://en.wikipedia.org/wiki/Kernel_density_estimation

into other language, the re-converted labels will change along with the transformation of textual representation. Then we propose NLSSum to improve the performance of multilingual zero-shot extractive summarization, by introducing multilingual labels. Finally, the summarization model is trained on English with the weighted multilingual labels and achieves great improvement on other languages.

Abstract

Previous work of class-incremental learning for Named Entity Recognition (NER) relies on the assumption that there exists abundance of labeled data for the training of new classes. In this work, we study a more challenging but practical problem, *i.e.*, few-shot class-incremental learning for NER, where an NER model is trained with only few labeled samples of the new classes, without forgetting knowledge of the old ones. To alleviate the problem of catastrophic forgetting in few-shot class-incremental learning, we generate synthetic data of the old classes using the trained NER model, augmenting the training of new classes. We further develop a framework that distills from the NER model from previous steps with both synthetic data, and real data from the current training set. Experimental results show that our approach achieves significant improvements over existing baselines.

1 Introduction

Existing models of Named Entity Recognition (NER) are usually trained on a large scale dataset with predefined entity classes, then deployed for entity extraction on the test data without further adaptation or refinement. In practice, data of new entity classes that the NER model has not seen during training arrives constantly, thus it is desirable that the NER model can be incrementally updated over time with knowledge of data for these new classes. In this case, one challenge is that the training data of old entity classes may not be available due to privacy concerns or memory limitations (Ma et al., 2020). Then, the model can easily degrade in terms of the performance on old classes when being fine-tuned with only annotations of new entity classes, *i.e.*, *catastrophic forgetting*. In addressing this problem, previous work in class-incremental learning for NER (Monaikul et al., 2021) regularizes the current model by distilling from the previous model trained on old (existing) classes, using text from the training dataset of new classes. However, this requires abundance of data in the new training dataset being used for distillation. Such an assumption is usually unrealistic since the token-level annotations required by NER training are labor-consuming and scarce, especially for the new unseen classes. In this paper, we study a more realistic setting, *i.e.*, few-shot class-incremental learning for NER, where the model (i) incrementally learns on new classes with few annotations, and (ii) without requiring access to training data for old classes.

There is very limited work in few-shot class-incremental learning for NER. Such a setting is more challenging compared with class-incremental learning for NER. First, the few-shot datasets in few-shot class-incremental learning may not contain enough information for the trained model to generalize during testing. Second, it is more challenging to solve the catastrophic forgetting problem in few-shot class-incremental learning when data for old classes is not available and new data is scarce. In class-incremental learning for NER (Monaikul et al., 2021), the same training sequence may contain entities of different classes. Therefore, when the training dataset for new classes is sufficiently large, its context, *i.e.*, words labeled as not from entities of new classes, may also contain abundant entities of the old classes. That is, the new training data can be regarded as an unlabeled *replay* dataset of the existing entity classes. In such case, we can simply address the problem of catastrophic forgetting by distilling from the previous model (trained on old classes) to the current one, using text from such a replay dataset (Monaikul et al., 2021). However, in few-shot class-incremental learning, we cannot expect to avoid catastrophic forgetting by distilling with only the few samples from the new training dataset, since

there may not exist sufficient (if any) entities of the old classes.

In this paper, we propose a framework to enable few-shot class-incremental learning for NER. As mentioned above, since the few-shot dataset may not contain enough entities of old classes as *replay* data for distilling from the previous model, which leads to catastrophic forgetting, we consider generating synthetic data of the old entity classes for distillation. Such data is termed as *synthetic replay*. Specifically, we generate synthetic data samples of old classes by inverting the NER model. Given the previous model trained on the old classes, we optimize the token embeddings of the synthetic data, so that predictions from the previous model can contain old entity classes, given the synthetic data as input. In this way, the synthetic data is likely to contain entities of old classes, and distilling from the previous model with such data will thus encourage knowledge preservation of old classes. Additionally, to ensure the synthetic (reconstructed) data to be realistic, we propose to leverage the readily available real text data for new classes, via adversarially matching the hidden features of tokens from the synthetic data and those from the real data. Note that the synthetic data generated from such adversarial match with real data will contain semantics that are close to the real text data for new classes. Consequently, compared with training with only the few samples of new classes, the synthetic data will provide more diverse context that are close to the samples of the few-shot dataset, augmenting the few-shot training for the new classes. Further, with the generated synthetic data, we propose a framework that trains the NER model with annotations of the new classes, while distilling from the previous model with both the synthetic data and real text from the new training data. Our contributions of this work are summarized as follows:

- We present the first work of studying few-shot incremental learning for Named Entity Recognition (NER), a more practical but challenging problem compared with class-incremental learning for NER.

- We approach the problem by proposing a framework that distills from the existing model with both, real data of new entity classes and synthetic data reconstructed from the model as replay data of old entity classes.

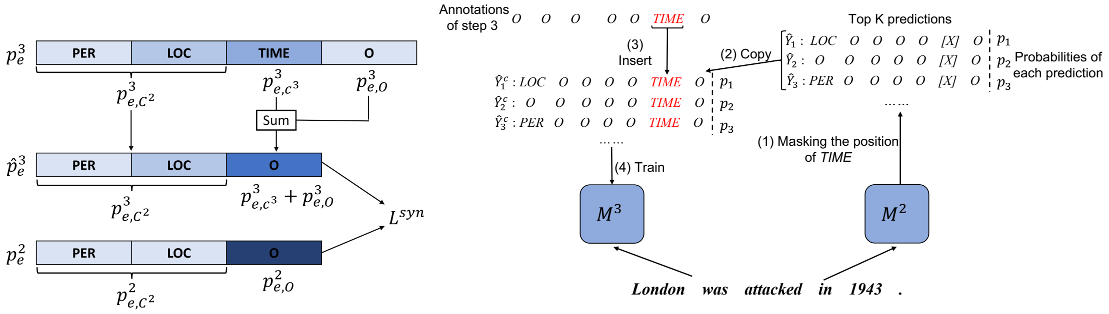
- Experiments show that our method significantly improves over existing baselines for the task of few-shot class-incremental learning in NER.

2 Background

2.1 Problem Definition

Assume there is a stream of NER datasets $\mathcal{D}^1, \ldots, \mathcal{D}^t, \ldots$, annotated with disjoint entity classes, where t is the time step and $\mathcal{D}^t = \{(X_i^t, Y_i^t)\}_{i=1}^{|\mathcal{D}^t|}$ contains c^t entity classes. Here $X_i^t = [x_{i,1}^t, \cdots, x_{i,N_i}^t]$ and $y_i^t = [y_{i,1}^t, \cdots, y_{i,N_i}^t]$ are the NER token and label sequences, respectively, with length N_i, and $|\mathcal{D}^t|$ is the size of the dataset. Dataset $\mathcal{D}^1$ is the base dataset, assumed of reasonably large size for classes of step $t = 1$. The datasets $\{\mathcal{D}^t\}_{t>1}$ are the few-shot datasets with about K samples for each class. In few-shot class-incremental learning, the NER model will be incrementally trained with $\mathcal{D}^1, \mathcal{D}^2, \ldots$, over time, with data from $\mathcal{D}^t$ only available at the t^{th} time step. After being trained with $\mathcal{D}^t$, the model will be evaluated jointly on all entity classes encountered in $\mathcal{D}^1, \cdots, \mathcal{D}^t$, *i.e.*, we do not learn separate prediction modules for each time step. Figure 1 shows an example of annotations for different incremental learning steps on classes of *PER*, *LOC*, and *TIME*.

In Figure 1, we should note that tokens that are labeled as *O* in the current step are likely to contain abundant entities from the previous classes. For instance, tokens annotated as *O* in step 3 include entities of previous classes, *i.e.*, *PER* and *LOC*. Therefore, when a large amount of training data is available for the new classes, the new dataset can be regarded as unlabeled replay data of previous classes. As an example, in Monaikul et al. (2021),



(a) (b)

Figure 2: (a) An example of L^{syn} of Eq (4) at step 3 of Figure 1. (b) An example of distilling with D^t at step 3 of Figure 1. M^2 and M^3 are models from step 2 and 3, respectively. We replace the predictions on the position of "1943" from M^2 with the correct annotation, "TIME", from D^3 before training on M^3.

their performance of class-incremental learning on CoNLL2003 has been comparable or even better than training with full annotations of all the classes encountered, by just distilling with the training data of the new classes. However, in few-shot class-incremental learning, the few training samples of the current step may not contain enough entities of the previous classes. In Section 4, we also discuss the difference between few-shot class-incremental and few-shot learning for NER.

3 Few-Shot Class-Incremental Learning for NER

3.1 The Proposed Framework

Following Beltagy et al. (2019); Souza et al. (2019), we use the BERT-CRF as our NER model, which consists of a BERT$_{base}$ (Devlin et al., 2018) encoder with a linear projection and a conditional random field (CRF) (Lafferty et al., 2001) layer for prediction. We denote M^t as the NER model for step t. M^t is initialized from M^{t-1} to preserve knowledge of old classes. For time step $t > 1$, M^t is expected to learn about the new classes from $\mathcal{D}^t$, while not forgetting the knowledge from $\{\mathcal{D}^k\}_{k=1}^{t-1}$. Assume we have already obtained a synthetic dataset $\mathcal{D}_r^t = \{E_i^{t,r}, Y_i^{t,r}\}_{i=1}^{|\mathcal{D}_r^t|}$ of previous entity classes from $\{\mathcal{D}^k\}_{k=1}^{t-1}$, where $E_i^{t,r} = [e_{i,1}^{t,r}, \cdots, e_{i,N_i}^{t,r}]$ and $Y_i^{t,r} = [y_{i,1}^{t,r}, \cdots, y_{i,N_i}^{t,r}]$ are the reconstructed token embeddings and reference label sequence. $Y_i^{t,r}$ is a randomly sampled label sequence containing classes from the previous steps and $E_i^{t,r}$ is optimized so the output from M^{t-1} with $E_i^{t,r}$ matches $Y_i^{t,r}$. We will discuss the construction of the synthetic $\mathcal{D}_r^t$ in Section 3.2. Given the current training data $\mathcal{D}^t$ and M^{t-1} that has been trained on $\mathcal{D}^{t-1}$, we propose to train M^t by distilling from M^{t-1} with both the real data from D^t and synthetic data from $\mathcal{D}_r^t$. The challenge of such distillation is that the predictions from M^t and M^{t-1} are likely to contain different set of labels, *i.e.*, M^t should also predict with the new entity classes from D^t. This is different from the standard setting of distillation, where the teacher and student models share the same label space (Hinton et al., 2015). In tackling such a problem of label space discrepancy, we propose separate approaches of distillation for $\mathcal{D}^t$ and $\mathcal{D}_r^t$, respectively.

3.1.1 Distilling with Real Data $\mathcal{D}^t$

The distillation from M^{t-1} to M^t involves matching the output distributions between M^t to M^{t-1}. However, given an input sequence X from $\mathcal{D}^t$, the CRF layer outputs correspond to a sequence-level distribution $P_\theta(Y|X)$, *i.e.*, probabilities for all possible label sequences of X, the cardinality of which, grows exponentially large with the length of X. Therefore, it is infeasible to match with the exact output distributions of CRF. Following the current state-of-the-art approach of NER distillation (Wang et al., 2020b), we approximate the sequence-level output distribution of CRF with only its top S predictions. Specifically, for model M^{t-1}, we have,

$$\hat{P}_{M^{t-1}}(Y|X) = [P_{M^{t-1}}(\hat{Y}_1|X), \ldots, \\ P_{M^{t-1}}(\hat{Y}_S|X), 1 - \sum_{s=1}^{S} P_{M^{t-1}}(\hat{Y}_s|X)], \tag{1}$$

where $\{\hat{Y}_s\}_{s=1}^S$ are the top S most probable predictions of label sequence from M^{t-1}. We set $S = 10$. In this way, the output from the CRF of M^{t-1} becomes tractable. However, M^t still cannot be trained with such an output from M^{t-1}. This is because M^{t-1} was not trained with the new classes in $\mathcal{D}^t$. Therefore, when X is from $\mathcal{D}^t$, M^{t-1} will have wrong predictions on the tokens labeled as being from entities of new classes. In order to distill with M^{t-1}, we propose a correction for $\{\hat{Y}_s\}_{s=1}^S$. Figure 2(b) shows an example of such a process. Specifically, on the positions of the sequence where $\mathcal{D}^t$ has labeled as new classes, we replace the predictions in $\{\hat{Y}_s\}_{s=1}^S$ with the annotations from $\mathcal{D}^t$. We denote the corrected set of predictions as $\{\hat{Y}_s^c\}_{s=1}^S$. For training of M^t, we first calculate the predicted distribution of M^t with respect to $\{\hat{Y}_s^c\}_{s=1}^S$, as

$$\begin{aligned}\hat{P}_{M^t}(Y|X) =& [P_{M^t}(\hat{Y}_1^c|X), \cdots, P_{M^t}(\hat{Y}_S^c|X),\\ & 1 - \sum_{s=1}^{S} P_{M^t}(\hat{Y}_s^c|X)],\end{aligned} \quad (2)$$

where we compute the predicted probabilities from M^t with regard to $\{\hat{Y}_s^c\}_{s=1}^S$ from M^{t-1}. Then, M^t can be trained by minimizing the cross entropy between $\hat{P}_{M^{t-1}}(Y|X)$ and $\hat{P}_{M^t}(Y|X)$ via

$$\begin{aligned}& L^{real}(\mathcal{D}^t) = \quad (3)\\ & -\frac{1}{|D^t|}\sum_{X\in D^t} CE(\hat{P}_{M^{t-1}}(Y|X), \hat{P}_{M^t}(Y|X)),\end{aligned}$$

where $CE(\cdot,\cdot)$ is the cross entropy function. Note that the definition of *O* is different in M_{t-1} and M_t. Take Figure 2(b) as an example, the prediction of *O* in step 2 corresponds to both *O* and *TIME* for step 3, since *TIME* is not in the target entity classes of step 2. However, from the annotation of step 3, we know that tokens annotated as *O* are not *TIME*. Therefore, we can safely assume that the prediction of *O* in $\{\hat{Y}_s^c\}_{s=1}^S$ from M_2 matches the definition of *O* in M_3, *i.e.*, the semantics of *O* in $\{\hat{Y}_s^c\}_{s=1}^S$ is the same for M_t and M_{t-1}.

3.1.2 Distilling with Synthetic Data D_r^t

Different from data in $\mathcal{D}^r$, in which we know tokens annotated as *O* are not from the new classes, data from $\mathcal{D}_r^t$ is reconstructed from M_{t-1} and only contains labels for the previous classes. Any token predicted with "O" from M^{t-1} can be potentially labeled as *O* or the new classes by M^t. Therefore, with $\mathcal{D}_r^t$, it is unclear how to correct the output of CRF from M^{t-1}, *i.e.* $\{\hat{Y}_s\}_{s=1}^S$, for training of M^t. By considering the above, we resort to another approach that decomposes the output from CRF, *i.e.*, sequence level label distribution, into marginal label prediction for each token, using the forward and backward method in Lafferty et al. (2001). Figure 2(a) shows a graphic example of our distillation loss L^{syn} with D_r^t. Specifically, let C^t be the cumulative number of possible labels for any given token in NER at step t, *i.e.*, $C^t = \sum_{k=1}^t c^t$, with c^t be the number of class in $\mathcal{D}^t$. For each token with embedding e, we define $p_e^t = [p_{e,O}^t; p_{e,C^{t-1}}^t; p_{e,c^t}^t]$ and $p_e^{t-1} = [p_{e,O}^{t-1}; p_{e,C^{t-1}}^{t-1}]$ as the predicted marginal distribution of a token from M^t and M^{t-1}, respectively. $p_{e,O}^t, p_{e,O}^{t-1} \in \mathbb{R}$ are the probabilities for class O, whereas $p_{e,C^{t-1}}^t, p_{e,C^{t-1}}^{t-1} \in \mathbb{R}^{C^{t-1}}$ are the probabilities for entity classes encountered up to step $t-1$. Further, $p_{e,c^t}^t \in \mathbb{R}^{c^t}$ are probabilities for the new classes in step t. Since *O* from step $t-1$ corresponds to the *O* and the c^t new classes in step t, we first collapse p_e^t by computing $\hat{p}_e^t = [\mathrm{sum}(p_{e,O}^t, p_{e,c^t}^t); p_{e,C^{t-1}-1}^t]$, where we merge the predictions of *O* and c^t new classes. In this way, $\hat{p}_e^t$ will have the same dimension as p_e^{t-1}. Let E_r^t be the set of embeddings for all tokens contained in $\mathcal{D}_r^t$. The distillation loss for $\mathcal{D}_r^t$ is

$$L^{syn}(D_r^t) = \mathbb{E}_{e\in E_r^t}\mathrm{KL}(\hat{p}_e^t || p_e^{t-1}), \quad (4)$$

where $\mathrm{KL}(\cdot||\cdot)$ is the KL divergence.

3.1.3 General Objective

The general objective of M^t for training at step t is given by

$$L^t = L^{real}(\mathcal{D}^t) + \alpha L^{syn}(\mathcal{D}_r^t), \quad (5)$$

where $L^{real}(\cdot)$ and $L^{syn}(\cdot)$ corresponds to distillation with the real data in $\mathcal{D}^t$ and synthetic data in $\mathcal{D}_r^t$, respectively, and α is a parameter balancing between the losses for $\mathcal{D}^t$ and $\mathcal{D}_r^t$. We set $\alpha = 1$ in the experiment.

3.2 Synthetic Data Reconstruction

Now we describe how to reconstruct $\mathcal{D}_r^t$ from M^{t-1}. Given a randomly sampled label sequence Y containing the old entity classes from $\{\mathcal{D}^k\}_{k<t}$, we seek to reconstruct the embedding sequence E corresponding to its training data. In doing so, we randomly initialize embeddings E, then optimize the parameters of E with gradient descent so that its output with M^{t-1} matches the expected label sequence Y. Formally, we optimize E by minimizing the training loss of the CRF as

$$L^{crf} = -\log P_{M^{t-1}}(Y|E). \quad (6)$$

One problem of such reconstruction is that *the resulting synthetic E may not be realistic*. This will result in a domain gap of training on the synthetic data of old entities but testing on the real data. To alleviate this problem, we propose to encourage synthetic data to be more realistic by leveraging the real data from $\mathcal{D}^t$.

Let $h_l^{t-1,syn}(E_r^t)$ be the hidden state from the l^{th} layer of the BERT encoder in M^{t-1}, regarding the set of synthetic token embeddings, E_r^t. Similarly, let $h_l^{t-1,real}(emb(X^t))$ be the output hidden states from the l^{th} layer of M^{t-1}, regarding the set of real tokens, X^t, from $\mathcal{D}_r^t$. Moreover, $emb(\cdot)$ is the embedding layer. We propose to adversarially match $h_l^{t-1,syn}(E_r^t)$ and $h_l^{t-1,real}(emb(X^t))$ so that hidden states from the real and synthetic are not far away from each other. In this way, the reconstructed embeddings from $\mathcal{D}_r^t$ are likely to be more realistic. Specifically, let M_l be a binary discriminator module, *i.e.*, one layer linear projection with sigmoid output, whose inputs are the real and synthetic hidden states,

$$\begin{aligned} M_l^* &= \text{argmin}_{M_l} - \mathbb{E}_{h\in h_l^{t-1,syn}(E_r^t)} \log M_l(h) \\ &\quad - \mathbb{E}_{h\in h_l^{t-1,real}(emb(X^t))} \log(1-M_l(h)), \\ L_l^{adv} &= \mathbb{E}_{h\in h_l^{t-1,syn}(E_r^t)} \log(1-M_l^*(h)). \end{aligned} \tag{7}$$

Finally, the loss for reconstructing D_r^t is

$$L^r = L^{crf} + \beta \sum_{l\in l^s} L_{adv}^l, \tag{8}$$

where $l^s = 2, 4, \cdots, 12$, *i.e.*, we match every two layers of the BERT encoder in M^{t-1}. β is a balancing parameter and is default to 10 in the experiment. Since we train M^t with the reconstructed token embeddings from M^{t-1}, we freeze the BERT token embedding layer during training, so that M^{t-1} and M^t can share the same token embeddings. This is also reasonable for the setting of few shot learning, since tuning all the model parameters with few samples will result in overfitting.

Another problem we should consider is that *the real data $\mathcal{D}^t$ and synthetic data $\mathcal{D}_r^t$ may contain different sets of entity classes*, *i.e.*, the few-shot dataset $\mathcal{D}^t$ may not contain entities of old classes in $\mathcal{D}_r^t$. In this case, for the token embeddings of old classes in $\mathcal{D}_r^t$, *s.t.*, $\{e_{i,j}|y_{i,j}^{t,r} \neq O\}$, matching the hidden states of these embeddings with those from D^t will distract these embedding from being optimized into the entities of old classes, which we will show in the experiments. Therefore, we overload the definition of E_r^t in (4) by excluding embeddings of the old entity classes in $\mathcal{D}_r^t$ from matching, *i.e.*, $E_r^t = \{e_{i,j}|y_{i,j}^{t,r} = O\}$, while X^t contains all the real tokens from $\mathcal{D}^t$. Algorithm 1 shows the complete procedure for constructing $\mathcal{D}_r^t$.

Since $\mathcal{D}_r^t$ contains entities of old classes from previous steps, distilling with $L^{syn}(D_r^t)$ will help preserving knowledge of old entity classes, *i.e.*, avoiding catastrophic forgetting, without accessing the real data from previous steps. Additionally, with $\mathcal{D}_r^t$, M^t is no longer trained with only few samples from $\mathcal{D}^t$, thus is less likely to overfit. This is because $\mathcal{D}_r^t$ can construct a relative larger scale, *e.g.*, several thousand sentences, within the computation limit. Additionally, the semantics of $\mathcal{D}_r^t$ can be close to $\mathcal{D}^t$, since their token embeddings are closely matched. Thus, compared with training only with $\mathcal{D}^t$, $\mathcal{D}_r^t$ provides more diverse text information for M^t during training. Moreover, the entity of old classes from $\mathcal{D}_r^t$ can be regarded as negative samples for training of the new classes in $\mathcal{D}^t$, thus reducing the confusion between old and new classes for M^t during training.

4 Related Work

Class-Incremental Learning: Different from continual learning, *e.g.*, (Hu et al., 2018), which sequentially learn on different tasks (usually with different classes) and requires task labels for prediction, class-incremental learning aims at jointly predicting with all the encountered classes without knowing task labels. Sun et al. (2019); Ke et al. (2021) have study continual learning for different tasks of NLP. Recently, Monaikul et al. (2021) studies class-incremental learning for NER, building a unified NER classifier for all the classes encountered over time. There are two problems regarding this method. Firstly, Monaikul et al. (2021) only works with a non-CRF-based model. However, many current state-of-the-art NER models are built with a CRF module (Liu et al., 2019; Chen et al., 2020; Wang et al., 2021). Secondly, it assumes that a large amount of data for the new classes is available, which is unrealistic since annotations for unseen classes are usually scarce. In this work, we assume only few-shot datasets are available for the new classes, *i.e.*, few-shot class-incremental learning, which was proposed in Tao et al. (2020); Mazumder et al. (2021), yet not studied in NER. Also, note that class-incremental learning is different meta-learning with episode training (Ding et al., 2021; Finn et al., 2017), since tasks/classes of meta-leaning may appear multiple times in episode training, while we assume the dataset of each class only appear once in class-incremental learning.

Few-Shot Learning: Models of few-shot learning are generally trained with a base dataset, then learned to predict unseen target classes with few samples. One branch of the works is based on metric learning. These generally involves predicting by learning to compare token features with class prototypes (Hou et al., 2020) or stored query samples (training data) of target classes (Yang and Katiyar, 2020). The latter violates our setting of class-incremental learning, for which it is prohibitive to store the training data for *e.g.*, privacy issue. Alternatively, Huang et al. (2020) avoids overfitting of few-shot learning by augmenting with noisy or unlabeled data from the web. Our approach is similar to Huang et al. (2020), in that we also augment few-shot training of the current step with additional data, except we use generated synthetic instead of real data. Recently, (Cui et al., 2021) proposes *Template NER*, a few-shot friendly model for NER that convert NER into a sequence-to-sequence problem. Our few-shot class-incremental learning is different from few-shot learning in that *i)* Few-shot learning requires data of different classes arrives at the same time and with complete annotations for all the target classe, while data of few-shot class-incremental learning arrives sequentially, containing annotation of only classes of the current step. *ii)* Existing works of few-shot NER build separate prediction modules for the target and base classes and ignore the performance of base classes during evaluation, thus incompatible with class-incremental learning.

Data-Free Distillation: Data-free distillation refers to the case in which we distill from a teacher model to a student model with the training data of the teacher not available. A typical solution is to reconstruct synthetic training data from the trained teacher model for distillation. Such a setting was previously explored for model compression of image classification (Yin et al., 2020) and text classification (Ma et al., 2020). However, it has not been studied for NER scenarios. We use data-free distillation for transferring knowledge between models from the current and previous steps for few-shot class-incremental learning.

5 Experiments

5.1 Datasets and Implementation

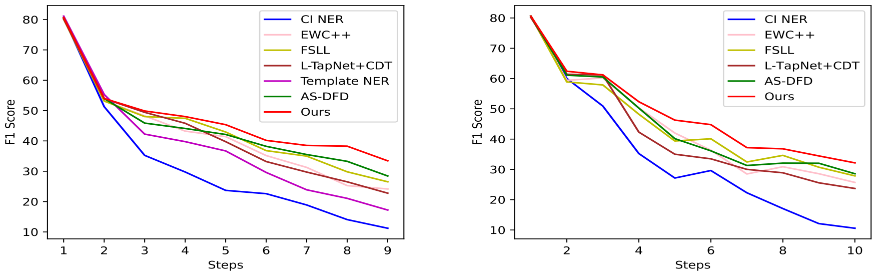
Following the previous work of class-incremental learning for NER (Monaikul et al., 2021), we experiment with two datasets: CoNLL2003 and Ontonote 5.0. For CoNLL2003, our results are average over eight ordering of entity classes for each step as in Monaikul et al. (2021). For Ontonote 5.0, we rank the entities in alphabetic order and experiment with two combinations of different entity classes for different steps. Table 3 and 4 in the Appendix list the entity classes used for each step. Since CoNLL2003 is a relative smaller dataset, we conduct both 5-shot and 10-shot experiments for CoNLL2003 and 5-shot experiments for OntoNote 5.0. Following Yang and Katiyar (2020), our base datasets, *i.e.*, dataset of step 1, is the training data of CoNLL2003 and OntoNote 5.0, labeled with only entity classes included in step 1. The few-shot datasets are sampled from the evaluation dataset with greedy sampling (Yang and Katiyar, 2020). The resulting NER model of each step is tested on the entire test set. Please refer to the Appendix for addition details.

Algorithm 1 Algorithm for constructing D_r^t from M^{t-1}.

```
Input: Model from the previous step, $M^{t-1}$, set of old classes up to $t-1$, $V = \{v_i\}_{i=1}^{C^{t-1}}$.
Output: The reconstructed data $D_r^t$.
$D_r^t = \emptyset$
for $v$ in $V$ do
    for $i$ in $1 \cdots N$ do
        Uniformly sample $n_e \in [1, n_e^{max}]$.
        Uniformly sample $n_s \in [n_e, n_s^{max}]$.
        Uniformly sample $k \in [1, n_s - n_e + 1]$.
        Construct a target label sequence $Y$ of length $n_s$, with a length $n_e$ entity of class $v$ starting from position $k$.
        Randomly initialize an embedding sequence $E$ of length $n_s$.
        while not converge do
            Update $E$ with (8)
        end while
        Add $\{E, Y\}$ to $D_r^t$.
    end for
end for
```

5.2 Baselines and Ablation Study

We compare with the state-of-the art work of class-incremental learning for NER (*CI NER*). Additionally, we implement EWC++ (Chaudhry et al., 2018) with $\alpha = 0$, *i.e.*, using weights regularization to avoid forgetting instead of generating synthetic data. We also implement FSLL (Mazumder et al.,



(a) (b)

Figure 3: 5-shot Class-Incremental few-shot learning for OntoNote 5.0 data with two combination of classes for each step. (a) P_1 (b) P_2. In the appendix, we include the class combinations, P_1 and P_2, for OntoNote 5.0 and corresponding ablation study.

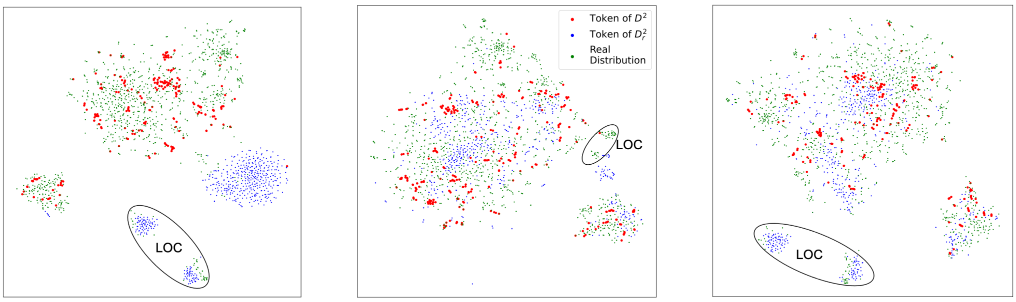
2021), a state-of-the-art method of few-shot class-incremental learning for *image classification* with metric learning. As mentioned in the related work section, our method can be considered as data-free distillation. Therefore, we also include *AS-DFD* (Ma et al., 2020), the state-of-the-art method of data-free distillation in *text classification*. Specifically, we construct D_r^t with the adversarial regularization described in *AS-DFD* instead of (8). We also adapt *L-TAPNet+CDT* (Hou et al., 2020) for comparison. *L-TAPNet+CDT* is a state-of-the-art work of few-shot learning for sequence labeling with CRF module. Please refer to Appendix for how we adapt it for class-incremental learning.

As an ablation study, we compare our method with: *i) Ours (*$\alpha = 0$*)*, only train with only D^t with $\alpha = 0$. *ii) Ours (*$\alpha = 0$*, marg)*, which is also training with $\alpha = 0$. The difference is that instead of using the sequence-level distillation with $L^{real}(D^t)$, we decompose the output of CRF into marginal predictions for each token, as described before (4). In this way, we can directly apply the token-level distillation in *CI NER* (Monaikul et al., 2021) for the CRF-based NER model. Compared with *Ours (*$\alpha = 0$*)*, this is included to show the performance of directly applying token-level distillation for CRF-based model. *iii)* In *Ours (*$\beta = 0$*)*, we examine the usefulness of L^{adv} by setting $\beta = 0$. *iv) Ours (all tokens)*, which matches all the synthetic tokens in D_r^t with real tokens in D^t, instead of matching with only those labeled as *O* in D_r^t, as described after eq (8).

5.3 Results of Few-Shot Class-Incremental Learning

Table 1 and 2 show the F1 scores from different steps of few-shot class-Incremental learning on CoNLL2003. The values are averaged over eight permutations as in (Monaikul et al., 2021). Our methods outperform all the considered baselines for both 5-shot and 10-shot learning. Especially, *CI NER* (Monaikul et al., 2021) has the worst result among all the methods. This is because the performance of *CI NER* relies on a large amount of data from D^t for replay of previous entities. Therefore, it does not work well in the few-shot scenario, where D^t with only few samples may not contain entities of old classes for replay. Additionally, we find that the performance of *AS-DFD* (Ma et al., 2020) is slightly lower than *Ours (*$\beta = 0$*)*, *i.e.*,



(a) (b) (c)

Figure 4: T-SNE plots of real and synthetic token embeddings with 10-shot *LOC*→*PER*, *i.e.*, training on *LOC* for step 1 and *PER* for step 2. D^2 is a 10-shot dataset for *PER*. We visualize the token embedding from the the last layer of the BERT encoder in M^1, *i.e.*, trained only on *LOC*. (a) *Ours* ($\beta = 0$), no adversarial matching between tokens from D^2 and D_r^2. (b) *Ours (all tokens)*, matching all the tokens from D^2 and all the tokens from D_r^2. (c) *Ours*, excluding the synthetic tokens that are labeled as of entities from old classes, *i.e.*, *LOC*, from adversarial matching. The *real distribution* refers to tokens from the testing dataset, which are not available during training. We use black ellipses to mark tokens from the *real distribution* that are predicted as *LOC*, *i.e.*, the old entities.

distilling using data reconstructed with only L^{crf}. *AS-DFD* is designed for text classification, where they use the feature of the special token *[CLS]* from BERT for classification, while features of the non-special tokens (within text) are trained with an augmented task of language modeling. However, in NER, features of the non-special tokens are directly used for prediction. Thus, simultaneously training such features with language modeling may distract the model from learning the task specific information needed for NER.

In the ablation study, we find that our adversarial matching indeed improves the quality of the synthetic data (*Ours vs. Ours* ($\beta = 0$)), especially when excluding tokens of the reconstructed old entities from matching (*Ours vs. Ours (all tokens)*). Further, *Ours* ($\alpha = 0$, *marg*) has lower performance than *Ours* ($\alpha = 0$), showing that it might not be optimal to directly apply *CI NER* (Monaikul et al., 2021) with CRF based models.

Figure 3 shows the results of class-incremental with OntoNote 5.0. Since there are more steps relative to the experiments for CoNLL2003, following previous works in few-shot class-incremental learning (Tao et al., 2020; Mazumder et al., 2021), we plot the F1 scores as curves, to highlight the relative difference of different methods over time. Our method consistently outperforms the baselines. Note that with larger number of steps of incremental learning, the curves may not be necessarily monotonically decreasing. This may indeed happen because training with some classes can benefit the performance of other downstream classes, thus (locally) increasing the overall performance. In Appendix, we also present the ablation study with OntoNote 5.0.

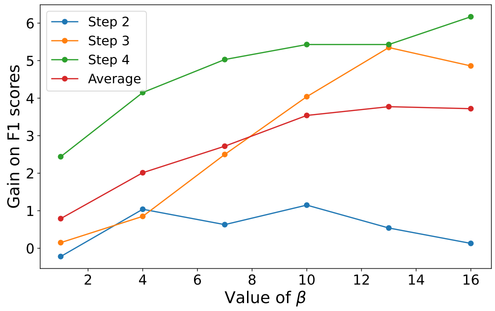


Figure 5: F1 score gains of 10-shot learning with different values of β on CoNLL2003, relative to $\beta = 0$.

5.4 Visualization of Token Embeddings

Figure 4 shows the t-sne plots of hidden states of tokens from 10-shot *LOC*→*PER* (explained in the caption). In (a), we can find that there are synthetic tokens that are very close to the real *LOC* tokens (green dots in the black ellipse). These synthetic tokens (within the black ellipse) are the reconstructed *LOC*. On the contrary, the synthetic context, *i.e.*, the rest of the synthetic tokens outside the ellipse, are far away from the real distribution. This may because the context contains more diverse information, which makes it more difficult to be reconstructed. Such a difference between real and synthetic tokens may cause a domain shift between training and testing, since we are training on synthetic token and testing on real tokens.

Note that there is no tokens from D^2 (red dots) in the black ellipse of *LOC*, indicating that there may not be *LOC* entities in the few-shot dataset D^2, unlike in non-few-shot learning where D^2 can contain a lot of entities of the old classes (*LOC*). (b) shows the result of matching all the synthetic tokens from D^2_r with all the real ones from D^2. In this way, most of the synthetic tokens are matched with the real ones, except that only few synthetic tokens are aligned with the real *LOC* tokens. This is because the few-shot dataset D^2 may not contain entities from the old classes *LOC*. In this case, the adversarial matching will distract synthetic tokens from being reconstructed as *LOC*. Then, the reconstructed embedding sequences will contain less information from the old classes (*LOC*). In (c), we exclude synthetic tokens that are intended to be reconstructed as the old class *LOC*, *i.e.*, labeled as *LOC* in the target label sequence Y in Algorithm 1. As a result, the synthetic tokens contain both *LOC* and context that is aligned with the real distribution.

5.5 Results of Varying β

We investigate the relationship between model performance and the value of β, *i.e.*, the parameter controlling the degree of adversarial matching. Figure 5 shows the the F1 scores from different steps on CoNLL2003, with different values of β. We experiment with 10-shot and report the gain of F1 score compared with $\beta = 0$. We noticed that there is positive gain of the average F1 score on the whole experiment for a range of β values, *i.e.*, $[1, 16]$. These results demonstrate that the proposed adversarial matching between the real and synthetic data (D^t and D^t_r) is generally beneficial and is not sensitive to the selection of β.

6 Conclusion

We present the first work of few-shot class-Incremental learning for NER To address the problem of catastrophic forgetting, we proposed to reconstruct synthetic training of the old entity classes from the model trained at the previous time step. Additionally, the synthetic data allows the model to be trained with a more diverse context, thus less likely to overfit to the few training samples of current step. Experimental results showed that our method outperforms the baselines, enabling the NER model to incrementally learning from new classes with few samples.

D Additional Details

We set the learning rate for our NER model is 5e-5. The model is trained with 50 epochs of D^t, with learning batch size of 1 for 5-shot and 2 for 10-shot experiments. The batch size of training with D^t_r is 5 for each reconstructed class. Following Ma et al. (2020), the token embeddings in D^t_r are initialized with $N(0, 0.35)$, then optimized with a learning rate of 1e-2. We have $n^{max}_e = 4$ and $n^{max}_s = 30$. Our code is modified based on Huggingface[*] with python 3.7 and pytorch 1.7.0, run on 8 P100 GPUs, each with a 16GB memory. Following the prior work[*], when constructing D^t_r, we add the tokens of *[CLS]* and *[SEP]* before and after the sequence of token embeddings that are intended to be reconstructed, so that it is consistent with the input format of BERT. Then, we append after *[SEP]* with *[PAD]* to construct a padded embedding sequence of length 128. In algorithm 1, we freeze the embedding of *[CLS]*, *[SEP]* and *[PAD]*, *i.e.*, the gradients from eq (10) in the main paper are not backpropagated into embeddings of *[CLS]*, *[SEP]* and *[PAD]*. At each time step, we reconstructed 150 samples for each previous class. These samples are discarded after training of the current step.

E Adapting *L-TapNet+CDT* for Class-Incremental Learning

There are two challenge adapting *L-TapNet+CDT* for class-incremental learning. *i)* Unlike dew-shot

learning, where the few-shot dataset contains complete annotations for all the target classes, dataset of class-incremental leanring only contains data of the current classes, *i.e.*, entities of old or future classes are labeled as O. *ii)* The sematics of O changes with different time step. Without a complete annotation of both current and previous classes, it is unclear how to collect O tokens for constructing the prototype of O for the current class, since tokens labeled as O in the current step may be within span if old entity classes.

To solve the above problem, for each time step, we samples a *fake* few-shot dataset labeled with both current and old classes. We use entities of new classes to construct corresponding prototypes. These prototypes are saved for future steps, *i.e.*, fixed as classification weights for classification of these classes. We use tokens labeled as O in the *fake* dataset for constructing the current O prototypes. Labels for the old classes in the *fake* dataset are not directly used for prediction. Note that this can be a easier problem compared with few-shot class-incremental learning, since the *fake* dataset contains labels of old classes, though we avoid using them for prediction.

Improving Meta-learning for Low-resource Text Classification and Generation via Memory Imitation

Abstract

Building models of natural language processing (NLP) is challenging in low-resource scenarios where only limited data are available. Optimization-based meta-learning algorithms achieve promising results in low-resource scenarios by adapting a well-generalized model initialization to handle new tasks. Nonetheless, these approaches suffer from the *memorization overfitting* issue, where the model tends to memorize the meta-training tasks while ignoring support sets when adapting to new tasks. To address this issue, we propose a memory imitation meta-learning (MemIML) method that enhances the model's reliance on support sets for task adaptation. Specifically, we introduce a task-specific memory module to store support set information and construct an imitation module to force query sets to imitate the behaviors of some representative support-set samples stored in the memory. A theoretical analysis is provided to prove the effectiveness of our method, and empirical results also demonstrate that our method outperforms competitive baselines on both text classification and generation tasks.

1 Introduction

Building natural language processing (NLP) models in low-resource scenarios is of great importance in practical applications because labeled data are scarce. Meta-learning-based methods (Thrun and Pratt, 2012) have been commonly used in such scenarios owing to their fast adaptation ability. Notable successes have been achieved by meta-learning on low-resource NLP tasks, such as multi-domain sentiment classification (Yu et al., 2018; Geng et al., 2019) and personalized dialogue generation (Madotto et al., 2019; Song et al., 2020; Zheng et al., 2020).

Among different meta-learning approaches (Hospedales et al., 2021), optimization-based approaches have been widely used in various low-resource NLP scenarios (Madotto et al., 2019; Qian and Yu, 2019; Li et al., 2020; Mi et al., 2019) because they are model-agnostic and easily applicable. Concretely, optimization-based meta-learning algorithms aim to learn a well-generalized global model initialization θ that can quickly adapt to new tasks within a few steps of gradient updates. In the meta-training process, we first train θ on a *support set* (i.e., a few training samples of a new task i) to obtain task-specific parameters θ'_i. Then, we optimize θ based on the performance of θ'_i on a *query set* (i.e., another set of samples in task i).

Despite its effectiveness, optimization-based meta-learning algorithms usually suffer from the *memorization overfitting* issue [1] (Yin et al., 2020; Rajendran et al., 2020), where the learned model tends to solve all the meta-training tasks by memorization, rather than learning how to quickly adapt from one task to another via support sets. This is acceptable for training process, but results in poor generalization on the meta-testing sets, because the memorized model does not have knowledge of those tasks and does not know how to utilize the base learner to learn new tasks. Hence, this issue hinders the model from capturing task-specific characteristics from support sets and thus prevents the model from adapting to distinct new tasks (Rajendran et al., 2020). For instance, in personalized dialogue generation, this implies that the dialog model cannot adapt to individual users based on short conversation histories and hence fails to generate personalized responses.

Several works have been proposed to tackle the memorization overfitting issue for regression and image classification tasks. Some studies try to explicitly regularize the model parameters (Yin et al.,

---

*Corresponding author

[1] Memorization overfitting is different from the overfitting in conventional supervised learning (Hawkins, 2004). The latter means that the model overfits to the training tasks and fails to generalize to the testing tasks.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 583 - 595
May 22-27, 2022

2020; Rajendran et al., 2020), but this restricts the complexity of model initialization and reduces the model capacity. Another line of research integrates samples from support sets into the corresponding query sets via data augmentation (Yao et al., 2021). However, data augmentation on textual data may result in noisy labels or distribution shifts, which impairs the model performance (Chen et al., 2021).

In this paper, we address the memorization overfitting issue by enhancing the model's dependence on support sets when learning the model initialization, which forces the model to better leverage information from support sets. As an analogy, consider a young investor who has the ability to adapt to new circumstances rapidly but little memory of learned experiences, and an old investor who is experienced but refuses to be flexible. Our idea is to make the young investor adaptive to the various situations when he assesses his benefits so that he can not only take advantage of the old one's experience but also learn from the old investor how to leverage the learned experience. In this paper, the young investor stands for a standard meta-learning algorithm (e.g., MAML), which is prone to memorization overfitting, and the old investor is a memory module we integrate into the method, carrying information of support sets.

Specifically, we propose a Memory-Imitation Meta-Learning (MemIML) method that forces query set predictions to depend on their corresponding support sets by dynamically imitating behaviors of the latter. We therefore, introduce a memory module and an imitation module to enhance such dependence. The memory module is task-specific, storing representative information of support sets. The imitation module assists in predicting samples of query sets by dynamically imitating the memory construction. In this way, the model has to access the support set by memory imitation each time it makes a prediction on a query-set sample, hence it's no longer feasible for the model to memorize all meta tasks.

The contributions of this work are:

1. A novel method MemIML is proposed to alleviate the memorization overfitting for optimization-based meta-learning algorithms. It encourages the utilization of support sets with the help of a memory module and an imitation module when adapting to new tasks.
2. Comprehensive experiments on text classification and generation tasks show that MemIML significantly outperforms competitive baselines.
3. Theoretical proofs are given to demonstrate the effectiveness of our method.

2 Related Work

Meta-Learning. Meta-Learning aims to improve the learning algorithm itself based on the previously learned experience (Thrun and Pratt, 1998; Hospedales et al., 2021). In general, there are three categories of meta-learning methods: model-based methods, (Santoro et al., 2016; Obamuyide et al., 2019) which depend on the particular model design to facilitate fast learning; metric-based methods, (Vinyals et al., 2016; Snell et al., 2017; Geng et al., 2019) which encode samples into an embedding space and classify them based on the learned distance metric; optimization-based methods (Finn et al., 2017; Mi et al., 2019) that learn a well-generalized model initialization which allows for fast adaptation to new tasks. For low-resource scenarios in NLP, optimization-based meta-learning methods achieved promising results on tasks such as personalized dialog generation (Madotto et al., 2019; Song et al., 2020; Tian et al., 2021), low-resource machine translation (Gu et al., 2018; Sharaf et al., 2020) and question answering (Yan et al., 2020), few-shot slot tagging (Wang et al., 2021), and so on.

Memorization overfitting of Meta-learning. Meta-learning algorithms suffer from memorization overfitting. Yin et al. (2020) build an information bottleneck to the model, while this approach decreases the model performance with this passive regularization. Rajendran et al. (2020) inject random noise to the ground truth of both support and query sets, while little extra knowledge is introduced to learn a good initialization. Yao et al. (2021) address overfitting issues by augmenting meta-training tasks through mixing up support and query sets. However, such augmentation for text needs to be based on the assumption of keeping the label and the data distribution unchanged, which is often not true in practice (Chen et al., 2021). Instead of regularization and data augmentation, we leverage the support sets information stored in the memory to augment the meta-learning.

External Memory for Few-shot Learning. Memory mechanism has proven to be powerful for few-shot learning (Geng et al., 2019; Santoro et al., 2016; Munkhdalai et al., 2019). Current methods either refine representations stored in the memory (Ramalho and Garnelo, 2018) or refining parameters using the memory (Munkhdalai and Yu, 2017; Cai et al., 2018; Wang et al., 2020). In the NLP domain, some methods store encoded contextual information into a memory (Kaiser et al., 2017; Holla et al., 2020; Zheng et al., 2019). Geng et al. (2019) propose a memory induction module with a dynamic routing algorithm for few-shot text classification tasks. Munkhdalai et al. (2019) augment the model with an external memory by learning a neural memory. Wang et al. (2021) reuse learned features stored in the memory on the few-shot slot tagging.

3 Preliminaries

We first formulate model-agnostic meta-learning (MAML) (Finn et al., 2017). Specifically, denote the base model used in MAML as f_θ and assume each task $\mathcal{T}_i$ sampled from a task distribution $p(\mathcal{T})$ associates with a dataset $\mathcal{D}_i$. Each dataset $\mathcal{D}_i$ consists of a support set $\mathcal{D}_i^s = \{(X_j^s, Y_j^s)\}_{j=1}^{N^s}$ and a query set $\mathcal{D}_i^q = \{(X_j^q, Y_j^q)\}_{j=1}^{N^q}$, where X and Y denote the input and ground truth of a sample, respectively. During the meta-training stage, a task-specific (a.k.a., post-update) model $f_{\theta_i'}$ is first obtained for each task $\mathcal{T}_i$ via gradient descent over its support set $\mathcal{D}_i^s$. Then MAML updates its initialization (a.k.a., pre-update) θ according to the performance of $f_{\theta_i'}$ on the query set $\mathcal{D}_i^q$ as in Eq.1:

$$\theta^* = \min_\theta E_{\mathcal{T}_i \sim p(\mathcal{T})} \left[\mathcal{L}\left(f_{\theta_i'}\left(X_i^q\right), Y_i^q \right) \right] \quad (1)$$

$$\text{s.t. } \theta_i' = \theta - \alpha \nabla_\theta \mathcal{L}\left(f_\theta\left(X_i^s\right), Y_i^s\right) \quad (2)$$

where α is the inner loop learning rate. During the meta-testing stage, the learned initialization θ^* is fine-tuned on the support set $\mathcal{D}_t^s$ for task $\mathcal{T}_t$, and the resulting model is evaluated on the query set $\mathcal{D}_t^q$ with the post-update parameters θ_t'.

4 Methodology

To alleviate the memorization overfitting issue in meta-learning, we propose MemIML, which includes a memory module and an imitation module on the grounds of a base model. The memory module is task-specific, recording the mapping behaviors between inputs and outputs of support sets for each task. The imitation module is shared across tasks and predicts values for each query-set sample by dynamically imitating the memory construction. The acquired support set information leveraged by the imitation module augments the model initialization learning, enhancing the dependence of the model's task adaptation on support sets. Fig. 1 shows our model architecture.

4.1 Memory Module

We design a memory module M_i for each task $\mathcal{T}_i$ and incorporate it in the MAML framework. In order to fully leverage information from support sets, we construct key-value pairs from support-set samples and store them in the memory module. The key is the sentence representation of a sample input from support sets obtained from an introduced key network. The corresponding value is constructed to store the information of the sample output (ground truth) as in Sec. 4.3: in NLG tasks, the value is the sentence embedding of the output sentence; in NLU tasks, the value is the one hot embedding of the class label (a scalar) of the sample. Our memory has two operations: *memory writing* that constructs the memory and *memory reading* that acquires information from memory. In the following, we elaborate on these contents in detail.

Key Network represents a sample with a vector. Specifically, we use a frozen pre-trained BERT model (Devlin et al., 2019) as the key network. The input of the key network is the sample input sentence $X_j^s \in \mathcal{D}_i^s$ ($X_j^q \in \mathcal{D}_i^q$), and the output is the encoded representation of the first token (i.e. [CLS] token) of the sentence. The acquired representation is regarded as the key K_j^s for X_j^s (K_j^q for X_j^q).

Memory Writing constructs the memory using the information of samples in the support set $\mathcal{D}_i^s$. For each task $\mathcal{T}_i$, the task-specific memory M_i consists of N^i memory slots (i.e. key-value pairs $\{K_l^s, V_l^s\}_{l=1}^{N_i}$). To build these memory slots, we select samples from support sets and write their information into the memory. The sample selection is according to a diversity-based selection criterion (Xie et al., 2015) to ensure the diversity and representativeness of the memory content. The detailed description of this criterion is in Appendix. D.

For each task-specific memory module M_i, we adopt the diversity score as $S(M_i)$ on the stored keys. Here, a more diverse memory gets a higher diversity score. When the memory is not full, we directly write support-set samples without selection; otherwise, we compute the diversity score of the current memory and scores after every old key-value pair is replaced with a new key-value pair. Then we replace the old pair with the new one

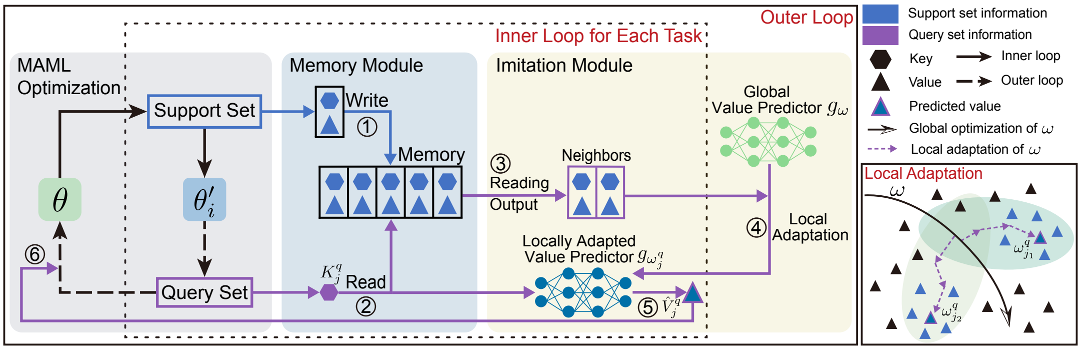

Figure 1: The architecture of our model, MemIML. The left area details the procedure of predicting a query-set sample X_j^q in each task with a task-specific memory module and an imitation module shared across tasks. The right area illustrates the local adaption of the value predictor. The two green areas represent the neighboring areas of the global parameters ω for two query-set samples in one task.

where the replacement can maximize the diversity score. In this way, the memory we build can carry more distinguishable and representative information and efficiently utilize the storage space.

Memory Reading obtains information from memory to enhance the meta-learning. The input is the sentence representation of the sample in query sets encoded by the key network, and the output is the memory slots similar to the query sample. Specifically, given the key representation K_j^q of a sample $X_j^q \in \mathcal{D}_i^q$, we retrieve the top N most similar slots from its task-specific memory M_i. The similarity is measured based on the Euclidean distance between K_j^q and each key K_l^s in the memory slots. The retrieved key-value pairs $\{K_l^s, V_l^s\}_{l=1}^N$ act as the output of memory reading.

4.2 Imitation Module

In order to better leverage the retrieved memory and enhance the dependence of our model on support sets, we propose an imitation module to encourage the imitation of support sets behaviors when making predictions on query sets. For each sample X_j^q in the query set, the inputs of the imitation module are the key K_j^q and its retrieved N memory slots, and the output is the predicted value $\hat{V}_j^q$ for X_j^q. To achieve the imitation, we construct a value predictor that can model the behaviors of support-set samples (i.e. key-value matching) stored in the memory. For estimating the value of each query-set sample, we conduct *local adaptation* on the value predictor to adapt the matching.

In this way, the proposed imitation module is customized for each query-set sample, which facilitates better capture of specific task information than directly using the memory reading output, especially when tasks are versatile. The reason is that the similarity measurement of previous memory reading operations is based on the fixed BERT representations, which ignores the task-specific information.

4.2.1 Value Predictor

In MemIML, the proposed value predictor aims to build a mapping from keys to values of the memory module mentioned in Sec. 4.1. The input of the value predictor is a key obtained from the key network, and the output is the associated value.

Specifically, we use a two-layer fully-connected network g_ω with parameters ω to build the mapping. The value predictor is learned over constructed key-value pairs of support sets across all tasks. Given the key K_j^q of a query-set sample input X_j^q, we can then estimate its associated value as $\hat{V}_j^q$.

4.2.2 Training of The Value Predictor

To train the value predictor, we minimize the reconstruction loss $\mathcal{L}_\omega^{rec}(\hat{V}, V)$ to make the predicted values as close as possible to values constructed from the ground truths of support-set samples, where $\mathcal{L}_\omega^{rec}$ is the cross-entropy loss if the value V is a label and is the mean square loss if V is a vector.

The training procedure includes the global optimization shared across tasks and the local adaptation for each specific task. Specifically, we first train the value predictor with samples from support sets of all tasks. After feeding the memory reading output of a query-set sample to this network, we perform local adaptation and employ the adapted network to estimate the value for the query sample.

Global Optimization. To obtain the task-independent global parameters ω, we train the value predictor over constructed keys (i.e., as inputs) and values (i.e., as outputs) from support-set samples of all tasks. The global optimization keeps updating in the whole meta-training phase.

Local Adaptation. To make the value predictor adaptive to each query-set sample X_j^q, inspired by (Sprechmann et al., 2018), we propose local adaptation that fine-tunes the global value predictor g_ω to get an adapted one with parameters ω_j^q. The local adaptation only works when predicting X_j^q.

Based on the initial parameters ω from the global optimization, we perform several gradient descent steps to minimize the loss $\mathcal{L}^{loc}$, which is:

$$\mathcal{L}^{loc} = \gamma \|\tilde{\omega} - \omega\|_2^2 + \frac{1}{N} \sum_{l=1}^{N} \mathcal{L}_{\tilde{\omega}}^{rec}(\hat{V}_l^s, V_l^s) \quad (3)$$

Here, $\hat{V}_l^s = g_{\tilde{\omega}}(K_l^s)$, $\{K_l^s, V_l^s\}_{l=1}^N$ is the memory reading output of the query-set sample, and the factor γ restricts the distance between ω_j^q and ω. Minimizing the second term encourages $g_{\omega_j^q}$ to better estimate the retrieved memory values $\{V_l^s\}_{l=1}^N$. Then we can acquire the locally adapted value prediction network $g_{\omega_j^q}$ with parameters $\omega_j^q = \arg\min_{\tilde{\omega}} \mathcal{L}^{loc}(\tilde{\omega})$. Given a query-sample key K_j^q, we can thus predict its associated value as

$$\hat{V}_j^q = g_{\omega_j^q}(K_j^q), \quad (4)$$

where the adapted parameters ω_j^q are discarded thereafter, and the model does not back-propagate through $\hat{V}_j^q$.

In this sense, besides the task-specific parameter θ_i' provided by MAML, there will also be ω_j^q learned from support sets specific to each query-set sample. This guarantees that the model relies more on support sets for task adaptation. Fig. 1 (right part) illustrates the mechanism of local adaptation.

4.3 MemIML on NLP Applications

In this part, we will elaborate on two few-shot applications in NLP (i.e., text generation and text classification) to solve the memorization overfitting problem of MAML. The model structures of these applications are basically the same, except for the following three points: the base model, the way to get the value V_l^s stored in the memory module, and the way to leverage the output $\hat{V}_j^q$ of Sec. 4.2.

Personalized Dialogue Generation. The base model is the transformer (Vaswani et al., 2017) consisting of an encoder and a decoder. In this task, each sample consists of an input utterance and a ground truth utterance, so the value V_l^s stored in the memory is obtained from the ground truth utterance Y_l^s of a support-set sample, which is embedded by the key network followed by an LSTM (Hochreiter and Schmidhuber, 1997). This LSTM is optimized with the base model. The $\hat{V}_j^q$, concatenated with the encoder outputs, serves as a new input for the decoder. Hence, we acquire the prediction of a query-set sample via $\hat{Y}_j^q = \text{Decoder}([\hat{V}_j^q; \text{Encoder}(X_j^q)])$.

Multi-domain Sentiment Classification. The base model is a BERT (Devlin et al., 2019) followed by a fully-connected network. Each sample consists of an input sentence and a sentiment label (ground truth), so the memory value V_l^s is the sentiment label. To leverage $\hat{V}_j^q$, we interpolate it with the original output of the base model $\tilde{Y}_j^q$ as

$$\hat{Y}_j^q = \beta \tilde{Y}_j^q + (1 - \beta) \hat{V}_j^q \quad (5)$$

where β balances $\tilde{Y}_j^q$ and $\hat{V}_j^q$. Notice that the interpolation not only works on the prediction output but also guides the training via gradient descent based on the interpolated output. We verify the effectiveness of the interpolation in Appendix. C.

Algorithm 1 Memory Imitation Meta-training

```
Require: $p(\mathcal{T})$: task distribution, $\alpha_{1-4}$: step sizes
Initialize $\theta$ from pretrained model; initialize $\omega$ randomly;
  initialize memory for $T$ tasks as $\{M_i\}_{i=1}^{T} = \{\phi\}_{j=1}^{T}$
while not converge do
    Sample batch of tasks $\{\mathcal{T}_i\}_{i=1}^{n}$, where $\mathcal{T}_i \sim p(\mathcal{T})$
    for all task $\mathcal{T}_i$ do
        Sample support set $\mathcal{D}_i^s$ and query set $\mathcal{D}_i^q$ from $\mathcal{T}_i$
        Obtain the keys $\{K_l^s\}_{l=1}^{N^s}$ and the values $\{V_l^s\}_{l=1}^{N^s}$
          for the support set $\mathcal{D}_i^s$ as in Sec. 4.1
        $M_i \leftarrow \{< K_l^s, V_l^s >\}_{l=1}^{N^s}$ # Write memory
        $\omega \leftarrow \omega - \alpha_1 \nabla_\omega \mathcal{L}^{rec}$ # Global optimization
        $\theta_i' \leftarrow \theta - \alpha_2 \nabla_\theta \mathcal{L}^{base}$ # Learn $\theta_i'$ in Eq. 2
        for $(X_j^q, Y_j^q)$ in $\mathcal{D}_i^q$ do
            Obtain the keys $K_j^q$ for each sample $X_j^q$
            Retrieve $N$ nearest neighbors of $K_j^q$ from $M_i$.
            $\omega_j^q \leftarrow \omega - \alpha_3 \nabla_\omega \mathcal{L}^{loc}$ # Local adaptation
            $\hat{V}_j^q = g_{\omega_j^q}(K_j^q)$ # Predict memory output
            Predict $\hat{Y}_j^q$ as in Sec. 4.3
        end for
    end for
    Update $\theta \leftarrow \theta - \alpha_4 \nabla_\theta \sum_{\mathcal{T}_i \sim p(\mathcal{T})} \mathcal{L}_{\mathcal{T}_i,\theta_i'}^{base}(\hat{Y}^q, Y^q)$
end while

Table 1: Overall performance over Persona-Chat dataset. The results with * indicate that the improvements of our model overall baselines are statistically significant with $p < 0.05$ under t-test.

4.4 Theoretical Analysis

We theoretically investigate how our method helps to alleviate the memorization overfitting problem. Following Yin et al. (2020), we use mutual information $\mathcal{I}(\hat{Y}_i^q;\mathcal{D}_i^s|\theta, X_i^q)$ to measure the level of the memorization overfitting. When the learned model ignores support sets to predict query sets, $\mathcal{I}(\hat{Y}_i^q;\mathcal{D}_i^s)|\theta, X_i^q) = 0$ occurs, which indicates the complete memorization overfitting in meta-learning (Yin et al., 2020). Hence, lower mutual information means more serious memorization overfitting issues.

We propose a criterion similar to (Yao et al., 2021) to measure the validity of our method for tackling this problem. For a task $\mathcal{T}_i = \{D_i^s, D_i^q\}$, the criterion aims to mitigate the memorization overfitting by enhancing the model's dependence on the support set $\mathcal{D}_i^s$, i.e. increasing the mutual information between support set and $\hat{Y}_i^q$ as follows:

$$\mathcal{I}(\hat{Y}_i^q;[\mathcal{D}_i^s,\mathcal{M}_i]\,|\,\theta,X_i^q)>\mathcal{I}(\hat{Y}_i^q;\mathcal{D}_i^s\,|\,\theta,X_i^q), \quad (6)$$

where $\mathcal{M}_i$ means additional memory information we provide, which contains support sets information to augment the inference of the sample X_i^q in $\mathcal{D}_i^q$. We demonstrate our method MemIML meets the above criterion (See details in Appendix. A.).

4.5 The Procedure of Training and Testing

In the meta-training phase (shown in Alg. 1), MemIML first constructs an empty memory for each task and then follows the bi-level optimization process of MAML. In the inner loop, MemIML adapts the base model initialization θ to task-specific parameters via training on the support set. At the same time, from each support-set sample, MemIML obtains a key-value pair and determines whether to write it into the memory or not. Then, MemIML conducts the global optimization of the value predictor over these key-value pairs. In the outer loop, each sample of the query set reads the memory to retrieve the most similar memory slots. Local adaptation fine-tunes the value predictor on those retrieved slots. Next, the adapted value predictor estimates the value of each query sample and uses it to augment the learning of the model initialization. The total loss function in the inner loop is $\mathcal{L}^{total} = \mathcal{L}^{base} + \mathcal{L}^{rec}$, where $\mathcal{L}^{base} = \mathcal{L}(f(X^s), Y^s)$ is the cross-entropy loss.

The procedure of meta-training and meta-testing are almost the same except that meta-testing does not optimize the learned model initialization θ and the initial parameter ω of the value predictor. For each task $\mathcal{T}_t$ in the meta-testing phase, MemIML also adapts θ to task-specific parameters θ_i' in the inner-loop and constructs the task-specific memory. In the outer-loop, MemIML retrieves key-value pairs from the memory to conduct local adaptation based on the initial parameter ω. The estimated value $\hat{V}_t^q$ from local adaptation helps the base model to infer the final output $\hat{Y}_t^q$.

5 Experiments and Analysis

Experiments on personalized dialogue generation and multi-domain sentiment classification verify our model on text generation and classification, respectively, where we use Persona-Chat and ARSC datasets.

5.1 Personalized Dialogue Generation

Dataset. Following (Zhang et al., 2018), we use Persona-chat (Madotto et al., 2019) by regarding building a dialog model for each person as a task. The dataset consists of a training/validation/testing set with 1137/99/100 persons (tasks) separately. In the Persona-Chat dataset, each persona description has 8.3 unique dialogues on average, and each task consists of three samples.

Baselines. We compare our methods with the following baselines: **Base Model**: We pretrain a conventional transformer-based dialog generation

Type	Methods	Accuracy
Non meta-learning	Fine-tune	80.73
Metric-based meta-learning	Matching Net	81.22
	Prototypical Net	80.13
	Proto ++	82.41
	Relation Net	81.32
	Induction Net	79.31
Optimization-based meta-learning	MAML	82.17
	MR-MAML	78.14
	Meta-Aug	83.57
	MetaMix	83.63
	MemIML (Ours)	**85.69***

Table 2: The results of mean accuracy over the ARSC. * indicates that our improvement overall baselines is statistically significant with $p < 0.01$ under t-test.

model over all the training tasks ignoring the speakers' personality. **Fine-tune**: We fine-tune the pre-trained base model on the support sets of each meta-testing task. **MAML**: We apply MAML (Madotto et al., 2019) to the base model. **MR-MAML**: Yin et al. (2020) tackle the memorization overfitting of MAML via regularization.

Metrics. Automatic evaluation has three aspects,

- *Quality*: **BLEU-n** (Papineni et al., 2002), **CIDEr** (Vedantam et al., 2015), and **ROUGE** (Lin, 2004) measures the n-gram matching between the generated response and ground truth. **PPL** (perplexity) measures the sentence fluency.
- *Diversity*. **Dist-n** (Li et al., 2016) evaluates the response diversity by counting unique n-grams.
- *Consistency*: **C score** (Madotto et al., 2019) measures the consistency between the generated responses and persona descriptions through a pre-trained natural language inference model.

Human evaluation consists of **Quality** and **Consistency**. (See details in Appendix. B.1).

Overall Performance. As shown in Table 1. **Fine-tune** outperforms **Base Model** in all metrics, which verifies that the task-specific data is helpful to its performance on specific tasks. Compared to **Fine-tune**, **MAML** behaves better on diversity and consistency but behaves worse on quality. Pre-training the base model achieves the best perplexity (lowest PPL) as shown by **Base Model** and **Fine-tune**. We analyze that it's because pretraining leads to a considerable degree of fluency in their generated utterances and is careless about each task's specific information, resulting in low consistency with tasks. Our model, **MemIML**, performs the best in most aspects, including quality, diversity, and task consistency. In particular, MemIML significantly improves MR-MAML in alleviating the memorization overfitting issue, suggesting that memory imitation is more effective than only regularizing model initialization.

5.2 Multi-domain Sentiment Classification

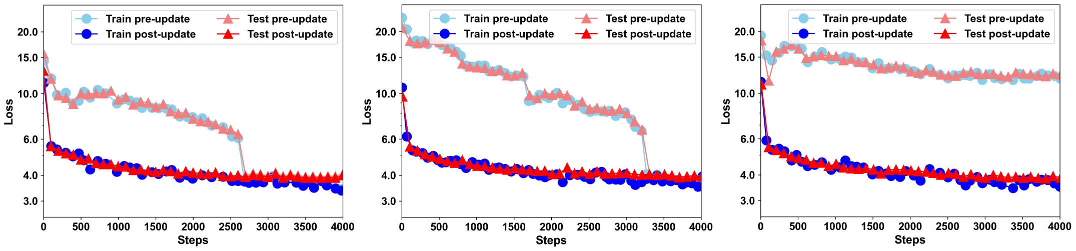
Dataset. Amazon Review sentiment classification dataset (ARSC) (Yu et al., 2018) contains 69 tasks in total. Following (Geng et al., 2019), we build a 2-way 5-shot meta-learning with 57 tasks for meta-training and 12 tasks for meta-testing. We conduct experiments on the ARSC (Yu et al., 2018). It contains English reviews of 23 types of Amazon products, where each product consists of three different binary classification tasks. Following Geng et al. (2019), we select 12 tasks from 4 domains (*Books, DVD, Electronics, Kitchen*) for meta-testing tasks, and the support sets of these tasks are fixed (Yu et al., 2018).

Baselines. We compare our methods with the following baselines: **Fine-tune**: We fine-tune a pre-trained BERT on the support set of meta-testing tasks (non-meta-learning method) as in Appendix. B.2. We choose five metric-based meta-learning baselines: **Matching Net** (Vinyals et al., 2016), **Prototypical Net** (Snell et al., 2017), **Proto ++**, (Ren et al., 2018), **Relation Net** (Sung et al., 2018), and **Induction Net** (Geng et al., 2019). We apply an optimization-based baseline (**MAML**) (Finn et al., 2017) to the base model, and implement some approaches tackling the memorization overfitting problem based on MAML: **MR-MAML** (Yin et al., 2020), **MetaMix**, (Yao et al., 2021) and **Meta-Aug** (Rajendran et al., 2020).

Overall Performance. Table 2 shows the performance measured by the mean accuracy of meta-testing tasks. Our model, **MemIML** outperforms all competing approaches including non-meta-learning, metric-based meta-learning, and optimization-based meta-learning methods. Particularly, our model surpasses the current solutions to the memorization overfitting problem (**MR-MAML, Meta-Aug, MetaMix**), indicating that our method is more effective compared to regularization and textual augmentation.

5.3 Memorization Overfitting Analysis

In Figure 2, the gaps of the losses on query sets between pre-update θ (before training on support sets)



(a) MAML (b) MR-MAML (c) MemIML (Ours)

Figure 2: Memorization overfitting analysis on Persona-Chat. Small loss gaps between pre-update θ and post-update θ_i' (in MAML and MR-MAML) indicate the serious memorization overfitting issue (i.e., the gap between sky-blue and blue curves in meta-training and the gap between pink and red curves in meta-testing). The large gap in MemIML demonstrates the effectiveness of our method.

80%	85.69	10	84.47
50%	84.84	20	85.69
20%	84.35	50	85.04

Table 4: Memory analysis on ARSC.

and post-update θ_i' (after training on support sets) indicate the memorization overfitting problem. The gap between sky-blue and blue curves measures the memorization overfitting of meta-training (the gap between pink and red curves measures meta-testing). Small loss gaps indicate a severe memorization overfitting where support sets are almost useless for task adaptation. Those loss gaps between θ and θ_i' collapse in MAML and MR-MAML after about 3000 steps. This indicates that the post-update θ_i' barely benefits from the support set, and thus the memorization overfitting issue is severe. In Figure 2 (c), MemIML has large gaps between θ and θ_i', implying that θ_i' better leverages support sets when adapting to new tasks and thus alleviates the memorization overfitting issue.

5.4 Ablation Studies

In Table 3, we conduct ablation studies to verify the effectiveness of each component. Removing *Similarity-Search* means the memory reading operation randomly outputs memory slots instead of searching for similar memory slots. This variant underperforms MemIML, indicating that similar samples stored in the memory provide more useful information to improve the model performance. Removing the *value predictor* means directly using the memory output without a learnable network. Its results are not too bad, indicating that the memory module helps to mitigate the memorization overfitting problem. However, this usage simply aggregates the support set information into the query set, which is not as precise as learning the information required by the query set itself. Therefore, it is still inferior to our model. Removing *Local adaptation* means we only use the global value predictor to estimate the memory output. It is crucial to the value predictor since removing it from the value predictor results in an even worse performance than removing the *value predictor*. Besides, the significant drop in task consistency (C-score) shows that local adaptation contributes a lot to making the model adaptive to specific tasks, as it learns to adapt to each query-set sample.

5.5 Analysis of Memory Operations

Memory Size. In Table 4 and 5, we investigate the variants of our task-specific memory module of different sizes. We control the memory size through $|M|$ = store ratio $\times$ $|D^s|$. The results demonstrate that our model is able to maintain high performance even with only a 20% memory size by storing diverse and representative samples of support sets. Besides, as the ratio of stored samples increases, the model's performance is improved since it provides more information for the inference of query samples and the optimization of the model initialization. Storing all the encountered samples (i.e., with store ratio 100%) in the memory instead introduces some noise that damages the model performance.

		PPL	C-score	BLEU3	BLEU4	Dist1	Dist2	ROUGE	CIDEr
Store ratio	1	43.54	0.197	4.224	2.447	0.014	0.055	0.179	0.174

Table 5: Analysis of Persona-Chat dataset.

Number of Neighbors. We also investigate the effects of different numbers of neighbors for the model performance in Table 4 and Table 5. In both datasets, the model performs better with a larger number of neighbors. However, when the number of neighbors is too large, the model retrieves some dissimilar slots from the memory module. These dissimilar slots bring much noise, which makes the predictions of query samples inaccurate.

5.6 Case Study

We present two generated cases in personalized dialog in Table. 6. **Base Model**, **Fine-tune**, and **MAML** generate general responses with little useful information or responses that are not consistent with the personality of personas. **MR-MAML** generates irrelevant responses to the dialogue context. Our model not only responds coherently to the dialog history but also caters to the persona descriptions of each user.

6 Conclusion

In this paper, we tackle the memorization overfitting problem of meta-learning for text classification and generation applications. We propose MemIML to enhance the dependence of the model on the support sets for task adaptation. MemIML introduces a memory module storing the information of support sets, and propose an imitation module to better leverage the support set information by imitating the behaviors of the memory. Both empirical and theoretical results demonstrate that our method MemIML effectively alleviates the memorization overfitting problem.

7 Ethical Considerations

The persona-based dialogue generation task aims to build a dialogue model which generates meaningful, fluent, and consistent responses. It will facilitate human-computer interactions in practice. However, the training of the model for personalized dialogues may lead to the leakage of personal privacy information. In this work, the data source we use is from a published dataset and does not involve privacy issues for the data collection. Our proposed method does not include inference or judgments about individuals and does not generate any discriminatory, insulting responses. Our work validates the proposed method and baseline models on human evaluation which involves manual labor. We hire five annotators to score 750 generated sentences in total (250 sentences for each model we evaluate). The hourly pay is set to 15 US$ per person, which is higher than the local statutory minimum wage.

Persona A	I am a professional singer. I graduated from USC. I love watching horror films. I was born in South Carolina.
Dialogues	A: Where are you from? I grew up in South Carolina. B: I was born in Arkansas, but I now live in Chicago. A: Did you go to college there? B: Yes, I am in school now while working part-time as a barista.
Human Response	I graduated recently from USC.My parents pushed me into it.
Base Model	What do you do for a living?
Fine-tune	Are you in trouble?
MAML	Do you work in the fitness industry?
MR-MAML	That sounds illegal. Are they not protected?
MemIML	That would be cool! I love horror films.
Persona A	I have a large garden. My hobby is walking. I love to travel. I teach biology at a college.
Dialogues	B: Hi, Merna here. Single, 32 and scared of dogs. You? A: I am dave, 40. B: Oh, okay. I am a good cook!
Human Response	Cool, I grow my own vegetables in my garden garden.
Base Model	What do you do for a living?
Fine-tune	What do you teach?
MAML	What do you do?
MR-MAML	I am doing great. How are you tonight?
MemIML	Oh, i am a science teacher and love travel.

Table 6: Two generated examples in the Persona-Chat dataset. Colored texts indicate that the responses match the personality descriptions.

A Validity of Memory Imitation Strategy

Proof of inequality in Eqn. 6. We check the validity of memory imitation by examining whether the criterion in Section 4.4 is met. We check the increase of mutual information between predictions of query sets with the provided support-set information after augmented with the memory information $\mathcal{M}$.

$$\begin{aligned}
&\mathcal{I}(\hat{Y}^q;[D^s,\mathcal{M}]|\theta,X^q)-\mathcal{I}(\hat{Y}^q;D^s|\theta,X^q)\\
=&\,H(\hat{Y}^q|\theta,X^q)-H(\hat{Y}^q|D^s,\mathcal{M},\theta,X^q)\\
&\;-H(\hat{Y}^q|\theta,X^q)+H(\hat{Y}^q|D^s,\theta,X^q)\\
=&\;-H(\hat{Y}^q|X^q,X^s,Y^s,\mathcal{M},\theta)\\
&\;+H(\hat{Y}^q|X^q,X^s,Y^s,\theta).
\end{aligned}\tag{7}$$

For short, we use notation $\boldsymbol{Z}=(X^q,X^s,Y^s,\theta)$ to denote a set of variables. Then we can rewrite (7) as

$$\begin{aligned}
&-H(\hat{Y}^q|\boldsymbol{Z},\mathcal{M})+H(\hat{Y}^q|\boldsymbol{Z})\\
=&\,E_{\hat{Y}^q,\boldsymbol{Z},\mathcal{M}}\left[\log p(\hat{Y}^q|\boldsymbol{Z},\mathcal{M})\right]\\
&-E_{\hat{Y}^q,\boldsymbol{Z}}\left[\log p(\hat{Y}^q|\boldsymbol{Z})\right].
\end{aligned}$$

Note that trivially, we have $E_{\mathcal{M}}[1]=1$, so we get

$$E_{\hat{Y}^q,\boldsymbol{Z}}\left[p(\hat{Y}^q|\boldsymbol{Z})\right]=E_{\hat{Y}^q,\boldsymbol{Z},\mathcal{M}}\left[p(\hat{Y}^q|\boldsymbol{Z})\right]$$

since $p(\hat{Y}^q,\boldsymbol{Z})$ does not rely on the variable $\mathcal{M}$. Hence, we can just write $E_{\hat{Y}^q,\boldsymbol{Z},\mathcal{M}}$ as E for short. Then the equation (7) will become to

$$\begin{aligned}
&E[\log p(\hat{Y}^q|\boldsymbol{Z},\mathcal{M})]-E[\log p(\hat{Y}^q|\boldsymbol{Z})]\\
=&\,E[\log\frac{p(\hat{Y}^q|\mathcal{M},\boldsymbol{Z})}{p(\hat{Y}^q|\boldsymbol{Z})}]\\
=&\sum_{\hat{Y}^q,\mathcal{M},\boldsymbol{Z}}p(\boldsymbol{Z})p(\hat{Y}^q,\mathcal{M}|\boldsymbol{Z})\log\frac{p(\hat{Y}^q,\mathcal{M}|\boldsymbol{Z})}{p(\hat{Y}^q|\boldsymbol{Z})p(\mathcal{M}|\boldsymbol{Z})}\\
=&\,E_{\boldsymbol{Z}}[KL(p(\mathcal{M},\hat{Y}^q|\boldsymbol{Z})\|p(\hat{Y}^q|\boldsymbol{Z})p(\mathcal{M}|\boldsymbol{Z}))]\\
>&\,0
\end{aligned}$$

where the last inequality holds due to $\hat{Y}^q$ is dependent on $\mathcal{M}$. □

We also investigate that memory imitation improves the learning of model initialization via another criterion $\mathcal{I}(\theta;[D^q,\mathcal{M}]|D^q)>0$ following Yao et al. (2021). This criterion guarantees that the additional memory knowledge contributes to updating the initialization in the outer loop. Since all the meta-training tasks satisfy this criterion, the generalization ability of the model initialization improves.

Proof.

$$
\begin{aligned}
&\mathcal{I}(\theta; [D^q, \mathcal{M}]|D^q) \\
&= H(\theta|D^q) - H(\theta|D^q, \mathcal{M}) \\
&= E[-\log P(\theta|D^q)] + E[\log p([\theta|D^q, \mathcal{M})])] \\
&= E[\log \frac{p(\theta|D^q, \mathcal{M})}{p(\theta|D^q)}] > 0
\end{aligned}
$$

□

B Experimental Details

B.1 Personalized Dialogue Generation

Experimental Setup. We implement our model based on the transformer (Dehghani et al., 2018; Vaswani et al., 2017) with pre-trained Glove embedding (Pennington et al., 2014) following (Madotto et al., 2019). The hidden dimensions of the LSTM unit are set to 1024. We set the number of neighbors $N = 10$ and the number of local adaptation steps $L = 20$. We follow all other hyperparameter settings in Madotto et al. (2019): we use SGD for the inner loop training and Adam for the outer loop update with learning rates 0.01 and 0.0003, respectively. We set batch size as 16 and use beam search with beam size 5.

Human Evaluation We conduct human evaluation following Song et al. (2020) considering two aspects **Quality** and **Consistency** where five well-educated volunteers annotate 250 generated responses for each model. The annotators score each response from two aspects: **Quality** and **Consistency** in a 3-point scale: 2 for good, 1 for fair, and 0 for bad. *Quality* measures coherence, fluency, and informativeness. *Consistency* measures the task consistency between the generated responses and the person's persona description.

B.2 Multi-domain Sentiment Classification

Experimental Setup. We utilize a BERT (Devlin et al., 2019) as the encoder. We fine-tune the off-the-shelf pre-trained BERT on the masked language modeling task following (Dopierre et al., 2021) as it greatly improves embeddings' quality (Sun et al., 2019). The fine-tuned BERT is then used as the initialization for all few-shot models. We use Adam (Kingma and Ba, 2015) optimizer for both inner and outer loop update with learning rate $2e^{-5}$ and $1e^{-5}$ respectively, and we set $\beta = 0.2$ in Eqn. 5, the number of neighbors $N = 20$ and the number of local adaptation steps $L = 5$.

C Effectiveness of the Interpolation

To measure whether MemIML improves the learned model initialization, we add an experiment that does not incorporate the memory module during meta-testing (i.e., $\beta = 1$ in Eq. 5) for the multi-domain sentiment classification task. The better result of MemIML than MAML and other regularization methods demonstrate the superiority of our model.

Model	Mean Accuracy
MAML	82.17
MR-MAML	78.14
Meta-Aug	83.57
MetaMix	83.63
MemIML ($\beta = 1$)	84.95

Table 7: Comparison of mean accuracy on the ARSC.

D Diversity-selection Criterion

For each task-specific memory module M, following Xie et al. (2015), we adopt the diversity score as $S(M) = \mu(M) - \sigma(M)$ on the stored keys, where $\mu(M) = \frac{1}{N^2}\sum_{j=1}^{N}\sum_{h=1}^{N}\angle(K_j, K_h)$ denotes the mean of angles between every two stored key representations and $\sigma(M) = \frac{1}{N^2}\sum_{j=1}^{N}\sum_{h=1}^{N}(\angle(K_j, K_h) - \mu(M))^2$ denotes the variance of those angles [2].

---

[2] $\angle(K_j, K_h) = arccos(\frac{K_j \cdot K_h}{\|K_j\|_2\|K_h\|_2})$

Quality Controlled Paraphrase Generation

Abstract

Paraphrase generation has been widely used in various downstream tasks. Most tasks benefit mainly from high quality paraphrases, namely those that are semantically similar to, yet linguistically diverse from, the original sentence. Generating high-quality paraphrases is challenging as it becomes increasingly hard to preserve meaning as linguistic diversity increases. Recent works achieve nice results by controlling specific aspects of the paraphrase, such as its syntactic tree. However, they do not allow to directly control the quality of the generated paraphrase, and suffer from low flexibility and scalability. Here we propose QCPG, a quality-guided controlled paraphrase generation model, that allows directly controlling the quality dimensions. Furthermore, we suggest a method that given a sentence, identifies points in the quality control space that are expected to yield optimal generated paraphrases. We show that our method is able to generate paraphrases which maintain the original meaning while achieving higher diversity than the uncontrolled baseline. The models, the code, and the data can be found in `https://github.com/IBM/quality-controlled-paraphrase-generation`.

1 Introduction

Paraphrase generation, namely rewriting a sentence using different words and/or syntax while preserving its meaning (Bhagat and Hovy, 2013), is an important technique in natural language processing, that has been widely used in various downstream tasks including question answering (Fader et al., 2014a; McCann et al., 2018), summarization (Rush et al., 2015), data augmentation (Yu et al., 2018) and adversarial learning (Iyyer et al., 2018). However, not all paraphrases are equally useful. For most real-world applications, paraphrases which are too similar to the original sentence are of limited value, while those with high linguistic diversity, i.e. with large syntactic/lexical differences between the paraphrase and the original sentence, are more beneficial to the robustness and accuracy of automatic text evaluation and classification, and can avoid the blandness caused by repetitive patterns (Qian et al., 2019). The quality of paraphrases is often evaluated using three dimensions, where high quality paraphrases are those with high semantic similarity as well as high lexical and/or syntactic diversity (McCarthy et al., 2009).

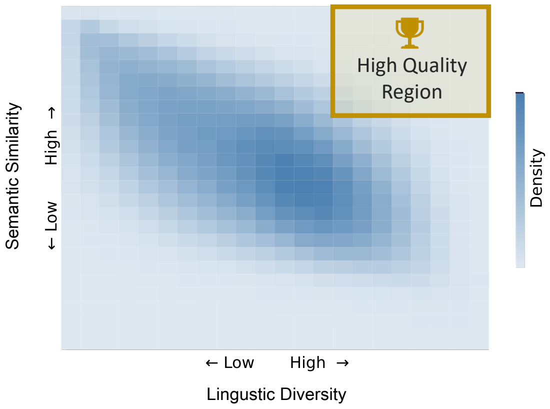

Figure 1: Density of paraphrases in WikiAnswers as a function of the semantic similarity and the linguistic diversity. The marked area, which contains high quality paraphrases, is very sparse (The measures used in the figure are described in Section 2.1) .

Generating high quality paraphrases can be challenging (for both humans and automatic models) since it is increasingly difficult to preserve meaning with increasing linguistic diversity. Indeed, when examining the quality of paraphrases among paraphrase generation datasets, one can find a wide range of paraphrase qualities, where the area of high quality is often very sparse (see Figure 1). This in turn results in scarcity of supervised data for high-quality paraphrase generation.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 596 - 609

A recent approach aiming to produce high quality paraphrases is controlled paraphrase generation, which exposes control mechanisms that can be manipulated to produce diversity. While the controlled generation approaches have yielded impressive results, they require providing the model with very specific information regarding the target sentence, such as its parse tree (Iyyer et al., 2018) or the list of keywords it needs to contain (Zeng et al., 2019). However, for most downstream applications, the important property of the paraphrase is its overall quality, rather than its specific syntactic or lexical form. The over-specificity of existing control-based methods not only complicates their usage and limits their scalability, but also hinders their coverage. Thus, it would be desirable to develop a paraphrase generation model, which uses a simple mechanism for directly controlling paraphrase quality, while avoiding unnecessary complications associated with fine-grained controls.

In this paper we propose QCPG, a Quality Controlled Paraphrase Generation model, that given an input sentence and quality constraints, represented by a three dimensional vector of semantic similarity, and syntactic and lexical distances, produces a target sentence that conforms to the quality constraints.

Our constraints are much simpler than previously suggested ones, such as parse trees or keyword lists, and leave the model the freedom to choose how to attain the desired quality levels.

Enabling the direct control of the three quality dimensions, allows flexibility with respect to the specific requirements of the task at hand, and opens a range of generation possibilities: paraphrases of various flavors (e.g. syntactically vs. lexically diverse), quasi-paraphrases (with lower semantic similarity), and even non-paraphrases which may be useful for downstream tasks (e.g. hard negative examples of sentences that are linguistically similar but have different meanings (Guo et al., 2018; Reimers and Gurevych, 2020)).

Our results show that the QCPG model indeed enables controlling paraphrase quality along the three quality dimensions.

Furthermore, even though the training data is of mixed quality, and exhibits scarcity in the high quality area (see Figure 1), our model is able to learn high quality paraphrasing behavior, i.e. it increases the linguistic diversity of the generated paraphrases without decreasing the semantic similarity compared to the uncontrolled baseline.

2 Method

In this section we provide a general description of our approach. We first explain how the different quality dimensions are measured. We then describe the controlled paraphrase generation model, QCPG, and finally we suggest a method that given the task requirements, detects the input control values which maximize the quality of the generated paraphrases. Figure 2 summarizes our proposed solution for generating controlled paraphrases, which is detailed in the rest of the section.

2.1 Quantifying Paraphrase Quality

The most common dimensions for measuring paraphrase quality are the semantic, syntactic and lexical dimensions. Several previous works used also a fluency evaluation metric (Siddique et al., 2020). However, since our focus is on the supervised setting, we rely on the gold paraphrases as fluency guidance for the model (McCarthy et al., 2009). Thus, given a sentence s and a paraphrase s', we define the paraphrase quality as a three dimensional vector $\mathbf{q}(s, s') = (q_{sem}(s, s'), q_{syn}(s, s'), q_{lex}(s, s'))$, where q_{sem} is a measure of semantic similarity, and q_{syn} and q_{lex} are measures of syntactic and lexical variation, respectively. For the syntactic score, inspired by Iyyer et al. (2018) we choose $q_{syn}(s, s')$ to be the normalized tree edit distance (Zhang and Shasha, 1989) between the third level constituency parse-trees of s and s', after removing the tokens - to increase the decoupling from the lexical distance metric. We define the lexical score $q_{lex}(s, s')$ to be the normalized character-level minimal edit distance between the bag of words. This measure is independent of word order, and hence increases the decoupling from syntactic measures. Additionally, calculating the token distances on the character level enables to capture tokens that share the same stem/lemma. Character-level distance is also more robust to typos that may be found in noisy data. As for the semantic score, several strong metrics have been recently proposed for measuring semantic similarity between sentences. In order to select $q_{sem}(s, s')$, we studied the agreement between the candidate metrics and human judgments, using only development data, and found Bleurt (Sellam et al., 2020) to have the highest correlation with human judgments (see Appendix A). Thus, we define

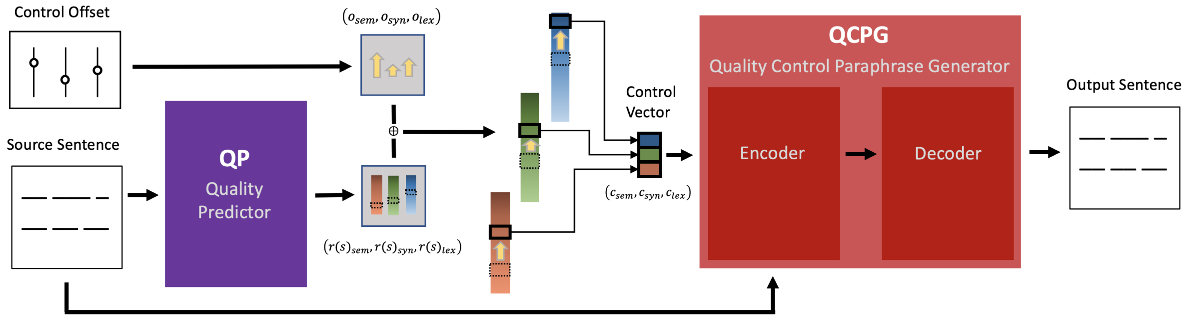

Figure 2: Solution Architecture. The input to the paraphrase generation model, QCPG, is composed of two elements: a sentence s, and a three-dimensional quality vector $c = (c_{sem}, c_{syn}, c_{lex})$, which controls the quality of the generated paraphrase. Selecting appropriate values of c is crucial for obtaining high-quality paraphrases. The quality predictor model, QP, helps select suitable input quality vectors, by predicting the typical quality, $r(s)$, of the paraphrases of s. The control vector c is the sum of $r(s)$, and an offset vector o, which indicates the extent to which the requested quality deviates from the typical value. Dev-set results can help the user in selecting suitable values of o, as shown in Figure 5

$q_{sem}(s, s')$ to be the Bleurt score, normalized using the sigmoid function to ensure a uniform range of values, $[0, 1]$, for all three quality dimensions. For ease of presentation all metrics are presented on a $0 - 100$ scale.

2.2 The QCPG Model

The main component of our solution is a quality controlled paraphrase generation model (QCPG), which is an encoder-decoder model trained on the task of controlled paraphrase generation. Given an input sentence s and a control vector $\mathbf{c} = (c_{sem}, c_{syn}, c_{lex})$, the goal of QCPG is to generate an output paraphrase $QCPG(s, \mathbf{c})$ that conforms to $\mathbf{c}$. We train QCPG using the training set pairs (s, t), by setting $\mathbf{c}$ to be $\mathbf{q}(s, t)$, and maximizing $P(t|s, \mathbf{c} = \mathbf{q}(s, t))$ over the training set via the autoregressive cross entropy loss.

2.3 Control Values Selection

A major challenge in the research of controlled paraphrase generation, is selecting appropriate input control values that can be achieved by the model (Goyal and Durrett, 2020). Clearly, given a sentence, not all paraphrase qualities are achievable. Some sentences are more amenable to paraphrasing than others. For example, named entities and numbers are much harder to be replaced while keeping sentence meaning, and hence, the potential lexical diversity of paraphrases involving such terms is relatively limited. Forcing QCPG to conform to quality control values that are too high with respect to the input sentence, may lead to suboptimal quality of the resultant paraphrases. Thus, for a more effective use of QCPG, the control values should be determined with respect to the input sentence.

Below we describe the second part of our solution, namely a method that given a sentence, predicts the input control values, $\mathbf{c}(s)$, that optimize the expected quality of the paraphrases generated by QCPG. For simplicity we assume that the quality distribution $p(\mathbf{q}|s)$ of all paraphrases of sentence s, is approximately normally distributed around a sentence dependent mean $\mathbf{q_0}(s)$, and that the variance is approximately sentence-independent. We further assume that given an input sentence s, the difficulty to generate a paraphrase of a given quality, $\mathbf{q}$, is dominated by $p(\mathbf{q}|s)$ rather than by the quality vector $\mathbf{q}$ itself.

Following our assumptions, the level of difficulty can be expressed by the offset, $\mathbf{o} = (o_{sem}, o_{syn}, o_{lex})$ of $\mathbf{q}$ from $\mathbf{q_0}(s)$. Thus, the input control, $\mathbf{c}(s)$, for QCPG, is the sum of $\mathbf{q_0}(s)$ and an offset $\mathbf{o}$.

Our aim is to analyze the model results for varying levels of difficulty, namely under different offsets, $\mathbf{o}$, from $\mathbf{q_0}(s)$.

The Quality Predictor (QP): Since $\mathbf{q_0}(s)$ is unknown, we introduce QP, a regressor whose output, termed the reference of s, $\mathbf{r}(s) = (r_{sem}(s), r_{syn}(s), r_{lex}(s))$, approximates $\mathbf{q_0}(s)$. During training, QP aims to predict $\mathbf{q}(s, t)$ given s, where (s, t) are the input-output pairs of the training data.

To summarize, we define *sentence-aware quality control* by decomposing the QCPG input control, $\mathbf{c}$, into a sum of a sentence dependent reference point, $\mathbf{r}(s)$, and a sentence independent offset, $\mathbf{o}$.

3 Data and Implementation Details

3.1 Datasets

To test the ability of our model to learn high quality behavior from mixed quality data we use weakly annotated datasets. These datasets are large but noisy, and contain only a relatively small amount of high quality paraphrases.

MSCOCO: This dataset consists of 123K images, where each image contains at most five human-labeled captions (Lin et al., 2014). Similar to previous works we consider different captions of the same image as paraphrases.

WikiAnswers (WikiAns for short): The WikiAnswers corpus contains clusters of questions tagged by wiki-answers.com users as similar. There are $30,370,994$ clusters with 25 question in each on average. In total, the corpus contains over 70 million question pairs (Fader et al., 2014b).

ParaBank2.0: A dataset containing clusters of sentential paraphrases, produced from a bilingual corpus using negative constraints, inference sampling, and clustering (Hu et al., 2019). The dataset is composed of avarage of 5 paraphrases in every cluster and close to 100 million pairs in total.

To get comparable results across all datasets, we randomly sub-sampled ParaBank2.0 and WikiAns to the same size as MSCOCO, and split them to train, dev and test sets, of sizes $900K$, $14K$ and $14K$ respectively. We carefully made sure that there are no pairs from the same cluster in different splits of the data. The full data splits will be published with our code.

3.2 Implementation Details

All models are trained with batch size of 32 on 2 NVIDIA A100 GPUs for 6 epochs. Full details as well as train and dev results can be found in Appendix C.1.

QCPG: We use the pre-trained T5-base (Raffel et al., 2020) as the encoder-decoder model. The control input vector to QCPG is quantized at every dimension into 20 equally spaced values ranging from 0 to 100. Each value is assigned to a special saved-token. The three tokens corresponding to the quantized values of the control vector $\mathbf{c}$, are concatenated to the head of the input sentence, and together used as input to the model. $\mathbf{r}(\mathrm{s})$ and $\mathbf{o}$ are also quantized in a similar way.

QP: An Electra base model (Clark et al., 2020) finetuned with MSE loss to predict the typical quality values (see Section 2.3).

Baseline Model (BL): A T5-base model finetuned on the training data.

For all the models, we adopt the experimental setup used in (Devlin et al., 2019), i.e. we train the model with several learning rates and choose the one that achieves the highest dev set performance (see appendix C.1).

4 Results

4.1 Controlling the Quality Dimensions

The aim of the following analysis is to study the level of control achieved by QCPG. To this end, we measure the model response to changes in the input offsets. We compute the expected difference in paraphrase quality, as a result of applying an input offset $\mathbf{o}$ compared to zero offset as a reference. More formally, we define the 3-dimensional responsiveness vector of QCPG at an offset $\mathbf{o}$, $\mathbf{R}(\mathbf{o})$ as $\mathbf{Q}(\mathbf{o}) - \mathbf{Q}((0,0,0))$, where $\mathbf{Q}(\mathbf{o})$ is the expected quality of the paraphrases generated by QCPG at an offset $\mathbf{o}$. We estimate $\mathbf{Q}(\mathbf{o})$ by averaging $\mathbf{q}(QCPG(s, \mathbf{r}(s) + \mathbf{o}))$ over the input sentences s of the dev set, and denote this estimate by $\tilde{\mathbf{Q}}(\mathbf{o}) = (\tilde{\mathbf{Q}}_{\mathbf{sem}}(\mathbf{o}), \tilde{\mathbf{Q}}_{\mathbf{syn}}(\mathbf{o}), \tilde{\mathbf{Q}}_{\mathbf{lex}}(\mathbf{o}))$, and the corresponding estimate of $\mathbf{R}(\mathbf{o})$ by $\tilde{\mathbf{R}}(\mathbf{o})$.

Specifically, in the following analysis we are interested in studying the model response to each of the dimensions separately, i.e. how changing the input offset along a given quality dimension dim – the *controlled* dimension – while keeping the two other dimensions constant, affects the responsiveness in each of the three dimensions. A good control mechanism would imply that increasing the input offset in one dimension will result in a monotonically increasing responsiveness in that dimension, with relatively small responsiveness in the other two dimensions.

Figure 3 shows, for each of the three datasets, the responsiveness in the three quality dimensions, when changing the input offset along each of the three dimensions, while fixing the input offsets in the other two dimensions at 0. Examining the actual values of quality in the paraphrases of the dev sets, reveals that the standard deviation is different in each dimension. Hence, for clarity of presentation, we present the input offset values and the responsiveness in units of standard deviation as measured in the respective dimension and dev set.

For the range of offsets displayed in Figure 3, the responsiveness in the controlled dimension increases monotonically with the input offsets across all datasets and dimensions. As expected, the responsiveness in the uncontrolled dimensions does not zeros due to the inherent coupling between the dimensions. For example, many changes that increase syntactic diversity, also increase lexical diversity (e.g. a move from passive to active voice). Still, our control mechanism is able to increase the responsiveness in the controlled dimension with relative low responsiveness in the uncontrolled dimensions. Specifically, focusing on the relation between semantic similarity and expression diversity, the figure shows that there is a minor decrease in semantic similarity in response to an increase in lexical and syntactic diversity. In the next section, we will show that this does not prevent our model from generating paraphrases that are not only more lexically and syntactically diverse, but also more semantically similar to the source sentences, compared to the paraphrases generated by the uncontrolled baseline.

Figure 3 focused on small to moderate input offsets, i.e. offsets up to 2 stds from the reference point. However, as we speculated before, with increasing offsets, i.e. the more the requested control value deviates from the typical value, it becomes increasingly difficult to generate a paraphrase that conforms to the requested control value. Figure 4 depicts the responsiveness in the syntactic and lexical dimensions for a larger range of offset values. For the semantic dimension, the typical values are too high to allow large positive offsets, which for most sentences result in exceeding the upper limit of the semantic score. Indeed, as can be seen in Figure 4, when moving to high offset values, the responsiveness in the syntactic and lexical dimensions starts to decrease. This behavior is in line with our aforementioned hypothesis, and reflects the detrimental effect of feeding QCPG with input control values that are too far from the typical paraphrase qualities of the input sentence. The non-monotonic behavior of the responsiveness implies that the input offsets should be selected carefully in order to optimize the quality of the resultant paraphrases. In Section 4.2 we suggest a method for identifying these optimal offsets.

4.2 Selecting Optimal Input Control Values

In this section, we suggest a method that given task requirements, selects the input offsets that are expected to yield the desired quality of paraphrases. The idea is to compute the estimated expected quality, $\tilde{\mathbf{Q}}(\mathbf{o})$, for each input offset $\mathbf{o}$, using the dev set as described in Section 4.1, and then search the 3D grid of input offsets to find the point for which $\tilde{\mathbf{Q}}(\mathbf{o})$ is best suited for the user's requirements. We envision this analysis as a preliminary step in which the user chooses the input control parameters that best achieve his desired paraphrasing operation point, and then uses the chosen values at inference – which is why we use the dev set.

We study the behavior of $\tilde{\mathbf{Q}}(\mathbf{o})$ as a function of the 3D grid of offset points in the relevant range, i.e every $\mathbf{o}$ where o_{sem}, o_{syn} and o_{lex} in $0, 5, 10...50$. Figure 5 depicts $\tilde{\mathbf{Q}}(\mathbf{o})$ for WikiAns, on a slice of the full offset grid. The results for the full grid on all datasets are shown in Figure 6. The right-hand-side map depicts the estimated linguistic diversity (the average of $\tilde{\mathbf{Q}}_{\mathbf{syn}}(\mathbf{o})$ and $\tilde{\mathbf{Q}}_{\mathbf{lex}}(\mathbf{o})$) and the left-hand-side depicts the semantic similarity, $\tilde{\mathbf{Q}}_{\mathbf{sem}}(\mathbf{o})$). The maps are presented for $o_{sem} = 50$, and for different values of o_{syn} and o_{lex}. As expected, the two measures are anti-correlated, where areas with increased semantic similarity are characterized by decreased linguistic diversity. The QCPG results are compared to two reference points, which are invariant to $\mathbf{o}$ and are marked on the colorbars with black squares: 'Dataset' is the semantic-similarity/linguistic-diversity average value over the corresponding dev set paraphrases, and 'Baseline' is the average semantic-similarity/linguistic-diversity of the uncontrolled baseline over the corresponding dev set. Notice that the average diversity level achieved by the uncontrolled baseline is lower than that of the dev set mean, reflecting the difficulty of this model to generate diverse paraphrases. QCPG on the other hand, with suitable input offset values, is able to generate paraphrases which are on average higher than the baseline both in their linguistic diversity and in their semantic similarity, and in fact even higher in many cases than the values of the ground truth paraphrases in the dev-set.

In general, the estimates of the expected quality achieved by QCPG at different input offsets, enable a user to generate paraphrases at different operation points, by manipulating the input offset control $\mathbf{o}$ to meet her desired quality values. Con-

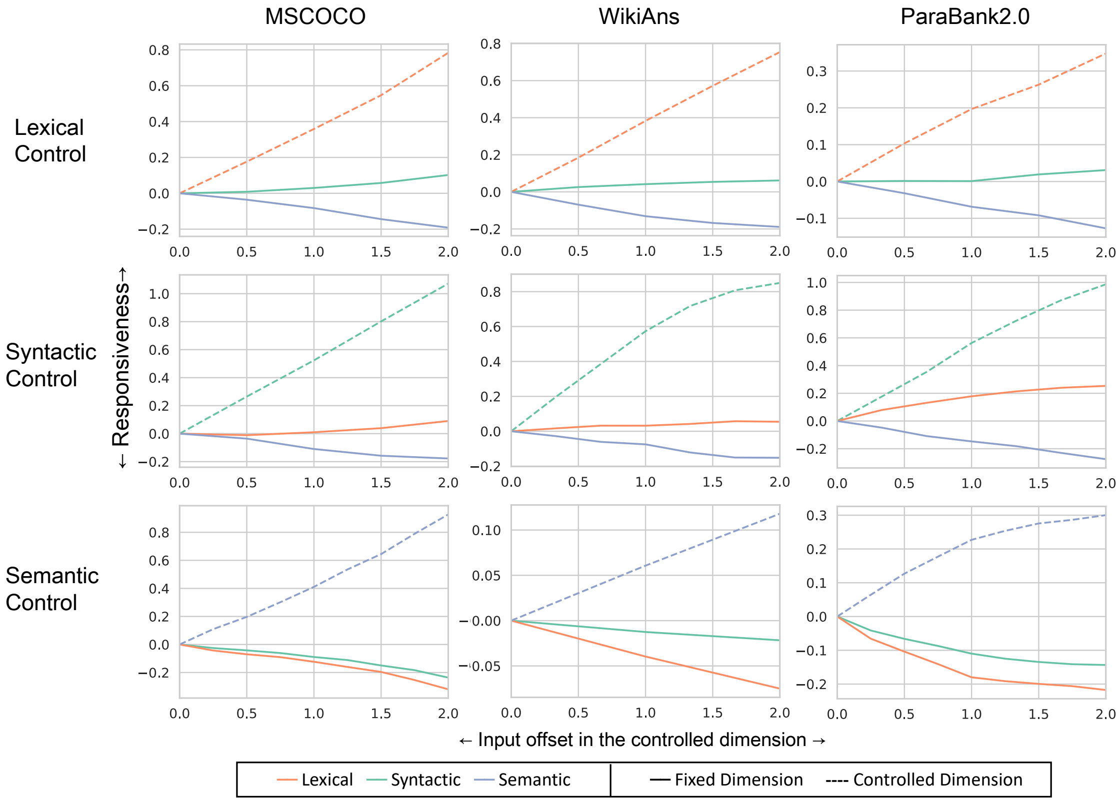

Figure 3: Controllability of QCPG. The responsiveness of QCPG to changes in the input quality vector. In each graph only one dimension of the input is changed (the control dimension), where the other two dimensions are fixed at zero offset. The control dimensions in the top middle and bottom rows are the lexical syntactic and semantic dimensions respectively. Each color represents a different quality dimension of the generated paraphrases. The responsiveness in the control dimension is plotted in a dashed line. Responsiveness and offsets are shown in standard deviation units.

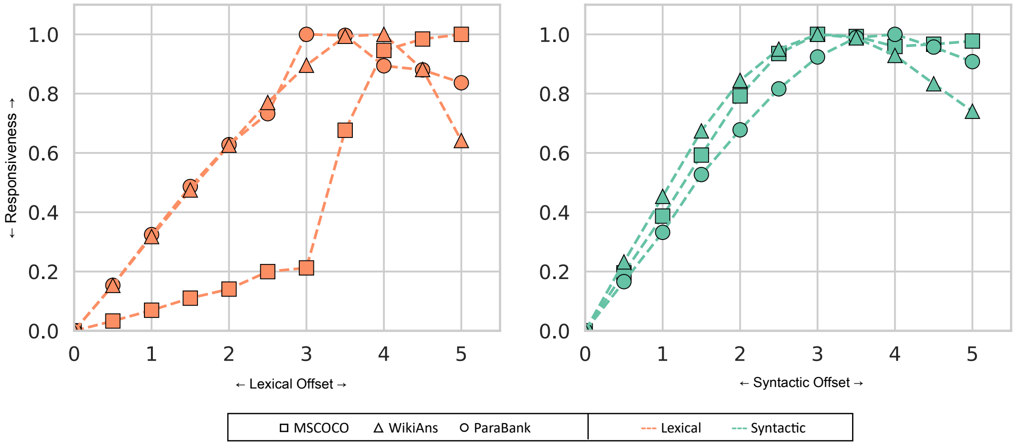

Figure 4: Monotonicity break in the responsiveness of QCPG. The responsiveness of QCPG in the controlled quality dimension vs. the input offset in that dimension in the three datasets. Left: Lexial control. Right: Syntactic control. Each curve is normalized by its maximal value, to create a uniform y-axis range across all datasets. Offsets are shown in standard deviation units.

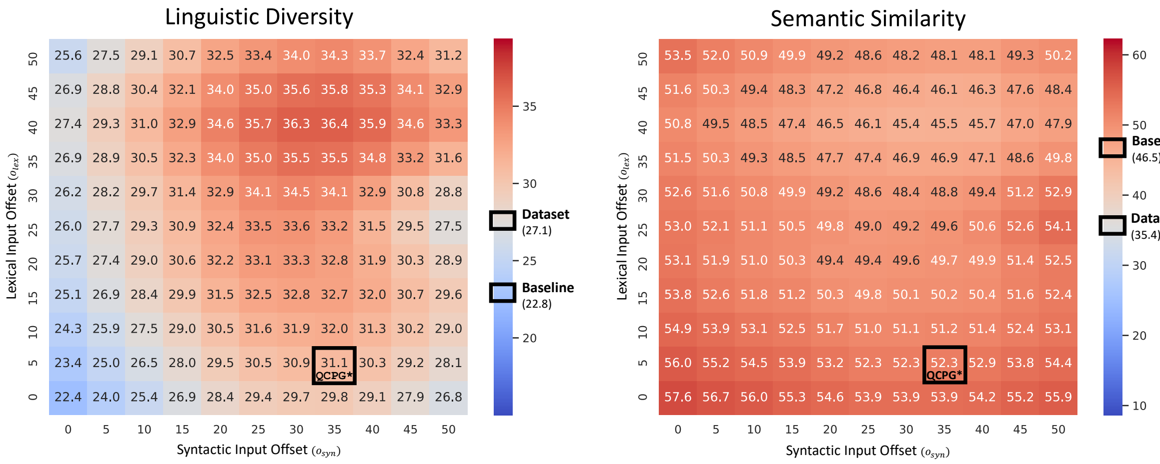

Figure 5: Estimated Quality at different offset values for WikiAns. Average of linguistic diversity (left) and semantic similarity (right) of the paraphrases generated for the dev-set sentences, as a function of o_{syn} and o_{lex}, for fixed $o_{sem} = 50$. The average quality of the gold-label paraphrases, and the average values achieved by the uncontrolled baseline, are marked on the color bars. Red/blue shades correspond to above/below the dev-set mean.

sider for example a typical use case, of aiming to maximize linguistic diversity under a constraint on semantic similarity. An example of such a case is an operation point, denoted by $QCPG^{\star}$, which aims to exemplify the advantage of QCPG over the baseline, by maximizing linguistic diversity under the constraint that the semantic similarity is at least 5 points higher than the baseline. The input offset values to obtain this operation point depend on the dataset, and can be found using heatmaps such as in Figure 5. For WikiAns the input offset for the $QCPG^{\star}$ operation point values are $(50, 35, 5)$ (entry marked by the black square).

4.3 Quality Evaluation on the Test Set

In the previous section we saw, using estimates based on the dev sets, that there are many operation points which generate paraphrases with higher quality than those achieved by the uncontrolled baseline. We now turn to evaluate one such operation point, namely $QCPG^{\star}$, using the source sentences of the *test* sets which were not used in the selection of the input offset values.

Automatic Evaluation We use four quality measures to evaluate different aspects of generated paraphrases. The three quality measures used in the control of QCPG (Section 2.1) and Self-BLEU (Zhu et al., 2018) as adapted in Li et al. (2019); Liu et al. (2020a), which aims to measure the linguistic diversity in the generated paraphrases by penalizing copying from input sentences. As can be seen in Table 1, $QCPG^{\star}$ outperforms the baseline in all metrics across all datasets, as predicted using the dev-set heatmaps. A clear advantage is obtained even for Self-BLEU, which was not part of the metrics used as input controls. Importantly, the quality of the paraphrases generated by our model is comparable to, or at times better than the quality of the paraphrases in the ground truth of the datasets. Examples of paraphrases generated by $QCPG^{\star}$ compared to the ground truth paraphrases appear in Table 10. This is an important step towards the goal of obtaining paraphrases in the sparse area of high quality (recall the top right corner of Figure 1).

Additionally, we examined QCPG from another perspective: the effect of the quality guidance on the model's ability to predict the ground truth paraphrases. Tables 5 and 6 show the BLEU scores (Papineni et al., 2002) obtained by QCPG and the uncontrolled baseline respectively. The results verify that the input quality vectors induced by the target sentences are effectively utilized by QCPG to achieve better prediction performance.

Human Evaluation While linguistic diversity can be automatically measured by reliable metrics such as Self-BLEU, measuring semantic similarity is more challenging. We therefore rely on automatic metrics for evaluating the lexical and syntactic diversity, but use human annotation for validating the semantic evaluation. To this end, we selected a sample of 50 source sentences from each test set, and generated one paraphrase using the uncontrolled baseline and one using $QCPG^{\star}$. The

	MSCOCO				WikiAns				ParaBank2			
	q_{sem} ↑	q_{syn} ↑	q_{lex} ↑	Self-BLEU↓	q_{sem} ↑	q_{syn} ↑	q_{lex} ↑	Self-BLEU↓	q_{sem} ↑	q_{syn} ↑	q_{lex} ↑	Self-BLEU↓
Gold	29.9	34.5	28.0	8.7	34.6	30.7	24.4	16.4	75.0	18.5	20.9	23.9

$QCPG^{\star}$	**56.6**	**29.6**	**42.4**	**18.0**	**48.5**	**41.5**	**24.8**	**21.4**	**81.4**	**18.9**	**19.6**	**27.1**

Table 1: Automatic evaluation of the QCPG model on the test set. The semantic similarity (q_{sem}), syntactic diversity (q_{syn}) and lexical diversity (q_{lex}), are measured using Bleurt, Tree edit distance, and character-level edit distance respectively, as described in Section 2. Self-BLUE is an external measure of linguistic diversity (see text for details). BL: uncontrolled baseline. Gold: the test set ground truth paraphrases. $QCPG^{\star}$ is the QCPG model in the operation point defined in Section 4.2. Best performance amongst the compared models is highlighted in **bold**. Best results amongst the models and the gold labels are underlined.

	Votes			Agreement
	$QCPG^{\star}$	BL	(Tie)	Cohen's Kappa
MSCOCO	**.56**	.36	(.08)	.38
WikiAns	**.48**	.36	(.16)	.47
ParaBank2	**.30**	.26	(.44)	.57

Table 2: Human evaluation of semantic similarity. The numbers represent the proportion of annotators that voted for each method. $QCPG^{\star}$: the QCPG model in the operation point defined in Section 4.2. BL: Uncontrolled Baseline.

annotators were shown the source sentence, along with the two generated paraphrases (randomly ordered), and were asked which of the two better preserves the semantic meaning of the source sentence (ties are also allowed). In total, 150 triplets were evaluated by 5 judges. Table 2 demonstrates an advantage for $QCPG^{\star}$ in all datasets, with a large margin in MSCOCO and WikiAns. This advantage is statistically significant ($p-value < 0.05$) as obtained by applying the Wilcoxon signed-rank test to the difference between the number of annotators that voted for $QCPG^{\star}$ and those voted for the baseline, across all datasets. Thus, the human evaluation is in line with the results of the automatic semantic similarity measure. We also verified, that the results of this sample, in terms of linguistic diversity, are very similar to those shown in Table 1.

For examples of paraphrases generated by $QCPG^{\star}$ see Table 10 in the Appendix.

5 Related Work

Many recent works on paraphrase generation have been focused on attempting to achieve high-quality paraphrases. These works can be divided into supervised and unsupervised approaches.

Supervised Approaches To achieve diversity, some works focused on diverse decoding using heuristics such as Hamming distance or distinct n-grams to preserve diverse options during beam search (Vijayakumar et al., 2018). Other works generate multiple outputs by perturbing latent representations (Gupta et al., 2018; Park et al., 2019). or by using distinct generators (Qian et al., 2019). These methods achieve some diversity, but do not control generation in an interpretable manner.

The works that are most similar to ours strive to gain diversity using controlled-paraphrase generation, by exposing control mechanisms that are manipulated to produce either lexically (Zeng et al., 2019; Thompson and Post, 2020) or syntactically (Chen et al., 2019; Goyal and Durrett, 2020) diverse paraphrases. One approach is to use an exemplar sentence for guiding the syntax of the generated paraphrase (Chen et al., 2019; Bao et al., 2019; Hosking and Lapata, 2021). An alternative is to directly employ constituency tree as the syntax guidance (Iyyer et al., 2018; Li and Choi, 2020). Goyal and Durrett (2020) promote syntactic diversity by conditioning over possible syntactic rearrangements of the input. Zeng et al. (2019) use keywords as lexical guidance for the generation process. Here we introduce a simple model for jointly controlling the lexical, syntactic and semantic aspects of the generated paraphrases.

Unsupervised Approaches Niu et al. (2020) rely on neural models to generate high quality paraphrases, using a decoding method that enforces diversity by preventing repetitive copying of the input tokens. Liu et al. (2020b) optimize a quality oriented objective by casting paraphrase generation as an optimization problem, and searching the sentence space to find the optimal point. Garg et al. (2021) and Siddique et al. (2020) use reinforcement learning with quality-oriented reward combining textual entailment, semantic similarity, expression diversity and fluency. In this work, we employ similar metrics for guiding the generation of paraphrases within the *supervised* framework.

6 Discussion

In this paper, we propose a novel controlled paraphrase generation model, that leverages measures of paraphrase quality for encouraging the generation of paraphrases with desired quality. We demonstrate the high level of control achieved by the model, and suggest a method for coping with the challenging problem of finding suitable control values.

Aside from offering a simple and effective way for controlling models' output quality, the quality control paradigm enables a holistic view of the data, the training process and the final model analysis. Namely: (I) Examination of the training data through the lens of data quality enables to characterize the data at hand, its strengths and limitations. (II) A quality-aware training process can be viewed as multi-task learning, where each quality level is a separate task with its own accurate supervision, as opposed to the standard quality-agnostic approach, where low quality data is in fact used as a poor supervision for a model which aims at generating higher quality output. (III) Analyzing the model behavior under different quality controls, allows finer understanding of the different model behaviors and the trade-offs between their output qualities. Better understanding the expected output quality of neural NLG models, for different input quality controls, can increase the trust in their output.

Finally, our model analysis consistently shows that although the models generally follow the quality requirements, there is still room for improvement. A possible direction for future research is exploring methods, such as reinforcement learning, for further improving the ability of the model to satisfy the quality requirements.

A Selecting the semantic similarity measure

Recently, several strong metrics have been proposed for measuring semantic similarity between sentences (Reimers and Gurevych, 2019; **?**; Sellam et al., 2020). In order to select the semantic similarity metric for QCPG, we performed a small experiment over the three dev sets, with the aim of measuring the agreement of the candidate metrics with human judgments. To this end, we leveraged two properties that characterize weakly labeled datasets, the underlying clusters of sentences, and the high variability of semantic similarity. Given a dataset, we randomly selected 100 clusters, and picked three sentences at random from each cluster. For each triplet of sentences $t = (t_1, t_2, t_3)$ we asked 5 human annotators to choose which of the two sentences, t_2 or t_3, better preserves the semantic meaning of t_1. In order to find the candidate similarity measure with the highest agreement with human judgments, we first computed, for each triplet, the difference between the number of annotators voted for t_2 and those voted for t_3. We then computed for each candidate measure, the difference between the similarity of t_2 to t_1 and and of t_3 to t_1. We then measured Kendall's Tau correlation (Daniel, 1990) between the difference vector of the human judgments and that of the judgments of each of the candidate measures. Table 3 shows the resultant correlations. The highest correlations are obtained for SBERT (Reimers and Gurevych, 2019), but since it was trained on WikiAns and MSCOCO, we could not use it in our study. We selected Bleurt due to its highest correlation with human judgments over the three datasets (among the methods that were not exposed to the considered datasets). We normalize Bleurt score using the sigmoid function to ensure a uniform range of values, $[0, 1]$, for the three quality dimensions.

BLEURT	**.45**	**.4**	**.36**

Table 3: Correlation of different semantic similarity models with human evaluations.

B Correlation of semantic similarity measures with linguistic diversity

We study the coupling between the different semantic similarity measures and the linguistic diversity. We assume that the level of coupling of a good similarity measure will resemble that of humans, and will be less sensitive to lexical and syntactic properties of the paraphrase. Table 4 presents the Kendall tau correlation between the different similarity measures and the linguistic diversity. Results for human judgments are also shown for a reference. The correlation calculation is performed between the vectors of differences as described in section A). The results show that Bleurt demonstrates the lowest coupling with linguistic diversity among the automatic measures (aside from SBERT which, as mentioned before, was trained with MSCOCO and WikiAns). The comparison to human judgments shows that Bleurt is more influenced by linguistic features, indicating that automatic measures need to be further improved to reach the decoupling level achieved by humans.

C Models Details and Training Results

The learning rates for the QCPG and the Baseline models were selected in the following way. For a given dataset, we finetuned the models with 4 learning rates ($1e$-3, $1e$-4, $5e$-3, $5e$-4) (The training results of the baseline presented in Table 5 and the results of QCPG presented in Table 6.). For the baseline we selected the one which yielded the best BLEU score (Papineni et al., 2002) on the corresponding dev set The best learning rate for every dataset was chosen based on the Dev set BLEU score. For the QCPG we chose the model that best conforms to the control input as measured by the MSE between the input control vector and the output quality vector (see Table 9). The QP model is an Electra-Base model finetuned with 4 different learning rates ($1.5e$-4, $1e$-4, $3e$-5, $5e$-5). We choose the learning rate the yields the minimal MSE on the dev set (For full results see Table 8)

Controllable Dictionary Example Generation: Generating Example Sentences for Specific Targeted Audiences

hexingwei15@gmail.com, smyiu@cs.hku.hk

Abstract

Example sentences for targeted words in a dictionary play an important role to help readers understand the usage of words. Traditionally, example sentences in a dictionary are usually created by linguistics experts, which are labor-intensive and knowledge-intensive. In this paper, we introduce the problem of *dictionary example sentence generation*, aiming to automatically generate dictionary example sentences for targeted words according to the corresponding definitions. This task is challenging especially for polysemous words, because the generated sentences need to reflect different usages and meanings of these targeted words. Targeted readers may also have different backgrounds and educational levels. It is essential to generate example sentences that can be understandable for different backgrounds and levels of audiences. To solve these problems, we propose a controllable target-word-aware model for this task. Our proposed model can generate reasonable examples for targeted words, even for polysemous words. In addition, our model allows users to provide explicit control over attributes related to readability, such as length and lexical complexity, thus generating suitable examples for targeted audiences. Automatic and human evaluations on the Oxford dictionary dataset show that our model can generate suitable examples for targeted words with specific definitions while meeting the desired readability.

1 Introduction

A dictionary usually consists of targeted words, part-of-speech (POS) tags, definitions and corresponding example sentences. Definitions and their corresponding examples enable audiences to better master new words, understand unfamiliar texts and the usage of the words in typical sentences, where a definition is a simple description for the meaning of the targeted word, and an example shows audiences how to use the word under this definition. Both definitions and examples are critical, playing an important role in language acquisition and natural language understanding. However, it is often the case that audiences cannot find satisfactory example sentences for rarely used or newly coined words. On the other hand, it is time-consuming for experts to create dictionary examples for these words. With the advancement of AI technologies, it is a natural direction to study how to generate dictionary examples automatically, to assist dictionary compilation and help humans understand the corresponding targeted words.

Dictionary example sentence generation aims to generate example sentences for targeted words to reflect their definitions and usages automatically. Recently, definition generation (Noraset et al., 2017; Gadetsky et al., 2018; Ishiwatari et al., 2019) has been extensively studied, yet generating example sentences is not well-studied. To the best of our knowledge, we are the first group to introduce this challenging problem. One main challenge for this task is that targeted words must appear in outputs. Another challenge is that polysemous words (e.g. *'bank'*), which have multiple senses, even multiple POS tags, are ubiquitous. Thus, a polysemous word in generated examples should convey the given sense and POS tag.

Lexically constrained text generation is meant to incorporate some specific keywords into outputs, which has been widely studied. Previous lexically constrained models inject the given keywords into outputs either by manipulating the decoding process (Mou et al., 2015; Hokamp and Liu, 2017), or using the keywords as the initial state and refining it with a series of actions, such as insertion and replacement until it is completed (He and Li, 2021). It is natural to use these lexically constrained models as baselines, since they have solved the first challenge. In response to the second one, we further extend these lexically constrained models by feeding the definition into the encoder and then

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 610 - 627
May 22-27, 2022

injecting the targeted word during decoding. However, these models have two inherent drawbacks for this task: (1) During inference, these models generate a sentence based on the definition and force the targeted word to appear in outputs. However, they fail to explore the correlation between the targeted word and input, thus sacrificing the generation quality to ensure the targeted word appears in outputs. (2) These models are computation-intensive, as they need to manipulate the decoding process.

To circumvent these problems, the proposed model is expected to understand this task so that there is no need to interfere with the decoding process. To achieve this goal, we directly feed the targeted word and definition into the model. This simple change brings two advantages over lexically constrained generation models: (1) During training, our model fully explores the correlation between targeted words and definitions, and gradually acquires this task. As a result, even the proposed model does not control decoding, outputs contain targeted words in 99.6% of cases. (2) With the release of control over decoding, our model significantly improves the generation quality and dramatically reduces the inference latency.

Apart from the above two challenges, the proposed model should generate suitable examples to match the readability levels of different audiences, such as children and college students. To address the third challenge, the proposed model is expected to control the readability-related attributes of outputs, namely length and lexical complexity. Inspired by Keskar et al. (2019), the proposed model is trained on discrete control tokens, which are related to the length and lexical complexity of gold example sentences. By doing so, the proposed model will learn to associate the control tokens with the length and lexical complexity of outputs. As a result, we can control the readability of outputs by varying the length and lexical control tokens.

Our contributions are summarized as follows: (1) We introduce the *dictionary example sentence generation* task. (2) We propose a large dataset for dictionary example generation. (3) We propose a controllable target-word-aware model and several baselines for this task[1]. (4) We propose two BERT-based classifiers to automatically evaluate whether the target word in the generated example conveys the given sense and POS tag, respectively. (5) Our experiment results on the Oxford dictionary dataset show that our model outperforms baselines in terms of generation quality, diversity, POS and definition accuracy. More importantly, our model can tailor examples to fit the needs of targeted audiences by controlling the length and lexical complexity.

2 Problem Statement

Dictionary Example Sentence Generation aims to generate a fluent example $E = \{e_1, \ldots, e_T\}$ for the targeted word w^* under a specific definition $D = \{d_1, \ldots, d_S\}$, where w^* should appear in E and convey D. During training, this task aims to maximize the conditional probability of E:

$$p(E|w^*, D; \theta) = \prod_{t=1}^{T} p(e_t|e_{i<t}, w^*, D; \theta). \quad (1)$$

3 Methodology

3.1 Motivation

Our motivation is to make the model understand *dictionary example sentence generation* so that we do not need to interfere with the decoding process. Intuitively, if the model has mastered the requirements of this task, the model will know reasonable outputs should contain the targeted word under the specific sense when seeing the target word and definition. Driven by this motivation, we use an encoder-decoder architecture, initialized with BART (Lewis et al., 2020), where the encoder directly takes the targeted word and definition as inputs. During training, the model gradually learns to incorporate the targeted word under the specific meaning into output, otherwise, it will suffer a large cross-entropy loss between the predicted distributions of the decoder and golden examples.

To gain control over the readability of outputs, the model is also trained on the readability-related control tokens of gold examples. In this way, the model will gradually learn to correlate the special token with a readability attribute of outputs, otherwise, it will also suffer a large cross-entropy loss. See Section 3.2 for readability-related control tokens. The overview of the proposed model is shown in Figure 1. The encoder input consists of five parts: the targeted word, POS tag, length, lexical complexity, and definition. Each part begins with a special token, indicating the start of this part. For example, <Word> means the following content is the targeted word. The decoder aims to generate examples based on the encoder inputs.

---

[1] Our dataset and code are available at https://github.com/NLPCode/CDEG.

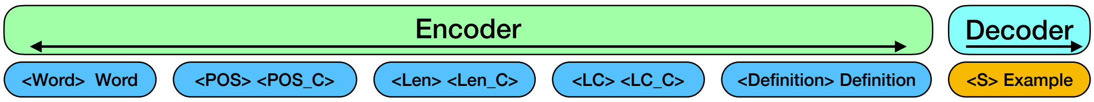

Figure 1: The overview of our proposed model. <Word>, <POS>, <Len>, <LC> and <Definition> are special tokens, which are used to separate the different parts of an encoder input. <POS_C> is the POS tag of a targeted word. <Len_C> and <LC_C> refer to the length and lexical complexity of an example. <S> denotes the start of a sentence.

Words (tokens)	Examples (tokens)
‘banked’ (**b, anked**)	‘a banked racetrack’ (a, **Ġbank**, **ed**, Ġrac, etr, ack)
Add an initial space to words/examples	
‘ banked’ (**Ġbank, ed**)	‘ a banked racetrack’ (Ġa, **Ġbank**, **ed**, Ġrac, etr, ack)

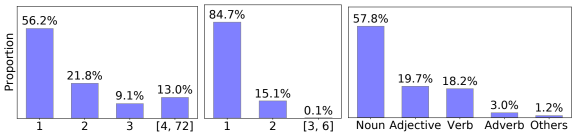
Table 1: Tokens are achieved by using the BART tokenizer to tokenize the inputs w/o (top) or w/ (bottom) a leading space. BART uses ‘Ġ’ to denote a space.

3.2 Readability-Related Control Tokens

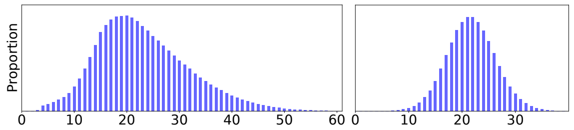
To control the readability of outputs, we need to find out which attributes of outputs are related to readability. Flesch-Kincaid Grade Level (FKGL) and Flesch Reading-Ease Score (FRES) (Kincaid et al., 1975) are widely used to assess the difficulty of English text. Both metrics are related to the average sentence length and assume that the longer the sentence, the more difficult the text is to understand. On the other hand, lexical complexity also affects readability (Shardlow, 2014). For example, too many complicated words appearing in a text may hinder audiences’ understanding of the text.

Length (Len). Len denotes the number of tokens in a tokenized[2] example. Figure 2 (d) shows that example lengths range from 3 to 60. Hence, we add 58 learnable Len control tokens to the vocabulary.

Lexical Complexity (LC). Word frequencies are the most reliable predictor of word complexity (Paetzold and Specia, 2016). Given this, we use word frequencies as a proxy of LC. In the following, we will show how to compute the LC of an example. First, we tokenize all examples in the training set with NLTK word tokenizer[3]. Next, we rank unique words by word frequencies in descending order. Then, we compute the word ranks for all words in one example. After that, we calculate the third-quartile of log-ranks and use it as the LC for the example. Finally, we discretize all LC values into 40 discrete LC labels. LC label distribution is shown in Figure 2 (e). Therefore, we add 40 trainable LC control tokens (0-39) to the vocabulary.



(a) #Senses (b) #POS tags (c) POS tags



(d) Len distribution (e) LC distribution

Figure 2: Subfigures (a) and (b) show the unique lemma distribution over #Senses, and #POS tags in the training set, respectively. #Senses denotes the number of unique definition triplets (lemma, POS, definition). In this paper, we use a definition triplet to denote a sense for a lemma. Subfigure (c) shows the distinct definition distribution over POS tags in the training set. Subfigures (d) and (e) show the Len and LC label distributions of examples in the training set.

3.3 Improve the Word Coverage

Since we utilize the BART tokenizer, feeding the original form of a targeted word into the encoder may hinder the decoder from injecting it into the output. As shown in Table 1, the token sequence for the targeted word ‘banked’ does not appear in the tokenized example (row 1). Therefore, the model must learn to map {**b**, **anked**} to {**Ġbank**, **ed**} to include it in outputs, which undoubtedly increases the difficulty of incorporating the word into outputs. This problem is caused by the discrepancy between the token sequences of the targeted word and example. To solve this, we add an initial space to the targeted word and example so that the tokenized word appears in the tokenized example (row 2). By doing so, the decoder can copy the targeted word from the encoder to outputs instead of mapping, thus improving the word coverage by 8.6%.

3.4 Training and Inference

During training, we feed the targeted word, golden POS, Len and LC labels of examples into the en-

coder, and then fine-tune the model by minimizing the cross-entropy loss. During inference, we set Len and LC to fixed values to generate examples with expected Len and LC.

3.5 Assess the Definition and POS Accuracy

In text style transfer, Shen et al. (2017), Hu et al. (2017) and Li et al. (2018) used a pre-trained classifier to assess whether outputs have the desired attribute. Inspired by this, we propose a definition classifier to evaluate whether the targeted word w^* in the example E conveys the given meaning D. The definition model takes a triple of word, definition and example (w^*, D, E) as input. To train the definition model, we first create the synthetic data $\{(w^*, D, E, L)\}$. If w^* in E conveys D, the label L is 1, denoting the data instance is positive. Otherwise, L is 0, denoting the data instance is negative. We directly select the positive data instance (w^*, D, E) from the Oxford training or validation set. Then, we create three kinds of negative data instances based on a positive data instance by (1) replacing w^* with another word in E or vocabulary; (2) replacing D with another definition of w^* or other words; (3) replacing E with another sentence, which does not contain w^*. For ease of understanding, we show several synthetic data instances in Table 12 in the Appendix. We fine-tune BERT-base (Devlin et al., 2019) on the synthetic training set (see Figure 3 for the model input), achieving 89.9% F1 on the validation set. Similarly, we train a BERT-based POS classifier to assess whether w^* in E reflects the given POS tag, which achieves 98.5% F1 on the synthetic validation set. We show the statistics of synthetic data for the definition and POS models, and their performance on the validation set in Appendix A and B.

4 Experiments

4.1 Experiment Setups

Dataset and Pre-processing. We evaluate our proposed model on Oxford Dictionary[4]. Gadetsky et al. (2018) released a dataset based on this resource for definition generation. However, this dataset is unsuitable for dictionary example generation due to the following limitations (Chang et al., 2018): (1) each definition has only one example sentence; (2) some examples in their dataset do not contain targeted words. To solve these problems, we collect a new Oxford dataset by filtering out definitions with the number of examples less than two, and examples not containing the targeted word. In addition, we remove targeted words containing letters less than two or greater than 20. Each data instance is a quadruplet, containing a targeted word, POS tag, definition and examples of the word usage. We split the dataset into training, validation and test sets based on the triplets (lemma, POS, definition), which are mutually exclusive across three sets (see Table 2 for statistics of this dataset).

Different from the training set, the validation/test set only contains polysemous words with at least two definitions, since it is more challenging to generate examples for polysemy. During training, each sense along with all corresponding example sentences will be used to update models. During inference, we will generate only one example sentence for each sense, but each lemma in English may have multiple inflections (For example, inflected forms of the verb ‘bank’ include ‘banked’, ‘banking’, etc). Given that we use BLEU to evaluate the generation quality, we only keep the word form with most example sentences for each definition tuple (lemma, POS, definition) in the validation/test set. For the sense (‘bank’, Verb, ‘heap (a substance) into a mass or mound’) in the test set, two examples contain ‘banked’ and only one example contains ‘banking’, so we keep examples containing ‘banked’.

The data distributions of the training set are shown in Figure 2. See Appendix C for the data distributions of validation and test sets.

Baselines. We first implement two retrieval baselines by randomly selecting examples containing

Table 3: Results on the Oxford test set. For our model, the subscript integers denote the selected control labels for Len and LC, with which the model performs best on the validation set. 'greedy' and 'beam 5' denote generating sentences using greedy or beam search with a beam size of 5. 'AveLen' means the average length of examples. 'Latency' is the average decoding time (second) per sentence computed on the test set without mini-batching.

the targeted words from the One-Billion-Word[5] corpus or the training set, respectively. We adopt four lexically constrained generation models: two variants of the backward forward model (sep-B/F and asyn-B/F) (Mou et al., 2015), grid beam search (GBS) (Hokamp and Liu, 2017) and X-MCMC-C (He and Li, 2021). We implement the former three baselines based on GPT-2 small (117M). We train X-MCMC-C with the code provided by He and Li (2021), which is based on XLNet-base (110M). These methods generate sentences containing targeted words without considering definitions. To remedy this, we re-implement the former three models based on BART-base (139M), where the encoder takes the definition as input and the decoder incorporates the word during inference.

Implementation Details. We initialize our model with BART-base, which has comparable parameters to generation baselines. For generation baselines and our models, we use AdamW (Loshchilov and Hutter, 2019) with an initial learning rate of $1e-5$ to update parameters for four epochs and choose the checkpoints with the lowest validation loss.

During inference, we run beam search decoding with beam width = 5 on generation baselines and our model. We also run greedy decoding on our model. Following He and Li (2021), we run X-MCMC-C for 200 steps and select the example with the lowest negative log-likelihood (NLL) as output. To discourage the generation of repetitive tokens, we apply the repetition penalty strategy Keskar et al. (2019) with the penalized parameter = 1.3 to all models. We implement all models with the HuggingFace Transformers library (Wolf et al., 2019). All models are trained and tested on a single GeForce RTX 2080 Ti GPU.

Evaluation Metrics. We evaluate the generated examples from four aspects: **Q1:** Whether the generated example contains the targeted word? **Q2:** Whether the targeted word in the generated example conveys the given sense? **Q3 & Q4:** Whether the outputs are fluent and diverse? First, we check whether the targeted word appears in the example, indicated as word **Coverage**. If so, we will further assess whether the targeted word conveys the given POS tag and sense with the BERT-based POS and definition models, called POS Accuracy (**POSA**) and Definition Accuracy (**DefA**).

As for Q3, it is non-trivial to evaluate the generation quality. In this paper, we do not use NLL as a metric for sentence fluency, since lower NLL does not always denote better sentence quality (Holtzman et al., 2020). We use **BLEU** (Papineni et al., 2002) to measure the n-gram similarity between the generated examples and human references, which is a widely-used automatic metric for generation quality. One concern is that BLEU may be not ideal for dictionary example generation, since there may exist many sentences that could be appropriate for a given word and definition. To remedy this, each sense (i.e., definition triplet) in the validation and test sets contains an average of 11 examples, which provide a richer and more diverse test-bed for further automatic evaluation. To answer Q4, we use Self-BLEU (Zhu et al., 2018) and Distinct n-gram (Li et al., 2016) to measure the generation diversity. Self-BLEU-4 (**SB-4**) is computed by treating one sentence as the hypothesis, and the first 1K generated sentences excluding the hypothesis as

---

[5] http://www.statmt.org/lm-benchmark/

references. Distinct bigram (**D-2**) and 4-gram (**D-4**) indicate the proportions of unique bigrams and 4-grams, respectively.

4.2 Experimental Results

Table 3 reports the main experiment results on the test set, from which we can draw four conclusions:
(1) **Generation models are critical.** We cannot retrieve examples for all words. For example, only 97.3% of the words in the test set appear in the training set. We do not see any improvements with a larger dataset (rows 2), yet brings a much higher retrieval latency. By comparison, the generation models have the potential to generate examples for unseen words, thus greatly improving coverages.
(2) **The definition is helpful.** Compared with generation baselines w/o definitions (rows 3-6), their counterparts w/ definitions (rows 7-9) significantly improve DefA to around 77%. As we have mentioned before, all words in the test set are polysemous (see Figure 6 (a)). That is why the definition is useful and indispensable for this task.
(3) **The pre-trained model does matter.** Compared with the random counterpart (row 10), our model initialized with the BART-base model (row 11) can generate more fluent (B-4) and diverse (SB-4, D2, D4) sentences while improving DefA by around 6%. That is possibly because BART acquires some syntactic and semantic knowledge during pre-training, which is useful for this task.
(4) **The proposed models outperform other generation baselines in most metrics.** One problem with lexically constrained generation models (rows 7-9) is that they do not explicitly explore the correlation between the targeted word and input. When feeding a definition into these models, they just generate a sentence based on the encoder input and force the targeted word to appear in outputs. By interfering with decoding, they can achieve 100% word coverage, yet this is achieved at the cost of generation quality, POSA and DefA. Another problem is that their manipulations of decoding cause higher inference latency.

By comparison, our proposed model directly takes the targeted word as input instead of compulsorily injecting it into outputs during inference. This simple change brings two advantages over the lexically constrained generation methods: (1) Our model can fully explore the correlation between the targeted word and the definition, and gradually acquires this task during training. As a result, when feeding a targeted word and a definition into the proposed model, it will understand that the reasonable outputs should contain the targeted word under the specific sense. That is why even the proposed model does not control the decoding process, it does not sacrifice the word coverage (e.g. 99.6% word coverage in row 11). (2) Eliminating interference to decoding brings substantial improvements in generation quality (B-4), POSA, and DefA, and dramatically reduces inference latency.

# **Variants**	Coverage↑	POSA↑	DefA↑	B-4↑	D-4↑
1 Full model	99.6%	97.2%	87.7%	7.6%	86.4%
2 – Word	14.5%	17.3%	16.1%	3.6%	85.9%
3 – POS	99.6%	96.6%	87.6%	7.5%	86.6%
4 – Definition	99.4%	97.4%	35.8%	4.3%	73.2%

Table 4: Results of ablation study on the test set. Compared with the full model (row 11 of Table 3), the metric with the largest change in each row is underlined.

Space	**Pointer**	Coverage↑	POSA↑	DefA↑	B-4↑	D-4↑
		91.0%	89.1%	81.2%	7.1%	87.1%
√		99.6%	97.2%	87.7%	7.6%	86.4%
	√	89.7%	88.0%	79.4%	7.5%	86.5%
√	√	99.5%	97.2%	86.9%	8.2%	85.1%

Table 5: Results of ablation study on the test set.

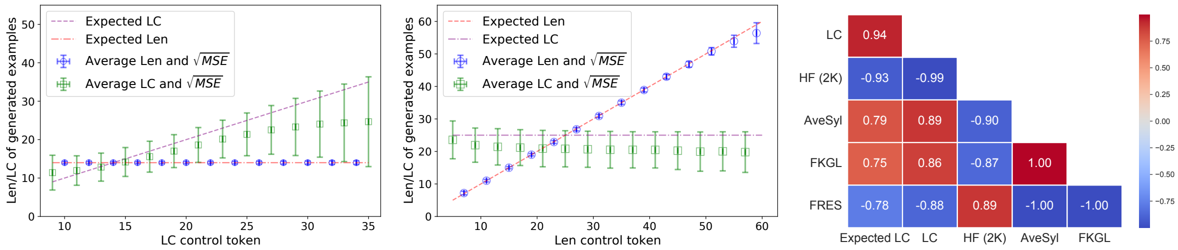
4.3 Ablation Study

We perform an ablation study to demonstrate the importance of each design. We first train variants of the full model by removing the word, POS, and definition, and then run greedy decoding on the well-trained models to generate examples. We show the results on the test set[6] in Table 4. Compared with the full model (row 1), we note that: (1) removing the targeted word significantly decreases the word coverage (row 2). (2) POS helps to improve the POSA (row 3). (3) the definition improves the DefA (row 4). These observations verify the effectiveness of these components. Len and LC control tokens are mainly used to control the readability of outputs, which do not degrade the generated examples (see Table 13 in the Appendix).

We also test the effect of leading space. As shown in Table 5, adding the space increases the word coverage by 8.6%, establishing the importance of this design. The pointer network (Gulcehre et al., 2016; See et al., 2017) is used to copy content from the source into outputs. However, only using the pointer network cannot improve the word coverage, as it does not solve the mapping issue mentioned in Section 3.3. Therefore, we do not use the pointer network.

---

[6] We observe similar results on the validation set.



(a) Effect of the LC control token (b) Effect of the Len control token (c) Pearson correlation coefficient

Figure 4: The impact of control tokens on generated examples. Subfigures (a) and (b) demonstrate the statistics of the corresponding attributes of the generated examples on the test set, including average, standard deviation (std), and mean squared error (MSE) values. Subfigure (c) shows the Pearson correlation coefficients for LC and a set of metrics. All examples are generated by running greedy decoding on the model (row 11 of Table 3) with Len$_{14}$+LC (Subfigures (a) and (c)), and Len+LC$_{25}$ (Subfigure (b)) control tokens. Expected LC/Len is the gold LC/Len label used to generate examples; LC/Len means the average lexical complexity/length of outputs.

Cases	Coverage↑	POSA↑	DefA↑	B-4↑	#POS	#Senses
2	99.6%	**97.7%**	**92.2%**	6.1%	1.2	2.0
3	**99.7%**	96.6%	88.8%	6.6%	1.4	3.0
≥4	99.5%	97.4%	85.4%	**8.6%**	1.9	10.6
Noun	99.7%	**98.7%**	88.5%	7.1%	1.5	6.3
Adjective	99.2%	95.1%	87.5%	6.9%	1.6	5.1
Verb	**99.8%**	98.6%	**89.1%**	**9.6%**	1.8	10.2
Adverb	99.6%	84.9%	75.7%	4.5%	1.6	6.1

Table 6: Results on different cases, where the test set is separated according to the #Senses (part one), and POS tags (part two), respectively. All examples are generated by the model (row 11 of Table 3) with Len$_{14}$+LC$_{25}$. #Sense and #POS denote the average number of senses and POS tags owned by each word.

4.4 More Analysis and Discussion

Effect of Control Tokens. In Table 13, we have shown that Len and LC control tokens affect readability via HF, but two questions are still unclear: **Q1:** Whether these control tokens have the desired effects on their associated attributes, length and lexical complexity? **Q2:** What is the correlation between LC and readability? To answer Q1, we generate examples by running greedy decoding on our model (row 11 of Table 3) with different control tokens. From Figure 4 (a) and (b), we see that: (1) the average LC and Len of outputs increase linearly with the gold LC and Len labels; (2) the MSE values between Len and gold Len labels are negligible, while the MSE values between LC and gold LC labels are relatively large, especially when LC $>$ 30 indicating that the control ability of the model on LC decreases, possibly due to the limited training data (see Figure 2 (e)). Therefore, we can conclude that Len and LC control tokens do affect their associated attributes.

To answer Q2, we compute the Pearson correlation coefficients (PCC) between LC and two widely used readability metrics, FKGL and FRES. Since LC is based on the word frequency, we compute the PCC between LC and the proportion of high-frequency words with a word rank lower than 2K (HF (2K)). FKGL and FRES are related to the average number of syllables of outputs (AveSyl), so we also compute PCC between LC and AveSyl. As shown in Figure 4 (c), LC values of outputs are strongly positively correlated with the gold/expected LC labels, which again verifies our model's control ability over LC. We also notice that PCC between LC and HF is -0.99, proving that LC can control the other readability-related metrics of outputs by controlling HF. We show more results of control tokens in Appendix H.

Effect of the Number of Senses. As shown in the first part of Table 6, with the increase of the number of definitions, it becomes more and more challenging to generate examples satisfying the definition(s), thus causing a decrease in DefA.

Effect of POS Tags. As shown in the second part of Table 6, our model performs worst on the adverb case, especially in POSA and DefA. We found that our model may ignore the adverb POS tag and use the adjective POS tag (see the targeted word '*worse*' in Table 15). We presume that there are two possible reasons: (1) in the training set, the adverb training data is far less than the adjective data (see Figure 2 (c)), so the adverb embedding may not be well learned and updated; (2) for some adverb, such as *'worse'*, the adjective definition is much more common, so the pre-trained model, BART, may bias towards the adjective meaning.

Overall speaking, as shown in Table 7, our model can generate high-quality examples for different

Words	POS	Definitions	Generated examples
banks	Noun	the land alongside or sloping down to a river or lake	The river **banks** are a natural habitat for wildlife.
banked	Verb	heap (a substance) into a mass or mound	The ground was **banked** with mud and the water had been pumped into a bucket.
star	Noun	an outstandingly successful person or thing in a group	The **star** of the show is a young man who has been in the spotlight for years.
star	Noun	a fixed luminous point in the night sky . . .	The **star** is a bright, luminous object that shines brightly in the night sky.
satisfy	Verb	meet the expectations, needs, or desires of (someone)	The company has been trying to **satisfy** customers with its new products.
satisfy	Verb	fulfil (a desire or need)	The only way to **satisfy** this desire is by making a new one.
sentences	Noun	a set of words that is complete in itself . . .	The first two **sentences** are the same, but they have different meanings.
sentence	Verb	declare the punishment decided for (an offender)	The court will **sentence** him to life in prison.
sentenced			The offender was **sentenced** to a total of six months in prison.
sentencing			The judge was **sentencing** the offender to a maximum of five years in prison.
sentences			The court **sentences** him to life in prison without parole.

Table 7: Examples generated with different words, POS tags and definitions from the test set. All examples are generated by running greedy decoding on the model trained with the targeted word, POS tag, and definition.

Word: banks **POS:** Noun	**Definition:** the land alongside or sloping down to a river or lake
Human	Massive housing projects are springing up on the banks of lakes.
Len$_{5}$	The banks of the river.
Len$_{10}$	The river banks are a ***haven*** for the fish.
Len$_{20}$	The river banks are a natural habitat for wildlife, and the water is not too ***polluted*** or ***salty***.
Len$_{14}$**+LC**$_{10}$	The river banks are the only way to get water from this area.
Len$_{14}$**+LC**$_{20}$	The river banks are a natural habitat for the birds and their ***larvae***.
Len$_{14}$**+LC**$_{30}$	The river banks are the most ***productive*** of all the ***estuaries***.

Table 8: The impact of control tokens on generated examples. All examples are generated by the model (row 11 of Table 3) with different control tokens. Text in bold and italics denotes low-frequency ***words*** with the word rank higher than 5K.

Models	Fluency	Definition	POS
asyn-B/F	4.08	2.19	77.3%
GBS	4.43	2.27	84.0%
Our model	**4.83**	**2.59**	**90.7%**
Our model	LC$_{10}$	LC$_{20}$	LC$_{30}$
Readability	1.08	1.44	1.68

Table 9: Human evaluation results on the test set for fluency, definition and POS scores, and readability of our model with different LC control tokens are shown at the top and bottom. The differences between models' scores and baselines' are statistically significant due to the paired t-test comparisons (p-value$<$0.05).

words and the same word with different definitions, such as *'star'* and *'satisfy'*. Moreover, our model can generate plausible examples for different inflected forms of words, such as *'sentence'*. Table 8 shows that we can control the length and lexical complexity of examples generated with our model by varying the control labels.

To summarize, our model not only can generate meaningful examples for existing words, but also has a strong control ability over the length and lexical complexity of outputs.

Please refer to Appendix E, F and G for the effect of word frequencies, unseen words and the size of training data. Please refer to Appendix I for more detailed sample analysis.

4.5 Human Evaluation

We conduct a human evaluation to further compare our model with asyn-B/F and GBS (rows 8, 9 and 11 of Table 3). For each model, we randomly select 50 generated examples and invite three annotators [7] to label the sentences. Annotators first rate the sentence fluency on a 5-point Likert scale from 1 (not fluent) to 5 (extremely fluent). Then, annotators assess whether the meaning of the targeted word in the output is the same as the given definition on a 3-point Likert scale, from 1 (totally different) to 3 (exactly the same). Finally, annotators judge whether the POS of the targeted word in the output is consistent with the given POS. We show the detailed annotation method in Appendix D. As shown in Table 9, our proposed model outperforms baselines in human evaluation on all metrics.

PCCs between two automatic evaluation metrics (DefA, POSA) and related human evaluation scores are 73.5% and 90.3% (p-value$<$0.05), indicating positive and strong correlations.

We also conduct a human evaluation to assess our model's control ability over readability. We first randomly select 50 groups of examples generated by our model with different LC (10, 20,

---

[7] All annotators are Ph.D. students and are independent of our research group.

30) + LC$_{14}$. Then, we ask annotators to rank the sentences on readability in each group. The most difficult sentence receives a score of 3, the others receive scores of 2, 1. Annotators can give the same rank to different examples if they have no preference. As shown at the bottom of Table 9, the difficulty of the generated sentences increases with LC, verifying that our model can control the readability of outputs via LC control tokens. Inter-rater agreement measured by Fleiss' $kappa$ (Fleiss, 1971) is 0.51, 0.73, 0.90 and 0.60 for fluency, definition, POS and readability, indicating moderate, substantial, almost perfect and moderate inter-rater agreement, according to Landis and Koch (1977).

5 Related Work

Word Sense Disambiguation. Word Sense Disambiguation (WSD) (Navigli, 2009) is a fundamental task and long-standing challenge in NLP, which aims to associate an ambiguous word in context with the exact sense from a finite set of possible choices. Previous work formulates the task as a token classification problem (Raganato et al., 2017) or sentence-pair (context and gloss pair) classification problem (Huang et al., 2019). WiC (Pilehvar and Camacho-Collados, 2019) is framed as a binary classification problem, which aims to identify if the occurrences of the targeted word in the first context and second context correspond to the same meaning or not. Our proposed work is related to word disambiguation, yet it is a generation task, which is more challenging.

Controllable Text Generation. Controllable text generation aims to generate text in a controlled way, which has attracted wide attention. One line of research injects pre-specified keywords into outputs by controlling the decoding process (Mou et al., 2015; Hokamp and Liu, 2017; Post and Vilar, 2018) or refining candidate outputs iteratively (Miao et al., 2019; Sha, 2020; He and Li, 2021; He, 2021). Another kind of work uses control tokens to manipulate text attributes, such as the length (Kikuchi et al., 2016; Fan et al., 2018), topic (Ficler and Goldberg, 2017; Keskar et al., 2019), and grade level for text simplification (Scarton and Specia, 2018; Nishihara et al., 2019).

In this paper, we first introduce the dictionary example generation task, which also requires the targeted word to appear in outputs. To this end, we use a target-word-aware model to generate examples for given words. Different from the former line of work, our proposed model does not interfere with the decoding process, thus reducing the inference time and improving the generation quality. Moreover, we expect to tailor-made outputs for different audiences. Inspired by the latter kind of work, our model takes readability-related control tokens to generate suitable example sentences with the desired readability.

Dictionary Example Generation. Two recent works are related to dictionary example generation. One work is GPT-3 (Brown et al., 2020), a large-scale autoregressive language model. To qualitatively test GPT-3's ability for the few-shot task of using a new/nonexistent word in a sentence, Brown et al. (2020) gave GPT-3 the definition of a nonexistent word, such as "screeg", and then asked GPT-3 to use it in a sentence. However, they did not formally define this task.

Similar to our work, another concurrent work (Barba et al., 2021) also gives a formal statement of the dictionary example generation task. However, they did not evaluate the quality of generated examples directly. In their work, they aimed to improve WSD models by augmenting WDS datasets with the generated examples. Compared with their work, we directly evaluate whether the targeted work in the generated example reflects the given sense and POS tag with the proposed BERT-based classifiers. Our work also explores how to generate suitable examples for different targeted audiences.

6 Conclusions

In this paper, we first introduce the dictionary example sentence generation problem, and propose a controllable target-word-aware model and several strong baselines for it. We propose two BERT-based classifiers to evaluate the definition and POS accuracy of generated examples. Our experiment results on the Oxford dictionary dataset show that our model outperforms baselines in most metrics and can generate appropriate examples meeting different audiences' understanding levels.

Models	Labels	Training	Validation
POS	Negative	3,337,293	417,733
	Positive	1,138,316	141,626
Definition	Negative	4,219,163	532,272
	Positive	1,138,316	141,626

Table 10: Statistics of the synthetic training and validation sets for BERT-based POS and definition models.

Models	Labels	P	R	F1
POS	Negative	0.994	0.991	0.993
	Positive	0.974	0.983	0.978
	Macro-average	0.984	0.987	0.985
Definition	Negative	0.968	0.944	0.956
	Positive	0.806	0.882	0.843
	Macro-average	0.887	0.913	0.899

Table 11: Results of the BERT-based POS and definition models on the synthetic validation set. “P” and “R” denote precision and recall.

A BERT-based Definition Evaluation Classifier

The definition classifier takes a triple of word, definition and example (w^*, D, E) as input, which aims to assess whether the targeted word w^* in the example E conveys the given meaning D. To train the definition model, we should create the synthetic data $\{(w^*, D, E, L)\}$. If w^* in E conveys D, the label L is 1, denoting the data instance is positive. Otherwise, the label L is 0, denoting the data instance is negative.

We can directly select the positive data instance (w^*, D, E) from the Oxford training or validation set. For each positive data instance, we first create one negative data instance by replacing the targeted word w^* with another word in the example E with a 50% probability or another word in the vocabulary with a 50% probability. Next, we create at most two negative instances by replacing the definition D with any two definitions of the word. Then, we construct a negative instance by replacing the definition D with any definition of other words. Finally, we create a negative instance by replacing the example E with another sentence with a 50% probability, which does not contain the targeted word w^*. For ease of understanding, we show several synthetic data instances for the BERT-based definition model in Table 12. We show the statistics of the synthetic data in Table 10.

We fine-tune the BERT-base-cased model on the synthetic training set for two epochs with the initial learning rate of $1e{-}5$ and select the best checkpoint on the validation set. We show the performance of the definition model on the synthetic validation set in Table 11.

B BERT-based POS Evaluation Classifier

The POS model takes a triple of word, POS tag, and example (w^*, P, E) as input, which aims to assess whether the targeted word w^* in the example E conveys the given POS tag P. To train the POS model, we should create the synthetic data $\{(w^*, P, E, L)\}$. If w^* in E conveys P, the label L is 1, denoting the data instance is positive. Otherwise, the label L is 0, denoting the data instance is negative.

We can directly select the positive data instance (w^*, P, E) from the Oxford training or validation set. For each positive data instance, we first create several negative data instances by replacing the POS tag P with all other POS tags of the targeted word. Then, we construct at most two negative instances by replacing the POS tag P with any two POS tags not belonging to the targeted word. Finally, we create a negative instance by replacing the example E with another sentence with a 50% probability, which does not contain the targeted word w^*. We show the statistics of the synthetic data in Table 10.

We resort to the same training strategy with the definition model and show the performance of the POS model on the synthetic validation set in Table 11.

C Data Distributions of Validation and Test Sets

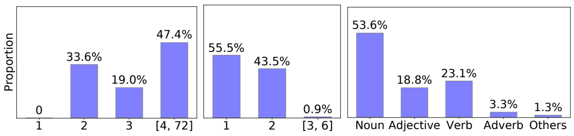
Figure 5/6 (a) and (b) show the unique lemma distribution over the number of senses, and the number of POS tags in the validation/test set, respectively. Similar to the training set, the validation and test sets have ten POS tags (noun, adjective, verb, adverb, preposition, interjection, numeral, pronoun, determiner, conjunction). Figure 5/6 (c) shows the distinct definition distribution over POS tags in the validation/test set.

D Details on Human Evaluation

For human evaluation, we first show graders the inputs used to generate example sentences, consisting of the targeted word, POS tag, and specific definition. Next, we show them a group of sentences generated by asyn-B/F, GBS and our proposed model. To avoid bias, sentences in each

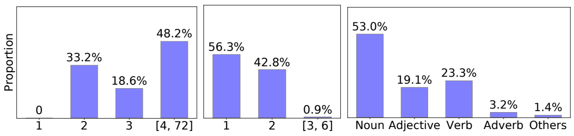
Word	Definition	Example	Label
bank	The land alongside or sloping down to a river or lake.	Willows lined the bank of the stream.	1
stream	The land alongside or sloping down to a river or lake.	Willows lined the bank of the stream.	0
bank	Heap (a substance) into a mass or mound.	Willows lined the bank of the stream.	0
bank	The land alongside or sloping down to a river or lake.	I'm happy with his performance.	0

Table 12: Synthetic data instances for the BERT-based definition model.



(a) #Sense (b) #POS tags (c) POS tags

Figure 5: Subfigures (a) and (b) show the unique lemma distribution over #Senses, and #POS tags in the validation set, respectively. Subfigure (c) shows the distinct definition distribution over POS tags in the validation set.



(a) #Sense (b) #POS tags (c) POS tags

Figure 6: Subfigures (a) and (b) show the unique lemma distribution over #Senses, and #POS tags in the test set, respectively. Subfigure (c) shows the distinct definition distribution over POS tags in the test set.

group are shuffled before annotation. Then, annotators should compare these sentences and score them on three criteria: sentence fluency, POS and definition accuracy.

D.1 Fluency

To evaluate the sentence fluency, graders should answer the first question:
Q1: How fluent do you think the sentence is?

Specifically, graders are asked to score the sentence fluency on a 5-point Likert scale from 1 to 5, based on the following rules:
1: the sentence cannot be understood and all segments are not fluent;
2: the sentence cannot be understood, but some segments are fluent;
3: the sentence can be understood to some extent, but with many grammatical errors;
4: the sentence can be understood with several grammatical errors;
5: the sentence is extremely fluent without any grammatical errors.

D.2 Definition Accuracy

To assess the definition accuracy, graders need to answer the second question:
Q2: How consistent do you think the meaning of the targeted word in the generated sentence is with respect to the given definition?

To finish this task, we ask graders to refer to all definitions and examples of the targeted word on Oxford Dictionary. Concretely, graders are asked to score the definition accuracy on a 3-point Likert scale from 1 to 3, based on the following rules:
1: the meaning reflected by the targeted word in the generated sentence is totally different from the given definition;
2: the meaning reflected by the targeted word in the generated sentence is similar or relevant to the given definition;
3: the meaning reflected by the targeted word in the generated sentence is exactly the same as the given definition.

Suppose that the targeted word, POS tag, given definition are *'bank'*, verb, *'Heap up (a fire) with tightly packed fuel so that it burns slowly.'* We will ask graders to label the following four examples as 1, 1, 2 and 3.
(1) *'a grassy bank'*
In this example, the POS tag of *'bank'* is a noun different from the given POS tag, so graders need to label this example as 1.
(2) *'I banked the aircraft steeply and turned.'*
In this example, the POS tag of *'bank'* is a verb, yet it conveys an entirely different meaning *'(with reference to an aircraft or vehicle) tilt or cause to tilt sideways in making a turn.'* Therefore, we ask graders to label this sentence as 1.
(3) *'Purple clouds banked up over the hills.'*
Graders need to label this as 2, since *'bank'* conveys a relevant meaning (*'Form into a mass or mound.'*) to the given definition.
(4) *'She banked up the fire.'*
Graders are asked to label this as 3, since *'bank'* exactly reflects the given definition.

# Variants	Coverage↑	POSA↑	DefA↑	B-4↑	D-4↑
1 BART-base	99.6%	97.2%	87.7%	7.6%	86.4%
2 – Word	14.5%	17.3%	16.1%	3.6%	85.9%
3 – POS	99.6%	96.6%	87.6%	7.5%	86.6%
4 – Definition	99.4%	97.4%	35.8%	4.3%	73.2%
5 – Len	99.6%	97.4%	87.4%	7.2%	83.5%
6 – LC	99.7%	97.2%	88.1%	7.7%	84.2%

Table 13: Results of ablation study on the test set.

Cases	Coverage↑	POSA↑	DefA↑	B-4↑	#POS	#Senses
[1, 1K]	99.5%	94.3%	74.3%	7.8%	2.2	19.8
(1K, 2K]	99.3%	97.1%	83.5%	8.9%	1.9	13.9
(2K, 5K]	99.1%	97.6%	83.5%	8.8%	1.7	10.7
(5K, 10K]	99.6%	97.5%	85.7%	**9.1%**	1.6	8.0
>10K	**99.7%**	**97.7%**	**91.0%**	7.0%	1.5	4.1
Seen	99.6%	97.1%	87.1%	**7.9%**	1.6	7.7
Unseen	**99.7%**	**98.8%**	**92.3%**	6.0%	1.5	2.9

Table 14: Results on different cases, where the test set is separated according to word frequencies (part one) and unseen/seen words (part two), respectively. All examples are generated by running greedy decoding on the model (row 11 of Table 3) with Len_{14}+LC_{25}. #Sense and #POS denote the average number of definitions and POS tags owned by each word.

These examples and definitions are extracted from Oxford Dictionary.

D.3 POS Accuracy

As for POS, annotators should judge whether the POS tag of the targeted word in the generated example is consistent with the given POS tag.

E Effect of Word Frequencies

As shown in the first part of Table 14, high-frequency words have more definitions and POS tags, and in turn have lower POSA and DefA. As for the sentence quality, high-frequency words have more definitions, while low-frequency (rare) words may not appear in the training set. Both factors may hinder the model from generating satisfactory sentences. That is why words in range $(5K, 10K]$ have the best generation quality (B-4).

F Effect of Unseen and Seen Words

We split the words in the test set into seen and unseen. If a word in the test set has at least one definition in the training set, it will be regarded as a seen word. Otherwise, it will be treated as unseen. The bottom of Table 14 shows that seen words have more #Def than unseen words, since most seen words are high-frequency words, resulting in a lower DefA.

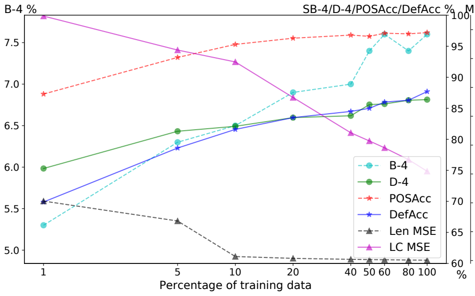


Figure 7: Results of our proposed model variants (row 11 of Table 3) trained with different size of training data.

G Effect of the Size of Training Data

From Figure 7, we see that the size of training data matters, as there is a clear performance gain in sentence quality (B-4), diversity (D-4), definition accuracy and POS accuracy when the data size increases. In addition, the control ability of our model over Len and LC also improves with the increase of the data size.

H Effect of Control Tokens

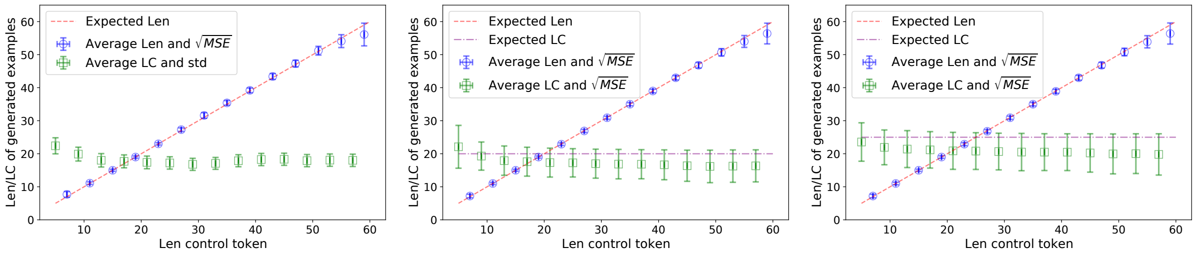
To further evaluate the effect of control tokens, we generate examples by running greedy decoding on the model (row 11 of Table 3) with different control tokens and show the results on the test set in Figure 8. We witness that the proportion of high-frequency (HF 2K) words significantly reduces from around 90% to 30% with the increase of LC, which again verifies that LC affects the readability of generated examples (see row 4, col 1-3 of Figure 8). However, there is an opposite trend for NLL, in line with the conclusion given by Holtzman et al. (2020) that generic (high-frequency) text tends to have low NLL. As for the generation diversity, the model achieves the highest D-4 when LC is around 25, where the model can balance the high-frequency and low-frequency words.

I Further Sample Analysis

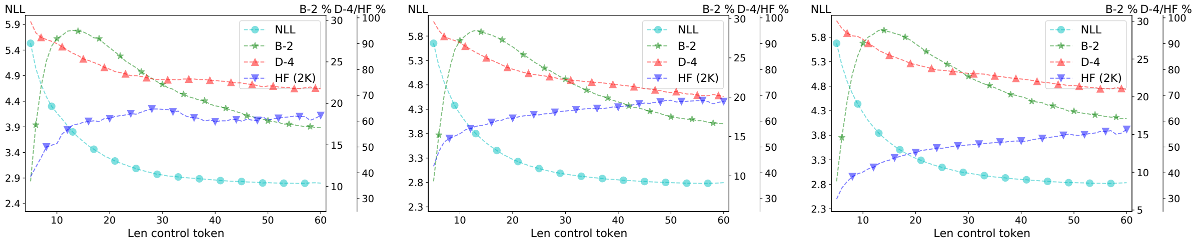
We show some example sentences generated by different models in Table 15. Compared with baselines, our models can generate fluent example sentences, and the targeted words in the generated sentences can reflect the given meanings in most cases. For example, for the first case (‘*happy*’), both sep-B/F and asyn-B/F fail to generate meaningful sentences. Although GBS can generate a fluent sentence, the meaning reflected by the targeted word is not the same as the given definition. As for the fourth case (*'plain'*), all baselines ignore the given definition and use the more general definition (*'Not decorated or elaborate; simple or basic in character.'*) and adjective POS tag to generate examples. By comparison, all our models can generate satisfying example sentences.

However, for the last case (*'worse'*), our models seem to ignore the adverb POS tag and use the adjective POS tag. We presume that there are two possible reasons: (1) in the training set, the adverb training data is far less than the adjective data, so the adverb embedding may not be well learned and updated; (2) for the given word, *'worse'*, the adjective definition is much more common, so the pretrained model, BART, may have a bias towards the adjective meaning. Therefore, it is still challenging to generate example sentences for polysemous words with uncommon definitions and POS tags.

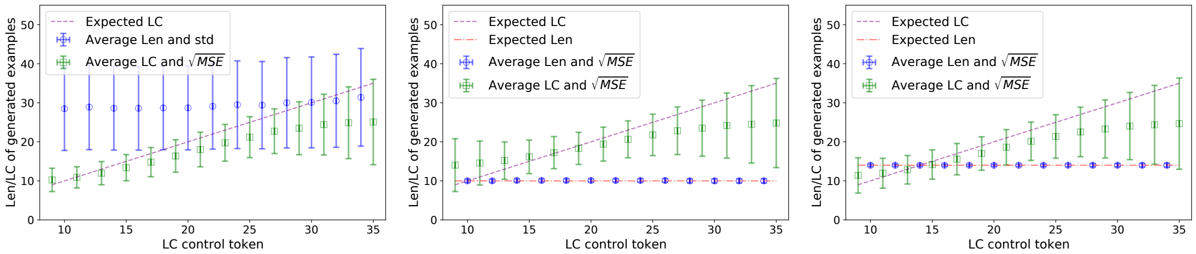
To demonstrate the impact of Len and LC control tokens on generated examples, we show some examples generated by running greedy decoding on our proposed model (row 11 of Table 3) with different control labels in Table 16.



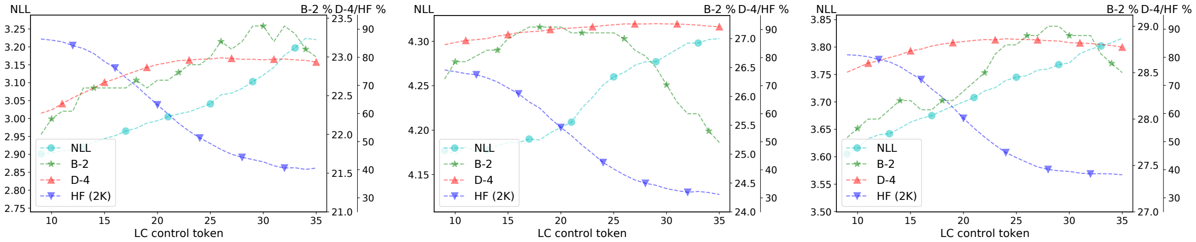
(a) Len (b) Len+LC$_{20}$ (c) Len+LC$_{25}$



(d) Len (e) Len+LC$_{20}$ (f) Len+LC$_{25}$



(g) LC (h) Len$_{10}$+LC (i) Len$_{14}$+LC



(j) LC (k) Len$_{10}$+LC (l) Len$_{14}$+LC

Figure 8: The impact of control tokens on generated examples. The first and third rows demonstrate the statistics of the corresponding attributes of the generated examples on the test set, including average, standard deviation (std), and mean squared error (MSE) values. The second and fourth rows illustrate the results on NLL, B-2, D-4 and HF (2K) of the test set. All examples are generated by running greedy decoding on the model (row 11 of Table 3) with **Len** (rows 1-2, col 1), **Len+LC**$_{20}$, (rows 1-2, col 2), **Len+LC**$_{25}$, (rows 1-2, col 3), **LC** (rows 3-4, col 1), **Len**$_{10}$**+LC**, (rows 3-4, col 2), and **Len**$_{14}$**+LC**, (rows 3-4, col 3) control tokens. **Len** means sentences are generated using different Len without using LC. **Len+LC**$_{20}$ denotes sentences are generated using different Len and a fixed LC of 20. The meaning of other abbreviations can be inferred from these two abbreviations.

Word	**POS**	**Definition**
happy	Adjective	satisfied with the quality or standard of
Human reference		Are you **happy** with the role of these representative groups in the diversity programme?
Lexically Constrained Models w/ Definitions		
sep-B/F		A quality **happy** hour. It was well worth the wait, and we were very pleased with ourselves for our efforts.
asyn-B/F		A quality **happy** hour. The food was good and the service excellent, but it wasn't cheap either.
GBS		The quality of the food is not very good, but it's **happy** to eat what you like.
Our Models+Word+POS+Len$_{14}$+LC$_{25}$		
BART-base (greedy)		I'm not **happy** with the way they've been treated by me.
BART-large (greedy)		I'm not **happy** with the quality of my own e-mail.
BART-large (beam 5)		I wasn't **happy** with the quality of the food and the service.
BART-large (top-k 50)		I am **happy** with the quality of the product and its ergonomics.
happy	Adjective	willing to do something
Human reference		United Future is always pleased and **happy** to support sensible legislation.
Lexically Constrained Models w/ Definitions		
sep-B/F		That's not to say that he is one of the **happy** ones, but I think it would be better for him.
asyn-B/F		That's not to say that he is one of the **happy** people I've ever met.
GBS		I am **happy** to say that the Government has decided not to do anything about it.
Our Models+Word+POS+Len$_{14}$+LC$_{25}$		
BART-base (greedy)		I'm **happy** to be a part of the new millennium's celebrations.
BART-large (greedy)		I'm **happy** to do that, but don't be so harsh.
BART-large (beam 5)		I'm **happy** to do that, but I don't like it.
BART-large (top-k 50)		I'm **happy** to do that as long as it doesn't hurt.
sample	Verb	try the qualities of (food or drink) by tasting it
Human reference		There will be cookery demonstrations, videos, information and, of course, a chance to **sample** some of the delicious food that will be on display.
Lexically Constrained Models w/ Definitions		
sep-B/F		You will be able to taste and **sample** a variety of wines from the region.
asyn-B/F		You will be able to taste and **sample** a range of wines, beers and spirits from around the world.
GBS		The **sample** was tastefully tanned and tasted very well.
Our Models+Word+POS+Len$_{14}$+LC$_{25}$		
BART-base (greedy)		We **sample** the wines and savoury snacks of our local restaurants.
BART-large (greedy)		The judges **sample** the wines and then invited their guests to sample them.
BART-large (beam 5)		Guests will be able to **sample** a variety of cheeses and wines.
BART-large (top-k 50)		We sampled the wines and appetizers and had a chance to **sample**.
plain	Adverb	used for emphasis
Human reference		Your statement on Nicaragua shows how utterly naive and just **plain** stupid you are.
Lexically Constrained Models w/ Definitions		
sep-B/F		This is in stark contrast to the **plain** fact that it's not just a matter of whether or not you want them.
asyn-B/F		This is in stark contrast to the **plain** fact that most of us have no idea what we are talking about.
GBS		I'm not sure if it's a good thing or bad, but there is something **plain** and simple about this.
Our Models+Word+POS+Len$_{14}$+LC$_{25}$		
BART-base (greedy)		The whole thing is just **plain** uninteresting, and it's frustrating.
BART-large (greedy)		I'm just **plain** tired of the constant barrage of e-mails.
BART-large (beam 5)		It's just **plain** tacky, and I don't like it.
BART-large (top-k 50)		It was just **plain** rude, and I didn't mean to offend.
worse	Adverb	more seriously or severely
Human reference		At this point, Kohaku's stomach had already began hurting far **worse** than Muteki's.
Lexically Constrained Models w/ Definitions		
sep-B/F		He said he was seriously **worse** off than before and had to be taken out of hospital for treatment.
asyn-B/F		He said he was seriously **worse** affected by the accident and had been taken to hospital for treatment.
GBS		He was seriously injured in a car accident on the way home from work and **worse** still had to be taken by ambulance.
Our Models+Word+POS+Len$_{14}$+LC$_{25}$		
BART-base (greedy)		The situation has gotten **worse** since the end of the Cold War.
BART-large (greedy)		The situation is getting **worse**, and the people are being scapegoated.
BART-large (beam 5)		He was in a wheelchair and his condition was getting **worse** and worse.
BART-large (top-k 50)		He was seriously ill, but his condition didn't get **worse** overnight.

Table 15: Example sentences generated by different models with definition triplets (word, POS, definition) extracted from the test set. 'top-k 50' refers to running top-k decoding with k=50 on our model.

Word: banks **POS:** Noun	**Definition:** the land alongside or sloping down to a river or lake
Human reference	Massive housing projects are springing up on the banks of lakes.
Len$_{5}$	The banks of the river.
Len$_{10}$	The river banks are a ***haven*** for the fish.
Len$_{15}$	The river banks are a natural habitat for the birds and their ***migratory***.
Len$_{20}$	The river banks are a natural habitat for wildlife, and the water is not too ***polluted*** or ***salty***.
Len$_{25}$	The river banks are a natural habitat for wildlife, and the water is not too ***salty*** to be used as an ***aquatic*** environment.
Len$_{30}$	The river banks are a natural habitat for wildlife, and the water is not too ***salty*** to be used as an ***aquatic*** ***feeder*** or even a ***fertilizer***.
Len$_{5}$+LC$_{25}$	The banks of the ***Thames***.
Len$_{10}$+LC$_{25}$	The banks of the River ***Thames*** are also ***flooded***.
Len$_{15}$+LC$_{25}$	The river banks are a ***haven*** for the wildlife and its ***inhabitants***, too.
Len$_{20}$+LC$_{25}$	The river banks are a ***haven*** for the wildlife, and they're also an important habitat for birds.
Len$_{25}$+LC$_{25}$	The river banks are a ***haven*** for the wild, and there is no need to worry about the ***dangers*** of ***overfishing***.
Len$_{30}$+LC$_{25}$	The river banks are a ***haven*** for the wild, and there is no need to worry about the ***waterlogged*** trees that litter the ***shoreline***.
Len$_{14}$+LC$_{10}$	The river banks are the only way to get water from this area.
Len$_{14}$+LC$_{20}$	The river banks are a natural habitat for the birds and their ***larvae***.
Len$_{14}$+LC$_{30}$	The river banks are the most ***productive*** of all the ***estuaries***.

Word: banked **POS:** Verb	**Definition:** deposit (money or valuables) in a bank
Human reference	Obviously, we banked the money because we didn't know whether or not it was a donation.
Len$_{5}$	A ***banked*** account.
Len$_{10}$	The money was ***banked*** in a ***Swiss franc***.
Len$_{15}$	The money was ***banked*** in a trust account and the company's shares.
Len$_{20}$	The money was ***banked*** in a trust account and the company's accounts were transferred to its ***subsidiary***.
Len$_{25}$	The money was ***banked*** in a trust account, which is now being used to pay for the purchase of new homes and ***apartments***.
Len$_{30}$	The ***banked*** money was ***deposited*** in a safe ***deposit*** box, which is where the cash will be stored for up to three months before it goes into ***circulation***.
Len$_{5}$+LC$_{25}$	A ***banked*** loan.
Len$_{10}$+LC$_{25}$	The money was ***banked*** in a ***Swiss franc***.
Len$_{15}$+LC$_{25}$	The money was ***banked*** in a trust account at the Bank of England.
Len$_{20}$+LC$_{25}$	The money was ***banked*** in a trust account and the company's assets were transferred to its ***subsidiaries***.
Len$_{25}$+LC$_{25}$	The money was ***banked*** in a trust account, which is now owned by the Bank of England and ***administered*** through its ***subsidiaries***.
Len$_{30}$+LC$_{25}$	The money was ***banked*** in a trust account, which is now owned by the Bank of England and has been ***deposited*** into an ***escrow*** fund.
Len$_{14}$+LC$_{10}$	The money was ***banked*** in the first place and sent to us.
Len$_{14}$+LC$_{20}$	The money was ***banked*** in a trust account and sent to China.
Len$_{14}$+LC$_{30}$	The money was ***banked*** in the Bank of England's ***Money Reserve***.

Table 16: The impact of control tokens on generated examples. All examples are generated by running greedy decoding on our proposed model (row 11 of Table 3) with different control tokens. Text in bold and italics denotes low-frequency ***words*** with the word rank higher than 5,000.

AraT5: Text-to-Text Transformers for Arabic Language Generation

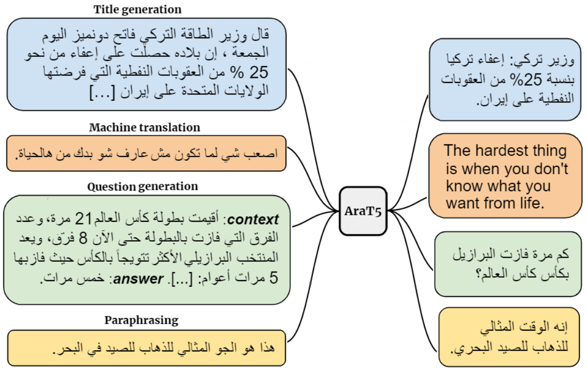
El Moatez Billah Nagoudi* **AbdelRahim Elmadany*** **Muhammad Abdul-Mageed***
Deep Learning and Natural Language Processing Group
The University of British Columbia
`{moatez.nagoudi,a.elmadany,muhammad.mageed}@ubc.ca`

Abstract

Transfer learning with a unified Transformer framework (T5) that converts all language problems into a text-to-text format was recently proposed as a simple and effective transfer learning approach. Although a multilingual version of the T5 model (mT5) was also introduced, it is not clear how well it can fare on non-English tasks involving *diverse* data. To investigate this question, we apply mT5 on a language with a wide variety of dialects–Arabic. For evaluation, we introduce a novel benchmark for **AR**abic language **GEN**eration (ARGEN), covering *seven* important tasks. For model comparison, we pre-train three powerful Arabic T5-style models and evaluate them on ARGEN. Although pre-trained with $\sim$ 49% less data, our new models perform significantly better than mT5 on *all* ARGEN tasks (in 52 out of 59 test sets) and set several new SOTAs. Our models also establish new SOTA on the recently-proposed, large Arabic language understanding evaluation benchmark ARLUE (Abdul-Mageed et al., 2021). Our models are publicly available. We also link to individual ARGEN datasets through our public repository.[1]

1 Introduction

Due to their remarkable ability to transfer knowledge from unlabeled data to downstream tasks, pre-trained Transformer-based language models have emerged as important components of modern natural language processing (NLP) systems. In particular, the unified framework that converts all text-based language problems into a text-to-text format presented through the T5 model (Raffel et al., 2019) is attractive. In addition to its simplicity, this approach is effective since it allows knowledge transfer from high-resource to low-resource tasks without the need for changing model architecture. Unlike models such as BERT (Devlin et al., 2019), which are based on encoders only, the T5 model is an encoder-decoder that can naturally be employed for natural language generation. Although the T5 model, originally pre-trained for English, was recently extended to the multilingual setting as mT5 (Xue et al., 2020), it is not clear how suited it is to individual languages (and varieties of these languages). In addition, systematic issues have been discovered in multilingual corpora on which language models have been trained (Kreutzer et al., 2021). In absence of comparisons with monolingual pre-trained language models that serve different non-English contexts, it remains unknown how multilingual models really fare against language-specific models.



قال وزير الطاقة التركي فاتح دونميز اليوم الجمعة ، إن بلاده حصلت على إعفاء من نحو 25 % من العقوبات النفطية التي فرضتها الولايات المتحدة على إيران [...]

اصعب شي لما تكون مش عارف شو بدك من هالحياة.

هذا هو الجو المثالي للذهاب للصيد في البحر.

وزير تركي: إعفاء تركيا بنسبة 25% من العقوبات النفطية على إيران.

The hardest thing is when you don't know what you want from life.

كم مرة فازت البرازيل بكأس العالم؟

إنه الوقت المثالي للذهاب للصيد البحري.

Figure 1: Our AraT5 encoder-decoder model and prompt samples from four investigated tasks, namely: title generation, machine translation, question generation, and paraphrasing.

In this work, we offer the first comparison of the mT5 model to similar encoder-decoder models dedicated to Arabic. We choose Arabic as our context due to its large set of diverse varieties as well as its wide use on social media. Our work aims at uncovering the extent to which mT5 can serve Arabic's different varieties. Our work also meets an existing need for pre-trained Transformer-based sequence-to-sequence models. In other words, while several BERT-based models have been pre-trained for Arabic (Antoun et al., 2020; Abdul-Mageed et al.,

2021; Inoue et al., 2021), no such attempts have been made to create sequence-to-sequence models that we know of. Another motivation for our work is absence of an evaluation benchmark for Arabic language generation tasks. Apart from machine translation where researchers are starting to propose benchmarks such as AraBench (Sajjad et al., 2020), there are no benchmarks that can be used to methodically measure Arabic natural language generation performance.

Our main contributions are as follows: **(1)** We introduce three powerful variants of the text-to-text transformer (T5) model dedicated to Modern Standard Arabic (MSA) and a diverse set of Arabic dialects. We include in our vocabulary 11 languages other than Arabic (e.g., English, French, German, Russian), which also allows us to evaluate our models under zero-shot pre-training conditions involving these languages. **(2)** We propose a novel unified benchmark for **AR**abic natural language **GE**neration (**ARGEN**) composed of *seven* tasks: machine translation, code-switched text translation, summarization, news title generation, question generation, paraphrasing, and transliteration. ARGEN is collected from a total of 19 datasets, including 9 *new datasets* proposed in this work. **(3)** To show the utility of our new models, we evaluate them on ARGEN under both *full* and *zero-shot* pre-training conditions. Our models set new SOTA on the majority of datasets in *all* seven tasks. **(4)** Although the main focus of our work is language *generation*, we also show the effectiveness of our models on Arabic language *understanding* by fine-tuning our new models on a large, recently proposed Arabic language understanding benchmark. Again, our models establish new SOTA on the majority of language understanding tasks.

The rest of the paper is organized as follows: Section 2 describes our Arabic pre-tained models. In Section 3, we introduce ARGEN, our new natural language generation benchmark. We evaluate our models on ARGEN in Section 4. Section 5 is an analysis and discussion of our results. In Section 6, we provide an overview of related work. We conclude in Section 7. We now introduce our new pre-trained models.

2 Our Models

2.1 Pre-Training Data

MSA Data. We use 70GB of MSA text (7.1B tokens) from the following sources: AraNews (Nagoudi et al., 2020), El-Khair El-Khair (2016), Gigaword,[2], OSCAR (Suárez et al., 2019), OSIAN (Zeroual et al., 2019), Wikipedia Arabic, and Hindawi Books.[3]

Twitter Data. We randomly sample 1.5B Arabic tweets (178GB) from a large in-house dataset of $\sim$ 10B tweets. We use string matching to only include tweets with at least 3 Arabic words, regardless whether the tweet has non-Arabic string or not.

Our combined MSA and Twitter data make up 29B tokens, and hence is $\sim$ 49% less than Arabic tokens on which mT5 is pre-trained (57B Arabic tokens). More information about our pre-training data is in Table 1.

MSA Vs. Dialect Distribution. In order to analyze MSA-dialect distribution in our Twitter data, we run the binary (MSA-dialect) classifier introduced in Abdul-Mageed et al. (2020b) on a random sample of 100M tweets. We find the data to involve 28.39% predicted dialect tweets and 71.61% predicted MSA. We also acquire country-level dialect labels using an in-house strong classifier on the dialectal portion of the data (i.e., $\sim$ 28.39 millions tweets), finding dialectal tweets to be truly *geographically diverse* as shown in Figure 2.

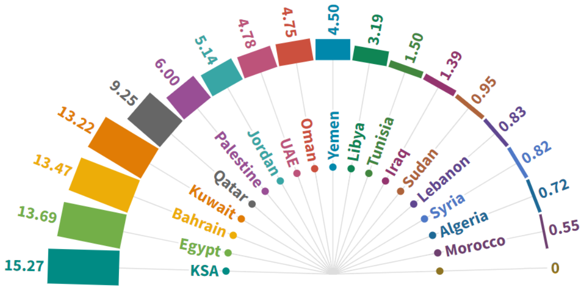

Figure 2: Country-level distribution in the dialectal portion of our data.

Naturally-Occurring Code-Switching. Using 1M random tweets from our data, we perform an analysis of code-switching. For this, we employ simple string matching to identify Arabic and run the CLD3 language ID tool[4] on the non-Arabic string sequences. We find the data to have 4.14% non-Arabic. These turn out to be almost always natural code-switching involving many foreign languages (e.g., English, French, Korean, etc.).

ALL	**248GB**	**29.0B**

Table 1: The MSA and Twitter resources used to pretrain AraT5$_{\text{MSA}}$, AraT5$_{\text{TW}}$, and AraT5.

2.2 Pre-Processing and Vocabulary

We remove diacritics and replace URLs and user mentions with `<URL>` and `<USER>`. We also clean the data by removing HTML tags, elongation, and the hash signs. Further, we reduce repetitive characters, emojis, and emoticons to one. To create our language model vocabulary, we use SentencePiece (Kudo, 2018) to encode text as WordPiece tokens (Sennrich et al., 2016) with 110K WordPieces. To allow for further pre-training (and/or fine-tuning) on additional languages, we extract our vocabulary as follows: 70M MSA sentences, 200M Arabic twitter data, 15M sentences from Wikipedia English, and 5M sentences from the Wikipedia of 10 other languages (Bulgarian, French, German, Greek, Italian, Portuguese, Russian, Spanish, Turkish, Czech).[5] In § 3.1.2, we describe parallel data from four of these languages on which we fine-tune our models for X→Arabic MT. Our respective results (reported in Table 4.2) demonstrate the utility of including foreign vocabulary in our models.

2.3 AraT5

Model Architecture. We leverage our unlabeled MSA and Twitter data described in § 2.1 to pre-train three models: **`AraT5`$_{\text{MSA}}$** on MSA data, **`AraT5`$_{\text{TW}}$** on twitter data, and **`AraT5`** on both MSA and twitter data using the T5$_{\text{Base}}$ encoder-decoder architecture (Raffel et al., 2019). Each of the encoder and decoder components is similar in size and configuration to BERT$_{\text{Base}}$ (Devlin et al., 2019), with 12 layers each with 12 attention heads, and 768 hidden units. In total, this results in a model with $\sim$ 220 million parameters.[6] **Objective.** Raffel et al. (2019) pre-train T5$_{\text{Base}}$ using a self-supervised (denoising) objective. The main idea is to feed the model with masked (corrupted) versions of the original sentence, and train it to reconstruct the original sequence. Inspired by BERT's objective (Devlin et al., 2019), the denoising objective (Raffel et al., 2019) works by randomly sampling and dropping out 15% of tokens in the input sequence. All consecutive spans of dropped-out tokens are then replaced by a single sentinel token. **Pre-Training.** For all three of our pre-trained models, we use a learning rate of 0.01, a batch size of 128 sequences, and a maximum sequence length of 512, except for AraT5$_{\text{TW}}$ where the maximum sequence is 128.[7] We pre-train each model for 1M steps. Pre-training of each model took $\sim$ **80 days** on one Google Cloud TPU with 8 cores (v3.8) from TensorFlow Research Cloud (TFRC).[8] We now introduce our language generation and understating benchmarks.

3 ARGEN

In order to evaluate our pre-trained language models, we introduce our new benchmark for Arabic language generation evaluation **ARGEN**. It includes *19 different datasets* with *59 test splits* and covers *seven* tasks: machine translation (MT), code-switched translation (CST), text summarization (TS), news title generation (NGT), question generation (QG), transliteration (TR), and paraphrasing (PPH). As such, ARGEN has wide-coverage both in terms of the number of tasks and datasets. It is also linguistically diverse as it covers both MSA and various Arabic dialects, in addition to *Arabizi* (romanized Arabic in the TS task) and code-switching (in the CST task). We now describe each component of ARGEN.

3.1 Machine Translation

To design the MT component of ARGEN, **ARGEN$_{\text{MT}}$**, we consolidate 7 unique datasets with 46 different test splits. The datasets come from both MSA and Arabic dialects, and range between 600-138K sentences (details in Table C.2 in Appendix). We introduce each dataset briefly here.

3.1.1 Arabic → English

(1) United Nations Parallel Corpus. Ziemski et al. (2016) introduce this parallel corpus of man-

---

[5] The MSA and twitter data are extracted from our training data presented in Section 2.1.

[6] The output dimensionality is $d_{ff} = 3,072$ and inner dimensionality of $d_{kv} = 64$.

[7] We choose the same maximum sequence used in MARBERT (Abdul-Mageed et al., 2021), the most powerful model trained on Arabic twitter to date (Farha and Magdy, 2021).

[8] https://www.tensorflow.org/tfrc.

ually translated UN documents covering the six official UN languages (i.e., Arabic, Chinese, English, French, Russian, and Spanish). The corpus consists of development and test sets only, each of which comprise $4,000$ sentences that are one-to-one alignments across all official languages.

(2) IWSLT Corpus. Several Arabic-to-English parallel datasets were released during IWSLT evaluation campaigns (Federico et al., 2012; Cettolo et al., 2013, 2014, 2016). The datasets are mainly extracted from transcriptions of TED talks between 2010 and 2016, and the QCRI Educational Domain Corpus (QED 2016) (Abdelali et al., 2014).

AraBench Datasets. Sajjad et al. (2020) introduce AraBench, an evaluation suite for MSA and dialectal Arabic to English MT consisting of *five* publicly available datasets: **(3) ADPT:** Arabic-Dialect/English Parallel Text (Zbib et al., 2012), **(4) MADAR:** Multi-Arabic Dialect Applications and Resources dataset (Bouamor et al., 2018), **(5) QAraC:** Qatari-English speech corpus (Elmahdy et al., 2014), and **(6) Bible:** The English Bible translated into MSA, Moroccan, and Tunisian Arabic dialects.[9] For all these datasets, we use the same splits as Sajjad et al. (2020) in our experiments.

3.1.2 X → Arabic

To investigate ability of our models to generate Arabic starting from foreign languages in our vocabulary, we create an X→Arabic benchmark of four languages (English, French, German, and Russian) by extracting parallel data from OPUS (Tiedemann, 2012). For each language, we pick 1M sentences for training and 5K sentences for each of development and test splits. This gives us our seventh **ARGEN$_{\text{MT}}$** dataset, which we call **(7) OPUS-X-Ara**.

3.2 Code-Switched Translation

There is rising interest in translating *code-switched* data (Nagoudi et al., 2021). Our purpose here is to translate Arabic text involving code-switching from a foreign language into **(i)** that foreign language as well as into **(ii)** MSA. Hence we create **ARGEN$_{\text{CST}}$**, our code-switched translation benchmark component, using *four* sub-test sets. Two of these are *natural* and two are *synthetic*, as follows:

Natural Code-Switched Data. We create two human written (natural) code-switched parallel datasets: **(1) ALG-CST.** This is collected from Algerian Twitter and consists of code-switched Arabic-French posts. We translate these manually into monolingual French. **(2) JOR-CST.** This is collected from Jordanian Twitter and consists of code-switched Arabic-English posts, which we manually translate into monolingual English. Each of ALG-CST and JOR-CST comprises 300 tweets (total=600). Human translation is performed by one native speaker from each dialect with semi-native English/French fluency.

Synthetic Code-Switched Data. We use the multilingual sequence-to-sequence model mBART (Liu et al., 2020) to create synthetic code-switched data following Jawahar et al. (2021). We exploit the UN multi-parallel data (Ziemski et al., 2016) using the Arabic-English and Arabic-French test splits ($4,000$ sentences each, described in § 3.1) to generate our two code-switched test sets **(3) MSA-EN** and **(4) MSA-FR**. In each case, we use mBART to translate $\sim 30\%$ random Arabic n-grams into the target language (i.e., English or French).

3.3 Text Summarization

To build our *text summarization* benchmark component, **ARGEN$_{\text{TS}}$**, we use the following:

Essex Arabic Summaries Corpus (EASC). EASC (El-Haj et al., 2010) contains 153 Arabic Wikipedia and newspaper articles, each with 5 human-generated extractive summaries (total=765 summaries). The summaries are crowdsourced via Mechanical Turk.[10]

WikiLingua. An abstractive summarization dataset in 18 languages, including Arabic (Faisal Ladhak and McKeown, 2020). It contains articles and their summaries from WikiHow.[11] The Arabic part includes summaries for 29.2K articles, which we split into 80% Train (23.4K), 10% Dev (2.9K), and 10% Test (2.9K).

3.4 News Title Generation

The purpose of the *news title generation (NTG)* task is to produce proper news article titles (Liang et al., 2020). We introduce NTG as a *new* task for Arabic language generation. Given an article, a title generation model needs to output a short grammatical sequence of words suited to the article content. For this, we introduce **ARGEN$_{\text{NTG}}$**, a novel NTG dataset exploiting 120K articles along

---

[9] The United Bible Societies https://www.bible.com.

[10] http://www.mturk.com/

[11] http://www.wikihow.com

with their titles extracted from AraNews (Nagoudi et al., 2020).[12] We only include titles with at least three words in this dataset. We split ARGEN$_{\text{NTG}}$ data into 80% Train (93.3K), 10% Dev (11.7K), and 10% Test (11.7K). Details about ARGEN$_{\text{NTG}}$ are in Table C.1 (Appendix). A sample of a news article from our Test split and example titles generated by our models are in Table D.5 (Appendix).

3.5 Question Generation

In the *question generation (QG)* task, a question is produced for a passage (Gehrmann et al., 2021). Given the absence of an Arabic QG dataset, we create a new Arabic QG dataset (**ARGEN$_{\text{QG}}$**) using a publicly available Arabic question answering (QA) resource. We follow Kriangchaivech and Wangperawong (2019) who train a model to generate simple questions relevant to passages and answers extracted from SQuAD (Rajpurkar et al., 2016). In our case, we build ARGEN$_{\text{QG}}$ by extracting 96K (passage, answer, and question) triplets from **(1)** The Arabic QA dataset ARCD (Mozannar et al., 2019), and **(2)** three multi-lingual QA datasets: XTREME benchmark (Hu et al., 2020), MLQA (Lewis et al., 2019), XQuAD (Artetxe et al., 2020), and TyDi QA (Artetxe et al., 2020).

3.6 Paraphrasing

The main goal of this task is to produce for a given Arabic sentence a *paraphrase* with the same meaning. In order to build our paraphrasing benchmark component (**ARGEN$_{\text{PPH}}$**), we use the following three datasets:

AraPara. We introduce AraPara, a new multi-domain Arabic paraphrasing dataset we create using English-Arabic parallel OPUS data (Tiedemann, 2012). AraPara covers several domains such as news, religion, politics, movies, and technology. To create a high quality machine generated paraphrase dataset, we follow four careful steps involving human validation (more details are offered in Appendix C.1). AraPara consists of 122K paraphrase pairs. We only use AraPara for model development, and hence we split it into 116K Train and 6K Dev.

Arabic SemEval Paraphrasing (ASEP). We also create a new Arabic paraphrasing dataset using three existing Arabic semantic similarity datasets released during SemEval 2017 (Cer et al., 2017). These are MSR-Paraphrase (510 pairs), MSR-Video (368 pairs), and SMTeuroparl (203 pairs). The pairs are labeled with a similarity score on a scale from 0 to 5. For our purpose, we only keep sentence pairs with a semantic similarity score ≥ 3.5 which gives us 603 pairs. We merge and shuffle all three ASEP datasets for our use.

Arabic Paraphrasing Benchmark (APB). APB is created by Alian et al. (2019). It consists of 1,010 Arabic sentence pairs that are collected from different Arabic books. Paraphrasing was performed manually using six transformation procedures (i.e., addition, deletion, expansion, permutation, reduction, and replacement).

3.7 Transliteration.

Transliteration involves mapping a text written with orthographic symbols in a given script into another (Beesley, 1998). We use the *BOLT Egyptian Arabic SMS/Chat and Transliteration dataset* (Song et al., 2014),[13] a collection of naturally-occurring chat and short messages (SMS) from Egyptian native speakers. The messages (sources) were natively written in either romanized Arabizi or Egyptian Arabic orthography. The target is the Egyptian transliteration of these message.[14] For experiments, we use the same split proposed by Shazal et al. (2020) (58.9K for Train and 5.4K for Dev and Test each). We refer to this dataset as **ARGEN$_{\text{TR}}$**.

4 Evaluation on ARGEN

Baselines and Procedure. For all tasks, we compare our models to models fine-tuned with mT5 using the same training data. In addition, for MT, we compare to a vanilla sequence-to-sequence (S2S) Transformer (Vaswani et al., 2017) trained from scratch as implemented in Fairseq (Ott et al., 2019). For all models and baselines, across all tasks, we identify the best model on the respective Dev data and blind-test it on Test data. As a rule, we report on both Dev and Test sets. All our Dev results are in Section C.2 in the Appendix.

4.1 Machine Translation.

We train two S2S Transformers models on 2M (S2S$_{\text{2M}}$) and 10M (S2S$_{\text{10M}}$) MSA-English parallel sentences extracted from OPUS. We take these

---

[12] We ensure no overlap exists between ARGEN$_{\text{TG}}$ and the AraNews data we use to pre-train our language models (described in § 2.3).

[13] https://catalog.ldc.upenn.edu/LDC2017T07

[14] Some transliteration sequences involve code mixing between Egyptian Arabic and English.

Table 2: English to Arabic results in BLEU using ARGEN_{MT} datasets. **Baseline I :** Sequence-to-Sequence Transformer models trained from scratch on 2M and 10M parallel sentences. **Baseline II :** mT5 (Xue et al., 2020). **Our models :** $\text{ArT5}_{\text{Tweet}}$, ArT5_{MSA}, ArT5. **SOTA :** † Sajjad et al. (2020) trained on ∼ 42M sentences, ‡ Durrani et al. (2017) trained on ∼ 59M sentences, †† Junczys-Dowmunt et al. (2016) trained on ∼ 12M sentences.

two models as our **baseline I**. We also fine-tune our three models as well as mT5 on the same OPUS 2M MSA-English parallel sentences used for baseline I. Fine-tuned mT5 is our second baseline **baseline II**.

Arabic → English. Results of ARGEN$_{\text{MT}}$ are reported in Table 2. Results show that our models achieve best BLEU score in 37 out of the 42 tests splits. AraT5$_{\text{MSA}}$ acquires best results in 32 of these test splits, outperforming all the baselines (S2S$_{\text{2M}}$), (S2S$_{\text{10M}}$), and mT5 with +5.25, +4.99, and +0.45 BLEU points. These results are striking since our language models are pre-trained on Arabic data only (although they include English vocabulary and marginal amounts of code-switching; see § 2.1). In other words, even under this arguably *zero-shot* setting,[15] the models perform very well. In addition, our AraT5 model outperforms even the S2S model trained with 5X more data. For completeness, we also provide the current SOTA on each of our datasets. We do not compare our results to SOTA since these are acquired by models fine-tuned on much larger datasets than ours. For example, Sajjad et al. (2020) exploit ∼ 42M parralel sentences to train their models. To limit GPU needs during our experiments, especially given the time-consuming fine-tuning process typical of T5 models, we do not fine-tune the models on the full amounts of available parallel data. However, in the future we plan to compare our models under the full data setting.

X → Arabic. Our language models are not pre-trained on foreign data, but we include vocabulary from 11 foreign languages. Our X → Arabic experiments here are hence zero-shot (from the perspective of pre-training). Table 4.2 shows the results of AraT5$_{\text{MSA}}$ and mT5 on OPUS-X-Ara.[16] We observe that our model outperforms mT5 in the four X → Arabic sub-tasks with an average of +1.12 and +0.86 BLEU points on Dev and Test, respectively.

4.2 Code-Switched Translation.

For this task, we test on the two natural code-switched translation (CST) test sets that we manually created, ALG-FR→FR and JOR-EN→EN. We also evaluate on our two synthetic CST datasets, MSA-EN and MSA-FR, one time with EN/FR as target (e.g., MSA-EN→EN) and another with MSA as target (e.g., MSA-EN→MSA). We fine-tune our three pre-trained models as well as mT5 on the OPUS-X-Ara segments involving English and French (each with 1M parallel sentences, described in § 3.1.2), in both directions. Since these MT models are only fine-tuned on parallel monolingual data, we refer to these experiments as *zero-shot*. We test these models on both our natural and synthetic code-switched data (described in § 3.2). We report results in Table 3. Our models achieve best results in one out of the two natural test sets (with +4.36 BLEU points on ALG-FR) and *all four* synthetic test sets (e.g., +4.55 BLEU points on MSA-EN→MSA). *These results clearly show our models' remarkable language generation ability especially in the Arabic direction.*

Dataset	Split	mT5	AraT5$_{\text{Tw}}$	AraT5$_{\text{MSA}}$	AraT5
Natural	ALG-FR → FR	23.83	**28.19**	26.27	26.17
	JOR-EN → EN	**23.06**	21.60	21.58	20.45
Synthetic	MSA-FR → FR	12.76	10.57	**13.78**	13.25
	MSA-EN → EN	11.06	8.99	**11.53**	11.42
	MSA-FR → MSA	12.93	12.14	**14.39**	13.92
	MSA-EN → MSA	19.82	18.43	23.89	**24.37**

Table 3: Performance of our models on **ARGEN$_{\text{CS}}$**.

4.3 Text Summarization

For the two ARGEN$_{\text{ST}}$ datasets, we fine-tune and identify the best model on the Train and Dev splits of WikiLingua (Faisal Ladhak and McKeown, 2020) and test on all EASC and the Test of WikiLingua. We report different ROUGE scores (Lin, 2004) in Table 5. As the Table shows, AraT5$_{\text{Tw}}$ acquires best results on WikiLingua data, while mT5 outperforms us on EASC (we hypothesize since EASC is older data that is likely part of the mC4 on which mT5 was pre-trained). *On both datasets, we establish new SOTA* (both with our pre-trained models and mT5).

4.4 News Title and Question Generation

For both tasks, we fine-tune all our models on the Train splits of ARGEN$_{\text{NTG}}$ and ARGEN$_{\text{QG}}$, respectively. As Table 6 shows, *all* our models outperform mT5 on each of the two tasks. AraT5$_{\text{MSA}}$ excels with 20.61% BLEU on ARGEN$_{\text{NTG}}$ and AraT5 is at 16.99% on ARGEN$_{\text{QG}}$.

4.5 Paraphrasing and Transliteration

For the *paraphrasing* task, we fine-tune and validate on our new AraPra dataset and blind-test on both APB and ASEP datasets (described in§ 3.6).

---

[15] At best, this can be viewed as *few-shot* pre-training.

[16] To limit GPU time, we fine-tune only AraT5$_{\text{MSA}}$ model on the X→Arabic direction since it performed best on Arabic→English section above.

Dataset	DEV		TEST	
	mT5	AraT5$_{\text{MSA}}$	mT5	AraT5$_{\text{MSA}}$
EN → AR	13.60	**15.72**	17.80	**18.58**
DE → AR	12.88	**13.74**	11.92	**12.80**
FR → AR	17.52	**17.96**	18.61	**18.99**
RU → AR	26.78	**27.87**	26.63	**28.01**
Average	17.70	**18.82**	18.74	**19.60**

Table 4: Performance of MT models on OPUS-X-Ara.

Dataset	Metric	mT5	AraT5$_{\text{Tw}}$	AraT5$_{\text{MSA}}$	AraT5
EASC	Rouge1	**62.98**	60.74	59.54	54.61
	Rouge2	**51.93**	48.89	47.37	43.58
	RougeL	**62.98**	60.73	59.55	54.55
WikiLin.	Rouge1	71.63	**74.61**	72.64	73.48
	Rouge2	63.60	**67.00**	64.21	65.09
	RougeL	71.56	**74.52**	72.57	73.37

Table 5: Performance of summarization models on Test. We consider mT5 as SOTA for WikiLin, and Alami et al. (2021) (ROUGE1=59.17) for EASC.

As Table 6 shows, AraT5$_{\text{MSA}}$ is best on APB (17.52 BLEU) and ASEP (19.38 BLEU). For *transliteration*, we fine-tune our models on the Train split of ARGEN$_{\text{TR}}$. As Table 6 shows, each of AraT5$_{\text{MSA}}$ and AraT5 outperform mT5. Notably, AraT5$_{\text{MSA}}$ is at 65.88 BLEU, outperforming previous SOTA (Shazal et al., 2020) by 7.1 points.

Dataset	mT5	AraT5$_{\text{Tw}}$	AraT5$_{\text{MSA}}$	AraT5
ARGEN$_{\text{NTG}}$	19.49	20.00	**20.61**	20.51
ARGEN$_{\text{QG}}$	15.29	12.06	14.18	**16.99**
ARGEN$_{\text{TR}}$	60.81	59.55	**65.88**	62.51
ARGEN$_{\text{PPH}}$ I	19.32	18.17	**19.38**	19.03
ARGEN$_{\text{PPH}}$ II	19.25	17.34	**19.43**	18.42

Table 6: Performance of our models on title, question generation, transliteration, and paraphrasing tasks in BLEU. **ARGEN$_{\text{PPH}}$ I and II**: results on ASEP and APB paraphrase datasets, respectively. We consider mT5 as SOTA for NTG, QG, and PPH **ARGEN$_{\text{NTG}}$**, **ARGEN$_{\text{QG}}$**, and **ARGEN$_{\text{PPH}}$**. For **ARGEN$_{\text{TR}}$**, SOTA is Shazal et al. (2020) (BLEU=65.88).

4.6 Evaluation on Arabic NLU

We also evaluate our new pre-trained models on the recently proposed Arabic language understanding and evaluation benchmark, ARLUE (Abdul-Mageed et al., 2021) that involves six cluster tasks (i.e., sentiment analysis, social meaning, topic classification, dialect identification, named entity recognition, and question answering). Our models establish new SOTA on the benchmark with an *ARLUE score of* 77.52 vs. the previous SOTA of 76.53, reported by ARLUE authors. We provide results of this set of experiments in Appendix B.

5 Analysis and Discussion

5.1 Multilingual vs. Dedicated Models.

Our results confirm the utility of dedicated language models as compared to multilingual models such as mT5 (101+ languages). Our AraT5 model outperforms mT5, even though it is pre-trained with 49% less data (see § 2.1). One reason might be that massively multilingual models are more prone to suffering from capacity issues. Data quality is another challenge for multilingual models. As pointed out earlier, Kreutzer et al. (2021) find systematic issues with data representing several languages (including Arabic) in the mC4 dataset on which mT5 is pre-trained. We perform a data quality study confirming the findings of Kreutzer et al. (2021). We also find Arabic mC4 data to be less geographically diverse than our Twitter pretraining data (described in § 2.1). Our mC4 data study is in Appendix A.

Code-Switching. We also study code-switching in both our Twitter dataset and the Arabic part of mC4. We find that while our Twitter data involves natural code-switching ($\sim$ 4% of sequences), code-switching in Arabic mC4 is very rare. This explains the strong performance of our AraT5$_{\text{Tw}}$ model on the natural code-switched translation data on French. We conjecture that mT5 good performance on English code-switched data is due to it being pre-trained on very large amounts of English rather than natural code-switching.

5.2 Effect of Sample Length on MT.

We were inquisitive how MT models fine-tuning our pre-trained language models compare to mT5 under different length conditions. For this, we **(1)** merge all MSA and dialectal Test datasets in our Arabic→English experiments to form a single dataset that we then **(2)** split into three bins/Test sets based on sentence length as shown in Table D.1. As the Table shows, our AraT5$_{\text{MSA}}$ outperform mT5 in *all* but one condition (where our model acquires marginally less performance). We also performed similar evaluation on the merged Dev sets of all MSA and dialectal Arabic MT datasets in the Arabic→English direction. We do not show related results here, but we note our AraT5$_{\text{MSA}}$ outperforms mT5 on *all* conditions.

(1) Source:	J'aime une vidéo Episode 1 - نسيبتي العزيزة 4 **:ALG-FR**
Target:	**FR :** J' aime une vidéo Episode 1 - ma chère belle-mère 4
mT5	J' aime une v- Chère nièce 4.
AraT5$_{\text{Tw}}$	J'aime une vidéo Episode 1 - ma chère tante 4.
AraT5$_{\text{MSA}}$	J'aime une vidéo 1 - Ma chère **sœur** 4.
AraT5	J'aime une vidéo 1 - Ma chère **bébé**
(2) Source:	بطلة العالم في ال comfort zone وهاد شيء بائس حقيقة **:JOR-EN**
Target:	**EN :** The world champion in the comfort zone and this is really miserable
mT5	the world world champion in comfort zone, and that's really a **bad** thing.
AraT5$_{\text{Tw}}$	the world **hero** in comfort zone and it's really a **miserable** thing.
AraT5$_{\text{MSA}}$	world champion in comfort zone, and that's really a **bad** thing.
AraT5	the world's the world's **hero** in the comfort zone, and it's a really **bad** thing.

Table 7: CS sentences with their English/French translations using our Models and mT5. Data samples are extracted from the Dev datasets. **Green** refers to good translation. **Red** refers to problematic translation.

5.3 Qualitative Analysis.

We also perform qualitative analyses of the outputs of several of our models, including as to length of MT source data (Appendix D). In particular, our analyses are for the following tasks: machine translation, code-switched translation, paraphrasing, transliteration, and news title generation. **MT Model.** Table D.2 (Appendix) shows three examples of Arabic→English MT models. Sentence (1) is in **MSA source**, sentence (2) is in Levantine Arabic source, and sentence (3) is in Egyptian source. In all three examples, one or more of our models generate(s) more fluent translations than mT5. This includes ability of our models to translate dialectal sentences where mT5 seems to struggle (e.g., mT5 is not able to translate the equivalents of "drive" from Egyptian Arabic).

Code-Switched Translation Model. Table 7 shows two code-switched examples from ARGEN$_{\text{CS}}$. Sentence (1) is Algerian dialect at source translated into French, while sentence (2) is Jordanian dialect translated into English. In both cases, our models not only handle the dialects but also their use in code-switched contexts better than mT5.

Paraphrasing, Transliteration, and Title Generation. Each of Tables D.3, D.4, and D.5 (Appendix D) shows two output samples from our paraphrasing, transliteration, and title generation models, respectively. In each case, the samples are high-quality, informative, and fluent. Our paraphrase samples also tightly capture the meaning of the source sentences.

6 Related Work

Multilingual LMs. ***mBERT*** is the multilingual version of BERT (Devlin et al., 2019), which is an encoder model with bidirectional representations from Transformers trained with a denoising objective. mBERT is trained on Wikipedia for 104 languages, including Arabic. ***XLM-R*** (Conneau et al., 2020) is also a Transformer-based multilingual masked language model pre-trained on more than 2TB of CommonCrawl (CC) data in 100 languages, including Arabic (2.9B tokens). XLM-R model uses the same masking objective as BERT, but not the next sentence prediction. ***mT5*** (Xue et al., 2020) is the multilingual version of **T**ext-**t**o-**T**ext **T**ransfer **T**ransformer model (T5) (Raffel et al., 2019). T5 is an encoder-decoder Transformer similar in configuration and size to a BERT$_{Base}$. It is trained on mC4, which is $\sim$ 26.76TB for 101 languages generated from 71 CC dumps.
Arabic LMs. ***AraBERT*** (Antoun et al., 2020) is an Arabic pre-trained language model based on the BERT$_{\text{Base}}$ architecture with 24GB of MSA data. ***ARBERT*** and ***MARBERT*** (Abdul-Mageed et al., 2021) are two BERT-based models, with the first focused on MSA (61GB) and the second on both MSA and dialects (128GB). MARBERT achieves SOTA on most Arabic NLU tasks. ***QARiB*** (Abdelali et al., 2021) is similarly a BERT-based model covering both MSA and dialects. ***CamelBERT*** (Inoue et al., 2021) is also a BERT-based model pretrained with MSA, dialectal, and classical Arabic.

7 Conclusion

We introduced three powerful Arabic-specific text-to-text Transformer models trained on large MSA and/or Arabic dialectal data. We also introduced ARGEN, a unified benchmark for Arabic Natural Language *generation* evaluation composed of *seven* tasks collected from a total of 19 datasets. Our models outperform mT5 on *all* ARGEN tasks (52 out of 59 test sets, i.e., 88.14%). This is true even for MT involving four foreign languages from which the models have seen marginal or no pretraining data (i.e., zero- and few-shot pre-training). Our models also set new SOTA on the large Arabic language *understanding* evaluation benchmark ARLUE. Our models involve vocabulary from 11 languages other than Arabic, and hence can easily be further pre-trained/fine-tuned in these languages. Our models are publicly available, and ARGEN datasets are accessible from our repository.

We thank Bashar Talafha for help with code-switching data preparation.

Ethics Statement

Energy efficiency. Our models, similar to many deep learning language models, take significant pre-training time and are not energy efficient. We acknowledge this important issue and believe work on creating energy efficient models should receive scholarly attention.

Data. Our pre-training datasets are collected from the public domain and cover diverse communities. As we have demonstrated, our resulting models are better equipped to power applications involving several varieties of Arabic as well as code-switched language use involving Arabic. From this perspective, we hope they add to ongoing efforts in the community to design models that are fairer and more representative.

ARGEN Benchmark Release. We design ARGEN using both existing datasets and new datasets that we create for this work. In our accompanying GitHub repository, we link to all existing publicly available components of the benchmark with standard splits from source as well as components that can be acquired from data organizations. In addition, we released all the new datasets we have developed. While we have prioritized standardizing evaluation on as many unified and consolidated datasets and tasks as possible, we also report performance on individual test sets so as to enable the community to replicate our work even on particular parts or tasks of ARGEN if they so wish.

AraT5 Models Release. All our pre-trained models are publicly available for non-malicious use. We acknowledge our models may still be misused in real world. However, we hope the models will be deployed in domains such as education, disaster management, health, recreation, travel, etc. in socially beneficial ways. These meaningful potential use cases are behind our decision to release the models.

Appendices

A A Study of Arabic mC4 Data Quality

Xue et al. (2020) train mT5 on the mC4 dataset. They report 57B Arabic tokens (almost double our token size) from 53M webpages, making 1.66% of all mT5 data. For our analysis, we randomly sample 1M paragraphs from the Arabic part of mC4. We use paragraphs rather than whole documents for a more fine-grained analysis that is more comparable to our own data (especially in the case of Twitter). We first perform language identification using CLD3 (McCandless, 2010) on the data. We find a sizable amount of the data (i.e., 13.59%) to be non-Arabic (mostly English or French). We manually inspect $\sim$ 100 random samples of the data predicted as non-Arabic. We find these are mostly either non-linguistic content (e.g., java-script or HTML code) or non-Arabic text. The non-Arabic text is sometimes foreign language advertising or even full translation of the Arabic text in some cases. In many cases, non-Arabic is also boilerplate text such as that in web fora. Also, no samples of the non-Arabic included real **code-switching**.

We also run an in-house MSA-dialect classifier on the same 1M data sample. The classifier predicts an overriding majority of the data (99.83%) as MSA. We again manually inspect $\sim$ 100 samples from the small fraction predicted as dialects (i.e., 0.17%). While we find some of these to be actual dialectal text (usually short belonging to either Egyptian or Saudi dialects) from web fora, in the majority of cases the text is simply names of soap operas or advertisements. Our own pre-training data in the case of Twitter, in comparison, involve much more dialectal content (28.39% as listed in § 2.1).

B Evaluation on Arabic NLU

B.1 ARLUE Benchmark

Recently, Abdul-Mageed et al. (2021) introduced ARLUE, a natural language understanding benchmark for Arabic. ARLUE is composed of 42 publicly available datasets, making it the largest and most diverse Arabic NLP benchmark. ARLUE is arranged into the six cluster tasks of sentiment analysis (SA), social meaning (SM), topic classification (TC), dialect identification (DI), named entity recognition (NER), and question answering (QA). We methodically evaluate each cluster task, ultimately reporting a single ARLUE score following Abdul-Mageed et al. (2021). Table B.1, shows a summary of the ARLUE benchmark. We briefly describe ARLUE tasks next.

ARLUE$_{\textbf{Senti}}$. To construct this task cluster Abdul-Mageed et al. (2021) merged 17 MSA and DA publicly available datasets.

ARLUE$_{\textbf{SM}}$. ARLUE$_{\text{SM}}$ refers to eight social meaning datasets covering prediction of age, dangerous speech, emotion, gender, hate speech, irony, offensive language, and sarcasm. used in this benchmark. We will follow Abdul-Mageed et al. (2021) in not merging the social meaning datasets, but rather report performance on each individual dataset as well as average performance across all tasks as part of an overall ARLUE score.

ARLUE$_{\textbf{Topic.}}$ This benchmark component is a concatenation [20] of three topic classification datasets: Arabic News Text (ANT) (Chouigui et al., 2017), Khaleej (Abbas et al., 2011), and OSAC (Saad and Ashour, 2010).

ARLUE$_{\textbf{Dia.}}$ Five datasets are used for dialect classification. These are AOC Zaidan and Callison-Burch (2014), ArSarcasm$_{\text{Dia}}$ (Farha and Magdy, 2020), MADAR (sub-task 2) (Bouamor et al., 2019), NADI-2020 (Abdul-Mageed et al., 2020a), and QADI (Abdelali et al., 2020).

ARLUE$_{\text{Dia}}$ involve three categories, namely, **ARLUE$_{\textbf{Dia-B}}$** for MSA-dialect classification (*binary*). **ARLUE$_{\textbf{Dia-R}}$**, and **ARLUE$_{\textbf{Dia-C}}$** for the region and country level classification into four classes (*region*), and 21 classes (*country*) respectively.

ARLUE$_{\textbf{QA}}$. Four Arabic and multilingual QA datasets are concatenated to build ARLUE$_{\text{QA}}$: ARCD (Mozannar et al., 2019) MLQA (Lewis et al., 2019), XQuAD (Artetxe et al., 2020), and TyDi QA (Artetxe et al., 2020).[21]

B.2 ARLUE Evaluation

Baselines. For comparison, we fine-tune a number of models on the same training data as our new models. These include the multilingual sequence-to-sequence model mT5 (Xue et al., 2020), and the powerful Arabic-specific BERT-based model MARBERT (Abdul-Mageed et al., 2021). We note

---

[20] We note that the classes were straightforwardly merged without modifying any class labels.

[21] All corresponding splits from the different QA datasets are merged.

that MARBERT achieves the SOTA [22] across the majority of 6 cluster tasks of ARLUE, with the highest ARLUE score.

Settings and Evaluation. We evaluate our models on the language understanding benchmark, ARLUE, under two settings: (i) single task learning and (ii) multi-task learning. We present results on all the task clusters included in ARLUE except for NER which is a token-level task that is not straightforward with the text-to-text set up we adopt. Table B.2 shows our evaluation results using the relevant metric for each task.

Abdul-Mageed et al. (2021) introduced **ARLUE score**, a metric used to score pre-trained language model performance on multiple datasets. ARLUE score is a simply macro-average of the different scores across all task clusters, where each task is weighted equally following (Wang et al., 2018). We compute the ARLUE score (i.e., overall macro-average) for each of our three models (i.e., AraT5$_{\text{MSA}}$, AraT5$_{\text{Tw}}$, and AraT5) and the baseline (mT5).

Dataset	**#Datasets**	**Task**	**TRAIN**	**DEV**	**TEST**

ARLUE$_{\text{Score}}$	76.53	75.05	75.33	77.50	**77.52**

Table B.2: Performance of our models on ARLUE TEST datasets (Acc / F$_1$). * Metric for ARLUE$_{\text{Senti}}$ is Acc/ F$_1$$^{\text{PN}}$. ‡ Metric for ARLUE$_{\text{QA}}$ is Exact Match (EM) / F$_1$.† ARLUE$_{\text{SM}}$ results is the average score across the social meaning tasks. **SOTA:** MARBERT (Abdul-Mageed et al., 2021).

Single Task. We fine-tune our three models and mT5 individually on each of the six tasks of ARLUE. We typically (i.e., in *all* our experiments) identify the best checkpoint for each model on the development set, and report its performance on both development and test data. As Table B.2 shows, our AraT5 model achieves the highest ARLUE score (77.52), followed by AraT5$_{\text{MSA}}$ (77.50) and AraT5$_{\text{TW}}$ (75.33). We note that all our models outperform mT5 and the MARBERT (SOTA) by $\sim +2.74$ and $\sim +1$ ARLUE score points, respectively.

ARLUE$_{\text{SM}}$	S	80.26 / 73.59	80.41 / 75.08	81.97 / **76.60**	81.09 / 75.99
	M	79.46 / 73.56	81.92 / 76.19	**82.08** / 73.75	81.14 / 75.95

Table B.4: Performance of our models on ARLUE social meaning (SM) Test datasets on single- and multi-tasks setting (Acc / F$_1$). **S**: Single Task. **M**:Multi-task.

Multitask. We also investigate multitask learning (Caruana, 1997; Ruder, 2017) with our AraT5 models. This approach consists of training the model on multiple tasks simultaneously (i.e., the model and its parameters are shared across all tasks) in order to eventually improve performance on each individual task. In our case, we fine-tune our models on many tasks at the same time using: (i) The three dialect datasets: ARLUE$_{\text{Dia-B}}$, ARLUE$_{\text{Dia-R}}$, and ARLUE$_{\text{Dia-C}}$ and (ii) the social meaning datasets

---

[22] MARBERT outperform both multilingual encoder-only Transformers mBERT, XLM-R$_{\text{Base}}$, XLM-R$_{\text{Large}}$, and Arabic-specific BERT-based AraBERT (Antoun et al., 2020), ARBERT (Abdul-Mageed et al., 2021).

of ARLUE$_{SM}$. Table B.3 and Table B.4 show the results of multi-task experiments for dialect settings and social meaning, respectively. Our results show that multi-task training outperforms single task models in the majority of the dialects experiments (n=7 out of 9 experiments, 77.78% of the tasks) and half of the social meaning tasks (n=18 out of 36 experiments, 50% of the tasks). These results are promising, and hence we plan to further investigate multi-task learning with our new models in the future.

C ARGEN

C.1 Arabic Paraphrase Data

AraPara. is a new multi-domain Arabic paraphrasing dataset we create using English-Arabic parallel OPUS data (Tiedemann, 2012). To ensure high-quality, we follow four careful steps: **(1)** We pick 1 million English-Arabic parallel sentences from OPUS (Tiedemann, 2012) covering the different domains. **(2)** We translate the English sentences using a high-quality in-house English→Arabic MT model. **(3)** We run the multi-lingual semantic similarity model from Yang et al. (2019) on the Arabic machine translated sentences and the human translation (i.e., original Arabic sentences from OPUS), keeping only sentences with an arbitrary semantic similarity score between 0.70 and 0.99. This allows us to filter out identical sentence pairs (i.e., similarity score = 1) and those that are not good translations (i.e., those with a semantic similarity score < 0.70). **(4)** In order to maximize syntactic and lexical diversity of the pairs of paraphrased sentences, we perform an analysis based on word overlap between the semantically similar pair sentences (i.e., the output of the previous step). We then perform a *manual* analysis of the data, identifying sentences with unigram token overlap between 35% and 70% as sufficiently distinct paraphrase pairs. This gives us 122K paraphrase pairs. We split these sentence pairs into 116K for training and 6K for validation.

C.2 Evaluation on DEV

In this section we describe the ARGEN$_{MT}$ datasets splits and report the evaluation results in validation datasets. Details about ARGEN$_{NTG}$ are in Table C.1 and ARGEN$_{MT}$ datasets splits are shown in Table C.2. Moreover, The evaluation on validation datasets for ARGEN$_{TS}$ are described in Table C.3 and C.4, respectively. Finally, Table C.5 shows the validation results of ARGEN$_{NTG}$, ARGEN$_{QG}$, ARGEN$_{TR}$, and ARGEN$_{PHP}$ datasets.

Split	Article/Title	Avg article len	Avg title len
TRAIN	93.3K	256.46	10.06
DEV	11.7K	253.11	10.03
TEST	11.7K	260.32	10.03
Total	116.6K	256.63	10.04

Table C.1: Main characteristics of ARGEN$_{NTG}$ data splits. For each split, we provide the number of article-title pairs and the average length of the articles and titles.

D Qualitative Analysis of Models

In this section, we explore ability of our models to generate MSA and dialectal Arabic under various conditions. We now overview various types of analyses in this regard. While samples presented here are handpicked, we note that they are mostly representative of outputs from our models since we mainly chose them to demonstrate different linguistic attributes that we believed would be relevant to the analysis.

Effect of Sample Length on MT. We were inquisitive how **MT models** fine-tuning our pre-trained language models compare to mT5 under **different length conditions**. For this, we **(1)** merge all MSA and dialectal Test datasets in our Arabic→English experiments to form a single dataset that we then **(2)** split into three bins/Test sets based on sentence length as shown in Table D.1. As the Table shows, our AraT5$_{MSA}$ outperform mT5 in *all* but one condition (where our model acquires marginally less performance). We also performed similar evaluation on the merged Dev sets of all MSA and dialectal Arabic MT datasets in the Arabic→English direction. We do not show related results here, but we note our AraT5$_{MSA}$ outperforms mT5 on *all* conditions.

MT Model Output. Table D.2 shows three examples of Arabic→English MT models. Sentence (1) is in **MSA source**, sentence (2) is in Levantine Arabic source, and sentence (3) is in Egyptian source. In all three examples, on or more of our models generate(s) more fluent translations than mT5. This includes ability of our models to translate dialectal sentences where mT5 seems to struggle (e.g., mT5 is not able to translate the equivalents of “drive" from Egyptian Arabic).

Code-Switched Translation Model Output. Table 7 shows two code-switched examples from **ARGEN$_{CS}$**. Sentence (1) is Algerian dialect at source translated into French, while sentence (2)

Abstract

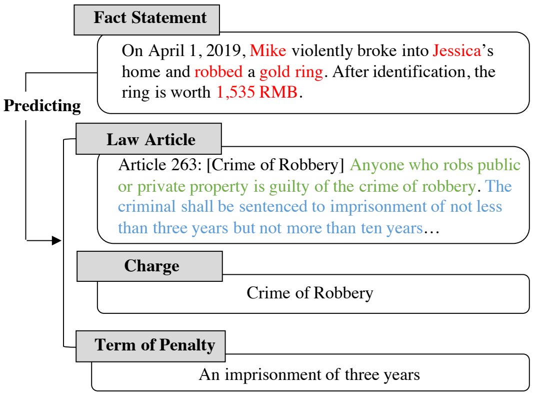
While significant progress has been made on the task of Legal Judgment Prediction (LJP) in recent years, the incorrect predictions made by SOTA LJP models can be attributed in part to their failure to (1) locate the key event information that determines the judgment, and (2) exploit the cross-task consistency constraints that exist among the subtasks of LJP. To address these weaknesses, we propose *EPM*, an Event-based Prediction Model with constraints, which surpasses existing SOTA models in performance on a standard LJP dataset.

1 Introduction

Legal Judgment Prediction (LJP) is a crucial task in the legal judgment decision making process. Given the facts of a legal case, the goal is to predict the court's outcome. So far, English LJP has focused on predicting law articles (Chalkidis et al., 2019a, 2021) and court decisions (Malik et al., 2021) while French LJP (Sulea et al., 2017b) has focused on predicting court rulings. In this paper, we examine LJP in the context of Chinese via the widely used CAIL dataset (Zhong et al., 2018; Xu et al., 2020), which involves three subtasks: predicting (1) law articles, (2) charges and (3) terms of penalty, as shown in Figure 1.

While state-of-the-art (SOTA) LJP models have several fundamental limitations (Binns, 2019), one of the technical issues they face concerns their failure to locate the key event information that determines the judgment results. Consider Figure 2, where the fact statement of a robbery case involves the illegal break-in description. Existing models wrongly predict that the law article is about illegal search since many words describe the break-in process even though the main point is about robbery.

How can we address this problem? Recall that in the continental judicial system, a law article consists of two parts: (1) the event pattern, which stipulates the behavior that violates the law, and (2) the judgment, which describes the corresponding penalties. In the law article related to Robbery in Figure 1, the event pattern is *Anyone robs public or private property* and the judgment is *be sentenced to imprisonment of not less than three years and not more than ten years*. The event pattern and the corresponding judgment defined by each law article can be viewed as a causal pair: if an event pattern is detected, the corresponding judgment can be inferred from the causal pair. In other words, it is the event information described in the case facts on which the reasoning judgment for the case is based. If we use the fine-grained key event information extracted from the facts to match the event pattern defined in the law articles, the law articles that are applicable to the case could be retrieved accurately and the penalty could be inferred with the judgment in the law article. For example, if we could compress the fact statement in Figure 1 into the fine-grained event in Table 1, we could easily match it with the event pattern defined in Article 263 (see Figure 1). Then the penalty defined in this article can be used as the predicted judgment.



On April 1, 2019, Mike violently broke into Jessica's home and robbed a gold ring. After identification, the ring is worth 1,535 RMB.

Article 263: [Crime of Robbery] Anyone who robs public or private property is guilty of the crime of robbery. The criminal shall be sentenced to imprisonment of not less than three years but not more than ten years…

Crime of Robbery

An imprisonment of three years

Figure 1: An illustration of legal judgment prediction. The green and blue texts of the law article describe the event pattern and the judicial consequence respectively. The red words are fine-grained event information.

Inspired by this observation, we seek to leverage event information for improving LJP, specifically

What were robbed?	gold ring	Property
What is the price of swag?	1,535 RMB	Quantity
Judgment Results: Article 263, Robbery, three-year imprisonment		

Table 1: An example of the judging process of a real case based on event information.

by (1) extracting the fine-grained key event of the case and then (2) predict the judgment based on the extracted event information (instead of the whole fact statement). To this end, we propose a hierarchical event definition referring to the hierarchy of law articles. Since there is no public LJP dataset that is annotated with event information, we manually annotate a legal event dataset on the top of CAIL (a public LJP dataset widely used by SOTA methods) (Xiao et al., 2018). Nevertheless, event extraction is challenging. So, to guide the learning process, we design output constraints on event extraction (e.g., what role types are compulsory for a given trigger type) and employ them in our model.

Another weakness associated with SOTA methods concerns their failure to exploit the *consistency* constraints among the three LJP subtasks. Specifically, each law article imposes constraints on what charge and term penalty are possible. However, SOTA methods typically frame LJP as a multi-task learning problem in which the three tasks are jointly learned in a model via a shared representation, without guaranteeing that the aforementioned cross-task constraints are satisfied. To address this problem, we introduce consistency constraints.

In sum, our contributions are three-fold. First, we present the first study on leveraging event extraction from case facts to solve LJP tasks. Second, we define a hierarchical event structure for legal cases and collect a new LJP dataset with event annotations. Finally, we propose a model that learns LJP and event extraction jointly subject to two kinds of constraints. Experiments show that our model surpasses the existing SOTA models in performance.

2 Related Work

Legal judgment prediction. LJP has been investigated in the context of different jurisdictions, such as China (Luo et al., 2017; Zhong et al., 2018; Yue et al., 2021; Feng et al., 2021), the U.S. (Katz et al., 2017), Europe (Chalkidis et al., 2019a, 2021), French (Sulea et al., 2017b,a), India (Malik et al., 2021; Paul et al., 2020). While early works relied on rule-based approaches (Kort, 1957; Segal, 1984; Nagel, 1963), later approaches use classification techniques (Aletras et al., 2016; Liu et al., 2015; Sulea et al., 2017a,b; Katz et al., 2017). More recently, neural models are learned to predict judgment results jointly by sharing parameters in a unified framework (Zhong et al., 2018; Xu et al., 2020; Dong and Niu, 2021; Yang et al., 2019; Feng et al., 2019), applying pre-trained language models (Chalkidis et al., 2020, 2021; Xiao et al., 2021; Niklaus et al., 2021; Zhong et al., 2019), exploiting label-attention mechanisms (Wang et al., 2018, 2019), or injecting legal knowledge (Hu et al., 2018; Gan et al., 2021; Zhong et al., 2020). Unlike our work, these works do not explore the use of case events for LJP. Though existing works exploit dependency between subtasks (Zhong et al., 2018; Yang et al., 2019), they merely utilize the subtasks' prediction results as auxiliary features to influence each other and therefore may still predict inconsistent results. In contrast, our cross-task consistency constraints can guarantee that the predictions are consistent.

Event extraction in legal domain. Some works have defined legal events and built models to automatically extract legal events from fact statements using these definitions (Shen et al., 2020; Li et al., 2019; Chen et al., 2020). However, we cannot use these event-annotated legal datasets for two reasons. First, the legal documents in these datasets do not contain legal judgment predictions, so we cannot use them to jointly extract events and make legal judgment predictions. Second, there is a key difference between our work and previous work in terms of how legal events (i.e., the trigger types and argument roles) are defined: while existing works define legal events solely from the perspective of event extraction, we define legal events so that the trigger types and argument roles are useful for LJP.

Dataset	CAIL-small	CAIL-big
#Training Set Cases	96,540	1,489,932

#Testing Set Cases	24,848	185,647
#Law Articles	101	127
#Charges	117	140
#Term of Penalty	11	11

Table 2: Statistics on CAIL.

3 Dataset and Task Definition

Dataset. We employ as our dataset CAIL (Xiao et al., 2018), a large-scale publicly available Chinese legal document dataset that has been widely used. In CAIL, each judgment document consists of a fact statement and judgment results (law articles, charges and term of penalty). We follow prior works (Xu et al., 2020; Yang et al., 2019) for preprocessing CAIL (see Appendix H). CAIL is composed of two subdatasets: CAIL-big and CAIL-small, and their statistics are shown in Table 2. LJP on CAIL is by no means trivial: there are 127, 140 and 11 categories for article, charge and penalty respectively on CAIL-big.

Task definition. Given a fact statement, LJP on CAIL involves three prediction subtasks $t_a, t_c, t_p \in \mathcal{T}$, which correspond to law article, charge and term of penalty respectively. Following previous works (Xu et al., 2020; Yang et al., 2019), we formalize each subtask $t \in \mathcal{T}$ as a multi-class classification problem and predict for each t the corresponding result $y^t \in \mathcal{Y}^t$, where $\mathcal{Y}^t$ is the label set of t.

4 Baseline LJP Model

We begin by designing a multi-task legal judgment prediction model, which we will use as a baseline and augment with event extraction and constraints in subsequent sections. The framework of our model is shown in Figure 3.

Token representation layer. Given a fact statement represented as a character sequence $D = \{x_1, x_2, ...x_{l_f}\}$, we first encode each character by passing them into a pretrained legal BERT encoder (Zhong et al., 2019).

$$\mathbf{h}_1, \mathbf{h}_2, ...\mathbf{h}_{l_f} = \text{Legal-BERT}(x_1, x_2, ...x_{l_f}) \quad (1)$$

where $\mathbf{H}_f = \{\mathbf{h}_1, \mathbf{h}_2, ...\mathbf{h}_{l_f}\}$ is the hidden vector sequence of the fact statement and l_f is the length of the fact statement.

Generating context features. Next, we generate the context representation of the fact statement by applying a max-pooling layer to $\mathbf{H}_f$:

$$\bar{\mathbf{h}} = maxpooling(\mathbf{h}_1, \mathbf{h}_2, ...\mathbf{h}_{l_f}) \quad (2)$$

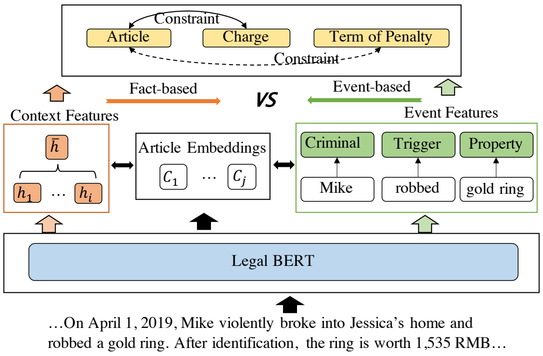

Figure 3: Model architecture. Note that the green box, which computes event features, and the "Constraint"s in the uppermost box are not part of the baseline.

Incorporating law article semantics. Using the aforementioned context representation to predict judgment essentially treats each law article as an atomic label, leaving its semantic information unexploited. Inspired by previous work (Chalkidis et al., 2019b; Rios and Kavuluru, 2018), we employ an attention mechanism to incorporate article semantics into the model. Specifically, we match $\bar{\mathbf{h}}$ with all candidate law articles. To do so, we first use the same encoder to encode the character sequence of each law article and obtain the hidden vector sequence $\mathbf{H}_a = \{\mathbf{h}_1, \mathbf{h}_2, ...\mathbf{h}_{l_a}\}$, where l_a is the length of a law article text. Then we apply a max-pooling layer to $\mathbf{H}_a$ to get the context representation $\mathbf{c}$. Next, we use the context representation of the fact statement, $\bar{\mathbf{h}}$, to query all candidate articles in order to mine the most relevant semantics in the article texts. Specifically, we first obtain the relevance scores between $\bar{\mathbf{h}}$ and the j-th article $\mathbf{c}_j$:

$$\alpha_j = \bar{\mathbf{h}}^T \mathbf{W}_c \mathbf{c}_j \quad (3)$$

where $\mathbf{W}_c$ is a trainable matrix. Then the most relevant semantics are summed in a weighted fashion to represent the features from the article texts:

$$\bar{\mathbf{c}} = \sum \frac{exp(\alpha_j)}{\sum_{k=1} exp(\alpha_k)} \mathbf{c}_j \quad (4)$$

where $\bar{\mathbf{c}}$ contains the integrated article semantics.

Legal judgment prediction layer. To predict legal judgment, we input $\bar{\mathbf{h}}$ and $\bar{\mathbf{c}}$ into three task-specific classifiers as follows:

$$\hat{\mathbf{y}}^t = softmax(\mathbf{W}_t[\bar{\mathbf{h}}; \bar{\mathbf{c}}] + \mathbf{b}_t) \quad (5)$$

where $\mathbf{W}_t$ and $\mathbf{b}_t$ are the learnable parameters and $\hat{\mathbf{y}}^t$ is the prediction distribution of task t.

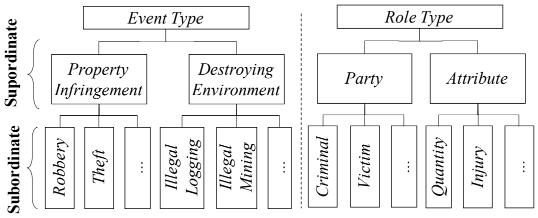

Figure 4: Examples of hierarchical events and roles.

Training. For each legal judgment prediction task t, we employ cross-entropy as the loss function to measure the distance between the predicted $\hat{\mathbf{y}}^t$ and the ground-truth $\mathbf{y}^t$.

$$\mathcal{L}_t = -\sum \mathbf{y}^t log \hat{\mathbf{y}}^t \tag{6}$$

The final loss is composed of the losses of three subtasks, and is defined as follows:

$$\mathcal{L}(\Theta) = \lambda_{t_a}\mathcal{L}_{t_a} + \lambda_{t_c}\mathcal{L}_{t_c} + \lambda_{t_p}\mathcal{L}_{t_p} \tag{7}$$

where hyperparameters λ determine the trade-off between all subtask losses. The model is trained to minimize $\mathcal{L}(\Theta)$.

5 Improving LJP via Event Extraction

In this section, we propose a novel method to leverage event extraction to improve LJP.

5.1 Hierarchical Legal Event Definition

Event definition. Each law article stipulates what event violates this article, so it is easy to define legal events based on law articles. The Chinese law articles have been organized in a hierarchical manner. For example, robbery-related and theft-related articles belong to *Property Infringement*, which is the general name of robbery-related and theft-related articles. We define legal events following this hierarchy. As shown in Figure 4, *Property Infringement* is treated as a superordinate event type, whereas *Robbery* and *Theft* are treated as subordinate event types. This hierarchy can express the connections between different legal events.

Trigger and role definitions. An event trigger is a word that realizes the occurrence of an event and has a type. There is a one-to-one correspondence between event type and trigger type. For example, the *Robbery* event has the trigger type *Trigger-Rob*.

Next, we define the roles for each event such that they reflect the key elements of the event that would be useful for making legal judgments. For example, the *Criminal* and *Victim* roles specify the parties involved in a case, whereas the *Quantity* role measures the value of loot, based on which term penalty is derived. We define the roles in a hierarchical manner. As seen in Figure 4, the *Party* arguments are the people involved in the cases, and its subordinate roles include *Criminal* and *Victim*.[1]

5.2 Dataset Collection

To investigate the use of event extraction for LJP, we manually create an event-annotated LJP dataset since no such dataset is publicly available.

Step 1: judgment document collection. We construct LJP-E, our event-annotated dataset, based on CAIL. Specifically, we first analyze the performance of the SOTA models (Xu et al., 2020; Zhong et al., 2018) on the validation portion of CAIL-small and identify the 15 law articles for which they achieved poor performance, and then select a subset of the cases that can be judged by these 15 law articles for annotation. This subset consists of 1367 documents (957 as training set, 136 as validation set and 274 as test set). We henceforth refer to this set of judgment documents as D_o.

Step 2: event trigger and argument role annotation. Next, we hire two annotators to manually produce event triggers and argument roles for each case in D_o after giving them a three-hour tutorial on how to annotate events. The annotators are native speakers of Chinese who are graduate students in NLP with significant experience with working on legal problems (none of them are the authors).

The annotation process. Given the fact statement and the gold law article of a case, each annotator is asked to independently highlight the salient words in the fact statement that reflect the core event of the case and correlate well with the event pattern of the law article. Then each of them is asked to (1) select a trigger word and assign it a subordinate trigger type, and (2) assign a subordinate role type to each of its arguments from a predefined role list. The trigger type and role type inventories were designed by the authors after having read a large number of fact statements and corresponding articles. Inter-annotator agreement numbers can be found in Appendix E.

After the above steps, each case in D_o is annotated with a trigger, its type, its arguments and roles. The average number of arguments per event is 4.13.

---

[1] Details of the event and role definitions together with their explanations can be found in Appendix A and B.

There are 16 distinct subordinate roles and 15 distinct subordinate trigger types.[2] Each disagreement between the annotators is resolved via discussion.

5.3 Hierarchical Event Extraction

To make use of the event annotations, we augment our baseline model with a hierarchical event extraction layer that detects event triggers and arguments and determines trigger types and arguments roles (see Figure 3). The resulting model simultaneously learns event extraction and LJP.

We formalize event extraction as a token labeling problem. Given the hidden vectors of the fact tokens $\mathbf{H}_{l_f} = \{\mathbf{h}_1, \mathbf{h}_2, ...\mathbf{h}_{l_f}\}$, we assign each token a subordinate trigger (if it is part of a trigger) or a subordinate role type (if it is part of an argument).

The hierarchical event extraction layer consists of two modules: (1) a *superordinate* module that attends each hidden vector to all superordinate types/roles for obtaining their correlations, and (2) a *subordinate* module that computes the subordinate type/role probability distribution based on hierarchical information, as described below.

For a specific superordinate type/role j, we represent its semantic features with a trainable vector $\mathbf{p}_j$. We adopt a fully-connected layer to calculate the correlation score between hidden vector $\mathbf{h}_i$ and superordinate type/role $\mathbf{p}_j$.

$$u_{ij} = \mathbf{W}_p[\mathbf{h}_i; \mathbf{p}_j] \tag{8}$$

where u_{ij} represents the correlation score and $[;]$ denotes the concatenation of two vectors. Then, we apply a softmax operation to get the superordinate type/role feature for each token x_i.

$$\beta_{ij} = \frac{exp(u_{ij})}{\sum_{k=1} exp(u_{ik})} \tag{9}$$

$$\mathbf{o}_i = \sum_{j=1} \beta_{ij}\mathbf{p}_j \tag{10}$$

where $\mathbf{o}_i$ is the integrated superordinate type/role feature, which provides superordinate-oriented information useful for predicting subordinate types/ roles. Next, we concatenate each $\mathbf{h}_i$ with $\mathbf{o}_i$ as the input feature for the trigger type and argument role classifier and estimate the probability that token x_i belongs to subordinate type/role r_j as follows:

$$s_r(x_i, \hat{y}^{r_j}_{(i)}) = \frac{exp(\mathbf{q}_j^T[\mathbf{h}_i; \mathbf{o}_i])}{\sum_{k=1} exp(\mathbf{q}_k^T[\mathbf{h}_i; \mathbf{o}_i]]} \tag{11}$$

where $\mathbf{q}_j$ is the trainable vector of r_j. After obtaining the type/role probability distribution of x_i, we apply a CRF (Lafferty et al., 2001) to produce the sequence of types/roles with the highest score, where the score of a sequence of types/roles $\hat{\mathbf{y}}^r = \{\hat{y}^r_{(1)}, \hat{y}^r_{(2)}...\}$ is computed as:

$$score(D, \hat{\mathbf{y}}^r) = \sum_{i=1}^{l_f} \mathbf{T}_{\hat{y}^r_{(i-1)}, \hat{y}^r_{(i)}} + \sum_{i=1}^{l_f} s_r(x_i, \hat{y}^r_{(i)}) \tag{12}$$

Here, $\mathbf{T}$ is the score of transitioning from one tag to another tag.

Instead of predicting LJP based on the context fact representation $\bar{\mathbf{h}}$, we replace it with the detected event features. Specifically, we input the extracted trigger word and arguments with their type/role embeddings into the three task-specific classifiers. Denote an extracted span as $\mathbf{H}_s = \{\mathbf{h}_1, \mathbf{h}_2, ...\mathbf{h}_{l_s}\}$. We apply a max-pooling layer to each span and concatenate with the corresponding subordinate type/role embedding $\mathbf{q}$:

$$\mathbf{g}_i = [maxpooling(\mathbf{H}_s); \mathbf{q}] \tag{13}$$

where $\mathbf{g}_i$ denotes the representation of span i, which contains both semantics and subordinate type/role features. Based on $\mathbf{g}_i$, we can calculate the context span representation $\bar{\mathbf{g}}$ as follows:

$$\bar{\mathbf{g}} = maxpooling(\mathbf{g}_1, \mathbf{g}_2...) \tag{14}$$

which is used to replace the context fact representation $\bar{\mathbf{h}}$ in Equation 2.

Training. The event extraction loss is defined as:

$$\mathcal{L}_r = -\sum log \frac{e^{score(D,\mathbf{y}^r)}}{\sum e^{score(D,\hat{\mathbf{y}}^r)}} \tag{15}$$

where $\mathbf{y}^r$ is the gold tag sequence. We incorporate $\mathcal{L}_r$ into he total loss in Equation 7 as follows:

$$\mathcal{L}(\Theta) = \lambda_{t_a}\mathcal{L}_{t_a} + \lambda_{t_c}\mathcal{L}_{t_c} + \lambda_{t_p}\mathcal{L}_{t_p} + \lambda_r\mathcal{L}_r \tag{16}$$

6 Exploiting Constraints

To improve model performance, we explore two types of constraints, as described below.

6.1 Event-Based Constraints

Event-based constraints are output constraints on events. We propose two such constraints.

---

[2] Statistics of LJP-E can be found in Appendix D.

Absolute constraint. For a legal event, the trigger must appear exactly once and certain roles are compulsory (e.g., subordinate role *Criminal* should appear at least once). If the trigger is missing, we impose the following penalty:

$$\begin{aligned}\mathcal{P}_t = \sum_{\tilde{r}\in\mathcal{TG}} \sum_{i=1}^{l_f} s_r(x_i, \hat{y}^{\tilde{r}}_{(i)}) - \max_{i,\tilde{r}\in\mathcal{TG}}[s_r(x_i, \hat{y}^{\tilde{r}}_{(i)})] \\ + |1 - \max_{i,\tilde{r}\in\mathcal{TG}}[s_r(x_i, \hat{y}^{\tilde{r}}_{(i)})]|\end{aligned} \tag{17}$$

where $\mathcal{TG}$ is the trigger inventory.[3] If a required role r is missing, we impose the following penalty:

$$\mathcal{P}_r = |1 - \max_i [s_r(x_i, \hat{y}^{r}_{(i)})]| \tag{18}$$

Event-Based consistency constraint. If a trigger type is detected, all and only its related roles should be detected. For example, if a *Illegal Doctoring* event is detected, no roles related to *Illegal Logging* should be predicted. If a trigger r is predicted, we impose the following penalty:

$$\begin{aligned}\mathcal{P}_e = \sum_{\tilde{r}\in\mathcal{R}^+} |1 - \max_i [s_r(x_i, \hat{y}^{\tilde{r}}_{(i)})]| \\ + \sum_{\tilde{r}\in\mathcal{R}^-} \sum_{i=1}^{l_f} s_r(x_i, \hat{y}^{\tilde{r}}_{(i)})\end{aligned} \tag{19}$$

where $\mathcal{R}^+$ is the set of roles that should occur if r is predicted, and $\mathcal{R}^-$ is the set of roles that cannot occur. We sum all the penalty terms and incorporate them into the total loss as follows:

$$\begin{aligned}\mathcal{L}(\Theta) = \lambda_{t_a}\mathcal{L}_{t_a} + \lambda_{t_c}\mathcal{L}_{t_c} + \lambda_{t_p}\mathcal{L}_{t_p} \\ + \lambda_r\mathcal{L}_r + \lambda_p \sum \mathcal{P}_i\end{aligned} \tag{20}$$

6.2 Cross-Task Consistency Constraints

While the multi-task learning setup employed by our model allows subtasks of LJP to benefit each other via the shared representation layer, it fails to exploit the dependency explicitly that exist among them. Below we exploit two such dependencies, one between law article and charge and the other between law article and term of penalty.

Each law article states the allowable charges and range of term of penalty. Hence, we can utilize these dependencies to constrain (and hopefully improve) the prediction of charge and term of penalty using the predicted law article. More specifically, we make the model learn how to predict charge and term of penalty based on the predicted article during training by modifying the cross entropy loss as follows. If the law article is predicted correctly by the model, then when calculating $\mathcal{L}_{t_c}$ (i.e., the cross-entropy loss associated with the charge prediction task), we mask each term in the loss corresponding to a charge that is not allowed according to the predicted article:

$$\mathcal{L}_{t_c} = -\sum\sum mask * y^{t_c} log \hat{y}^{t_c} \tag{21}$$

where $mask$ is equal to 0 if the charge is not allowed according to the predicted article and 1 otherwise. However, if the article is predicted incorrectly by the model, $\mathcal{L}_{t_c}$ is the standard cross entropy loss. Intuitively, through masking, the model is forced to predict a charge that is allowed according to the predicted article. During testing, since we do not know whether the law article is predicted correctly or not, we always mask the charge probability distribution according to the predicted article. We adopt the same strategy to compute $\mathcal{L}_{t_p}$ when enforcing the consistency constraint between law article prediction and term of penalty prediction.

7 Evaluation

7.1 Experimental Setup

We train our model *EPM* using the pre-training and fine-tuning strategy. Specifically, we pre-train *EPM* without event components on the training portion of CAIL (Table 2), and then fine-tune *EPM* on the training portion of LJP-E, our event-annotated LJP dataset, to learn from the event annotations.

As for the encoder, the maximum fact length is set to 512. For training, we utilize the Adam optimizer with learning rate of 10^{-4} and the batch size is 32. The warmup step is 3000. For the hyperparameters, λ, in the loss function, the best setting is {0.5, 0.5, 0.4, 0.2, 0.1} for $\{\lambda_{t_a}, \lambda_{t_c}, \lambda_{t_p}, \lambda_r, \lambda_p\}$. Models are trained for a maximum of 20 epochs. [4] LJP results are reported in terms of Accuracy (Acc), Macro-Precision (MP), Macro-Recall (MR) and Macro-F1 (F1).

7.2 Comparison with the SOTA

We compare *EPM* with SOTA models on the test portion of our annotated dataset LJP-E in Table 3. and the official test portion of the CAIL dataset in

---

Table 5: Comparisons with the SOTA models on CAIL-small.

Table 4 and 5. Since LJP-E only contains the 15 case types of CAIL, when applying *EPM* on the CAIL test set we use the pretrained version of *EPM* (i.e., without fine-tuning) to predict samples that do not belong to the 15 types and use the fine-tuned version of *EPM* to predict samples that belong to one of the 15 types. In order to determine whether a sample belongs to one of the 15 types, we train a binary classifier using legal BERT on the training set of CAIL. We refer to this model as the *Switch*.[5]

We compare *EPM* with four SOTA neural models: (1) **MLAC** (Luo et al., 2017), which jointly modeled charge prediction and the relevant article extraction task in a unified framework. Here, we add a fully-connected layer in order to predict the term of penalty; (2) **TOPJUDGE** (Zhong et al., 2018), which formalized the subtasks of LJP in a joint framework as a directed acyclic graph in which the subtasks share parameters; (3) **MPBFN** (Yang et al., 2019), which proposed a multi-perspective forward and backward prediction framework to make the sharing of parameters by different subtasks effectively, as well as a number embedding method for term of penalty prediction; (4) **LADAN** (Xu et al., 2020), which developed a

---

[5] Details of the Switch can be found in Appendix J.

graph networks to learn the subtle differences between law articles in order to extract compelling discriminative features from fact statements; and (5) **NeurJudge** (Yue et al., 2021), which utilized the results of intermediate subtasks to separate the fact statement into different circumstances and exploits them to make the predictions of other subtasks.

As shown in Tables 3, 4 and 5, *EPM* (row 6) achieves the best results, substantially outperforming not only MLAC but also TOPJUDGE, MPBFN, LADAN and NeurJudge, which *further leverage extensions like number embedding and graph networks*, particularly on law article prediction.

Next, we conduct two *oracle* experiments involving *EPM*. First, we use *gold* rather than *predicted* event annotations to make predictions for the three subtasks.[6] The results, which are show in row 7 of Table 3, show that considerably better results can be obtained when gold event annotations are used. These results suggest that existing LJP results can be substantially improved by improving event extraction. Next, we assume that the *Switch* is perfect when obtaining the *EPM* results on CAIL. Perhaps not surprisingly, results, which are shown in row 7 of Table 4 and 5, are better w.r.t. all subtasks.

Further, we apply *EPM* to *MLAC*, *TOPJUDGE*, *MPBFN*, *LADAN* and *NeurJudge* on CAIL, the five SOTA models following the same scheme (i.e., use fine-tuned *EPM* to classify when the *Switch* says the sample belongs to the 15 types and use the SOTA model to classify otherwise), showing the results in rows 8 to 12 in Table 4 and 5. We see that *EPM* can also improve the performance of the four SOTA models, yielding new SOTA results.

Finally, we examine whether *modifying* a SOTA model, *TOPJUDGE*, by having it jointly perform event extraction and the LJP tasks can improve its performance. To do so, we replace its CNN encoder by an LSTM and feed the LJP classifiers with the extracted events rather than the case facts in the same way as in *EPM*. We can see that *TOPJUDGE+Event* outperforms *TOPJUDGE*, which shows the usefulness of event information. However, *TOPJUDGE+Event* underperforms *TOPJUDGE+EPM*. This suggests that better LJP results can be achieved by treating *TOPJUDGE* as a black box (by exploiting event information using the *Switch*) rather than a glass box (by modifying the model to learn from event annotations).

7.3 Usefulness of Events and Constraints

We conduct experiments on the ablated versions of *EPM*. Ablation results on *LJP-E* and *CAIL* are shown in Tables 6 and 7, 8.

Event extraction. To test the usefulness of event extraction, we delete all event components from *EPM*. Results are shown in row 2. As we can see, performance degrades substantially on all three subtasks in terms of both Acc and F1.

Event-based constraints. Next, we evaluate the usefulness of the two event-based constraints (Section 6.1) on the outputs of event extraction. Removing the absolute constraint (*w/o CSTR1*, row 3) or the event-based consistency constraint (*w/o CSTR2*, row 4) generally yields worse results in terms of both Acc and F1. In particular, removing the consistency constraint generally provides bigger deterioration than the absolute constraint.

Cross-task consistency constraints. We also evaluate the cross-task consistency constraints. Removing the article-charge constraint (*w/o DEP1*, row 5) or the article-term constraint (*w/o DEP2*, row 6) negatively impacts performance, with the largest negative impact observed on charge prediction. While these constraints are intended to employ the predicted law article results to improve charge prediction and term prediction, we see that law article performance also deteriorates.

Superordinate types. So far, we have assumed that hierarchical event extraction would be beneficial to LJP. To better understand whether the hierarchy is indeed useful, we evaluate a version of *EPM without* using superordinate features. In other words, the model predicts the subordinate types/roles directly. Results are shown in row 7. Comparing rows 1 and 7, we see that Acc and F1 scores drop across all subtasks when superordinate features are not used, indicating their usefulness.

Event extraction as an auxiliary task. In *EPM*, we use the predicted event features as inputs for the three LJP task classifiers. Another way to exploit event information would be to treat event extraction as an auxiliary task in the model by having it share encoders with the LJP tasks. Results of treating event extraction as an auxiliary task are shown in row 8. As we can see, these results are worse than those of *EPM* (row 1), which means that *EPM*'s way of exploiting event information is better, but they are better than those when event information is

---

[6] Event extraction results in *EPM* are as follows: 53.75% (R), 47.52% (P), and 50.37% (F1) for trigger detection and 55.69% (R), 49.88% (P), and 52.59% (F1) for role prediction.

Table 8: Ablation on CAIL-small.

not use (row 2), which means that using predicted events for LJP is still better than not using them.

7.4 Qualitative Analysis

Next, we perform a qualitative analysis of *EPM* to better understand the role played by event information and constraints. In CAIL, the data distribution of term penalty for the same law article is skewed towards larger penalty values, thus causing *EPM* to inherit this bias in its prediction of term penalty when cross-task consistency constraints are not used. However, when constraints are used, *EPM* was forced to only predict those term penalties that are allowed by the predicted law article and was thus more robust to the skewed data distribution. As for events, the use of event information prevents *EPM* from focusing on certain words in a case fact that could trigger the prediction of wrong law articles. A detailed analysis can be found in Appendix F.

8 Conclusion

We proposed the first model that uses event extraction and hand-crafted constraints to improve LJP, achieving SOTA results. To facilitate future research, we make our codes and annotations publicly available at https://github.com/WAPAY/EPM.

Acknowledgments

We thank the three anonymous reviewers for their comments on an earlier draft of this paper. This work was supported in part by the National Natural Science Foundation of China (No. 61802167), the US National Science Foundation (Grant IIS1528037). Chuanyi Li is the corresponding author. Any opinions, findings, conclusions or recommendations expressed in this paper are those of the authors and do not necessarily reflect the views or official policies, either expressed or implied, of the funding agencies.

Ethics Statement

Automatic legal judgment prediction is a sensitive research area. The proposed EPM model is a preliminary work and is not ready to be productized. The goal of designing the EPM model is to surpass the performances of existing SOAT approaches which are not ready to be productized either.

Legal cases contain personal privacy information. Therefore, we use a public dataset that has been anonymized, i.e., CAIL, which is collected from the official website for disclosing legal case information. The private information of the cases has been anonymized when the cases are published on the official website.

A The Definition of Hierarchical Event

Table 9 shows the hierarchical relationship between legal events.

Property Infringement: seizing public or private property for the purpose of illegal possession or deliberately destroying public or private property.

- Robbery: robbing public or private property by violence, coercion or other means.
- Theft: stealing public and private property.
- Fraud: swindling public and private property.
- Racketeering: extorting public and private property.

Personal Rights Infringement: the illegal violation of citizens' personal rights and democratic rights.

- Intentional Injury: deliberately and illegally harming the health of others.
- Rape: forcibly having sexual intercourse with the victim by violence, threat or other means against the will of the victim.
- Kidnapping: using violence, coercion or other means to control others, restrict their personal freedom, or coerce others as hostages for the purpose of extorting money or property.

Disturbing Public Order: gathering people to disturb public place and traffic order, and resisting or hindering state security administration personnel from performing their duties according to law.

- Obstructing Official Duties: obstructing State functionaries from performing their duties according to law by means of violence or threat.
- Forgery: illegally manufacturing, altering, buying and selling official documents, certificates and seals of state organs.
- Gambling: gathering people to gamble or gambling for the purpose of profit.

Endangering Public Health: endangering the state's health management.

- Illegal Doctoring: engaging in diagnosis and treatment activities without medical qualification.

Destroying Environment: intentionally violating environmental protection laws, polluting or damaging environmental resources.

- Endangering Rare Wildlife: illegally hunting and killing precious and endangered wild animals under special state protection.
- Illegal Logging: cutting down state, collective or individual owned forests without authorization.

Drug: violation of relevant national and international drug control laws and regulations.

- Drug Possession: illegally possessing drugs.
- Drug Cultivation: cultivating opium poppy, marijuana and other original drug plants.

Superordinate type	Subordinate type
Property Infringement	Robbery Theft Fraud Racketeering
Personal Rights Infringement	Intentional Injury Rape Kidnapping
Disturbing Public Order	Obstructing Official Duties Forgery Gambling
Endangering Public Health	Illegal Doctoring
Destroying Environment	Endangering Rare Wildlife Illegal Logging
Drug	Drug Possession Drug Cultivation

Table 9: Hierarchical event types.

Superordinate type	Subordinate type
Party	Criminal Victim Officer
State	Qualified Intention Method
Object	Property Instrument Animal Plant Drug Drug plant Gambling device License
Attribute	Quantity Attribute Injury Attribute

Table 10: Hierarchical role types.

B The Definition of Hierarchical Role

Table 10 shows the hierarchical relationship between role types.

Party: a person who enters a lawsuit.

- Criminal: the person violating law articles.
- Victim: the aggrieved party.
- Officer: government officials.

State: the form that people or things show.

- Qualified: whether obtaining qualification certificate, medical license and logging qualification.

- Intention: the motivation of crime.
- Method: the means of crime.

Object: the items involved in the crime.

- Property: public and private property.
- Instrument: tools for criminal purpose.
- Animal: endangered animals.
- Plant: trees, such as pine tree, coconut tree.
- Drug: drugs, such as heroin, marijuana.
- Drug Plant: drug plants, such as opium poppy.
- Gambling Device: gambling tools.
- License: certificates and licenses.

Attribute: the abstract characterization of items, such as value, length.

- Quantity Attribute: measure words.
- Injury Attribute: the degree of injury.

C Details of Event Constraints

C.1 Absolute Constraint

During extraction trigger and role types, one subordinate trigger type must be extracted. And Criminal role type should appear at least once.

C.2 Consistency Constraint

A subordinate trigger type has its related subordinate role types. We show the corresponding in Table 11.

D Statistics of LJP-E

Table 12 shows the statistics of our proposed dataset LJP-E. There are 957 cases for training, 136 cases for validation and 274 cases for testing. The average number of arguments in a case is 4.13.

E Inter-Annotator Agreement

First, we measure inter-annotator agreement on trigger and argument annotations. Since these annotations involve annotation of text spans, we follow Araki et al. (2018), treating one person's annotations as gold and the other person's annotations as predicted and calculating the F1 score under two settings: strict matching and partial matching. The former measures whether two annotations have the exact same span. The latter measures whether there is an overlap between annotations. Note that partial matching has the restriction that each annotation can only be matched to one annotation by the other annotator. We then use the resulting F1 score as the inter-annotator agreement. The agreement scores are 0.8013 (strict) and 0.8425 (partial) for trigger annotation and 0.6728 (strict) and 0.7819 (partial) for argument annotation.

Next, we measure agreement on trigger type and argument role annotations. We follow the way we measured agreement on trigger and argument annotations, computing the F1 score using both strict matching and partial matching, where two annotations strictly match if both their spans and their types/roles exactly match, and two annotations partially match if they spans overlap and their types/roles are identical. The agreement scores are 0.7838 (strict) and 0.8255 (partial) for trigger type annotation and 0.6405 (strict) and 0.7332 (partial) for argument role annotation.

F Qualitative Analysis

Term of penalty error analysis. Compared to law article and charge prediction, the F1 score of term of penalty prediction is significantly low. Hence, we give an error analysis to show more insights of term penalty prediction subtask. Specifically, we calculate the error rate of the 11 penalty categories of *EPM* on the test portion of CAIL-small. As shown in Table 13, the category *5-7 years* has the highest error rate. In average, the model performs worse on severe penalty categories than mild penalty categories (take 3 years as the boundary). It may cause from the data imbalance problem, as there are fewer cases of severe penalty categories than that of mild penalty categories. Furthermore, we find that term of penalty prediction is significantly impacted by fine-grained information. For example, in two cases of intentional injury, the victim in one case is seriously injured, whereas the other case's victim is slightly injured. Though the other parts of the fact statements are similar, the final sentence is completely different (5 years for severe injury and 1 year for slight injury). Law article and charge prediction involve judging whether the fact statement matches with the event pattern in the relevant law article, whereas term of penalty prediction involves detecting event patterns and analyzing fine-grained information simultaneously, which make it more difficult. In the future, we will focus on improving term of penalty prediction.

Law article error analysis. We also give an error analysis of law article prediction. We select several cases for which *EPM* predicts wrong law articles. We find that *EPM* shows weakness in handling multiple events. If there are multiple events in the fact statement, *EPM* prefers to ex-

Subordinate Trigger Type	Subordinate Role Types
Robbery	Criminal, Victim, Property, Quantity
Theft	Criminal, Victim, Property, Quantity
Fraud	Criminal, Victim, Intention, Property, Quantity
Racketeering	Criminal, Victim, Intention, Property, Quantity
Intentional Injury	Criminal, Victim, Intention, Instrument, Injury
Rape	Criminal, Victim, Method
Kidnapping	Criminal, Victim, Method
Obstructing Official Duties	Criminal, Victim, Method, Officer, Injury

0 month	81.86%	3.50%

Table 13: The error rate of penalty. *# of Class* is the percentage of each class in the test portion of CAIL-small. *Error Rate* is the error percentage of each class.

tract the event type with more training data. For example, kidnapping and racketeering cases may contain intentional injury facts. There are more training samples of intentional injury than that of kidnapping/racketeering. When predicting law articles for kidnapping/racketeering cases with intentional injury facts, *EPM* tends to extract the event of intentional injury and ignore the events of kidnapping/racketeering, which leads to wrong predictions. It gives us motivation to solve the problem of multiple events in the future work.

Fact Statement: 被告人宋某于2016年3月29日，在京沪高速服务区卫生间内产下一名男婴，并将该名男婴遗弃在卫生间内离开... (The criminal Song gave birth to a baby boy in the bathroom of the Beijing-Shanghai Expressway Service Area at about 9:30 on March 29, 2016, and abandoned the baby boy in the bathroom...) **TOPJUDGE**: Article 261; Crime of child trafficking; 1-2 years imprisonment **EPM**: Article 261; Crime of abandoning babies; 9-12 moths imprisonment **Ground-truth**: Article 261; Crime of abandoning babies; 9-12 moths imprisonment
Fact Statement: 2013年5月，李某为参加工程招标，联系他人为其伪造了名称为“浙江大有构件有限公司”营业执照... (In May 2013, in order to participate in the project bidding, Li contacted others to forged a business license named "Zhejiang Dayou Component Co., Ltd."...) **TOPJUDGE**: Article 280; Crime of forging national agency certificates; 6-9 moths imprisonment **EPM**: Article 280; Crime of forging business unit certificates; 0-6 moths imprisonment **Ground-truth**: Article 280; Crime of forging business unit certificates; 0-6 moths imprisonment

Table 14: Examples of inconsistent predictions.

Charge error analysis. Obviously, the main charge prediction errors of *EPM* come from the wrong predicted law articles, as the predicted charge is dependent on the predicted law article by the cross-task constraint. Another type of errors comes from the weakness in discriminating charges with subtle difference, such as illegal hunting and illegal fishing, illegal hunting and endangering rare wildlife.

Consistency analysis. Recall that we propose cross-task constraints to reduce inconsistent predictions. The SOTA model *TOPJUDGE* also exploits the dependency between different subtasks. *TOPJUDGE* uses prediction results as auxiliary features, which can not guarantee the predictions of subtasks are consistent. Different from *TOPJUDGE*, our cross-task constraints can ensure that the outputs are consistent by forcing the model to predict allowable charges or terms of penalty based on the predicted articles during inference. To analyze the impacts of cross-task constraints, we select cases from the test portion of CAIL for which *TOPJUDGE* predicts the correct law articles, but wrong charges or terms of penalties, whereas *EPM -w/o event* predicts the correct law articles, charges and terms of penalty. We find that *TOPJUDGE* without cross-task constraints may predict the wrong charges that are not allowable regrading the predicted law article. For example, as shown in Table 14, *TOPJUDGE* predicts child trafficking for an abandoning babies case, whereas *EPM -w/o event* exploits the cross-task constraint to select results among allowable candidates during inference and predicts correctly.

As for term of penalty prediction, *TOPJUDGE* has high possibility to predict severe penalty. In cases where the same law article applies, the proportion of large penalty values is higher than that of small penalty values. Thus, models may inherit this data bias and predict more severe penalty. As shown in Table 14, *TOPJUDGE* predicts 1-2 years imprisonment for a abandoning babies case, but its ground-truth penalty is 9-12 months imprisonment, whereas *EPM -w/o event* exploits cross-task constraints to predict allowable penalty regarding the predicted law article and alleviate the data bias problem.

Event impacts To analyze the impacts of predicted event information, we select 200 cases with case types belonging to LJP-E annotation inventory from the tesing portion of CAIL. For these 200 cases, *TOPJUDGE* predicts wrong law articles whereas *EPM -w/o all DEP* predicts correct law articles. We find that there are two main types of errors predicted by *TOPJUDGE* without event extraction. The first is "specialisation over generalisation", which is completely incorrect. To be specific, *TOPJUDGE* may focus on some words that strongly trigger wrong law articles. As shown in Table 15, in a case of illegal logging, the facts describe that *two criminals negotiated to cut down tree by discussion*. *negotiated* and *by discussion* strongly imply it is a contract crime related case. Hence, *TOPJUDGE* wrongly predicts the *Crime of contract fraud*. In contrast, *EPM* can overcome this bias and predict results based on events instead of single words. The other type of errors is "multiple choice", which is partially incorrect. A case may contain several facts that violate different law articles, which is a problem of dealing with multiple crimes. *TOPJUDGE* prefers to predicting one possible article without referring to global information. As shown in Table 15, a illegal doctoring case wrongly predicted by *TOPJUDGE* as a intentional injury case because of the fact that the victim was assessed as *a serious injury grade II*. In contrast, *EPM* exploits event information and predicts the correct article in global (note that a illegal doctoring event contains injury degree arguments that defined as role type "Injury"). Moreover, which wrong law articles does *TOPJUDGE* prefer to predict in the second error type? We find that *TOPJUDGE* prefers to predict the wrong law article having similar texts with the ground-truth. For example, the illegal doctoring law article and the intentional injury law article all have the texts about injury degree.

Fact Statement: 2014年4月，刘某和王某（另案处理）经过商量决定砍伐大新公司所种植的桃树，并协商好由王某负责销售。被告人刘某砍伐桃树达一百多吨... (In April 2014, Liu and Wang (handled in a separate case) decided to cut down the peach trees planted by Daxin Company after discussion, and negotiated that Wang would be responsible for the sale. Liu cut down 100 tons of peach trees...)

Ground-truth: Article 336 [Crime of illegal doctoring]

Table 15: Examples of event impacts.

G Event Extraction Performance

We show the event extraction performance on LJP-E. The metrics are macro-precision (P), macro-recall (R) and macro-F1 (F1). Here, both text span

	Role			Trigger		
	F1%	**P%**	**R%**	**F1%**	**P%**	**R%**
EPM	52.59	49.88	55.69	50.37	47.52	53.75
w/o CSTR1	50.07	50.09	50.38	48.41	49.21	47.90
w/o CSTR2	48.97	49.18	49.24	47.17	48.45	46.19
w/o DEP1	50.52	51.08	50.13	49.96	49.29	50.82
w/o DEP2	51.97	49.56	54.82	48.97	47.39	50.82
w/o hierarchy	48.97	51.07	47.04	47.62	45.45	50.00
w/ auxiliary	51.73	49.16	54.94	49.81	47.13	53.35

Table 16: Event extraction results on LJP-E.

and trigger type/argument role should be predicted correctly simultaneously. From Table 16, *EPM* achieves the best results on both trigger extraction and role extraction. Removing the two event constraints (i.e., *w/o CSTR1* and *w/o CSTR2*) degrades the event extraction results and negatively impacts LJP.

H Preprocessing CAIL

We follow existing works (Xu et al., 2020; Yang et al., 2019) to preprocess the CAIL dataset. Specifically, we filter out the case samples with multiple applicable law articles and multiple charges. Also, we only keep law articles and charges that applicable to not less than 100 corresponding case samples. Note the frequency of each law article or charge is calculated on the training and validation portions. Besides, cases of second instance are removed. And we follow (Zhong et al., 2018) to divide the terms of penalty into non-overlapping intervals.

I Experimental Details

For training, we utilize the Adam optimizer with learning rate of 10^{-4} and the batch size is 32. The warmup step is 3000. Models are trained for a maximum of 20 epochs. For testing, we calculate Macro-F1 score for each subtask on the validation portion after each epoch and select the model with the maximum Macro-F1 score on the validation portion for testing each subtask. Note the CAIL-big subdataset has no validation portion and the validation portion of CAIL-small is employed. For LJP-E dataset, we run experiments 5 times and report the average results. For the hyperparameters, λ, in the loss function, the best setting is {0.5, 0.5, 0.4, 0.2, 0.1} for $\{\lambda_{t_a},\lambda_{t_c},\lambda_{t_p},\lambda_r,\lambda_p\}$ for both CAIL-big and CAIL-small. The experiments have been performed on two Tesla V100 GPUs.

J Details of the Switch

During testing on CAIL, we train a BERT-based *Switch* model using Legal-BERT (Zhong et al., 2019) as backbone to make binary classification. We split the training portion of CAIL into two clusters. One only contains the 15 case types of our annotate dataset. The other contains other case types of CAIL. The input of *Switch* is a fact statement and the output is a binary value. The binary value determines whether to use the pretrained version of *EPM* or the fine-tuned version of *EPM*. Specifically, we takes the hidden vector of [CLS] token for making binary classification. we set batch size to 32 and epoch to 20. We take Adam as the optimize and the learning rate is 0.0001. After training, the Switch achieves 89.82% and 85.32% Accuracy on the testing portion of CAIL-big and CAIL-small respectively.

K Explanation of Event constraints in Detail

We list our event constrains and then explain them.

Absolute constraint. For a legal event, the trigger must be present. If the trigger is missing, we impose the following penalty:

$$\mathcal{P}_t = \sum_{\tilde{r}\in\mathcal{TG}} \sum_{i=1}^{l_f} s_r(x_i, \hat{y}_{(i)}^{\tilde{r}}) - \max_{i,\tilde{r}\in\mathcal{TG}}[s_r(x_i, \hat{y}_{(i)}^{\tilde{r}})] + |1 - \max_{i,\tilde{r}\in\mathcal{TG}}[s_r(x_i, \hat{y}_{(i)}^{\tilde{r}})]| \tag{17}$$

where $\mathcal{TG}$ is the trigger inventory. $s_r(x_i, \hat{y}_{(i)}^{\tilde{r}})$ is the predicted softmax probability of trigger $\tilde{r}$ for x_i.

In the equation, $\sum_{\tilde{r}\in\mathcal{TG}} \sum_{i=1}^{l_f} s_r(x_i, \hat{y}_{(i)}^{\tilde{r}})$ is the summation of probabilities of all trigger types in the sequence and $\max_{i,\tilde{r}\in\mathcal{TG}}[s_r(x_i, \hat{y}_{(i)}^{\tilde{r}})]$ is the maximum probability of all trigger types in the sequence. $|.|$ denotes the absolute operation. The operations before absolute operation ensure that all probabilities of trigger types except the max one should be close to 0. It forces the model to predict only one trigger. The absolute operation guarantees that the max probability should be close to 1 (note $s_r(x_i, \hat{y}_{(i)}^{\tilde{r}})$ is a value after softmax). It means at least one trigger should be predicted and its softmax probability should be close to 1. The all operations makes the model to predict exactly one trigger.

If a required role r is missing, we impose the following penalty:

$$\mathcal{P}_r = |1 - \max_i [s_r(x_i, \hat{y}^{\tilde{r}}_{(i)})]| \tag{18}$$

This equation ensures that the maximum probability of the required role in the sequence should be close to 1. It enforces the model to predict the required role at least once.

Event-Based consistency constraint. If a trigger type is detected, all and only its related roles should be detected. For example, if a Illegal Doctoring event is detected, no roles related to Illegal Logging should be predicted. If a trigger r is predicted, we impose the following penalty:

$$\begin{aligned} \mathcal{P}_e = &\sum_{\tilde{r} \in \mathcal{R}^+} |1 - \max_i [s_r(x_i, \hat{y}^{\tilde{r}}_{(i)})]| \\ &+ \sum_{\tilde{r} \in \mathcal{R}^-} \sum_{i=1}^{l_f} s_r(x_i, \hat{y}^{\tilde{r}}_{(i)}) \end{aligned} \tag{19}$$

where $\mathcal{R}^+$ is the set of roles that should occur if r is predicted, $\mathcal{R}^-$ is the set of roles that cannot occur.

This equation ensures that the maximum probability of positive roles in the sequence should be close to 1. It means each positive role type should appear at least once. The equation also ensures that the probabilities of negative roles in the sequence should be close to 0. It means none of negative role types should be predicted. When applying this type of penalty, we first obtain the predicted trigger and then dynamically add the corresponding penalty into the loss function.

Answer-level Calibration for Free-form Multiple Choice Question Answering

Sawan Kumar
Indian Institute of Science, Bangalore
`sawankumar@iisc.ac.in`

Abstract

Pre-trained language models have recently shown that training on large corpora using the language modeling objective enables few-shot and zero-shot capabilities on a variety of NLP tasks, including commonsense reasoning tasks. This is achieved using text interactions with the model, usually by posing the task as a natural language text completion problem. While using language model probabilities to obtain task specific scores has been generally useful, it often requires task-specific heuristics such as length normalization, or probability calibration. In this work, we consider the question answering format, where we need to choose from a set of (free-form) textual choices of unspecified lengths given a context. We present ALC (Answer-Level Calibration), where our main suggestion is to model context-independent biases in terms of the probability of a choice without the associated context and to subsequently remove it using an unsupervised estimate of similarity with the full context. We show that our unsupervised answer-level calibration consistently improves over or is competitive with baselines using standard evaluation metrics on a variety of tasks including commonsense reasoning tasks. Further, we show that popular datasets potentially favor models biased towards easy cues which are available independent of the context. We analyze such biases using an associated F1-score. Our analysis indicates that answer-level calibration is able to remove such biases and leads to a more robust measure of model capability.

1 Introduction

Language models (LM), trained on large corpora, have been shown to exhibit few-shot and zero-shot learning capability (Radford et al., 2019; Brown et al., 2020) using only text interactions, as opposed to finetuning the model parameters using task specific training examples. Relying purely on text interactions for few-shot ability shifts the focus to designing and utilizing suitable task-specific natural language templates.

In this work, we focus on free-form multiple choice question answering (and commonsense reasoning tasks in particular), where given a context and a set of choices of unspecified lengths, a model is required to select the most suitable choice. To enable zero-shot learning, the typical approach is to form textual sequences by concatenating the context independently with each choice and then scoring the concatenated strings using a pre-trained LM.

While LM probabilities have been shown to provide useful estimates of choice probabilities given a context, there is no incentive to treat the choices as equal in the absence of the associated context. For example, the LM probabilities in a neutral context are likely to be determined by frequency. In this work, we explore the role of biases that are likely to be associated with the choices naturally due to the language modeling objective. We propose ALC[1] (Answer-Level Calibration), where we use a neutral context to model such biases and remove them using a scaling factor determined by how similarly a model handles the question context as compared to a neutral context.

Further, we show that popular datasets favor models which rely on easy cues which are context independent. We use a bias-specific F1 score to analyze such biases. Our results indicate the need for answer-level calibration for more accurate estimates of model capabilities, or equivalently the design of better datasets. We hope our work will be useful for further research in both those directions. Specifically, we analyze context-independent biases related to length, part-of-speech (POS) and neutral context probabilities of the choices.

In summary, we make the following contributions:

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 665 - 679
May 22-27, 2022

1. We present ALC, a model-agnostic approach to improve the unsupervised performance of pretrained LMs for free-form multiple choice question answering, including commonsense reasoning tasks.
2. We show that popular datasets favor models relying on context-independent easy cues and demonstrate the need for answer-level calibration to better estimate model capabilities.

2 Related Work

Prompts Jiang et al. (2020) show that manually created templates can be sub-optimal in extracting knowledge from LMs, and propose mining and paraphrasing-based approaches using training examples. Schick and Schütze (2021) highlight the importance of selecting templates for enabling few-shot learning.

Calibration Probabilities output by neural networks are known to suffer from lack of calibration (Guo et al., 2017), including LM output probabilities (Braverman et al., 2020). Zhao et al. (2021) use token-level calibration to improve on few-shot classification and generation tasks. In contrast, we show that answer-level calibration is more suitable for the multiple choice setting that we consider.

While we focus on free-form multiple choice questions in this work, when the choices are single tokens, for example in a classification task where the choices are *True* and *False*, answer-level calibration would behave similar to token-level calibration. As a result, answer-level calibration can be seen to have a more general scope as also illustrated empirically through our experiments.

Further, our analysis (Section 3.4) shows that answer-level calibration provides a more reliable measure of model performance on datasets with potential biases.

Finally, Jiang et al. (2021) explore supervised methods, including finetuning as well as post-hoc methods, to improve calibration using training examples. In this work, we focus mainly on unsupervised calibration.

Answer-level calibration Brown et al. (2020) generally perform length normalization over the token probabilities for a choice, while observing that for a select few tasks they obtain performance gains when using an answer-level calibration scheme (which corresponds to the unscaled version in Equation 3 of ALC). They use task specific development sets to choose between length normalization and answer-level calibration which is undesirable for few-shot learning (Kann et al., 2019), and specifically for zero-shot learning. In this work, we show that unscaled calibration (as in Equation 3) is sub-optimal, compared to our proposed scaled version.

More recently, Holtzman et al. (2021) also arrive at a formulation equivalent to the unscaled version of ALC but are motivated differently. Specifically, they hypothesize that the possibility of different surface forms of the same concept causes a competition between surface forms when scored by the LM. In contrast, we are motivated by calibration concerns and the presence of context-independent biases. We justify this motivation through bias associated evaluation (Section 5.2) for both the unscaled and scaled versions of ALC.

Alternative approaches using enhanced context One way to make the probability estimates of the choices more accurate is to enhance the context using more task-specific cues. For example, Brown et al. (2020) show that with just a few in-context examples, significant gains in performance can be obtained. At the same time, it has been shown that the order of examples as well as token-level calibration in such prompts can be critical for getting good performance (Zhao et al., 2021; Kumar and Talukdar, 2021).

While the gains from enhanced context through additional examples may be complementary to answer-level calibration, we focus on the zero-shot setting in this work. In the zero-shot setting, Shwartz et al. (2020), working on the question answering format, propose generating textual clarifications using the pre-trained LM itself, to enhance the context and improve zero-shot performance of pre-trained LM on commonsense reasoning tasks. While their method has a much higher computational cost, we use it as an unsupervised baseline and show improvement over it on most tasks we consider.

3 ALC: Proposed Method

We introduce the problem setting and notation in Section 3.1. We briefly describe our motivation in Section 3.2 and discuss the core idea of removing context-independent biases in Section 3.3. We provide the natural language formatting used in our experiments in Section A.3. We discuss bias associated measures in Section 3.4.

3.1 Notation

We consider a problem setting where an example consists of a textual context C and K textual choices (or options) $O_k, k \in [K]$, and we need to predict which choice O_k fits best in context C. For example, in the case of question answering, this amounts to answering a question contained in the context C. Additionally, we define an instance-independent neutral context C_ϕ, where we expect all choices to be equally likely.

Denoting the gold answer by Y, the evaluation data is comprised of N instances defined by the tuples $(C^i, [O^i_k], Y^i), k \in [K], i \in [N]$.

3.2 Motivation

Our main motivation is to evaluate the suitability of pretrained LMs for free-form multiple choice question answering where we contend that raw conditional phrase probabilities do not satisfy a natural requirement for such tasks (Equation 2). We suggest and evaluate modifications to meet this requirement.

3.3 Removing Context-independent Biases

We aim to obtain a probabilistic model M which provides estimates $P_M(O|C)$, the probability of a choice O given the context C. Predictions y for an example can subsequently be made using:

$$y = \text{argmax}_k(P_M(O_k|C)) \tag{1}$$

We wish to build such a model using a pretrained LM, e.g., GPT2. Such a LM, trained on the task of next word prediction, is expected to provide estimates of word probabilities given a textual context. For example, given the sequence of words $w_1 w_2 ... w_i$, we expect GPT2 to provide probability estimates $P_L(w_{i+1}|w_1 w_2 ... w_i)$. Applying chain rule, we can obtain estimates of phrases given a textual context. For example, we could obtain estimates of $P_L(O|C)$.

Can $P_L(O|C)$ serve as a proxy for $P_M(O|C)$? It is tempting to expect the LM probabilities $P_L(O|C)$ to serve as a proxy for $P_M(O|C)$ when we can format the task in natural language. However, under the assumption that all choices O_k are equally likely given a neutral context C_ϕ, this approximation can be sub-optimal. For it to be optimal, we would need

$$P_L(O_1|C_\phi) = P_L(O_2|C_\phi) ... = P_L(O_K|C_\phi) \tag{2}$$

However, given that these are task and instance specific choices, there is no incentive in the language modeling objective to ensure this condition.

To address this, we define a new score $S_L(O|C)$ to behave as expected with a neutral context:

$$S_L(O_k|C) = \log P_L(O_k|C) - \log P_L(O_k|C_\phi) \tag{3}$$

Predictions can subsequently be made using:

$$y' = \text{argmax}_k(S_L(O_k|C)) \tag{4}$$

Scaling the bias term: Equation 3, while desirable, makes a strong assumption about how the bias is present in the LM. While valid unquestionably for the neutral context, the bias in a trained (on task-specific data, or on a task-independent pretraining corpus) model is likely to depend on the context as well. For instance, a longer or more familiar context (in terms of similarity to training contexts) may mean the model is less reliant on context-independent cues. We therefore define a scaled version for removing biases, where the function g outputs the scaling term (ranging in $[0, 1]$):

$$S'_L(O_k|C) = \\ \log P_L(O_k|C) - g(C, C_\phi) * \log P_L(O_k|C_\phi) \tag{5}$$

We would want this formulation to preserve the requirement in Equation 2 which was satisfied by the unscaled version in Equation 3. Specifically, we want $g(C_\phi, C_\phi) = 1$ which would assign an equal score to each choice O_k given a neutral context.

To get a model-agnostic[2] estimate of g, we think of $\log P_L(O_k|C)$ and $\log P_L(O_k|C_\phi)$ as outputs from different models M and M_ϕ respectively, and g as a measure of similarity between the models. Note that while M uses the available context C, M_ϕ uses only the neutral context C_ϕ. The intuition is that if M and M_ϕ are identical, there is no new information provided by M and we want to set $g(C, C_\phi) = 1$, leading to $S'_L(O_k|C) = 0$. On the other hand, if M and M_ϕ are very dissimilar, we can rely on the contextual scores of M and set $g(C, C_\phi) = 0$, leading to $S'_L(O_k|C) = \log P_L(O_k|C)$. Specifically, to estimate g, we compute a similarity metric between the token probabilities (across the model's entire vocabulary) output by the two models.

---

[2] By model-agnostic, we mean we only access the probabilities output by the model and don't rely on any knowledge of the model architecture.

$$g(C, C_\phi) = \mathrm{Sim}(p_L^f(C), p_L^f(C_\phi)) \quad (6)$$

where p_L^f indicates the probability vector output by the model across the vocabulary for the first token given the corresponding context. In this work, we consider Total Variation Distance (TVD), and Bhattacharyya Coefficient (BC) (Bhattacharyya, 1943).

When using TVD, we subtract it from 1, to obtain a similarity estimate:

$$g^{\mathrm{TVD}}(C, C_\phi) = 1 - 0.5 * ||p_L^f(C) - p_L^f(C_\phi)||_1 \quad (7)$$

while we directly use BC:

$$g^{\mathrm{BC}}(C, C_\phi) = \sum_{i=1}^{V} \sqrt{p_L^f(C)[i] * p_L^f(C_\phi)[i]} \quad (8)$$

3.4 Bias Associated Measures

Consider an instance and choice specific attribute $A^i(O_k^i)$ which can take values $a_j, j \in [J]$. If we expect the attribute to be uncorrelated with task performance, we expect a model to perform similarly when evaluating subsets with different distributions of attributes $A^i(O_k) = a_j$. If a model relies on specific values of the attribute and if the evaluation data has sufficient representation of that value, standard evaluation metrics which ignore this attribute may provide an erroneous estimate of the model capability. As an extreme example, consider $A(.)$ to denote whether the selected choice corresponds to the shortest choice among all choice $O_k, k \in [K]$, with the attribute values being true/false. Assume then that the evaluation data is dominated by instances where $A^i(Y^i) = \text{true}$, i.e., with a high probability, the correct answer in the evaluation data is the shortest choice. Consider also a model which always chooses the shortest choice, irrespective of the content. The model would return close to perfect scores using standard evaluation metrics such as accuracy against gold labels.

To analyze the impact of such attributes, we use a macro F1 score which takes into account the partitions created by an attribute. Recalling that an instance is represented by the tuple $(C^i, [O_k^i], Y^i), i \in [N]$, and letting $\hat{Y}^i$ be the model prediction, we define precision (P), recall (R) and F1 scores for each attribute value a_j, and subsequently an attribute specific macro F1 score ($\mathrm{F1}_A$).

$$P_{(A,a_j)} = \frac{\#\{(A^i(\hat{Y}^i) = a_j) \;\&\; (\hat{Y}^i = Y^i)\}}{\#\{A^i(\hat{Y}^i) = a_j\}} \quad (9)$$

$$R_{(A,a_j)} = \frac{\#\{(A^i(\hat{Y}^i) = a_j) \;\&\; (\hat{Y}^i = Y^i)\}}{\#\{A^i(Y^i) = a_j\}} \quad (10)$$

$$\mathrm{F1}_{(A,a_j)} = \frac{2 * P_{(A,a_j)} * R_{(A,a_j)}}{P_{(A,a_j)} + R_{(A,a_j)}} \quad (11)$$

$$\mathrm{F1}_A = \mathrm{Average}(\{\mathrm{F1}_{(A,a_j)}\}) \quad (12)$$

where $\#\{.\}$ denotes the count of the corresponding set. If the model performs similarly irrespective of the attribute value, the macro F1 score $\mathrm{F1}_A$ is equal to the standard measure of accuracy:

$$\mathrm{Accuracy} = \frac{\#\{\hat{Y}^i = Y^i\}}{N} \quad (13)$$

4 Experimental Setup

The datasets used and the corresponding prompts are described in Section 4.1. The LMs used are described in Section 4.2 and the baseline approaches in Section 4.3. Experimental results and analyses are presented in Section 5.

4.1 Data

We used a series of commonsense reasoning tasks and evaluated on the publicly available development sets. We used the same versions of the data as Shwartz et al. (2020) to allow for a direct comparison — COPA (Gordon et al., 2012), CommonsenseQA (Talmor et al., 2019), MCTACO (Zhou et al., 2019), SocialIQA (Sap et al., 2019), PIQA (Bisk et al., 2020), WinoGrande (Sakaguchi et al., 2020). We also report on the adversarially generated large-scale SWAG dataset (Zellers et al., 2018).

Further, we report on the AI2 Reasoning Challenge (ARC) (Clark et al., 2018), which has Easy and Challenge versions.

As a representative dialog understanding task, we report on the DREAM (Sun et al., 2019) dataset.

Finally, we report on a recent benchmark introduced for measuring multitask accuracy of pretrained models (referred to as Hendrycks in the following) Hendrycks et al. (2020).

For MCTACO, we used a reduced subset as provided by Shwartz et al. (2020) where each question

Model		COPA	COPA-test	CSQA	MCTACO	MCTACO-test	SocialIQA	PIQA	WG
Accuracy with gpt2-xl (zero-shot)									
Majority		55.0	50.0	20.9	50.0	51.32	33.6	50.5	50.4

Table 1: *Standard evaluation results on unsupervised commonsense question answering tasks:* (**Top**) Dev set accuracies (unless specified otherwise) with gpt2-xl are presented for baselines and ALC along with an unscaled version of ALC where the bias term is not scaled. The highest accuracies are marked in bold font. Note that while the unscaled version provides gains over the uncalibrated baseline, on the CommonsenseQA and SocialIQA tasks, there is also a drop in performance on some datasets, notably on PIQA. The scaled version, on the other hand, outperforms the LM-Baseline on all datasets except WinoGrande (on which all models perform close to majority accuracy). While token calibration improves over the majority accuracy on all datasets, it performs worse than the uncalibrated baseline. Finally, ALC outperforms or is competitive with Self-talk, while being computationally more efficient. (**Middle**) We also report on the gain over the uncalibrated baseline over different gpt2 variants and observe similar trends. (**Bottom**) Finally, we report on few-shot evaluation with gpt2-xl and again observe similar trends. Please see Section 5.1 for more details.

is associated with only one correct choice. For COPA, we also report on the test split due to the small size of COPA dev set. The sizes of the datasets used are reported in Appendix Table 8. All datasets contain questions in English language. We briefly describe these datasets in Section A.2. Examples for each dataset along with contextual (C) and neutral (C_ϕ) prompts used in this work are captured in Section A.3.

4.2 Models

We experiment with GPT2 (Radford et al., 2019) variants - distilgpt2, gpt-small, gpt-medium, gpt2-large and gpt2-xl. The size of models used is reported in Appendix Table 9. While the gpt-* models have been trained similarly as described in Radford et al. (2019), distilgpt2 has been pretrained with the supervision of GPT2[3] (Wolf et al., 2020). For most of our experiments, we utilize the gpt2-xl model.

Please refer Section A.1 for additional details about the experimental setup.

4.3 Baselines

Uncalibrated: Predictions are made using uncalibrated probabilities from a LM, $\log P_L(O|C)$, computed as the sum of conditional log-probabilities output by the model for the tokens in O.

Length normalized: Predictions are made using length-normalized probabilities from a LM, $\log P_L(O|C)$, computed as the mean of conditional log-probabilities output by the model for the tokens in O.

ALC (Unscaled)	49.2	27.82	35.54	40.76	58.94	48.19
ALC (BC)	47.92	38.05	42.41	44.06	52.58	47.95

Table 3: *Length bias analysis:* We consider subsets of data where the shortest/longest choice is correct, and report on P, R and F1 scores (lowest values are underlined). We compare ALC against the uncalibrated as well as length normalized baselines. While length normalization is commonly used to overcome length bias, we find that it overcompensates and severely penalizes short answers (see recall with Shortest=true; the recall is lower than that for a random baseline). On the other hand, the uncalibrated baseline severely penalizes longer answers as expected. ALC improves on both subsets and provides a better alternative to length normalization. Please see Section 5.2.1 for details.

Self-talk: We use the official code repository[4] of self-talk (Shwartz et al., 2020) using gpt2-xl as both the scoring model and the knowledge source.

Token calibration: Following Zhao et al. (2021), we use the probability vector output, p_N^f by the model at the first token given the neutral context to calibrate the model probabilities. Specifically, each token probability p is offset by p_N^f and renormalized: $p' = \text{softmax}(p - p_N^f)$. We also tried an alternative variant suggested by Zhao et al. (2021) where $p' = \text{softmax}(p/p_N^f)$ but this generally did worse and we skip the corresponding results.

5 Experimental Results

We aim to answer the following questions:

Q1 How does ALC compare with baselines using standard evaluation (accuracy) on free-form multiple choice question answering tasks? (Section 5.1)

Q2 Does the aforementioned evaluation reflect true model capability? To answer this question, we perform a series of bias associated evaluations (see Section 3.4) and also evaluate whether ALC helps overcome such biases. Specifically, we evaluate on biases related to answer length, POS tag and context-ignorant LM probability. (Section 5.2)

Q3 Does ALC improve expected calibration error (Guo et al., 2017)? (Section 5.3)

5.1 Standard Evaluation

The overall results for the commonsense reasoning tasks (considered by Shwartz et al. (2020)) using standard evaluation of ALC, as well as the base-

Uncalibrated	36.93	39.47	38.16	39.57	36.91	38.19	40.48	23.94	30.09
Length normalized	35.07	31.37	33.12	33	44.97	38.07	33.33	33.8	33.57
ALC (Unscaled)	48.68	45.01	46.77	43.75	56.38	49.27	52.74	54.23	53.47
ALC (BC)	49.32	48.34	48.82	48.84	56.38	52.34	59.32	49.3	53.85

Table 4: *POS bias analysis:* We consider subsets of data using the POS tag of the first token and report on P, R and F1 scores (lowest values are underlined). We limit to the larger subsets of nouns, verbs and adjectives (adj). We note that the uncalibrated baseline does worse on adjectives when compared to nouns and verbs. Both length normalized and ALC provide more even scores across POS tags. Please see Section 5.2.2 for details.

lines, with gpt2-xl are presented in Table 1 (top). We also report on an unscaled ablation of ALC. Note that ALC outperforms the uncalibrated baseline on all datasets except WinoGrande (where all models perform poorly and we drop it from further discussions). Further, the significant gains compared to token calibration (which generally does worse than the uncalibrated baseline) show that answer-level calibration is more suited for unsupervised commonsense question answering when there is no constraint on the lengths of candidate choices. Finally, ALC outperforms or is competitive with self-talk[5] while being significantly less computationally intensive. ALC requires scoring two strings (context input and neutral input) for each choice, while self-talk requires generating hundreds of clarification texts using data-dependent templates and subsequently scoring them.

We also report on the average gain over the uncalibrated baseline across gpt2 models of varying sizes (Table 9) in Table 1 (middle) and observe similar trends as in the case of gpt2-xl.

While our focus is zero-shot unsupervised evaluation, we also perform few-shot (1-shot and 4-shot) evaluation In general, for k-shot evaluation, we sample 100 sets of size k from an unseen split[6] of the dataset. A few-shot context is obtained by concatenating training examples with a newline token. We report the average performance on the evaluation set in Table 1 (bottom) and observe similar trends as before.

We present the standard zero-shot evaluation on additional datasets in Table 2. The trends are similar except for the SWAG (see Section 5.2 for an explanation) and the Hendrycks datasets (see Table 11).

Finally, while our focus is causal language models, we also present results using RoBERTa-large (a masked language model) in Table 10. Again, we observe similar trends.

In the subsequent sections, we show that the evaluation using the accuracy metric may not reveal true model capabilities as the datasets may favor models which utilize easy cues for predicting the answer.

5.2 Bias Associated Evaluation

Next, to gain a better understanding of the model capabilities, we analyze the performance associated with undesirable biases related to length, POS tag and context-ignorant LM probability. Specifically, we define the following attributes (see Section 3.4):

Shortest Attribute $A^i(O^i_k)$ is set to true if O^i_k is the shortest (number of tokens) choice among the choices $O^i_{k'}, k' \in [K]$. Otherwise, the attribute is set to false.

Longest Defined similar to Shortest, but set to true if O^i_k is the longest answer and false otherwise.

POS Attribute $A^i(O^i_k)$ is set to the POS tag of the first token in the choice O^i_k. We don't consider POS tags which occur less than a threshold (25) in the evaluation data.

LM-Best Attribute $A^i(O^i_k)$ is set to true if O^i_k is the most likely choice using context-ignore (neutral input) LM probability. Otherwise, it is set to false.

LM-Worst Defined similar to LM-Best, but set to true when O^i_k is the least likely choice and false otherwise.

Finally, we consider length-normalized versions of LM-Best and LM-Worst, referred to as **LM-**

---

[5] Please see Section A.4 for a note explaining the unusually high relative performance of baselines on some tasks when compared to self-talk.

[6] For few-shot evaluation, we sample from the training split for all except COPA and MCTACO datasets where we sample from the dev set and report on the test set.

Model	LM-Best = true			LM-Worst = True		
	P	R	F1	P	R	F1
PIQA						
Size	1195			643		
Uncalibrated	70.53	94.31	80.7	71.67	26.75	38.96

Length normalized	27.55	42.19	33.33	29.03	20.93	24.32
ALC (Unscaled)	38.71	18.75	25.26	33.87	48.84	40
ALC (BC)	29.76	39.06	33.78	36.99	31.4	33.96

Table 5: *Context-ignorant LM bias analysis:* We consider subsets of data where the correct choice corresponds to the best/worst choice as per the context-ignorant (neutral context) LM probability and report on P, R and F1 scores (lowest values are underlined). Note that the F1 performance of uncalibrated and length-normalized baselines on PIQA and ARC (Easy) is much higher when LM-Best=true, i.e., when the correct choice is also the most likely choice without considering the context. An important takeaway here is that while standard evaluation did not distinguish ALC from the baselines, ALC is not overly reliant on context-ignorant LM probabilities. Please see Section 5.2.3 for more details.

Norm-Best and **LM-Norm-Worst** respectively.

Briefly, our experiments reveal that while the datasets considered don't share a similar bias pattern, each usually suffers from at least one bias considered in this work, i.e., there is a drop in performance when measured using the bias associated score. We present the detailed results for commonsense reasoning tasks in Appendix Table 12, using gpt2-xl model, while highlighting the key takeaways here. Recall that in the absence of biases in the model, the F1 score should match the accuracy score.

In the following sections, we provide a more directed analysis on the presence of such biases, on datasets where such biases are most prominent, and if ALC helps alleviate such biases.

5.2.1 Length

We create subsets of the CommonsenseQA and SocialIQA dev set with specific properties to evaluate if the LM-Baseline has the associated biases and if they are addressed by ALC. First, we create subsets of examples where the shortest/longest answer is the correct answer. We expect longer sentences to have lower probabilities than shorter sentences with the uncalibrated baseline. Additionally, with the length normalized variant, where the final score is obtained as the mean of conditional log-probabilities instead of the sum (as in the uncalibrated baseline), longer sentences could potentially be favored. We report the uncalibrated and ALC's performance in Table 3. Note that both uncalibrated baseline and the length-normalized variants favor one subset at the cost of the other, while ALC improves on both. In particular, the uncalibrated baseline has a much poorer recall when the longest answer is correct. On the other hand, the length normalized variant has a much poorer recall when the shortest answer is correct. The results indicate that ALC provides a viable alternative to length normalization for handling length biases.

5.2.2 POS

We analyze potential part of speech (POS) tag biases in Table 4. Considering the CommonsenseQA dataset, we create subsets of the data where the correct answer is of the POS tag noun, verb or adjective. Note that ALC shows less variation in performance (F1) across these subsets when compared to uncalibrated baseline while improving on

Model	PIQA	SWAG
LM-Norm-Best		
Baseline	65.38	49.38
Length normalized	60.16	**60.97**
ALC (Unscaled)	58.89	58.12
ALC (BC)	**67.92**	59.48
LM-Norm-Worst		
Baseline	65.38	39.90
Length normalized	60.16	46.99
ALC (Unscaled)	58.89	49.48
ALC (BC)	**67.92**	**51.14**

Table 6: *Context-ignorant normalized scores:* LM-Norm-Best (top) and LM-Norm-Worst (bottom) macro F1 evaluation on SWAG and PIQA datasets (lowest values are underlined and highest values are in bold). The macro F1 scores for LM-Norm-Best and LM-Norm-Worst are identical for PIQA as the dataset contains only two candidate answers for a question and the subsets created by the two measures are identical. Note that while length-normalization has a higher accuracy than ALC on the SWAG dataset (Table 2), it does worse than ALC on the LM-Norm-Worst F1 score. Please see Section 5.2.3 for more details.

each subset. In particular, the maximum difference in F1 scores is 8.1 for the uncalibrated baseline while it is 5.03 for ALC (BC). ALC also improves over the length normalized variant for each subset.

5.2.3 Context-ignorant LM Probability

To understand how much of the unsupervised performance comes from context-independent LM biases, we analyze subsets where the correct answer is most/least likely without the context. We report the performance on the PIQA and ARC datasets in Table 5 and show that such biases indeed exist. The key takeaway is that the standard evaluation metrics may not give an accurate estimate of performance and that ALC provides more reliable estimates.

Finally, we report macro F1 scores for LM-Norm-Best and LM-Norm-Worst evaluation in Table 6 on PIQA and SWAG datasets. The results indicate that the datasets favours length normalization aware scoring irrespective of the context. When we measure the bias associated score, ALC generally performs better.

5.3 Expected Calibration Error

Given a score $S(O_k|C)$ for each choice O_k, we can compute a confidence estimate $\mathrm{conf}(O_k|C)$ as:

$$\mathrm{conf}(O_k|C) = \frac{e^{S(O_k|C)}}{\sum_{k' \in [K]} e^{S(O_{k'}|C)}} \quad (14)$$

Model	Accuracy (↑)	ECE (↓)
Length normalized	-0.46 (5.90)	-0.21 (0.13)
ALC (Unscaled)	+1.17 (6.23)	-0.07 (0.06)
ALC (BC)	+3.73 (3.86)	-0.09 (0.04)

Table 7: *Expected Calibration Error:* Mean (and standard deviation) of difference with the uncalibrated baseline in accuracy and ECE over different evaluation datasets are reported. ALC improves both ECE and accuracy. Please see Section 5.3 for more details.

Guo et al. (2017) compute expected calibration error (ECE) by partitioning N confidence predictions into R equal bins $B_r, r \in [1, R]$ and computing the weighted average of the absolute difference between the confidence and accuracy in each bin:

$$\mathrm{ECE} = \sum_{r=1}^{R} \frac{|B_r|}{N} |\mathrm{acc}(B_r) - \overline{\mathrm{conf}}(B_r)| \quad (15)$$

where $\mathrm{acc}()$ and $\overline{\mathrm{conf}}()$ measure the accuracy and mean confidence respectively in a bin. We set the number of bins to be 20.

We report the average difference in accuracy and ECE compared to the uncalibrated baseline across the evaluation datasets (except WinoGrande) in Table 7. When compared to the uncalibrated baseline, ALC provides gains in calibration error while also improving performance. Length-normalization also improves ECE, presumably by correcting for length bias. However, length-normalization does not improve performance on an average. The relative performance gains of ALC can be explained through the handling of additional biases beyond length bias.

6 Conclusion

We propose ALC (Answer-Level Calibration), an unsupervised method to improve performance of pretrained language models. We show that, when compared to existing baselines, ALC is more suitable for free-form multiple choice question answering, including commonsense reasoning tasks. We also show that popular datasets favor models which rely on easy cues for predictions, and that ALC provides more reliable estimates of model capabilities by getting rid of some of these biases.

Table 9: Size of models used

A Appendix

A.1 Experimental Setup

We leverage the transformers library (Wolf et al., 2020) for accessing the LMs. All experiments were conducted using a single Nvidia GeForce GTX 1080 Ti Graphics Card. There was no training required. A typical experiment using gpt2-xl for CommonsenseQA task took around 15 minutes.

The model sizes are captured in Table 9. Size of evaluation datasets is captured in Table 8.

We used the nltk pos-tagger with the universal tagset for pos-tagging.

A.2 Datasets

COPA: The COPA dataset (Gordon et al., 2012) contains a premise associated with two alternatives where one has a more plausible causal connection with the premise. There are two types of examples, depending on whether the connection is of “effect" or “cause".

CommonsenseQA: The CommonsenseQA dataset (Talmor et al., 2019) contains common sense questions extracted from ConceptNet (Liu and Singh, 2004). The alternative choices are made challenging by selecting from related concepts in ConceptNet or through suggestions through crowdsourcing.

MCTACO: The MCTACO dataset (Zhou et al., 2019) contains common sense questions related to understanding of time. Difficult adversarial candidates are selected using BERT (Devlin et al., 2019) predictions.

SocialIQA: The SocialIQA dataset (Sap et al., 2019) contains questions about social interactions with crowdsourced answers.

PIQA: The PIQA dataset (Bisk et al., 2020) contains questions about common sense. The question corresponds to a goal derived from an instruction website and the answers were crowdsourced.

WinoGrande: The WinoGrande dataset (Sakaguchi et al., 2020) is based on the Winograd Schema Challenge (Levesque et al., 2012), where a pair of sentences differ in one or two words containing a referential ambiguity.

ARC: The ARC dataset (Clark et al., 2018) contains natural grade-school science questions. The authors provide Easy and Challenge splits. The Challenge version is created using examples where retrieval-based and word-occurrence based methods fail (Clark et al., 2018). The Easy version contains the remaining questions.

DREAM: DREAM (Dialogue-based REAding comprehension exaMination) (Sun et al., 2019) provides a benchmark for reading comprehension focusing on multi-turn multi-party dialog understanding.

SWAG: SWAG (Situations With Adversarial Generations) (Zellers et al., 2018) provides a large-scale dataset for grounded commonsense inference where different possible endings of a context are provided where the correct answer is derived from video captions while alternatives are adversarially generated.

Hendrycks: Hendrycks et al. (2020) provide a test suite containing 57 tasks to test the multitask accuracy of pretrained models. The tasks are broadly categorized into Humanities, STEM, Social Sciences and Other. We run our experiments on subsets associated with these categories.

A.3 Data Formatting

In this section, we provide the formatting used to convert task-specific examples into natural language prompts as used in our experiments. We first give examples of the **Context** (if any), the **Question** and **Choices** as present in the corresponding dataset, followed by the **Context input** and **Neutral input** as fed to the pretrained LM.

A.4 Note on Comparison with Self-talk

While it seems surprising that the self-talk results in Table 1 are generally lower than the uncalibrated baseline, we note that we haven't underestimated the performance of self-talk. Self-talk performance was obtained using the official repository of the project and the results align well with those reported in the original work. What has changed is the performance of the baseline, which is higher here (which in turn shows the significane of the numbers reported in this work). We note two differences with respect to the self-talk repository. First, self-talk uses a length-normalized baseline, while we evaluate both uncalibrated and length-normalized baselines. Second, there is a bug in the self-talk repository regarding calculating baseline performance, also noted in a GitHub issue[7].

A.5 Additional Results

We show results across commonsense reasoning datasets for bias-associated F1 scores in Table 12.

Learning When to Translate for Streaming Speech

Abstract

How to find proper moments to generate partial sentence translation given a streaming speech input? Existing approaches waiting-and-translating for a fixed duration often break the acoustic units in speech, since the boundaries between acoustic units in speech are not even. In this paper, we propose MoSST, a simple yet effective method for translating streaming speech content. Given a usually long speech sequence, we develop an efficient **mo**notonic **s**egmentation module inside an encoder-decoder model to accumulate acoustic information incrementally and detect proper speech unit boundaries for the input in **s**peech **t**ranslation task. Experiments on multiple translation directions of the MuST-C dataset show that MoSST outperforms existing methods and achieves the best trade-off between translation quality (BLEU) and latency. Our code is available at `https://github.com/dqqcasia/mosst`.

1 Introduction

Speech translation (ST) aims at translating from source language speech into target language text, which is widely helpful in various scenarios such as conference speeches, business meetings, cross-border customer service, and overseas travel. There are two kinds of application scenarios, including the non-streaming translation and the streaming one. The non-streaming models can listen to the complete utterances at one time and then generate the translation afterward. While, the streaming models need to balance the latency and quality and generate translations based on the partial utterance, as shown in Figure 1.

Figure 1: An illustration of streaming speech-to-text translation. ST models listen to the audio in source language, and generate tokens in target language.

Recently, end-to-end approaches have achieved remarkable progress in non-streaming ST. Previous work (Weiss et al., 2017; Bérard et al., 2018; Livescu and Goldwater, 2019; Bansal et al., 2019; Alinejad and Sarkar, 2020; Stoian et al., 2020) Ansari et al. (2020) has shown that an end-to-end model achieves even better performance compared to the cascaded competitors. However, attempts at end-to-end streaming ST are still not fully explored. Traditional streaming ST is usually formed by cascading a streaming speech recognition module with a streaming machine translation module (Oda et al., 2014; Dalvi et al., 2018). Most of the previous work focuses on simultaneous text translation (Gu et al., 2017a). Ma et al. (2019a) propose a novel wait-k strategy based on the prefix-to-prefix framework, which is one of the popular research methods of simultaneous text translation. For end-to-end streaming ST, Ma et al. (2020b); Ren et al. (2020); Ma et al. (2021a) introduce the methodology of streaming machine translation into streaming ST and formalize the task, which belongs to the first study to propose simultaneous ST in an end-to-end manner.

However, those previous streaming ST systems generally treat a fixed time-span of audio as a acoustic unit and translate new words based on fixed time segmentation, which might be unfavorable for streaming ST translation. Since the speaker's speech speed and the length of the phonemes are

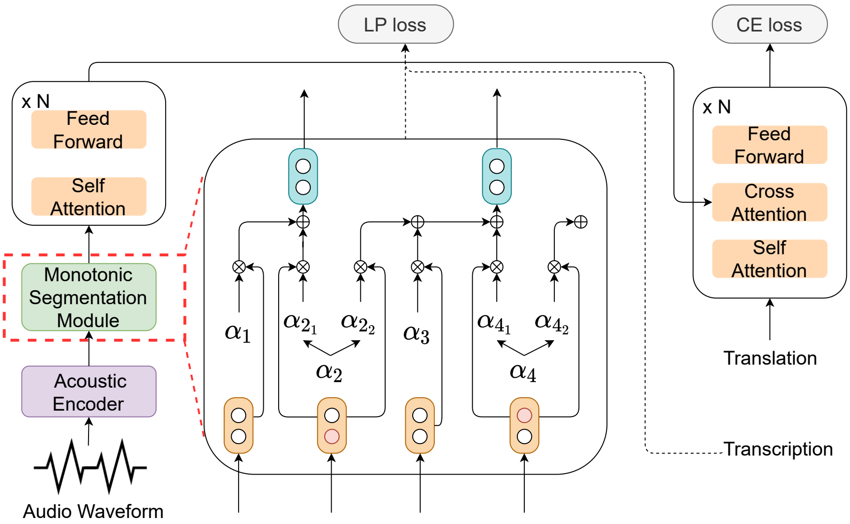

Figure 2: Overview of the proposed MoSST. MoSST consists of a pre-trained acoustic model, a monotonic segmentation module (MSM) module, and standard Transformer blocks. The acoustic model extracts features from the raw audio waveform. MSM learns a soft and monotonic alignment over the extracted features from the acoustic model and outputs accumulated acoustic vectors as the input for down-streaming Transformer blocks.

distinct, previous methods cannot find the best policy to tell whether to continue reading source audio or translate new words when the source audio is streaming in. Hence, we expect the model can determine whether the streaming audio information input is enough to translate new words, similar to the manual simultaneous interpretation. This idea inspires Monotonic-segmented Streaming Speech Translation (MoSST) system. Specifically, we design a new module that helps to judge the acoustic boundaries of the input audio. We then propose a translation strategy that enables the model to decide whether to read the audio stream or write new tokens given the audio prefix. With the new module and decoding strategy, the model's performance on streaming speech translation has been significantly improved.

We highlight our innovations and findings as follows:

- We propose a simple but effective framework, MoSST for streaming speech translation.
- We introduce a new monotonic segmentation module to segment audio waveform into acoustic units, based on which we design the adaptive decision strategy which dynamically decides when to translate a new word in streaming scenarios.
- We validate MoSST on the MuST-C dataset. The results show that our model significantly outperforms SOTA baselines. Surprisingly, we also find that MoSST can rival or even surpass other SOTA systems in non-streaming speech translation. Furthermore, we conduct a comprehensive study to analyze the utility of the proposed module and decoding strategy.

2 Proposed Method: MoSST

This section first formulates the ST task in streaming and non-streaming scenarios. Then, we introduce the detailed architecture of MoSST, as shown in Figure 2. Finally, we give the training and inference strategies of MoSST for streaming and non-streaming cases.

2.1 Problem Formulation

The ST corpus usually contains speech-transcription-translation triples $(\mathbf{x}, \mathbf{z}, \mathbf{y})$. Specially, $\mathbf{x} = (x_1, ..., x_{T_x})$ is a sequence of acoustic features. $\mathbf{z} = (z_1, ..., z_{T_z})$ and $\mathbf{y} = (y_1, ..., y_{T_y})$ represents the corresponding transcription in source language and the translation in target language respectively. Usually, the acoustic feature $\mathbf{x}$ is much longer than text sequences $\mathbf{z}$ and $\mathbf{y}$, as the sampling rate of audio is usually above 16,000 Hz, and each word syllable (about 300 ms) will be recorded by thousands of sampling points.

The streaming ST model aims to translate instantly when speech audio streams in, that is, given a valid audio prefix $\mathbf{x}_{<\tau}$, where τ is the time span of the audio piece, we expect the model can translate enough information $\mathbf{y}_{<K}$, where K is the maxi-

mum number of tokens that the model can translate as time τ, *i.e.*:

$$\Pr(\mathbf{y}_{<K}|\mathbf{x}_{<\tau}) = \prod_{t=1}^{K} \Pr(y_t|\mathbf{x}_{<\tau}, \mathbf{y}_{<t}; \theta) \quad (1)$$

where θ is the parameters of the streaming ST model. Our goal is to find the best θ^* that maximizes the $\Pr(\mathbf{y}_{<K}|\mathbf{x}_{<\tau})$ in Eq. 1.

Note that in our research scenario, we require that the translated piece of the sentence shall not be modified once generated, similar to the settings in simultaneous machine translation (Ma et al., 2019a).

2.2 Model Structure

MoSST consists of an acoustic encoder, a monotonic segmentation, and a standard Transformer.

Acoustic Encoder The conventional acoustic encoder using FBANK (log-Mel filterbank, FBANK) as feature extractors faces reduced performance with insufficient training data (San et al., 2021), which is especially the case in speech-to-text translation tasks. The FBANK also leads to potential information loss, and may corrupt long-term correlations (Pardede et al., 2019).

To tackle such problems, we apply the recently-proposed pre-trained acoustic models (Chen et al., 2020; Baevski et al., 2020) as the feature extractor for MoSST. Those pre-trained acoustic models learn the speech representation in a self-supervised learning (SSL) way. Since pre-trained acoustic models require only a large amount of unlabeled speech, which also alleviates the corpus shortage of ST tasks. In this paper, we utilize Wav2Vec2 (Baevski et al., 2020) as our instance.

Monotonic Segmentation Module The previous speech translation model generally attends the whole audio sequence to the translation tokens with a sequence-to-sequence (seq2seq) framework, which brings two problems: *1)* the model does not learn the alignment between audio and translation explicitly, which may confuse the streaming translation model on whether it has read enough acoustic information when generating the translated text; *2)* the audio sequences are usually much longer than text sequences, which is computationally demanding for the conventional encoder-decoder speech-to-text model to apply the global attention mechanism. Such high computational cost deviates from the requirements in streaming translation scenarios.

We introduce a Monotonic Segmentation Module (MSM), to relieve drawbacks of existing models. The MSM is inspired by the integrate-and-fire (IF) model (Abbott, 1999; Dong and Xu, 2020; Yi et al., 2021). Specifically, IF neuron has two modes: *integrate* and *firing*. In integrate mode, the IF neuron dynamically receives signals and accumulates information; when the received information exceeds a certain threshold, IF neuron enters firing mode, at which time it outputs a signal (a.k.a. spiking), where the accumulated state contains information received in the previous integrate phase; and finally, the IF neuron will reset itself and re-enter the integrate mode once the firing mode ends.

In the MSM, we utilize the integrate-and-fire cycle to dynamically locate the boundaries of meaningful speech segments. At the integrate mode, the model keeps reading and processing speech frames, while at firing mode the model writes the translated tokens. MSM takes the representation from the Acoustic Encoder and uses one of the dimensions as signals for integrate-and-fire. These signals are passed through a Sigmoid function to produce integration weights. Once the weights are accumulated to a certain threshold (e.g. =1.0), the module marks the boundary of the current segment and enters a firing mode. It then aggregates the rest dimensions of encoder representations according to the weights within this segment. These are passed to further processing blocks for WRITE operation.

The MSM operations are defined as follows:

$$\alpha_t = \text{sigmoid}(\mathbf{h}_{t,d}) \quad (2)$$

$$\boldsymbol{l}_u = \sum_{t}^{S_u} \alpha'_t \mathbf{h}_{t,1:d-1} \quad (3)$$

$$\hat{n} = \sum_{t}^{T} \alpha_t \quad (4)$$

$$\alpha'_t = \frac{n^*}{\hat{n}} \alpha_t, \quad (5)$$

Where $\mathbf{h}$ is the acoustic vector as an output of the acoustic encoder, and its subscript denotes the scale value of $\mathbf{h}$ at timestamp t and d-th dimension (*i.e.*, we use the last dimension as the input of IF neurons). The Sigmoid value of the scale $\mathbf{h}_{t,d}$ is the current weight, denoted as α_t. We use the current weight to decide mode conversion from integrate to firing: when the accumulated sum of α_t exceeds the threshold value, the model is believed to have READ sufficient speech signals in this integrate stage, and the IF neural fires the accumulated information $\boldsymbol{l} = (\boldsymbol{l}_1, ..., \boldsymbol{l}_u)$ to fulfill one integrate-and-fire cycle. And S_u represents the firing step corresponding to $\boldsymbol{l}_u$.

Note that the accumulated information $\boldsymbol{l}$ is calculated as a weighted sum of acoustic vectors $\mathbf{h}_t$ at a single integrate stage t. We call it as information weight α'_t, which helps to scale the amount of information contained in each integrate stage. We calculate the information weight α'_t by normalizing the current weight α_t with the number of tokens in the corresponding transcription n^*, which divides the length of the accumulated acoustic vector $\hat{n}$.

Transformer block The last module of the MoSST is the standard Transformer. The Transformer blocks take the integrated acoustic vector $\boldsymbol{l}$ from the MSM layer as the input, which aims to extract the semantic feature ($\mathbf{h}^{SE}$) of the input audio. Since MSM has significantly compressed the length of acoustic features, the Transformer can attend the input and output directly without the excessive computational overhead. Note that to ensure that MSM learns the correct length of acoustic units, we use the length of the corresponding transcription as a supervised signal and introduce length penalty loss ("LP loss" in Figure 2) to assist MSM's learning.

$$\mathcal{L}_{\mathrm{lp}}(\theta; \mathbf{x}, \mathbf{z}) = ||n^* - \hat{n}||_2, \qquad (6)$$

During inference, an extra rounding operation is applied on $\hat{n}$ to simulate n^*. Based on the matched sequence length, the accumulated acoustic vector $\boldsymbol{l}$ is mapped back into the model size by a randomly initialized fully connected layer.

2.3 Training Strategies

Multi-task Joint Training with ASR MoSST jointly fulfills the ST and ASR tasks with the multi-task learning (MTL) strategy as its main model. To distinguish two tasks, we add two special task indicators at the beginning of the text as the *BOS* operator for decoding. For example, if the audio input for "`Thank you .`" is in English, for ASR, we use `[en]` as the *BOS* and decode $\mathbf{z}$= "`[en] Thank you .`". We add `[De]` at the start of German translation, thus $\mathbf{y}$ is "`[De] Danke .`"

Both ST and ASR are optimized with cross-entropy ("CE loss" in Figure 2) losses, defined in Equation (7) and (8) respectively.

$$\mathcal{L}_{st}(\theta; \mathbf{x}, \mathbf{y}) = -\sum_{i=1}^{T_y} \log p_\theta(y_i | y_{<i}, \mathbf{h}^{SE}) \qquad (7)$$

$$\mathcal{L}_{asr}(\theta; \mathbf{x}, \mathbf{z}) = -\sum_{i=1}^{T_z} \log p_\theta(z_i | z_{<i}, \mathbf{h}^{SE}) \qquad (8)$$

where the decoder probability p_θ is calculated from the final softmax layer based on the output of the decoder.

We use the joint training strategy to optimize all modules. The overall objective function is the weighted sum for all aforementioned losses:

$$\mathcal{L}(\theta; \mathbf{x}, \mathbf{y}, \mathbf{z}) = \alpha \mathcal{L}_{\mathrm{lp}}(\theta; \mathbf{x}, \mathbf{z}) + \beta \mathcal{L}_{ce} \qquad (9)$$

Where $\mathcal{L}_{ce}$ represents $\mathcal{L}_{asr}$ or $\mathcal{L}_{st}$. In the following experimental sections, α is set to 0.05, and β is set to 1 by default.

2.4 Inference Strategies

Wait-k Policy MoSST adopts wait-k policy for streaming translation, which originates from simultaneous machine translation (Ma et al., 2019a). Wait-k policy waits for K source tokens and then translates target tokens concurrently with the source streams in (*i.e.*, output N tokens when given $N + K$ source tokens).

The previous online ST systems adopt *Pre-fix Decision* (Ma et al., 2021b, 2020b) for wait-k policy, where a fixed time span (usually 280ms) of the source waveform is regarded as a new unit. However, the pre-fixed decision is limited on real-world scenarios since the speech speed of speakers and the length of acoustic units are distinct, where a fixed time stride guarantees neither sufficient information if the phonemes are too long, nor a proper translation latency if the phonemes are too short.

Adaptive Decision We propose a new decision strategy for streaming speech translation, namely *Adaptive Decision*. Our new strategy dynamically decides when to write the new token according to the integrated state length of MSM (*i.e.*, $|\boldsymbol{l}_u|$ in Equation (5)).

Since MSM scales up the acoustic information monotonically, the model can estimate the acoustic boundary for each units in the audio. We use such integrate feature as a basis to tell whether the information carried by the waveform segment is sufficient; hence the proposed adaptive decision revises the drawbacks in fixed decision.

We propose our new decoding policy in Algorithm 1. The new policy utilizes wait-k to decide when to write new translation tokens and adaptive

Algorithm 1: Adaptive Decision Strategy

```
   Input: The waveform sequence $\mathbf{x}$, the MSM model
          $\mathbf{M}$, wait lagging $K$
   Output: The translated sentence $\hat{\mathbf{y}}$
1  initialization: the read waveform segment $\hat{\mathbf{x}} = []$, the
     output sentence $\hat{\mathbf{y}} = []$;
2  while $\hat{\mathbf{y}}_{i-1}$ is not EndOfSentence do
3      calculate MSM integrated state $\boldsymbol{l}_u$ ;
4      if $\hat{\mathbf{x}} == \mathbf{x}$ ;
5       then
           /* the waveform is finished
              */
           /* write new token            */
6          $\hat{\mathbf{y}} = \hat{\mathbf{y}} +$ decoder.predict();
7          M.decoder.update($\hat{\mathbf{y}}$) ;
8      else if $|\boldsymbol{l}_u| - |\hat{\mathbf{y}}| < K$ ;
9       then
           /* read waveform              */
10         $\hat{\mathbf{x}} = \hat{\mathbf{x}} +$ new_segment($\mathbf{x}$);
11         M.encoder.update($\hat{\mathbf{x}}$)
12     else
           /* write new token            */
13         $\hat{\mathbf{y}} = \hat{\mathbf{y}} +$ decoder.predict();
14         M.decoder.update($\hat{\mathbf{y}}$) ;
15 end
16 return $\hat{\mathbf{y}}$ ;
```

decisions to decide how long the input is regarded as a unit. Specifically, during the online ST translation, the model shall decide whether to read new audio frames or translate a new word at any time, called the READ/WRITE decision. We denote $\hat{\mathbf{x}}$ as the audio sub-sequence that the model has READ from the source and $\hat{\mathbf{y}}$ as the sentence prefix that has been already generated. The wait-k policy makes the READ/WRITE decision according to the length difference between the MSM integrated state $|\boldsymbol{l}_u|$ and the generated sentence $|\hat{\mathbf{y}}|$. When the integrated state $|\boldsymbol{l}_u|$ is K word behind the generated $|\hat{\mathbf{y}}|$, the MoSST generates a new token (line 12) and updates decoder states recursively, otherwise, the model waits and reads the audio streaming (line 9), and updates the encoder states.

Train-full Test-k Streaming translation needs to predict the output based on part of the input. If the *train-full test-k* paradigm is applied, the streaming performance will decrease a lot due to the mismatch between training and inferring. The previous streaming work generally uses a prefix-to-prefix training framework (Ma et al., 2019a), implemented by a unidirectional encoder and decoder, and equipped with the waik-k policy. In MoSST, the learned monotonic segmentation module allows our model to have streaming decoding capability without performance drop.

3 Experiments

3.1 Dataset

MuST-C[1] (Di Gangi et al., 2019a) is a multilingual ST corpus with triplet data sources: source audio, transcripts, and text translations. To the best of our knowledge, MuST-C is currently the largest ST dataset available. It includes data from English TED talks with auto-aligned transcripts and translations at the sentence level. We mainly conduct experiments on English-German and English-French language pairs. And we use the dev and tst-COMMON sets as our development and test data, respectively.

k	1	3	5	7	9	inf
SimulSpeech †	10.73	15.52	16.90	17.46	17.87	18.29
MoSST	**11.76**	**15.57**	**18.23**	**18.71**	**19.37**	**19.95**

Table 1: Comparison with SimulSpeech on MuST-C EN-DE tst-COMMON test set. † represents results from Ren et al. (2020).

3.2 Preprocessing

For speech input, the 16-bit raw wave sequences are normalized by a factor of 2^{15} to the range of $[-1, 1)$. For text input, on each translation pair, all texts (including transcript and translation) are preprocessed in the same way. Texts are case-sensitive. We keep and normalize the punctuations, but remove non-print characters. We tokenize sentences with Moses tokenizer [2] and filter out samples longer than 250 words. For subword modeling, we use a unigram sentencepiece (Kudo and Richardson, 2018) with a dictionary size of 10000. On each translation direction, the sentencepiece model is learned on all text data from ST corpora.

3.3 Model and Experimental Configuration

Model Configuration For audio input, the Wav2Vec2 module follows the base[3] configuration in Baevski et al. (2020). It uses parameters self-supervised pre-trained on LibriSpeech audio data only. The subsequently shared Transformer module has a hidden dimension of 768 and 4 attention heads. The encoder is 8 layers, and the decoder

---

[2] `https://github.com/moses-smt/mosesdecoder/blob/master/scripts/tokenizer/tokenizer.perl`

[3] `https://dl.fbaipublicfiles.com/fairseq/wav2vec/wav2vec_small.pt`

is 6 layers. We use the simplified version of the Continuous IF implementation (Yi et al., 2021) for MSM module, which introduces no additional parameters except for a fully connected layer.

Experimental Configuration We use an Adam optimizer with $\beta_1 = 0.9, \beta_2 = 0.98$, and 4k warm-up updates. We set the maximum training batch of the waveform audio token to be 3.2 million. We apply an inverse square root schedule algorithm for the learning rate. We average 10 consecutive checkpoints around the one with the best dev loss and adopt a beam size of 5. We implement our models in Fairseq (Ott et al., 2019).

3.4 Evaluation

For offline translation, the model's performance is mainly evaluated with quality metrics. While for streaming translation, ST model is evaluated by the latency-quality trade-off curves.

Quality Metrics We quantify translation accuracy with detokenized BLEU (Papineni et al., 2002) using sacreBLEU [5].

Latency Metrics Existing simultaneous translation work mainly focuses on the latency evaluation of text translation, and has proposed computation unaware metrics, such as Average Proportion (AP) (Cho and Esipova, 2016), Average Latency (AL) (Ma et al., 2019a), Continues Wait Length (CW) (Gu et al., 2017b) and Differentiable Average Lagging (DAL) (Cherry and Foster, 2019). Ma et al. (2020a) extends the latency metrics of text translation into ST, including AL, AP, and DAL. The latency metrics for streaming MoSST are evaluated by AL, DAL, and AP based on the SimulEval toolkit [6] (Ma et al., 2020a).

3.5 Experimental Results

3.5.1 Streaming Speech-to-text Translation

We compare the performance of our method with published work on streaming ST tasks. SimulST (Ma et al., 2020b) introduces the wait-k training strategy in simultaneous text translation into simultaneous ST tasks. The comparison result on MuST-C EN-DE tst-COMMON set is shown in Figure 3. It can be seen that MoSST is significantly better than the baseline system in all the three latency metrics and the quality metric. SimulSpeech (Ren et al., 2020) also adopts the wait-k strategy and leverages the connectionist temporal classification (CTC) decoding to split the input streaming speech chunk in real-time. Besides, SimulSpeech introduces attention-level and data-level knowledge distillation (KD) to improve performance. The comparison result on MuST-C EN-DE tst-COMMON set is shown in Table 1. It can be seen that when k ranges from 1 to infinite, our method significantly outperforms SimulSpeech. Existing work all uses the wait-k training strategy implemented with a unidirectional mask, which would damage the performance of offline evaluation in full context. While MoSST can serve well both non-streaming and streaming translation. At the same time, the shrinking mechanism based on the MSM can speed up model convergence, which we give a detailed analysis in Sec A.2.2 of the Appendix.

3.5.2 No-streaming Speech-to-text Translation

We also compare the performance of our method with published work on offline ST tasks under experimental settings without external supervised training data. The result is shown in Table 2. Fairseq (Wang et al., 2020a), ESPnet (Inaguma et al., 2020), and NeurST (Zhao et al., 2020) are recently emerging R&D toolkits for ST. Transformer ST uses a standard SpeechTransformer (Dong et al., 2018) model structure, with a pre-trained ASR model to initialize the encoder and a pre-trained MT model to initialize the decoder. Zhang et al. (2020a) propose adaptive feature selection (AFS) for ST, which applies $\mathcal{L}_0$Drop (Zhang et al., 2020b) to dynamically estimate the importance of each encoded speech feature. STAST (Liu et al., 2020b) uses a speech-to-text adaptation method to bridge the modality gap in the semantic space by MTL and representation regulation with MT. Le et al. (2020) adapt the dual-decoder transformer with a dual-attention mechanism to joint ASR and ST for both bilingual (BL) and multilingual (ML) settings. Compared with the best results published so far, MoSST can achieve an improvement of 1.3 BLEU and 0.7 BLEU respectively. It should be noted that the previous methods can be integrated into MoSST to expect better performance. We will leave it for further exploration.

Table 2: Results of non-streaming ST models on MuST-C EN-DE and EN-FR tst-COMMON test set. † indicates our improvement is statistically significant.

Model	**EN-DE**		**EN-FR**	
	BLEU	▽	BLEU	▽
MoSST	**24.9**	-	**35.3**	-
w/o MSM	22.7	-2.2	34.4	-0.9
w/o MTL	21.9	-0.8	33.8	-0.6
w/o Pretrain	20.0	-1.9	31.6	-2.2

Table 3: Results of ablation study on MuST-C EN-DE and EN-FR tst-COMMON test set. “w/o MSM” stands for MoSST augmented without the monotonic segmentation module in the acoustic encoder.“w/o MTL” means removing multi-task joint learning with ASR task. “w/o Pretrain” represents using FBANK as input instead of the self-supervised acoustic representation.

4 Analysis

4.1 Ablation Studies

We conduct ablation studies to demonstrate the effectiveness of the design of MoSST, including the monotonic segmentation module, multi-task joint training with ASR, and self-supervised acoustic representation. The ablation study results can be seen in Table 3. The translation quality decreases

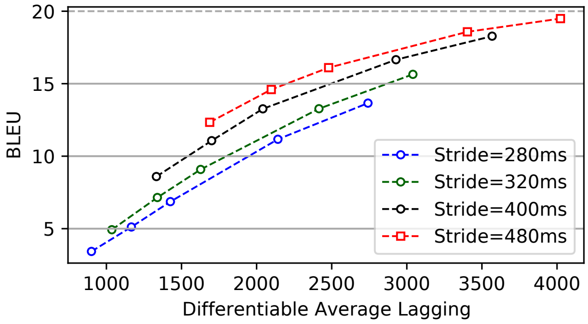

Figure 4: The translation quality against the latency metrics (DAL) on the tst-COMMON set of MuST-C En-De dataset. Decoding strategy here is pre-fixed decision. Points on the curve correspond to k in SimulEval with 5, 7, 9, 15 and 20, respectively.

significantly when each of the modules or strategies is emitted successively. The self-supervised acoustic representation can bring almost 2 BLEU on both EN-DE and EN-FR datasets, which shows that large-scale SSL brings hope to solving the data scarcity problem of end-to-end ST. For EN-DE language pair, joint training with the auxiliary ASR task has a performance gain of 0.8 BLEU. And the monotonic segmentation module has an additional 2.2 performance gain to our method. The results show a consistent performance improvement on EN-FR language pair. This verifies the outstanding advantage of the monotonic soft attention mechanism of MSM in extracting contextual acoustic representations.

4.2 Effects of Decoding Strategy

4.2.1 Pre-fix Decision

For the pre-fixed decision decoding strategy, the parameter setting of stride is very important. In Fig-

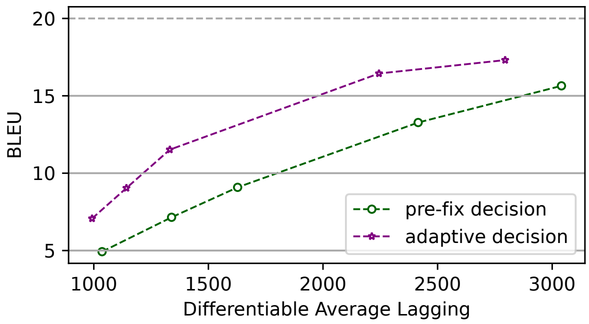

Figure 5: The translation quality against the latency metrics (DAL) on the tst-COMMON set of MuST-C En-De dataset. Pre-fixed decision is tested with the stride size of 320ms.

ure 4, we compare the influence of different strides on the pre-fixed decision strategy. It can be seen that increasing stride within a certain range will have a positive impact on the latency-bleu trade-off. But the model also tends to fall into the field of a larger latency.

4.2.2 Adaptive Decision

We have proposed an adaptive decision in Section 2.4. To better emphasize the latency factor, we compare the performance of the adaptive decision and the pre-fixed decision on the tst-COMMON test subset of MuST-C EN-DE. The results are shown in Figure 5. Compared with the pre-fixed strategy decoding method, the adaptive strategy decoding method has a better balance between delay and quality. Through observation, it is found that the adaptive strategy can ignore the silent frames. For example, after predicting a punctuation, it will read continuously to accumulate enough source acoustic information. In addition, the adaptive strategy can further reduce the delay by setting the number of WRITE operations after the accumulated information is sufficient according to the length ratio of the source sentences and the target sentences between different language pairs, which requires further exploration.

4.2.3 Alignment Visualization

In Figure 6, we show the ground truth alignment and the predicted firing positions learned by MoSST. We can see that what MSM learned is the acoustic boundary, not to mimic wait-k. Therefore, the length of the audio chunk can be adaptively read in during streaming decoding, while ensuring that each chunk includes a complete acoustic unit.

5 Related Work

Speech Translation Bérard et al. (2016) have given the first proof of the potential for end-to-end speech-to-text translation without using the intermediate transcription. The training method based on pre-training (Weiss et al., 2017; Bérard et al., 2018; Livescu and Goldwater, 2019; Bansal et al., 2019; Alinejad and Sarkar, 2020; Stoian et al., 2020; Dong et al., 2021a) can effectively use pre-trained models with better performance as initialization to speed up the convergence of the ST model. Multi-task learning (Weiss et al., 2017; Bérard et al., 2018; Liu et al., 2020a; Indurthi et al., 2020; Han et al., 2021; Ye et al., 2021) can fully optimize the model parameters and improve the performance with the aid of auxiliary tasks. Knowledge distillation has been proved to be efficient to learn from pre-trained models (Liu et al., 2019, 2020b; Dong et al., 2021b). Le et al. (2021) introduce adapter for multilingual speech translation. Similarly, Kano et al. (2017); Wang et al. (2020b) introduce curriculum learning methods, including different learning courses of increasing difficulty. To overcome data scarcity, Jia et al. (2019); Pino et al. (2019) augment data with pseudo-label generation, and Bahar et al. (2019); Di Gangi et al. (2019b); McCarthy et al. (2020) introduce noise-based spectrum feature enhancement. Zhang et al. (2020a) propose adaptive feature selection to eliminate uninformative features and improve performance.

Streaming Speech Translation Traditional streaming ST is usually formed by cascading a streaming ASR module and a streaming machine translation module (Oda et al., 2014; Dalvi et al., 2018). The ASR system continuously segments and recognizes the transcription of the audio segment, and then the machine translation system continuously translates the text segment output from the upstream. Most of the previous work focuses on simultaneous text translation (Gu et al., 2017a). Gu et al. (2017a) learn an agent to decide when to read or write. Ma et al. (2019a) propose a novel wait-k strategy based on the prefix-to-prefix framework to synchronize output after reading k history tokens. Many following work propose some improvement strategies based on adaptive wait-k (Zheng et al., 2019; Zhang et al., 2020c; Zhang and Zhang, 2020) and efficient decoding (Elbayad et al., 2020; Zheng et al., 2020). Some monotonic attention methods (Arivazhagan et al., 2019; Ma et al., 2019b;

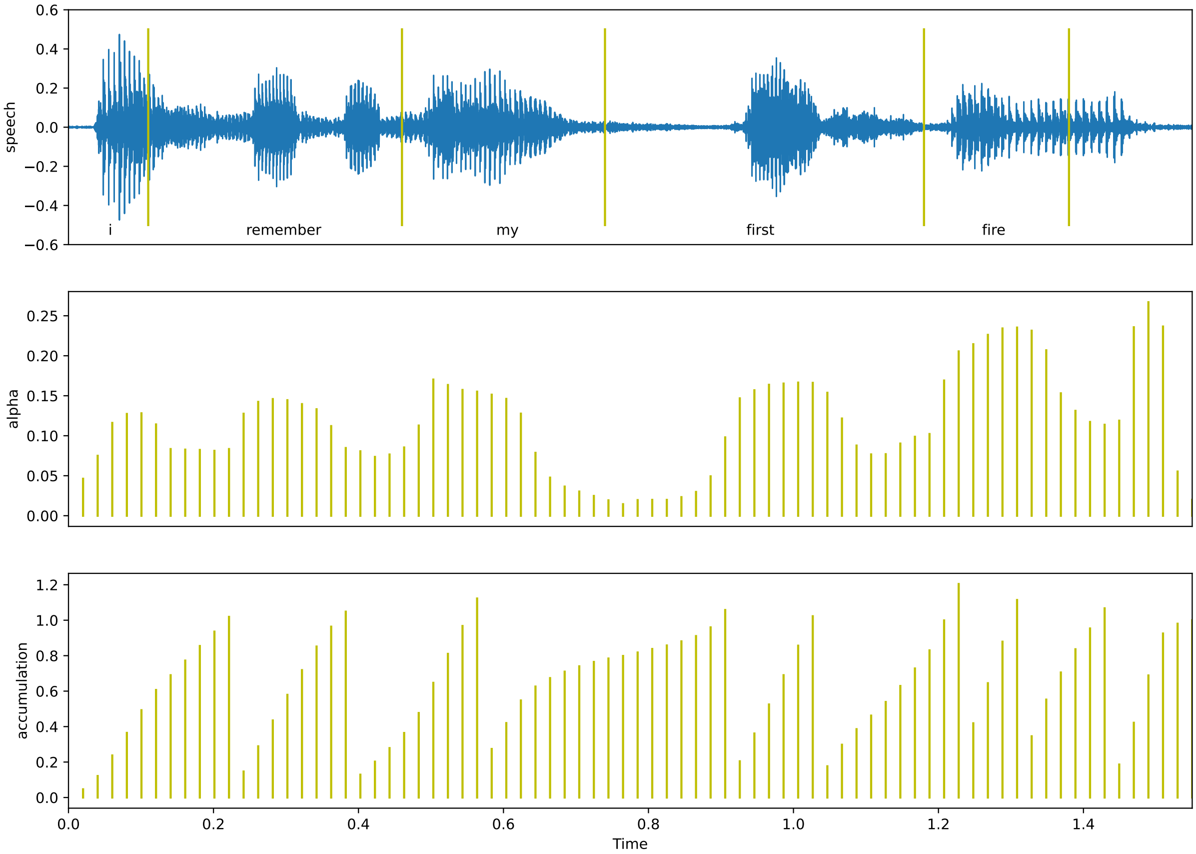

Figure 6: An example speech and its corresponding learned firing positions by MoSST. Top: the waveform of speech sequence and the true segmentation boundary corresponding to each word. Middle: the learned weights (corresponding to α in Eq.(2)) using the last dimension from acoustic encoder states. Bottom: the integrated weights by MSM in MoSST. MSM will fire and start to compute the segment's representation once the accumulated weights exceed a certain threshold (=1.0).

Schneider and Waibel, 2020) have been proposed to model the monotonic alignment of input and output. Arivazhagan et al. (2020a,b) propose a re-translation strategy, allowing the model to modify the decoding history to improve the performance of streaming translation. Ma et al. (2020b) propose SimulST, which applies the wait-k method from streaming machine translation (Ma et al., 2019a) into streaming ST. Ren et al. (2020) propose SimulSpeech, which uses knowledge distillation to guide the training of the streaming model and the connectionist temporal classification (CTC) decoding to segment the audio stream in real-time. Ma et al. (2021a) enable the streaming model to handle long input by equipping with an augmented memory encoder. Chen et al. (2021) use a separate and synchronized ASR decoder to guide the ST decoding policy. Zeng et al. (2021b) introduce a blank penalty to enhance performance in simultaneous scenarios.

6 Conclusion

We propose MoSST, a simple and effective framework for online speech-to-text translation. MoSST consists of a pretrained acoustic model, a monotonic segmentation module, and a standard Transformer, along with the multitask training strategy and the adaptive decision strategy. The monotonic segmentation module and the adaptive decision strategy tell our method when to translate. Moreover, the pre-trained acoustic encoder and the multitask training strategy boost our method's ability to predict what to generate.

The experiment on MUST-C datasets validates the effectiveness of MoSST over previous work. The results show that MoSST can achieve a better trade-off between quality and latency over prior end-to-end models and cascaded models in diverse latency settings. Besides, we also find MoSST can rival non-streaming speech translation SOTA systems given the complete audio waveform.

A Appendix

A.1 Case Study

A.1.1 Streaming Translation

In Table 9, we show an example of simultaneous decoding for cascaded systems and end-to-end systems. The cascade system has the drawbacks of error accumulation and delay accumulation. While the end-to-end model has inherent advantages in this respect. For example, in this example, our method can attend to the speaker's prosody information from the original audio input, such as pauses, so it can accurately predict the punctuation in the target language text.

A.2 Effects of MSM

A.2.1 Performance on ASR

We also validate the effects of MSM with FBANK as input on the ASR task on MuST-C EN-DE tst-COMMON set. The results are shown in Table 4. There is also a performance improvement of 1.5 points, indicating that the integrate-and-fire model indeed plays an important role in learning encoded shrunk acoustic representation.

Model	ASR (WER ↓)
SpeechTransformer	15.95
SpeechTransformer w/ MSM	**14.48**

Table 4: Results of ASR models on MuST-C EN-DE tst-COMMON set.

A.2.2 Training Time

Our method can be trained in parallel without the help of wait-k strategy, which observably improves training efficiency. And the integration mechanism of MSM module can effectively reduce the output length of the encoder, which can reduce memory usage and increase training batch size. We experiment with FBANK feature as input on MuST-C EN-DE data set. The training time (4 Tesla-V100) for different structures is shown in Table 5.

Model	Training Time ↓
SpeechTransformer w/ wait-k	18 hours
SpeechTransformer w/ MSM	**13 hours**

Table 5: Training time of ST models on MuST-C EN-DE data set.

A.4 Compared with Cascaded System

We build a streaming cascaded system as a baseline system by cascading a streaming speech recognition model and a text translation model. Note that the transcription generated by ASR system in the cascade streaming system is also uncorrectable. The results are shown in Table 10. The error accumulation problem of the cascade system still exists in the streaming model. Compared with the results of the cascaded system, MoSST also has obvious performance advantages in terms of quality metrics.

	1	2	3	4	5	6	7	8	9	10	11	12	13	14
En (Source)	If	you	have	something	to	give	,	give	it	now	.			
De (target)	Wenn	Sie	etwas	zu	geben	haben	,	geben	Sie	es	jetzt	.		
ASR	If	you	have	something	to	give	and	give	it	now	.			
Cascades				Wenn	Sie	etwas	zu	geben	haben	und	es	jetzt	geben	.
MoSST				Wenn	Sie	etwas	geben	,	geben	Sie	es	jetzt	.	

Table 9: An example from the test set of MuST-C En-De dataset. “ASR” means a streaming system with 440ms’ waiting latency. “Cascades” means a streaming pipeline contains ASR (wait-440ms) and NMT (wait-3). MoSST represents MoSST with the pre-fixed decision and wait-3 strategy.

System	$k = 1$	$k = 2$	$k = 3$	$k = 4$	$k = 5$	$k = 6$	$k = 7$	$k = \text{inf}$
ASR (WER↓)	51.9	43.9	42.1	40.6	39.6	39.0	38.7	16.25
MT (BLEU↑)	17.11	19.68	22.80	24.93	26.44	27.20	27.83	31.28
Cascaded ST (BLEU↑)	9.72	11.24	12.74	13.92	14.59	15.22	15.51	17.60

Table 10: Results of Cascaded Systems on MuST-C EN-DE tst-COMMON test set. For $k = \text{inf}$, the streaming model degrades into an offline model without beam search decoding strategy. Here the ASR model is based on SpeechTransformer (Dong et al., 2018), and the MT model is based on Transformer (Vaswani et al., 2017). Since the delays of cascaded system involving speech recognition and text translation modules are more complicated, latency metrics are not reported here. Note that cascaded ST is consisted of streaming ASR (wait-440ms, segment-40ms) and streaming MT system.

Compact Token Representations with Contextual Quantization for Efficient Document Re-ranking

Yingrui Yang, Yifan Qiao, Tao Yang
Department of Computer Science, University of California at Santa Barbara, USA
`{yingruiyang, yifanqiao, tyang}@cs.ucsb.edu`

Abstract

Transformer based re-ranking models can achieve high search relevance through context-aware soft matching of query tokens with document tokens. To alleviate runtime complexity of such inference, previous work has adopted a late interaction architecture with pre-computed contextual token representations at the cost of a large online storage. This paper proposes contextual quantization of token embeddings by decoupling document-specific and document-independent ranking contributions during codebook-based compression. This allows effective online decompression and embedding composition for better search relevance. This paper presents an evaluation of the above compact token representation model in terms of relevance and space efficiency.

1 Introduction

Modern search engines for text documents typically employ multi-stage ranking. The first retrieval stage extracts top candidate documents matching a query from a large search index with a simple ranking method. The second stage or a later stage uses a more complex machine learning algorithm to re-rank top results thoroughly. Recently neural re-ranking techniques from transformer-based architectures have achieved impressive relevance scores for top k document re-ranking, such as MacAvaney et al. (2019). However, using a transformer-based model to rank or re-rank is extremely expensive during the online inference (Lin et al., 2020). Various efforts have been made to reduce its computational complexity (e.g. Gao et al. (2020)).

A noticeable success in time efficiency improvement is accomplished in ColBERT (Khattab and Zaharia, 2020) which conducts late interaction of query terms and document terms during runtime inference so that token embeddings for documents can be pre-computed. Using ColBERT re-ranking after a sparse retrieval model called DeepImpact (Mallia et al., 2021) can further enhance relevance. Similarly BECR (Yang et al., 2022), CEDR-KNRM (MacAvaney et al., 2019), and PreTTR (MacAvaney et al., 2020) have also adopted the late interaction architecture in their efficient transformer based re-ranking schemes.

While the above work delivers good search relevance with late interaction, their improvement in time efficiency has come at the cost of a large storage space in hosting token-based precomputed document embeddings. For example, for the MS MARCO document corpus, the footprint of embedding vectors in ColBERT takes up to 1.6TB and hosting them in a disk incurs substantial time cost when many embeddings are fetched for re-ranking. It is highly desirable to reduce embedding footprints and host them in memory as much as possible for fast and high-throughput access and for I/O latency and contention avoidance, especially when an online re-ranking server is required to efficiently process many queries simultaneously.

The **contribution** of this paper is to propose a compact representation for contextual token embeddings of documents called Contextual Quantization (CQ). Specifically, we adopt codebook-based quantization to compress embeddings while explicitly decoupling the ranking contributions of document specific and document-independent information in contextual embeddings. These ranking contributions are recovered with weighted composition after quantization decoding during online inference. Our CQ scheme includes a neural network model that jointly learns context-aware decomposition and quantization with an objective to preserve correct ranking scores and order margins. Our evaluation shows that CQ can effectively reduce the storage space of contextual representation by about 14 times for the tested datasets with insignificant online embedding recovery overhead and a small relevance degradation for re-ranking passages or documents.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 695 - 707

2 Problem Definition and Related Work

The problem of neural text document re-ranking is defined as follows. Given a query with multiple terms and a set of candidate documents, rank these documents mainly based on their embeddings and query-document similarity. With a BERT-based re-ranking algorithm, typically a term is represented by a token, and thus in this paper, word "term" is used interchangeably with "token". This paper is focused on minimizing the space cost of token embeddings for fast online re-ranking inference.

Deep contextual re-ranking models. Neural re-ranking has pursued representation-based or interaction-based algorithms (Guo et al., 2016; Dai et al., 2018; Xiong et al., 2017). Embedding interaction based on query and document terms shows an advantage in these studies. The transformer architecture based on BERT (Devlin et al., 2019) has been adopted to re-ranking tasks by using BERT's [CLS] token representation to summarize query and document interactions (Nogueira and Cho, 2019; Yang et al., 2019; Dai and Callan, 2019; Nogueira et al., 2019a; Li et al., 2020). Recently BERT is integrated in late term interaction (MacAvaney et al., 2019; Hofstätter et al., 2020c,b; Mitra et al., 2021) which delivers strong relevance scores for re-ranking.

Efficiency optimization for transformer-based re-ranking. Several approaches have been proposed to reduce the time complexity of transformer-based ranking. For example, architecture simplification (Hofstätter et al., 2020c; Mitra et al., 2021), late interaction with precomputed token embeddings (MacAvaney et al., 2020), early exiting (Xin et al., 2020), and model distillation (Gao et al., 2020; Hofstätter et al., 2020a; Chen et al., 2020b). We will focus on the compression of token representation following the late-interaction work of ColBERT (Khattab and Zaharia, 2020) and BECR (Yang et al., 2022) as they deliver fairly competitive relevance scores for several well-known ad-hoc TREC datasets. These late-interaction approaches follow a dual-encoder design that separately encodes the two sets of texts, studied in various NLP tasks (Zhan et al., 2020; Chen et al., 2020a; Reimers and Gurevych, 2019; Karpukhin et al., 2020; Zhang et al., 2020).

Several previous re-ranking model attempted to reduce the space need for contextual token embeddings. ColBERT has considered an option of using a smaller dimension per vector and limiting 2 bytes per number as a scalar quantization. BECR (Yang et al., 2022) uses LSH for hashing-based contextual embedding compression (Ji et al., 2019). PreTTR (MacAvaney et al., 2020) uses a single layer encoder model to reduce the dimensionality of each token embedding. Following PreTTR, a contemporaneous work called SDR in Cohen et al. (2021) considers an autoencoder to reduce the dimension of representations, followed by an off-the-shelf scalar quantizer. For the autoencoder, it combines static BERT embeddings with contextual embeddings. Inspired by this study, our work decomposes contextual embeddings to decouple ranking contributions during vector quantization. Unlike SDR, CQ jointly learns the codebooks and decomposition for the document-independent and dependent components guided by a ranking loss.

Vector quantization. Vector quantization with codebooks was developed for data compression to assist approximate nearest neighbor search, for example, product quantizer (PQ) from Jégou et al. (2011), optimized product quantizer (OPQ) from Ge et al. (2013); residual additive quantizer(RQ) from Ai et al. (2015) and local search additive quantizer (LSQ) from Martinez et al. (2018). Recently such a technique has been used for compressing static word embeddings (Shu and Nakayama, 2018) and document representation vectors in a dense retrieval scheme called JPQ (Zhan et al., 2021a). None of the previous work has worked on quantization of contextual token vectors for the re-ranking task, and that is the focus of this paper.

3 Contextual Quantization

Applying vector quantization naively to token embedding compression does not ensure the ranking effectiveness because a quantizer-based compression is not lossless, and critical ranking signals could be lost during data transformation. To achieve a high compression ratio while maintaining the competitiveness in relevance, we consider the ranking contribution of a contextual token embedding for soft matching containing two components: 1) document specific component derived from the self attention among context in a document, 2) document-independent and corpus-specific component generated by the transformer model. Since for a reasonable sized document set, the second component is invariant to documents, its storage space is negligible compared to the first component. Thus the second part does not need compres-

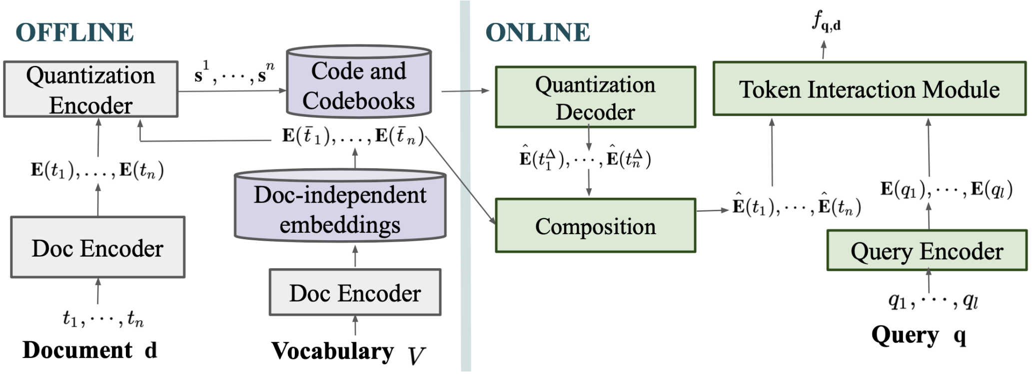

Figure 1: Offline processing and online ranking with contextual quantization

sion. We focus on compressing the first component using codebooks. This decomposition strategy can reduce the relevance loss due to compression approximation, which allows a more aggressive compression ratio. Our integrated vector quantizer with contextual decomposition contains a ranking-oriented scheme with an encoder and decoder network for jointly learning codebooks and composition weights. Thus, the online composition of decompressed document-dependent information with document-independent information can retain a good relevance.

3.1 Vector Quantization and Contextual Decomposition

A vector quantizer consists of two steps as discussed in Shu and Nakayama (2018). In the compression step, it encodes a real-valued vector (such as a token embedding vector in our case) into a short code using a neural encoder. The short code is a list of reference indices to the codewords in codebooks. During the decompression step, a neural decoder is employed to reconstruct the original vector from the code and codebooks.

The quantizer learns a set of M codebooks $\{\mathcal{C}^1, \mathcal{C}^2, \cdots, \mathcal{C}^M\}$ and each codebook contains K codewords ($\mathcal{C}^m = \{\mathbf{c}_1^m, \mathbf{c}_2^m, \cdots, \mathbf{c}_K^m\}$) of dimension h. Then for any D-dimensional real valued vector $\mathbf{x} \in \mathbb{R}^D$, the encoder compresses $\mathbf{x}$ into an M dimensional code vector $\mathbf{s}$. Each entry of code $\mathbf{s}$ is an integer j, denoting the j-th codeword in codebook $\mathcal{C}^m$. After locating all M codewords as $[\mathbf{c}^1, \cdots, \mathbf{c}^M]$, the original vector can be recovered with two options. For a product quantizer, the dimension of codeword is $h = D/M$, and the decompressed vector is $\hat{\mathbf{x}} = \mathbf{c}^1 \circ \mathbf{c}^2 \cdots \circ \mathbf{c}^M$ where symbol $\circ$ denotes vector concatenation. For an additive quantizerthe decompressed vector is $\hat{\mathbf{x}} = \sum_{j=1}^{M} \mathbf{c}^j$.

Codebook-based contextual quantization. Now we describe how codebook-based compression is used in our contextual quantization. Given a token t, we consider its contextual embedding vector $\mathbf{E}(t)$ as a weighted combination of two components: $\mathbf{E}(t^{\Delta})$ and $\mathbf{E}(\bar{t})$. $\mathbf{E}(t^{\Delta})$ captures the document-dependent component, and $\mathbf{E}(\bar{t})$ captures the document-independent component discussed earlier. For a transformer model such as BERT, $\mathbf{E}(t)$ is the token output from the last encoder layer, and we obtain $\mathbf{E}(\bar{t})$ by feeding [CLS] $\circ\, t \circ$ [SEP] into BERT model and taking last layer's output for t.

During offline data compression, we do not explicitly derive $\mathbf{E}(t^{\Delta})$ as we only need to store the compressed format of such a value, represented as a code. Let $\hat{\mathbf{E}}(t^{\Delta})$ be the recovered vector with codebook-based decompression, as a close approximation of $\mathbf{E}(t^{\Delta})$. Let $\hat{\mathbf{E}}(t)$ be the final composed embedding used for online ranking with late-interaction. Then $\hat{\mathbf{E}}(t) = g(\hat{\mathbf{E}}(t^{\Delta}), \mathbf{E}(\bar{t}))$ where $g(.)$ is a simple feed-forward network to combine two ranking contribution components.

The encoder/decoder neural architecture for contextual quantization. We denote a token in a document $\mathbf{d}$ as t. The input to the quantization encoder is $\mathbf{E}(t) \circ \mathbf{E}(\bar{t})$. The output of the quantization encoder is the code vector $\mathbf{s}$ of dimension M. Let code $\mathbf{s}$ be $(s_1, \cdots, s_m, \cdots, s_M)$ and each entry s_m will be computed below in Eq. 4. This computation uses the hidden layer $\mathbf{h}$ defined as:

$$\mathbf{h} = \tanh(\mathbf{w}_0(\mathbf{E}(t) \circ \mathbf{E}(\bar{t})) + \mathbf{b}_0). \qquad (1)$$

The dimension of $\mathbf{h}$ is fixed as $1 \times MK/2$. The hidden layer $\mathbf{a}$ is computed by a feed forward layer with a softplus activation (Eq. 2) with an output dimension of $M \times K$ after reshaping, Let $\mathbf{a}^m$ be the m-th row of this output.

$$\mathbf{a}^m = \text{softplus}(\mathbf{w}_1^m \mathbf{h} + \mathbf{b}_1^m). \quad (2)$$

To derive a discrete code entry for s_m, following the previous work (Shu and Nakayama, 2018), we apply the Gumbel-softmax trick (Maddison et al., 2017; Jang et al., 2017) as shown in Eq. 3, where the temperature τ is fixed at 1 and ϵ_k is a noise term sampled from the Gumbel distribution $-\log(-\log(\text{Uniform}[0,1]))$. Here $\mathbf{p}^m$ is a vector with dimension K. $(\mathbf{p}^m)_j$ is the j-th entry of the vector. Similarly, $(\mathbf{a}^m)_j$ is the j-th entry of $\mathbf{a}^m$.

$$(\mathbf{p}^m)_j = \frac{\exp(\log((\mathbf{a}^m)_j + \epsilon_j)/\tau)}{\sum_{j'=1}^{K} \exp(\log((\mathbf{a}^m)_{j'} + \epsilon_{j'})/\tau)}. \quad (3)$$

$$s_m = \arg \max_{1 \le j \le K} (\mathbf{p}^m)_j. \quad (4)$$

In the decompression stage, the input to the quantization decoder is the code $\mathbf{s}$, and this decoder accesses M codebooks $\{\mathcal{C}^1, \mathcal{C}^2, \cdots, \mathcal{C}^M\}$ as M parameter matrices of size $K \times h$ which will be learned. For each m-entry of code $\mathbf{s}$, s_m value is the index of row vector in $\mathcal{C}^m$ to be used as its corresponding codeword. Once all codewords $\mathbf{c}^1$ to $\mathbf{c}^M$ are fetched, we recover the approximate vector $\hat{\mathbf{E}}(t^\Delta)$ as $\sum_{j=1}^{M} \mathbf{c}^j$ for additive quantization or $\mathbf{c}^1 \circ \mathbf{c}^2 \cdots \circ \mathbf{c}^M$ for product quantization.

Next, we perform a composition with a one-layer or two-layer feed-forward network to derive the contextual embedding as $\hat{\mathbf{E}}(t) = g(\hat{\mathbf{E}}(t^\Delta, \mathbf{E}(\bar{t}))$. With one feed-forward layer,

$$\hat{\mathbf{E}}(t) = \tanh(\mathbf{w}_2(\hat{\mathbf{E}}(t^\Delta) \circ \mathbf{E}(\bar{t})) + \mathbf{b}_2). \quad (5)$$

The above encoder and decoder for quantization have parameter $\mathbf{w}_0, \mathbf{b}_0, \mathbf{w}_1, \mathbf{b}_1, \mathbf{w}_2, \mathbf{b}_2$, and $\{\mathcal{C}^1, \mathcal{C}^2, \cdots, \mathcal{C}^M\}$. These parameters are learned through training. Once these parameters are learned, the quantization model is fixed and the code for any new token embedding can be computed using Eq. 4 in offline processing.

Figure 1 depicts the flow of offline learning and the online inference with context quantization. Given a query with l tokens $\{q_1, q_2, ..q_l\}$, and a documents with n tokens $\{t_1, t_2, ..t_n\}$, The query token embeddings encoded with a transformer based model (e.g. BERT) are denoted as $\mathbf{E}(q_1), \cdots, \mathbf{E}(q_l)$. The embeddings for document tokens through codebook base decompression are $\hat{\mathbf{E}}(t_1), \cdots \hat{\mathbf{E}}(t_n)$. The online inference then uses the interaction of query tokens and document tokens defined in a re-ranking algorithm such as ColBERT to derive a ranking score (denoted as $f_{\mathbf{q},\mathbf{d}}$).

The purpose of injecting $\mathbf{E}(\bar{t})$ in Eq. 1 is to decouple the document-independent ranking contribution from contextual embedding $\hat{\mathbf{E}}(t^\Delta)$ so that this quantization encoder model will be learned to implicitly extract and compress the document-dependent ranking contribution.

Table 1 gives an example with several token codes produced by CQ for different sentences representing different contexts, and illustrates context awareness of CQ's encoding with a small codebook dimension (M=K=4). For example, 1 in code [4, 4, 3, 1] means the 4-th dimension uses the first codeword of the corresponding codebook. Training of CQ uses the MS MARCO passage dataset discussed in Section 4 and these sentences are not from this dataset. Our observation from this example is described as follows. First, in general token codes in the same sentences are closer to each other, and token codes in different sentences, even with the same word "bank", are far away with a visible Hamming distance. Thus CQ coding allows a context-based separation among tokens residing in different contexts. Second, by looking at boldfaced tokens at each sentence, their distance in terms of contextual semantics and proximity is reflected to some degree in their CQ codes. For instance, a small Hamming code distance of three words "actor", "poet" and "writer" resembles their semantic and positional closeness. A larger code distance of two "bank"s in the 3^{rd} and 4^{th} sentences relates with their word sense and positional difference.

Training loss for parameter learning. We have explored three training loss functions. The first option is to follow a general quantizer (Shu and Nakayama, 2018) using the mean squared error (MSE) between the reconstructed and original embedding vectors of all token t_i. Namely $\mathcal{L}_{MSE} = \sum \|\mathbf{E}(t_i) - \hat{\mathbf{E}}(t_i)\|_2^2$.

The second option is the pairwise cross-entropy loss based on rank orders. After warming up with the MSE loss, we further train the quantizer using $\mathcal{L}_{PairwiseCE} = \sum(-\sum_{j=\mathbf{d}^+,\mathbf{d}^-} P_j \log P_j)$ where $\mathbf{d}^+$ and $\mathbf{d}^-$ are positive and negative documents for query q.

We adopt the third option which borrows the idea of MarginMSE loss from Hofstätter et al. (2020a) proposed for BERT-based ranking model distillation. In MarginMSE, a student model is trained to

Context	**Token codes**		
William Shakespeare was widely regarded as the world's greatest **actor**, **poet**, **writer** and dramatist.	writer [4,4,3,1]	actor [4,4,3,1]	poet [1,4,3,1]
I would like to have either a cup of **coffee** or a good **fiction** to kill time.	coffee [3,3,3,4]	fiction [3,1,3,4]	
She sat on the river **bank** across from a series of wide, large steps leading up a hill to the **bank** of America building.	1^{st} bank [3,1,4,2]	2^{nd} bank [4,1,3,1]	
Some language techniques can recognize word senses in phrases such as a river **bank** and a **bank** building.	1^{st} bank [4,3,2,2]	2^{nd} bank [3,1,1,4]	
If you **get** a cold, you should drink a lot of water and **get** some rest.	1^{st} get [2,2,4,2]	2^{nd} get [2,1,2,4]	

Table 1: Example context-aware token codes produced by CQ using M=K=4 for the illustration purpose.

mimic the teacher model in terms of both ranking scores as well as the document relative order margins. In our case, the teacher model is the ranking model without quantization and the student model is the ranking model with quantization. It is defined as $\mathcal{L}_{MarginMSE} = \sum((f_{\mathbf{q},\mathbf{d}^+} - f_{\mathbf{q},\mathbf{d}^-}) - (\hat{f}_{\mathbf{q},\mathbf{d}^+} - \hat{f}_{\mathbf{q},\mathbf{d}^-}))^2$, where $f_{\mathbf{q},\mathbf{d}}$ and $\hat{f}_{\mathbf{q},\mathbf{d}}$ denote the ranking score with and without quantization, respectively. The above loss function distills the ColBERT ranking characteristics into the CQ model for better preservation of ranking effectiveness.

3.2 Related Online Space and Time Cost

Online space for document embeddings. The storage cost of the precomputed document embeddings in a late-interaction re-ranking algorithm is dominating its online space need. To recover token-based document embeddings, an online server with contextual quantization stores three parts: codebooks, the short codes of tokens in each document, and the document-independent embeddings.

Given a document collection of Z documents of length n tokens on average, let V be the number of the distinct tokens. For M codebooks with $M * K$ codewords of dimension h, we store each entry of a codeword with a 4-byte floating point number. Thus the space cost of codebooks is $M * K * h * 4$ bytes, and the space for document-independent embeddings of dimension D is $V * D * 4$ bytes. When $M = 16, K = 256$, $D = 128$ as in our experiments, if we use the product quantization with the hidden dimension $h = 8$, the codebook size is 131 MB. In the WordPiece English token set for BERT, $V \approx 32K$ and the space for document-independent embeddings cost about 16.4 MB. Thus the space cost of the above two parts is insignificant.

The online space cost of token-based document embeddings is $Z * n * (\frac{M \log_2 K}{8} + 2)$ bytes. Here each contextual token embedding of length D is encoded into a code of length M and the space of each code costs $\log_2 K$ bits. For each document, we also need to store the IDs of its tokens in order to access document-independent embeddings. We use 2 bytes per token ID in our evaluation because the BERT dictionary based on WordPiece (Wu et al., 2016) tokenizer has about 32,000 tokens.

In comparison, the space for document embeddings in ColBERT with 2 bytes per number costs $Z{*}D{*}n{*}2$ bytes. Then the space ratio of ColBERT without CQ and with CQ is about $\frac{2D \times 8}{M \log_2 K + 2 \times 8}$, which is about 14:1 when $D = 128$, $M = 16$ and $K = 256$. BECR uses 5 layers of the refinement outcome with the BERT encoder for each token and stores each layer of the embedding with a 256 bit LSH signature. Thus the space cost ratio of BECR over ColBERT-CQ is approximately $\frac{5 \times 256}{M \log_2 K + 2 \times 8}$, which is about 9:1 when $M = 16$ and $K = 256$. We can adjust the parameters of each of ColBERT, BECR, and ColBERT-CQ for a smaller space with a degraded relevance, and their space ratio to CQ remains large, which will be discussed in Section 4.

Time cost for online decompression and composition. Let k be the number of documents to re-rank. The cost of decompression with the short code of a token using the cookbooks is $O(M * h)$ for a product quantizer and $O(M * D)$ for an additive quantizer. Notice $M * h = D$. For a one-layer feed-forward network as a composition to recover the final embedding, the total time cost for decompression and composition is $O(\text{k} * n * D^2)$ with a product quantizer, and $O(\text{k} * n(M * D + D^2))$ with an additive quantizer. When using two hidden layers with D dimensions in the first layer output, there is some extra time cost but the order of time complexity remains unchanged.

Noted that because of using feed-forward layers in final recovery, our contextual quantizer cannot take advantage of an efficiency optimization called asymmetric distance computation in Jégou et al. (2011). Since embedding recovery is only applied to top k documents after the first-stage retrieval, the time efficiency for re-ranking is still reasonable without such an optimization.

4 Experiments and Evaluation Results

4.1 Settings

Dataset	# Query	# Doc	Mean Doc Length	# Judgments per query
MS MARCO passage Dev	6980	8.8M	67.5	1
TREC DL 19 passage	200	–	–	21
TREC DL 20 passage	200	–	–	18
MS MARCO doc Dev	5193	3.2M	1460	1
TREC DL 19 doc	200	–	–	33

Table 2: Dataset statistics. Mean doc length is the average number of WordPiece (Wu et al., 2016) tokens.

Datasets and metrics. The well-known MS MARCO passage and document ranking datasets are used. As summarized the in Table 2, our evaluation uses the MS MARCO document and passage collections for document and passage ranking (Craswell et al., 2020; Campos et al., 2016). The original document and passage ranking tasks provide 367,013 and 502,940 training queries respectively, with about one judgment label per query. The development query sets are used for relevance evaluation. The TREC Deep Learning (DL) 2019 and 2020 tracks provide 200 test queries with many judgment labels per query for each task.

Following the official leader-board standard, for the development sets, we report mean reciprocal rank (MRR@10, MRR@100) for relevance instead of using normalized discounted cumulative gain (NDCG) (Järvelin and Kekäläinen, 2002) because such a set has about one judgment label per query, which is too sparse to use NDCG. For TREC DL test sets which have many judgement lables per query, we report the commonly used NDCG@10 score. We also measure the dominating space need of the embeddings in bytes and re-ranking time latency in milliseconds. To evaluate latency, we uses an Amazon AWS g4dn instance with Intel Cascade Lake CPUs and an NVIDIA T4 GPU.

In all tables below that compare relevance, we perform paired t-test on 95% confidence levels. In Tables 3, 4, and 5, we mark the results with '†' if the compression method result in statistically significant degradation from the ColBERT baseline. In Table 6, '†' is marked for numbers with statistically significant degradation from default setting in the first row.

Choices of first-stage retrieval models. To retrieve top 1,000 results before re-ranking, we consider the standard fast BM25 method (Robertson and Zaragoza, 2009). We have also considered sparse and dense retrievers that outperform BM25. We have used uniCOIL (Lin and Ma, 2021; Gao et al., 2021) as an alternative sparse retriever in Table 3 because it achieves a similar level of relevance as end-to-end ColBERT with a dense retriever, and that of other learned sparse representations (Mallia et al., 2021; Formal et al., 2021b,a). ColBERT+uniCOIL has 0.369 MRR while end-to-end ColBERT has 0.360 MRR on MSMARCO Dev set. Moreover, retrieval with a sparse representation such as uniCOIL and BM25 normally uses much less computing resources than a dense retriever. Relevance numbers reported in some of the previous work on dense retrieval are derived from the exact search as an upper bound of accuracy. When non-exact retrieval techniques such as approximate nearest neighbor or maximum inner product search are used on a more affordable platform for large datasets, there is a visible loss of relevance (Lewis et al., 2021). It should be emphasized that the first stage model can be done by either a sparse or a dense retrieval, and this does not affect the applicability of CQ for the second stage as the focus of this paper.

Re-ranking models and quantizers compared. We demonstrate the use of CQ for token compression in ColBERT in this paper. We compare its relevance with ColBERT, BECR and PreTTR. We chose to apply CQ to ColBERT because assuming embeddings are in memory, ColBERT is one of the fastest recent online re-ranking algorithms with strong relevance scores and CQ addresses its embedding storage weakness. Other re-ranking models compared include: BERT-base (Devlin et al., 2019), a cross encoder re-ranker, which takes a query and a document at run time and uses the last layers output from the BERT [CLS] token to generate a ranking score; TILDEv2 (Zhuang and Zuccon, 2021), which expands each document and additively aggregates precomputed neural scores.

We also evaluate the use of unsupervised quantization methods discussed in Section 2 for ColBERT, including two product quantizers (PQ and OPQ), and two additive quantizers (RQ and LSQ).

Appendix A has additional details on the retrievers considered, re-ranker implementation, training, and relevance numbers cited.

4.2 A Comparison of Relevance

Table 3 and Table 4 show the ranking relevance in NDCG and MRR of the different methods and compare against the use of CQ with ColBERT (marked as ColBERT-CQ). We either report our experiment results or cite the relevance numbers from other papers with a * mark for such a model. For quantization approaches, we adopt M=16, K=256, i.e. compression ratio 14:1 compared to ColBERT.

For the passage task, ColBERT outperforms other re-rankers in relevance for the tested cases. ColBERT-CQ after BM25 or uniCOIL retrieval only has a small relevance degradation with around 1% or less, while only requiring 3% of the storage of ColBERT. The relevance of the ColBERT-CQ+uniCOIL combination is also competitive to the one reported in Mallia et al. (2021) for the ColBERT+DeepImpact combination which has MRR 0.362 for the Dev query set, NDCG@10 0.722 for TREC DL 2019 and 0.691 for TREC DL 2020.

For the document re-ranking task, Table 4 similarly confirms the effectiveness of ColBERT-CQ. ColBERT-CQ and ColBERT after BM25 retrieval also perform well in general compared to the relevance results of the other baselines.

From both Table 3 and Table 4, we observe that in general, CQ significantly outperforms the other quantization approaches (PQ, OPQ, RQ, and LSQ). As an example, we further explain this by plotting the ranking score of ColBERT with and without a quantizer in Figure 2(a). Compared to OPQ, CQ trained with two loss functions generates ranking scores much closer to the original ColBERT ranking score, and this is also reflected in Kendall's τ correlation coefficients of top 1,000 re-ranked results between a quantized ColBERT and the original ColBERT (Figure 2(b)). There are two reasons that CQ outperforms the other quantizers: 1) The previous quantizers do not perform contextual decomposition to isolate intrinsic context-independent information in embeddings, and thus their approximation yields more relevance loss; 2) Their training loss function is not tailored to the re-ranking task.

K=16	62G	5.6G	–	17ms	0.339†
K=4	37G	3.4G	–	17ms	0.326†

Table 5: Embedding space size in bytes for the document ranking task and for the passage ranking task. Re-ranking time per query and relevance for top 1,000 passages in milliseconds on a GPU using the Dev query set. M=16. For ColBERT-OPQ and ColBERT-CQ-undecomposed, K=256. Assume passage embeddings in PreTTR and ColBERT do not fit in memory. '†' is marked for MRR numbers with statistically significant degradation from the ColBERT baseline.

passage corpora, and compares CQ with other approaches. Each MS MARCO document is divided into overlapped passage segments of size up to 400 tokens, and there are 60 tokens overlapped between two consecutive passage segments, following the ColBERT setup. As a result, the number of WordPiece tokens per document changes from 1460 to about 2031 due to the addition of overlapping contextual tokens.

To demonstrate the tradeoff, we also list their estimated time latency and relevance in passage re-ranking as a reference and notice that more relevance comparison results are in Tables 3 and 4. The latency is the total time for embedding decompression/recovery and re-ranking.

For PreTTR and ColBERT, we assume that their passage embedding data cannot fit in memory given their large data sizes. The disk I/O latency number is based on their passage embedding size and our test on a Samsung 870 QVO solid-state disk drive to fetch 1,000 passage embeddings randomly. Their I/O latency takes 110ms or 182ms with single-thread I/O and with no I/O contention, and their disk access can incur much more time when multiple queries are processed in parallel in a server dealing with many clients. For example, fetching 1,000 passage embeddings for each of ColBERT and PreTTR takes about 1,001ms and 3,870ms respectively when the server is handling 16 and 64 queries simultaneously with multiple threads.

For other methods, their passage embedding data is relatively small and we assume that it can be preloaded in memory. The query latency reported in the 4-th column of Table 5 excludes the first-stage retrieval time. The default ColBERT uses embedding dimension 128 and 2 byte floating numbers. ColBERT-small denotes an optional configuration suggested from the ColBERT paper using 24 embedding dimensions and 2-byte floating numbers with a degraded relevance performance.

As shown in Table 5, the embedding footprint of ColBERT CQ uses about 112GB and 10.2GB, respectively for document and passage re-ranking tasks. By looking at the latency difference of ColBERT with and without CQ, the time overhead of CQ for decompression and embedding recovery takes 1ms per query, which is insignificant.

Compared with another quantizer ColBERT-OPQ, ColBERT-CQ can achieve the same level of space saving with $K = 256$ while having a substantial relevance improvement. ColBERT-CQ with $K = 4$ achieves the same level of relevance as ColBERT-OPQ while yielding a storage reduction of 67% and a latency reduction of about 70%. Comparing ColBERT-CQ with no contextual decomposition, under the same space cost, ColBERT-CQ's relevance is 4% higher. CQ with $K = 16$ achieves the same level relevance as ColBERT-CQ-undecomposed with $K = 256$, while the storage of CQ reduces by 44%. Comparing with ColBERT-small which adopts more aggressive space reduction, ColBERT-CQ with $K = 16$ would be competitive in relevance while its space is about 4x smaller.

Comparing with other non-ColBERT baselines (BECR, PreTTR, and TILDEv2), ColBERT-CQ strikes a good balance across relevance, space and latency. For the fast CPU based model (BECR, TILDEv2), our model achieves better relevance with either lower or comparable space usage. For BECR, its embedding footprint with 89.9GB may fit in memory for MS MARCO passages, it becomes very expensive to configure a machine with much more memory for BECR's MS MARCO document embeddings with about 791GB.

4.4 Design Options for CQ

Table 6 shows the relevance scores for the TREC deep learning passage ranking task with different design options for CQ. As an alternative setting, the codebooks in this table use M=16 and K=32 with compression ratio 21:1 compared to ColBERT. Row 1 is the default design configuration for CQ with product operators and 1 composition layer,

	TREC19	**TREC20**
CQ, Product, 1 layer, MarginMSE	0.687	0.713
Different model configurations		
No decomposition. Product	0.663†	0.686
No decomposition. Additive	0.656†	0.693
CQ, Product, 1 layer, raw static embedding	0.655†	0.683†
CQ, Additive, 1 layer	0.693	0.703
CQ, Product, 2 layers	0.683	0.707
CQ, Additive, 2 layers	0.688	0.703
Different training loss functions		
CQ, Product, 1 layer, MSE	0.679	0.704
CQ, Product, 1 layer, PairwiseCE	0.683	0.705

Table 6: NDCG@10 of different design options for CQ in TREC DL passage ranking. If the compression method result in statistically significant degradation from the default setting, '†' is marked.

and the MarginMSE loss function.

Different architecture or quantization options. Rows 2 and 3 of Table 6 denote CQ using product or additive operators without decomposing each embedding into two components, and there is about 4% degradation without such decomposition.

Row 4 changes CQ using the raw static embeddings of tokens from BERT instead of the upper layer outcome of BERT encoder and there is an up to 4.7% degradation. Notice such a strategy is used in SDR. From Row 5 to Row 7, we change CQ to use additive operators or use a two-layer composition. The performance of product or additive operators is in a similar level while the benefit of using two layers is relatively small.

Different training loss functions for CQ. Last two rows of Table 6 use the MSE and PairwiseCE loss functions, respectively. There is an about 1.2% improvement using MarginMSE. Figure 2 gives an explanation why MarginMSE is more effective. While CQ trained with MSE and MarginMSE generates ranking scores close to the original ranking scores in Figure 2(a), the distribution of Kendall's τ correlation coefficients of 1,000 passages in Figure 2(b) shows that the passage rank order derived by CQ with the MarginMSE loss has a better correlation with that by ColBERT.

5 Concluding Remarks

Our evaluation shows the effectiveness of CQ used for ColBERT in compressing the space of token embeddings with about 14:1 ratio while incurring a small relevance degradation in MS MARCO passage and document re-ranking tasks. The quantized token-based document embeddings for the tested cases can be hosted in memory for fast and high-throughput access. This is accomplished by a neural network that decomposes ranking contributions of contextual embeddings, and jointly trains context-aware decomposition and quantization with a loss function preserving ranking accuracy. The online time cost to decompress and recover embeddings is insignificant with 1ms for the tested cases. The CQ implementation is available at https://github.com/yingrui-yang/ContextualQuantizer.

Our CQ framework is also applicable to the contemporaneous work ColBERTv2 (Santhanam et al., 2021). Using uniCOIL scores for the first-stage sparse retrieval and ColBERTv2+CQ (M=16, K=256) for top 1,000 passage reranking, we achieve 0.387 MRR@10 on the MSMARCO passage Dev set, 0.746 NDCG@10 on TREC DL19, and 0.726 NDCG@10 on DL20 with about 10.2GB embedding space footprint. Notice that ColBERTv2 achieves a higher MRR@10 number 0.397 for the passage Dev set when used as a standalone retriever (Santhanam et al., 2021) and dense retrieval with such a multi-vector representation is likely to be much more expensive than retrieval with a sparse representation on a large dataset. The previous work in dense retrieval has often employed faster but approximate search, but that comes with a visible loss of relevance (Lewis et al., 2021). Thus the above relevance number using ColBERTv2+CQ for re-ranking with uniCOIL sparse retrieval is fairly strong, achievable with a reasonable latency and limited computing resource. Its embedding space size is 2.8x smaller than the 29GB space cost in the standalone ColBERTv2 (Santhanam et al., 2021) for MS MARCO passages. Our future work is to investigate the above issue further and study the use of CQ in the other late-interaction re-ranking methods.

A Details on Retrieval Choices, Numbers Cited, and Model Implementations

First-stage retrieval models considered. To retrieve top results before re-ranking, we have considered the recent work in sparse and dense retrieval that outperforms BM25. For sparse retrieval with inverted indices, DeepCT (Dai and Callan, 2020) uses deep learning to assign more sophisticated term weights for soft matching. The docT5query work (Nogueira et al., 2019b) uses a neural model to pre-process and expand documents. The recent work on sparse representations includes DeepImpact (Mallia et al., 2021), uniCOIL (Lin and Ma, 2021; Gao et al., 2021), and SPLADE (Formal et al., 2021b,a), for learning neural contextualized term weights with document expansion. Instead of using a sparse inverted index, an alternative retrieval method is to use a dense representation of each document, e.g. (Lin et al., 2021; Zhan et al., 2021a; Xiong et al., 2021; Gao and Callan, 2021; Zhan et al., 2021b; Ren et al., 2021). We use BM25 because it is a standard reference point. We have also used uniCOIL for passage re-ranking because a uniCOIL-based sparse retriever is fairly efficient and its tested relevance result is comparable to that of the end-to-end ColBERT as a dense retriever and other learned sparse representations mentioned above. Certainly CQ is applicable for re-ranking with any of dense or sparse retrievers or their hybrid combination.

Model numbers cited from other papers. As marked in Tables 3 and 4, for DeepCT, JPQ and TILDEv2, we copy the relevance numbers reported in their papers. For TCT-ColBERT(v2), DeepImpact and uniCOIL, we obtain their performance using the released checkpoints of Pyserini [1]. For PreTTR (MacAvaney et al., 2020) on the passage task and BERT-base on the document task, we cite the relevance performance reported in Hofstätter et al. (2020a). There are two reasons to list the relevance numbers from other papers. One reason is that for some chosen algorithms, the running of our implementation version or their code delivers a performance lower than what has been reported in the authors' original papers, perhaps due to the difference in training setup. Thus, we think it is fairer to report the results from the authors' papers. Another reason is that for some algorithms, the authors did not release code and we do not have implementations.

In storage space estimation of Table 5, for BECR, we use the default 128 bit LSH footprint with 5 layers. For PreTTR we uses 3 layers with dimension 768 and two bytes per number following Hofstätter et al. (2020a). For TILDEv2, we directly cite the space cost from its paper.

Model implementation and training. For baseline model parameters, we use the recommended set of parameters from the authors' original papers. For ColBERT, we use the default version that the authors selected for fair comparison. The ColBERT code follows the original version released [2] and BERT implementation is from Huggingface [3]. For BERT-base and ColBERT, training uses pairwise softmax cross-entropy loss over the released or derived triples in a form of $(\mathbf{q}, \mathbf{d}^{+}, \mathbf{d}^{-})$ for the MS MARCO passage task. For the MS MARCO document re-ranking task, we split each positive long document into segments with 400 tokens each and transfer the positive label of such a document to each divided segment. The negative samples are obtained using the BM25 top 100 negative documents. The above way we select training triples for document re-ranking may be less ideal and can deserve an improvement in the future.

When training ColBERT, we use gradient accumulation and perform batch propagation every 32 training triplets. All models are trained using Adam optimizer (Kingma and Ba, 2015). The learning rate is 3e-6 for ColBERT and 2e-5 for BERT-base following the setup in its original paper. For ColBERT on the document dataset, we obtained the model checkpoint from the authors.

Our CQ implementation leverages the open source code [4] for Shu and Nakayama (2018). For PQ, OPQ, RQ, and LSQ, we uses off-the-shelf implementation from Facebook's faiss[5] library (Johnson et al., 2017). To get training instances for each quantizer, we generate the contextual embeddings of randomly-selected 500,000 tokens from passages or documents using ColBERT.

When using the MSE loss, learning rate is 0.0001, batch size is 128, and the number of training epochs is 200,000. When fine-tuning with PairwiseCE or MarginMSE, we freeze the encoder based on the MSE loss, set the learning rate to be 3e-6, and then train for additional 800 batch iterations with 32 training pairs per batch.

Early Stopping Based on Unlabeled Samples in Text Classification

HongSeok Choi[1] **Dongha Choi**[2] **Hyunju Lee**[1,2,*]

Abstract

Early stopping, which is widely used to prevent overfitting, is generally based on a separate validation set. However, in low resource settings, validation-based stopping can be risky because a small validation set may not be sufficiently representative, and the reduction in the number of samples by validation split may result in insufficient samples for training. In this study, we propose an early stopping method that uses unlabeled samples. The proposed method is based on confidence and class distribution similarities. To further improve the performance, we present a calibration method to better estimate the class distribution of the unlabeled samples. The proposed method is advantageous because it does not require a separate validation set and provides a better stopping point by using a large unlabeled set. Extensive experiments are conducted on five text classification datasets and several stop-methods are compared. Our results show that the proposed model even performs better than using an *additional* validation set as well as the existing stop-methods, in both balanced and imbalanced data settings. Our code is available at `https://github.com/DMCB-GIST/BUS-stop`.

1 Introduction

Early stopping, a form of regularization, is a widely used technique to prevent a model from over-fitting (Yao et al., 2007; Zhang et al., 2017). It is generally based on a separate validation set (Goodfellow et al., 2016). While monitoring the validation performance during training, the training process stops when the validation error starts to increase. Validation-based early stopping is advantageous because it is easy to implement and can be interpreted directly (Prechelt, 1998).

In a scenario where sufficient labeled data are available, the use of a validation set is generally preferred (Goodfellow et al., 2016). However, when only a few labeled data exist, a tradeoff problem is encountered (Kann et al., 2019; Choi and Lee, 2021). For example, although the usage of a relatively large validation set enables more reliable estimation, the number of samples for training becomes insufficient. Conversely, if small fractions of the samples are assigned to the validation set, the stopping point becomes ambiguous because the small validation set is not representative enough.

Early stopping is more important in a low resource setting because the prediction accuracy fluctuates highly during training. Such high fluctuations render it challenging when to stop the model. One way to mitigate these fluctuations is to use sufficient training data. In this context, training all the available samples would be more effective, and for this purpose, an appropriate stopping point should be determined without validation split. However, this has not been extensively studied. Duvenaud et al. (2016) and Mahsereci et al. (2017) proposed gradient-based stop-methods and applied statistical inference on the training samples. Lee and Chung (2021) suggested the usage of local intrinsic dimensionality (LID) for early stopping. In addition, some studies treat the stopping epoch as a hyperparameter: the stopping epoch is obtained by grid-search or averaging in cross validation (Choi and Lee, 2021). These methods allow the training of all the labeled samples. However, they do not consider the task-related performance metrics (e.g., accuracy) during training, and the LID and gradient-based stop criteria have not been commonly used in natural language processing (NLP). Furthermore, gradient-based stop-criteria depend on the training samples, the size of which may still be small to be representative.

In this study, we propose an early **stop**ping method **b**ased on **u**nlabeled **s**amples (BUS-stop). We are motivated by the following two considerations: (i) The probabilities of the predicted class label (i.e., the prediction confidences) can serve as

---

Volume 1: Long Papers, pages 708 - 718
May 22-27, 2022

an indicator for over-fitting or under-fitting. (ii) In a better model, the output class distribution is more likely to be closer to the class distribution of the true labels. To incorporate these two assumptions, two stop criteria are proposed, and combined in the BUS-stop method. Our method monitors the prediction results of unlabeled samples during training and utilizes them for determining the stop-criteria. The first proposed stop-criterion is based on confidence similarity (conf-sim). The model stops when the prediction confidences for the unlabeled samples are most similar to the reference confidences, which are precalculated on the labeled set with cross-validation. Conf-sim is observed to reflect the long-term trend of the loss curve, and thereby assist in preventing over-training. The second stop criterion is based on the class distribution similarity (class-sim). This criterion stops the model when the predicted class distribution on the unlabeled set is most similar to the pre-estimated distribution. To this end, we present a novel estimation method for the true class distribution, which calibrates the predicted distribution by extrapolation such that it is closer to the true distribution. Class-sim is observed to reflect the short-term trend of the accuracy. Our method requires several retraining steps to obtain the reference confidences for conf-sim and the estimated class distribution for class-sim. The BUS-stop method that combines class-sim and conf-sim includes the advantages of both, and thereby performs with better accuracy and loss compared to each (class-sim and conf-sim).

The following characteristics of our method contribute to performance improvement. Our method does not require a separate validation set; hence, all the labeled samples can be trained. Training can stop at a more generalized model, using a large unlabeled set. The proposed stop-criteria, conf-sim and class-sim, consider two performance metrics, namely, the loss and accuracy.

Our contributions are summarized as follows:

- We propose BUS-stop, an early stopping method, based on unlabeled samples. BUS-stop can stop the training at a more generalized model, and the performance is better even than using an *additional* validation set.
- Furthermore, we present a calibration method to better estimate the class distribution. This method calibrates the output class distribution to render it closer to the true distribution, improving the class-sim performance.
- Extensive experiments are conducted on five popular text classification datasets in English. Comparison with several stop-methods demonstrates that the proposed method outperforms these existing stop-methods in both balanced and imbalanced data settings.

2 Related Work

Prechelt (1998) experimented on 14 different validation-based stop criteria. Prechelt (1998) focused on an issue that the validation error during training may represent many local minima prior to a global optimum.

Existing non-validation stop-criteria are generally based on statistical inference. Duvenaud et al. (2016) interpreted stochastic gradient descent in terms of the variational inference and proposed an estimation method for the marginal likelihood of the posterior, which was applied as an early stopping criterion. However, this method requires considerable computation for the Hessian, which is not practical in large models. Mahsereci et al. (2017) also proposed a gradient-related stopping method referred to as evidence-based stopping (EB). The EB-criterion is based on the fast-to-compute local statistics of the computed gradients. The criterion represents whether the gradients of the training samples lie within the expected range. Intrinsic dimensionality (ID), which refers to the minimum number of parameters required to represent a dataset, has been used for analyzing the training or redundancy of neural networks (Amsaleg et al., 2015). LID is a version of ID that estimates the subspace dimensions of the local regions. Lee and Chung (2021) found that LID works well as a stopping-criterion in several few-shot image classification datasets. Moreover, LID can be applied to unlabeled samples. Another method involves the pre-estimation of the the number of training epochs by training the model multiple times, such as cross validation (Choi and Lee, 2021); the model can stop at the pre-estimated (PE) stop-epoch when training all the labeled samples.

However, these methods have not been commonly studied for NLP tasks and do not consider the performance metrics during training. Furthermore, comparisons among the non-validation stop-methods have not been reported. In this study, we compare our method with the EB, LID, PE, and validation-based stopping methods on five text classification datasets. The method proposed by

Algorithm 1 Preliminary stage for BUS-stop

```

  return $\vec{P_l}, \vec{C_u}$
```

Duvenaud et al. (2016) was not compared because it involves considerable computational cost.

3 Method

In this section, we describe the proposed method in detail. The main notations used are as follows: $D_l = \{(x_i, y_i)\}_{i=1}^{n_l}$ and $D_u = \{(x_i)\}_{i=1}^{n_u}$ denote the labeled and unlabeled sets, respectively. x_i and y_i are the i-th sample and its true label, respectively, and n_l and n_u are the numbers of labeled and unlabeled samples, respectively. p_{ij} denotes the prediction probability of the j-th class on the i-th sample. Let C be the true class distribution of the samples. The output probability (i.e., confidence) p_i associated with the predicted label on sample x_i and the predicted (i.e., output) class distribution $\hat{C}$ of the samples are defined as follows:

$$p_i = \max_j (p_{ij})$$

$$\hat{C}[j] = \sum_{i=1}^{n_{data}} p_{ij} / n_{data}$$

where $\forall j \in \{1, \cdots, n_c\}$; n_c is the number of classes.

3.1 Preliminary Stage

The pseudocode for the preliminary stage is summarized in Alg. 1. In the preliminary stage, the prediction confidences $\vec{P_l}$ for the labeled samples in D_l and the estimated class distribution $\vec{C_u}$ of the unlabeled set D_u are calculated. Using D_l, the model is reinitialized-and-retrained T-times using a resampling method such as cross-validation. In low-resource settings, such retraining enables more reliable predictions by averaging the results. Each sample in P_l is evaluated when the validation loss is the lowest. Each sample should be validated at least once; the prediction confidences are averaged for each sample. P_l (and P_u in Alg.2 as well) is sorted in order of size for confidence comparison between two different sample sets, D_l and D_u, in the main stage; we denoted it as $\vec{P_l}$ ($\vec{P_u}$ for P_u). When retraining T-times, the output class distributions of the unlabeled set D_u are obtained and calibrated (this calibration is defined in Section 3.3). Then, the T calibrated class distributions are averaged, resulting in $\vec{C_u}$. After this stage, $\vec{P_l}$ and $\vec{C_u}$ are used to calculate the similarities for the two stop criteria, conf-sim and class-sim, respectively.

3.2 Main Stage Applying BUS-stop

After the preliminary stage, we train all the labeled samples and refer to this stage as the main stage. The combined BUS-stop method applied in the main stage is summarized in Alg. 2. The unlabeled set is predicted at every epoch during training.

Conf-sim The first proposed stop criterion conf-sim S_{conf} represents the similarity of the prediction confidences $\vec{P_u}$ for the unlabeled samples with the reference confidences $\vec{P_l}$. To calculate the similarity between $\vec{P_u}$ and $\vec{P_l}$, their dimensions must be the same. We sample $\vec{P_u}$ at regular intervals $\frac{n_u}{n_l}$ such that it is the same size as $\vec{P_l}$ and denoted it as $\dddot{P}_u$. We use the Euclidean distance to calculate the similarity, resulting in S_{conf}. Then, the first stop criterion is when S_{conf} has the lowest value, i.e., $\dddot{P}_u$ is most similar to $\vec{P_l}$. There is a natural concern that $\dddot{P}_u$ is likely to produce higher (thus dissimilar) confidences than $\vec{P_l}$ because $\dddot{P}_u$ is obtained by training all the labeled samples, unlike $\vec{P_l}$. However, the fact that the confidence for each sample in $\vec{P_l}$ is obtained when the validation error is the lowest can alleviate this concern. Thereby, S_{conf} can be a rough criterion for avoiding under- and overfitting, and can reflect the trend of the loss, based on comparison with the reference confidences.

Algorithm 2 BUS-stop in main stage

```
Input: $D_l$, $D_u$, $\vec{P_l}$, $\vec{C_u}$
Output: Expected best model $M_{best}$
  Let $Queue[1 \cdots n_{que}] = 0$
  Let $B_{conf} = $ inf, and $n_{pat} = 0$
  Initialize a model, $M$
  for $epoch \in \{1, 2, 3, \cdots\}$ do
      Train the $M$ one epoch on $D_l$
      $P_u, \hat{C_u} \leftarrow M(D_u)$
      $\vec{P_u} \leftarrow$ sort $P_u$ in ascending (or descending) order
      $\dddot{P_u} \leftarrow$ sampling $\vec{P_u}$ at regular intervals $\frac{n_u}{n_l}$
      $S_{conf} = Euclidian\text{-}distance(\dddot{P_u}, \vec{P_l})$
      $S_{class} = Cosine\text{-}similarity(\hat{C_u}, \vec{C_u})$
      if $S_{conf} < B_{conf}$ then
          $n_{pat} = 0$
          $B_{conf} = S_{conf}$
      else
          $n_{pat} = n_{pat} + 1$
      end if
      if $n_{pat} < n_{que}$ then
          if $S_{class} > \max(Queue)$ then
              $M_{best} \leftarrow$ save the current $M$
          end if
          $Queue \xleftarrow[\text{enqueue}]{\text{dequeue \&}} S_{class}$
      else
          End training
      end if
  end for
  return $M_{best}$
```

Class-sim The second proposed stop criterion is class-sim, S_{class}. The predicted class distribution $\hat{C_u}$ on the unlabeled set is compared with the estimated class distribution $\vec{C_u}$ from the preliminary stage. The assumption is that a well-trained model can also predict the class distribution more accurately. Therefore, estimation of the true class distribution is crucial. A calibration method that facilitates better estimation of the class distribution is presented in Section 3.3. We use the cosine similarity to calculate the similarity between $\hat{C_u}$ and $\vec{C_u}$, and obtain S_{class}. The second stop criterion is when S_{class} has the highest value, i.e., $\hat{C_u}$ is most similar to $\vec{C_u}$. Thereby, S_{class} can reflect the short-term trend of the accuracy because it is more likely that the outputs of a higher accuracy model are closer to the true class distribution.

BUS-stop Finally, we combine the two stop-criteria, conf-sim and class-sim, to form the BUS-stop method, as depicted in Alg. 2. A simple product of the two stop criteria can be an ineffective stop criterion because the sizes of S_{conf} and S_{class} are relative. Our combined stop-criterion is to save the model with the highest S_{class} among of the epochs from the lowest S_{conf} to the subsequent $(n_{que}-1)$-th epoch. This technique enables fine-stopping by considering both S_{conf} and S_{class}, which reflect the long-term and short-term performances, respectively. It is to be noted that early stopping methods should be operated as an ongoing process, and not as a type of post-hoc method. To this end, we use a fixed-size queue $Queue$, and its size n_{que} as a hyperparameter, as shown in Alg. 2.

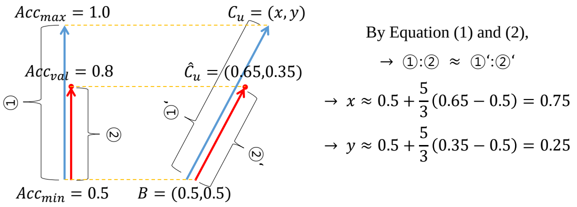

Figure 1: Calibration example in binary classification.

3.3 Calibration of Class Distribution

In this section, we describe the calibration of the predicted class distribution. The calibration method aims to better estimate the true class distribution of the unlabeled set, thereby improving the performance of class-sim, particularly for imbalanced classification.

Trained neural networks often involve sampling biases. For example, in binary classification, the prediction results of a model trained with a class ratio a:b tend to follow the distribution of a:b. Thus, when the class distributions are different in the test and training sets, the model performance can deteriorate. Let us suppose the following somewhat ideal and naive situations. Let C_u be the true class distribution of the unlabeled set. If the model is perfectly trained with an accuracy of 1.0, the output class distribution will be equal to C_u. On the other hand, if the model fails to learn any inference knowledge from training, the model will output the predictions only by its sampling bias; i.e., when the accuracy is the same as the random expectation (denoted as Acc_{min}, e.g., 0.5 in binary classification), the output class distribution will be equal to the sampling bias B. Thus, the model accuracy can reflect whether the output class distribution is closer to the sampling bias or the true distribution. In the preliminary stage, we obtained the models' proxy accuracy and output class distribution as Acc_{val}

Data	Class	Train	Test	Len
SST-2	2	6.9K	1.8K	19
IMDB	2	25K	25K	231
Elec	2	25K	25K	107
AG-news	4	120K	7.6K	38
DBpedia	14	560K	70K	49

Table 1: Statistics for datasets. **Len** denotes the average number of words per sample.

and $\hat{C}_u$, respectively. Assuming that there is an approximate linear relationship, we can define a proportional expression as follows:

$$\begin{aligned}(1 - Acc_{min}) : (Acc_{val} - Acc_{min})& \\ \approx (C_u - B) : (\hat{C}_u - B)&\end{aligned} \tag{1}$$

We rearrange the above expression in terms of C_u:

$$C_u \approx B + \frac{(1 - Acc_{min})}{(Acc_{val} - Acc_{min})}(\hat{C}_u - B) \tag{2}$$

Then, we denote the approximation of C_u as $\vec{C}_u$. Considering the class distribution as a vector, Eq. (2) is a type of extrapolation. B can be defined as the class distribution of D_{train} or the predicted distribution in the validation set, $\hat{C}_{val}$, of the preliminary stage. In addition, the Acc can be replaced with F1-score. Fig. 1 illustrates an example of our calibration method.

4 Experimental

4.1 Datasets

We conducted extensive experiments using five text classification datasets. The statistics are summarized in Table 1. These datasets have been extensively used in NLP research, and are publicly available. The SST-2 (Socher et al., 2013), IMDB (Maas et al., 2011), and Elec (McAuley and Leskovec, 2013) datasets are used for sentiment analysis. SST-2 and IMDB include movie reviews, and Elec includes reviews on Amazon electronics. AG-news (Zhang et al., 2015) and DBpedia (Zhang et al., 2015) are topic classification tasks for Wikipedia and news articles, respectively. For each dataset, we sampled K labeled samples per class from the training set. K was set to 50 for low-resource settings; we also experimented by varying $K \in \{50, 100, 200, 400, 800, 1600\}$. We used the test samples as the unlabeled set for each dataset, which is referred to as transductive setting in few-shot classification (Liu et al., 2019).

4.2 Methods for Comparison

In this section, we describe the various stop-criteria for comparison with our method.

EB The EB (Mahsereci et al., 2017) is a criterion based on gradients of training samples. The EB-criterion stops when the following condition is met:

$$1 - \frac{|\mathcal{S}|}{D}\sum_{k=1}^{D}[\frac{(\nabla L_{\mathcal{S},k})^2}{\hat{\Sigma}_k}] > 0 \tag{3}$$

where $\mathcal{S}$ represents a sample set, D is the number of parameters, ∇L is the gradients of loss, and subscript k indicates the k-th weight of the total parameters. $\hat{\Sigma}$ is the variance estimator, which is calculated as follows:

$$\hat{\Sigma}_k = \frac{1}{(|\mathcal{S}| - 1)}\sum_{x\in\mathcal{S}}(\nabla l_k(x) - \nabla L_{\mathcal{S},k})^2 \tag{4}$$

where $\nabla l(x)$ is the loss gradient on sample x. Note that $L_{\mathcal{S}} = \frac{1}{|\mathcal{S}|}\sum_{x\in\mathcal{S}} l(x)$. For further details, refer Mahsereci et al. (2017).

LID Lee and Chung (2021) approximated LID as follows:

$$LID = -\sum_{x\in D_u}\left[\frac{1}{m}\sum_{i=1}^{m}\ln\frac{d_i(\vec{z}(x))}{d_m(\vec{z}(x))}\right]^{-1} \tag{5}$$

where $\vec{z}(x)$ is the representation vector of sample x, and d_i is the Euclidean distance of $\vec{z}(x)$ and its i-th nearest neighbor. m is a hyperparameter, which denotes the number of nearest neighbors. The lowest LID is the stop criterion.

Val-stop$_{split(x)}$ and Val-stop$_{add(x)}$ Val-stop denotes validation-based stopping. Val-stop$_{split(x)}$ indicates that x validation samples per class are taken from the labeled set. Therefore, $K-x$ samples are trained and x samples are validated for each class. Val-stop$_{add(x)}$ indicates that x additional samples per class are used for validation; i.e., Val-stop$_{add(x)}$ uses a total of $K+x$ labeled samples per class. Val-stop$_{add(x)}$ has an unfair advantage because it uses additional labeled samples.

PE-stop-epoch The stopping epoch is considered a hyperparameter, which is **p**re-**e**stimated with cross-validation, as described in Section 2. We use four-fold cross-validation.

Conf-sim and **class-sim** can also be used as a single stop-criterion, as mentioned before. We compare the single criteria with the combined BUS-stop criterion. Conf-sim stops when S_{conf} is the lowest, and class-sim stops when S_{class} is the highest.

Dataset	SST-2		IMDB		Elec		AG-news		DBpedia		Average

Table 2: Performance comparison of different stop-criteria in balanced classification. We used 50 labeled samples per class for all stop-criteria except for Val-stop$_{add(25)}$. *Note that the Val-stop$_{add(25)}$ has an unfair advantage: for each class, it used 25 additional labeled samples for validation while using 50 labeled samples for training. The best performances, except for the Val-stop$_{add(25)}$, are denoted in bold. '$\simeq$' denotes that the performance is statistically similar to the BUS-stop (i.e., p-value over 0.05).

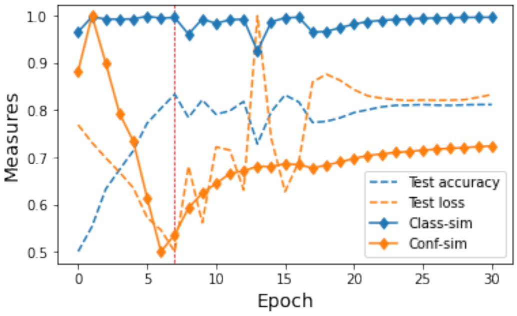

Figure 2: Example of the accuracy and loss curves with SST-2 dataset. The loss and conf-sim were scaled between 0.5-1.0. The red vertical line denotes the best model selected by the BUS-stop method.

4.3 Implementation

BERT-base (Devlin et al., 2019) was adopted as our text encoder. The Adam optimizer (Kingma and Ba, 2015) was applied for categorical cross-entropy loss (i.e., $-\sum y_i \log p_i$), and its learning rate was set to $3e$-5. The dropout (Srivastava et al., 2014) was set to 0.2, and the batch size was 16. All the stop-criteria were evaluated simultaneously for each run to reduce the variance of the estimation. We averaged 10 results in all the experiments. In EB, 64 random training samples were used for S in Eq. (3). In LID, the final vector of the [CLS] token in the BERT model was assigned to $\vec{z}(x)$ in Eq. (5), and the best m was selected from $\{5, 10, 20, 50, 100\}$. In BUS-stop, n_{que} in Alg. 2 was set to five. Note that K is the number of training samples per class. When K was set to 50, T and r in the preliminary stage (see Alg. 1) were set to 5 and 1:1, respectively. When K was set above 50, T and r were set to 4 and 3:1, respectively. In our calibration method, we used $\hat{C}_{val}$ as B and macro F1-score as the Acc_{val}.

5 Results

5.1 Balanced Classification

Table 2 shows the results when K=50 for training. It is noted that the original test sets have a balanced class distribution. We also report the loss measure as well as accuracy because loss can imply over-training. As shown in Table 2, our BUS-stop method exhibits the best performance on an average, and the accuracy is better even than Val-stop$_{add(25)}$, which uses a larger numbers of labeled samples. Note that Val-stop$_{add(25)}$ uses a total of 75 labeled samples per class. The performance of Val-stop$_{split(25)}$ indicates that splitting data for validation can result in poor performance in low-resource settings. LID underperforms compared to the PE-stop-epoch that does not require unlabeled samples. Conf-sim shows the second-best loss on an average. Class-sim underperforms as a stop criterion by itself. However, the BUS-stop method, which combines these two methods, shows better performance than each one on an average. Figure 2 displays the results of conf-sim and class-sim over the epochs. More examples are presented in Appendix A. In Fig. 2, the conf-sim curve is similar to the long-term trend of the loss; however, it does

Table 5: Accuracy comparison in various imbalanced settings (negative:positive) of the SST-2. The bold denotes the best performance of the three stop-criteria.

not accurately reflect the short-term fluctuation of the performance from epochs 7–16. On the other hand, class-sim is observed to be well responsive to the short-term fluctuation of the accuracy, but does not reflect the long-term trend. BUS-stop, which is a combination of these two methods, takes advantage of the short- as well as long-term methods, and thereby facilitates fine stopping. The EB-criterion shows the statistically similar accuracy to the BUS-stop method in most datasets. In the EB-criterion and PE-stop-epoch, the average loss is not good enough compared to the high accuracy. The accuracy and loss show somewhat conflicting results. That was due to over-confidence on the misclassified samples, caused by over-training. Note that $Loss = -\sum y_i \log p_i$. Overconfidence on the wrong label makes p_i close to zero on its true label y_i. Thus, excessively low p_i can increase the loss drastically. Table 3 lists the over-confidence error (OE); the equation for OE is presented in Thulasidasan et al. (2019). This confidence error can be detrimental in various applications, as described by Guo et al. (2017).

5.2 Imbalanced Classification

We experimented with an imbalanced setting in binary classification tasks. For testing, we sampled 1,000 instances in the SST-2 test set, and 10,000 instances each in the IMDB and Elec test sets, with a class distribution of 2:8 (negative:positive). The macro F1-score is also reported. Table 4 shows the results when K was set to 50 for training. In most cases, BUS-stop exhibits the best performance with respect to the accuracy as well as loss. In addition, it is noted that BUS-stop outperforms the other methods with a greater margin in an imbalanced setting than in a balanced one (Table 2). It is observed that ratios marked with '$\simeq$' are fewer in the imbalanced setting. Class-sim shows the best or second-best accuracy among the datasets. It is observed that the output class distribution can be an important indicator for a better model.

Table 5 shows the results in various imbalanced settings of the SST-2 (both the training and test sets are imbalanced). The number of training samples was fixed to 100 for the different class-distribution settings. In general, when the class distributions of the training and test sets are similar, the results shows better performance for all the three methods, EB, BUS-stop, and Val-stop$_{add(25)}$. In most cases, BUS-stop consistently outperforms Val-stop$_{add(25)}$ and EB, and the margin is greater when the class distributions are more different between the training and test sets. This result indicates that BUS-stop is robust to imbalanced classification.

6 Discussion

Impact of the training size Figure 3 indicates the accuracy curve with respect to the training size, using the IMDB dataset. The x values of Val-stop$_{add(x)}$ and Val-stop$_{split(x)}$ were set to 25, 25, 50, 100, 200, and 400, according to the increase

Table 6: Cosine similarity between the class distribution of the test set and the estimated distribution in various imbalanced settings of the SST-2 dataset.

in K. It can be observed that the performance of BUS-stop is good in the sufficient-data regime as well. However, the performances of the three stop-criteria converge almost similarly with the increase in the training size. The impact of splitting the samples for validation does not deteriorate the performance when K is greater than 400. Rather, Val-stop$_{split(x)}$ performs slightly better when K is 1600. This result suggests that when sufficient labeled data are available, validation-based stopping can be a better choice.

Calibration performance In the BUS-stop method, accurate estimation of the class distribution plays a crucial role. The cosine similarity between the class distribution of the test set and the estimated distributions by various estimators are shown in Table 6, where the uncalibrated output distributions ($\hat{C}_u$) and the estimated distributions by the calibration methods, based on the Acc-score (Cali$_{Acc}$) and macro F1-score (Cali$_{F1}$), were compared. When the class distributions are similar between the test and training sets, the performance of $\hat{C}_u$ is slightly better than those of the other estimators. However, the estimation by calibration based on the F1-score (Cali$_{F1}$) is better on an average, and particularly when the class distributions of the test and training sets are different. Figure 4 indicates the BUS-stop accuracies when each model stops based on the estimated class distribution in Table 6 (the same color corresponds to one cell in Table 6). For example, the yellow colors correspond to the settings in which the class distribution is 2:8 and 8:2 in the training and test sets, respectively. As shown in Fig. 4, the better the class distribution is estimated, the higher is the accuracy of BUS-stop. Such high correlation indicates the importance of the class distribution estimator. This result is consistent with our assumption that the output class distribution of better models will be closer to the true distribution.

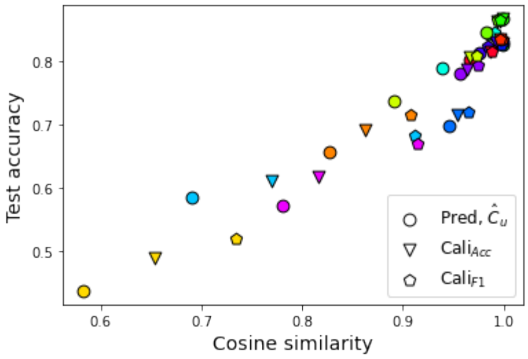

Figure 4: BUS-stop accuracy for different class distribution estimators in the 16 imbalanced settings depicted in Table 6.

Method	Time complexity	Measured time	
		SST-2 ($n_u = 1.8$k)	DBpedia ($n_u = 70$k)
EB	$g(n_l) + \alpha$	0.32 m	0.49 m
LID	$g(n_l) + p(n_u)$	0.12 m	**5.02** m
PE-stop-epoch	$(T + 1) * g(n_l)$	**0.43** m	1.14 m
BUS-stop	$(T + 1) * g(n_l) + p(n_u)$	**0.47** m	**5.97** m
Val-stop$_{add(25)}$	$g(n_l)$	0.07 m	0.19 m

Table 7: Running time comparison for different stop-criteria. The two longest times are denoted in bold.

Running time The running times are not directly comparable owing to the different hyperparameter settings for each method. For example, the BUS-stop and PE-stop-epoch require a separate preliminary stage that consumes additional time. We add up both the times taken in the preliminary stage and main stage. We denote the average running time per epoch as $g(n_l)$ for training the labeled samples and $p(n_u)$ for predicting the unlabeled samples. The time complexity and the measured time are shown in Table 7. Note that T is

Method	Val-stop$_{split(25)}$		Val-stop$_{add(25)}$		BUS-stop
Selection	local	global	local	global	local
Balanced classification					
SST-2	0.775	0.785	0.819	**0.840**	0.831
IMDB	0.746	0.786	0.824	**0.838**	0.828
Elec	0.781	0.805	0.842	**0.852**	0.848
AG-news	0.846	0.857	0.867	**0.871**	0.865
Imbalanced classification

IMDB	0.732	0.757	0.820	0.834	**0.849**
Elec	0.783	0.820	0.837	0.853	**0.876**

Table 8: Accuracy by global selection in Val-stop.

the number of retrainings in the preliminary stage, which was set to five. The experimental settings are the same as in Section 5.1. The time measurement was conducted on a PC with an Intel Core i7 CPU, 64-GB RAM and an NVIDIA Titan X Pascal GPU. As shown in the expression of time complexity, the running time depends on the numbers of labeled and unlabeled samples, n_l and n_u, respectively. In DBpedia, which has a large number of unlabeled samples, n_u, the LID and BUS-stop methods take the two longest running times. On the other hand, in SST-2, the PE-stop-epoch and BUS-stop methods show the two longest running times, because the n_u is relatively small such that the $g(n_l)$ is more dominant than the $p(n_u)$. The BUS-stop requires a longer running time than other methods due to the T-times retraining and the continual prediction on the unlabeled set. To reduce the time, we can adjust the T value or sample a smaller amount of data from the unlabeled set.

Limitations The proposed BUS-stop method was designed for classification tasks, and thereby can be applied when the model can output confidences. Regression tasks as well can be addressed by converting into classification problems. The continuous values normalized between 0-1 can be represented as confidences in a binary classification. However, it may be difficult to apply to other more complex tasks (e.g., text summarization). This study is limited to classification tasks. Another limitation is that the BUS-stop, which is a non-validation stop-method, cannot make direct comparisons between two models with different runs. Early stopping can be seen as selecting the best resulting model over the epochs. In a similar way, it is also possible to select the best model among multiple runs. We refer to the former as local selection and the latter as global selection. In validation-based stopping, the global selection is simply to select the model with the lowest validation loss over multiple runs. However, the non-validation methods have no clear criterion for this purpose. We repeated training five runs for each and selected the best model among the runs based on validation loss. Other experimental settings are the same as in Section 5. As shown in Table 8, the global selection in validation-based stopping improves performance across the datasets in both balanced and imbalanced settings. However, in the imbalanced setting, the BUS-stop still results in better performance. Note that Val-stop$_{add(25)}$ uses additional labeled samples. We also report that the global selections that are based on the S_{conf}, S_{class}, and LID did not show significant performance improvement in our experiment. The development of non-validation global selection methods is left for future work.

7 Conclusion and Future Work

Validation-based early stopping can be detrimental in low-resource settings because the reduction in the number of samples by validation split may result in insufficient samples for training. In this study, we proposed an early stopping method called BUS-stop, based on unlabeled samples. Moreover, we proposed a calibration method to better estimate the true class distribution, which was used in the BUS-stop method to improve the performance. We conducted experiments on five popular text classification datasets. The results indicated that BUS-stop outperformed the existing stop-criteria in both balanced and imbalanced settings. In particular, BUS-stop showed robustness to imbalanced classification. The proposed BUS-stop method enables the training of all the available samples and presents a better stopping point using large unlabeled samples. In future, we plan to better exploit the unlabeled samples in self-training schemes. We can also combine BUS-stop and self-training methods. BUS-stop can be used to improve the performance of the initial model, which plays an important role in the final self-training performance. Additionally, we consider applying the BUS-stop to domain adaptation tasks in the future.

A Appendix

Fig. 5 provides several examples of the learning curves and the stop-criteria measurements over the epochs.

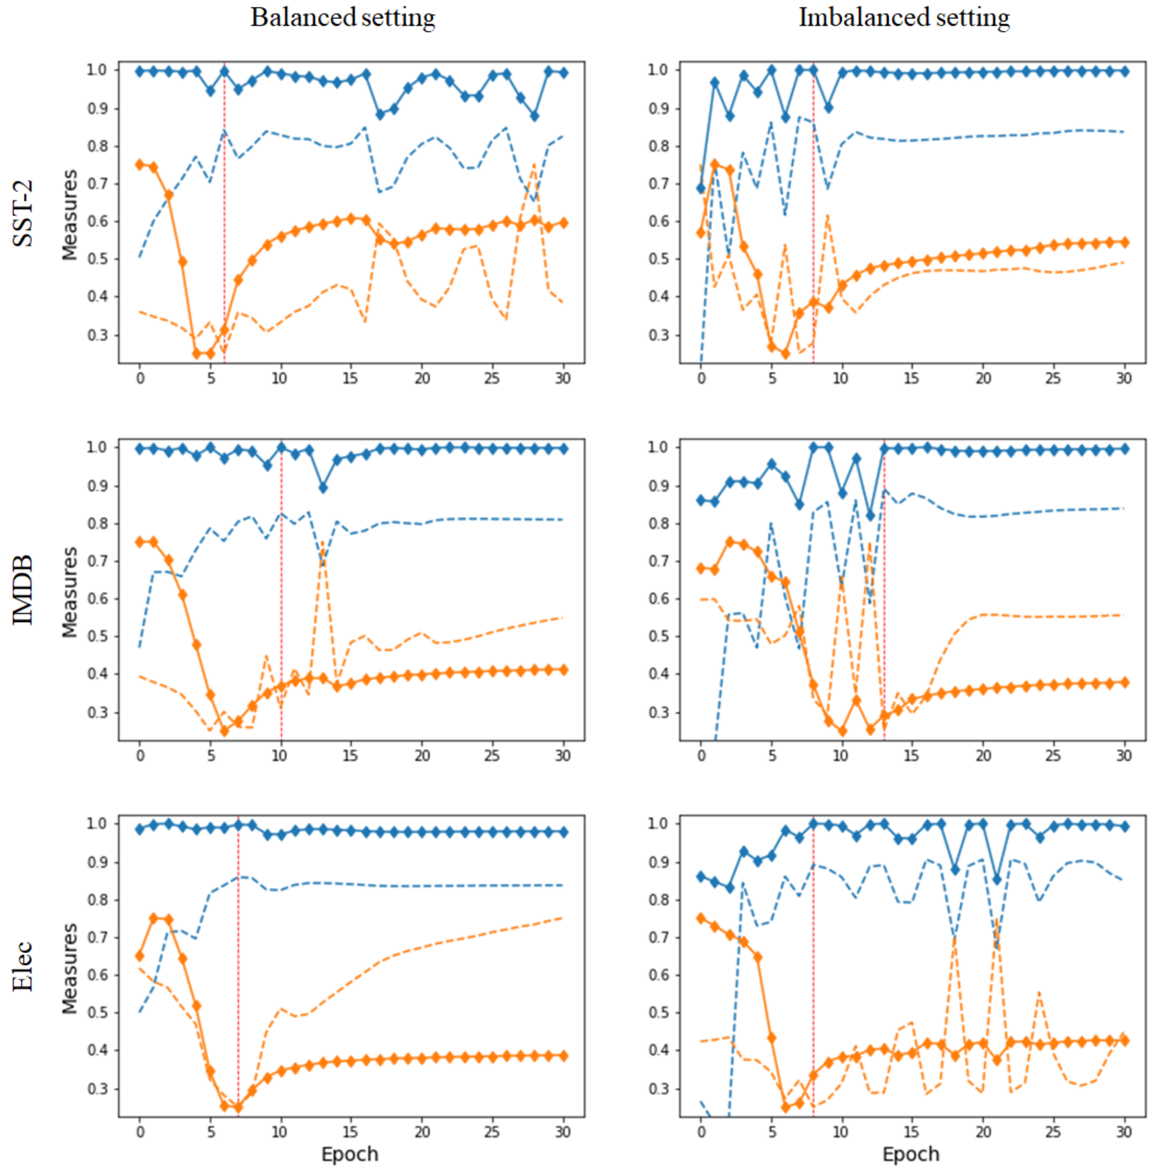

Figure 5: Examples in balanced and imbalanced settings of the SST-2, IMDB, and Elec datasets. ◆ and ◆ denotes conf-sim and class-sim, respectively; --- and --- denotes the test loss and accuracy, respectively. The red vertical line denotes the best model selected by the BUS-stop method. The balanced and imbalanced settings are the same as the settings in Section 5.1 and 5.2, respectively. The loss and conf-sim were scaled between 0.25-0.75 for easy comparison. The BUS-stop enables fine-stopping. As shown in these figures, our method skillfully avoids the points where the performance is decreased by fluctuations.

Meta-learning via Language Model In-context Tuning

Abstract

The goal of meta-learning is to learn to adapt to a new task with only a few labeled examples. Inspired by the recent progress in large language models, we propose *in-context tuning* (ICT), which recasts task adaptation and prediction as a simple sequence prediction problem: to form the input sequence, we concatenate the task instruction, labeled in-context examples, and the target input to predict; to meta-train the model to learn from in-context examples, we fine-tune a pre-trained language model (LM) to predict the target label given the input sequence on a collection of tasks.

We benchmark our method on two collections of text classification tasks: LAMA and BinaryClfs. Compared to MAML which adapts the model through gradient descent, our method leverages the inductive bias of pre-trained LMs to perform pattern matching, and outperforms MAML by an absolute 6% average AUC-ROC score on BinaryClfs, gaining more advantage with increasing model size. Compared to non-fine-tuned in-context learning (i.e. prompting a raw LM), in-context tuning meta-trains the model to learn from in-context examples. On BinaryClfs, ICT improves the average AUC-ROC score by an absolute 10%, and reduces the variance due to example ordering by 6x and example choices by 2x.

1 Introduction

Few-shot learning (FSL) refers to a system's ability to quickly adapt to new tasks when very few labeled examples are available for training. FSL is a key feature of human learning (Lake et al., 2016), but current machine learning systems often rely on large amounts of labeled training data (Silver et al., 2016; He et al., 2016; Adiwardana et al., 2020).

Recently, prompting large pre-trained language models (LMs) for FSL has achieved remarkable progress (Brown et al., 2020; Schick and Schütze, 2021a). LM prompting with in-context learning reduces the "task learning and predict" process to a simple sequence prediction problem. To perform a new task, Brown et al. (2020) prompt a *raw* LM (i.e., a pre-trained LM not fine-tuned on any labeled data) with the concatenation of the task instruction, some input-output examples, and the target input to be predicted on; then they extract the answer from the LM's continuation of the concatenated sequence (Figure 1 left). For example, to coax the model into performing sentiment classification on the target input "*This movie is a waste of time*", we prompt the LM with the sequence "*I like the movie! Positive review? Yes. Horrible Movie! Positive review? No. This movie is a waste of time. Positive review?* ___", and predict "positive" if the next word is more likely to be "*Yes*" rather than "*No*".

However, raw LMs are not optimized for in-context FSL during pre-training, and exhibit undesirable behavior when used for FSL. For example, Zhao et al. (2021) observed that LMs suffer from the "recency bias", which assigns higher probability to labels that appear closer to the target input. As a result, the accuracy becomes extremely sensitive to the ordering of the in-context examples. Previous work has also shown that prompting raw LMs is often oversensitive to example choices and instruction wording (Schick and Schütze, 2021a; Jiang et al., 2020; Gao et al., 2021; Liu et al., 2021).

We address this weakness through a meta-learning lens and directly fine-tune the LM for FSL. Under the meta-learning framework, we meta-train a model to learn to adapt to new tasks from a few examples on a wide range of tasks, so that it learns to leverage the few-shot examples to adapt to new tasks at test time. Since LM prompting already reduces the "task learning and predict" process to a simple sequence prediction problem, we meta-train a LM by directly fine-tuning it to optimize for this sequence prediction problem on a wide range of tasks (Figure 1 left). Since we fine-

May 22-27, 2022

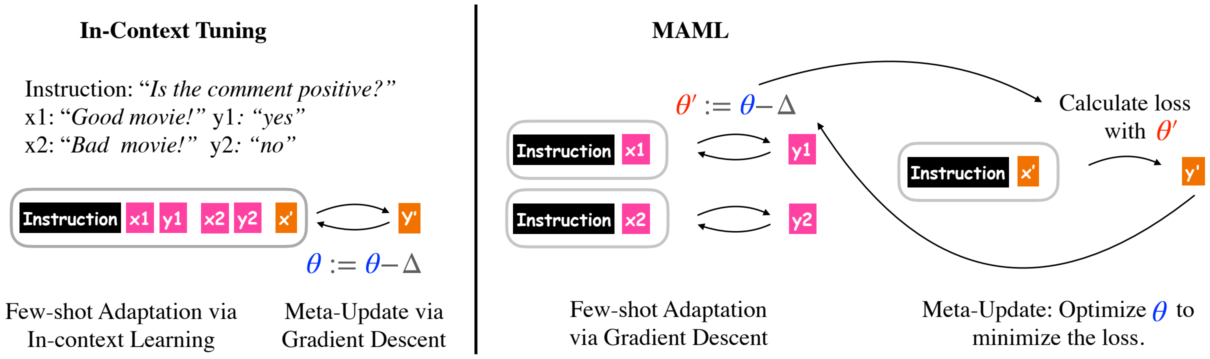

Figure 1: **MAML** (right): MAML aims to learn a task-agnostic model initialization θ that can adapt fast to new tasks. To adapt the model initialization to a new task $\tilde{T}$, a task-specific model θ' initialized with θ is updated with gradient descent using task examples from $\tilde{T}$. Meta-training of MAML involves bi-level optimization, where the inner optimization learns a task-specific model θ' using task examples from $\tilde{T}$, and the outer optimization learns a meta-initialization θ to minimize few-shot prediction loss of θ' on task $\tilde{T}$. **In-context Tuning (ours)** (left): our approach adapts to new tasks via in-context learning, and learns a single model θ shared across all tasks that is directly optimized with the FSL objective (Section 2.2). Because model parameters are frozen during task adaptation, our approach does not involve bi-level optimization during meta-training.

tune our model to learn in-context learning, we call our approach ***in-context tuning*** (ICT). Unlike optimization-based meta learning approaches such as MAML (Finn et al., 2017), in-context tuning adapts to new tasks through in-context learning where model parameters are frozen, thus it avoids the challenging nested optimization problem in MAML (Figure 1).

We benchmark our algorithm on LAMA (Petroni et al., 2019), a dataset for testing models' factual knowledge, and BinaryClfs (Zhong et al., 2021), a wide range of binary classification tasks each annotated with a few language descriptions of the task. Compared to prompting raw LMs, in-context tuning improves performance by 7.6 Precision@1 points on LAMA and 10.6% AUC-ROC score on BinaryClfs. In addition, in-context tuning mitigates the over-sensitivity of raw LM prompting, significantly reducing the variance of the performance with respect to example ordering (by 68% on LAMA and 83% on BinaryClfs), example choices (by 56% on LAMA and 40% on BinaryClfs), and instruction wording (by 19% on LAMA).

Our approach also out-performs MAML, which adapts the model by gradient descent on a few examples and learns an initialization that can adapt to a new task through a few gradient steps (Finn et al., 2017; Nichol et al., 2018). Since our approach better takes advantage of the inductive bias of LMs to extrapolate from in-context examples, our approach out-performs first-order MAML by 2.8 points on LAMA and 5.1 points on BinaryClfs, with increasing advantage as models become larger.

Given the empirical effectiveness of in-context tuning (Section 4.1), we conjecture that the few-shot learning potential of large LMs (e.g., GPT-3) may be broadly underestimated if prompted without any direct optimization for FSL. We also conjecture that in-context tuning can mitigate various undesirable properties of LM prompting, such as over-sensitivity to example ordering, example choices, and instruction wording (Section 4.2).

2 Approach

We introduce the problem setup (Section 2.1), describe our in-context tuning algorithm (Section 2.2), compare our algorithm to gradient-based adaptation methods (Section 2.3) and other baselines (Section 2.4).

2.1 Problem Setup

We focus on the few-shot classification problem, where the model first learns from a set of training tasks $T \in T_{\text{train}}$, each associated with its natural language instructions I_T and a large amount of task input-output examples $D_T = \{(x_T^i, y_T^i)\}$ (see Figure 1 left for examples). At test time, we ask the model to learn a new task $\tilde{T}$ given its instruction and only a few (K) labeled examples, i.e. $S_{\tilde{T}} \subseteq D_{\tilde{T}}, |S_{\tilde{T}}| = K$. We denote the task input to be predicted at test time as $x_{\tilde{T}}^{\text{target}}$.

Note that "task input" is different from "model input". For example, on the left panel of Figure 1, the task input is "*Good movie!*" while the model input can be a concatenation of the instruction, task inputs and task outputs.

2.2 In-context Tuning Algorithm

In-context tuning directly optimizes pre-trained LMs with the few-shot in-context learning objective (Brown et al., 2020): task-agnostic LMs are meta-trained to perform few-shot in-context learning on a wide variety of training tasks. Similar to in-context learning, LMs trained with in-context tuning adapt to a new task by using few-shot training examples as the input prefix.

Formally, during meta-training, we build the model input by concatenating the task instruction I_T, task input-output pairs $S_T \subseteq D_T$, and the task input x_T^{target}[1] to be classified. We then fine-tune a pre-trained LM to predict y_T^{target} and hope that the model learns to use the in-context examples S_T. Here is the few-shot in-context tuning objective $\mathcal{L}$:

$$\mathcal{L}_T(\theta) := \sum_{(x_T^{\text{tgt}}, y_T^{\text{tgt}}) \in D_T} [-\log p_\theta(y_T^{\text{tgt}} | x_T^{\text{tgt}}, S_T, I_T)] \tag{1}$$

$$\mathcal{L}(\theta) := \sum_{T \in T_{\text{train}}} \mathcal{L}_T(\theta) \tag{2}$$

To adapt to a new task $\tilde{T}$ at test time, we directly concatenate the few-shot examples $S_{\tilde{T}}$ with the instruction $I_{\tilde{T}}$ and the target task input $x_{\tilde{T}}^{\text{target}}$ to be classified to form the model input, and ask the model to predict its corresponding output. No gradient update is performed during adaptation.

2.3 Gradient-based Task Adaptation

We compare in-context tuning with two classical few-shot learning methods: multi-task fine-tuning (instruction tuning + fine-tuning) and MAML. Both methods adapt the model parameters to new tasks by gradient descent on few-shot examples.

Instruction Tuning + Fine-tuning (InsT + FT) We extend the recent work on zero-shot instruction tuning (Wei et al., 2021) to the FSL setting as a *multi-task fine-tuning* baseline. During meta-training, the model is optimized to predict the task output given the task instruction and the task input on a wide range of tasks (Zhong et al., 2021). Formally, we train the model parameter θ to predict y_T^i given $I_T \circ x_T^i$, where θ is shared across all tasks and $\circ$ represents the concatenation operation. During the few-shot adaptation phase, the model is presented with a new task $\tilde{T}$, its natural language instruction $I_{\tilde{T}}$ and a small set of (K) task input-output examples $S_{\tilde{T}} = \{(x_{\tilde{T}}^i, y_{\tilde{T}}^i) | i \in [K]\}$. We then fine-tune the model to predict the task output $y_{\tilde{T}}^i$ from the new task given $I_{\tilde{T}} \circ x_{\tilde{T}}^i$ and update θ with a few gradient steps to get $\theta_{\tilde{T}}$. Finally, we use the updated model $\theta_{\tilde{T}}$ to predict the output from the task input $x_{\tilde{T}}^{\text{target}}$ and the instruction $I_{\tilde{T}}$ under the test task $\tilde{T}$.

MAML The few-shot adaptation stage of MAML is the same as instruction tuning + fine-tuning, where we update the model parameters (initialized with θ) by gradient descent on K examples $S_{\tilde{T}} \subseteq D_{\tilde{T}}$. However, during meta-training, MAML aims to learn a task-agnostic model initialization θ such that, θ_T, which is to be found by initializing with θ and performing gradient descent on S_T, would lead to good performance (Finn et al., 2017).

Therefore, MAML involves two levels of optimization, an inner optimization to learn θ_T given θ and $S_T \subseteq D_T$, and an outer optimization to learn θ given θ_T. Due to the bi-level structure in this optimization problem, MAML has been found to be empirically unstable, sensitive to hyperparameters, and computationally expensive (Finn et al., 2017; Nikolaev et al., 2020). Even worse, few-shot task adaptation is known to be highly sensitive to optimization hyperparameters (Antoniou et al., 2019), while a large labeled validation set for hyperparameter tuning may not be available under a FSL setting (Perez et al., 2021).

In comparison, in-context tuning simplifies the two-stage process of (1) few-shot task adaptation and (2) task-specific prediction as one sequence prediction problem, where task-specific examples are concatenated to the model input to provide information about the task. Hence, in-context tuning removes the bi-level optimization during meta-training, which can be empirically unstable and expensive. Additionally, since model weights are frozen during task adaptation, it is not sensitive to adaptation hyperparameters.

2.4 Other Baselines

Raw In-context Learning (Raw IC-L) We directly evaluate a raw LM on a new task using the same evaluation set-up for in-context tuning, without fine-tuning the LM on any labeled data.

---

[1] We sometimes abbreviate "target" as "tgt" to save space.

Method	Adaptation	Meta-train
In-context Tuning	In-context	Few-shot
MAML	Gradient	Few-shot
InsT	None	Zero-shot
InsT + FT	Gradient	Zero-shot
Raw IC-L	In-context	LM

Table 1: We categorize our approach and the baselines according to 1) how the few-shot examples (if any) are used for adaptation, and 2) the meta-training objective. Ins-T refers to instruction tuning.

Instruction Tuning (InsT) The model learns to predict the target output only based on the instruction and the target input. Only the instruction is available during the adaptation phase, and this setup is also known as zero-shot learning.

We categorize all approaches in our paper based on their meta-training objective and how they use task-specific examples in Table 1. In-context tuning is the *only* method that directly optimizes the FSL objective without gradient-based adaptation.

3 Experimental Setup

3.1 Datasets and Metrics

We experiment with two meta-datasets that contain a wide range of tasks, LAMA and BinaryClfs. Each task is associated with several different natural language descriptions, and we call them *instructions* for convenience, even though some of them are realized as questions.

LAMA **LA**nguage **M**odel **A**nalysis (Petroni et al., 2019) is a dataset that tests the factual and commonsense knowledge learned by LMs. In our experiments, we use the TREx-UHN portion of LAMA (Poerner et al., 2020), which consists of (subject, relation, object) triples from Wikidata. LAMA is an entity prediction task, where a model is asked to predict the object entity given the subject entity and the relation. In our experiments, we treat one relation as a task as in Perez et al. (2021).

Initial experiments on LAMA showed that LMs take significant advantage of "majority label bias" (Zhao et al., 2021), where they assign higher probability to object entities that have appeared in the in-context examples, thus inflating the accuracy. To reflect the improvement due to few-shot learning rather than this simple heuristic to copy answers, for all tasks we prune the LAMA dataset so that all object entities appear less than 2.5% of times. Our final filtered LAMA dataset consists of 29 relations (tasks) and 12k (subject, relation, object) examples.

We use task instructions from two datasets: LAMA and LPAQA (Jiang et al., 2020). LAMA contains one task instruction for each task, and the auxiliary LPAQA dataset contains on average 10 additional instructions for each LAMA task.

We use the same evaluation protocol as in Petroni et al. (2019): 1) the object entity is predicted from a pre-defined vocabulary set of 21k words (each LAMA task is 21k-way classification); 2) we compute mean precision at one (P@1) for each task, and report the average across tasks. Because LAMA does not have an official train-validation-test split, we use 8-fold cross-validation in our experiments. We randomly partition the 29 tasks into 8 groups of similar sizes. For each cross-validation split, we use six groups for training, one group for validation, and one group for testing. The test sets of the eight folds are disjoint and their union is the set of all tasks.

BinaryClfs This dataset contains a wide range of **binary cl**assi**f**ication task**s**, and each task can be described by 1-4 "yes/no" questions, which we concatenate to the input context as instructions. There are in total 204 different tasks, and 73 of them are used for testing, which include sentiment classification, topic classification, definition detection, stance classification, etc. We use the same evaluation protocol as in Zhong et al. (2021): 1) we group the tasks by similarity and do not allow training tasks to be similar to testing tasks; 2) we treat "Yes" answer as the positive class and calculate the AUC-ROC score for each instruction of each task.

To fit model inputs (concatenation of in-context examples and task input to classify) within the maximum context length (1024) of our LMs, we leave out five evaluation tasks where the maximum task input length exceeds 230 BPE tokens. We also leave out the spam classification task due to its small test set. BinaryClfs does not come with an official validation set. To perform hyperparameter tuning, for each testing group, we randomly sample another testing group as its validation group.

3.2 Implementation Details

Architecture We use BERT models for LAMA (BERT-Base [110M parameters], BERT-Large [340M] and DeBERTa-XLarge-V2 [900M]) and GPT2 models for BinaryClfs (GPT2-Medium [345M] and GPT2-Large [774M]). We use the Hug-

Table 2: Few-shot learning accuracy of our in-context tuning approach (ICT) compared to in-context learning with raw LMs (Raw IC-L) and instruction tuning + fine-tuning (InsT + FT). K-S: K-shot learning. GPT2-M: GPT2-Medium. GPT2-L: GPT2-Large. Task instructions are used except the last two rows labeled with "w/o Ins". By definition, InsT + FT is the same as ICT for 0-S. We only experiment with the no-instruction setting on the LAMA dataset. Since we modify the LAMA dataset and BinaryClfs dataset (Section 3.1), the numbers reported in our work are not directly comparable to other work.

	LAMA		BinaryClfs

MAML	16.9	21.4	63.3	63.9
ICT	**19.6**	**24.3**	**67.4**	**69.8**

Table 3: In-context tuning consistently out-performs MAML on both datasets and all model sizes under the 5-shot setting. BB: BERT-Base. BL: BERT-Large. GPT2-M: GPT2-Medium. GPT2-L: GPT2-Large.

gingface implementation (Wolf et al., 2020).

Hyperparameters We select hyperparameters based on few-shot classification accuracy on validation tasks. Our validation tasks and testing tasks are disjoint, so hyperparameter tuning on validation tasks does not use extra labeled examples on the testing tasks (Perez et al., 2021). See Appendix A for the hyperparameters we tuned.

Sampling Different instructions and few-shot example choices can lead to different predictions (Section 2.2). At training time, we expose the model to diverse task instructions and few-shot choices by randomly sampling task instructions and few-shot examples for each target example.

At test time, we report the average accuracy across task instructions and few-shot choices. Since computing the average across all few-shot choices is intractable (there are combinatorically many distinct few-shot choices), we thus calculate the average accuracy of multiple random samplings of few-shot choices as approximation.

4 Results

In-context tuning out-performs MAML and various baselines on the two text classification meta-datasets (Section 4.1). It also significantly reduces model sensitivity to instruction wording, example choices, and example ordering compared to prompting raw LMs (Section 4.2).

4.1 Few-shot Learning Performance

In-context tuning improves in-context learning accuracy over raw LMs. We compare ICT with Raw IC-L in Table 2. In-context tuning consistently out-performs raw LM prompting by 7.6 points on LAMA and 10.6 points on BinaryClfs (averaged across model size and number of few-shots). As expected, directly optimizing the few-shot in-context learning objective (Section 2.2) improves the few-shot in-context learning accuracy.

Few-shot examples lead to more effective task adaptation. We compare few-shot in-context tuning with instruction tuning (equivalent to 0-shot ICT) in Table 2. Few-shot in-context tuning consistently out-performs instruction tuning on both LAMA and BinaryClfs, with increasing performance gains as number of shots increases. Specifically, we observe that 5-shot in-context tuning out-performs instruction tuning by 6.1 points on LAMA and 4.0 points on BinaryClfs. Results show that demonstration examples besides task instructions facilitate more effective task adaptation.

In-context tuning better leverages the inductive bias for pattern matching. By comparing MAML (the first row of Table 3) to instruction tuning (equivalent to 0-shot ICT) of Table 2, we see that MAML out-performs instruction tuning in most evaluation settings, which indicates that MAML is indeed able to take advantage of the few-shot task examples for task adaptation. However, Table 3 shows that our approach of 5-shot in-context tuning out-performs 5-shot MAML consistently on both datasets with an accuracy gain of 2.8 points on LAMA and 5.1 points on BinaryClfs (averaged across model size). We argue that in-context tuning out-performs MAML because in-context tuning better leverages the existing inductive bias of pre-trained LMs to perform pattern matching with in-context examples.

We also compare in-context tuning to the pipeline of instruction tuning + task-specific fine-tuning (Table 2). Surprisingly, fine-tuning an instruction-tuned model on as few as one task-specific example significantly improves task accuracy, without over-fitting to the few labeled examples. We observe that instruction tuning + 1-shot fine-tuning out-performs instruction tuning (equivalent to 0-shot ICT) by 3.1 points on LAMA (Table 2). Our in-context tuning approach performs comparable or better than instruction tuning + fine-tuning, with increasing accuracy gains as models get bigger (Table 2). For DeBERTa-XLarge-v2 (the largest models we use in this work), in-context tuning out-performs InsT + FT across all numbers of shots, achieving an accuracy gain of 1.7 points on LAMA (averaged across all numbers of shots). We conjecture that in-context tuning will be increasingly effective for bigger models that have a stronger inductive bias of pattern matching.

In-context tuning reduces the need of task instructions. As coming up with good task instructions can be hard (Schick and Schütze, 2021a; Jiang et al., 2020), we further investigate the effectiveness of in-context tuning without task instructions (Table 2). In-context tuning is effective in the no-instruction setting as well, consistently out-performing raw in-context learning with no instructions by an average margin of 9.5 points on LAMA. Comparing raw in-context learning with (Raw IC-L) and without instructions (Raw IC-L w/o Ins) (Table 2), we observe that task instructions yield the most significant performance gains when model size is relatively small (+2.5 points on BERT-Base, +7.7 points on BERT-Large, only +0.6 points on DeBERTa-xlarge). We conjecture that smaller models may be weaker at inferring patterns from in-context examples alone compared to larger models, which is why instructions yield larger performance gains on smaller models. On BERT-Base and BERT-Large models where task instructions are most helpful, in-context tuning reduces the improvement gain from task instructions from 5.1 points (raw in-context learning) to 1.8 points (averaged across BERT-Base and BERT-Large), which indicates that in-context tuning reduces the need of task instructions compared to raw in-context learning. However, we note that instructions still yield performance improvement even if in-context tuning is applied.

	LAMA		**BinaryClfs**

Table 4: In-context tuning is significantly less sensitive to example ordering compared to in-context learning with raw LMs.

4.2 Sensitivity Analysis

We analyze the sensitivity of in-context tuning accuracy with respect to example ordering, example choices, and instruction wording, and compare it with prompting raw LMs. Let I denote a random selection of task instruction, S_T a random unordered set of few-shot training examples with size K, σ a random permutation of K examples. The accuracy μ is a function of these three random variables, i.e. $\mu : (S_T, \sigma, I) \mapsto [0, 1]$. We can decompose the total variance of μ into its variance w.r.t. each of the three random variables, since they are independent (order variance is independent to choice variance because S_T is *unordered*):

$$\begin{aligned}\mathrm{Var}_{S_T,\sigma,I}[\mu] = \; & \underbrace{\mathrm{Var}_I[\mathbb{E}_{S_T,\sigma}[\mu|I]]}_{\text{instruction wording variance}} \\ + & \underbrace{\mathbb{E}_I[\mathrm{Var}_{S_T}[\mathbb{E}_\sigma[\mu|I,S_T]]]}_{\text{example choice variance}} \\ + & \underbrace{\mathbb{E}_{I,S_T}[\mathrm{Var}_\sigma[\mu|I,S_T]]}_{\text{example order variance}}\end{aligned}$$

We analyze each type of variance below.

In-context tuning is significantly less sensitive to example ordering. We compare the variance with respect to example ordering for in-context

	LAMA		BinaryClfs	
	BB	**BL**	**GPT2-M**	**GPT2-L**
Raw IC-L	3.74	6.30	18.52	20.33
ICT	**1.78**	**2.57**	**11.46**	**11.62**

Table 5: In-context tuning is significantly less sensitive to example choices compared to in-context learning with raw LMs.

	BERT-Base		BERT-Large	
	Raw IC-L	ICT	Raw IC-L	ICT
1-shot	35.38	**26.31**	34.03	**28.78**
2-shot	33.79	**25.40**	**17.71**	19.35
5-shot	24.90	**15.64**	6.36	**5.16**

Table 6: In-context tuning is much less sensitive to task instruction wording compared to in-context learning with raw LMs.

tuning and in-context prompting with raw LMs in Table 4. Results show that in-context tuning is significantly less sensitive to ordering of in-context examples compared to in-context prompting with raw LMs, reducing the sensitivity by 68% on LAMA and 83% on BinaryClfs.

In-context tuning is significantly less sensitive to example choices. We compare the variance with respect to example choices for in-context tuning and in-context prompting with raw LMs in Table 5. Results show that in-context tuning is significantly less sensitive to selection of in-context examples compared to in-context prompting with raw LMs across both datasets and all model sizes, reducing the sensitivity by 56% on LAMA and 40% on BinaryClfs (averaged across model sizes). We conjecture that in-context tuning is significantly less sensitive to example ordering and selection because the model is exposed to various example orderings and selections during in-context tuning.

In-context tuning is less sensitive to instruction wording. We report the variance with respect to instruction wording for in-context tuning and in-context prompting with raw LMs in Table 6. Results show that in-context tuning is less sensitive to instruction wording compared to in-context prompting with raw LMs in five out of six evaluation settings, reducing the variance by 19% on LAMA (averaged across model size and number of shots).

We also observe that in-context tuning is especially effective on task instructions with low accuracy under raw in-context learning. For each task, we compute the Pearson correlation between the raw in-context learning accuracy and the accuracy gain from in-context tuning (over raw in-context learning) on all instructions. On the LAMA dataset, we see a strong negative correlation of -0.563 (averaged across all tasks), with p-value < 0.05 on 63% of the tasks. We conjecture that in-context tuning is much less sensitive to instruction wording because the model is exposed to a wide variety of different task instructions during in-context tuning.

In-context examples are complementary to instructions. We observe that in-context tuning is especially effective on task instructions with low accuracy under instruction tuning. For each task, we compute the Pearson correlation between the instruction tuning accuracy and the accuracy gain from in-context tuning (over instruction tuning) on all instructions. On the LAMA dataset, we see a strong negative correlation of -0.910 (averaged across all tasks), with p-value < 0.01 on 91% of the tasks. We conjecture that in-context tuning is much less sensitive to instruction wording because few-shot in-context examples provide additional task information besides the task instructions.

5 Related Work

LM Prompting for FSL Pre-trained LMs can be used to perform various FSL tasks when prompted with a natural language task instruction and several task examples (Radford et al., 2019; Brown et al., 2020; Schick and Schütze, 2021b; Li and Liang, 2021; Lester et al., 2021; Qin and Eisner, 2021). However, prompting pre-trained LMs directly for FSL is known to be sensitive to various artifacts, such as the wording of the task instruction and the selection and ordering of few-shot training examples (Schick and Schütze, 2021a; Jiang et al., 2020; Zhao et al., 2021; Gao et al., 2021; Liu et al., 2021). Our work is the first to show that meta-learning with an explicit FSL objective significantly reduces the sensitivity of LM prompting with respect to the in-context examples and instruction wording.

Meta-learning for FSL Meta-learning is a widely used technique in NLP to improve cross-domain transfer (Yu et al., 2018; Geng et al., 2019; Holla et al., 2020; Deng et al., 2020) and cross-task transfer (Gu et al., 2018; Bansal et al., 2020; Dou et al., 2019). Existing optimization-based meta-learning methods mostly perform task adaptation by fine-tuning a task-agnostic model on task-specific examples using gradient descent (Finn et al., 2017; Jiang et al., 2019; Nichol et al., 2018). However, fine-tuning on few-shot task examples is sensitive to hyperparameters (Antoniou et al., 2019) and nested optimization during meta-training is often unstable (Nichol et al., 2018; Antoniou et al., 2019; Rajeswaran et al., 2019). In contrast, our approach performs few-shot task adaptation by using task-specific examples as part of the model input while keeping the model parameters frozen and task-agnostic during the adaptation stage.

Multi-task Learning In multi-task learning, a single model is trained on the union of training sets of multiple tasks to learn a shared representation (Liu et al., 2019). The multi-task model is then fine-tuned on task-specific examples to adapt to new tasks. Multi-task learning is shown to improve performance on various downstream tasks, especially tasks with small training sets (Khashabi et al., 2020; Ye et al., 2021; Aghajanyan et al., 2021). Compared to meta-learning, multi-task learning does not optimize task adaptation directly.

Fine-tuned LMs for Instruction Learning Recent work shows that fine-tuning LMs to learn task instructions on a wide variety of tasks can further leverage the inductive bias of LMs to perform instruction learning (Zhong et al., 2021; Mishra et al., 2021; Wei et al., 2021). Our work is partially inspired by this line of work, but we work under the more generic few-shot meta-learning setting, and show that our approach out-performs both instruction tuning and existing few-shot meta-learning methods (e.g., MAML). While previous work focuses on the accuracy improvement gained from instruction fine-tuning, our work also looks into the well-known over-sensitivity issue of FSL and shows that in-context tuning effectively reduces the sensitivity of FSL with respect to various factors.

Concurrent to our work, Min et al. (2021) also explores in-context tuning under more general Seq2Seq tasks. In comparison, our work compares in-context tuning to a meta-learning baseline MAML, and shows that in-context tuning mitigates the well-known oversensitivity issue of LM prompting. Contrary to our paper, Min et al. (2021) finds that in-context tuning under-performs InsT + FT. This might be because they use many more shots (16-shot), which could give gradient-based methods more advantage.

6 Future Directions

Scaling Up and Broader Applications Our work only considers simple binary classification and knowledge retrieval tasks, at most 5 in-context examples, and models with fewer than 1 billion parameters. Nevertheless, it is straightforward to scale up our framework to a wider and more diverse range of general sequence-to-sequence tasks (Ye et al., 2021), more few-shot examples (which requires a longer context size (Dai et al., 2019; Wang et al., 2020)), and larger models (Brown et al., 2020; Kaplan et al., 2020). It is also straightforward to apply in-context tuning to a broader range of scenarios that require adapting to a new setup, e.g., adapting to a new label in classification tasks (Xia et al., 2021), an unseen database in semantic parsing tasks (Suhr et al., 2020; Lee et al., 2021), or a new language pair in machine translation (Gu et al., 2018; Aharoni et al., 2019), etc.

Meta-learning for Robustness Our work assumed that the few-shot training examples come from the same distribution as the test examples, but this assumption does not necessarily hold in practice. For example, the test distribution might constitute new input compositions (Lake and Baroni, 2018), rare subgroups (Sagawa et al., 2019), other types of distribution shifts (Hendrycks and Dietterich, 2019), or even adversarial examples (Kang et al., 2019). More effective meta-learning methods might learn a more robust learning mechanism and combat these generalization challenges.

Understanding In-context Learning Many properties of in-context learning are still unknown. Is in-context learning more robust to distribution shift (Lester et al., 2021)? Can we combine in-context learning and gradient learning to get the benefit of both worlds (Wortsman et al., 2021)?

7 Conclusion

In this work, we propose meta-learning via in-context tuning, which recasts the few-shot learning process of task adaptation and task-specific prediction as a simple sequence prediction problem, where few-shot labeled examples are concatenated with the target example to form the model input. In-context tuning out-performs a wide variety of baselines in terms of accuracy, including raw LM prompting, MAML and instruction tuning. Meanwhile, sensitivity study shows that our FSL approach of in-context tuning is significantly less sensitive to few-shot examples and instruction wording compared to raw LM prompting.

Given the empirical effectiveness of in-context tuning, we conjecture that the few-shot learning potential of large LMs (e.g., GPT-3) might be broadly underestimated, and that in-context tuning can eliminate well-known artifacts of few-shot LM prompting such as over-sensitivity to example ordering, example selection and instruction wording.

A Hyperparameters

In this section, we report the hyperparameters we tuned for our approach and each baseline.

In-Context Tuning (ours) We tune number of training epochs ([10, 15, 30] for LAMA and [1e-7, 3e-7, 1e-6, 3e-6] for BinaryClfs) and learning rate ([1e-7, 3e-7, 1e-6, 3e-6] for LAMA and [3e-6, 1e-5, 3e-5, 1e-4] for BinaryClfs).

MAML We assume that inner optimization and outer optimization use the same learning rate. We tuned number of adapt steps ([1, 2, 4] for both datasets) and learning rate ([3e-7, 1e-6, 3e-6, 1e-5, 3e-5, 1e-4, 3e-4, 1e-3] for LAMA and [3e-6, 1e-5, 3e-5, 1e-4, 3e-4, 1e-3] for BinaryClfs).

Instruction-Tuning + Fine-tuning For instruction tuning we tuned the same set of hyperparameters as in in-context tuning. The instruction tuning model with the highest validation performance are used for downstream task fine-tuning. For task fine-tuning, we tuned number of training epochs ([5, 10, 15, 30, 40] for LAMA and [5, 10, 15, 30, 40] for BinaryClfs) and learning rate ([1e-7, 3e-7, 1e-6, 3e-6, 1e-5, 3e-5] for LAMA and [3e-6, 1e-5, 3e-5, 1e-4, 3e-4, 1e-3] for BinaryClfs).

It is AI's Turn to Ask Humans a Question:
Question-Answer Pair Generation for Children's Story Books

Abstract

Existing question answering (QA) techniques are created mainly to answer questions asked by humans. But in educational applications, teachers often need to decide what questions they should ask, in order to help students to improve their narrative understanding capabilities. We design an automated question-answer generation (QAG) system for this education scenario: given a story book at the kindergarten to eighth-grade level as input, our system can automatically generate QA pairs that are capable of testing a variety of dimensions of a student's comprehension skills. Our proposed QAG model architecture is demonstrated using a new expert-annotated FAIRYTALEQA dataset, which has 278 child-friendly storybooks with 10,580 QA pairs. Automatic and human evaluations show that our model outperforms state-of-the-art QAG baseline systems. On top of our QAG system, we also start to build an interactive story-telling application for the future real-world deployment in this educational scenario.

1 Introduction

There has been substantial progress in the development of state-of-the-art (SOTA) question-answering (QA) models in the natural language processing community in recent years (Xiong et al., 2019; Karpukhin et al., 2020; Cheng et al., 2020; Mou et al., 2021). However, the opposite of QA tasks–question-answer generation (QAG) tasks that generate questions based on input text–is yet under-explored. We argue, being able to ask a reasonable question is also an important indicator whether the reader comprehends the document, thus belongs to the reading comprehension(RC) task family. QAG also contributes to important real-world applications, such as building automated systems to support teachers to efficiently construct assessment questions (and its correct answer) for the students at a scale (Xu et al., 2021; Snyder et al., 2005).

FAIRYTALEQA Dataset Source (Section)

Maie sighed. she knew well that her husband was right, but she could not give up the idea of a cow. the buttermilk no longer tasted as good as usual in the coffee;

… …

they were students, on a boating excursion, and wanted to get something to eat.'bring us a junket, good mother,' cried they to Maie.'ah! if only i had such a thing!' sighed Maie.

Ground-Truth

- **Q**: What did the three young men ask for?
- **A**: A junket.

`2-Step Baseline` (Shakeri et al., 2020)

- **Q**: Why no more buttermilk for her husband to make?
- **A**: She could not give up the idea of a cow.

`PAQ Baseline` (Lewis et al., 2021)

- **Q**: What did maie think of when she thought of buttermilk?
- **A**: Sweet cream and fresh butter.

Our System

- **Q**: Why did the three young men want a junket?
- **A**: They wanted to get something to eat.

Table 1: A sample of FAIRYTALEQA story section as input and the QA pairs generated by human education experts, `2-step baseline` model, `PAQ` baseline, and our QAG System.

Similar to training QA models, QAG model training requires high-quality and large-scale RC datasets (e.g., NarrativeQA (Kočiskỳ et al., 2018)). However, many of the existing datasets are either collected via crowd-sourcing (Rajpurkar et al., 2016; Kočiskỳ et al., 2018; Reddy et al., 2019), or using automated retrievers (Nguyen et al., 2016;

Joshi et al., 2017; Dunn et al., 2017; Kwiatkowski et al., 2019), thus risking the quality and validity of labeled QA-pairs. This risk becomes especially problematic when building applications in the education domain: While existing QA models may perform well for the general domain, they fall short in understanding what are the most *useful* QA pairs to generate for educational purposes. Specifically, RC is a complex skill vital for children's achievement (Snyder et al., 2005), the datasets should contain questions that focus on a well-defined construct (e.g., narrative comprehension) and measure a full coverage of sub-skills within this construct (e.g., reasoning causal relationship and understanding emotion within narrative comprehension) using items of varying difficulty levels (e.g., inference making and information retrieval) (Paris and Paris, 2003).

In this work, we aim to develop a QAG system to generate high-quality QA-pairs, emulating how a teacher or parent would ask children when reading stories to them (Xu et al., 2021). Our system is built on a novel dataset that was recently released, FairytaleQA (Xu et al., 2022). This dataset focuses on narrative comprehension for elementary to middle school students and contains 10,580 QA-pairs from 278 narrative text passages of classic fairytales. As reported in Xu et al. (2022), FairytaleQA was annotated by education experts and includes well-defined and validated narrative elements laid out in the education research (Paris and Paris, 2003), making it particularly appealing for RC research in the education domain.

Our QAG system design consists of a three-step pipeline: (1) to extract candidate answers from the given storybook passages through carefully designed heuristics based on a pedagogical framework; (2) to generate appropriate questions corresponding to each of the extracted answers using a state-of-the-art (SOTA) language model; and (3) to rank top QA-pairs with a specific threshold for the maximum amount of QA-pairs for each section.

We compare our QAG system with two existing SOTA QAG systems: a `2-step baseline` system (Shakeri et al., 2020) fine-tuned on FairytaleQA, and the other is an end-to-end generation system trained on a large-scale automatically generated RC dataset (`PAQ`) (Lewis et al., 2021). We evaluate the generated QA-pairs in terms of similarity by Rouge-L precision score with different thresholds on candidate QA-pair amounts and semantic as well as syntactic correctness by human evaluation. We demonstrate that our QAG system performs better in both automated evaluation and human evaluation. Table 1 is a sample of FairytaleQA story as input and the QA pairs generated by human education experts, `2-step baseline` model, `PAQ` baseline, and our QAG System.

We conclude the paper by demoing an interactive story-telling application that built upon our QAG system to exemplify the applicability of our system in a real-world educational setting.

2 Related Work

2.1 General QA Datasets

There exists a large number of datasets available for narrative comprehension tasks. These datasets were built upon different knowledge resources and went through various QA-pair creating approaches. For instance, some focus on informational texts such as Wikipedia and website articles(Rajpurkar et al. (2016), Nguyen et al. (2016), Dunn et al. (2017), Kwiatkowski et al. (2019), Reddy et al. (2019)). Prevalent QA-pair generating approaches include crowd-sourcing (Rajpurkar et al., 2016; Kočiský et al., 2018; Reddy et al., 2019), using automated QA-pair retriever (Nguyen et al., 2016; Joshi et al., 2017; Dunn et al., 2017; Kwiatkowski et al., 2019), and etc. Datasets created by the approaches mentioned above are at risk of not consistently controlling the quality and validity of QA pairs due to the lack of well-defined annotation protocols specifically for the targeting audience and scenarios. Despite many of these datasets involving large-scale QA pairs, recent research (Kočiský et al., 2018) found that the QA pairs in many RC datasets do not require models to understand the underlying narrative aspects. Instead, models that rely on shallow pattern matching or salience can already perform very well.

NarrativeQA, for instance, (Kočiský et al., 2018) is a large dataset with more than 46,000 human-generated QA-pairs based on abstractive summaries. Differing from most other RC datasets that can be answerable by shallow heuristics, the NarrativeQA dataset requires the readers to integrate information about events and relations expressed throughout the story content. Indeed, NarrativeQA includes a significant amount of questions that focus on narrative events and the relationship among events (Mou et al., 2021). One may expect that NarrativeQA could also be used for QAG tasks.

In fact, a couple of recent works use this dataset and train a network by combining a QG module and a QA module with a reinforcement learning approach(Tang et al., 2017). For example, Wang et al. (2017) use the QA result to reward the QG module then jointly train the two sub-systems. In addition, Nema and Khapra (2018) also explore better evaluation metrics for the QG system. However, the NarrativeQA dataset is in a different domain than the educational context of our focus. Thus the domain adaptation difficulty is unknown.

2.2 The FairytaleQA Dataset

As previously mentioned, the general-purpose QA datasets (*e.g.,* SQuAD (Rajpurkar et al., 2016), MS MARCO (Nguyen et al., 2016)) are unsuitable for children's education context, as they impose little structure on what comprehension skills are tested and heavily rely on crowd workers typically with limited education domain knowledge. FairytaleQA (Xu et al., 2022) is a newly released RC dataset that precisely aims to solve those issues and complement the lack of a high-quality dataset resource for the education domain. This dataset contains over 10,000 high-quality QA-pairs from almost 300 children's storybooks, targeting students from kindergarten to eighth grade.

As discussed in Xu et al. (2022), FairytaleQA has two unique advantages that make it particularly useful for our project. First, the FairytaleQA was developed based on an evidence-based reading comprehension framework (Paris and Paris, 2003), which comprehensively focuses on seven narrative elements/relations contributing to reading comprehension: `character`, `setting`, `feeling`, `action`, `causal relationship`, `outcome resolution`, and `prediction` (Detailed definition and example of each aspect is described in Appendix A). Second, the development of FairytaleQA followed a rigorous protocol and was fulfilled by trained annotators with educational research backgrounds. This process ensured that the annotation guideline was followed, the style of questions generated by coders was consistent, and the answers to the questions were factually correct. FairytaleQA was reported to have high validity and reliability through a validation study involving actual students (Xu et al., 2022).

2.3 QAG Task

A few years back, rule-based QAG systems (Heilman and Smith, 2009; Mostow and Chen, 2009; Yao and Zhang, 2010; Lindberg et al., 2013; Labutov et al., 2015) were prevalent, but the generated QA suffered from the lack of variety. Neural-based models for question generation tasks (Du et al., 2017; Zhou et al., 2017; Dong et al., 2019; Scialom et al., 2019; Zhao et al., 2022) have been an emerging research theme in recent years. But their focus are on the general domain QAG thus they only used the available general QA dataset for training, we have no idea how these models may perform in an education contxt.

In this paper, we use one recent work Shakeri et al. (2020) as our baseline. They proposed a two-step and two-pass QAG method that firstly generate questions (QG), then concatenates the questions to the passage and generates the answers in a second pass (QA). In addition, we include the recently-published Probably-Asked Questions (PAQ) (Lewis et al., 2021) work as a second baseline. The PAQ system is an end-to-end QAG system trained on the PAQ dataset, a very large-scale QA dataset containing 65M automatically generated QA-pairs from Wikipedia. The primary issue with deep-learning-based models in the targeted children education application is that existing datasets and models do not consider the specific audience's language preference and the educational purposes (Hill et al., 2015; Yao et al., 2012).

Because both rule-based and neural-network-based approaches have their limitations inherently, in our work, we combine these two approaches to balance both the controllability of what types of QA pairs should be generated to better serve the educational purpose, and the diversity of the generated QA sequences.

3 Pre-processing FairytaleQA Dataset

The released FairytaleQA contained 10,580 QA-pairs from 278 books, and each question comes with a label indicating the narrative element(s)/relation(s) the question aims to assess.

We split the dataset into train/validation/test splits with 232/23/23 books and 8,548/1,025/1,007 QA pairs. The split is random, but the statistical distributions in each split are consistent. Table 2 shows core statistics of the FairytaleQA dataset in each split, and Figure 1 shows the distribution of seven types of annotations for the QA pairs across

FairytaleQA Dataset	Train				Validation				Test

the three splits.

4 Question Answer Generation System Architecture

There are three sub-modules in our QA generation (QAG) pipeline: a heuristics-based answer generation module (AG), followed by a BART-based (Lewis et al., 2019) question generation module (QG) module fine-tuned on FairytaleQA dataset, and a DistilBERT-based(Sanh et al., 2019) ranking module fine-tuned on FairytaleQA dataset to rank and select top *N* QA-pairs for each input section. The complete QAG pipeline of our system is shown in Figure 2.

4.1 Heuristics-based AG Module

Based on our observation of the FairytaleQA dataset, educational domain experts seem to have uniform preferences over certain types of question and answer pairs (Figure 1). This may be because these experts take the young children's learning objectives into consideration – children's learning ability should be oriented toward specific types of answers to maximize their learning outcome. That is why educational experts rarely ask yes/no questions in developing or assessing children's reading comprehension. For automated QAG systems, we can design the system to mimic human behaviors either by defining heuristics rules for the answer extraction module, or leaving the filtering step to the end after the QA pairs are generated. However, the latter approach may have inherent risks that the training data could influence the types of answers generated.

We decided to develop and apply the heuristic rules to the answer extraction module. We observed that some narrative elements such as `characters`, `setting`, and `feelings` are mostly made up of name entities and noun chunks, for instance, the character name in a story, a particular place where the story takes place, or a specific emotional feeling. We then leverage the Spacy[1] English model for Part-of-speech tagging on the input content to

---

[1] `https://spacy.io/`

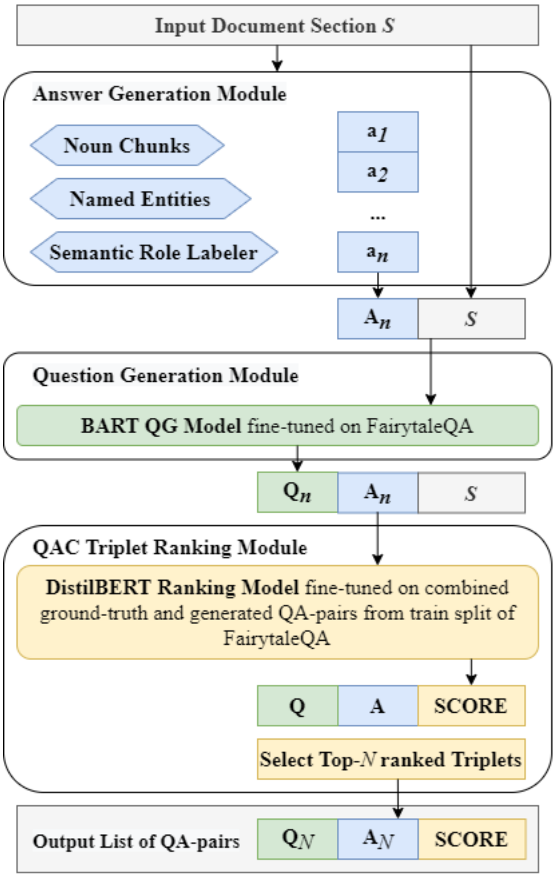

Figure 2: QAG system design with three steps: rule-based answer extraction, NN-based question generation, and NN-based ranking.

extract named entities and noun chunks as candidate answers to cover these three types of narrative elements.

We further observed that the QA pairs created by education experts around the `action`, `causal relationship`, `prediction`, and `outcome resolution` categories are all related to a particular *action event* in the story. Thus, the answers to these four types of questions are generally the description of the action event. We realize that Propbank's semantic roles labeler (Palmer et al., 2005) toolkit is constructive for extracting the action itself and the event description related to the action. We then leverage this toolkit to extract the trigger verb as well as other dependency nodes in the text content that can be put together as a combination of subject, verb, and object and use these as candidate answers for the latter four categories.

Our answer extraction module can generate candidate answers that cover all 7 narrative elements with the carefully designed heuristics.

QG Models Comparison for Our QAG System	Rouge-L	
	Validation	Test
BART fine-tuned on NarrativeQA	0.424	0.442
BART fine-tuned on FairytaleQA	**0.527**	**0.527**
BART fine-tuned on NarrativeQA + FairytaleQA	0.508	0.519

Table 3: Comparison on FairytaleQA dataset among QG models fine-tuned with different settings for the QG module of our QAG system.

4.2 BART-based QG Module

Following the answer extraction module that yields candidate answers, we design a QG module which takes a story passage and an answer as input, and generates the corresponding question as output. The QG task is basically a reversed QA task. Such a QG model could be either transfer-learned from another large QA dataset or fine-tuned on our FairytaleQA dataset. Mainstream QA datasets do cover various types of questions in order to comprehensively evaluate QA model's reading comprehension ability; for instance, NarrativeQA (Kočiský et al., 2018) is a large-scale QA corpus with questions that examine high-level abstractions to test the model's narrative understanding.

We choose NarrativeQA dataset as an alternative option for fine-tuning our QG model because this dataset requires human annotators to provide a diverse set of questions about characters, events, etc., which is similar to the types of questions that education experts created for our FairytaleQA dataset. In addition, we leverage BART(Lewis et al., 2019) as the backbone model because of its superior performance on NarrativeQA according to the study in (Mou et al., 2021).

We perform a QG task comparison to examine the quality of questions generated for FairytaleQA dataset by one model fine-tuned on NarrativeQA, one on FairytaleQA, and the other on both the NarrativeQA and FairytaleQA. We fine-tune each model with different parameters and acquire the one with the best performance on the validation and test splits of FairytaleQA dataset. Results are shown in Table 3. We notice that the model fine-tuned on FairytaleQA alone outperforms the other methods. We attribute this to the domain and distribution differences between the two datasets. That is why the model fine-tuned on both NarrativeQA and FairytaleQA may be polluted by the NarrativeQA training. The best-performing model is selected for our QG module in the QAG pipeline.

4.3 DistilBERT-based Ranking Module

Our QAG system has generated hundreds of candidate QA-pairs through the first two modules. However, we do not know the quality of these generated QA-pairs by far, and it is unrealistic to send back all the candidate QA-pairs to users in a real-world scenario. Consequently, a ranking module is added to rank and select the top candidate QA-pairs, where the user is able to determine the upper limit of generated QA-pairs for each input text content. Here, the ranking task can be viewed as a classification task between the ground-truth QA-pairs created by education experts and the generated QA-pairs generated by our systems.

We put together QA-pairs generated with the first two modules of our QAG system as well as ground-truth QA-pairs from the train/validation/test splits of FairytaleQA dataset, forming new splits for the ranking model, and fine-tuned on a pre-trained DistilBERT model. We test different input settings for the ranking module, including the concatenation of text content and answer only, as well as the concatenation of text content, question, and answer in various orders. Both input settings can achieve over 80% accuracy on the test split, while the input setting of the concatenation of text content, question, and answer can achieve $F1 = 86.7\%$ with a leading more than 5% over other settings. Thus, we acquire the best performing ranking model for the ranking module in our QAG system and allow users to determine the amount of top N generated QA-pairs to be outputted.

5 Evaluation

We conduct both automated evaluation and human evaluation for the QAG task. The input of the QAG task is a section of the story (may have multiple paragraphs), and the outputs are generated QA pairs. Unlike QA or QG tasks that each input corresponds to a single generated output no matter what model is used, the QAG task does not have a fixed number of QA-pairs to be generated for each section. Besides, various QAG systems will generate different amounts of QA-pairs for the same input content. Therefore, we carefully define an evaluation metric that is able to examine the quality of generated QA-pairs over a different amount of candidate QA-pairs. The comparison is on the validation and test splits of FairytaleQA.

QA Models for `2-Step Baseline`	**Rouge-L**	
	Validation	Test
BART fine-tuned on NarrativeQA	0.475	0.492
BART fine-tuned on FairytaleQA	0.533	0.536
BART fine-tuned on NarrativeQA + FairytaleQA	**0.584**	**0.601**

Table 4: Comparison on FairytaleQA dataset among QA models fine-tuned with different settings for the `2-Step Baseline` system (Shakeri et al., 2020).

5.1 Automated Evaluation of QAG Task

5.1.1 Baseline QAG Systems

We select a SOTA QAG system that uses a two-step generation approach (Shakeri et al., 2020) as one baseline system (referred as `2-Step Baseline`). In the first step, it feeds a story content to a QG model to generate questions; then, it concatenates each question to the content passage and generates a corresponding answer through a QA model in the second pass. The quality of generated questions not only relies on the quality of the training data for the QG and QA models but also is not guaranteed to be semantically or syntactically correct because of the nature of neural-based models.

We replicate this work by fine-tuning a QG model and a QA model on FairytaleQA dataset with the same procedures that help us select the best model for our QG module. We use pre-trained BART just like ours as the backbone model to ensure different model architectures do not influence the evaluation results. Unlike our QG module that takes both an answer and text content as the input, their QG model only takes the text content as input. Thus, we are not able to evaluate the QG model solely for this baseline. We replicate the fine-tuning parameters for our QG module to fine-tune the baseline QG model. For the selection of QA model used in the `2-Step Baseline`, similar to the QG experiments we present in Table 3, we fine-tune a pre-trained BART on each of the three settings: NarrativeQA only, FairytaleQA only, and both datasets. According to Table 4, the model that fine-tuned on both NarrativeQA and FairytaleQA datasets performs much better than the other settings and outperforms the model that fine-tuned on FairytaleQA only by at least 6%. We leverage the best performing QA model for the `2-Step Baseline` system.

In addition, we also include the recently published Probably-Asked Questions (`PAQ`) work as a second baseline system (Lewis et al., 2021). PAQ dataset is a semi-structured, very large scale Knowledge Base of 65M QA-pairs. `PAQ` system is an end-to-end QA-pair generation system that is made up of four modules: Passage Scoring, Answer Extraction, Question Generation, and Filtering Generated QA-pairs. The `PAQ` system is trained on the PAQ dataset. It is worth pointing out that during the end-to-end generation process, their filtering module requires loading the complete PAQ corpus into memory for passage retrieval, which leads us to an out-of-memory issue even with more than 50G RAM. [2] In comparison, our QAG system requires less than half of RAM in the fine-tuning process. In Table 1, we show a sample of FairytaleQA story section as input and the QA pairs generated by human education experts, `2-step baseline` model, `PAQ` baseline, and our QAG System. A few more examples are provided in Appendix C.

5.1.2 Evaluation Metrics

Since the goal of QAG is to generate QA-pairs that are most similar to the ground-truth QA-pairs given the same text content, we concatenate the question and answer to calculate the Rouge-L precision score for every single QA-pair evaluation. However, the amount of QA-pairs generated by various systems is different. It is unfair and inappropriate to directly compare all the generated QA-pairs from different systems. Moreover, we would like to see how QAG systems perform with different thresholds on candidate QA-pair amounts. In other words, we are looking at ranking metrics that given an upper bound N as the maximum number of QA-pairs can be generated per section, how similar the generated QA-pairs are to the ground-truth QA-pairs.

Generally, there are three different ranking metrics: Mean Reciprocal Rank (MRR), Mean Average Precision (MAP), and Normalized Discounted Cumulative Gain (NDCG). While MRR is only good to evaluate a single best item from the candidate list and NDCG requires complete rank ratings for each item, neither metric is appropriate in our case. As a result, We decide to use $MAP@N$, where $N \in [1, 3, 5, 10]$, as our evaluation metric for the QAG generation task. Furthermore, since the average amount of ground-truth answers are close to 3 per section in FairytaleQA dataset (Table 2), we expect the $MAP@3$ is the most similar to the actual use case, and we provide four N to describe the comparison results and trends for QAG systems on the FairytaleQA.

Here is the detailed evaluation process on $MAP@N$: for each ground-truth QA-pair, we find the highest Rouge-L precision score on the concatenation of generated question and answer, among top N generated QA-pairs from the same story section. Then we average overall ground-truth QA-pairs to get the $MAP@N$ score. This evaluation metric evaluates the QAG system's performance on different candidate levels and is achievable even there is no ranking module in the system. For our QAG system, we just need to filter top N QA-pairs from our ranking module; for the `2-Step Baseline` and the `PAQ` baseline system, we simply adjust a *topN* parameter in the configuration.

5.1.3 Evaluation Results

Table 5 presents the evaluation results of our system and two SOTA baseline systems in terms of $MAP@N, N \in [1, 3, 5, 10]$. We observe our system outperforms both the `2-Step baseline` system and `PAQ` system in all settings with significantly better Rouge-L precision performance on both the validation and test splits of FairytaleQA dataset. According to the evaluation results, the `2-Step baseline` system suffers from the inherent lack of quality control of neural models over both generated answers and questions. We notice that the ranking module in our QAG system is an essential component of the system in locating the best candidate QA-pairs across different limits of candidate QA-pair amounts. The more candidate QA-pairs allowed to be selected for each section, the better our system performs compared to the other two baseline systems. Still, the Rouge-L score lacks the ability to evaluate the syntactic and semantic quality of generated QA-pairs. As a result, we further conduct a human evaluation to provide qualitative interpretations.

5.2 Human Evaluation of QA Generation

We recruited five human participants ($N = 5$) to conduct a human evaluation to evaluate further our model generated QA quality against the ground-truth and the baseline (only against `PAQ` system as it outperforms the `2-Step Baseline`).

In each trial, participants read a storybook section and multiple candidate QA pairs for the same section: three generated by the baseline `PAQ` system, three generated by our system (top-3), and the

---

[2] We do not use the filtering module for `PAQ` system because of unable to solve the memory issue with their provided code.

QAG Systems	MAP@N with Rouge-L Precision on Q+A for val/test splits			
	$N = 10$	$N = 5$	$N = 3$	$N = 1$
Ours	**0.620 / 0.596**	**0.543 / 0.523**	**0.485 / 0.452**	**0.340 / 0.310**
`2-Step Baseline`	0.443 / 0.422	0.370 / 0.353	0.322 / 0.305	0.225 / 0.216
`PAQ Baseline`	0.504 / 0.485	0.436 / 0.424	0.387 / 0.378	0.288 / 0.273

Table 5: Results of QAG task by our system and two baseline systems. Left numbers are for validation split and right numbers are for test split.

	Ours		**`PAQ Baseline`**		**`Groundtruth`**	
	M	**SD**	**M**	**SD**	**M**	**SD**
Readability (1 to 5)**	4.71	0.70	4.08	1.13	4.95	0.28
Question Relevancy* (1 to 5)	4.39	1.15	4.18	1.22	4.92	0.33
Answer Relevancy (1 to 5)	3.99	1.51	3.90	1.62	4.83	0.57

Table 6: Human evaluation results.

others were the ground-truth. Participants did not know which model each QA pair was from. The participant was asked to rate the QA pairs along three dimensions using a five-point Likert-scale.

- *Readability*: The generated QA pair is in readable English grammar and words.
- *Question Relevancy*: The generated question is relevant to the storybook section.
- *Answer Relevancy*: The generated answer is relevant to the question.

We first randomly selected 7 books and further randomly selected 10 sections out of these 7 books (70 QA pairs). Each participant was asked to rate these same 70 QA pairs to establish coding consistency. The intercoder reliability score (Krippendorff's alpha (Krippendorff, 2011)) among five participants along the four dimensions are between 0.73 and 0.79, which indicates an acceptable level of consistency.

Then, we randomly selected 10 books (5 from test and 5 from validation splits), and for each book, we randomly selected 4 sections. Each section, on average, has 9 QA-pairs (3 from each model). We assigned each section randomly to two coders. In sum, each coder coded 4 books (i.e. 16 sections and roughly 140 QA-pairs), and in total 722 QA-pairs were rated.

We conducted *t-tests* to compare each model's performance. The result (Table 6) shows that for the *Readability* dimension, our model (avg=4.71, s.d.=0.70) performed significantly better than the `PAQ` model (avg=4.08, s.d.=1.13, $t(477) = 7.33, p < .01$), but was not as good as the ground-truth (avg=4.95, s.d.=0.28, $t(479) = -4.85, p < .01$).

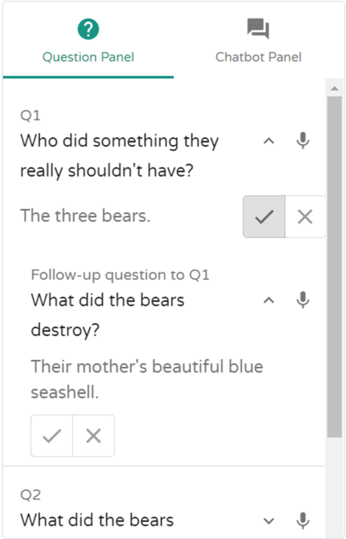
For the *Question Relevancy* dimension, ground-truth also has the best rating (avg=4.92, s.d.=0.33), which was significantly better than the other two models. Our model (avg=4.39, s.d.=1.15) comes in second and outperforms baseline (avg=4.18, s.d.=1.22, $t(477) = 1.98, p < .05$). The result suggests that questions generated by our model can generate more relevant to the story plot than those generated by the baseline model.

For the *Answer Relevancy* dimension, in which we consider how well the generated answer can answer the generated question, the ground-truth (avg=4.83,s.d.=0.57) significant outperformed two models again. Our model (avg=3.99, s.d.=1.51) outperformed `PAQ` baseline model (avg=3.90, s.d.=1.62, $t(477) = 0.58, p = .56$), but the result is not significant.

All results show our model has above-average (>3) ratings, which suggests it reaches an acceptable user satisfaction along all three dimensions.

5.3 Question Answer Generation in an Interactive Storytelling Application

To exemplify the real-world application of our QAG system, we developed an interactive storytelling application built upon our QAG system. This system is designed to facilitate the language and cognition development of pre-school children via interactive QA activities during a storybook reading session. For example, as children move on to a new storybook page, the back-end QAG system will generate questions for the current section. Furthermore, to optimize child engagement in the QA session, the QAG system also generates follow-up questions for each answered question



Q1
Who did something they really shouldn't have?

The three bears.

Follow-up question to Q1
What did the bears destroy?

Their mother's beautiful blue seashell.

Q2
What did the bears

Figure 3: The QA panel of our interactive storytelling application built upon our QAG system. The full user interface is shown in Appendix D.

as shown in Figure 3. A conversational chatbot interacts with children, reads the story, facilitates questioning-and-answering via speech. The system can also keep track of child performance for the parents.

A preliminary user study with 12 pairs of parents and children between the ages of 3-8 suggests that this application powered by our QAG system can successfully maintain engaging conversations with children about the story content. In addition, both parents and children found the system useful, enjoyable, and easy to use. Further evaluation and deployment details of this interactive storytelling system can be found in (Zhang et al., 2022).

6 Conclusion and Future Work

In this work, we explore the question-answer pair generation task (QAG) in an education context for young children. Leveraging a newly-constructed expert-annotated QA dataset built upon child-oriented fairytale storybooks (`FairytaleQA`), we implemented a QA-pair generation pipeline which, as observed in human and automated evaluation, effectively supports our objective of automatically generating high-quality questions and answers at scale. To examine the model's applicability in the real world, we further built an interactive conversational storybook reading system that can surface the QAG results to children via speech-based interaction.

Our work lays a solid foundation for the promising future of using AI to automate educational question answering tasks. In the future, we plan to recruit educational experts to evaluate the educational efficacy of the QA-pairs as an additional evaluation dimension. Another future direction is to develop a context-aware multi-turn QAG system grounded by the story narratives (similar to (Li et al., 2021)), where the generation of a new turn of QA is conditioned on previous generations as well as the book, so that it can enable new automated dialogue systems in the education setting.

Narrative Element	Definition	Example
Character	Ask test takers to identify the character of the story or describe characteristics of characters	Q: *Who does Cassim marry after the death of their father?* A: *A wealthy woman*
Setting	Ask about a place or time where/when story events take place and typically start with "Where" or "When."	Q: *Where did Lucdina and Jane Doll-cook buy their groceries?* A: *Ginger and Pickles*
Feeling	Ask about the character's emotional status or reaction to certain events and are typically worded as "How did/does/do … feel"	Q: *How did Ivan and Marie feel when Snowflake disappeared?* A: *sad*
Action	Ask characters' behaviors or additional information about that behavior	Q: *What does Ali Baba do when his brother does not come back?* A: *goes to the cave to look for him*
Casual Relationship	Focus on two events that are causally related where the prior events have to causally lead to the latter event in the question. This type of question usually begins with "Why" or "What made/makes."	Q: *Why does Cassim forget the magic words to seal the cave?* A: *his greed and excitement over the treasures*
Outcome Resolution	Ask for identifying outcome events that are causally led to by the prior event in the question. This type of question is usually worded as "What happened/happens/has happened… after..."	Q: *What happened when January 1st came?* A: *There was still no money, and Pickles was unable to buy a dog license*
Prediction	Ask for the unknown outcome of a focal event. This outcome is predictable based on the existing information in the text	Q: *What will happen to the Snow-man when the weather changes?* A: *thaw*

Table 7 shows detailed definition and example for each of the 7 narrative elements in FairytaleQA dataset.

B Distribution of FairytaleQA annotations on 7 narrative elements

Table 8 shows the distribution of QA-pair annotations on 7 essential narrative elements that are defined in (Paris and Paris, 2003) of FairytaleQA dataset. The distribution of narrative elements is consistent across train/validation/test splits.

C QAG generation examples with 3 systems

Table 9 shows two more examples of FairytaleQA story section as input and the QA pairs generated by human education experts, `2-step baseline` model, `PAQ` baseline, and our QAG System.

D User Interface of down-streaming application

Figure 4 is a screenshot of the interactive storytelling system interface StoryBuddy (Zhang et al., 2022) for the down-streaming task of our QAG system in a real-world use scenario. Children can listen to the automatic story reading and try to answer the plot-relevant questions generated by the QAG system. They can answer the question via a microphone, and the system will judge the correctness of their answer. After answering a 'parent' question, children can go further to answer a follow-up question or try out other 'parent' questions.

E Fine-tuning Parameters

For fine-tuning the QA model for the `2-Step Baseline`, we select the best performing model with the following hyper-parameters: *learning rate* = $5e^{-6}$; *batch size* = 1; *epoch* = 1.
For fine-tuning the QG model for our QAG system, we select the best performing model with the following hyper-parameters: *learning rate* = $5e^{-6}$; *batch size* = 1; *epoch* = 3.

Category	**Train**		**Validation**		**Test**

Abstract

Weakly-supervised learning (WSL) has shown promising results in addressing label scarcity on many NLP tasks, but manually designing a comprehensive, high-quality labeling rule set is tedious and difficult. We study interactive weakly-supervised learning—the problem of iteratively and automatically discovering novel labeling rules from data to improve the WSL model. Our proposed model, named PRBoost, achieves this goal via iterative prompt-based rule discovery and model boosting. It uses boosting to identify large-error instances and then discovers candidate rules from them by prompting pre-trained LMs with rule templates. The candidate rules are judged by human experts, and the accepted rules are used to generate complementary weak labels and strengthen the current model. Experiments on four tasks show PRBoost outperforms state-of-the-art WSL baselines up to 7.1%, and bridges the gaps with fully supervised models.Our Implementation is available at `https://github.com/rz-zhang/PRBoost`.

1 Introduction

Weakly-supervised learning (WSL) has recently attracted increasing attention to mitigate the label scarcity issue in many NLP tasks. In WSL, the training data are generated by weak labeling rules obtained from sources such as knowledge bases, frequent patterns, or human experts. The weak labeling rules can be matched with unlabeled data to create large-scale weak labels, allowing for training NLP models with much lower annotation cost. WSL has recently achieved promising results in many tasks including *text classification* (Awasthi et al., 2020; Mekala and Shang, 2020; Meng et al., 2020; Yu et al., 2021b), *relation extraction* (Zhou et al., 2020), and *sequence tagging* (Lison et al., 2020; Safranchik et al., 2020; Li et al., 2021b).

Despite its success, WSL is limited by two major factors: 1) the labeling rules, and 2) the static learning process. First, it is challenging to provide a comprehensive and high-quality set of labeling rules a priori. Labeling rules are often human-written (Ratner et al., 2017; Hancock et al., 2018), but the process of writing labeling rules is tedious and time-consuming even for experts. A few works attempt to automatically discover labeling rules by mining labeled data (Varma and Ré, 2018), or enumerating predefined types. However, the pre-extracted rules are restricted to frequent patterns or predefined types, which are inadequate for training an accurate model. Second, most existing WSL methods are static and can suffer from the noise in the initial weak supervision (Ratner et al., 2017; Zhou et al., 2020; Yu et al., 2021b; Meng et al., 2020; Zhang et al., 2022). As the labeling rule set remains fixed during model training, the initial errors can be amplified, resulting in an overfitted end model. Interactive rule discovery has been explored in two recent works (Boecking et al., 2021; Galhotra et al., 2021), which solicits human feedback on candidate rules to refine the rule set. Unfortunately, their rule forms are limited to simple repetitive structures such as *n*-grams (Boecking et al., 2021), and the huge rule search space makes an enumerating-pruning pipeline not scalable for large datasets (Galhotra et al., 2021).

Due to the above reasons, state-of-the-art WSL methods still underperform fully-supervised methods by significant gaps on many NLP tasks. As shown in a recent study (Zhang et al., 2021), the best WSL methods fall behind the best fully-supervised methods in 15 out of 18 NLP benchmarks; and the average performance gap is 18.84% in terms of accuracy or F1 score.

To bridge the gap between weakly-supervised and fully-supervised approaches, we propose an iterative rule discovery and boosting framework, namely PRBoost for interactive WSL. Compared to existing works on WSL and active learning, PRBoost features three key designs:

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 745 - 758
May 22-27, 2022

First, we design a rule discovery module that uses rule templates for prompting pre-trained language models (PLMs). By feeding difficult instances and rule templates into PLMs, the module distills knowledge from PLMs via prompting and generates candidate rules that capture key semantics of the input instances. Compared to prior works based on *n*-grams (Boecking et al., 2021), our prompt-based rule discovery is more expressive and applicable to any tasks that support prompting.

Second, we design a boosting-style ensemble strategy to iteratively target difficult instances and adaptively propose new rules. In each iteration, we reweigh data by the boosting error to enforce the rule discovery module to focus on larger-error instances. This avoids enumerating all the possible rules and implementing post-filtering for novel rules, but directly targets rule discovery on large-error instances to provide complementary information to the current model.

Third, we strategically solicit human feedback to evaluate the candidate rules. Humans are asked to judge whether a candidate rule should be accepted or abstained. The accepted high-quality rules are then used to generate new weak labels that are fed into boosted model training. As the prompt-generated rules are highly interpretable, the rule evaluation is simply a binary choice task for human experts and thus effortless. Unlike traditional active learning methods that annotate individual instances, such a rule-level annotation is more label-efficient because the annotated rules can match large amounts of instances.

We compare our method with supervised, weakly-supervised and interactive learning baselines on four tasks: relation extraction, ontology classification, topic classification, and chemical-protein interaction prediction. The results show: 1) Our method outperforms state-of-the-art weakly-supervised baselines by up to 7.1%; 2) The rule-level annotation helps the model achieve higher model performance compared to the instance-level annotation under the same budget; 3) The machine-discovered and human-evaluated rules are of high quality, which consistently refine the weak labels and the model in each iteration.

Our key contributions are: (1) a prompt-based rule discovery framework for interactive WSL, which provides flexible rule representation while capturing subtle semantics in rule generation; (2) an iterative boosting strategy for discovering novel rules from hard instances and strengthening the model by an ensemble of complementary weak models; (3) an interpretable and easy-to-annotate interactive process for rule annotation; (4) comprehensive experiments demonstrating the effectiveness of our framework.

2 Related Work

Weakly-Supervised Learning WSL has recently attracted much attention in various NLP tasks. Despite their promising performance on various tasks, manually designing the rules can be time-consuming. Moreover, the noise and incompleteness of the initial rules could be propagated in model training (Zhang et al., 2021). A few works attempt to reduce human efforts in manually designing labeling rules by discovering rules from data. For example, Snuba (Varma and Ré, 2018) generates heuristics based on a small labeled dataset with pre-defined rule types; TALLOR (Li et al., 2021a) and GLaRA (Zhao et al., 2021) study rule expansion for NER problem based on lexical information and then select rules based on a hand-tuned threshold. However, these methods discover rules in a static way and are constrained to task-specific rule types. In contrast, our framework discovers rules iteratively from the entire unlabeled dataset, which can refine the rule set and enlarge its diversity on-the-fly.

Interactive Learning Our work is related to *active learning* (AL) as both involve human annotators in the learning process. However, the key difference is that AL labels *instances* based on various query policies (Holub et al., 2008; Shen et al., 2017; Zhang et al., 2020; Ein-Dor et al., 2020; Margatina et al., 2021; Yu et al., 2021a), while our method does not annotate individual instances, but uses annotated rules to match unlabeled data. This makes our method more label-efficient in leveraging human feedback for creating large-scale labeled data. To the best of our knowledge, only a few works have studied *interactive WSL* (Boecking et al., 2021; Galhotra et al., 2021; Choi et al., 2021; Hsieh et al., 2022) as in our problem. However, they either use simple n-gram based rules (Boecking et al., 2021; Hsieh et al., 2022) that fail to capture sentence-level semantics, or suffer from a huge searching space for context-free grammar rules (Galhotra et al., 2021). Unlike these works, our method uses flexible rule representations based on prompts, and also uses boosting for targeted rule discovery to avoid enumerating all possible rules and performing post-filtering for novel rules.

Language Model Prompting Our work is also related to prompt-based learning for PLMs, which converts the original task to a cloze-style task and leverages PLMs to fill the missing information (Brown et al., 2020; Liu et al., 2021a). Prompting has been explored in various tasks, including text classification (Hu et al., 2021; Han et al., 2021; Schick and Schütze, 2021a,b), information extraction (Lester et al., 2021; Chen et al., 2021) and text generation (Dou et al., 2021; Li and Liang, 2021). Recent works focus on generating better prompt templates or learning implicit prompt embeddings (Gao et al., 2021; Liu et al., 2021b,c). However, none of these works studied prompting for generating weak labels. Our work is orthogonal to them since we do not aim to optimize prompts for the original task, but uses prompts and PLMs as a knowledge source for rule discovery.

3 Preliminaries

Problem Formulation Weakly-supervised learning (WSL) creates weak labels for model training by applying labeling rules over unlabeled instances D_u. Given an unlabeled instance $\boldsymbol{x} \in D_u$, a labeling rule $r(\cdot)$ maps $\boldsymbol{x}$ into an extended label space: $r(\boldsymbol{x}) \rightarrow y \in \mathcal{Y} \cup \{0\}$. Here $\mathcal{Y}$ is the original label set for the task, and 0 is a special label indicating $\boldsymbol{x}$ is unmatchable by r. Given a set $\mathcal{R}$ of labeling rules, we can apply each rule in $\mathcal{R}$ on unlabeled instances to create a weakly labeled dataset $\mathcal{D}_l'$.

However, the initial weak labels $\mathcal{D}_l'$ can be highly noisy and incomplete, which hinder the performance of WSL. We thus study the problem of *interactive* WSL: *how can we automatically discover more high-quality labeling rules to enhance the performance of WSL?* Besides D_u and $\mathcal{D}_l'$, we also assume access to a small set of clean labels $\mathcal{D}_l$ ($|\mathcal{D}_l| \ll |\mathcal{D}_u|$), and the task is to iteratively find a set of new rules for model improvement. In each iteration t, we assume a fixed rule annotation budget $\mathcal{B}$, *i.e.*, one can propose at most $\mathcal{B}$ candidate rules $\mathcal{R}_t = \{r_j\}_{j=1}^{\mathcal{B}}$ to human experts for deciding whether each rule should be accepted or not. The accepted rules $\mathcal{R}_t^+$ are then used to create new weakly labeled instances $\mathcal{D}_t'$. From $\mathcal{D}_t' \cup \mathcal{D}_l'$, a model $m_t : \mathcal{X} \rightarrow \mathcal{Y}$ can be trained to boost the performance of the current WSL model.

Rule Representation Multiple rule representations have been proposed in WSL for NLP tasks. For example, *keyword-based rules* are widely used to map certain keywords to their highly correlated labels (Boecking et al., 2021; Meng et al., 2020; Mekala and Shang, 2020; Liang et al., 2020). *Regular expression* is another common rule format, which matches instances with pre-defined surface patterns (Awasthi et al., 2020; Yu et al., 2021b; Zhou et al., 2020). *Logical rules* (Hu et al., 2016; Li et al., 2021a) perform logical operations (such as conjunction $\wedge$ and negation $\neg$) over atomic rules and can thus capture higher-order compositional patterns.

We adopt a prompt-based rule representation (Section 4.1), which is flexible to encompass any existing rule representations. Our prompt-based rule relies on a rule template $\tau(\cdot)$ for the target task, which contains a `[MASK]` token to be filled by a PLM $\mathcal{M}$ along with an unlabeled instance $\boldsymbol{x}$. From the rule template τ , each candidate rule can be automatically derived by $r = g(\mathcal{M}, \tau, \boldsymbol{x})$. Such a prompt-based rule representation is highly flexible and can be applied to any NLP tasks that support prompting (see examples in Table 1).

4 Methodology

Overview PRBoost is an iterative method for interactive WSL. In each iteration, it proposes candidate rules from large-error instances, solicits human feedback on candidate rules, generates weak labels, and trains new weak models for ensembling. Figure 1 shows the process in one iteration of PRBoost, which relies on three key components:

1. *Candidate rule generation.* This component proposes candidate rules to be evaluated by human annotators. Using the small labeled dataset $\mathcal{D}_l$, it measures the weakness of the current model by identifying large-error instances on $\mathcal{D}_l$, and proposes rules based on these instances using PLM prompting.

2. *Rule annotation and weak label creation.* This component collects human feedback to improve the weak supervision quality. It takes as input the candidate rules proposed by the previous component, and asks humans to select the high-quality ones. Then the human-selected rules $\mathcal{R}_t$ are used to generate weak labels for the unlabeled instances $\mathcal{D}_u$ in a soft-matching way.

3. *Weakly supervised model training and ensemble.* We train a new weak model m_{t+1} on the updated

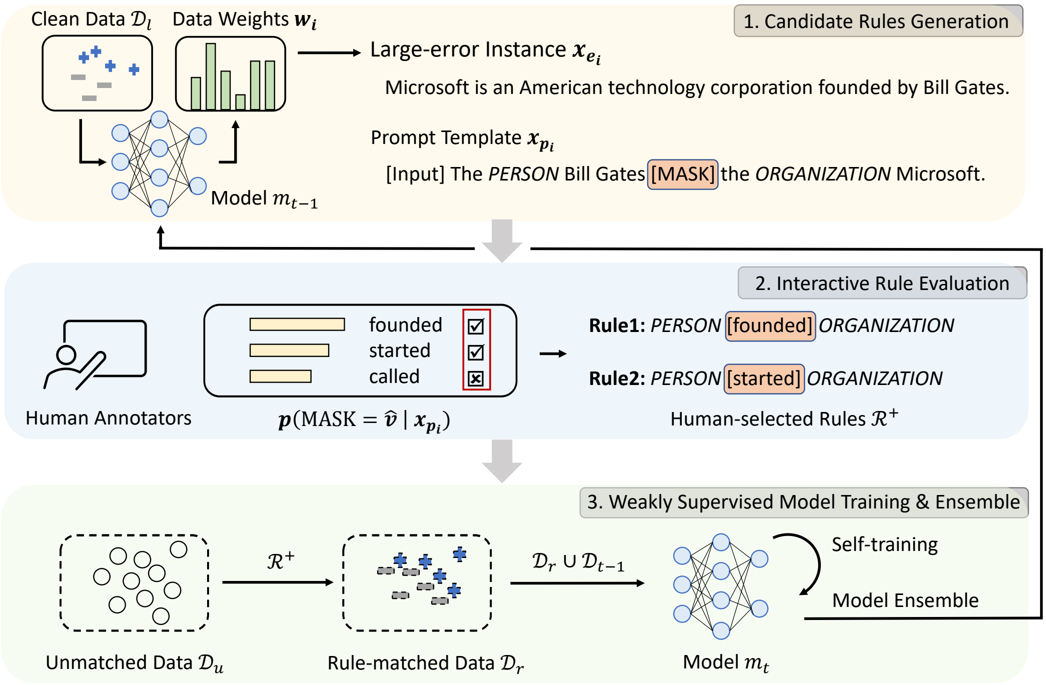

Figure 1: Overall framework for PRBoost. In each iteration, PRBoost (1) identifies large-error instances from the limited clean data and converts each large-error instance to a prompt template for prompting-based rule discovery; (2) presents candidate rules to human experts for annotation and uses accepted rules to generate new weak labels; (3) trains a new weak model with self-training and ensembles it with the previous models.

weakly labeled dataset $\mathcal{D}_r$. Then we self-train the weak model m_{t+1} and integrate it into the ensemble model.

4.1 Candidate Rule Generation

Target rule proposal on large-error instances We design a boosting-style (Hastie et al., 2009) strategy for generating prompt-based candidate rules. This strategy iteratively checks feature regimes in which the current model m_t is weak, and proposes candidate rules from such regimes. We use the small labeled dataset $\mathcal{D}_l$ to identify hard instances, i.e., where the model tends to make cumulative mistakes during iterative learning. The discovered rules can complement the current rule set $\mathcal{R}$ and refine the weak labels, so the next model m_{t+1} trained on the refined weakly labeled data can perform better in the weak regimes.

We initialize the weights of the instances in $\mathcal{D}_l$ as $w_i = 1/|\mathcal{D}_l|, i = 1, 2, \cdots, |\mathcal{D}_l|$. During the iterative model learning process, each w_i is updated as the model's weighted loss on instance $\boldsymbol{x}_i \in \mathcal{D}_l$. Specifically, in iteration $t \in \{1, \cdots, n\}$, we weigh the samples by

$$w_i \leftarrow w_i \cdot e^{\alpha_t \mathbb{I}(y_i \neq m_t(\boldsymbol{x}_i))}, i = 1, 2, \ldots, |\mathcal{D}_l|. \quad (1)$$

In Equation 1, α_t is the weight of model m_t, which will be used for both detecting hard instances and model ensembling (Section 4.3). We compute α_t from the model's error rate on $\mathcal{D}_l$:

$$\alpha_t = \log \frac{1 - \text{err}_t}{\text{err}_t} + \log(K - 1), \quad (2)$$

where err_t is given by

$$\text{err}_t = \sum_{i=1}^{|\mathcal{D}_l|} w_i \mathbb{I}\left(y_i \neq m_t\left(\boldsymbol{x}_i\right)\right) / \sum_{i=1}^{|\mathcal{D}_l|} w_i. \quad (3)$$

Intuitively, a sample $\boldsymbol{x}_i$ receives a larger weight w_i (Equation 1) if the model ensemble consistently make mistakes on $\boldsymbol{x}_i$. A large error is often caused by poor coverage (unlabeled instances matched by few or no rules) or dominating noise in the local feature regimes (rule-matched labels are wrong). The weights can thus guide the rule generator to target the top-n large-error instances $\mathcal{X}_e = \{\boldsymbol{x}_{e_i}\}_{i=1}^n$. By proposing rules from such instances, we aim to discover novel rules that can complement the current rule set and model ensemble most effectively.

Prompt-based rule proposal For a wide range of NLP tasks such as relation extraction and text classification, we can leverage prompts to construct informative rule templates, which naturally leads to expressive labeling rules for WSL.

Motivated by this, we design a rule proposal module based on PLM *prompting*. We present concrete examples of our prompt-based rules in Table 1. The input instance comes from the large-error in-

Input :	Microsoft is an American technology corporation founded by Bill Gates.
Prompt :	`[Input]` The Person Bill Gates `[Mask]` the Organization Microsoft.
Rule :	$\{$Entity Pair $==$ (Person, Org)$\} \wedge \{$`[Mask]` $==$ *founded*$\} \wedge \{s_{t,j} \geq$ threshold$\} \rightarrow$ **per:found**
Input :	Marvell Software Solutions Israel is a wholly owned subsidiary of Marvell Technology Group.
Prompt :	`[Input]` The Marvell Software Solutions Israel is a `[Mask]`.
Rule :	$\{$`[Mask]` $==$ *subsidiary* $\vee$ *corporation* $\vee$ *company*$\} \wedge \{s_{t,j} \geq$ threshold$\} \rightarrow$ **Company**
Input :	Liverpool short of firepower for crucial encounter. Rafael Benitez must gamble with Liverpools Champions League prospects tonight but lacks the ammunition to make it a fair fight.
Prompt :	`[Mask]` News: `[Input]`
Rule :	$\{$`[Mask]` $==$ *Liverpool* $\vee$ *Team* $\vee$ *Football* $\vee$ *Sports*$\} \wedge \{s_{t,j} \geq$ threshold$\} \rightarrow$ **Sports**

Table 1: The examples of prompt-based rules for relation extraction, ontology classification, and news topic classification. Here `[Input]` denotes the original input, `[Mask]` denotes the mask token, and $\wedge$, $\vee$ are the logical operators. We use bold words to show the ground-truth label of the original input.

stances identified on the clean dataset $\mathcal{D}_l$. For each task, we have a task-specific template to reshape the original input for prompting PLMs. The resulting prompt typically includes the original input as the context and a mask token to be filled by the PLMs. The final rule encompasses multiple atomic parts to capture different views of information. Each rule is accompanied by a ground-truth label of the original input instance, such a label will be assigned to the unlabeled instances matched by this rule.

For example, as shown in Table 1, the prompt of the relation extraction task can be "*entity* `[MASK]` *entity*", which rephrases the original input using relation phrases while keeping the key semantics. Take news topic classification as another example, by filling the masked slot in the prompt, PLMs propose candidate keyword-based rules for topic classification. Different from the rules extracted from surface patterns of the corpus (*e.g.*, n-gram rules), such a prompt-based rule proposal can generate words that do not appear in the original inputs—this capability is important to model generalization.

Given a large-error instance $\boldsymbol{x}_{e_i} \in \mathcal{X}_e$, we first convert it into a prompt by $\boldsymbol{x}_{p_i} = \tau(\boldsymbol{x}_{e_i})$. Such a prompt consists of the key components of the original input and a `[MASK]` token. By inheriting the original input, we construct context for the `[MASK]` token to be predicted by a pre-trained LM $\mathcal{M}$. To complete the rule, we feed each $\boldsymbol{x}_{p_i}$ to $\mathcal{M}$ to obtain the probability distribution of the `[MASK]` token over the vocabulary $\mathcal{V}$:

$$p(\texttt{MASK} = \hat{\mathbf{v}} \mid \boldsymbol{x}_{p_i}) = \frac{\exp\left(\hat{\mathbf{v}} \cdot \mathcal{M}(\boldsymbol{x}_{p_i})\right)}{\sum\limits_{\mathbf{v} \in \mathcal{V}} \exp\left(\mathbf{v} \cdot \mathcal{M}(\boldsymbol{x}_{p_i})\right)}, \tag{4}$$

where $\mathcal{M}(\cdot)$ denotes the output vector of $\mathcal{M}$, $\mathbf{v}$ is the embedding of the token in the vocabulary $\mathcal{V}$, and $\hat{\mathbf{v}}$ is the embedding of the predicted masked token. We collect the top-k predictions with highest $p(\texttt{MASK} = \hat{\mathbf{v}} \mid \boldsymbol{x}_{p_i})$ to form the candidate rules. By filling the rules based on $\boldsymbol{x}_{e_i}$ with the prompt predictions, we obtain the candidate rule set in iteration t, denoted as $\mathcal{R}_t = \{r_j\}_{j=1}^{\mathcal{B}}$.

4.2 Rule Annotation and Matching

Interactive rule evaluation As the candidate rules $\mathcal{R}_t$ can be still noisy, PRBOOST thus presents $\mathcal{R}_t$ to humans for selecting high-quality rules. Specifically, for each candidate rule $r_j \in R_t$, we present it along with its prompt template $\boldsymbol{x}_{p_j}$ to human experts, then they judge whether the rule r_j should be accepted or not. Formally, r_j is associated with a label $d_j \in \{1, 0\}$. When a rule is accepted ($d_j = 1$), it will be incorporated into the accepted rule set $\mathcal{R}^+$ for later weak label generation.

Weak Label Generation After human evaluation, the accepted rules $\mathcal{R}_t^+$ are used to match unlabeled instances $\mathcal{D}_u$. We design a mixed soft-matching procedure for matching rules with unlabeled instances, which combines embedding-based similarity and prompt-based vocabulary similarity. The two similarities complements each other: the embedding-based similarity captures global semantics, while the prompt-based similarity captures local features in terms of vocabulary overlapping. Given a rule $r_j \in \mathcal{R}_t^+$ and an unlabeled instance $\boldsymbol{x}_u \in \mathcal{D}_u$, we detail the computations of the two similarities below.

First, the embedding similarity is computed as the cosine similarity between the rule and instance embeddings (Zhou et al., 2020):

$$s_j^a = (\mathbf{e}_u \cdot \mathbf{e}_{r_j}) / (\|\mathbf{e}_u\| \cdot \|\mathbf{e}_{r_j}\|), \tag{5}$$

where $\mathbf{e}_u$ is the instance embedding of $\boldsymbol{x}_u$ and $\mathbf{e}_{r_j}$ is the rule embedding of r_j, both embeddings are obtained from a PLM encoder.

Next, to compute the prompt-based similarity, we feed $\tau(\boldsymbol{x}_u)$ into the prompting model (Equation 4) and use the top-k candidates of the `[MASK]` position as the predicted vocabulary for instance $\boldsymbol{x}_u$.

We measure the vocabulary overlapping between $\mathcal{V}_u$ and $\mathcal{V}_{r_j}$ as

$$s_j^b = \mid \mathcal{V}_u \cap \mathcal{V}_{r_j} \mid / k, \tag{6}$$

where $\mathcal{V}_u$ is the vocabulary of instance $\boldsymbol{x}_u$ and $\mathcal{V}_{r_j}$ is the vocabulary of rule r_j. Note that for the unlabeled instance, we have $|\mathcal{V}_u| = k$, while for the rule, we have $|\mathcal{V}_{r_j}| \leq k$ because human annotators may abstain some candidate predictions.

The final *matching score* is computed by combining the above two similarities:

$$s_j = \alpha s_j^a + (1-\alpha) s_j^b. \tag{7}$$

The instance $\boldsymbol{x}_u$ is matched by the rule r_j if s_j is higher than the matching threshold σ obtained on the development set. When $\boldsymbol{x}_u$ is matched by multiple rules that provide conflicting labels, we use the one with the highest matching score to assign the weak label. If $\forall j \in 1, \cdots, k$, the matching score s_j is lower than σ, we abstain from labeling the instance $\boldsymbol{x}_u$.

4.3 Model Training & Ensemble

In iteration t, with the new rule-matched data $\mathcal{D}_r$, we obtain an enlarged weakly labeled dataset $\mathcal{D}_t = \mathcal{D}_{t-1} \cup \mathcal{D}_r$. We fit a weak model m_t on $\mathcal{D}_t$ by optimizing:

$$\min_\theta \frac{1}{|\mathcal{D}_t|} \sum_{(\boldsymbol{x}_i, \hat{y}_i) \in \mathcal{D}_t} \ell_{\text{CE}} \left(m_t(\boldsymbol{x}_i), \hat{y}_i \right), \tag{8}$$

where $\hat{y}_i$ is the weak label for instance $\boldsymbol{x}_i$, and ℓ_{CE} is the cross entropy loss.

While the weakly labeled dataset has been enlarged, there are still unmatched instances in D_u. To exploit such unlabeled and unmatched instances, we adopt the self-training technique for weak model training (Lee, 2013). The self-training process can propagate information from the matched weak labels to the unmatched instances to improve the model m_t. Following previous models (Xie et al., 2016; Yu et al., 2021b), for each instance $\boldsymbol{x}_i \in \mathcal{D}_u$, we generate a soft pseudo-label $\widetilde{\boldsymbol{y}}_{ij}$ from the current model m_t:

$$\widetilde{\boldsymbol{y}}_{ij} = \frac{q_{ij}^2 / f_j}{\sum_{j' \in \mathcal{Y}} (q_{ij'}^2 / f_{j'})}, \quad f_j = \sum_i q_{ij} \tag{9}$$

where $q_i = m_t(\boldsymbol{x}_i)$ is a probability vector such that $q_i \in \mathbb{R}^K$, and q_{ij} is the j-th entry, $j \in 1, \cdots, K$.

The above process yields a pseudo-labeled $\widetilde{\mathcal{D}}_u$. We update m_t by optimizing:

$$\mathcal{L}_c(m_t, \widetilde{\boldsymbol{y}}) = \frac{1}{|\widetilde{\mathcal{D}}_u|} \sum_{\boldsymbol{x} \in \widetilde{\mathcal{D}}_u} \mathcal{D}_{\text{KL}}(\widetilde{\boldsymbol{y}} \| m_t(\boldsymbol{x})), \tag{10}$$

where $\mathcal{D}_{\text{KL}}(P \| Q) = \sum_k p_k \log(p_k / q_k)$ is the Kullback-Leibler divergence.

Finally, we incorporate the self-trained weak model into the ensemble model. The final model is a weighted ensemble of the weak models:

$$f_\theta(\cdot) = \sum_t^n \alpha_t m_t, \tag{11}$$

where a weak model m_t with a low error rate err_t will be assigned a higher coefficient α_t according to Equation 2.

5 Experiments

5.1 Experiment Setup

Tasks and Datasets We conduct experiments on four benchmark datasets, including *TACRED* (Zhang et al., 2017) for relation extraction, *DBPedia* (Zhang et al., 2015) for ontology classification, *ChemProt* (Krallinger et al., 2017) for chemical-protein interaction classification and *AG News* (Zhang et al., 2015) for news topic classification. For the initial weak supervision sources, we use the labeling rules provided by existing works: Zhou et al. (2020) for TACRED, Meng et al. (2020) for DBPedia, and Zhang et al. (2021) for Chemprot and AG News. The statistics of the four datasets are shown in table 5. For the development set, we do not directly use the full development set as suggested by the recent works (Gao et al., 2021; Perez et al., 2021). This prevents the model from taking the advantage of the massive number of labeled data in the development set. Instead, we create a real label-scarce scenario and keep the number of sample in validation set $\mathcal{D}_v$ the same as the limited clean labeled set $\mathcal{D}_l$, namely $|\mathcal{D}_v| = |\mathcal{D}_l|$.

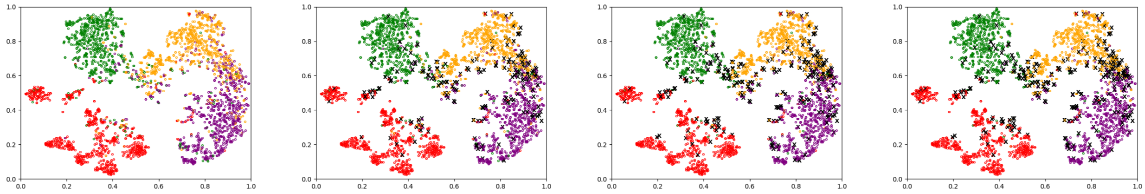
Baselines We include three groups of baselines:

Fully Supervised Baseline: **PLM**: We use the pretrained language model RoBERTa-base (Liu et al., 2019) as the backbone and fine-tune it with the full clean labeled data except for ChemProt. On ChemProt, we choose BioBERT (Lee et al., 2020) as the backbone for all the baselines and our model to better adapt to this domain-specific task. The performance of fully supervised methods serves as an upper bound for weakly-supervised methods.

Weakly Supervised Baselines: (1) **Snorkel** (Ratner et al., 2017) is a classic WSL model. It aggregates different labeling functions with probabilistic models, then fed the aggregated labels to PLM for the target task. (2) **LOTClass** (Meng et al., 2020) is a recent model for weakly-supervised text classification. It uses label names to probe PLMs to generate weak labels, and performs self-training using the weak labels for classification. (3) **CO-**

Method (Metrics)	**TACRED (F1)**	**DBpedia (Acc.)**	**ChemProt (Acc.)**	**AG News (Acc.)**
Supervised Baselines				
PLM w. 100% training data	66.9 (66.3/67.6)	99.4	79.7	94.4
PLM w. limited training data†	32.9 (40.8/27.6)	98.0	59.4	86.4
Weakly Supervised Baselines				
Rule Matching	20.1 (**85.0**/11.4)	63.2	46.9	52.3
Snorkel (Ratner et al., 2017)	39.7 (39.2/40.1)	69.5	56.4	86.2
LOTClass (Meng et al., 2020)	—	91.1	—	86.4
COSINE (Yu et al., 2021b)	39.5 (38.9/40.3)	73.1	59.8	87.5
Snorkel + fine-tuning†	40.8 (41.0/40.6)	97.6	64.9	87.7
LOTClass + fine-tuning†	—	98.1	—	88.0
COSINE + fine-tuning†	41.0 (40.4/41.7)	97.9	65.7	88.0
PRBoost	**48.1** (42.7/**55.1**)	**98.3**	**67.1**	**88.9**

Table 2: Main results on four benchmark datasets. †: we use different proportions of clean data for fine-tuning as described in Section 5.1. We use gray background to show the results of WLS baselines fine-tuned on the clean data. We highlight the best fine-tuned results with purple font, and the best WSL results with blue font.



(a) Iteration 0 (b) Iteration 1 (c) Iteration 4 (d) Iteration 10

Figure 2: T-SNE visualization (Van der Maaten and Hinton, 2008) of rule-matched data that mis-classified by the model on AG News dataset. The four classes are represented by different colors, and the black cross denotes the rule-matched data.

SINE (Yu et al., 2021b) is a state-of-the-art method on fine-tuning PLMs with weak supervision. It adopts self-training and contrastive learning to fine-tune LMs with weakly-labeled data.

Interactive Learning Baselines: (1) **Entropy**-based AL (Holub et al., 2008) is a simple-yet-effective method for AL which acquires samples with the highest predictive entropy. (2) **CAL** (Margatina et al., 2021) is the most recent method for active learning. It selects samples has the most diverge predictions from their neighbors for annotation. (3) **IWS** (Boecking et al., 2021) is an interactive WSL model. It firstly generates n-gram terms as candidate rules, then selects quality rules by learning from humans' feedback. Note that IWS is designed for binary classification, which makes it hard to adapt to classification with multiple labels.

Evaluation Protocol To propose rules on large-error instances, we assume access to a dataset $\mathcal{D}_l$ with a limited number of clean labeled data. For our method, such a clean dataset is only used for identifying large-error instances. For fair comparison, for the WSL baselines, we further fine-tune them using the same clean data and compare with such fine-tuned results. Specifically, we use 5% clean data for TACRED and ChemProt, 0.5% for AG News and 0.1% for DBPedia. We then implement a 10-iteration rule proposal and weak model training. In each iteration, we identify the top-10 large-error instances and propose 100 candidate rules in total (*i.e.*, 10 candidate rules per instance). Each rule is annotated by three humans, and the annotated rule labels are majority-voted for later weak label generation. Following the common practice (Zhang et al., 2017, 2021), we use F1 score for TACRED and accuracy for other datasets.

5.2 Main Results

Table 2 shows the performance of PRBoost and the baselines on the four datasets. The results show that PRBoost outperforms the weakly supervised baselines on all the four datasets. When the weakly supervised baselines are not fine-tuned on $\mathcal{D}_l$, PRBoost outperforms the strongest WSL baseline by 8.4%, 7.2%, 7.3%, 2.4% on the four benchmarks. Even when the WSL models are further fine-tuned using clean labeled data, PRBoost still outperform them by 2.4% on average. Compared against supervised baselines, PRBoost is significantly better than the fine-tuned model on TA-

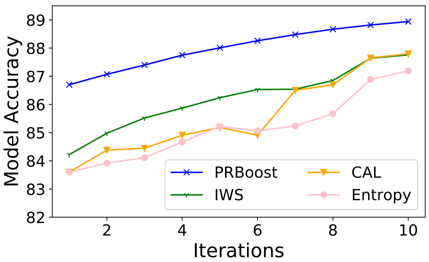


Figure 3: Results of interactive methods on AG News

CRED, ChemProt and AG News when the training data is limited. For the model fine-tuned with 100% training data, we narrow the gap to fully supervised learning, compared to other WS approaches.

Comparing the performance gains across datasets, the performance gap between PRBoost and the baselines is the largest on TACRED, which is the most challenging task among the four with 41 different relation types. ChemProt is the smallest dataset with only 5400 training data, so the gain is larger when the WSL methods are fine-tuned with clean labels. The performance gaps among different methods are small on DBPedia, especially after they are fine-tuned using clean labeled data. DBpedia, being a relatively simple dataset, using only 0.1% clean data for fine-tuning RoBERTa already achieves 98% accuracy, and the other WSL methods after fine-tuning perform similarly.

It is worth noting that PRBoost performs strongly across all the tasks because we can easily design a task-specific prompt template to adapt to each task. In contrast, some WSL baselines are difficult to apply to certain tasks. For example, LOTClass achieves strong performance for DBpedia and AGNews as its weak sources are tailored for text classification. However, it is hard to apply it to relation extraction tasks. Similarly, IWS performs well on binary classification problems using n-gram based rules, but the method is only designed for binary classification, making it unsuitable for complex multi-class tasks.

5.3 Rule Annotation Agreement and Cost

In this set of experiments, we benchmark model performance and annotation cost against interactive learning baselines (detailed in Appendix D): IWS, CAL, and Entropy-based AL. As shown in Figure 3, PRBoost outperforms IWS that also features rule-level annotation by 1.2% with very close annotation cost. Our method outperforms the best interactive baseline CAL by 1.1% in terms of accuracy, while using about 0.6× annotation cost. While annotating model-proposed rule or instances, we asked all the three annotators to time their annotation. On average, it takes each annotator less than 3 seconds to annotate one rule, while it takes nearly 10 seconds to annotate one instance. Rule-level annotation is much more efficient than instance-level annotation because 1) we show the prompt rather than the original instance to humans, which is shorter and easier to read; 2) upon scanning the prompt, the annotators can swiftly select qualified rules as they only differ at the `[MASK]` position. This shows that rule-level annotation is an efficient and suitable paradigm for interactive WSL.

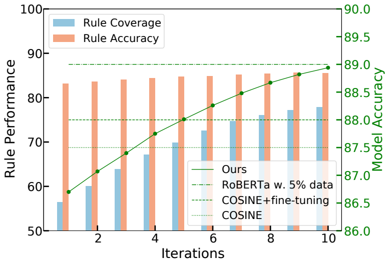

Figure 4: Rule performance and model accuracy v.s. iterations on AG News.

Iteration	1	2	3	4	5	6	7	8	9	10	Overall

$\bar{P}_e$	.63	.59	.73	.71	.62	.73	.66	.56	.68	.68	.65
κ	.71	.77	.73	.66	.65	.71	.75	.79	.60	.68	.71

Table 3: Annotation agreement measured by the Fleiss-Kappa κ on AG News. $\bar{P}$ measures annotation agreement over all categories; $\bar{P}_e$ computes the quadratic sum of the proportion of assignments to each category.

For the annotation agreement, we compute Fleiss' kappa κ (Fleiss, 1971) to evaluate the agreement among multiple human annotators. This statistic assesses the reliability of agreement among multiple annotators. $\kappa = 1$ indicates complete agreement over all the annotators, and no agreement results in $\kappa \leq 0$. As shown in Table 3, we obtained an average $\kappa = 0.71$, which means the annotators achieve substantial agreement. For each iteration, the κ ranges between $[0.60, 0.79]$ indicating the stability of the annotation agreement.

5.4 Rule Quality in Iterative Learning

In this set of experiments, we evaluate the quality of the rules discovered by PRBoost. Figure 2 visualizes the discovered rules on AG News dataset. We observe that 1) the rules can rectify some misclassified data, and 2) the rules can complement each other. For the first observation, we can take Figure 2(a) and Figure 2(b) for example. In iteration 0 where new rules have not been proposed, it is obvious that some green data points and purple data points are mixed into the orange cluster.

After the first-round rule proposal, PRBoost has already rectified parts of wrong predictions via rule-matching. This is because our rule proposal is targeted on the large-error instances, such adaptively discovered rules can capture the model's weakness more accurately compared to the simply enumerated rules. For the second observation, we found that more mis-classified data points get matched by the newly discovered rules as the iteration increases. It demonstrates PRBoost can gradually enlarge the effective rule set by adding complementary rules, which avoids proposing repetitive rules that can not improve the rule coverage.

Figure 4 shows the changes in rule accuracy, rule coverage, and model performance in the iterative learning process on AG News. As shown, the model's accuracy increases steadily during learning, which is improved from 86.7% to 88.9% after 10 iterations. This improvement arises from two key aspects of PRBoost. First, the enlarged rule set continuously augments weakly labeled data, which provides more supervision for the weak model training. Second, the model ensemble approach refines the previous large errors step by step, resulting in increasing ensemble performance.

Regarding the rule coverage and accuracy, we observe the coverage of the rule set is improved from 56.4% to 77.8%, and rule accuracy from 83.1% to 85.6%. Such improvements show that PRBoost can adaptively propose novel rules to complement the previous rule set, which can match more instances that were previously unmatchable. Note that the increased rule converge has not compromised rule accuracy, but rather improved it. The reason is two-fold: (1) the human-in-the-loop evaluation can select high-quality rules for generating new weak labels; (2) for the instances with wrong initial weak labels, PRBoost can discover more rules for the same instances and correct the weak labels through majority voting.

5.5 Ablation Study

We study the effectiveness of various components in PRBoost and show the ablation study results in Figure 5. We have the following findings:

First, the boosting-based iterative rule discovery strategy is effective. For the "w/o ensemble" setting, we fix the annotation budget $\mathcal{B}$ but discover candidate rules from large-error samples in one iteration. The results show the superiority of the iterative strategy in PRBoost , which brings 1.2% performance gain. PRBoost iteratively identifies the current model's weaknesses and proposes rules to strengthen itself, therefore it adaptively discovers more effective rules than static rule discovery.

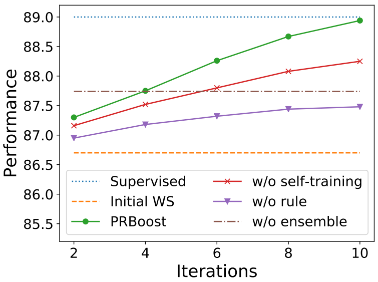

Figure 5: Ablation study on AG News. The three horizontal lines represent the no-iterative methods. We use COSINE as the initial WS baseline. For the supervised baseline, we fine-tune RoBERTa on 5% clean data.

Second, ensembling alone without new rule discovery is not as effective. For the "w/o rule" variant, we do not propose new rules, but ensemble multiple self-trained weak classifiers instead. The final performance drops significantly under this setting by 1.5%. It demonstrates the newly proposed rules provide complementary weak supervision to the model. Although simply ensembling multiple weak classifiers also helps WSL, it is not as effective as training multiple complementary weak models as in PRBoost.

Third, self-training benefits learning from new weak labels. For the "w/o self-training" setting, we do not use the self-training technique when learning each weak classifier. The performance deteriorates by 0.6%. This is because part of the data are still unmatched after we propose new rules, and self-training leverages the unlabeled data to help the model generalize better.

6 Conclusion

We proposed PRBoost to iteratively discover prompt-based rules for interactive weakly-supervised learning. Through a boosting-style ensemble strategy, it iteratively evaluates model weakness to identify large-error instances for new rule proposal. From such large-error instances, its prompt-based rule discovery module leads to expressive rules that can largely improve rule coverage while being easy to annotate. The discovered rules complement the current rule set and refine the WSL model continuously. Our experiments on four benchmarks demonstrate that PRBoost can largely improve WSL and narrow the gaps between WSL models and fully-supervised models.

A Dataset Details

Weak sources For each dataset above, we have an existing weak source that uses labeling rules to generate weakly labeled data.

1. *TACRED*: We use the rules in Zhou et al. (2020) for the relation extraction task. Their rules are in the form of relation phrases, which include the entity pair and a keyword.
2. *DBPedia*: We use the keywords provided in (Meng et al., 2020) as the labeling rules. Such keywords are indicative to the categories, where the words for the same category have close semantics.
3. *AGNews, ChemProt*: We use the rules in Zhang et al. (2021) as the labeling fucntions. They also extract lexical patterns for weak supervision.

B Hyper-parameters

We show the hyper-parameter configuration in Table 6. We search the batch size in $\{8, 16, 32, 64, 128\}$, AND the coefficient α between $[0, 1]$ with an interval of 0.25. For the optimizer, we use AdamW (Loshchilov and Hutter, 2019) and choose learning rate from $\{5\times10^{-6}, 1\times10^{-5}, 2\times10^{-5}\}$. We keep the number of iterations as 10 for all the tasks and show the top-10 candidate rules to solicit human feedback. ChemProt is a special case where we present the top-20 candidate rules, because this task is more domain-specific than the others, and the involved human annotators have no relevant domain background.

C Implementation Setting

We test our code on the System *Ubuntu 18.04.4 LTS* with CPU: *Intel(R) Xeon(R) Silver 4214 CPU @ 2.20GHz* and *GPU: NVIDIA GeForce RTX 2080*. We implement our method using Python 3.6 and PyTorch 1.2 (Paszke et al., 2019).

D Interactive baselines

For interactive learning, We include an interactive weak supervision framework IWS (Boecking et al., 2021), the most recent AL method CAL (Margatina et al., 2021) and the entropy-based AL as baselines. Our goal is 1) to compare the annotation cost of rule-level annotation and instance-level annotation; 2) to compare the model performance with the same annotation budget.

Because IWS is designed for the binary classification problem, we revise its implementation by integrating multiple binary predictions for multi-class tasks. Specifically, we obtain the predicted probability over all categories from each classifier, and select the category with the highest probability as the final prediction. When the number of category is large, this approach becomes cumbersome as training multiple classifiers is time-consuming. Therefore, we only run IWS on AG News, which has 4 categories. We report the results of these interactive methods in Section 5.3 and the following Appendix E.

E User Study

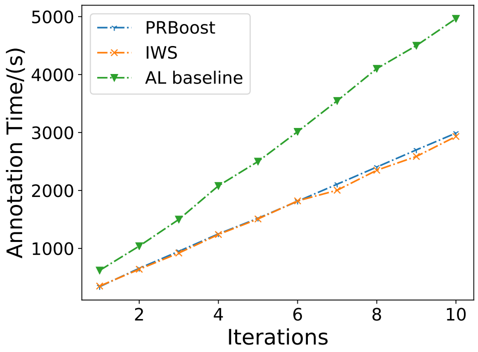

Figure 6: Annotation cost of interactive methods measured by annotation time on AGNews. Both PRBoostand IWS use rule-level annotation, while AL baselines use instance-level annotation.

In this user study, we aim to measure the annotation cost and the inter-annotator agreement during the rule annotation process. We ask three human annotators to participate in the 10-iteration experiment. In each iteration, humans are asked to annotate 100 candidate rules. We count the time in each iteration and their binary decisions on each candidate rule. The averaged annotation time is compared in Section 5.3 and we present more details in Figure 6.

The rule-level annotation agreement is measured by the Fleiss' kappa κ defined as

$$\kappa = (\bar{P} - \bar{P}_e)/(1 - \bar{P}_e), \tag{12}$$

where $\bar{P}$ measures the annotation agreement over all categories, and $\bar{P}_e$ computes the quadratic sum of the proportion of assignments to each category. The results in Section5.3 demonstrate that human annotators can achieve substantial agreement on rule-level annotation.

The rules to be annotated are generated from

Rule	**Label**

open-source PLMs and public data. We believe this rule-level annotation process will not amplify any bias in the original data. We do not foresee any ethical issues or direct social consequences.

F Model Ensemble

In practice, we keep α_t for each weak model as same during the model ensemble. Equation 11 weights each weak model m_t by a computed coefficient α_t. Intuitively, the weak model m_t with higher α_t impacts the ensemble results more. This paradigm is proved to be effective under fully-supervised settings, but we found it is not directly applicable in WSL. Since we initialize a model m_0 on the given weak source and it can achieve a relatively strong performance (much better than random guess), *i.e.*, the error rate err_0 is low. It makes a high α_0 based on Equation 2, so the initialized model will dominate the following prediction, thus limiting the effectiveness of the model ensemble. Therefore, we assign the same weight to each weak model but still follow the design of identifying large-error instances. This is reasonable as the weight w_i computed by Equation 1 still reflects the model weakness and can guide the rule proposal. By discovering rules based on the large-error instances, we iteratively complement the feature regimes through the model training on rule-matched data and strengthen the ensemble model.

Constrained Multi-Task Learning for Bridging Resolution

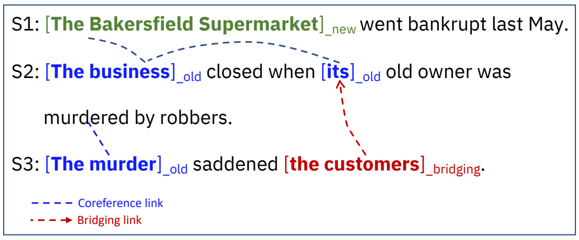
Abstract

We examine the extent to which supervised bridging resolvers can be improved without employing additional labeled bridging data by proposing a novel constrained multi-task learning framework for bridging resolution, within which we (1) design cross-task consistency constraints to guide the learning process; (2) pretrain the entity coreference model in the multitask framework on the large amount of publicly available coreference data; and (3) integrate prior knowledge encoded in rule-based resolvers. Our approach achieves state-of-the-art results on three standard evaluation corpora.

1 Introduction

Bridging (Clark, 1975) plays an important role in establishing entity coherence in a text. In contrast to *direct anaphors*, which indicate the coreference relation between a nominal expression and its antecedent, *bridging anaphors* or *associative anaphors* link to their antecedents via non-identical relations. *Bridging resolution* is the task of recognizing and resolving bridging anaphors in a text.

Bridging resolution and coreference resolution are closely related to *Information Status* (IS henceforth) classification, the goal of which is to assign an IS to each discourse entity that indicates how these entities are referred to in a text (Prince, 1981; Nissim et al., 2004; Markert et al., 2012). In general, an entity is *old* if it is coreferent with an entity that has been mentioned before (e.g., "[The business]" and "[its]" in Figure 1). *Bridging anaphors* are discourse-new but hearer-old. They have not been introduced in the discourse directly, but are inferrable from previously mentioned entities (e.g., "[the customers]" in Figure 1). *New* entities are introduced into the discourse for the first time and are not known to the hearer before (e.g. "[The Bakersfield Supermarket]" in Figure 1).



S1: [The Bakersfield Supermarket]_new went bankrupt last May.
S2: [The business]_old closed when [its]_old old owner was murdered by robbers.
S3: [The murder]_old saddened [the customers]_bridging.

Figure 1: Illustration of information status, bridging and coreference. Example is from Yu and Poesio (2020).

Progress on bridging resolution research is limited in part by the scarcity of annotated training data. While one of the largest annotated entity coreference resolution datasets, OntoNotes, is composed of 2802 English documents in its training split, the two most commonly used English corpora for bridging resolution research, ISNotes (Markert et al., 2012) and BASHI (Rösiger, 2018), are composed of 50 WSJ documents each. Perhaps the most straightforward way to mitigate this data scarcity problem is to combine existing annotated bridging datasets to create a larger training set (Yu and Poesio, 2020). While it makes sense to combine corpora that are created using the same annotation guidelines (e.g., ISNotes and BASHI), attempting to combine corpora created using different guidelines (e.g., ARRAU (Poesio and Artstein, 2008) and ISNotes) will likely confuse the learner, thus limiting the applicability of this method. Some researchers have instead attempted to create *automatically* labeled data via lexico-syntactic patterns (Hou, 2018) and distant supervision (Hou, 2020), but a manual analysis of the resulting data instances reveals that they may be too noisy for training: on average only one-fourth of them are correctly labeled (Hou, 2020).

By contrast, we aim to investigate the extent to which supervised bridging resolvers can be improved *without* increasing the amount of labeled bridging data. To this end, we begin by proposing a novel constrained multi-task learning (MTL) framework for bridging resolution. While Yu and Poesio (2020) develop a standard MTL model for

bridging resolution and use coreference resolution as the only auxiliary task, we propose to (1) exploit the close connection between IS and bridging/coreference resolution by introducing IS classification as the third task into the MTL framework and (2) guide the learning process by designing cross-task consistency constraints. For instance, in Figure 1, the prediction from the coreference resolution module indicating that both "[The business]" and "[The murder]" are *old* entities can help the bridging resolution module to avoid misclassifying these two mentions as bridging anaphors. Similarly, if the IS classification module predicts "[the customers]" as a bridging anaphor, then the bridging resolution module should find an antecedent for it. We hypothesize that such constraints can guide the training of a complex model to produce a more coherent output across different tasks, thereby improving bridging resolution performance.

While the cross-task consistency constraints could improve performance, they could also hurt performance. Returning to our example in Figure 1, if the IS classification module misclassifies "[the customers]" as non-bridging, the constraints will propagate this error to the bridging resolution module, causing it *not* to resolve the mention. To address this problem, we (1) formulate these constraints as *soft* rather than hard constraints, and (2) improve entity coreference resolution performance by leveraging the large amount of publicly-available coreference-annotated data in OntoNotes to *pre-train* the coreference module.

Finally, since previous work (Hou et al., 2014; Roesiger et al., 2018) has shown that manually defined rules based on various syntactic and semantic properties are valuable to recognize and resolve bridging anaphors, we integrate such prior knowledge about bridging into our MTL framework. Note that the only *hybrid* rule-based and learning-based approach to bridging resolution (Kobayashi and Ng, 2021) merely applies the rule-based resolver and the learning-based resolver in a sequential manner, without combining them into a single model.

In sum, our contributions are two-fold. First, we propose a novel constrained MTL framework that jointly learns three tasks, bridging resolution, coreference resolution, and IS classification, via the use of soft cross-task consistency constraints, prior knowledge provided by rule-based approaches, and pre-training on coreference data. Second, experimental results demonstrate that our framework achieves new state-of-the-art results for full bridging resolution on three datasets (ISNotes, BASHI, and ARRAU).

The rest of the paper is structured as follows. Section 2 describes related work on bridging resolution and constrained multi-task learning with deep neural networks. Section 3 describes our model, including our multi-task framework for jointly learning IS classification, entity coreference resolution and bridging resolution, our cross-task consistency constraints, and how we integrate rule knowledge into the framework. We present evaluation results in Section 4 and our conclusions in Section 5.

2 Related Work

Bridging resolution. Bridging resolution is composed two sub-tasks: *bridging anaphora recognition* and *antecedent selection*. Most previous work tackles them separately. One line of research models bridging recognition as part of IS classification (Rahman and Ng, 2011; Markert et al., 2012; Cahill and Riester, 2012; Rahman and Ng, 2012; Hou, 2021), while others have focused on antecedent selection based on gold bridging anaphors (Poesio et al., 2004; Lassalle and Denis, 2011; Hou et al., 2013; Hou, 2020).

There are a few studies tackling the challenging task of full bridging resolution (i.e., bridging anaphor recognition *and* resolution). Hou et al. (2014) and Roesiger et al. (2018) develop rules to identify bridging links based on syntactic and semantic constraints. Hou et al. (2018) propose a pipeline system built on top of complex manually designed features. Yu and Poesio (2020) design a MTL neural model for bridging resolution that uses coreference resolution as an auxiliary task. Recently, Kobayashi and Ng (2021) show the effectiveness of a hybrid rule-based and MTL approach for bridging resolution. For a detailed overview of these approaches, we refer the reader to a recent survey by Kobayashi and Ng (2020).

Constrained multi-task learning with deep neural networks. Multi-task learning has been widely adopted in various NLP applications to improve the performance of individual tasks (Ruder, 2017). Recently, several studies have demonstrated that multi-task training in neural networks can be further improved by integrating logical constraints to enforce a coherent output across different tasks (Li et al., 2019; Wang et al., 2020; Lu and Ng, 2021). However, for a complex task like bridging resolution, it is non-trivial to choose auxiliary tasks and model the relationships between these tasks in deep neural networks. In this work, we (1) jointly train three tasks (i.e., bridging resolution, coreference resolution, and IS classification); (2) design five soft cross-task consistency constraints to guide the training process; and (3) integrate prior knowledge about bridging into our MTL model.

3 Model

In this section, we present our constrained MTL framework for bridging resolution. Inspired by Yu and Poesio's (2020) span-based model for bridging resolution, which employs an *unconstrained* MTL framework that jointly learns bridging and coreference, our model takes as input a document D represented as a sequence of word tokens and gold mentions M, from which we create span representations. Our model simultaneously learns three tasks, namely IS classification, bridging, and coreference, as defined below.

The IS classification task aims to assign each span i an IS y_{is} taken from an IS inventory. The model predicts the IS of i to be $y_{is}^* = \arg\max_{y_{is}} s_{is}(i, y_{is})$, where s_{is} is a function suggesting i's likelihood of having y_{is} as its IS.

The bridging resolution task involves determining an antecedent for each bridging anaphor. Formally, it assigns span i an antecedent y_b, where $y_b \in \mathcal{Y}(i) = \{1, ..., i-1, \epsilon\}$. In other words, the value of each y_b is the id of its antecedent, which can be one of the preceding spans or a dummy antecedent ϵ (if the mention underlying i is not a bridging anaphor) in the associated document. We define the following scoring function:

$$s_b(i,j) = \begin{cases} 0 & j = \epsilon \\ s_a(i,j) & j \neq \epsilon \end{cases} \tag{1}$$

where $s_a(i,j)$ is a pairwise bridging score computed over i and a preceding span j. The model predicts the antecedent of i to be $y_b^* = \arg\max_{y_b \in \mathcal{Y}(i)} s_b(i, y_b)$.

The entity coreference resolution task involves determining an antecedent for each identity anaphor. Formally, it aims to assign span i an antecedent y_c based on a scoring function s_c that can be defined in an analogous manner as the s_b function in the bridging resolution task.

3.1 Model Structure

Figure 2 shows the structure of our constrained MTL framework. Below we describe the details.

Span Representation Layer Following Yu and Poesio (2020), we use BERT embeddings as the input to a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) to encode tokens and their contexts. Then, we set $\mathbf{g}_i$, the representation of span i, to $[\mathbf{h}_{start(i)}; \mathbf{h}_{end(i)}; \mathbf{h}_{head(i)}; \mathbf{f}_i]$, where $\mathbf{h}_{start(i)}$ and $\mathbf{h}_{end(i)}$ are the hidden vectors of the start and end tokens of i, $\mathbf{h}_{head(i)}$ is an attention-based head vector and $\mathbf{f}_i$ is a span width feature embedding.[1]

IS Prediction Layer For each span i, we pass its representation $\mathbf{g}_i$ to FFNN$_{is}$, a standard feed-forward neural network. FFNN$_{is}$ outputs a vector $\mathbf{oi}_i$ of dimension of S, where S is the number of possible IS labels. Specifically:

$$\mathbf{oi}_i = \text{FFNN}_{is}(\mathbf{g}_i) \tag{2}$$

$$s_{is}(i, y_{is}) = \mathbf{oi}_i(y_{is}) \tag{3}$$

where $\mathbf{oi}_i(y_{is})$, the y_{is}-th element of $\mathbf{oi}_i$, is a score that indicates i's likelihood of belonging to IS y_{is}. This score is then used to compute s_{is}.

Bridging Prediction Layer To predict bridging links, we define the pairwise score between span i and span j as follows:

$$s_a(i,j) = \text{FFNN}_b([\mathbf{g}_i; \mathbf{g}_j; \mathbf{g}_i \circ \mathbf{g}_j; \mathbf{u}_{ij}]) \tag{4}$$

where $\circ$ denotes element-wise multiplication, $\mathbf{g}_i \circ \mathbf{g}_j$ encodes the similarity between span i and span j, $\mathbf{u}_{ij}$ is a feature embedding encoding the distance between two spans[1], and FFNN$_b$ is the FFNN used in the bridging prediction layer. This pairwise score is then used to compute s_b (see Equation (1)).

Coreference Prediction Layer The coreference prediction layer is defined in the same way as the bridging prediction layer, with the coreference pairwise score $s_c(i,j)$ between two spans i and j computed by another FFNN, FFNN$_c$. Note that the first few layers of FFNN$_c$ and FFNN$_b$ are shared.

3.2 Incorporating Consistency Constraints

As noted before, we propose to guide the learning process by incorporating consistency constraints on the three tasks involved in our model. Below we design five cross-task consistency constraints and show how they can be incorporated into our model in a *soft* manner.

---

[1] This feature embedding is originally proposed by Clark and Manning (2016). See their paper for details.

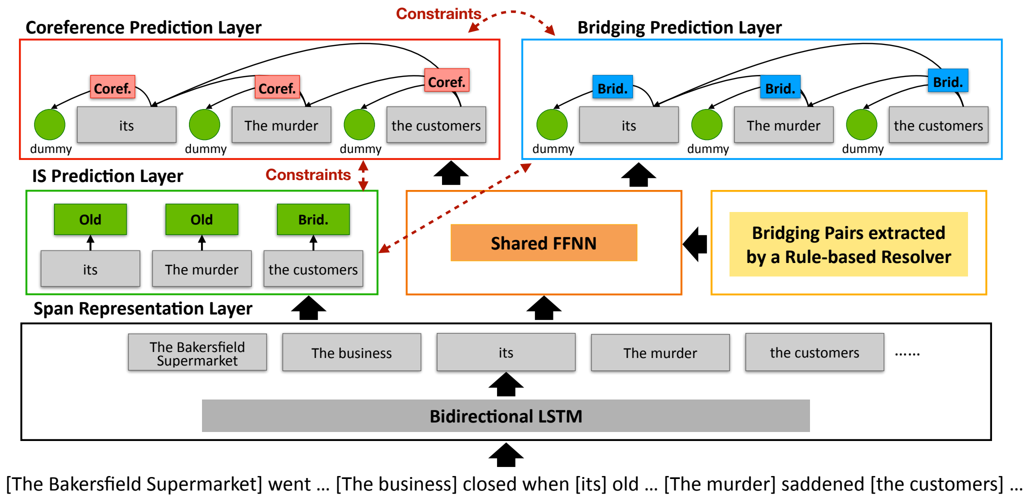

Figure 2: Model structure of the constrained MTL framework for bridging resolution.

Constraint P1: If a span i has BRIDGING as its IS value, then its bridging antecedent must not be the dummy antecedent.

To enforce **P1** in a soft manner in our model, we define a penalty function p_1, which imposes a penalty on span i if it violates the constraint, as shown below:

$$p_1(i) = \begin{cases} 0 & \arg\max_{y_{is}\in\mathcal{Y}} s_{\text{is}}(i, y_{is}) \neq \text{brid} \\ s_{\text{is}}(i, \text{brid}) - \max_{y_{is}\in\mathcal{Y}\setminus\{\text{brid}\}} s_{\text{is}}(i, y_{is}) & \text{otherwise} \end{cases} \tag{5}$$

where $\mathcal{Y}$ is the set of possible IS labels. Intuitively, p_1 estimates the minimum amount that needs to be adjusted so that span i's IS type is not BRIDGING. In particular, p_1 returns 0 (i.e., no penalty) if i's IS type is not BRIDGING.

We incorporate p_1 into the model as a penalty term in s_b (Equation (1)). Specifically, we redefine $s_b(i, j)$ when $j = \epsilon$, as shown below:

$$s_b(i, \epsilon) = s_b(i, \epsilon) - \gamma_1 p_1(i) \tag{6}$$

where γ_1 is a positive constant that controls the hardness of the constraint. The smaller γ_1 is, the softer the constraint is. Intuitively, if **P1** is violated, $s_b(i, \epsilon)$ will be lowered by the penalty term, and the dummy antecedent will less likely be selected as the antecedent of i.

Constraint P2: If a span i has OLD as its IS value, then its coreference antecedent must not be the dummy antecedent.

The penalty function p_2 used to enforce **P2** is formulated in the same way as **P1**.

Constraint P3: If the IS task predicts a span i as non-BRIDGING, then its antecedent selected in the bridging task must be the dummy antecedent.

Similar to **P1**, we define a penalty function p_3 to enforce **P3**:

$$p_3(i) = \begin{cases} 0 & \arg\max_{y\in\mathcal{Y}} s_{\text{is}}(i, y) = \text{brid} \\ \max_{y\in\mathcal{Y}\setminus\{\text{brid}\}} s_{\text{is}}(i, y) - s_{\text{is}}(i, \text{brid}) & \text{otherwise} \end{cases} \tag{7}$$

We employ p_3 to update s_b as follows:

$$s_b(i, j) = s_b(i, j) - \gamma_3 p_3(i) \tag{8}$$

where γ_3, like γ_1, is the hardness coefficient. This penalty is applied only when **P3** is violated. Specifically, if IS task predicts a span i as non-BRIDGING but its antecedent selected in the bridging task is not the dummy antecedent, then the penalty term will lower the s_b score for each of i's non-dummy antecedents, which in turn makes it more likely for the dummy antecedent to be selected as the antecedent of i.

Constraint P4: If a span i does not have OLD as its IS value, then its coreference antecedent must be the dummy antecedent.

The penalty function p_4 used to enforce **P4** is formulated in the same way as **P3**.

Constraint P5: If a span i has a non-dummy antecedent as its coreference antecedent, then its bridging antecedent must be the dummy antecedent.

The penalty function p_5 used to enforce **P5** is defined as follows:

$$p_5(i) = \begin{cases} 0 & \arg\max_{j\in\mathcal{Y}(i)} s_c(i, j) = \epsilon \\ \max_{j\in\mathcal{Y}(i)\setminus\{\epsilon\}} s_c(i, j) & \text{otherwise} \end{cases} \tag{9}$$

where $\mathcal{Y}(i)$ is the set of candidate antecedents of span i. We employ p_5 to update s_b as follows:

$$s_b(i,j) = s_b(i,j) - \gamma_5 p_5(i) \quad (10)$$

where γ_5 is the hardness coefficient.

3.3 Incorporating Prior Knowledge

Next, we incorporate the prior knowledge provided by rule-based resolvers into our model. Specifically, we employ the set of corpus-specific rules designed by Rösiger et al. (2018). Recall that the output of a rule-based bridging resolver is a set of links between a bridging anaphor and one of its antecedents. We incorporate these bridging links into our model by encoding them as a binary feature, $\mathbf{r}_{ij}$, whose value is 1 if and only if the rule-based resolver posits a bridging link between span i and span j. This feature will be used as an additional feature for FFNN_b and FFNN_c.

As noted by Rösiger et al. (2018), rule-based resolvers are precision- rather than recall-oriented. The reason is that these hand-crafted rules are designed to resolve specific (rather than all) categories of bridging anaphors. For instance, one rule is designed to resolve a building part (e.g., "the door") to the building of which it is a part (e.g., "the house"). Because of the low-recall nature of rule-based resolvers, the feature $\mathbf{r}_{ij}$, which we compute based on the rule-based outputs, could be perceived as not particularly useful by our model. Consequently, to encourage the model to seriously take into consideration the potentially useful information encoded in $\mathbf{r}_{ij}$, we design a rule loss (see Section 3.4), which imposes a penalty on the model during *training* if the antecedent selected by the model is a non-dummy antecedent that is neither a correct antecedent of i nor the one selected by the rules (as encoded in $\mathbf{r}_{ij}$).

3.4 Training

The loss function, $L(\Theta)$, consists of the losses of the three tasks and the rule loss as follows:

$$L(\Theta) = \sum_{i=1}^{d} (\lambda_b L_b + \lambda_c L_c + \lambda_{is} L_{is} + \lambda_r L_r) \quad (11)$$

where d is the number of training documents and the hyperparameters (i.e., the λ's), which determine the trade-off between the task losses, are tuned using grid search to maximize the average resolution F-scores on development data.

Task Losses We employ a max-margin loss for the bridging and coreference resolution tasks.

Defining the bridging loss is tricky since the antecedents for each bridging anaphor are evaluated in the form of coreference clusters. We adopt the entity coreference loss function originally defined by Wiseman et al. (2015). Specifically, let $\text{GOLD}_b(i)$ denote the set consisting of span i's bridging antecedent as well as the spans preceding i that are coreferent with the antecedent, and y_b^l be $\arg\max_{y \in \text{GOLD}_b(i)} s_b(i,y)$. In other words, y_b^l is the highest scoring (latent) antecedent of i according to s_b among all the antecedents of i.

The loss function for bridging is defined as:

$$L_b(\Theta) = \sum_{i=1}^{n} \max_{j \in \mathcal{Y}(i)} (\Delta_b(i,j)(1 + s_b(i,j) - s_b(i,y_b^l))) \quad (12)$$

where $\Delta_b(i,j)$ is a mistake-specific cost function that returns the cost associated with a particular type of error if an error exists and 0 otherwise (Durrett and Klein, 2013).[2] Intuitively, the loss function penalizes a span i if the predicted antecedent j has a higher score than the correct latent antecedent y_b^l.

The task loss for coreference, L_c, is defined in the same way as the bridging loss, having an analogous mistake-driven cost function $\Delta_c(i,j)$.[3]

The task loss for the IS prediction task, L_{is}, is the weighted softmax cross entropy loss, where misclassified bridging mentions and non-bridging mentions are weighted according to a mistake-driven cost function $\Delta_{is}(i,j)$.[4]

The rule loss is motivated by the bridging loss. Specifically, the model will be penalized if there exists an incorrect non-dummy candidate antecedent whose s_b score is higher than the score of the antecedent chosen by the rules, as shown below:

$$L_r(\Theta) = \sum_{i \in N'} \max_{j \in \mathcal{Y}(i) \setminus \epsilon} (\Delta_r(i,j)(1 + s_b(i,j) - s_b(i,y_r))) \quad (13)$$

where N' is the set of candidate anaphors for which the rule-based system found a (non-dummy) an-

---

[2] In $\Delta_b(i,j)$, there are three error types: (1) false link (incorrectly resolved anaphoric mentions); (2) false new (anaphoric mentions misclassified as non-anaphoric); and (3) wrong link (non-anaphoric mentions misclassified as anaphoric). We use hyperparameters α_{b1}, α_{b2}, and α_{b3} to determine their trade-offs.

[3] In $\Delta_c(i,j)$, the error types are the same as those in $\Delta_b(i,j)$. We use hyperparameters α_{c1}, α_{c2}, and α_{c3} to determine their trade-offs.

[4] In $\Delta_{is}(i,j)$, there are two error types: (1) false new (bridging mentions misclassified as non-bridging); and (2) false bridging (non-bridging mentions misclassified as bridging). We use hyperparameters α_{is1} and α_{is2} to determine their trade-offs.

tecedent, y_r is the antecedent selected by the rules, and $\Delta_r(i,j)$ is an indicator function that returns 0 if j is the correct antecedent and 1 otherwise.

3.5 Pre-Training

As mentioned in the introduction, we pre-train the coreference module in our MTL framework on the English portion of OntoNotes 5.0[5], excluding those documents that appear in ISNotes or BASHI. To do so, we pre-train the full model shown in Figure 2, setting λ_b to 1 and the remaining λ's to 0 in the loss function so that only the network weights associated with the coreference module will be updated. Note that we follow Yu and Poesio (2020) and use the softmax cross entropy loss rather than the max-margin loss for L_b during pre-training, the reason being that this could simplify pre-training by obviating the need to tune the hyperparameters associated with the mistake-specific cost functions.

4 Evaluation

4.1 Experimental Setup

4.1.1 Corpora

We use three English corpora that are arguably the most widely used corpora for bridging evaluation, namely ISNotes (composed of 50 WSJ articles in OntoNotes) (Markert et al., 2012) , BASHI (The Bridging Anaphors Hand-annotated Inventory, composed of another 50 WSJ articles in OntoNotes) (Rösiger, 2018), and ARRAU (composed of articles from four domains, RST, GNOME, PEAR, and TRAINS) (Poesio and Artstein, 2008; Uryupina et al., 2020). Following previous work, we report results only on RST, the most comprehensively annotated segment of ARRAU. Table 1 shows the statistics on these corpora.

Corpora	Docs	Tokens	Mentions	Anaphors
ISNotes	50	40,292	11,272	663
BASHI	50	57,709	18,561	459
ARRAU RST	413	228,901	72,013	3,777

Table 1: Statistics on different corpora.

For ARRAU RST, we use the standard train-test split. For ISNotes and BASHI, we divide the documents in each corpus into 10 folds (8 folds for training, 1 fold for development, and 1 fold for testing) and report 10-fold cross-validation results.

4.1.2 Evaluation Setting

Following previous work (Hou et al., 2014; Roesiger et al., 2018), we report results for *full bridging resolution* based on gold mentions. In this setting, a system is given as input both a document and its the *gold* mentions. The goal is to identify bridging anaphors from the gold mentions and resolve them to their antecedents, which are also chosen from the gold mentions.

There is a caveat in this evaluation setting, however. In ISNotes and BASHI, some bridging antecedents correspond to *events* (see Example (4) in Table 5), and previous studies differ in terms of how event antecedents should be handled. The reason is that while these event antecedents are annotated, they are *not* annotated as gold mentions. When reporting results on resolving gold mentions, some previous work (e.g., Hou et al. (2014), Hou et al. (2018)) chose not to include these event antecedents in the list of candidate antecedents and others (e.g., Roesiger et al. (2018), Yu and Poesio (2020)) did. Obviously, the setting in which gold event antecedents are not included in training/evaluation is harsher because it implies that anaphors with event antecedents will always be resolved incorrectly. We believe that including gold event antecedents during evaluation does not represent a realistic setting, and will only report results using the "harsh" setting in this paper.

4.1.3 Evaluation Metrics

Following Yu and Poesio (2020), we report results for bridging recognition and resolution in terms of precision (P), recall (R), and F-score (F). For recognition, recall is the fraction of gold bridging anaphors that are correctly identified, whereas precision is the fraction of bridging anaphors identified by the system that is correct. For resolution, recall and precision are defined in a similar fashion. In addition, we report IS classification results in terms of accuracy and coreference results in terms of CoNLL score (Pradhan et al., 2014), which is the unweighted average of the F-scores provided by three metrics, MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), and CEAF$_e$ (Luo, 2005).

4.1.4 Implementation Details

To train the neural models in our experiments, we use ADAM (Kingma and Ba, 2014) as the optimizer and set all model parameters that originated in Yu and Poesio's (2020) model to the same values as those reported in their paper. Each model is trained for up to 150 epochs in ISNotes and BASHI

Table 2: Results of different resolvers on bridging resolution and related tasks. Each result is the average of two runs. For each model with a learning component, the recognition and resolution F-scores are accompanied with the corresponding standard deviation scores (in parentheses).

and up to 200 epochs in ARRAU, with early stopping based on the development set.

For our model, we pre-train the coreference model for 15 epochs, and the remaining parameters are chosen jointly using grid search to maximize resolution F-score on development data. Specifically, the weights associated with each task and the rule in the loss function (i.e., the λ_i's) are searched out of $\{0.1, 0.5, 1, 5, 10, 20, 30\}$. The weights associated with the mistake-driven cost functions (i.e., the Δ_i's) are searched out of $\{0.1, 0.5, 1, 5, 10, 15, 20\}$. The hardness coefficients of the consistency constraints (i.e., the γ_i's) are searched out of $\{0.05, 0.1, 0.5, 1, 5, 10, 20, 30\}$.[6]

4.2 Baseline Systems

We employ three baselines. The first one is Rösiger et al.'s (2018) rule-based approach, which consists of rules that are built on top of Hou et al. (2014).[7] The second one, Y&P-MTL, is Yu and Poesio's (2020) MTL system.[8] The third one is the Hybrid rule-based and learning-based system proposed by Kobayashi and Ng (2021) in which the rules are first applied and then Y&P-MTL is used to resolve the remaining bridging anaphors.

4.3 Results and Discussion

Results are shown in Table 2. A few points about the baseline results deserve mention. First, in terms of bridging recognition and resolution performance, the best baselines are Hybrid for both ISNotes and BASHI and Y&P-MTL for ARRAU RST. Hence, these two baselines can be viewed as the prior state of the art. Second, while Rösiger et al.'s rule-based model never achieves the best results on any of the three datasets, it is not always the worst performer: Y&P-MTL is the worst baseline on BASHI in terms of resolution.[9] Third, Hybrid fails to improve the performance of Y&P-MTL in ARRAU RST, meaning that the rules fail to provide additional benefits to Hybrid. This could be attributed to the fact that the rules in ARRAU RST have much lower recognition and resolution precision scores than those in ISNotes and BASHI (Roesiger et al., 2018).

While Y&P-MTL uses undersampling (to reduce the number of negative examples used to train the bridging module) and a likelihood loss, we additionally experiment with a max-margin loss (see Section 3.4) without undersampling in our model. To see how these two changes impact performance, we create another model, MM-MTL, which is simply a max-margin version of Y&P-MTL without

---

[6] See Appendix A for the final hyperparameters chosen for the full model.

[7] We used the publicly available implementation of these rule-based systems from `https://github.com/InaRoesiger/BridgingSystem`.

[8] We used their publicly available implementation from `https://github.com/juntaoy/dali-bridging`.

[9] The baseline results in Table 2 are lower than those reported in the original papers because (1) we report results using the "harsh" setting (see Section 4.1.2); (2) Roesiger et al. (2018) and Kobayashi and Ng (2021) postprocess the system output with gold coreference information, and (3) Yu and Poesio (2020) and Kobayashi and Ng (2021) use additional labeled data for model training.

undersampling. Results on the development set are mixed: while MM-MTL outperforms Y&P-MTL on ISNotes and BASHI, the reverse is true on ARRAU RST. Consequently, we use the max-margin loss without undersampling when training our model on ISNotes and BASHI, but fall back on the likelihood loss with undersampling for ARRAU RST. To better understand the impact of using a max-margin loss with undersampling, we show in Table 2 the test results of MM-MTL. As we can see, MM-MTL outperforms Y&P-MTL by 6.7–10.7% points in F-score for bridging recognition and 1.7–2.8% points in F-score for bridging resolution in ISNotes and BASHI.

The last row of each section of Table 2 shows the results of our full model, which outperforms the best baseline by 5.2–11.3% points in F-score for bridging recognition and 2.6–4.1% points in F-score for bridging resolution. Hence, the full model establishes new state-of-the-art results on these three datasets. For bookkeeping purposes, we also report the scores for each component of our model in terms of IS classification accuracy and coreference CoNLL score.

4.4 Model Ablations

To evaluate the contribution of the different components in our full model, we show in Tables 3 and 4 ablation results on ISNotes, which we obtain by removing one component at a time from the model and retraining it. Note that for coreference we show the anaphor recognition results as they are affected by the consistency constraints.

Consistency constraints. Ablating the consistency constraints means removing all the penalty terms from s_b and s_c. The resulting system resembles a typical multi-task learning setup, where the different tasks only interact via a shared representation. As we can see in Table 3, bridging resolution F-score drops by 1.7% points, coreference recognition F-score drops by 0.5% points, and IS bridging recognition F-score drops by 1.2% points. These results suggest the effectiveness of using consistency constraints in a multi-task setup.

Soft→Hard. Next, we replace soft constraints with hard constraints. Comparing with the results in row 2, bridging resolution F-score drops by 1.2% points. This indicates that having hard constraints is worse than having *no* constraints at all.

Rule loss and feature. Bridging resolution F-score drops by 1.1% points when ablating only the rule loss and by 2.4% points when ablating both the rule loss and the rule feature. These results suggest that the rule feature is useful and that the rule loss enhances the effectiveness of the rule feature.

		Bridging		IS		Coref.
		Recog.	Resol.	Brid.	Old	Recog.
1	Full	**50.9**	**26.0**	48.3	86.7	88.4
2	– Constraints	46.1	24.3	47.1	86.7	87.9
3	Soft→Hard	47.7	23.1	46.4	87.1	88.8
4	– Rule loss	49.8	24.9	47.6	86.6	88.3
5	– Rule loss+feat.	48.1	23.6	46.9	86.5	88.1
6	– Pre-training	49.6	20.2	49.1	86.6	84.5
7	– Coref. task	47.4	22.6	46.3	88.6	-
8	– IS task	44.2	22.7	-	-	87.8

Table 3: Ablation results of the full model.

	Constraints	Bridging		IS		Coref.
		Recog.	Resol.	Brid.	Old	Recog.
1	Full	**50.9**	**26.0**	48.3	86.7	88.4
2	– P1	50.2	24.2	49.6	86.7	88.2
3	– P2	49.1	24.5	48.1	86.5	88.0
4	– P3	48.2	24.8	48.0	86.6	88.0
5	– P4	49.5	24.3	47.9	86.8	88.1
6	– P5	50.0	23.7	48.1	86.6	88.0

Table 4: Ablation results of the full model w.r.t individual soft constraints.

Pre-training. Next, we do not pre-train the coreference component in the multi-task framework. This causes bridging resolution F-score and coreference recognition F-score to drop abruptly by 5.8% points and 3.9% points respectively, suggesting the important role played by pre-training.

Coreference resolution and IS classification tasks. Next, we ablate one of the tasks in the multi-task framework. Bridging resolution F-score drops by 3.4% points when ablating coreference and by 3.3% points when ablating IS classification. These results suggest that both tasks contribute considerably to bridging resolution performance.

Individual soft constraints. Finally, we ablate one soft constraint at a time from the full model. Results are shown in Table 4. Bridging resolution F-score drops by 1.2–2.3% points, suggesting the positive contribution of each soft constraint.

While our discussion of these results has focused on bridging resolution, the same trends can be observed for bridging recognition for the most part. Overall, these results suggest that each component contributes positively to bridging resolution.

4.5 Error Analysis

Although our full model outperforms all previous models for bridging resolution, it is still far from perfect. To better understand what areas of improvement are required, we discuss some common errors made by our full model in this subsection.

Bridging anaphora recognition errors. Recall errors in bridging anaphora recognition are the result of a system's failure in identifying bridging anaphors. We find that on the three datasets, the highest proportion of the recall errors (57% on ISNotes, 61% on ARRAU, and 82% on BASHI) is due to the fact that a large number of bridging anaphors are misclassified as *new* or *other*[10] mentions in the IS classification module, such as "**income**" in Example (1) in Table 5.

Precision errors in bridging anaphora recognition are the result of a system's misclassification of non-bridging mentions as bridging anaphors. Similar to the recall errors described above, most precision errors are *new* or *other* mentions being misclassified as bridging, which account for 50%, 74% and 82% of the precision errors in ISNotes, ARRAU, and BASHI, respectively. In Example (2), "**service**" is misclassified by both the bridging and IS components as a bridging anaphor.

In general, it seems that our system struggles to distinguish bridging anaphors from generic *new* mentions with simple syntactic structures, an observation that has also been reported in previous work (Hou, 2021; Kobayashi and Ng, 2021). Note that most of these *bridging* or *new* mentions are relational nouns (de Bruin and Scha, 1988). Normally, whether additional implicit arguments are required to interpret such relational nouns depends on the surrounding context. In Example (1), "*the industry*" is necessary to fully understand the meaning of "**income**"; while in Example (2), no additional implicit arguments are required to understand the meaning of "**service**".

Bridging anaphora resolution precision errors. Precision errors in bridging anaphora resolution appear when a system selects the wrong antecedent for a bridging anaphor. A major reason for this error is that our model largely fails to exploit contextual information. In Example (3), the model links the bridging anaphor "*a spokesman*" to the wrong antecedent "[the state]", which is reasonable if one does not look into the context. However, according to the context, the correct antecedent should be "*Gov. Deukmejian*", which requires a system to know that "Gov." is the abbreviation for "Governor" and that normally a governor will have a spokesman.

(1) In 1984, an attempt was made to crack down on *the industry* with tougher restrictions. Then, in 1988, a proposal to keep better track of **income** by selling prepaid cards for pachinko was fielded in parliament.
(2) The Bay Area Rapid Transit system, which runs subway trains beneath the bay, is braced for a doubling of its daily regular ridership to 300,000. BART has increased **service** to 24 hours a day in preparation for the onslaught.
(3) Both Mr.Brown, the state's most influential legislator, and *Gov. Deukmejian* favor a temporary sales tax increase – should more money be needed than [the state] can raise from existing sources and the federal government. According to **a spokesman**, the governor is also studying the possibility of raising state gasoline taxes.
(4) ... the drug still *lacks* federal approval for use in the youngest patients. As **a result**, many youngsters have been unable to obtain the drug ...

Table 5: Examples of the errors made by our full model.

In addition, on ISNotes, 6% of the bridging anaphors have a non-mention antecedent (see "**a result**" in Example (4)) and 12% of the bridging anaphors have antecedents that are more than five sentences away. Currently our system does not handle these difficult cases.

5 Conclusion

We proposed the first neural model for full bridging resolution that (1) exploits the connection between information status classification, entity coreference resolution, and bridging resolution in a multi-task learning framework, (2) employs soft cross-task consistency constraints to guide the learning process, (3) pre-trains the entity coreference model, and (4) integrates prior knowledge encoded in hand-crafted bridging resolution rules into the learning framework. Our model outperformed several strong baselines and achieved state-of-the-art results on three evaluation datasets. Ablation results provided suggestive evidence that each component of our model contributed positively to bridging resolution performance.

---

[10] Unlike ISNotes and ARRAU, BASHI does not have IS annotations. We use heuristics to derive four IS types: *old*, *mediated/bridging*, *mediated/comparative* and *other*. A mention's IS is *other* if it is not annotated as *mediated* and is not coreferent with any previous mentions.

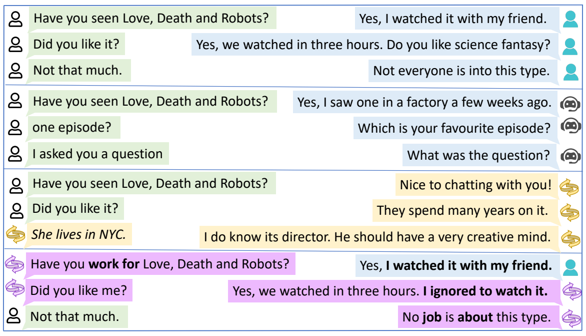
Abstract

Automatic evaluation metrics are essential for the rapid development of open-domain dialogue systems as they facilitate hyper-parameter tuning and comparison between models. Although recently proposed trainable conversation-level metrics have shown encouraging results, the quality of the metrics is strongly dependent on the quality of training data. Prior works mainly resort to heuristic text-level manipulations (e.g. utterances shuffling) to bootstrap incoherent conversations (negative examples) from coherent dialogues (positive examples). Such approaches are insufficient to appropriately reflect the incoherence that occurs in interactions between advanced dialogue models and humans. To tackle this problem, we propose DEAM, a Dialogue coherence Evaluation metric that relies on Abstract Meaning Representation (AMR) to apply semantic-level Manipulations for incoherent (negative) data generation. AMRs naturally facilitate the injection of various types of incoherence sources, such as coreference inconsistency, irrelevancy, contradictions, and decrease engagement, at the semantic level, thus resulting in more natural incoherent samples. Our experiments show that DEAM [1] achieves higher correlations with human judgments compared to baseline methods on several dialog datasets by significant margins. We also show that DEAM can distinguish between coherent and incoherent dialogues generated by baseline manipulations, whereas those baseline models cannot detect incoherent examples generated by DEAM. Our results demonstrate the potential of AMR-based semantic manipulations for natural negative example generation.

1 Introduction

Despite the effectiveness of large pretrained language models (Radford et al., 2019; Lewis et al., 2020) for dialogue response generation (Zhang et al., 2020; Adiwardana et al., 2020; Ghazarian et al., 2021a), it is still challenging for the models to imitate human-human conversations and maintain conversational-level coherence. To better evaluate such models, recent works propose trainable automatic evaluation metrics to benchmark and compare the performance of dialogue models (Wu et al., 2020; Zhang et al., 2021). Most trainable automatic evaluation metrics focus on turn-level interactions, where they learn to assess the quality of one user-system utterance pair (Tao et al., 2018; Huang et al., 2020; Ghazarian et al., 2020). However, these metrics cannot appropriately model the whole conversation flow (Yeh et al., 2021), and thus are insufficient for dialogue-level evaluation.



Have you seen Love, Death and Robots? — Yes, I watched it with my friend.
Did you like it? — Yes, we watched in three hours. Do you like science fantasy?
Not that much. — Not everyone is into this type.

Have you seen Love, Death and Robots? — Yes, I saw one in a factory a few weeks ago.
one episode? — Which is your favourite episode?
I asked you a question — What was the question?

Have you seen Love, Death and Robots? — Nice to chatting with you!
Did you like it? — They spend many years on it.
She lives in NYC. — I do know its director. He should have a very creative mind.

Have you **work for** Love, Death and Robots? — Yes, **I watched it with my friend.**
Did you like me? — Yes, we watched in three hours. **I ignored to watch it.**
Not that much. — No **job** is **about** this type.

Figure 1: Examples of human-human (first dialogue) and human-chatbot (second dialogue) conversations alongside manipulations resulted from baseline (indicated with yellow color) and our proposed perturbations (indicated with purple color), respectively. Similar to the human-chatbot interaction, our manipulations result in more subtly-incoherent dialogue compared to baseline manipulations.

In this work, we focus on the automatic evaluation of the coherence of *dialogues*, which is under-explored. **Coherence** is a conversation-level metric that measures how well the utterances in a conversation are unified leading to a consistent interaction (Byron and Stent, 1998; Mesgar et al., 2020).

Previous works pursue different models such as graph-based (Vakulenko et al., 2018; Zhang

---

et al., 2021) or text-based (Mesgar et al., 2020) approaches to develop automatic trainable coherence evaluation metrics. Those models take a *contrastive learning* approach, where they build binary classifiers to differentiate positive, or coherent examples from negative, or incoherent dialogues. Those classifiers are usually trained on datasets constructed by using human-human conversations as positive examples and applying *text-level heuristic manipulations* to generate incoherent conversations. The *text-level manipulations* directly change the structures of the conversation such as shuffling the order of utterances, replacing some random utterances from external conversations (Vakulenko et al., 2018; Mesgar et al., 2020; Zhang et al., 2021), as shown in the third dialogue of Figure 1.

We posit that such text-level manipulations are too simplistic to adequately represent more nuanced coherence errors presented in the current state-of-the-art dialogue systems. For example, the second conversation in Figure 1 shows a human-system interaction from the FED dataset (Mehri and Eskénazi, 2020), where the incoherence is much more subtle than the ones created by text-level manipulations.

In this paper, we investigate *manipulation techniques* to generate negative samples that represent coherence errors more likely to happen in the state-of-the-art dialogue systems. To this end, we propose DEAM, a model that uses Abstract Meaning Representation (AMR) to apply *semantic-level manipulations* to generate negative examples. AMRs are intended to capture the meaning of a sentence by abstracting away irrelevant syntactic features. Thus, injecting targeted and controlled perturbations into an AMR is easy and can introduce semantic incoherence into the corresponding sentences.

DEAM starts with parsing conversations into semantic AMR representations and then injects incoherence types that are usually observed in current state-of-the-art models into the AMR graphs. It concludes this process by translating the manipulated AMRs back to conversations as negative examples using a controllable generation model. A fine-tuned RoBERTa model is then trained on the created dataset to distinguish coherent and incoherent conversations as the evaluation metric.

Our main contributions are as follows:

- We propose DEAM, an evaluation metric that leverages AMR graphs and injects incoherence sources at the semantic level to generate incoherent conversations for training.
- We propose four manipulation strategies to represent four common incoherence sources of the state-of-the-art dialogue models: contradiction, coreference inconsistency, irrelevancy and decrease engagements.
- We empirically show that the model trained on our proposed manipulations significantly outperforms strong baselines in terms of correlation with human judgments. Moreover, DEAM is capable of distinguishing positive and negative examples generated by baselines that use text-level manipulations, whereas the opposite is not true – classifiers trained on text-level manipulations cannot detect negative examples generated by DEAM. This demonstrates the effectiveness of the semantic-level AMR-based manipulations.

2 Related Works

Automatic evaluation of open-domain dialogue systems has a multifaceted nature with many fine-grained quality aspects (Mehri and Eskénazi, 2020). Turn-level aspects show the quality of the system's utterance given a dialogue context from different perspectives including appropriateness, relevance, engagement, and etc (Lowe et al., 2017; Tao et al., 2018; Ghazarian et al., 2020). Whereas, conversation-level facets such as coherence, diversity, informativeness take into account the whole dialog flow (Vakulenko et al., 2018; Zhang et al., 2021; Mehri and Eskénazi, 2020).

Dialogue coherence evaluation is pertinent to discourse coherence since a dialogue is counted as a multi-party discourse. Similar to discourse coherence, many original coherence evaluation metrics derived from the Centering Model for monitoring the local focus of utterances and their entities distribution (Grosz and Sidner, 1986; Miltsakaki and Kukich, 2004; Lapata and Barzilay, 2005). A group of studies assess the coherence of dialogues with respect to entities and dialogue acts (Cervone and Riccardi, 2020; Mesgar et al., 2020). Another inspected approach for dialogue coherence evaluation is to represent dialogue in a structured graph format where contextually dependent neighbor utterances or concepts are connected nodes in the graph (Vakulenko et al., 2018; Mesgar et al., 2020; Huang et al., 2020). Graph convolutional networks are used to complete this task.

High-quality training dataset is identified as one of the momentous and indelible components in automatic coherence evaluation. Some previous works construct such datasets by collecting human judgments (Higashinaka et al., 2014; Cervone and Riccardi, 2020). While many recent works rely on a more timely and costly affordable approach by automatically generating negative samples. The utterances of the coherent conversations from human-human interactions are manipulated by shuffling their order, inserting or replacing irrelevant utterances (Vakulenko et al., 2018; Mesgar et al., 2020; Huang et al., 2020; Zhang et al., 2021). In this work, we show that such changes can not truly represent machine-generated incoherent conversations. One work that is closely related to us and proposed abstract-level manipulations is Ghazarian et al. (2021b). However, their application domain is open-domain story evaluation, and they use story plot, rather than AMR, for the manipulation, which is more domain-specific.

3 DEAM Overview

Our goal is to build an evaluation metric that measures the conversation-level coherence of dialogues. We follow the trainable evaluation metrics (Vakulenko et al., 2018) to formulate the evaluation as a classification task. We train the evaluator on positive (coherent) and negative (incoherent) conversations, and take the predicted probability for the positive class as the coherence score.

As is discussed above, the main challenge for building a reliable metric is to obtain negative samples that can adequately represent the incoherence issues presented in advanced dialogue systems. To this end, we propose to generate negative examples by leveraging AMR-based manipulations. We then build a RoBERTa-based classifier as the evaluation metric by fine-tuning RoBERTa on the automatically generated training data. Figure 2 illustrates an overview of our proposed evaluation method.

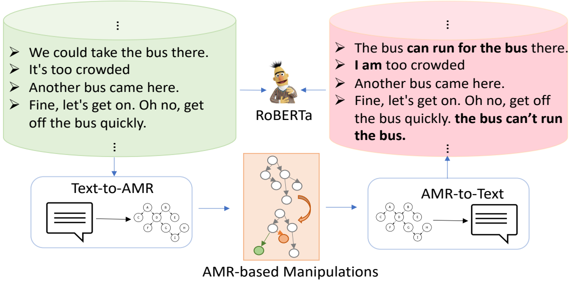

Figure 2: Overall architecture of DEAM metric trained on positive (green box) interactions and negative (red box) conversations generated from AMR-based manipulations (orange box)

Figure 3: AMR representation of a dialogue utterance

The first step of DEAM is to apply Text-to-AMR models to the conversations. Text-to-AMR or AMR parsing (Jin and Gildea, 2019; Xu et al., 2020; Zhou et al., 2021; Lam et al., 2021) that translates conversation texts to directed and acyclic AMR graphs containing relation edges between concept nodes (Banarescu et al., 2013) has been effectively accomplished by transformer-based models in a sequence-to-sequence (seq2seq) training fashion (Xu et al., 2020; Zhou et al., 2021). We use the fine-tuned T5 (Raffel et al., 2020) model[2] for this purpose.

We then manipulate the AMR graphs (section 4.2) and back translate them into conversation texts to be used as negative examples for training the text-based coherence evaluator. Similar to AMR parsing, we use finetuned T5[3] that is shown to be effective for the AMR-to-Text generation task (Mager et al., 2020; Ribeiro et al., 2020).

4 Incoherent Dialogue Generation

The challenge that automatic trainable evaluation metrics face is in providing training data that can appropriately replicate moderate to low quality conversations with incoherence sources that usually happen in the current dialogue models. The common solution is to apply manipulations to positive conversations. In this section, we summarize the baselines manipulations and state our proposed AMR-based perturbations.

4.1 Baselines Manipulations

Baseline manipulations can be classified as:

---

[2] We leverage the released parse_t5 model from https://github.com/bjascob/amrlib

[3] We leverage the released generate_t5wtense model from https://github.com/bjascob/amrlib.

1) Shuffling-based manipulations: In such manipulations, turns order (Vakulenko et al., 2018), sequence of speakers utterances (Mesgar et al., 2020; Vakulenko et al., 2018; Zhang et al., 2021), or the position of the first and second sections of conversations (Vakulenko et al., 2018) are swapped.

2) Insertion-based manipulations: This group of manipulations add incoherence sources by replacing (Mesgar et al., 2020; Zhang et al., 2021) or inserting (Mesgar et al., 2020) a random utterance from a randomly selected conversation. Each baseline metric fuses multiple manipulations, hence we use their citations (Vakulenko et al., 2018), (Mesgar et al., 2020) to easily refer them in later sections.

4.2 AMR-based Manipulations

AMR is originally proposed by Banarescu et al. (2013) as a semantic representation language that helps to abstract away the text from surface syntactic. Many abstract-level semantic information such as named entities, negations, questions, coreferences and modalities in the texts can be encoded by AMR graphs. These potential capabilities of AMR make it lucrative in many semantic-related NLP tasks such as summarization (Liao et al., 2018) and machine translation (Song et al., 2019). Conversations between two interlocutors contain many semantic details that can be captured by these graphs. Therefore, we explore AMR features' usage in the dialogue systems evaluation task by manipulating the AMR graphs of coherent conversations, each manipulation reflecting a specific reason for incoherence in dialogue systems. Figure 3 demonstrates a linearized version of an utterance AMR graph.

In AMR graphs, entities and concepts are shown as nodes and their relations are depicted with various relation edges (Banarescu et al., 2013). Each AMR concept is either a word, or a PropBank framesets keyword (Kingsbury and Palmer, 2002). The PropBank framesets with their predefined arguments are used to abstract away concepts from syntactic structures. As an example, *located* concept of PropBank framesets in Figure 3 comes with two arguments the subject (*i*) and the place (*school*).

In DEAM, we pursue the idea of manipulating abstract-level semantic information extracted from AMRs to generate incoherent conversations. In this work, we mainly focus on four major logical flaws that could happen in state-of-the-art dialogue models such as cases when a chatbot contradicts its previously stated utterances, uses incorrect coreferences, responds users with irrelevant utterances, does not engage enough in the conversation. We explain each of these logical flaws in detail.

4.2.1 Contradiction

One of the common issues that dialogue systems struggle with is directly or indirectly contradicting previous utterances in dialogue. To replicate this type of error, a contradicted version of a subgraph from the original AMR is copied to other locations. This negative form AMRs can be accomplished by directly adding *polarity* to the concepts or replacing concepts with their antonyms that hold *Antonym*, *NotDesires*, *NotCapableOf*, and *NotHasProperty* relations in ConceptNet (Speer and Havasi, 2012). After adding contradictions, the AMR-to-Text model will use the encoded context to output incoherent yet natural conversations. In the bottom right example of Figure 4, speaker B contradicts its previously stated opinion that badly effects the linkage of the utterances.

4.2.2 Coreference Inconsistency

The coherence of a conversation is preserved by the correct references of previously mentioned entities and words in the dialogue context. Pronouns in the conversation play an essential role in this regard. Coreferences in AMRs are presented as arguments (*ARG*) and all three different types of pronouns such as subjective, objective and possessive pronouns are shown in their subjective format.

To disrupt the coreferences relations, we randomly replace some pronouns in the conversation's AMR with another pronoun or noun identified as *ARG* or operand (*op*) from the same conversation. After replacements, the AMR-to-Text model adapts other sections of the utterance accordingly and reassures us that outputs have natural look and correct grammar. The third utterance in Figure 4 demonstrates an example of coherence inconsistency which makes the utterance to be not logical.

4.2.3 Irrelevancy

Random utterance substitution from other conversations is a simple way to inject incoherence sources in dialogues, which has been frequently used in prior work (Tao et al., 2018; Ghazarian et al., 2019; Mesgar et al., 2020; Zhang et al., 2021). Conversations with completely off-topic utterances are rarely generated by advanced dialogue models due to their ability in encoding dialogue history for continuing the conversation.

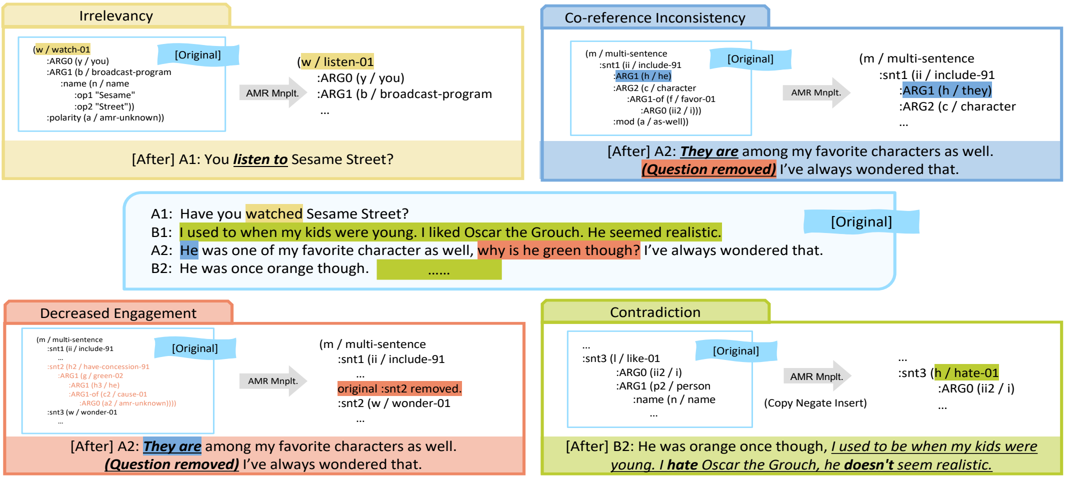

Figure 4: An abbreviated sample conversation to illustrate four different AMR-based DEAM manipulations

We propose to apply irrelevancy sources to AMR graphs. We select some AMR items such as concepts, *op*s, *ARG*s and replace them with random items from other utterances. In this approach, the replacement items are not from randomly selected conversations but still, they do not fit well in their newly selected locations which hurts the coherence of the conversation. In Figure 4 *watch* is replaced with *listen*. The benefits of using AMR-to-Text model emerge here where some new adaptations (such as *to*) have been augmented with new verb replacement to give the utterance a fluent look.

4.2.4 Decrease Engagement

In coherent conversations, speakers exchange opinions about different topics by stating detailed information, asking and answering questions. This coherence will be faded if one of the interlocutors evades to answer questions or talk in detail. In contrast to previous works that ignored this important feature, we augment such kind of incoherence sources into the negative sampling generation. In order to decrease the engagement of coherent conversations, we take the advantage of AMRs which are able to demonstrate detailed utterances and those containing questions. In AMR graphs, detailed utterances include more number of nested layers and concepts, *ARG*s and *op*s. Question-type utterances can be easily distinguished via *amr-unknown* concept notation and therefore with relying on AMRs the goal of decreasing engagement in the conversation is easily achievable.

We propose three different approaches to decrease the engagement and consequently the coherence of the conversations:

1) Remove question-type utterances in the conversation: we select a multi-sentence utterance including *amr-unknown* concept and remove it and all its children nodes from the graph; 2) Remove the most detailed utterance in the conversation: the utterance having the largest depth in the graph is selected as the utterance with the most transferred information and all its children alongside its parent concept are removed from the graph; 3) Remove fine-grained information in the utterances: the main concepts' detailed information that are presented as *ARG* or *op* in the AMRs are randomly selected and eliminated from the graph. The higher-level concepts in the graph are preserved while its lower-level child nodes are deleted which makes the utterance not transfer its meaning and diminishes the linkage of topics. The question part in the third utterance of Figure 4 has been removed causing the coming utterances to not be completely sensible.

5 Experimental Setup

We compare DEAM and its negative example generation techniques with baseline models and manipulations. We aim to have a data-driven analysis under three setups:

Setup 1): In this setup, we compare DEAM with baseline models by varying both the data manipulation strategies and the classification models. We fix the positive examples to be the same set of human-human conversations.

Setup 2): Since baseline models are trained on different datasets, we conduct pairwise comparisons between DEAM and each baseline evaluator by training on the baseline's dataset. Note that we only take the positive examples from the baseline's dataset, and apply different manipulations to get

Dataset	size	conv. len	utt. len
TOPICAL_DEAM	17.3k/2.2k	530/530	24/24
PERSONA_DEAM	17.9k/2.0k	187/202	13/13
FED	125	168	11
DSTC9	2.2K	318	11

Table 1: Statistics (size, average length of conversations and utterances) of TopicalChat and PersonaChat train/valid datasets (augmented with AMR-based manipulated conversations), alongside with FED and DSTC9 test datasets.

negative examples to compose a balanced set for training. We also train different classifiers (DEAM vs. baselines) for the evaluators.

Setup 3): This setup is designed to show the effectiveness of different manipulations to generate negative examples. We fix the positive examples and the classifier (i.e., RoBERTa).

5.1 Datasets

5.1.1 Training Datasets

We conduct our experiments on two crowd-sourced datasets, TopicalChat (Gopalakrishnan et al., 2019) and PersonaChat (Zhang et al., 2018). Both datasets are composed of conversations between Amazon Mechanical Turk (AMT) participants. In TopicalChat, AMT workers were supposed to have coherent and engaging conversations regarding the provided reading sets about different topics, while in the PersonaChat dataset coherent conversations were conditioned on the provided 1155 personas each including 5 personality description sentences collected via AMT. We take these conversations as coherent conversations. We follow DEAM's steps to generate and add a balanced number of incoherent conversations. Table 1 shows the train/valid statistics of the newly constructed datasets called TOPICAL_DEAM and PERSONA_DEAM.

5.1.2 Evaluation Datasets

In the literature of automatic evaluation metrics, the prevalent way of assessing the evaluators' performance is to compare the correlation of their predicted scores with human judgments. FED (Mehri and Eskénazi, 2020) and Interactive Evaluation of Dialog track of the Dialog State Tracking Challenge 9 (DSTC9) (Gunasekara et al., 2020) are two publically available benchmark datasets including human ratings on the coherence aspect of human-human or human-systems conversations.

The participants of FED dataset, have judged 125 conversations; 41 human-human, 44 human-Mitsuku chatbot and 40 human-Meena (Adiwardana et al., 2020) chatbot. Humans have assessed the conversations from 11 conversation-level evaluation aspects including the coherence and overall scores. Each conversation in FED is judged by 5 distinct annotators. Coherence and overall scores are in the range of 0-2 and 0-4, respectively.

In DSTC9 dataset[4], AMT workers have rated 2200 conversations between invited participants and knowledge-grounded response generation models using the same 11 fine-grained conversation-level evaluation aspects. Coherence and overall scores that we use in our experiments are in the range of 1-3 and 1-5, respectively. In our experiments, we take the average of judgments for conversations with more than one annotator's ratings and compute the Spearman correlations between human evaluations and evaluator's generated scores.

5.2 Implementation Details

In our work, we train and run all the models on a machine with a GeForce RTX 2080 Ti GPU. We fine-tune RoBERTa-large pretrained model on TOPICAL_DEAM and PERSONA_DEAM datasets for three epochs and optimize parameters using Adam optimizer with 1e-5 learning rate.

To conduct experiments in setup 1, we train Vakulenko et al. (2018)'s graph-based model for 128 epochs with 1e-5 learning rate. Mesgar et al. (2020)'s LSTM-based model is trained for 8 epochs with 5e-5 learning rate. We retrain DynaEval (Zhang et al., 2021) for 20 epochs. All baselines are trained using Adam optimizer. Due to not publically published models proposed by Vakulenko et al. (2018) and Mesgar et al. (2020), we need to retrain these models on their original datasets; Ubuntu (Lowe et al., 2015) and DailyDialog (Li et al., 2017); using the same hyperparameters published in the aforementioned papers to complete experiments in setup 2. We use DynaEval's published checkpoints to run experiments in this setup.

In experimental setup 3, we start from TOPICALCHAT and PERSONACHAT datasets, and augment negative samples pursuing different manipulation techniques. We fix the evaluator and finetune RoBERTa-large model for 3 epochs with a 1e-5 learning rate. Since Vakulenko et al. (2018)'s proposed manipulations are in the entity level, we adapt the perturbations to the text level by replac-

ing the sequence of entities with a sequence of utterances substitutions to be acceptable by the RoBERTa model.

6 Results

Through our experiments, we report the Spearman correlation of evaluation metrics with human annotations under different experimental setups.

6.1 Metrics Performance

Table 2 depicts the quantitative results for different evaluation models on both FED and DSTC9 datasets of experimental setup 1. According to the reported correlations, the superiority of DEAM shown in the last row versus other baselines is obviously recognizable. This superiority could originate from the subtle negative sampling technique.

In experimental setup 1, manipulation techniques and models vary between evaluators, therefore we complete our investigation via experimental setup 2 by conducting one by one comparison of DEAM with each baseline model training each pair on the same dataset that the baseline model has been trained on. Table 4 shows the output of this type of pairwise comparisons separated each pair into one section. Even though most of the baseline models correlations increased, yet DEAM takes the lead. It is noteworthy that the correlation of DynaEval reported in the original paper for FED dataset has decreased, this could be due to the less number of negative samples that we consider for each positive conversation and its major impact on this model's performance.

6.2 Manipulations Effect

Table 3 illustrates the results of experimental setup 3, where we fix both RoBERTa evaluator and TopicalChat and PersonaChat original datasets and apply different manipulation techniques to add negative samples. Even though the correlation for baseline manipulations increased drastically, which shows the effectiveness of strong pretrained language models in better encoding conversations information used for the evaluation task, DEAM's performance is still higher. This interprets the beneficial effect of AMR-based manipulations. The positive slops of the regression line in Figures 5 and 6 between DEAM predicted coherence scores and human coherence and overall evaluations for FED dataset show the proposed manipulations superiority from a different angle. The distribution of baseline models predicted low scores for high-quality conversations and vice versa present their ineffectiveness in correctly distinguishing between low-quality and high-quality conversations.

6.3 Ablation Studies

Next, we inspect the role of each of the four proposed manipulations in the metric's performance. We conduct an ablation study on TopicalChat and PersonaChat datasets to assess the effectiveness of each manipulation. For each specific manipulation, we remove it from the list of possible

Model	Manipulations	Dataset	FED		DSTC9	
			Coherence	Overall	Coherence	Overall

DYNAEVAL DEAM	DYNAEVAL DEAM	EMPATHETIC EMPATHETIC	0.17 **0.48**	0.10 **0.47**	-0.01 **0.20**	-0.02 **0.20**

Table 4: Pairwise comparisons between DEAM with the proposed AMR-based manipulations and different baseline models using their original datasets, manipulations, and models (setup 2). All models have been trained on balanced sets of coherent/incoherent examples.

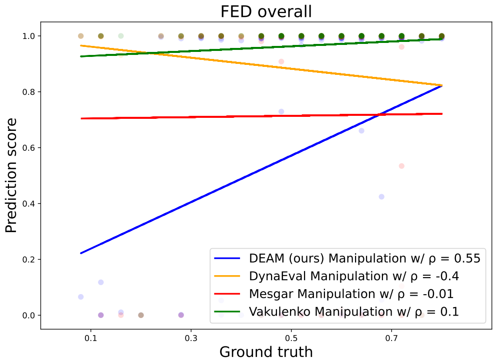

Figure 6: Scatter plots and regression lines of different models predicted scores versus FED-overall human evaluations. Overlapped points are represented darker.

manipulations and try to randomly sample one up to three different manipulations to create negative samples.

In Table 5, we witness an overall drop by eliminating each of the manipulations that indicates the positive impact of all of the manipulations on generating higher quality negative samples that are closer to the samples generated by state-of-the-art models and consequently the evaluator's accuracy. Removing irrelevancy and decrease engagement manipulations have the most detrimental impact on the metric, which suggests that many state-of-the-art models struggle with such issues. By eliminating these manipulations the model does not have access to such negative examples during training, which significantly limits its ability to detect such incoherences during inference time. On the other hand, omitting coreference inconsistency from the manipulations has the lowest impact on DEAM, specifically for DSTC9 dataset which can be interpreted as the state-of-the-art models are safer regarding such issues. We also note that the performance difference between DSTC9 and FED could be due to the long conversations in DSTC9 that mostly include very limited coreferences.

Manipulation	FED		DSTC9	
	Coh	Overall	Coh	Overall
DEAM	**0.47**	**0.55**	**0.19**	**0.20**

DEAM	0.68	0.67	0.65	0.84

Figure 7: The accuracy of evaluation metrics to distinguish coherent/incoherent conversations in test data (y-axis) generated using baseline manipulations (x-axis).

6.4 Qualitative Analysis

We analyze the quality of DEAM versus baseline evaluators in terms of examining each model's performance to distinguish between positive and negative examples constructed leveraging various manipulations. Some examples are shown in Table 6 of Appendix. Figure 7 illustrates a heat map of the accuracy scores. X-axis and Y-axis show the manipulations used for creating training and testing datasets, respectively. As is expected the highest accuracies can be found on the diagonal where models have been trained and tested on datasets generated from pursuing the same manipulation techniques. The light-colored cells are mainly related to models trained on baseline manipulated data and tested on AMR-based perturbed data. This indicates that the baseline models trained on such

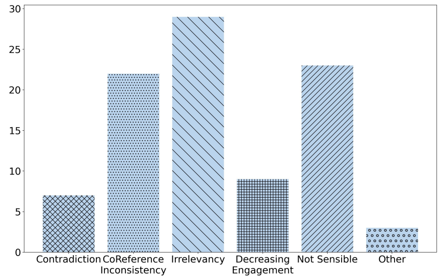

Figure 8: Statistics of different types of logical flaws observed in 50 randomly selected low-quality interactions between human and state-of-the-art dialogue systems (25 dialogues from FED and 25 from DSTC9)

types of text-level heuristic manipulations can not perform well and indeed have a random guess on more challenging incoherent examples that are generated by DEAM. While the higher accuracies of DEAM model on baseline test datasets show its capability to more effectively distinguish between positive and heuristically created their counterpart manipulations' negative conversations.

Our proposed manipulations in DEAM are directly influenced by the quality of Text-to-AMR and AMR-to-Text generation models. Even though finetuned T5 (Raffel et al., 2020) models used here have been shown to be effective (Ribeiro et al., 2020), there are still not perfect and suffer from some errors. We conducted a quick analysis of different deficiencies in conversations obtained by AMR-based back-translations. Most of these flaws are due to the fact that in Text-to-AMR generations some syntactic information such as verb tense, passive type of sentences, are removed from the text due to the semantic-based structure of the AMRs. Table 8 in the Appendix shows such flaws. Ongoing work on improving AMR parsers and generators will lead to more robust AMR models, thus improving the quality of the proposed manipulations as well.

6.5 Manipulation Coverage

In the end, we conduct an analysis to explore the coverage rate of our proposed manipulations in the test datasets. To accomplish this, we analyze different commonly occurring logical flaws by advanced dialogue models via randomly selecting 25 low-quality interactions from FED (Mehri and Eskénazi, 2020) and 25 poor dialogues from DSTC9 datasets. The low-quality scores specified by human annotators indicate various types of flaws in the conversations. Our analysis suggests that we can classify those flaws into distinct categories as demonstrated in Figure 8. Most of the frequently happening flaws have been covered in our work except *not_sensibility* showing the sensibility of the generated responses. We leave *not_sensibility* evaluation for future works as replicating such issues besides the AMR-based manipulations mostly requires external knowledge bases which is not the focus of this work.

7 Conclusion

Reliable automatic trainable coherence evaluation metrics that can efficiently measure the dynamics of interactions between interlocutors are principally influenced by the quality of the training instances. We show that leveraging text-level manipulations can not adequately mirror the incoherence errors that current dialogue systems face. According to our study, DEAM can more effectively accomplish this task by relying on capabilities that AMR-based semantic perturbations and pretrained language models present. We leave the investigations regarding the effectiveness of AMRs for evaluating sensibility of the generated responses with taking into account knowledge bases for the future.

8 Ethics

We acknowledge the importance of ACM Code of Ethics and totally agree with it. We ensure that our study is compatible with the provided code, specifically in the terms of providing non-offensive dataset construction.

In our proposed approach, we start from publically available human-human conversational datasets and attempt to apply our proposed manipulations at the AMR level. The main concern that arises here is the probability of generating offensive conversations from manipulated AMRs. The chance of such generations is faded with leveraging TopicalChat (Gopalakrishnan et al., 2019) and PersonaChat (Zhang et al., 2018) datasets that have been originally collected asking users to converse without profanity and inappropriate utterances. We should note that the possibility of perturbations that would have the possibility of generating objectionable outputs is not zero therefore we acknowledge there may be biases or abusive content via attacks that can be resolved by security trended studies which is out of this work's scope.

A Appendix

In Table 6, we present examples of incoherent conversations generated by DEAM's AMR-based and other baselines' text-based manipulations each with a specific color. Due to the long length of the conversations, we include subsections from the conversations in that their utterances are separated by </UTT> separator. The colored lines and boldly written parts show types of manipulations and applied changes to the conversations using different approaches. It is obvious that the first three baseline manipulations result in very unnatural incoherent conversations while the last one which applies three out of four of our proposed semantic-based manipulations results in more challenging incoherent conversations that could be generated by state-of-the-art generative models.

The original and manipulated AMR graphs of the conversation in Figure 4 is shown in Table 7. We linearized the AMR graphs to be placed in the table.

Table 8 demonstrates different syntactical issues that could be resulted from text-to-AMR and AMR-to-text models. The issues have been bolded in the table.

Incoherent Conversation
Vakulenko et al., 2018 – Permute bolded section with another random dialogue ...</UTT>**No clue. Wonder if the Model T ever won an award? It is from 1908. It was one of the first cars that ws accessible to the masses.</UTT>What is your favorite car brand?</UTT>I like Cadillacs which were named after French explorer Antoine de la Mothe Cadillac who founded Detroit. It's about time for a drive now, goodbye!</UTT>1886 is thought of as the birth year of the modern car.</UTT>Yeah, I didn't know that. It was his Benz Patent-Motorwagen.</UTT>That is true, do you know when the first car was invented?**</UTT>Great question. I love that they experience eureka moments.</UTT>Yeah I never knew that, thats pretty awesome. Do you have a dog?</UTT>I do not have a dog. Do you?</UTT>I do, shes 2, a rescue. I think my dog is the exception when they say dogs an elephants can understand pointing lol shes obivious.</UTT>Thats funny. Do you consider dogs to be man's best friend.</UTT>...

HIBRIDS: Attention with Hierarchical Biases for Structure-aware Long Document Summarization

Shuyang Cao and **Lu Wang**
Computer Science and Engineering
University of Michigan
Ann Arbor, MI
{caoshuy, wangluxy}@umich.edu

Abstract

Document structure is critical for efficient information consumption. However, it is challenging to encode it efficiently into the modern Transformer architecture. In this work, we present HIBRIDS, which injects Hierarchical Biases foR Incorporating Document Structure into the calculation of attention scores. We further present a new task, hierarchical question-summary generation, for summarizing salient content in the source document into a hierarchy of questions and summaries, where each follow-up question inquires about the content of its parent question-summary pair. We also annotate a new dataset with $6,153$ question-summary hierarchies labeled on long government reports. Experiment results show that our model produces better question-summary hierarchies than comparisons on both hierarchy quality and content coverage, a finding also echoed by human judges. Additionally, our model improves the generation of long-form summaries from lengthy government reports and Wikipedia articles, as measured by ROUGE scores.

1 Introduction

Document structure facilitates information searching, reading comprehension, and knowledge acquisition by providing an informative overview of the content (Guthrie et al., 1991; Meyer et al., 1980; Taylor and Beach, 1984; Shavelson, 1974; Jonassen, 1988). Specifically, for summarization, its utility is twofold: (1) *Source* document structures, such as sections and paragraphs, can be instructive for summary generation (Cohan et al., 2018; Celikyilmaz et al., 2018; Zhang et al., 2019); (2) Structures in *output* summaries, e.g., timelines (Shahaf et al., 2012; Wang et al., 2015) or aspects (Angelidis and Lapata, 2018), can also ease content understanding.

Nonetheless, state-of-the-art abstractive summarization systems, all built on the Transformer architecture (Zhang et al., 2020; Lewis et al., 2020), use attentions to estimate relations between pairwise tokens and largely ignore document structures. While hierarchical encoding has been investigated (Zhang et al., 2019; Balachandran et al., 2021), its need for training large amounts of additional parameters leads to increased memory footprint and thus limits the allowed input length. As for the output, the structure of single document summaries remains largely "flat", such as a list of aspects (Meng et al., 2021). We argue that it is imperative to develop systems that can output summaries with rich structures to support knowledge acquisition, which is especially critical for long documents that cover numerous subjects with varying details (Huang et al., 2021; Kryściński et al., 2021).

This work consists of two main objectives: (1) effectively informing summarization models of the source document's structure, and (2) presenting a new summarization task that produces hierarchically organized question-summary pairs to facilitate information consumption. To this end, we propose **HIBRIDS** (Hierarchical Biases foR Incorporating Document Structure).[1] We design learnable *hierarchical biases*, as part of the Transformer attention calculation, to adjust attention weights based on tokens' relative positions with regard to the document structure, inspired by the relative position method that modifies attention calculation (Raffel et al., 2020). Concretely, we leverage the natural structure of a document, i.e., section levels, to construct a *document structure tree* (Figure 2). Each learnable bias corresponds to the relation between a pair of sections, based on the distance between them in the structure tree. Intuitively, hierarchical biases adjust attention weights between tokens based on how conceptually close/distant their corresponding sections are, and they also enable summarizers to capture long-range

Volume 1: Long Papers, pages 786 - 807
May 22-27, 2022

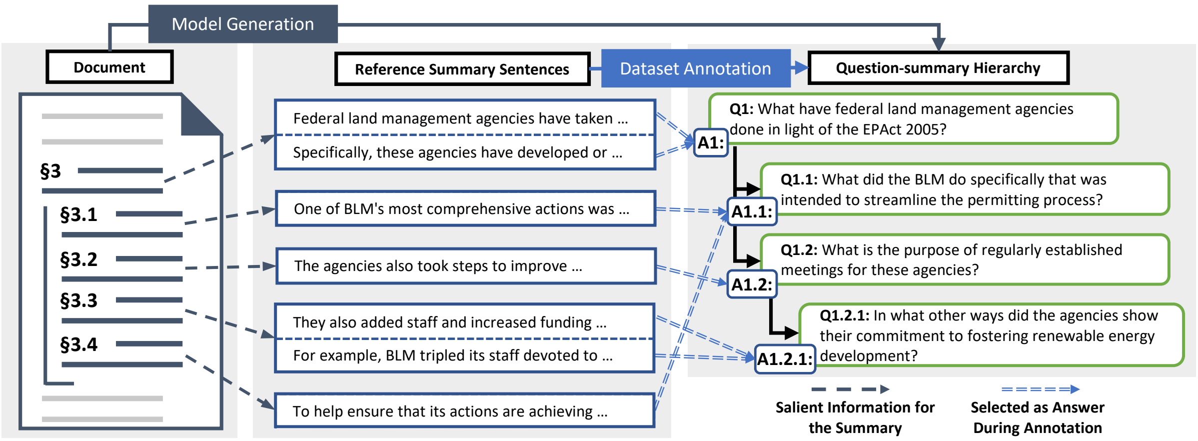

Figure 1: The question-summary hierarchy annotated for sentences in a reference summary paragraph. Summarization models are trained to generate the question-summary hierarchy *from the document*, which signifies the importance of encoding the document structure. For instance, to generate the follow-up question-summary pairs of Q1.1 and A1.1 from A1, it requires the understanding of both the content and the parent-child and sibling relations among §3, §3.1, and §3.4.

relatedness for better document understanding.

Furthermore, we design a new summarization task, **hierarchical question-summary generation**: Given a document, automatically generate questions and summaries that are organized hierarchically to lay out details for topics at different levels. As shown in Figure 1, each question asks about *salient* content of the document (to be summarized) and its child questions focus on content in the corresponding summary. This hierarchy not only exposes salient topics and their relations, but also allows readers to quickly identify aspects of interest to focus on. Our task design is inspired by the top-down knowledge learning process: People start by asking broad questions to acquire general knowledge, and then dive into details (Hintikka, 1981; Stede and Schlangen, 2004). Notably, as there is no available dataset with such annotations, we also label a new dataset, **GOVREPORT-QS**, consisting of 6,153 question-summary (QS) hierarchies for summary paragraphs based on 1,714 reports from the GOVREPORT dataset (Huang et al., 2021). Each summary paragraph contains 4.07 questions with an average QS hierarchy depth of 2.26 levels.

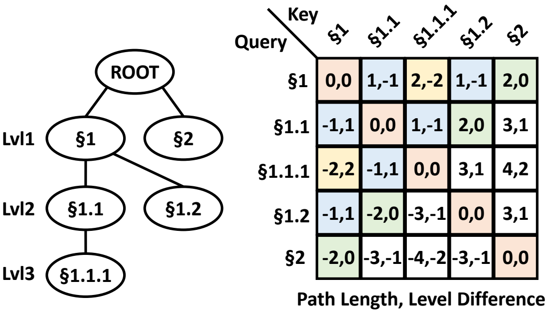
We first compare HIBRIDS with models that use structure-aware architectures (Rohde et al., 2021) and linear relative positions (Raffel et al., 2020). We conduct experiments on the hierarchical QS generation dataset using two setups: (1) generating a full hierarchy given the first question, and (2) generating follow-up questions given a QS pair. Automatic evaluation shows that our model produces better follow-up questions and summaries than comparisons, while also achieving better or comparable content coverage of full summaries, when compared with a hierarchical model (Rohde et al., 2021) that learns 2M more parameters. In human evaluation, HIBRIDS is considered to build better hierarchies that require fewer manual corrections with more relevant summaries. We further test on the long document summarization task to produce full summaries using GOVREPORT and *a newly collected dataset* consisting of about 21k high-quality biographies with summaries from Wikipedia. Again, our system summaries obtain uniformly higher ROUGE scores than comparisons, demonstrating the generalizability of HIBRIDS.

2 Related Work

Document Structure-aware Summarization. Structural information has long been leveraged for identifying summary-worthy content, including discourse structures labeled by experts (Marcu, 1997) or automatic parsers (Hirao et al., 2013; Durrett et al., 2016; Xu et al., 2020), and topical structures derived from lexical chains (Barzilay and Elhadad, 1999) or probabilistic models (Barzilay and Lee, 2004; Daumé III and Marcu, 2006). Natural structures of documents, such as sentences, have been used for pre-training a sentence-level encoder (Zhang et al., 2019) or inducing dependencies among them (Liu et al., 2019) for building extractive summarization systems. Based on separately encoded paragraphs, deep communication agents (Celikyilmaz et al., 2018) and inter-paragraph attentions (Liu and Lapata, 2019) are employed to build abstractive summarization models by exchanging information from different paragraphs. Using section structures, Cohan et al. (2018) design a section-level encoder based on the output of a word-level encoder for long document summarization. Nevertheless, multi-level encoders are more expensive since they introduce a significant amount of parameters and add extra padding at multiple levels of model design. By contrast, HIBRIDS effectively informs models of document structure by introducing a novel bias term in attention calculation among tokens, which only introduces a small number of learnable parameters.

Long Document Summarization also benefits from the inclusion of document structure information. For example, extractive summarization methods are developed to combine section-level and sentence-level information encoded by multi-level encoders (Xiao and Carenini, 2019) and include longer context via sliding encoding over sections (Cui and Hu, 2021). Recent work on summarizing long documents focuses on designing efficient Transformers with sparse attentions to produce abstractive summaries for long documents in an end-to-end fashion (Beltagy et al., 2020; Zaheer et al., 2020; Huang et al., 2021). However, they all ignore the natural structure of long documents, such as sections and subsections. Based on a simple design, HIBRIDS can be integrated into any efficient Transformer seamlessly for incorporating document structure information.

Generating question-answer (QA) pairs has been studied to facilitate information seeking within documents, mainly for producing questions that can be addressed by short phrases (Du and Cardie, 2018; Liu et al., 2020). Prior work mostly focuses on improving QA pair relevance by leveraging additional QA systems (Sachan and Xing, 2018), measuring roundtrip consistency (Alberti et al., 2019), or refining questions iteratively (Qu et al., 2021). Generating a two-level hierarchy of QA pairs from a given paragraph is investigated by Krishna and Iyyer (2019). Our work is different in at least three aspects. First, our goal is to provide a structured summary that focuses on the *salient content* of the given document, rather than creating questions about any generic information, as done in most QA data construction (Rajpurkar et al., 2016; Choi et al., 2018). Second, our GOVREPORT-QS data concerns richer hierarchies for presenting content in long documents, e.g., 23.6% of our hierarchies contain at least *three levels*. Our parent-child pairs also cover diverse relations, e.g., adding explanations or expanding the topics, beyond asking about specific details as done in Krishna and Iyyer (2019). Third, our questions are designed to be open-ended and grounded in the given document, so our new task is more suitable for summarization models.



Query \ Key	§1	§1.1	§1.1.1	§1.2	§2
§1	0,0	1,-1	2,-2	1,-1	2,0
§1.1	-1,1	0,0	1,-1	2,0	3,1
§1.1.1	-2,2	-1,1	0,0	3,1	4,2
§1.2	-1,1	-2,0	-3,-1	0,0	3,1
§2	-2,0	-3,-1	-4,-2	-3,-1	0,0

Figure 2: Example path lengths and level differences (right) that encode the relative positions with regard to the document tree structure (left). Each query/key represents a block of tokens that belong to the same section. We highlight important section relations: self, parent-child, ancestor-descendant (other than parent-child), and sibling. From §1 (level 1) to §1.2 (level 2), the level difference is **-1** and path length is **1** since §1 occurs *before* §1.2. When looking back from §1.2 to §1, both numbers' signs are flipped, i.e, (**1**, **-1**).

3 HIBRIDS with Hierarchical Biases

In this section, we first introduce how relative positions are defined over the document structure tree. Then we present HIBRIDS, which can be included in encoder self-attentions or decoder cross-attentions to adjust the attention scores based on tokens' relative positions.

3.1 Document Structure Tree and Tree-based Relative Positions

We first construct a *document structure tree* (Figure 2, left), by leveraging the natural structure of sections and subsections (henceforth sections) in documents, which is available in our experiment data extracted from government reports and Wikipedia articles. We then capture the relative position between pairwise tokens x and y in two different sections, e.g., S_x and S_y, with two tree-based measures. (1) $\texttt{PathLen}(x, y)$: the length of the shortest path from S_x to S_y; (2) $\texttt{LvlDiff}(x, y)$: the level difference from S_x to S_y. `PathLen` is designed to be *asymmetric* to capture content ordering, i.e., its value is positive if S_x appears before S_y in the document, and vice versa. Examples are displayed in Figure 2.

3.2 Attentions with Hierarchical Biases

The design of HIBRIDS is based on a lookup table $B[\cdot,\cdot]$: Each item in it corresponds to a learnable hierarchical bias defined by path length and level difference, which is then used to bias the attention calculation for tokens in different sections. Each head maintains its own lookup table B.

We first apply HIBRIDS to Transformer encoder self-attention computation, which is called **HIBRIDS-ENC**. Given the i-th query $\boldsymbol{q}_i$ and the matrix $\boldsymbol{K}$ formed by n keys for all input tokens, HIBRIDS adds a bias for each key, with respect to the i-th query, to attention calculation:

$$a_{ij} = \mathrm{softmax}(\boldsymbol{q}_i \boldsymbol{K}^T + \boldsymbol{b}_i)_j \tag{1}$$

where the vector $\boldsymbol{b}_i = [b_{i1}, \ldots, b_{ij}, \ldots, b_{in}]$ contains the bias terms derived from our hierarchical biases as follows:

$$b_{ij} = B[\texttt{PathLen}(i,j), \texttt{LvlDiff}(i,j)] \tag{2}$$

where $\texttt{PathLen}(i,j)$ and $\texttt{LvlDiff}(i,j)$ are the path length and level difference between the sections that tokens i and j belong to. Note that b_{ij} varies among different heads. HIBRIDS-ENC guides tokens to attend to structurally related tokens during encoding.

We then apply HIBRIDS to decoder cross-attention calculation, named as **HIBRIDS-DEC**, to encourage more coherent generation by establishing better alignment with the source document. At the generation step t, the cross-attention weight to the j-th input token adjusted by bias b_{tj} is obtained similarly as in Eq. 1 with the following modification. We calculate b_{tj} as the weighted sum of the hierarchical biases for all input tokens (indexed with l) to the j-th token. The weight is chosen as the decoder's second last layer's cross-attention score between the t-th generated token and the l-th input token, which is shown to better capture word alignment (Garg et al., 2019; Cao and Wang, 2021a). b_{tj} is only applied to the decoder's last layer with the following formulation:

$$b_{tj} = \sum_l a_{tl}^{crs} \cdot B[\texttt{PathLen}(l,j), \texttt{LvlDiff}(l,j)] \tag{3}$$

where a_{tl}^{crs} is the decoder's second last layer's cross-attention weight for the generation step t to the l-th input token.

HIBRIDS$_\text{S}$ with Selected Relations. We further consider only keeping salient relations from the tree to reduce the number of parameters to learn, including *self* (same section), *parent-child*, *ancestor-descendant*, *sibling*, *neighboring in text*, and *within the same top-level section* (e.g., §1.1.1 and §1.2 are both in §1). In total, they account for 21.6% of all relation occurrences. The modified HIBRIDS$_\text{S}$ can also be applied to both encoder and decoder.

4 A New Task: Hierarchical Question-summary Generation

We introduce a new summarization task in this section: Given a document or several sections of a document, we aim to generate question-summary (QS) pairs that are organized hierarchically. As shown in Figure 1, this QS hierarchy lays out details for topics at multiple levels, with each child QS pair expanding the content of its parent. Our task is motivated by how human learns knowledge in a top-down fashion, where general knowledge is acquired first and details and in-depth content are explored later (Hintikka, 1981). This hierarchy proactively highlights the document structure, to further promote content engagement and comprehension (McKeown et al., 2009).

4.1 Question-summary Hierarchy Annotation Procedure

We first annotate a new dataset, GOVREPORT-QS, with hierarchical QS pairs, based on articles and corresponding summaries selected from the GOVREPORT dataset (Huang et al., 2021). As these documents and summaries have 9,409 and 553 words on average respectively, directly annotating full documents with a QS hierarchy presents a challenge. To address this, we ask annotators to create hierarchical questions for a selected summary paragraph and only allow them to select complete sentences from the summary paragraph as the corresponding answers. Each question created should be fully addressed by its answer and the answer should not contain information irrelevant to the question. For follow-up questions, they are encouraged to ask about specific details or issue questions that can yield summaries that elaborate from their parents. Annotators are also instructed to construct hierarchies of as many levels as possible. Figure 1 demonstrates how hierarchical questions are created and how answer sentences are selected when annotating a report on the development of renewable energy.

To cover more documents and avoid collecting shallow hierarchies, each summary paragraph is annotated by one annotator and we select high-quality summary paragraphs for annotation based on heuristic rules, e.g., each paragraph should have at least 3 sentences and 70 words and an adequate level of abstractiveness as measured by normalized density of extractive fragments (Grusky et al., 2018) (with a threshold of < 0.15). Annotation instructions and details of paragraph selection are in Appendix A.

We hired 11 college students who are native English speakers to carry out the annotation tasks in multiple rounds. Feedback was provided to each annotator after each round. A finalization stage was conducted after collecting all annotations, where 4 high-quality annotators were asked to correct typos, remove factoid questions, and make minor adjustment to the hierarchies when errors were detected.

GOVREPORT-QS Statistics. In total, 6,153 summary paragraphs are annotated with 25,055 QS pairs. On average, 4.07 QS pairs are created per summary paragraph, spanning 2.26 levels. 70.5% and 23.6% of paragraphs are annotated with *two* and *three* levels of questions, making our dataset a valuable benchmark for studying QS hierarchy generation, query-focused summarization, and question generation.

4.2 Aligning Summary Paragraphs with Document Sections

The QS hierarchies then become the target generation, and we construct inputs to our QS hierarchy generation system by mapping annotated summary paragraphs back to *sections* in source documents.

Concretely, we match each summary sentence to a document paragraph based on a combination of BERT-based, word overlap-based, and entity overlap-based similarities (details in Appendix A). All *sections* where matched paragraphs belong, along with the titles of their ancestor sections, are combined together to serve as the system input for generating the corresponding QS hierarchy, as demonstrated in Figure 1. The paired sections have an average length of 2,029, longer than documents in many standard summarization benchmarks.

5 Experiment Setups

5.1 Datasets and Tasks

We evaluate HIBRIDS on three different tasks with outputs of varying structures.

Task I: QSGen-Hier. Based on GOVREPORT-QS, we first experiment with a setup where, given the aligned document sections and a root question, the model is expected to produce a summary that addresses the question as well as the rest of the hierarchy. To linearize a QS hierarchy for the Transformer sequential decoder, we concatenate its QS pairs following a depth-first traversal. Special tokens are inserted before each QS pair to indicate the change of its level from the previous QS pair: `[L↓]`, `[L↑]`, and `[L-]` indicate that the level has incremented, decremented, and not changed, respectively. For example, the sample hierarchy in Figure 1 can be formulated as: "*A1* `[L↓]` *Q1.1 A1.1* `[L-]` *Q1.2 A1.2* `[L↓]` *Q1.2.1 A1.2.1*". On this task, we divide our samples into train/dev/test splits with sizes of 4,878/644/631.

Task II: QSGen-ChildQ. Next, we leverage GOVREPORT-QS for follow-up question generation: Given a QS pair and the aligned document sections, we aim to generate all child questions. With this setup, two samples can be created from the example in Figure 1. The first one takes as input *"Q1 A1"* and the aligned sections to generate *"Q1.1 Q1.2"*, whereas the other reads in *"Q1.2 A1.2"* and the aligned sections to produce *"Q1.2.1"*. Here we construct train/dev/test splits with sizes of 7,157/958/942.

Task III: Full Summary Generation. We also conduct experiments on GOVREPORT to test HIBRIDS on generating long-form summaries for long inputs. We use the original data splits with 17,516/974/973 samples in train/dev/test sets. We further collect *a new dataset* from WikiProject Biography[2] (WIKIBIOSUM) to perform biography summarization. After collecting all available biographies, we keep the ones with at least two levels of section hierarchy and preserve section structures of all levels. For each article, the paragraph before the first section is treated as the target summary, and the rest becomes the input. The finalized dataset has 20,833 pairs, divided into 18,751/1,041/1,041 samples for train/dev/test sets.

---

[2] `https://en.wikipedia.org/wiki/Wikipedia:WikiProject_Biography`

The average lengths of the input and output for WikiBioSum are 3,478 and 1,266. Details of WikiBioSum data collection and filtering procedures are in Appendix B.

We set the maximum input length to 5,120 for QSGen-Hier, QSGen-ChildQ, and full document summarization on WikiBioSum. On GovReport, the limit is set to 16,384.

5.2 Evaluation and Comparisons

Evaluation Metrics. We use ROUGE (Lin, 2004) for summarization evaluation and additionally report BLEU up to 4-gram (Papineni et al., 2002) for evaluating the generated questions.

We propose to evaluate the generated QS hierarchy against the reference hierarchy with F1 scores calculated as follows, inspired by labeled attachment score in dependency parsing (Zeman et al., 2017): We first map each generated QS pair to a reference QS pair following the highest sum of ROUGE-1 and ROUGE-2 scores between their summaries. After that, we consider two QS pairs with parent-child relation in the generated hierarchy. A *match* is established only when their mapped QS pairs have a parent-child or ancestor-descendant relation in the reference hierarchy. Precision can then be calculated based on the matching results. We further weight each match based on the sum of the ROUGE-1 and ROUGE-2 scores calculated over both parent and child summaries. Weighted recall and F1 are calculated similarly.

Comparisons. All tasks in this work involve long inputs. To allow efficient encoding, we use **Longformer** (Beltagy et al., 2020) with a window size of 1024 as the base model, and fine-tune it for all systems and comparisons.

We first consider comparisons by adding special tokens to encode document structure: (1) **SecTok** inserts a special token `[SEC]` at the start of each section. (2) **LvlSecTok** further differentiates sections at varying levels using different tokens (e.g., `[SEC-L1]` for §1, `[SEC-L2]` for §1.1).

Based on LvlSecTok, we build all HIBRIDS variants and other comparisons listed below:

- **HierEnc**: We implement the hierarchical model by Rohde et al. (2021), where we replace its sentence encoder with a section encoder of 12 layers to maintain section structures. Among all models, HierEnc requires the most architecture change and adds the most parameters to learn.
- **MultiTask**: We also consider predicting the selected relations used by HIBRIDS$_S$ (§3) in a multi-task prediction setup with a bilinear classifier, operating on the representations of section tokens. We use equal weights for prediction loss and summarization loss.

Model	Hier F1	Summary R1	Summary R2	Summary RL	Ques B4
Longformer	12.67	42.34	16.18	37.60	10.00
SecTok	12.86	42.67	16.34	38.01	10.02
LvlSecTok	12.74	42.34	16.31	37.61	10.09
Structure-aware Comparisons					
HierEnc	11.77	**42.82**	16.32	**38.06**	9.89
MultiTask	12.64	41.19	15.49	36.58	9.66
Models with Linear Bias					
TokBias	12.43	42.58	16.41	37.71	10.06
SecBias	12.54	42.54	16.39	37.80	10.00
Our Models					
HIBRIDS-enc	**13.26**	42.74	**16.55**	38.03	**10.16**
HIBRIDS$_S$-enc	13.16	42.50	16.16	37.69	10.09
HIBRIDS-dec	12.68	42.31	16.17	37.58	9.75
HIBRIDS$_S$-dec	12.71	42.44	16.42	37.82	9.84

Table 1: Results for QSGen-Hier on GovReport-QS. The best result per metric is **bolded**. Applying HIBRIDS on the encoder produces better QS hierarchies (higher F1) and questions (higher BLEU). Our models also yield better or comparable ROUGE scores, especially compared with HierEnc which requires 43% more parameters and extra engineering efforts for architecture change. **Ques**: question; **Hier**: hierarchy.

- **TokBias** uses linear relative position biases as in T5 (Raffel et al., 2020), which changes Eq. 2 to $b_{ij} = R[i - j]$ where $R[\cdot]$ is a lookup table with each item corresponding to a learnable bias for a given relative distance.
- **SecBias** replaces token-level linear distance in TokBias with section-level linear distance.

Notably, Longformer and models using special tokens have 4.59M parameters. HIBRIDS and models with linear relative position biases use about 4.60M parameters in total. On the other hand, HierEnc and MultiTask modify the architecture and have 6.62M and 4.66M parameters, which is less efficient for learning compared with models that use bias terms to adjust attention calculation.

6 Experiment Results

6.1 Hierarchical Question-summary Generation

Results on QSGen-Hier. We report results on the task of generating QS hierarchies in Table 1. HIBRIDS-enc *uniformly outperforms other variants and all comparisons on all metrics,* except

HIBRIDS$_S$-DEC	26.29	8.50	25.09	14.30

Table 2: Results for QSGen-ChildQ. The best result per metric is **bolded**. Using HIBRIDS on encoder generates better follow-up questions according to ROUGE scores.

for ROUGE-1 and ROUGE-L scores by HIERENC. Note that HIERENC learns 2M more new parameters than our models, and it produces QS hierarchies of lower quality despite its competitive ROUGE scores (Figure 3). This signifies the effectiveness of our design that directly injects structural information into word-level relation computation. Meanwhile, HIBRIDS *on encoder is better at hierarchy quality than its variant on decoder*, suggesting the importance of resolving section relations during encoding.

Though not reported here, we experiment with HIBRIDS on both the encoder and the decoder, and it results in degraded performance. One possible cause is that HIBRIDS functions differently in these two setups (discussed in §7). We will explore better fusion techniques in future work.

Results on QSGen-ChildQ. Results on generating follow-up questions further validate the usefulness of hierarchical biases as shown in Table 2, where *questions generated by* HIBRIDS-ENC *have the best quality* as measured by all metrics except for BLEU. SECBIAS, which is aware of section-level linear distance, also obtains outstanding performance, since it focuses on intra-section information and thus better determines what child questions should be asked for better relevance.

Human evaluation is conducted on QSGen-Hier, for five models with the highest automatic scores, to help understand how well the generated hierarchies are structured. We hire three judges who have *extensive experience* in summarization annotation and evaluation tasks to assess 50 groups of question-summary hierarchies. Human inspection on randomly selected outputs shows that most system generations have an appropriate coverage of the salient content in the source. Therefore, we focus on evaluating both global coherence and local coherence of the QS hierarchies based on the following two aspects. First, we ask evaluators to correct each generated hierarchy by rearranging the QS pairs so that each pair is attached to the parent that forms the best follow-up relation in steps. For each step, they are only allowed to attach a pair to its grandparent or sibling (i.e., the parent or child of its current parent). They then report the **number of edits** conducted for the rearrangement. Second, for each QS pair, we ask them to determine if the question can be **answered** by the summary. Details of human evaluation are in Appendix C.

As can be seen from Table 3, QS hierarchies generated by HIBRIDS-ENC model contain the best structured summaries as they require the fewest number of corrections and the generated questions are also more likely to be addressed by the corresponding summaries. Despite being competitive on automatic metrics, SECTOK generates hierarchies that require the most corrections. Upon additional inspection, we find that HIBRIDS's outputs often have better local coherence than the comparisons. Additionally, all models struggle to generate more engaging questions, which poses another challenge to future studies.

Model	**# of Edits (↓)**	**Answerable Qs (↑)**
SecTok	4.73	81.8%
LvlSecTok	4.62	78.6%
HierEnc	4.17	81.4%
TokBias	3.77	82.8%
HIBRIDS-enc	**3.67**	**84.1%**

Table 3: Human evaluation results on QSGen-Hier. Hierarchies produced by HIBRIDS-enc require fewer correction edits by human and contain more answerable questions by the generated summaries. Krippendorff's α: 0.55, 0.44.

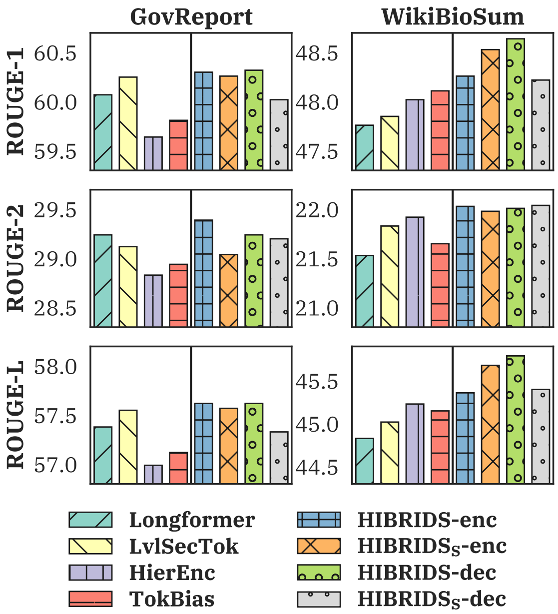

Figure 4: Results on full summary generation. In each subfigure, the left panel includes models for comparisons and the right panel shows our models. HIBRIDS on either encoder and decoder uniformly outperforms the comparisons on both datasets.

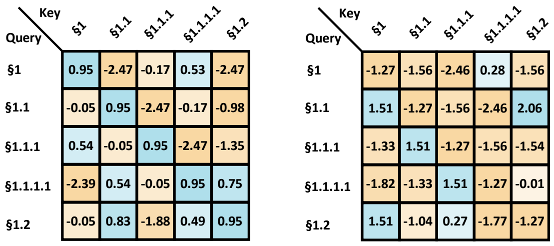
6.2 Full Summary Generation

As demonstrated in Figure 4, HIBRIDS *with full hierarchical biases outperform all comparisons* on both datasets, suggesting that our design of including structural relations in bias terms can generalize to other tasks. Compared to the results on QS hierarchy generation, using HIBRIDS on the decoder yields greater improvement on full summary generation, especially in the biography domain where HIBRIDS-dec obtains the best performance. It is likely that the longer summary length and higher compression ratio on WikiBioSum (1,266 and 0.45) makes generation coherence more important by using better alignment. This highlights how hierarchical biases can aid long text generation.



Query \ Key	§1	§1.1	§1.1.1	§1.1.1.1	§1.2
§1	0.95	-2.47	-0.17	0.53	-2.47
§1.1	-0.05	0.95	-2.47	-0.17	-0.98
§1.1.1	0.54	-0.05	0.95	-2.47	-1.35
§1.1.1.1	-2.39	0.54	-0.05	0.95	0.75
§1.2	-0.05	0.83	-1.88	0.49	0.95

Figure 5: Visualization of hierarchical biases in HIBRIDS-enc (left) and HIBRIDS-dec (right) on QSGen-Hier. Positive and negative values are shaded in **blue** and **orange**. Displayed values are 100X of actual values. HIBRIDS-enc biases towards current, grandparent and preceding sibling sections, while HIBRIDS-dec focuses on parent and succeeding sibling sections.

7 Further Analyses

7.1 Visualizing the Learned Biases

Here we aim to understand what is learned by our hierarchical biases. For HIBRIDS-enc and HIBRIDS-dec trained on QSGen-Hier, we visualize the values of their *learned* hierarchical biases averaged over all heads at all layers for each (path length, level difference) pair on an example structure. Additional visualization is in Appendix D.

From Figure 5 we see that using HIBRIDS on the encoder encourages models to encode various relations, e.g., by upweighing grandparent (§1.1.1 to §1, §1.1.1.1 to §1.1) and preceding sibling (§1.2 to §1.1), and downweighing children (§1 to §1.1 and §1.2, §1.1 to §1.1.1). This highlights the need of learning heterogeneous relations among sections beyond token distances. By contrast, HIBRIDS on the decoder consistently biases towards parent and sibling contexts. It might be because that the generation of fluent and coherent question-summary pairs relies on being aware of the scope of sections at the same or higher levels.

7.2 Ablation Study for HIBRIDS

We examine which design choices contribute the most to the performance gain by HIBRIDS, by carrying out ablation studies on QSGen-Hier with HIBRIDS-enc. We consider taking out (1) level difference, (2) path length, and (3) asymmetry of path length. As shown in Table 4, removing any component reduces summaries' content coverage and hierarchy quality, underscoring their contributions in more precisely representing structural relations for better document encoding. Level difference adds the most to hierarchy quality, as levels

Model	Summary RL	Question B4	Hierarchy F1
HIBRIDS-ENC	38.03	10.16	13.26
w/o Level Difference	–0.50	–0.08	–0.51
w/o Path Length	–0.43	+0.05	–0.18
w/o Asymmetric Path	–0.15	–0.12	–0.18

Table 4: Ablation study results. Performance change compared to the full model are reported. Larger decreases of metrics are shaded with darker orange. Removing level difference hurts the hierarchy quality substantially.

	QSGen-Hier			GOVREPORT	
Model	R-2	R-L	Hier F1	R-2	R-L
HIERENC	16.32	38.06	11.77	28.83	56.99
w/ HIBRIDS	+0.44	+0.37	+0.22	+0.15	+0.22

Table 5: Effects of applying HIBRIDS to the extra section-level encoders of HIERENC on two tasks. HIBRIDS improves the performance of HIERENC on all metrics.

directly signal when to generate follow-up questions.

7.3 Can HIBRIDS Improve Hierarchical Encoding?

We further study if HIBRIDS can boost the section encoder of HIERENC. Table 5 shows that HIERENC with HIBRIDS gains further improvements on generating QS hierarchies and full document summarization on GOVREPORT. This points to promising future adoptions of HIBRIDS by existing models that would benefit from encoding document structure.

8 Conclusion

We present HIBRIDS, which effectively and efficiently injects document structure information into abstractive summarization models via hierarchical learnable biases that adjust the attention score matrix. A new task, hierarchical question-summary generation, is then introduced for generating hierarchically organized question-summary pairs, to expose document structure and salient content to readers. We annotate a new dataset consisting of 6,153 summary paragraphs with question-summary hierarchies to facilitate our study, and it can also be used for query-focused summarization and question generation. Experiments on hierarchical question-summary generation and full summary generation show that HIBRIDS produces question-summary hierarchies of higher quality as measured by both automatic metrics and human judges, and achieves higher content coverage of summaries than competitive comparisons as reported by ROUGE.

Ethical Consideration

Collection of GOVREPORT-QS and WIKIBIOSUM. We comply with the terms of use and copyright policies of all data sources during the collection of GOVREPORT-QS and WIKIBIOSUM. Personal and other sensitive information is not collected to ensure the privacy of content creators. Before annotating GOVREPORT-QS, we obtain consents from the annotators and inform them of their rights to temporarily suspend or quit the annotation process. During annotation, annotators are fairly compensated (≈ $15 per hour).

Limitations and Potential Risks of HIBRIDS and GOVREPORT-QS. While our experiments focus on datasets consisting of formal long documents, we recognize that long documents could be written in informal languages where our model might not perform reasonably and could generate degraded or even incorrect outputs. Despite recent advancement in improving summary factuality along with its evaluation (Kryscinski et al., 2020; Goyal and Durrett, 2020; Scialom et al., 2021; Cao and Wang, 2021b), the accuracy of existing factuality evaluation metrics has not been verified on long documents, which further increases the risk of incorrect outputs by our model.

As our GOVREPORT-QS is based on reports from the United States (US) Government, the topics covered by the dataset are mostly relevant to the national interest of US. Therefore, models trained on our dataset might not be suitable for producing structured summaries for documents published by other countries that focus on other topics. Moreover, our GOVREPORT-QS might bias the model towards a pro-US perspective, which could produce outputs that are harmful to certain populations.

A Details of GOVREPORT-QS

Dataset Choice. We choose GOVREPORT dataset (Huang et al., 2021) for our annotation because it contains long documents (9409 tokens) and summaries (553 tokens) with key information spread throughout documents, which ensures the building of rich question-summary hierarchies. Moreover, the documents in GOVREPORT are organized into multiple levels of sections, which justifies our decision to present salient document information with question-summary hierarchies.

Summary Paragraph Selection. Documents that are short or contain very few sections are less likely to yield rich QS hierarchies. To select high-quality paragraphs for annotation, we first consider using summary paragraphs associated with documents that have at least 3 sections. Moreover, the average number of paragraphs in each section should be at least 5. We then discard summaries that have less than 3 paragraphs. Among the paragraphs of the remaining summaries, we select those with at least 3 sentences and 70 words. To incorporate more abstractive summaries in the question-summary pairs, we further calculate the normalized density (Grusky et al., 2018) between each summary paragraph and its corresponding document, and then keep the paragraphs with a normalized density less than 0.15. The selection process results in $25{,}063$ summary paragraphs which are then randomly sampled for annotation.

Annotation Process. We hire 11 college students who are native English speakers as annotators. They are informed of the job opportunity through email lists that advertise on-campus jobs. They sign up for the annotation job by filling a Google Form containing a detailed job description and consent form. The employment process is handled through the school employment system. Before annotating, they read the annotation instruction and examples with annotated question summary hierarchies. In each round of the annotation, each annotator is given 28–33 summary paragraphs, which takes about 2 hours to finish. We pay each annotator \$30 ($\approx$ \$15 per hour) for each round. Appen[3] is used for building the annotation interface and collecting annotations. The annotation instruction is shown in Figure 7–10.

Section Alignment. We align each annotated summary paragraph with sections in the source document (§ 4) in the following way. Three similarity scores are computed for each pair of summary sentence and document paragraph: (1) cosine similarity between the representations computed by Sentence BERT (Reimers and Gurevych, 2019) for the summary sentence and the document paragraph; (2) the percentage of unique bigrams in the summary sentence that occur in the document paragraph; and (3) the percentage of unique named entities[4] that

---

[3] `https://appen.com`

[4] We use SpaCy 3.0.3 (Honnibal and Montani, 2017) with `en_core_web_sm` for named entity recognition.

occur in the document paragraph. The final similarity score is the sum of these three scores, with weights 0.4, 1.0, and 0.2, respectively. We tune the weights based on the manual alignment for 836 summary paragraphs associated with 42 report documents. Finally, each summary sentence is mapped to the document paragraph with the highest similarity score.

Copyright Policy. Documents and summaries in GOVREPORT dataset are published by Government Accountability Office (GAO)[5] and Congressional Research Service (CRS)[6]. The original publications are not protected by copyright law and Huang et al. (2021) make GOVREPORT publicly available. We release the new annotations under the CC BY 4.0 license[7]. Users of the data must also acknowledge GAO and CRS as the sources of the original publications.

B Details of WIKIBIOSUM

Data Collection. To collect biographies from WikiProject Biography[8], we first use Scrapy[9] to get the names of articles curated by the project. We then extract article content with WikiExtractor[10] from the English Wikipedia dump[11] at 2021/08/01 using the article names.

Data Filtering. In addition to keeping biographies with at least two levels of section hierarchy, we discard biographies that have a quality class that lower than C.[12] The quality class of each biography is assessed by the members of WikiProject Biography. To get rid of samples where summaries can be generated by reading the first half of the documents only, we check the occurrences of summary bigrams in the documents and keep the samples where the second half of the documents contain at least 9% of new summary bigrams that do not occur in the first half.

Statistics. As reported in the main paper, the average lengths of the input and output are 3,478 and 1,266. The average number of sections in the input is 11.65, with an average depth of 2.22 levels. Moreover, each document has 32.19 paragraphs.

Copyright Policy. We follow the Wikipedia copyright policy[13] to collect the WIKIBIOSUM dataset. The WIKIBIOSUM dataset will be released under the CC BY-SA 3.0 license[14]. Usage of the WIKIBIOSUM dataset is limited by the copyright policy of Wikipedia.

C Details of Human Evaluation

model	Avg QS Pairs / Hier
SECTOK	5.29
LVLSECTOK	5.10
HIERENC	5.29
TOKBIAS	4.95
HIBRIDS-ENC	5.17

Table 6: Average numbers of QS pairs generated for each hierarchy by models in our human evaluation.

We conduct human evaluation for question-summary hierarchies generated by five models. Human evaluation instructions are shown in Figure 11. The annotators use an HTML interface (Figure 12). Model names are not displayed, and their outputs in each group are randomly shuffled. The interface displays all the annotations made by the same annotator, which helps human subjects achieve better annotation consistency across different model outputs. Finally, we report the average numbers of QS pairs per hierarchy for each model in Table 6.

D Additional Visualization

We show the biases learned by HIBRIDS for full document summarization on GOVREPORT in Figure 6. Behaviors of HIBRIDS on GOVREPORT are different from those observed on QSGen-Hier in §7. On GOVREPORT, using HIBRIDS on the encoder encourages each token to attend to other tokens within the same section, highlighting its focus on recency. By contrast, HIBRIDS on the decoder biases towards short-term contexts before a given token and strongly discourages attentions to long-range contexts. It might be because that

Figure 6: Visualization of hierarchical biases in HIBRIDS-ENC (left) and HIBRIDS-DEC (right) on GOVREPORT. Positive and negative values are shaded in **blue** and **orange**. Displayed values are 100X of actual values. HIBRIDS-ENC biases towards recency, while HIBRIDS-DEC focuses on parent sections.

the generation of fluent and coherent summaries mainly depends on local and past contexts.

E Sample Output

We show more outputs by HIBRIDS-ENC on QSGen-Hier in Table 7.

F Details of Implementation

We take the implementation of Longformer from Huggingface 4.8.1 (Wolf et al., 2020), which is licensed under the Apache License 2.0[15]. The model configuration and pre-trained weights of `allenai/led-large-16384`[16] are used. For model training, we use Fairseq (commit `f34abcf2`) (Ott et al., 2019) that adopts MIT License[17]. Both model training and decoding are performed on the A6000 GPU with 48GB memory and the A100 GPU with 40GB memory.

Training Settings. During training, we set the number of tokens in each batch to 10,240 for QSGen-Hier, QSGen-ChildQ, and full summary generation on WIKIBIOSUM. On GOVREPORT, each batch contains 16,384 tokens. As limited by the design of Longformer, the maximum output length for all tasks is set to 1,024. We use Adam (Kingma and Ba, 2015) as the optimizer, with a maximum learning rate of 5×10^{-5}. The optimizer updates the model parameters every 8 batches. We set the maximum numbers of update steps to 500, 700, 2,400, and 5,000 respectively for QSGen-Hier, QSGen-ChildQ, WIKIBIOSUM, and GOVREPORT. Importantly, we adopt gradient checkpointing (Chen et al., 2016) to reduce the memory consumption of back propagation.

Decoding Settings. A beam search with a beam size of 4 is used for decoding. The maximum decoding length is 1,024. We also disable the generation of repeated 5-grams.

Running Time. HIBRIDS takes 2, 2, 5, and 12 hours for training on QSGen-Hier, QSGen-ChildQ, WIKIBIOSUM, and GOVREPORT with 4 GPUs. Decoding on QSGen-Hier and QSGen-ChildQ takes one hour. For decoding on WIKIBIOSUM, and GOVREPORT, it uses 3 and 4 hours.

Evaluation. We compute ROUGE scores (Lin, 2004) using the implementation by Google Research[18]. For BLEU scores, we use NLTK 3.5 (Bird et al., 2009).

Example 1

Q1: What incited the start of the FY2009 appropriation process?

A1: On February 4, 2008, President Bush sent his FY2009 budget to Congress, which included a request for $39 billion for the Department of Housing and Urban Development (HUD).

Q1.1: How did Congress respond to this request?

A1.1: On June 4, 2008, the Senate passed the FY2009 budget resolution conference agreement (H.Rept. 110-659) and the House passed it the following day.

Q1.2: What was the result of the FY2009 appropriations process?

A1.2: On March 11, 2009, a FY2009 omnibus appropriations bill was signed into law, funding HUD for the remainder of the fiscal year (P.L. 111-8). It provides a more than 10% increase in regular, non-emergency appropriations over the FY2008 level.

Q1.2.1: How did the omnibus appropriations bill affect HUD?

A1.2.1: It provided nearly $13.7 billion for HUD programs.

Example 2

Q1: To what extent is democracy promotion an element of U.S. foreign policy?

A1: For decades U.S. policymakers have connected U.S. national security and other core interests with the spread of democracy around the world. Reflecting this, the promotion of democracy has been a longstanding and multifaceted element of U.S. foreign policy, and one often interrelated with U.S. efforts to promote human rights.

Q1.1: How has the promotion of democracy promotion been supported by Congress?

A1.1: Congress has often played an important role in supporting and institutionalizing U.S. democracy promotion by passing key legislation, appropriating funds for foreign assistance programs and other democracy promoting activities, and conducting oversight of aspects of U.S.-led foreign policy relevant to democracy promotion.

Q1.2: What is the current state of democracy promotion?

A1.2: Widespread concerns exist among analysts and policymakers over the current trajectory of democracy around theworld and multiple hearings in the 115th Congress reflected bipartisan concern over this issue.

Q1.2.1: What are some of these concerns?

A1.2.1: Frequently cited concerns include the rise of authoritarian populist and nationalist leaders, the potential negative influence on democracy from internationally assertive authoritarian states, questions over the enduring appeal of democracy as a political system, new tools nondemocratic governments are using to stifle potential democratizing forces, and others.

Example 3

Q1: How should GA strategies be approached?

A1: GA security poses significant challenges for policymakers and security experts because GA is highly diverse, geographically dispersed, and relatively open compared to commercial airports servicing passenger airlines and other protected infrastructure such as nuclear reactors and chemical plants.

Q2: What is the primary threat posed by GA aircraft?

A2: The primary threat posed to GA aircraft is not so much to GA assets themselves, but rather, from terrorists seeking to exploit GA assets to attack critical infrastructure or high-profile targets.

Q2.1: What is a secondary threat to GA aircraft?

A2.1: A secondary threat is that terrorists may infiltrate or otherwise exploit GA to gain knowledge and/or access to the airspace system in the United States.

Q2.1.1: What are some examples of this threat?

A2.1.1: For example, some corporate aviation operators have expressed concern that aircraft carrying high-profile business leaders and executives, such as presidents of major U.S. corporations, could be targeted, particularly when operating overseas in areas where security concerns exist.

Table 7: Example outputs by HIBRIDS-ENC on QSGen-Hier. Indentation indicates the levels of question-summary pairs.

Task description and guidelines

We are building a dataset of Question-Answer pairs based on given texts. In this task, you will be shown a paragraph from a summary of a US government report. You are expected to (1) read the paragraph, (2) create questions, and (3) provide their respective answers using the given paragraph such that your question-answer pairs cover the whole essence of the given paragraph. More details are given below.

We have compiled a list of FAQ below regarding the details and rules for the task. Please read them carefully before you start.

Q1:How many paragraphs do I annotate?

A1:The annotation task given to you contains **about 30 summary paragraphs**. Notice that each page contains only two paragraphs, you need to click the **"Submit and Continue"** button to see the next two paragraphs. The time limit for each page is **30 minutes**. You're expected to finish each page within 30 minutes. If you exceed the time limit, you need to re-open the given link and continue your task.

These summary paragraphs are extracted from summaries of US government reports (CRS and GAO). Summary paragraphs belonging to the same report occur in order (as in the original report), but some paragraphs in the original report might not be included and thus the paragraphs you are annotating might not be consecutive. We recommend you **finish annotating paragraphs of the same report in one sitting** so that you can have better context for the paragraphs. Each summary paragraph comes with a title (from the paragraph's corresponding report). You will generate your question-answer pairs based on this summary paragraph.

Q2:What types of questions should I create?

A2:In short, you are expected to write **complex (narrative) questions**, the answers of which usually consist of one or more sentences and function as reasoning or explaining a concept.

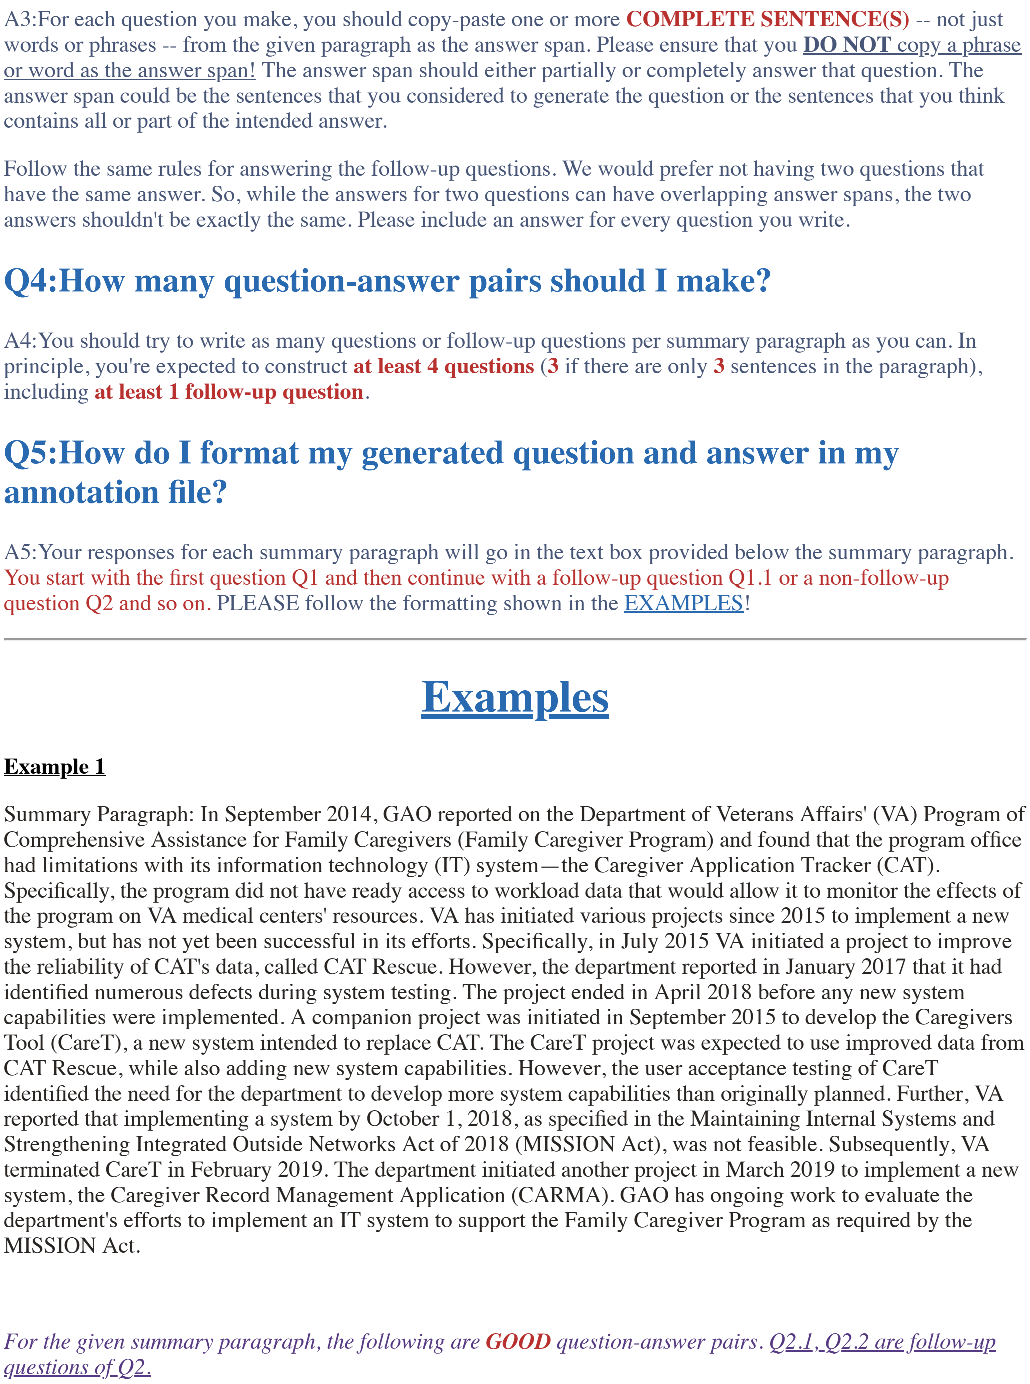
We are trying to build a dataset with narrative/complex questions and their answer pairs. The answers to such complex questions are more than just a few words -- they should be one or more complete sentences. You may want to ask questions starting with **"why", "how", or "what"**. These tend to create complex questions whose corresponding answers try to reason or explain a concept. Please **REFRAIN** from asking questions that start with "who", "which", "when", "how many", "how much", etc. Make sure that your questions are complete and grammatical. See EXAMPLES.

In addition to this, you can also ask another ("why", "how", or "what") question as a follow-up to one or more of your questions if possible for the given summary paragraph. You can create multiple follow-ups for a question and even follow-ups to a follow-up question.

For each paragraph, you're expected to ask **at least 1 follow-up question**. We encourage you to try to make as many follow-ups ("why", "how" or "what" questions) as you can without writing factoid questions (answer to which is a number, data, name, etc). See the examples to understand what are some good/bad questions and answers as well as follow-up pairs.

Q3:How should I provide the answers to the questions I ask?

Figure 7: Question-summary hierarchy annotation instructions. (Page 1 / 4)



A3:For each question you make, you should copy-paste one or more **COMPLETE SENTENCE(S)** -- not just words or phrases -- from the given paragraph as the answer span. Please ensure that you **DO NOT** copy a phrase or word as the answer span! The answer span should either partially or completely answer that question. The answer span could be the sentences that you considered to generate the question or the sentences that you think contains all or part of the intended answer.

Follow the same rules for answering the follow-up questions. We would prefer not having two questions that have the same answer. So, while the answers for two questions can have overlapping answer spans, the two answers shouldn't be exactly the same. Please include an answer for every question you write.

Q4:How many question-answer pairs should I make?

A4:You should try to write as many questions or follow-up questions per summary paragraph as you can. In principle, you're expected to construct **at least 4 questions** (**3** if there are only **3** sentences in the paragraph), including **at least 1 follow-up question**.

Q5:How do I format my generated question and answer in my annotation file?

A5:Your responses for each summary paragraph will go in the text box provided below the summary paragraph. You start with the first question Q1 and then continue with a follow-up question Q1.1 or a non-follow-up question Q2 and so on. PLEASE follow the formatting shown in the EXAMPLES!

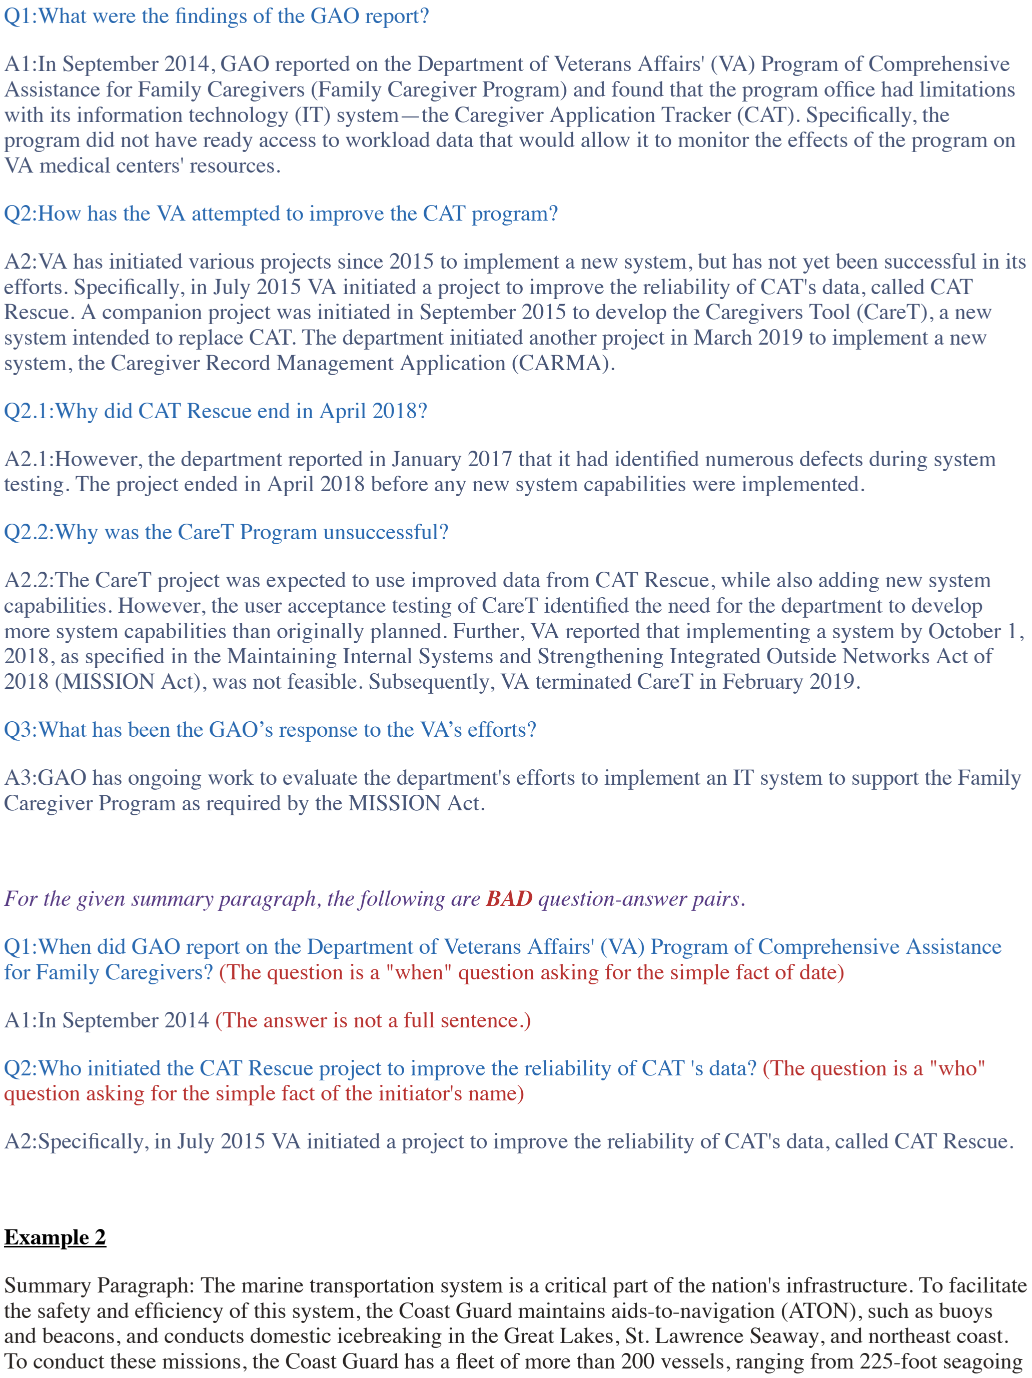
Examples

Example 1

Summary Paragraph: In September 2014, GAO reported on the Department of Veterans Affairs' (VA) Program of Comprehensive Assistance for Family Caregivers (Family Caregiver Program) and found that the program office had limitations with its information technology (IT) system—the Caregiver Application Tracker (CAT). Specifically, the program did not have ready access to workload data that would allow it to monitor the effects of the program on VA medical centers' resources. VA has initiated various projects since 2015 to implement a new system, but has not yet been successful in its efforts. Specifically, in July 2015 VA initiated a project to improve the reliability of CAT's data, called CAT Rescue. However, the department reported in January 2017 that it had identified numerous defects during system testing. The project ended in April 2018 before any new system capabilities were implemented. A companion project was initiated in September 2015 to develop the Caregivers Tool (CareT), a new system intended to replace CAT. The CareT project was expected to use improved data from CAT Rescue, while also adding new system capabilities. However, the user acceptance testing of CareT identified the need for the department to develop more system capabilities than originally planned. Further, VA reported that implementing a system by October 1, 2018, as specified in the Maintaining Internal Systems and Strengthening Integrated Outside Networks Act of 2018 (MISSION Act), was not feasible. Subsequently, VA terminated CareT in February 2019. The department initiated another project in March 2019 to implement a new system, the Caregiver Record Management Application (CARMA). GAO has ongoing work to evaluate the department's efforts to implement an IT system to support the Family Caregiver Program as required by the MISSION Act.

For the given summary paragraph, the following are ***GOOD*** *question-answer pairs. Q2.1, Q2.2 are follow-up questions of Q2.*

Figure 8: Question-summary hierarchy annotation instructions. (Page 2 / 4)



Q1:What were the findings of the GAO report?

A1:In September 2014, GAO reported on the Department of Veterans Affairs' (VA) Program of Comprehensive Assistance for Family Caregivers (Family Caregiver Program) and found that the program office had limitations with its information technology (IT) system—the Caregiver Application Tracker (CAT). Specifically, the program did not have ready access to workload data that would allow it to monitor the effects of the program on VA medical centers' resources.

Q2:How has the VA attempted to improve the CAT program?

A2:VA has initiated various projects since 2015 to implement a new system, but has not yet been successful in its efforts. Specifically, in July 2015 VA initiated a project to improve the reliability of CAT's data, called CAT Rescue. A companion project was initiated in September 2015 to develop the Caregivers Tool (CareT), a new system intended to replace CAT. The department initiated another project in March 2019 to implement a new system, the Caregiver Record Management Application (CARMA).

Q2.1:Why did CAT Rescue end in April 2018?

A2.1:However, the department reported in January 2017 that it had identified numerous defects during system testing. The project ended in April 2018 before any new system capabilities were implemented.

Q2.2:Why was the CareT Program unsuccessful?

A2.2:The CareT project was expected to use improved data from CAT Rescue, while also adding new system capabilities. However, the user acceptance testing of CareT identified the need for the department to develop more system capabilities than originally planned. Further, VA reported that implementing a system by October 1, 2018, as specified in the Maintaining Internal Systems and Strengthening Integrated Outside Networks Act of 2018 (MISSION Act), was not feasible. Subsequently, VA terminated CareT in February 2019.

Q3:What has been the GAO’s response to the VA’s efforts?

A3:GAO has ongoing work to evaluate the department's efforts to implement an IT system to support the Family Caregiver Program as required by the MISSION Act.

For the given summary paragraph, the following are ***BAD*** *question-answer pairs.*

Q1:When did GAO report on the Department of Veterans Affairs' (VA) Program of Comprehensive Assistance for Family Caregivers? (The question is a "when" question asking for the simple fact of date)

A1:In September 2014 (The answer is not a full sentence.)

Q2:Who initiated the CAT Rescue project to improve the reliability of CAT 's data? (The question is a "who" question asking for the simple fact of the initiator's name)

A2:Specifically, in July 2015 VA initiated a project to improve the reliability of CAT's data, called CAT Rescue.

Example 2

Summary Paragraph: The marine transportation system is a critical part of the nation's infrastructure. To facilitate the safety and efficiency of this system, the Coast Guard maintains aids-to-navigation (ATON), such as buoys and beacons, and conducts domestic icebreaking in the Great Lakes, St. Lawrence Seaway, and northeast coast. To conduct these missions, the Coast Guard has a fleet of more than 200 vessels, ranging from 225-foot seagoing

Figure 9: Question-summary hierarchy annotation instructions. (Page 3 / 4)

buoy tenders and 140-foot domestic icebreakers to 21-foot boats. After the terrorist attacks of September 11, 2001, many of these assets took on additional responsibilities for security patrols and other homeland security duties. Although some assets have been recently acquired, many others are reaching or have exceeded their design service lives, raising concerns about how well and for how much longer these older assets may be able to carry out their missions. In response, GAO examined (1) recent trends in the amount of time these assets have spent performing missions; (2) asset condition and its effect on mission performance; and (3) the actions taken by the Coast Guard to continue to achieve the missions of these assets. To conduct this work, GAO reviewed Coast Guard documents, interviewed Coast Guard officials, and made site visits to various locations around the country. In commenting on a draft of this report, the Coast Guard provided technical comments, which were incorporated as appropriate.

For the given summary paragraph, the following are ***GOOD*** *question-answer pairs.* ***(Notice the follow-up questions)****Q1.1, Q1.2 are follow-up questions of Q1 and Q1.2.1 is a follow-up question of Q1.2.*

Q1:How does the Coast Guard maintain the safety and efficacy of the country's marine transportation system?

A1:The marine transportation system is a critical part of the nation's infrastructure. To facilitate the safety and efficiency of this system, the Coast Guard maintains aids-to-navigation (ATON), such as buoys and beacons, and conducts domestic icebreaking in the Great Lakes, St. Lawrence Seaway, and northeast coast. To conduct these missions, the Coast Guard has a fleet of more than 200 vessels, ranging from 225-foot seagoing buoy tenders and 140-foot domestic icebreakers to 21-foot boats.

Q1.1:How did the terrorist attacks of September 11 affect the Coast Guard's work in maintaining the marine transport system?

A1.1:After the terrorist attacks of September 11, 2001, many of these assets took on additional responsibilities for security patrols and other homeland security duties.

Q1.2:What are the concerns regarding Coast Guard assets for maintaining the marine transport system?

A1.2:Although some assets have been recently acquired, many others are reaching or have exceeded their design service lives, raising concerns about how well and for how much longer these older assets may be able to carry out their missions.

Q1.2.1:How has GAO responded to these concerns?

A1.2.1:In response, GAO examined (1) recent trends in the amount of time these assets have spent performing missions; (2) asset condition and its effect on mission performance; and (3) the actions taken by the Coast Guard to continue to achieve the missions of these assets. To conduct this work, GAO reviewed Coast Guard documents, interviewed Coast Guard officials, and made site visits to various locations around the country.

Figure 10: Question-summary hierarchy annotation instructions. (Page 4 / 4)

In this study, you will evaluate 50 sets of **question-summary (QS) hierarchies** produced by five systems. The hierarchy is presented by the IDs of questions and summaries (e.g., Q1 is the parent of Q1.1 and Q1.2). We also consider there is a dummy root to be the parent of the top-level questions (e.g., Q1, Q2).
Please go through the hierarchy generated by each system in order. For each QS pair in the hierarchy, you need to **adjust it step by step** such that it has the most appropriate QS pair as its parent. Meanwhile, please also check if the question can be **answered** by its corresponding summary. The descriptions of how to make the adjustment and determine answerability are detailed as follows with an example.

Example

(DUMMY ROOT)
Q1: What did state officials report about the effectiveness of identification verification procedures?
A1: State officials interviewed by GAO report that identity verification procedures have been effective at combating certain kinds of fraud, but vulnerabilities remain. Officials in most of the 11 states GAO contacted reported a decline in the use of counterfeit identity documents, and officials in states using facial recognition said they detected a number of identity theft attempts.
Q1.1: How can criminals use someone else's identity to get a license in another state?
A1.1: However, criminals can still steal the identity of someone in one state and use it to get a license in another because states lack the capacity to consistently detect such cross-state fraud.
Q1.1.1: What is one solution to this existing issue?
A1.1.1: For example, one state officials told GAO a check against the problem driver database (Problem Driver Pointer System) will not detect a license in another state if it is not associated with any driving violation.
Q2: ...
A2: ...

Step-by-step Adjustment: In QS hierarchies, the children of a QS pair ask about follow-up information that could be specific descriptions or elaborations of the content in the QS pair. For each QS pair, you need to first determine another QS pair (or the dummy root) as its parent such that they form the best follow-up relation. After identifying the most appropriate parent, adjustment of the QS pair is conducted step by step. In each step, you can attach the QS pair to its grandparent or sibling (i.e., the parent or child of its current parent).
Please report the **number of steps** required to complete the adjustment. If no adjustment is needed, please report 0.
For example, the most appropriate parent for Q1.1 is the DUMMY ROOT because it asks about a concrete flaw of the identification verification procedure while Q1 and A1 talk about the effectiveness of the procedure. These two questions are regarding the current status of the identification verification procedure and they should be at the same level. As there is an edge between Q1 and DUMMY ROOT, you only need **one** step to finish attaching Q1.1 to DUMMY ROOT. (Q1 → DUMMY ROOT).
Note that the parent-child relation remains unchanged for the children and descendants of an adjusted QS pair. For example, after attaching Q1.1 to DUMMY ROOT, attaching Q1.1.1 to Q2 only needs two steps as Q1.1 is already attached to DUMMY ROOT (Q1.1 → DUMMY ROOT → Q2).

Answerability: Whether the question can be answered by the associated summary.
Please select "True" or "False" for each QS pair.
For example, Q1.1.1 is not answerable because A1.1.1 does not mention any solution. Both Q1 and Q1.1 are answerable.

Q1: In what ways has ARNG improved its recruitment process?
A1: In response to GAO's prior work, the ARNG has taken steps to increase oversight of its recruitment process, including establishing a pilot program to help provide oversight over state-level recruiting activities, but has not permanently established a program to ensure ongoing monitoring.

Answerable: ○True ○False

Edit Steps: 0

Q1.1: How has the ARNG improved its recruitment process?
A1.1: For example, the ARNG Strength Maintenance Division began a pilot program in June 2014 to help provide oversight of states' recruiting activities, but the branch has not been permanently established to ensure ongoing monitoring, and the ARNG has not provided recruiters with training to help ensure that recruiters understand what financial incentives are available to help fill critical positions.

Answerable: ○True ○False

Edit Steps: 0

Q1.1.1: What is the purpose of the ARNG's new financial incentives system?
A1.1.1: The ARNG implemented a new financial incentives system in fiscal year 2012, but has not provided training to recruiters to help ensure that they understand what incentives are available to fill critical positions.

Answerable: ○True ○False

Edit Steps: 0

Q1.1.2: What is the ARNG's approach to tracking soldiers who complete initial military training?
A1.1.2: Further, the ARNG does not regularly track whether ARNG soldiers who join in a given fiscal year complete their initial term of service.

Answerable: ○True ○False

Edit Steps: 0

Q1.1.3: What is GAO's recommendation for the ARNG?
A1.1.3: GAO recommends that the Secretary of the Army take the following actions: (1) establish a permanent program for ARNG oversight of state- level recruiting activities, and (2) provide ARNG officials with training to better enable the use of available financial incentives to fill critical positions; (3) ensure that ARNG recruiters understand which positions have financial incentives; and (4) ensure that financial incentives are being used effectively to fill

model1

Q1: In what ways has ARNG improved its recruitment process?
A1: In response to GAO's prior work, the ARNG has taken steps to increase oversight of the recruitment process and improve its oversight of state-level recruiting activities.

Answerable: ○True ○False

Edit Steps: 0

Q1.1: How has the ARNG improved its recruitment process?
A1.1: For example, in January 2010, GAO found that the ARNG's data on recruiter irregularities—or, wrongdoings on the part of recruiters—were incomplete and recommended that DOD take actions to increase visibility and track recruiter-irregularities. In February 2012, the Department of the Army Inspector General found errors in processing enlistment packages and recommended that the ARNG create an entity to provide oversight of recruiting standards.

Answerable: ○True ○False

Edit Steps: 0

Q1.1.1: How did the ARNG respond to this recommendation?
A1.1.1: In response, in June 2014, the ARNG Strength Maintenance Division began a pilot effort through its Recruiting Standards Branch to help provide oversight over state- level recruiting activities, but the branch has not been permanently established to ensure ongoing monitoring.

Answerable: ○True ○False

Edit Steps: 0

Q1.1.1.1: What is the goal of the ARNG?
A1.1.1.1: The goal is to complete at least 12 state inspections each year, but the ARNG has not established a permanent program for monitoring state-level recruiting.

Answerable: ○True ○False

Edit Steps: 0

Q1.1.1.1.1: How does the ARNG plan to conduct inspections?
A1.1.1.1.1: ARNG officials stated that there are tools, such as a search function, within GIMS for state recruiting personnel that would assist in understanding which positions are considered critical and have an incentive. However, officials stated that the tools are not being fully utilized, which is another contributing factor in not understanding which positions have a financial incentive.

Answerable: ○True ○False

Edit Steps: 0

model2

Q1: In what ways has ARNG improved its recruitment process?
A1: The ARNG has recently taken steps to increase oversight of the recruitment process, such as establishing a pilot program to help provide oversight over state-level recruiting activities, but has not permanently established a program to ensure ongoing monitoring.

Answerable: ○True ○False

Edit Steps: 0

Q1.1: How did the ARNG establish its financial incentives program?
A1.1: In June 2014, the ARNG established a pilot program through its Recruiting Standards Branch to help provide oversight of states' recruiting activities, but the branch has not been permanently established to ensure ongoing monitoring of ARNG's financial incentives programs.

Answerable: ○True ○False

Edit Steps: 0

Q1.1.1: What is the purpose of the ARNG's pilot program?
A1.1.1: Officials from the ARNG Strength Maintenance Division stated that the branch was established in response to GAO's findings in a prior report and a Department of the Army Inspector General's report.

Answerable: ○True ○False

Edit Steps: 0

Q1.1.1.1: How has the ARNG failed to ensure that recruiters understand financial incentives?
A1.1.1.1: However, ARNG officials from all of the four selected states that GAO visited stated that they did not understand which vacant ARNG positions were considered critical and had incentives attached.

Answerable: ○True ○False

Edit Steps: 0

Q1.1.1.1.1: Why is it difficult to utilize financial incentives as a recruiting tool?
A1.1.1.1.1: Recruiters GAO interviewed stated that they are trained to persuade applicants to join the ARNG based on areas other than financial incentives, such as service to country and skills training, but the training did not teach recruiters how to use financial incentives to fill critical positions. Further, the ARNG has not provided recruiters with training to help ensure that they understand what financial incentives are available to help fill critical

model3

Q1: In what ways has ARNG improved its recruitment process?
A1: In response to GAO's prior work, the ARNG has taken steps to increase oversight of the recruitment process and improve its oversight of state-level recruiting activities.

Answerable: ○True ○False

Edit Steps: 0

Q1.1: How has the ARNG improved its recruitment process?
A1.1: For example, in 2010, GAO found that the ARNG's data on recruiter irregularities—or, wrongdoings on the part of recruiters—were incomplete and recommended that DOD take actions to increase visibility and track recruiter-irregularities.

Answerable: ○True ○False

Edit Steps: 0

Q1.1.1: How did the ARNG respond to GAO's recommendations?
A1.1.1: DOD concurred with GAO's recommendations and took steps to clarify, share, and track recruiter irregularity data.

Answerable: ○True ○False

Edit Steps: 0

Q1.1.1.1: How has ARNG improved its oversight of the recruiting process?
A1.1.1.1: In response to GAO's prior work as well as others, the ARNG took steps to increase its oversight of the state-level recruiting process, including establishing a permanent program for monitoring state-level recruiting.

Answerable: ○True ○False

Edit Steps: 0

Q1.1.1.1.1: How has the program been implemented?
A1.1.1.1.1: In June 2014, the ARNG Strength Maintenance Division began a pilot effort through its Recruiting Standards Branch to help provide oversight over state- level recruiting activities, but the branch has not been permanently established to ensure ongoing monitoring.

Answerable: ○True ○False

Edit Steps: 0

Q1.1.1.1.1.1: What is the goal of the program?
A1.1.1.1.1.1: The goal is to complete at least 12 state inspections each year.

Answerable: ○True ○False

De-Bias for Generative Extraction in Unified NER Task

Shuai Zhang, Yongliang Shen, Zeqi Tan, Yiquan Wu, Weiming Lu*
College of Computer Science and Technology, Zhejiang University
`{zsss, luwm}@zju.edu.cn`

Abstract

Named entity recognition (NER) is a fundamental task to recognize specific types of entities from a given sentence. Depending on how the entities appear in the sentence, it can be divided into three subtasks, namely, Flat NER, Nested NER, and Discontinuous NER. Among the existing approaches, only the generative model can be uniformly adapted to these three subtasks. However, when the generative model is applied to NER, its optimization objective is not consistent with the task, which makes the model vulnerable to the incorrect biases. In this paper, we analyze the incorrect biases in the generation process from a causality perspective and attribute them to two confounders: pre-context confounder and entity-order confounder. Furthermore, we design Intra- and Inter-entity Deconfounding Data Augmentation methods to eliminate the above confounders according to the theory of backdoor adjustment. Experiments show that our method can improve the performance of the generative NER model in various datasets.

1 Introduction

Named entity recognition (NER) is a task aimed at identifying distinct and independent entities from a given text while classifying them into predefined types. As a fundamental work in Natural Language Processing (NLP), its research facilitates the application of many downstream tasks (Ganea and Hofmann, 2017; Miwa and Bansal, 2016; Shen et al., 2021b). In previous work (Sang and Meulder, 2003; Pradhan et al., 2013a; Doddington et al., 2004; Kim et al., 2003; Karimi et al., 2015), three kinds of different NER subtasks were raised (as shown in Figure 1), which are Flat NER, Nested NER and Discontinuos NER.

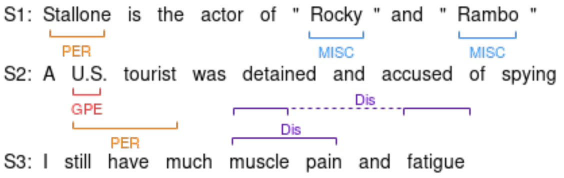

Figure 1: Examples involving flat, nested and discontinuous NER types, Entities are highlighted with colored markers

The existing NER methods can be divided into three main categories, including labeling-based (Ju et al., 2018; Straková et al., 2019), span-based (Luan et al., 2019a; Shen et al., 2021a) and generative-based (Straková et al., 2019; Paolini et al., 2021; Yan et al., 2021a) methods. Non-generative methods have different problems when applied to all three different subtasks: the labeling-based methods need to design different tagging schema for various types (Ratinov and Roth, 2009; Metke-Jimenez and Karimi, 2016; Straková et al., 2019; Dai et al., 2020) while the span-based methods suffers from ambiguity of boundary when applied to discontinuous task. Although generative-based methods are able to model all NER subtasks uniformly (Yan et al., 2021a), the training objective differ significantly from NER task due to the autoregressive generation mannner, resulting in some incorrect biases learned by the model during the training process.

From a causal perspective, the incorrect biases stem from two confounders: pre-context confounder and entity-order confounder. Pre-context confounder means that the model is affected by pre-context words that may be extra-entity words when generating a particular entity word. For example, in S3 of Figure 1, the autoregressive generation mannner causes the model to generate the word *"fatigue"* of the entity *"muscle fatigue"* conditioned on the extra-entity words *"muscle"* and *"pain"*. This causes the model to mistakenly establish dependen-

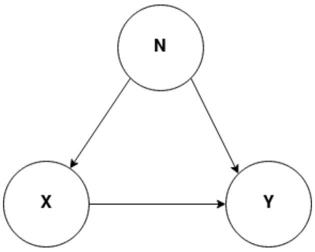

Figure 2: Structural Causal Model of the generative NER method. The confounder N causes the spurious correlation $X \leftarrow N \rightarrow Y$ to mislead the model from the true objective $X \rightarrow Y$.

cies between the intra-entity word *"fatigue"* and the extra-entity words *"muscle"* and *"pain"*, while ignoring the dependency between the intra-entity words *"muscle"* and *"fatigue"*. Therefore, when only the entity *"muscle fatigue"* is in the input sentence, the model cannot predict the entity accurately and completely due to the learned incorrect dependency bias. Entity-order confounder refers to the fact that the model is affected by a predetermined order of entities when generating an entity sequence. The entities in a sentence are essentially a set structure without decoding order among them. In contrast, the generative NER model pre-specifies the decoding order of entities, which introduces incorrect bias and ignores the bidirectional dependency between entities. As in S1 of Figure 1, after fixing the set of entities as *"Stallone"* → *"Rocky"* → *"Rambo"*, the model only models the unidirectional dependency of *"Rambo"* on *"Stallone"* and *"Rocky"*, without considering the reverse dependency of *"Stallone"* on *"Rocky"* and *"Rambo"*. In this case, if *"Rambo"* is decoded first, it is difficult for the model to decode the other two entities *"Stallone"* and *"Rocky"* due to the lack of the reverse dependency.

We can formulate the causalities in the process of entity sequence generation with a Structural Causal Model (SCM). As illustrated in Figure 2, the direct links denote the causality between the two nodes: cause → effect. $X \rightarrow Y$ represents the generation process of the target sequence, which can be divided into two cases according to the location of the generated words: intra-entity generation and inter-entity generation. In the former case, N denotes the pre-context words, which can affect the generation of the next word ($N \rightarrow Y$). While in the latter case, N denotes the entity decoding order, and can affect the generation of the next entity ($N \rightarrow Y$). In both cases, the representation of input X is contaminated by the backdoor path $X \leftarrow N \rightarrow Y$. Therefore, N is a confounder for the $X \rightarrow Y$ process which introduces a incorrect bias to the model.

In order to eliminate the bias caused by confounders N in both cases, we designed the Intra- and Inter-entity Deconfounding Data Augmentation method from the theory of backdoor adjustment. Our contributions are as follows:

- We analyzed the incorrect bias of the generative model on the NER task from a causal perspective, concluding that the pre-context confounder and the entity-order confounder are the main causes of the bias.
- Based on the backdoor adjustment theory, we designed the Intra- and Inter-entity Deconfounding Data Augmentation methods to remove the pre-context confounder and the entity-order confounder, respectively, to eliminate the incorrect bias of the generative model on the NER task.
- Experiments on three kinds of NER tasks show that our proposed method can de-bias the generative NER model and thus improve the model performance.

2 Prerequisite

For subsequent analysis, in this section we first illustrate how the NER task is modeled as a generative task, after which we illustrate the training and inference process of the generative model.

2.1 Problem Definition

The three kinds of NER tasks can all be formulated as follows, given an input sentence of l tokens $x = \{x_1, x_2, ..., x_l\}$, the target sequence $y = \{[ss], E_1, \cdots, E_M, [ee]\}$, where $E_i = \{[s], y_{e_1^i}, ..., y_{e_{\mathcal{E}}^i}, [e]\}$ is a word sequence of entity e^i, M denotes the number of the entities, $\mathcal{E}$ denotes the length of the entity, $[ss]$ and $[ee]$ are the start and end tags for the sequence, $[s]$ and $[e]$ are the start and end tags for the entity, and $y_{e_j^i}$ is the j-th word of i-th target entity.

2.2 Generative Model

In general, given an input sentence x, the generative model will return a sequence consisting of a collection of entities arranged in fixed order $y = \{[ss], E_1, \cdots, E_M, [ee]\}$. To this end, we first computes the hidden vector representation $H = h_1, ..., h_l$ of the input via a multi-layer transformer encoder:

$$H = Encoder(x_1, ..., x_l) \tag{1}$$

where each layer of Encoder($\cdot$) is a transformer block with multi-head attention mechanism.

After the input sentence is encoded, the decoder predicts the output token-by-token according to the sequential inputs' hidden vectors. At the step i of generation, the self-attention decoder predicts the $i\text{-}th$ token y_i in the linearized form and decoder state h_i^d as:

$$y_i, h_i^d = Decoder([H; h_1^d, ..., h_{i-1}^d], y_{i-1}) \tag{2}$$

where each layer of Decoder($\cdot$) is a transformer block that contains self-attention with decoder hidden state $h_{<i}^d$ and cross-attention with encoder state H.

Specifically, the optimization objective of the generated model is to maximize the conditional probability of the entire output sequence $p(y|x)$, which is progressively combined by the probability of each step $p(y_i|y_{<i}, x)$:

$$p(y|x) = \prod_i^{|y|} p(y_i|y_{<i}, x) \tag{3}$$

3 The Proposed Solution

In the above, we have analyzed that the bias in the traditional generative NER model $P(Y|X)$ is introduced by two kinds of confounders: the pre-context confounder and the entity-order confounder. Now we need to perform the deconfounding using backdoor adjustment to obtain a debiased model $P(Y|do(X))$. Deconfounding seeks the true causal effect of one variable on another, and it is appealing to the objective of NER: given a sentence X, we hope Y extracted by the model being faithful only to the content of the input X itself. And the backdoor adjustment promotes the posterior probability $P(Y|do(X))$ from passive observation to active intervention as shown below:

$$P(Y \mid do(X)) = \sum_n P(Y \mid X, n) P(n) \tag{4}$$

where n is the stratum for the confounder N. This encourages the model to maximize $P(Y|X, n)$ for every stratum n, only subject to a prior $P(n)$ listening to no one, and hence the model is deconfounded.

In the next sections, we apply Equation 4 to design two data augmentation (DA) methods, Intra-entity Deconfounding DA and Inter-entity Deconfounding DA, for the pre-context confounder and the entity-order confounder, respectively.

3.1 Intra-entity Deconfounding DA

We first focus on the generation of words inside the entity. The autoregressive decoder needs to decode the word at the current step conditioned on the pre-context words, i.e., the already generated word sequence. The pre-context words may be in other entities that are not associated with the entity currently being generated. Thus it will learn the wrong dependencies and bring in bias to the model. From the SCM in Figure 2, the pre-context words are the confounder in the generation of words inside the entity, causing the spurious correlation $X \leftarrow N \rightarrow Y$ to mislead the model from the true objective $X \rightarrow Y$.

Next we implement Intra-entity Deconfounding by data augmentation to eliminate pre-context confounder. As the backdoor adjustment shown in Equation 4, we stratify the confounder N, pre-context words, and train the model on each stratum. To avoid the influence of other entity words, we split the target sequences of the samples by entity and construct separate target sequences for each entity. Specifically, we randomly sample a context word $[CW]$ of an entity e^i from X and concatenate it in front of the entity as a target sequence Y', denoted as:

$$\{[CW], y_{e_1^i}, y_{e_2^i}, \cdots, y_{e_{\mathcal{E}}^i}\}$$

where $\mathcal{E}$ denotes the length of the entity e^i. If there are M entities in a sentence X, we can construct M augmented samples (X, Y'). It is worth noting that, compared to the target sequence Y of the original sample, the target sequence in the augmented sample does not contain tags denoting the beginning and end of the sequence, i.e., $[ss]$ and $[ee]$. This is to tell the model to generate only a single entity on the augmented sample instead of all the entities, as a way to prevent the model trained by the augmented samples from exiting early in the practical prediction.

3.2 Inter-entity Deconfounding DA

Another generation case is that after the current entity is generated, the model is expected to generate the first word of the next entity. In traditional generative NER models (Paolini et al., 2021; Yan et al., 2021a), the target sequence is fixed in the order of entities, for example, Yan et al. (2021a) pre-specified entity order according to the occurrence. However, entities are essentially set structures and the decoding sequence is not supposed to be fixed. A pre-specified entity order can make the optimization target inconsistent with the task and introduce an incorrect bias to the model. As shown in the SCM of Figure 2, entity order is the confounder N who affects the generation $X \rightarrow Y$ through the backdoor path $X \leftarrow N \rightarrow Y$.

According to Equation 4, we design an Inter-entity Deconfounding data augmentation to eliminate entity-order confounder. Similar to Section 3.1, we construct augmented samples by sampling from all possible entity orders. Specifically, for the original sample (X,Y), we keep the last entity of its target sequence fixed and permute the order of the other entities. The target sequence Y' of the augmented sample can be represented as:

$$\{[ss], \operatorname{Perm}\left(E_1, \cdots, E_{M-1}\right), E_M, [ee]\}$$

where $\operatorname{Perm}(\cdot)$ represents the permutation operation. During the training, we only compute the loss for the first token of the last entity, while the other entities are fed directly to the decoder as decoded sequences.

3.3 Constrained Prediction

As the model uses a token-by-token approach for prediction, in order to reduce the search space and the impact of exposure bias, we restrict the model to generating only tokens from the original sentence at generation time, and control the entire generation process by limiting tokens that can be generated at each step.

Specifically, we add special start and end tokens for the generation of each entity and the generation of the whole sequence. At the time of prediction, the generation of the sequence must start from the sequence start token, and the generation of the entity must start from the entity start token, and when the end token of the entity is generated, the next token that could be generated can only be the sequence end token and entity start token. Also, when generating each entity, we restrict the category of the entity to be generated only after the entity is generated, and the category can only be followed by the [e].

4 Experiments

In this section, we first describe the dataset we used, then we present related implementation details and experimental results, after which we make an analysis based on the experimental results.

4.1 Datasets

As same as (Yan et al., 2021b), to show that our proposed method can be used in various NER subtasks, we conducted experiments on eight datasets.

4.1.1 Flat NER Datasets

We selected the CoNLL2003 (Sang and Meulder, 2003) and OntoNotes (Pradhan et al., 2013b) datasets to do the experiments of Flat NER subtask. For CoNLL2003, we follow (Lample et al., 2016; Yu et al., 2020) to train our model on the concatenation of the train and development sets. For OntoNotes, we use the same train, development and test splits as (Pradhan et al., 2012; Yu et al., 2020).

4.1.2 Nested NER Datasets

For Nested NER subtask, we adopt ACE2004 (Doddington et al., 2004), ACE2005 and Genia datasets (Kim et al., 2003). In experiment conducted on ACE2004 and ACE2005, we use the same data split as (Lu and Roth, 2015; Muis and Lu, 2017; Yu et al., 2020), the ratio between train, development and test is 8:1:1. For Genia, we follow (Wang et al., 2020b; Shibuya and Hovy, 2020) to use five types of entities and split the train, development and test as 8.1:0.9:1.0.

4.1.3 Discontinuous NER Datasets

We follow (Dai et al., 2020) to use CADEC (Karimi et al., 2015), ShARe13 (Pradhan et al., 2013a) and ShARe14 (Mowery et al., 2014) datasets to do our experiment. Since only the Adverse Drug Events (ADEs) entities include discontinuous annotation, only this kind of entity is considered. (Karimi et al., 2015; Metke-Jimenez and Karimi, 2016; Tang et al., 2018).

4.2 Implementation Details

Because of the use of special tokens, we use the pretrained language model T5 (Raffel et al., 2020) as our encoder-decoder generative architecture. The

Table 3: Results for Discontinuous NER datasets.

T5 pre-trained model provides 100 default sentinel tokens for unsupervised training, here we use these special tokens to control the sequence generation process for avoiding the occupation of real tokens in the word list. Specifically, we use <*extra_id_2*> and <*extra_id_3*> to represent $[s]$ and $[e]$, <*extra_id_0*> and <*extra_id_1*> to represent $[ss]$ and $[ee]$, <*extra_id_11*> to <*extra_id_30*> to represent different NER categories, and <*extra_id_50*> to mark the sample of inter-entity deconfounding samples. In addition, we use the AdamW (Loshchilov and Hutter, 2019) optimizer with a linear learning rate schedule (with peak learning rate of 1e-4). For simplicity, we assume that entities are unique, and for words with referential relations, such as *"we"*, which appears frequently in ACE2005, we tag each *"we"* with a different label in a sentence such as *"we_1"*, *"we_2"*, ... to distinguish them from each other.

4.3 Results

4.3.1 Comparision between Baselines

For simplicity of comparison, we use the results reproduced by (Yan et al., 2021b) on the dataset with different subtasks. Moreover, since we conducted the experiments on the subtoken-level, we only kept the experimental results of BPE in (Yan et al., 2021b). As can be seen from Tables 1 to 3, our model achieves similar or even better results on all three subtasks than the model in (Yan et al., 2021b). This may be caused by the fact that we use a different pre-trained model and not use pointer mechanism. Compared with other non-generative models, same as (Yan et al., 2021b), our method achieves comparable results with models focusing on only one subtask of NER on most of datasets, for exceptional cases, (Akbik et al., 2019) in Table 1 tags tokens at token-level; (Wang et al., 2020a) in Table 2 classifies candidate span, which integrates information of all subtokens in span, and is based on span-level; while our model only focuses on subtoken, which is based on subtoken-level.

4.3.2 Analysis of Intra-entity Deconfounding

In comparing the results of Without-De and Intra-De in Table 1-3, we can see that when intra-entity deconfounding are performed, the model has different degrees of improvement in all datasets. It is worth noting that the selection method we used to do augmentation differs slightly from dataset to dataset. Specifically, in each dataset we select entities considering on occurrence frequency, nesting status and character length of entity, in particular, we kick out some special entities that have referential relationships with others.

4.3.3 Analysis of Inter-entity Deconfounding

In comparing the results of Without-De and Inter-De in Table 1-3, we can see that when inter-entity deconfounding are performed, the model also have different degrees of improvement in all datasets. Here, it is worth noting that when selecting the sample for inter-entity deconfounding, we select samples based on factors with which the order confounder is most likely to have impact, such as the minimum order of last entity in the whole training dataset and whether it is easy to perform permutation such as the number of target entities. Besides, we have not select all samples for augmentation, and the results in Table 1-3 may not be the best.

Table 5: Robustness Testing for the Entity-order Confounder

4.4 Robustness Testing

To verify the effectiveness of the two data augmentation methods we designed for de-confounding, we conducted robustness testing experiments on CoNLL03, ACE04 and CADEC, respectively.

The pre-context confounder introduce error bias into the model by incorrectly relying on prefix sequences during entity sequence generation in the training phase. To verify the effectiveness of our Intra-entity Deconfounding Data Augmentation method in eliminating the pre-context confounder, we designed robustness testing experiments. In decoding, we randomly sample several words as pre-context sequences, and then require the model to continue decoding the entities. The experimental results are shown in Table 4. We can observe that the performance of both the baseline model and the Intra-entity Deconfounding model have different degrees of degradation after the attack of random fixed pre-context. However, the relative performance degradation of the Intra-entity Deconfounding model is less, and the Δ F1 on ACE04, CADEC and CoNLL are improved by+1.44%, +1.21% and +0.43% relative to the baseline model. This indicates that after Intra-entity Deconfounding Data Augmentation, the model can eliminate the pre-context confounder to some extent.

We also verify the robustness of the Inter-entity Deconfounding Data Augmentation method against the entity-order confounder. We first randomly sample k entities as the prefix of the decoding sequence, and then let the model continue to generate entities. For convenience, we choose a sample of the test set with the number of entities greater than k for evaluation, and we do not consider the k randomly sampled correct entities in our evaluation. In our experiments, $k = 4$. From Table 5, we can observe that the performance of both models decreases after the attack of random entity order. However, after deconfounding the entity sequences by the Inter-entity Deconfounding Data Augmentation method, the model degradation is reduced, and the Δ F1 on ACE04, CADEC, and CoNLL are improved by +0.49%, +0.71%, and +0.19% relative to the baseline model. This indicates that the Inter-entity Deconfounding Data Augmentation method we designed can enhance the robustness of the model to cope with random entity order when generating entity sequences, i.e., the entity-order confounder are eliminated to some extent.

5 Related Work

5.1 NER Task

The existing models can be basically divided into sequence labeling formulation, span-based formulation and generative-based formulation. Among them, the sequence labeling formulation was earlier applied to solve the NER problem (McCallum and Li, 2003; Collobert et al., 2011; Huang et al., 2015; Chiu and Nichols, 2016; Lample et al., 2016; Straková et al., 2019; Yan et al., 2019; Li et al., 2020a). After Nested NER and Discontinuous NER were discovered and raised, inspired by the successful application of sequence labeling formulation on Flat NER subtask, Metke-Jimenez and Karimi (2016); Muis and Lu (2017) attempted to extend this approach to the new subtasks. Others chose a different path, based on the characteristics of Nested NER, Xu et al. (2017); Wang and Lu (2019); Yu et al. (2020) try to traverse all possible spans and do classification at the span-level. Shen et al. (2021a) try to reduce the number of candidate spans and Tan et al. (2021) make the left and right boundaries of the candidate spans completely unfastened. In addition, in order to apply span-based formulation to the Discontinuous NER, the concept of hypergraph was introduced to efficiently represent spans (Lu and Roth, 2015; Katiyar and Cardie, 2018; Muis and Lu, 2016).

Although sequence labeling formulation and span-based formulation can be applied to different subtasks separately, these formulations are difficult to be applied to them simultaneously. Among them, sequence labelling formulation needs to design different tagging schema for different NER subtasks (Ratinov and Roth, 2009; Metke-Jimenez and Karimi, 2016; Straková et al., 2019; Dai et al., 2020), while span-based formulation needs to sacrifice a certain degree of performance. For example, span-based methods need to set a maximum span length to avoid the number of candidate spans to be traversed (Xu et al., 2017; Luan et al., 2019b; Wang and Lu, 2018), since it is impossible to enumerate all possible spans, which is quadratic to the length of the sentence and fragment numbers of discontinuous entity.

Contrary to sequence-labeling and span-based formulation, generative-based formulation can be used to model these subtasks in a unified manner because it can generate variable-length sequences (Yan et al., 2021b). However, since the generative model uses autoregressive generation, its optimization objective differs significantly from the extraction objective of the NER task, which results in the model being influenced by some confounders and thus reduces the performance of model.

5.2 Causal Inference

Causal inference is a science that studies the relationship between correlation and causality. It is not only an explanatory framework, but also a way to provide solutions to achieve desired goals by pursuing causal effects (Pearl et al., 2016; Fenton et al., 2020). So far, it has been achieved greatly success in various domains such as psychology, politics and epidemiology for years (Mackinnon et al., 2007; Luke, 2015; Alves et al., 2014). Recently, causal inference has also attracted increasing attention in nature language process for improving model's performance in various ways. For example, Gardner et al. (2020) constructs counterfactual samples by manually rewriting the rules, and Garg et al. (2019) frames counterfactual samples by heuristically replace some keywords. Compared to them, our method offers a fundamental way to remove the confounder in training phase for generative models which is applied to various tasks of essentially non-sequential problem.

6 Conclusion

In this paper, we analyze two kinds of confounder that generative models arised when applied to NER and use backdoor adjustment methods in causal inference to perform deconfounding. Specifically, for pre-context confounder and entity-order confounder, we respectively design Intra-entity and Inter-entity De-confounding Data Augmentation methods. Experiments show that the performance of the model improves on all datasets after deconfounding. In the future, we will continue to explore the application of causal inference to other tasks.

Abstract

Pre-trained language models derive substantial linguistic and factual knowledge from the massive corpora on which they are trained, and prompt engineering seeks to align these models to specific tasks. Unfortunately, existing prompt engineering methods require significant amounts of labeled data, access to model parameters, or both. We introduce a new method for selecting prompt templates *without labeled examples* and *without direct access to the model*. Specifically, over a set of candidate templates, we choose the template that maximizes the mutual information between the input and the corresponding model output. Across 8 datasets representing 7 distinct NLP tasks, we show that when a template has high mutual information, it also has high accuracy on the task. On the largest model, selecting prompts with our method gets 90% of the way from the average prompt accuracy to the best prompt accuracy and requires no ground truth labels.

1 Introduction

It is well-known that large pre-trained language models (LMs) learn substantial linguistic (Liu et al., 2019; Amrami and Goldberg, 2018) and factual world knowledge (Petroni et al., 2020; Bosselut et al.; Bouraoui et al.; Zuo et al., 2018), achieving state-of-the-art performance on classic NLP tasks like closed-book question-answering, sentiment analysis, and many other tasks (Radford et al., 2019; Devlin et al., 2019; Raffel et al., 2019). The largest models can do this in a few-shot way–that is, being trained only with generic, semi-supervised objectives and "taught" tasks with just instructions and a few examples of the task provided via a natural language "prompt" in the context window (Brown et al., 2020). This suggests that pre-training equips them to potentially do many tasks that can be formulated as natural language generation, if only they can be primed in the right way.

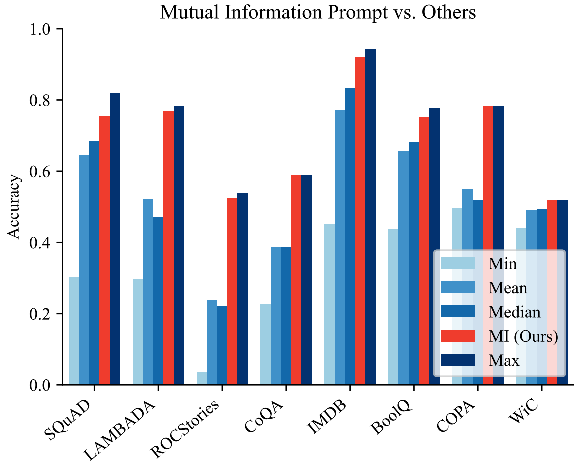

Figure 1: Performance of template selected by our maximum mutual information method (MI) compared to the the worst, mean, median, and best prompt on GPT-3 Davinci (175B). Our method performs at almost oracle levels, without labels or access to model weights.

Such priming is not a trivial task. The few-shot learning breakthrough can give the impression that if the LM is given a sensible prompt, it will "understand" what is meant and perform well on the task if it has the capacity. However, LMs can generate substantially different output distributions–and thus text–given two distinct prompts that appear semantically invariant (e.g., alternative orderings, lexical changes like capitalization, and general rephrasing (Zhao et al., 2021; Lu et al., 2021)). This can lead to surprisingly high variance in performance from prompt to prompt. Clearly, some prompts are better than others for aligning a model to a task.

Prompt engineering is a nascent field that aims to find aligning prompts (Reynolds and McDonell, 2021). While "prompt" refers to any language passed to the model via the context window, a *template* refers to a natural language scaffolding filled in with raw data, resulting in a prompt. Thus, prompt engineering includes finding high-quality templates (i.e., those with high test accuracy). Generally, this is done by optimizing for accuracy over

a validation set: a template is chosen from a candidate set based on its performance on labeled examples. Such labeled examples can be challenging to procure for some tasks and impossible for others. Some recent methods optimize prompts using backpropagation, which requires access to model weights. In this paper, we propose a new method for selecting prompts by using mutual information, which allows prediction of a prompt's performance without labels or access to model parameters.

Mutual information (MI) is a metric that quantifies the shared information between two random variables (see Section 3.2). We demonstrate that the mutual information between a prompt and a language model's output can serve as a useful surrogate for the test accuracy of a template. Specifically, for eight popular datasets representing seven classic NLP tasks, we generate a diverse set of 20 templates for each and show that template mutual information and template accuracy are highly correlated. These results are strongest on the largest models we study, for which our method chooses prompts that, on average, get 90% of the way from mean accuracy to maximum accuracy and even selects the best prompt on three of eight datasets.

This suggests that, across a variety of NLP tasks, mutual information can be used to select one of the best prompts from a set of candidate prompts, even without making use of model weights or ground truth labels. In the following pages, we outline each step of our general method for generating and evaluating templates so that it can easily be ported to any other task. Code is available online.[1]

2 Related Work

The promise of language models and the challenge of aligning them has given rise to the field of prompt engineering, which seeks to construct the best prompt given a task and a language model (Liu et al., 2021a). The best performance on prompt engineering is often achieved using backpropagation in continuous prompt embedding space (Lester et al., 2021; Li and Liang, 2021; Gu et al., 2021; Liu et al., 2021b; Zhang et al., 2021) in contrast to generating a discrete set of prompts by hand and testing them. While optimizing in continuous prompt space via backprop allows for similar performance to model-tuning (at least at higher model sizes) (Lester et al., 2021), not all models are publicly available. Thus, these methods are only feasible for those who have direct access to the model and can perform backprop on it. Prompts optimized in continuous space are also not interpretable in natural language, making it harder to transfer insights from prompts that work well for one task to another task. Additionally, these methods require labeled examples, while ours does not.

Other selection protocols not based on gradient descent can include cross-validation or minimum description length, as in (Perez et al., 2021). These methods yield prompts that perform marginally better than average in terms of test accuracy.

Mutual information has been used in n-gram clustering, part-of-speech tagging, probing classifiers, and LM training objective reframing (Brown et al., 1992; Stratos, 2019; Voita and Titov, 2020; Kong et al., 2019). Ours is the first work of which we are aware to apply MI to prompt engineering. (Lu et al., 2021) make use of entropy statistics to determine performant orderings for few-shot examples in prompts. Our work is focused on selecting high quality templates with no special focus on example ordering or need for multiple examples to order (the few-shot case). Our method uses no artificial "probing set," making our prompt selection much cheaper, and we also explore open-ended tasks. While the GlobalE and LocalE statistics they use are similar (and in the case of LocalE identical) to the two parts of our MI calculation (see 3.2), we use the two statistics jointly and choose prompts by minimizing, rather than maximizing, LocalE.

3 Methods

At the most abstract, our method is as follows (see Appendix A for a more thorough description):

1. Generate a set of K prompt templatizing functions.
2. Playground a couple of examples to ensure that templates give roughly expected output.
3. Estimate mutual information for each template given a set of inputs $\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_N$ where $\mathbf{x}_i \sim X, \forall i$.
4. Choose template(s) based on mutual information and perform inference.

We find it useful to unify all the tasks we study within a single framework, which we describe in

---

[1] github.com/BYU-PCCL/information-theoretic-prompts

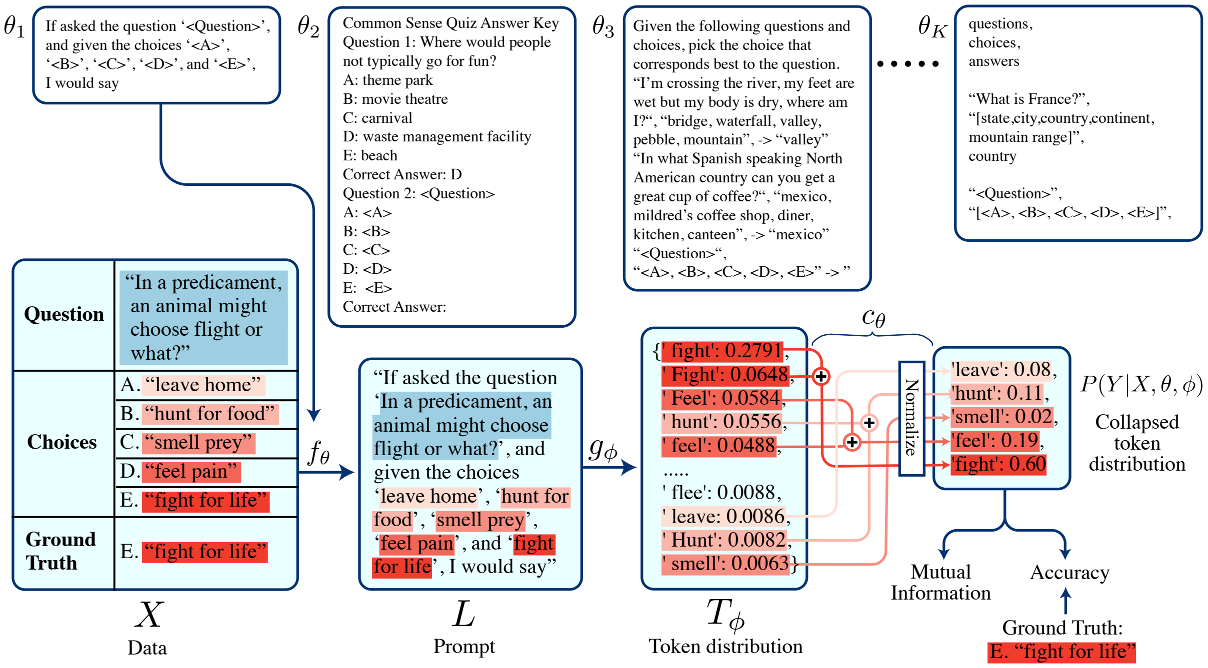

Figure 2: We choose $\theta \in \{\theta_i\}_{i=1}^{K}$ and templatize a sampled instance from the dataset X. We pass this prompt through the language model via g_ϕ, yielding a probability distribution over the model's tokens T_ϕ. The collapsing function c_θ sums the weight given to each token corresponding to each possible answer $y \in Y$ and normalizes, giving a probability distribution $P(Y|\mathbf{x}_i)$, which we can use to estimate mutual information or obtain a guess for y_i.

Section 3.1. We also justify our use of mutual information as a surrogate for prompt quality and specify how we estimate it in Section 3.2.

3.1 Task Definition

In order to demonstrate our method's widespread applicability and general effectiveness, we validate it across many datasets and tasks. This requires us to estimate MI and accuracy, and this is most straightforward in the case where, given a context, a language model produces just one probability distribution $P(\mathbf{t}_n|\text{context} = \mathbf{t}_1, \mathbf{t}_2, ..., \mathbf{t}_{n-1})$. This is in contrast to other experimental setups that use multi-token sampling methods (e.g., beam search), although our method is easily tractable in such setups.[2] Any NLP task is tractable in this framework so long as the output space consists of a set of options that each start with a unique token. In this case, the language model can "give" an answer by assigning probability to tokens that begin giving each of these answers (invariant to lexical variation like capitalization and leading/trailing spaces). While, for open-ended tasks, this method might artificially inflate accuracy if the model starts to give a wrong answer that happens to start with the same token as the correct one, we find that this difference is small and does not affect our results.[3] Irrelevant tokens (with which none of the desired answers begin) are ignored, and the resulting collapsed probabilities are normalized. We term this approach *One-token Response* (OTR). Although our method isn't limited to OTR tasks, we choose tasks that can be cast as OTR tasks for simplicity and to reduce computational expense. Many NLP tasks fit within this framework, although a few do not (e.g., machine translation and summarization). This basic approach is in common use (Brown et al., 2020), but we formalize it for clarity below.

Generally, the OTR framework casts a natural language task as a classification problem with raw data input $\mathbf{x}_i \in X$ and output $P(Y|\mathbf{x}_i)$, a probability distribution over targets. In order to use a language model ϕ for this task, a templatizing function $f_\theta : X \rightarrow L$ is needed to map raw data

---

[2] The only difference: For each considered answer, simply calculate its unnormalized probability by multiplying the probabilities of the decisions taken at each branch in the sequence of tokens, then normalize the resulting probability scores.

[3] Our open-ended datasets are SQuAD, LAMBADA, and ROCStories, and none of these seemed more likely than ROCStories to exhibit this issue. We reran our experiment on ROCStories by sampling with temperature 0 until reaching a space, and only counted responses as accurate if they exactly matched the corresponding ground truth labels. Results were virtually unchanged: accuracy decreased by only 0.03 on average, and the correlation between mutual information and test accuracy increased by 0.04, from 0.68 to 0.72.

into natural language prompts. $g_\phi : L \to T_\phi$ maps prompts to a probability distribution over T_ϕ, the token set represented by the model tokenizer. Finally, a collapsing function $c_\theta : T_\phi \to P(Y|\mathbf{x}, \theta, \phi)$ (see Appendix A) yields an estimate of $P(Y|X)$:

$$P(Y|\mathbf{x}, \theta, \phi) = c_\theta(g_\phi(f_\theta(\mathbf{x}))), \mathbf{x} \in X \qquad (1)$$

We also refer to $P(Y|\mathbf{x}, \theta, \phi)$ as $P(Y|f_\theta(\mathbf{x}))$.

The above pipeline can be specified in many ways using different θ and ϕ (see Figure 2), which will result in different accuracies. Our ultimate aim is to select the best θ given ϕ. Whereas past prompt engineering methods rely on scores calculated by comparing model answers and ground truth, our method selects θ by maximizing mutual information, which requires no ground truth labels.

3.2 Mutual Information

Mutual information is a measure of the amount of shared information between two random variables (Cover and Thomas, 2006); in other words, it is the reduction in entropy that is observed in one random variable when the other random variable is known.

We expect MI to serve as a good criterion for comparing prompts. Previous work has shown that large networks trained with cross-entropy loss are calibrated (e.g., a 60% confidence corresponds to a 60% chance of the model being correct) when in the early-stopped ($\sim$ 1 epoch) regime (Ji et al., 2021), but become miscalibrated in the overfit regime (Nakkiran and Bansal, 2020). According to (Brown et al., 2020), GPT-3 was trained for a different number of epochs on each corpus in its training data. We calculate it was trained for an average of 1.57 epochs, so we have reason to believe that GPT-3 is generally well-calibrated. Thus, we postulate that a prompt that elicits a very confident response (high MI) from the language model is more likely than a less confident prompt to score well.

We denote the mutual information between random variables X and Y as $I(X;Y)$ and the entropy of X as $H(X) = -\int_{\mathbf{x}\in X} P(\mathbf{x}) \log(P(\mathbf{x}))d\mathbf{x}$. The mutual information between X and Y is defined as $D_{\text{KL}}(P_{(X,Y)}||P_X \otimes P_Y)$, and can be rewritten as $H(Y) - H(Y|X)$ (the reduction in entropy in Y given knowledge of X).

Using the OTR framework, we fix a model ϕ and generate a diverse set of K prompt templatizing functions $f_{\theta_1}, f_{\theta_2}, ..., f_{\theta_K}$ along with their corresponding collapsing functions c_{θ_k} (see Appendix A). Treating $f_\theta(X) := \{f_\theta(\mathbf{x}), \mathbf{x} \in X\}$ as a random variable, we can calculate $I(f_\theta(X); Y)$ and use it as a criterion for selecting prompt templatizing functions with which to do inference.

We hypothesize that a θ_i with higher mutual information will align a language model to a task better than a θ_j with lower mutual information. Formally, we select $\hat{\theta} = \text{argmax}_\theta\{I(f_\theta(X); Y)\}$.

Mutual information is estimated as:

$$I\left(f_\theta(X); Y\right) = H(Y) - H(Y|f_\theta(X)) \qquad (2)$$

where each term is estimated in expectation using draws $\mathbf{x}_i \sim X$ and Equation 1 as follows:

$$H(Y) \approx H\left(\frac{1}{N}\sum_{i=1}^{N} P(Y|f_\theta(\mathbf{x}_i))\right) \qquad (3)$$

$$H(Y|f_\theta(X)) \approx \frac{1}{N}\sum_{i=1}^{N} H(P(Y|f_\theta(\mathbf{x}_i)))) \qquad (4)$$

The marginal entropy $H(Y)$ is the entropy of the mean of the conditional distributions, and the conditional entropy $H(Y|f_\theta(X))$ is the mean of entropies of the individual conditional distributions.

This definition gives us another reason to expect that mutual information will work well. Since mutual information is the marginal entropy minus the conditional entropy, maximizing mutual information is equivalent to maximizing marginal entropy and minimizing conditional entropy. Thus, MI is high for templates that are, on average, less biased towards any given answer (high marginal entropy) and templates with outputs the model is confident about (low conditional entropy). These attributes are desirable in constructing prompts, and we postulate that maximizing mutual information will yield a well-aligned template.

Looking at it another way, by the data processing inequality (Cover and Thomas, 2006), $I(f_\theta(X); Y) \leq I(X; Y)$. Thus, $I(f_\theta(X); Y)$ gives a lower bound for $I(X; Y)$, and the highest mutual information is the tightest lower bound. The prompt corresponding to this lower bound preserves the most information between X and Y.

4 Experimental Setup

4.1 Datasets

We validate the efficacy of our prompt engineering method with experiments on eight well-known NLP datasets[4]–SQuAD2.0 (Rajpurkar et al., 2018), LAMBADA (Paperno et al., 2016), ROCStories

---

[4] Datasets are listed in descending order here and throughout the paper, first by $|Y|$, and then by method performance.

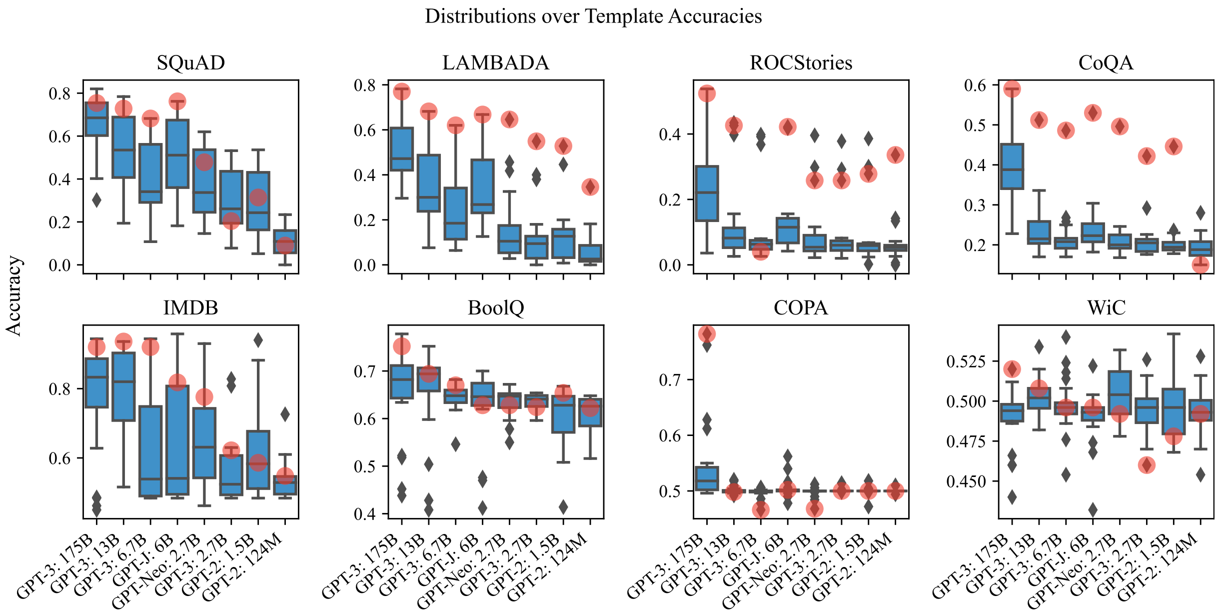

Figure 3: Distributions of accuracies over $K = 20$ templates for each model/dataset pair, compared to the prompts selected with MI (translucent red dots).

Dataset	Task	$\lvert Y\rvert$	Base Acc.	Size N_{all}
SQuAD	Open Book QA	$\lvert T_\phi\rvert$	~ 0	16K
LAMBADA	Cloze	$\lvert T_\phi\rvert$	~ 0	5K
ROCStories	Cloze	$\lvert T_\phi\rvert$	~ 0	52K
CoQA	Closed Book QA	5	0.2	9K
IMDB	Sentiment Analysis	2	0.5	50K
BoolQ	Reading Comprehension	2	0.5	16K
COPA	Choice of Positive Alternatives	2	0.5	1K
WiC	Word in Context	2	0.5	5K

Table 1: All datasets used in our experiments. $|Y|$ is the size of the label space and N_{all} is the size of the dataset we sample from (after any modifications).

(Mostafazadeh et al., 2016), CommonsenseQA (CoQA) (Talmor et al., 2018), IMDB (Maas et al., 2011), BoolQ (Clark et al., 2019), COPA (Gordon et al., 2012), and WiC (Pilehvar and Camacho-Collados, 2018))–that span seven unique NLP tasks (see Table 1). We used a random sample of $N = 500$ samples from each dataset for our experiments.[5] For ROCStories, which consists of a set of five sentence stories, we randomly masked a word from each story in order to use the data for masked word prediction (cloze).

We made minor changes to two of the datasets in order to cast the associated tasks into OTR. For the SQuAD dataset, we dropped all questions that did not have a one word answer. For the CoQA dataset we dropped all questions with answer choices that started with a shared first word (e.g, the dog, the cat, the monkey). Both changes were to decrease ambiguity about which option the model was choosing given its output distribution for a single token.

4.2 Models

We assess our method on eight models ranging from 124 million to 175 billion parameters : These include GPT-2 124M & 1.5B (Radford et al., 2019), GPT-Neo 2.7B (Black et al., 2021), GPT-J (6B) (Wang and Komatsuzaki, 2021), and (Ada, Babbage, Curie, & Davinci) GPT-3 (Brown et al., 2020). We assume (per (Perez et al., 2021)) these models to correspond, respectively, to the 2.7B, 6.7B, 13B, and 175B models in (Brown et al., 2020). Each is a causal language model, and although we do not include masked language models, this is a promising area for future work.

5 Results

In this section, we analyze our experiments. First, we look at our method's ability to select high-accuracy prompts across models and datasets (Section 5.1). Next, we correlate template mutual information and accuracy in Section 5.2. After that, we compare our method and template selection using labeled examples in Section 5.3. In Section 5.4, we

---

[5] We sampled from the train sets of CoQA and SQuAD; the train and validation sets of WIC, COPA, and BoolQ; the full datasets of ROCStories and IMDB; and the test set for LAMBADA.

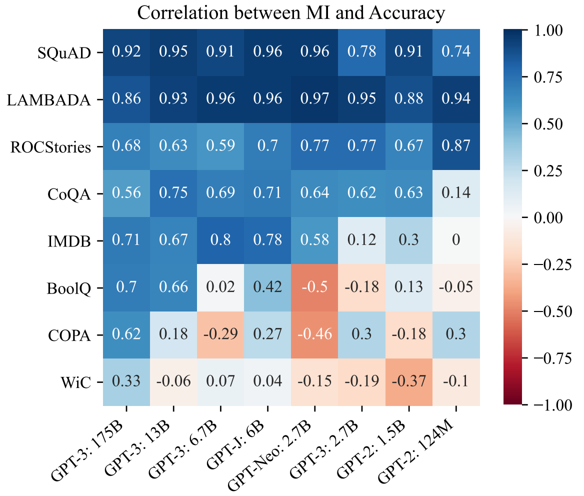

Figure 4: Correlations are more consistently high across all tasks for the largest models, suggesting that our method is most useful at those model sizes.

explore the robustness of MI and use ensembling to improve it. Finally, we compare the tranferability of prompt templates selected with MI from model to model in Section 5.5.

5.1 Template Selection Performance

We first define baselines against which we compare our approach. Other prompt engineering methods generally require either access to model weights, labeled data (validation set selection), or both (backprop/continuous prompt embedding methods). Our method does not require these, so we instead compare to random and oracle baselines. A random template selection method would give us the average accuracy of our template set (in expectation), while an oracle selection method would give us the best accuracy every time. To understand how our MI method compares to these two baselines for each dataset, refer to Figure 1, where we analyze performance on GPT-3 175B. On each of the eight datasets, mutual information selects a prompt template that outperforms both the mean and median accuracies (random baseline performance). In three of the eight datasets, mutual information selects the best (highest accuracy) template from the 20 proposed (equivalent to oracle performance).

Given our method's promising performance with GPT-3 175B, it is natural to ask how it performs with smaller models. Figure 3 shows the accuracy distributions over prompt templates for each dataset/model pair. With every model, MI gives above-average performance on several datasets. Although MI is more likely to select a high accuracy template for larger models, it is a good criterion even for smaller models on all but two datasets, COPA and WiC. Note that, for these two datasets, none of the templates do significantly better than chance (∼50%) besides the largest model on COPA, which is in line with previous work.[6] Thus, we observe that mutual information performs best when there is a high-signal prompt to select, and worse when all prompts are low-signal.

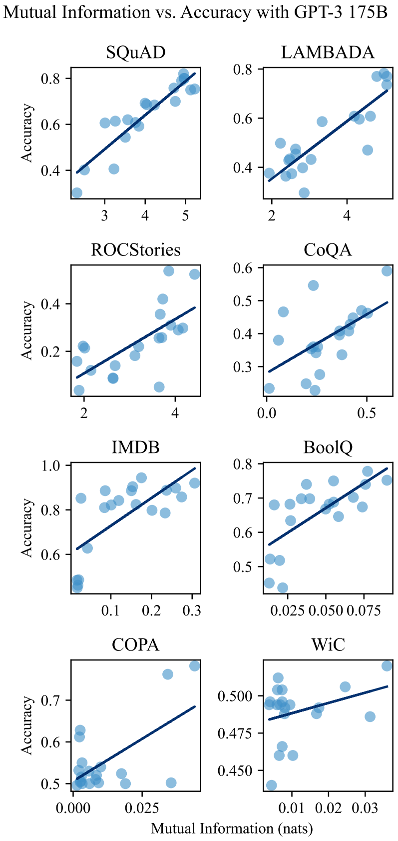

Figure 5: Each dot represents a template and its average mutual information and accuracy over $N = 500$ task instances. Linear best fit (by mean standard error) lines are included to show overall trends.

When considering all other datasets, MI selects an above average prompt 83% of the time for all models; for the largest two models, MI selects an above average template 100% of the time.

5.2 Correlation between Template Mutual Information and Accuracy

In Section 5.1, we see how the mutual information selected template does in terms of accuracy compared to all other templates. We have not dis-

---

[6] Our template's best accuracy is 54% for WiC, and 78.2% for COPA, which is similar to previous work (WiC: (Brown et al., 2020) - 49.4%, (Perez et al., 2021) - 54.1%; COPA: (Brown et al., 2020) - 92.0%, (Perez et al., 2021) - 84.8%).

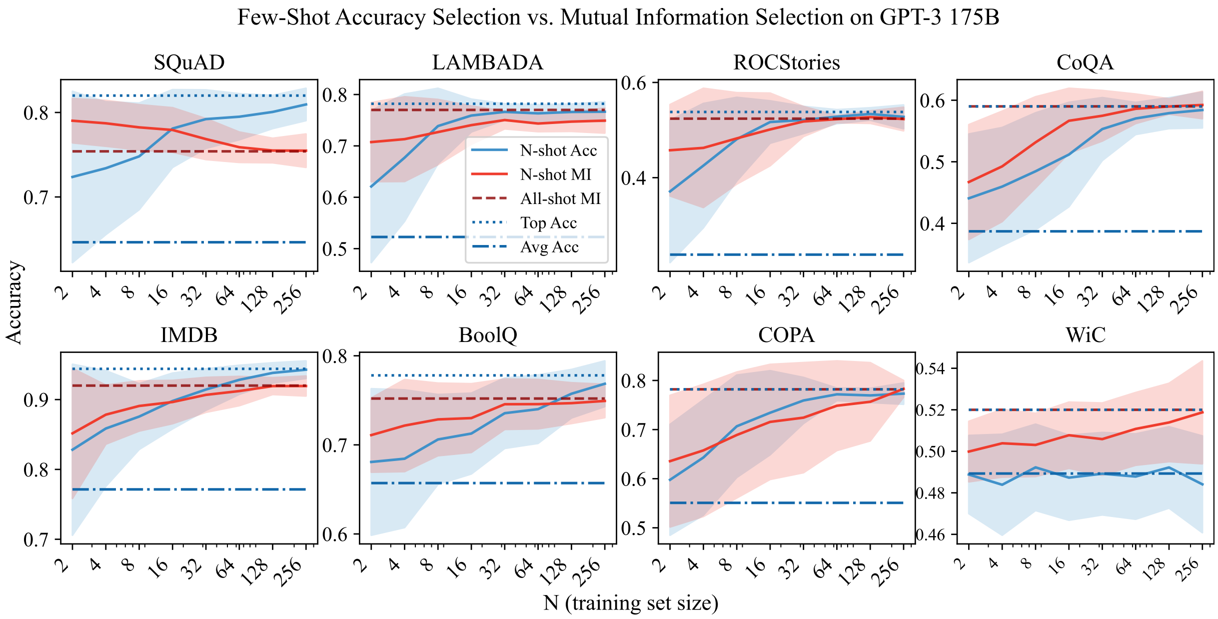

Figure 6: For $P = 100$ random train/test set partitions for each training size $N = 2, 4, 8, ..., 256$, we select a template based on accuracy (N-shot Acc) and based on mutual information based on just those N examples (N-shot MI). Then, we report accuracy of that template on the test set (size: $500 - N$). Error bars ($\pm\sigma$) are reported across the $P = 100$ partitions. For reference, the highest, average, and full-dataset MI template accuracy is also reported.

cussed, however, how generally MI and accuracy are correlated, except that the highest MI template tends to have anomalously high accuracy. Here, we establish that their correlation is high across all templates for the largest LMs. Each of the $K = 20$ templates has two corresponding measures: average accuracy and average MI. We can use these pairs to correlate MI and accuracy via Pearson's R.

We see in Figure 4 that the correlations are surprisingly high for the majority of models and datasets. For SQuAD, LAMBADA, ROCStories, and CoQA, this pattern holds across all model sizes; for the remainder, results are good on larger models and are much less reliable on smaller models. Overall, this is evidence that as mutual information increases, so does accuracy. In other words, mutual information can be used to make an educated guess about accuracy without having to use any ground truth labels, especially on larger models.

5.3 Compared to Few Labeled Examples

Next, we ask: How does our method compare to selecting a template based on the accuracy of a few-labeled examples? Also, how many unlabeled examples does MI need to be able to perform well?

Results with the largest model are reported in Figure 6. Note that with as few as $N = 2$ instances, MI selects a far better than average template, allowing performance gains even in the low-data, unlabeled regime. Additionally, for low N and across all eight datasets, MI even selects a better template on average than selecting based on labeled train set accuracy. This suggests that, even with labeled examples, selecting based off of MI may be preferable to test accuracy with few examples. Selecting by labeled train set accuracy often begins to perform better at higher N, but at the cost of requiring labeled data, while our method needs no labels.

5.4 Method Robustness and Ensembling

To explore our method's robustness we consider the question: what if we had included a different subset of templates, especially not including the top MI template? Figure 5 shows average MI/accuracy data for all $K = 20$ prompt templates on GPT-3 175B (similar plots for other models are found in Appendix B.1). For six of eight datasets, the results are robust; the top few prompt templates (by MI) are all high performers. The performance for COPA and WiC is more brittle; excluding the top-MI template would have resulted in a large drop in accuracy. This attests to the utility of generating a diverse slate of templates as recommended in Appendix A and also to the risk that outliers could compromise our method's effectiveness.

A comprehensive discussion of remedies for outliers is beyond the scope of this paper, but it is

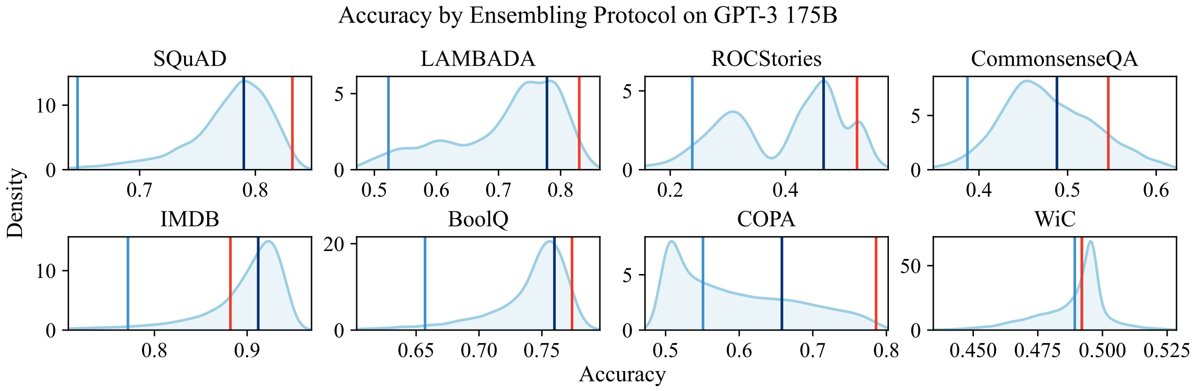

Figure 7: For each dataset the KDE plot represents accuracy over each of the $\binom{20}{5}$ ensembles of 5 templates from the 20 templates associated with the dataset. Each plot also includes lines representing the average accuracy of all single templates for the dataset, the accuracy of the ensemble of all 20 templates, and the accuracy of the ensemble of the top 5 templates chosen by MI. In only one case does all-20 beat top-5-MI, and it does so at 4× the cost.

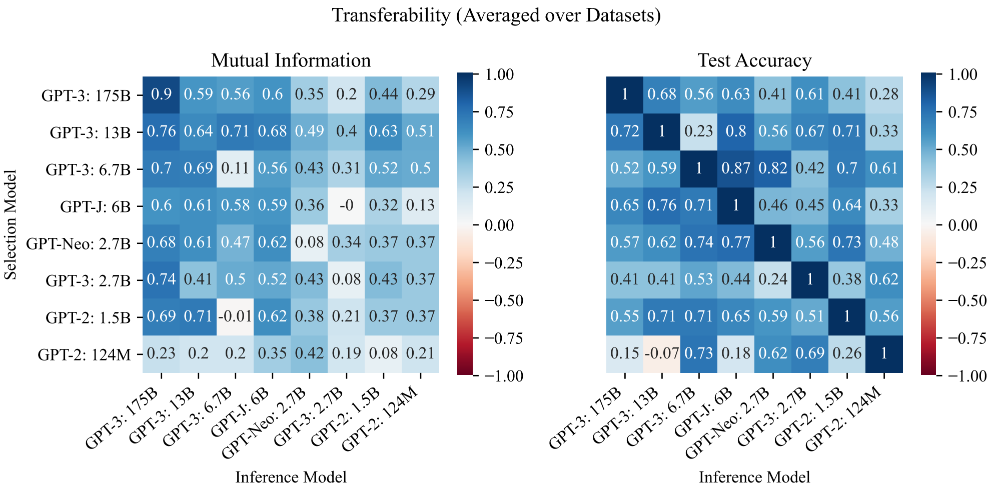

Figure 8: For each model/dataset pair, accuracies are normalized linearly so that 0 is the average prompt accuracy and 1 is the highest test accuracy. Using the prompt chosen by either MI or test accuracy on each selection model, average performance across datasets is reported for each inference model.

an important concern. Considering the strength of MI/accuracy correlations, one simple approach is to ensemble the top 5 MI templates.

To compare this principled top-5 ensemble to other possible ensembles of templates, we take all $\binom{20}{5}$ subsets of 5 templates from all 20 templates and calculate the accuracy of each ensemble. For each dataset, we plot this distribution's kernel density estimate, which models the p.d.e. of the random variable "accuracy of 5 random templates ensembled together". We then compare the top-5 MI ensemble to other possible ensembles. The results are shown in Figure 7.

We found that the top-5 MI ensemble does at least as well as the top-20 ensemble in all but one case. Two reasons to use MI are, then, that 1) the MI ensemble gets as good or better a result as ensembling all prompt templates and 2) at a fourth of the experimental cost. In short, ensembling by MI is a cheap and effective way to guard against anomalous high MI/low accuracy templates.

5.5 Transferability across Models

Finally, we explore how well-chosen templates generalize between models. Concretely, we choose templates by maximizing either test accuracy (oracle) or mutual information (our method) using a selection model ϕ_s, and then calculate test accuracy using a different inference model ϕ_i. We calculate absolute test accuracy and then normalize it such that 0 and 100 correspond to the average and maximum scores across templates for a model/dataset pair. We average our results across datasets and present the results in Figure 8. Prompt transfer for each dataset can be found in Appendix B.2.

MI performance is best when the largest model (GPT-3 175B) is used as both the selection and inference model: on average, MI scores 90% on this normalized scale. Additionally, performance is most consistently high when the largest models are used either for selection or inference. But almost all transfer scores are well above 0 (only one negative average gain out of 64 transfer permutations), suggesting that transfer is often effective.

Overall, we have observed that prompt selection by mutual information is surprisingly effective across a variety of datasets and model sizes. This method works best on larger models and for tasks that the LM is capable of performing. Given the high diversity of tasks that we have explored, we expect this method to transfer well to many other NLP tasks, including regimes with little labeled data.

6 Conclusion

In this paper, we introduce a method for selecting prompts that effectively align language models to NLP tasks. Over a set of candidate prompts, our method selects the template that maximizes the mutual information between the input and the model output. We demonstrate that 1) mutual information is highly correlated with test accuracy and 2) selecting a prompt based on mutual information leads to significant accuracy gains over random choice, approaching oracle performance on GPT-3 175B, and it does so across model sizes and tasks.

Whereas other methods rely on ground truth labels and/or direct model access, ours requires neither. Many applications characterized by lack of computational resources, limited model access (e.g., inference only), and lack of ground truth data prohibiting testing of candidate prompts become feasible with our method.

7 Ethics

There are many ways to prompt a language model poorly, and there still seem to be NLP tasks which are beyond alignment regardless of model size or prompt quality. This method cannot align a LM to a task if the entire set of prompts is poor or, obviously, if the model cannot be aligned. High mutual information does not necessarily imply high accuracy despite the strong correlation we found. Thus, our method should only be employed on a task if there is some understanding of how high MI needs to be on a domain or set of templates to imply a sufficiently high accuracy for safe use.

Otherwise, we introduce no model, dataset, or other contribution that might warrant ethical concern.

A Prompt Engineering Process

In this section, we step through our method in detail. Again, note that this method uses no ground truth labels and does not require gradient updates or model parameter access. Given a task that can be represented in natural language with the OTR framework, the only requirements for our approach are a) several candidate prompt templates and b) some instances (X) on which to do inference.

1. **Generate a set of K prompt templatizing functions with corresponding collapsing functions.** Each prompt template function f_{θ_k} should take in an input from the dataset and output a prompt ready for processing by the language model. We chose to generate our template functions by hand, i.e., a human writes a sensible, custom natural language scaffolding that can be filled with input data (see examples in C).

Each template must also have a collapsing function c_{θ_k} that takes the language model output logprobs, exponentiates and sums "equivalent" logprobs, and normalizes the resulting probabilities to produce a distribution over targets. Equivalent logprobs are those that indicate the same answer. For example, a template might be designed for a question-answering task with possible answers "Yes" and "No". We consider all logits corresponding to possible lexical variants of each of these answers to be equivalent. For example, what logits should count toward the answer "Yes"? Not just the exact token "Yes", since "ye", " yes", and "YES" are all lexical variants of the same answer or the beginning of it, just with surrounding white space and alternative capitalization. The collapsing function lower-cases and strips white space from all logits, and if the lower-cased answer begins with a token, that token's probability (the exponentiated logprob) is added to the sum of probability for that answer. Finally, the sums of probabilities for all individual answers are normalized. Prompt template functions should be chosen to be as diverse as possible to increase the probability of finding high-quality prompts. For example, we use templates that frame input from datasets as test questions, back and forth dialogue between friends, Python code, test answer banks, etc. A sample of the prompt templates used in this work is provided in Appendix C. A good resource for coming up with prompt template function ideas is the OpenAI API examples collection[7]. While we aimed for as diverse a set of prompts as possible in this work, additional dimensions of variation in prompt templates could be explored in future work (e.g., ordering of few-shot examples).

2. **Playground.** For each chosen f_{θ_k}, calculate $g_\phi(f_{\theta_k}(x))$ for a few dataset samples. Do not look at associated ground truth labels for these samples. Simply check to ensure that g_ϕ puts high probability on the tokens one would expect given f_{θ_k} that could be reasonably collapsed by c_{θ_k} into $P(Y)$. For example, on the BoolQ reading comprehension task, the language model predicts the answer to a yes/no question with a corresponding passage. Given this task, we would expect the highest probability to be on tokens like "Yes" or "No". A poor prompt template, though, might put the highest probability on unrelated tokens like "I", "think", or "\n". Revise or replace any template that fails to put high probability mass on the tokens expected.

3. **Estimate mutual information for each template f_{θ_k}.** Choose how many data points N to use for estimating mutual information for each template function. A higher N will allow for estimation of mutual information based on a more representative sample of the dataset at the cost of more LM computation. Sample N samples from your dataset. Since we do not require any Y labels, one could even choose the X's on which you desire to do inference (as we do). Then, for each sample x and each template f_{θ_k}, calculate $P(Y|f_\theta(x))$ using Equation 1. Use the output to estimate MI for each prompt template with Equation 2.

For all of our experiments, c_θ takes in a distribution of tokens $g_\phi(f_{\theta_k}(x))$ and a mapping between the set of possible ground truth labels for $f_{\theta_k}(x)$ and model vocabulary T_ϕ. For a sentiment analysis task, that mapping would be from the ground truth labels "positive" and "negative" to the expected tokens "positive" and "negative" respectively. If a prompt template for the task was phrased as a yes/no question, the mapping for it would be from "positive" and "negative" to "yes" and "no" respectively. Our c function returns a probability over Y (target label space), and the highest probability label is treated as the prediction. To keep things simple, the values in our map are always single tokens. See examples in Appendix C.

4. **Choose prompt template(s) to use for inference based on mutual information.** For choosing

---

[7] beta.openai.com/examples

a single prompt template to use for inference, select the template with highest estimated mutual information. With an increased computational budget, one could also ensemble the top p prompt templates, as we describe in Section 5.4.

5. **Use chosen prompt template(s) to perform inference** Use chosen prompt template(s) $f_{\hat{\theta}}$ to calculate $c_{\hat{\theta}}(g_{\phi}(f_{\hat{\theta}}(x))$ for each dataset sample. Inference can be done with the language model used for estimating mutual information or a smaller model if cost is prohibitive (for information on performance statistics with this approach, see Figure 8).

C Template Examples

The following are example template f_θs provided for each dataset. We include all used templates, ordered by accuracy. In blue, we highlight the data that is filled in from X; in red, we highlight the area where we ask the model to predict the next token; everything that is not highlighted is static from instance to instance. We also include the token sets used in the collapsing functions.

C.1 SQuAD

Prompt 1 (MI: 4.950, Acc: 0.820):

TASK: Answer the questions below using the phrasing from the context.

CONTEXT:
As of the census of 2000, there were 197,790 people, 84,549 households, and 43,627 families residing in the city. The population density was 3,292.6 people per square mile (1,271.3/km). There were 92,282 housing units at an average density of 1,536.2 per square mile (593.1/km). The racial makeup of the city was 38.3% White, 57.2% African American, 0.2% Native American, 1.3% Asian, 0.1% Pacific Islander, 1.5% from other races, and 1.5% from two or more races. Hispanic or Latino of any race were 2.6% of the population.

QUESTIONS:
1) In 2000, how many families lived in Richmond?
Answer: "43,627"

2) What percentage of the Richmond population of 2000 was Pacific Islander?
Answer: "

Collapsing token sets: None, all tokens are considered

Prompt 2 (MI: 4.965, Acc: 0.800):

Given the following passages and questions, provide a brief, correct answer from the text.

"BYU students arrive with superb preparation. The entering class has an average high school GPA of 3.71 (on a 4.0 scale) and an average ACT score that ranks in the 89th percentile nationally. The University consistently places in the top 20 for enrollment of National Merit Scholars.", "What high school GPA for BYU freshmen have on average?" -> "3.71""BYU students arrive with superb preparation. The entering class has an average high school GPA of 3.71 (on a 4.0 scale) and an average ACT score that ranks in the 89th percentile nationally. The University consistently places in the top 20 for enrollment of National Merit Scholars.", "What high school GPA for BYU freshmen have on average?" -> "3.71"
"In meteorology, precipitation is any product of the condensation of atmospheric water vapor that falls under gravity. The main forms of precipitation include drizzle, rain, sleed, snow, graupel, and hail... Precipitation forms as smaller droplets coalesce via collision with other rain drops or ice crystals within a cloud. Short, intense periods of rain in scattered locations are called"showers".", "What causes precipitation to fall?" -> "gravity"

Collapsing token sets: None, all tokens are considered

Prompt 14 (MI: 3.760, Acc: 0.608):

As of the census of 2000, there were 197,790 people, 84,549 households, and 43,627 families residing in the city. The population density was 3,292.6 people per square mile (1,271.3/km). There were 92,282 housing units at an average density of 1,536.2 per square mile (593.1/km). The racial makeup of the city was 38.3% White, 57.2% African American, 0.2% Native American, 1.3% Asian, 0.1% Pacific Islander, 1.5% from other races, and 1.5% from two or more races. Hispanic or Latino of any race were 2.6% of the population.

What percentage of the Richmond population of 2000 was Pacific Islander?
The correct answer is:

Collapsing token sets: None, all tokens are considered

Prompt 15 (MI: 3.006, Acc: 0.606):

I read this in a book today:
As of the census of 2000, there were 197,790 people, 84,549 households, and 43,627 families residing in the city. The population density was 3,292.6 people per square mile (1,271.3/km). There were 92,282 housing units at an average density of 1,536.2 per square mile (593.1/km). The racial makeup of the city was 38.3% White, 57.2% African American, 0.2% Native American, 1.3% Asian, 0.1% Pacific Islander, 1.5% from other races, and 1.5% from two or more races. Hispanic or Latino of any race were 2.6% of the population.
From that context, did you catch What percentage of the Richmond population of 2000 was Pacific Islander?
Yes, the answer is

Collapsing token sets: None, all tokens are considered

Prompt 16 (MI: 3.843, Acc: 0.592):

TASK: Answer the questions below using the phrasing from the context.

CONTEXT:
As of the census of 2000, there were 197,790 people, 84,549 households, and 43,627 families residing in the city. The population density was 3,292.6 people per square mile (1,271.3/km). There were 92,282 housing units at an average density of 1,536.2 per square mile (593.1/km). The racial makeup of the city was 38.3% White, 57.2% African American, 0.2% Native American, 1.3% Asian, 0.1% Pacific Islander, 1.5% from other races, and 1.5% from two or more races. Hispanic or Latino of any race were 2.6% of the population.

QUESTIONS:
1) What percentage of the Richmond population of 2000 was Pacific Islander?
Answer: "

Collapsing token sets: None, all tokens are considered

Prompt 17 (MI: 3.508, Acc: 0.544):

I read this in a book today:
As of the census of 2000, there were 197,790 people, 84,549 households, and 43,627 families residing in the city. The population density was 3,292.6 people per square mile (1,271.3/km). There were 92,282 housing units at an average density of 1,536.2 per square mile (593.1/km). The racial makeup of the city was 38.3% White, 57.2% African American, 0.2% Native American, 1.3% Asian, 0.1% Pacific Islander, 1.5% from other races, and 1.5% from two or more races. Hispanic or Latino of any race were 2.6% of the population.
What percentage of the Richmond population of 2000 was Pacific Islander?
Answer:

Collapsing token sets: None, all tokens are considered

Prompt 18 (MI: 3.227, Acc: 0.406):

Context: As of the census of 2000, there were 197,790 people, 84,549 households, and 43,627 families residing in the city. The population density was 3,292.6 people per square mile (1,271.3/km). There were 92,282 housing units at an average density of 1,536.2 per square mile (593.1/km). The racial makeup of the city was 38.3% White, 57.2% African American, 0.2% Native American, 1.3% Asian, 0.1% Pacific Islander, 1.5% from other races, and 1.5% from two or more races. Hispanic or Latino of any race were 2.6% of the population.

Q: What percentage of the Richmond population of 2000 was Pacific Islander?

A:

Collapsing token sets: None, all tokens are considered

Prompt 19 (MI: 2.497, Acc: 0.402):

A friend of mine told me this:
As of the census of 2000, there were 197,790 people, 84,549 households, and 43,627 families residing in the city. The population density was 3,292.6 people per square mile (1,271.3/km). There were 92,282 housing units at an average density of 1,536.2 per square mile (593.1/km). The racial makeup of the city was 38.3% White, 57.2% African American, 0.2% Native American, 1.3% Asian, 0.1% Pacific Islander, 1.5% from other races, and 1.5% from two or more races. Hispanic or Latino of any race were 2.6% of the population.
My friend then asked: What percentage of the Richmond population of 2000 was Pacific Islander?
I answered:

Collapsing token sets: None, all tokens are considered

Prompt 20 (MI: 2.312, Acc: 0.302):

ANSWER KEY:

QUESTION1:
"As of the census of 2000, there were 197,790 people, 84,549 households, and 43,627 families residing in the city. The population density was 3,292.6 people per square mile (1,271.3/km). Prompt 8 (MI: 3.338, Acc: 0.586):

Fill in the blank with the missing word to complete the sentence.

Passage: I like to eat peanut butter and jelly ____.
Missing Word: sandwiches

Passage: "I would speak to you privately," Bowen said, casting a glance around at the others milling about.

The worry in her eyes deepened, but she nodded hesitantly and awaited Bowen's directive.

He led her through the great hall, annoyance biting at him when he saw no place where people weren't congregated. He stepped outside the back of the keep, where, finally, he spied an area near the bathhouses, where it was quiet and ____.
Missing Word: "

Collapsing token sets: None, all tokens are considered

Prompt 9 (MI: 2.230, Acc: 0.498):

"I would speak to you privately," Bowen said, casting a glance around at the others milling about.

The worry in her eyes deepened, but she nodded hesitantly and awaited Bowen's directive.

He led her through the great hall, annoyance biting at him when he saw no place where people weren't congregated. He stepped outside the back of the keep, where, finally, he spied an area near the bathhouses, where it was quiet and ____.

The missing word in the story should be: "

Collapsing token sets: None, all tokens are considered

Prompt 10 (MI: 2.632, Acc: 0.474):

"I would speak to you privately," Bowen said, casting a glance around at the others milling about.

The worry in her eyes deepened, but she nodded hesitantly and awaited Bowen's directive.

He led her through the great hall, annoyance biting at him when he saw no place where people weren't congregated. He stepped outside the back of the keep, where, finally, he spied an area near the bathhouses, where it was quiet and ____.
Fill in the blank with the missing word or phrase.
What is the missing word? The missing word is "

Collapsing token sets: None, all tokens are considered

Prompt 11 (MI: 4.549, Acc: 0.470):

It was a cold night. The wind was ____ around the courtyard as I stepped out of the car and into the darkness.
Word: whistling

"I would speak to you privately," Bowen said, casting a glance around at the others milling about.

The worry in her eyes deepened, but she nodded hesitantly and awaited Bowen's directive.

He led her through the great hall, annoyance biting at him when he saw no place where people weren't congregated. He stepped outside the back of the keep, where, finally, he spied an area near the bathhouses, where it was quiet and ____.

Word:

Collapsing token sets: None, all tokens are considered

Prompt 12 (MI: 2.637, Acc: 0.454):

P1: I'm going to tell you a story, but leave a word out. Once I'm done telling the story, pick the word that best fits in the blank.
"I would speak to you privately," Bowen said, casting a glance around at the others milling about.

The worry in her eyes deepened, but she nodded hesitantly and awaited Bowen's directive.

He led her through the great hall, annoyance biting at him when he saw no place where people weren't congregated. He stepped outside the back of the keep, where, finally, he spied an area near the bathhouses, where it was quiet and ____.
P2: The word which fits best is "

Collapsing token sets: None, all tokens are considered

Prompt 13 (MI: 2.476, Acc: 0.434):

"I would speak to you privately," Bowen said, casting a glance around at the others milling about.

The worry in her eyes deepened, but she nodded hesitantly and awaited Bowen's directive.

He led her through the great hall, annoyance biting at him when he saw no place where people weren't congregated. He stepped outside the back of the keep, where, finally, he spied an area near the bathhouses, where it was quiet and ____.
Fill in the blank with the missing word or phrase to complete the sentence.
What is the missing word? The missing word is "

Collapsing token sets: None, all tokens are considered

Prompt 14 (MI: 3.043, Acc: 0.432):

Read the following sentences, and try to guess which word goes in the blank.
"I would speak to you privately," Bowen said, casting a glance around at the others milling about.

The worry in her eyes deepened, but she nodded hesitantly and awaited Bowen's directive.

He led her through the great hall, annoyance biting at him when he saw no place where people weren't congregated. He stepped outside the back of the keep, where, finally, he spied an area near the bathhouses, where it was quiet and ____.
Answer: "

Collapsing token sets: None, all tokens are considered

Prompt 15 (MI: 2.450, Acc: 0.428):

Fill in blank:

"I would speak to you privately," Bowen said, casting a glance around at the others milling about.

The worry in her eyes deepened, but she nodded hesitantly and awaited Bowen's directive.

He led her through the great hall, annoyance biting at him when he saw no place where people weren't congregated. He stepped outside the back of the keep, where, finally, he spied an area near the bathhouses, where it was quiet and ____. ->

Collapsing token sets: None, all tokens are considered

Prompt 16 (MI: 2.820, Acc: 0.398):

Fill in the blank with the missing word.
"I would speak to you privately," Bowen said, casting a glance around at the others milling about.

The worry in her eyes deepened, but she nodded hesitantly and awaited Bowen's directive.

He led her through the great hall, annoyance biting at him when he saw no place where people weren't congregated. He stepped outside the back of the keep, where, finally, he spied an area near the bathhouses, where it was quiet and ____.
Answer: "

Collapsing token sets: None, all tokens are considered

Prompt 17 (MI: 1.931, Acc: 0.376):

"I would speak to you privately," Bowen said, casting a glance around at the others milling about.

The worry in her eyes deepened, but she nodded hesitantly and awaited Bowen's directive.

He led her through the great hall, annoyance biting at him when he saw no place where people weren't congregated. He stepped outside the back of the keep, where, finally, he spied an area near the bathhouses, where it was quiet and ____.
Which word should we put in the blank to complete the story?
Let's use the word "

Collapsing token sets: None, all tokens are considered

Prompt 18 (MI: 2.530, Acc: 0.374):

P1: What word do you think fits best in the following story?
"I would speak to you privately," Bowen said, casting a glance around at the others milling about.

The worry in her eyes deepened, but she nodded hesitantly and awaited Bowen's directive.

He led her through the great hall, annoyance biting at him when he saw no place where people weren't congregated. He stepped outside the back of the keep, where, finally, he spied an area near the bathhouses, where it was quiet and ____.
P2: The word which fits best is "

Collapsing token sets: None, all tokens are considered

Prompt 19 (MI: 2.372, Acc: 0.364):

"I would speak to you privately," Bowen said, casting a glance around at the others milling about.

The worry in her eyes deepened, but she nodded hesitantly and awaited Bowen's directive.

He led her through the great hall, annoyance biting at him when he saw no place where people weren't congregated. He stepped outside the back of the keep, where, finally, he spied an area near the bathhouses, where it was quiet and ____.
Which word fills in the blank best?
The word that fills in the blank best is "

Collapsing token sets: None, all tokens are considered

Prompt 20 (MI: 2.860, Acc: 0.296):

Pick the best word to replace the blank.
Story: "I would speak to you privately," Bowen said, casting a glance around at the others milling about.

The worry in her eyes deepened, but she nodded hesitantly and awaited Bowen's directive.

He led her through the great hall, annoyance biting at him when he saw no place where people weren't congregated. He stepped outside the back of the keep, where, finally, he spied an area near the bathhouses, where it was quiet and ____.
Answer: "

Collapsing token sets: None, all tokens are considered

C.3 ROCStories

Prompt 1 (MI: 3.859, Acc: 0.538):

Fill in the blank for the following sentences.

"Marissa loved _____ pokemon go game. It is the biggest thing right now. She had done so much more walking since she started playing it. She walked all day and evening sometimes. She walked almost 10 miles in two days." -> "Marissa loved

Collapsing token sets: None, all tokens are considered

Prompt 3 (MI: 3.728, Acc: 0.420):

Poke GO!

Marissa loved

Collapsing token sets: None, all tokens are considered

Prompt 4 (MI: 3.670, Acc: 0.356):

Fill in the blank with the missing word or phrase to complete the sentence.

I like to eat _____ and jelly sandwiches.
Answer: peanut butter

Marissa loved _____ pokemon go game. It is the biggest thing right now. She had done so much more walking since she started playing it. She walked all day and evening sometimes. She walked almost 10 miles in two days.
Answer:

Collapsing token sets: None, all tokens are considered

Prompt 5 (MI: 3.904, Acc: 0.310):

Fill in the blank with the missing word or phrase.

Sentence: I like to eat _______ and jelly sandwiches.
Missing Word/Phrase: peanut butter

Sentence: Marissa loved _____ pokemon go game. It is the biggest thing right now. She had done so much more walking since she started playing it. She walked all day and evening sometimes. She walked almost 10 miles in two days.
Missing Word/Phrase:

Collapsing token sets: None, all tokens are considered

Prompt 6 (MI: 4.167, Acc: 0.298):

P1: I'm going to tell you a story, but leave a word out. Once I'm done telling the story, pick the word that best fits in the blank.
It was a cold night. The wind was _____ around the courtyard as I stepped out of the car and into the darkness.
P2: whistling
P1: I'm going to tell you a story, but leave a word out. Once I'm done telling the story, pick the word that best fits in the blank.
Marissa loved _____ pokemon go game. It is the biggest thing right now. She had done so much more walking since she started playing it. She walked all day and evening sometimes. She walked almost 10 miles in two days.
P2:

Collapsing token sets: None, all tokens are considered

Prompt 7 (MI: 4.066, Acc: 0.290):

P1: I'm going to tell you a story, but leave a word out. Once I'm done telling the story, pick the word that best fits in the blank.
I like to eat _____ and jelly sandwiches.
P2: peanut butter
P1: I'm going to tell you a story, but leave a word out. Once I'm done telling the story, pick the word that best fits in the blank.
Marissa loved _____ pokemon go game. It is the biggest thing right now. She had done so much more walking since she started playing it. She walked all day and evening sometimes. She walked almost 10 miles in two days.
P2:

Collapsing token sets: None, all tokens are considered

Prompt 8 (MI: 3.707, Acc: 0.258):

Guess the word in the blank to complete the story.
Story: Marissa loved _____ pokemon go game. It is the biggest thing right now. She had done so much more walking since she started playing it. She walked all day and evening sometimes. She walked almost 10 miles in two days.
Answer:

Collapsing token sets: None, all tokens are considered

Prompt 9 (MI: 3.644, Acc: 0.256):

Pick the best word to replace the blank.
Story: Marissa loved _____ pokemon go game. It is the biggest thing right now. She had done so much more walking since she started playing it. She walked all day and evening sometimes. She walked almost 10 miles in two days.
Answer:

Collapsing token sets: None, all tokens are considered

Prompt 10 (MI: 1.979, Acc: 0.222):

Marissa loved _____ pokemon go game. It is the biggest thing right now. She had done so much more walking since she started playing it. She walked all day and evening sometimes. She walked almost 10 miles in two days.
Fill in the blank with the missing word or phrase.
What is the missing word? The missing word is "

Collapsing token sets: None, all tokens are considered

Prompt 11 (MI: 3.199, Acc: 0.220):

Fill in the blank with the missing word or phrase.
Marissa loved _____ pokemon go game. It is the biggest thing right now. She had done so much more walking since she started playing it. She walked all day and evening sometimes. She walked almost 10 miles in two days.
Answer:

Collapsing token sets: None, all tokens are considered

Prompt 12 (MI: 2.013, Acc: 0.214):

Marissa loved _____ pokemon go game. It is the biggest thing right now. She had done so much more walking since she started playing it. She walked all day and evening sometimes. She walked almost 10 miles in two days.
Fill in the blank with the missing word or phrase to complete the sentence.
What is the missing word? The missing word is "

Collapsing token sets: None, all tokens are considered

Prompt 13 (MI: 3.116, Acc: 0.182):

Read the following sentences, and try to guess which word goes in the blank.
Marissa loved _____ pokemon go game. It is the biggest thing right now. She had done so much more walking since she started playing it. She walked all day and evening sometimes. She walked almost 10 miles in two days.
Answer:

Collapsing token sets: None, all tokens are considered

Prompt 14 (MI: 1.843, Acc: 0.158):

Marissa loved _____ pokemon go game. It is the biggest thing right now. She had done so much more walking since she started playing it. She walked all day and evening sometimes. She walked almost 10 miles in two days.

The missing word in the story should be: "

Collapsing token sets: None, all tokens are considered

Prompt 15 (MI: 2.681, Acc: 0.140):

P1: I'm going to tell you a story, but leave a word out. Once I'm done telling the story, pick the word that best fits in the blank.
Marissa loved _____ pokemon go game. It is the biggest thing right now. She had done so much more walking since she started playing it. She walked all day and evening sometimes. She walked almost 10 miles in two days.
P2: The word which fits best is "

Collapsing token sets: None, all tokens are considered

Prompt 16 (MI: 2.150, Acc: 0.120):

Marissa loved _____ pokemon go game. It is the biggest thing right now. She had done so much more walking since she started playing it. She walked all day and evening sometimes. She walked almost 10 miles in two days.
Which word should we put in the blank to complete the story?
Let's use the word "

Collapsing token sets: None, all tokens are considered

Prompt 17 (MI: 2.634, Acc: 0.088):

Marissa loved _____ pokemon go game. It is the biggest thing right now. She had done so much more walking since she started playing it. She walked all day and evening sometimes. She walked almost 10 miles in two days.
Which word fills in the blank best?
The word that fills in the blank best is "

Collapsing token sets: None, all tokens are considered

Prompt 18 (MI: 2.637, Acc: 0.086):

P1: What word do you think fits best in the following story?
Marissa loved _____ pokemon go game. It is the biggest thing right now. She had done so much more walking since she started playing it. She walked all day and evening sometimes. She walked almost 10 miles in two days.
P2: The word which fits best is "

Collapsing token sets: None, all tokens are considered

Prompt 19 (MI: 3.648, Acc: 0.050):

It was a cold night. The wind was _____ around the courtyard as I stepped out of the car and into the darkness.
Word: whistling

Marissa loved _____ pokemon go game. It is the biggest thing right now. She had done so much more walking since she started playing it. She walked all day and evening sometimes. She walked almost 10 miles in two days.
Put the best word in the blank to complete the story.
Word:

Collapsing token sets: None, all tokens are considered

Prompt 20 (MI: 1.891, Acc: 0.036):

Marissa loved _____ pokemon go game. It is the biggest thing right now. She had done so much more walking since she started playing it. She walked all day and evening sometimes. She walked almost 10 miles in two days.
Choose a word to replace the blank.
Word: "

Collapsing token sets: None, all tokens are considered

C.4 CoQA

Prompt 1 (MI: 0.600, Acc: 0.590):

Instructions: For each question below, choose the answer from the answer bank corresponding to the question that best answers the question.

Question 1 Answer Bank: ladybug, bunny, goldfish, leopard, caterpillarQuestion: What animal would be most dangerous for a human to encounter in the wild?

Answer: leopard

Question 2 Answer Bank: wrong, pleasure, encouragement, depression, relief

Question: If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?

Answer:

Collapsing token sets: {'A': ['wrong'], 'B': ['pleasure'], 'C': ['encouragement'], 'D': ['depression'], 'E': ['relief']}

Prompt 2 (MI: 0.233, Acc: 0.546):

Common Sense Quiz Answer Key

Question 1: Where would people not typically go for fun?
A: theme park
B: movie theatre
C: carnival
D: waste management facility
E: beach
Correct Answer: D

Question 2: If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?
A: wrong
B: pleasure
C: encouragement
D: depression
E: relief
Correct Answer:

Collapsing token sets: ['A', 'B', 'C', 'D', 'E']

Prompt 3 (MI: 0.474, Acc: 0.470):

Given the following questions and choices, pick the choice that corresponds best to the question.

"I'm crossing the river, my feet are wet but my body is dry, where am I?", "bridge, waterfall, valley, pebble, mountain", -> "valley"
"In what Spanish speaking North American country can you get a great cup of coffee?", "mexico, mildred's coffee shop, diner, kitchen, canteen", -> "mexico"
"If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?", "wrong, pleasure, encouragement, depression, relief" -> "

Collapsing token sets: {'A': ['wrong'], 'B': ['pleasure'], 'C': ['encouragement'], 'D': ['depression'], 'E': ['relief']}

Prompt 4 (MI: 0.083, Acc: 0.466):

What would you use to put out a fire?
A: gasoline
B: poison
C: laundry detergent
D: water
E: pencil
Answer: D. water

If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?
A: wrong
B: pleasure
C: encouragement
D: depression
E: relief
Answer:

Collapsing token sets: ['A', 'B', 'C', 'D', 'E']

Prompt 5 (MI: 0.504, Acc: 0.462):

multiple choice quiz questions and answers

qa = ['q': 'What is France?', 'choices': ['state', 'city', 'country', 'continent', 'mountain range'], 'answer': 'country',], '[q': 'If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?', 'choices': [wrong, pleasure, encouragement, depression, relief], 'answer': '

Collapsing token sets: {'A': ['wrong'], 'B': ['pleasure'], 'C': ['encouragement'], 'D': ['depression'], 'E': ['relief']}

Prompt 6 (MI: 0.431, Acc: 0.448):

Given the following questions and choices, pick the choice that corresponds best to the question.

"I'm crossing the river, my feet are wet but my body is dry, where am I?", "bridge, waterfall, valley, pebble, mountain", -> "valley"
"If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?", "wrong, pleasure, encouragement, depression, relief" -> "

Collapsing token sets: {'A': ['wrong'], 'B': ['pleasure'], 'C': ['encouragement'], 'D': ['depression'], 'E': ['relief']}

Prompt 7 (MI: 0.417, Acc: 0.428):

Choose the best single answer to the question, and explain your answer.

Question: I'm crossing the river, my feet are wet but my body is dry, where am I?
Choices: bridge, waterfall, valley, pebble, mountain
Answer: "valley" is the best answer. While "bridge" also seems to make sense at first, your feet would not be wet if you crossed over a river on a bridge. Meanwhile, if you crossed the river at a valley, the river would be shallow, only getting your feet wet.

Question: In what Spanish speaking North American country can you get a great cup of coffee?
Choices: mildred's coffee shop, mexico, diner, kitchen, canteen
Answer: "mexico" is the best answer. It's true that you can get a cup of coffee in a coffee shop or a diner, but the question specifically asks for a Spanish speaking North American country. Mexico is the only country listed, so that must be the correct answer.

Question: If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?
Choices: wrong, pleasure, encouragement, depression, relief
Answer: "

Collapsing token sets: {'A': ['wrong'], 'B': ['pleasure'], 'C': ['encouragement'], 'D': ['depression'], 'E': ['relief']}

Prompt 8 (MI: 0.364, Acc: 0.408):

Q: What might a vegan eat for breakfast?

Choices: oats, bacon, sausage, omelet, ham

A: oats

Q: If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?

Choices: wrong, pleasure, encouragement, depression, relief

A:

Collapsing token sets: {'A': ['wrong'], 'B': ['pleasure'], 'C': ['encouragement'], 'D': ['depression'], 'E': ['relief']}

Prompt 9 (MI: 0.410, Acc: 0.408):

What would you use to put out a fire?
A: gasoline
B: poison
C: laundry detergent
D: water
E: pencil
Answer: water

If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?
A: wrong
B: pleasure
C: encouragement
D: depression
E: relief
Answer:

Collapsing token sets: ['A', 'B', 'C', 'D', 'E']

Prompt 10 (MI: 0.363, Acc: 0.396):

Choose the best single answer to the question, and explain your answer.

Question: I'm crossing the river, my feet are wet but my body is dry, where am I?
Choices: bridge, waterfall, valley, pebble, mountain
Answer: "valley" is the best answer. While "bridge" also seems to make sense at first, your feet would not be wet if you crossed over a river on a bridge. Meanwhile, if you crossed the river at a valley, the river would be shallow, only getting your feet wet.

Question: If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?
Choices: wrong, pleasure, encouragement, depression, relief
Answer: "

Collapsing token sets: {'A': ['wrong'], 'B': ['pleasure'], 'C': ['encouragement'], 'D': ['depression'], 'E': ['relief']}

Prompt 11 (MI: 0.059, Acc: 0.380):

Common Sense Quiz Answer Key

Question 1: If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?

A: wrong
B: pleasure
C: encouragement
D: depression
E: relief

Correct Answer:

Collapsing token sets: ['A', 'B', 'C', 'D', 'E']

Prompt 12 (MI: 0.233, Acc: 0.360):

Given the question, order the options from best answer to the question to worst answer to the question.

Question: I'm crossing the river, my feet are wet but my body is dry, where am I?
Choices: bridge, waterfall, valley, pebble, mountain
Answers (in order of best to worst): valley, bridge, waterfall, mountain, pebble

Question: If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?
Choices: wrong, pleasure, encouragement, depression, relief
Answers (in order of best to worst):

Collapsing token sets: {'A': ['wrong'], 'B': ['pleasure'], 'C': ['encouragement'], 'D': ['depression'], 'E': ['relief']}

Prompt 13 (MI: 0.255, Acc: 0.360):

Given the question, order the options from best answer to the question to worst answer to the question.

Question: I'm crossing the river, my feet are wet but my body is dry, where am I?
Choices: bridge, waterfall, valley, pebble, mountain
Answers (in order of best to worst): valley, bridge, waterfall, mountain, pebble

Question: In what Spanish speaking North American country can you get a great cup of coffee?
Choices: mildred's coffee shop, mexico, diner, kitchen, canteen
Answers (in order of best to worst): mexico, mildred's coffee shop, diner, kitchen, canteen

Question: If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?
Choices: wrong, pleasure, encouragement, depression, relief
Answers (in order of best to worst):

Collapsing token sets: {'A': ['wrong'], 'B': ['pleasure'], 'C': ['encouragement'], 'D': ['depression'], 'E': ['relief']}

Prompt 14 (MI: 0.222, Acc: 0.354):

Q: If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?

Choices: wrong, pleasure, encouragement, depression, relief

A:

Collapsing token sets: {'A': ['wrong'], 'B': ['pleasure'], 'C': ['encouragement'], 'D': ['depression'], 'E': ['relief']}

Prompt 15 (MI: 0.246, Acc: 0.342):

Teacher: I'm going to ask you a common sense question.

Student: Alright.

Teacher: If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?

Student: What are the possible answers?

Teacher: The answer is either "wrong," "pleasure," "encouragement," "depression," or "relief."

Student: I know the right answer - it's "

Collapsing token sets: {'A': ['wrong'], 'B': ['pleasure'], 'C': ['encouragement'], 'D': ['depression'], 'E': ['relief']}

Prompt 16 (MI: 0.376, Acc: 0.336):

questions,choices,answers
"What is France?","[state,city,country,continent,mountain range]",country
"If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?","[wrong,pleasure,encouragement,depression,relief]",

Collapsing token sets: {'A': ['wrong'], 'B': ['pleasure'], 'C': ['encouragement'], 'D': ['depression'], 'E': ['relief']}

Prompt 17 (MI: 0.265, Acc: 0.276):

Me: I watched the most recent episode of the "Is It Really Common Sense" game show yesterday night.
Friend: Oh, how was it?
Me: It was good. I remember one of the questions.
Friend: What was the question?
Me: If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?
Friend: What were the options?
Me: wrong, pleasure, encouragement, depression, or relief
Friend: Did the contestant get the answer right?
Me: Yep!
Friend: Which of the options was correct?
Me: The correct answer was

Collapsing token sets: {'A': ['wrong'], 'B': ['pleasure'], 'C': ['encouragement'], 'D': ['depression'], 'E': ['relief']}

Prompt 18 (MI: 0.197, Acc: 0.248):

Given the question, order the options from best answer to the question to worst answer to the question.

Question: If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?
Choices: wrong, pleasure, encouragement, depression, relief
Answers (in order of best to worst):

Collapsing token sets: {'A': ['wrong'], 'B': ['pleasure'], 'C': ['encouragement'], 'D': ['depression'], 'E': ['relief']}

Prompt 19 (MI: 0.013, Acc: 0.234):

If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?

A: wrong
B: pleasure
C: encouragement
D: depression
E: relief

Answer:

Collapsing token sets: ['A', 'B', 'C', 'D', 'E']

Prompt 20 (MI: 0.241, Acc: 0.228):

Teacher: I'm going to ask you a common sense question.

Student: Alright.

Teacher: What would you not expect to read about in a book on the founding of the United States?

Student: What are the possible answers?

Teacher: The answer is either "george washington," "declaration of independence," "boston tea party," "star spangled banner," or "vampire assassins."

Student: I know the right answer - it's "vampire assassins."

Teacher: That's right! Here's another common sense question for you. If you're still in love and end up stopping being married to your partner, what emotion are you likely to experience?

Student: What are the possible answers?

Teacher: The answer is either "wrong," "pleasure," "encouragement," "depression," or "relief."

Student: I know the right answer - it's "

Collapsing token sets: {'A': ['wrong'], 'B': ['pleasure'], 'C': ['encouragement'], 'D': ['depression'], 'E': ['relief']}

C.5 IMDB

Prompt 1 (MI: 0.175, Acc: 0.944):

P1: How was the movie?
P2: John Cassavetes is on the run from the law. He is at the bottom of the heap. He sees Negro Sidney Poitier as his equal and they quickly become friends, forming a sort of alliance against a bully of a foreman played by Jack Warden.

As someone who has worked in a warehouse myself when I was younger, I can tell you that the warehouse fights, complete with tumbling packing cases and flailing grappling hooks are as realistic as it gets. I've been in fights like these myself, although no one got killed.

The introduction of Sidney Poitier's widow is a variation on Shakespeare's Shylock "Do I not bleed?" This is an anti racist film, which, at the time, was much needed.

All the three principle characters - Warden, Cassavetes and Poitier - are superb, with Warden the most outstanding of the three.
P1: Would you say your review of the movie is negative or positive?
P2: I would say my review review of the movie is

Collapsing token sets: {'positive': ['positive'], 'negative': ['negative']}

Prompt 2 (MI: 0.306, Acc: 0.920):

P1: Could you give me a review of the movie you just saw?
P2: Sure, John Cassavetes is on the run from the law. He is at the bottom of the heap. He sees Negro Sidney Poitier as his equal and they quickly become friends, forming a sort of alliance against a bully of a foreman played by Jack Warden.

As someone who has worked in a warehouse myself when I was younger, I can tell you that the warehouse fights, complete with tumbling packing cases and flailing grappling hooks are as realistic as it gets. I've been in fights like these myself, although no one got killed.

The introduction of Sidney Poitier's widow is a variation on Shakespeare's Shylock "Do I not bleed?" This is an anti racist film, which, at the time, was much needed.

All the three principle characters - Warden, Cassavetes and Poitier - are superb, with Warden the most outstanding of the three.
P1: So, overall, would you give it a positive or negative review?
P2: I would give it a

Collapsing token sets: {'positive': ['positive'], 'negative': ['negative']}

Prompt 3 (MI: 0.154, Acc: 0.904):

Considering this movie review, determine its sentiment.

Review: John Cassavetes is on the run from the law. He is at the bottom of the heap. He sees Negro Sidney Poitier as his equal and they quickly become friends, forming a sort of alliance against a bully of a foreman played by Jack Warden.

As someone who has worked in a warehouse myself when I was younger, I can tell you that the warehouse fights, complete with tumbling packing cases and flailing grappling hooks are as realistic as it gets. I've been in fights like these myself, although no one got killed.

The introduction of Sidney Poitier's widow is a variation on Shakespeare's Shylock "Do I not bleed?" This is an anti racist film, which, at the time, was much needed.

All the three principle characters - Warden, Cassavetes and Poitier - are superb, with Warden the most outstanding of the three.

Pyruvic acid – Pyruvic acid (CHCOCOOH) is the simplest of the alpha-keto acids, with a carboxylic acid and a ketone functional group. Pyruvate (/paruvet/), the conjugate base, CHCOCOO, is a key intermediate in several metabolic pathways.

Is pyruvic acid and pyruvate the same thing?
Answer: "

Collapsing token sets: {'True': ['yes'], 'False': ['no']}

Prompt 14 (MI: 0.050, Acc: 0.668):

Read the following passage: "Pyruvic acid – Pyruvic acid (CHCOCOOH) is the simplest of the alpha-keto acids, with a carboxylic acid and a ketone functional group. Pyruvate (/paruvet/), the conjugate base, CHCOCOO, is a key intermediate in several metabolic pathways."

Given this question: "Is pyruvic acid and pyruvate the same thing?"
I would answer: "

Collapsing token sets: {'True': ['yes'], 'False': ['no']}

Prompt 15 (MI: 0.058, Acc: 0.646):

Read the following passage: "Pyruvic acid – Pyruvic acid (CHCOCOOH) is the simplest of the alpha-keto acids, with a carboxylic acid and a ketone functional group. Pyruvate (/paruvet/), the conjugate base, CHCOCOO, is a key intermediate in several metabolic pathways."

Given this question: "Is pyruvic acid and pyruvate the same thing?"
I would respond: "

Collapsing token sets: {'True': ['yes'], 'False': ['no']}

Prompt 16 (MI: 0.027, Acc: 0.634):

Based on the passage: "Pyruvic acid – Pyruvic acid (CHCOCOOH) is the simplest of the alpha-keto acids, with a carboxylic acid and a ketone functional group. Pyruvate (/paruvet/), the conjugate base, CHCOCOO, is a key intermediate in several metabolic pathways."

And answering the question: "Is pyruvic acid and pyruvate the same thing?"
By choosing yes or no
My answer would be: "

Collapsing token sets: {'True': ['yes'], 'False': ['no']}

Prompt 17 (MI: 0.013, Acc: 0.522):

Read the following passage: "Pyruvic acid – Pyruvic acid (CHCOCOOH) is the simplest of the alpha-keto acids, with a carboxylic acid and a ketone functional group. Pyruvate (/paruvet/), the conjugate base, CHCOCOO, is a key intermediate in several metabolic pathways.

Given this question: "Is pyruvic acid and pyruvate the same thing?"

If asked to choose "true" or "false", My answer would be: "

Collapsing token sets: {'True': ['true'], 'False': ['false']}

Prompt 18 (MI: 0.020, Acc: 0.518):

Read the following passage: "Pyruvic acid – Pyruvic acid (CHCOCOOH) is the simplest of the alpha-keto acids, with a carboxylic acid and a ketone functional group. Pyruvate (/paruvet/), the conjugate base, CHCOCOO, is a key intermediate in several metabolic pathways."

Given this question: "Is pyruvic acid and pyruvate the same thing?"
If asked to choose yes or no, My answer would be: "

Collapsing token sets: {'True': ['yes'], 'False': ['no']}

Prompt 19 (MI: 0.013, Acc: 0.452):

Read the following passage: "Pyruvic acid – Pyruvic acid (CHCOCOOH) is the simplest of the alpha-keto acids, with a carboxylic acid and a ketone functional group. Pyruvate (/paruvet/), the conjugate base, CHCOCOO, is a key intermediate in several metabolic pathways."

Given this question: "Is pyruvic acid and pyruvate the same thing?"
If asked to choose "true" or "false", I would answer: "

Collapsing token sets: {'True': ['true'], 'False': ['false']}

Prompt 20 (MI: 0.022, Acc: 0.438):

Read the following passage: "Pyruvic acid – Pyruvic acid (CHCOCOOH) is the simplest of the alpha-keto acids, with a carboxylic acid and a ketone functional group. Pyruvate (/paruvet/), the conjugate base, CHCOCOO, is a key intermediate in several metabolic pathways."

Given this question: "Is pyruvic acid and pyruvate the same thing?"
If asked to choose yes or no, I would answer: "

Collapsing token sets: {'True': ['yes'], 'False': ['no']}

C.7 COPA

Prompt 1 (MI: 0.044, Acc: 0.782):

For the following premises, choose the alternative that is either a cause or result of the premise, and justify your answer.

Premise: The man broke his toe. What was the CAUSE of this?
Alternative 1: He got a hole in his sock.
Alternative 2: He dropped a hammer on his foot.
Answer: Alternative 2. Getting a hole in your sock would not break your toe, unless there is additional information. Dropping a hammer (which is a heavy object), on the other hand, would almost certainly break your toe. Thus, the best answer is Alternative 2.

Premise: I tipped the bottle. What happened as a RESULT?
Alternative 1: The liquid in the bottle froze.
Alternative 2: The liquid in the bottle poured out.
Answer: Alternative 2. Tipping a bottle causes liquid to fall out, not to freeze. Freezing is caused by being placed in a cold place. Pouring out (Alternative 2) is correct because it makes the most sense.

Premise: I knocked on my neighbor’s door. What happened as a RESULT?
Alternative 1: My neighbor invited me in.
Alternative 2: My neighbor left his house.
Answer: Alternative 1. When you knock on a neighbor’s door, it is likely that if they are home they will answer and invite you in. It does not make much sense, however, that a neighbor would leave their house without explanation. Therefore, Alternative 1 is the best result of the premise.

Premise: My foot went numb. What happened as a RESULT?
Alternative 1: I put my shoes on.
Alternative 2: I shook my foot.
Answer: Alternative

Collapsing token sets: {’1’: [’1’], ’2’: [’2’]}

Prompt 2 (MI: 0.034, Acc: 0.762):

The Choice Of Plausible Alternatives (COPA) evaluation provides researchers with a tool for assessing progress in open-domain commonsense causal reasoning. COPA consists of 1000 questions, split equally into development and test sets of 500 questions each. Each question is composed of a premise and two alternatives, where the task is to select the alternative that more plausibly has a causal relation with the premise. The correct alternative is randomized so that the expected performance of randomly guessing is 50%.

Examples

Premise: The man broke his toe. What was the CAUSE of this?
Alternative 1: He got a hole in his sock.
Alternative 2: He dropped a hammer on his foot.
Answer: Alternative 2

Premise: I tipped the bottle. What happened as a RESULT?
Alternative 1: The liquid in the bottle froze.
Alternative 2: The liquid in the bottle poured out.
Answer: Alternative 2

Premise: I knocked on my neighbor’s door. What happened as a RESULT?
Alternative 1: My neighbor invited me in.
Alternative 2: My neighbor left his house.
Answer: Alternative 1

Premise: My foot went numb. What happened as a RESULT?
Alternative 1: I put my shoes on.
Alternative 2: I shook my foot.
Answer: Alternative

Collapsing token sets: {’1’: [’1’], ’2’: [’2’]}

Prompt 3 (MI: 0.003, Acc: 0.628):

What is the effect of the following premise: "My foot went numb."

Choice 1. I put my shoes on.
Choice 2. I shook my foot.
Answer: Choice

Collapsing token sets: {’1’: [’1’], ’2’: [’2’]}

Prompt 4 (MI: 0.002, Acc: 0.612):

Solve the following COPA task by choosing the sentence which makes the most sense after the premise.

Premise: My foot went numb.
Choice 1. I put my shoes on.
Choice 2. I shook my foot.
Answer: Choice

Collapsing token sets: {’1’: [’1’], ’2’: [’2’]}

Prompt 5 (MI: 0.003, Acc: 0.550):

If asked to pick between choice 1 ("I put my shoes on.") or choice 2 ("I shook my foot.") to see what the effect of this premise ("My foot went numb.") was, I would say: "choice

Collapsing token sets: {’1’: [’1’], ’2’: [’2’]}

Prompt 6 (MI: 0.010, Acc: 0.540):

Solve the following COPA tasks by choosing the sentence which makes the most sense after the premise.

Premise: The man broke his toe.
Choice 1. He got a hole in his sock.
Choice 2. He dropped a hammer on his foot.
Answer: Choice 2.

Premise: My foot went numb.
Choice 1. I put my shoes on.
Choice 2. I shook my foot.
Answer: Choice

Collapsing token sets: {’1’: [’1’], ’2’: [’2’]}

Prompt 7 (MI: 0.002, Acc: 0.532):

What is the effect of the following premise: "My foot went numb."

If asked to choose between Choice 1: "I put my shoes on." or Choice 2: "I shook my foot."
My answer would be: Choice

Collapsing token sets: {’1’: [’1’], ’2’: [’2’]}

Prompt 8 (MI: 0.006, Acc: 0.530):

I will give you a premise and you will choose either sentence 1) or 2) which is the better plausible alternative.
Premise: My foot went numb.
1) I put my shoes on.
2) I shook my foot.
The most plausible alternative is: Sentence

Collapsing token sets: {’1’: [’1’], ’2’: [’2’]}

Prompt 9 (MI: 0.018, Acc: 0.524):

Read the following premise and answer by choosing "effect1" or "effect2"
Premise: "My foot went numb."
effect1: "I put my shoes on."
effect2: "I shook my foot."
Answer: "effect

Collapsing token sets: {’1’: [’1’], ’2’: [’2’]}

Prompt 10 (MI: 0.008, Acc: 0.520):

Read the following premise and pick "effect2" or "effect1"
Premise: "My foot went numb."
effect1: "I put my shoes on."
effect2: "I shook my foot."
Answer: "effect

Collapsing token sets: {'1': ['1'], '2': ['2']}

Prompt 11 (MI: 0.003, Acc: 0.516):

Based on this premise: "My foot went numb."

If asked to choose between
Choice 1: "I put my shoes on."
or
Choice 2: "I shook my foot."
My answer would be: Choice

Collapsing token sets: {'1': ['1'], '2': ['2']}

Prompt 12 (MI: 0.008, Acc: 0.510):

Which one of these stories makes the most sense?
Story 1: My foot went numb. I put my shoes on.
Story 2: My foot went numb. I shook my foot.
Answer: Story

Collapsing token sets: {'1': ['1'], '2': ['2']}

Prompt 13 (MI: 0.003, Acc: 0.506):

P1: Here's a premise: "The man broke his toe."
Which sentence provides the better alternative?
1. "He got a hole in his sock", or
2. "He dropped a hammer on his foot."
P2: The better alternative is sentence

P1: Here's a premise: "My foot went numb.".Which sentence provides the better alternative? 1. "I put my shoes on", or 2. "I shook my foot."P2: The better alternative is sentence

Collapsing token sets: {'1': ['1'], '2': ['2']}

Prompt 14 (MI: 0.003, Acc: 0.504):

Based on this premise: "My foot went numb."

If asked to pick between
Choice 1: "I put my shoes on." or Choice 2: "I shook my foot." to get the effect
of the predeciding sentence, I would say: "Choice

Collapsing token sets: {'1': ['1'], '2': ['2']}

Prompt 15 (MI: 0.036, Acc: 0.502):

I am going to tell you two stories, one of them will make sense and the other will not.
Story 1: My foot went numb. I put my shoes on.
Story 2: My foot went numb. I shook my foot.
The story that makes sense is Story

Collapsing token sets: {'1': ['1'], '2': ['2']}

Prompt 16 (MI: 0.009, Acc: 0.502):

My foot went numb.
Which of the following alternatives is most plausible for the previous sentence?
Sentence 1) I put my shoes on.
Sentence 2) I shook my foot.
The most plausible alternative is sentence

Collapsing token sets: {'1': ['1'], '2': ['2']}

Prompt 17 (MI: 0.006, Acc: 0.500):

I will give you a premise and you will choose either sentence 1) or 2) which is the better plausible alternative.

Premise: The man broke his toe.
1) He got a hole in his sock.
2) He dropped a hammer on his foot.
The most plausible alternative is: Sentence 2).

I will give you a premise and you will choose either sentence 1) or 2) which is the better plausible alternative.
Premise: My foot went numb.
1) I put my shoes on.
2) I shook my foot.
The most plausible alternative is: Sentence

Collapsing token sets: {'1': ['1'], '2': ['2']}

Prompt 18 (MI: 0.003, Acc: 0.500):

P1: Here's a premise: My foot went numb..Which sentence provides the better alternative? 1. "I put my shoes on", or 2. "I shook my foot."P2: The better alternative is sentence

Collapsing token sets: {'1': ['1'], '2': ['2']}

Prompt 19 (MI: 0.019, Acc: 0.500):

"The man broke his toe."
Which of the following alternatives is most plausible for the previous sentence?

Sentence 1) He got a hole in his sock.
Sentence 2) He dropped a hammer on his foot.
The most plausible alternative is sentence 2).
"My foot went numb."
Which of the following alternatives is most plausible for the previous sentence?
Sentence 1) I put my shoes on.
Sentence 2) I shook my foot.
The most plausible alternative is sentence

Collapsing token sets: {'1': ['1'], '2': ['2']}

Prompt 20 (MI: 0.001, Acc: 0.496):

I want to figure out which effect of this sentence is more probably: "My foot went numb."
Choice 1: "I put my shoes on." or Choice 2: "I shook my foot."
I would say: "Choice

Collapsing token sets: {'1': ['1'], '2': ['2']}

C.8 WiC

Prompt 1 (MI: 0.036, Acc: 0.520):

Classify whether the following two sentences' use of the word has the same meaning or not.

Word: bright
Usage 1: He is a bright child
Usage 2: The sun is very bright today
Meaning: different

Word: didacticism
Usage 1: The didacticism of the 19th century gave birth to many great museums.
Usage 2: The didacticism expected in books for the young.
Meaning:

Collapsing token sets: {'True': ['same'], 'False': ['different']}

Prompt 2 (MI: 0.006, Acc: 0.512):

"The didacticism of the 19th century gave birth to many great museums."
"The didacticism expected in books for the young."

True or false, the word didacticism has the same meaning.
Answer:

Collapsing token sets: {'True': ['true'], 'False': ['false']}

Prompt 3 (MI: 0.025, Acc: 0.506):

Depending on its context, an ambiguous word can refer to multiple, potentially unrelated, meanings. Mainstream static word embeddings, such as Word2vec and GloVe, are unable to reflect this dynamic semantic nature. Contextualised word embeddings are an attempt at addressing this limitation by computing dynamic representations for words which can adapt based on context. A system's task on the WiC dataset is to identify the intended meaning of words. WiC is framed as a binary classification task. Each instance in WiC has a target word w, either a verb or a noun, for which two contexts are provided. Each of these contexts triggers a specific meaning of w. The task is to identify if the occurrences of w in the two contexts correspond to the same meaning or not. In fact, the dataset can also be viewed as an application of Word Sense Disambiguation in practise.
WiC features multiple interesting characteristics:

It is suitable for evaluating a wide range of applications, including contextualized word and sense representation and Word Sense Disambiguation;
It is framed asa binary classification dataset, in which, unlike Stanford Contextual Word Similarity (SCWS), identical words are paired with each other (in different contexts); hence, a context-insensitive word embedding model would perform similarly to a random baseline;
It is constructed using high quality annotations curated by experts.

Examples from the dataset:
Context-1 // Context-2 // Target // Label
There's a lot of trash on the bed of the river // I keep a glass of water on my bed when I sleep // bed // Different
Air pollution // Open a window and let in some air // air // Same
The didacticism of the 19th century gave birth to many great museums. // The didacticism expected in books for the young. // didacticism //

Collapsing token sets: {'True': ['same'], 'False': ['different']}

Prompt 4 (MI: 0.007, Acc: 0.504):

"The didacticism of the 19th century gave birth to many great museums."
"The didacticism expected in books for the young."

True or False, the word "didacticism" has the same meaning.
Answer:

Collapsing token sets: {'True': ['true'], 'False': ['false']}

Prompt 5 (MI: 0.006, Acc: 0.504):

Q: What does 2 + 2 equal?
A: 4

Q: Does the word "didacticism" have the same meaning in the following sentences? "The didacticism of the 19th century gave birth to many great museums."; "The didacticism expected in books for the young."
A:

Collapsing token sets: {'True': ['yes'], 'False': ['no']}

Prompt 6 (MI: 0.007, Acc: 0.496):

Q: What year did America first land on the moon?
A: 1969

Q: Does the word "didacticism" have the same meaning in the following sentences? "The didacticism of the 19th century gave birth to many great museums."; "The didacticism expected in books for the young."
A:

Collapsing token sets: {'True': ['yes'], 'False': ['no']}

Prompt 7 (MI: 0.004, Acc: 0.496):

I am going to answer true or false questions about whether a word that appears in two sentences has the same meaning or not.

True or False, the word "didacticism" has the same meaning in the following sentences.

Sentence 1: The didacticism of the 19th century gave birth to many great museums.
Sentence 2: The didacticism expected in books for the young.
Answer:

Collapsing token sets: {'True': ['true'], 'False': ['false']}

Prompt 8 (MI: 0.006, Acc: 0.494):

Classify whether the following two sentences' use of the word has the same meaning or not.

Word: bright
Usage 1: He is a bright child
Usage 2: The sun is very bright today
Meaning: different

Word: air
Usage 1: Utah has too much air pollution.
Usage 2: Open a window and let in some air.
Meaning: same

Word: cool
Usage 1: Her pants are cool.
Usage 2: Let your food cool.
Meaning: different

Word: didacticism
Usage 1: The didacticism of the 19th century gave birth to many great museums.
Usage 2: The didacticism expected in books for the young.
Meaning:

Collapsing token sets: {'True': ['same'], 'False': ['different']}

Prompt 9 (MI: 0.007, Acc: 0.494):

Q: What does 2 + 2 equal?
A: 4

Q: If you are 60 inches tall how tall are you in feet?
A: 5 feet

Q: Does the word "didacticism" have the same meaning in the following sentences? "The didacticism of the 19th century gave birth to many great museums."; "The didacticism expected in books for the young."
A:

Collapsing token sets: {'True': ['yes'], 'False': ['no']}

Prompt 10 (MI: 0.004, Acc: 0.494):

True or False, the word "didacticism" has the same meaning in the following sentences.

Sentence 1: "The didacticism of the 19th century gave birth to many great museums."
Sentence 2: "The didacticism expected in books for the young."

Answer:

Collapsing token sets: {'True': ['true'], 'False': ['false']}

Prompt 11 (MI: 0.009, Acc: 0.494):

In the sentences "The didacticism of the 19th century gave birth to many great museums." and "The didacticism expected in books for the young.", true or false, the statement "the word didacticism has the same meaning" is

Collapsing token sets: {'True': ['true'], 'False': ['false']}

Prompt 12 (MI: 0.008, Acc: 0.492):

Q: What year did America first land on the moon?
A: 1969

Q: What is the average height in America?
A: 5 feet 9 inches

Q: Does the word "didacticism" have the same meaning in the following sentences? "The didacticism of the 19th century gave birth to many great museums."; "The didacticism expected in books for the young."
A:

Collapsing token sets: {'True': ['yes'], 'False': ['no']}

Prompt 13 (MI: 0.017, Acc: 0.492):

"The didacticism of the 19th century gave birth to many great museums."
"The didacticism expected in books for the young."

"True" or "False", the word didacticism has the same meaning.
Answer: "

Collapsing token sets: {'True': ['true'], 'False': ['false']}

Prompt 14 (MI: 0.017, Acc: 0.488):

The didacticism of the 19th century gave birth to many great museums. // The didacticism expected in books for the young.
Choose "yes" or "no". Does the word didacticism have the same meaning in the previous sentences? "

Collapsing token sets: {'True': ['yes'], 'False': ['no']}

Prompt 15 (MI: 0.008, Acc: 0.488):

In the sentences "The didacticism of the 19th century gave birth to many great museums." and "The didacticism expected in books for the young." and choosing "true" or "false", the statement "the word didacticism has the same meaning" is "

Collapsing token sets: {'True': ['true'], 'False': ['false']}

Prompt 16 (MI: 0.031, Acc: 0.486):

In linguistics, a word sense is one of the meanings of a word. Words are in two sets: a large set with multiple meanings (word senses) and a small set with only one meaning (word sense). For example, a dictionary may have over 50 different senses of the word "play", each of these having a different meaning based on the context of the word's usage in a sentence, as follows:

"We went to see the play Romeo and Juliet at the theater."
"The coach devised a great play that put the visiting team on the defensive."
"The children went out to play in the park."
In each sentence we associate a different meaning of the word "play" based on hints the rest of the sentence gives us.

People and computers, as they read words, must use a process called word-sense disambiguation[1][2] to find the correct meaning of a word. This process uses context to narrow the possible senses down to the probable ones. The context includes such things as the ideas conveyed by adjacent words and nearby phrases, the known or probable purpose and register of the conversation or document, and the orientation (time and place) implied or expressed. The disambiguation is thus context-sensitive.

Advanced semantic analysis has resulted in a sub-distinction. A word sense corresponds either neatly to a seme (the smallest possible unit of meaning) or a sememe (larger unit of meaning), and polysemy of a word of phrase is the property of having multiple semes or sememes and thus multiple senses.

The following are examples of two sentences where the meaning of the word is either the same or different.

Examples:
There's a lot of trash on the bed of the river // I keep a glass of water on my bed when I sleep // bed // Different
Air pollution // Open a window and let in some air // air // Same
The didacticism of the 19th century gave birth to many great museums. // The didacticism expected in books for the young. // didacticism //

Collapsing token sets: {'True': ['same'], 'False': ['different']}

Prompt 17 (MI: 0.007, Acc: 0.466):

Classify whether the following two sentences' use of the word has the same meaning or not.

Word: bright
Usage 1: He is a bright child
Usage 2: The sun is very bright today
Meaning: different

Word: air
Usage 1: Utah has too much air pollution.
Usage 2: Open a window and let in some air.
Meaning: same

Word: cool
Usage 1: Her pants are cool.
Usage 2: Let your food cool.
Meaning: different

Word: fight
Usage 1: My wife and I had a fight.
Usage 2: I fight for my freedom.
Meaning: same

Word: didacticism
Usage 1: The didacticism of the 19th century gave birth to many great museums.
Usage 2: The didacticism expected in books for the young.
Meaning:

Collapsing token sets: {'True': ['same'], 'False': ['different']}

Prompt 18 (MI: 0.010, Acc: 0.460):

Classify whether the following two sentences' use of the word has the same meaning or not.

Word: bright
Usage 1: He is a bright child
Usage 2: The sun is very bright today
Meaning: different

Word: air
Usage 1: Utah has too much air pollution.
Usage 2: Open a window and let in some air.
Meaning: same

Word: didacticism
Usage 1: The didacticism of the 19th century gave birth to many great museums.
Usage 2: The didacticism expected in books for the young.
Meaning:

Collapsing token sets: {'True': ['same'], 'False': ['different']}

Prompt 19 (MI: 0.007, Acc: 0.460):

Q: Is the United States in South America?
A: No

Q: Does the word "didacticism" have the same meaning in the following sentences? "The didacticism of the 19th century gave birth to many great museums."; "The didacticism expected in books for the young."
A:

Collapsing token sets: {'True': ['yes'], 'False': ['no']}

Prompt 20 (MI: 0.004, Acc: 0.440):

Q: Is the United States in South America?
A: No

Q: Is the following sentence missing a comma? Before leaving I ate breakfast.
A: Yes

Q: Does the word "didacticism" have the same meaning in the following sentences? "The didacticism of the 19th century gave birth to many great museums."; "The didacticism expected in books for the young."
A:

Collapsing token sets: {'True': ['yes'], 'False': ['no']}

Expanding Pretrained Models to Thousands More Languages via Lexicon-based Adaptation

Xinyi Wang[1] **Sebastian Ruder**[2] **Graham Neubig**[1]
[1]Language Technology Institute, Carnegie Mellon University
[2]Google Research
xinyiw1@cs.cmu.edu, ruder@google.com, gneubig@cs.cmu.edu

Abstract

The performance of multilingual pretrained models is highly dependent on the availability of monolingual or parallel text present in a target language. Thus, the majority of the world's languages cannot benefit from recent progress in NLP as they have no or limited textual data. To expand possibilities of using NLP technology in these under-represented languages, we systematically study strategies that relax the reliance on conventional language resources through the use of bilingual lexicons, an alternative resource with much better language coverage. We analyze different strategies to synthesize textual or labeled data using lexicons, and how this data can be combined with monolingual or parallel text when available. For 19 under-represented languages across 3 tasks, our methods lead to consistent improvements of up to 5 and 15 points with and without extra monolingual text respectively. Overall, our study highlights how NLP methods can be adapted to thousands more languages that are under-served by current technology.[1]

1 Introduction

Multilingual pretrained models (Devlin et al., 2019; Conneau and Lample, 2019; Conneau et al., 2020) have become an essential method for cross-lingual transfer on a variety of NLP tasks (Pires et al., 2019; Wu and Dredze, 2019). These models can be finetuned on annotated data of a down-stream task in a high-resource language, often English, and then the resulting model is applied to other languages. This paradigm is supposed to benefit under-represented languages that do not have annotated data. However, recent studies have found that the cross-lingual transfer performance of a language is highly contingent on the availability of monolingual data in the language during pretraining (Hu et al., 2020). Languages with more monolingual data tend to have better performance while languages not present during pretraining significantly lag behind.

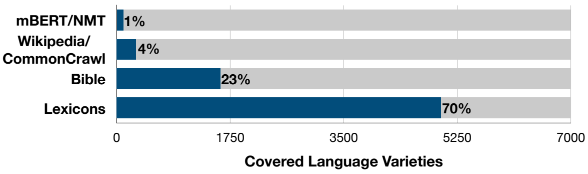

Figure 1: The percentage of the world's ≈7,000 languages covered by mBERT, monolingual data sources and lexicons.

Several works propose methods to adapt the pretrained multilingual models to low-resource languages, but these generally involve continued training using monolingual text from these languages (Wang et al., 2020; Chau et al., 2020; Pfeiffer et al., 2020, 2021). Therefore, the performance of these methods is still constrained by the amount of monolingual or parallel text available, making it difficult for languages with little or no textual data to benefit from the progress in pretrained models. Joshi et al. (2020) indeed argue that unsupervised pretraining makes the 'resource-poor poorer'.

Fig. 1 plots the language coverage of multilingual BERT (mBERT; Devlin et al., 2019), a widely used pre-trained model, and several commonly used textual data sources.[2] Among the 7,000 languages in the world, mBERT only covers about 1% of the languages while Wikipedia and CommonCrawl, the two most common resources used for pretraining and adaptation, only contain textual data from 4% of the languages (often in quite small quantities, partially because language IDs are difficult to obtain for low-resource languages (Caswell et al., 2020)). Ebrahimi and Kann (2021) show that continued pretraining of multilingual models on a small amount of Bible data can significantly improve the performance of uncovered languages. Although the Bible has much better language coverage of 23%, its relatively small data size and

Volume 1: Long Papers, pages 863 - 877
May 22-27, 2022

constrained domain limits its utility (see § 6)—and 70% of the world's languages do not even have this resource. The failure of technology to adapt to these situations raises grave concerns regarding the fairness of allocation of any benefit that may be conferred by NLP to speakers of these languages (Joshi et al., 2020; Blasi et al., 2021). On the other hand, linguists have been studying and documenting under-represented languages for years in a variety of formats (Gippert et al., 2006). Among these, bilingual lexicons or word lists are usually one of the first products of language documentation, and thus have much better coverage of the worlds' languages than easily accessible monolingual text, as shown in Fig. 1. There are also ongoing efforts to create these word lists for even more languages through methodologies such as "rapid word collection" (Boerger, 2017), which can create an extensive lexicon for a new language in a number of days. As Bird (2020) notes:

> After centuries of colonisation, missionary endeavours, and linguistic fieldwork, all languages have been identified and classified. There is always a wordlist. . . . In short, we do not need to "discover" the language ex nihilo (L1 acquisition) but to leverage the available resources (L2 acquisition).

However, there are few efforts on understanding the best strategy to utilize this valuable resource for adapting pretrained language models. Bilingual lexicons have been used to synthesize bilingual data for learning cross-lingual word embeddings (Gouws and Søgaard, 2015; Ruder et al., 2019) and task data for NER via word-to-word translation (Mayhew et al., 2017), but both approaches precede the adoption of pre-trained multilingual LMs. Khemchandani et al. (2021) use lexicons to synthesize monolingual data for adapting LMs, but their experimentation is limited to several Indian languages and no attempt was made to synthesize downstream task data while Hu et al. (2021) argue that bilingual lexicons may hurt performance.

In this paper, we conduct a systematic study of strategies to leverage this relatively under-studied resource of bilingual lexicons to adapt pretrained multilingual models to languages with little or no monolingual data. Utilizing lexicons from an open-source database, we create synthetic data for both continued pretraining and downstream task fine-tuning via word-to-word translation. Empirical results on 19 under-represented languages on 3 different tasks demonstrate that using synthetic data leads to significant improvements on all tasks (Fig. 2), and that the best strategy depends on the availability of monolingual data (§ 5, § 6). We further investigate methods that improve the quality of the synthetic data through a small amount of parallel data or by model distillation.

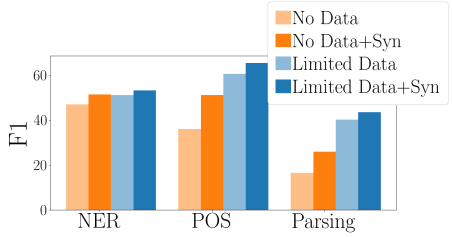

Figure 2: Results for baselines and adaptation using synthetic data for both resource settings across three NLP tasks.

2 Background

We focus on the cross-lingual transfer setting where the goal is to maximize performance on a downstream task in a target language T. Due to the frequent unavailability of labeled data in the target language, a pretrained multilingual model M is typically fine-tuned on labeled data in the downstream task $\mathcal{D}_{label}^{S} = \{(x_i^S, y_i^S)\}_{i=1}^{N}$ in a source language S where x_i^S is a textual input, y_i^S is the label, and N is the number of labeled examples. The fine-tuned model is then directly applied to task data $\mathcal{D}_{test}^{T} = \{x_i^T, y_i^T\}_i$ in language T at test time.[3] The performance on the target language T can often be improved by further adaptation of the pretrained model.

2.1 Adaptation with Text

There are two widely adopted paradigms for adapting pretrained models to a target language using monolingual or parallel text.

MLM Continued pretraining on monolingual text $\mathcal{D}_{mono}^{T} = \{x_i^T\}_i$ in the target language (Howard and Ruder, 2018; Gururangan et al., 2020) using a masked language model (MLM) objective has proven effective for adapting models to the target language (Pfeiffer et al., 2020). Notably, Ebrahimi and Kann (2021) show that using as little as several thousand sentences can significantly improve the model's performance on target languages not covered during pretraining.

---

[3] We additionally examine the few-shot setting where some task data $\mathcal{D}_{label}^{T}$ in T is available for fine-tuning in § 7.

Trans-Train For target languages with sufficient parallel text with the source language $\mathcal{D}^{ST}_{par} = \{(x^S_i, x^T_i)\}_i$, one can train a machine translation (MT) system that translates data from the source language into the target language. Using such an MT system, we can translate the labeled data in the source language $\mathcal{D}^S_{label}$ into target language data $\widehat{\mathcal{D}}^T_{label} = \{(\widehat{x}^T_i, y^S_i)\}^N_{i=1}$, and fine-tune the pretrained multilingual model on both the source and translated labeled data $\mathcal{D}^S_{label} \cup \widehat{\mathcal{D}}^T_{label}$. This method often brings significant gains to the target language, especially for languages with high-quality MT systems (Hu et al., 2020; Ruder et al., 2021).

2.2 Challenges with Low-resource Languages

Both methods above require $\mathcal{D}^T_{mono}$ or $\mathcal{D}^{ST}_{par}$ in target language T, so they cannot be directly extended to languages without this variety of data. Joshi et al. (2020) classified the around 7,000 languages of the world into six groups based on the availability of data in each language. The two groups posing the biggest challenges for NLP are:

"The Left-Behinds," languages with virtually no unlabeled data. We refer to this as the *No-Text* setting.

"The Scraping-Bys," languages with a small amount of monolingual data. We refer to this as the *Few-Text* setting.

These languages make up 85% of languages in the world, yet they do not benefit from the development of pretrained models and adaptation methods due to the lack of monolingual and parallel text. In this paper, we conduct a systematic study of strategies directly targeted at these languages.

3 Adapting to Under-represented Languages Using Lexicons

Since the main bottleneck of adapting to under-represented languages is the lack of text, we adopt a data augmentation framework (illustrated in Fig. 3) that leverages bilingual lexicons, which are available for a much larger number of languages.

3.1 Synthesizing Data Using Lexicons

Given a bilingual lexicon $\mathcal{D}^{ST}_{\text{lex}}$ between the source language S and a target language T, we create synthetic sentences $\widetilde{x}^T_i$ in T using sentences x^S_i in S via word-to-word translation, and use this synthetic data in the following adaptation methods.

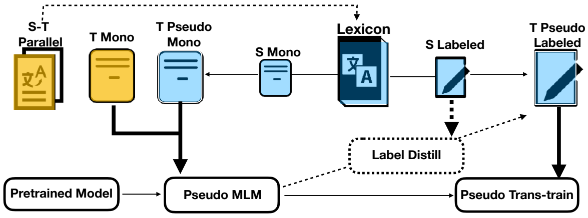

Figure 3: Pipelines for synthesizing data for both No-text and Few-text settings and utilizing extra data for the Few-Text setting. Solid lines indicate adaptation methods and dashed lines are synthetic data refinement methods.

Pseudo MLM Using monolingual text $\mathcal{D}^S_{mono} = \{x^S_i\}_i$, we generate pseudo monolingual text $\widetilde{\mathcal{D}}^T_{mono} = \{\widetilde{x}^T_i\}_i$ for T by replacing the words in x^S_i with their translation in T based on the lexicon $\mathcal{D}^{ST}_{\text{lex}}$. We keep the words that do not exist in the lexicon unchanged, so the pseudo text $\widetilde{x}^T_i$ can include words in both S and T. We then adapt the pretrained multilingual model on $\widetilde{\mathcal{D}}^T_{mono}$ using the MLM objective. For the Few-Text setting where some gold monolingual data $\mathcal{D}^T_{mono}$ is available, we can train the model jointly on the pseudo and the gold monolingual data $\widetilde{\mathcal{D}}^T_{mono} \cup \mathcal{D}^T_{mono}$.

Pseudo Trans-train Given the source labeled data $\mathcal{D}^S_{label} = \{(x^S_i, y^S_i)\}^N_{i=1}$, for each text example x^S_i we use $\mathcal{D}^{ST}_{\text{lex}}$ to replace the words in x^S_i with its corresponding translation in T, resulting in pseudo labeled data $\widetilde{\mathcal{D}}^T_{label} = \{(\widetilde{x}^T_i, y^S_i)\}^N_{i=1}$. We keep the original word if it does not have an entry in the lexicon. We then fine-tune the model jointly on both pseudo and gold labeled data $\widetilde{\mathcal{D}}^T_{label} \cup \mathcal{D}^S_{label}$.

Since these methods only require bilingual lexicons, we can apply them to both No-Text and Few-Text settings. We can use either of the two methods or the combination of both to adapt the model.

Challenges with Pseudo Data Our synthetic data $\widetilde{\mathcal{D}}^T$ could be very different from the true data $\mathcal{D}^T$ because the lexicons do not cover all words in S or T, and we do not consider morphological or word order differences between T and S.[4] Nonetheless, we find that this approach yields significant improvements in practice (see Tab. 3). We also outline two strategies that aim to improve the quality of the synthetic data in the next section.

3.2 Refining the Synthetic Data

Label Distillation The pseudo labeled data $\widetilde{\mathcal{D}}^T_{label} = \{(\widetilde{x}^T_i, y^S_i)\}^N_{i=1}$ is noisy because the syn-

---

[4] In fact, we considered more sophisticated methods using morphological analyzers and inflectors, but even models with relatively broad coverage (Anastasopoulos and Neubig, 2019) did not cover many languages we used in experiments.

eng $x^S \in \mathcal{D}^S_{mono}$	Anarchism calls for the abolition of the state , which it holds to be undesirable , unnecessary , and harmful .
Pseudo Mono $\widetilde{x}^T \in \widetilde{\mathcal{D}}^T_{mono}$	Anarchism calls gal il abolition ta' il stat , lima hi holds gal tkun undesirable , bla bzonn , u harmful .
eng $x^S \in \mathcal{D}^S_{label}$	I suspect the streets of Baghdad will look as if a war is looming this week .
Pseudo Labeled $\widetilde{x}^T \in \widetilde{\mathcal{D}}^T_{label}$	jien iddubita il streets ta' Bagdad xewqa hares kif jekk a gwerra is looming dan ġimga .
Pseudo Labeled $y^S \in \widetilde{\mathcal{D}}^T_{label}$	PRON VERB DET NOUN ADP PROPN AUX VERB SCONJ SCONJ DET NOUN AUX VERB DET NOUN PUNCT
Label Distilled $\widetilde{y}^T \in \widetilde{\mathcal{D}}^T_{distill}$	PRON VERB DET NOUN ADP PROPN NOUN NOUN SCONJ SCONJ DET NOUN AUX VERB DET NOUN PUNCT

Table 1: Examples of pseudo monolingual data and pseudo labeled data for POS tagging for Maltese (mlt). Words in red have different labels between the source language and the label distilled data. This is because "xewqa" in Maltese is a noun meaning "desire,will", while the word "will" is not used as a noun in the original English sentence.

thetic examples $\widetilde{x}^T_i$ could have a different label from the original label y^S_i (see Tab. 1). To alleviate this issue, we propose to automatically "correct" the labels of pseudo data using a teacher model. Specifically, we fine-tune the pretrained multilingual model as a teacher model using only $\mathcal{D}^S_{label}$. We use this model to generate the new pseudo labeled data $\widetilde{\mathcal{D}}^T_{distill} = \{(\widetilde{x}^T_i, \widetilde{y}^T_i)\}^N_{i=1}$ by predicting labels $\widetilde{y}^T_i$ for the pseudo task examples $\widetilde{x}^T_i$. We then fine-tune the pretrained model on both the new pseudo labeled data and the source labeled data $\widetilde{\mathcal{D}}^T_{distill} \cup \mathcal{D}^S_{label}$.

Induced Lexicons with Parallel Data For the Few-Text setting, we can leverage the available parallel data $\mathcal{D}^{ST}_{par}$ to further improve the quality of the augmented data. Specifically, we use unsupervised word alignment to extract additional word pairs $\widetilde{\mathcal{D}}^{ST}_{lex}$ from the parallel data, and use the combined lexicon $\widetilde{\mathcal{D}}^{ST}_{lex} \cup \mathcal{D}^{ST}_{lex}$ to synthesize the pseudo data.

4 General Experimental Setting

In this section, we outline the tasks and data setting used by all experiments. We will then introduce the adaptation methods and results for the No-Text setting in § 5 and the Few-Text setting in § 6.

4.1 Tasks, Languages and Model

We evaluate on the gold test sets of three different tasks with relatively good coverage of under-represented languages: named entity recognition (NER), part-of-speech (POS) tagging, and dependency parsing (DEP). We use two NER datasets: WikiAnn NER (Pan et al., 2017; Rahimi et al., 2019) and MasakhaNER (Adelani et al., 2021). We use the Universal Dependency 2.5 (Nivre et al., 2018) dataset for both the POS and DEP tasks.

Table 2: Languages used for evaluation.

We use English as the source language for all experiments. For each dataset, we use the English training data and select the checkpoint with the best performance on the English development set. For MasakhaNER, which does not have English training data, we follow Adelani et al. (2021) and use the CoNLL-2003 English NER training data. We run each fine-tuning experiment with 3 random seeds and report the average performance. For NER and POS tagging, we follow the data processing and fine-tuning hyper-parameters in Hu et al. (2020). We use the Udify (Kondratyuk and Straka, 2019) codebase and configuration for parsing.

Languages For each task, we select languages that have task data but are not covered by the mBERT pretraining data. The languages we use can be found in Tab. 2. Most fall under the Few-Text setting (Joshi et al., 2020). We employ the same languages to simulate the No-Text setting as well.

Model We use the multilingual BERT model (mBERT) because it has competitive performance on under-represented languages (Pfeiffer et al., 2020). We find that our mBERT performance on WikiNER and POS is generally comparable or exceeds the XLM-R large results in Ebrahimi and Kann (2021). We additionally verify our results also hold for XLM-R in § 7.

4.2 Adaptation Data

Lexicon We extract lexicons between English and each target language from the PanLex database.[5] The number of lexicon entries varies from about 0.5k to 30k, and most of the lexicons have around 5k entries. The lexicon statistics for each language can be found in Tab. 2.

Pseudo Monolingual Data English Wikipedia articles are used to synthesize monolingual data. We first tokenize the English articles using Stanza (Qi et al., 2020) and keep the first 200k sentences. To create pseudo monolingual data for a given target language, we replace each English word with its translation if the word exists in the bilingual lexicon. We randomly sample a target word if the English word has multiple possible translations because it is difficult to estimate translation probabilities due to lack of target text.

Pseudo Labeled Data Using the English training data for each task, we simply replace each English word in the labeled training data with its corresponding translation and retain its original label. For the sake of simplicity, we only use lexicon entries with a single word.

5 No-Text Setting

We analyze the results of the following adaptation methods for the setting where we do not have any monolingual data.

Pseudo MLM The mBERT model is trained on the pseudo monolingual data using the MLM objective. We train the model for 5k steps for the NER tasks and 10k steps for the POS tagging and Parsing tasks.

Pseudo Trans-train We fine-tune mBERT or the model adapted with Pseudo MLM for a downstream task on the concatenation of both the English labeled data and the pseudo labeled data.

Label Distillation We use the model adapted with Pseudo MLM as the teacher model to generate new labels for the pseudo labeled data, which we use jointly with the English labeled data to fine-tune the final model.

5.1 Results

The average performance of different adaptation methods averaged across all languages in each task can be found in Tab. 3.

Pseudo Trans-train is the best method for No-Text. Pseudo MLM and Pseudo Trans-train can both bring significant improvements over the mBERT baseline for all tasks. Pseudo Trans-train leads to the best aggregated result across all tasks, and it is also the best method or very close to the best method for each task. Adding Pseudo Trans-train on top of Pseudo MLM does not add much improvement. Label Distillation generally leads to better performance, but overall it is comparable to only using Pseudo Trans-train.

6 Few-Text Setting

We test same adaptation methods introduced in § 5 for the Few-Text setting where we have a small amount of gold data. First we introduce the additional data and adaptation methods for this setting.

6.1 Gold Data

Gold Monolingual Data We use the JHU Bible Corpus (McCarthy et al., 2020) as the monolingual data. Following the setup in Ebrahimi and Kann (2021), we use the verses from the New Testament, which contain 5000 to 8000 sentences for each target language.

Gold Parallel Data We can use the parallel data between English and the target languages from the Bible to extract additional word pairs. We use an existing unsupervised word alignment tool, eflomal (Östling and Tiedemann, 2016), to generate word alignments for each sentence in the parallel Bible data. To create high quality lexicon entries, we only keep the word pairs that are aligned more than once, resulting in about 2k extra word pairs for each language. We then augment the PanLex lexicons with the induced lexicon entries.

6.2 Adaptation Methods

Gold MLM The mBERT model is trained on the gold monolingual Bible data in the target language using the MLM objective. Following the setting in Ebrahimi and Kann (2021), we train for 40 epochs for the NER task, and 80 epochs for the POS and Parsing tasks.

Pseudo MLM We conduct MLM training on both the Bible monolingual data and the pseudo monolingual data in the target language. The Bible data is up-sampled to match the size of the pseudo monolingual data. We train the model for 5k steps

Table 3: Average F1 score for languages in each task. We record F1 of the LAS for Parsing. We compare three adaptation methods (Δ indicates gains over baselines): Pseudo Trans-train, Pseudo MLM, and Both. We also examine two data refinement methods: Label Distillation (Δ is gains over Both) and PanLex+Induced (Δ is gains over PanLex). **Bold** is the best result for each dataset, and underline indicates the best improvements among the three adaptation methods over the baselines. We test the significance of the average gains over the baselines in the last column using paired bootstrap resampling. * indicates significant gains with $p < 0.001$ and † indicates significant gains with $p < 0.05$.

for the NER task and 10k steps for the POS tagging and Parsing tasks.

6.3 Results

The average performance in each task for Few-Text can be found in Tab. 3.

Pseudo MLM is the competitive strategy for Few-Text. Unlike the No-Text setting, Pseudo Trans-train only marginally improves or even decreases the performance for three out of the four datasets we consider. On the other hand, Pseudo MLM, which uses both gold and pseudo monolingual data for MLM adaptation, consistently and significantly improves over Gold MLM for all tasks. Again, using Pseudo Trans-train on top of Pseudo MLM does not help and actually leads to relatively large performance loss for the syntactic tasks, such as POS tagging and Parsing.

Label Distillation brings significant improvements for the two syntactic tasks. Notably, it is the best performing method for POS tagging, but it still lags behind Pseudo MLM for Parsing. This is likely because Parsing is a much harder task than POS tagging to generate correct labels. The effect of Label Distillation on the NER task is less consistent—it improves over Pseudo Trans-train for WikiNER but not for MasakhaNER. This is because the named entity tags of the same words in different languages likely remain the same so that the pseudo task data probably has less noise for Label Distillation to have consistent benefits.

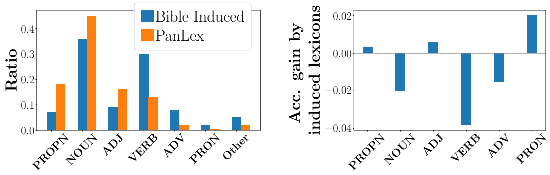

Figure 4: *left*: Ratio of words with different POS tags in each lexicon. right: POS accuracy gain of test words with different POS tags by using induced lexicons. The induced lexicons have more verbs but lead to worse performance on verbs.

Adding Induced Lexicons We examine the effect of using the lexicons augmented by word pairs induced from the Bible parallel data. The results can be found in Tab. 3. Adding the induced lexicon significantly improves the NER performance, while it hurts the two syntactic tasks.

To understand what might have prevented the syntactic tasks from benefiting from the extra lexicon entries, we plot the distribution of the part-of-speech tags of the words in PanLex lexicons and the lexicons induced from the Bible in Fig. 4. PanLex lexicons have more nouns than the Bible lexicons while the Bible lexicons cover more verbs than PanLex. However, the higher verb coverage in induced lexicons actually leads to a larger prediction accuracy drop for verbs in the POS tagging task. We hypothesize that the pseudo monolingual data created using the induced lexicons would contain more target language verbs with the wrong word order, which could be more harmful for syntactic tasks than tasks that are less sensitive to word order such as NER.

Table 4: Results for POS tagging with XLM-R. Our methods follow similar trend as on mBERT and they lead to significant gains compared to prior work.

Discrepancies between the two NER datasets While WikiNER, along with POS tagging and Parsing, benefit the most from Pseudo MLM for Few-Text, MasakhaNER achieves the best result with Pseudo Trans-train. One possible explanation is that MasakhaNER contains data from the news domain, while WikiNER is created from Wikipedia. The pseudo monolingual data used for MLM is created from English Wikipedia articles, which could benefit WikiNER much more than MasakhaNER. On the other hand, the English NER training data for MasakhaNER is from the news domain, which potentially makes Pseudo Trans-train a stronger method for adapting the model simultaneously to the target language and to the news domain. One advantage of Pseudo MLM is that the English monolingual data is much cheaper to acquire, while Pseudo Trans-train is constrained by the amount of labeled data for a task. We show in § A.4 that Pseudo MLM has more benefit for MasakhaNER when we use a subset of the NER training data.

7 Analyses

Performance with XLM-R We mainly use mBERT because it has competitive performance for under-represented languages and it is more computationally efficient due to the smaller size. Here we verify our methods have the same trend when used on a different model XLM-R (Conneau et al., 2020). We focus on a subset of languages in the POS tagging task for the Few-Text setting and the results are in Tab. 4. We use the smaller XLM-R base for efficiency, and compare to the best result in prior work, which uses XLM-R large (Ebrahimi and Kann, 2021). Tab. 4 shows that our baseline is comparable or better than prior work. Similar to the conclusion in § 6, Pseudo MLM is the competitive strategy that brings significant improvements over prior work. While adding Pseudo Trans-train to Pseudo MLM does not help, using Label Distillation further improves the performance.

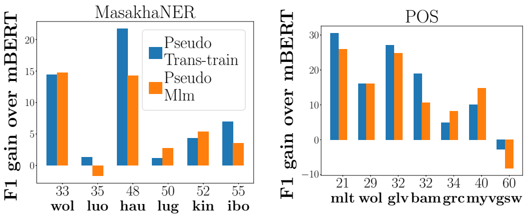

Figure 5: F1 gain over the baselines for languages with increasing baseline performance from left to right. Pseudo data tends to help more for languages with lower performance.

Effect of Baseline Performance Using pseudo data might be especially effective for languages with lower performance. We plot the improvement of different languages over the baseline in Fig. 5, where languages are arranged with increasing baseline performance from left to right. We mainly plot Pseudo MLM and Pseudo Trans-train for simplicity. Fig. 5 shows that for both resource settings, lower performing languages on the left tend to have more performance improvement by using pseudo data.

Using NMT Model to Synthesize Data One problem with the pseudo data synthesized using word-to-word translation is that it cannot capture the correct word order or syntactic structure in the target language. If we have a good NMT system that translates English into the target language, we might be able to get more natural pseudo monolingual data by translating the English sentences to the target language.

Since the target languages we consider are usually not supported by popular translation services, we train our own NMT system by fine-tuning an open sourced many-to-many NMT model on the Bible parallel data from English to the target language (details in § A.2). Instead of creating pseudo monolingual data using the lexicon, we can simply use the fine-tuned NMT model to translate English monolingual data into the target language.

The results of using NMT as opposed to lexicon for Pseudo MLM on all four tasks can be found in Tab. 5. Unfortunately, NMT is consistently worse than word-to-word translation using lexicons. We find that the translated monolingual data tend to have repeated words and phrases that are common in the Bible data, although the source sentence is from Wikipedia. This is because the NMT model overfits to the Bible data, and it fails to generate good translation for monolingual data from a different domain such as Wikipedia.

Comparison to Few-shot Learning Lauscher et al. (2020) found that using as few as 10 labeled

Table 6: Results on MasakhaNER for k-shot learning. We compare to the zero-shot mBERT baseline and our best adapted model.

examples in the target language can significantly outperform the zero-shot transfer baseline for languages included in mBERT. We focus on the zero-shot setting in this paper because the languages we consider have very limited data and it could be expensive or unrealistic to annotate data in every task for thousands of languages. Nonetheless, we experiment with k-shot learning to examine its performance on low-resource languages in the MasakhaNER task. Tab. 6 shows that using 10 labeled examples brings improvements over the mBERT baseline for a subset of the languages, and it is mostly worse than our best adapted model without using any labeled data. When we have access to 100 examples, few-shot learning begins to reach or exceed our zero-shot model. In general, few-shot learning seems to require more data to consistently perform well for under-represented languages while our adaptation methods bring consistent gains without any labeled data. Combining the best adapted model with few-shot learning leads to mixed results. More research is needed to understand the annotation cost and benefit of few-shot learning for low-resource languages.

8 Related Work

Several methods have been proposed to adapt pretrained language models to a target language. Most of them rely on MLM training using monolingual data in the target languages (Wang et al., 2020; Chau et al., 2020; Muller et al., 2021; Pfeiffer et al., 2020; Ebrahimi and Kann, 2021), competitive NMT systems trained on parallel data (Hu et al., 2020; Ponti et al., 2021), or some amount of labeled data in the target languages (Lauscher et al., 2020). These methods cannot be easily extended to low-resource languages with no or limited amount of monolingual data, which account for more than 80% of the World's languages (Joshi et al., 2020).

Bilingual lexicons have been commonly used for learning cross-lingual word embeddings (Mikolov et al., 2013; Ruder et al., 2019). Among these, some work uses lexicons to synthesize pseudo bilingual (Gouws and Søgaard, 2015; Duong et al., 2016) or pseudo multilingual corpora (Ammar et al., 2016). Mayhew et al. (2017) propose to synthesize task data for NER using bilingual lexicons. More recently, Khemchandani et al. (2021) synthesize monolingual data in Indian languages for adapting pretrained language models via MLM. Hu et al. (2021) argue that using bilingual lexicons for alignment hurts performance compared to word-level alignment based on parallel corpora. Such parallel corpora, however, are not available for truly under-represented languages. Reid and Artetxe (2021) employ a dictionary denoising objective where a word is replaced with its translation into a random language with a certain probability. This can be seen as text-to-text variant of our approach applied to multilingual pre-training. None of the above works provide a systematic study of methods that utilize lexicons and limited data resources for adapting pretrained language models to languages with no or limited text.

9 Conclusion and Discussion

We propose a pipeline that leverages bilingual lexicons, an under-studied resource with much better language coverage than conventional data, to adapt pretrained multilingual models to under-represented languages. Through comprehensive studies, we find that using synthetic data can significantly boost the performance of these languages while the best method depends on the data availability. Our results show that we can make concrete progress towards including under-represented languages into the development of NLP systems by utilizing alternative data sources.

Our work also has some limitations. Since we focus on different methods of using lexicons, we restrict experiments to languages in Latin script and only use English as the source language for simplicity. Future work could explore the effect of using different source languages and combining transliteration (Muller et al., 2021) or vocabulary extension (Pfeiffer et al., 2021) with lexicon-based data augmentation for languages in other scripts. We also did not test the data augmentation methods on higher-resourced languages as MLM fine-tuning and translate-train are already effective in that setting and our main goal is to support the languages with little textual data. Nonetheless, it would be interesting to examine whether our methods can deliver gains for high-resource languages, especially for test data in specialized domains.

We point to the following future directions: First, phrases instead of single word entries could be used to create pseudo data. Second, additional lexicons beyond PanLex could be leveraged.[6] Third, more effort could be spent on digitizing both existing monolingual data such as books (Gref, 2016) and lexicons into a format easily accessible by NLP practitioners. Although PanLex already covers over 5000 languages, some language varieties have only as little as 10 words in the database, while there exist many paper dictionaries that could be digitized through technologies such as OCR (Rijhwani et al., 2020).[7] Lexicon collection is also relatively fast, which could be a more cost effective strategy to significantly boost the performance of many languages without lexicons. Finally, the quality of synthetic data could be improved by incorporating morphology. However, we find that there is virtually no existing morphological analysis data or toolkits for the languages we consider. Future work could aim to improve the morphological analysis of these low-resource languages.

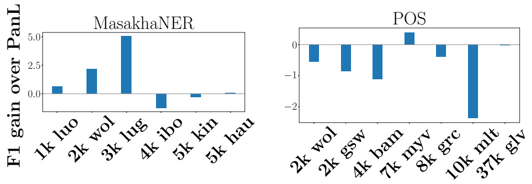

Figure 6: Improvements of using combined lexicons compared to PanLex lexicons for Pseudo MLM. Languages with fewer PanLex lexicons tend to benefit more from the combined lexicons.

A Appendix

A.1 Experiment Details

For all experiments using MLM training for NER tasks, we train 5000 steps, or about equivalent to 40 epochs on Bible; for MLM training for POS tagging and Parsing, we train 10000 steps, or equivalent to 80 epochs on Bible. We use learning rate of $2e-5$, batch size of 32, and maximum sequence length of 128. We did not tune these hyperparameters because we mostly follow the ones provided in (Ebrahimi and Kann, 2021).

To finetune the model for a downstream task, we use learning rate of $2e-5$ and batch size of 32. We train all models for 10 epochs and pick the checkpoint with the best performance on the English development set.

We use a single GPU for all adaptation and fine-tuning experiments. Pseudo MLM usually takes less than 5 hours. Pseudo Trans-train and other task specific fine-tuning usually takes around 2 to 3 hours.

A.2 NMT Models

We use the many-to-many NMT models provided in the fairseq repoo (Ott et al., 2019). We use the model with 175M parameters and finetune the NMT model for 50 epochs on the parallel data from the Bible.

We use beam size of 5 to generate translations.

A.3 Induced lexicons help languages with Fewer PanLex Entries

We plot the performance difference between using combined lexicons and PanLex for the Few-Text in Fig. 6. The languages are arranged from left to right based on increasing amount of PanLex entries. For MasakhaNER, the three languages with fewer entries in PanLex have much more significant gains by using the combined lexicon. While using the combined lexicons generally hurts POS tagging, the languages with fewer entries in PanLex tend to have less performance decrease.

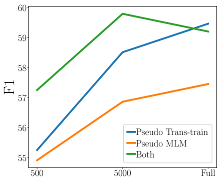

Figure 7: F1 on MasakhaNER with different amount of labeled data. Pseudo MLM becomes beneficial when the labeled training data is small.

A.4 Effect of Task Data Size

Our experiments in Tab. 3 show that MasakhaNER benefits more from Pseudo Trans-train, likely because the labeled data is closer to the domain of the test data. However, this result might not hold when the amount of labeled data is limited. One advantage of Pseudo MLM over Pseudo Trans-train is that it only requires English monolingual data to synthesize pseudo training data, while Pseudo Trans-train is constrained by the availability of labeled data. We subsample the amount of English NER training data for MasakhaNER and plot the average F1 score of Pseudo Trans-train, pseudo MLM and using both. Fig. 7 shows that the advantage of Pseudo Trans-train on MasakhaNER decreases as the number of labeled data decreases, and using both methods is more competitive when the task data is small.

A.5 List of Bilingual Lexicons

We provide a list of bilingual lexicons beyond PanLex:

- Swadesh lists in about 200 languages in Wikipedia[8]
- Words in 3156 language varietities in CLICS[9]
- Intercontinental Dictionary Series in about 300 languages[10]
- 40-item wordlists in 5,000+ languages in ASJP[11]
- Austronesian Basic Vocabulary Database in 1,700+ languages[12]
- Diachronic Atlas of Comparative Linguistics in 500 languages[13]

Abstract

While BERT is an effective method for learning monolingual sentence embeddings for semantic similarity and embedding based transfer learning (Reimers and Gurevych, 2019), BERT based cross-lingual sentence embeddings have yet to be explored. We systematically investigate methods for learning multilingual sentence embeddings by combining the best methods for learning monolingual and cross-lingual representations including: masked language modeling (MLM), translation language modeling (TLM) (Conneau and Lample, 2019), dual encoder translation ranking (Guo et al., 2018), and additive margin softmax (Yang et al., 2019a). We show that introducing a pre-trained multilingual language model dramatically reduces the amount of parallel training data required to achieve good performance by 80%. Composing the best of these methods produces a model that achieves 83.7% bi-text retrieval accuracy over 112 languages on Tatoeba, well above the 65.5% achieved by Artetxe and Schwenk (2019b), while still performing competitively on monolingual transfer learning benchmarks (Conneau and Kiela, 2018). Parallel data mined from CommonCrawl using our best model is shown to train competitive NMT models for en-zh and en-de. We publicly release our best multilingual sentence embedding model for 109+ languages at `https://tfhub.dev/google/LaBSE`.

1 Introduction

In this paper, we systematically explore using pre-training language models in combination with the best of existing methods for learning cross-lingual sentence embeddings. Such embeddings are useful for clustering, retrieval, and modular use of text representations for downstream tasks. While existing cross-lingual sentence embedding models incorporate large transformer models, using large pretrained language models is not well explored. Rather in prior work, encoders are trained directly on translation pairs (Artetxe and Schwenk, 2019b; Guo et al., 2018; Yang et al., 2019a), or on translation pairs combined with monolingual input-response prediction (Chidambaram et al., 2019; Yang et al., 2019b).

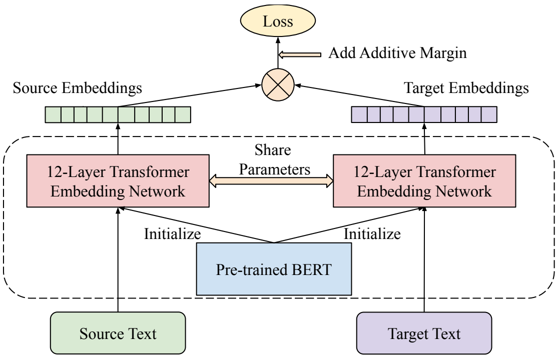

Figure 1: Dual encoder model with BERT based encoding modules.

In our exploration, as illustrated in figure 1, we make use of dual-encoder models, which have been demonstrated as an effective approach for learning bilingual sentence embeddings (Guo et al., 2018; Yang et al., 2019a). However, diverging from prior work, rather than training encoders from scratch, we investigate using pre-trained encoders based on large language models. We contrast models with and without additive margin softmax (Yang et al., 2019a)[1]. Figure 2 illustrates where our work stands (shaded) in the field of LM pre-training and sentence embedding learning.

Our massively multilingual models outperform the previous state-of-the-art on large bi-text retrieval tasks including the United Nations (UN)

corpus (Ziemski et al., 2016) and BUCC (Zweigenbaum et al., 2018). Table 1 compares our best model with other recent multilingual work.

Both the UN corpus and BUCC cover resource rich languages (fr, de, es, ru, and zh). We further evaluate our models on the Tatoeba retrieval task (Artetxe and Schwenk, 2019b) that covers 112 languages. Compare to LASER (Artetxe and Schwenk, 2019b), our models perform significantly better on low-resource languages, boosting the overall accuracy on 112 languages to 83.7%, from the 65.5% achieved by the previous state-of-art. Surprisingly, we observe our models performs well on 30+ Tatoeba languages for which we have no explicit monolingual or bilingual training data. Finally, our embeddings perform competitively on the SentEval sentence embedding transfer learning benchmark (Conneau and Kiela, 2018).

The contributions of this paper are:

- A novel combination of pre-training and dual-encoder finetuning to boost translation ranking performance, achieving a new state-of-the-art on bi-text mining.
- A publicly released multilingual sentence embedding model *spanning 109+ languages*.
- Thorough experiments and ablation studies to understand the impact of pre-training, negative sampling strategies, vocabulary choice, data quality, and data quantity.

We release the pre-trained model at `https://tfhub.dev/google/LaBSE`.

2 Cross-lingual Sentence Embeddings

Dual encoder models are an effective approach for learning cross-lingual embeddings (Guo et al., 2018; Yang et al., 2019a). Such models consist of paired encoding models that feed a scoring function. The source and target sentences are encoded separately. Sentence embeddings are extracted from each encoder. Cross-lingual embeddings are trained using a translation ranking task with in-batch negative sampling:

$$\mathcal{L} = -\frac{1}{N}\sum_{i=1}^{N} log \frac{e^{\phi(x_i,y_i)}}{e^{\phi(x_i,y_i)} + \sum_{n=1,n\neq i}^{N} e^{\phi(x_i,y_n)}} \tag{1}$$

The embedding space similarity of x and y is given by $\phi(x, y)$, typically $\phi(x, y) = xy^T$. The loss attempts to rank y_i, the true translation of x_i, over all $N-1$ alternatives in the same batch. Notice that $\mathcal{L}$ is asymmetric and depends on whether the softmax is over the source or the target sentences. For bidirectional symmetry, the final loss can sum the source-to-target, $\mathcal{L}$, and target-to-source, $\mathcal{L}'$, losses (Yang et al., 2019a):

$$\bar{\mathcal{L}} = \mathcal{L} + \mathcal{L}' \tag{2}$$

Dual encoder models trained using a translation ranking loss directly maximize the similarity of translation pairs in a shared embedding space.

2.1 Additive Margin Softmax

Additive margin softmax extends the scoring function ϕ by introducing margin m around positive pairs (Yang et al., 2019a):

$$\phi'(x_i, y_j) = \begin{cases} \phi(x_i, y_j) - m & \text{if } i = j \\ \phi(x_i, y_j) & \text{if } i \neq j \end{cases} \tag{3}$$

The margin, m, improves the separation between translations and nearby non-translations. Using $\phi'(x_i, y_j)$ with the bidirectional loss $\bar{\mathcal{L}}_s$, we obtain the additive margin loss

$$\mathcal{L} = -\frac{1}{N}\sum_{i=1}^{N} \frac{e^{\phi(x_i,y_i)-m}}{e^{\phi(x_i,y_i)-m} + \sum_{n=1,n\neq i}^{N} e^{\phi(x_i,y_n)}} \tag{4}$$

2.2 MLM and TLM Pre-training

Only limited prior work has combined dual encoders trained with a translation ranking loss with encoders initialized using large pre-trained language models (Yang et al., 2021). We contrast using a randomly initialized transformer, as was done in prior work (Guo et al., 2018; Yang et al., 2019a), with using a large pre-trained language model. For pre-training, we combined Masked language modeling (MLM) (Devlin et al., 2019) and Translation language modeling (TLM) (Conneau and Lample, 2019). MLM is a variant of a cloze task, whereby a model uses context words surrounding a [MASK] token to try to predict what the [MASK] word should be. TLM extends this to the multilingual setting by modifying MLM training to include concatenated translation pairs.

Multilingual pre-trained models such as mBERT (Devlin et al., 2019), XLM (Conneau and Lample, 2019) and XLM-R (Conneau et al., 2019) have led to exceptional gains across a variety of cross-lingual natural language processing tasks (Hu et al., 2020). However, without a sentence level objective, they do not directly produce good sentence embeddings. As shown in Hu et al. (2020), the performance of such models on bitext retrieval tasks is very weak, e.g XLM-R Large gets 57.3% accuracy on a selected 37 languages[2] from the Tatoeba dataset compared to 84.4% using LASER (see performance of more models in table 5). We contribute a detailed exploration that uses pre-trained language models to produce useful multilingual sentence embeddings.

3 Corpus and Training Details

3.1 Corpus

We use bilingual translation pairs and monolingual data in our experiments[3].

Monolingual Data We collect monolingual data from CommonCrawl[4] and Wikipedia[5]. We use the 2019-35 version of CommonCrawl with heuristics from Raffel et al. (2019) to remove noisy text. Additionally, we remove short lines $<$ 10 characters and those $>$ 5000 characters.[6] The wiki data is extracted from the 05-21-2020 dump using WikiExtractor[7]. An in-house tool splits the text into sentences. The sentences are filtered using a sentence quality classifier.[8] After filtering, we obtain 17B monolingual sentences, about 50% of the unfiltered version. The monolingual data is only used in custom pre-training.

Bilingual Translation Pairs The translation corpus is constructed from web pages using a bitext mining system similar to the approach described in Uszkoreit et al. (2010). The extracted sentence pairs are filtered by a pre-trained contrastive-data-selection (CDS) scoring model (Wang et al., 2018). Human annotators manually evaluate sentence pairs from a small subset of the harvested pairs and mark the pairs as either GOOD or BAD translations. The data-selection scoring model threshold is chosen such that 80% of the retained pairs from the manual evaluation are rated as GOOD. We limit the maximum number of sentence pairs to 100 million for each language to balance the data distribution. Many languages still have far fewer than 100M sentences. The final corpus contains 6B translation pairs.[9] The translation corpus is used for both dual encoder training and custom pre-training.

3.2 Configurations

In this section, we describe the training details for the dual encoder model. A transformer encoder is used in all experiments (Vaswani et al., 2017). We train two versions of the model, one uses the public BERT multilingual cased vocab with vocab size 119,547 and a second incorporates a customized vocab extracted over our training data. For the customized vocab, we employ a wordpiece tokenizer (Sennrich et al., 2016), with a cased vocabulary extracted from the training set using TF Text.[10] The language smoothing exponent for the vocab generation tool is set to 0.3 to counter imbalances in the amount of data available per language. The final vocabulary size is 501,153.

The encoder architecture follows the BERT Base model, with 12 transformer blocks, 12 attention

---

[2] The number is counted from official evaluation script despite the original paper says 33 languages.

[3] See the detailed list of supported languages in supplemental material.

[6] Long lines are usually JavaScript or attempts at SEO.

[7] https://github.com/attardi/wikiextractor

[8] The quality classifier is trained using sentences from the main content of webpages as positives and text from other areas as negatives.

[9] Experiments in later sections show that even 200M pairs across all languages is sufficient.

[10] https://github.com/tensorflow/text

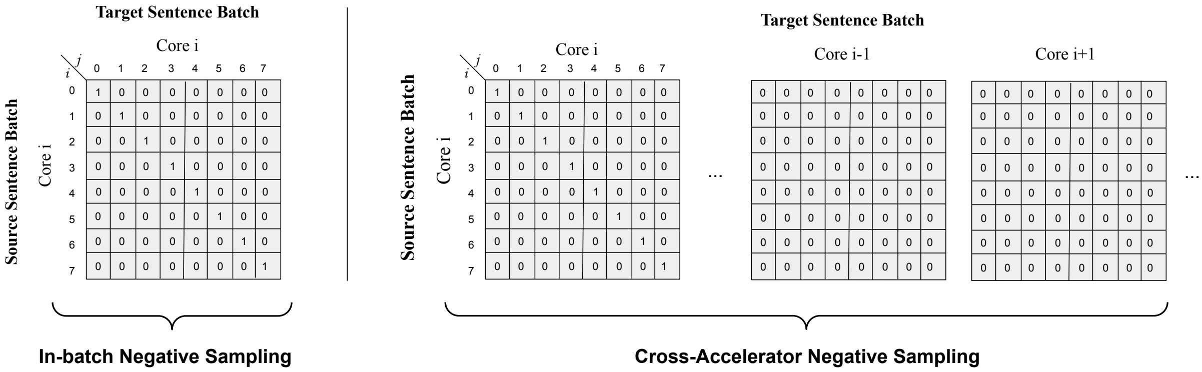

Figure 3: Negative sampling example in a dual encoder framework. **[Left]**: The in-batch negative sampling in a single core; **[Right]**: *Synchronized multi-accelerator negative sampling* using n TPU cores and batch size 8 per core with examples from other cores all treated as negatives.

heads and 768 per-position hidden units. The encoder parameters are shared for all languages. Sentence embeddings are extracted as the l_2 normalized `[CLS]` token representations from the last transformer block.[11]

Our models are trained on Cloud TPU V3 with 32-cores using a global batch size of 4096 with a maximum sequence length of 128, using the AdamW (Loshchilov and Hutter, 2019) optimizer with initial learning rate 1e-3, and linear weight decay. We train for 50k steps for pre-trained models, and 500k steps for models without pre-training. We observe that additional training did not change the performance significantly. The default margin value for additive margin softmax is set to 0.3. Hyperparameters are tuned on a held-out development set.

3.3 Cross-Accelerator Negative Sampling

Cross-lingual embedding models trained with in-batch negative samples benefit from large training batch sizes (Guo et al., 2018). Resource intensive models like BERT, are limited to small batch sizes due to memory constraints. While data-parallelism does allow us to increase the global batch size by using multiple accelerators, the batch-size on individual cores remains small. For example, a 4096 batch run across 32 cores results in a local batch size of 128, with each example then only receiving 127 negatives.

We introduce *cross-accelerator negative sampling*, which is illustrated in figure 3.[12] Under this strategy each core encodes its assigned sentences and then the encoded sentence representations from all cores are broadcast as negatives to the other cores. This allows us to fully realize the benefits of larger batch sizes while still distributing the computationally intensive encoding work across multiple cores.

Note the dot-product scoring function makes it efficient to compute the pairwise scores in the same batch with matrix multiplication. In figure 3, the value in the grids indicates the ground truth labels, with all positive labels located in diagonal grids. A softmax function is applied on each row.

3.4 Pre-training

The encoder is pre-trained with Masked Language Model (MLM) (Devlin et al., 2019) and Translation Language Model (TLM) (Conneau and Lample, 2019)[13] training on the monolingual data and bilingual translation pairs, respectively. For an L layer transformer encoder, we train using a 3 stage progressive stacking algorithm (Gong et al., 2019), where we first learn a $\frac{L}{4}$ layers model and then $\frac{L}{2}$ layers and finally all L layers. The parameters of the models learned in the earlier stages are copied to the models for the subsequent stages.

Pre-training uses TPUv3 with 512-cores and a batch size of 8192. The max sequence length is set to 512 and 20% of tokens (or 80 tokens at most) per sequence are masked for MLM and TLM predictions. For the three stages of progressive stacking,

---

[11] During training, the sentence embeddings after normalization are multiplied by a scaling factor. Following Chidambaram et al. (2018), we set the scaling factor to 10. We observe that the scaling factor is important for training a dual encoder model with the normalized embeddings.

[12] While our experiments use TPU accelerators, the same strategy can also be applied to models trained on GPU.

[13] Diverging from Conneau and Lample (2019), we do not provide a language hint to encourage multilinguality.

we respectively train for 400k, 800k, and 1.8M steps using all monolingual and bilingual data.

4 Evaluation Tasks

4.1 Bitext Retrieval

We evaluate models on three bitext retrieval tasks: United Nations (UN), Tatoeba, and BUCC. All tasks are to retrieve the correct English translation for each non-English sentence.

United Nations (UN) contains 86,000 sentence aligned bilingual documents over five language pairs: en-fr, en-es, en-ru, en-ar and en-zh (Ziemski et al., 2016). A total of 11.3 million[14] aligned sentence pairs can be extract from the document pairs. The large pool of translation candidates makes this data set particularly challenging.

Tatoeba evaluates translation retrieval over 112 languages (Artetxe and Schwenk, 2019b). The dataset contains up to 1,000 sentences per language along with their English translations. We evaluate performance on the original version covering all 112 languages, and also the 36 languages version from the XTREME benchmark (Hu et al., 2020).

BUCC is a parallel sentence mining shared task (Zweigenbaum et al., 2018). We use the 2018 shared task data, containing four language pairs: fr-en, de-en, ru-en and zh-en. For each pair, the task provides monolingual corpora and gold true translation pairs. The task is to extract translation pairs from the monolingual data, which are evaluated against the ground truth using F1. Since the ground truth for the BUCC test data is not released, we follow prior work using the BUCC training set for evaluation rather than training (Yang et al., 2019b; Hu et al., 2020). Sentence embedding cosine similarity is used to identify the translation pairs.[15]

4.2 Downstream Classification

We also evaluate the transfer performance of multilingual sentence embeddings on downstream classification tasks from the SentEval benchmark (Conneau and Kiela, 2018). We evaluate on select tasks from SentEval including: (**MR**) movie reviews (Pang and Lee, 2005)), (**SST**) sentiment analysis (Socher et al., 2013), (**TREC**) question-type (Voorhees and Tice, 2000), (**CR**) product reviews (Hu and Liu, 2004), (**SUBJ**) subjectivity/objectivity (Pang and Lee, 2004), (**MPQA**) opinion polarity (Wiebe et al., 2005), and (**MRPC**) paraphrasing detection (Dolan et al., 2004). While SentEval is English only, we make use of this benchmark in order to directly compare to prior work on sentence embedding models.

5 Results

Table 2 shows the performance on the UN and Tatoeba bitext retrieval tasks and compares against the prior state-of-the-art bilingual models Yang et al. (2019a), LASER (Artetxe and Schwenk, 2019b), and the multilingual universal sentence encoder (*m*-USE) (Yang et al., 2019b)[16]. Row 1-3 show the performance of baseline models, as reported in the original papers.

Row 4-7 shows the performance of models that use the public mBERT vocabulary. The baseline model shows reasonable performance on UN ranging from 57%-71% P@1. It also perform well on Tatoeba with 92.8% and 79.1% accuracy for the 36 language group and all languages, respectively. Adding pre-training both helps models converge faster (see details in section 6.2) and improves performance on the UN retrieval task using both vocabularies. Pre-training also helps on Taoeba, but only using the customized vocabulary.[17] Additive margin softmax significantly improves the performance on all model variations.

The last two rows contain models using the customized vocab. Both of them are trained with additive margin softmax given the strong evidence from the experiments above. Both models outperform the mBERT vocabulary based models, and the pre-trained model performs best of all. The top model (Base w/ Customized Vocab + AMS + PT) achieves a new state-of-the-art on 3 of the 4 languages, with P@1 91.1, 88.3, 90.8 for en-es, en-fr, en-ru, respectively. It reaches 87.7 on zh-en, only 0.2 lower than the best bilingual en-zh model and *nearly 9 points better than the previous best multilingual model*. On Tatoeba, the best model also outperform the baseline model by a large margin, with +10.6 accuracy on the 36 language group

---

[14] About 9.5 million after de-duping.

[15] Reranking models can further improve performance (e.g. margin based scorers (Artetxe and Schwenk, 2019a) and BERT based classifiers (Yang et al., 2019a)). However, this is tangential to assessing the raw embedding retrieval performance.

[16] universal-sentence-encoder-multilingual-large/3

[17] The coverage of the public mBERT vocabulary on the tail languages is bad with many [UNK] tokens for such languages, e.g. the [UNK] token rate is 71% for language **si**, which could be the reason pre-training doesn't help on the tatoeba task.

Model	UN (en → xx)					Taoeba (xx → en)	
	es	fr	ru	zh	avg	36 Langs	All Langs
LASER (Artetxe and Schwenk, 2019b)	–	–	–	–	–	84.4	65.5
m-USE (Yang et al., 2019b)	86.1	83.3	88.9	78.8	84.3	–	–
Yang et al. (2019a)	89.0	86.1	89.2	**87.9**	88.1	–	–
Base w/ mBERT Vocab	67.7	57.0	70.2	71.9	66.7	92.8	79.1
+ PT	68.5	59.8	65.8	71.7	66,5	92.7	78.6
+ AMS	88.2	84.5	88.6	86.4	86.9	93.7	81.2
+ AMS + PT	89.3	85.7	89.3	87.2	87.9	93.2	78.4
Base w/ Customized Vocab							
+ AMS	90.6	86.5	89.5	86.8	88.4	94.8	82.6
+ AMS + PT (**LaBSE**)	**91.1**	**88.3**	**90.8**	87.7	**89.5**	**95.0**	**83.7**

from XTREME and +18.2 on all languages.

It is worth noting that all our models perform similarly on Tatoeba but not on UN. This suggests it is necessary to evaluate on large scale bitext retrieval tasks to better discern differences between competing models. For the rest of the paper we refer to **LaBSE** as the best performing model here, *Base w/ Customized Vocab + AMS + PT*, unless otherwise specified.

Table 3 provides LaBSE's retrieval performance on BUCC, comparing against strong baselines from Artetxe and Schwenk (2019a) and Yang et al. (2019a). Following prior work, we perform both forward and backward retrieval. Forward retrieval treats en as the target and the other language as the source, and backward retrieval is vice versa. LaBSE not only systematically outperforms prior work but also covers all languages within a single model. The previous state-of-the-art required four separate bilingual models (Yang et al., 2019a).

5.1 Results on Downstream Classification Tasks

Table 4 gives the transfer performance achieved by LaBSE on the SentEval benchmark (Conneau and Kiela, 2018), comparing against other state-of-the-art sentence embedding models. Despite its massive language coverage in a single model, LaBSE still obtains competitive transfer performance with monolingual English sentence embedding models and the 16 language *m*-USE model.

6 Analysis

6.1 Additive Margin Softmax

The above experiments show that additive margin softmax is a critical factor in learning good cross-lingual embeddings, which is aligned with the findings from Yang et al. (2019a). We further investigate the effect of margin size on our three model variations, as shown in figure 4. The model with an additive margin value 0 performs poorly on the UN task with ∼60 average P@1 across all three model variations. With a small margin value of 0.1, the model improves significantly compare to no margin with mid 70 to mid 80 average P@1. Consistently across models, increasing the margin value improves performance until it reaches 0.3.

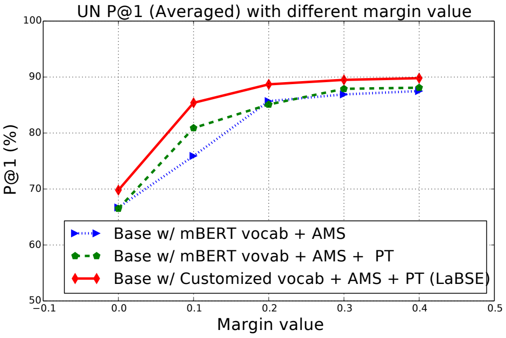

Figure 4: Average P@1 (%) on UN retrieval task of models trained with different margin values.

6.2 Effectiveness of Pre-training

To better understand the effect of MLM/TLM pre-training on the final LaBSE model, we explore training a variant of this model using our customized vocab but without pre-training. The results are shown in figure 5. We experiment with varying the number of training steps for both models, including: 50k, 100K, 200K, and 500K steps. A model with pre-trained encoders achieves excellent performance when trained for only 50K steps and further training doesn't increase the performance significantly. However, the model without pre-training performs poorly when only trained 50k steps. Its performance increases with additional steps and approaches the model with pre-training at 500k steps. The overall performance is, how-

	Models	fr-en			de-en			ru-en			zh-en		
		P	R	F	P	R	F	P	R	F	P	R	F
Forward	Artetxe and Schwenk (2019a)	82.1	74.2	78.0	78.9	75.1	77.0	-	-	-	-	-	-

Table 4: Performance on English transfer tasks from SentEval (Conneau and Kiela, 2018). We compare LaBSE model with InferSent (Conneau et al., 2017), Skip-Thought LN (Ba et al., 2016), Quick-Thought (Logeswaran and Lee, 2018), $\text{USE}_{\text{Trans}}$ (Cer et al., 2018), and $m\text{-USE}_{\text{Trans}}$ (Yang et al., 2019b).

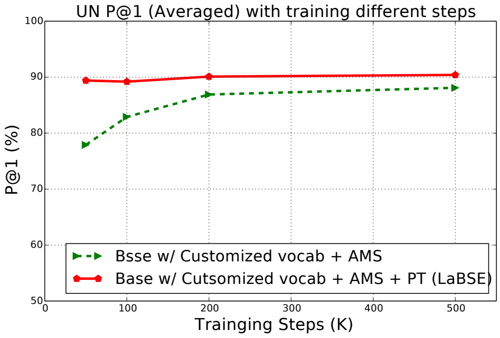

Figure 5: Average P@1 (%) on UN retrieval task of models trained with training different steps.

ever, still slightly worse. Moreover, further training past 500k steps doesn't increase the performance significantly. Pre-training thus both improves performance and dramatically reduces the amount of parallel data required. Critically, the model sees 1B examples at 500K steps, while the 50K model only sees 200M examples.[18]

6.3 Low Resource Languages and Languages without Explicit Training Data

We evaluate performance through further experiments on Tatoeba for comparison to prior work and to identify broader trends. Besides the 36 language group and all-languages group, two more groups of 14 languages (selected from the languages covered by *m*-USE), and 82 languages (covered by the LASER training data) are evaluated. Table 5 provides the macro-average accuracy achieved by LaBSE on the four language groupings drawn from Tatoeba, comparing against LASER and *m*-USE. All three models perform well on the 14 major languages support by *m*-USE, with each model achieving an average accuracy $>93\%$. Both LaBSE and LASER perform moderately better than *m*-USE, with an accuracy of 95.3%. As more languages are included, the averaged accuracy for both LaBSE and LASER decreases, but with a notably more rapid decline for LASER. LaBSE systematically outperforms LASER on the groups of 36 languages (+10.6%), 82 languages (+11.4%), and 112 languages (+18.2%).

Figure 6 provides the Tatoeba accuracies for languages where we don't have any explicit training data. There are a total of 30+ such languages. The performance is surprisingly good for most of the languages with an average accuracy around 60%. Nearly one third of them have accuracy greater than 75%, and only 7 of them have accuracy lower than 25%. One possible reason is that language mapping is done manually and some languages are close to those languages with training data but are treated differently according to ISO-639 standards. Additionally, since automatic language detection is used, some limited amount of data for the missing languages might be included during training. We suspect that the well performing zero-shot languages are close to some language(s) that we have in the training data. For example, *yue* and *wuu* are related to *zh* (Chinese) and *fo* has similarities to *is* (ICELANDIC). Multilingual generalization across so many languages is only possible due to

---

[18] We note that it is relative easy to get 200M parallel examples for many languages from public sources like Paracrawl, TED58, while obtaining 1B examples is generally much more challenging.

Model	14 Langs	36 Langs	82 Langs	All Langs
m-USE$_{\text{Trans.}}$	93.9	–	–	–

the massively multilingual nature of LaBSE.

6.4 Semantic Similarity

The Semantic Textual Similarity (STS) benchmark (Cer et al., 2017) measures the ability of models to replicate fine-grained human judgements of pairwise English sentence similarity. Models are scored according to their Pearson correlation, r, on gold labels ranging from 0, unrelated meaning, to 5, semantically equivalent, with intermediate values capturing carefully defined degrees of meaning overlap. STS is used to evaluate the quality of sentence-level embeddings by assessing the degree to which similarity between pairs of sentence embeddings aligns with human perception of sentence meaning similarity.

Table 6 reports performance on the STS benchmark for LaBSE versus existing sentence embedding models. Following prior work, the semantic similarity of a sentence pair according to LaBSE is computed as the arccosine distance between the pair's sentence embeddings.[19] For comparison, we include numbers for SentenceBERT when it is fine-tuned on the STS task as well as ConvEmbed when an additional affine transform is trained to fit the embeddings to STS. We observe that LaBSE performs worse on pairwise English semantic similarity than other sentence embedding models. We suspect training LaBSE on translation pairs biases the model to excel at detecting meaning equivalence, but not at distinguishing between fine grained degrees of meaning overlap.

Model	dev	test

ConvEmbed (Yang et al., 2018)	81.4	78.2
InferSent (Conneau et al., 2017)	80.1	75.6
LaBSE	74.3	72.8
STS Benchmark Tuned		
SentenceBERT-STS (Reimers and Gurevych, 2019)	-	86.1
ConvEmbed (Yang et al., 2018)	83.5	80.8

Table 6: Semantic Textual Similarity (STS) benchmark (Cer et al., 2017) performance as measured by Pearson's r.

Recently, Reimers and Gurevych (2020) demonstrated that an English sentence embedding model can be distilled to a multilingual student model using a language alignment loss. The distilled model performs well on multilingual STS benchmarks, but underperforms on bitext retrieval tasks when compared to state-of-the-art models. Our approach is complimentary and can be combined with their method to distill better student models.

7 Mining Parallel Text from CommonCrawl

We use the LaBSE model to mine parallel text from CommonCrawl, a large-scale multilingual web corpus, and then train NMT models on the mined data. We experiment with two language pairs: English-to-Chinese (en-zh) and English-to-German (en-de). We mine translations from monolingual CommonCrawl data processed as described above for self-supervised MLM pretraining. After processing, there are 1.17B, 0.6B, 7.73B sentences for Chinese (zh), German (de), and English (en), respectively. LaBSE embeddings are used to pair each non-English sentence with its nearest English neighbor, dropping pairs with a similarity score < 0.6.[20] For en-de and en-zh, we train a model with Transformer-Big (Vaswani et al., 2017) in the following way: First we train the model on the mined data as is for 120k steps with batch size 10k. Then we select the best 20% using Wang

---

[19] Within prior work, *m*-USE, USE and ConvEmbed use arccos distance to measure embedding space semantic similarity, while InferSent and SentenceBERT use cosine similarity.

[20] The threshold 0.6 is selected by manually inspecting sampled data. We found pairs greater or equal to this threshold are likely to be translations or partial translations of each other. This results in 715M and 302M sentence pairs for en-zh and en-de, respectively. Note that the pairs may still be noisy, which is why we perform additional filtering before training NMT models (Wang et al., 2018) .

Langs	# of XX Sents	# of En Sents	# of Mined Pairs	BLEU News	 TED
en-zh	1.17B	7.73B	715M	36.3	15.2
en-de	601M	7.73B	302M	28.1	31.3

Table 7: The number of source / target sentences and number of mined parallel text from CommonCrawl. BLEU scores (en→xx) are evaluated on WMT News dataset and TED dataset. We use wmtnews17 and wmtnews14 for zh-en and de-en respectively in WMT News set.

et al. (2018)'s data selection method, and train for another 80k steps.

Results in table 7 show the effectiveness of the mined training data. By referencing previous results (Edunov et al., 2018), we see that the model using the en-de mined data yields performance that is only 2.8 BLEU away from performance of the best system that made use of the official WMT17 en-de parallel data. Compare to prior en-zh results (Sennrich et al., 2017), we see that our model using mined en-zh training data is as good as a WMT17 NMT model that is trained on the official WMT en-zh parallel data. The table also gives BLEU performance on the TED test set (Qi et al., 2018), with performance of models trained on our mined training data being comparable with models trained using CCMatrix (Schwenk et al., 2019).[21]

8 Conclusion

This paper presents a language-agnostic BERT sentence embedding (LaBSE) model supporting 109 languages. The model achieves state-of-the-art performance on various bi-text retrieval/mining tasks compare to the previous state-of-the-art, while also providing increased language coverage. We show the model performs strongly even on those languages where LaBSE doesn't have any explicit training data, likely due to language similarity and the massively multilingual natural of the model. Extensive experiments show additive margin softmax is a key factor for training the model, parallel data quantity matters, but the effect of increased amounts of parallel data diminishes when a pre-trained language model is used. The pretrained model is released at `https://tfhub.dev/google/LaBSE`.

Acknowledgments

We thank our teammates from Descartes, Translate and other Google groups for their feedback and suggestions. Special thanks goes to Sidharth Mudgal, and Jax Law for help with data processing; as well as Jialu Liu, Tianqi Liu, Chen Chen, and Anosh Raj for help on BERT pretraining.

A LaBSE$_{\text{Large}}$

Motivated by the recent progress of giant models, we also train a model with increased model capacity. Following BERT$_{\text{Large}}$, we develop LaBSE$_{\text{Large}}$ using a 24 layers transformer with 16 attention heads and 1024 hidden size. Constrained by computation resource, we train 1M steps one stage pre-training instead of the progressive multi-stage pre-training used when training LaBSE model. Fine-tuning configs are exact the same as the base LaBSE model.

Table 8 shows the UN performance of the LaBSE$_{\text{Large}}$ model compared to LaBSE model. The results are mixed, and the average performances are very close. We also evaluate the model on Tatoeba, and the average performances across all languages are also very close: 83.7 (LaBSE) v.s. 83.8 (LaBSE$_{\text{Large}}$).

Model	**es**	**fr**	**ru**	**zh**	**avg.**
LaBSE	91.1	88.3	90.8	87.7	89.5
LaBSE$_{\text{Large}}$	90.9	87.9	89.4	89.5	89.4

Table 8: P@1 on UN (en→xx) .

We suspect that the translate matching training objective is too easy, the model cannot learn more information from the current in-batch negative sampling approach. An improved negative contrast could help the larger model to learn better representations. We experimented with one type of hard negatives in the section below, but more types of hard negatives could be explored as described in (Lu et al., 2020). We leave this as a future work.

B Hard Negative Mining

Since their introduction into models that make use of dual encoders to learn cross-lingual embeddings, hard negatives (Guo et al., 2018) have become the de facto data augmentation method for learning cross-lingual sentence embeddings (Chidambaram et al., 2019; Yang et al., 2019a). To get the hard negatives, a weaker dual encoder model is trained using a similar model but with less parameters and less training data. For each training example, those incorrect translations that are semantically similar to the correct translation are retrieved as "hard-negatives" from a candidates pool. Semantically similarity is determined using the cosine similarity of the embeddings generated by the weaker model. It is challenging to apply hard negative to large datasets as it is very time consuming and computationally costly .

We investigate hard negative mining closely following Guo et al. (2018). By contacting the original authors, we obtained their negative mining pipeline, which employs a weaker dual encoder that uses a deep averaging network trained to identify translation pairs. Similar to the cross-accelerator negatives, the mined negatives are also appended to each example.

We only experiment using hard negative for Spanish (es) as it is very costly to get hard negative for all languages. Due to memory constraints, we only append 3 mined hard negatives in es for each en source sentence. Since the amount of examples increased 4x per en sentence in es batches,we also decrease batch size from 128 to 32 in the hard negative experiment. For languages other than es, the training data was the same as other the experiments but with batch size decreased to 32 together. Other languages are trained as usual. Table 9 shows the results of these models on UN. The accuracy of all four languages went down, even for en-es where we have the hard negatives. We suspect the worse performance is caused by the decreasing of batch size due to the memory constrain with more hard negative per example.

Model	**es**	**fr**	**ru**	**zh**	**avg.**
LaBSE	91.1	88.3	90.8	87.7	89.5
LaBSE + es HN	90.4	87.1	89.9	87.2	88.7

Table 9: P@1 on UN (en→xx) with hard negative examples in en-es.

Nested Named Entity Recognition with Span-level Graphs

Juncheng Wan, Dongyu Ru, Weinan Zhang,[*] Yong Yu
Shanghai Jiao Tong University
{junchengwan,maxru,wnzhang,yyu}@apex.sjtu.edu.cn

Abstract

Span-based methods with the neural networks backbone have great potential for the nested named entity recognition (NER) problem. However, they face problems such as degenerating when positive instances and negative instances largely overlap. Besides, the generalization ability matters a lot in nested NER, as a large proportion of entities in the test set hardly appear in the training set. In this work, we try to improve the span representation by utilizing retrieval-based span-level graphs, connecting spans and entities in the training data based on n-gram features. Specifically, we build the entity-entity graph and span-entity graph globally based on n-gram similarity to integrate the information of similar neighbor entities into the span representation. To evaluate our method, we conduct experiments on three common nested NER datasets, ACE2004, ACE2005, and GENIA datasets. Experimental results show that our method achieves general improvements on all three benchmarks (+0.30 $\sim$ 0.85 micro-F1), and obtains special superiority on low frequency entities (+0.56 $\sim$ 2.08 recall).

1 Introduction

Named entity recognition is one of the major subtasks of information extraction for extracting categorized named entities from unstructured text. Recently, neural-based NER architectures have shown remarkable performance with minimal feature engineering, such as CNN-CRF (Collobert et al., 2011), BiLSTM+CRF (Lample et al., 2016), LSTM-CNN-CRF (Ma and Hovy, 2016) and Lattice LSTM (Zhang and Yang, 2018a). Despite their great success, nested NER raises new challenges due to the deeply overlapping or nested entities (Finkel and Manning, 2009). In nested NER, a token may be included in multiple entities (Wang and Lu, 2018) instead of a single one in the conventional setting, making the problem more difficult to solve.

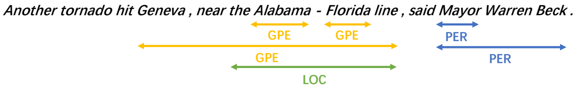

Figure 1: An example of nested NER in ACE2005 dataset.

Previous exploration on nested NER can be mainly divided into three categories, using various architectures or different formulation for adaptation to the nested scenario. *Hypergraph-based* methods use explicit hypergraphs to represent the possible nested structure or investigate the graph-shaped lexical/syntactic features (Lu and Roth, 2015; Katiyar and Cardie, 2018; Wang and Lu, 2018). *Layered-based* methods construct the nested structure through an action sequence (Wang et al., 2018; Fisher and Vlachos, 2019; Shibuya and Hovy, 2020) or layered-models (Ju et al., 2018; Wang et al., 2020). *Span-based* methods directly enumerate spans in a sentence, and perform categorical prediction on each span (Lin et al., 2019; Eberts and Ulges, 2020; Luan et al., 2019; Tan et al., 2020). *Span-based* methods adopt the most simple and straightforward formulation as span classification, thus widely used and applied in joint relation extraction recently.

Despite the simplicity of span-based models, they can hardly fully utilize the rich semantics in spans. Previous investigation has shown that span-based models are usually confused when the positive and negative instances are largely overlapped (Finkel and Manning, 2009; Tan et al., 2020), as shown in Fig. 1. The minor differences between long entities and their similar spans can easily fool the span-based models. Besides, most entities during inference statistically never appear in the training set in nested NER. For example, in ACE2004, ACE2005, and GENIA, there are

---

Volume 1: Long Papers, pages 892 - 903
May 22-27, 2022

53.06%, 41.64% and 51.42% entity mentions from the validation set appear fewer than three times in the training set. Learning powerful span representations for the prediction of those “unfamiliar” entities is difficult for conventional span-based models.

In this work, we try to improve the span representation in span-based methods by utilizing retrieval-based span-level graphs. We seek helpful information in the training set beyond the current sentence. The intuitive assumption is that the entity spans similar to the candidate spans contain related information for discrimination on the candidate spans. We use n-gram similarity to measure the distance between spans. Specifically, we treat each entity in the training set and each raw span as nodes, connecting those with high n-gram similarity. The constructed span-level heterogeneous graph records the lexical correlations among entities and various raw spans. We enhance the span representation by including the retrieved local subgraph for feature extraction of a specific span. We perform message passing with GCNs (Kipf and Welling, 2017) on the retrieved subgraph for neighbor entities representation. The representation of neighbor entities provides rich correlations beyond the current sentence, thus improving the performance on confusing long spans and low-frequency spans. Our main contributions are listed as follows:

- We firstly introduce retrieval-based span-level graphs in nested NER to model the lexical correlations among candidate spans and entities beyond the current sentence.

- We perform message passing with GCNs and conduct multitask learning to effectively extract the rich information from the entity neighbors of candidate spans.

- We conduct experiments on three common nested NER datasets (ACE2004, ACE 2005, and GENIA). The empirical results and extensive analysis show that our method outperforms strong baselines on all three benchmarks and has special superiority on long and low-frequency spans.

2 Related Work

Our work is closely related to nested NER and graphs used in NER. We introduce them accordingly as below.

2.1 Nested NER

Nested NER, with the challenging nested entities included, has attracted many researchers recently. There are three categories of mainstream solutions: span-based, hypergraph and layered methods.

Span-based method exhausts all spans in the sequence and predicts their classes instead of performing sequence labeling. The classifier can be a maximum entropy tagger (Byrne, 2007) or a neural network (Sohrab and Miwa, 2018; Fu et al., 2021; Ouchi et al., 2020; Li et al., 2020). Some works propose to utilize relations (Luan et al., 2019; Eberts and Ulges, 2020) for span prediction or correlation intensities (Xu et al., 2021), while Tan et al. (2021) proposes to learn the patterns of the valuable spans. The span-based method is also improved by the two-stage method, including locating entities and predicting type (Lin et al., 2019; Tan et al., 2020; Zheng et al., 2019; Shen et al., 2021). Our method abuses complicated tagger or the boundary auxiliary but utilizes the n-gram features to improve the span representation.

Hypergraph method learns hypergraph of nested relationship (Lu and Roth, 2015), dependency tree (Yu et al., 2020) or others (Dozat and Manning, 2017; Muis and Lu, 2017; Wang and Lu, 2018; Katiyar and Cardie, 2018). This method with the designed proprietary structures can explicitly capture the nested entities. While a proper graph needs subtle work or external tools, such as the parser.

Layered method stacks flat NER layers and is naturally suitable for nested structures. While it suffers from layer disorientation or error propagation problem. Ju et al. (2018) recognizes inner entities and then entities of next layers. Others enhance this idea with a merge and label method (Fisher and Vlachos, 2019) or by applying a pyramid-shaped decoder (Wang et al., 2020). The second-best path decoding method is explored (Shibuya and Hovy, 2020) and improved (Wang et al., 2021) by excluding the influence of the best path.

2.2 Graphs Used in NER

Graphs, as a common formulation for structured information, are widely used in flat NER and nested NER. For Chinese NER, models with lexicon-based graph (Zhang and Yang, 2018b; Ding et al., 2019; Gui et al., 2019) are proposed to fully use gazetteers. Cetoli et al. (2017) investigates the use of the dependency tree. Yu et al. (2020) improves the idea from graph-based dependency parsing via

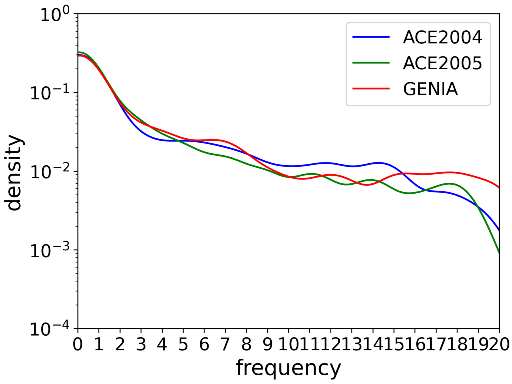

Figure 2: The density of entity frequency in the test set, where entities have frequency ≤ 20 in the training set.

a biaffine model. The biaffine model is also explored with the graph of original token sequence and the graph of tokens in recognized entities (Luo and Zhao, 2020). Muis and Lu (2017); Wang and Lu (2018); Katiyar and Cardie (2018) resolve spurious structures and ambiguous issues of hypergraph structure of nested NER. Relation information is used in the graph (Fu et al., 2019) with a relation extraction model. Instead of building graphs from a single sentence, our span-level graphs are built from the whole training set, which has better data utilization. Besides, our method does not use the parser for dependency tree or gazetteers as external knowledge.

3 Our Approach

In this part, we introduce the details of our approach. We first formulate the target problem, nested NER, as follows.

Nested NER as Span Classification Following Eberts and Ulges (2020), we formulate the nested NER problem as the span classification task. The span classification task treats multiple adjacent tokens as a span and predicts the corresponding label. Specifically, for a sentence $X = \{x_1, \ldots, x_n\}$ of n tokens, we extract all spans (with length ≤ 10) to a span set $S_X = \{s_{ij} | 1 \leq i \leq j \leq n\}$, where s_{ij} indicates the span from x_i to x_j. We predict the corresponding label of s_{ij} as one of the pre-defined entity types or NA (not an entity).

The formulation as span classification instead of sequence labeling is more suitable for NER in nested scenarios but brings two challenges. The *insensitivity to boundaries* make the long candidate spans hard to identify. The *low-frequency spans*, taking the majority in data (Fig. 2), also increase the difficulty on capturing intra-span representations. We use span-level graphs connecting entities and raw spans to tackle the problems.

The overview of our model architecture is shown in Fig. 3. We construct the span-level graph with n-gram similarity to determine the adjacency (Sec. 3.1). We initialize the representation of spans and entities with the encoder described in Sec. 3.2. The structured correlations among entities and spans are modeled with GCN (Sec. 3.3). We incorporate in training the entity categorical prediction to utilize the label of entity mentions on the graph (Sec. 3.4).

3.1 Span-level Graph

We propose to improve the span representation by constructing retrieval-based graphs according to n-gram features. Our method uses two span-level graphs, i.e. entity-entity graph and span-entity graph. If treating each entity mention or raw span as a span of multiple adjacent tokens, both of these two graphs model the relationship between spans.

Before describing the method, we denote $\mathcal{E}$ the set of entity mentions, $\mathcal{R}$ the set of raw spans, $\mathcal{S} = \mathcal{E} \bigcup \mathcal{R}$ the set of all spans, and $\mathcal{N}_G^k(v)$ the set of k hop neighborhood vertices of vertex v in graph G. In this work, we design the n-gram similarity function between spans $f_n : \mathcal{S} \times \mathcal{S} \longrightarrow \mathbb{R}$ at byte pair encodings (BPE) (Sennrich et al., 2016) level. More precisely, f_n is the cardinality of the intersection set of n-gram BPE sets, i.e. $f_n(s, s') = |n\text{-gram}(\texttt{BPE}(s)) \cap n\text{-gram}(\texttt{BPE}(s'))|$ for $s, s' \in \mathcal{S}$.

Entity-entity graph First, we introduce the entity-entity graph $G_{EE} = (V_{EE}, E_{EE})$. In G_{EE}, nodes are from the set of entity mentions $\mathcal{E}$. Entity mentions with the same tokens but different types are treated as different nodes. For $e_i, e_j \in V_{EE}$, the edge weight $w(e_i, e_j)$ is calculated by the weighted n-gram similarity from f_n as follows:

$$w(e_i, e_j) = \frac{1}{N} \sum_{n=1}^{N} \alpha_n f_n(e_i, e_j) \qquad (1)$$

where α_n indicates the importance of each n-gram feature, and N is the largest gram length. A high value of $w(e_i, e_j)$ indicates high frequency of the words co-occurrence between e_i and e_j.

Span-entity graph Span-entity graph $G_{SE} = (V_{SE}, E_{SE})$ models the relationship between raw

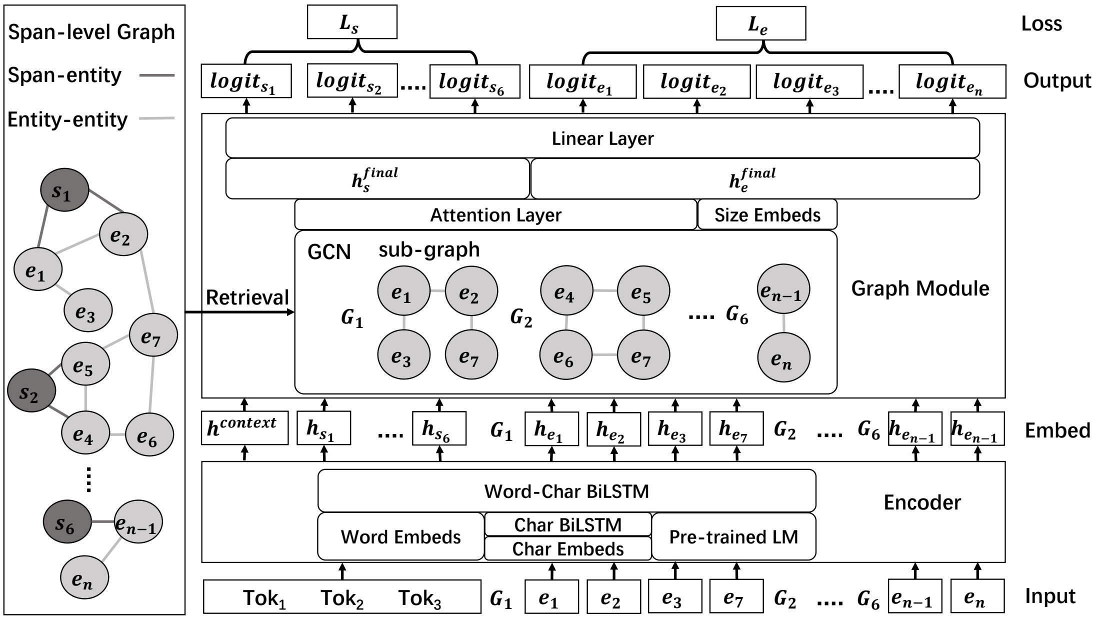

Figure 3: An overview of our model. The sub-graph takes 2-hop neighbors of raw spans.

spans and entity mentions, which is more complicated. In G_{SE}, nodes include raw spans and entity mentions from $\mathcal{S}$ and each edge connects one raw span and one entity mention. By observation, the gram features of raw spans in natural sentences are different from that of entities in two aspects. (1) A raw span can be arbitrary long, as it can be a single token to the whole sentence. A raw span of the whole sentence unfairly has more gram overlap with entity mentions than other spans within it. (2) Raw spans have more irregular patterns than entities and always link to meaningless entity mentions as noise.

Thus, constructing G_{SE} as G_{EE} is not suitable. Here we propose two simple and effective methods for these problems. For problem (1), we penalize long raw spans s_{ij} for any edge weight $w(s_{ij}, e)$ by the length $l(s_{ij}) = j - i + 1$ as follows:

$$w(s_{ij}, e) = \frac{1}{N \cdot l(s_{ij})} \sum_{k=1}^{N} \alpha_n f_n(s_{ij}, e) \qquad (2)$$

For problem (2), we exclude those noise span-entity edges simply by setting the hard threshold $\tau \in \mathbb{R}^+$ and remove edges with weight below it.

Span-level (sub-)graph The span-level graph $G = (V, E)$ is the union of G_{EE} and G_{SE} excluding raw spans. We exclude raw spans for the training efficiency of a homogeneous graph. Thus, $V = V_{EE} \bigcup V_{SE} - \mathcal{R}$ and $E = E_{EE}$. For mini-batch training, we dynamically extract span-level sub-graphs from G_{EE} and G_{SE}. As the inference goal is to classify raw spans, we only extract the K-hop sub-graph of raw spans during training.

The extraction process is as follows. (1) For the raw span node v_s, we take its first-order neighbors $V_1 = \mathcal{N}^1_{G_{SE}}(v_s)$ from G_{SE}. (2) The union of i-hop $(1 \leq i \leq K-1)$ entity neighbors of $\mathcal{N}^1_{G_{SE}}(v_s)$, i.e. $V_2 = \bigcup_{v \in \mathcal{N}^1_{G_{SE}}(v_s)} \bigcup_{1 \leq i \leq K-1} \mathcal{N}^i_{G_{EE}}(v)$, are extracted from G_{EE}. (3) We exclude the raw span node v_s and preserve edges between the rest nodes. Thus, the sub-graph of v_s is an induced sub-graph $G[V_1 \bigcup V_2 - v_s]$ from G.

3.2 The Encoder

For the initialization of raw spans and entity mentions, we use char embeddings, word embeddings, and pre-trained LM. Both sentence and entity mentions are treated as a sequence of tokens and are encoded separately. First, the char embeddings are fed into bidirectional LSTM (Lample et al., 2016) (Char-BiLSTM) to capture the orthographic and morphological features of words. Then, the pre-trained LM, such as BERT (Devlin et al., 2019), is used for contextualized representation. The representations are averaged BPE embeddings in the last layer. Finally, the char hidden states, contextualized embeddings, and word embeddings are concatenated and then fed into another bidirectional LSTM (Word-Char BiLSTM) for the encoded representation of words. For the span-level representation, we use max-pooling for encoded representation of words within the span.

3.3 Graph Module

To model the span-level graph, we adopt graph convolutional networks (GCN) (Kipf and Welling, 2017). Let A be the normalized symmetric adjacency matrix of G. The number of GCN layers is also the hop number K of the sub-graph. The $(k+1)$-th layer of the feature matrix H^{k+1} is computed as:

$$H^{k+1} = \texttt{ReLU}(AH^kW_k) \tag{3}$$

where W_k is the learnable matrix, $0 \leq k \leq K$, H^0 is the output from the encoder.

To integrate the representations of neighborhood nodes for sub-graph embedding, we use the attention mechanism. Denote h_0^k $(0 \leq k \leq K)$ the hidden state of the raw span in the k-th layer of GCN and h_i^k $(i \geq 1)$ that of the i-th entity mention neighbor of the span in the k-order neighbors. The sub-graph embedding h^{graph} of the raw span is:

$$\gamma_i = \frac{\exp((h_i^K)^T W_a h_0^0)}{\sum_{j\geq 1}\exp((h_j^K)^T W_a h_0^0)} \tag{4}$$

$$h^{\text{graph}} = \sum\nolimits_{i\geq 1} \gamma_i h_i^K \tag{5}$$

where W_a is a learnable matrix.

Besides, context information of entities is important as entities are interpreted differently under different contexts. We use the last hidden state of "[CLS]" token in pre-trained LM as the context representation h^{context}. We use a learnable weight matrix for size embeddings h^{size}.

The raw span representations consists of the encoder output h_0^0, the raw span sub-graph embedding, context embedding, and size embedding. The final representation of a raw span h_0^{final} or a entity mention h_i^{final} $(i \geq 1)$ is as follows:

$$h_0^{\text{final}} = \texttt{concat}(h_0^0, h^{\text{graph}}, h^{\text{context}}, h^{\text{size}}) \tag{6}$$

$$h_i^{\text{final}} = \texttt{concat}(h_i^0, h_i^K, h^{\text{size}}) \tag{7}$$

3.4 Multitask Learning

To utilize the label of entity mentions, we force GCN to predict graph neighbors of the raw span simultaneously. We use feed-forward layers to get logits as follows:

$$logits_s = \texttt{Linear}_s(h_0^{\text{final}}) \tag{8}$$

$$logits_{e_i} = \texttt{Linear}_e(h_i^{\text{final}}) \tag{9}$$

Thus, our algorithm contains two losses to minimize, the cross entropy loss $\mathcal{L}_s$ ($\mathcal{L}_e$) of raw span (entity mention) prediction.

$$\mathcal{L}_s = \texttt{CE}(logits_s) \tag{10}$$

$$\mathcal{L}_e = \sum\nolimits_i \texttt{CE}(logits_{e_i}) \tag{11}$$

To balance the two losses, we adopt a multi-task learning framework with a hyperparameter β:

$$\mathcal{L} = \mathcal{L}_s + \beta\mathcal{L}_e \tag{12}$$

where $\mathcal{L}$ is the total loss. At the inference stage, we only infer the raw span.

4 Experiments

In this section, we evaluate our method on three common nested NER datasets, including ACE2004, ACE2005, and GENIA.

4.1 Dataset

We use three nested English NER datasets: ACE2004[1], ACE2005[2], and GENIA (Kim et al., 2003). For GENIA, we use GENIAcorpus3.02p3, and follow the train/validation/test split of previous works (Finkel and Manning, 2009; Lu and Roth, 2015) i.e.: (1) split first 81%, subsequent 9%, and last 10% as train, dev and test set, respectively; (2) collapse all DNA, RNA, and protein subtypes into DNA, RNA, and protein, keeping cell line and cell type, and (3) remove other entity types, resulting in 5 entity types. There are statistical results of these datasets in Table 1.

4.2 Baselines

As we use pre-trained LM, we compare our method with methods with similar settings. Besides, we also include the results of models using additional supervision, which are not directly comparable to ours. Our baselines are as follows.

Models without pre-trained LM: Hyper-Graph (Katiyar and Cardie, 2018) proposes a hypergraph-based model based on LSTMs. **Stack-LSTM** (Wang et al., 2018) uses a scalable transition-based method to model the nested structure of mentions. **Seg-Graph** (Wang and Lu, 2018) proposes a segmental hypergraph representation to model overlapping entitys. **ARN**

(Lin et al., 2019) leverages the head-driven phrase structures of entity mentions.

Models with pre-trained LM: Seq2seq (Straková et al., 2019) views the nested NER as a sequence-sequence problem. **Path-BERT** (Shibuya and Hovy, 2020) treats the tag sequence as the second-best path within the span of their parent entity. **ML** (Fisher and Vlachos, 2019) proposes a merge and label method. **Pyramid** (Wang et al., 2020) is a layered model, in which text region embeddings are recursively inputted into stacked flat NER layers. **SpERT** (Eberts and Ulges, 2020) is an attention model for span-based joint entity and relation extraction. We implement this method with BERT. **BENSC** (Tan et al., 2020) is a boundary enhanced span classification model.

Models with additional supervision: BERT-MRC (Li et al., 2020) formulates NER as a machine reading comprehension task. **NER-DP** (Yu et al., 2020) uses ideas from graph-based dependency parsing to model nested structure. **DYGIE** (Luan et al., 2019) shares span representations using dynamically constructed span graphs.

4.3 Training Details

For word embeddings, we use 100-dimensional GloVe embeddings trained on 6B tokens [3] for ACE2004/ACE2005, 200-dimensional embeddings trained on biomedical[4] for GENIA. We fix word embeddings during training. We use 30-dimensional char embeddings and Char BiLSTM of 60-dimensional hidden state. The hidden size of Word-Char BiLSTM is 300-dimensional. For size embeddings, we use 25-dimensional vectors.

For pretrained LM, we use BERT-base-cased model (Devlin et al., 2019) [5] for ACE2004 and ACE2005, BioBERT v1.1 (Lee et al., 2020)[6] for GENIA. We fine-tune BERT with optimizer Adam (Kingma and Ba, 2015) with learning rate in $\{1e-5, 2e-5, 3e-5\}$ and weight regularization $1e-8$. For other model parameters, we use learning rate in $\{1e-4, 5e-4, 1e-3\}$. Batch size is in $\{2, 4, 8\}$ and dropout in $\{0.1, 0.2, 0.3\}$. For stable convergence, we use linear learning rate scheduler, with maximal number of epoch 50 and warm-up ratio 0.01.

For the graph, we set the largest gram size $N = 3$ and use BERT-base-cased tokenizer for BPE encoding. The n-gram weight $\alpha_k = 0.5k$, where $k \in \{1, 2, 3\}$. We prune the span-level graph G with $\tau = 0.8$ and edges with weight below it are removed. The GCN layer size $K = 2$ and hidden size is 400. These hyperparameters are selected by ourselves and more detailed analyses are in Appendix A. During training, we sample 100 negative spans randomly. The multi-task coefficient $\beta = 0.1$. We use DGL[7] to implement GCN. The inference speed and GPU usage are discussed in Appendix B.

We pick the model by the performance in the validation set. We use span-level micro-averaged precision, recall, and F1 on the test set for evaluation. Results are averaged on 3 runs for reproducibility.

4.4 Main Results

In Table 2, our method has significant improvement compared with nested NER models without pre-trained LM and with pre-trained LM. Compared with models without pre-trained LM, our method has at least +6.01, +5.69, +1.50 F1 improvement for ACE2004, ACE2005, and GENIA, which is statistically significant. Compared with methods using pre-trained LM, our method also yields at least +0.85, +0.78 F1 improvement for ACE2004 and ACE2005. Besides, our method has

comparable results with the Pyramid model in GENIA. Although a little worse than BERT-MRC and NER-DP, our method does not introduce additional supervision, such as the syntax and dependency structures, or human prior knowledge.

4.5 Ablation Study

In Table 3, we conduct an ablation study on the ACE2005 dataset by adding components to our method step by step. It shows that the span-entity graph is the most effective component (+0.55 F1 score). As the first-order sub-graph in the span-level graph, it provides direct guidance for the prediction of the raw span. Besides, multitask training also improves our method by +0.47 F1 score. As multitask training utilizes the label of graph neighbors, which may contain the ground truth of the raw span.

Table 6: Comparison of SpERT and our method on low-frequency entities on ACE2004 and ACE2005 test sets.

ties with different lengths, and entities with different frequencies in training data, respectively.

Nested entities In Table 4, we compare the recall of nested entities of our method and baseline SpERT on the validation and test sets of nested NER. Our method improves the recall of nested entities in both validation and test set by +1.00 $\sim$ 5.87. Generally, the improvement on nested entities is slightly larger than overall entities, which proves that our method tackles the nested problem better than the baseline.

Entities of different length Table 5 makes a detailed comparison with SpERT for entities of length 1 $\sim$ 10 on ACE2005 test set. Generally, our method has a higher F1 score. It can be seen that our method can effectively handle long entities with length ≥ 6. The largest improvement is +13.11 F1 for entities of length 8. We attribute it to that longer entities have richer n-gram features. The longer entities link more useful entity mentions in the span-level graph. The more informative neighbors of long entities significantly boost the performance by utilizing the label information of neighbors.

Low-frequency entities Table 6 compares with SpERT on the recall of entities with frequency ≤ 4 in the training set in ACE2004 and ACE2005 test sets. Our method yields +2.08 $\sim$ 2.56 and +0.56 $\sim$ 0.83 improvements in ACE2004 and ACE2005 respectively. For entities not in the training set, our method has +2.35 and $+0.81$ improvement in ACE2004 and ACE2005. Our span-level graphs provide information beyond the current entity and the sentence as lexically correlated similar entities. The information beyond the current sentence help improve the performance of "unseen" entities.

4.7 Case Study

Figure 4 is a case study in ACE2005 validation set to compare our method with SpERT. The original sentence has three entities to recognize. One entity is "The Bradleys", which is the Bradley fighting vehicle (VEH). However, the baseline SpERT classifies "The Bradleys" as a person (PER) with the misleading context. Our sub-graph links 2 VEH entities and makes the prediction correct. Besides, our method predicts "coaxial machine guns" correctly as a whole entity instead of "machine guns" partially. This attributes to the external guidance of 23 weapon (WEA) entity nodes in the span-level graph.

5 Conclusions

In this work, we enhance the span-based method for nested NER by including retrieval-based span-level graphs. Our method builds the entity-entity graph and the span-entity graph globally based on n-gram feature similarity. We use GCN to encode such structured correlations to obtain better span representation. We include multi-task learning to encode the label information of similar entities in the graph. The experimental results on three commonly used nested NER datasets, i.e. ACE2004, ACE2005 and GENIA, show that our method can improve the F1 score generally and improve recall for entities with low frequency in the training set.

A Hyper-parameters Analysis

Loss coefficient Multi-task loss coefficient β is important for the balance of raw span classification and entity label usage. We set $\beta \in \{0.0, 0.1, 0.2, 0.3, 0.4, 0.5\}$ and test the sensitivity in Fig. 5. The results show that both large and small values of β degenerate the performance. The best results are attained when β is $0.1 \sim 0.3$ for ACE2004 and ACE2005, and 0.1 for GENIA. Small β won't train entity representation sufficiently, which the raw span takes attention from. While β disables models focusing on span classification.

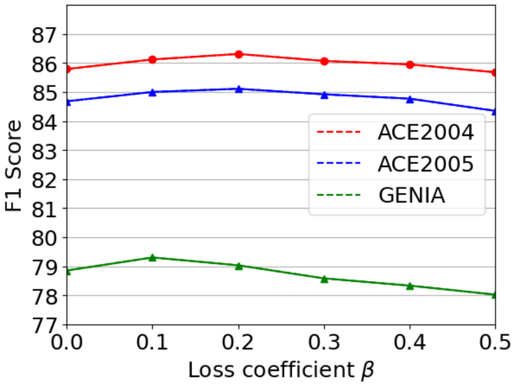

Figure 5: The effect of loss balance coefficient β. We set $\beta \in \{0.0, 0.1, 0.2, 0.3, 0.4, 0.5\}$ for each dataset.

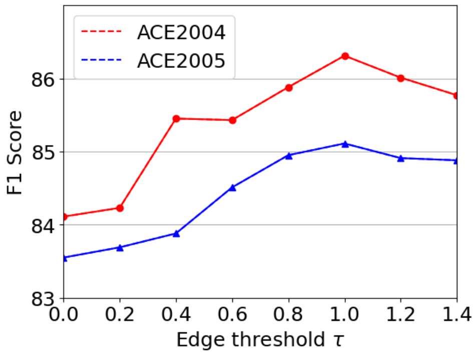
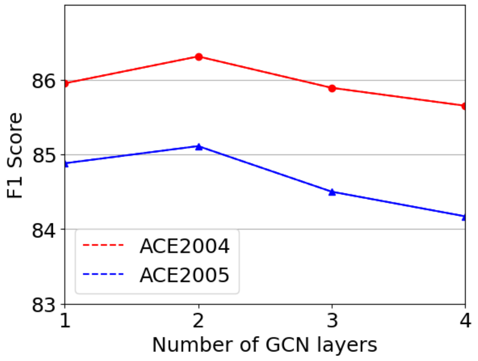
Graph hyper-parameters We explore two graph hyper-parameters edge threshold τ and GCN layers K in ACE2004/ACE2005. In Fig. 6(a), we set $\tau \in \{0.0, , 0.2, 0.4, 0.6, 0.8, 1.0, 1.2, 1.4\}$ and τ around 1.0 achieves the best performance. Large edge threshold influences the performance slightly while small τ degenerates the performance a lot by introducing much noise into the graph.

In Fig. 6(b), we set GCN layers $K \in \{1, 2, 3, 4\}$ and find that 2-layer GCN with 2-hop span-level graph performs better. When $K = 1$, our method degrades to using only a span-entity graph and the performance decreases a little. Stacking multiple layers of GCNs leads to high complexity in backpropagation, which is not conducive to the training.



(a) Edge Threshold



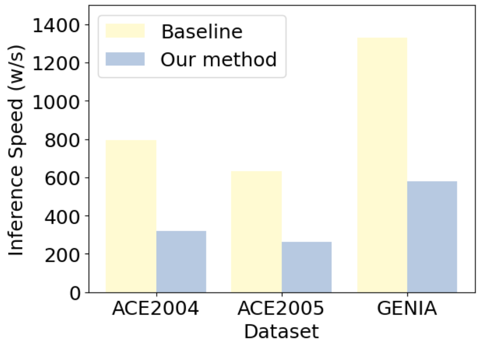
(b) GCN Layers

Figure 6: The effect of graph hyper-parameters in ACE2004 and ACE2005 datasets. We set edge threshold $\tau \in \{0.0, , 0.2, 0.4, 0.6, 0.8, 1.0, 1.2, 1.4\}$ and GCN layers $M \in \{1, 2, 3, 4\}$.

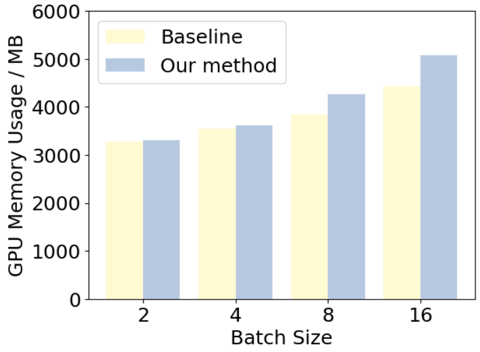
B Time and Space Analysis

Inference speed In Fig. 7(a), we compare our method with SpERT at the inference speed, where metrics is the number of words decoded per second. We evaluate at four nested NER test set on GTX 1080 Ti. The batch size is fixed to 4. Our inference speed is around half of SpERT. Although the introduction of the graph module increases the inference time, the cost is acceptable considering the significant recognition improvement.

GPU usage In Fig. 7(b), we compare the GPU memory usage (/MB) of our method and baseline SpERT on ACE2005 test set with batch size in $\{2, 4, 8, 16\}$. It shows that the graph module only increases the GPU usage for a small part, around $100 \sim 500$ MB. With the increase of batch size, the GPU usage increment also increases.



(a) Inference Speed



(b) GPU Usage

Figure 7: The inference speed of our method and baseline on the test sets. We evaluate word per second (w/s). The GPU memory usage (/MB) of our method and baseline with different batch size on ACE2005 training set. We use GeForce GTX 1080 Ti as the device.

CogTaskonomy: Cognitively Inspired Task Taxonomy Is Beneficial to Transfer Learning in NLP

Yifei Luo† , **Minghui Xu**† and **Deyi Xiong***
College of Intelligence and Computing, Tianjin University, Tianjin, China
`{yfluo,xuminghui,dyxiong}@tju.edu.cn`

Abstract

Is there a principle to guide transfer learning across tasks in natural language processing (NLP)? Taxonomy (Zamir et al., 2018) finds that a structure exists among visual tasks, as a principle underlying transfer learning for them. In this paper, we propose a cognitively inspired framework, CogTaskonomy, to learn taxonomy for NLP tasks. The framework consists of Cognitive Representation Analytics (CRA) and Cognitive-Neural Mapping (CNM). The former employs Representational Similarity Analysis, which is commonly used in computational neuroscience to find a correlation between brain-activity measurement and computational modeling, to estimate task similarity with task-specific sentence representations. The latter learns to detect task relations by projecting neural representations from NLP models to cognitive signals (i.e., fMRI voxels). Experiments on 12 NLP tasks, where BERT/TinyBERT are used as the underlying models for transfer learning, demonstrate that the proposed CogTaskonomy is able to guide transfer learning, achieving performance competitive to the Analytic Hierarchy Process (Saaty, 1987) used in visual Taskonomy (Zamir et al., 2018) but without requiring exhaustive pairwise $O(m^2)$ task transferring. Analyses further discover that CNM is capable of learning model-agnostic task taxonomy. The source code is available at `https://github.com/tjunlp-lab/CogTaskonomy.git`.

1 Introduction

Transfer learning (TL) has attracted extensive research interests in natural language processing with a wide range of forms, e.g., TL from pretrained language models (PLM) to downstream tasks (Devlin et al., 2018; Radford et al., 2018), from a task with rich labeled data to a task with low resource (Chu and Wang, 2018; Yu et al., 2021), from high-resource languages to low-resource languages (Gu et al., 2018; Ko et al., 2021), etc.[1] A high-level concept or question on cross-task transfer learning is how these involved tasks are related to each other. Is sentiment analysis related to paraphrasing? Is textual entailment more related to question answering than named entity recognition? All these sub-questions resolve themselves into whether a structure exists among NLP tasks. Such task taxonomy is of notable values to transfer learning in NLP in that it has the potential to guide TL and reduce redundancies across tasks (Zamir et al., 2018).

In this paper, partially inspired by the task taxonomy in visual tasks (Zamir et al., 2018), we study the hierarchical task structure for NLP tasks. But significantly different from the visual Taskonomy (Zamir et al., 2018), we construct NLP taskonomy from a cognitively inspired perspective.

Cognitively inspired NLP is the intersection of NLP and cognitive neuroscience that aims at uncovering cognitive processes in the brain, including cognition in language comprehension. With the increasing availability of cognitively annotated data, on the one hand, cognitive processing signals (e.g., eye-tracking, EEG, fMRI) have been explored to enhance neural models for a wide range of NLP tasks (Barrett and Søgaard, 2015; Bingel et al., 2016; Hollenstein and Zhang, 2019; Hollenstein et al., 2019a). On the other hand, representations learned in NLP models are used to predict brain activation patterns recorded in cognitive processing data (Mitchell et al., 2008; Pereira et al., 2018; Hale et al., 2018; Hollenstein et al., 2019b). These studies on the bidirectional association between the two areas demonstrate that information underlying cognitive processing data is closely related to tasks and representations in NLP. Hence we want to know whether it is feasible to isolate task repre-

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 904 - 920

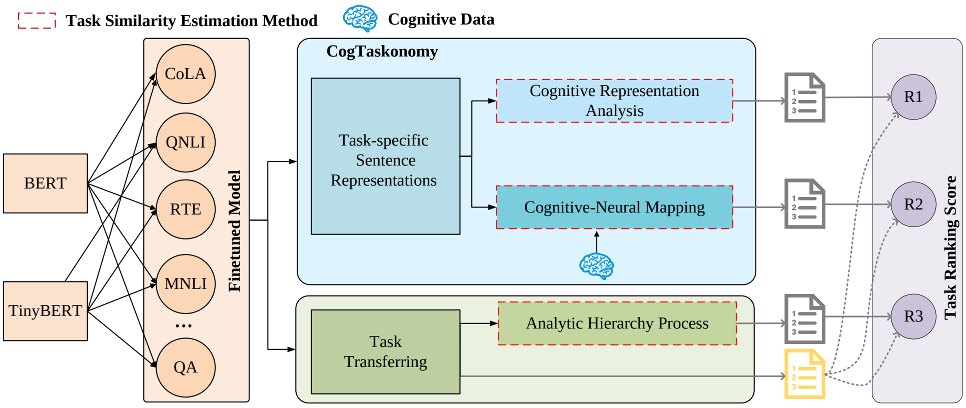

Figure 1: Illustration of CogTaskonomy. Pretrained language models are fine-tuned on downstream tasks to obtain task-specific sentence representations, which are then fed into CRA, CNM for estimating task similarity. We can obtain the most similar task for each target task by the corresponding task similarity estimation method and rank it according to the oracle task ranking obtained according to transfer learning performance. R is the task ranking score which is averaged over all target tasks.

sentations from cognitive processing data and use them to learn task taxonomy in NLP.

To examine this hypothesis, we propose CogTaskonomy, a **Cog**nitively Inspired **Task** Tax**onomy** framework, as illustrated in Figure 1, to learn a task structure for NLP tasks. CogTaskonomy consists of two main cognitively inspired components: Cognitive Representation Analytics (CRA) and Cognitive-Neural Mapping (CNM). CRA extracts task representations from NLP models and employs Representational Similarity Analysis (RSA) (Kriegeskorte et al., 2008), which is commonly used to measure the correlation between brain activity and computational model, to estimate NLP task similarity. CNM trains fully connected neural networks to build the mapping from sentence representations of pretrained models fine-tuned on specific tasks to fMRI signals recorded when human subjects read those sentences. It then uses mapping correlation coefficients as task representations to compute task similarity.

Both methods require sentence representations to compute task representations. We use pretrained language models fine-tuned on specific tasks, particularly BERT (Devlin et al., 2018) and TinyBERT (Jiao et al., 2020), to obtain sentence representations.

We compare the proposed CogTaskonomy against the Analytic Hierarchy Process (AHP) used in Taskonomy (Zamir et al., 2018). We guide TL across tasks with the learned task structure and evaluate the effectiveness of these methods by estimating TL performance from various source to target tasks.

Contributions Our main contributions include:

- We propose CogTaskonomy, a cognitively inspired framework to measure task similarity and to build the task taxonomy in NLP. This is the first attempt to study NLP task structures with cognitive processing data.
- We present two cognitively inspired methods, CRA and CNM, and compare them against AHP. Different from AHP, the two methods do not require $O(m^2)$ exhaustive pairwise transfer learning for task similarity estimation.
- We build a taxonomy tree for 12 NLP tasks, including sentiment analysis, question answering, natural language inference, semantic textual similarity, passage ranking, etc., to guide transfer learning across them.
- TL experiments and analyses validate the effectiveness of the proposed CogTaskonomy and find that CNM is able to learn stable task relations that are general to different underlying models.

2 Related Work

Our work is related to cognitively inspired NLP and a variety of learning formalisms that involve knowledge transfer across different tasks. We briefly review these topics within the scope of NLP and the constraint of space.

2.1 Cognitively Inspired NLP

Using NLP Representations for Brain Activity Prediction Since the pioneering work (Mitchell et al., 2008), connecting statistical NLP representations with cognition has attracted widespread attention. Chang et al. (2009) explore adjective-noun composition in fMRI based on co-occurrence statistics. Huth et al. (2016) use distributed word representations to map fMRI data to activated brain regions, revealing a semantic map of how words are distributed in the human cerebral cortex. A great deal of research (Murphy et al., 2012; Anderson et al., 2016; Søgaard, 2016; Bulat et al., 2017) has been devoted to word decoding. Pereira et al. (2018) extend brain decoding to sentence stimuli, suggesting that neural network language models can be used to interpret sentences in a long-term context. Ren and Xiong (2022) investigate the relationship between linguistic features and cognitive processing signals by developing a unified attentional network to bridge them.

Augmenting NLP Models with Cognitive Processing Signals Recent years have witnessed that many efforts have been devoted to exploring cognitive processing signals (e.g., eye-tracking, EEG, fMRI) in neural NLP models. Muttenthaler et al. (2020) use cognitive data to regularize attention weights in NLP models. Hollenstein et al. (2019a) evaluate word embeddings using cognitive data. Toneva and Wehbe (2019) utilize fMRI scans to interpret and improve BERT. Many other works use cognitive processing signals to improve NLP models (Barrett and Søgaard, 2015; Bingel et al., 2016; Gauthier and Levy, 2019; Hollenstein and Zhang, 2019; Ren and Xiong, 2021), just to name a few.

2.2 Learning across Tasks

A very important trend in recent NLP is that models, algorithms, and solutions are not developed for only a single task, but for multiple tasks or across tasks (Devlin et al., 2018; Radford et al., 2018; McCann et al., 2018; Worsham and Kalita, 2020). Learning methods that are capable of handling a set of tasks simultaneously or sequentially, e.g., multi-task learning, transfer learning, meta learning, have attracted growing research interests in NLP. Beyond learning methods, yet another important dimension to this research trend is task relation learning, which is the topic of this work.[2]

Multi-task Learning is to jointly train all tasks of interests with task linkages, e.g., in the form of regularization or sharing parameters across tasks (Collobert et al., 2011). It is important in multi-task learning to find related tasks for target tasks as auxiliary tasks (Ruder, 2017).

Transfer Learning targets at transferring knowledge from a source task to a target task. According to the task and domain difference in the source and target, TL is divided into transductive TL (same task, different domain, a.k.a. domain adaptation), inductive TL (same domain, different task) and unsupervised TL (both different) (Eaton and desJardins, 2011; Ghifary et al., 2014; Wang et al., 2019; Yuan and Wen, 2021). If the source and target are dissimilar, negative transfer may hurt TL (Niu et al., 2020).

Meta Learning aims to gain experience over a set of related tasks for improving the learning algorithm itself (Hospedales et al., 2020). Existing meta learning methods implicitly assume that tasks are similar to each other, but it is often unclear how to quantify task similarities and their roles in learning (Venkitaraman and Wahlberg, 2020).

Lifelong Learning is to learn continuously and accumulate knowledge along a sequence of tasks and uses it for future learning (Chen and Liu, 2018). The system is tuned to be able to select the most related prior knowledge to bias the learning towards a new task favourably (Silver et al., 2013).

2.3 Learning Task Relations

As task relatedness is important for cross-task learning formalisms mentioned in Section 2.2, efforts have also been made to learn task relations. Crawshaw (2020) groups previous methods on task relationship learning into three categories. The first is task grouping or clustering, which divides a set of tasks into clusters so that tasks in the same cluster can be jointly trained (Bingel and Søgaard, 2017; Standley et al., 2019). The second is learning transfer relationships, which analyzes whether transfer between tasks is beneficial to learning, regardless of whether tasks are related or not (Zamir et al., 2018; Dwivedi and Roig, 2019; Song et al., 2019). The third is task embedding, which learns a specific representation space for tasks (James et al., 2018; Lan et al., 2019).

Our research can be considered as a mix of these categories. CNM learns cognition-based task representations while both CNM and CRA learn task relations aiming at transfer learning. Additionally, significantly different from previous studies, we

---

[2] Task taxonomy learned by our methods could be applicable to other learning formalisms beyond transfer learning. We leave this to our future work.

learn task structures from a cognitive perspective[3], which is expected to estimate task relatedness in a cognitively tuned space. As will be demonstrated below, our cognitively motivated methods incur a low computation cost and exhibit generalization across underlying models to some extend.

3 CogTaskonomy

Figure 1 illustrates the basic framework of CogTaskonomy. First, we obtain task-specific sentence representations of text stimuli from cognitive data by feeding them into fine-tuned or distilled pretrained language models on 12 downstream tasks (Section 3.1). Subsequently, task-specific representations are fed into two cognitively inspired components, cognitive representation analytics (Section 3.2) and cognitive-neural mapping (Section 3.3), for estimating task similarity and inducing task taxonomy.

3.1 Task-Specific Sentence Representations

Fine-tuning a pretrained language model for an end task is a widely used strategy for quickly and efficiently building a model for that task with limited labeled data. Zhou and Srikumar (2021) find that fine-tuning reconfigures underlying semantic space to adjust pretrained representations to downstream tasks. In view of this, we take sentence-level textual stimuli of cognitive data as input data for a specific fine-tuned model to obtain representations that contain information specific to that task.[4] Additionally, Cheng et al. (2020) suggest that knowledge distillation (KD) helps models to be more focused on task-relevant concepts. Therefore, without loss of generality, we use BERT and TinyBERT (performing KD) to obtain task-specific sentence representations.

BERT Following Devlin et al. (2018), we prepend a special classification token [CLS] to each input sentence in order to extract the contextualized representation of the corresponding sentence. Merchant et al. (2020) find that fine-tuning primarily affects top layers of BERT. Hence, we take the hidden state of the prepended token of each sequence in the last layer as the sentence representation.

TinyBERT TinyBERT (Jiao et al., 2020) performs knowledge distillation at both the pretraining and fine-tuning stage. By leveraging KD, TinyBERT learns to transfer knowledge encoded in the large teacher BERT (Devlin et al., 2018) to itself. As a result, TinyBERT can capture both general and task-specific knowledge. Similarly, we use the hidden state of [CLS] token in the last layer as the contextualized representation for a given sentence.

3.2 Cognitive Representation Analytics

With task-specific representations learned by feeding text stimuli of cognitive data into a fine-tuned model, we can estimate pairwise task similarity for any two tasks in a given task list $T = \{t_1, t_2, ..., t_m\}$. The first cognitively inspired method is the cognitive representation analytics that adapts a common method in computational neuroscience to our scenario. We first briefly introduce the common method, representational similarity analysis, and then elaborate the adaptation.

Representational Similarity Analysis is widely applied in cognitive neuroscience, which can not only realize cross-modal cognitive data comparison but also quantitatively relate brain activity measurements to computational models. It first calculates a representation dissimilarity matrix (RDM) of different modal data, and then estimates the correlation between RDMs. In this way, it successfully captures cross-modal data relationships (Kriegeskorte et al., 2008). RSA can be also applied for the comparison between computational models and cognitive data. The RDM of a computational model is obtained by comparing the dissimilarity of data representations obtained from the computational model in pairs. It is then compared with the RDM of brain activity measurements.[5]

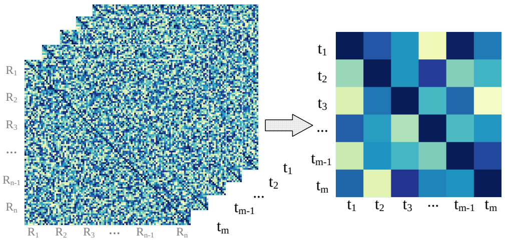
We take all sentence representations R_i generated by a task-specific model PLM_i^{FT} (a pretrained language model (either BERT or TinyBERT) fine-tuned on the ith task) as the base to simulate cognitive representations required by RSA. For each pair of sentence representations $(R_{ij}, R_{ij'})$ for the jth and j'th sentence of the ith task, we compute a dissimilarity score in three metrics (e): Euclidean distance ($euclidean$), Canberra distance ($canberra$) and Pearson correlation coefficient (ρ). Among

---

[3] Dwivedi and Roig (2019) also use RSA to learn task taxonomy, in some way similar to our CRA. But they learn relations for visual tasks and use different correlation functions from our CRA.

[4] Sentence-level textual stimuli of cognitive data refer to natural textual stimuli, i.e., sentences presented to subjects for collecting cognitive processing signals.

[5] In our CRA, only RDMs from computational models are used. This is because we don't have cognitive data that are curated for specific NLP tasks. In our preliminary experiments, we have created pseudo cognitive data for different NLP tasks by predicting cognitive signals with a mapping model similar to that used in CNM. But it performs poorly.



Representation Dissimilarity Matrix **Task Similarity Matrix**

Figure 2: RDMs and task similarity matrix calculated by RSA from task-specific sentence representations.

them, the first two distance metrics can naturally represent dissimilarity (Dis), while the last ρ needs to be converted to $1 - \rho$ to indicate dissimilarity, as follows:

$$\text{Dis}^i_{jj'} = \begin{cases} e(R_{ij}, R_{ij'}) & e \text{ is not } \rho \\ 1 - e(R_{ij}, R_{ij'}) & e \text{ is } \rho \end{cases} \tag{1}$$

RDM for the ith task consists of the dissimilarity scores of all sentence pairs. We formulate it as follows:

$$\begin{aligned} \text{RDM}_i = [&\text{Dis}^i_{12}, \text{Dis}^i_{13}, \ldots, \text{Dis}^i_{1n}, \ldots \\ &\text{Dis}^i_{jj'}, \ldots, \text{Dis}^i_{(n-1)n}], \qquad j \neq j' \end{aligned} \tag{2}$$

where n is the number of sentences. RDMs computed in this way are then used for estimating similarity between NLP tasks. The pairwise similarity $\text{Sim}_{ii'}$ of the ith and i'th task is computed as follows:

$$\text{Sim}_{ii'} = \text{Similarity}(\text{RDM}_i^{\intercal} \cdot \text{RDM}_{i'}) \tag{3}$$

Similarity$(\cdot)$ is a similarity function, which can be Spearman rank correlation (r_s), ρ and cosine (cos, by default).

In summary, we calculate the similarity between each RDM pair and finally obtain a similarity matrix for a set of tasks, as shown in Figure 2.

3.3 Cognitive-Neural Mapping

The idea behind cognitive-neural mapping is to project sentence representations of NLP models fine-tuned in a specific task to cognitive signals (i.e., fMRI voxels in this paper) recorded when humans read those sentences with a neural network. The connections between the specific task and cognitive signals learned in this way could be transformed into cognitively inspired task representations for further task similarity estimation. The mapping can be considered as a way to isolate brain activity related to the specific task from fMRI cognitive signals. Particularly, for the ith task and sth subject, we use a fully connected 3-layer feed-forward neural network to project sentence representation R_{ij} specific to this task to fMRI $\boldsymbol{y}_j^{is}$ of the sth subject reading the jth sentence as follows:

$$\boldsymbol{y}_j^{is} = \boldsymbol{W}_2^i(\text{ReLU}(\boldsymbol{W}_1^i(R_{ij}))) \tag{4}$$

To optimize the mapping model, we use the mean squared error (MSE) as loss function. 5-fold cross-validation is performed for each mapping model. Before training, grid search is conducted, and the optimal number of hidden layer units in the mapping network is obtained by three times of cross-validation on the verification set accounting for 20% training data.

Each mapping is run 5 times. We average models over all subjects and 5 runs and then evaluate mapping model performance in all voxels. Particularly, we compute the cognitively inspired task representation CogR_i for the ith task, which consists of the correlation coefficients on all voxels between predicted values and ground-truth values, defined as follows :

$$\begin{aligned} \text{CogR}_i =& [c(\hat{\boldsymbol{y}}_0^i, \boldsymbol{y}_0), \ldots, c(\hat{\boldsymbol{y}}_k^i, \boldsymbol{y}_k), \\ & \ldots, c(\hat{\boldsymbol{y}}_v^i, \boldsymbol{y}_v)], 0 \leq k \leq v \end{aligned} \tag{5}$$

where $\hat{\boldsymbol{y}}_k^i$ is a vector of all predicted values for the kth voxel from all input sentences by the mapping model tuned for the ith task, $\boldsymbol{y}_k$ is a vector of the ground-truth values for the kth voxel from all sentence-level signals of text stimuli in fMRI data, v is the number of voxels used, and $c(\cdot)$ is a function for comparing two input vectors. We instantiate c in two functions: the coefficient of determination (R^2) and ρ.[6]

We then use cosine similarity to calculate pairwise task similarity as follows:

$$\text{Sim}_{ii'} = \cos(\text{CogR}_i^{\intercal} \cdot \text{CogR}_{i'}) \tag{6}$$

4 Experiments

We conducted experiments with widely-used NLP benchmark datasets and cognitive data to evaluate the effectiveness of CogTaskonomy.

4.1 Cognitive Dataset

The brain fMRI dataset in our experiments is from Pereira et al. (2018), which is recorded on a whole-body 3-Tesla Siemens Trio scanner with a 32-channel head coil by showing 627 natural language sentences to 5 adult subjects.[7] Since voxels were

---

[6] R^2 is a statistical measure that examines how much a model is able to predict or explain an outcome, usually defined as the square of the correlation between predicted values and actual values. According to the results in Appendix A.1, we set R^2 as c in CNM by default.

[7] This dataset is publicly available at `https://osf.io/crwz7/`. The cognitive data of subjects who both partic-

randomly selected, Z-Score standardization was carried out for voxels obtained from different stimuli at each location on the basis of the original data set to avoid the influence of outliers. Subjects are asked to read each encyclopedic statement carefully, while the fMRI scanner records brain signals at this point. As a result, each fMRI scan covers multiple words at a time, subject to continuous stimulation. Each fMRI recording contains a number of voxels. We flattened 3d fMRI images into 1d vectors. v voxels were randomly selected, yielding matrices $I_s \in \mathbb{R}^{627 \times v}$ for each subject s.

4.2 Tasks

We selected 8 NLP tasks from the GLUE benchmark (Wang et al., 2018), including CoLA, MNLI, MRPC, QNLI, QQP, RTE, SST-2, STS-B. These tasks are considered important for generalizable natural language understanding, exhibiting diversity in domains, dataset sizes, and difficulties (Wang et al., 2018). To cover the spectrum of NLP tasks as much as possible, we also included Extractive Question Answering (QA), Relation Extraction (RE), Named Entity Recognition (NER), and Passage Reranking (PR). The datasets of these four tasks are SQuAD 2.0 (Rajpurkar et al., 2018), Semeval-2010 task 8 (Hendrickx et al., 2010), CoNLL 2003 (Sang and Meulder, 2003), MS MARCO (Nguyen et al., 2016; Craswell et al., 2020), respectively.

4.3 Baselines and Settings

We mainly used two methods as our baselines, including Direct Similarity Estimation (DSE), Analytic Hierarchy Process (AHP) (Zamir et al., 2018). Detailed experimental settings are shown in Appendix A.2.

Direct Similarity Estimation (DSE) A straightforward way to estimate pairwise task similarity is to calculate sentence-level similarities based on task-specific sentence representations and then average them. Concretely, let R_{ij} be the task-specific representation for the jth sentence in the ith task. The task similarity $\text{Sim}_{ii'}$ for a task pair (i, i') is computed as follows:

$$R_{ij} = \text{PLM}_i^{\text{FT}}(\boldsymbol{x}_j) \tag{7}$$

$$\text{Sim}_{ii'} = \frac{\sum_j \text{Similarity}(R_{ij}^{\mathsf{T}} \cdot R_{i'j})}{n} \tag{8}$$

where PLM_i^{FT} is the pretrained language model fine-tuned on the ith task. PLM can be instantiated as TinyBERT or BERT.

Analytic Hierarchy Process (AHP) The main idea is to construct a matrix W_t for each target task t, where the element at $(i,\ i')$ in the matrix shows how many times the ith source task is better than i'th source task in terms of the transferability to the target task on a held-out set. The principal eigenvector of W_t is then taken as the task representation for the corresponding task, and all task representations are stacked up to obtain an affinity matrix.[8] The affinity matrix is then viewed as the task similarity matrix.

4.4 Evaluation Metric

Task Transferring To assess the similarity between tasks, all models fine-tuned on non-target tasks will be used as source models, and continue to be fine-tuned in the same way to transfer on the target task. In task transferring, all parameters of source models are fine-tuned (i.e., not fixed). We used the same learning rate and a number of training steps for all task transferring. This allows a fair comparison between different source tasks.

Oracle Task Ranking The final similarity ranking of source tasks to a given target task is based on the results obtained from the task transferring experiments. Generally speaking, the better the source-to-target transfer performance is, the more similar the two tasks are, since the essence of TL is to apply knowledge learned in the source task to the target task. Based on this concept, we rank tasks in terms of transfer learning performance, for more details please see Appendix A.3.

Task Ranking Score Based on similarity results computed by each task estimation method, we can obtain the most similar task for each target task. We then check the ranking position of the most similar task in the oracle task ranking. We average ranking positions of all target tasks as the final task ranking score for the corresponding task estimation method. Note that we exclude the transfer to the target task itself in computing task ranking scores.[9]

---

ipated in experiments 2 and 3 were chosen in this paper.

[8] For more details about AHP, please refer to (Zamir et al., 2018). Since the test sets of our NLP tasks are not publicly available, we obtain AHP results based on the validation set of each task except the NER task of which the test set is publicly available. In all experiments, the hyper-parameters are the same for all tasks.

[9] Generally, the lower the task ranking score, the better the task similarity estimation method. A perfect estimation

Method	TRS	
	TinyBERT	BERT
DSE	6.2	4.8
CRA	3.5	4.4
CNM	4.2	4.6
AHP	**1.4**	**2.5**
CRA+CNM	2.8	4.3
Random	6.0

Sent. Diss.	Task Sim.	TRS	
		BERT	TinyBERT
$euclidean$	r^s	5.6	4.5
	$\cos$	5.0	2.6
	ρ	5.6	3.5
$canberra$	r^s	5.0	5.2
	$\cos$	5.8	**2.2**
	ρ	5.5	5.1
ρ	r^s	5.5	6.7
	$\cos$	**4.4**	3.5
	ρ	5.1	4.3

Table 2: Task ranking scores of CRA with different combinations of sentence dissimilarity an task similarity measurements.

4.5 Main Results

Task ranking scores (using the ranking of task transferring as the oracle ranking) of different task similarity estimation methods are shown in Table 1. From these results, we have the following observations:

- Both CRA and CNM are better than random ranking and DSE, suggesting that cognitively inspired task similarity estimation is able to capture relations of NLP tasks.
- When TinyBERT is used, DSE is even worse than random ranking. This suggests that simply using task-specific sentence representations cannot well detect task relations and distinguish different tasks.
- TinyBERT performs better than BERT across three task estimation methods (i.e., CRA, CNM and AHP) although the number of parameters in the former is only half of that in the latter. We conjecture that TinyBERT uses knowledge distillation, making sentence representations more relevant to individual tasks and hence resulting in better task similarity estimation.
- We can also combine CRA and CNM (CRA+ CNM) by averaging task similarity scores estimated by them. Such combination is better than both methods alone.

Although AHP is better than our methods, it directly uses the results of transfer learning to measure similarities between different tasks, which is very time-consuming. if we have m tasks, we have to perform $O(m^2)$ transfer learning to obtain the task similarity matrix across all task pairs. In contrast, our methods do not require any costly transfer learning between tasks. It is hence easier to perform and able to guide transfer learning across tasks. We further evaluated the actual transfer learning performance of each target task from the most similar source task according to different task similarity estimation methods. Results are shown in Appendix A.4, which further validate the effectiveness of our methods and show that CRA+CNM is very close to that of AHP. In later experiments and analyses, we will show more advantages of our methods over AHP.

4.6 Evaluating CRA with Different Dissimilarity/Similarity Measurement Combinations

CRA adopts RSA to transform the dissimilarity of task-specific sentence representations into the similarity of tasks. We have different options for dissimilarity measurement (e.g., $euclidean$,$canberra$) in sentences and for similarity measurement (e.g., $\cos$,ρ) in tasks. Hence we want to know the impact of the combinations of different measurements in sentence dissimilarity and task similarity on final performance. Results are provided in Table 2. Again, we have several interesting observations. First, with different combinations of these measurements, our CRA significantly outperforms random ranking in almost all cases. This suggests that RSA is able to be adapted to NLP task structure detection. Second, in comparison to the combination of ρ and r^s in the original RSA (Kriegeskorte et al., 2008), in our case, the combination of ρ and $\cos$ is better than other combinations in the majority of cases. Third, TinyBERT is more robust to these

---

similarity method would yield a task ranking score of 1 on each target task. A random method would yield a ranking score of $0.5(1 + 11) = 6$ in our experiments theoretically. We have also conducted random sampling 5000 times on TinyBERT and BERT, and obtained mean task ranking scores of 6.05 and 6.04 respectively. Hence, we take the 6 as the task ranking score for random ranking.

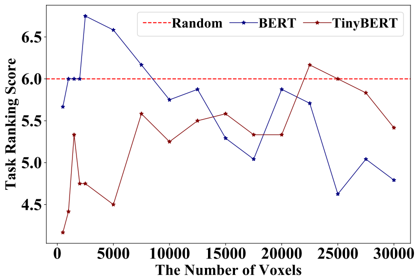

Figure 3: Task ranking scores of CNM with TinyBERT and BERT predicting different numbers of voxels.

different combinations than BERT.

4.7 Evaluating CNM with Different PLMs and Numbers of Voxels

Since CNM bridges pretrained language models on the input side and voxels in fMRI images on the output side, we further evaluated CNM by varying the selection of PLMs (either BERT or TinyBERT) and the numbers of voxels. Results are displayed in Figure 3. It is interesting to find that with a small number of cognitive signals (voxels), TinyBERT for CNM can achieve a good task ranking score. By contrast, without sufficient cognitive signals, BERT for CNM fails in task similarity estimation, obtaining a task ranking score worse than random ranking. This is consistent with our previous finding in the main results that TinyBERT (with KD) captures more task-relevant knowledge than BERT for task relation detection.

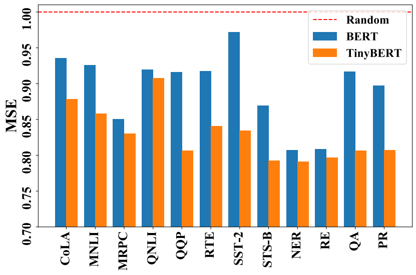
5 Analysis

5.1 CNM: Voxel Prediction Evaluation

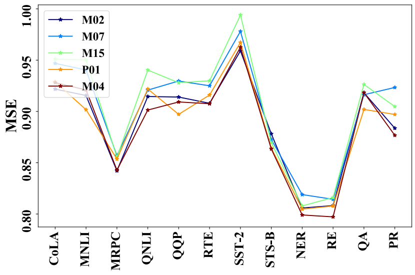
We conducted experiments to take a deep look into the feed-forward neural mapping model in CNM. The number of voxels was set to 30K.

Pretrained Language Models We compared the prediction performance (measured by MSE between predicted results and ground-truth voxels) across different tasks using BERT vs. TinyBERT as the pretrained language model to obtain task-specific sentence representations. Results are shown in Figure 4(a). We can clearly see that both BERT and TinyBERT are better than the random baseline across all tasks. And TinyBERT is better than BERT on all tasks, which resonates with the main results shown in Section 4.5.

Subjects We analyzed prediction performance across different subjects, as shown in Figure 4(b). Although the prediction performance varies across different tasks, the shapes of the prediction performance curve over 12 tasks for different subjects are similar to each other, indicating that similar brain activities are activated for these tasks across different subjects.



(a) MSEs (averaged over 5 subjects and 30K voxels) for different tasks with BERT vs. TinyBERT being used as the pretrained language model.



(b) MSEs (averaged over 30K voxels) for different tasks across different subjects. BERT is used as the pretrained language model.

Figure 4: CNM voxel prediction results (i.e., the mean square errors between predicted results by CNM and ground-truth voxels). Y-coordinate is the ratio of the MSE value of BERT to the MSE of the random prediction baseline.

5.2 Analysis on the Generality of Task Similarity Estimation to Underlying PLMs

Models underlying our cross-task transfer learning are different pretrained language models, which is a widely acknowledged practice for transfer learning in NLP. We therefore want to investigate how general our task similarity estimation methods (e.g., CNM, CRA, AHP) are to the underlying models. This is important as we want to find a task taxonomy method that is not sensitive to underlying models. That is, the learned task taxonomy can be used to guide transfer learning for any model. For this, we first computed the Pearson correlation coefficient (ρ) and the Spearman rank correlation (r_s) between task similarities obtained with TinyBERT and those with BERT using the same similarity estimation method. The correlation coefficients

Method	TB→B			B→TB		
k	3	4	5	3	4	5
CRA	0.39	0.40	0.42	0.61	0.54	0.58
CNM	**0.64**	**0.58**	**0.62**	**0.75**	**0.79**	**0.73**
AHP	0.53	0.52	0.52	0.69	0.65	0.67

Table 3: Probabilities that transferability learned with TinyBERT (TB) can be used for BERT (B) or vice versa.

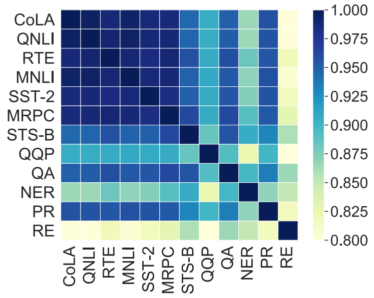
between BERT-based and TinyBERT-based task similarity matrices obtained by the CRA, CNM and AHP are ($\rho = 0.23$, $r^s = 0.11$), ($\rho = 0.85$, $r^s = 0.76$) and ($\rho = 0.36$, $r^s = 0.34$) respectively. Both AHP and CRA show pool correlations between task similarity matrices using BERT and TinyBERT. On the contrary, CNM is very robust to the variations of underlying models. We speculate that both CRA and AHP capture task relations specific to underlying models while CNM could remove such bias by building the task taxonomy based on the cognitive data. In other words, CNM is able to detect model-agnostic task relations, yet another desirable advantage over AHP with exhaustive computation cost.

To further examine this hypothesis, we used the task ranking estimated with another underlying PLM x to guide transfer learning with an underlying PLM y. In our work, this would be using TinyBERT to guide BERT (TB → B) or vice versa. For each target task, we used the top k source tasks according to the task ranking with the guiding PLM x for transfer learning with the PLM y. The results were compared to the actual performance of transfer learning to the target task from the top 6 source tasks according to the task ranking with the PLM y itself. The probability of the top k source tasks occurring in the real top 6 tasks shows how much transferability learned with the PLM x can be used for the PLM y. Results are shown in Table 3, which again suggests the superiority of CNM over AHP.

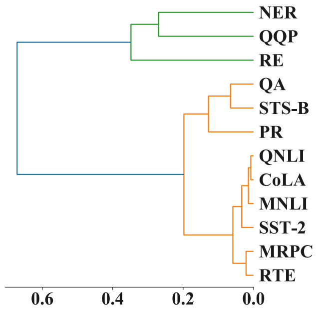
We further analyzed the generality of CNM to different subjects of cognitive data used in CNM, which can be found in Appendix A.5. The experimental results show that the CNM is also robust to different subjects.

5.3 Taxonomy Tree of 12 NLP Tasks

We visualize all pairwise task similarities for 12 tasks learned by CNM (averaged over 5 subjects) as a heatmap, shown in Figure 5(a). It is clear to see from the heatmap that 6 GLUE tasks (i.e., CoLA, QNLI, RTE, MNLI, SST-2, and MRPC) form a cluster. These tasks are all related to sentence understanding. We further perform hierarchical clustering over the 12 tasks according to their similarities to create a taxonomy tree, which is illustrated in Figure 5(b).



(a) Task similarity matrix



(b) Taxonomy tree

Figure 5: Task similarity learned by CNM: (a) Task similarity matrix learned by CNM. (b) Taxonomy tree for the 12 tasks learned by CNM.

6 Conclusions

In this paper, we have presented a cognitively inspired framework, termed CogTaxonomy, to learn relation and structure for NLP tasks. Experiments demonstrate that the task taxonomy detected by CogTaxonomy can be used to guide transfer learning across 12 different NLP tasks. Both CRA and CNM, the two essential components of CogTaxonomy, do not require exhaustive transfer learning across all source-target task pairs. The former is robust to different combinations of dissimilarity/similarity measurements. The latter resorts to cognitive signals to learn model-agnostic task relations.

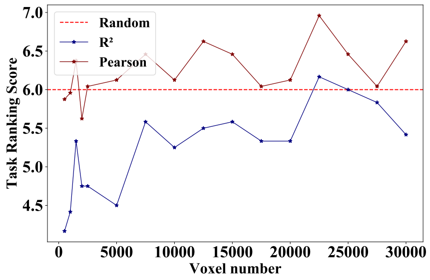
(a) BERT



(b) TinyBERT

Figure 6: Task ranking scores with different correlation coefficients in Cognitive-Neural Mapping based on BERT (a) and TinyBERT (b).

A Appendix

A.1 Correlation Selection in Cognitive-Neural Mapping

We have different options for the calculation of CogR (e.g., R^2 and ρ). Therefore, we computed task ranking scores with different options for CNM with BERT and TinyBERT. Results are shown in Figure 6. We find that R^2 is better than ρ in almost all cases.

A.2 Experimental Settings

Fine-tuning and Transferring For most tasks, we fine-tuned BERT to obtain task-specific representations, with the exception of RE and PR. REDN (Li and Tian, 2020) was used for RE tasks, and Cross-Encoder (Reimers and Gurevych, 2019) was used for PR. Table 4 shows the hyper-parameters and configuration for task training in our experiments.

For source-to-target task transfer learning, all source models were fine-tuned on the target task dataset with the same settings as the target model.

Knowledge Distillation Since TinyBERT has officially released models distilled on GLUE, we directly used them on our 8 GLUE tasks. For the PR task, we used the open-source model (Reimers and Gurevych, 2019) with the same TinyBERT architecture directly. For NER, QA, and RE tasks, we adopted the above fine-tuned models as the teacher model and used the open-source General TinyBERT for task-specific distillation, following the recommended practice of TinyBERT (Jiao et al., 2020). The number of epochs in the task-specific distillation phase is shown in Table 5, and the settings of other parameters are consistent with fine-tuning. In CoNLL 2003 (Sang and Meulder, 2003), we also carried out data augmentation according to the method proposed by TinyBERT (Jiao et al., 2020), while no data augmentation was performed on other datasets.

Task	epoch	batch size	lr	optimizer
GLUE	3	32	2e-5	AdamW
NER	3	32	2e-5	AdamW
QA	3	16	3e-5	AdamW
PR	1	8	2e-5	AdamW
RE	50	64	3e-5	AdamW

Table 4: Hyper-parameter settings for fine-tuning and transfer learning. lr: learning rate.

Task	ID	PD
NER	5	3
QA	5	3
RE	25	25

Table 5: The number of epochs for NER, RE, and PR tasks in the task-specific knowledge distillation phase. ID/PD: intermediate/prediction layer knowledge distillation.

A.3 Oracle Task Ranking

Evaluation Metrics for 12 Tasks Among the 8 GLUE tasks, Matthews correlation was used in the CoLA task, Spearman correlation coefficient was used in the STS-B task. For the passage reranking task, NDCG@10 was used. All other tasks used F_1 score as the evaluation metric.

Pairwise Transfer Learning Results and Oracle Ranking We obtain pair-wise transfer learning results based on the validation set of each task except the NER task of which the test set is publicly available. The results with BERT and TinyBERT are shown in the Table 6 and Table 7 respectively. Sorted by transfer performance, the oracle ranking of each source task to a target task is marked in parentheses.

Table 7: Pairwise transfer learning results based on TinyBERT.

A.4 Actual Transfer Learning Performance from the Top 1 Source Task Selected by Different Task Similarity Estimation Methods to Each Target Task

Transfer Learning with Same Underlying PLMs We use different task similarity estimation methods to find the most similar source task for each target task and obtain the transfer learning performance from the most similar source task to the target task. Both the task similarity estimation and transfer learning use the same underlying PLM. For each task similarity estimation method, average performance over all target tasks are reported in Table 8. It can be seen that the CRA, CNM, and CRA+CNM methods show good performance. Significantly, in terms of average target task performance, CRA+CNM is very close to AHP that requires exhaustive transfer learning across all source-target task pairs.

Transfer Learning with Different Underlying PLMs This time the underlying PLMs for task similarity estimation and transfer learning are different from each other. Results are displayed in Table 9. Similarly, CRA+CNM achieves very competitive results to AHP in TinyBERT → BERT and even better results than AHP in BERT → TinyBERT.

In the two tables, we calculate the average transfer learning performance over 12 tasks shown in the last column of the two tables for easy compar-

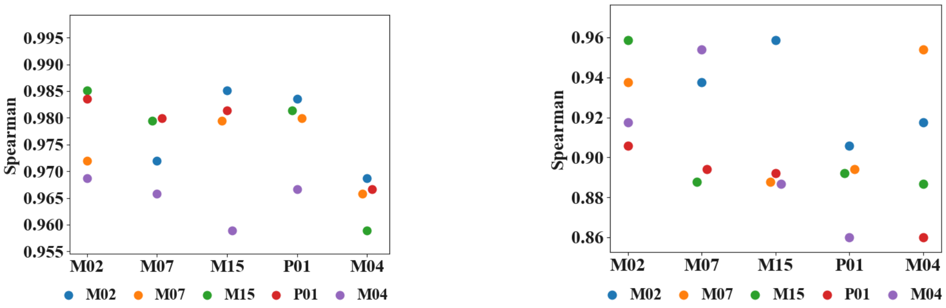
Table 9: Actual target task performance when task similarity estimation and transfer learning use different underlying PLMs. B/TB: BERT/TinyBERT. Type ($x \rightarrow y$) denotes that the most similar source task selected according to a task similarity estimation method with underlying PLM x is used for transfer learning to a target task with underlying PLM y.

ison. The results of "Random" in the two tables are averaged over 5000 times of random sampling. Specifically, each round of random sampling selects a task other than itself for each target task as the source task for transfer learning.

A.5 Analysis on the Generality of CNM across Subjects

We calculate task similarity matrices that are averaged over 5 subjects in CNM. Are results for individual subjects are consistent with each other? Hence we separately calculated task similarity matrices for each subject and used the Spearman correlation coefficient to measure task similarity matrix correlations among subjects. Results are shown in Figure 7, which indicates high correlations among subjects.



(a) BERT

(b) TinyBERT

Abstract

Large-scale pretrained language models have achieved SOTA results on NLP tasks. However, they have been shown vulnerable to adversarial attacks especially for logographic languages like Chinese. In this work, we propose ROCBERT: a pretrained Chinese Bert that is robust to various forms of adversarial attacks like word perturbation, synonyms, typos, etc. It is pretrained with the contrastive learning objective which maximizes the label consistency under different synthesized adversarial examples. The model takes as input multimodal information including the semantic, phonetic and visual features. We show all these features are important to the model robustness since the attack can be performed in all the three forms. Across 5 Chinese NLU tasks, ROCBERT outperforms strong baselines under three black-box adversarial algorithms without sacrificing the performance on clean testset. It also performs the best in the toxic content detection task under human-made attacks.

1 Introduction

Large-scale pretrained models, by finetuning on sufficient annotated data, have been able to approach or even surpass human performance on many benchmark testsets (Peters et al., 2018; Radford et al.; Devlin et al., 2019; Liu et al., 2019; Brown et al., 2020). However, even pretrained with huge amounts of text, the models are still vulnerable under adversarial attacks like synonyms, word deletion/swapping, misspelling, etc (Li et al., 2019a; Jin et al., 2020; Sun et al., 2020a; Eger and Benz, 2020). These adversarial examples occur frequently in the real-world scenario and can be made either naturally (e.g., typos) or maliciously (e.g., to avoid auto detection of toxic content) [1]. The lack of robustness with them can easily lead to large performance drop when testing in the noisy real-world traffic. The issue is particularly outstanding for logographic languages like Chinese since the attack can be either with the glyph character, pinyin (the romanized phonetic representations) or a combination of them (Wang et al., 2020; Li et al., 2020d; Zhang et al., 2020; Nuo et al., 2020). We show some examples in Table 1. The word "科比(Kobe)" can be replaced with synonyms, phonetically or visually similar words. The attacker can also replace the character with its pinyin then continue the attack in the alphabet-level ("keb1" in the table). The isolation of semantics and phonetics, and the rich set of glyph characters in written Chinese makes the attacking forms much more diverse than in alphabetic languages like English.

Attacker	**Text**
phonetic	克(kè)比的精神值得永远学习
visual	科此的精神值得永远学习
character split	禾斗匕匕的精神值得永远学习
synonym	我(wǒ)科(kē)的精神值得永远学习
synonym + phonetic	蜗(wō)壳(ké)的精神值得永远学习
to pinyin	kebi的精神值得永远学习
to pinyin + unicode	keb1的精神值得学习永远
swap	科比的精神值得永远习学
insertion	科比的精神九值得永远学习
deletion	科比的神值得永远学习
Original: 科(kē)比(bǐ)的精神值得永远学习	
Translation: Kobe's spirit is worth studying forever.	

Table 1: Examples of various attackers. Contents in the brackets are corresponding pinyins of Chinese characters.

Current research works usually adopt two ways to defend adversarial attacks: (1) Run spell checking to correct the written errors before feeding to the prediction model (Pruthi et al., 2019; Li et al., 2020b; Mozes et al., 2021), and (2) Adversarial training, which adds adversarial example to the training data (Zang et al., 2020; Li et al., 2020a; Liu et al., 2020). For the former, Chinese spell checking itself is even a more difficult task because it requires the model to accurately recover the original text. Any tiny errors of the spell checking can

---

*Equal contribution.

[1] The concept of adversarial examples is quite wide. In this paper, we focus on adversarial examples that do *NOT* change the original semantics (Mozes et al., 2021)

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 921 - 931
May 22-27, 2022 ©2022 Association for Computational Linguistics

lead to unpredicted model behaviors. For the latter, it is hard for the model to adapt to all adversarial variants only in the finetuning stage, especially when the training data is sparse (Meng et al., 2021).

To address the above challenges, we propose RoCBert, a Robust Chinese Bert pretrained with the contrastive learning objective by maximizing the label consistency under various adversarial examples. The adversarial examples are synthesized from an algorithm that encapsulates common types of attacks. We also consider combinatorial attacks where multiple types of attacks can be added on top of each other, which has never been considered in previous research. To defend attacks in all levels, we incorporate multimodal information into the encoder. The phonetic and visual features are inserted into one self-attention layer then dynamically fused in later layers. Across 5 standard NLU tasks and one toxic content detection task, we show the pretrained model achieves new SOTAs under various adversarial attackers.

In short, our contribution are (1) We propose pretraining a robust Chinese Bert with adversarial contrastive learning, such that the model can perform well on not only clean testbeds, but also adversarial examples. (2) The model is pretrained with synthesized adversarial examples covering combinations of semantic, phonetic and visual attacks. It takes as input multimodal features to handle all levels of possible attacks. (3) The pretrained model outperforms strong baselines across 5 NLU tasks and 1 toxic content detection task under various adversarial attackers. (4) We perform an extensive ablation studies for pretraining options and have a wide comparison with popular defending methods, which we hope will benefit future research.

2 Related Work

Adversarial attack There have been a lot of works showing the vulnerability of NLP models under adversarial examples (Li et al., 2020c; Garg and Ramakrishnan, 2020; Zang et al., 2020), which are understandable by humans yet lead to significant model prediction drops. There are usually two types of attacks: (1) semantic equivalent replacement, which can be synthesized by replacing words based on vector similarity (Jin et al., 2020; Wang et al., 2020), WordNet synonyms (Zang et al., 2020), masked prediction from pretrained models (Li et al., 2020c; Garg and Ramakrishnan, 2020; Li et al., 2020d), etc. (2) noise injection, which can be synthesized by adding/deleting/swapping words (Li et al., 2019a; Gil et al., 2019; Sun et al., 2020a), replacing words with phonetically or visually similar ones (Eger et al., 2019; Eger and Benz, 2020). For logographic languages like Chinese, the noise can be much more complex as it can be injected on both the glyph characters or romanized pinyins (Zhang et al., 2020; Nuo et al., 2020).

Adversarial defense The most common way of adversarial defense is adversarial training, which simply appends synthesized adversarial examples into the training data (Zang et al., 2020; Li et al., 2020a). Nonetheless, it relies only on the limited labeled training data. In contrast, the proposed RoCBert is pretrained on billions of text and can better adapted to diverse adversarial variants. Another popular way is to first remove the noise with off-the-shelf spell checkers, then feed the corrected text into the model (Li et al., 2020b). However, Chinese spell checking requires fully recovering the correct text and current model performances are far from satisfactory (Liu et al., 2021; Xu et al., 2021; Wang et al., 2021a). Any tiny error in the spell checking process can lead to unpredicted model behaviors. It also incurs significant latency to model prediction. RoCBert does not add additional latency and can perform well even if fully recovery is difficult due to its consistency-maximization pretraining objective. There have also been works on pretraining more robust models through virtual adversarial training and noise regularization (Yoo and Qi, 2021; Wang et al., 2021b; Meng et al., 2021), but they perform poorly on man-made attacks.

3 Adversarial Example Synthesis

3.1 Attacking Chinese Characters

As we focus on Chinese in this paper and Chinese characters are much more diverse than in alphabetical languages, we design the following 5 Chinese-specific attacking algorithms first.

phonetic: Replace a Chinese character with a random homonym (ignoring diacritics). For polyphones, we consider the 2 most common pinyins [2].

Visual: Replace Chinese characters with their visually similar characters (with the similarity table in the Kanji Database Project) [3].

Character Split: Split one character into two parts with every part still being (or visually similar to) a valid Chinese character. We follow the Chinese

---

[2] https://unicode.org/charts/unihan.html

[3] http://kanji-database.sourceforge.net/

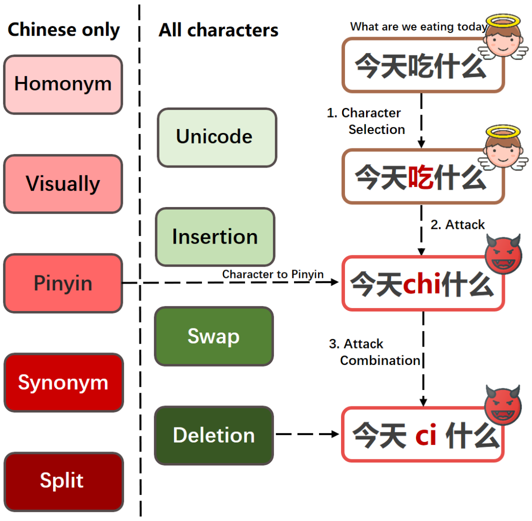

Figure 1: Adversarial example synthesis process.

splitting dictionary [4], which contains 17,803 splitting ways for Chinese characters in total.
Synonym: Segment Chinese characters into words with the jieba tokenizer [5], then randomly replace the word with one of its synonyms. Two words are treated as synonym if they share a similarity score of over 0.75 [6]. We only replace adjectives or nouns as we find other words can be hardly replaced without changing the semantics.
Character to Pinyin: Replaces the character into its pinyin representation (without diacritics).

3.2 Attacking Other Characters

Apart from Chinese characters, there are often other characters like the pinyin, numbers, punctuations and foreign words in the Chinese corpus. The following 4 types of attacks apply to not only Chinese characters, but also all other characters.
Unicode: Randomly sample one of the visually similar unicodes as a replacement [7].
Random Insertion: Sample one character from the vocabulary set, then randomly insert the character to the left or right of the current character.
Swap: Swap the character with its neighbor.
Deletion: Delete the character directly.
Examples of all types of attacks are in Table 1.

3.3 Synthesis Process

The synthesis process of adversarial examples is as follow: Given one sentence, we first select several characters to attack. For each selected character, we then combine the above mentioned character-level attacking algorithms [8] to get its attacked form.
Attack Ratio: The attack ratio γ decides how many characters we will attack. Let n_c be the number of characters in the sentence, we define γ as:

$$\begin{aligned}\gamma &= \min(\max(\text{int}(\epsilon), 1), n_c) \\ \epsilon &\sim \mathcal{N}(\max(1, 0.15 n_c), 1)\end{aligned} \tag{1}$$

where the int function rounds ϵ into the closest integer. The intuition is that we want to attack 15% of the characters on average [9]. If the sentence is short, we will make sure to attack at least one character. We insert normal Gaussian noise on top of the average ratio to add some randomness.

Character Selection: There have been many research works showing that attacking informative words is more effective than random words (Li et al., 2019a; Sun et al., 2020a). Therefore, we decide the chance of one character c_i being selected based on its informativeness in the sentence. Let $w(c_i)$ denote the word c_i belongs to, the informative score for c_i is counted as the difference of the language model loss after deleting $w(c_i)$ (denoted as $\mathcal{L}(\nabla w(c_i))$ (Li et al., 2016) [10]. The chance that c_i will be selected to be attacked is:

$$p(c_i) = \frac{e^{\mathcal{L}(\nabla w(c_i))}}{|w(c_i)| \sum_{j=1}^{n_w} e^{\mathcal{L}(\nabla w_j)}} \tag{2}$$

where n_w is the number of words in the sentence. $|w(c_i)|$ means the number of characters in $w(c_i)$ such that characters in the same word have equal chances to be selected.
Attack Combination: There can be combinations of attacks for one character. For example, we can transfer one Chinese character into its pinyin then continue to attack it in the alphabet level ("to pinyin + unicode" in Table 1). We define it as a sequential process where a new attack can be added on top at each step. Specifically, the new character $\tilde{c}$ after all the attack combinations applied to c is:

$$\begin{aligned}\tilde{c} &= A_{S(c)} \circ \cdots \circ A_2 \circ A_1(c) \\ p(S(c) = k) &= q(1-q)^{k-1}\end{aligned} \tag{3}$$

---

[5] https://github.com/fxsjy/jieba

[6] https://github.com/chatopera/Synonyms

[7] http://www.unicode.org/Public/security/revision-03/confusablesSummary.txt

[8] For synonym replacement which applies in the word level, we apply it on the word that the selected character belongs to.

[9] The ratio is chosen by manual annotation. 15% is the highest ratio we can attack without hurting human reading.

[10] We use ChineseGPT (Zhang et al., 2021) as the language model, so "word" here means the subword token defined in the vocabulary of ChineseGPT.

wher $\circ$ means applying a new attacking algorithm A to the output of the last step. At each step i, the attacking algorithm A_i is randomly selected from all algorithms that are applicable to the output from step $i-1$. $S(c)$ is the number of attacking steps applied to c, which follows an exponentially decay function. We set $q = 0.7$ empirically. The full process of adversarial example synthesis is illustrated in Figure 1.

4 Multimodal Contrastive Pretraining

With the above-mentioned algorithm to sample adversarial examples, we can pretrain the model with the multimodal contrastive learning objective.

4.1 Multimodal Features

We follow the standard Bert architecture (Devlin et al., 2019) as our backbone, based on which we integrate phonetic and visual features for input text.

Feature Representation: For every character c in our vocabulary, apart from the standard semantic embedding $Se(c)$, we include two more vectors $Ph(c)$ and $Vi(c)$ to encode its phonetic and visual features respectively. If c is not a Chinese character, it has its own phonetic vector. Otherwise, $Ph(c) = \sum_{k \in pinyin(c)} Ph(k)$ where $pinyin(c)$ is its pinyin sequence. $Vi(c)$ is extracted from its 32×32 image $I(c)$. The image is in simsun (宋体) for Chinese characters and arial for others, the default fonts for most online text. $Vi(c)$ is defined as:

$$Vi(c) = \text{LayerNorm}(M^T \text{ResNet18}(I(c))) \quad (4)$$

M is a learnable matrix and we utilize Resnet18 (He et al., 2016) to map $I(c)$ into a one-dimentional vector (freezed during training).

Visual Representation Pretrain: To get an reasonable initialization, we add another pretraining stage only for the visual representation. Phonetic representations are randomly initialized [11]. M in Eq 4 is pretrained with the same contrastive loss as in Eq 5. The positive sample for the character c is its visually adversarial form $\tilde{c} = \mathcal{A}(c)$. $\mathcal{A} \sim \mathbb{U}(\text{visual, character split, unicode})$, which means uniform sampling from the three visual attacking algorithms mentioned in §3. If c is split into two characters c_1 and c_2, we sum the visual representation of the two split characters $Vi(\tilde{c}) = Vi(c_1) + Vi(c_2)$. The negative samples are all other characters in the same batch. After training, visually similar characters will be close in their representation space.

Feature Integration: A straightforward way to integrate these multimodal features is to fuse them before fed to the encoder (Sun et al., 2021; Liu et al., 2021). However, three features will be given equal weights and the model cannot dynamically attend to only useful features. Another way is a two-step encoding which first decides the weight, then encode with selective attention (Xu et al., 2021), but it will significantly slow down the system. We propose a lightweight fusion method *layer-insert*, which insert multimodal features in only one encoder layer. Let $H^k(i)$ denote the representation of the ith word in the kth layer, we insert by:

$$\begin{aligned} W_1 &= K_1^T H^k(i) H^k(i) V_1 \\ W_2 &= K_2^T H^k(i) Ph(i) V_2 \\ W_3 &= K_3^T H^k(i) Vi(i) V_3 \\ H^k(i) &= \frac{W_1 H^k(i) + W_2 Ph(i) + W_3 Vi(i)}{W_1 + W_2 + W_3} \end{aligned}$$

where $Ph(i)$ and $Vi(i)$ are the phonetic and visual representations and K_j/V_j are learnable matrices. Intuitively we can use the layer 0 to $k-1$ to decide the weights of three multimodal representations and use the rest layers for sentence representation learning. It allows dynamic fusion according to sentence context yet adds marginal complexity.

4.2 Model Loss

The model loss has two components: the contrastive learning loss and the standard masked language model (MLM) loss.

Contrastive Learning: The idea of contrastive learning (Chen et al., 2020; Kim et al., 2021) is that the representation space should be made closer for similar (positive) samples and farther for dissimilar (negative) samples. For each sentence, we treat its adversarial form (obtained from the algorithm in §3) as positive and all the other sentences in the same batch as negative. Given a batch with N sentences, the loss to the ith sentence s_i is:

$$\mathcal{L}_c(i) = -\log \frac{e^{sim(s_i, \tilde{s}_i)/\tau}}{\sum_{j=1}^{N} e^{sim(s_i, s_j)/\tau}}, \quad (5)$$

where τ is a temperature hyperparameter and $\tilde{s}_i$ is the adversarial example synthesized from s_i. We set $\tau = 0.01$ based on our pilot experiments and

---

[11] We show in Section 5.3 that pretraining is necessary for visual features not but for phonetic features.

define $sim(s_i, \tilde{s_i})$ as $\frac{h_i^\top \tilde{h_i}}{\|h_i\| \cdot \|\tilde{h_i}\|}$, which is the cosine similarity in their representation space h_i and $\tilde{h_i}$.

Mix with MLM: We mix the contrastive learning loss with the standard masked language model (MLM) loss (Devlin et al., 2019) to enable both sentence and word level representation learning. We use a character-based tokenizer because (1) Chinese characters as themselves stand for individual semantic units (Li et al., 2019b) and (2) char-based models are much more robust under noisy and adversarial scenarios (El Boukkouri et al., 2020). For Chinese characters, we use two masking strategies – Whole Word Masking (WWM) and Char Masking (CM) because a large number of words in Chinese consist of multiple characters (Cui et al., 2019; Sun et al., 2021). The contrastive learning loss and the MLM loss are equally weighted.

5 Experiments

5.1 Experiment Setup

Model Details We use a vocabulary size of 16224, out of which 14642 are Chinese characters. We provide two versions of RoCBert: base and large. The base version has 12 layers/heads with 768 hidden neurons. It is trained for 600k steps with a batch size of 4k, learning rate of 1e-4 and warmup rate of 25k steps. The large version has 48 layers and 24 attention heads with 1024 hidden neurons. It is trained for 500K steps with a learning rate of 3e-4, warmup of 70K steps and batch size of 8k.

Pretraining Details Following the common practice, we pretrain our model on 2TB text extracted from a mixture of THUCTC [12], Chinese Wikipedia and Common Crawl. Models are trained on 64 NVIDIA V100 (32GB) GPUs with FP16 and ZERO-stage-1 optimization (Rasley et al., 2020). To make better use of the GPU, we train our model with PatricStar [13] which applies a dynamic memory scheduling with a chunk-based memory management module (Fang et al., 2021). The memory management offloads everything but the current computing part of the model to CPUs. This results in training a much larger model within the same hardware environment. The chunk-based memory management takes advantage of the linear structure of the transformer-based model, so that it will inherently prefetch the upcoming layers to GPUs.

Baseline Models We compare our model with SOTA pretrained Chinese models: (1) MBert-Chinese (Devlin et al., 2019), (2) Bert-wwm (Cui et al., 2019), (3) MacBert (Cui et al., 2020), (4) Ernie-gram (Sun et al., 2019, 2020b) and (5) ChineseBert (Sun et al., 2021). BERT-wwm continues pretraining from MBert-Chinese with the Whole Word Masking pretraining strategy. MacBERT applies the MLM-As-Correlation (MAC) pretraining strategy as well as the sentence-order prediction (SOP) task. ERNIE-gram adopts various masking strategies including token-level, phrase-level and entity-level masking to pretrain BERT on largescale heterogeneous data. Chinese-Bert is pretrained with the glyph and phonetic features.

Tasks We test our model on 5 standard Chinese NLU tasks and one toxic detection tasks. The 5 NLU tasks are: (1) ChnSentiCorp, Chinese sentiment classification with 2k training data [14], (2) TNEWS: news title classification with 50k training data, (3) AFQMC: question matching with 34k training data, (4) CSL, keyword recognition from paper abstracts with 20k training data ChnSentiCorp: 2k (Xu et al., 2020) and (5) CMNLI, Chinese Multi-Genre NLI with 390k data (Conneau et al., 2018). Toxic detection can server as a task with “human-made" attacks in contrast with the synthesized ones. It is collected from user interactions (written) with a popular online conversational platform, where users sometimes use various man-made attacks to avoid automatic system filtering of junk ads, porn and abusive information. We manually annotate 50k user inputs and identify 2k toxic contents (positive), out of which 90% are in adversarial forms. We randomly sample 2k negative text then split the whole into train/dev/test with 8:1:1.

Attacker We test the model performance under three different attackers (all untargeted as we do not need restrictions to the target class): (1) *ADV*, our own attacking algorithm, (2) *TextFooler* (Jin et al., 2020), a black-box algorithm replacing important words with semantically similar ones and (3) *Argot* (Zhang et al., 2020), a black-box attacking algorithm considering Chinese-specific features. We set the maximum attacking ratio for all the three algorithms as 20%. TextFooler is originally designed for English, we reimplement it with corresponding pretrained Chinese-version models.

5.2 Experiment Results

Chinese NLU Results We show the results on 5 Chinese NLU tasks in tables 2 to 6. For every task, we report the model accuracy measured in the clean testset and the adversarial testsets under 3 adversarial algorithms *ADV*, *TextFooler* and *Argot*. We report the performance of all base-version models for a fair comparison. We select the best-performed base-version model to test its large-version performance and compare it with RoCBert. As can be seen, our attacking algorithm *ADV* do not affect much on TNEWS, AFQMC and CSL because they rely more on the global sentence structure instead of individual words. On tasks like sentiment classification and NLI, single words contribute mostly to the model decision and therefore the attacking can lead to significant performance drop. *Argot* and *TextFooler* lead to more drop compared with *ADV* because they explicitly select words that affect the model decisions most while *ADV* selects words to attack based on the general language model scores. *Argot* is more effective than *TextFooler* because it tailors its character replacement to consider Chinese-specific features. Overall RoCBert *outperforms other models over all attacking algorithms on all the 5 tasks*. Even in the clean dataset, it performs the best on 4 out of the 5 tasks. *ChineseBert* performs the second under various attacks because it also considers multimodal features during its pretraining same as RoCBert, which further confirms the importance of using mulimodal features in Chinese language pretraining.

Toxic Content Detection Results We train all models in the toxic content detection task. As can be seen in Table 7, RoCBert *outperforms all other models over 4 metrics*. This confirms the its effectiveness at capturing the true semantics regardless of its adversarial form. The difference among models is smaller because they have all been finetuned on this task. All models can get adapted to different forms of attacks in the training process while the tables 2 to 6 are testing the zeroshot generalization to unknown attacks.

Table 6: Performance on CMNLI

fending methods on top of the best-performed base model (on clean testsets) in different tasks: ChineseBert for TNEWS, Ernie-gram for AFQMC, CSL and CMNLI, MacBert for ChnSentiCorp. We apply the spell-checker in Cheng et al. (2020). The results are visualized in Figure 2. We can see that spell checking improves the performance only marginally and sometimes even hurt the performance (best-other under ADV in CI). The reason could be that the spell checker performs poorly for out-of-domain adversarial examples. The errors could be propagated and further reduce the performance. *advtrain* can significantly benefit the performance, but note that it explicitly “peeps" at the adversarial algorithm applied in the testset while ROCBERT is not aware of the testing adversarial algorithm. Nevertheless, it is still comparable and in some cases even outperforms *advtrain*. By combining ROCBERT and advtrain, the model robustness can be further improved.

5.3 Ablation Study

We perform a set of ablation studies to understand the choice of different components in ROCBERT. All models in this section are pretrained with the *same base architecture and hyperparameters for one epoch on 1M sampled training text* then tested in TNEWS. The results are shown in Table 8.

Table 8: Ablation studies on *TNEWS* with different settings. *Best* indicates the best setting used in ROCBERT.

Loss To study the effects of the loss function used in the pretraining stage. We tried two other settings: (1) *contrastive only*, where the model is pretrained only with the contrastive learning loss in Eq 5 and (2) *MLM-only*, where the model is pretrained only with the MLM objective as in standard Bert. We can see that both options lowers down the model performance. By combining both loss, the model can be robust under adversarial attacks without affecting the performance in clean data.

Tokenization It has been widely demonstrated that char-based tokenization is preferred for Chinese characters (Li et al., 2019b), but it is rather unclear how we should model pinyins and non-Chinese words. We try different tokenization methods for non-Chinese characters: (1) *bpe* (Sennrich et al., 2016). We set the vocabulary as 20k and train the split on the training data (after convert-

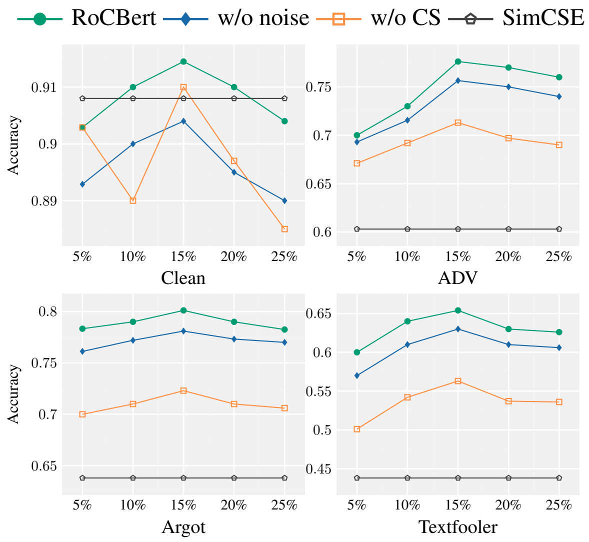

Figure 3: Ablation study with varying attacking ratio, w/o Gaussian noise, w/o character selection (CS) and SimCSE.

ing all Chinese characters into pinyin). (2) *char-cnn* (Zhang et al., 2015), which process each character individually but get the pinyin embedding with a char-cnn. The best setting in RoCBert used *char-sum* which processes each character individually and set the pinyin embedding as the sum of its character embeddings. We can see that bpe hurt the performance. This might be because the bpe split is trained on clean data only. For adversarial examples, the letters in pinyins can be easily perturbed and break its vocabulary. Char-based tokenization is more robust under adversarial attacks. Char-cnn does not lead to improvement here, probably because there are a limited combination of letters in Chinese pinyins (~ 400), each pinyin can usually be uniquely identified by its bag of characters without the need of order information.

Multimodal feature We tried removing the visual feature pretraining as mentioned in §4 and observe the performance drop (-vis-pretrain). It is even worse than removing the visual feature completely (-vis), suggesting the pretraining for visual features is essential, without which the model can be hard to learn meaningful visual features. The phonetic feature is less crucial than visual features but also brings positive improvement. By adding a pretraining stage for the phonetic features too (+pho-pretrain), the improvement is very marginal. As the phonetic features are also based on character embeddings, it might be easier for the model to automatically learn the phonetic features compared with the visual features.

Multimodal integration We compare our proposed *layer-insert* with three other ways of integrating multimodal features: (1) *sum* (Liu et al., 2021), which sums the multimodal embeddings, (2) *concatenation*, which concatenate(Sun et al., 2021), which concatenate the multimodal embeddings then fuse with an MLP layer, (3) *two-step* (Xu et al., 2021), which first determine the weight of different embeddings then fuse to the encoder. We can see that RoCBert performs best with only marginal computational overhead by updating the encoder representation in one layer.

Insert Layer We further analyze the effects of the insertion layer. Our best setting inserts the multimodal features in layer 1 for the base model and layer 3 for the large model. From Table 8, we can see that when inserting them in the upper layer 4,7 and 10, the performance gradually drops, suggesting an earlier insert is helpful for the model to incorporate these features in-depth. However, inserting them in layer 0 is also worse since the model can only learn weight among multimodal features solely from bag of words.

Attacking Algorithm We change the settings in our attacking algorithm to see the effects in Figure 3. We can see the attacking ratio can neither be too small nor too large. 15% is a sweet spot for pretraining. The Gaussian noise added in Eq 1 also brings positive effects consistently, suggesting we should not use a fixed attacking ratio in the pretraining stage. The character selection is also crucial and removing it significantly reduces the performance. To show whether it is necessary to adopt our attacking algorithm with complex combinations of attacking forms. We further compare with pretraining the model with SimCSE (Gao et al., 2021), an algorithm which uses drop out as the noise instead of our adversarial examples. We can see that SimCSE is rarely helpful under different attacks. This suggests it is important to define rule-based attacking algorithms to better fit the real-world attacks. *General drop-out regularizations cannot adapt well to complex real-world attacks.*

6 Conclusion

We present RoCBert: the first pretrained Chinese language model that is robust under various forms of adversarial attacks. It is pretrained with the multimodal contrastive learning objective and achieves the best performance on 5 Chinese NLU tasks under three different attacking algorithms without negative effects on clean testsets. It also significantly outperforms the others in the toxic content detection task. Extensive ablation studies are provided to benefit future research.

Abstract

It is a common practice for recent works in vision language cross-modal reasoning to adopt a binary or multi-choice classification formulation taking as input a set of source image(s) and textual query. In this work, we take a sober look at such an "unconditional" formulation in the sense that no prior knowledge is specified with respect to the source image(s). Inspired by the designs of both visual commonsense reasoning and natural language inference tasks, we propose a new task termed "**P**remise-based **M**ulti-modal **R**easoning" (PMR) where a textual premise is the background presumption on each source image. The PMR dataset contains 15,360 manually annotated samples which are created by a multi-phase crowd-sourcing process. With selected high-quality movie screenshots and human-curated premise templates from 6 pre-defined categories, we ask crowd-source workers to write one true hypothesis and three distractors (4 choices) given the premise and image through a cross-check procedure. Besides, we generate adversarial samples to alleviate the annotation artifacts and double the size of PMR. We benchmark various state-of-the-art (pretrained) multi-modal inference models on PMR and conduct comprehensive experimental analyses to showcase the utility of our dataset.

1 Introduction

Cross-modal reasoning between image and text has been recognized as a fundamental and long-standing task in both academia and industry, which has recently attracted intensive attention from both natural language processing and computer vision communities (Su et al., 2019; Yu et al., 2020; Chen et al., 2020). Researchers try to teach machines to perceive, understand and reason with both visual and textual clues, which mimics human cognitive process (Lake et al., 2016).

The canonical form for the cross-modal reasoning tasks usually take the source image(s) as the input and request the inference model to perform a multi-choice classification according to the specified textual query, including visual question answering (Antol et al., 2015; Goyal et al., 2017), visual commonsense reasoning (Zellers et al., 2018), visual entailment (Xie et al., 2019) and image-text grounding (Suhr et al., 2017, 2019), etc. We argue the default cross-modal setting is "static" or "unconditional" in the sense that no prior presumption or belief is attached to the input images (Ren et al., 2021). The lack of prior presumption would be insignificant while answering factoid questions according to the images, e.g. "how many dogs are lying on the grass?" (Suhr et al., 2019) or "is the bowl to the right of the green apple?" (Hudson and Manning, 2019). However it may not be the case for more sophisticated cross-modal reasoning that involves human-like cognition and commonsense, e.g. "what may happen to [personA]?", "what will [personA] say to [personB]" or "what will [personA] do to [personB]". The answers to these questions are ambiguous by merely looking at the source images, instead we offer an extra textual premise, which serves as the prior belief to the source images, such as "to [personA], nothing could be more somber", "[personA] is the son of [personB]". We name the proposed task as "**P**remise-based **M**ulti-modal **R**easoning" (PMR)[1]. In PMR, the inference model should be able to reason with both textual (from the premise) and visual (from images) clues.

The motivations for PMR are two-folds. 1) From the social psychology perspective, the design of PMR is inspired by the ABC Theory (Ellis, 1995) , which represents a widely accepted framework for how one's feelings and behavioral patterns are connected. As illustrated in Figure 1, the theory

May 22-27, 2022

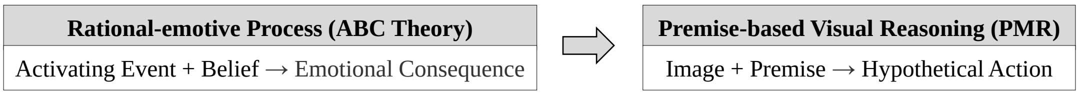

Figure 1: Connections between the ABC theory (Ellis, 1995) and the proposed PMR.

claims that human emotions and resulting behavior do not come directly from the events, but from the interpretations (textual premise) we make of those events (depicted in the source images). 2) From the methodology perspective, PMR gains insights from both visual commonsense reasoning (Zellers et al., 2018; Lei et al., 2020; Park et al., 2020) and natural language inference (Dagan et al., 2006; Bowman and Zhu, 2019; Xie et al., 2019) tasks. From the view of commonsense reasoning, the textual premise serves as the prior belief to the image as mentioned before. Meanwhile in the world of natural language inference, the input image can be viewed as the supplementary evidence that supports the textual premise-hypothesis classification. The proposed PMR could be readily seen as a meaningful extension on the joint cross-modal entailment and commonsense reasoning with both visual and textual clues.

Given the input premise-image pair, the practitioners are requested to choose the only true hypothetical action from four candidates in PMR. All four hypothetical actions are written by crowdsourced workers in a multi-phase cross-check annotation pipeline. We encourage the annotators to write challenging distracting actions that are logically correct with respect to either the premise or the image, but are contradicted with the joint premise-image pair while combining the visual and textual clues. In order to succeed on PMR, the reasoning model should excel at both language grounding among premise, image and candidate actions, and cross-modal understanding on commonsense and logical inference. We establish multiple competitive cross-modal pretrained models as baselines. We hope the proposed PMR could pave the way for the "conditional" cross-modal commonsense and logical reasoning that requires a human-like cognitive process.

2 Dataset and Task Overview

We describe the proposed PMR task with an example in Figure 2 I&II. Given a source image and a textual premise, the inference model should perceive and understand the image in combination with the premise so as to choose the exclusive correct action among the four hypothetical candidates. The premise would serve as the background knowledge or domain-specific commonsense for the given image. In the running example, the model should be able to recognize what [person2] wears from the image and infer whether [person4] would give his seat to [person2] under the premise "[person4] is very friendly". The corrected answer is 'C' according to the visual and textual clues. In total, we collect about 15k instances for PMR. We list the statistics for PMR in Table 2.

3 Data Collection

We collect PMR dataset in a multi-step crowdsourcing pipeline, including 1) image and premise creation, 2) annotator recruitment and instruction, 3) cross-checking annotation.

3.1 Image and Premise Creation

The source images of PMR are selected from the image pool[2] in the VCR (Zellers et al., 2018) dataset. The entire image pool contains 110k high-quality movie screenshots. To make the images fit better with PMR, we screened out those which have low brightness, more than five people, or more than 15 tags, and finally got 29,987 images. We also kept the object anchor information in VCR along with the source images, which was identified using Mask-RCNN (He et al., 2017).

As there are so many possible choices while writing premise for an image, to facilitate analysis of model performance by premise type, we constrained the premise to six categories and manually wrote templates for each category (see Appendix D). As Figure 4 shows, the six categories are personality, identity, emotion, relationship, environment and antecedent. To complete templates, we create multiple word sets and fill corresponding words into the slots randomly. And finally, we obtained 30,759 predefined premises, which would be presented to annotators for selection.

---

3.2 Annotator Recruitment and Instruction

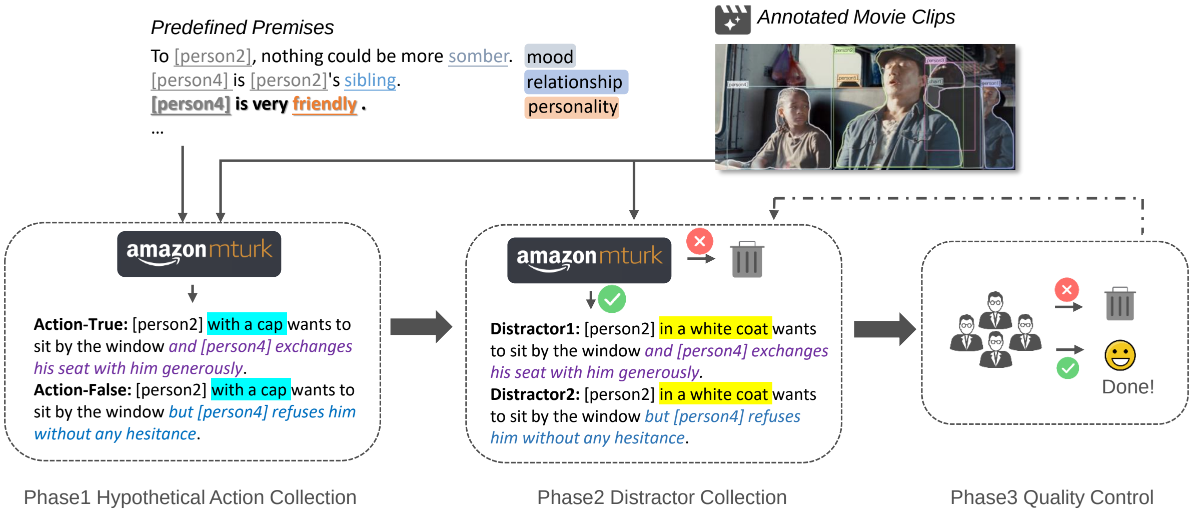
Through job descriptions posted on the online forums, we invite more than a hundred applicants who hold a bachelor of arts or higher degree to attend the online pre-annotating instruction and qualification test. In the pre-annotating instruction, we organized a two-hour training session, which covers the basics and goals of PMR, to better instruct the annotators, we extracted the text from VCR as the reference actions. Specifically, we filtered out questions about the following behavior of persons and retrieved the correct answers as the reference actions.

After the pre-annotating instruction, we conducted a qualification test by asking each participant to write the true and false hypothetical actions for 10 sampled image-premise pairs, the authors manually assess the annotation quality and eventually select 61 annotators whose educational background covers literature, linguistics, sociology, etc. Among them, 19 annotators who got higher scores in the qualification test were recognized as advanced workers and assigned to the distractor collection phase (phase 2 in Figure 3), while the other annotators were assigned to the hypothetical action creation phase (phase 1 in Figure 3).

3.3 Cross-check Annotation

We divide the annotation process into 3 phases. In phase 1, workers are presented with an image with bounding boxes on it, six predefined premises of different categories and six reference actions. Firstly, they are supposed to choose an appropriate premise. Workers can adjust the person tags to meet with the given image, but they have to assure that the modified premise still belongs to one of the six categories. Secondly, they ought to write two hypothetical actions, which describe what will happen next. Among them, **Action-True** contains image information and meets the chosen premise. In contrast, **Action-False** contains image information but does not meet the chosen premise. Thirdly, to make it easier for replacing certain words in phase 2, they need to enclose the words with curly brackets that mention the information of the image in both written actions.

In phase 2, advanced workers, serving as examiners, are responsible for checking whether the



To [person2], nothing could be more somber.

[person4] is very friendly .
...

Action-True: [person2] with a cap wants to sit by the window *and [person4] exchanges his seat with him generously.*
Action-False: [person2] with a cap wants to sit by the window *but [person4] refuses him without any hesitance.*

Distractor1: [person2] in a white coat wants to sit by the window *and [person4] exchanges his seat with him generously.*
Distractor2: [person2] in a white coat wants to sit by the window *but [person4] refuses him without any hesitance.*

Figure 3: The overview for the cross-check annotation for PMR. In the textual premises, the underlined tokens denote the slots in the pre-defined templates. In the hypothetical action collection, the words related with visual information are highlighted in blue , while the correspondent substitution in the distractors is highlighted in yellow .

annotation in phase 1 conforms to labeling instruction. They can drop it while meeting poor-quality one, and once they accept it, they need to write another two distractors corresponding to Action-True and Action-False respectively. We instruct the annotators to write challenging distractors that are logically correct with respect to either the premise or the image, but contradict with the joint premise-image pair while combining the visual and textual clues.

In phase 3, to ensure the quality of the examiners' work, we sample 10% HITs in phase 2 to check if the annotation meets our standard. This work is performed by the authors of this paper, and we feedback to examiners timely.

Post-Processing In order to ground objects from images with entities in text, we follow the VCR which substitutes all the tags both in premise and answers with the index in objects list. Besides, since crowd workers can conditionally modify the given premises, which results in the missing of labels of category, we calculate the BLEU (Papineni et al., 2002) score between premise and each template from six categories and labeled it with the most likely category with the highest BLEU score.

Annotation Cost We drop all the annotations that are rejected in phase3 and obtained 15,360 items after 60-day work. (See Appendix E for detailed pricing strategy) We split the total dataset into train, valid and test set in 8:1:1.

Adversarial Samples Generation To alleviate the possible bias introduced by annotation artifacts, inspired by Zellers et al., for each sample in the crowd-sourcing set of PMR, we pick three actions from other samples but similar to the premise as negatives and generate adversarial samples with the same scale. See Appendix C for detailed methods.

4 Experiments

To set up the benchmark, we introduce multiple text-only and pretrained multi-modal baseline models as well as human performance on PMR.

4.1 Baselines

Text-only Baselines We begin with a "blind" setting, where only the text is given without access to the image or bounding boxes annotations. In this setting, the models have to choose the correct answers with only textual clues. Specifically we finetune the BERT (Devlin et al., 2018) model in the action-only and premise+action scenarios. (See Appendix 6 for training details)

Multi-modal Baselines Throughout the visual reasoning tasks, cross-modal pretrained models have achieved state-of-the-art performance (Zellers et al., 2018; Goyal et al., 2017; Hudson and Manning, 2019). We introduce three powerful pretrained models and test their performance on PMR:

- **VL-BERT**(Su et al., 2019) A dual-stream pretrained model, is extended from BERT by appending visual feature embedding along with the subsequent sentences.

- **ERNIE-VL**(Yu et al., 2020) is a knowledge-enhanced approach to learning joint representations of vision and language, which introduced structure knowledge with scene graph prediction tasks while pretraining.

- **UNITER**(Chen et al., 2020) is also an extension of BERT to the visual domain. It is trained with a conditional masking strategy that allows the model to learn an informative representation of one modality conditioned on the other.

4.2 Detailed Experiment Settings

Before feeding into BERT, we concatenate the question and each answer as a sequence and replace detection tags with object names in it. As for person detection tags, we substitute them with gender-neutral names to bridge the gap between PMR and pretraining corpus (Zellers et al., 2018).

In terms of multimodal baselines, while an annotation is processed as above, we regard region features as visual tokens to be concatenated along with text sequence. Region features are extracted with Faster RCNN. Different from ERNIE-VL and UNITER which freeze Faster RCNN all the time, VL-BERT updates it while pretraining and finetuning.

4.3 Results

Are Premises Critical for Models to Predict? As is shown in Table 2, E-L achieves the highest accuracy while training and testing on the original split, but if trained with only actions as text inputs, the accuracy of it decreases sharply by 23.3%. More details can be found in Table 3. Premises help E-L correct the prediction of Action-False with the ratio from 30.5% to 8.2%.

Is Vision Modality Useful? As for the performance of text-only models and multi-modal models in Table 2, considering the information from images improves the accuracy by 10%-14.7%. Besides, Distractor1, as generated by substituting objects in Action-True, contradicts with corresponding images, which can be hard negatives while the visual signal is imperceptible. In Table 3, trained on the original split, E-L predicts Distractor1 with a ratio of 10.7%, nearly half of the prediction of BERT, suggesting that vision modality is beneficial to distinguish distractors.

	Ori. Train		Adv. Train		Mix Train		
	OT	AT	OT	AT	OT	AT	MT
Random	25.0	25.0	25.0	25.0	25.0	25.0	25.0
B-B†	39.3	23.1	22.9	41.9	25.6	25.0	25.3

E-L	79.9	10.7	8.2	1.2	77.1	9.6	11.1	2.1

Table 3: Detailed performance on Ori. Test. AT, D1, AF and D2 represent the ratio of the four-type prediction of models, Action-True, Distractor1, Action-False and Distractor2 respectively.

Does Crowd-sourcing Introduce Annotation Artifacts to Dataset? Table 2 shows that BERT with only actions outperforms random baseline by 14.3 on accuracy, indicating that textual bias is introduced by manual annotations, which is inevitable due to fixed patterns of thinking during labeling but is tolerable. Adding premises as background presumption, BERT can discover the relation between premises and actions with the performance improved a lot.

We also conduct a quantitative analysis of bias in data. To check whether labels are significantly associated with certain words, we compute the point-

Word	green	red	n't	fight	throw	hit
No. (Ori.)	1	2	7	11	18	23
PMI (Ori.)	1.620	1.562	1.322	1.318	1.305	1.301
No. (Mix)	1	2	26	16	52	155
PMI (Mix)	1.488	1.408	1.231	1.242	1.212	1.172

Table 4: PMI calculated for the words in Ori. and Mix datasets. No. is the reverse order in vocabulary according to PMI.

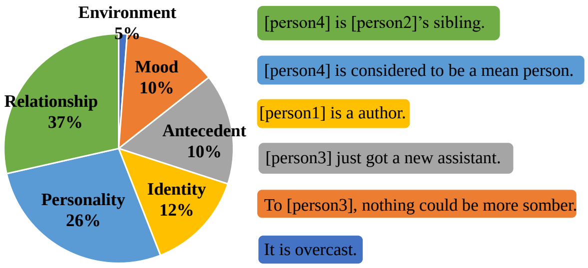

Figure 4: An overview of the premises from the samples in validation set.

wise mutual information (PMI) (Gururangan et al., 2018). As each sample in PMR has four choices, we consider the premise concatenated respectively with four answers as four binary-class items with label *False* if the answer is incorrect, and compute PMI between words and *False* label.

As Table 4 shows, among the top 30 words, green and red are the top two with the highest PMI, they are commonly used by crowd workers to modify the objects and generate distractors mismatched with images. Other words such as leave, fight and hit, crowd workers tend to write universal negative containing these words so as to pass the qualification check, which also results in high PMI of these words.

Does Training with Adversarial Samples Help to Relieve the Above Issue? Yes, firstly in Table 4, we can find that the PMIs of words decrease, indicating that adversarial samples help to balance the correlation of words and labels.

Secondly, Table 2 shows that there is a great gap in the performance of multi-modal models between testing on OT and AT while training on the original set, which also testifies the existence of bias in the original set. Nevertheless, after training on mixed data, multi-modal models are able to achieve high accuracy both on OT and AT, suggesting that adversarial samples are helpful to improve models' robustness. Besides, We can notice that E-L may be misled by the fewer incorrect samples in the adversarial split, and it results in a decline of 2.8% on OT, which can be seen as a compromise between generalization and performance.

Thirdly, we find that another huge gap of 39.4% on OT between BERT trained on the original set and mixed set, and it indicates that the adversarial samples help to change the data distribution and alleviate the bias from the text.

5 Analysis

5.1 Premise Distribution

From Figure 4, we can find that Relationship and Personality account for nearly two thirds of the samples, while the other four categories hold the rest one third, which indicates that the understanding of interpersonal relationships and the correlation between character's personalities and behaviors are test points of PMR. In terms of the reason why there is such a distribution, we maintain that this is because Relationship and Personality are more likely to conform with the instruction of annotation. As presented in Section 2, we expect premises as a supplement of images, so the information implied in premises should not be repeated or contradictory with the content of the image. Choosing the other four premises is more likely to violate the above requirements. For instance, people's mood tends to explicitly show through expression; the dressing of the characters can reflect their identity and occupation.

5.2 Substitution Strategy

We manually classified 100 samples from the validation set into nine types, which is presented in Table 5. As we can see, the types of substitution are varied ,and most of them are related to PERSON supertype, which reflects the emphasis on the characters' behavior.

In terms of the understanding of images, the levels of difficulty vary among different types. For instance, in APPEARANCE, CLOTHING, OBJECTS and COLOR, the words involved in the replacement process are relatively simple, such as long->short, white->red, knives->guns, which are likely to appear as labels in the datasets of object detection. Thus, systems with pre-trained objects detection models are expected to have an excellent performance on the four types. On the contrary, as for the types like EMOTION, BODY STATE and LOCATION, the texts substituted tend to be abstract and mostly are phrases consisting of more than one word. Consequently, these types are more

Supertype	Type	Action-True	Distractor1
PERSON	Appearance (8.0%)	[person2] with long hair will fall on the [couch1] and have a sleep immediately .	[person2] with short hair will fall on the [couch1] and have a sleep immediately .
	Emotion (3.0%)	[person1] weeps and tells [person2] his sad story , and he listens attentively .	[person1] smiles and tells [person2] his sad story , and he listens attentively .
	Clothing (22.0%)	[person2] will button up his shirt , because now it does n't look neat .	[person2] will button up his coat , because now it does n't look neat .
	Body State (10.0%)	As [person2] is ill in bed , [person1] will take care of [person2] .	As [person2] is ill sitting in the chair , [person1] will take care of [person2] .
	Location (18.0%)	[person4] who is in a car will ask [person2] to live with him because [person2] 's roommate has just died of an accident .	[person4] hiding behind the column will ask [person2] to live with him because [person2] 's roommate has just died of an accident .
GENERAL	Objects (23.0%)	[person1] and [person2] are trying to kill each other with knives .	[person1] and [person2] are trying to kill each other with guns .
	Color (1.0%)	[person3] with a red tie will play a beautiful tune with his guitar .	[person3] with a white tie will play a beautiful tune with his guitar .
	Texture (8.0%)	[person1] will have a rest on the chair .	[person1] will have a rest on the stone chair .
ENVIRONMENT	Scenery (7.0%)	[person1] and [person2] are walking down the street together .	[person1] and [person2] are walking down the park together .

Table 5: Nine types of substitution in Phase 2, the percentage of which in the original validation subset and the examples. For each one, the words before and after the replacement are highlighted in red and blue respectively.

challenging, and in order to succeed on them, the model is supposed to excel at in-depth image understanding and fine-grained grounding.

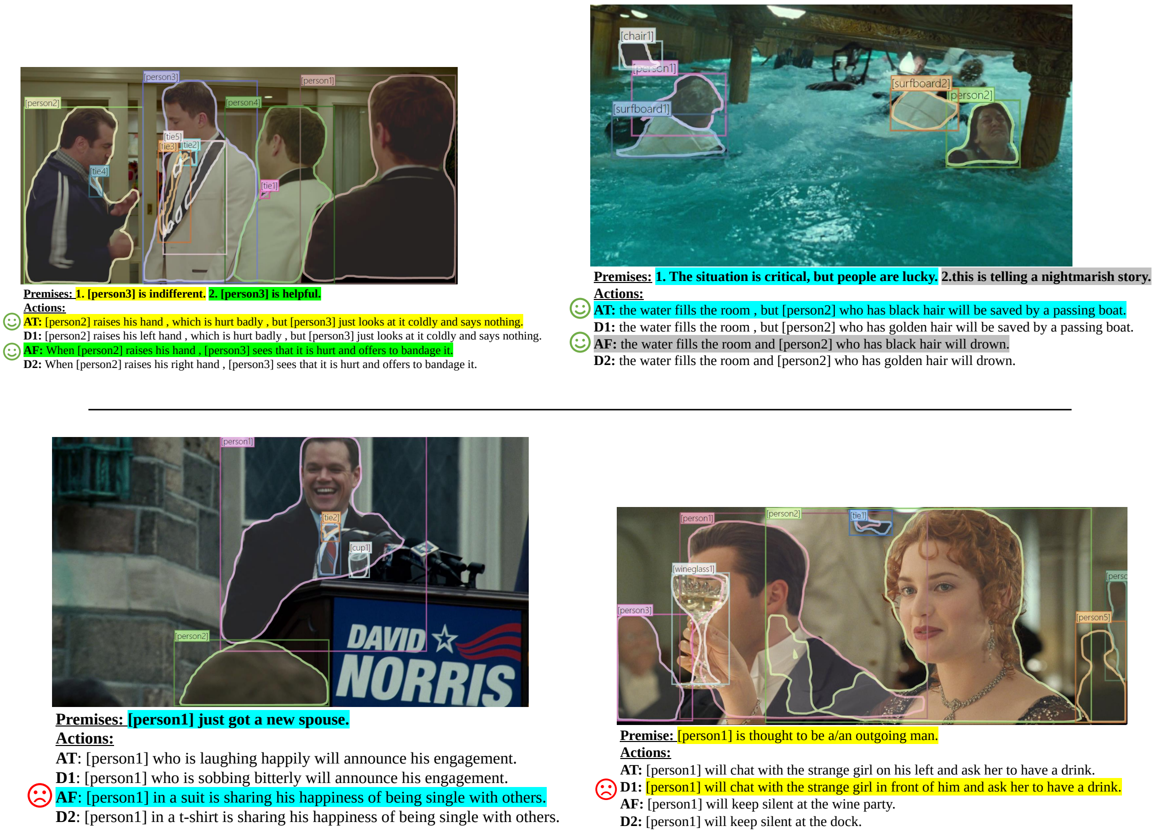
Comparing the difference before and after the substitution, we may notice that the substitution, within the scope of several consecutive words, can be regarded as a method of disturbance, and correspondingly, the distractors served as adversarial choices are beneficial to counter the possibility of models exploiting unimodal priors.

5.3 Case Study

We conduct a qualitative analysis shown in Figure 5, where the first two samples are correctly predicted by ERNIE-VIL. For each of them, premise 1 is the original. To explore the influence of different premises on the model predictions with the same image as background, we write premise 2 for the test, with which the model is expected to choose Action-False as the correct answer. The result shows that ERNIE-VIL predicted correctly both with premise 1 and 2, which indicates the model can distinguish the possible person's behaviors resulting from the two opposite premises. But for case 3, the model makes an incorrect prediction with Action-False chosen, suggesting that the performance is still unsatisfactory due to limited commonsense knowledge. Besides, even if the simple objects substitution can be easily detected by comparing the text with the images directly, case 4 shows that the model is not able to determine the relative position of people, which indicates that a powerful understanding capacity of images is needed to be added.

6 Related Work

Multimodal Commonsense Reasoning A series of tasks and datasets have been proposed for cross-modal commonsense reasoning. VCR (Zellers et al., 2018) is the most related work to the proposed PMR. It requires machines to understand a image and answer a multi-choice question. Specifically, questions are like ‘what is going to happen next’, ‘infer the relationship between [personA] and [personB]’ and ‘why is [personA] smiling’, as well as the rationale why the answer is true. In the video understanding regime, VLEP (Lei et al., 2020) is a dataset for future event prediction from videos. Given a video with aligned dialogue, and two possible future events, the AI system is required to choose the more likely event from two provided options. In the world of cross-modal com-



Premises: 1. [person3] is indifferent. 2. [person3] is helpful.
Actions:
☺ **AT:** [person2] raises his hand , which is hurt badly , but [person3] just looks at it coldly and says nothing.
D1: [person2] raises his left hand , which is hurt badly , but [person3] just looks at it coldly and says nothing.
☺ **AF:** When [person2] raises his hand , [person3] sees that it is hurt and offers to bandage it.
D2: When [person2] raises his right hand , [person3] sees that it is hurt and offers to bandage it.

Premises: **1. The situation is critical, but people are lucky.** **2.this is telling a nightmarish story.**
Actions:
☺ **AT:** the water fills the room , but [person2] who has black hair will be saved by a passing boat.
D1: the water fills the room , but [person2] who has golden hair will be saved by a passing boat.
☺ **AF:** the water fills the room and [person2] who has black hair will drown.
D2: the water fills the room and [person2] who has golden hair will drown.

Premises: [person1] just got a new spouse.
Actions:
AT: [person1] who is laughing happily will announce his engagement.
D1: [person1] who is sobbing bitterly will announce his engagement.
☹ **AF**: [person1] in a suit is sharing his happiness of being single with others.
D2: [person1] in a t-shirt is sharing his happiness of being single with others.

Premise: [person1] is thought to be a/an outgoing man.
Actions:
AT: [person1] will chat with the strange girl on his left and ask her to have a drink.
☹ **D1:** [person1] will chat with the strange girl in front of him and ask her to have a drink.
AF: [person1] will keep silent at the wine party.
D2: [person1] will keep silent at the dock.

Figure 5: There are four prediction samples from ERNIE-VIL. For each sample, We list actions in the order of AT, D1, AF and D2, which represent Action-True, Distractor1, Action-False, Distractor2 respectively. Model predictions are highlighted in different colors, which correspond to different premises, and the predictions are tagged with ☺ if correct, and ☹ otherwise.

monsense graph, VisualCOMET (Park et al., 2020) is a repository of Visual Commonsense Graphs that consists of 1.4 million textual descriptions of visual commonsense inferences. The proposed PMR is different from the above-mentioned dataset as we request the models to perceive and understand the source image with the supervision from a specified textual premise, and reason conditionally with joint visual and textual clues.

Natural Language Inference Early methods for textual NLI mainly relied on conventional, feature-based methods trained from small-scale datasets (Dagan et al., 2006). The release of larger datasets, such as SNLI (Bowman et al., 2015), MultiNLI (Williams et al., 2018), made neural network methods feasible. In the field of cross-modal entailment, the SNLI-VE (Xie et al., 2019) dataset casts the source image as the visual premise, and asks the inference model judge whether the specified textual hypothesis entails or contradicts with the visual premise. The proposed PMR can also be viewed as a cross-modal entailment task, however difference from SNLI-VE, both premise and hypothetical actions are textual, and the corresponding source images can be viewed as the supplementary evidence while judging the entailment labels. Besides, the existing textual and visual-related NLI tasks are formulated in a three-way classification, while the proposed PMR is model as a 4-choice classification task.

7 Conclusion

We propose a premise-based cross-modal reasoning (PMR) task, in which the textual premise serves as the presumptions to the source images. With selected images and human-curated premise templates, the collected dataset is formulated as a 4-choice classification task, in which we ask human annotators to write one true hypothetical action and three distracting actions. The PMR task gains insights from both the visual commonsense reasoning and the natural language inference tasks. We hope the proposed dataset and task can pave the way for human-like cognitive reasoning from both visual and textual clues.

A Author Statement

Hereby we confirm that we bear all responsibility in case of violation of rights, etc., and confirmation of the data license. This work is licensed under a CC BY-NC license, and both images and annotations can be accessed at https://2030nlp.github.io/PMR/.

B Additional Data Analysis

We explore the features of the language in PMR. As is shown in Table 1, the number of 2-grams has reached 84,365, the length of premises average to over 9, and additionally, our action texts average at more than 14 words, which is higher than the common question answering datasets and indicates PMR has high language complexity and diversity. Furthermore, we calculate the average number of objects mentioned in each sample. Since PMR aims to test the model's capability to infer the action of people, the objects mentioned are mainly persons, but due to our proposed generation strategy of distractors, the text also mention a variety of other objects, such as 'bowl' and 'chair'. Figure 10 shows the objects distribution both in text(reference) and images(total).

C Details for Adversarial Samples Generation

For each example, manually writing three distractors is expensive and unscalable, which costs nearly 1.5 times as much as a single question-answer pair. Therefore, Zellers et al. proposes Adversarial Matching to obtain high-quality negatives automatically. For a bunch of question-answer pairs, it aims to take the answer from other question as a negative for a question, with the constraint that the negative is supposed to be relevant to the question, but not overly similar to its true positive at the same time.

Inspired by it, we regarded the 15k premises and their Action-Trues as pairs and took a similar method to double the scale of PMR. Specifically, we chose the most related three actions from other pairs as negatives for a premise according to the relevance scores. Firstly, for a premise p_i, in order not to conflict with o_i, the objects list of p_i's corresponding image, we performed remapping[3], that's substituting the objects mentioned in candidate actions with objects in o_i. Secondly, we calculated the relevance scores for p_i with each remapped action by a bert-base model, which was trained with randomly sampled premise action pairs. Then, we picked the top3 actions with the highest confidence as negatives.

This method is simple but effective and efficient compared to the original adversarial matching. Due to the remapping strategy, the objects in actions are going to be randomly substituted, which may cause the contradiction with the premise and thus avoid them being false negatives. To figure out the effectiveness of our methods, we performed a human test on the 50 items from the adversarial samples generated by it, and the result showed that the human got an accuracy of 0.86 which demonstrated that our methods can generate high-quality negatives. What's more, overemphasizing the difference with the true positive tends to lead the distractors to be more distinguishable and lower the difficulty of datasets, which was testified by the performance of VL-BERT with an accuracy of 1.0 on the test set of adversarial samples generated in the same way of VCR.

Therefore, we maintain that the remapping strategy is enough to balance the difficulty with the correctness of adversarial samples.

D Manually Written Templates for Premises

We list all the templates for premises by category. "[ ]" indicates the slots to be filled with words of different types.

1. Relationship

- They are [N].
- [person1] and [person2] are [N].
- The two speakers are [N].
- [person1] is [person2]'s [n].
- [person1] is talking with his/her [n].
- Because of what happened before, they have a [adj] relationship now.
- The relationship between [person1] and [person2] is very [adj].

2. Personality

- [person1] is [adj].
- [person1] has a [adj] temper.
- Both [person1] and [person2] are [adj].
- [person1]'s personality is very [adj].

---

[3] https://groups.google.com/group/visualcommonsense/attach/500d18f416f1b/dataloader.py?part=0.1

- [person1] is thought to be a/an [adj] man.
- [person1] gives people a [adj] feeling.
- They all know that [person1] is a/an [adj] person.
- [person1] is considerd to be a/an [adj] person.
- [person1] is quite [adj] about most things.

3. Identity

- [person1] is a [job1].
- [person1]'s job is a [job1].
- The occupation of [person1] is a [job1].
- [person1] works in [place1].
- [person1] works for a/an [place1].
- The line of work that the [person1] is in is [place1]

4. Antecedent

- There was a/an [incident1].
- [incident1] happened.
- [person1] and [person2] had a fight.
- [person1] had no idea who [person2] was supposed to be.
- [person1] and [person2] were very familiar with each other.
- [person1] broke things on accident.
- Something unfortunate had just happened.
- Something fortunate had just happened.
- [person1] just lost [relative1].
- [person1] just got a new [relative1].

5. Mood

- [person1] is [adj].
- [person1] feels [adj].
- To [person1], nothing could be more [adj].
- Having a conversation with [person2], [person1] is very [adj].
- [person1] has a [adj] time with [person2].
- Because of [person2]'s behavior, [person1] feels very [adj].
- [person1] is so [adj] to talk with [person2].
- people have [adj] looks on their faces.
- [person1] looks [adj] today.
- Recently, [person1] is becoming more and more [adj].
- This scene makes them very [adj].
- [person1] makes [person2] [adj].
- [person1] is feeling a bit [adj].
- [person1] is in a [adj] mood today.
- [person1] is filled with [n].

6. Environment

- It is [weather1].
- The atmosphere is [emotion1].
- There is a/an [emotion1] in the air.
- This is telling a [emotion1] story.
- The scene is [emotion1].

E Payment for Worker

Crowd workers performed annotations mainly in phase1 and phase2, and we paid them different prices according to the workload and the quality. In Phase 1, workers are responsible for selecting the premise and writing two hypothetical actions. If accepted in Phase 2, they would be paid 0.15$ for each sample. And they would only obtain 1.5 cents per sample if rejected. In Phase 2, the total salary was calculated by multiplying the basic salary by qualification rate. For basic salary, if anyone accepted the annotation in Phase 1 and generate another two distractors, he or she would get 7.5 cents, otherwise, they only got 1.5 cents (No distracter needs to be generated in such a case certainly). In terms of qualification rate, it was obtained by checking the quality of the result in Phase 2, and we would calculate it for every worker. On average, the annotators were paid about 3 times as much as the prevailing local minimum wage per hour.

F Data Availability and Copyright

According to Section 107 of the Copyright Law[4],and 28A and 30 of the Copyright Acts[5], there is one exception to copyright infringement which is fair use (or fair dealing). Fair use is appropriate for public benefit purposes, like research. Our use is not of commercial nature. Besides, we only use texts that are publicly available, and the source will be stated according to law. Users can download the images directly from the original source.

G Experimental Details

We list all the hyperparameters training different models in Table 6.

H Annotation Interface

We present instruction for annotation in Figure 6, and the interfaces[6] used in 3 phases in Figure 7, Figure 8 and Figure 9.

Instructions:

1. According to the image and its label information (click "show/hide" below), choose one of the six optional premises that can be used as the supplementary information of the image (if the options given are not suitable, you can modify or rewrite one to fill in the blank freely).

2. Write two hypothetical actions, which describe what will happen next. Among them, action-True containing image information and meets the chosen premise. In contrast, action-False contains image information but **does not** meet the chosen premise.

3. Please enclose the words with "{ }" that mention the information of image in both written actions.

Tip: If there is no idea, you can click "Unfold Action" to get the reference items.

Note:

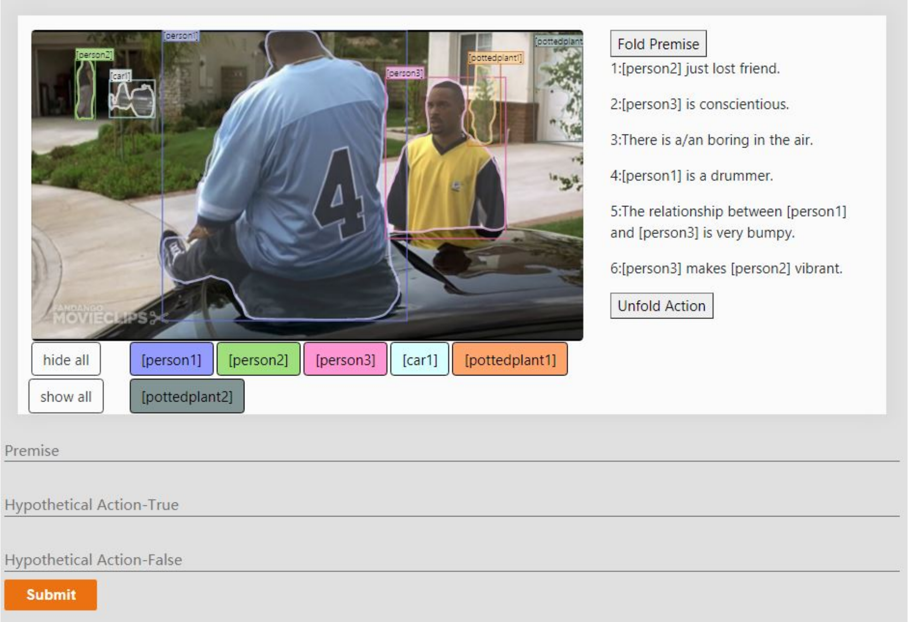
1. For high-quality results, please read More Instructions conscientiously before annotating.

2. **Text** is supposed to be filled in the blank instead of the indexes of reference premises or actions.

3. No other language except **English** should be used.

4. PERSON should be enclosed with **[ ]** if you want to refer to someone from the image in the premise and actions. That's, to write *[person1]* instead of *person1* or *person 1*.

Figure 6: Annotation Instruction.



1:[person2] just lost friend.

2:[person3] is conscientious.

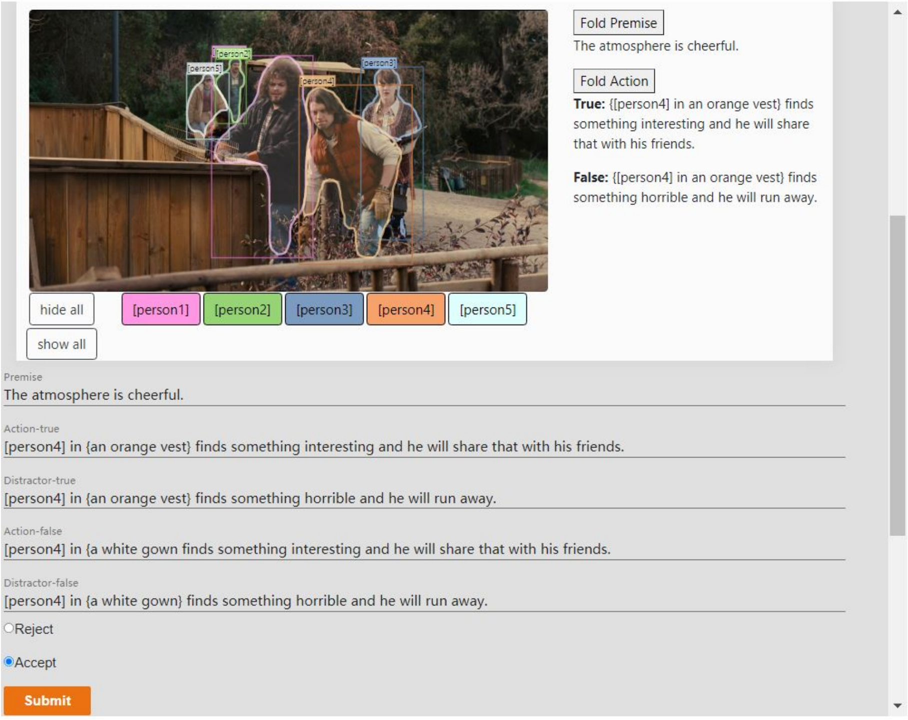
3:There is a/an boring in the air.

4:[person1] is a drummer.

5:The relationship between [person1] and [person3] is very bumpy.

6:[person3] makes [person2] vibrant.

Figure 7: Annotation interface for phase 1.



The atmosphere is cheerful.

True: {[person4] in an orange vest} finds something interesting and he will share that with his friends.

False: {[person4] in an orange vest} finds something horrible and he will run away.

Premise
The atmosphere is cheerful.

Action-true
[person4] in {an orange vest} finds something interesting and he will share that with his friends.

Distractor-true
[person4] in {an orange vest} finds something horrible and he will run away.

Action-false
[person4] in {a white gown finds something interesting and he will share that with his friends.

Distractor-false
[person4] in {a white gown} finds something horrible and he will run away.

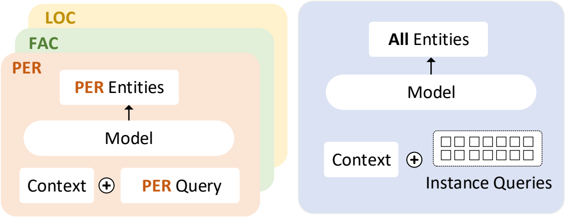
Abstract

Named entity recognition (NER) is a fundamental task in natural language processing. Recent works treat named entity recognition as a reading comprehension task, constructing type-specific queries manually to extract entities. This paradigm suffers from three issues. First, type-specific queries can only extract one type of entities per inference, which is inefficient. Second, the extraction for different types of entities is isolated, ignoring the dependencies between them. Third, query construction relies on external knowledge and is difficult to apply to realistic scenarios with hundreds of entity types. To deal with them, we propose Parallel Instance Query Network (PIQN), which sets up global and learnable instance queries to extract entities from a sentence in a parallel manner. Each instance query predicts one entity, and by feeding all instance queries simultaneously, we can query all entities in parallel. Instead of being constructed from external knowledge, instance queries can learn their different query semantics during training. For training the model, we treat label assignment as a one-to-many Linear Assignment Problem (LAP) and dynamically assign gold entities to instance queries with minimal assignment cost. Experiments on both nested and flat NER datasets demonstrate that our proposed method outperforms previous state-of-the-art models[1].

1 Introduction

Named Entity Recognition (NER) aims to identify text spans to specific entity types such as Person, Location, Organization. It has been widely used in many downstream applications such as entity linking (Ganea and Hofmann, 2017; Le and Titov, 2018) and relation extraction (Li and Ji, 2014; Miwa and Bansal, 2016; Shen et al., 2021b). Traditional approaches for NER are based on sequence labeling, assigning a single tag to each word in a sentence. However, the words of nested entities have more than one tag, thus these methods lack the ability to identify nested entities.



(a) Type-specific Query (b) Instance Query

Figure 1: (a) For a sentence, type-specific queries can only extract entities of one type per inference, so the model needs to be run multiple times. (b) In contrast, instance-based queries can be input into the model simultaneously, and all entities can be extracted in parallel. Furthermore, the parallel manner can model the interactions between entities of different types.

Recently, Ju et al. (2018); Straková et al. (2019); Wang et al. (2020a) redesign sequence labeling models to support nested structures using different strategies. Instead of labeling each word, Luan et al. (2019); Tan et al. (2020); Li et al. (2021); Shen et al. (2021a) perform a classification task on the text span, and Straková et al. (2019); Paolini et al. (2021); Yan et al. (2021); Tan et al. (2021) treat NER as a sequence generation or set prediction task and design encoder-decoder models to generate entities. Recently, Li et al. (2020b); Mengge et al. (2020); Zheng et al. (2021) reformulate the NER task as a machine reading task and achieve a promising performance on both flat and nested datasets. As shown in Figure 1(a), they treat the sentence as context and construct type-specific queries from external knowledge to extract entities. For example, for the sentence *"U.S. President Barack Obama and his wife spent eight years*

Volume 1: Long Papers, pages 947 - 961
May 22-27, 2022 ©2022 Association for Computational Linguistics

in the White House", Li et al. (2020b) constructs the `PER`-specific query in natural language form - *"Find person entity in the text, including a single individual or a group"* to extract the `PER` entities, such as *"U.S. President"*, *"Barack Obama"*. However, since the queries are type-specific, only one type of entities can be extracted for each inference. This manner not only leads to inefficient prediction but also ignores the intrinsic connections between different types of entities, such as *"U.S."* and *"U.S. President"*. In addition, type-specific queries rely on external knowledge for manual construction, which makes it difficult to fit realistic scenarios with hundreds of entity types.

In this paper, we propose the Parallel Instance Query Network (PIQN), where global and learnable instance queries replace type-specific ones to extract entities in parallel. As shown in Figure 1(b), each instance query predicts one entity, and multiple instance queries can be fed simultaneously to predict all entities. Different from previous methods, we do not need external knowledge to construct the query into natural language form. The instance query can learn different query semantics during training, such as position-related or type-related semantics. Since the semantics of instance queries are implicit, we cannot assign gold entities as their labels in advance. To tackle this, we treat label assignment as a one-to-many Linear Assignment Problem (LAP) (Burkard and Çela, 1999), and design a dynamic label assignment mechanism to assign gold entities for instance queries.

Our main contributions are as follow:

- Different from type-specific queries that require multiple rounds of query, our model employs instance queries that can extract all entities in parallel. Furthermore, the style of parallel query can model the interactions between entities of different types.

- Instead of relying on external knowledge to construct queries in natural language form, instance queries learn their query semantics related to entity location and entity type during training.

- To train the model, we design a dynamic one-to-many label assignment mechanism, where the entities are dynamically assigned as labels for the instance queries during training. The one-to-many manner allows multiple queries to predict the same entity, which can further improve the model performance.

- Experiments show that our model achieves state-of-the-art performance consistently on several nested and flat NER datasets.

2 Related Work

Traditional approaches for NER can be divided into three categories, including tagging-based, hypergraph-based and span-based approaches. The typical sequence labeling approach (Huang et al., 2015) predicts labels for each token, and struggles to address nested NER. Some works (Alex et al., 2007; Wang et al., 2020a) adapt the sequence labeling model to nested entity structures by designing a special tagging scheme. Different from the decoding on the linear sequence, the hypergraph-based approaches (Lu and Roth, 2015; Muis and Lu, 2017; Katiyar and Cardie, 2018) construct hypergraphs based on the entity nesting structure and decode entities on the hypergraph. Span-based methods first extract spans by enumeration (Sohrab and Miwa, 2018; Luan et al., 2019) or boundary identification (Zheng et al., 2019; Tan et al., 2020), and then classify the spans. Based on these, Shen et al. (2021a) treats NER as a joint task of boundary regression and span classification and proposes a two-stage identifier of locating entities first and labeling them later.

Three novel paradigms for NER have recently been proposed, reformulating named entity recognition as sequence generation, set prediction, and reading comprehension tasks, respectively. Yan et al. (2021) formulates NER as an entity span sequence generation problem and uses a BART (Lewis et al., 2020) model with the pointer mechanism to tackle NER tasks. Tan et al. (2021) formulates NER as an entity set prediction task. Different from Straková et al. (2019), they utilize a non-autoregressive decoder to predict entity set. Li et al. (2020b); Mengge et al. (2020) reformulate the NER task as an MRC question answering task. They construct type-specific queries using semantic prior information for entity categories.

Different from Li et al. (2020b); Jiang et al. (2021), our method attempts to query at the entity level, where it adaptively learns query semantics for instance queries and extracts all types of entities in parallel. It is worth noting that Seq2Set (Tan et al., 2021) is quite different from ours: (1)

Seq2Set attempts to eliminate the incorrect bias introduced by specified entity decoding order in the seq2seq framework, and proposes an entity set predictor, while we follow the MRC paradigm and focus on extracting entities using instance queries. (2) Seq2Set is an encoder-decoder architecture, while our model throws away the decoder and keeps only the encoder as in Wang et al. (2022a), which speeds up inference and allows full interaction between query and context. (3) Seq2Set uses bipartite graph matching to compute the entity-set level loss, while we focus on the label assignment for each instance query and propose a one-to-many dynamic label assignment mechanism.

3 Method

In this section, we first introduce the task formulation in § 3.1, and then describe our method. As shown in Figure 2, our method consists of three components: the Encoder (§ 3.2), the Entity Prediction (§ 3.3) and the Dynamic Label Assignment (§ 3.4). The encoder encodes both the sentence and instance queries. Then for each instance query, we perform entity localization and entity classification using Entity Pointer and Entity Classifier respectively. For training the model, we introduce a dynamic label assignment mechanism to assign gold entities to the instance queries in § 3.4.

3.1 Task Formulation

We use (X, Y) to denote a training sample, where X is a sentence consisting of N words labeled by a set of triples $Y = \{< Y_k^l, Y_k^r, Y_k^t >\}_{k=0}^{G-1}$. $Y_k^l \in [0, N-1]$, $Y_k^r \in [0, N-1]$ and $Y_k^t \in \mathcal{E}$ are the indices for the left boundary, right boundary and entity type of the k-th entity, where $\mathcal{E}$ is a finite set of entity types. In our approach, We set up $M (M > G)$ global and learnable instance queries $I = \mathbb{R}^{M \times h}$, each of which (denoted as a vector of size h) extracts one entity from the sentence. They are randomly initialized and can learn the query semantics automatically during training. Thus we define the task as follows: given an input sentence X, the aim is to extract the entities Y based on the learnable instance queries I.

3.2 Encoder

Model input consists of two sequences, the sentence X of length N and the instance queries I of length M. The encoder concatenates them into one sequence and encodes them simultaneously.

Input Embedding We calculate the token embeddings E_{tok}, position embeddings E_{pos} and type embeddings E_{typ} of the input from two sequences as follows ($E_{tok}, E_{pos}, E_{typ} \in \mathbb{R}^{(N+M)\times h}$):

$$\begin{aligned} E_{tok} &= \text{Concat}(V, I) \\ E_{pos} &= \text{Concat}(P^w, P^q) \\ E_{typ} &= \text{Concat}([U^w]^N, [U^q]^M) \end{aligned} \qquad (1)$$

where $V \in \mathbb{R}^{N\times h}$ are token embeddings of the word sequence, $I \in \mathbb{R}^{M\times h}$ are the vectors of instance queries, $P^w \in \mathbb{R}^{N\times h}$ and $P^q \in \mathbb{R}^{M\times h}$ are separate learnable position embeddings. U^w and U^q are type embeddings and $[\cdot]^N$ means repeating N times. Then the input can be represented as $H^0 = E_{tok} + E_{pos} + E_{typ} \in R^{(N+M)\times h}$.

One-Way Self-Attention Normal self-attention would let the sentence interact with all instance queries. In such a way, randomly initialized instance queries can affect the sentence encoding and break the semantics of the sentence. To keep the sentence semantics isolated from the instance queries, we replace the self-attention in BERT (Devlin et al., 2019) with the one-way version:

$$\text{OW-SA}(H) = \alpha H W_v \qquad (2)$$

$$\alpha = \text{softmax}\left(\frac{HW_q(HW_k)^T}{\sqrt{h}} + \mathcal{M}\right) \qquad (3)$$

where $W_q, W_k, W_v \in \mathbb{R}^{h\times h}$ are parameter matrices and $\mathcal{M} \in \{0, -\inf\}^{(N+M)\times(N+M)}$ is a mask matrix for the attention score where elements in $\mathcal{M}$ set to 0 for kept units and $-\inf$ for removed ones. In our formula, the upper right sub-matrix of $\mathcal{M}$ is a full $-\inf$ matrix of size $(N \times M)$ and other elements are zero, which can prevent the sentence encoding from attending on the instance queries. In addition, the self-attention among instance queries can model the connections between each other, and then enhance their query semantics.

After BERT encoding, we further encode the sequence at word-level by two bidirectional LSTM layers and L extra transformer layers. Finally we split $H \in \mathbb{R}^{(N+M)\times h}$ into two parts: the sentence encoding $H^w \in \mathbb{R}^{N\times h}$ and the instance query encoding $H^q \in \mathbb{R}^{M\times h}$.

3.3 Entity Prediction

Each instance query can predict one entity from the sentence, and with M instance queries, we can predict at most M entities in parallel. Entity prediction

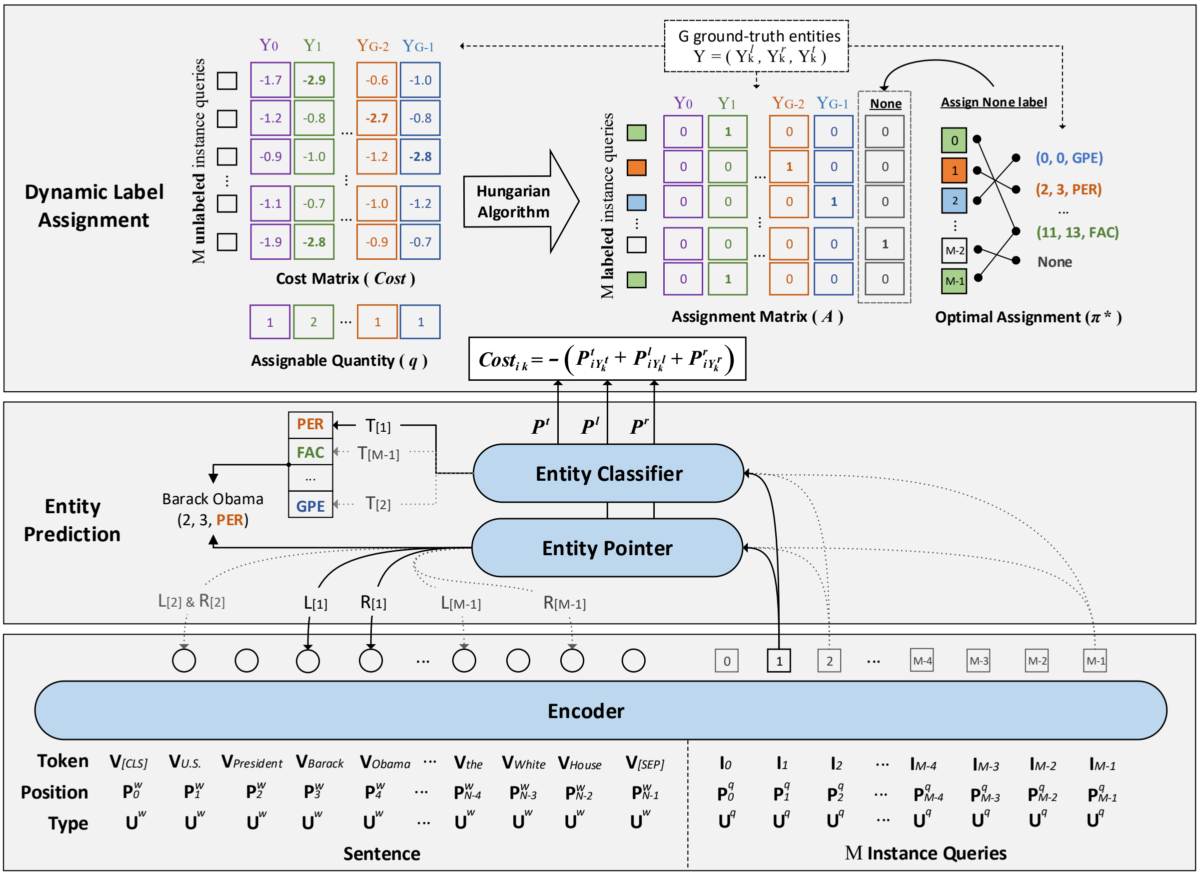

Figure 2: The overall architecture of the model.

can be viewed as a joint task of boundary prediction and category prediction. We design Entity Pointer and Entity Classifier for them respectively.

Entity Pointer For the i-th instance query H_i^q, we first interact the query with each word of the sentence by two linear layers. The fusion representation of the i-th instance query and j-th word is computed as:

$$S_{ij}^{\delta} = \mathrm{ReLU}(H_i^q W_\delta^q + H_j^w W_\delta^w) \qquad (4)$$

where $\delta \in \{l, r\}$ denotes the left or right boundary and $W_\delta^q, W_\delta^w \in \mathbb{R}^{h \times h}$ are trainable projection parameters. Then we calculate the probability that the j-th word of the sentence is a left or right boundary:

$$P_{ij}^{\delta} = \mathrm{sigmoid}(S_{ij}^{\delta} W_\delta + b_\delta) \qquad (5)$$

where $W_\delta \in \mathbb{R}^h$ and b_δ are learnable parameters.

Entity Classifier Entity boundary information are useful for entity typing. We use $P_i^\delta = [P_{i0}^\delta, P_{i1}^\delta, \cdots, P_{iN-1}^\delta], \delta \in \{l, r\}$ to weigh all words and then concatenate them with instance queries. The boundary-aware representation of the i-th instance query can be calculated as:

$$S_i^t = \mathrm{ReLU}\left(\left[H_i^q W_t^q; P_i^l H^w; P_i^r H^w\right]\right) \qquad (6)$$

where $W_t^q \in \mathbb{R}^{h \times h}$ is a learnable parameter. Then we can get the probability of the entity queried by the i-th instance query belonging to category c:

$$P_{ic}^t = \frac{\exp(S_i^t W_t^c + b_t^c)}{\sum_{c' \in \mathcal{E}} \exp(S_i^t W_t^{c'} + b_t^{c'})} \qquad (7)$$

where $W_t^{c'} \in \mathbb{R}^h$ and $b_t^{c'}$ are learnable parameters.

Finally, the entity predicted by the i-th instance query is $\mathcal{T}_i = (\mathcal{T}_i^l, \mathcal{T}_i^r, \mathcal{T}_i^t)$. $\mathcal{T}_i^l = \arg\max_j(P_{ij}^l)$ and $\mathcal{T}_i^r = \arg\max_j(P_{ij}^r)$ are the left and right boundary, $\mathcal{T}_i^t = \arg\max_c(P_{ic}^t)$ is the entity type. We perform entity localization and entity classification on all instance queries to extract entities in parallel. If multiple instance queries locate the same entity but predict different entity types, we keep only the prediction with the highest classification probability.

3.4 Dynamic Label Assignment for Training

Dynamic Label Assignment Since instance queries are implicit (not in natural language form), we cannot assign gold entities to them in advance. To tackle this, we dynamically assign labels for the instance queries during training. Specifically, we treat label assignment as a Linear Assignment Problem. Any entity can be assigned to any instance query, incurring some cost that may vary depending on the entity-query assignment. We define the cost of assigning the k-th entity ($Y_k = < Y^l_k, Y^r_k, Y^t_k >$) to the i-th instance query as:

$$Cost_{ik} = -\left(P^t_{iY^t_k} + P^l_{iY^l_k} + P^r_{iY^r_k}\right) \tag{8}$$

where Y^t_k, Y^l_k and Y^r_k denote the indices for the entity type, left boundary and right boundary of the k-th entity. It is required to allocate as many entities as possible by assigning at most one entity to each query and at most one query to each entity, in such a way that the total cost of the assignment is minimized. However, the one-to-one manner does not fully utilize instance queries, and many instance queries are not assigned to gold entities. Thus we extend the traditional LAP to one-to-many one, where each entity can be assigned to multiple instance queries. The optimization objective of this one-to-many LAP is defined as:

$$\begin{aligned} \min \ & \sum_{i=0}^{M-1} \sum_{k=0}^{G-1} A_{ik} Cost_{ik} \\ s.t. \ & \textstyle\sum_k A_{ik} \leq 1 \\ & \textstyle\sum_i A_{ik} = q_k \\ & \forall i, k, A_{ik} \in \{0,1\} \end{aligned} \quad . \tag{9}$$

where $A \in \{0,1\}^{M \times G}$ is the assignment matrix, G denotes the number of the entities and $A_{ik} = 1$ indicates the k-th entity assigned to the i-th instance query. q_k denotes the assignable quantity of the k-th gold entity and $Q = \sum_k q_k$ denotes the total assignable quantity for all entities. In our experiments, the assignable quantities of different entities are balanced.

We then use the Hungarian (Kuhn, 1955) algorithm to solve Equation 9, which yields the label assignment matrix with the minimum total cost. However, the number of instance queries is greater than the total assignable quantity of entity labels ($M > Q$), so some of them will not be assigned to any entity label. We assign `None` label to them by extending a column for the assignment matrix. The new column vector a is set as follows:

$$a_i = \begin{cases} 0, & \sum_k A_{ik} = 1 \\ 1, & \sum_k A_{ik} = 0 \end{cases} \tag{10}$$

Based on the new assignment matrix $\hat{A} \in \{0,1\}^{M \times (G+1)}$, we can further get the labels $\hat{Y} = Y.\mathrm{indexby}(\pi^*)$ for M instance queries, where $\pi^* = \underset{dim=1}{\arg\max}(\hat{A})$ is the label index vector for instance queries under the optimal assignment.

Training Objective We have computed the entity predictions for M instance queries in § 3.3 and got their labels $\hat{Y}$ with the minimum total assignment cost in § 3.4. To train the model, we define boundary loss and classification loss. For left and right boundary prediction, we use binary cross entropy function as a loss:

$$\begin{aligned} \mathcal{L}_b = - \sum_{\delta \in \{l,r\}} \sum_{i=0}^{M-1} \sum_{j=0}^{N-1} & \mathbb{1}[\hat{Y}^\delta_i = j] \log P^\delta_{ij} \\ & + \mathbb{1}[\hat{Y}^\delta_i \neq j] \log \left(1 - P^\delta_{ij}\right) \end{aligned} \tag{11}$$

and for entity classification we use cross entropy function as a loss:

$$\mathcal{L}_t = - \sum_{i=0}^{M-1} \sum_{c \in \mathcal{E}} \mathbb{1}[\hat{Y}^t_i = c] \log P^t_{ic} \tag{12}$$

where $\mathbb{1}[\omega]$ denotes indicator function that takes 1 when ω is true and 0 otherwise.

Follow Al-Rfou et al. (2019) and Carion et al. (2020), we add Entity Pointer and Entity Classifier after each word-level transformer layer, and we can get the two losses at each layer. Thus, the total loss on the train set D can be defined as:

$$\mathcal{L} = \sum_{D} \sum_{\tau=1}^{L} \mathcal{L}^\tau_t + \mathcal{L}^\tau_b \tag{13}$$

where $\mathcal{L}^\tau_t, \mathcal{L}^\tau_b$ are classification loss and boundary loss at the τ-th layer. For prediction, we just perform entity prediction at the final layer.

4 Experiment Settings

4.1 Datasets

To provide empirical evidence for the effectiveness of the proposed model, we conduct our experiments

on eight English datasets, including five nested NER datasets: ACE04 (Doddington et al., 2004) , ACE05 (Walker et al., 2006), KBP17 (Ji et al., 2017), GENIA (Ohta et al., 2002), NNE(Ringland et al., 2019) and three flat NER dataset: FewNERD (Ding et al., 2021), CoNLL03 (Tjong Kim Sang and De Meulder, 2003), OntoNotes (Pradhan et al., 2013), and one Chinese flat NER dataset: MSRA (Levow, 2006). FewNERD and NNE are two datasets with large entity type inventories, containing 66 and 114 fine-grained entity types. Please refer to Appendix A for statistical information about the datasets.

4.2 Implementation Details

In our experiments, we use pretrained BERT (Devlin et al., 2019) in our encoder. For a fair comparison, we use `bert-large` on ACE04, ACE05, NNE, CoNLL03 and OntoNotes, `bert-base` on KBP17 and FewNERD, `biobert-large` (Chiu et al., 2016) on GENIA and `chinese-bert-wwm` (Cui et al., 2020) on Chinese MSRA. For all datasets, we train our model for 30-60 epochs and use the Adam Optimizer (Kingma and Ba, 2015) with a linear warmup-decay learning rate schedule. We initialize all instance queries using the normal distribution $\mathcal{N}(0.0, 0.02)$. See Appendix B for more detailed parameter settings and Appendix C for all baseline models.

4.3 Evaluation Metrics

We use strict evaluation metrics that an entity is confirmed correct when the entity boundary and the entity type are correct simultaneously. We employ precision, recall and F1-score to evaluate the performance. We also report the F1-scores on the entity localization and entity classification subtasks in § 5.2 and Appendix D.2. We consider the localization as correct when the left and right boundaries are predicted correctly. Based on the accurately localized entities, we then evaluate the performance of entity classification.

5 Results and Analysis

5.1 Performance

Overall Performance Table 1 illustrates the performance of the proposed model as well as baselines on the nested NER datasets. We observe significant performance boosts on the nested NER datasets over previous state-of-the-art models, achieving F1-scores of 81.77%, 88.14%, 87.42% and 84.50% on GENIA, ACE04, ACE05, KBP17 and NNE datasets with +1.23%, +0.73%, +0.37%, +0.45% and +0.96% improvements. Our model can be applied to flat NER. As shown in Table 2, our model achieves state-of-the-art performance on the FewNERD and Chinese MSRA datasets with +1.44% and +0.88% improvements. On the CoNLL03 and OntoNotes datasets, our model also achieves comparable results. Compared with the type-specific query-based method (Li et al., 2020b), our model improves by +2.85%, +2.16%, +0.54%, +3.53% on the GENIA, ACE04, ACE05 and KBP17 datasets. We believe there are three reasons: (1) Rather than relying on external knowledge to inject semantics, instance queries can learn query semantics adaptively, avoiding the sensitivity to hand-constructed queries of varying quality. (2) Each query no longer predicts a group of entities of a specific type, but only one entity. This manner refines the query to the entity level with more precise query semantics. (3) Instance queries are fed into the model in parallel for encoding and prediction, and different instance queries can exploit the intrinsic connections between entities.

Inference Speed We compare the inference speed on ACE04 and NNE, as shown in Table 4. Compared to the type-specific query method (Li et al., 2020b), our model not only improves the performance, but also gains significant inference speedup. In particular, on the NNE dataset with 114 entity types, our model speeds up by 30.46× and improves performance by +39.2%. This is because Li et al. (2020b) requires one inference for each type-specific query, while our approach performs parallel inference for all instance queries and only needs to be run once. We also compare previous state-of-the-art models (Tan et al., 2021; Shen et al., 2021a) and our method is still faster and performs better.

5.2 Ablation Study

In this section, we analyze the effects of different components in PIQN. As shown in Table 3, we have the following observations: (1) Compared to the static label assignment in order of occurrence, the dynamic label assignment shows significant improvement on localization, classification, and NER F1-score, which improves NER F1-score by +5.71% on ACE04 and +8.84% on GENIA. This shows that modeling label assignment as a LAP problem enables dynamic assignment of optimal labels to instance queries during training, eliminating the incorrect bias when pre-specifying labels. Furthermore, one-to-many for label assignment is more effective than one-to-one, improving the F1-score by +3.86% on ACE04 and +0.51% on GENIA. (2) The one-way self-attention blocks the attention of sentence encoding on instance queries, which improves the F1-score by +0.98% on ACE04 and +0.57% on GENIA. It illustrates the importance of keeping the semantics of the sentence independent of the query. In contrast, semantic interactions between queries are effective, which improves the F1-score by +0.92% on ACE04 and +0.67% on GENIA. The major reason is that entities in the same sentence are closely related and the interaction between instance queries can capture the relation between them.

5.3 Analysis

In order to analyze the query semantics learned by the instance query in the training, we randomly selected several instance queries and analyzed the locations and types of entities they predicted.

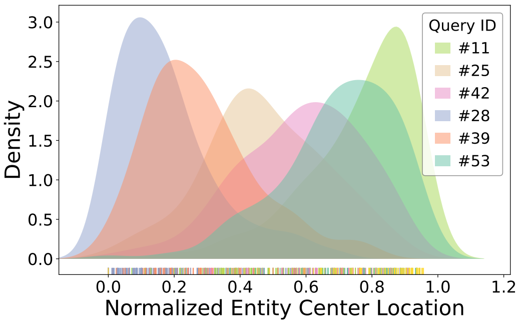

Figure 3: Kernel density estimation of entity distribution at different locations.

Entity Location We normalize the predicted central locations of the entities and use kernel density estimation to draw the distribution of the predicted entity locations for different queries, as shown in Figure 3. We observe that different instance queries focus on entities at different positions, which means that the instance queries can learn the query semantics related to entity position. For example, instance queries #28 and #39 prefer to predict entities at the beginning of sentences, while #11 and #53 prefer entities at the end.

Entity Type We count the co-occurrence of different instance queries and different entity types they predicted. To eliminate the imbalance of entity types, we normalize the co-occurrence matrix on the entity type axis. As shown in Figure 4, different instance queries have preferences for different entity types. For example, instance queries #11 and #13 prefer to predict `PER` entities, #30 and #43 prefer `VEH` entities, #25 and #49 prefer `WEA` entities, #12 prefers `FAC` entities, and #35 prefers `LOC` entities.

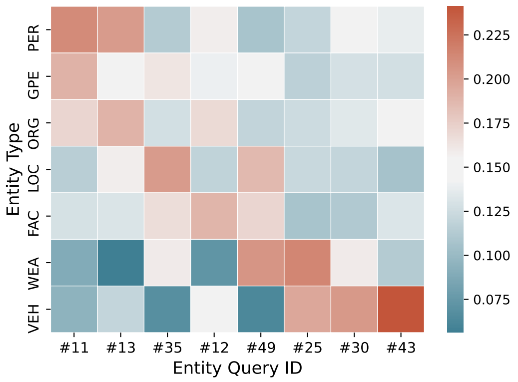

Figure 4: Co-occurrence statistics between instance queries and different entity types

We also analyze the auxiliary loss, the dynamic label assignment mechanism, and the performance on entity localization and classification, please see the Appendix D.

Table 5: Cases Study. In the left column, the label in the lower right corner indicates the type of entity, and the superscripts indicate the positions of the left and right boundary words. In the right column, we show the correspondence between the instance queries and the predicted entities.

long entities well. In case 1, the entities of length 31 or with the three-level nested structure are predicted accurately. And thanks to the one-to-many dynamic label assignment mechanism, each entity can be predicted by multiple instance queries, which guarantees a high coverage of entity prediction. However, the model's ability to understand sentences is still insufficient, mainly in the following ways: (1) There is a deficiency in the understanding of special phrases. *Yahoo ! Communications Services* in case 2 is misclassified as `ORG`, but in fact *Yahoo !* is `ORG`. (2) Over-focus on local semantics. In case 3, the model misclassifies *Venezuelan consumer* as `PER`, ignoring the full semantics of the long phrase *the Venezuelan consumer protection agency*, which should be `ORG`. (3) Insensitivity to morphological variation. The model confused *Venezuelan* and *Venezuela*, and misidentified the former as `GPE` in case 3.

7 Conclusion

In this paper, we propose Parallel Instance Query Network for nested NER, where a collection of instance queries are fed into the model simultaneously and can predict all entities in parallel. The instance queries can automatically learn query semantics related to entity types or entity locations during training, avoiding manual constructions that rely on external knowledge. To train the model, we design a dynamic label assignment mechanism to assign gold entities for these instance queries. Experiments on both nested and flat NER datasets demonstrate that the proposed model achieves state-of-the-art performance.
