To avoid these issues, we ran syntactic parsing on the definition and the expression within each context, requiring that the expression in context begins with the same part of speech as the definition and that it does not end inside of another phrase.

Additionally, for each replacement, we ensured that the verb conjugation matched the context. For this, we identified the conjugation in the context, and used a de-lemmatization script to conjugate the replacement verb to match the original.

3.2.1 Additional Issues

In implementing and analyzing this procedure, we noted a number of practical issues. First, a large number of the MEs provided are actually idiomatic or proverbial: the focus word does not actually contribute to the metaphor, but rather the entire expression is necessary. Similarly, we found that replacing individual parts of MEs is often insufficient to fully remove the metaphoric meaning. We iterated over possible solutions to circumvent these issues and found that it is best to simply skip instances for which a replacement does not yield a feasible literal interpretation.

3.3 Evaluating Pair Quality

In order for these automatically created pairs to be useful for NLI-based evaluation, they need to be of sufficiently high quality. As the annotators were generating novel definitions and pairs, rather than inter-annotator agreement, we instead evaluate the quality of the resulting pairs by testing whether the automatically generated pairs contained the appropriate entailment relation. For this task, each annotator was given 100 samples for each general category of silver generations (idiomatic entailments, idiomatic non-entailments, and metaphoric entailments). They were asked if the entailment relation between the two sentences was as expected. An expert than adjudicated disagreements to determine the final percentage of valid pairs.

To evaluate the syntactic validity of the generated pairs, we additionally ran the Stanford PCFG dependency parser (Klein and Manning, 2003) on

---

[4] `https://commoncrawl.org/`

	→ Idioms	↛ Idioms	→ Met.
Correct Entailments	%88	%90	%97
Premise S root	%89	%90	%82
Hypothesis S root	%90	%90	%82

Table 4: **Valid pairs**. Percentage of valid pairs, syntactically and with regard to the intended entailments, of automatic data generation.

the pairs. Per previous work in NLI (Williams et al., 2018), we evaluate the proportion of sentences for which the root node is S.

Table 4 shows the results. The semi-supervised examples evoked the correct entailment relation between %88 and %97 of the time: while there is still noise present, this indicates the effectiveness of the proposed methods. With regard to syntax, we see S node roots for between 82% and %90 of the sentences: within the range of the SNLI performance (74%-88%), and slightly behind the MNLI (91%-98%). We find that the generated hypotheses are not significantly different in quality than the premises. This indicates that the method for generation preserves the original syntax.

These methods allow us to quickly generate a substantial number of high-quality pairs to evaluate NLI systems on figurative language. However, they may introduce additional bias as we employ a number of restrictions in order to ensure syntactic and semantic compatibility, and we lack full non-entailment pairs for metaphoric data. We therefore expand our dataset with manually generated pairs.

3.4 Manual Creation of Gold Pairs

To create gold pairs, annotators were given a figurative sentence along with the focus of the figurative expression: for idioms, this is the IE; for metaphors, the focus word of the metaphor. For idioms, we used the MAGPIE dataset to collect contextually figurative expressions. For metaphors, we collected metaphoric sentences from the VUA Metaphor Corpus (Steen et al., 2010), the metaphor dataset of (Mohammad et al., 2016), and instances from the Gutenberg poetry corpus (Jacobs, 2018) annotated for metaphoricity (Chakrabarty et al., 2021b; Stowe et al., 2021) . Annotators were instructed to rewrite the sentence literally. This was done by removing or rephrasing the figurative component of the sentence. This yields gold standard paraphrases for idiomatic and metaphoric contexts.

We then asked annotators to write non-entailed hypotheses for each premise. They were encouraged to keep as much of the original utterance as possible, ensuring high lexical overlap, while removing the main figurative element of the sentence. For idioms, this comes from adding or adjusting words to force a literal reading of the idiom:

- The old girl finally kicked the bucket. ↛ The girl kicked the bucket on the right.

For metaphors, this typically involves keeping the same phrasing while adapting the sentence to have a different, non-metaphoric meaning.

- You must adhere to the rules. ↛ You must adhere the rules to the wall.

3.5 Antonyms

Previous work in NLI has employed the technique of replacing words in the literal sentences with their antonyms to yield non-entailing pairs (Chakrabarty et al., 2021a). We replicate this process for idioms: for the manually elicited definitions, we replace key words as determined by annotators with their antonyms. This yields sentences which negate the original figurative meaning and are thus suitable non-entailment pairs. Previous work found this antonym replacement for figurative language remains relatively easy for NLI systems, which we can additionally explore with regard to idioms.

These manual annotations provide a number of concrete benefits. First, they are not restricted to individual words or phrases (excluding antonyms): the figurative components can be rewritten freely, allowing for diverse, interesting pairs. Second, they are written by experts, ensuring higher quality than the automatic annotations, which may be noisy.

4 Experiments / Results

Using the `IMPLI` dataset, we aim to answer a series of questions via NLI pertaining to language models' ability to understand and represent figurative language accurately. These questions are:

- R1: *How well do pre-trained models perform on figurative entailments and non-entailments?*
- R2: *Does adding idiomatic pairs into the training data affect model performance?*
- R3: *Does the flexibility of idiomatic expressions affect model performance?*

Our dataset provides unique advantages in addressing these research questions that cover gaps

			Idioms						Metaphors		
Model	MNLI	MNLI-MM	$\rightarrow$ S	$\nrightarrow S^l$	$\nrightarrow S^d$	$\rightarrow$ G	$\nrightarrow G^a$	$\nrightarrow$ G	$\rightarrow$ S	$\rightarrow$ G	$\nrightarrow$ G
`roberta-base`	.878	.876	.848	.539	.409	.890	.771	.311	.947	.818	.818
`roberta-large`	.899	.899	.866	.536	.418	.889	.777	.348	.936	.871	.840

Table 5: **R1: Model accuracy**. Accuracy on MNLI and **`IMPLI`** pairs, divided into silver (S) and gold (G) datasets. S^l Silver non-entailment based on replacement in literal contexts, S^d Silver non-entailment based on adversarial definitions, G^a Gold non-entailment based on antonyms.

in previous work: it contains a large number of both entailments and non-entailments and is large enough to be used for training the models.

R1: pre-trained Model Performance

We obtain baseline NLI models by fine-tuning `roberta-base` and `roberta-large` models on the MNLI dataset (Williams et al., 2018), with entailments as the positive class and all others as the negative and evaluate them on their original test sets as well as **`IMPLI`**.[5] Due to variance in neural model performance (Reimers and Gurevych, 2017), we take the mean score over 5 runs using different seeds.

We report results in Table 5. We observe that idiomatic entailments are relatively easy to classify, with accuracy scores over .84. Non-entailments were much more challenging. Silver pairs generated through adversarial definitions were especially difficult: the pairs contain high lexical overlap, and in many cases the premise and hypotheses are semantically similar. The replacement into literal samples were easier, as the idiomatic definition clashes more starkly with the original premise, making non-entailment predictions more likely. Consistent with Chakrabarty et al. (2021a)'s work in metaphors, non-entailment through antonym replacement is easiest for idioms: the antonymic relationship can be a marker for non-entailment, despite the high word overlap.

With regard to metaphors, silver entailment pairs are relatively easy. Manual pairs are more challenging but are still much easier than idioms. This is supported by the fact that metaphors are common in everyday language: these models have likely seen the same (or similar) metaphors in training. Our findings show that in fact metaphoricity may not be particularly challenging for deep pre-trained models, as they are able to effectively capture the metaphoric entailment relations. The `roberta-large` model performs better for metaphoric expressions than `roberta-base`, but the difference on other partitions is relatively small.[6] We also find that lexical overlap plays a significant role here as noted by previous work (McCoy et al., 2019): sentences with high overlap tend to be classified as entailments regardless of the true label (for more, see Appendix B).

We note that the manual pairs tend to be more difficult for both idioms and metaphors: these pairs can be more flexible and creative, whereas the silver pairs are restricted to more regular patterns.

R2: Incorporating Idioms into Training To evaluate incorporating idioms into training, we then split the idiom data by idiomatic phrase types, keeping a set of IEs separate as test data to assess whether the model can learn to correctly handle novel, unseen phrases. Our goal is to assess whether poor performance is due to models' not containing these expressions in training, or because their ability to represent figurative language inherently limited. We hypothesize that the non-compositional nature of these types of figuration should lead to poor performance on unseen phrases, even if the model is trained on other idiomatic data.

For each task, we split the data into 10 folds by IE and incrementally incorporate these folds into the original MNLI for training, leaving one fold out for testing. We experiment with incorporating all training data for both labels, as well as using only entailment or non-entailment samples. We then evaluate our results on the entire test set, as well as the entailment and non-entailment partitions.

Figure 4 shows the results, highlighting that additional training data yields only small improvements. Pairs with non-entailment relations remain exceedingly difficult, with performance capping out at only slightly better than chance. As hypothesized, additional training data is only somewhat effective in improving language models' idiomatic capabilities; this is not sufficient to overcome difficulties from literal usages of idiomatic phrases and adversarial definitions, indicating that idiomatic

---

[5] Model hyperparameters found in Appendix A.

[6] We found minimal differences between these models across R1-R3.

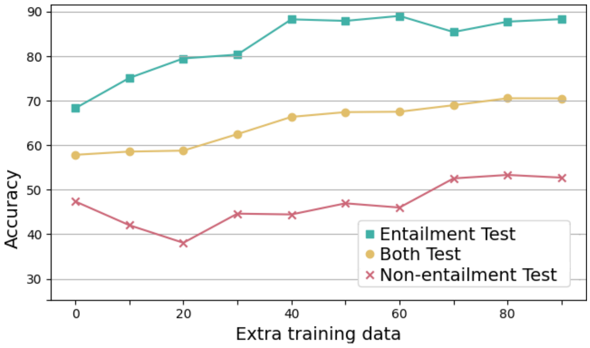

Figure 4: **R2: Training**. Performance of the `roberta-base` models as more idiom examples are added to the training data.

language remains difficult for pre-trained language models to learn to represent.

R3: Syntactic Flexibility Finally, we assess models' representation of idiomatic compositionality. Nunberg et al. (1994) indicate that there are two general types of idioms: "idiomatic phrases", which exhibit limited flexibility and generally occur only in a single surface form, and "idiomatically combining expressions" or ICEs, in which the constituent elements of the idiom carry semantic meaning which can influence their syntactic properties, allowing them to be more syntactically flexible.

For example, in the idiom *spill the beans*, we can map the spilling activity to divulging of information, and the beans to the information. Because this expression has semantic mappings to figurative meaning for its syntactic constituents, Nunberg et al. (1994) argue that it can be more syntactically flexible, allowing for expressions like *the beans that were spilled by Martha* to maintain idiomatic meaning. For fixed expressions such as *kick the bucket*, no syntactic constituents map directly to the figurative meaning ("die"). We then expect less syntactic flexibility, and thus *the bucket that was kicked by John* loses its idiomatic meaning.

We hypothesize that model performance will be correlated with the degree to which a given idiom type is flexible: more fixed expressions may be easier, as they are seen in regular, fixed patterns that the models can memorize, while more flexible ICEs will be more difficult, as they can appear in different patterns, cases, and word order, often even mixing in with other constituents. To test this, we define an ICE score as the percentage of times a phrase occurs in our test data in a form that does not match its original base form. Higher percentages mean the phrase occurs more frequently in a non-standard form, acting as a measure for the syntactic flexibility of the expression. We assessed the performance of the `roberta-base` model for each idiom type, evaluating Spearman correlations between performance and idioms' ICE scores.

We found no correlation between ICE scores and performance for entailments, nor for adversarial definition non-entailments ($r = .004/.45$, $p = .921/.399$, see Appendix C). However, we do see a weak but significant correlation ($r = .188$, $p = 0.016$) with non-entailments from literal contexts: the model performs better when the phrases are more flexible, contrary to our initial hypothesis.

One possible explanation is that the model memorizes a specific figurative meanings for each fixed expression, disregarding the possibility of these words being used literally. When the expression is used in a literal context, the model then still assumes the figurative meaning, resulting in errors on non-entailment samples. The ICEs are more fluid, and thus the model is less likely to have a concrete representation for the given phrase: it is better able to reason about the context and interacting words within the expression, making it easier to distinguish the entailing and non-entailing samples.

5 Conclusions and Future Work

In this work, we introduce the **`IMPLI`** dataset, which we then use to evaluate NLI models' capabilities on figurative language. We show that while widely used MNLI models handle entailment admirably and metaphoric expressions are relatively easy, non-entailment idiomatic relationships are more difficult. Additionally, adding idiom-specific training data fails to alleviate poor performance for non-entailing pairs. This highlights how currently language models are inherently limited in representing some figurative phenomena and can provide a target for future model improvements.

For future work, we aim to expand our data collection processes to new data sources. Our dataset creation procedure relies on annotated samples and definitions: as more idiomatic and metaphoric resources become available, this process is broadly extendable to create new figurative/literal pairs. Additionally, we only explore this data for evaluating NLI systems: this data could also be used for other parallel data tasks such as figurative language interpretation (Shutova, 2013; Su et al., 2017) and figurative paraphrase generation. As natural language generation often relies on training or fine-tuning models with paired sentences, this data could be a valuable resource for figurative language generation systems.

A Model Hyperparameters

We use a fixed set of hyperparameters for all NLI fine-tuning experiments: learning rate of $1e^{-5}$, batch size 32, and maximum input length of 128 tokens. The models are trained for 3 epochs. We used the HuggingFace implementation of the models (Wolf et al., 2020).

B Lexical Overlap

Previous research shows that NLI systems exploit cues based on lexical overlap, predicting entailment for overlapping sentences (McCoy et al., 2019; Nie et al., 2019). Our dataset consists mostly of pairs with high overlap: this could explain why the non-entailment sections are more difficult. We thus evaluate system predictions for our datasets as a function of lexical overlap. Figure 5 shows density-based histograms of the results, comparing overlap via Levenshtein distance (Levenshtein, 1965) for correctly and incorrectly classified pairs.

Our data contains higher overlap than the MNLI data, with the bulk of the density falling on minimally distant pairs. We also note a distinct difference between our entailment and non-entailment pairs: non-entailments contain extremely high overlap and are frequently misclassified in these cases where the distance is small, matching previous reports for NLI tasks: lexical overlap is a key artifact for entailment, and this reliance persists when classifying idiomatic pairs.

C Syntactic Flexibility Correlations

Figure 6 shows correlations between ICE scores (determined by frequency of occurences of a given IE outside of its normal form) and `roberta-base` model performance on that IE.

D Dataset Examples

Table 6 shows examples from each type of pair generation.

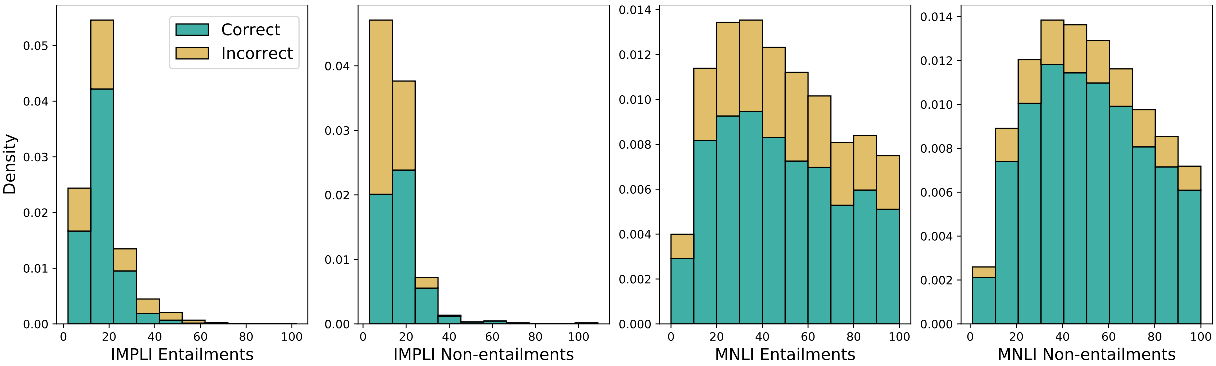

Figure 5: **R2: Lexical Overlap**. Classification performance by lexical overlap. The x-axis shows Levenshtein distance; the y-axis shows stacked density of correctly and incorrectly tagged pairs. The `IMPLI` non-entailments contain extremely high overlap, and are thus frequently misclassified as entailment.

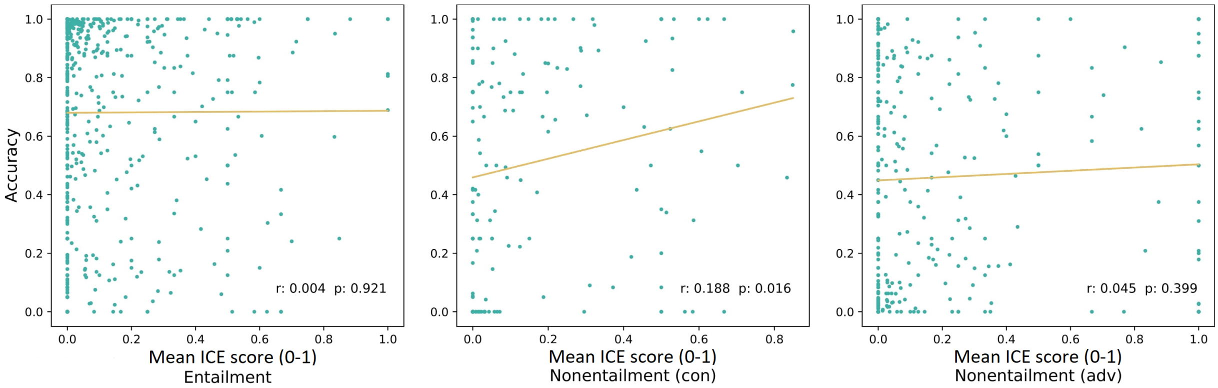

Figure 6: **R3: Syntactic Flexibility**. Performance of idiom types compared to their syntactic flexibility (based on ICE score defined in **R3**), with Spearman coefficient correlations *r* and significance values *p*. The middle figure is non-entailments based on replacement in literal context; the right is those based on adversarial definitions. Further right on the x-axis indicates greater flexibility.

Idioms
(→ S) Replace idiom used in figurative context with definition
BITTER BLOW: Beer sales are *feeling the pinch*. → BITTER BLOW: Beer sales are *suffering a hardship*. I must *have a word* with them. → I must *speak privately* with them. I've been knocked *out cold*. → I've been knocked *unconscious*.
(↛ S^l) Replace idiom used in literal context with definition
It would be good to roll *in hot water* all over. ↛ It would be good to roll *in a difficult situation* all over. Pour in *the soup*. ↛ Pour in *trouble*. There's a marina down *in the docks*. ↛ There's a marina down *under scrutiny*.
(↛ S^d) Replace idiom used in figurative context with adversarial definition
After *taking a bow*, the cast met Margaret backstage. ↛ After *apologizing*, the cast met Margaret backstage. I've been knocked *out cold* ↛ I've been knocked *out into the cold air*. It worked *like a charm*! ↛ It worked *poorly*!
(→ G) Hand written literal definition of idiom
How have you *weathered the storm*? → How have you *succeeded in getting through the difficult situation*? It *breaks my heart* that his career has been ruined. → It *overwhelms me* that his career has been ruined. Jamie rushed out *pissed off* and upset this afternoon. → Jamie rushed out *irritated* and upset this afternoon.
(↛ G^a) Manual replacement of key words in definition w/ antonyms
Alison *makes the grade* for Scotland ↛ Alison *fails* for Scotland. I'll *catch a cold* ↛ I'll become *healthy* It's very much *swings and roundabouts* ↛ It's very much *one-sided*.
(↛ G) Hand written non-entailed sentence
How have you *weathered the storm*? ↛ How have you *calmed the storm*? Now Paul will *think twice*. ↛ Now Paul will *score twice*. They *went to ground* somewhere in the area. ↛ They *went to party* somewhere in the area.
Metaphors
(→ S) Replace metaphoric construction with literal construction
Do not go and *blow* your *paycheck*. → Do not go and *waste* your *paycheck*. My computer *battery died*. → My computer *battery lost all power*. Competition is *dropping prices*. → Competition is *reducing prices*.
(→ G) Hand written literal paraphrase of metaphor
He *absorbed* the knowledge or beliefs of his tribe. → He *mentally assimilated* the knowledge or beliefs of his tribe. Avon *treads* warily. → Avon proceeds warily. All the *hearts of men were softened*. → All the *men were made kindler and gentler*.

Abstract

This paper introduces QAConv, [1], a new question answering (QA) dataset that uses conversations as a knowledge source. We focus on informative conversations, including business emails, panel discussions, and work channels. Unlike open-domain and task-oriented dialogues, these conversations are usually long, complex, asynchronous, and involve strong domain knowledge. In total, we collect 34,608 QA pairs from 10,259 selected conversations with both human-written and machine-generated questions. We use a question generator and a dialogue summarizer as auxiliary tools to collect and recommend questions. The dataset has two testing scenarios: chunk mode and full mode, depending on whether the grounded partial conversation is provided or retrieved. Experimental results show that state-of-the-art pretrained QA systems have limited zero-shot performance and tend to predict our questions as unanswerable. Our dataset provides a new training and evaluation testbed to facilitate QA on conversations research.

1 Introduction

Having conversations is one of the most common ways to share knowledge and exchange information. Recently, many communication tools and platforms are heavily used with the increasing volume of remote working, and how to effectively retrieve information and answer questions based on past conversations becomes more and more important. In this paper, we focus on QA on conversations such as business emails (e.g., Gmail), panel discussions (e.g., Zoom), and work channels (e.g., Slack). Different from daily chit-chat (Li et al., 2017) and task-oriented dialogues (Budzianowski et al., 2018), these conversations are usually long, complex, asynchronous, multi-party, and involve strong domain knowledge. We refer to them as informative conversations and an example is shown in Figure 1.

However, QA research mainly focuses on document understanding (e.g., Wikipedia) not dialogue understanding, and dialogues have significant differences with documents in terms of data format and wording style, and important information is scattered in multiple speakers and turns (Wolf et al., 2019b; Wu et al., 2020). Moreover, existing work related to QA and conversational AI focuses on conversational QA (Reddy et al., 2019; Choi et al., 2018) instead of QA on conversations. Conversational QA has sequential dialogue-like QA pairs that are grounded on a short document paragraph, but what we are more interested in is to have QA pairs grounded on conversations, treating past dialogues as a knowledge source.

QA on conversation has several unique challenges: 1) information is distributed across multiple speakers and scattered among dialogue turns; 2) Harder coreference resolution problem of speakers and entities, and 3) missing supervision as no training data in such format is available. The most related work to ours is the FriendsQA dataset (Yang and Choi, 2019) and the Molweni dataset (Li et al., 2020). However, the former is built on chit-chat transcripts of TV shows with only one thousand dialogues, and the latter has short conversations in a specific domain (i.e., Ubuntu). The dataset comparison is shown in Table 1.

Therefore, we introduce QAConv dataset, sampling 10,259 conversations from email, panel, and channel data. The longest dialogue sample in our data has 19,917 words (or 32 speakers), coming from a long panel discussion. We segment long conversations into shorter conversational chunks to collect human-written (HW) QA pairs or to modify machine-generated (MG) QA pairs from Amazon Mechanical Turk (AMT). We train a multi-hop question generator and a dialogue summarizer to

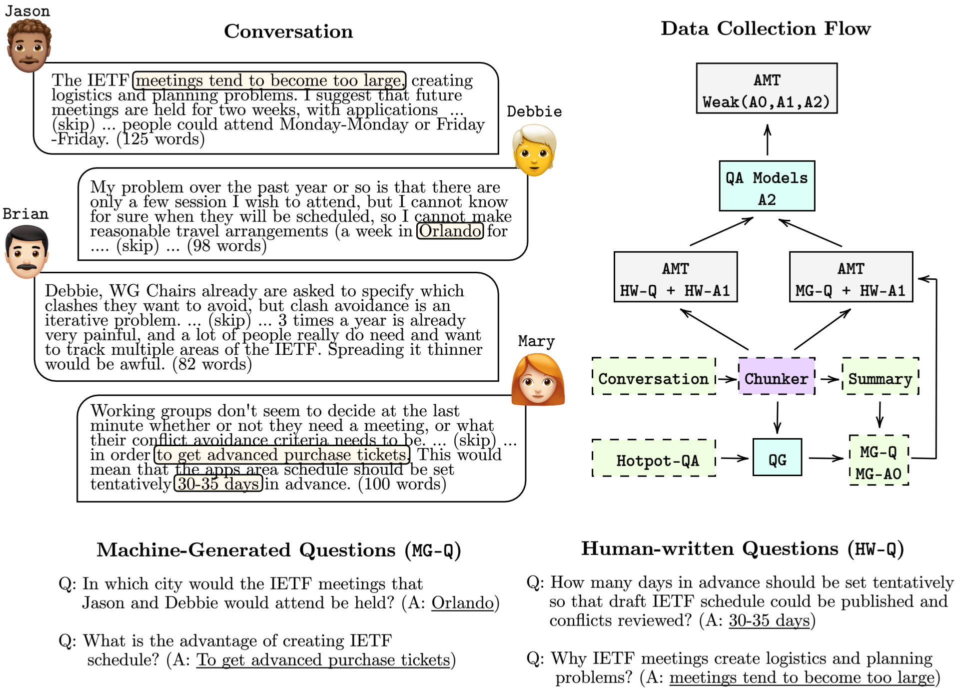
Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 5389 - 5411
May 22-27, 2022



The IETF meetings tend to become too large, creating logistics and planning problems. I suggest that future meetings are held for two weeks, with applications ... (skip) ... people could attend Monday-Monday or Friday -Friday. (125 words)

My problem over the past year or so is that there are only a few session I wish to attend, but I cannot know for sure when they will be scheduled, so I cannot make reasonable travel arrangements (a week in Orlando for .... (skip) ... (98 words)

Debbie, WG Chairs already are asked to specify which clashes they want to avoid, but clash avoidance is an iterative problem. ... (skip) ... 3 times a year is already very painful, and a lot of people really do need and want to track multiple areas of the IETF. Spreading it thinner would be awful. (82 words)

Working groups don't seem to decide at the last minute whether or not they need a meeting, or what their conflict avoidance criteria needs to be. ... (skip) ... in order to get advanced purchase tickets. This would mean that the apps area schedule should be set tentatively 30-35 days in advance. (100 words)

Machine-Generated Questions (`MG-Q`)

Q: In which city would the IETF meetings that Jason and Debbie would attend be held? (A: Orlando)

Q: What is the advantage of creating IETF schedule? (A: To get advanced purchase tickets)

Human-written Questions (`HW-Q`)

Q: How many days in advance should be set tentatively so that draft IETF schedule could be published and conflicts reviewed? (A: 30-35 days)

Q: Why IETF meetings create logistics and planning problems? (A: meetings tend to become too large)

Figure 1: An example of question answering on conversations and the data collection flow.

generate QA pairs. We use QA models to identify uncertain samples and conduct an additional human verification stage. The data collection flow is shown in Figure 1. In total, we collect 34,608 QA pairs.

We construct two testing scenarios: 1) In the chunk mode, a conversational chunk is provided to answer questions, similar to the SQuAD dataset (Rajpurkar et al., 2016); 2) In the full mode, a conversational-retrieval stage is required before answering questions, similar to the open-domain QA dataset (Chen and Yih, 2020). We explore several state-of-the-art QA models such as the span extraction RoBERTa-Large model (Liu et al., 2019) trained on SQuAD 2.0 dataset, and the generative UnifiedQA model (Khashabi et al., 2020) trained on eight different QA datasets and showed its generalization ability to 12 unseen QA corpora. We investigate the statistic-based BM25 (Robertson et al., 1994) retriever and the neural-based dense passage retriever (Karpukhin et al., 2020) trained on Wikipedia (DPR-wiki). We show zero-shot and finetuning performances in both modes and conduct improvement study and error analysis.

The main contributions of our paper are threefold: 1) QAConv provides a new testbed for QA on informative conversations including emails, panel discussions, and work channels. We show the potential of treating long conversations as a knowledge source, and point out a performance gap between QA on documents and QA on conversations; 2) We incorporate question generation (QG) model into the QA data collection, and we show the effectiveness of such approach in human evaluation. 3) We introduce chunk mode and full mode settings for QA on conversations, and our training data enables existing QA models to perform better on dialogue understanding.

2 QAConv Dataset

Our dataset is collected in four stages: 1) selecting and segmenting informative conversations, 2) generating question candidates by QG models, 3) crowdsourcing question-answer pairs on those conversations/questions, and 4) conducting quality verification and data splits.

2.1 Data Collection

2.1.1 Selection and Segmentation

Full data statistics are shown in Table 2. First, we use the British Columbia conversation corpora (BC3) (Ulrich et al., 2008) and the Enron Corpus (Klimt and Yang, 2004) to represent business email use cases. The BC3 is a subset of the World Wide Web Consortium's (W3C) sites that are less technical. We sample threaded Enron emails

Table 2: Dataset statistics of different dialogue sources.

from (Agarwal et al., 2012), which were collected from the Enron Corporation. Second, we select the Court corpus (Danescu-Niculescu-Mizil et al., 2012) and the Media dataset (Zhu et al., 2021) as panel discussion data. The Court data is the transcripts of oral arguments before the United States Supreme Court. The Media data is the interview transcriptions from National Public Radio and Cable News Network. Third, we choose the Slack chats (Chatterjee et al., 2020) to represent work channel conversations. The Slack data was crawled from several public software-related development channels such as *pythondev#help*. All data we use is publicly available and their license and privacy (Section A.3) information are shown in the Appendix.

One of the main challenges in our dataset collection is the length of input conversations and thus resulting in very inefficient for crowd workers to work on. For example, on average there are 13,143 words per dialogue in the Court dataset, and there is no clear boundary annotation in a long conversation of a Slack channel. Therefore, we segment long dialogues into short chunks by a turn-based buffer to assure that the maximum number of tokens in each chunk is lower than a fixed threshold, i.e., 512. For the Slack channels, we use the disentanglement script from (Chatterjee et al., 2020) to split channel messages into separated conversational threads, then we either segment long threads or combine short threads to obtain the final conversational chunks.

2.1.2 Question Generation

Synthetic dataset construction has been shown to improve robustness (Gupta et al., 2021) and improve the complexity of test sets (Feng et al., 2021). We leverage a question generator and a dialogue summarizer to generate and recommend some questions to workers. We train a T5-Base (Raffel et al., 2019) model on HotpotQA (Yang et al., 2018), which is a QA dataset featuring natural and multi-hop questions, to generate questions for our conversational chunks. By the second hypothesis, we first train a BART (Lewis et al., 2020) summarizer on News (Narayan et al., 2018) and dialogue summarization corpora (Gliwa et al., 2019) and run QG models on top of the generated summaries.

We filter out generated questions that a QA model can predict the same answers we used in our QG model, which we hypothesize that these questions could be easy questions that we would like to avoid. Note that our QG model has grounded answers since it is trained to generate questions by giving a text context and an extracted entity. We hypothesize that these questions are trivial questions in which answers can be easily found, and thus not interesting for our dataset. Examples of

our generated multi-hop questions are shown in the Appendix (Table 18).

2.1.3 Crowdsourcing QA Pairs

We use two strategies to collect QA pairs, human writer and machine generator. We first ask crowd workers to read partial conversations, and then we randomly assign two settings: 1) writing QA pairs themselves or 2) selecting one recommended machine-generated question to answer. We apply several on-the-fly constraints to control the quality of the collected QA pairs: 1) questions should have more than 6 words with a question mark in the end; 2) questions and answers cannot contain first-person and second-person pronouns (e.g., I, you, etc.); 3) answers have to be less than 20 words , and 4) all words have to appear in source conversations.

We randomly select four MG questions from our question pool and ask crowd workers to answer one of them, without providing any potential answers. They are allowed to modify questions if necessary. To collect unanswerable questions, we ask crowd workers to write questions with at least three entities mentioned in the given conversations but they are not answerable. We pay crowd workers roughly $8-10 per hour, and the average time to read and write one QA pair is approximately 4 minutes.

2.1.4 Quality Verification and Data Splits

We design a filter mechanism based on different potential answers: human writer's answers, answer from existing QA models, and QG answers. If all the answers have a pairwise fuzzy matching ratio (FZ-R) scores [2] lower than 75%, we then run another crowdsourcing round and ask crowd workers to select one of the following options: A) the QA pair looks good, B) the question is not answerable, C) the question has a wrong answer, and D) the question has a right answer but I prefer another answer. We run this step on around 40% samples which are uncertain. We filter the questions of the (C) option and add answers of the (D) option into the ground truth. In questions marked with

---

[2] https://pypi.org/project/fuzzywuzzy

option (B), we combine them with the unanswerable questions that we have collected. In addition, we include 1% random questions (questions that are sampled from other conversations) to the same batch of data collection as a qualification test. We filter crowd workers' results if they fail to indicate such a question as an option (B). Finally, we split the data into 27,287 training samples, 3,660 validation samples, and 3,661 testing samples. There are 4.7%, 5.1%, 4.8% unanswerable questions in train, validation, and test split, respectively.

2.2 QA Analysis

In this section, we analyze our collected questions and answers. We first investigate question type distribution and we compare human-written questions and machine-generated questions. We then analyze answers by an existing named-entity recognition (NER) model and a constituent parser.

2.2.1 Question Analysis

Question Type. We show the question type tree map in Figure 2 and the detailed comparison with other datasets in Table 3. In QAConv, the top 5 question types are what-question (29%), which-question (27%), how-question (12%), who-question (10%), and when-question (6%). Comparing to SQuAD 2.0 (49% what-question), our dataset have a more balanced question distribution. The question distribution of unanswerable questions is different from the overall distribution. The top 5 unanswerable question types are what-question (45%), why-question (15%), how-question (12%), which-question (10%), and when-question (8%).

Human Writer v.s. Machine Generator. As shown in Table 4, there are 41.7% questions which are machine-generated questions. Since we still give crowd workers the freedom to modify questions if necessary, we cannot guarantee these questions are unchanged. We find that 33.56% of our recommended questions have not been changed (100% fuzzy matching score) and 19.92% of them are slightly modified (81%-99% fuzzy matching score). To dive into the characteristics and differences of these two question sources, we further conduct the human evaluation by sampling 200 conversation chunks randomly. We select chunks that have QG questions unchanged (i.e., sampling from the 33.56% QG questions). We ask three annotators to first write an answer to the given question and conversation, then label fluency (how fluent and grammatically correct the question is, from 0 to 2), complexity (how hard to find an answer, from 0 to 2), and confidence (whether they are confident with their answer, 0 or 1). More details of each evaluation dimension (Section A.4) and performance difference (Table 12) are shown in the Appendix. The results in Table 4 indicate that QG questions are longer, more fluent, more complex, and crowd workers are less confident that they are providing the right answers. This observation further confirmed our hypothesis that the question generation strategy is effective to collect harder QA examples.

Source	**Question Generator**				**Human Writer**	
Questions	14,426 (41.7%)				20,178 (58.3%)	
Type	100	81-99	51-79	0-50	Ans.	Unans.
Ratio	33.56%	19.92%	24.72%	21.80%	91.39%	8.61%
Avg. Words	**12.94** (±5.14)				10.98 (±3.58)	
Fluency	**1.808**				1.658	
Complexity	**0.899**				0.674	
Confidence	**0.830**				0.902	

Table 4: HW v.s. MG: Ratio and human evaluation.

2.2.2 Answer Analysis

Following Rajpurkar et al. (2016), we used Part-Of-Speech (POS) (Kitaev and Klein, 2018) and Spacy NER taggers to study answers diversity. Firstly, we use the NER tagger to assign an entity type to the answers. However, since our answers are not necessary to be an entity, those answers without entity tags are then pass to the POS tagger, to extract the corresponding phrases tag. In Table 5, we can see that Noun phrases make up 30.4% of the data; followed by People, Organization, Dates, other numeric, and Countries; and the remaining are made up of clauses and other types. Full category distribution is shown in the Appendix (Figure 3). Note that there are around 1% of answers in our dataset are coming from multiple source text spans (examples are shown in Appendix Table 17).

2.3 Chunk Mode and Full Mode

The main difference between the two modes is whether the conversational chunk we used to collect QA pairs is provided or not. In the chunk mode, our task is more like a traditional machine reading comprehension task that answers can be found (or cannot be found) in a short paragraph, usually less than 500 words. In the full mode, on the other hand, we usually need an information retrieval stage before the QA stage. For example, in the Natural Question dataset (Kwiatkowski et al., 2019), they split Wikipedia into millions of passages and retrieve the most relevant one to answer.

Answer type	Percentage	Example
Prepositional Phrase	1.3%	with ‘syntax-local-lift-module‘
Nationalities or religious	1.3%	white Caucasian American
Monetary values	1.6%	$250,000
Clause	5.4%	need to use an external store for state
Countries, cities, states	8.9%	Chicago
Other Numeric	9.6%	page 66, volume 4
Dates	9.6%	2020
Organizations	11.4%	Drug Enforcement Authority
People, including fictional	12.5%	Tommy Norment
Noun Phrase	30.4%	the Pulitzer Prize

Table 5: Answer type analysis.

We define our full mode task with the following assumptions: 1) for the email and panel data, we assume to know which dialogue a question is corresponding to, that is, we only search chunks within the dialogue instead of all the possible conversations. This is simpler and more reasonable because each conversation is independent; 2) for slack data, we assume that we only know which channel a question belongs to but not the corresponding thread, so the retrieval part has to be done in the whole channel. Although chunk mode may be a better way to evaluate the ability of machine reading comprehension, the full mode is more practical as it is close to our setup in the real world.

3 Experimental Results

3.1 State-of-the-art Baselines

There are two categories of question answering models: span-based extractive models which predict answers' start and end positions, and free-form text generation models which directly generate answers token by token. All the state-of-the-art models are based on large-scale language models, which are first pretrained on the general text and then finetuned on other QA tasks. We evaluate all of them on both zero-shot and finetuned settings (further finetuned on the QAConv training set), and both chunk mode and full mode with retrievers. In addition, we run these models on the Molweni (Li et al., 2020) dataset for comparison and find out our baselines outperform the best-reported model, DADgraph (Li et al., 2021a) model, which used expensive discourse annotation on graph neural network. We show the Molweni results in the Appendix (Table 11).

3.1.1 Span-based Models

We use several models finetuned on the SQuAD 2.0 dataset as span extractive baselines. We use uploaded models from huggingface (Wolf et al., 2019a) library. DistilBERT (Sanh et al., 2019) is a knowledge-distilled version with 40% size reduction from the BERT model, and it is widely used in mobile devices. The BERT-Base and RoBERTa-Base (Liu et al., 2019) models are evaluated as the most commonly used in the research community. We also run the BERT-Large and RoBERTa-Large models as stronger baselines. We use the whole-word masking version of BERT-Large instead of the token masking one from the original paper since it performs better.

3.1.2 Free-form Models

We run several versions of UnifiedQA models (Khashabi et al., 2020) as strong generative QA baselines. UnifiedQA is based on T5 model (Raffel et al., 2019), a language model that has been pretrained on 750GB C4 text corpus. UnifiedQA further finetuned T5 models on eight existing QA corpora spanning four diverse formats, including extractive, abstractive, multiple-choice, and yes/no questions. It has achieved state-of-the-art results on 10 factoid and commonsense QA datasets. We finetune UnifiedQA on our datasets with T5-Base, T5-Large size, and T5-3B. We report T5-11B size for the zero-shot performance.

3.1.3 Retrieval Models

Two retrieval baselines are investigated in this paper: BM25 and DPR-wiki (Karpukhin et al., 2020). The BM25 retriever is a bag-of-words retrieval function weighted by term frequency and inverse document frequency. The DPR-wiki model is a BERT-based dense retriever model trained for open-domain QA tasks, learning to retrieve the most relevant Wikipedia passage.

3.1.4 Computational Details

We train most of our experiments on 2 V100 NVIDIA GPUs with a batch size that maximizes their memory usage, except T5-3B we train on four A100 NVIDIA GPUs with batch size 1 with several parallel tricks, such as fp16, sharded_ddp and deepseep library. We train 10 epochs for all T5 models and 5 epochs for all BERT-based models. We release hyper-parameter setting and trained models to help reproduce baseline results.

3.2 Evaluation Metrics

We follow the standard evaluation metrics in the QA community: exact match (EM) and F1 scores. The EM score is a strict score that predicted answers have to be the same as the ground truth

	Zero-Shot			Finetune		
	EM	**F1**	**FZ-R**	**EM**	**F1**	**FZ-R**
Human Performance*	79.99	89.87	92.33	-	-	-

answers. The F1 score is calculated by tokens overlapping between predicted answers and ground truth answers. In addition, we also report the FZ-R scores, which used the Levenshtein distance to calculate the differences between sequences. We follow Rajpurkar et al. (2016) to normalize the answers in several ways: remove stop-words, remove punctuation, and lowercase each character. We add one step with the *num2words* and *word2number* libraries to avoid prediction difference such as "2" and "two".

3.3 Performance Analysis

3.3.1 Chunk Mode

As the chunk mode results on the test set shown in Table 6, UnifiedQA T5 models, in general, outperform BERT/RoBERTa models in the zero-shot setting, and the performance increases as the size of the model increases. This observation matches the recent trend that large-scale pretrained language model finetuned on aggregated datasets of a specific downstream task (e.g., QA tasks (Khashabi et al., 2020) or dialogue task (Wu et al., 2020)) can show state-of-the-art performance by knowledge transfer. Due to the space limit, all the development set results are shown in the Appendix.

We observe a big improvement from all the baselines after finetuning on our training set, suggesting the effectiveness of our data to improve dialogue understanding. Those span-based models, meanwhile, achieve similar performance to UnifiedQA T5 models with smaller model sizes. BERT-Base model has the largest improvement gain by 22.6 EM score after finetuning. We find that the UnifiedQA T5 model with 11B parameters cannot achieve performance as good as the 3B model, we guess that the released checkpoint has not been optimized well by Khashabi et al. (2020). In addition, we estimate human performance by asking crowd workers to answer around 10% QA pairs in test set. We collect two answers for each question and select one that has a higher FZ-R score. We observe an EM score at around 80% and an F1 score at 90%, which still shows a considerable gap with existing

	Zero-Shot				Finetune			
	Ans.		Unans. Binary		Ans.		Unans. Binary	
	EM	**F1**	**Recall**	**F1**	**EM**	**F1**	**Recall**	**F1**
DistilBERT-Base (SQuAD)	38.12	45.32	77.97	16.84	57.81	70.00	46.89	40.85
BERT-Base (SQuAD2)	34.07	42.84	78.53	16.17	59.18	71.98	51.98	43.36
BERT-Large (SQuAD2)	**52.15**	**61.66**	80.79	**24.41**	65.44	77.76	54.80	49.39
RoBERTa-Base (SQuAD2)	47.50	56.34	76.84	20.28	64.32	76.81	50.28	46.19
RoBERTa-Large (SQuAD2)	48.91	58.32	**87.57**	23.18	**68.25**	**79.81**	**58.76**	**54.55**

T5-Large-UnifiedQA	61.80	75.31	0.0	0.0	67.54	80.05	51.41	51.17
T5-3B-UnifiedQA	**62.97**	**76.78**	0.0	0.0	**67.74**	**80.35**	**61.02**	**55.21**

Table 9: Answerable/Unanswerable results: Chunk mode on the test set.

models.

3.3.2 Full Mode

The retriever results are shown in Table 8, in which we find that BM25 outperforms DPR-wiki by a large margin in our dataset on the recall@k measure, where we report $k = 1, 3, 5, 10$. The two possible reasons are that 1) the difference in data distribution between Wikipedia and conversation is large and DPR is not able to properly transfer to unseen documents, and 2) questions in QAConv are more specific to those mentioned entities, which makes the BM25 method more reliable. We show the full mode results in Table 7 using BM25 (DPR-wiki results in the Appendix Table 16). We use the top one retrieved conversational chunk as input to feed the trained QA models. As a result, the performance of UnifiedQA (T5-3B) drops by 18.2% EM score in the zero-shot setting, and the finetuned results of RoBERTa-Large drop by 22.2% EM score as well, suggesting a serious error propagation issue in the full mode that requires further investigation in the future work.

4 Error Analysis

We further check the results difference between answerable and unanswerable questions in Table 9. The UnifiedQA T5 models outperform span-based models among the answerable questions, however, they are not able to answer any unanswerable questions and keep predicting some "answers". More interestingly, we observe that those span-based models perform poorly on answerable questions, as they can achieve a high recall but a low F1 score on unanswerable questions with a binary setting (predict answerable or unanswerable). This implies that existing span-based models tend to predict our task as unanswerable, revealing their weakness of dialogue understanding ability.

Then we check what kinds of QA samples in the test set are improved the most while finetuning on our training data using RoBERTa-Large. We find that 75% of such samples are incorrectly predicted to be unanswerable, which is consistent with the results in Table 9. We also analyze the error prediction after finetuning. We find that 35.5% are what-question errors, 18.2% are which-question errors, 12.1% are how-question errors, and 10.3% are who-question errors.

In addition, we sample 100 QA pairs from the errors which have an FZ-R score lower than 50% and manually check and categorize these predicted answers. We find out that 20% of such examples are somehow reasonable and may be able to count as correct answers (e.g., UCLA v.s. University of California, Jay Sonneburg v.s. Jay), 31% are predicted wrong answers but with correct entity type (e.g., Eurasia v.s. China, Susan Flynn v.s. Sara Shackleton), 38% are wrong answers with different entity types (e.g., prison v.s. drug test, Thanksgiving v.s., fourth quarter), and 11% are classified as unanswerable questions wrongly. This finding reveals the weakness of current evaluation metrics that they cannot measure semantic distances between two different answers.

5 Related Work

QA datasets can be categorized into four groups. The first one is cloze-style QA where a model has to fill in the blanks. For example, the Children's Book Test (Hill et al., 2015) and the Who-did-What dataset (Onishi et al., 2016). The second one is reading comprehension QA where a model picks the answers for multiple-choice questions or a yes/no question. For examples, RACE (Lai et al., 2017) and DREAM (Sun et al., 2019) datasets. The third one is span-based QA, such as SQuAD (Rajpurkar et al., 2016) and MS MARCO (Nguyen et al., 2016) dataset, where a model extracts a text span from the given context as the answer. The fourth one is open-domain QA, where the answers are selected and extracted from a large pool of passages, e.g., the WikiQA (Yang et al., 2015) and Natural Question (Kwiatkowski et al., 2019) datasets.

Conversation-related QA tasks have focused on asking sequential questions and answers like a conversation and are grounded on a short passage. DoQA (Campos et al., 2020) is collected based on Stack Exchange, CoQA (Reddy et al., 2019) and QuAC (Choi et al., 2018) are the two most representative conversational QA datasets under this category. CoQA contains conversational QA pairs, free-form answers along with text spans as rationales, and text passages from seven domains. QuAC collected data by a teacher-student setting on Wikipedia sections and it could be open-ended, unanswerable, or context-specific questions. Closest to our work, Dream (Sun et al., 2019) is a multiple-choice dialogue-based reading comprehension examination dataset, but the conversations are in daily chit-chat domains between two people. FriendsQA (Yang and Choi, 2019) is compiled from transcripts of the TV show Friends, which is also chit-chat conversations among characters and only has around one thousand dialogues. Molweni (Li et al., 2020) is built on top of Ubuntu corpus (Lowe et al., 2015) for machine-reading comprehension tasks, but its conversations are short and focused on one single domain, and their questions are less diverse due to their data collection strategy (10 annotators).

In general, our task is also related to conversations as a knowledge source. The dialogue state tracking task in task-oriented dialogue systems can be viewed as one specific branch of this goal as well, where tracking slots and values can be reframed as a QA task (McCann et al., 2018; Li et al., 2021b). Moreover, extracting user attributes from open-domain conversations (Wu et al., 2019), getting to know the user through conversations, can be marked as one of the potential applications. The very recently proposed query-based meeting summarization dataset, QMSum (Zhong et al., 2021), can be viewed as one application of treating conversations as databases and conduct an abstractive question answering task.

6 Conclusion

$\mathbb{QAC}\mathbb{onv}$ is a new dataset that conducts QA on informative conversations such as emails, panels, and channels. We show the unique challenges of our tasks in both chunk mode with oracle partial conversations and full mode with a retrieval stage. We find that state-of-the-art QA models have limited dialogue understanding and tend to predict our answerable QA pairs as unanswerable. We provide a new testbed for QA on conversation tasks to facilitate future research.

Ethical Considerations

The $\mathbb{QAC}\mathbb{onv}$ benchmark proposed in this work could be helpful in creation of more powerful conversation retrieval and QA on conversations. However, $\mathbb{QAC}\mathbb{onv}$ benchmark only covers a few domains as background conversations. Furthermore, even with our best efforts to ensure high quality and accuracy, the dataset might still contain incorrect labels and biases in some instances, which could be the inherent mistakes from the original dialogue datasets. This could pose a risk if models that are evaluated or built using this benchmark are used in domains not covered by the dataset or if they leverage evidence from unreliable or biased dialogues. Thus, the proposed benchmark should not be treated as a universal tool for all domains and scenarios. We have used only the publicly available transcripts data and adhere to their guideline, for example, the Media data is for research-purpose only and cannot be used for commercial purpose. As conversations may have biased views, for example, specific political opinions from speakers, the transcripts and QA pairs will likely contain them. The content of the transcripts and summaries only reflect the views of the speakers, not the authors' point-of-views. We would like to remind our dataset users that there could have potential bias, toxicity, and subjective opinions in the selected conversations which may impact model training. Please view the content and data usage with discretion.

A Appendix

A.1 Dataset documentation and intended uses

We follow datasheets for datasets guideline to document the followings.

A.1.1 Motivation

- For what purpose was the dataset created? Was there a specific task in mind? Was there a specific gap that needed to be filled?
  - ℚ𝔸ℂ𝕠𝕟𝕧 is created to test understanding of informative conversations such as business emails, panel discussions, and work channels. It is designed for QA on informative conversations to fill the gap of common Wikipedia-based QA tasks.
- Who created the dataset (e.g., which team, research group) and on behalf of which entity (e.g., company, institution, organization)?
  - Salesforce AI Research team and HKUST CAiRE team work together to create this dataset.
- Who funded the creation of the dataset? If there is an associated grant, please provide the name of the grantor and the grant name and number.
  - Salesforce AI research team funded the creation of the dataset.

A.1.2 Composition

- What do the instances that comprise the dataset represent (e.g., documents, photos, people, countries)? Are there multiple types of instances (e.g., movies, users, and ratings; people and interactions between them; nodes and edges)? Please provide a description.
  - ℚ𝔸ℂ𝕠𝕟𝕧 has conversations (text) among speakers (people) and a set of corresponding QA pairs (text).
- How many instances are there in total (of each type, if appropriate)?
  - ℚ𝔸ℂ𝕠𝕟𝕧 has 34,608 QA pairs and 10,259 conversations. Each conversation has 568.8 words in average and the longest one has 19,917 words.
- Does the dataset contain all possible instances or is it a sample (not necessarily random) of instances from a larger set? If the dataset is a sample, then what is the larger set? Is the sample representative of the larger set (e.g., geographic coverage)? If so, please describe how this representativeness was validated/verified. If it is not representative of the larger set, please describe why not (e.g., to cover a more diverse range of instances, because instances were withheld or unavailable).
  - The conversations in ℚ𝔸ℂ𝕠𝕟𝕧 are randomly sampled from several conversational datasets, including BC3, Enron, Court, Media, and Slack, and the number of samples is decided based on related work and the budget.
- What data does each instance consist of? “Raw” data (e.g., unprocessed text or images) or features? In either case, please provide a description.
  - Each sample has raw text of conversations, speaker names, and QA pairs.
- Is there a label or target associated with each instance? If so, please provide a description.
  - Each answerable sample has at least one possible answer in a list format.
- Is any information missing from individual instances? If so, please provide a description, explaining why this information is missing (e.g., because it was unavailable). This does not include intentionally removed information, but might include, e.g., redacted text.
  - We do not include the crowd worker information due to the potential privacy issue.
- Are relationships between individual instances made explicit (e.g., users’ movie ratings, social network links)? If so, please describe how these relationships are made explicit.
  - N/A
- Are there recommended data splits (e.g., training, development/validation, testing)? If so, please provide a description of these splits, explaining the rationale behind them.
  - We provide official training, development, and testing splits.

- Are there any errors, sources of noise, or redundancies in the dataset? If so, please provide a description.
  - There could have some potential noise of question or answer annotation.

- Is the dataset self-contained, or does it link to or otherwise rely on external resources (e.g., websites, tweets, other datasets)? If it links to or relies on external resources, a) are there guarantees that they will exist, and remain constant, over time; b) are there official archival versions of the complete dataset (i.e., including the external resources as they existed at the time the dataset was created); c) are there any restrictions] (e.g., licenses, fees) associated with any of the external resources that might apply to a future user? Please provide descriptions of all external resources and any restrictions associated with them, as well as links or other access points, as appropriate.
  - QAConv is self-contained.

- Does the dataset contain data that might be considered confidential (e.g., data that is protected by legal privilege or by doctorpatient confidentiality, data that includes the content of individuals' nonpublic communications)? If so, please provide a description.
  - No, all the samples in QAConv is public available.

- Does the dataset contain data that, if viewed directly, might be offensive, insulting, threatening, or might otherwise cause anxiety? If so, please describe why.
  - No

- Does the dataset relate to people? If not, you may skip the remaining questions in this section.
  - Yes

- Does the dataset identify any subpopulations (e.g., by age, gender)? If so, please describe how these subpopulations are identified and provide a description of their respective distributions within the dataset.
  - QAConv contains different speakers with their names. Some samples have their role information, e.g., petitioner.

- Is it possible to identify individuals (i.e., one or more natural persons), either directly or indirectly (i.e., in combination with other data) from the dataset? If so, please describe how.
  - Yes, because some of the conversations are coming from public forums, therefore, people may be able to find the original speaker if they find the original media source.

- Does the dataset contain data that might be considered sensitive in any way (e.g., data that reveals racial or ethnic origins, sexual. orientations, religious beliefs, political opinions or union memberships, or locations; financial or health data; biometric or genetic data; forms of government identification, such as social security numbers; criminal history)? If so, please provide a description.
  - N/A.

A.1.3 Collection Process

- How was the data associated with each instance acquired? Was the data directly observable (e.g., raw text, movie ratings), reported by subjects (e.g., survey responses), or indirectly inferred/derived from other data (e.g., part-of-speech tags, model-based guesses for age or language)? If data was reported by subjects or indirectly inferred/derived from other data, was the data validated/verified? If so, please describe how.
  - The QA data is collected by Amazon Mechanical Turk. The data is directly observable.

- What mechanisms or procedures were used to collect the data (e.g., hardware apparatus or sensor, manual human curation, software program, software API)? How were these mechanisms or procedures validated? If the dataset is a sample from a larger set, what was the sampling strategy (e.g., deterministic, probabilistic with specific sampling probabilities)?
  - The QA data is collected by Amazon Mechanical Turk, we design a user interface with instructions on the top and then given partial conversation as context.

- Who was involved in the data collection process (e.g., students, crowdworkers, contractors) and how were they compensated (e.g., how much were crowdworkers paid)?

  - Crowdworkers. We paid them roughly $8-10 per hour, calculated by the average time to read and wriite one QA pair is approximately 4 minutes.

- Over what timeframe was the data collected? Does this timeframe match the creation timeframe of the data associated with the instances (e.g., recent crawl of old news articles)? If not, please describe the timeframe in which the data associated with the instances was created.
  - The data was collected during Feb 2021 to March 2021.

- Were any ethical review processes conducted (e.g., by an institutional review board)? If so, please provide a description of these review processes, including the outcomes, as well as a link or other access point to any supporting documentation.
  - We have conduct an internal ethical review process by Salesforce ethical AI team, `https://einstein.ai/ethics`.

- Does the dataset relate to people? If not, you may skip the remainder of the questions in this section.
  - Yes.

- Did you collect the data from the individuals in question directly, or obtain it via third parties or other sources (e.g., websites)?
  - We obtain the data through AMT website.

- Were the individuals in question notified about the data collection? If so, please describe (or show with screenshots or other information) how notice was provided, and provide a link or other access point to, or otherwise reproduce, the exact language of the notification itself.
  - Yes, the turkers know the data collect procedure. Screenshots are shown Figure 4, Figure 5, Figure 6 in the Appendix.

- Did the individuals in question consent to the collection and use of their data? If so, please describe (or show with screenshots or other information) how consent was requested and provided, and provide a link or other access point to, or otherwise reproduce, the exact language to which the individuals consented.
  - AMT has its own data policy. `https://www.mturk.com/acceptable-use-policy`.

- If consent was obtained, were the consenting individuals provided with a mechanism to revoke their consent in the future or for certain uses? If so, please provide a description, as well as a link or other access point to the mechanism (if appropriate).
  - `https://www.mturk.com/acceptable-use-policy`.

- Has an analysis of the potential impact of the dataset and its use on data subjects (e.g., a data protection impact analysis) been conducted? If so, please provide a description of this analysis, including the outcomes, as well as a link or other access point to any supporting documentation.
  - N/A

A.1.4 Preprocessing/cleaning/labeling

- Was any preprocessing/cleaning/labeling of the data done (e.g., discretization or bucketing, tokenization, part-of-speech tagging, SIFT feature extraction, removal of instances, processing of missing values)? If so, please provide a description. If not, you may skip the. remainder of the questions in this section.
  - We conduct data cleaning such as removing code snippets before asking the crowd workers to provide corresponding QA pairs. Thus, no additional cleaning or preprocessing is done for the released dataset, only the reading scripts used to change the format for model reading are used.

- Was the "raw" data saved in addition to the preprocessed/cleaned/labeled data (e.g., to support unanticipated future uses)? If so, please provide a link or other access point to the "raw" data.
  - Yes, in the same link.

- Is the software used to preprocess/clean/label the instances available? If so, please provide a link or other access point.
  - `https://github.com/salesforce/QAConv`

A.1.5 Uses

- Has the dataset been used for any tasks already? If so, please provide a description.
  - It is proposed to use for QA on conversations task.
- Is there a repository that links to any or all papers or systems that use the dataset? If so, please provide a link or other access point.
  - It is a new dataset. We run existing state-of-the-art models and release the code.
- What (other) tasks could the dataset be used for?
  - Many conversational AI related tasks can be applied or transferred, for examples, conversational retrieval and conversational machine reading.
- Is there anything about the composition of the dataset or the way it was collected and preprocessed/cleaned/labeled that might impact future uses? For example, is there anything that a future user might need to know to avoid uses that could result in unfair treatment of individuals or groups (e.g., stereotyping, quality of service issues) or other undesirable harms (e.g., financial harms, legal risks) If so, please provide a description. Is there anything a future user could do to mitigate these undesirable harms?
  - Different ways to disentangle conversations could impact the overall performance. In our current setting, we use and release the buffer-based chunking mechanism.
- Are there tasks for which the dataset should not be used? If so, please provide a description.
  - Conversations from Media corpus should not be used for commercial usage.

A.1.6 Distribution

- Will the dataset be distributed to third parties outside of the entity (e.g., company, institution, organization) on behalf of which the dataset was created? If so, please provide a description.
  - No.
- How will the dataset will be distributed (e.g., tarball on website, API, GitHub)? Does the dataset have a digital object identifier (DOI)?
  - Release on Github. No DOI.
- When will the dataset be distributed?
  - Released.
- Will the dataset be distributed under a copyright or other intellectual property (IP) license, and/or under applicable terms of use (ToU)? If so, please describe this license and/or ToU, and provide a link or other access point to, or otherwise reproduce, any relevant licensing terms or ToU, as well as any fees associated with these restrictions.
  - BSD 3-Clause "New" or "Revised" License.
- Have any third parties imposed IP-based or other restrictions on the data associated with the instances? If so, please describe these restrictions, and provide a link or other access point to, or otherwise reproduce, any relevant licensing terms, as well as any fees associated with these restrictions.
  - No.
- Do any export controls or other regulatory restrictions apply to the dataset or to individual instances? If so, please describe these restrictions, and provide a link or other access point to, or otherwise reproduce, any supporting documentation.
  - Media dataset is restricted their conversations to be research-only usage.

A.1.7 Maintenance

- Who is supporting/hosting/maintaining the dataset?
  - Salesforce AI Research team. Chien-Sheng (Jason) Wu is the corresponding author.
- How can the owner/curator/manager of the dataset be contacted (e.g., email address)?
  - Create an open issue on our Github repository or contact the authors.
- Is there an erratum? If so, please provide a link or other access point.
  - No.
- Will the dataset be updated (e.g., to correct labeling errors, add new instances, delete instances)? If so, please describe how often, by whom, and how updates will be communicated to users (e.g., mailing list, GitHub)?

  - No. If we plan to update in the future, we will indicate the information on our Github repository.

- If the dataset relates to people, are there applicable limits on the retention of the data associated with the instances (e.g., were individuals in question told that their data would be retained for a fixed period of time and then deleted)? If so, please describe these limits and explain how they will be enforced.
  - No.

- Will older versions of the dataset continue to be supported/hosted/maintained? If so, please describe how. If not, please describe how its obsolescence will be communicated to users.
  - Yes. If we plan to update the data, we will keep the original version available and then release the follow-up version, for example, QAConv-2.0

- If others want to extend/augment/build on/contribute to the dataset, is there a mechanism for them to do so? If so, please provide a description. Will these contributions be validated/verified? If so, please describe how. If not, why not? Is there a process for communicating/distributing these contributions to other users? If so, please provide a description.
  - Yes, they can submit a Github pull request or contact us privately.

A.2 Test Data Additional Verification

After random split, we run an additional verification step on the dev and test set. If the new collected answer is very similar with the original answer (FZR score > 90), we keep the original answer. If the new answer is similar within a margin (90 > FZR score > 75), we keep both answers. If the new answer is very different from the original answer (75 > FZR score), we will run one more verification step to get the 3rd answers. We pick the most similar two answers as the gold answers if their FZR score is > 75, otherwise, we manually looked into those controversial QA pairs and made the final judgement.

A.3 License and Privacy

- BC3: Creative Commons Attribution-Share Alike 3.0 Unported License.
- Enron: Creative Commons Attribution 3.0 United States license.
- Court: This material is based upon work supported in part by the National Science Foundation under grant IIS-0910664. Any opinions, findings, and conclusions or recommendations expressed above are those of the author(s) and do not necessarily reflect the views of the National Science Foundation.
- Media: Only the publicly available transcripts data from the media sources are included.
- Slack: Numerous public Slack chat channels (`https://slack.com/`) have recently become available that are focused on specific software engineering-related discussion topics.

A.4 Human evaluation description of human-written and machine-generated questions.

Rate [Fluency of the question]:

- (A) The question is fluent and has good grammar. I can understand clearly.
- (B) The question is somewhat fluent with some minor grammar errors. But it does not influence my reading.
- (C) The question is not fluent and has serious grammar error. I can hardly understand it.

Rate [Complexity of the question]:

- (A) The answer to the question is hard to find. I have to read the whole conversation back-and-forth more than one time.
- (B) The answer to the question is not that hard to find. I can find the answer by reading several sentences once.
- (C) The answer to the question is easy to find. I can find the answer by only reading only one sentence.

Rate [Confidence of the answer]:

- (A) I am confident that my answer is correct.
- (B) I am not confident that my answer is correct.

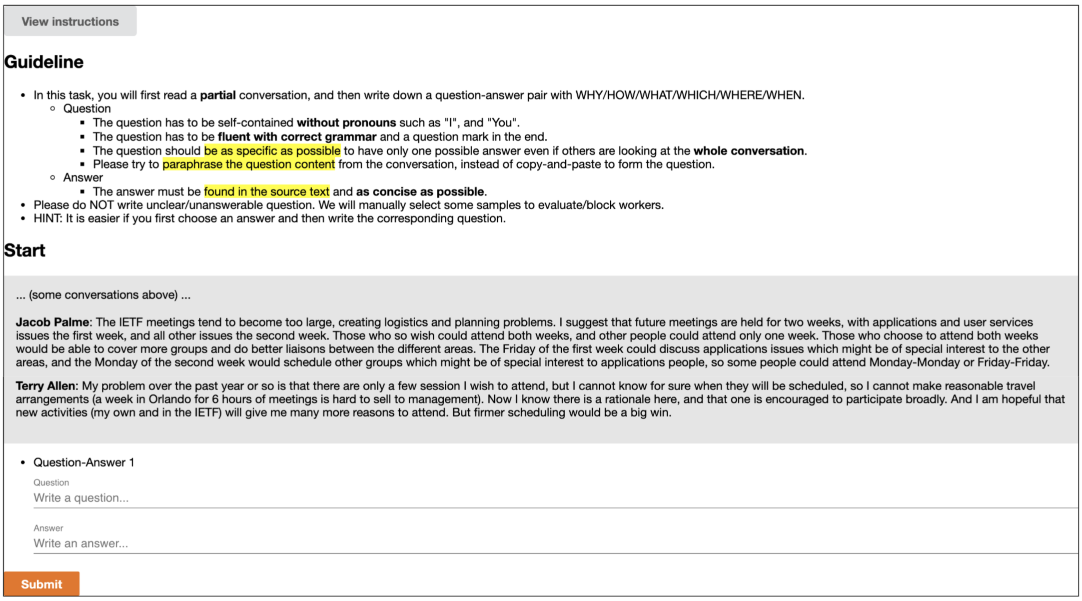
Partial Context	... Steve Duffy: ..., but I don’t know if Enron would even consider this. Studdert might have\nthe best feel for this. Separately, the defendant group will get back to us\non any offer they might be willing to make to settle just the Montana case,\nbut it appears that their real interest would be in a \"global\" deal. Any\ncomments? SWD Michael Burke: Steve, Stan and I have discussed this and we agree that Mike Moran should\ntake the lead and explore all aspects of an Enron Global deal. I know that\nyou will assist Mike in this endeavor. thanks, mike Steve Duffy: Sounds good. Mike Moran has the numbers for our Montana lawyers and I will\nassist him any way I can. The big question is whether Enron, as a whole,\nwould be willing to give up any protection they might still have under the\nold InterNorth policies. SWD ...
Question	What person has the numbers for the Montana lawyers and is best qualified to explore the deal?
Partial Context	... OFEIBEA QUIST-ARCTON, BYLINE: One woman we spoke to has lived here all her life. She was born here, married here, has children here. She said I’m going. I don’t feel safe. You know, the ground was shaking when we heard those bombs. We don’t feel ... JENNIFER LUDDEN, HOST: We are talking about the tensions and violence in Nigeria. We’ll have more with NPR’s Ofeibea Quist-Arcton from Nigeria, and also former Ambassador John Campbell coming up. We’ll also talk with an activist from Nigeria. If you have questions, ... JENNIFER LUDDEN, HOST: This is TALK OF THE NATION from NPR News. I’m Jennifer Ludden. Nigeria has long faced challenges from corruption, an economy that relies on oil exports and simmering ethnic and religious tensions, tensions made evident in the recent series of bombings by Boko Haram, the militant ... JENNIFER LUDDEN, HOST: It’s the latest crisis for President Goodluck Jonathan. We’re talking today with Ofeibea Quist-Arcton, NPR’s foreign correspondent, now in Kano, Nigeria; and John Campbell, former U.S. ambassador and political counselor to Nigeria. He’s now a senior fellow for Africa policy studies at the Council on Foreign Relations. ...
Question	Who is the president of the country where Ofeibea quist-arcton is talking about the tensions and violence in Nigeria ?
Partial Context	... Karoline: are you using pytest? there are a couple of plugins for parallelization Valeri: Yes pytest Eliana: pytest-xdist is pretty good Valeri: What does that do? Karoline : yeah that and pytest-parallel are worth a look . basically they allow you to paralelize your tests Valeri: Okay Valeri: Will definitely look into those Valeri: Thanks <@Eliana><@Karoline>,taco, . . .
Question	What program allows the user to parallelize the tests and is recommended by Karoline?
Partial Context	. . . MR. FREEDMAN (RESPONDENT): . . . They both deserve the death penalty. They – they were – the prosecutors were aware that the – the death penalty is what stirs the pot here, and so they were urging somebody to be the shooter to get the death penalty. If this wasn’t a death penalty case, I don’t think they – it would have mattered who killed who. And so they were urging – JUSTICE KENNEDY: Well, I think there’s quite a difference in – in case A where you say our position is that Stumpf was the shooter, pure and simple. That’s it. In case B, they say we think Stumpf was the shooter. We’re not 100 percent sure, but he should get the death penalty. The alternative is before the sentencer and the sentencer can make that determination. . . .
Question	Which person was mentioned as the shooter in case A and B?

Table 18: Examples of multi-hop questions



Guideline

- In this task, you will first read a **partial** conversation, and then write down a question-answer pair with WHY/HOW/WHAT/WHICH/WHERE/WHEN.
  - Question
    - The question has to be self-contained **without pronouns** such as "I", and "You".
    - The question has to be **fluent with correct grammar** and a question mark in the end.
    - The question should be as specific as possible to have only one possible answer even if others are looking at the **whole conversation**.
    - Please try to paraphrase the question content from the conversation, instead of copy-and-paste to form the question.
  - Answer
    - The answer must be found in the source text and **as concise as possible**.
- Please do NOT write unclear/unanswerable question. We will manually select some samples to evaluate/block workers.
- HINT: It is easier if you first choose an answer and then write the corresponding question.

Start

... (some conversations above) ...

Jacob Palme: The IETF meetings tend to become too large, creating logistics and planning problems. I suggest that future meetings are held for two weeks, with applications and user services issues the first week, and all other issues the second week. Those who so wish could attend both weeks, and other people could attend only one week. Those who choose to attend both weeks would be able to cover more groups and do better liaisons between the different areas. The Friday of the first week could discuss applications issues which might be of special interest to the other areas, and the Monday of the second week would schedule other groups which might be of special interest to applications people, so some people could attend Monday-Monday or Friday-Friday.

Terry Allen: My problem over the past year or so is that there are only a few session I wish to attend, but I cannot know for sure when they will be scheduled, so I cannot make reasonable travel arrangements (a week in Orlando for 6 hours of meetings is hard to sell to management). Now I know there is a rationale here, and that one is encouraged to participate broadly. And I am hopeful that new activities (my own and in the IETF) will give me many more reasons to attend. But firmer scheduling would be a big win.

Start

... (some conversations above) ...

Kimbery: I would bet the majority of the work would be extending `raco pkg install` to do constraint solving and handle the notion of version conflicts.

Jacob: Suppose the four main items are designed and made available in a side-branch of the racket mainline. Would it be able to accommodate the current style of additive changes. Suppose one package favors the additive style and other one takes the version numbering approach. How do we manage users experience so they don't get confused by two different styles?

Kimbery: A package could easily just only make additive changes by only ever bumping the minor version.

Kimbery: But there would certainly be some tricky migration/compat issues to work out.

Kimbery: I don’t think any of them are super hard, though.

Jacob: and by setting max version to #f indefinitely really

Kimbery: IIRC, the proposed compatibility solution was to basically (for now) treat packages specified without bounds as `>=1 && <2`.

Chantelle: The version constraint solving doesn't sound like the hard part, especially if it's implemented with the aid of a logic programming dsl

Kimbery: I don’t really mean the constraint solving algorithm itself, but I mean plumbing the inputs and outputs of that algorithm through the rest of the system.

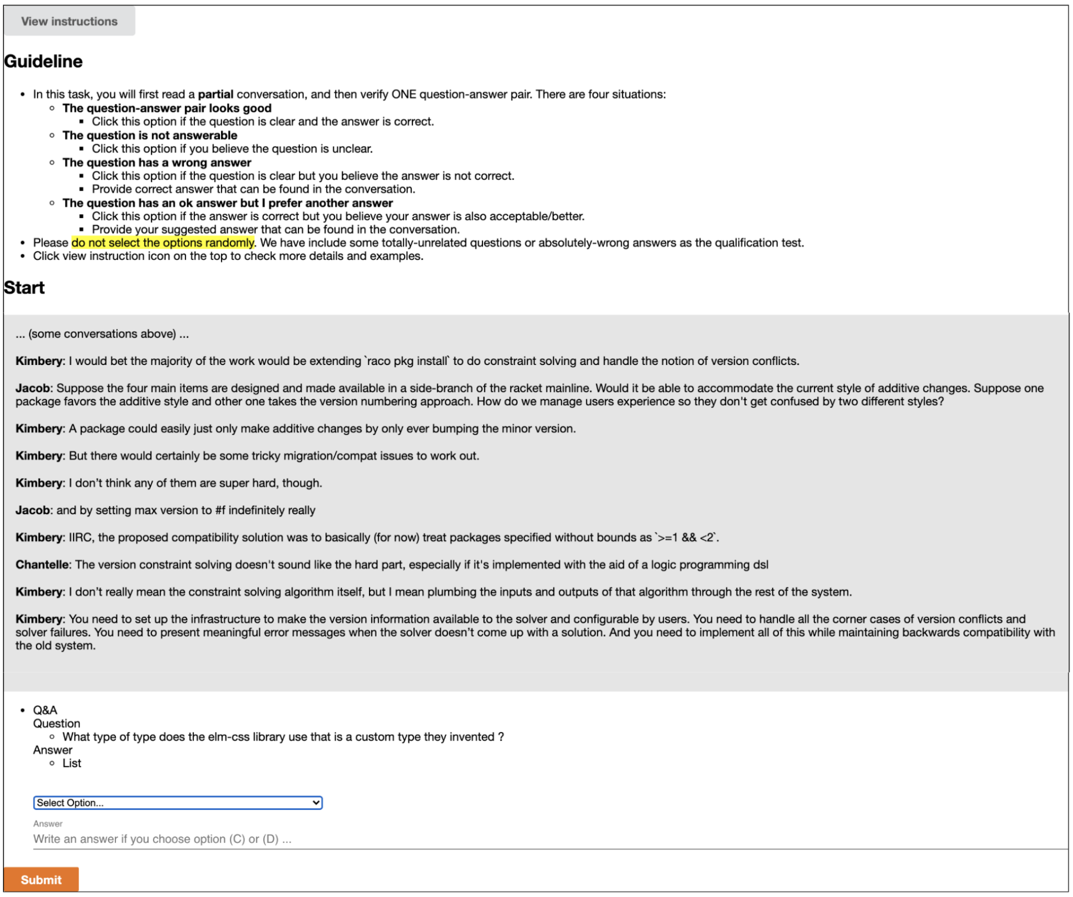
Kimbery: You need to set up the infrastructure to make the version information available to the solver and configurable by users. You need to handle all the corner cases of version conflicts and solver failures. You need to present meaningful error messages when the solver doesn’t come up with a solution. And you need to implement all of this while maintaining backwards compatibility with the old system.

- Recommended Questions
  - What type of type does the elm-css library use that is a custom type they invented ?
  - What is the name of the type signature of the library elm-css uses to create a namespace ?
  - What part of the code is NOT helping?
  - Who is the host of the discussions?
- Question-Answer

Question
Copy and modify a question

Answer
Write an answer...

Figure 5: Screenshot for machine-generated QA collection.



Guideline

- In this task, you will first read a **partial** conversation, and then verify ONE question-answer pair. There are four situations:
    - **The question-answer pair looks good**
        - Click this option if the question is clear and the answer is correct.
    - **The question is not answerable**
        - Click this option if you believe the question is unclear.
    - **The question has a wrong answer**
        - Click this option if the question is clear but you believe the answer is not correct.
        - Provide correct answer that can be found in the conversation.
    - **The question has an ok answer but I prefer another answer**
        - Click this option if the answer is correct but you believe your answer is also acceptable/better.
        - Provide your suggested answer that can be found in the conversation.
- Please do not select the options randomly. We have include some totally-unrelated questions or absolutely-wrong answers as the qualification test.
- Click view instruction icon on the top to check more details and examples.

Abstract

Knowledge bases (KBs) contain plenty of structured world and commonsense knowledge. As such, they often complement distributional text-based information and facilitate various downstream tasks. Since their manual construction is resource- and time-intensive, recent efforts have tried leveraging large pretrained language models (PLMs) to generate additional monolingual knowledge facts for KBs. However, such methods have not been attempted for building and enriching multilingual KBs. Besides wider application, such multilingual KBs can provide richer combined knowledge than monolingual (e.g., English) KBs. Knowledge expressed in different languages may be complementary and unequally distributed: this implies that the knowledge available in high-resource languages can be transferred to low-resource ones. To achieve this, it is crucial to represent multilingual knowledge in a shared/unified space. To this end, we propose a unified representation model, `Prix-LM` 🏆, for multilingual KB construction and completion. We leverage two types of knowledge, *monolingual triples* and *cross-lingual links*, extracted from existing multilingual KBs, and tune a multilingual language encoder XLM-R via a causal language modeling objective. `Prix-LM` integrates useful multilingual and KB-based factual knowledge into a single model. Experiments on standard entity-related tasks, such as link prediction in multiple languages, cross-lingual entity linking and bilingual lexicon induction, demonstrate its effectiveness, with gains reported over strong task-specialised baselines.

1 Introduction

Multilingual knowledge bases (KBs), such as DBPedia (Lehmann et al., 2015), Wikidata (Vrandečić and Krötzsch, 2014), and YAGO (Suchanek et al., 2007), provide structured knowledge expressed in multiple languages. Those KBs are modeled as knowledge graphs (KGs) that possess two types of knowledge: *monolingual triples* which describe relations of entities, and *cross-lingual links* which match entities across languages. The knowledge stored in such KGs facilitates various downstream applications such as question answering (Dai et al., 2016; Bauer et al., 2018; Wang et al., 2021b), recommendation (Zhang et al., 2016; Wang et al., 2018, 2021c), and dialogue systems (Madotto et al., 2018; Liu et al., 2019; Yang et al., 2020).

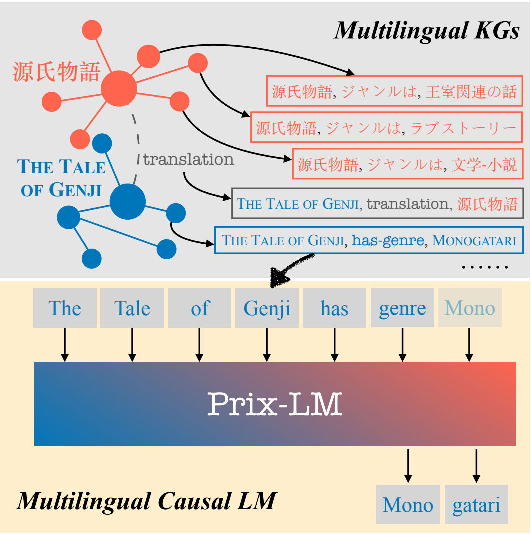

Figure 1: An illustration of the main idea supporting `Prix-LM`: it infuses complementary multilingual knowledge from KGs into a multilingual causal LM; e.g., Japanese KG stores more comprehensive genre information of THE TALE OF GENJI than KGs in other languages. Through cross-lingual links (translations), such knowledge is then propagated across languages.

Manually constructing large-scale knowledge bases has been labor-intensive and expensive (Paulheim, 2018), leading to a surge of interest in automatic knowledge base construction (Ji et al., 2022). Recent research (Bosselut et al., 2019; Yao et al., 2019; Wang et al., 2020, *inter alia*) proposes to generate structured knowledge using pretrained lan-

guage models (PLMs; Devlin et al. 2019), where missing elements in KB facts (i.e., triples) can be completed (i.e., filled in) by the PLM.

While these methods arguably perform well for English, such automatic KB construction has not yet been tried for multilingual KBs – improving the knowledge in multilingual KBs would have a positive impact on applications in other languages beyond English. Moreover, KBs in multiple languages may possess complementary knowledge, and knowledge bases in low-resource languages often suffer severely from missing entities and facts. This issue could be mitigated by propagating knowledge from multiple well-populated high-resource languages' KBs (e.g., English and French KBs) to the KBs of low-resource languages, this way 'collectively' improving the content stored in the full multilingual KB.[1]

However, training LMs to capture structural knowledge independently for each language will fall short of utilizing complementary and transferable knowledge available in other languages. Therefore, a unified representation model is required, which can capture, propagate and enrich knowledge in multilingual KBs. In this work, we thus propose to train a language model for constructing multilingual KBs. Starting from XLM-R (Conneau et al., 2020) as our base model, we then pretrain it on the multilingual DBpedia, which stores both monolingual triples and cross-lingual links (see Figure 1). We transform both types of knowledge into sequences of tokens and pretrain the language model with a causal LM objective on such transformed sequences. The monolingual triples infuse structured knowledge into the language model, while the cross-lingual links help align knowledge between different languages. This way, the proposed model `Prix-LM` 🏆 (Pre-trained Knowledge-incorporated Cross-lingual Language Model) is capable of mapping knowledge of different languages into a unified/shared space.

We evaluate our model on four different tasks essential for automatic KB construction, covering both high-resource and low-resource languages: link prediction, cross-lingual entity linking, bilingual lexicon induction, and prompt-based LM knowledge probing. The main results across all tasks indicate that `Prix-LM` brings consistent and substantial gains over various state-of-the-art methods, demonstrating its effectiveness.

2 `Prix-LM`

We now describe `Prix-LM`, first outlining the data structure and pretraining task, and then describing its pretraining procedure in full (§2.1), and efficient inference approaches with `Prix-LM` (§2.2).

Pretraining Task. We rely on multilingual DBpedia, but note that `Prix-LM` is also applicable to other KBs. DBpedia contains two types of structured knowledge: monolingual knowledge triples, and cross-lingual links between entities. The monolingual triples represent (relational) facts expressed in a structured manner. Each triple is denoted as $\{e_1, r, e_2\}$: the elements of a triple are identified as the subject entity e_1, relation (or predicate) r, and object entity e_2, respectively (see also Figure 1 for examples). For instance, the fact "*The capital of England is London*" can be represented as $\{\text{England}, \texttt{capital}, \text{London}\}$. The cross-lingual links, denoted as $\{e_a, e_b\}$, represent the correspondence of 'meaning-identical' entities e_a and e_b in two different languages: e.g., the English entity London is mapped to Londres in Spanish.

We treat both types of knowledge using the same input format $\{s, p, o\}$, where $s = e_1, p = r, o = e_2$ for monolingual knowledge triples, and $s = e_a, p = null, o = e_b$ for cross-lingual entity links. The pretraining task is then generating o given s and p. This objective is consistent with the link prediction task and also benefits other entity-related downstream tasks, as empirically validated later.

2.1 Pretraining Language Models

`Prix-LM` is initialized by a multilingual PLM such as XLM-R (Conneau et al., 2020): starting from XLM-R's pretrained weights, we train on the structured knowledge from a multilingual KB.

Input Representation. We represent knowledge from the KB as sequences of tokens. In particular, given some knowledge fact $\{s, p, o\}$, where each element is the surface name of an entity or a relation, we tokenize[2] the elements to sequences of subtokens X_s, X_p, and X_o. We treat each element in the knowledge fact as a different text segment and concatenate them to form a single sequence.

---

[1] This intuition is illustrated by the example in Figure 1. Consider the prediction of facts (e.g., *genre*) about the oldest Japanese novel The Tale of Genji. English DBpedia records its genre only as *Monogatari* (story), whereas complementary knowledge can be propagated from the Japanese KB, which provides finer-grained genre information, including *Love Story*, *Royal Family Related Story*, and *Monogatari*.

[2] XLM-R's dedicated multilingual tokenizer is used to processes entity and relation names in each language.

We further introduce special tokens to represent different types of knowledge:

(1) Monolingual Triples. We use special tokens to indicate the role of each element in the triple, which converts the sequence to the following format:

> `<s> [S]`$\boldsymbol{X_s}$ `</s> </s> [P]`$\boldsymbol{X_p}$ `</s> </s> [O]`$\boldsymbol{X_o}$ `[EOS]</s>`.

`<s>` is the special token denoting beginning of sequence; `</s>` is the separator token, both adopted from XLM-R. Additional special tokens `[S]`, `[P]` and `[O]` denote the respective roles of subject, predicate, and object of the input knowledge fact. `[EOS]` is the end-of-sequence token.

(2) Cross-Lingual Links. As the same surface form of an entity can be associated with more than language, we use special language tokens to indicate the actual language of each entity. These extra tokens can also be interpreted as the relation between entities. The processed sequence obtains the following format:

> `<s> [S]`$\boldsymbol{X_s}$ `</s> </s> [P][`*`S-LAN`*`][`*`O-LAN`*`] </s> </s> [O]`$\boldsymbol{X_o}$ `[EOS]</s>`.

`<s>` and `</s>` are the same as for monolingual triples. `[`*`S-LAN`*`]` and `[`*`O-LAN`*`]` denote two placeholders for language tokens, where they get replaced by the two-character ISO 639-1 codes of the source and target language, respectively. For example, if the cross-lingual connects an English entity LONDON to a Spanish entity LONDRES, the two language tokens `[`*`EN`*`][`*`ES`*`]` will be appended to the token `[P]`. The new special tokens are randomly initialized, and optimized during training. The original special tokens are kept and also optimized.

Training Objective. The main training objective of `Prix-LM` is to perform completion of both monolingual knowledge triples and cross-lingual entity links (see §2). In particular, given X_s and X_p, the model must predict 1) X_o from monolingual triples (i.e., X_p is a proper relation), or X_o as the cross-lingual counterpart of X_s for cross-lingual pairs (i.e., X_p is a pair of language tokens). This task can be formulated into an autoregressive language modeling training objective:

$$\mathcal{L}_{\mathrm{LM}} = - \sum_{x_t \in X_o \cup \{\texttt{[EOS]}\}} \log \mathrm{P}\left(x_t \mid x_{<t}\right),$$

where $\mathrm{P}\left(x_t \mid x_{<t}\right)$ is the conditional probability of generating x_t given previous subtokens. The probability of generating token x_t is calculated from the hidden state of its previous token $\boldsymbol{h}_{t-1}$ in the final layer of Transformer as follows:

$$\mathrm{P}\left(x_t \mid x_{<t}\right) = \mathrm{softmax}(\boldsymbol{W}\boldsymbol{h}_{t-1}),$$

where $\boldsymbol{W}$ is a trainable parameter initialized from PLMs for subtoken prediction. Note that this training objective is applied to both monolingual knowledge triples and cross-lingual links as they can both be encoded in the same $\{s, p, o\}$ format.

Since models like mBERT or XLM-R rely on masked language modeling which also looks 'into the future', subtokens can be leaked by attention. Therefore, we create adaptations to support causal autoregressive training using attention masks (Yang et al., 2019), so that the X_o subtokens can only access their previous subtokens. In particular, in the Transformer blocks, given the query $\boldsymbol{Q}$, key $\boldsymbol{K}$, and value $\boldsymbol{V}$, we adapt them to a causal LM:

$$\mathrm{ATT}\left(\boldsymbol{Q}, \boldsymbol{K}, \boldsymbol{V}\right) = \mathrm{softmax}\left(\frac{\boldsymbol{Q}\boldsymbol{K}^{\top}}{\sqrt{d}} + \boldsymbol{M}\right)\boldsymbol{V},$$

where $\boldsymbol{Q}, \boldsymbol{K}, \boldsymbol{V} \in \mathbb{R}^{l \times d}$; l is the length of the input sequence, d is the hidden size, $\boldsymbol{M} \in \mathbb{R}^{l \times l}$ is an attention mask, which is set as follows:

$$\boldsymbol{M}_{ij} = \begin{cases} 0 & x_i \notin X_o \cup \{\texttt{[EOS]}\} \\ 0 & x_i \in X_o \cup \{\texttt{[EOS]}\}, j \leq i \\ -\infty & x_i \in X_o \cup \{\texttt{[EOS]}\}, j > i \end{cases}$$

2.2 Inference

Different downstream tasks might require different types of inference: e.g., while link prediction tasks should rely on autoregressive inference, similarity-based tasks such as cross-lingual entity linking rely on similarity-based inference, that is, finding nearest neighbors in the multilingual space. In what follows, we outline both inference types.

Autoregressive Inference. For link prediction tasks test input is in the format of $\{s, p, ?\}$, where the model is supposed to generate the missing o given s and p. For such tasks, o comes from a known set of candidate entities $\mathcal{O}$. A simple way to perform inference is to construct candidate tuples $\{s, p, o'\}$ using each $o' \in \mathcal{O}$ and return the one with the minimum LM loss. This straightforward approach requires encoding $|\mathcal{O}|$ sequences. However, as $|\mathcal{O}|$ can be large for high-resource languages (e.g., 2M items for English), this might yield a prohibitively expensive inference procedure. We thus propose to speed up inference by applying and adapting the constrained beam search (Anderson et al., 2017). In a nutshell, instead of calculating loss on the whole sequence, we generate one subtoken at a time and only keep several most promising sequences in the expansion set for beam search. The generation process ends when we exceed the maximum length of entities.

More precisely, given s and p (or only s when dealing with cross-lingual links), we concatenate them as the initial sequence X_0 and initialize the sequence loss to 0. We then extend the sequence using subtokens from the PLM's vocabulary $\mathcal{V}$. For each subtoken $w_1 \in \mathcal{V}$, we create a new sequence $\{X_0, w_1\}$ and add $-\log \mathrm{P}(w_1|X_0)$ to the sequence loss. For the next round, we only keep the sequences that can be expanded to an entity in the expansion set, and retain at most K sequences with the smallest sequence loss, where K is a hyperparameter. This process is repeated until there are no more candidate sequences to be added to the expansion set. Finally, for any candidate entity $o \in \mathcal{O}$, if it has been generated from a corresponding candidate sequence, we set its loss to the total LM loss (sum of sequence losses), otherwise we set its loss to ∞. Finally, we return the entity with the smallest loss. A more formal description of this procedure is summarized in Alg. 1 in the Appendix.

This inference variant only requires encoding at most $L \cdot K$ sequences, where L is the maximum number of subtokens in an entity. It is much more efficient when $L \cdot K \ll |\mathcal{O}|$, which generally holds for tasks such as link prediction.

Similarity-Based Inference. For some tasks it is crucial to retrieve nearest neighbors (NN) via embedding similarity in the multilingual space. Based on prior findings concerning multilingual PLMs (Liu et al., 2021b) and our own preliminary experiments, out-of-the-box `Prix-LM` produces entity embeddings of insufficient quality. However, we can transform them into entity encoders via a simple and efficient unsupervised Mirror-BERT procedure (Liu et al., 2021a). In short, Mirror-BERT is a contrastive learning method that calibrates PLMs and converts them into strong universal lexical or sentence encoders. The NN search is then performed with the transformed "Mirror-BERT" `Prix-LM` variant.[3]

3 Experiments and Results

In this section, we evaluate `Prix-LM` in both high-resource and low-resource languages. The focus is on four tasks that are directly or indirectly related to KB construction. 1) Link prediction (LP) is the core task for automatic KB construction since it discovers missing links given incomplete KBs. 2) Knowledge probing from LMs (LM-KP) can also be seen as a type of KB completion task as it performs entity retrieval given a subject entity and a relation. 3) Cross-lingual entity linking (XEL) and 4) Bilingual lexicon induction (BLI) can be very useful for multilingual KB construction as they help to find cross-lingual entity links.

3.1 Experimental Setup

Training Configuration. We train our model on knowledge facts for 87 languages which are represented both in DBpedia and in XLM-R (Base). The training set comprises 52M monolingual knowledge triples and 142M cross-lingual links.

We implement our model using Huggingface's Transformers library (Wolf et al., 2020), and primarily follow the optimization hyperparameters of XLM-R.[4] For LP we use the final checkpoint; for LM-LP, results are reported using the checkpoint at 20k steps; for BLI and XEL, the checkpoint at 150k steps is used. We discuss the rationales of checkpoint selection in §3.6.

Inference Configuration. For similarity-based inference, as in previous work (Liu et al., 2021a) the Mirror-BERT procedure relies on the 10k most frequent English words for contrastive learning.[5] For constrained beam search, used with the LP task, we set the hyperparameter K to 50.

3.2 Link Prediction

(Short) Task Description. Following relevant prior work (Bosselut et al., 2019; Yao et al., 2019),

---

[3] For a fair comparison, we also apply the same transformation on baseline PLMs.

[4] In summary: The model is trained for 5 epochs with the Adam optimizer (Kingma and Ba, 2015) using $\beta_1 = 0.9$, $\beta_2 = 0.98$ and a batch size of 1,024. The learning rate is 5e−5, with a warmup for the first 6% steps followed by a linear learning rate decay to 0. We use dropout (Srivastava et al., 2014) with a rate of 0.1 on all layers and attention weights. For efficiency, we drop all triples with sequence lengths ≥ 30, which only constitutes less than 1.3% of all triples. The full training takes about 5 days with one Nvidia RTX 8000 GPU.

[5] We use English words only for simplicity and direct comparisons. According to Liu et al. (2021a), Mirror-BERT tuning which uses words from the actual test language pair might yield even better performance. Our training config is identical to the original Mirror-BERT work, except the use of a smaller batch size (128 instead of 200) due to hardware constraints.

Table 2: XEL accuracy on the LR-XEL task for low-resource languages.

given a subject entity e_1 and relation r, the aim of the LP task is to determine the object entity e_2.

Task Setup. We evaluate all models on DBpedia. We randomly sample 10% of the monolingual triples as the test set for 9 languages and use remaining data to train the model.[6] The data statistics are reported in Tab. 1. The evaluation metrics are standard *Hits@1*, *Hits@3*, and *Hits@10*.[7]

Models in Comparison. We refer to our model as `Prix-LM` (All) and compare it to the following groups of baselines. First, we compare to three representative and widely used KG embedding models[8]: 1) TransE (Bordes et al., 2013) interprets relations as translations from source to target entities, 2) ComplEx (Trouillon et al., 2016) uses complex-valued embedding to handle binary relations, while 3) RotatE (Sun et al., 2019) interprets relations as rotations from source to target entities in the complex space. In fact, RotatE additionally uses a self-adversarial sampling strategy in training, and offers state-of-the-art performance on several KG completion benchmarks (Rossi et al., 2021). Second, `Prix-LM` (Single) is the ablated monolingual version of `Prix-LM`, which uses an identical model structure to `Prix-LM` (All), but is trained only on monolingual knowledge triples of the test language. Training adopts the same strategy from prior work on pretraining monolingual LMs for KG completion (Bosselut et al., 2019; Yao et al., 2019). We train the `Prix-LM` (Single) for the same number of epochs as `Prix-LM` (All): this means that the embeddings of subtokens in the test language are updated for the same number of times.

Results and Discussion. The results in Tab. 1

---

[6] Following Bordes et al. (2013), we use the *filtered* setting, removing corrupted triples appearing in the training or test set. Moreover, following existing LP tasks (Toutanova et al., 2015; Dettmers et al., 2018) we remove redundant triples (e_1, r_1, e_2) from the test set if (e_2, r_2, e_1) appears in the training set.

[7] We do not calculate mean rank and mean reciprocal rank as constrained beam search does not yield full ranked lists.

[8] The KG embedding baselines are implemented based on OpenKE (Han et al., 2018) and trained using the default hyper-parameters in the library.

show that the `Prix-LM` (All) achieves the best *Hits@1* on average, outperforming TransE, ComplEx, and RotatE by 21.5%, 11.8%, and 5.6%, respectively. It also outperforms the baselines on *Hits@3* and *Hits@10*. Moreover, `Prix-LM` (All) outperforms in almost all languages its monolingual counterpart `Prix-LM` (Single): the average improvements are $>3\%$ across all metrics, demonstrating that the model can effectively leverage complementary knowledge captured and transferred through massive pretraining on multiple languages. Interestingly, the advantages of `Prix-LM` (both Single and All models) over baselines are not restricted to low resource languages but are observed across the board. This hints that, beyond integrating multilingual knowledge, `Prix-LM` is essentially a well-suited framework for KB completion in general.

3.3 Cross-lingual Entity Linking

(Short) Task Description. In XEL[9], a model is asked to link an entity mention in any language to a corresponding entity in an English KB or in a language-agnostic KB.[10] XEL can contribute to multilingual KB construction in two ways. First, since XEL links mentions extracted from free text to KBs, it can be leveraged to enrich KBs with textual attributes. Second, it also provides a way to disambiguate knowledge with similar surface forms but different grounded contexts.

Task Setup. We evaluate `Prix-LM` on two XEL benchmarks: (i) the Low-resource XEL benchmark (LR-XEL; Zhou et al. 2020) and (ii) cross-lingual biomedical entity linking (XL-BEL; Liu et al. 2021b). LR-XEL covers three low-resource languages TE, LO, and MR[11] where the model needs to associate mentions in those languages to the English Wikipedia pages. XL-BEL covers ten typologically diverse languages (see Tab. 3 for the full list). It requires the model to link an entity mention to entries in UMLS (Bodenreider, 2004), a language-agnostic medical knowledge base.

Models in Comparison. For XEL and all following tasks, we use multilingual MLMs (i.e. mBERT and XLM-R) as our baselines as they are the canonical models frequently used in prior work and have shown promising results in cross-lingual entity-centric tasks (Vulić et al., 2020; Liu et al., 2021b; Kassner et al., 2021). We remind the reader that the 'Mirror-BERT' fine-tuning step is always applied, yielding an increase in performance.

Results and Discussion. On LR-XEL, `Prix-LM` achieves gains for all three languages over its base model XLM-R. Especially on MR, where XLM-R and mBERT are almost fully ineffective, `Prix-LM`

---

[9] XEL in our work refers only to entity mention *disambiguation*; it does not cover the mention detection subtask.

[10] A language-agnostic KB has universal interlingual concepts without being restricted to a specific language.

[11] Marathi (MR, an Indo-Aryan language spoken in Western India, written in Devanagari script), Lao (LO, a Kra-Dai language written in Lao script) and Telugu (TE, a Dravidian language spoken in southeastern India written in Telugu script).

leads to over 20% of absolute accuracy gain, again showing the effectiveness of incorporating multilingual structural knowledge. On LO, mBERT is slightly better than `Prix-LM`, but `Prix-LM` again yields gains over its base model: XLM-R. On XL-BEL, a large increase is again observed for almost all target languages (see `Prix-LM` (All) + Mirror). The only exception is English, where the model performance drops by 3.5%. This is likely to be a consequence of trading-off some of the extensive English knowledge when learning on multilingual triples. Beyond English, substantial improvements are obtained in other Indo-European languages including Spanish, German and Russian (+10-20%), stressing the necessity of knowledge injection even for high-resource languages. Like LP, we also experimented with `Prix-LM` trained with only monolingual data (see `Prix-LM` (Single) + Mirror). Except for English, very large boosts are obtained on all other languages when comparing All and Single models, confirming that multilingual training has provided substantial complementary knowledge.

3.4 Bilingual Lexicon Induction

(Short) Task Description. BLI aims to find a counterpart word or phrase in a target language. Similar to XEL, BLI can also evaluate how well a model can align a cross-lingual (entity) space.

Task Setup. We adopt the standard supervised embedding alignment setting (Glavaš et al., 2019) of VecMap (Artetxe et al., 2018) with 5k translation pairs reserved for training (i.e., for learning linear alignment maps) and additional 2k pairs for testing. The similarity metric is the standard cross-domain similarity local scaling (CSLS; Lample et al. 2018).[12] We experiment with six language pairs and report accuracy (i.e., *Hits@1*) and mean reciprocal rank (MRR).

Results and Discussion. The results are provided in Tab. 4. There are accuracy gains observed on 4/6 language pairs, while MRR improves for all pairs. These findings further confirm that `Prix-LM` in general learns better entity representations and improved cross-lingual entity space alignments.

3.5 Prompt-based Knowledge Probing

(Short) Task Description. LM-KP (Petroni et al., 2019) queries a PLM with (typically human-designed) prompts/templates such as *Dante was born in* __. (the answer should be *Florence*). It can be viewed as a type of KB completion since the queries and answers are converted from/into KB triples: in this case, {DANTE, `born-in`, FLORENCE}.

Task Setup. We probe how much knowledge a PLM contains in multiple languages relying on the multilingual LAnguage Model Analysis (mLAMA) benchmark (Kassner et al., 2021). To ensure a strictly fair comparison, we only compare XLM-R and `Prix-LM`. We exclude multi-token answers as they require multi-token decoding modules, which will be different for causal LMs like `Prix-LM` versus MLMs such as XLM-R. For both `Prix-LM` and XLM-R, we take the word with highest probability at the [MASK] token as the model's prediction. Punctuation, stop words, and incomplete WordPieces are filtered out from the vocabulary during prediction.[13]

Results and Discussion. Tab. 5 indicates that `Prix-LM` achieves better performance than XLM-R on mLAMA across all languages. We suspect that the benefits of `Prix-LM` training are twofold. First, multilingual knowledge is captured in the unified LM representation, which improves LM-KP as a knowledge-intensive task. The effect of this is particularly pronounced on low-resource languages such as FI, ET and HU, showing that transferring knowledge from other languages is effective. Second, the `Prix-LM` training on knowledge triples is essentially an *adaptive fine-tuning* step (Ruder, 2021) that exposes knowledge from the existing PLMs' weights. We will discuss this conjecture, among other analyses, in what follows.

3.6 Additional Analysis

Inconsistency of the Optimal Checkpoint across Tasks (Fig. 2). How many steps should we pretrain `Prix-LM` on knowledge triples? The plots in Fig. 2 reveal that the trend is different on tasks that require language understanding (mLAMA) versus tasks that require only entity representations (LP and XL-BEL). On mLAMA, `Prix-LM`'s performance increases initially and outperforms the base model (XLM-R, at step 0). However, after around 20k steps it starts to deteriorate. We speculate

---

[12] Note that the models are not fine-tuned but only their embeddings are used. Further, note that the word translation pairs in the BLI test sets have < 0.001% overlap with the cross-lingual links used in `Prix-LM` training.

[13] The exclusion of multi-token answers and also a customised set of non-essential tokens make our results incomparable with the original paper. However, this is a fair probing setup for comparing `Prix-LM` and XLM-R since they share the same tokenizer and their prediction candidate spaces will thus be the same.

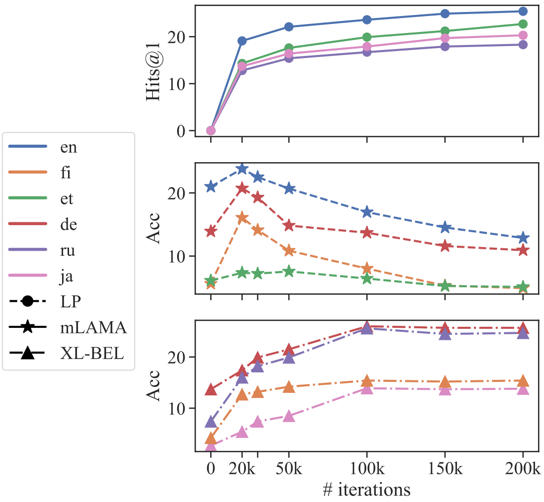

Figure 2: `Prix-LM` performance on LP, mLAMA, and XL-BEL over different checkpoints. Results of a sample of languages are shown for clarity.

that this might occur due to catastrophic forgetting, as mLAMA requires NLU capability to process queries formatted as natural language. Training on knowledge triples may expose the PLMs' capability of generating knowledge at the earlier training stages: this explains the steep increase from 0-20k iterations. However, training on knowledge triples for (too) long degrades the model's language understanding capability. On the other hand, longer training seems almost always beneficial for LP and XL-BEL: these tasks require only high-quality entity embeddings instead of understanding complete sentences. A nuanced difference between LP and XL-BEL is that `Prix-LM`'s performance on XL-BEL saturates after 100k-150k steps, while on LP the *Hits@1* score still increases at 200k steps.

Link Prediction on Unseen Entities (Tab. 6). KG embedding models such as RotatE require that entities in inference must be seen in training. However, the `Prix-LM` is able to derive (non-random) representations also for unseen entities. We evaluate this ability of `Prix-LM` on triples (s, r, o) where the subject entity s or object entity o is unseen during training. The results indicate that `Prix-LM` can generalize well also to unseen entities.

4 Related Work

Injecting Structured Knowledge into LMs. Conceptually, our work is most related to recent work on knowledge injection into PLMs. KnowBERT (Peters et al., 2019) connects entities in text and KGs via an entity linker and then recontextualizes BERT representations conditioned on the KG embeddings. KG-BERT (Yao et al., 2019) trains BERT directly on knowledge triples by linearizing their entities and relations into a sequence and predicting plausibility of the sequence. Wang et al. (2021a) improve KG-BERT by splitting a subject-relation-object knowledge triple into a subject-relation pair representation and an object entity representation, then modeling their similarities with a dual/Siamese neural network. Other work on knowledge injection such as K-BERT (Liu et al., 2020a) and ERNIE (Zhang et al., 2019) mainly aims to leverage external knowledge to improve on downstream NLU tasks instead of performing KG completion.

While prior studies have focused on incorporating monolingual (English) structured knowledge into PLMs, our work focuses on connecting knowledge in many languages, allowing knowledge in each language to be transferred and collectively enriched.

Multilingual LMs pretrained via MLM, such as mBERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020), cover 100+languages and are the starting point (i.e. initialization) of `Prix-LM`.[14] With the notable exception of Calixto et al. (2021) who rely on the prediction of Wikipedia hyperlinks as an auxiliary/intermediate task to improve XLM-R's multilingual representation space for cross-lingual transfer, there has not been any work on augmenting multilingual PLMs with structured knowledge. Previous work has indicated that off-the-shelf mBERT and XLM-R fail on knowledge-intensive multilingual NLP tasks such as entity linking and KG completion, and especially so for low-resource languages (Liu et al., 2021b). These are the crucial challenges addressed in this work.

KB Completion and Construction. Before PLMs, rule-based systems and multi-staged information extraction pipelines were typically used for automatic KB construction (Auer et al., 2007; Fabian et al., 2007; Hoffart et al., 2013; Dong et al., 2014). However, such methods require expensive human effort for rule or feature creation (Carlson et al., 2010; Vrandečić and Krötzsch, 2014), or they rely on (semi-)structured corpora with easy-to-

---

[14] We will explore autoregressive multilingual PLMs such as mBART (Liu et al., 2020b) and mT5 (Xue et al., 2021) in the future. While they adopt autoregressive training objectives at pretraining, it is non-trivial to extract high-quality embeddings from such encoder-decoder architectures, which is crucial for some tasks in automatic KB completion (e.g. XEL and BLI).

lang.→	EN	IT	DE	FR	FI	ET	TR	HU	JA	avg.
Hits@1	17.2	22.9	17.0	16.0	18.3	31.3	19.2	28.5	12.4	20.3

Hits@10	31.0	34.9	28.9	27.8	31.9	42.3	30.8	44.2	23.6	32.8

Table 6: LP scores of `Prix-LM` (All) on unseen entities.

consume formats (Lehmann et al., 2015). Petroni et al. (2019) showed that modern PLMs such as BERT could also be used as KBs: querying PLMs with fill-in-the-blank-style queries, a substantial amount of factual knowledge can be extracted. This in turn provides an efficient way to address the challenges of traditional KB methods. Jiang et al. (2020) and Kassner et al. (2021) extended the idea to extracting knowledge from multilingual PLMs.

Work in monolingual settings closest to ours is COMET (Bosselut et al., 2019): `Prix-LM` can be seen as an extension of this idea to multilingual and cross-lingual setups. `Prix-LM`'s crucial property is that it enables knowledge population by transferring complementary structured knowledge across languages. This can substantially enrich (limited) prior knowledge also in monolingual KBs.

In another line of work, multilingual KG embeddings (Chen et al., 2017, 2021; Sun et al., 2020a, 2021) were developed to support cross-KG knowledge alignment and link prediction. Such methods produce a unified embedding space that allows link prediction in a target KG based on the aligned prior knowledge in other KGs (Chen et al., 2020). Research on multilingual KG embeddings has made rapid progress recently, e.g., see the survey of Sun et al. (2020b). However, these methods focus on a closed-world scenario and are unable to leverage open-world knowledge from natural language texts. `Prix-LM` combines the best of both worlds and is able to capture and combine knowledge from (multilingual) KGs and multilingual texts.

5 Conclusion

We have proposed `Prix-LM`, a unified multilingual representation model that can capture, propagate and enrich knowledge in and from multilingual KBs. `Prix-LM` is trained via a casual LM objective, utilizing monolingual knowledge triples and cross-lingual links. It embeds knowledge from the KB in different languages into a shared representation space, which benefits transferring complementary knowledge between languages. We have run comprehensive experiments on 4 tasks relevant to KB construction, and 17 diverse languages, with performance gains that demonstrate the effectiveness and robustness of `Prix-LM` for automatic KB construction in multilingual setups. The code and the pretrained models will be available online at: `https://github.com/luka-group/prix-lm`.

Semantic Composition with PSHRG for Derivation Tree Reconstruction from Graph-Based Meaning Representations

Chun Hei Lo **Wai Lam** **Hong Cheng**
Department of Systems Engineering and Engineering Management
The Chinese University of Hong Kong
{chlo, wlam, hcheng}@se.cuhk.edu.hk

Abstract

We introduce a data-driven approach to generating derivation trees from meaning representation graphs with probabilistic synchronous hyperedge replacement grammar (PSHRG). SHRG has been used to produce meaning representation graphs from texts and syntax trees, but little is known about its viability on the reverse. In particular, we experiment on Dependency Minimal Recursion Semantics (DMRS) and adapt PSHRG as a formalism that approximates the semantic composition of DMRS graphs and simultaneously recovers the derivations that license the DMRS graphs. Consistent results are obtained as evaluated on a collection of annotated corpora. This work reveals the ability of PSHRG in formalizing a syntax–semantics interface, modelling compositional graph-to-tree translations, and channelling explainability to surface realization.

1 Introduction

General graph-based meaning representations (MRs) that model sentence-level semantics aim to provide interpretable intermediate representations that are application- and domain-independent (Koller et al., 2019). Recently, graph grammars and algebras that formalize semantic constructions were introduced to MR processing (for example: (Koller, 2015; Drewes and Jonsson, 2017; Groschwitz et al., 2017; Chen et al., 2018; Groschwitz et al., 2018; Lindemann et al., 2019; Donatelli et al., 2019; Chen and Sun, 2020)). These formal grammars bridge between linguistic assumptions and data-driven parsing, and offer the benefit of cross-framework adaptability. For instance, the Apply–Modify algebra was adopted in parsing across 5 MR frameworks (Oepen et al., 2019) (Lindemann et al., 2019; Donatelli et al., 2019). Another formalism that was adopted in generating semantic graphs from syntax trees is synchronous hyperedge replacement grammar (SHRG) (Peng et al., 2015; Chen et al., 2018; Chen and Sun, 2020). The use of SHRG in recovering syntax trees from MRs has however received scant research coverage. Empirical results of PSHRG's application are limited to Jones et al. (2012)'s work in semantic-based machine translation.

An immediate application of MR-to-tree parsing is surface realization. Previous data-driven approaches to it include rule-based (Flanigan et al., 2016; Song et al., 2017; Horvat, 2017; Ye et al., 2018) and neural methods (Song et al., 2018; Damonte and Cohen, 2019; Hajdik et al., 2019). All these methods do not generate syntactic analyses. In contrast, the Answer Constraint Engine (ACE; Carroll et al., 1999; Carroll and Oepen, 2005; Velldal and Oepen, 2006), an HPSG grammar-based parser, generates both derivations and sentences from Minimal Recursion Semantics (MRS; Copestake et al., 2005). If we can induce an SHRG from data, MRs can be translated into derivation trees without relying on a hand-engineered grammar, and natural language texts can be obtained by realizing the terminals. Combining the strengths of rule-based systems and the data-driven paradigm, such an approach gives both linguistically-informed realization processes and explainable results, removes syntactic ambiguities that would otherwise exist in flattened surface strings, and provides potential usage for downstream tasks such as chunking.

Among the different MR frameworks, we investigate Dependency Minimal Recursion Semantics (DMRS; Copestake, 2009). DMRS are directed graphs derived losslessly from MRS, whereas an MRS structure with respect to a reading of an English sentence is composed along with a derivation tree using the English Resource Grammar (ERG; Flickinger, 2000, 2011), a broad-coverage hand-engineered HPSG grammar of English. DMRS encodes logical formulae with underspecified scopes (for an introduction, see: Copestake, 2009). Fig. 1 shows an example of an ERG analysis.

Copestake et al. (2001) gave a compositional se-

$\_some\_q(x, \_boy\_n\_1(x), \_want\_v\_1(e_1, x, \_go\_v\_1(e_2, x))$

Figure 1: A DMRS (left), an HPSG derivation (right) that licenses the DMRS by an ERG analysis of the sentence *Some boys want to go*, and a scope-resolved representation of the DMRS with variables (bottom). Each DMRS node is aligned to the surface string as indicated by the colours. In the derivation, each preterminal is a lexical item, e.g., *_go_v1*, and each nonterminal above is labelled by a lexical or syntactic rule, e.g., *hd-cmp_u_c* denotes the head–complement construction. In a DMRS, each node is either a predicate corresponding to a lexeme (e.g., *_boy_n_1*) or a nonlexical predicate (e.g., *loc_nonsp*) (see Fig. 4). For ease of exposition, node attributes (e.g., number and tense) are not shown. The primary edge labels (e.g., ARG1) denote argument relationship, the secondary edge labels (e.g., /NEQ and /H) encode constraints on scopal relationships, and TOP specifies the top scopal non-quantifier node. Based on the scopal information in the DMRS, the bottom scope is the only scope possible.

mantic algebra on the constructions of MRS, where the introduced constraints allow the semantics of complex sentences to be derived from simple composition rules. The compositionality exhibited in the MRS (for a discussion, see: Bender et al., 2015) is not obvious in some other MRs, e.g., Abstract Meaning Representation (AMR; Banarescu et al., 2013) (Bender et al., 2015), and we suggest that HRG be particularly suitable to simulate the DMRS algebra if equipped with adequate adaptations.

In this paper, we shed light on the applicability of a succinct grammar formalism in approximating the semantic compositions of a graph-based MR. Essentially, we capture the syntax–semantics interface of the ERG by inducing a PSHRG from an annotated treebank to provide generative models for both DMRS graphs and derivation trees. With the induced PSHRG, derivation trees that license the DMRS graphs can be reconstructed through graph parsing. We describe the procedures and the relevant adaptations involved, from PSHRG induction, parsing to generating derivation trees. Finally, we present the empirical results on derivation trees and surface strings reconstruction from DMRS graphs under different configurations.

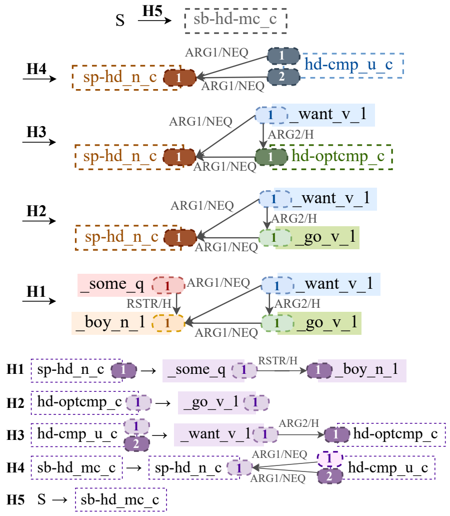

Figure 2: Derivation of an HRG for the hypergraph of DMRS in Fig. 1 using five productions **H5** to **H1** in order. A labelled rectangle represents a labelled hyperedge, where a hollow one represents a nonterminal. The numbered rounded rectangles attached to each hyperedge denote the ordered collection of nodes the hyperedge connects to, each of which corresponds to a DMRS node. A labelled arrow is a terminal hyperedge that connects to exactly two nodes and that corresponds to a DMRS edge. In an HRG production $A \longrightarrow R$, each external node of R is mapped to a node of the same colour in A. **H5** rewrites the start symbol to a hyperedge that connects to one node. Note that all nodes of **H4** are non-external nodes of the hypergraph fragment.

2 Probabilistic Synchronous Hyperedge Replacement Grammar

Hyperedge replacement grammar (HRG) is a context-free rewriting formalism for generating graphs (Drewes et al., 1997). A synchronous HRG (SHRG) defines mappings between languages of graphs, which in our context are an HRG and a context-free grammar (CFG) for strings. We give the definitions in this section.

Hypergraph and Hypergraph Fragments. A hypergraph is specified by a tuple $H = \langle V, E, l \rangle$, where V is a finite set of nodes, $E \subseteq V^+$ is a finite set of hyperedges, each of which connects one or more distinct nodes, $l : E \longrightarrow L$ assigns a label from the finite set L to each hyperedge. A hypergraph fragment is a tuple $R = \langle V, E, l, X \rangle$, where $\langle V, E, l \rangle$ is a hypergraph and $X \in V^+$ is an ordered list of distinct nodes called the external nodes.

HRG. An HRG is a tuple $G = \langle N, T, P, S \rangle$, where N and T are disjoint finite sets of nonterminal and terminal symbols respectively, P is a finite set of productions of the form $A \rightarrow R$, where $A \in N$ and R is a hypergraph fragment where hyperedge labels are over $N \cup T$, and $S \in N$ is the start symbol. In a step of rewriting a hyperedge e by a production $A \rightarrow R$, e is replaced with a copy of R by identifying each of the nodes connected by e with a distinct external node of R, whose mapping is specified in the production. Fig. 2 illustrates the HRG rewriting process.

Synchronous HRG. An SHRG is a tuple $G = \langle N, T, T', P, S \rangle$, where N is a finite set of nonterminal symbols in both the CFG and the HRG, T and T' are finite sets of terminal symbols in HRG and CFG respectively, $S \in N$ is the start symbol, and P is a finite set of productions of the form $A \rightarrow \langle R, R', \sim \rangle$, where R is a hypergraph fragment with hyperedge labels over $N \cup T$, R' is a symbol sequence over $N \cup T'$, and $\sim$ is a bijection between the nonterminal hyperedges of the same labels in R and R'. When applying a production $A \rightarrow \langle R, R', \sim \rangle$, $A \rightarrow R$ rewrites the graph as described in the HRG and the synchronous operation on the CFG counterpart is a string rewrite by $A \rightarrow R'$ (see Fig. 3).

Probabilistic SHRG. A probabilistic SHRG is obtained by assigning a constant probability to each production in the SHRG, where probabilities of the productions that rewrite the same nonterminal add up to one. In this work, the probability of $A \rightarrow \langle R, R', \sim \rangle$ is simply modelled as the fraction of times it appears among all $A \rightarrow *$ in the training data. The probability of a derivation is the product of the probabilities of the context-free SHRG productions applied.

3 PSHRG Induction and Parsing

In this section, we describe how a PSHRG is induced from training data and how a derivation tree is reconstructed from a DMRS of the test data with the induced grammar. We also describe two methods for modelling the semantics of lexical items.

DMRS as Hypergraph. We first establish the connections between DMRS and HRG. A DMRS graph is modelled as a hypergraph H with terminal hyperedges. In H, each terminal hyperedge corresponds to a DMRS node or edge: the former can connect to an arbitrary number of nodes in H, and the latter connects to only two nodes in H.

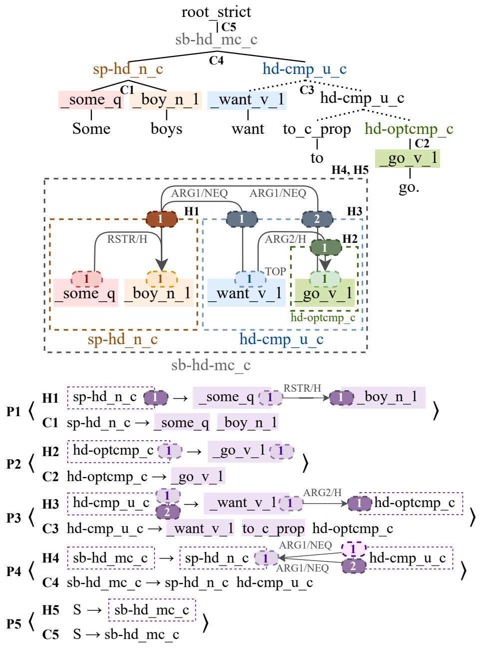

Figure 3: Illustration of the derivation, induction and parsing processes of an SHRG for the analysis in Fig. 1. At the top is the normalized derivation (see §4.1). Each SHRG production comprises one HRG and one CFG rule. During SHRG derivation, nonterminal hyperedges are rewritten by **H5** to **H1** and strings by **C5** to **C1** sequentially. During SHRG induction, synchronous rules **P1** to **P5** are extracted in order. During SHRG parsing, **H1** to **H5** are recognized in order, and **C1** to **C5** are applied synchronously. **P3** extracts (recovers) the subtree connected by dotted lines that contains the semantically empty word *to* during induction (parsing).

3.1 PSHRG Induction

We describe how to induce a PSHRG from pairs of aligned trees and graphs. The PSHRG induction procedure generally follows Chen et al. (2018)'s SHRG extraction algorithm, which operates based on the surface string alignment information between DMRS graphs and their derivation trees (for expositions, see: Chen et al., 2018). Fig. 3 illustrates the grammar induction process. For each nonterminal in the tree, i.e., a node labelled by an ERG syntactic construction (a label of the form **_c*, e.g., *hd-cmp_u_c*), a production $A \rightarrow \langle R, R', \sim \rangle$ is extracted, where A, R and R' are the ERG syntactic construction, connected DMRS hypergraph fragment and daughter ERG rule(s) respectively. For a binary ERG construction, if any of its daughters is a semantically empty terminal (e.g., for the lower *hd-cmp_u_c* in Fig. 3), no productions are extracted (discussed in §3.3.3). The DMRS hypergraph fragment specified by R is then rewritten to a nonterminal hyperedge labelled by A. We perform the same rule extraction procedure for each training instance to induce an SHRG from the training data, thus a PSHRG when we consider the frequency information.

3.2 PSHRG Parsing

To recover the derivation tree of a DMRS, we can translate the semantic compositions to the corresponding syntactic operations by parsing the DMRS with the induced PSHRG (see Fig. 3). We aim at recognizing the best derivation according to a PSHRG model, which requires exact graph parsing. Chiang et al. (2013); Groschwitz et al. (2015); Ye and Sun (2020) studied HRG parsing and proposed various techniques on improving the efficiency, but no evaluation on accuracy is performed on the parsed results with respect to a gold-standard grammar. Although efficient algorithms are developed for HRG parsing, existing parsers do not provide convenient adaptations to the extensions introduced in this work. Rather than efficiency, our work focuses on the correctness of derivations as measured against the original derivations that license each DMRS. Therefore, we implement a parser that returns the best PSHRG derivation of DMRS via bottom–up passive chart parsing (for details of the parsing algorithms, see Appendix A).

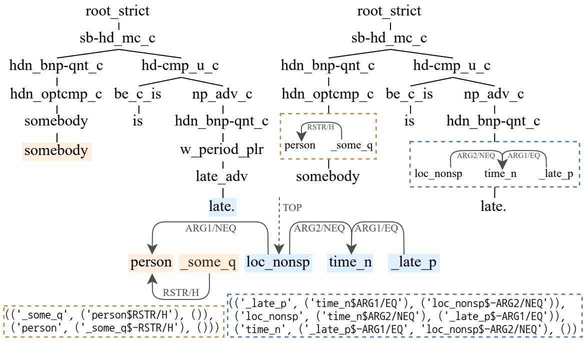
3.3 PSHRG Adaptations

We introduce two adaptations to align PSHRG with the semantics introduced by the ERG lexical items.

3.3.1 Semantics of Lexical Items

Complex semantics. While most lexical items introduce just one DMRS predicate each, some introduce more complex semantics. As an example, Fig. 4 shows that *somebody* provides both the *_some_q* quantifier and the *person* predicate. Therefore, the R.H.S. hypergraph fragment of an SHRG production is not confined to a hypergraph fragment with one or two terminal hyperedges, but one with more than two terminal hyperedges that corresponds to a connected DMRS subgraph.

Empty semantics. There are semantically empty lexical items that do not contribute predicates to the DMRS, e.g., auxiliary verbs and particles. This poses another challenge for derivation reconstruction because the syntactic properties of these lexical items are highly language-dependent, yet they are not captured by general semantic representations as they are not semantically functional.



```
(('_some_q', ('person$RSTR/H'), ()),
 ('person', ('_some_q$-RSTR/H'), ()))
```

```
(('_late_p', ('time_n$ARG1/EQ'), ('loc_nonsp$-ARG2/NEQ')),
 ('loc_nonsp', ('time_n$ARG2/NEQ'), ('_late_p$-ARG1/EQ')),
 ('time_n', ('_late_p$-ARG1/EQ', 'loc_nonsp$-ARG2/NEQ'), ()))
```

Figure 4: Canonization of two small subgraphs. The top left tree is the original derivation, where the terminals are aligned to DMRS nodes as indicated by the colour. The top right tree is the normalized derivation, where two preterminals are replaced by their DMRS subgraphs, each represented by its canonical form at the bottom.

3.3.2 Canonization of Small Subgraphs

To recognize complex semantics, we borrow the idea of the graph canonization method described by Horvat (2017) that isomorphic DMRS subgraphs can be identified by comparing if their canonical representations are the same. Graph canonization is achieved in two steps: first, each node in the DMRS subgraph is given a canonical node representation by encoding its 1- and 2-hop neighbours; then the final canonical form is obtained by concatenating the sorted node representations based on a canonical ordering. Most subgraphs introduced contain fewer than seven DMRS nodes, for which the canonization method is sound (Horvat, 2017). Fig. 4 exemplifies the idea.

During grammar induction, the canonical forms of all small subgraphs that correspond to ERG lexical items are extracted from the training data. Then, given a DMRS from the test data, we first identify its subgraphs that are isomorphic to any of the extracted ones before parsing. This is achieved by first enumerating all small subgraphs from the DMRS, then computing the canonical form for each of them, and finally comparing the canonical forms with those of the subgraphs extracted. The process can be sped up by computing the canonical form of a subgraph only if its collection of DMRS predicates is present in the set of those extracted from the training data.

3.3.3 Semantically Empty Lexical Items

We devise a semi-automatic method to extract (during grammar induction) and recover (during parsing) the syntax of common semantically empty words. To this set of words with empty semantics, we define a collection of linguistic signals that can serve as their cues, and match each signal to the set of lexical items it can recover. For example, the tense and aspects of verbs and predicative adjectives are signals for auxiliary verbs.

During SHRG induction, the signals are first identified from the DMRS node attributes and are then generally passed up from the syntactic head daughter. When extracting a binary construction, if the unextracted subtree (described in §3.1) contains a semantically empty lexical item that matches a signal of any of the daughters, a hypergraph fragment is extracted together with the subtree associated with that signal. During parsing, the same bottom–up signal passing procedures apply. If the R.H.S. hypergraph fragment of a binary production is recognized and any signal passed up matches that of an extracted subtree, the HRG production is applied and the CFG subtree is added on top of the two daughters in the derivation tree (see Fig. 3).

4 Towards Practical Grammar Approximation and Modelling

To approximate complex grammars or implicit relations established between trees and graphs by PSHRG, we introduce extensions for improving on both the precision and generalizability of modelling. The application of most of the proposed techniques is not limited to the DMRS, but to general MR parsing by PSHRG.

4.1 Annotations for Refining Compositions

Three techniques are introduced to impose restrictions to semantic compositions, allow probability to be estimated on more fine-grained SHRG productions, and prevent overgeneration.

Typed HRG. Chen and Sun (2020) introduced typed HRG, where each node of a hypergraph (fragment) and hyperedge is assigned a label chosen from a finite set. In typed HRG, an R.H.S. hypergraph fragment is recognized only if the type of its every node matches that of the corresponding node in the input graph. In our case, we propose to type a node by the major sense tag of the corresponding DMRS predicate. For example, in Fig. 5, the nodes on the R.H.S. correspond to *_want_v_1* and *_go_v_1* respectively, so both are typed *v*.

Annotation and Normalization of Derivation. An HPSG derivation tree merely records the recipe of a derivation, where the non-atomic rule symbols only convey highly generalized linguistic principles. Each rule represents a unification of typed feature structures. Inspired by Zhang and Krieger (2011), we annotate each syntactic construction with that of their immediate parent (order-2 vertical markovization) and the syntactic category of the phrase (see Fig. 5). This adds extra contextual information to the constituents. We further normalize the derivations by substituting chains of unary lexical rules, affixation rules for punctuation marks, and the preterminals by the canonical form of a DMRS node or subgraph (see Fig. 4).

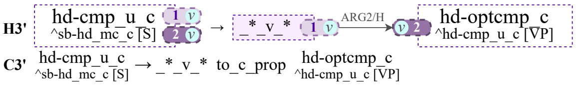


Figure 5: **P3** in Fig. 3 with annotated syntactic constructions, typed nodes and a delexicalized DMRS predicate.

Framework-Specific Constraints. PSHRG Parsing on DMRS without regard for the MRS semantic algebra leads to inefficiency and overgeneration. In particular, the features INDEX and LTOP in MRS specify the semantic materials of a phrase that are accessible during composition. In the ERG, their values are determined by the type of composition.[1] Hence, when parsing a DMRS, every composition should ensure that subsequent compositions can only happen to the two variables of the newly composed item. This procedure resembles Carroll and Oepen (2005)'s proposal on index accessibility filtering. The checks can be easily incorporated into SHRG parsing (for the details, see Appendix B). Nevertheless, INDEX and LTOP are not the only features that permit compositions in the ERG. Therefore, the constraints introduced prevent overgeneration to a large extent but lead to undergeneration. In this work, we examine the two most prominent features, and how we should further integrate the MRS algebra to HRG is an open question.

4.2 Underspecification for Generalization

Two underspecification methods are developed to alleviate the rule sparsity and out-of-vocabulary (OOV) problems, which are the main challenges faced by general rule-based systems.

---

[1] The precise algebras of the two features in the ERG are not discussed fully here. In brief, the INDEX and the LTOP usually come from the syntactic head, but come from a scopal modifier if the semantic composition is scopal. For expositions, see: Copestake et al. (2001); Copestake (2009).

Extended HRG Productions. When recognizing an HRG production $A \rightarrow R$ on a hypergraph H, we suggest that the external nodes of R be not distinguished from the non-external nodes. Consequently, the rewriting hyperedge A connects to a variable number of nodes, and such number depends on H. To motivate such decision, consider **H1** of Fig. 3. The fact that the hyperedge *_boy_n_1* connects to an external node is not significant to the characterization of the *sp-hd_n_c* (the specifier–head construction where the specifier is the semantic head). This effectively creates more SHRG productions that share the same probabilities if their R.H.S. hypergraphs (minus external nodes) are identical.

Delexicalization. The PSHRG models are estimated based on delexicalized productions: the lexeme stems of verbs, adjectives, adverbs, and nouns (whose DMRS predicates are in the form of '_*_*v*_*', '_*_*a*_*' and '_*_*n*_*' respectively) are underspecified (see Fig. 5). This is a significant distinction between our grammar and the ERG since the ERG is highly lexicalized.[2] Hence, delexicalization trades lexical preciseness for OOV coverage. Furthermore, since an approximation grammar is assumed to have no access to the lexical information of the underlying grammar, the results of our experiments would reflect the viability of PSHRG as a general approach to grammar approximation.

5 Experiments

The main objective of the experiments is to assess the performance of PSHRG models on simulating DMRS compositions and producing approximating derivation trees. Specifically, we reconstruct a derivation tree for each DMRS whose nonterminals are aligned to DMRS subgraphs and labelled by an ERG syntactic construction; the ERG 1214 contains more than 210 fine-grained syntactic constructions that reflect the distinguishing properties of different syntactic constructions.

As a secondary evaluation, we analyze our performance on the task of surface realization. The purpose of this is twofold: first, assessing the quality of the surface strings produced from the reconstructed derivation trees gives additional perspectives on the evaluation of our models; and secondly, there are existing works on surface realization from DMRS, so our models can be benchmarked against.

Finally, we evaluate the significance of the two proposed adaptations, namely recovering words with empty semantics and incorporating framework-specific constraints to PSHRG parsing. An instance of sample input and sample output are provided in Appendix C.

5.1 Data

The main data set we experiment on is the Ninth Growth of the Redwoods Treebank (Oepen et al., 2002).[3] It contains English sentences from a range of domains including Wall Street Journal (WSJ) and the Brown corpus, each paired with the analyses of the 1214 version of the ERG. Each MRS is converted into a DMRS using Pydelphin (Copestake et al., 2016).[4] We discard the instances with ambiguous analysis, disconnected DMRS, and unparsable MRS by Pydelphin.

To assess the scalability of our models, we further sampled sentences from the Gigaword v.5 corpus (Parker et al., 2011) for model training, where extra training instances are obtained by parsing sentences with the ACE and choosing the best ERG analysis for each sentence as ranked by the ACE.

After preprocessing, the total number of instances in the training and test sets are 70,774 and 10,042 respectively under the standard Redwoods data split. 70,774 extra training instances are created from the Gigaword corpus.

5.2 Experimental Configurations

We removed the mostly uninformative syntactically covert quantifiers (e.g., *udef_q*, *proper_q*) in all DMRS graphs. The numbers of DMRS nodes reported below are counted after the removal. Subgraph canonization (§3.3.2) was performed only on the DMRS subgraphs of fewer than seven nodes. The maximum length of the unary chains in the generated derivation trees was set to be three. The parser was implemented in PyPy3.6 and ran under one Intel Xeon E5-2697 CPU on x86_64 Linux. Our implementation is available online.[5]

---

[2] Each lexical entry in the ERG is assigned to exactly one lexical type, which determines most of its syntactic and semantic properties. For example, *inform*, *advise* and *remind* share a lexical type because they all select a noun phrase and a sentential complement. The detailed lexical types interact with the highly generalized linguistic principles to produce precise linguistic interpretations.

Table 1: Results on the accuracy of derivation reconstruction under standard Redwoods data split.

5.3 Results

5.3.1 On Derivation Tree Reconstruction

If a DMRS is parsed correctly, the synchronously reconstructed derivation should not deviate too much from the original derivation. Nevertheless, equivalence is a sufficient, but not necessary condition for a parse to be correct since syntactic differences do not necessarily contribute to semantic differences.

We devise a modified version of the ParsEval (Black et al., 1991) measure, ParsEval-Graph, to assess the quality of the generated trees, as the constituents of the trees are not aligned to a surface string but on the input semantics. In ParsEval-Graph, the alignment of a constituent refers to the DMRS nodes covered instead of the characters covered in the surface string. Following ParsEval, ParsEval-Graph only accounts for binary rules, and preterminals are disregarded. All ParsEval-Graph scores are evaluated on the parsable instances of the respective models on unannotated derivation trees.

As introduced in §4.1, we experiment with the typed variant of PSHRG, PSTHRG, and two configurations of tree annotation, namely order-2 vertical markovization with syntactic category annotation (M2C), and only syntactic category annotation (M1C). Since no existing works on data-driven DMRS parsing or surface realization produce syntactic derivations, we develop a baseline model SHRG–PCFG for benchmarking. SHRG–PCFG parses a DMRS with the SHRG induced and the probability of each parse is given by a PCFG model where the probability of each CFG production $A \rightarrow R'$ is modelled as the fraction of times $A \rightarrow R'$ appears among all $A \rightarrow *$ in the training data. The ACE is not evaluated because it always generates derivations faithful to the ERG.

As reported in Table 1, all PSHRG models attain F_1 scores of over 80 consistently across settings and outperform the baseline under the same annotation configurations. More extensive annotation and typing the grammar respectively improve the F_1 score by about 2, at the expense of coverage reduction caused by rule sparsity when the Redwoods training set does not provide adequate data for the over-specific annotation. It is insightful to note that the baseline under M2C performs at a level between the PSHRG model and PSTHRG model on M1C, which conveys that the contextual information of a nonterminal node could already provide ample information on the semantic compositions.

Model	Training Set	ParsEval-Graph			Coverage
		P	R	F_1	
PSHRG (M1C)	Redwoods	81.86	79.85	80.84	80.58%
	Redwoods + Gigaword	81.60	79.66	80.62	85.11%
PSTHRG (M1C)	Redwoods	83.81	81.23	82.50	74.31%
	Redwoods + Gigaword	83.39	80.85	82.10	80.62%

Table 2: Results on derivation reconstruction on the Redwoods test set with different training sets.

To study models' performance with respect to the size of the training data, we add the Gigaword instances on top of the Redwoods training set. This doubles the amount of training data. As reported in Table 2, the coverages of the two models increase by 4.50% and 6.31% respectively with more data. Nevertheless, the accuracy of derivations does not improve further, as frequency-based context-free probability models have low learning capacities.

Despite all DMRS being generated by the ERG, the ACE does not parse every DMRS–parsing fails when a DMRS predicate is OOV. In contrast, our models parse more instances than the ACE when given more training data, since they generalize to OOV with delexicalization. Although delexicalization removes much lexical information, we suggest that SHRG-based parsing and the incorporation of MRS-specific constraints can restrict compositions outside of the ERG to a large extent.

5.3.2 On Surface Realization

To produce a surface string from a DMRS, we realize the most frequently recorded surface form for each preterminal from the reconstructed derivation tree. We compare our work with the Neural MRS (Hajdik et al., 2019) and the ACE. The Neural MRS generates in an end-to-end manner without intermediate syntactic derivations. For more comparable results, we evaluate the models under M1C annotation configuration since they have similar parse

Model	BLEU			Generate Syntactic Structures
	Redwoods	WSJ	Brown	
Neural MRS	66.11	65.78	45.00	No
ACE (ERG)	62.21	-	-	Yes
PSHRG (M1C)	59.33	63.65	58.29	Yes
PSTHRG (M1C)	60.67	64.77	59.47	Yes

Table 3: Results on surface realization. Redwoods, WSJ and Brown refer to the Redwoods standard splits, WSJ–WSJ and WSJ–Brown splits respectively.

[Sys]	Earlier this year bankers and other investors were willing to provide financing because they assumed that it would be major gains in profitability and sales, added Mr. Rosenthal.

Table 4: Examples of syntactic variations demonstrated in the generated texts. In the first example, the canonical subject–verb order is recovered when the original text is an inverted sentence. In the second example, inversion is preserved and preposition fronting is adopted instead of stranding as in the reference sentence (see Fig. 8 of Appendix C). The third example reflects multiple linguistic variations, including the insertion of complementizer *that*, omission of semantically empty *both* and quotative subject–verb inversion .

coverages to the ACE.

We evaluate the generation quality with BLEU (Papineni et al., 2002) using SacreBLEU (Post, 2018)[6]. Following (Hajdik et al., 2019)'s evaluation on in- and out-of-domain performances, we experiment on the different training–test data splits, namely the WSJ–WSJ and WSJ–Brown splits. WSJ contains 34,751 training instances and 1,442 test instances, and Brown contains 2,181 test instances.[7] All BLEU scores are evaluated on the parsable instances of the respective models.

Table 3 shows that our models perform consistently across data splits. Under the Redwoods standard data split, our models are worse than the neural model. With similar parse coverages to the ACE, our performance is also close to the ACE. Under the WSJ-Brown split, our PSHRG models outperform the Neural MRS.[8] The PSHRG (M1C) parses 74.90% of the test set under the WSJ–WSJ split. When the model is typed and when switching from in- to out-of-domain, the models parse about 7% less data respectively. The coverages of M1C models reported here are lower than those in Table 1 since the amount of training data is halved. Therefore, we consider the relative decreases in coverage from in- to out-of-domain of our respective models to be more insightful on models' transferability between domains than the absolute coverage.

Apart from the automatic evaluation, we also value qualitative details and seek linguistically interesting phenomena that result from a grammar-based approach. To this end, we observe that our models identify different realization possibilities from the original sentence to the same semantics that conform to the ERG. Some syntactic variations are reported and explained in Table 4.

Compared to neural approaches, PSHRG is a shallow statistical model with a high inductive bias. It encodes a syntax–semantics interface effectively through tree- and graph- rewriting. Even though our models are not engineered towards the task of surface realization, and with limited morphological analyses and no language modelling, our approach is still competitive as evaluated quantitatively and qualitatively. We suggest that PSHRG-based approaches and neural models be decent alternatives to each other for general surface realization from MR: neural models provide full-coverage and high-quality generation when substantial training data is available, whereas PSHRG-based solutions extrapolate from limited data and in out-of-domain scenarios, and produce interpretable derivations.

5.3.3 Ablation Studies

We conduct a few more experiments to test against the significance of two proposed adaptations, namely the solution to semantically empty words (§3.3.3) and framework-specific constraints (§4.1). We implement two models, PSTHRG-$\varnothing$ (M1C) and PSTHRG-λ (M1C), which parse DMRS without regard for semantically empty lexical items and MRS constraints respectively.

As reported in Table 5, The treatment of empty semantics not only adds 15.51% more parsable instances but also corrects some parses in the 58.80% that require analyses of empty semantics, thus pro-

---

[6] `https://github.com/mjpost/sacreBLEU`

[7] The numbers of training and test instances of Neural MRS are slightly greater than ours after respective preprocessing.

[8] To provide context on assessing our model under a full-coverage scenario, we try to provide a naive fallback for the unparsable instances: For each of these instances, the partially realized non-overlapping constituents are concatenated in order of decreasing number of the DMRS nodes covered to form the final sentence. With this quick fix, our PSHRG (M1C) model attains a BLEU score of 51.08 on the WSJ–Brown split.

Model	ParsEval-Graph			BLEU	Coverage
	P	R	F_1

Table 6: Results of ablation of framework-specific constraints on derivation reconstruction and surface realization qualities under the WSJ-WSJ split.

Fig. 6 shows the importance of MRS constraints on parsing efficiency. We set a time limit of 300 seconds on parsing, and the parsing of 16.71% of the WSJ test set exceeds the time limit. When the DMRS contains 24 or more nodes, timeouts occur on at least one DMRS graph of each size. Table 6 shows that when the constraints are enforced, all parses are completed in much shorter times and the derivations reconstructed are more accurate.

6 Discussion

The proposed frequency-based PSHRG models are simple yet competitive data-driven baselines for recovering derivations of DMRS. They can be further combined with sophisticated machine learning methods for a more accurate parse ranking. More extensive features can also be included to enhance grammar approximation. For instance, the feature-paths of ERG signs are shown to be helpful for PCFG approximation (Zhang and Krieger, 2011). Language-specific knowledge about words with empty semantics is also critical for syntactic purposes. In terms of efficiency, Ye and Sun (2020) showed that exact parsing can be very practical on Elementary Dependency Structures (EDS; Oepen and Lønning, 2006), a close equivalent to DMRS that excludes scopal information. Different from Ye and Sun (2020)'s implementation, we retain more than 210 ERG syntactic constructions for precision and adopt delexicalization for generalization, both of which increase the search space of parsing and trade efficiency. We suggest that the described PSHRG-based approach can be a potential alternative to the unification-based ACE generator for surface realization from DMRS, whilst improving parsing coverage, accuracy and efficiency without sacrificing one another would be a critical problem for future research. In this paper, we report our findings with respect to the engineering decisions we investigated based on the data at hand.

In principle, the application of the described PSHRG-based approach is not limited to DMRS, but also to generic graph-to-tree translations that exhibit compositionality, if suitable data of aligned trees and graphs is available. If explicit associations do not exist between the trees and graphs, the induced grammar formalizes the underlying relations and patterns; otherwise, the induced grammar provides an approximation to such relations, which can be desirable for computation purposes.

7 Conclusion

Based on the experimental results, we can assess the contributions of this work from three perspectives: (1) PSHRG with framework-specific adaptions as a formalism that approximates the semantic composition process of DMRS, (2) PSHRG graph parsing with framework-independent extensions as a general approach to modelling compositional graph-to-tree translation, and (3) derivation reconstruction with a PSHRG induced from data as a solution to surface realization from MRs that provides explainability, syntactic disambiguation, and syntactic variations. We hope that this work provides relevant and substantial empirical insights to stimulate more research on approaching MR processing with linguistically-motivated methods.

A A Passive Chart Parser

Although it is not the intent of this work to suggest a new HRG parsing algorithm, we provide more information on the parser implemented so that it provides more context for comprehending the absolute parsing time in Fig. 6.

A.1 Rewriting DMRS Hypergraph

As described in §3, a hypergraph can be instantiated corresponding to a DMRS. During SHRG parsing, the hypergraph undergoes graph-rewriting, where its subgraphs are rewritten by nonterminal hyperedges, and produces other hypergraphs.

For every hypergraph H, we categorize every hyperedge into one of the two types, s-hyperedge or c-hyperedge. An s-hyperedge is a terminal hyperedge that is identified and labelled by a DMRS edge. It connects to exactly two nodes of H. A c-hyperedge corresponds to a node or a connected DMRS subgraph. A terminal c-hyperedge is labelled by a DMRS predicate. A nonterminal c-hyperedge is labelled by the canonical form of a DMRS subgraph (see §3.3.2) or an ERG syntactic construction.

A.2 Representation of Chart Items

In our chart parser, a passive item is essentially a c-hyperedge packed with additional information. It is represented by $M = \langle Y, A, \Sigma \rangle$, where Y is the set of DMRS nodes covered by the item, A is the c-hyperedge label and Σ is the set of s-hyperedges incident to the item. In a passive item $M = \langle Y, A, \Sigma \rangle$, each of the s-hyperedges $\sigma \in \Sigma$ is represented by $\sigma = \langle s, t, k, d, x \rangle$, where s, t, k represent the source and target DMRS node, and the key of the edge. These three variables together specify a unique edge in a DMRS multigraph; d is a boolean variable indicating if the DMRS edge $\langle s, t, k \rangle$ is an outgoing edge from the c-hyperedge and $x \in \mathbb{Z}^+$ specifies the order of the node of the c-hyperedge this s-hyperedge connects to. Fig. 7 illustrates three example passive items.

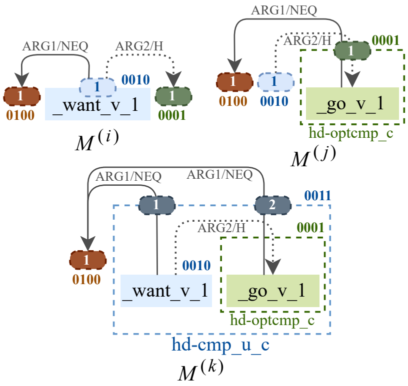

Figure 7: Example of an application of a binary rule on two passive items $M^{(i)}$ and $M^{(j)}$ to compose the item $M^{(k)}$. With respect to $M^{(i)}$ and $M^{(j)}$, the interior s-hyperedges are represented by dotted arrows and the exterior s-hyperedges by solid arrows. The bit vectors on the top right corner of each c-hyperedge indicate sets of DMRS nodes the passive item covers.

Algorithm 1 shows the high-level procedures of a minimal PSHRG parsing algorithm for DMRS. It only includes the application of unary and binary rules without constructional content[9] and semantically empty words. The synchronous CFG part is also omitted for simplicity. It parses a DMRS D given a PSHRG G with production probabilities π and returns the best parse. Z is the set of the small subgraphs extracted from training data.

A.3 Bottom–Up Parsing

Line 3 of Algorithm 1. We first initialize the adjacency information of each DMRS node. α maps a set of DMRS nodes to the set of their adjacent nodes. A DMRS node set of size n is represented by an n-hot bit vector. N_D returns the neighbour-

---

[9] Some ERG constructions introduce semantic content (DMRS predicates) that interact with the daughter's semantic materials to the resulting MRS structure.

Algorithm 1: A minimal PSHRG parsing algorithm for DMRS.

```
1  Function Parse($G = \langle N, T, T', P, S, \pi \rangle, D, Z$)
2      $C_{\text{new}} \leftarrow \{\}$;
3      for $v \in V(D)$ do $\alpha(\{v\}) \leftarrow N_D(v)$;
4      for $Y \subseteq V(D) \mid |Y| < 7$ do
5          if $|Y| = 1 \wedge \varphi_D(Y) \in T$ then
6              $A \leftarrow \varphi_D(Y)$;
7              $\Sigma \leftarrow \{\}$;
8              for $\langle s, t, k \rangle \in E(D) \mid (s \in Y \oplus t \in Y)$
                 do
9                  $\sigma \leftarrow \langle s, t, k, [\![ s \in Y ]\!], 1 \rangle$;
10                 $\Sigma \leftarrow \Sigma \cup \sigma$;
11         else if $|Y| > 1 \wedge D[Y] \in Z$ then
12             $A, \Sigma \leftarrow$ Canonize($D[Y]$);
13             $\alpha(Y) \leftarrow$ And($N_D(Y)$, Not($Y$));
14         $M \leftarrow \langle Y, A, \Sigma \rangle$;
15         $C_{\text{new}} \leftarrow C_{\text{new}} \cup M$;
16         $p_{\log}(M) \leftarrow 0$;
17     $C_S \leftarrow \{\}$;
18     $R_G \leftarrow \{R \mid A \rightarrow \langle R, R', \sim \rangle \in P\}$;
19     $R'_G \leftarrow \{R' \mid A \rightarrow \langle R, R', \sim \rangle \in P\}$;
20     while $C_{\text{new}} \neq \emptyset$ do
21         $C_{\text{unary}}, p_{\log} \leftarrow$
             ApplyUnary($P, \pi, C_{\text{new}}, p_{\log}$);
22         $C_{\text{new}} \leftarrow C_{\text{new}} \cup C_{\text{unary}}$;
23         $C_S \leftarrow C_S \cup \{\langle Y, A, \Sigma \rangle \in C_{\text{all}} \mid$
             $Y = V(D) \wedge A = S\}$;
24         $C_{\text{all}} \leftarrow C_{\text{all}} \cup C_{\text{new}}$;
25         $C_{\text{binary}}, p_{\log}, \alpha \leftarrow$ ApplyBinary(
             $P, \pi, D, C_{\text{new}}, C_{\text{all}}, p_{\log}, \alpha, R_G, R'_G$);
26         $C_{\text{new}} \leftarrow C_{\text{binary}}$;
27     return $\arg\max_{M \in C_S} p_{\log}(M)$;
```

hood of a set of nodes in D.

Line 4 to 16 of Algorithm 1. In this section, we instantiate passive items for the terminal c-hyperedges which correspond to a DMRS node, and for the nonterminal c-hyperedges which correspond to a connected DMRS subgraph of fewer than seven nodes. $V(D)$ and $E(D)$ denote the sets of DMRS nodes and edges in D respectively. $\varphi_D(Y)$ returns the DMRS predicate of the unit set Y in D. For a recognized terminal, we compute the incident s-hyperedges Σ of it. CANONIZE returns A, the canonical form, and Σ, the incident s-hyperedges of $D[Y]$, where $D[Y]$ is the node-induced subgraph formed by the node set Y. The node order of the s-hyperedges in Σ follows the order of the corresponding node representation in the canonical form. The procedures of obtaining Σ here is similar to those described at line 7 to 10 and are omitted. Line 13 updates the adjacency information of Y (for the detailed procedure, refer to line 16 of Algorithm 2). Then, a passive item $M = \langle Y, A, \Sigma \rangle$ is created and added to the chart. $p_{\log}(M)$ maps the passive item M to the highest possible log probability of M at that instant.

Line 20 to 27 of Algorithm 1. Given the extracted SHRG productions P, new items are created by applying unary rules to the passive items just created (APPLYUNARY), then binary rules between all the new passive items and their respective adjacent passive items (APPLYBINARY). These two steps are iterated repeatedly until no more passive items are created. Line 22 records the successful parses, i.e. the items that cover all DMRS nodes and whose c-hyperedge label equals the start symbol S of G. Finally, the successful parse with the highest log probability is returned.

A.4 Grammar Intersection

The grammar intersection of an HRG is similar to that of a CFG for strings in the CYK algorithm. where neighbouring constituents are combined to form new passive items. Algorithm 2 describes the generation of new passive items via binary rules (Line 24 of Algorithm 1).

For a set of passive items, we further define the following: the common incident s-hyperedges are called interior s-hyperedges; and the remaining s-hyperedges are called exterior s-hyperedges, which connect to other c-hyperedges in the subsequent rewriting steps (for an illustration, see Fig. 7).

Line 3 of Algorithm 2. Grammar intersection is performed only on the adjacent passive items (there exists at least one s-hyperedge that connects them) that cover disjoint sets of DMRS nodes. For efficiency, all passive items are indexed by Y, so that validating adjacency and disjointness of DMRS subgraphs can be manipulated by quick bitwise operations to return the pairs of items possible for grammar intersection. All items covering Y are further indexed by A so that we only consider the pairs of items whose labels exist in the set of the CFG daughter sequences of productions, R'_G.

Line 4 to 7 of Algorithm 2. For each pair of passive items in $C_\cap$, we try to generate possible new passive items. Line 5 first computes the union of set of DMRS nodes covered by the two items. Then, the interior s-hyperedges of the new passive item are computed at line 6. As the notion of external nodes is dropped when we match an R.H.S. hypergraph fragment R (see §4.2), the recognition only requires the identification of the set of c-hyperedges in R plus the interior s-hyperedges.

Algorithm 2: Generation of passive items with binary rules.

```
1  Function ApplyBinary($P, \pi, D, C_{\text{new}}, C_{\text{all}}, p_{\text{log}}, \alpha, R_G, R'_G$)
2      $C_{\text{binary}} \leftarrow \{\}$;
3      $C_\cap \leftarrow \{\langle\langle Y^{(i)}, A^{(i)}, \Sigma^{(i)}\rangle, \langle Y^{(j)}, A^{(j)}, \Sigma^{(j)}\rangle\rangle \in C_{\text{new}} \times C_{\text{all}} \mid$
         $(\textsc{And}(Y^{(i)}, Y^{(j)}) = 0 \wedge \textsc{And}(\alpha(Y^{(i)}, Y^{(j)}) \neq 0 \wedge (\langle A^{(i)}, A^{(j)}\rangle \in R'_G \vee \langle A^{(j)}, A^{(i)}\rangle \in R'_G))\}$;
4      for $\langle\langle Y^{(i)}, A^{(i)}, \Sigma^{(i)}\rangle, \langle Y^{(j)}, A^{(j)}, \Sigma^{(j)}\rangle\rangle \in C_\cap$ do
5          $Y^{(k)} \leftarrow \textsc{Or}(Y^{(i)}, Y^{(j)})$;
6          $I^{(k)} \leftarrow \textsc{GetInteriorS-Hyperedges}(\Sigma^{(i)}, \Sigma^{(j)})$;
7          $H^{(k)} \leftarrow \textsc{GetHypergraph}(A^{(i)}, A^{(j)}, I^{(k)})$;
8          if $H^{(k)} \in R_G$ then
9              $\Sigma^{(k)} \leftarrow \textsc{GetExteriorS-Hyperedges}(\Sigma^{(i)}, \Sigma^{(j)})$;
10             for $A \rightarrow \langle R, R', \sim\rangle \in P \mid (R = H^{(k)} \wedge \textsc{IsValidComposition}(D, I^{(k)}, \Sigma^{(k)}, A))$ do
11                 $M^{(k)} \leftarrow \langle Y^{(k)}, A, \Sigma^{(k)}\rangle$;
12                 $\hat{p} \leftarrow p_{\text{log}}(\langle Y^{(i)}, A^{(i)}, \Sigma^{(i)}\rangle) + p_{\text{log}}(\langle Y^{(j)}, A^{(j)}, \Sigma^{(j)}\rangle) + \log(\pi(A \rightarrow \langle H^{(k)}, R', \sim\rangle))$;
13                 if $M^{(k)} \in C_{\text{binary}} \cup C_{\text{all}}$ then
14                     $p_{\text{log}}(M^{(k)}) \leftarrow \max(\hat{p}, p_{\text{log}}(M^{(k)}))$;
15                 else
16                     $p_{\text{log}}(M^{(k)}) \leftarrow \hat{p}$;
17                     $\alpha(Y^{(k)}) \leftarrow \textsc{And}(\textsc{Or}(\alpha(Y^{(i)}), \alpha(Y^{(j)})), \textsc{Not}(Y^{(k)}))$;
18                     $C_{\text{binary}} \leftarrow C_{\text{binary}} \cup M^{(k)}$;
19     return $C_{\text{binary}}, p_{\text{log}}, \alpha$;
```

Thus, the hypergraph $H^{(k)}$ is obtained at line 7 simply by gluing the two c-hyperedges with the interior s-hyperedges.

Line 8 to 18 of Algorithm 2. If the hypergraph obtained at line 8 appeared on the R.H.S of any production in P (line 8), we proceed to compute the exterior s-hyperedges of the new passive item (line 9). Line 10 searches for the productions of G whose (1) R.H.S. hypergraph is $H^{(k)}$ and (2) rewriting syntactic construction A licenses a valid composition (see §4.1; for the detailed procedures, see Appendix B). Line 11 to 13 factor local ambiguities; if we wish to extend the algorithm to obtain k-best derivations, we just keep the k-best hypotheses instead of the 1-best. Line 16 updates the adjacency information of $Y^{(k)}$ through bitwise operations. Finally, the newly generated passive items, the updated log probabilities, and the adjacency map are returned.

B MRS-Specific Constraints in HRG parsing

We describe how the MRS-specific constraints introduced in §4.1 can be incorporated into HRG parsing. In general, the accessibility check amounts to validating the following conditions for each c-hyperedge e in the R.H.S. hypergraph fragment when composing a new c-hyperedge a: (1) if e is not the INDEX of a, it is not the INDEX of the DMRS, and no s-hyperedges of type /EQ or /NEQ outside a are connected to e, and (2) if the scope of e, l, is not the LTOP of a, l is not the TOP of the DMRS, and no s-hyperedges of type /H, /HEQ or /EQ outside a are connected to e. By scanning the interior s-hyperedges once, we can decide on the new LTOP, and by scanning the exterior s-hyperedges once, we can verify the accessibility of both variables. Our implementation excludes the check of /NEQ edges due to undergeneration as described in §4.1.

C Sample Input and Output

Fig. 8 shows an instance of sample input and output compared against the original derivation. The model used to produce the results is PSTHRG (M1C) trained on the Redwoods training data.

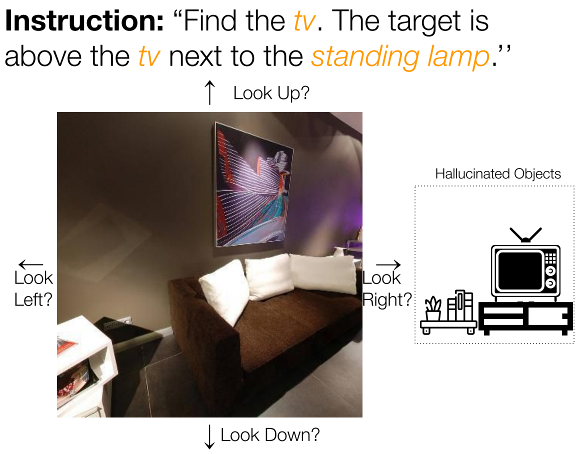
Abstract

AI systems embodied in the physical world face a fundamental challenge of partial observability; operating with only a limited view and knowledge of the environment. This creates challenges when AI systems try to reason about language and its relationship with the environment: objects referred to through language (e.g. giving many instructions) are *not immediately visible*. Actions by the AI system may be required to bring these objects in view. A good benchmark to study this challenge is Dynamic Referring Expression Recognition (`dRER`) task where the goal is to find a target location by dynamically adjusting the field of view (FoV) in a partially observed 360° scenes. In this paper, we introduce HOLM, **H**allucinating **O**bjects with **L**anguage **M**odels, to address the challenge of partial observability. HOLM uses large pre-trained language models (LMs) to infer object hallucinations for the unobserved part of the environment. Our core intuition is that if a pair of objects co-appear in an environment frequently, our usage of language should reflect this fact about the world. Based on this intuition, we prompt language models to extract knowledge about object affinities which gives us a proxy for spatial relationships of objects. Our experiments show that HOLM performs better than the state-of-the-art approaches on two datasets for `dRER`; allowing to study generalization for both indoor and outdoor settings.

1 Introduction

One of the fundamental challenges in building AI systems physically present in the world is addressing the issue of partial observability, the phenomenon where the entire state of the environment is not known or available to the system. People cope with partial observability by reasoning about what is not immediately visible (see example in Figure 1). People combine their general knowledge about the world and adapt their knowledge to specific contexts (Torralba et al., 2006). General knowledge about kitchens can help to know approximately where to look for pans or utensils in a kitchen that has never been seen before. How can an AI system build general knowledge about objects and their environment to help with a similar task? Even more interestingly, can we gather this information from language, using readily available resources such as language models trained on a large collection of unlabeled text?



Instruction: “Find the *tv*. The target is above the *tv* next to the *standing lamp*.”

Figure 1: Illustration of our main contribution: **Hallucinating Objects**. Knowledge about object relationships is helpful when navigating in an unknown and partially observed environment. In the example above, the TV is not visible, but the couch hints that a TV might be in front of it because usually couches face TVs.

In this paper, we introduce a method called HOLM, **H**allucinating **O**bjects with **L**anguage **M**odels, for reasoning about the unobserved parts of the environment. Inspired by the recent successes of large pre-trained language models (LM) extracting knowledge about the real world, we propose a methodology based on spatial prompts to extract knowledge from language models about object. HOLM extracts spatial knowledge about objects in the form of affinity scores, i.e., how often a pair of objects are observed together. This knowledge of objects are combined with observed spatial

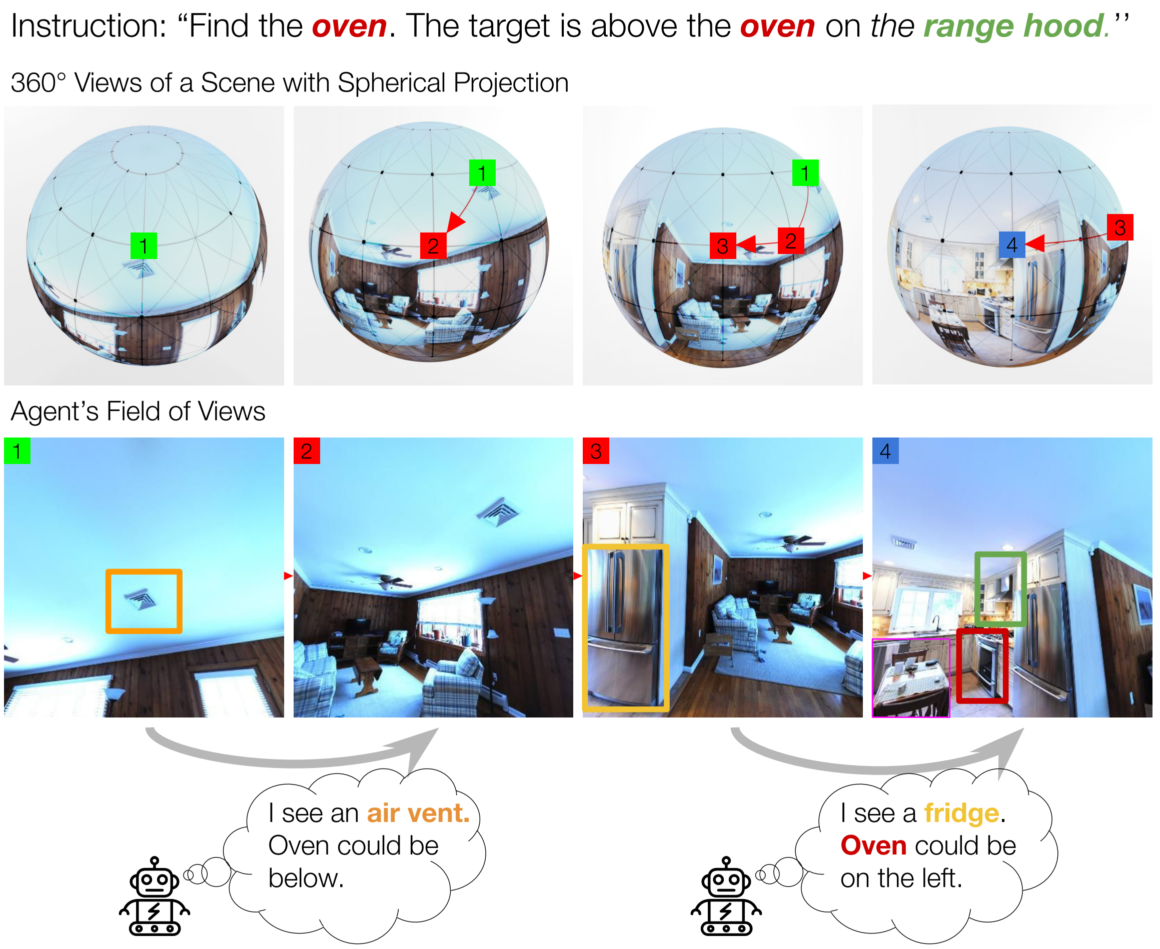

Figure 2: **Illustration of the `dRER` task with an example of language instruction and its recognition in four steps.**
The agent adjusts its FoV by looking at different directions and navigate on the graph in the spherical view. Note that objects mentioned in bold in the instruction are not visible at all until timestep 4. Thus, the agent needs to reason about possible locations of the mentioned object using its partial view of the scene.

layout to hallucinate what might appear in the unobserved part of the scene. We evaluate our HOLM approach on Dynamic Referring Expression Recognition (`dRER`) task where the goal is to find a target location by dynamically adjusting the field of view (FoV) in partially observed 360° scenes. We examine how HOLM compares with the state-of-the-art approaches on two publicly available datasets to study generalization for both indoor and outdoor settings.

2 Dynamic Referring Expression Recognition (`dRER`) Task

`dRER` task is designed to localize a target location in a dynamically observed 360° scene given natural language instruction. Unlike conventional referring expression recognition, which refers to an object in a static visual input, in `dRER`, only a small part of the scene is visible in a field of view. However, the system can adjust the field of view to find the described point in the scene. In Figure 2, we illustrate the `dRER` task and motivate our method. On top, natural language instruction is given. In the middle, the spherical view of the scene is illustrated – the agent explores only some portion of a 360° scene. FoVs on the sphere represented as square nodes form a graph. By *navigating to a neighboring node*, the agent adjusts its FoV and observes a different view of the scene. Note that objects mentioned in the instruction “oven” and “range hood” are not visible until the fourth timestep. However, we can reason about where to look using visible objects such as the air vent or the fridge. Thus, to perform well on this task, it is essential to reason about where objects might appear.

The `dRER` task can be formulated as a Markov Decision Process (MDP) (Howard, 1960) $\mathcal{M}$ =

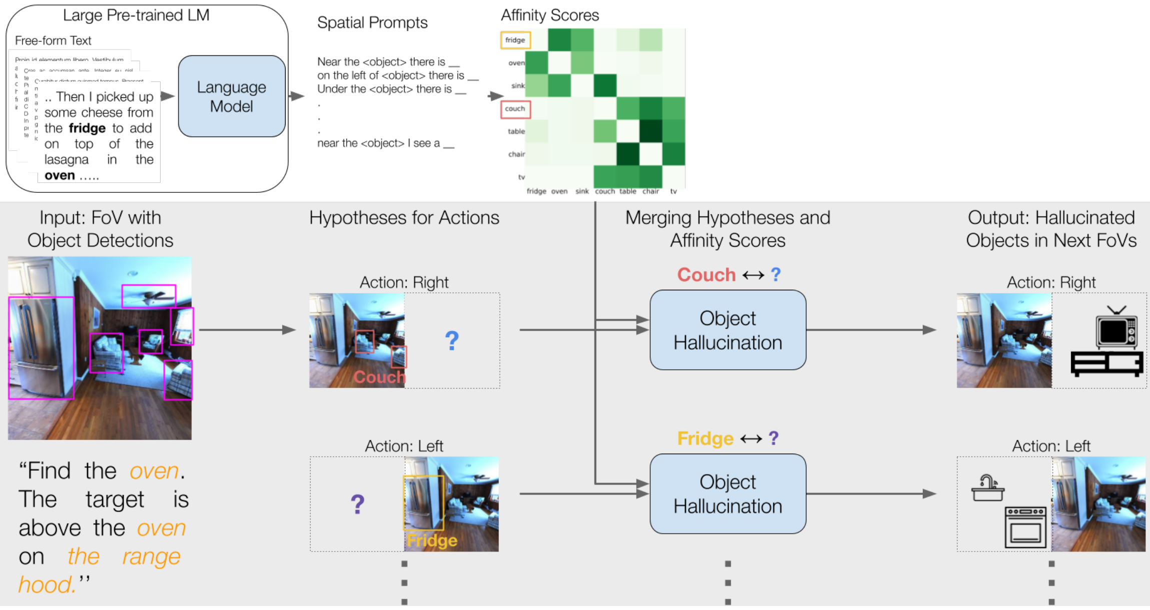

Figure 3: **HOLM for the dRER task**. **(Top)** We use language models trained on a large amount of text by prompting with the spatial relationship of objects to calculate co-occurrence statistics of objects. **(Bottom)** The flow of our hallucination method. We determine objects of interest for each action. Then, we combine objects of interest and co-occurrence table to hallucinate objects, i.e. what might appear after performing an action.

$\langle \mathcal{S}, \mathcal{A}, P_s, r \rangle$ where $\mathcal{S}$ is the visual state space, $\mathcal{A}$ is the discrete action space [1], P_s is the unknown environment probability distribution from which the next state is drawn, and $r \in \mathbb{R}$ is the reward function. For a time step t, the agent observes an image $s_t \in \mathcal{S}$, and performs and action $a_t \in \mathcal{A}$. As a result of this action, the environment generates a new observation $s_{t+1} \sim P_s(\cdot \mid s_t, a_t)$ as the next state. This interaction continues sequentially and ends when the agent performs a special `STOP` action or a pre-defined maximum episode length is reached. The resolution process is successful if the agent ends the episode at the target location.

In `dRER`, instructions are represented as N sequence of sentences represented as $x = \{x_i\}_{i=1}^{N}$. Each instruction sentence x_i consists of a sequence of L_i words, $x_i = [x_{i,1}, x_{i,2}, ..., x_{i,L_i},]$. The training dataset $\mathcal{D}_E = \{\mathcal{X}, \mathcal{T}\}$ consists of M pairs of the instruction sequence $x \in \mathcal{X}$ and its corresponding expert trajectory $\tau \in \mathcal{T}$. The agent learns to navigate by learning a policy π via maximum likelihood estimation (MLE):

$$\begin{aligned} &\max_{\theta} \mathcal{L}_\theta(\mathcal{X}, \mathcal{T}) \text{ , where} \\ \mathcal{L}_\theta(\mathcal{X}, \mathcal{T}) &= \log \pi_\theta(\mathcal{T}|\mathcal{X}) \\ \mathcal{L}_\theta(\mathcal{X}, \mathcal{T}) &= \frac{1}{M} \sum_{k=1}^{M} \log \pi_\theta(\tau^k|x^k) \end{aligned} \tag{1}$$

3 HOLM

In `dRER`, the system observes the current FoV and does not see the resulting FoV before taking any actions. Thus, it is essential to reason what might appear in a future observation using what is currently visible to the system. Our core intuition is that objects visible in the current FoV and their locations in the FoV give us a clue about what might appear if a particular action is taken. Here, we propose an approach for reasoning about future observations using what is visible and some background knowledge of objects. Let us go through the illustration in Figure 3 to explain our HOLM method. In the top panel, we feed spatial prompts to pre-trained language models to extract knowledge about objects in the form of affinity scores. In the bottom panel, we see the input of the system where there are natural language instructions, an FoV of the scene, and detected objects. Next, we calculate which objects are relevant to each action. For instance, couch detections are on the right side;

---

[1] For computational efficiency, we picked discrete action space. It could be continuous as well.

thus, they are relevant to the right action. Similarly, the fridge is relevant for the left action because it is on the left side. Then on the third step, using the affinity score of a pair of objects, we predict what might appear after performing an action. For right action, our model hallucinates a tv and tv-stand might appear because the couch and tv have a high affinity score according to the LM.

3.1 Affinity Scores from Language Models

Language models process a large amount of text to learn regularities in natural language. They do so by predicting the next word or masked token given a sequence of words. Our intuition is that objects that frequently appear in an environment close to each other will have similar language usage. Thus, we hypothesize that language models' capability of learning affinity scores of words in language also reflects objects' spatial properties. In Figure 3's top panel, we illustrate how we extract this capability. We query language models trained on a large amount of free-form text with spatial relationship prompts. These spatial prompts aim to capture the usage of words when they appear together in the world. An example of these prompt templates is "Near the o_1, there is ___" where $o_1 \in O$ is an object label where O is a set of object labels. If object o_1 co-occurs with o_2 with high frequency, the language model would provide a high probability for the phrase "Near the o_1, there is o_2". Using all pairs in O and K[2] spatial templates, we generate queries q. We then calculate affinity scores C_{o_1,o_2}, i.e., observing o_2 when o_1 is present as follows:

$$C_{o_1,o_2} = \sum_{i=1}^{K} p_{\text{LM}}(o_2|q_i) \qquad (2)$$

Where $p_{\text{LM}}(o_2|q)$ is a language model that calculates the probability of observing a token o_2 given a prefix sequence of tokens q.

3.2 Object Hallucination

Our main idea behind HOLM is to reason about what might be observed in a future observation by combining (1) which objects are visible in the current observation and (2) what we know about the spatial properties of those objects. We explain the details of our approach in this section.

Let $p_a \in \mathbb{R}^{|O|}$ be the vector of probabilities of observing an object among a set of all objects O after performing an action a. We calculate p_a as follows:

$$p_a = (p_{\texttt{FoV}} \odot \mathbb{1}_a)C \qquad (3)$$

Where $p_{\texttt{FoV}} \in \mathbb{R}^{|O|}$ is a vector of confidence values for objects detected in the current FoV. We use an off-the-shelf object detection system (Anderson et al., 2018a) to calculate $p_{\texttt{FoV}}$. C is the affinity scores of size $|O| \times |O|$. C represents how often a pair of object appear in a spatial relationship and represents the background knowledge of objects. $\mathbb{1}_a \in \{0,1\}^{|O|}$ is a binary vector representing spatially related objects for a direction a. This vector is calculated with an indicator function to determine whether an object is spatially related to action a.

We calculate the indicator function as follows. First, we separate the FoV into 4 imaginary regions called quadrants where each quadrant determines how a region in observed FoV is spatially relevant for canonical directions (i.e., up, down, left, right). In other words, quadrants are "hot-spots" for each direction i.e., the left side of the image is more relevant to the right side of the image if we are interested in what might appear on the left. For 8 directions (left, right, down, up, down-left, down-right, up-left, up-right), we calculate how much each objects' bounding box overlaps with these quadrants. If intersection-over-union is above a fixed threshold we keep this object for the hallucination process.

4 Experiments

We designed our experiments to study and evaluate our proposed HOLM approach under five different research questions. **RQ1:** What is the performance of HOLM when compared to other state-of-the-art approaches? **RQ2:** what is the impact of LM as a source of knowledge for HOLM when compared to other more conventional sources (e.g., images)? **RQ3:** How essential are external sources of data for learning knowledge about objects compared to in domain data? **RQ4:** How accurate is HOLM for predicting objects in future observations? **RQ5:** How do annotation-free language-based knowledge sources i.e., LMs and word embeddings compare for HOLM?

The following section explains the details of experimental setup. Our results are presented and discussed in Section 4.2.

---

[2] Please see Appendix A.1 for the full list of spatial prompt templates.

4.1 Experimental Setup

To study the research questions previously mentioned, we used two publicly available datasets and state-of-the-art methods as baselines to compare with.

Datasets. We selected the following two datasets to see if our method generalizes to both indoor and outdoor settings. The Refer360° dataset (Cirik et al., 2020) consists of 17K natural language instructions and ground-truth trajectory pairs for localizing a target point in 360° scenes. The ground-truth trajectories are annotated by human annotators in the form of successive FoVs in partially observed 360° scenes. The dataset uses a subset of the SUN360 dataset (Xiao et al., 2012) as the source of scenes and these scenes are from both indoor and two outdoor locations.

Touchdown (Chen et al., 2018) consists of 9K natural language instruction and ground-truth location pairs for 360° scenes on Google Streetview. Unlike the Refer360° dataset, Touchdown does not have expert trajectories – only expert predictions for the target location are provided. Thus, we generated ground-truth trajectories by calculating shortest path trajectories between a randomly selected starting point [3] and the target location.

Baselines Models. We compare our method with the state-of-the-art models and also few simple baselines (i.e., no parameter learning).

- The Self Monitoring Navigation Agent (SMNA) (Ma et al., 2019) model is trained with a co-grounding module where both visual and textual input is attended at the same time. The agent also measures its progress with a progress monitor module.
- FAST (Ke et al., 2019) stands for Frontier Aware Search with backTracking. The FAST model learns to score partial trajectories of an agent for efficiently backtracking to a previous location after a mistake.
- Speaker-Follower (Fried et al., 2018) uses a sequence-to-sequence speaker model to rerank a follower model's candidate trajectories. This pragmatic reasoning model has been shown to improve navigation agents' performance significantly.
- LingUNet (Misra et al., 2018) is an image-to-image encoder-decoder model for learning image-to-image mappings conditioned on language. We should emphasize that, unlike the previous methods, LingUNet is not a navigation model; instead, it predicts regions over an image.
- RANDOM agent randomly picks an action.
- STOP agent predicts the starting FoV as the target FoV.

For a fair comparison, the same model was used as the basis for all the compared models. For our proposed approach HOLM is used to enhance the SMNA baseline by hallucinating objects for unseen regions. After getting object hallucinations for each neighboring FoVs, we use the sum of word embeddings for object labels as the input representation for the neighboring FoV. In the oracle "Next FoV" scenario, we use ground-truth FoVs to do the same process. For a fair comparison, we use SMNA as the base agent for learning to recover from a mistake during navigation process with FAST and as the follower model for pragmatic reasoning with Speaker-Follower.

Evaluation Metrics. Our main evaluation metric for methods is FoV accuracy: the percentage of the time the target location is visible in the final FoV. The FoV accuracy sets an upper bound on the localization accuracy for predicting the pixel location of the target point, i.e., if the target is not visible, it is impossible to predict the exact location. Thus, we focus on this metric to compare systems.

Implementation. All models are trained for 100K iterations. We use Adam (Kingma and Ba, 2015) for optimization with a learning rate 0.0001 and weight decay parameter 0.0005 (Krogh and Hertz, 1992). For each model, we perform a grid-search over their hyperparameters (e.g., number of hidden units, number of layers, dropout rate) and pick the best performing model based on validation score [4]. All models are implemented using PyTorch (Paszke et al., 2019) and publicly available[5].

To speed up the training procedure, we used fixed a grid of FoVs for all 360° images where each FoV is connected to its neighboring FoVs. This grid forms the navigation graph depicted in

---

[3] Following (Cirik et al., 2020), we set the initial random point to be a fix heading and random yaw.

[4] For Refer360° we use validation unseen split. Touchdown does not have seen-unseen distinction.

Method	Oracle	Refer360°	Touchdown
Stop Agent		14.1	0.0
Random Agent		12.1	6.8
SMNA (Ma et al., 2019)		27.1	45.9
+ HOLM (this work)		**32.2**	**49.8**
SMNA (Ma et al., 2019)	Next FoV	33.5	50.2
LingUNet* (Chen et al., 2018)	Full Panorama	21.4	47.2

Table 1: FoV accuracy results for Refer360° and Touchdown with no hallucination baseline, best performing models, and Next FoV oracle model, i.e. the ability to look ahead for neighbor FoVs, and observing full 360° scenes. Our method outperforms the baseline models from the literature.

Method	Beam Search	Refer360°	Touchdown
Baseline SMNA (Ma et al., 2019)		27.1	45.9
+ HOLM (this work)		**+5.1**	+3.9
+ FAST (Ke et al., 2019)	✓	-6.4	**+4.7**
+ Speaker-Follower (Fried et al., 2018)	✓	-4.6	-11.1

Table 2: FoV accuracy results for Refer360° and Touchdown for methods using beam search or single candidate trajectory. HOLM consistently improves the baseline and does not use multiple trajectories.

the Figure 2. We use 30° of separation between successive FoVs which provides enough overlap to reveal relevant information about successive FoVs yet distant enough so that the model needs to reason about future steps. We then pre-calculated the rectilinear projection of each of the FoVs on the grid for all scenes.

4.2 Results and Discussion

In this section we present and discuss experimental results and analyses.

(RQ1) HOLM Improves performance. Our main results are presented in Table 1. In the first row block, we see that simple non-learning baselines fail to perform on the `dRER`. In the second row block, we compare our method with the baseline where the agent does not have any visual input from the next FoVs. HOLM improves the baseline by hallucinating objects for the next FoVs. In the third row block, we provide results for oracle scenarios. For SMNA, we feed ground-truth FoV as the input of the system. This result sets the upper bound on HOLM, because it cannot achieve better hallucination than the ground-truth FoVs. However, HOLM achieves pretty close to this upper bound and show that it can provide useful predictions for this task. For LingUNet, we feed the full 360° scenes as the visual input. Since LingUNet is not a navigation agent i.e. predicts the target location using full 360° scenes, we calculate FoV accuracy by drawing an FoV around the prediction, which explains '*'.

In Table 2, we compare HOLM with FAST and Speaker-Follower methods, both of which use beam search. During the beam search, these methods use multiple trajectories while deciding on a trajectory. However, this is not plausible in a real-world scenario, i.e. a robot would not generate many trajectories before performing action. HOLM, on the other hand completes the task on a single trajectory while predicting possible future states. FAST improves SMNA for Touchdown but not for Refer360° , which might be due to the richness of scenes in Refer360° whereas in Touchdown , the scenes are always in the same domain. Speaker-Model's decreases the score for SMNA possibly due to the Speaker models' poor performance where the BLEU score is around 6. HOLM consistently improves for both datasets and does not perform any expensive look-ahead operations such as beam search.

Knowledge Type	Human Annotation	Affinity Scores	Refer360°	Touchdown
Baseline	✓	Uniform	27.8	45.2
Baseline	✓	Identity	29.3	45.9
Visual	✓	VisualGenome	30.8	48.4
Knowledge Base	✓	WordNet	29.5	48.4
Pre-trained LM		XLM	**32.2**	**49.8**

Table 3: FoV accuracy results for Refer360° and Touchdown for different methods for calculating affinity scores for HOLM. XLM-based affinity scores achieve the best performance.

(RQ2) Pre-trained LM produces better affinity scores compared to other sources. In Table 3, we compare several baseline methods for calculating the affinity scores. First, we use uniform (i.e., each object pair has the same affinity score) and identity (i.e., object x can only have affinity score with itself) baselines. We also study calculating affinity scores using data annotated by humans. First, we use object annotations in VisualGenome (Krishna et al., 2017). VisualGenome provides a large collection of fine-grained annotations for objects and their spatial relationships. Second, ideally we would like to use human annotations for calculating the affinity score. However, this requires annotation of $|O|^2$ annotations. Instead, as a proxy, we use WordNet (Miller, 1995), a knowledge-base hierarchy annotated by experts. We use NLTK (Bird et al., 2009) to calculate the WordNet similarity to extract the affinity scores between objects. XLM-based HOLM achieves the best results among these baselines. This result shows that without using human annotations, we can extract useful knowledge about objects using pre-trained LMs.

Method	Data Source	Refer360°	Touchdown
HOLM with XLM	External	**32.2**	**49.8**
HOLM with Objects Counts	Internal	30.3	48.7
Hallucinating with 3-Layer MLP	Internal	27.5	46.3

Table 4: FoV accuracy results for Refer360° and Touchdown when task data is used for object hallucination. The limitation of the domain data can be addressed using external resources such as pre-trained LMs.

(RQ3) External sources may provide better information compared to task data. In Table 4, we compare methods that only use task data for object hallucination and HOLM with external sources such as pre-trained LM. For the second row in the table), we use the BUTD model (Anderson et al., 2018a) to annotate training images with object bounding boxes. Using bounding boxes of objects, we calculate affinity scores. For the third row in the table, we design a model that takes FoV and an object type as an input and predicts a direction (i.e., hallucinate where it might appear) as output. We pass the final feature map layer of 152-layer ResNet (He et al., 2016) as input to a 3-layer feed-forward neural network to predict objects that might appear in neighboring FoVs. This model achieves an F1 score of 40.3 for direction prediction. Both of these methods improve over the SMNA baseline but are worse than the pre-trained LM. This result indicates that task data may have limitations, and external sources such as a pre-trained LM may provide a signal for knowledge about objects.

Knowledge Type	Affinity Scores	Refer360°	Touchdown
Visual	VisualGenome	P 1.4 R 55.3 F1 2.7	P 1.5 R 55.2 F1 2.9
Knowledge Base	WordNet	P 1.3 R 55.4 F1 2.6	P 1.4 R 55.3 F1 2.8
Pre-trained LM	XLM	P 2.0 R 49.5 **F1 3.9**	P 2.2 R 63.2 **F1 4.3**

Table 5: Precision (P), Recall (R), and F1 scores for Refer360° and Touchdown for hallucinating objects in neighboring FoVs. Similar to the downstream task results, pre-trained LM performs the best.

(RQ4) Accuracy of HOLM translates to `dRER` So far, we measure the performance of HOLM for the downstream `dRER` task. We can also measure how accurate HOLM is at predicting the presence of an object in neighboring FoVs. We annotate each neighboring ground-truth FoVs with detections from BUTD. If the p_a^i for object $o_i \in O$ is above $\frac{1}{|O|}$, we count that as a prediction of an object in the neighboring FoV after performing action a. In Table 5, we provide precision, recall, and F1 score for the performance of different methods for calculating affinity scores for HOLM. XLM achieves the best performance among the methods we compare. We conclude that the performance for the intrinsic task (i.e., predicting the presence of objects) translates to `dRER` performance.

Method	Model	Refer360°	Touchdown
Baseline	SMNA	27.1	45.9
WE	+ HOLM with FastText (Mikolov et al., 2018)	31.6	46.8
	+ HOLM with GloVe (Pennington et al., 2014)	31.0	49.2
	+ HOLM with word2vec (Mikolov et al., 2013)	29.3	46.2
LM	+ HOLM with GPT3 (Brown et al., 2020)	31.1	46.3
	+ HOLM with Roberta (Liu et al., 2019c)	30.3	46.0
	+ HOLM with XLM (Conneau and Lample, 2019)	**32.2**	**49.8**

Table 6: FoV accuracy results for Refer360° and Touchdown for models processing unlabeled text. **WE** and **LM** are abbreviations for word embeddings and language models. All hallucination-based methods perform better than the baseline. XLM achieves the best performance in both datasets.

(RQ5) Both word embeddings and LMs are good sources of general knowledge of objects In Table 6, we compare word embedding methods and different language models. We use cosine similarities between pairs of objects to calculate the affinity scores. For language models, we compare Open AI's GPT3 (Brown et al., 2020) using their online API[6]. We use Transformers Library (Wolf et al., 2020) for RoBERTa (Liu et al., 2019c) and XLM (Conneau and Lample, 2019). All methods consistently improve over the baseline SMNA model, however, we achieve the best performance using XLM. This result indicates that we can extract useful knowledge about objects with methods relying on large amount of unlabeled text.

5 Related Work

Our work on `dRER` is closely related to previous studies focusing on Referring Expression Recognition (RER), Vision-and-Language Navigation (VLN), and methods we propose are related to pretraining language models for vision-and-language tasks, model-based reinforcement learning, and cooccurrence modeling for computer vision. We review these studies in this section.

RER is the task of localizing a target object or a point in an image described by a natural language expression. The most of existing datasets

---

[6] https://beta.openai.com/

poses the task in 2D images with objects as being the target (Kazemzadeh et al., 2014; Yu et al., 2016; Mao et al., 2016; Strub et al., 2017; Liu et al., 2019a; Akula et al., 2020; Chen et al., 2020). Several lines of work are proposed to address RER (Mao et al., 2016; Nagaraja et al., 2016; Yu et al., 2016; Hu et al., 2016; Fukui et al., 2016; Luo and Shakhnarovich, 2017; Liu et al., 2017; Yu et al., 2017; Zhang et al., 2018; Zhuang et al., 2018; Deng et al., 2018; Yu et al., 2018; Cirik et al., 2018; Liu et al., 2019b).

In Touchdown (Chen et al., 2018) and Refer360° (Cirik et al., 2020) the target is a point not an object in a 360° image. In the `dRER` setup, we also use 360° images of Touchdown and Refer360° , but we do not provide the full panoramic view of the scene. Instead, in a more realistic scenario, the agent observes a partial and dynamic view of the scene, i.e. the agent needs to adjust its FoV to find the target location. Closer to our work, in REVERIE (Qi et al., 2020b) an embodied setup is proposed where the agent needs to first navigate to a location where the target object is visible. Similar to Touchdown and Refer360° , at the final position, the full 360° view is visible to the agent. Unlike ours and similar to 2D image-based RER, the target is an object rather than a point in the scene.

VLN is a vision-and-language task where an agent in a simulated environment observes a visual input and is given a natural language instruction to navigate to a target location. The earlier work (MacMahon et al., 2006; Shimizu and Haas, 2009; Chen and Mooney, 2011) studies the task with synthetic images or in a very small scale (Vogel and Jurafsky, 2010). Anderson et al. (2018b) proposes Room-to-room (R2R) benchmark and revisit VLN task with a modern look. In R2R, the agent observes panoramic scans of a house (Chang et al., 2017) and needs to carry out the natural language instruction. EnvDrop (Tan et al., 2019) model shows generalization to unseen environments by dropping visual features. PREVALENT (Hao et al., 2020) tackles the data sparsity problem with a pretraining scheme. Hong et al. (2021) show that a pre-trained multi-modal can be enhanced with a memory state for the VLN task by recurrently feeding a contextualized state feature after each time step. `dRER` also poses a navigation task where locations in physical space in VLN correspond to FoVs in a fixed location. In `dRER`, a trajectory of the agent corresponds to its resolution process for finding the goal location.

Pre-trained models for Vision-and-Language has been recently studied after the huge success of transformer-based models (Vaswani et al., 2017) in NLP (Devlin et al., 2018; Liu et al., 2019c; Conneau and Lample, 2019; Sun et al., 2019b; Poerner et al., 2020; Raffel et al., 2020; Brown et al., 2020). Numerous studies extend these approaches to the multimodal domain (Tan and Bansal, 2019; Lu et al., 2019; Sun et al., 2019a; Su et al., 2020; Li et al., 2020; Qi et al., 2020a; Hu and Singh, 2021). They achieve the-state-of-the-art results in several tasks such as image captioning, text-to-image retrieval, or referring expression recognition. Our work differs from these studies in the sense that the previous approaches use large scaled paired image-text data (Chen et al., 2013; Divvala et al., 2014; Sadeghi et al., 2015; Radford et al., 2021; Jia et al., 2021) to learn efficient representations (Frome et al., 2013; Kottur et al., 2016) for visual and textual modalities whereas we are interested in spatial information learned in unimodal text representations.

Language priors for vision were explored in recent studies. Lu et al. (2016) use word embeddings in a language module to learn a representation for a object-predicate-object triplet for visual relationship detection task. Kiela et al. (2019) propose an approach to extend pre-trained transformer-based LMs for multimodal tasks. Similarly, Lu et al. (2021); Tsimpoukelli et al. (2021) show that pre-trained LMs can be finetuned to perform well in few-shot settings for image classification and open-domain Visual Question Answering (Marino et al., 2019). Marino et al. (2021) also show that multimodal transformer architectures capture implicit knowledge for a pair of objects. Our work differs from these studies (1) we use only unimodal models, (2) we do not finetune models – we do not update models during training. The most similar work to ours, Scialom et al. (2020) show that pre-trained LMs can perform reasonably well on Visual Question Generating (Yang et al., 2015; Mostafazadeh et al., 2016) out of the box. One difference is that we use object labels rather than object features or the appearance of objects to query the language model; however, they use object features as a visual token to the language model. Prompts we use in our work shares similarities with prompts designed in PIQA (Paranjape et al., 2021), but our work is evaluated in a multimodal setup. In contrast, PIQA is evaluated for textual commonsense reasoning tasks.

Hallucination idea is also related the work on predicting future observations in long horizons (Villegas et al., 2019) which has been studied in the context of learning planning (Hafner et al., 2019) and acquiring skills for control problems (Hafner et al., 2020), and efficient policy learning (Ha and Schmidhuber, 2018), and vision-and-language navigation (Koh et al., 2021). All these approaches are interested in longer horizons; however, in our work, we study predicting single-step future observation. More recent work (Hu et al., 2021; Rombach et al., 2021; Rockwell et al., 2021) study view synthesis from a single visual observation. Unlike these approaches, HOLM does not generate pixel-level views rather abstractions of views with object labels.

Affinity scores are mainly studied in computer vision tasks in the form of object co-occurrences. Previous studies have shown that object co-occurrences are efficient representations of visual prior for object categorization for object segmentation (Rabinovich et al., 2007; Galleguillos et al., 2008; Ladicky et al., 2010) and zero shot object-recognition (Mensink et al., 2014), and scene understanding (Wu et al., 2014). Our work differs from these studies: we do not calculate co-occurrence statistics, i.e. we do not count the frequency of times they appear together; instead, we calculate a probability measure using language models.

6 Conclusion

In this paper, we introduced HOLM – a model that can extract prior knowledge about objects from LMs and hallucinate objects in future observations. Our experiments showed that HOLM approach improves over various baselines from the literature. Surprisingly, our model which used background knowledge from LMs outperformed models with knowledge from human-annotated data showing that LMs learn useful knowledge about the world without requiring any visual observations. We also showed that out approach generalizes to both indoor and outdoor scenarios.

Our work has limitations in the following ways. First, the hallucination process solely conditions on the current field of view. However, the instruction and the previous observations are available to the system. Conditioning on these sources of information could improve the hallucination accuracy by getting more targeted information from the language model. Second, we assume a fixed lexicon of object labels for hallucination. For both the visual side i.e., the object detector, and the language side i.e., the language model, when an unknown object appears the system cannot use this object for hallucination. Another issue is the scalability, i.e, the affinity scores scale with $O(N^2)$ where N is the number of objects, which might be challenging when N is large. We hope the follow-up work could address these limitations.

Future work will explore the use of background knowledge in other domains such as vision-and-language navigation (Anderson et al., 2018c) and dialog (Thomason et al., 2020). We also believe background knowledge of objects would be handy in complex scenarios such as manipulating objects in a simulated environment (Shridhar et al., 2020). Our method examines extracting background knowledge in a zero-shot manner. However, the literature shows that learning how to prompt could be helpful in finding better (Liu et al., 2021). We strictly compared unimodal approaches for hallucination. Future work extend our work by comparing multimodal models (Tan and Bansal, 2019; Lu et al., 2019; Sun et al., 2019a; Su et al., 2020; Li et al., 2020; Qi et al., 2020a; Hu and Singh, 2021).

Another interesting direction would be to study the capability of transferring knowledge from indoor to outdoor settings and vise versa. Finally, the success of PREVALENT (Hao et al., 2020) and other pre-training approaches for VLN could stem from their ability to *implicitly* encode prior knowledge about objects. Hopefully, future studies examines this phenomenon.

Abstract

Massively Multilingual Transformer based Language Models have been observed to be surprisingly effective on zero-shot transfer across languages, though the performance varies from language to language depending on the pivot language(s) used for fine-tuning. In this work, we build upon some of the existing techniques for predicting the zero-shot performance on a task, by modeling it as a multi-task learning problem. We jointly train predictive models for different tasks which helps us build more accurate predictors for tasks where we have test data in very few languages to measure the actual performance of the model. Our approach also lends us the ability to perform a much more robust feature selection, and identify a common set of features that influence zero-shot performance across a variety of tasks.

1 Introduction

Multilingual models like mBERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020) have been recently shown to be surprisingly effective for zero-shot transfer (Pires et al., 2019) (Wu and Dredze, 2019), where on fine-tuning for a task on one or a few languages, called *pivots*, they can perform well on languages unseen during training. The zero-shot performance however, is often not uniform across the languages and the multilingual models turn out to be much less effective for low resource languages (Wu and Dredze, 2020; Lauscher et al., 2020) and the languages that are typologically distant from the pivots (Lauscher et al., 2020). What affects the zero-shot transfer across different languages is a subject of considerable interest and importance (K et al., 2020; Pires et al., 2019; Wu and Dredze, 2019; Lauscher et al., 2020), however there is little conclusive evidence and a few papers even show contradictory findings.

Lauscher et al. (2020) recently, showed that it is possible to predict the zero shot performance of mBERT and XLM-R on different languages by formulating it as a regression problem, with pretraining data size and typological similarities between the pivot and target languages as the input features, and the performance on downstream task as the prediction target. Along similar lines Srinivasan et al. (2021) and Dolicki and Spanakis (2021) explore zero-shot performance prediction with a larger set of features and different regression techniques.

However, the efficacy of these solutions are severely limited by the lack of training data, that is, the number of languages for which performance metrics are available for a given task. For instance, for most tasks in the popular XTREME-R (Ruder et al., 2021) benchmark, there are data points for 7-11 languages. This not only makes zero-shot performance prediction a challenging problem, but also a very important one because for practical deployment of such multilingual models, one would ideally like to know its performance for all the languages the model is supposed to handle. As Srinivasan et al. (2021) shows, accurate performance predictors can also help us build better and fairer multilingual models by suggesting data labeling strategies.

In this work, we propose multi-task learning (Zhang and Yang, 2017) as an approach to mitigate training-data constraints and consequent over-fitting of the performance predictors to tasks and/or datasets. The contributions of our work are fourfold. *First,* we experiment with different multi-task learning approaches, such as Group Lasso (Yuan and Lin, 2006), Collective Matrix Factorization (Cortes, 2018), Multi-Task Deep Gaussian Process Regression (Bonilla et al., 2008) and Meta Agnostic Meta Learning (Finn et al., 2017) for 11 tasks. We observe an overall 10% reduction in performance prediction errors compared to the best performing single-task models. The gains are even stronger when we just consider the tasks with very few data points (≤ 10), where we see a 20%

---

[*] Equal contribution

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 5454 - 5467

drop in the mean absolute errors. *Second,* an interesting consequence of modelling this problem via multi-task learning is that we are able to predict performance on low resource languages much more accurately, where in some cases single-task approaches may perform even worse than the simple averaging baselines. *Third,* apart from the features used for zero-shot performance prediction in the previous work (Lauscher et al., 2020; Srinivasan et al., 2021; Dolicki and Spanakis, 2021), we also utilize metrics quantifying the quality of multilingual tokenizers as proposed in (Rust et al., 2021) as features in our predictive models, which turn out to have strong predictive power for certain tasks. To the best of our knowledge, our work is the first to explore the impact of tokenizer quality specifically on zero-shot transfer. And *fourth,* our multi-task framework in general lends us with a much more robust selection of features affecting the zero-shot performance. This, in turn, lets us investigate the critical open question on what influences the zero-shot performances across languages more rigorously. As we shall see, our findings corroborate some of the previous conclusions, while others are extended or annulled.

2 Background and Related Work

Zero Shot Transfer. Multilingual models like mBERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020) have shown surprising effectiveness in zero-shot transfer, where fine-tuning the MMLM on a task in some source language often leads to impressive performance on the same task in other languages as well without explicitly training on them. Pires et al. (2019) first observed this phenomenon for NER (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003; Levow, 2006) and POS tagging (Nivre et al., 2018) tasks. Concurrently, Wu and Dredze (2019) also showed this surprisingly cross lingual transfer ability of mBERT additionally on tasks like Document Classification (Schwenk and Li, 2018), Natural Language Inference (Conneau et al., 2018) and Dependency Parsing (Nivre et al., 2018).

Factors Affecting Zero Shot Transfer. Pires et al. (2019) showed that vocabulary memorization played little role in zero-shot generalization as language pairs with little word piece overlap also exhibited impressive crosslingual performance. K et al. arrived at a similar conclusion by training BERT on an artificially generated language to zero out the word overlap with the target languages, and observed only minor drops in the performance compared to training the model on English. On the contrary Wu and Dredze (2019), observed strong correlations between the sub-word overlap and the zero-shot performance in four out of five tasks.

Wu and Dredze (2020) showed that mBERT performed much worse for zero-shot transfer to low resource languages (i.e., less pre-training data) than high resource ones on POS Tagging, NER and Dependency Parsing tasks. Lauscher et al. (2020) also had a similar observation on tasks like XNLI and XQuAD (Artetxe et al., 2020), though they found that the zero-shot performance on NER, POS tagging and Dependency Parsing tasks might not strictly depend on the pre-training size and could be better explained by different linguistic relatedness features like syntactic and phonological similarities between the language pair. Similar dependence on the typological relatedness such as word order had also been observed by Pires et al. (2019).

Performance Prediction. Prior work has explored predicting the performance of machine learning models from unlabelled data by either measuring (dis)agreements between multiple classifiers (Platanios et al., 2014, 2017) or by utilizing underlying information about data distribution (Domhan et al., 2015). In the context of NLP Birch et al. (2008) explored predicting the performance of a Machine Translation system by utilizing different explanatory variables for the language pairs. Lin et al. (2019) proposed a learning to rank approach to choose transfer languages for cross lingual learning using several linguistic and dataset specific features.

Recently, there has been an interest in predicting the performance of NLP models without actually training or testing them, by formulating it as a regression problem. Xia et al. (2020) showed that using experimental settings for an NLP experiment as inputs it is possible to accurately predict the performance on different languages and model architectures.Ye et al. (2021) extended this work by proposing methods to do a fine-grained estimation of the performance as well as predicting well-callibrated confidence intervals. Specifically predicting the zero-shot performance of MMLMs was first explored in Lauscher et al. (2020), where they used a linear regression model to estimate the cross-lingual transfer performance based on pre-training data size and linguistic relatedness features.

Srinivasan et al. (2021) tackled this problem by utilizing XGBoost Regressor for the prediction along with a larger set of features. Dolicki and Spanakis (2021) explored individual syntactic features for zero-shot performance prediction instead of working with aggregate similarity values, and showed about 2 to 4 times gain in performance. We extend all of these works by considering a multi-task learning approach, where performance prediction in a task utilizes not only the data available for that task, but also the patterns observed for other tasks.

3 Problem Setup

We begin by defining the multi-task performance prediction problem and then describe the different linguistic and MMLM specific features used.

3.1 Multi-Task Performance Prediction Problem

Consider a pre-trained multilingual model $\mathcal{M}$, trained using self supervision on a set of languages $\mathcal{L}$. Let $\mathfrak{T}$ be the set of downstream NLP tasks, $\mathcal{P}$ be the set of pivot (source) languages for which training data is available for the downstream tasks for fine-tuning and $\mathcal{T}$ be the set of target languages for which validation/test data is available. Note that $\mathcal{P} \subset \mathcal{L}$ and $\mathcal{T} \subseteq \mathcal{L}$. We use the zero-shot setting similar to Lauscher et al. (2020) which enforces $\mathcal{P}$ and $\mathcal{T}$ to be disjoint sets[1], i.e., $\mathcal{P} \cap \mathcal{T} = \emptyset$.

We then define $y_{p,t}^{\mathcal{M},\mathrm{t}} \in \mathbb{R}$ as the zero-shot performance on language $t \in \mathcal{T}$ on finetuning $\mathcal{M}$ on task t $\in \mathfrak{T}$ in pivot language $p \in \mathcal{P}$. Let $x_{p,t}^{\mathcal{M}} \in \mathbb{R}^n$ be the n-dimensional feature vector representing the corresponding train-test configuration. Since for our experiments we train and evaluate the performance prediction for a single model at a time, we will simplify the notations to $y_{p,t}^{\mathrm{t}}$ and $x_{p,t}$.

The predictor model can then be defined as the function $f_{\Theta,\Phi} : \mathbb{R}^n \times \mathfrak{T} \to \mathbb{R}$, where $\Theta \in \mathbb{R}^{d_g}$ denotes the shared parameters across the tasks and the task specific parameters are given by $\Phi \in \mathbb{R}^{d_s \times |\mathfrak{T}|}$. The objective function for training such a predictor model can be defined as:

$$J(\Theta, \Phi) = \sum_{\mathrm{t} \in \mathfrak{T}} \sum_{p \in \mathcal{P}} \sum_{t \in \mathcal{T}} \| f(x_{p,t}, \mathrm{t}; \Theta, \Phi) - y_{p,t}^{\mathrm{t}} \|_2^2 + \lambda_g \|\Theta\|_1 + \lambda_s \|\Phi\|_{1,1} + \lambda_{group} \|\Phi\|_{1,q} \quad (1)$$

The second and third terms regularize the global and task specific parameters independently, while the last term, l_1/l_q norm with $q > 1$, ensures a block sparse selection of the task specific parameters. This term ensures a multi-task learning behavior even when there are no parameters shared across the tasks (i.e., $\Theta = \emptyset$) through selection of common features across the tasks. Setting $\Theta = \emptyset$ and $\lambda_{group} = 0$ leads to the single task setup of Lauscher et al. (2020) and Srinivasan et al. (2021).

3.2 Features

We divide the set of features into two higher level categories, viz. the pairwise features defined for the pivot and target that measure the typological relatedness of the languages, and the individual features defined for the target language reflecting the state of its representation in $\mathcal{M}$.

3.2.1 Pairwise Features

Instead of directly using the different typological properties of the the two languages as features, we use the pairwise relatedness to avoid feature explosion.

Subword Overlap : We define the subword overlap as the percentage of unique tokens that are common to the vocabularies of both the pivot and target languages. Let V_p and V_t be the subword vocabularies of p and t. The subword overlap is then defined as :

$$o_{sw}(p, t) = \frac{|V_p \cap V_t|}{|V_p \cup V_t|} \quad (2)$$

Similarity between Lang2Vec vectors: Following Lin et al. (2019) and Lauscher et al. (2020), we compute the typological relatedness between p and t from the linguistic features provided by the URIEL project (Littell et al., 2017). We use syntactic ($s_{syn}(p, t)$), phonological similarity ($s_{pho}(p, t)$), genetic similarity ($s_{gen}(p, t)$) and geographic distance ($d_{geo}(p, t)$). For details, please see Littell et al. (2017).

3.2.2 Individual Features

Pre-training Size: We use the log_{10} of the size (in words) of the pre-training corpus in the target language, SIZE(t), as a feature.

Rare Typological Traits: Srinivasan et al. (2021) proposed this metric to capture the rarity of the typological features of a language in the representation of $\mathcal{M}$. Every typological feature in WALS

---

[1] Though beyond the scope of the current work, it is possible to extend this to a few-shot setting as discussed in Srinivasan et al. (2021).

database is ranked based on the amount of pretraining data for the languages that contain the feature. For the language t, Mean Reciprocal Rank (MRR) of all of its features is then calculated and used as a feature – WMRR(t).

Tokenizer Features : In their recent work, Rust et al. (2021) proposed two metrics, viz. tokenizer's *fertility* and proportion of continued words, to evaluate the quality of multilingual tokenizers on a given language. For target t, they define the tokenizer's fertility, FERT(t), as the average number of sub-words produced for every tokenized word in t's corpus. On the other hand, the proportion of continued words, PCW(t), measures how often the tokenizer chooses to continue a word across at least two tokens. They show that the multilingual models perform much worse on a task than their monolingual counterparts when the values of these metrics are higher for the multilingual tokenizer. We include FERT(t) and PCW(t) as features.

An important thing to note here is that the we do not use identity of a language as a feature while training the models, hence the performance prediction models are capable of generating predictions on new languages unseen during training. However, if the features of the new languages deviate significantly from the features seen during training, the predictions are expected to be less accurate as also observed in Xia et al. (2020); Srinivasan et al. (2021) and is one of the main reasons for exploring a multi-task approach.

4 Approaches

We extensively experiment with a wide-array of multi-task as well as single-task regression models to provide a fair comparison between different approaches to zero-shot performance prediction.

4.1 Baselines

Average Score Within a Task (AWT) : The performance for a pivot-target pair (p , t) on a task $\mathfrak{t}$ is approximated by taking the average of the performance on all other target languages (pivot being fixed) in the same task $\mathfrak{t}$, i.e., $f(x_{p,t}, \mathfrak{t}) = \frac{1}{|\mathcal{T}|-1} \sum_{t' \in \mathcal{T}-\{t\}} y^{\mathfrak{t}}_{p,t'}$.

Average Score across the Tasks (AAT) : Here instead of averaging over all the target languages within a task, we approximate the performance on a given target language by averaging the scores for that language across the other tasks, i.e., $f(x_{p,t}, \mathfrak{t}) = \frac{1}{|\mathfrak{T}|-1} \sum_{\mathfrak{t}' \in \mathfrak{T}-\{\mathfrak{t}\}} y^{\mathfrak{t}'}_{p,t}$.

4.2 Single Task Models

Lasso Regression: Lauscher et al. (2020) train different linear regression models for each task. Along similar lines, we experiment with linear regression, but also add an L1 regularization term, as we observed it usually leads to better predictors.

XGBoost Regressor: As shown in Srinivasan et al. (2021), XGBoost (Chen and Guestrin, 2016) generally obtains impressive performance on this task, and hence we include it in our experiments as well.

4.3 Multi Task Models

Group Lasso: l_1/l_q norm based block-regularization has been shown to be effective for multi-task learning in the setting of multi-linear regression (Yuan and Lin, 2006; Argyriou et al., 2008). For each task, consider separate linear regression models represented by the weight matrix $\Phi \in \mathbb{R}^{n \times |\mathfrak{T}|}$. The l_1/l_q regularization term is given as: $\|\Phi\|_{1,q} = \sum_{j=1}^{n} (\sum_{\mathfrak{t}=1}^{|\mathfrak{T}|} |\Phi_{j\mathfrak{t}}|^q)^{1/q}$, where $\Phi_{j\mathfrak{t}}$ denotes the weight for the feature j in the task $\mathfrak{t}$. For $q > 1$, minimizing this term pushes the l_q-norms corresponding to the weights of a given feature across the tasks to be sparse, which encourages multiple predictors to share similar sparsity patterns. In other words, a common set of features is selected for all the tasks. We use $q = 2$ for the group regularization term.

Since this can be restrictive in certain scenarios, some natural extensions to Group Lasso, such as Dirty Models (Jalali et al., 2010) and Multi Level Lasso (Lozano and Swirszcz, 2012), have been proposed that separate out the task specific and global parameters. We experimented with these methods and observed equivalent or worse performance compared to Group Lasso.

Collective Matrix Factorization (CMF) with Side Information: Low rank approximation for the task weights matrices forms one family of methods for multi-task learning (Zhang and Yang, 2017; Pong et al., 2010; Ando et al., 2005). As a direct analogue with collaborative filtering, here we can think of the tasks as *users* and pivot-target pairs as *items*. Consider the matrix $\mathbf{Y} \in \mathbb{R}^{|\mathfrak{T}| \times |\mathcal{P} \times \mathcal{T}|}$, where each element of the matrix correspond to $y^{\mathfrak{t}}_{p,t}$. We can then decompose the matrix into task and language-pair specific factors as

$$\mathbf{Y} \sim \mathbf{T}\mathbf{L}^T \quad (3)$$

where $\mathbf{T} \in \mathbb{R}^{|\mathfrak{T}| \times d_{latent}}$ and $\mathbf{L} \in \mathbb{R}^{|\mathcal{P} \times \mathcal{T}| \times d_{latent}}$ are the task and language-pair factor matrices, and d_{latent} is the number of factors.

Additionally, in order to incorporate the feature information about the language pairs as discussed in section 3.2, we incorporate Collective Matrix Factorization approach (Cortes, 2018). It incorporates the attribute information about items and/or users in the factorization algorithm by decomposing the language-pair feature matrix $\mathbf{X} \in \mathbb{R}^{|\mathcal{P} \times \mathcal{T}| \times n}$ as $\mathbf{L}\mathbf{F}^{T}$, such that $\mathbf{L}$ is shared across both decompositions. This helps to learn the latent representations for the pivot-language pairs from the task-wise performance as well as different linguistic and MMLM specific features[2]. In relation to Equation 1, we can think of task factors $\mathbf{T}$ to correspond to the task specific parameters Φ, language-pair factors $\mathbf{L}$ as the shared parameters Θ and the predictor model as $f(x_{p,t}, \mathrm{t}; \Theta, \Phi) = (\mathbf{T}\mathbf{L}^{T})_{(p,t),\mathrm{t}}$. Both $\mathbf{L}$ and $\mathbf{T}$ are regularized seperately, but there is no group regularization term ($\lambda_{group} = 0$).

Ye et al. (2021) also uses a Tensor Factorization approach for performance prediction which is similar to our CMF method. However, they train separate models for each task and factorize over metric specific attributes instead for a fine-grained prediction.

Multi-Task Deep Gaussian Process Regression (MDGPR): We use the multi-task variant of Gaussian Processes proposed in Bonilla et al. (2008) and utilize deep neural networks to define the kernel functions as in Deep GPs (Wilson et al., 2016). For comparison, we also report the scores of the single-task variant of this method which we denote as DGPR. See Appendix (section A.1) for details.

Apart from these we also explore other multi-task methods like Model Agnostic Meta Learning (MAML) (Finn et al., 2017), details of which we leave in the appendix (section A.1).

5 Experimental Setup

In this section, we discuss our test conditions, datasets and training parameters for the different experiments.

5.1 Test Conditions

We consider two different test conditions: Leave One Language Out (LOLO) and Leave Low Resource Languages Out (LLRO).

Leave One Language Out: LOLO is a popular setup for multilingual performance prediction (Lauscher et al., 2020; Srinivasan et al., 2021), where for a given task, we choose a target language and move all of its instances from the prediction dataset to the test data. The models are then trained on the remaining languages and evaluated on the unseen test language. This is done for all the target languages available for a task, and the Mean Absolute Error (MAE) across languages is reported. In the multi-task setting we evaluate on one task at a time while considering the rest as helper tasks for which the entire data is used including the test language[3].

Leave Low Resource Languages Out: Through this evaluation strategy we try to emulate the real world use case where we only have test data available in high resource languages such as English, German and Chinese, and would like to estimate the performance on under-represented languages such as Swahili and Bengali. We use the language taxonomy provided by Joshi et al. (2020) to categorize the languages into six classes (0 = low to 5 = high) based on the number of resources available. We then move languages belonging to class 3 or below to our test set and train the models on class 4 and 5 languages only. Similar to LOLO, here too we allow the helper tasks to retain all the languages.

5.2 Tasks and Datasets

We use the following 11 tasks provided in XTREME (Hu et al., 2020) and XTREME-R (Ruder et al., 2021) benchmarks: 1. **Classification**: XNLI (Conneau et al., 2018) , PAWS-X (Yang et al., 2019), and XCOPA (Ponti et al., 2020) 2. **Structure Prediction**: UDPOS (Nivre et al., 2018), and NER (Pan et al., 2017) 3. **Question Answering**: XQUAD (Artetxe et al., 2020), MLQA (Lewis et al., 2020), and TyDiQA-GoldP (Clark et al., 2020) 4. **Retrieval**: Tatoeba (Artetxe and Schwenk, 2019), Mewsli-X (Botha et al., 2020; Ruder et al., 2021), and LAReQA (Roy et al., 2020)

All of these datasets have training data present only in English i.e. $\mathcal{P} = \{\mathtt{en}\}$, and majority of the tasks have fewer than 10 target languages.

---

[2] Note that we can use a similar approach for providing side information for the tasks as well.

[3] Note that this is a reasonable relaxation to make as it is closer to the real world use case where we would have the evaluation data for some languages in the standard tasks and would like to utilize that to make predictions on the same languages for the new ftask.

MMLM	Task	$\|\mathcal{T}\|$	Baselines		Single Task Models			Multi Task Models

Table 1: Mean Absolute Error (scaled by 100 for readability) for LOLO for different approaches across tasks. We also report the average MAE across all tasks ("Average") and for tasks which has less than or equal to 10 languages ("Average ($|\mathcal{T}| \leq 10$)"). Task-wise results for mBERT can be found in the Appendix (table 2)

5.3 Training Details

We train and evaluate our performance prediction models for **mBERT** (*bert-base-multilingual-cased*) and **XLM-R** (*xlm-roberta-large*). For training XGBoost, we used 100 estimators with a maximum depth of 10. For Group Lasso, we used the implementation provided in the MuTaR software package[4], and used a regularization strength of 0.01. We optimized CMF's objective function using Alternating Least Squares (ALS), used 5 latent factors with a regularization parameter equal to 0.1, and used the Collective Matrix Factorization python library[5]. In case of MDGPR, we used Radial Basis Function as the kernel and a two-layer MLP for learning latent features, with 50 and 10 units followed by ReLU activation. We set the learning rate and epochs as 0.01 and 200, and implemented it using GPyTorch[6].

6 Results and Discussion

6.1 LOLO Results

Table 1 shows MAE (in %) for LOLO for different single-task and multi-task models on the tasks. For XLMR, we observe that multi-task models, primarily MDGPR, often outperform the best single-task models by significant margins, and for tasks like MewsliX we even see about 36% reduction in MAE. Overall, we see about 10% drop in LOLO errors on average for MDGPR compared to the best performing single-task model i.e. Lasso Regression. As expected, the benefit of multi-task learning is even more prominent when we consider the tasks for which only a few (≤ 10) data points are available. Here we see about 20% reduction in errors. For mBERT as well, we have similar observations, except that CMF performs slightly better than MDGPR.

Note that the *Average across task* baseline is quite competitive and performs better than single-task XGBoost and MAML in average, and better than all models for LAReQA.

Figure 2 plots the dependence of the number of helper tasks on the performance of the multi-task models. As expected, MAE decreases as helper tasks increase, especially for MDGPR and CMF. On a related note, the Pearson Correlation coefficient between MAE and number of tasks a target language is part of is found to be -0.39, though the trend in this case is not as clear.

6.2 LLRO Results

Predicting the performance on low resource languages, for which often standard training and test datasets are not available, can be an important use case where multi-task performance prediction can be helpful. Figure 6 in appendix shows the class-wise (Joshi et al., 2020) distribution of languages for the tasks that we consider in our experiments. As one would expect, for most tasks, test data is available for languages belonging to class-4 and class-5. Training performance prediction models without any task to transfer from can therefore, possibly lead to poor generalization on the low resource languages. On the other hand, for the same reason - lack of test data, building accurate predictors for low-resource languages is necessary.

---

[4] `https://github.com/hichamjanati/mutar`

[5] `https://github.com/david-cortes/cmfrec`

[6] `https://gpytorch.ai/`

MAE values for the LLRO evaluation setup are shown in figure 1 for XLMR. Results for mBERT follow similar trends and are reported in the Appendix (figure 7). For both XLMR and mBERT we observe that the three main multi-task models – Group Lasso, CMF and MDGPR – outperform the single-task models and baselines. Interestingly, for XLMR, the single task models XGBoost and Lasso perform even worse than the *Average within Tasks* baseline. Overall we see around 18% and 11% drop in MAE for Group Lasso over the best performing single-task model, for XLMR and mBERT respectively.

6.3 Feature Importance

An interesting consequence of zero-shot performance prediction is that the models can be directly used to infer the correlation (and possibly causation) between linguistic relatedness and pretraining conditions and zero-shot transferability. Multi-task learning, in this context, help us make more robust inferences, as the models are less prone to overfitting to a particular task or dataset.

Figure 3 shows the SHAP values of the features for the Group Lasso model trained on XLMR's zero-shot performance data. As expected for Group Lasso, we see a block-sparsity behavior among the tasks. Features such as Rare Typological Traits (WMRR(t)), Tokenizer's Fertility (FERT(t)) and Genetic Similarity ($s_{gen}(p,t)$) are ignored in all the tasks. In contrast, for the single-task lasso regression (Figure 9 in Appendix), we see different sets of features selected for different tasks, which for the scale at which we operate, might not be indicative of the actual factors that affect the zero-shot performance in these tasks.

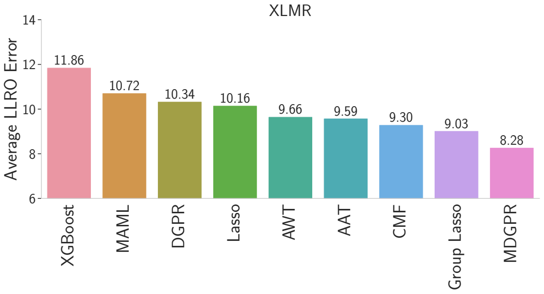

Figure 1: Leave Low Resource Out (LLRO) results for XLMR

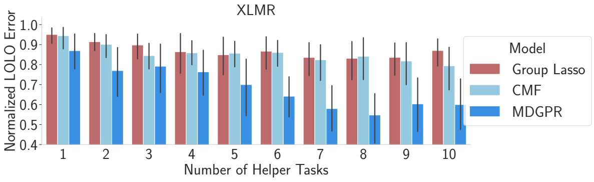

Figure 2: Number of helper tasks vs. LOLO MAE. Errors for different model types (Group Lasso, CMF and MDGPR) and tasks are scaled by diving them by the maximum error value.

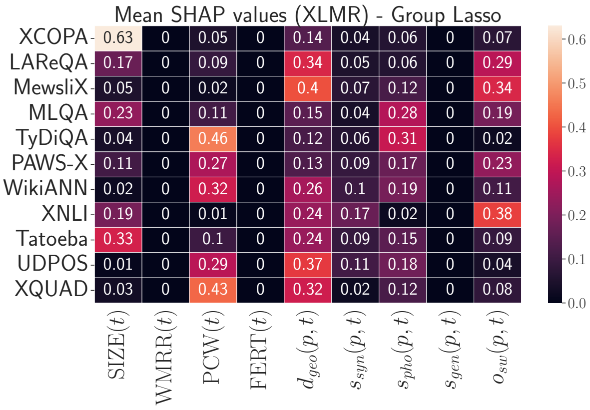

Mean SHAP values (XLMR) - Group Lasso

	SIZE(t)	WMRR(t)	PCW(t)	FERT(t)	$d_{geo}(p,t)$	$s_{syn}(p,t)$	$s_{pho}(p,t)$	$s_{gen}(p,t)$	$o_{sw}(p,t)$
XCOPA	0.63	0	0.05	0	0.14	0.04	0.06	0	0.07

Figure 3: Task-wise mean SHAP values of different features for the Group Lasso model trained on XLMR zero-shot performance data. Higher value implies stronger effect.

Subword Overlap. Among the features that get selected for all tasks, we observe that Subword Overlap ($o_{sw}(p,t)$) typically gets higher importance in retrieval (LAReQA and MewsliX) and sentence classification tasks (PAWS-X, XNLI). Since the retrieval tasks that we consider, as described in Ruder et al. (2021), measure the alignment between the cross lingual representations of semantically similar sentences, having a shared vocabulary between the languages can leak information from one to another (Wu and Dredze, 2019) which might improve the retrieval performance. Interestingly, if we compare this with the feature importance scores for the single task lasso model (Figure 9 in Appendix), we do see MewsliX task getting higher importance for the subword overlap, but LAReQA gets virtually zero SHAP value for this feature, showcasing how single-task models can misinterpret two similar tasks as requiring very different features. Our observation reinforce the generally held notion that vocabulary overlap between the pivot and target is beneficial for zero-shot transfer (Wu and Dredze, 2019), especially for retrieval tasks, though some studies have argued otherwise (Pires et al., 2019; K et al., 2020).

Tokenizer Features. For structure prediction (UDPOS and WikiAnn) and question answering

(XQUAD and TyDiQA) tasks that require making predictions for each token in the input, we see that the tokenizer feature, PCW(t), receive a higher SHAP value. In contrast, for single-task lasso, here too we do not observe high importance of this feature across these related tasks. Rust et al. (2021) note that languages such as Arabic where mBERT's multilingual tokenizer was found to be much worse than it's monolingual counterpart, there was a sharper drop in performance of mBERT compared to the monolingual model for QA, UDPOS and NER tasks than for sentiment classification. We believe that XLMR's surprisingly worse performance than mBERT for Chinese and Japanese on UDPOS might be correlated with it's significantly worse tokenizer for these languages based on the *fertility* (FERT) and *Percentage Continued Words* (PCW) feature values (see Appendix A.2 for exact values). The high SHAP values for PCW(t) further strengthen our belief[7].

Pre-training Size. Similar to the findings of Lauscher et al. (2020), we observe that pre-training corpus size has low SHAP value, and therefore, lower importance for lower level tasks such as UDPOS and NER, and higher SHAP values for higher level tasks like XNLI. Additionally, we extend their observations to tasks such as XCOPA, Tatoeba, MLQA and LAReQA where pre-training size seem to play a significant role in the performance prediction. Again, compared to single Lasso Regression model, we see a different selection pattern: Pre-training size receives a high SHAP value for UDPOS while for XNLI it is negligible. This neither fully conforms with our observations on the multi-task feature selections, nor with the previous work (Lauscher et al., 2020).

Typological Relatedness Features. Out of all the typological relatedness features, we found Geographical Distance ($d_{geo}(p,t)$) receiving highest SHAP values for all tasks, implying that geographical proximity between the pivot-target pair is an important factor in determining the zero-shot transferability between them. Lauscher et al. (2020) also observe positive correlations between geographical relatedness and zero-shot performance. The cross-task importance of geographic distance (unlike the other relatedness features) might be attributed to the 100% coverage across languages for the geographical vectors in the URIEL database. In contrast, Syntactic and Phonological vectors have missing values for a majority of the languages (Littell et al., 2017).

Like Lauscher et al. (2020), we also see some dependence on syntactic ($s_{syn}(p,t)$) and phonological ($s_{pho}(p,t)$) similarities for XLMR's zero shot performance on XNLI and XQUAD tasks respectively. However, in both cases we found that the tokenizer feature PCW(t) receives a much higher SHAP value. Interestingly, genetic similarity ($s_{gen}(p,t)$) is not selected for any task, arguably due to the block sparsity in feature selection of Group Lasso. We do see some tasks receiving high SHAP values for $s_{gen}(p,t)$ in single-task lasso (Figure 9 in Appendix). However, the number of such tasks as well as the SHAP values are on the lower side, implying that genetic similarity might not provide any additional information for zero-shot transfer over and above the geographical, syntactic and phonological similarities.

Similar trends are observed in the case of mBERT as well (Figure 10 in appendix), with some minor differences. For instance, instead of PCW(t), FERT(t) receives higher SHAP value; $s_{syn}(p,t)$ also receives higher importance, especially for tasks like UDPOS and XNLI, which is consistent with the findings of Lauscher et al. (2020).

7 Conclusion and Future Work

In this paper, we showed that the zero-shot performance prediction problem can be much more effectively and robustly solved by using multi-task learning approaches. We see significant reduction in errors compared to the baselines and single-task models, specifically for the tasks which have test sets available in a very few languages or when trying to predict the performance for low resource languages. Additionally, this approach allows us to robustly identify factors that influence zero-shot performance. Our findings in this context can be summarized as follows.

1. *Subword overlap* between the pivot and target has a strong positive influence on zero-shot transfer, especially for Retrieval tasks. 2. *Quality of the target tokenizer*, defined in terms of how often or how aggressively it splits the target tokens negatively influences zero-shot performance for word-level tasks such as POS tagging and Span extraction. 3. *Pre-training size* of the target positively

---

[7] Note that Rust et al. (2021) shows the importance of tokenizer metrics for the case where the multilingual models are fine-tuned on the target language, whereas we analyze their importance for zero-shot transfer.

influences zero-shot performance in many tasks, including XCOPA, Tatoeba, MLQA and LAReQA. 4. *Geographical proximity* between pivot and target is found to be uniformly important across all the tasks, unlike syntactic and phonological similarities, which are important for only some tasks.

This last finding is especially interesting. As described earlier, geographical proximity is a more clear, noise-free and complete feature compared to the other relatedness metrics. However, one could also argue that since neighboring languages tend to have high vocabulary and typological feature overlap due to contact processes and shared areal features, geographical distance is an extremely informative feature for zero-shot transfer. Two direct implications of these findings are: (1) for effective use of MMLMs, one should develop resources in at least one pivot language per geographic regions, and (2) one should work towards multilingual tokenizers that are effective for most languages.

There are a number of directions that can be explored in future related to our work. The prediction models can be extended to a multi-pivot and few-shot settings, as described in Srinivasan et al. (2021). Further probing experiments could be designed to understand the role of sub-word overlap on zero-shot transfer of Retrieval tasks.

A Appendix

A.1 Additional Details of Approaches Used

Gaussian Process Regression (GPR): We start by briefly reviewing Gaussian Processes (GP) in context of the zero-shot performance prediction problem. For a pivot-target language pair (p, t) and a task $\mathfrak{t}$, the GP prior and the likelihood function can be defined as:

$$f \sim \mathcal{N}(\mu^{\mathfrak{t}}, K^{\mathfrak{t}}); \quad y|f(x_{p,t}) \sim \mathcal{N}(y^{\mathfrak{t}}_{p,t}; f(x_{p,t}), \sigma^2_{\mathfrak{t}}) \tag{4}$$

where $\mu^{\mathfrak{t}}$ is the mean and $K^{\mathfrak{t}}_{(p,t),(p',t')} = k^{\mathfrak{t}}(x_{p,t}, x_{p',t'})$ is the kernel of the GP defined on the task $\mathfrak{t}$. $\sigma^2_{\mathfrak{t}}$ denotes the noise variance.

Deep Gaussian Process Regression (DGPR): We use DGP (Wilson et al., 2016) to learn rich features from the observed data. Specifically, the kernel $k^{\mathfrak{t}}(x_{p,t}, x_{p',t'})$ now takes the transformed inputs as

$$k^{\mathfrak{t}}(x_{p,t}, x_{p',t'}) = k^{\mathfrak{t}}(g(x_{p,t}), g(x_{p',t'})) \tag{5}$$

where $g(x)$ is a non-linear mapping given by a deep network. Please refer to Wilson et al. (2016) for a detail account on optimization of DGP.

Multi-Task Deep Gaussian Process Regression (MDGPR): We use the multi-task variant of Gaussian Processes proposed in Bonilla et al. (2008)

where inter-task similarities are learnt solely based on the task identities and the observed data for each task. Instead of learning task-specific kernels $k^{\mathfrak{t}}(g(x_{p,t}), g(x_{p',t'}))$, we will have a common kernel over the inputs as $k(g(x_{p,t}), g(x_{p',t'}))$ and a positive semi-definite matrix K_{task} for learning inter-task similarities. Specifically, we define the multi-task kernel K_m as follows

$$k_m([x_{p,t}, \mathfrak{t}], [x_{p',t'}, \mathfrak{t}']) = \\ k(g(x_{p,t}), g(x_{p',t'})) * k_{\text{task}}(\mathfrak{t}, \mathfrak{t}') \quad (6)$$

The GP prior will be defined by replacing the task specific kernel $K^{\mathfrak{t}}$ in the equation 4 with the multi-task kernel K_m. We use the optimization steps similar to DGP and the inference is done by using the standard GP formulae.

Relating MDGPR to equation 1, the global parameters Θ are the parameters of the deep network g, and the task specific parameter Φ is the positive semi-definite matrix K_{task}.

Model Agnostic Meta Learning (MAML): MAML (Finn et al., 2017) is a popular meta learning algorithm that can be used to quickly adapt Deep Neural Networks on new tasks in a few-shot setting. In MAML, the set of initialization parameters for the neural network are explicitly learned such that the network can generalize well on a new task with a small number of gradient steps and training samples.

Relating to equation 1, the global parameters Θ can be considered as the initial set of parameters for the neural network that are learned and shared across all the tasks. Task specific parameters Φ are adapted from Θ by taking K gradient steps using the task's performance data.

For evaluating a task $\mathfrak{t}$, we consider rest of the tasks in our dataset as helpers ($\mathfrak{t}' \in \mathfrak{T} - \{\mathfrak{t}\}$) and use them to train the initial set of parameters Θ. The initial parameters are then updated by fine-tuning the network on the training set for $\mathfrak{t}$ using gradient descent.

A.2 Comparison between mBERT and XLMR Tokenizers

The FERT and PCW metrics as proposed by Rust et al. (2021), have been compared for mBERT and XLMR in figure 4. As can be seen, for most languages the metric values are similar across the two tokenizers, however for languages like Chinese and Japanese, there is a dramatic increase in the values for XLMR. Interestingly, when we compare the zero-shot performance between mBERT and XLMR on structure prediction tasks like UDPOS and WikiANN, we see a surprisingly large drop (upto 20% absolute drop) in the performance for XLMR on these both Chinese and Japanese, whereas usually XLMR outperforms mBERT on these tasks (Refer to figure 5). This observation along with the feature importance for the tokenizer features that we observed for Group Lasso (3) indicate that tokenizer quality might play some role in the zero-shot transfer capabilities of the multilingual models.

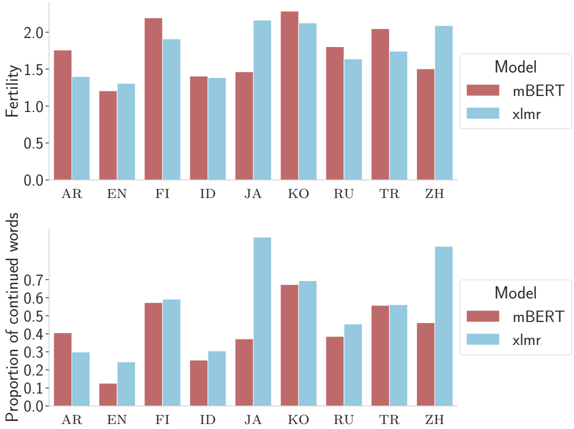

Figure 4: Comparison of Tokenizer metrics as described by Rust et al. (2021) on different languages for MBERT and XLMR. For most languages both model's have similar values of fertility and proportion of continued words, however for Chinese and Japanese the values for XLMR are much higher, which might indicate the subpar quality of XLMR's tokenizer in these languages.

Abstract

Transformers are unable to model long-term memories effectively, since the amount of computation they need to perform grows with the context length. While variations of efficient transformers have been proposed, they all have a finite memory capacity and are forced to drop old information. In this paper, we propose the ∞-*former*, which extends the vanilla transformer with an *unbounded* long-term memory. By making use of a continuous-space attention mechanism to attend over the long-term memory, the ∞-former's attention complexity becomes independent of the context length, trading off memory length with precision. In order to control where precision is more important, ∞-former maintains "sticky memories," being able to model arbitrarily long contexts while keeping the computation budget fixed. Experiments on a synthetic sorting task, language modeling, and document grounded dialogue generation demonstrate the ∞-former's ability to retain information from long sequences.[1]

1 Introduction

When reading or writing a document, it is important to keep in memory the information previously read or written. Humans have a remarkable ability to remember long-term context, keeping in memory the relevant details (Carroll, 2007; Kuhbandner, 2020). Recently, transformer-based language models have achieved impressive results by increasing the context size (Radford et al., 2018, 2019; Dai et al., 2019; Rae et al., 2019; Brown et al., 2020). However, while humans process information sequentially, updating their memories continuously, and recurrent neural networks (RNNs) update a single memory vector during time, transformers do not – they exhaustively query every representation associated to the past events. Thus, the amount of computation they need to perform grows with the length of the context, and, consequently, transformers have computational limitations about how much information can fit into memory. For example, a vanilla transformer requires quadratic time to process an input sequence and linear time to attend to the context when generating every new word.

Several variations have been proposed to address this problem (Tay et al., 2020b). Some propose using sparse attention mechanisms, either with data-dependent patterns (Kitaev et al., 2020; Vyas et al., 2020; Tay et al., 2020a; Roy et al., 2021; Wang et al., 2021) or data-independent patterns (Child et al., 2019; Beltagy et al., 2020; Zaheer et al., 2020), reducing the self-attention complexity (Katharopoulos et al., 2020; Choromanski et al., 2021; Peng et al., 2021; Jaegle et al., 2021), and caching past representations in a memory (Dai et al., 2019; Rae et al., 2019). These models are able to reduce the attention complexity, and, consequently, to scale up to longer contexts. However, as their complexity still depends on the context length, they cannot deal with unbounded context.

In this paper, we propose the ∞**-former** (*infinite former*; Fig. 1): a transformer model extended with an unbounded long-term memory (LTM), which allows the model to attend to arbitrarily long contexts. The key for making the LTM unbounded is a continuous-space attention framework (Martins et al., 2020) which trades off the number of information units that fit into memory (basis functions) with the granularity of their representations. In this framework, the input sequence is represented as a **continuous signal**, expressed as a linear combination of N radial basis functions (RBFs). By doing this, the ∞-former's attention complexity is $\mathcal{O}(L^2 + L \times N)$ while the vanilla transformer's is $\mathcal{O}(L \times (L + L_{\text{LTM}}))$, where L and L_{LTM} correspond to the transformer input size and the long-term memory length, respectively (details in §3.1.1). Thus, this representation comes with

two significant advantages: (i) the context can be represented using a number of basis functions N smaller than the number of tokens, reducing the attention computational cost; and (ii) N can be *fixed*, making it possible to represent unbounded context in memory, as described in §3.2 and Fig. 2, without increasing its attention complexity. The price, of course, is a loss in resolution: using a smaller number of basis functions leads to lower precision when representing the input sequence as a continuous signal, as shown in Fig. 3.

To mitigate the problem of losing resolution, we introduce the concept of "sticky memories" (§3.3), in which we attribute a larger space in the LTM's signal to regions of the memory more frequently accessed. This creates a notion of "permanence" in the LTM, allowing the model to better capture long contexts without losing the relevant information, which takes inspiration from long-term potentiation and plasticity in the brain (Mills et al., 2014; Bamji, 2005).

To sum up, our contributions are the following:

- We propose the ∞-former, in which we extend the transformer model with a continuous long-term memory (§3.1). Since the attention computational complexity is independent of the context length, the ∞-former is able to model long contexts.
- We propose a procedure that allows the model to keep unbounded context in memory (§3.2).
- We introduce sticky memories, a procedure that enforces the persistence of important information in the LTM (§3.3).
- We perform empirical comparisons in a synthetic task (§4.1), which considers increasingly long sequences, in language modeling (§4.2), and in document grounded dialogue generation (§4.3). These experiments show the benefits of using an unbounded memory.

2 Background

2.1 Transformer

A transformer (Vaswani et al., 2017) is composed of several layers, which encompass a multi-head self-attention layer followed by a feed-forward layer, along with residual connections (He et al., 2016) and layer normalization (Ba et al., 2016).

Let us denote the input sequence as $X = [x_1, \ldots, x_L] \in \mathbb{R}^{L \times e}$, where L is the input size and e is the embedding size of the attention layer. The queries Q, keys K, and values V, to be used in the multi-head self-attention computation are obtained by linearly projecting the input, or the output of the previous layer, X, for each attention head h:

$$Q_h = X_h W^{Q_h},\; K_h = X_h W^{K_h},\, V_h = X_h W^{V_h}, \tag{1}$$

where $W^{Q_h}, W^{K_h}, W^{V_h} \in \mathbb{R}^{d \times d}$ are learnable projection matrices, $d = {}^{e}\!/\!{}_{H}$, and H is the number of heads. Then, the context representation $Z_h \in \mathbb{R}^{L \times d}$, that corresponds to each attention head h, is obtained as:

$$Z_h = \mathsf{softmax}\left(\frac{Q_h K_h^\top}{\sqrt{d}}\right) V_h, \tag{2}$$

where the softmax is performed row-wise. The head context representations are concatenated to obtain the final context representation $Z \in \mathbb{R}^{L \times e}$:

$$Z = [Z_1, \ldots, Z_H] W^R, \tag{3}$$

where $W^R \in \mathbb{R}^{e \times e}$ is another projection matrix that aggregates all head's representations.

2.2 Continuous Attention

Continuous attention mechanisms (Martins et al., 2020) have been proposed to handle arbitrary continuous signals, where the attention probability mass function over words is replaced by a probability *density* over a signal. This allows time intervals or compact segments to be selected.

To perform continuous attention, the first step is to transform the discrete text sequence represented by $X \in \mathbb{R}^{L \times e}$ into a continuous signal. This is done by expressing it as a linear combination of basis functions. To do so, each x_i, with $i \in \{1, \ldots, L\}$, is first associated with a position in an interval, $t_i \in [0, 1]$, *e.g.*, by setting $t_i = i/L$. Then, we obtain a continuous-space representation $\bar{X}(t) \in \mathbb{R}^e$, for any $t \in [0, 1]$ as:

$$\bar{X}(t) = B^\top \psi(t), \tag{4}$$

where $\psi(t) \in \mathbb{R}^N$ is a vector of N RBFs, e.g., $\psi_j(t) = \mathcal{N}(t; \mu_j, \sigma_j)$, with $\mu_j \in [0, 1]$, and $B \in \mathbb{R}^{N \times e}$ is a coefficient matrix. B is obtained with multivariate ridge regression (Brown et al., 1980) so that $\bar{X}(t_i) \approx x_i$ for each $i \in [L]$, which leads to the closed form (see App. A for details):

$$B^\top = X^\top F^\top (F F^\top + \lambda I)^{-1} = X^\top G, \tag{5}$$

where $F = [\psi(t_1), \ldots, \psi(t_L)] \in \mathbb{R}^{N \times L}$ packs the basis vectors for the L locations. As $G \in \mathbb{R}^{L \times N}$ only depends of F, it can be computed offline.

Having converted the input sequence into a continuous signal $\bar{X}(t)$, the second step is to attend over this signal. To do so, instead of having a discrete probability distribution over the input sequence as in standard attention mechanisms (like in Eq. 2), we have a probability density p, which can be a Gaussian $\mathcal{N}(t; \mu, \sigma^2)$, where μ and σ^2 are computed by a neural component. A unimodal Gaussian distribution encourages each attention head to attend to a single region, as opposed to scattering its attention through many places, and enables tractable computation. Finally, having p, we can compute the context vector c as:

$$c = \mathbb{E}_p \left[\bar{X}(t) \right]. \tag{6}$$

Martins et al. (2020) introduced the continuous attention framework for RNNs. In the following section (§3.1), we will explain how it can be used for transformer multi-head attention.

3 Infinite Memory Transformer

To allow the model to access long-range context, we propose extending the vanilla transformer with a continuous LTM, which stores the input embeddings and hidden states of the previous steps. We also consider the possibility of having two memories: the LTM and a short-term memory (STM), which consists in an extension of the transformer's hidden states and is attended to by the transformer's self-attention, as in the transformer-XL (Dai et al., 2019). A diagram of the model is shown in Fig. 1.

3.1 Long-term Memory

For simplicity, let us first assume that the long-term memory contains an explicit input discrete sequence X that consists of the past text sequence's input embeddings or hidden states,[2] depending on the layer[3] (we will later extend this idea to an unbounded memory in §3.2).

First, we need to transform X into a continuous approximation $\bar{X}(t)$. We compute $\bar{X}(t)$ as:

$$\bar{X}(t) = B^\top \psi(t), \tag{7}$$

where $\psi(t) \in \mathbb{R}^N$ are basis functions and coefficients $B \in \mathbb{R}^{N \times e}$ are computed as in Eq. 5, $B^\top = X^\top G$. Then, we can compute the LTM keys, $K_h \in \mathbb{R}^{N \times d}$, and values, $V_h \in \mathbb{R}^{N \times d}$, for each attention head h, as:

$$K_h = B_h W^{K_h}, \quad V_h = B_h W^{V_h}, \tag{8}$$

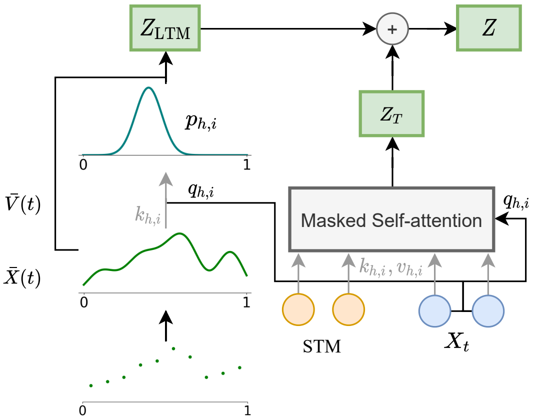

Figure 1: ∞-former's attention diagram with sequence of text, X_t, of size $L = 2$ and STM of size $L_{\text{STM}} = 2$. Circles represent input embeddings or hidden states (depending on the layer) for head h and query i. Both the self-attention and the attention over the LTM are performed in parallel for each head and query.

where $W^{K_h}, W^{V_h} \in \mathbb{R}^{d \times d}$ are learnable projection matrices.[4] For each query $q_{h,i}$ for $i \in \{1, \ldots, L\}$, we use a parameterized network, which takes as input the attention scores, to compute $\mu_{h,i} \in]0, 1[$ and $\sigma^2_{h,i} \in \mathbb{R}_{>0}$:

$$\mu_{h,i} = \text{sigmoid}\left(\text{affine}\left(\frac{K_h \, q_{h,i}}{\sqrt{d}}\right)\right) \tag{9}$$

$$\sigma^2_{h,i} = \text{softplus}\left(\text{affine}\left(\frac{K_h \, q_{h,i}}{\sqrt{d}}\right)\right). \tag{10}$$

Then, using the continuous softmax transformation (Martins et al., 2020), we obtain the probability density $p_{h,i}$ as $\mathcal{N}(t; \mu_{h,i}, \sigma^2_{h,i})$.

Finally, having the value function $\bar{V}_h(t)$ given as $\bar{V}_h(t) = V_h^\top \psi(t)$, we compute the head-specific representation vectors as in Eq. 6:

$$z_{h,i} = \mathbb{E}_{p_{h,i}}[\bar{V}_h] = V_h^\top \mathbb{E}_{p_{h,i}}[\psi(t)] \tag{11}$$

which form the rows of matrix $Z_{\text{LTM},h} \in \mathbb{R}^{L \times d}$ that goes through an affine transformation, $Z_{\text{LTM}} = [Z_{\text{LTM},1}, \ldots, Z_{\text{LTM},H}] W^O$.

The long-term representation, Z_{LTM}, is then summed to the transformer context vector, Z_{T}, to obtain the final context representation $Z \in \mathbb{R}^{L \times e}$:

$$Z = Z_{\text{T}} + Z_{\text{LTM}}, \tag{12}$$

which will be the input to the feed-forward layer.

---

[2] We stop the gradient with respect to the word embeddings or hidden states before storing them in the LTM.

[3] Each layer of the transformer has a different LTM.

[4] Parameter weights are not shared between layers.

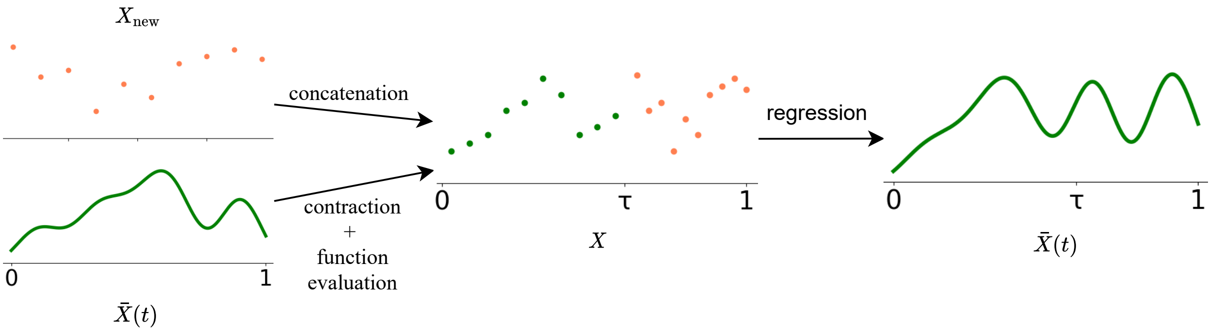

Figure 2: Diagram of the unbounded memory update procedure. This is performed in parallel for each embedding dimension, and repeated throughout the input sequence. We propose two alternatives to select the positions used for the function evaluation: linearly spaced or sticky memories.

3.1.1 Attention Complexity

As the ∞-former makes use of a continuous-space attention framework (Martins et al., 2020) to attend over the LTM signal, its key matrix size $K_h \in \mathbb{R}^{N \times d}$ depends only on the number of basis functions N, but *not* on the length of the context being attended to. Thus, the ∞-former's attention complexity is also independent of the context's length. It corresponds to $\mathcal{O}(L \times (L + L_{\text{STM}}) + L \times N)$ when also using a short-term memory and $\mathcal{O}(L^2 + L \times N)$ when only using the LTM, both $\ll \mathcal{O}(L \times (L + L_{\text{LTM}}))$, which would be the complexity of a vanilla transformer attending to the same context. For this reason, the ∞-former can attend to arbitrarily long contexts without increasing the amount of computation needed.

3.2 Unbounded Memory

When representing the memory as a discrete sequence, to extend it, we need to store the new hidden states in memory. In a vanilla transformer, this is not feasible for long contexts due to the high memory requirements. However, the ∞-former can attend to unbounded context without increasing memory requirements by using continuous attention, as next described and shown in Fig. 2.

To be able to build an unbounded representation, we first sample M locations in $[0, 1]$ and evaluate $\bar{X}(t)$ at those locations. These locations can simply be linearly spaced, or sampled according to the region importance, as described in §3.3.

Then, we concatenate the corresponding vectors with the new vectors coming from the short-term memory. For that, we first need to contract this function by a factor of $\tau \in]0, 1[$ to make room for the new vectors. We do this by defining:

$$X^{\text{contracted}}(t) = X(t/\tau) = B^\top \psi(t/\tau). \quad (13)$$

Then, we can evaluate $\bar{X}(t)$ at the M locations $0 \leq t_1, t_2, \ldots, t_M \leq \tau$ as:

$$x_m = B^\top \psi(t_m/\tau), \quad \text{for } m \in [M], \quad (14)$$

and define a matrix $X_{\text{past}} = [x_1, x_2, \ldots, x_M]^\top \in \mathbb{R}^{M \times e}$ with these vectors as rows. After that, we concatenate this matrix with the new vectors X_{new}, obtaining:

$$X = \left[{X_{\text{past}}}^\top, {X_{\text{new}}}^\top\right]^\top \in \mathbb{R}^{(M+L) \times e}. \quad (15)$$

Finally, we simply need to perform multivariate ridge regression to compute the new coefficient matrix $B \in \mathbb{R}^{N \times e}$, via $B^\top = X^\top G$, as in Eq. 5. To do this, we need to associate the vectors in X_{past} with positions in $[0, \tau]$ and in X_{new} with positions in $]\tau, 1]$ so that we obtain the matrix $G \in \mathbb{R}^{(M+L) \times N}$. We consider the vectors positions to be linearly spaced.

3.3 Sticky Memories

When extending the LTM, we evaluate its current signal at M locations in $[0, 1]$, as shown in Eq. 14. These locations can be linearly spaced. However, some regions of the signal can be more relevant than others, and should consequently be given a larger "memory space" in the next step LTM's signal. To take this into account, we propose sampling the M locations according to the signal's relevance at each region (see Fig. 6 in App. B). To do so, we construct a histogram based on the attention given to each interval of the signal on the previous step. For that, we first divide the signal into

D linearly spaced bins $\{d_1, \dots, d_D\}$. Then, we compute the probability given to each bin, $p(d_j)$ for $j \in \{1, \dots, D\}$, as:

$$p(d_j) \propto \sum_{h=1}^{H} \sum_{i=1}^{L} \int_{d_j} \mathcal{N}(t; \mu_{h,i}, \sigma_{h,i}^2)\, dt, \quad (16)$$

where H is the number of attention heads and L is the sequence length. Note that Eq. 16's integral can be evaluated efficiently using the erf function:

$$\int_a^b \mathcal{N}(t; \mu, \sigma^2) = \frac{1}{2}\left(\text{erf}\left(\frac{b}{\sqrt{2}}\right) - \text{erf}\left(\frac{a}{\sqrt{2}}\right)\right). \quad (17)$$

Then, we sample the M locations at which the LTM's signal is evaluated at, according to p. By doing so, we evaluate the LTM's signal at the regions which were considered more relevant by the previous step's attention, and will, consequently attribute a larger space of the new LTM's signal to the memories stored in those regions.

3.4 Implementation and Learning Details

Discrete sequences can be highly irregular and, consequently, difficult to convert into a continuous signal through regression. Because of this, before applying multivariate ridge regression to convert the discrete sequence X into a continuous signal, we use a simple convolutional layer (with stride $=$ 1 and width $=$ 3) as a gate, to smooth the sequence:

$$\tilde{X} = \mathsf{sigmoid}\left(\text{CNN}(X)\right) \odot X. \quad (18)$$

To train the model we use the cross entropy loss. Having a sequence of text X of length L as input, a language model outputs a probability distribution of the next word $p(x_{t+1} \mid x_t, \dots, x_{t-L})$. Given a corpus of T tokens, we train the model to minimize its negative log likelihood:

$$\mathcal{L}_{\text{NLL}} = -\sum_{t=0}^{T-1} \log p(x_{t+1} \mid x_t, \dots, x_{t-L}). \quad (19)$$

Additionally, in order to avoid having uniform distributions over the LTM, we regularize the continuous attention given to the LTM, by minimizing the Kullback-Leibler (KL) divergence, D_{KL}, between the attention probability density, $\mathcal{N}(\mu_h, \sigma_h)$, and a Gaussian prior, $\mathcal{N}(\mu_0, \sigma_0)$. As different heads can attend to different regions, we set $\mu_0 = \mu_h$, regularizing only the attention variance, and get:

$$\mathcal{L}_{\text{KL}} = \sum_{t=0}^{T-1} \sum_{h=1}^{H} D_{\text{KL}}\left(\mathcal{N}(\mu_h, \sigma_h) \mid\mid \mathcal{N}(\mu_h, \sigma_0)\right) \quad (20)$$

$$= \sum_{t=0}^{T-1} \sum_{h=1}^{H} \frac{1}{2}\left(\frac{\sigma_h^2}{\sigma_0^2} - \log\left(\frac{\sigma_h}{\sigma_0}\right) - 1\right). \quad (21)$$

Thus, the final loss that is minimized corresponds to:

$$\mathcal{L} = \mathcal{L}_{\text{NLL}} + \lambda_{\text{KL}} \mathcal{L}_{\text{KL}}, \quad (22)$$

where λ_{KL} is a hyperparameter that controls the amount of KL regularization.

4 Experiments

To understand if the ∞-former is able to model long contexts, we first performed experiments on a synthetic task, which consists of sorting tokens by their frequencies in a long sequence (§4.1). Then, we performed experiments on language modeling (§4.2) and document grounded dialogue generation (§4.3) by fine-tuning a pre-trained language model.[5]

4.1 Sorting

In this task, the input consists of a sequence of tokens sampled according to a token probability distribution (which is not known to the system). The goal is to generate the tokens in the decreasing order of their frequencies in the sequence. One example can be:

$$\underbrace{1\ 2\ 1\ 3\ 1\ 0\ 3\ 1\ 3\ 2}_{\text{1 occurs 4 times; 3 occurs 3 times, etc.}}\ \texttt{<SEP>}\ 1\ 3\ 2\ 0$$

To understand if the long-term memory is being effectively used and the transformer is not only performing sorting by modeling the most recent tokens, we design the token probability distribution to *change over time*: namely, we set it as a mixture of two distributions, $p = \alpha p_0 + (1-\alpha)p_1$, where the mixture coefficient $\alpha \in [0, 1]$ is progressively increased from 0 to 1 as the sequence is generated. The vocabulary has 20 tokens and we experiment with sequences of length 4,000, 8,000, and 16,000.

---

[5] See App.D for further experiments on language modeling.

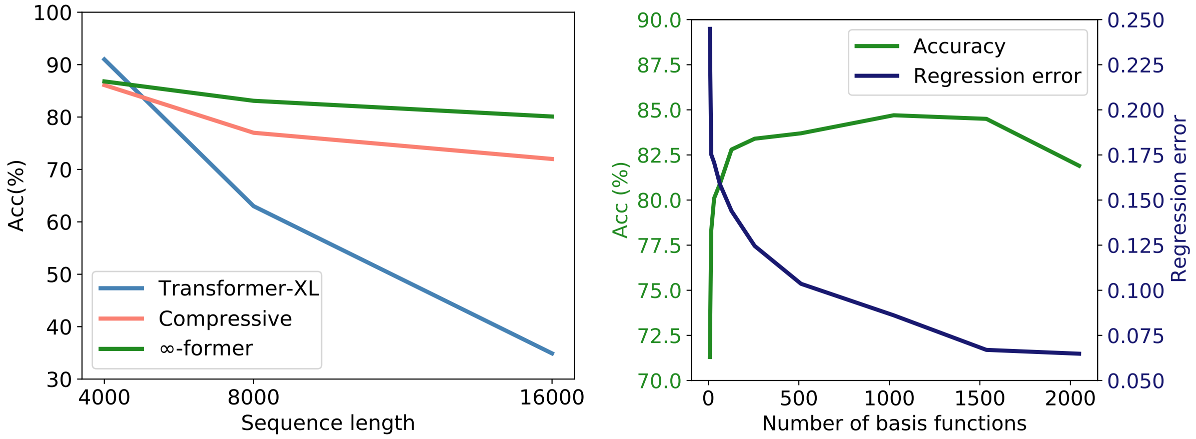

Figure 3: Left: Sorting task accuracy for sequences of length 4,000, 8,000, and 16,000. Right: Sorting task accuracy vs regression mean error, when varying the number of basis functions, for sequences of length 8,000.

Baselines. We consider the transformer-XL[6] (Dai et al., 2019) and the compressive transformer[7] (Rae et al., 2019) as baselines. The transformer-XL consists of a vanilla transformer (Vaswani et al., 2017) extended with a short-term memory which is composed of the hidden states of the previous steps. The compressive transformer is an extension of the transformer-XL: besides the short-term memory, it has a compressive long-term memory which is composed of the old vectors of the short-term memory, compressed using a CNN. Both the transformer-XL and the compressive transformer require relative positional encodings. In contrast, there is no need for positional encodings in the memory in our approach since the memory vectors represent basis coefficients in a predefined continuous space.

For all models we used a transformer with 3 layers and 6 attention heads, input size $L = 1,024$ and memory size 2,048. For the compressive transformer, both memories have size 1,024. For the ∞-former, we also consider a STM of size 1,024 and a LTM with $N = 1,024$ basis functions, having the models the same computational cost. Further details are described in App. C.1.

Results. As can be seen in the left plot of Fig. 3, the transformer-XL achieves a slightly higher accuracy than the compressive transformer and ∞-former for a short sequence length (4,000). This is because the transformer-XL is able to keep almost the entire sequence in memory. However, its accuracy degrades rapidly when the sequence length is increased. Both the compressive transformer and ∞-former also lead to smaller accuracies when increasing the sequence length, as expected. However, this decrease is not so significant for the ∞-former, which indicates that it is better at modeling long sequences.

Regression error analysis. To better understand the trade-off between the ∞-former's memory precision and its computational efficiency, we analyze how its regression error and sorting accuracy vary when varying the number of basis functions used, on the sorting task with input sequences of length 8,000. As can be seen in the right plot of Fig. 3, the sorting accuracy is negatively correlated with the regression error, which is positively correlated with the number of basis functions. It can also be observed, that when increasing substantially the number of basis functions the regression error reaches a plateau and the accuracy starts to drop. We posit that the latter is caused by the model having a harder task at selecting the locations it should attend to. This shows that, as expected, when increasing ∞-former's efficiency or increasing the size of context being modeled, the memory loses precision.

4.2 Language Modeling

To understand if long-term memories can be used to extend a pre-trained language model, we fine-tune GPT-2 small (Radford et al., 2019) on Wikitext-103 (Merity et al., 2017) and a subset of PG-19 (Rae et al., 2019) containing the first 2,000 books ($\approx$ 200 million tokens) of the training set. To do so, we extend GPT-2 with a continuous long-term memory (∞-former) and a compressed memory (compressive transformer) with a positional bias,

---

[6] We use the authors' implementation available at `https://github.com/kimiyoung/transformer-xl`.

[7] We use our implementation of the model.

	Wikitext-103	PG19
GPT-2	16.85	33.44
Compressive	16.87	33.09
∞-former	16.64	32.61
∞-former (SM)	**16.61**	**32.48**

Table 1: Perplexity on Wikitext-103 and PG19.

	PPL	F1	Rouge-1	Rouge-L	Meteor
GPT-2 w/o doc	19.43	7.82	12.18	10.17	6.10
GPT-2	18.53	8.64	14.61	12.03	7.15
Compressive	**18.02**	8.78	14.74	12.14	7.29
∞-former	**18.02**	8.92	15.28	12.51	7.52
∞-former (SM)	18.04	**9.01**	**15.37**	**12.56**	**7.55**

Table 2: Results on CMU-DoG dataset.

based on Press et al. (2021).[8]

For these experiments, we consider transformers with input size $L = 512$, for the compressive transformer we use a compressed memory of size 512, and for the ∞-former we consider a LTM with $N = 512$ Gaussian RBFs and a memory threshold of 2,048 tokens, having the same computational budget for the two models. Further details and hyperparameters are described in App. C.2.

Results. The results reported in Table 1 show that the ∞-former leads to perplexity improvements on both Wikitext-103 and PG19, while the compressive transformer only has a slight improvement on the latter. The improvements obtained by the ∞-former are larger on the PG19 dataset, which can be justified by the nature of the datasets: books have more long range dependencies than Wikipedia articles (Rae et al., 2019).

4.3 Document Grounded Dialogue

In document grounded dialogue generation, besides the dialogue history, models have access to a document concerning the conversation's topic. In the CMU Document Grounded Conversation dataset (CMU-DoG) (Zhou et al., 2018), the dialogues are about movies and a summary of the movie is given as the auxiliary document; the auxiliary document is divided into parts that should be considered for the different utterances of the dialogue. In this paper, to evaluate the usefulness of the long-term memories, we make this task slightly more challenging by only giving the models access to the document before the start of the dialogue.

We fine-tune GPT-2 small (Radford et al., 2019) using an approach based on Wolf et al. (2019). To allow the model to keep the whole document on memory, we extend GPT-2 with a continuous LTM (∞-former) with $N = 512$ basis functions. As baselines, we use GPT-2, with and without access (GPT-2 w/o doc) to the auxiliary document, with input size $L = 512$, and GPT-2 with a compressed memory with attention positional biases (compressive), of size 512. Further details and hyper-parameters are stated in App. C.3.

To evaluate the models we use the metrics: perplexity, F1 score, Rouge-1 and Rouge-L (Lin, 2004), and Meteor (Banerjee and Lavie, 2005).

Results. As shown in Table 2, by keeping the whole auxiliary document in memory, the ∞-former and the compressive transformer are able to generate better utterances, according to all metrics. While the compressive and ∞-former achieve essentially the same perplexity in this task, the ∞-former achieves consistently better scores on all other metrics. Also, using sticky memories leads to slightly better results on those metrics, which suggests that attributing a larger space in the LTM to the most relevant tokens can be beneficial.

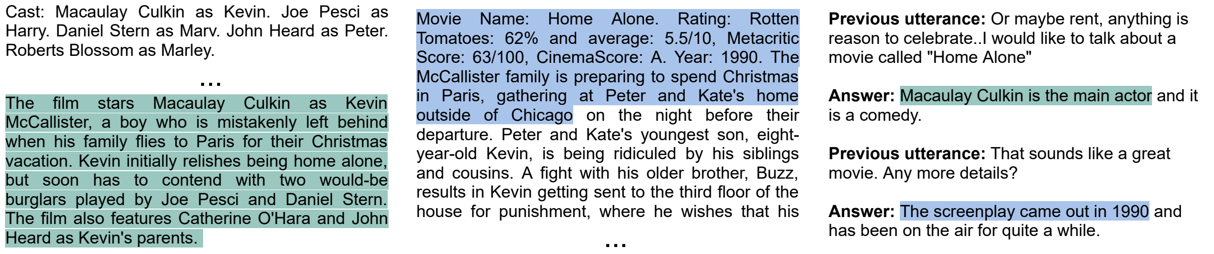
Analysis. In Fig. 4, we show examples of utterances generated by ∞-former along with the excerpts from the LTM that receive higher attention throughout the utterances' generation. In these examples, we can clearly see that these excerpts are highly pertinent to the answers being generated. Also, in Fig. 5, we can see that the phrases which are attributed larger spaces in the LTM, when using sticky memories, are relevant to the conversations.

5 Related Work

Continuous attention. Martins et al. (2020) introduced 1D and 2D continuous attention, using Gaussians and truncated parabolas as densities. They applied it to RNN-based document classification, machine translation, and visual question answering. Several other works have also proposed the use of (discretized) Gaussian attention for natural language processing tasks: Guo et al. (2019) proposed a Gaussian prior to the self-attention mechanism to bias the model to give higher attention to nearby words, and applied it to natural language inference; You et al. (2020) proposed the use

---

[8] The compressive transformer requires relative positional encodings. When using only GPT-2's absolute positional encodings the model gives too much attention to the compressed memory, and, consequently, diverges. Thus, we adapted it by using positional biases on the attention mechanism.



Cast: Macaulay Culkin as Kevin. Joe Pesci as Harry. Daniel Stern as Marv. John Heard as Peter. Roberts Blossom as Marley.

...

The film stars Macaulay Culkin as Kevin McCallister, a boy who is mistakenly left behind when his family flies to Paris for their Christmas vacation. Kevin initially relishes being home alone, but soon has to contend with two would-be burglars played by Joe Pesci and Daniel Stern. The film also features Catherine O'Hara and John Heard as Kevin's parents.

Movie Name: Home Alone. Rating: Rotten Tomatoes: 62% and average: 5.5/10, Metacritic Score: 63/100, CinemaScore: A. Year: 1990. The McCallister family is preparing to spend Christmas in Paris, gathering at Peter and Kate's home outside of Chicago on the night before their departure. Peter and Kate's youngest son, eight-year-old Kevin, is being ridiculed by his siblings and cousins. A fight with his older brother, Buzz, results in Kevin getting sent to the third floor of the house for punishment, where he wishes that his

...

Previous utterance: Or maybe rent, anything is reason to celebrate..I would like to talk about a movie called "Home Alone"

Answer: Macaulay Culkin is the main actor and it is a comedy.

Previous utterance: That sounds like a great movie. Any more details?

Answer: The screenplay came out in 1990 and has been on the air for quite a while.

Toy Story: Tom Hanks as Woody | animated buddy comedy | Toy Story was the first feature length computer animated film | produced by Pixar | toys pretend to be lifeless whenever humans are present | focuses on the relationship between Woody and Gold | fashioned pull string cowboy doll

La La Land: Ryan Gosling | Emma Stone as Mia | Hollywood | the city of Los Angeles | Meta critics: 93/100 | 2016 | During a gig at a restaurant Sebastian slips into a passionate jazz | despite warning from the owner | Mia overhears the music as she passes by | for his disobedience

Figure 5: Phrases that hold larger spaces of the LTM, when using sticky memories, for two dialogue examples (in App. E).

of hard-coded Gaussian attention as input-agnostic self-attention layer for machine translation; Dubois et al. (2020) proposed using Gaussian attention as a location attention mechanism to improve the model generalization to longer sequences. However, these approaches still consider discrete sequences and compute the attention by evaluating the Gaussian density at the token positions. Farinhas et al. (2021) extend continuous attention to multimodal densities, *i.e.*, mixtures of Gaussians, and applied it to VQA. In this paper, we opt for the simpler case, an unimodal Gaussian, and leave sparse and multimodal continuous attention for future work.

Efficient transformers. Several methods have been proposed that reduce the transformer's attention complexity, and can, consequently, model longer contexts. Some of these do so by performing sparse attention, either by selecting pre-defined attention patterns (Child et al., 2019; Beltagy et al., 2020; Zaheer et al., 2020), or by learning these patterns from data (Kitaev et al., 2020; Vyas et al., 2020; Tay et al., 2020a; Roy et al., 2021; Wang et al., 2021). Other works focus on directly reducing the attention complexity by applying the (reversed) kernel trick (Katharopoulos et al., 2020; Choromanski et al., 2021; Peng et al., 2021; Jaegle et al., 2021). Closer to our approach are the transformer-XL and compressive transformer models (Dai et al., 2019; Rae et al., 2019), which extend the vanilla transformer with a bounded memory.

Memory-augmented language models. RNNs, LSTMs, and GRUs (Hochreiter et al., 1997; Cho et al., 2014) have the ability of keeping a memory state of the past. However, these require backpropagation through time which is impractical for long sequences. Because of this, Graves et al. (2014), Weston et al. (2014), Joulin and Mikolov (2015) and Grefenstette et al. (2015) proposed extending RNNs with an external memory, while Chandar et al. (2016) and Rae et al. (2016) proposed efficient procedures to read and write from these memories, using hierarchies and sparsity. Grave et al. (2016) and Merity et al. (2017) proposed the use of cache-based memories which store pairs of hidden states and output tokens from previous steps. The distribution over the words in the memory is then combined with the distribution given by the language model. More recently, Khandelwal et al. (2019) and Yogatama et al. (2021) proposed using nearest neighbors to retrieve words from a key-based memory constructed based on the training data. Similarly, Fan et al. (2021) proposed retrieving sentences from a memory based on the training data and auxiliary information. Khandelwal et al. (2019) proposed interpolating the retrieved words probability distributions with the probability over the vocabulary words when generating a new word, while Yogatama et al. (2021) and Fan et al. (2021) proposed combining the information at the architecture level. These models have the disadvantage of needing to perform a retrieval step when generating each token / utterance, which can be computationally expensive. These approaches are orthogonal to the ∞-former's LTM and in future work the two can be combined.

6 Conclusions

In this paper, we proposed the ∞-former: a transformer extended with an unbounded long-term memory. By using a continuous-space attention framework, its attention complexity is independent of the context's length, which allows the model to attend to arbitrarily long contexts while keeping a fixed computation budget. By updating the memory taking into account past usage, the model keeps "sticky memories", enforcing the persistence of relevant information in memory over time. Experiments on a sorting synthetic task show that ∞-former scales up to long sequences, maintaining a high accuracy. Experiments on language modeling and document grounded dialogue generation by fine-tuning a pre-trained language model have shown improvements across several metrics.

Ethics Statement

Transformer models that attend to long contexts, to improve their generation quality, need large amounts of computation and memory to perform self-attention. In this paper, we propose an extension to a transformer model that makes the attention complexity independent of the length of the context being attended to. This can lead to a reduced number of parameters needed to model the same context, which can, consequently, lead to gains in efficiency and reduce energy consumption.

On the other hand, the ∞-former, as well as the other transformer language models, can be used on questionable scenarios, such as the generation of fake news (Zellers et al., 2019), defamatory text (Wallace et al., 2019), or other undesired content.

A Multivariate ridge regression

The coefficient matrix $B \in \mathbb{R}^{N \times e}$ is obtained with multivariate ridge regression criterion so that $\bar{X}(t_i) \approx x_i$ for each $i \in [L]$, which leads to the closed form:

$$B^\top = \arg\min_{B^\top} ||B^\top F - X^\top||_{\mathcal{F}}^2 + \lambda||B||_{\mathcal{F}}^2 \\ = X^\top F^\top (FF^\top + \lambda I)^{-1} = X^\top G, \tag{23}$$

where $F = [\psi(t_1), \ldots, \psi(t_L)]$ packs the basis vectors for L locations and $|| \cdot ||_{\mathcal{F}}$ is the Frobenius norm. As $G \in \mathbb{R}^{L \times N}$ only depends of F, it can be computed offline.

B Sticky memories

We present in Fig. 6 a scheme of the sticky memories procedure. First we sample M locations from the previous step LTM attention histogram (Eq. 16). Then, we evaluate the LTM's signal at the sampled locations (Eq. 14). Finally, we consider that the sampled vectors, X_{past}, are linearly spaced in $[0, \tau]$. This way, the model is able to attribute larger spaces of its memory to the relevant words.

C Experimental details

C.1 Sorting

For the compressive transformer, we consider compression rates of size 2 for sequences of length 4,000, from 2 to 6 for sequences of length 8,000, and from 2 to 12 for sequences of length 16,000. We also experiment training the compressive transformer with and without the attention reconstruction auxiliary loss. For the ∞-former we consider 1,024 Gaussian RBFs $\mathcal{N}(t; \tilde{\mu}, \tilde{\sigma}^2)$ with $\tilde{\mu}$ linearly spaced in $[0, 1]$ and $\tilde{\sigma} \in \{.01, .05\}$. We set $\tau = 0.75$ and for the KL regularization we used $\lambda_{\text{KL}} = 1 \times 10^{-5}$ and $\sigma_0 = 0.05$.

For this task, for each sequence length, we created a training set with 8,000 sequences and validation and test sets with 800 sequences. We trained all models with batches of size 8 for 20 epochs on 1 Nvidia GeForce RTX 2080 Ti or 1 Nvidia GeForce GTX 1080 Ti GPU with $\approx$ 11 Gb of memory, using the Adam optimizer (Kingma and Ba, 2015). For the sequences of length 4,000 and 8,000 we used a learning rate of 2.5×10^{-4} while for sequences of length 16,000 we used a learning rate of 2×10^{-4}. The learning rate was decayed to 0 until the end of training with a cosine schedule.

C.2 Pre-trained Language Models

In these experiments, we fine-tune the GPT-2 small, which is composed of 12 layers with 12 attention heads, on the English dataset Wikitext-103 and on a subset of the English dataset PG19[9] containing the first 2,000 books. We consider an input size $L = 512$ and a long-term memory with $N = 512$ Gaussian RBFs $\mathcal{N}(t; \tilde{\mu}, \tilde{\sigma}^2)$ with $\tilde{\mu}$ linearly spaced in $[0, 1]$ and $\tilde{\sigma} \in \{.005, .01\}$ and for the KL regularization we use $\lambda_{\text{KL}} = 1 \times 10^{-6}$ and $\sigma_0 = 0.05$. We set $\tau = 0.5$. For the compressive transformer we also consider a compressed memory of size 512 with a compression rate of 4, and train the model with the auxiliary reconstruction loss.

We fine-tuned GPT-2 small with a batch size of 1 on 1 Nvidia GeForce RTX 2080 Ti or 1 Nvidia GeForce GTX 1080 Ti GPU with $\approx$ 11 Gb of memory, using the Adam optimizer (Kingma and Ba, 2015) for 1 epoch with a learning rate of 5×10^{-5} for the GPT-2 parameters and a learning rate of 2.5×10^{-4} for the LTM parameters.

C.3 Document Grounded Generation

In these experiments, we fine-tune the GPT-2 small, which is composed of 12 layers with 12 attention heads, on the English dataset CMU - Document Grounded Conversations[10] (CMU-DoG. CMU-DoG has 4112 conversations, being the proportion of train/validation/test split 0.8/0.05/0.15.

We consider an input size $L = 512$ and a long-term memory with $N = 512$ Gaussian RBFs $\mathcal{N}(t; \tilde{\mu}, \tilde{\sigma}^2)$ with $\tilde{\mu}$ linearly spaced in $[0, 1]$ and $\tilde{\sigma} \in \{.005, .01\}$ and for the KL regularization we use $\lambda_{\text{KL}} = 1 \times 10^{-6}$ and $\sigma_0 = 0.05$. We set $\tau = 0.5$. For the compressive transformer we consider a compressed memory of size 512 with a compression rate of 3, and train the model with the auxiliary reconstruction loss. We fine-tuned GPT-2 small with a batch size of 1 on 1 Nvidia GeForce RTX 2080 Ti or 1 Nvidia GeForce GTX 1080 Ti GPU with $\approx$ 11 Gb of memory, using the Adam optimizer (Kingma and Ba, 2015) with a linearly decayed learning rate of 5×10^{-5}, for 5 epochs.

D Additional experiments

We also perform language modeling experiments on the Wikitext-103 dataset[11] (Merity et al., 2017)

---

[9] Dataset available at https://github.com/deepmind/pg19.

[10] Dataset available at https://github.com/festvox/datasets-CMU_DoG.

[11] Dataset available at https://blog.einstein.ai/the-wikitext-long-term-dependency-language-modeling-dataset/.

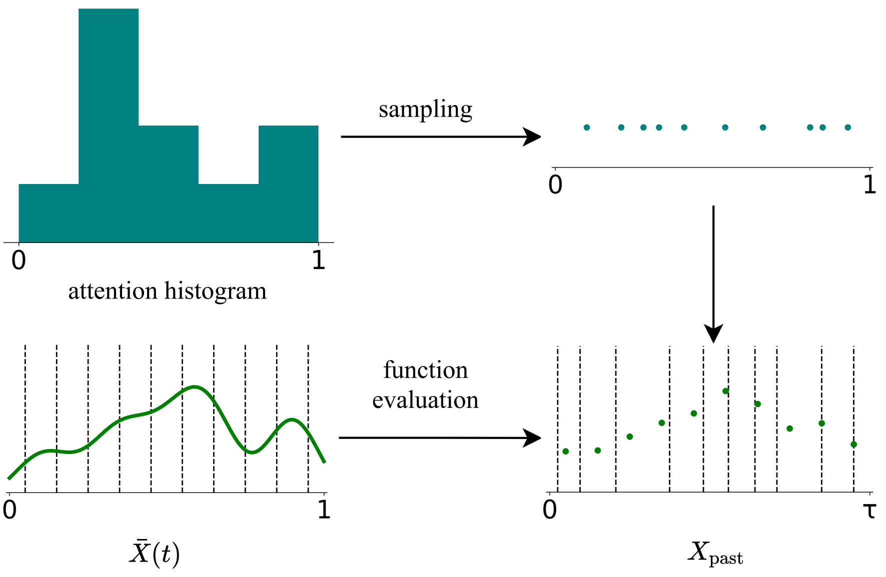

Figure 6: Sticky memories procedure diagram. The dashed vertical lines correspond to the position of the words in the LTM signal.

which has a training set with 103 million tokens and validation and test sets with 217,646 and 245,569 tokens, respectively. For that, we follow the standard architecture of the transformer-XL (Dai et al., 2019), which consists of a transformer with 16 layers and 10 attention heads. For the transformer-XL, we experiment with a memory of size 150. For the compressive transformer, we consider that both memories have a size of 150 and a compression rate of 4. For the ∞-former we consider a short-term memory of size 150, a continuous long-term memory with 150 Gaussian RBFs, and a memory threshold of 900 tokens.

For this experiment, we use a transformer with 16 layers, 10 heads, embeddings of size 410, and a feed-forward hidden size of 2100. For the compressive transformer, we follow Rae et al. (2019) and use a compression rate of 4 and the attention reconstruction auxiliary loss. For the ∞-former we consider 150 Gaussian RBFs $\mathcal{N}(t; \tilde{\mu}, \tilde{\sigma}^2)$ with $\tilde{\mu}$ linearly spaced in $[0, 1]$ and $\tilde{\sigma} \in \{.01, .05\}$. We set $\tau = 0.5$ and for the KL regularization we used $\lambda_{\text{KL}} = 1 \times 10^{-5}$ and $\sigma_0 = 0.1$.

We trained all models, from scratch, with batches of size 40 for 250,000 steps on 1 Nvidia Titan RTX or 1 Nvidia Quadro RTX 6000 with $\approx$ 24 GPU Gb of memory using the Adam optimizer (Kingma and Ba, 2015) with a learning rate of 2.5×10^{-4}. The learning rate was decayed to 0 until the end of training with a cosine schedule.

	STM	LTM	Perplexity
Transformer-XL	150	—-	24.52
Compressive	150	150	24.41
∞-former	150	150	24.29
∞-former (Sticky memories)	150	150	**24.22**

Table 3: Perplexity on Wikitext-103.

Results. As can be seen in Table 3, extending the model with a long-term memory leads to a better perplexity, for both the compressive transformer and ∞-former. Moreover, the ∞-former slightly outperforms the compressive transformer. We can also see that using sticky memories leads to a somewhat lower perplexity, which shows that it helps the model to focus on the relevant memories.

Analysis. To better understand whether ∞-former is paying more attention to the older memories in the LTM or to the most recent ones, we plotted a histogram of the attention given to each region of the long-term memory when predicting the tokens on the validation set. As can be seen in Fig. 7, in the first and middle layers, the ∞-former tends to focus more on the older memories, while in the last layer, the attention pattern is more uniform. In Figs. 8 and 9, we present examples of words for which the ∞-former has lower perplexity than the transformer-XL along with the attention given by the ∞-former to the last layer's LTM. We can see that the word being predicted is present several times in the long-term memory and ∞-former gives higher attention to those regions.

To know whether the sticky memories approach attributes a larger space of the LTM's signal to relevant phrases or words, we plotted the memory space given to each word[12] present in the long-term memory of the last layer when using and not using sticky memories. We present examples in Figs. 10 and 11 along with the phrases / words which receive the largest spaces when using sticky memories. We can see in these examples that this procedure does in fact attribute large spaces to old memories, creating memories that stick over time. We can also see that these memories appear to be relevant as shown by the words / phrases in the examples.

E Additional examples

In Fig. 12, we show additional examples of utterances generated by ∞-former along with the excerpts from the LTM that receive higher attention throughout the utterances' generation.

Additionally, ground truth conversations concerning the movies "Toy Story" and "La La Land", for which the sticky memories are stated in Fig. 5, are shown in Tables 4 and 5, respectively.

---

[12] The (Voronoi) memory space attributed to each word is half the distance from the previous word plus half the distance to the next word in the LTM's signal, being the word's location computed based on the sampled positions from which we evaluate the signal when receiving new memory vectors.

GT: as the respective audio releases of the latter two concerts, Zoo TV Live and Hasta la Vista Baby! U2

the Pet Shop Boys' synthpop cover of the song (titled "Where the Streets Have No Name (I Can't Take My Eyes off You) "). Bono parodied this by occasionally adopting the deadpan vocal style used in the Pet Shop Boys' cover. Critics welcomed the song in the group's setlist: The Independent said the song "induces instant euphoria, as U2 do what they're best at, slipping into epic rock mode, playing music made for the arena". In two other local newspaper reviews, critics praised the song's inclusion in a sequence of greatest hits.
For the PopMart Tour of 1997–1998, U2 returned to the electronic dance arrangement they occasionally played on the Zoo TV Tour. The set's massive video screen displayed a video that

Hot Press described as an "astonishing 2001-style trip into the heart of a swirling, psychedelic tunnel that sucks the audience in towards a horizontal monolith". Near the end of the song, peace doves were shown on the screen and bright beams of light flanking the set's golden arch were projected upwards. Hot Press said the effect transformed the stadium into a "UFO landing site". Shortly before the third leg of the Elevation Tour, the September 11 attacks occurred in New York City and Washington D.C.. During the band's first show in New York City following the attacks, the band performed "Where the Streets Have No Name", and when the stage lights illuminated the audience, the band saw tears streaming down the faces of many fans. The experience was

one inspiration for the song "City of Blinding Lights". The band paid tribute to the 9/11 victims during their performance of the song at the Super Bowl XXXVI halftime show on 3 February 2002. The performance featured the names of the September 11 victims projected onto a large white banner behind the band. U2's appearance was later ranked number 1 on Sports Illustrated's list of "Top 10 Super Bowl Halftime Shows". For the Vertigo Tour, the group originally considered dropping the song from their setlists, but Mullen and Clayton successfully argued against this. All 131 of the Vertigo Tour concerts featured a performance of the song, which were accompanied by the stage's LED video curtains displaying African flags. On the tour's opening night, this reminded Bono that he had

GT: for the first time on 26 January 1942, and attacked regularly thereafter, damaging some aircraft. The intact Hudsons were withdrawn to Darwin but Headlam

and fixed defences, Australia may be made practically invulnerable". According to Air Force historian Alan Stephens this paper "in effect, defined the anti-lodgment concept which has been a persistent feature of RAAF strategic thinking".
Headlam, completed a flying instructors course in July 1936 and joined the staff of No. 1 FTS. He was promoted to flight lieutenant on 1 March 1937. Commencing in July 1938, he was one of six students to take part in the RAAF's first Long Specialist Navigation Course, run by Flight Lieutenants Bill Garing and Alister Murdoch at Point Cook. The course involved several epic training flights that attracted considerable media attention, including a twelve-day, 10,800-kilometre (6,700 mi) round-Australia trip by

three Avro Ansons, one of which was piloted by Headlam, in November. The following month, Headlam led the three Ansons on a six-day journey back and forth over Central Australia. He subsequently passed the navigation course with a special distinction. On 27 January 1939 he was posted to RAAF Station Laverton, Victoria, as a flight commander. He served initially with No. 2 Squadron, before transferring to No. 1 Squadron on 29 August. Both units operated Ansons.
World War II
Following the outbreak of World War II, No. 1 Squadron was engaged in convoy escort and maritime reconnaissance duties off south-eastern Australia. Headlam continued to serve with the squadron as a flight commander until 15 January 1940, when he was assigned to Headquarters Laverton

as the station navigation officer. On 27 March he was posted to the staff of RAAF Headquarters, Melbourne. He was promoted to squadron leader on 1 June 1940. Two weeks later he married Katherine Bridge at St Paul's Anglican Church in Frankston; the couple would have a son and a daughter. Headlam was given command of No. 2 Squadron at Laverton on 15 April 1941, and raised to wing commander on 1 July. Equipped with Lockheed Hudsons, the squadron mainly conducted maritime patrols in southern waters until 5 December, when four of its aircraft were ordered to Darwin, Northern Territory, in response to fears of Japanese aggression in the Pacific. On 7 December, this detachment established itself at Penfui, near Koepang in Dutch Timor, while No. 2 Squadron's eight remaining Hudsons

Posted to Britain at the end of the year, he attended the Royal Air Force Staff College, Andover, and served with RAAF Overseas Headquarters, London."* The dashed vertical lines represent the limits of the memory segments for the various memory updates.

Cast: Jesse Eisenberg as Mark Zuckerberg. Andrew Garfield as Eduardo Saverin. Justin Timberlake as Sean Parker. Armie Hammer as Cameron and Tyler Winklevoss. Max Minghella as Divya Narendra.
Critical Response: David Fincher's film has the rare quality of being not only as smart as its brilliant hero, but in the same way. It is cocksure, impatient, cold, exciting and instinctively perceptive. The Social Network is the movie of the year

...

In October 2003, 19-year-old Harvard University student Mark Zuckerberg is dumped by his girlfriend Erica Albright. Returning to his dorm, Zuckerberg writes an insulting entry about Albright on his LiveJournal blog and then creates a campus website called Facemash by hacking into college databases to steal photos of female students, then allowing site visitors to rate their attractiveness. After traffic to the site crashes parts of Harvard's computer network,

...

Previous utterance: So, what movie are we going to chat about today? Right, the one about Zuckerberg?

Answer: Yep, Jesse Eisenberg plays Zuckerberg.

Previous utterance: So, have you seen it?

Answer: Yeah. Its about the founder of Facebook, Mark Zuckerberg who was basically dumped by his girlfriend, Erica, so he created "TheFacebook."

Figure 12: Examples of answers generated by ∞-former on a dialogue about the movie "The Social Network". The excerpts from the LTM that are more attended to throughout their generation are highlighted on each color correspondingly.

- Hi
- Yo you really need to watch Toy Story. It has 100% on Rotten Tomatoes!
- Really! 100% that's pretty good What's it about
- It's an animated buddy-comedy where toys come to life
- who stars in it
- The main characters are voiced by Tom Hanks and Tim Allen
- does it have any other critic ratings
- Yep, metacritic gave it 95/100 and Cinemascore gave it an A
- how old is it?
- It's a 1995 film so 23 years
- The old ones are always good :) I heard there were some sad parts in it is that true
- Yeah actually, the movie starts off pretty sad as the toys fear that they might be replaced and that they have to move
- is this a disney or dreamworks movie
- Disney, pixar to be exact
- Why do the toys think they will be replaced :(
- they thought so because Andy was having a birthday party and might get new toys
- What part does Tom Hanks play
- Woody, the main character
- How about Tim Allen
- Buzz, the main antagonist at first then he becomes a friend
- What kind of toy is Woody?
- A cowboy doll
- What is Buzz
- A space ranger
- so do all the toys talk
- yep! but andy doesn't know that
- Is andy a little kid or a teen
- He's 6!
- Sounds good. Thanks for the info. Have a great day

Table 4: Ground truth conversation about movie "Toy Story".

- hey
- hey
- i just watched la la land. It is a movie from 2016 starring ryan gosling and emma stone. they are too artists (one actress and one panist) and they fall in love and try to achieve their dreams. its a great movie
- It's a wonderful movie and got a score of 92% on rotten tomatoes
- yes, i think it also won an oscar
- Yes but I thought it was a little dull
- metacritics rating is 93/100 as well its pretty critically acclaimed
- the two leads singing and dancing weren't exceptional
- i suppose it is not for everyone
- It also sags badly in the middle I like how Sebastian slipped into a passionate jazz despite warnings from the owner.
- what do you think of the cover of "i ran so far away?" in the movie, sebastian found the song an insult for a serious musician
- I don't know, it is considered an insult for serious musicians not sure why
- yeah
- The idea of a one woman play was daring
- it was interesting how sebastian joined a jazz fusion band he couldnt find real happiness in any of the bands he was in its hard
- It is considering she didn't know of any of that until she attended one of his concerts
- yeah, that is daring the movie kind of speaks to a lot of people. she accussed him of abandoning his dreams but sometimes thats what you have to do.
- Not nice that she leaves because he told her she liked him better when he was unsuccessful The play was a disaster so he didn't miss anything when he missed it.
- yeah, but i dont blame her for dumping him for that
- She should didn't want to support him and she had to move back
- id be pretty upset as well to boulder city nevada
- yes she didn't want to forgive him, I didn't understand that
- well because that was a big deal to her and he missed it
- if she was with him when he was unsuccessful, she could have supported him to follow his dreams or other dreams
- i suppose that is true
- she wasn't successful either
- yeah she wasnt nobody showed up to her play
- so why the big hulabaloo about him
- not sure
- she was selfish I guess He missed her play because he had to go for a photo shoot with the band that he had previously missed
- yeah but he should have kept better track and scheduled it better
- this shows that he was trying to commit some and follow his dreams although not necessarily like them so she would be please if he didn't attend the photo shoot a second time, and came to her show
- i definitely felt bad for both of them though in that scene
- it's more of a do or don't he is still condemned I feel bad for him because he tried he tried to get her back by apologizing as well she didn't want any of it
- yeah because she felt like he didnt care enough because he missed it he's the one that suggested the one woman play
- They could have started all over again just like the beginning
- maybe so
- did she fail because of the one-woman play? she could have tried something else if she felt that
- she wanted to give it a shot
- she did and it failed, he did and it failed they just had to compromise so they could be together again, which was how the happiness was He signed up for the band after hearing her talking to her mom about how he is working
- on his career I think he did a lot for her

Systematic Inequalities in Language Technology Performance across the World's Languages

Abstract

Natural language processing (NLP) systems have become a central technology in communication, education, medicine, artificial intelligence, and many other domains of research and development. While the performance of NLP methods has grown enormously over the last decade, this progress has been restricted to a minuscule subset of the world's ≈6,500 languages. We introduce a framework for estimating the global utility of language technologies as revealed in a comprehensive snapshot of recent publications in NLP. Our analyses involve the field at large, but also more in-depth studies on both user-facing technologies (machine translation, language understanding, question answering, text-to-speech synthesis) as well as foundational NLP tasks (dependency parsing, morphological inflection). In the process, we (1) quantify disparities in the current state of NLP research, (2) explore some of its associated societal and academic factors, and (3) produce tailored recommendations for evidence-based policy making aimed at promoting more global and equitable language technologies.[1]

1 Introduction

The past decade has seen a rapid advance in natural language processing (NLP); it has grown from a relatively technical niche to a fundamental tool in virtually all domains that involve language data in any shape or form. NLP is now instrumental to not only bread-and-butter applications such as translation and question answering, but also tasks as wide ranging as detection of neurodegenerative diseases (Orimaye et al., 2017), exposing widespread gender and ethnic biases in societies (Caliskan et al., 2017), and predicting large-scale trends in collective consumer behavior (Kallus, 2014). Because of this NLP has become a staple technology for everyday frequent tasks in most contemporary societies of the world. For instance, an English speaker with a smartphone can now easily get accurate information on many topics through a quick query to a virtual assistant, they can consult an online translation service to translate a foreign language web page with a click, and they can interact with many different machines and computers through simple speech commands.

These technological capabilities can be attributed to several developments over the last few decades: 1. the advent of deep learning methods, which allow for more effective creation of NLP systems from existing data (Goldberg, 2017), 2. the existence of standardized benchmark datasets and evaluation metrics (Wang et al., 2018; Hu et al., 2020), 3. the prestige afforded by the research community to researchers who improve upon these benchmarks, 4. the resulting large number of resources, be they computation, data, or ingenuity, that are poured into optimizing performance thereon. As both a theoretical and technical endeavor, NLP is experiencing an explosive increase: the annual conference of the Association of Computational Linguistics (ACL) received in 2000 less than 300 papers, growing in 2010 to slightly less than 1,000, to over more than 3,500 submissions in its 2020 edition. Largely as a result of this expansion of research effort, state-of-the-art systems have also achieved evaluation benchmark scores on par with human performance on a variety of NLP tasks such as question answering on English (He et al., 2021), or on automatic translation of news from German, Russian, and Chinese to English (Barrault et al., 2020).[2]

These upward slanting curves on standard benchmarks fail to show how uneven this development has been for all potential NLP users. Extensive research across NLP tasks have found systematic

---

[1] Data and code to reproduce the findings discussed in this paper are available on GitHub (`https://github.com/neubig/globalutility`).

[2] Although the significance of these parity claims has been disputed (Läubli et al., 2018).

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 5486 - 5505
May 22-27, 2022

performance drops according to dimensions such as gender, racial identity, and language varieties, among others. The reasons for these biases are multifactorial and can be traced to virtually all stages in the process of NLP development, from the data used to train systems (Caliskan et al., 2017; Sap et al., 2019; De-Arteaga et al., 2019; Tatman, 2017; Tatman and Kasten, 2017; Buolamwini and Gebru, 2018; Raji and Buolamwini, 2019) to the very algorithms involved (Speicher et al., 2018; Bellamy et al., 2018; Adebayo et al., 2016). The growing awareness of these biases in NLP technologies brought by these studies, along with the development of novel metrics and tests to evaluate these disparities, have resulted in progressively more efficient and principled strategies to understand and mitigate them.

However, similarly systematic approaches are still lacking in one fundamental dimension of variation across individuals: their languages. Out of the over 6,500 languages spoken or signed in the world today (Hammarström, 2015), only a handful are systematically represented in academia and industry (Joshi et al., 2020; Yin et al., 2021). In spite of the aforementioned near-human results on translation or understanding of languages from the world's economic and political superpowers, the experience of any NLP practitioner is that, for the vast majority of languages, they fall far below such standards. Critically, the languages of the world showcase substantial variation in most domains of description, and in fact, the performance of language technologies has been shown to be sensitive to diverse aspects of the language under study, including morphology, word order, or phonological repertoire, as well as more mundane aspects like writing script or data availability (Arivazhagan et al., 2019; Tsarfaty et al., 2020; Xia et al., 2020; Muller et al., 2021). Hence, the transfer of NLP developments from one language to another is far from trivial, as it often means that building highly functional language technologies for any particular language is a non-automatic, costly, and technically challenging task.

Taking all these considerations together, and given that even the consequences brought by unequal NLP technologies across (racial, gender, socioeconomic) groups within the same nominal language are already substantial, there is a pressing need for measuring and understanding NLP performance inequalities across the world's languages. Here we develop novel estimates on how the utility afforded by NLP systems is distributed across individuals, languages, and tasks at an unprecedented global scale. These estimates allow us to identify which languages are systematically underserved by language technologies and could benefit the most individuals from focused technology development. We finally trace these inequalities to the societal, economic, and academic correlates of NLP systems' performance, shedding light on its latent causes, and indicate how our results favor specific evidence-based policies in research and development.

2 Methodology

2.1 Quantifying utility and demand

Our fundamental goal is evaluating the distribution of diverse representative language technologies (and their qualities) across the world's languages and their populations. Minimally, we would attempt to account for the patterns of association between the *demand* of language technologies and the *utility* they confer to users across languages. Thus, the first component of our analysis pertains quantifying the *utility* users in a given language l receive from a language technology. Ideally, such a measure would capture to what extent a given NLP system solves the specific problems an individual can pose to them - for instance, how successfully the user can obtain information from an automatically translated web page, or how satisfied the user is by a speech-based virtual assistant's execution of a series of verbal commands.

Intuitively, utility is associated with the nominal performance of the technology - a more performant system will allow the user to obtain a greater degree of utility. How "performance" is measured depends on the task (see Section 1). Since our purpose is to allow for comparisons, we define the utility of a task and language, u_l, as the corresponding performance normalized by the best possible performance afforded by such task, i.e.

$$u_l = \frac{\text{performance}_l}{\text{theoretical max performance}}$$

In cases where the best possible performance is undefined or technically unattainable, we take the empirical maximum as an estimate of the theoretical one and normalize by the best-performing language across all languages L, i.e. we replace the denominator in the above definition by $\max_{l' \in L}(\text{performance}_{l'})$.

Task	Description	Metric
Syntactic Analysis (DEP)	Infer syntactic dependencies between words in text	Labeled Attachment Score
Morphological Inflection (ING)	Produce an inflection given a lemma and morphological tags	Accuracy
Machine Translation (MT)	Translate text from a language into another	BLEU score
Speech Synthesis (TTS)	Produce speech on the basis of textual input	1-mel-cepstral distortion
Natural Language Inference (NLI)	Recognize entailment or contradiction between two sentences	Accuracy
Question Answering (QA)	Produce an answer for a textual query	Fscore

Table 1: NLP tasks evaluated in the present study, along with their corresponding performance metric.

Defining utility in this manner allow us to explore and contrast language technologies at the broadest scale, which is possible thanks to some necessary simplifying assumptions. As we pointed out before, not all users of the same language technology might benefit in the same manner given a fixed performance, and the relation between nominal performance and “true" utility might be complex and non-linear.[3]

With these caveats in mind, we further quantify the second component of our analysis, the *demand* for a language technology in each language l, d_l. We characterize d_l by taking into consideration demographic and linguistic perspectives. Under the first perspective, the demand for a given technology in a language is estimated to be proportional to the number of speakers of the language itself n_l ($d_l \propto n_l$). Under the second perspective, the demand across the approximately 6,500 languages of the world is identical ($d_l \propto 1$). These two alternatives as well as any intermediate combination of them can be simply parameterized through a single exponent τ,

$$d_l^{(\tau)} = \frac{n_l^\tau}{\sum_{l' \in L} n_{l'}^\tau}$$

where $\tau = 1$ correspond to a demographic notion of demand, $\tau = 0$ to a linguistic one, and $0 < \tau < 1$ is in between.

Equipped with these notions, we construct a simple family of global metrics (M_τ) revealing to what degree the global demand for language technologies is actually met:

$$M_\tau = \sum_{l \in \mathcal{L}} d_l^{(\tau)} \cdot u_l$$

M_τ has a number of intuitive properties we would like such a metric to have. M_τ is bounded between 0 and 1; 0 corresponds to a case where no-one benefits from a given language technology, whereas 1 would correspond to a situation where all languages enjoy perfect technology. Increasing the utility of a given language leads to an increase in M_τ, and the magnitude of this increase is influenced by both the size of the improvement and the demand in that language.

2.2 NLP tasks

We apply our measures of utility and demand to a set of diverse and representative NLP tasks, which are described below and summarized in Table 1.

The first three are tasks that technology users interact with directly in their everyday life, so that their output is already in a shape and form that is usable for most individuals. *Question Answering* (QA) consists of crafting a relevant answer to a question formulated in natural language, such as e.g. “what is the capital city of the Philippines?" or “why do dogs like bones?". This task is ubiquitous in online search or virtual assistants. *Machine Translation* (MT) is the task of translating from one language to another (e.g. from Tagalog to Estonian or from Japanese to Basque), and is typically used to facilitate inter-personal communication, information gathering, and e-commerce. *Text-to-speech* (TTS) is the task of rendering speech from textual input, which is used widely in spoken virtual assistants, car navigation systems, and is becoming a gateway for internet-of-things devices.

Next, *Natural Language Inference* (NLI) is a central task in AI and involves the evaluation of information presented in propositional format. More specifically, given a sentence called the “premise” (e.g. “the dog chewed a big bone”), NLI systems decide whether a separate sentence called the “hypothesis” is entailed by the premise (e.g. “the dog

---

[3] To give just one example, in machine-assisted human translation, the relationship between MT accuracy and productivity gain (directly associated with utility) is complex (Sanchez-Torron and Koehn, 2016).

gnawed at a bone"), negated by it (e.g. "the dog was sleeping"), or neither (e.g. "the dog likes bones"). While not a user-facing task *per se*, it measures the ability of NLP systems to adequately represent (and "understand") user queries.

Beyond these three (plus one) user-facing tasks, we also consider two more foundational linguistically-focused tasks, which often inform part of the pipelines of the user-facing tasks but which are rarely if ever encountered "in the wild" by language technology users. *Morphological Inflection* (Inflection) is the task of generating an inflected wordform given a lemma and a morphological specification, e.g. producing the third person singular form for "run": `run+3;SG→runs`. *Syntactic Parsing* under the dependency formalism (DEP) is the task of producing a syntactic parse of an input sentence, e.g. given the sentence "dogs like bones" specifying the "dogs" and "bones" are the subject and object of "like" respectively.

2.3 Correlates of NLP utility

Beyond the performance of individual tasks, we take a bird's-eye-view of the field of language technologies in general, as we analyze some of the correlates of the scientific production in NLP. In particular, we follow two broad guiding questions: (1) does the system of academic incentives promote the development of a more linguistically diverse NLP? and (2) is economic centrality or sheer demographic demand the best predictor of NLP technologies in any given language?

While a full understanding of the complex causal mechanisms binding society and NLP in general is outside of the scope of the present article, we set out to provide a first large-scale exploration of these matters by considering scientific publications appearing in major international NLP conferences as the basic units of science production. This simplification is not without challenges: for instance, some widely used language technologies are developed outside of the traditional scientific circuit based on proprietary technology, or they are published in local conferences, possibly in languages other than English.[4] In spite of this, studying scientific publications (and their correlates) allows us to evaluate transparent questions on the basis of publicly available data at a scale that is unfeasible for in-depth analyses.

Therefore, we study the first question by determining whether the cumulative number of citations a paper receives is correlated with the number of languages it is associated with. We investigate our second question by finding the best predictive model of the number of NLP papers in any given language by contrasting two predictors: estimated number of users worldwide and approximate GDP associated with its users. We model these regression problems in a Bayesian generalized mixed effects framework (see Appendix B).

2.4 Data

We manually aggregate information on task performance and demand for the tasks summarized in Table 1 from a number of sources (we relegate many details to Appendix A, and give a high-level overview here). The data is taken from a combination of multilingual benchmarks, shared tasks and published results in NLP conferences including:

Question answering: We use data from the TyDiQA (Clark et al., 2020), MLQA (Lewis et al., 2020), and SD-QA (Faisal et al., 2021) benchmarks and measure raw accuracy to calculate utility.

Machine translation: We aggregate scores from the WMT and IWSLT evaluation campaigns, and 50 studies from the last three years' ACL, EMNLP, and NAACL conferences, using BLEU (Papineni et al., 2002) as an accuracy metric.

Text-to-speech: We use data from the CMU Wilderness Project (Black, 2019) and use normalized negative mel-ceptral distortion (Kubichek, 1993) as an accuracy metric.

Natural language inference: We use results from the XNLI leaderboard (Conneau et al., 2018) and raw accuracy as the evaluation metric.

Syntactic parsing: We use the accuracies provided by UDPipe (Straka, 2018) and UDify (Kondratyuk and Straka, 2019) on the universal dependencies corpus (Zeman et al., 2017), with labeled attachment score as an accuracy metric.

Morphological inflection: We use results from SIGMORPHON workshops inflection shared tasks (e.g. (Vylomova et al., 2020)) measuring utility with exact-match accuracy.

---

[4] e.g. the Japanese NLP society's 2020 conference published 396 papers: `https://www.anlp.jp/proceedings/annual_meeting/2020/`

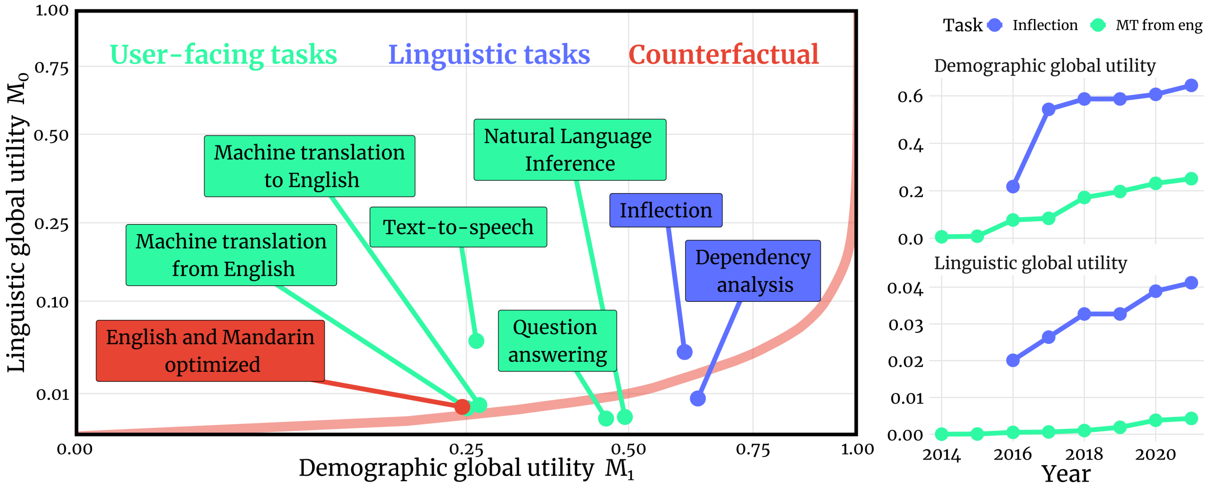

Figure 1: Left panel: linguistic and demographic global utility metrics for a number of language technology tasks. The red curve corresponds to the sequence where first the language with the largest number of users is set to utility 1, then the second, and so on. Right panel: recent historical progression of two language technology tasks: Inflection and Machine Translation from English.

Demographic and linguistic information necessary for the estimation of demands were obtained from a variety of sources, including Ethnologue, Glottolog, and the World Trade Organisation. For most tasks, the number of first-language speakers is used to measure demand, but for MT we estimate the need for translation between two languages based on economic indicators of interaction between countries, and the language-speaking populations within the countries where the language is spoken.

3 Results and Analysis

3.1 General observations

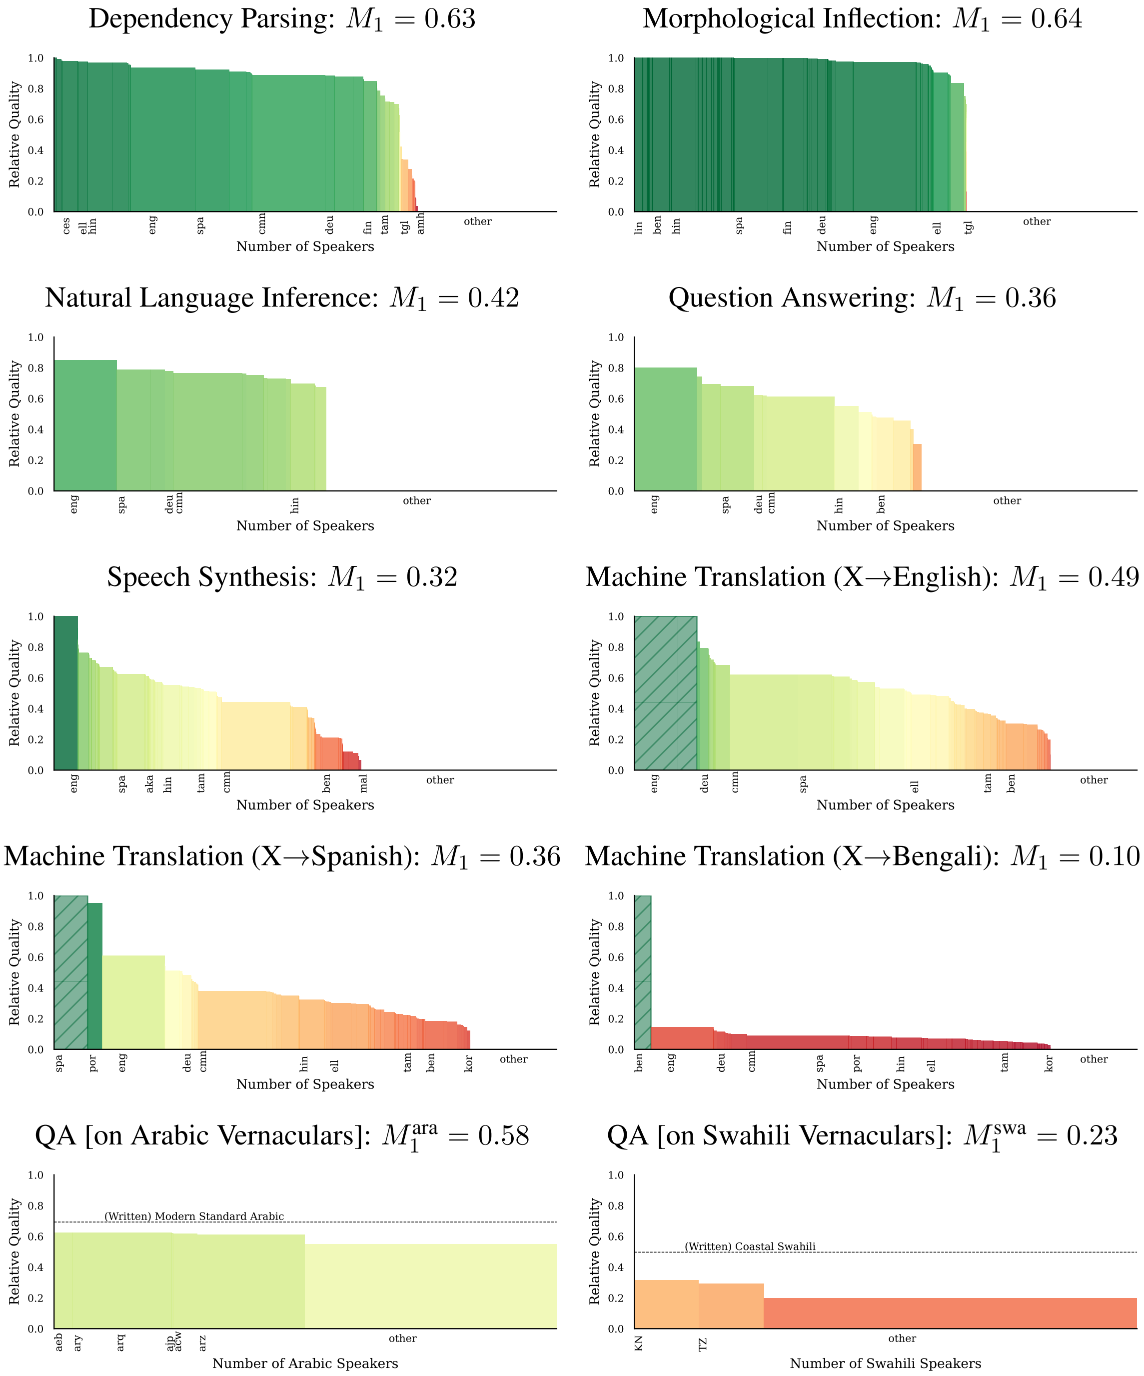
Figure 1 presents an overview of our main findings. Unsurprisingly, most NLP tasks we focus on fare substantially better when utility is measured demographically rather than linguistically.

Text-to-speech synthesis is the task with the most linguistic coverage: the published results (due to a single study (Black, 2019)) cover more than 630 languages (or about 10% of the world's languages). However, for the vast majority of these languages the measured quality of the generated speech is about half as good as the exceptionally good English system (Ren et al., 2021). The next most linguistically diverse tasks are those regarding morphosyntactic analysis, i.e. morphological inflection and dependency parsing, which have been evaluated over 140 and 90 languages respectively. For these more esoteric tasks which do not necessarily convey direct utility to a downstream user, the majority of the systems are in general very good.

Natural language inference (NLI; a representative natural language understanding task) and question answering (QA) lie on the opposite side of the spectrum: the established benchmarks have only focused on up to 15 and 17 languages respectively, leading to very low scores on the linguistic axis.

In Figure 1 (right panel) we observe the progress of the utility metrics in tasks for which we had access to comparable data across a span of the last 7 years. The extensive efforts of the UniMorph project (Kirov et al., 2018) to cover as many languages as possible are visible in the "Inflection" plot, with significant improvements over time. On the other hand, the machine translation field is still in the process of ramping up following demographics and/or socioeconomic priorities, with improved linguistic coverage over the years.

The granularity of these findings can be increased on the basis of available data. Figure 2 additionally presents demographic utility across language populations for all tasks. The visualization allows for identification of ostensive gaps in received utility. The two bottom plots of Figure 2 display our metrics over speakers of a single language, based on question answering results for different spoken Arabic and Swahili lectal varieties (Faisal et al., 2021). This analysis shows that utility differences are small between Arabic vernaculars although these systems still lag behind the systems for Modern Standard Arabic, while the utility level of Coastal Swahili speakers in Tanzania is about 10% lower than that for speakers in Kenya.



acw: Hijazi Arabic, aeb: Tunisian Arabic, ajp: South Levantine Arabic, aka: Aka, amh: Amharic, arq: Algerian Arabic, ary: Moroccan Arabic, arz: Egyptian Arabic, ben: Bengali, ces: Czech, cmn: Mandarin Chinese, deu: High German, ell: Greek, eng: English, fin: Finnish, hin: Hindi, kor: Korean, lin: Lingala, mal: Malayalam, por: Portuguese, spa: Spanish, swa: Swahili, tam: Tamil, tgl: Tagalog.

Figure 2: Illustration of our metric on demographic-focused utility ($\tau = 1$) on various NLP tasks.

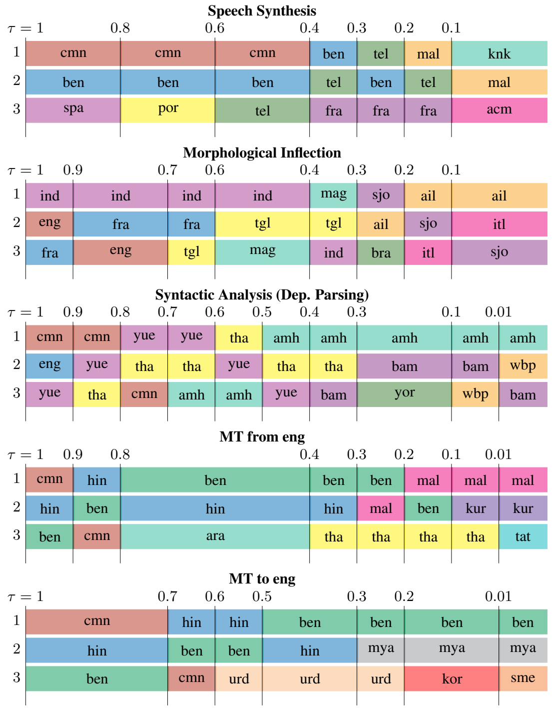


Figure 3: Priority languages (top-3 shown) change with different balancing of demographic and linguistic utility, with focus shifting from populous languages e.g. Mandarin (cmn) and Hindi (hin) to more under-served languages e.g. Kuranko (knk), Bambara (bam), Tatar (tat), or Aimele (ail).

3.2 Priorities in NLP development

Given the current snapshot of NLP systems, we could ask which languages will lead to the largest global utility improvement. The relative importance of linguistic vs. demographic demands determines the priority ranking, as it can be observed in Figure 3 for a sample of five tasks. Improving on the demographic-focused utility entails a greater emphasis on Mandarin Chinese, Hindi, Spanish, and other populous languages that are generally well-served by current technologies. Balancing linguistic and demographic considerations leads to prioritizing a more diverse set of languages, mostly Asian and African languages like Amharic, Bambara, Bengali, Thai, or Yoruba, which are both populous and under-served, along with also large but severely under-served languages like Kurdish, Urdu, and Oromo. Further emphasis on linguistic utility would lead to prioritization of indigenous and potentially endangered languages of small communities like Aimele, Itelmen, North Sami, or Warlpiri, which are currently largely ignored by NLP research (Bird, 2020).

3.3 The role of society, economy, and academia

Now we turn to our large-scale analysis of NLP publications. First, this reveals that a substantial proportion of publications do not even describe in a clear and unequivocal manner the language (or languages) they are dealing with (Bender, 2011). Given the current prevalence of English of a language of study in NLP, in most cases, the lack of an explicit reference to a particular language entails the system deals with English exclusively.

This reflects a more deep-seated issue reflected in the citation of papers over time. Independently of publication venue, year, or subfield of NLP research, the number of languages a publication deals with is not predictive of how many citations it will accrue over time (see Figure 4, top right panel). In other words, if citations can be regarded as a proxy for academic incentives, scientists and developers are presented with little to no additional academic reward when tackling data, problems, or tasks involving more than one language.

This naturally leads to the question of what explains the production of language technologies across languages to start with, which will necessarily involve agents, mechanisms, and data, outside of the scope of NLP publications themselves. Nevertheless, in order to contribute to this investigation, we determined whether approximate measures of economic centrality or number of language users were better predictors of sheer number of papers published for any given language (see Appendix C). While both variables are substantially collinear, we find that approximate GDP (rather than number of users) leads to a substantially smaller prediction error of number of published papers.

4 Discussion

Our study, covering diverse NLP tasks and types of evidence, makes apparent the immense inequality in the development of language technologies across the world's languages. After English, a handful of Western European languages dominate the field -in particular German, French, and and Spanish- as well as even fewer non-Indo-European languages, primarily Chinese, Japanese, and Arabic. Our preliminary investigation suggests it is the economic prowess of the users of a language (rather than the sheer demographic demand) what drives the development of language technologies.

In spite of this, for some tasks (such as In-

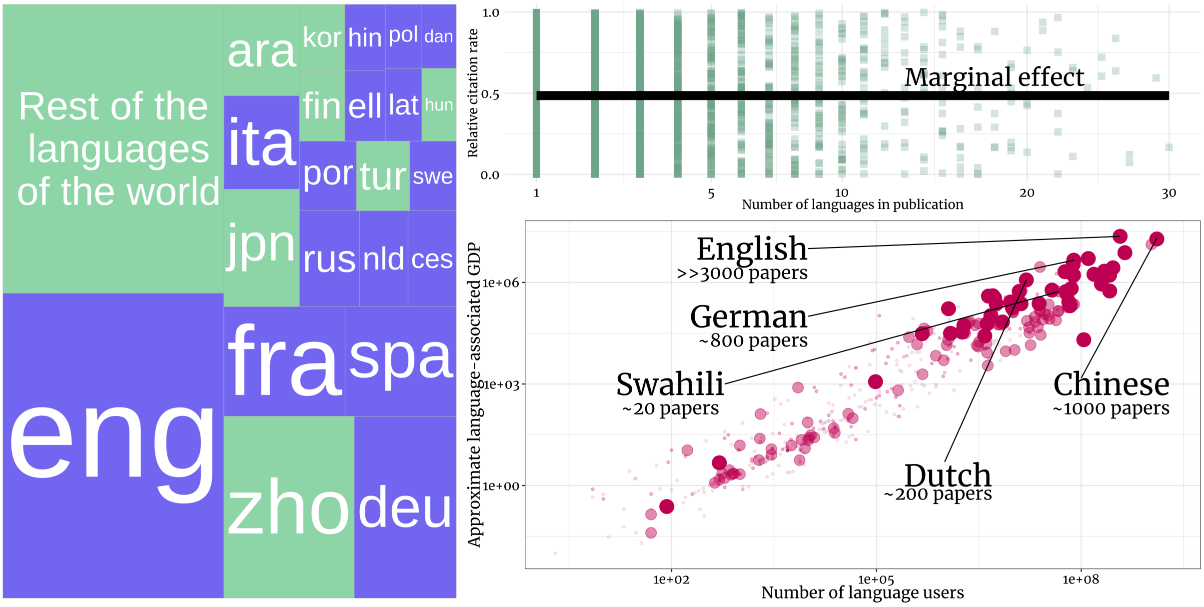

Figure 4: Left panel: treemap of the number of NLP publications per language (with area proportional to the number). Right top panel: Relative citation rate vs number of languages in the publication. Right bottom panel: Number of publications according to number of language users and approximate GDP. Point size and transparency scales with number of publications. eng: English, zho: Chinese, deu: German, fra: French, spa: Spanish, jpn: Japanese, rus: Russian, nld: Dutch, ces: Czech, por: Portuguese, tur: Turkish, swe: Swedish, ita: Italian, fin: Finnish, ell: Greek, lat: Latin, hun: Hungarian, ara: Arabic, kor: Korean, hin: Hindi, pol: Polish, dan: Danish.

flection) there is an encouraging trend of both demographic- and linguistic-utility improving year-over-year. This is due to the nature of the task; reasonably accurate solutions can be achieved through small but highly-curated data. Since linguistic expertise on the languages of the world is, naturally, globally distributed, the main hurdle these tasks face is to pool such expertise under the premise of a common technical goal. In this respect, relatively low-cost and bottom-up actions that gather experts to work on specific NLP tasks (such as Universal Dependencies and UniMorph) have succeeded in accelerating the cross-linguistic development of language technologies. These prosper mainly on the basis of academic incentives, as those individuals or groups who contribute data and/or expertise are rewarded with individual publications or co-authorship in collective publications. Many of these contributions - which do not necessarily involve hefty resource investments but instead linguistic expertise - are markedly different from the typical publications in language technologies.

However, these more esoteric tasks are tenuously associated with those that users are more likely to interact with, such as Machine Translation or Speech Synthesis. User-facing tasks all have in common a tight dependency on computational resources and large data, which in turn hinge on substantial financial means. In a context of pressing user needs across multiple populations and languages, we submit that future developments on policies aimed at furthering cross-linguistic technologies would benefit from clear (and possibly standardized) metrics that assist in streamlining complex decisions regarding resource allocation. Our measures of global coverage fulfill that role, and help identifying large but currently under-served languages. While we do not attempt to supplement the necessary in-depth evaluation of the need of each individual group and language, they provide a common ground for coordinating global efforts across heterogeneous actors.

In addition, we would like to reiterate that our work here has necessarily made a large number of simplifying assumptions to even attempt to quantify disparities in language technology utility on a global scale. These most notably involve simplifying assumptions regarding the measurement of demand (based on native-speaker population and/or economic indicators) and the measurement of utility (based on simple accuracy metrics). Future work may further clarify these assumptions, making more accurate estimates of true user demand on a technology-by-technology level, or more accurately clarifying the relationship between standard accuracy metrics and the utility derived by users.

A Materials

Publication data We rely on papers available through the Anthology of the Association of Computational Linguistics[5] which hosts more than 60 thousand papers from all major NLP conferences. We rely on Semantic Scholar (Ammar et al., 2018) for citation information.

We make the working assumption that a mention of a language in a research paper likely entails that the underlying research involves this language. We follow an automatic pipeline for finding language mentions in a paper, which starts by converting the paper PDF to a machine-readable format. We then search within the paper for any mention of a language's English name(s), its endonym, as well as its ISO or Glottolog code. We then apply a post-processing step to ensure the precision of this pipeline as our simple text-based search is prone to false positives for languages whose names match common English words (e.g. She, Male, Label, Even, The, Are), common placenames (e.g. Colorado, Nara, Sydney), parts of author names (e.g. Su, Kim, Dan, Ali, Rama), or mathematical notation (e.g. Dji, Dii).

In addition, we enrich each publication by imputing its research area. There were 16 research areas identified, based on the ones represented at recent major NLP conferences (specifically starting with the 2019 version of EMNLP, and removing some of the areas that were unique to that conference). For each area, we identified 1-6 publication venues from the ACL Anthology, where more venues were

---

[5] `https://www.aclweb.org/anthology/`

chosen when each venue had relatively few publications. Based on the abstracts of papers from each of these venues, we trained a bag-of-words classifier using the linear support vector machine implementation in scikit-learn[6], and applied this classifier to the abstracts of the papers we wanted to classify. Necessary data and code to reproduce these results are released in the supplementary material.

Data Sources and Metrics for Utility The majority of NLP research relies on automatic evaluation metrics over datasets annotated with gold-standard outputs. The advantage of this approach is that it allows consistent comparisons between systems and a seamless evaluation of progress on a specific evaluation set. On the other hand, there is no guarantee that even statistically significant improvement on an automatic metric translates to improvements on user-perceived utility. Nevertheless, the reality is that virtually all published NLP research reports automatic evaluation metrics, with only a tiny fraction diverging from the norm by e.g. using human evaluations.

Our analysis assumes that all named languages have standard versions that are comprehensible and acceptable to all members of the population identified as "speakers" in our sources. However, we have the demographic information necessary for more fine-grained analysis in only a handful of languages. While this assumption is certainly an oversimplification, we nevertheless believe it does not detract from our paper's arguments.

For a completely fair comparison across languages, one would ideally compute automatic metrics over the same or an equally representative evaluation set. For our language understanding case study this requirement is satisfied, as the XNLI 15 language test sets are translations of the same evaluation set. Utility in this case, where the evaluation metric m is accuracy, will be equal to the accuracy for each language's l test set: $\text{utility}(l, m) = m_l$.

Natural language understanding results are sourced from the XNLI leaderboard (Conneau et al., 2018), which contains test datasets with premise-hypothesis pairs in 15 languages.

For question answering (QA) we aggregate results from two established multilingual benchmarks, namely TyDi-QA (Clark et al., 2020) and MLQA (Lewis et al., 2009). Both benchmarks focus on extractive question answering, i.e. finding the text span of a given document that answers, if possible, a given question. We also include SD-QA (Faisal et al., 2021) for additional dialectal breakdown for some of the TyDi-QA languages. The benchmarks jointly cover 17 languages. We keep the highest results for languages that are shared between the two datasets (English and Arabic). For this task we equate utility with test set F-score, a measure that meaningfully combines precision and recall of the retrieved answer span.

For machine translation, we collected more than 500 published MT results from all WMT and IWSLT evaluations, as well as more than 50 MT studies from the last three years' ACL, EMNLP, and NAACL conferences (Barzilay and Kan, 2017; Gurevych and Miyao, 2018; Palmer et al., 2017; Riloff et al., 2018; Knight et al., 2016; Walker et al., 2018; Korhonen et al., 2019; Inui et al., 2019; Webber et al., 2020). In the machine translation field the most popular evaluation metric is BLEU (Papineni et al., 2002). In our MT case studies we estimate utility based on a normalized version of BLEU, such that for translation from s to t with $\text{BLEU}(s, t)$ over an established test set, we have $\text{utility}(s, t, \text{BLEU}) \approx \frac{\text{BLEU}(s,t)}{Z}$. The normalizing factor $Z = \max_{\mathcal{L}\times\mathcal{L}} \text{BLEU}$ is equivalent to the largest reported BLEU, which we equate to the largest attainable utility at the snapshot of interest. In all our MT case studies we use $Z = 70$, which is the BLEU score reported for translation between Serbian and Croatian (Arcan et al., 2016).

For text-to-speech synthesis, we relied on results from the CMU Wilderness project (Black, 2019), which builds TTS voices with FestVox (Anumanchipalli et al., 2011), and compared them to the English system of (Ren et al., 2021). The quality of the synthesized audio is evaluated using mel-cepstral distortion (Kubichek, 1993, MCD) a distortion measure that compares synthesized examples with originals (lower is better). Each MCD of x_l for a language l was converted to a relative utility score by applying the transformation $\frac{x_{\max}-x_l}{x_{\max}-x_{\min}}$, where $x_{\max}$ and $x_{\min}$ correspond to the highest (worst) and lowest (best) observed MCD scores across all languages.

For syntactic analysis through dependency parsing, we relied on results from two state-of-the-art systems, UDPipe (Straka, 2018) and UDify (Kondratyuk and Straka, 2019). The systems are typically evaluated using two measures, Unlabeled and Labeled Attachment Score (UAS and LAS), which measure the overlap between human-created and

---

[6] `https://scikit-learn.org/stable/`

automatically-produced syntactic trees, excluding punctuation. For our metrics we use LAS, which considers the semantic relation (e.g. Subj) used to label the attachment between two words.

The results on morphological inflection were taken from the findings of the corresponding shared tasks that have been taking place as part of the SIGMORPHON workshop for the past 5 years (Cotterell et al., 2016, 2017, 2018; McCarthy et al., 2019; Vylomova et al., 2020). The systems are evaluated using exact-match accuracy over a predefined test set in each language, simply comparing the correct inflected form with the system's output.

Population Demand We compile population statistics from various sources. We rely on Ethnologue (Eberhard et al., 2018) for language population statistics. We take special care when computing population statistics over macro-languages (e.g. Arabic, Chinese) and languages commonly spoken by L2 speakers (e.g. English) or across multiple dialects (e.g. for Spanish or Portuguese), aggregating populations across all variants.

Economic Indicators for Demand We aggregate economic information on international trade, as provided from the World Trade Organisation (WTO) through the World Integrated Trade Solution.[7] Since each language community can be geographically associated with a member nation of WTO, we can then estimate economic indicators for and between language communities.[8]

In a monolingual setting, we rely on the most recent GDP estimates, associated with each language community. For example, the 1.7 million Nahuatl speakers represent about 1.3% of Mexico's population, and thus the final GDP associated with the Nahuatl language will be 1.3% of Mexico's GDP.

Modeling demand in a bilingual setting (across two languages) is also feasible using economic indicators. For instance, the amount of trade between two language communities could be used to approximate the need for translation between the two. Specifically, if we use the normalized import volume per language community then we can estimate demand for an $s \rightarrow t$ translation system as $\mathrm{demand}(s,t) \propto v_{s\rightarrow t}^{\text{import}}$ such that $\sum_{s\in\mathcal{L}} v_{s\rightarrow t}^{\text{import}} = 1$.

Take the Azerbaijani language as an example: Azerbaijan's imports mainly come from the Russian Federation (16.8%), Turkey (14.7%), China (11.2%), the US (8.5%), Ukraine (5.5%), and Germany (5.5%).[9] Hence, we can assign a proportional weight to model demand for translation from Russian, Turkish, Chinese, English, Ukrainian, and German into Azerbaijani respectively. One could equivalently use the normalized volume of exports instead.

This is only straightforward to compute in cases where a language is easy to map to a specific country. In cases of languages that are commonly used across many countries e.g. German (which is the main language in both Germany and Austria) or macro-languages spoken in larger regions of the world, we combine the weights accordingly in order to jointly model the demand for the whole language community.

Table 3 presents the top-15 translation pairs based on demand estimated from economic indicators, namely the import (and export) partner share of the target (source) language. We note that this ranking does not take underlying populations into account, using only the *percentage* of demand for each language community. Several entries in Table 3 are language pairs that are rarely, if ever, studied in MT case studies, like Belarusian-Russian, Mongolian-Mandarin Chinese, Albanian-Italian, or Russian-Armenian.

B Methods

Predicting Utility on Unseen Languages/Pairs One of the main disadvantages of using solely published results for estimating quality and, hence, utility, is the lack of evaluations on all languages or language pairs. Furthermore, not all languages or pairs are consistently evaluated on newly developed models. To counter this issue, we propose a more comprehensive approach which attempts to predict the expected quality/utility over languages or language pairs unseen in the collected literature.

A naive approach is to make the approximation that utility on any unseen language is 0. However crude, this could be a valid assumption in many cases: consider the example of a language understanding system trained on all languages that appear in Wikipedia. Such a system, without proper

---

[7] `https://wits.worldbank.org/`

[8] Our conclusions and analyses based on WITS data are the responsibility of the authors and do not represent the opinion of the WTO.

[9] Source: `https://wits.worldbank.org/CountryProfile/en/Country/AZE/Year/2017/TradeFlow/Import`

modifications, would not be able to handle input in Yupik or Dhivehi (Maldivian), since these languages are not represented in Wikipedia and they use different writing systems than any other language. Note that, in such a case, for a language understanding system evaluated over a classification task as in a language understanding setting, the expected utility is not 0, but is rather the expected quality of random outputs (33% in the case of three-way classification).

Future work could make use of models explicitly trained to predict the accuracy (or other metrics) of NLP models on unseen languages or language pairs, such as the ones proposed by (Lin et al., 2019) or (Xia et al., 2020).

Estimating MT quality with pivoting In the case of machine translation, pivoting is a viable approach for producing translations between any arbitrary language pair, as long as the intermediate systems exist. Even if no published results exist on translation from German to Chinese, it is unreasonable to assign an expected utility of 0 to such a MT system, since there exist high-quality German-English and English-Chinese systems.

In the case of cascaded systems, though, estimating utility requires a careful approach, due to error propagation. Consider a system A with accuracy 80% and a system B with accuracy also 80%. A cascaded system where the output of system A is provided as input to system B will have an expected accuracy 64%, not 80%.

An important point is that there is no reason for pivoting through a single language. Consider the example of Catalan to Chinese translation. A path from Catalan to Spanish, to English, to Chinese might have a yield a higher estimated utility from a single-language pivoting path, since its components are of higher quality.

We devise a method that allows us to generalize this notion in order to find the highest estimated utility for every language pair. We construct a weighted directed graph $\mathcal{G}$=(V, E) with each node $v \in V$ representing a language. The weighted directed edge $e_{s \to t}$ between nodes s and t will have a weight equal to the highest reported normalized BLEU score on translation from s to t. If no results have been published on this language pair, we set the weight of that edge to 0.

With graph $\mathcal{G}$ in hand, as long as a path from nodes s to t exists, we can estimate the expected normalized BLEU of $s - t$ translation as the maximum cumulative (multiplicative) weight over any path from s to t. If a path does not exist, then the estimation is 0. This is possible in cases where a language is reported as only source or only target in the literature; for example, Greek (ell) only appears as a source in a single study (reporting Greek–English translation results) which allows us to estimate Greek–X utility by pivoting through English, but we cannot produce estimates for X–Greek. Table 4 presents translation pairs were our estimated utility (normalized BLEU score) is higher than the published results.

C Bibliometric Analysis

Analysis of Citations To each publication we associate its citation percentile relative to its year and event. We analyze normalized citations (C) through Bayesian generalized additive mixed effects models implemented in R with brms and Stan (Bürkner, 2017; Carpenter et al., 2017) We utilize default weakly informative priors for all parameters and we run four MCMC chains for each model which in all cases achieved convergence. The distribution of C is described through a beta distribution, of which its expected value is given by

$$\mathbb{E}[C] = \text{logit}(f(L) + \alpha_A + \beta_A \cdot L) \qquad (1)$$

where $f(L)$ is a smooth function (on the basis of thin plate splines) depending on the number of languages dealt with in the paper (L), and α_A and β_A are random intercepts and slopes according to each area, respectively. In order to evaluate the support in favor of $f(L)$, we compared the leave-one-out (LOO) performance of this model against a counterpart without this term,

$$\mathbb{E}[C] = \text{logit}(\alpha_A + \beta_A \cdot L) \qquad (2)$$

The difference in expected log pointwise predictive density (which serves to inform model selection, (Vehtari et al., 2017)) between the two models is -0.9 (SE=0.6), which implies there is no major performance difference between the two.

Analysis of Number of Publications We determine the total estimated number of papers in which each language l was involved (P_l). The resulting distribution has a large concentration of zero values, so we opt to model this through a zero-inflated negative binomial distribution. We focus on two parameters: the expected value of the number of publications ($\mathbb{E}[P]$) and the mixture probability (π).

In both cases, we fit models considering three possibilities: (1) A smooth (thin plate spline) function of the log-GDP, (2) a smooth (thin plate spline) function of the log-number of speakers, and (3) a fixed parameter. This leads to evaluating 9 models through a LOO criterion. The model that involves (1) for both parameters displays the best overall performance (see SI).

D Machine Translation Case Studies

We use this section to expand on the discussion of MT case studies.

Translation involving English Since translation involves two languages and language communities, there are two natural ways for a speaker to receive utility from a MT system: either by being the *source* (with their language being translated into another) or by having another language translated into theirs (*target*). We disentangle the two by only using each one at a time for our utility calculations.

Utilities based on demographics for both settings are similar, with $M = 0.25$ (from English) and $M_1 = 0.27$ (to English). Since published results only cover 101 languages, the linguistic diversity scores are much lower, with M_0 around 0.005.

Translation among all languages We extend our study on translation among all languages (still maintaining the distinction between a language used as source or target). We base our estimates for utility on any reported results, as well as on accuracy estimates based on a pivoting approach. Briefly outlined, our pivoting estimation approach finds the best performing translation path for language pairs without reported results, i.e. since no studies report translation accuracy when translating from Greek to Chinese, we find that among all possible translation paths, translating from Greek to English and from English to Chinese yields the highest expected accuracy. We outline the process in the Materials and Methods section.

Perhaps unexpectedly, the best (and often only) pivot is English in almost all cases. As a result, the final utility for a language X is very much dependent on the utility of the X-Eng (or Eng-X) systems. This is reflected by our scores for averaged by demographics and languages being very similar to the ones when we only focused on English. Nevertheless, the differences between scores for different languages are stark: the demographic-averaged utility for populous, well-studied languages like German ($M_1 = 0.356$), Chinese ($M_1 = 0.232$), or French ($M_1 = 0.309$) is almost double than underserved ones like Bengali ($M_1 = 0.148$), isiXhosa ($M_1 = 0.156$), Amharic ($M_1 = 148$), or Burmese ($M_1 = 0.092$). Figure 5 visualizes the different scores for translation from 24 languages under the demographic focus ($\tau = 1$).

Abstract

We introduce **CaMEL** (**Ca**se **M**arker **E**xtraction without **L**abels), a novel and challenging task in computational morphology that is especially relevant for low-resource languages. We propose a first model for CaMEL that uses a massively multilingual corpus to extract case markers in 83 languages based only on a noun phrase chunker and an alignment system. To evaluate CaMEL, we automatically construct a silver standard from UniMorph. The case markers extracted by our model can be used to detect and visualise similarities and differences between the case systems of different languages as well as to annotate fine-grained deep cases in languages in which they are not overtly marked.

1 Introduction

What is a case? Linguistic scholarship has shown that there is an intimate relationship between morphological case marking on the one hand and semantic content on the other (see Blake (1994) and Grimm (2011) for overviews). For example, the Latin case marker *-ibus*[1] (Ablative or Dative Plural) can express the semantic category of location. It has been observed that there is a small number of such semantic categories frequently found cross-linguistically (Fillmore, 1968; Jakobson, 1984), which are variously called *case roles* or *deep cases*. Semiotically, the described situation is complicated by the fact that the relationship between case markers and expressed semantic categories is seldom isomorphic, i.e., there is both *case polysemy* (one case, several meanings) and *case homonymy* or *case syncretism* (several cases, one marker) (Baerman, 2009). As illustrated in Figure 1, the Latin Ablative marker *-ibus* can express the semantic category of instrument besides location (case polysemy), and it is also the marker of the Dative Plural expressing a recipient (case syncretism). In addition, there is *case synonymy* (one case, several markers), which further complicates morphosemiotics; e.g., in Latin, *-is* is an alternative marker of the Ablative Plural.

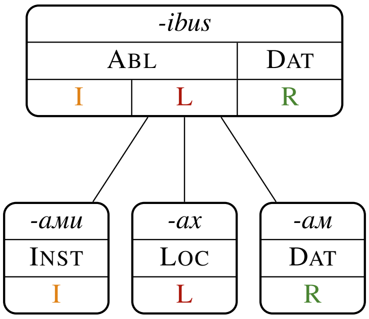

Figure 1: Morpho-semiotic foundation of this study. The Latin case marker *-ibus* is used for both the Ablative (ABL) and the Dative (DAT), which in turn express the three semantic categories of instrument (I), location (L), and recipient (R). This is an example of both case polysemy (one case: ABL, several meanings: I and L) and case syncretism (several cases: ABL and DAT, one marker: *-ibus*). Russian, on the other hand, has an isomorphic relationship between Instrumental (INST), Locative (LOC), and Dative (DAT), the case markers corresponding to them (*-ами*/*-ami*, *-ах*/*-ax*, *-ам*/*-am*), and the expressed semantic categories (I, L, R).

The key idea of this paper is to detect such complex correspondences between case markers and expressed semantic categories in an automated way. Specifically, we build on prior work by Cysouw (2014), who lays the theoretical foundation for our study by showing that deep cases can be induced from cross-linguistic usage patterns of case markers. As opposed to Latin, Russian has separate cases (with separate case markers) for the semantic categories of instrument (*-ами*/*-ami*), location (*-ах*/*-ax*), and recipient (*-ам*/*-am*). Thus, knowing the Russian case marker corresponding to Latin *-ibus* reduces the uncertainty about the expressed

---

[1] In this paper, we use *italic* when talking about case markers as morphemes in a linguistic context and `monospace` (accompanied by `$` to mark word boundaries) when talking about case markers in the context of our model. Transliterations of Cyrillic examples are given after slashes.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics

May 22-27, 2022

case role (Figure 1). This reduction of uncertainty can be particularly helpful in a low-resource setting where other means of analysis are unavailable.

In this work, we rely on the Parallel Bible Corpus (PBC; Mayer and Cysouw, 2014), a massively multilingual corpus, to investigate the relationship between surface cases and their deep meanings cross-linguistically. To put our idea into practice, we require an exhaustive set of case markers as well as a set of parallel noun phrases (NPs) that we can further analyze with respect to deep cases using the set of case markers. Both requirements pose a serious challenge for languages with limited available resources. We therefore introduce **CaMEL** (**Ca**se **M**arker **E**xtraction without **L**abels), a novel and challenging task of finding case markers using only (i) a highly parallel corpus covering many languages, (ii) a noun phrase chunker for English, and (iii) word-level pre-computed alignments across languages.

Our work uses the parallel nature of the data in two ways.

First, we leverage the word-level alignments for the initial step of our pipeline, i.e., the marking of NPs in all languages (even where no noun phrase chunker is available). To do so, we mark NPs in 23 different English versions of the Bible and project these annotations from each English to each non-English version using the word-level alignments, resulting in parallel NPs that express the same semantic content across 83 languages. Based on the projected annotations, we leverage the frequencies of potential case markers inside and outside of NPs as a filter to distinguish case markers from lexical morphemes and other grammatical morphemes typically found outside of NPs.

Second, we leverage the alignments for a fine-grained analysis of the semantic correspondences between case systems of different languages.

We make three main **contributions**.

- We define **CaMEL** (**Ca**se **M**arker **E**xtraction without **L**abels), a new and challenging task with high potential for automated linguistic analysis of cases and their meanings in a multilingual setting.
- We propose a simple method for CaMEL that is efficient, requires no training, and generalises well to low-resource languages.
- We automatically construct a silver standard based on human-annotated data and evaluate our method against it, achieving an F1 of 45%.

To foster future research on CaMEL, we make the silver standard, our code, and the extracted case markers publicly available[2].

2 Related Work

Unsupervised morphology induction has long been a topic of central interest in natural language processing (Yarowsky and Wicentowski, 2000; Goldsmith, 2001; Schone and Jurafsky, 2001; Creutz and Lagus, 2002; Hammarström and Borin, 2011). Recently, unsupervised inflectional paradigm learning has attracted particular interest in the research community (Erdmann et al., 2020; Jin et al., 2020), reflected also by a shared task devoted to the issue (Kann et al., 2020). Our work markedly differs from this line of work in that we are operating on the level of case markers, not full paradigms, and in that we are inducing morphological structure in a massively multilingual setting.

There also have been studies on extracting grammatical information from text by using dependency parsers (Chaudhary et al., 2020; Pratapa et al., 2021) and automatically glossing text (Zhao et al., 2020; Samardžić et al., 2015) as well as compiling full morphological paradigms from it (Moeller et al., 2020). By contrast, our method is independent of such annotation schemata, and it is also simpler as it does not aim at generating full grammatical or morphological descriptions of the languages examined. There has been cross-lingual work in computational morphology before (Snyder and Barzilay, 2008; Cotterell and Heigold, 2017; Malaviya et al., 2018), but not with the objective of inducing inflectional case markers.

Methodologically, our work is most closely related to the SuperPivot model presented by Asgari and Schütze (2017), who investigate the typology of tense in 1,000 languages from the Parallel Bible Corpus (PBC; Mayer and Cysouw, 2014) by projecting tense information from languages that overtly mark it to languages that do not. Based on this, Asgari and Schütze (2017) perform a typological analysis of tense systems in which they use different combinations of tense markers to further divide a single tense in any given language. Our work differs in a number of important ways. First, we do not manually select a feature to investigate

---

[2] `https://github.com/LeonieWeissweiler/CaMEL`

but model all features in our chosen sphere of interest (i.e., case) at once. Furthermore, we have access to word-level rather than verse-level alignments and can thus make statements at a more detailed resolution (i.e., about individual NPs). Finally, we extract features not only for a small selection of pivot languages, but even for languages that do not mark case "non-overtly", i.e., in a way that deviates to a large degree from a simple 1–1 mapping (see discussion in §1).

3 Linguistic Background

There is ongoing discussion in linguistic typology about the extent to which syntactic categories are shared and can be compared between the world's languages (see Hartmann et al. (2014) for an overview). While this issue is far from being settled, there is a general consensus that (while not being a language universal) there is a core of semantic categories that are systematically found cross-linguistically, and that are expressed as morphosyntactic case in many languages. Here, we adopt this assumption without any theoretical commitment, drawing upon a minimal set of deep cases detailed in Table 1. The set is loosely based on the classical approach presented by Fillmore (1968).

Going beyond deep cases, Cysouw (2014) envisages a more fine-grained analysis of what is conventionally clustered in a deep case or semantic role. Briefly summarised, the theoretical concept is this: if every language has a slightly different case system, with enough languages it should be possible to divide and cluster NPs at any desired level of granularity, from the conventional case system down to a specific usage of a particular verb in conjunction with only a small set of nouns. For example, the semantic category of location could be further subdivided into specific types of spatial relationships such as 'within', 'over' and 'under'. Taken together, it would then be possible to perform theory-agnostic typological analysis of case-like systems across truly divergent and low-resource languages by simply describing any language's case system in terms of its clustering of very fine-grained semantic roles into larger systems that are overtly marked.

The approach sketched in the last paragraph is not limited to case systems but has been applied to person marking (Cysouw, 2008), the causative/inchoative alternation (Cysouw, 2010), and motion verbs (Wälchli and Cysouw, 2012). The variety of linguistic application areas highlights the potential of developing methods that are much more automated than the work of Cysouw and collaborators. While we stay at the level of traditional deep cases in this paper, we hope to be able to extend our method into the direction of a more general analysis tool in the future.

The remainder of the paper is structured as follows. Section 4 describes our method in detail. Section 5 gives an overview of our results. Finally, Section 6 presents two exploratory analyses.

4 Methodology

4.1 Data

We work with the subset of the PBC (Mayer and Cysouw, 2014) for which the SimAlign alignment algorithm (Jalili Sabet et al., 2020) is available, resulting in 87 languages for our analysis. From the corpus, we only extract those verses that are available in all languages, thus providing for a relatively fair comparison, and remove Malagasy, Georgian, Breton, and Korean, as they have much lower coverage than the other languages. This leaves us with 83 languages and 6,045 verses as our dataset. We also select 23 English versions from the PBC that cover the same 6,045 verses. For each of the 6,045 verses, we then compute $83 \times 23 = 1909$ verse alignments: 83 (for each language) multiplied with 23 (for each English version). In the following, we will describe the components of our pipeline (Figure 2).

4.2 NP Annotation

Because our intermediate goal is to induce complete lists of case markers in all languages we cover, the first step is to restrict the scope of our search to NPs. We hope that this will allow us to retrieve case markers for nouns and adjectives while disregarding verb endings that might otherwise have similar distributional properties. As we are working with 83 languages, most of which are low-resource and lack high-quality noun phrase chunkers, we first identify NPs in English using the spaCy noun phrase chunker (Honnibal et al., 2020) and then project this annotation using the alignments to mark NPs in all other languages. The exception to this are German and Norwegian Bokmål, for which noun phrase chunkers are available directly in spaCy. Because both the spaCy noun phrase chunker and the alignments are prone to error, we make use of 23 distinct English versions

Deep Case	Description	Example
Nominative	The subject of the sentence	He is the Messiah!
Genitive	An entity that possesses another entity	Are you the Judean People's Front?
Recipient	A sentient destination	I gave the gourd to Brian.
Accusative	The direct object of the sentence	Consider the lilies.
Locative	The spatial or temporal position of an entity	They haggle in the market.
Instrumental	The means by which an activity is carried out	The graffiti was written by hand.

Table 1: Descriptions and examples for the deep cases distinguished in this paper, which loosely follow the core deep cases proposed in the classical approach of Fillmore (1968).

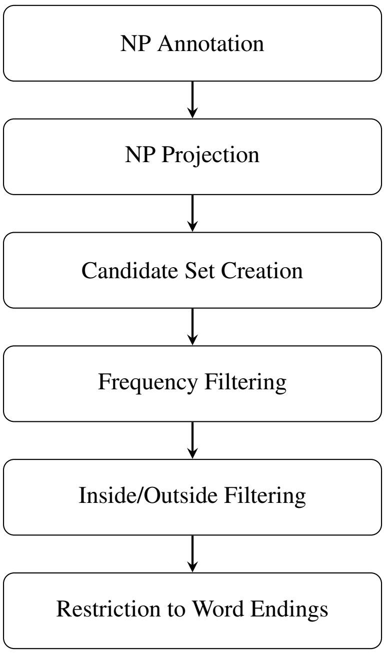

Figure 2: Overview of our pipeline.

of the Bible and mark the NPs in each of them with the goal of lessening the impact of noise.

4.3 NP Projection

We project the NP annotation of a given English version to a second language using the alignments. Specifically, we find the NP in the target language by following the alignments from all words in the English NP while maintaining the word order of the target sentence. We treat each annotated version of the corpus resulting from the different English versions as a separate data source. As an example, Figure 3 shows two English versions and the NP projections for Latin and German. While the alignments, particularly those from English to Latin, are not perfect, they result in complementary errors. The first wrongly aligns the first mention of *pastor bonus*, resulting in only *pastor* being marked as an NP. The second misses the alignment of *life* and *animam*. In these two cases, the other alignment corrects the error.

There are two major results from this process.

First, we obtain the set N of all NPs marked in English, each with all of its translations in the other languages. An example of an entry in this set, taken from Figure 3, would be *the fine shepherd, pastor bonus, der vortreffliche Hirte, ...*, while *the fine shepherd, pastor, der vortreffliche Hirte, ...* would be another, slightly defective, example.

Second, we obtain a pair of multisets, W^l_{in} and W^l_{out}, one for each language l. W^l_{in} (resp. W^l_{out}) is the multiset of all word tokens that appear inside (resp. outside) of NPs of language l. In the following, we will use $M(w)$ to refer to the frequency of word w in the multiset M.

For each language, we want to remove false positives from the word types contained within NPs (which are an artefact of wrong alignments) by using the frequency of each word type inside and outside of NPs.

In principle, this could be done by means of a POS tagger and concentrating on nouns, adjectives, articles, prepositions, and postpositions, but as we do not have access to a reliable POS tagger for most languages covered here, we use the relative frequency information gained from our NP annotations. More specifically, we assign each word type $w \in W^l_{\text{in}} \cup W^l_{\text{out}}$ to I_l (the set of words for language l that are NP-relevant) if $|W^l_{\text{in}}(w)| > |W^l_{\text{out}}(w)|$, and to O_l (the set of words for language l that are not NP-relevant) otherwise. This enhances the robustness of our method against occasional misannotations: for Latin, *ovibus* 'sheep', from our previous example, occurred once outside an NP but 45 times inside and is now an element of I_{Latin}, while *intellegent* 'they understand' occurred once inside an NP but 22 times outside and is therefore an element of O_{Latin}.

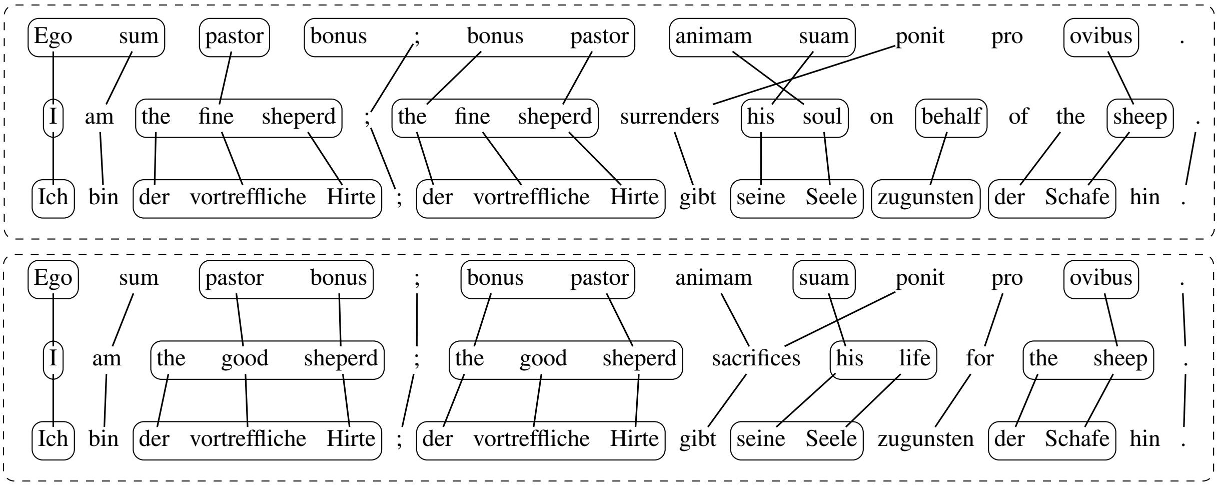

Figure 3: Example of alignments and NP projections (English to Latin and English to German) with two different English versions (top and bottom).

4.4 Candidate Set Creation

From each language, we create a set of candidate case markers candidates(w) for a word w by collecting all character n-grams of any length from w that are also members of I_l. We explicitly mark the word boundaries with `$` so that n-grams in the middle of words are distinct from those at the edges. For example, candidates extracted from *ovibus* would be `$ovi`, `ibus$`, but also `$ovibus$` and `i`. Our first candidate set is computed as $C_1^l = \bigcup\{\text{candidates}(w) \mid w \in I_l\}$.

4.5 Frequency Filtering

We define $I_l(c)$ as the number of words in I_l that contain the candidate c, and $O_l(c)$ analogously for O_l. As a first step, we filter out all n-grams with a frequency in I_l lower than a threshold θ.[3] This results in $C_2^l = \{c \mid c \in C_1^l, I_l(c) \geq \theta\}$.

4.6 Inside/Outside Frequency Filtering

For this step, we make use of the observation that case is a property of nouns. Hence, a case marker is expected to occur much more frequently within NPs. This will serve to distinguish the case markers from verb inflection markers, which should otherwise have similar distributional properties. To implement this basic idea, for each candidate c in language l, we first construct the contingency table shown in Table 2.

We use the table to test whether a candidate is more or less likely to appear inside NPs by comparing the frequencies of the candidate inside and outside NPs to those of all other candidates. Shown in the cells are the frequencies used for the test for each candidate. The columns correspond to the frequency of the candidate in question versus all other candidates while the rows distinguish the frequencies inside versus outside NPs. We carry out a Fisher's Exact Test (Fisher, 1922) on this table, which gives us a p-value and an odds ratio r. $r < 1$ if the candidate is more likely to occur outside an NP, and $r > 1$ if it is more likely to occur inside. The p-value gives us a confidence score to support this ratio (lower is better). We keep for C_{final}^l only those candidates for which $p < \phi$ and $r > \chi$.[4] For example, `ibus$` makes it past this filter with $p(\texttt{ibus\$}) = 2.869 \cdot 10^{-6}$ and $r(\texttt{ibus\$}) = 1.915$ – it is significant and it occurs inside NPs more often than outside NPs. In contrast, `t$` is discarded as it has $p(\texttt{t\$}) = 3.18 \cdot 10^{-149}$ and $r(\texttt{t\$}) = 0.249$ – it is significant, but it has been found to occur much more likely outside than inside NPs.

	c	$\neg c$
NP	$I_l(c)$	$\sum_{c' \neq c \in C_2^l} I_l(c')$
¬ NP	$O_l(c)$	$\sum_{c' \neq c \in C_2^l} O_l(c')$

Table 2: Contingency table for candidate case marker c in language l for inside/outside filtering. A morphological marker that occurs significantly more often inside NPs than outside of NPs is likely to be a nominal case marker.

4.7 Restriction to Word Endings

Suffixoidal inflection is cross-linguistically more common than prefixoidal and infixoidal inflection (Bauer, 2019). This is also reflected in our dataset,

---

[3] We set $\theta = 97$ based on grid search.

[4] We set $\phi = 0.08$ and $\chi = 0.34$ based on grid search.

where not a single language has prefixoidal or infixoidal inflection. We hence restrict the set of considered n-grams to ones at the end of words.

5 Evaluation of Retrieved Case Markers

We evaluate our method for case marker extraction without labels using a silver standard.

5.1 Silver Standard

As we are, to the best of our knowledge, the first to introduce this task, we cannot rely on an existing set of gold case markers for each language we cover. As most of the languages included are low-resource, reliable grammatical resources do not always exist, which makes the handcrafting of a gold standard difficult. Therefore, and also to ensure relative comparability, we evaluate against a silver standard automatically created from the UniMorph (Sylak-Glassman 2016, Kirov et al. 2018, McCarthy et al. 2020)[5] dataset. The UniMorph data consists of a list of paradigms, which we first filter by their POS tag, keeping only nouns and adjectives and filtering out verbs and adverbs. An example of a paradigm is given in Table 3. While the Nominative Singular (left column) is included in addition to the inflected forms (middle column), the straightforward approach of extracting the suffixes of the inflected forms is not optimal for every language, as the Nominative Singular form can differ from the root. We therefore proceed as follows.

First, we form a multiset of all inflected forms. In our example, this would result in {*Abflug, Abfluges, Abflug, Abflug, Abflüge, Abflüge, Abflügen, Abflüge*}. Next, we iterate over this multiset, removing one word each time if it occurs only once. This is meant to make the algorithm more robust against outlier words which do not share a common base with the rest of the paradigm. We then extract the longest common prefix for the remaining elements. We build a frequency list of these prefixes, which in our example has only one element, *Abfl*, with a frequency of 3. We take the most frequent element from the frequency list and compare it to the Nominative Singular, *Abflug*. Of these two candidates, we take the longer one. We thereby prioritise precision over recall as roots that are too short quickly result in many different suffixes that are too long, due to the high overall number of paradigms. Finally, we iterate over the inflected forms again, extracting the suffix if the chosen root is a prefix, which in our example yields one new suffix: `es$`, as *Abflüge* and *Abflügen* are not prefixed by *Abflug*. We examine the results for each language and exclude the languages where either basic knowledge of the language or common sense makes it apparent that sets are much too large or too small, resulting in a diverse set of 19 languages to evaluate our methods against. We note that this process automatically excludes adpositions and clitics, which is in line with our focus on suffixoidal inflection (Section 4.6). We make our silver standard publicly available.

Nominative Singular	inflected forms			unused information
	base		suffix	
Abflug	Abfl	ug		N NOM SG
	Abfl	ug	es	N GEN SG
	Abfl	ug		N DAT SG
	Abfl	ug		N ACC SG
	Abfl	üge		N NOM PL
	Abfl	üge		N GEN PL
	Abfl	ügen		N DAT PL
	Abfl	üge		N ACC PL

Table 3: Example of silver standard creation. Marked in orange is the Nominative Singular form, in red the base (“base”) as determined by the algorithm, and in green the only suffix (“suffix”) that is extracted from this paradigm. Additional, unused information in the UniMorph data is marked in grey.

5.2 Results

Our results are provided in Table 4. We observe that precision is higher, at times even substantially, than recall for most languages contained in the silver standard. Looking at Table 5 as an example, we can see that low precision is mostly due to retrieved case markers being longer (ение$/*enie*) or shorter (й$/*j*) than the correct ones. It is one of the main challenges in this task to select the correct length of a case marker from a series of substring candidates. The shorter substrings will automatically be more frequent and often correct, but this is not easily solved by a frequency threshold, which excludes other correct candidates that are naturally less frequent. Additionally, we observe that some recall errors are due to an incorrect length of n-grams in the silver standard (ьям/*'jam*), highlighting that this issue also exists in its creation process, and suggesting that our performance might even improve when measured against handcrafted data.

Table 4: Precision (P), Recall (R) and F1 on the task of case marker extraction without labels for languages contained in our silver standard. Nynorsk and Bokmål are two varieties of Norwegian.

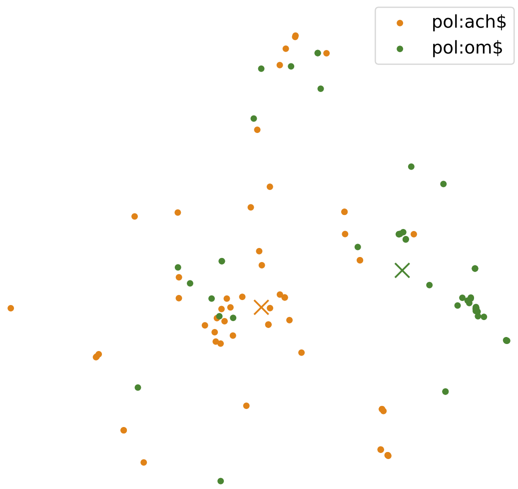

Figure 4: t-SNE plot of the contextual distribution of the Latin case marker *-ibus* and the Polish case markers *-ach* and *-om*. Outliers omitted. The plot shows NPs who in Latin are marked with the case marker `ibus$` and in Polish either with `ach$` (orange) or `om$` (green). Centroids are marked with an X. The plot shows that the Polish case markers exhibit a more fine-grained representation of the underlying semantic categories, which makes it possible to disambiguate the homonymous Latin case marker.

5.3 Ablation Study

We conduct an ablation study to assess the effects of the different pipeline components.

5.3.1 Evaluating NP Projection

In order to evaluate how well our method of projecting NP annotation using alignments to languages without an available NP chunker (see Section 4.3) works, we evaluate it against the monolingual spaCy chunkers for Norwegian Bokmål and German, which are the only available languages besides English. We do not directly compare annotated spans but instead their influence on our method as we have intentionally designed our pipeline to be robust to some noise. As I_l, the set of words considered to be NP-relevant, is the essential output of the annotation projection, we compare two versions, the set as a result of direct NP chunking and the set as a result of our annotation procedure. Taking the former as the ground truth for evaluating the latter (assuming that the directly chunked set has superior quality), we observe an F1 of 88.5 % for German and 67.8 % for Norwegian Bokmål. While these numbers seem low at first, the fact that our overall F1 on Norwegian Bokmål (.54, see Table 4) is better than on German (.50) indicates that the later elements of the pipeline are to a certain extent robust against misclassification of NPs.

5.3.2 Ablating Pipeline Components

We report the average Precison, Recall, and F1 across all languages in our silver standard without individual filtering components in Table 6. Simple frequency filtering (see "$\neg\theta$"), excluding n-grams within words (see "middle") and at the beginning of words (see "beginning") are all necessary for good performance. Inside/outside filtering based on p-value is the most important component of the pipeline (see "$\neg\phi$"). Surprisingly, inside/outside filtering based on odds ratio has almost no effect.

6 Exploratory Analyses

We can use our automatically extracted case markers, in combination with the parallel NPs that are extracted as part of the pipeline, for innovative linguistic analyses. We present two examples in this section.

6.1 Marking of Deep Cases

First, we demonstrate how, given a parallel NP, the case markers can be used to determine its deep

Intersection	Algorithm Only	Silver Standard Only
у, я, ом, ого, о, в, ой, и, ми, ам, ей, ю, ы, ов, ых, а, м, х, ами	ий, ные, ое, ение, ии, го, ый, ка, ые, к, ки, ия, ние, й, ния, ие	ыми, ах, ев, ьям, ому, ья, н, ьях, ями, ям, е, ях, ьев, ем, ым, ьями

case. We return to N (see Section 4.3), our set of parallel NPs extracted from the PBC, and for a selected subset of languages, group them by their combination of case markers. The basic idea is to infer an NP's (potentially very fine-grained) deep case by representing it as its combination of case markers across languages.

For example, we can disambiguate the Latin case marker *-ibus* by looking at the different groups the NPs containing it form with Russian case markers. Recall that *-ibus* can express location, instrument, and recipient and that Russian expresses these categories by separate case markers: *-ax*/*-ax* for location, *-ами*/*-ami* for instrument, and *-ам*/*-am* for recipient (see Figure 1) – all three of which have been retrieved by our method. Given a Latin NP marked by the ending *-ibus*, the parallel NP in Russian can help us determine its deep case. Thus, for domibus, дворцах/*dvorcax* shows that the semantic category is location, i.e., 'in the houses'. For operibus bonis, добрыми делами/*dobrymi delami* shows that the semantic category is instrument, i.e., 'through the good deeds'. Finally, for patribus, предкам/*predkam* shows that the semantic category is a recipient, i.e., 'for/to the parents'.

6.2 Similarities between Case Markers

We also demonstrate how we can use their distributional similarities over NPs to show how case markers that are similar in this respect correspond to similar combinations of deep cases. We first generate an NP-word cooccurrence matrix over the NP vocabulary of all languages in which each row, corresponding to an inflected word firm w in language l, indicates which NPs (corresponding to columns) cooccur with w. in the parallel data. We then reduce the dimensionality of the matrix by means of t-SNE (Van der Maaten and Hinton, 2008), allowing us to inspect systematic patterns with respect to the "contexts" in which certain case markers occur (where "context" refers to words the case marker is aligned to in other languages, not words the case marker coccurs with in its own language). In a semiotic situation like the one shown in Figure 1, this setup allows us to examine how the semantic region expressed by a certain homonymous case marker in one language is split into more fine-grained regions in another language that distinguishes the semantic categories that are lumped together by the case marker (and which, if they are at the right level of abstraction, can correspond to deep cases).

Figure 4 shows this scenario for the Latin Ablative marker *-ibus*. It corresponds to two distinct case markers in Polish, *-ach* (LOC) and *-om* (DAT). The figure shows that the region occupied by Latin *-ibus* splits into two distinct clusters in Polish, allowing us to visually determine which underlying case is expressed by the homonymous suffix *-ibus*.

This underscores the exploratory potential of our approach.

7 Conclusion and Future Work

We have introduced the new and challenging task of Case Marker Extraction without Labels (CaMEL) and presented a simple and efficient method that leverages cross-lingual alignments and achieves an F1 of 45% on 19 languages. We introduce an automatically created silver standard to conduct our evaluation. We have further demonstrated two ways in which our retrieved case markers can be used for linguistic analysis.

We see two potential avenues for future work. The first is the further improvement of case marker extraction. The main problem to tackle here is that of small sets of overlapping substrings of which only one is the correct marker, and developing some further measures by which they can be distinguished. Furthermore, it would be useful to find data from more low-resource languages and languages that have typological properties different from the extensively studied large language families (Indo-European, Turkic, Sino-Tibetan etc.). We could then verify that our method performs well across languages and attempt to expand our silver standard to more languages while still ensuring quality. The second area is that of further automating the analysis of deep case and case syncretism. Ideally, we would develop a method that can distinguish the different possible reasons for divergent case marking in languages, with the eventual goal of creating a comprehensive overview of case and declension systems for a large number of languages.

Abstract

Robustness of machine learning models on ever-changing real-world data is critical, especially for applications affecting human well-being such as content moderation. New kinds of abusive language continually emerge in online discussions in response to current events (e.g., COVID-19), and the deployed abuse detection systems should be updated regularly to remain accurate. In this paper, we show that general abusive language classifiers tend to be fairly reliable in detecting out-of-domain explicitly abusive utterances but fail to detect new types of more subtle, implicit abuse. Next, we propose an interpretability technique, based on the Testing Concept Activation Vector (TCAV) method from computer vision, to quantify the sensitivity of a trained model to the human-defined concepts of explicit and implicit abusive language, and use that to explain the generalizability of the model on new data, in this case, COVID-related anti-Asian hate speech. Extending this technique, we introduce a novel metric, *Degree of Explicitness*, for a single instance and show that the new metric is beneficial in suggesting out-of-domain unlabeled examples to effectively enrich the training data with informative, implicitly abusive texts.

1 Introduction

When machine learning models are deployed in the real world, they must be constantly monitored for their robustness to new and changing input data. One area where this is particularly important is in abusive language detection (Schmidt and Wiegand, 2017; Fortuna and Nunes, 2018; Nakov et al., 2021; Vidgen and Derczynski, 2020). The content of online conversation is constantly changing in response to political and social events. New categories of abusive language emerge, encompassing topics and vocabularies unknown to previously trained classifiers. Here, we tackle three main questions: How can a human user formalize new, relevant topics or concepts in text? How do we quantify the sensitivity of a trained classifier to these new concepts as they emerge? And how do we update the classifier so that it remains reliable?

As a case study, we consider the rise of COVID-related anti-Asian racism on social media. The COVID-19 pandemic represented an entirely new and unexpected situation, generating new vocabulary (*COVID-19*, *coronavirus*, *social distancing*, *masking*), new topics of conversation (dealing with isolation, working from home), and – unfortunately – new and renewed instances of hate speech directed towards Asian communities. We imagine the case of an abusive language detection algorithm which had been deployed prior to the pandemic: what are the new types of abusive language that have emerged with the recent pandemic? To what extent can deployed classifiers generalize to this new data, and how can they be adapted? Although social events can spark off a specific type of hate speech, they are rarely the root cause of the issue. Often such hateful beliefs existed before the event, and are only magnified because of it (Chou and Feagin, 2015). Therefore, we expect that the classifier should detect this new variety of hate speech to some extent.

An important factor in this study is whether the text expresses explicit or implicit abuse (Waseem et al., 2017; Caselli et al., 2020; Wiegand et al., 2021). Explicit abuse refers to utterances that include direct insults or strong rudeness, often involving profanities, whereas implicit abuse involves more indirect and nuanced language. Since understanding the offensive aspects of implicit abuse in our case study may require some knowledge of the context (i.e., the pandemic), we expect that the pretrained classifier will find these data especially difficult to handle.

To examine a classifier's ability to handle new type of abusive text (without access to extensive labeled data), we propose a technique based on the Testing Concept Activation Vector (TCAV) method

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 5517 - 5529
May 22-27, 2022

from the interpretability literature in computer vision (Kim et al., 2018). TCAV is used to explain whether a classifier associates a specific concept to a class label (e.g., the concept of *stripes* is associated with class *zebra* in image classification). Similarly, we define implicit and explicit COVID-related anti-Asian racism with a small set of human-chosen textual examples, and ask whether the pre-trained classifier associates these concepts with the positive (abusive) class label.

Further, we ask whether sensitivity to human-defined concepts can direct data augmentation[1] to improve generalizations. Intuitively, when updating a classifier, data enrichment should focus on adding examples of concepts to which the classifier is not yet sensitive. Conventional active learning frameworks suggest examples with the lowest classification confidence as the most informative augmentation samples (Zhu et al., 2008; Chen et al., 2019). However, deep neural networks' inability to provide reliable uncertainty estimates is one of the main barriers to adopting confidence-based sampling techniques (Schröder and Niekler, 2020). We suggest that, in the case of abuse detection, implicitly abusive examples are most informative for updating a general classifier. However, to the best of our knowledge, there is no quantitative metric that can measure the degree of explicitness of a candidate example, given a trained classifier. We extend the TCAV technique to provide a "degree of explicitness" measure at the utterance level and use that for efficient data augmentation.

The contributions of this work are as follows:

- We implement a variation of the TCAV framework for a RoBERTa-based classifier and show that it can be used to quantify the sensitivity of a trained classifier to a human-understandable concept, defined through examples, without access to the training dataset of the classifier or a large annotated dataset for the new category.
- We analyse the performance of two abusive language classifiers and observe that they generalize well to explicit COVID-related anti-Asian racism, but are unable to generalize to implicit racism of this type. We show that sensitivities to the concepts of implicit and explicit abuse can explain the observed discrepancies.
- We adjust the TCAV method to compute the *degree of explicitness*, for an unlabeled instance, as a metric to guide data augmentation when updating a general abusive language classifier to include a new kind of abuse. We test this method against confidence-based augmentation and show that it is able to reach higher accuracy with fewer training examples, while maintaining the accuracy on the original data.

The implementation code and data for the experiments are available at `https://github.com/IsarNejad/TCAV-for-Text-Classifiers`.

2 Datasets and Data Analysis

We consider the following four English datasets, summarized in Table 1: *Founta*[2] and *Wiki*[3] are large, commonly-used datasets for general abusive language detection, while *EA* and *CH* specifically target COVID-related anti-Asian racism. We binarize all datasets to two classes: positive (i.e., abusive or hateful) and negative. For *Founta*, this means combining Abusive and Hateful texts into a single positive class; for *EA*, "Hostility against an East-Asian entity" is considered positive, and all other classes are negative; and for *CH*, all hate speech is classed as positive, while counter-hate and hate-neutral texts are classed as negative.

2.1 Differences in Vocabulary

Central to our research question is the issue of vocabulary change as a new abusive topic emerges. As the *Wiki* and *Founta* datasets were collected before the COVID-19 pandemic, they do not contain novel vocabulary such as "chinavirus" or "wuhanflu", and the contexts and frequencies for words like "China" and "pandemic" may have changed. As a demonstration of the differences in vocabulary across the different datasets, we compute the top 100 most frequent words in the positive class of each dataset (after removing stop words[4]), and then calculate the overlap between each pair of datasets. We categorize the shared words into three categories: 1) generically profane and hateful words, 2) COVID-related words, and 3) all other words.

---

[1] In this paper, we use the term *augmentation* to refer to the process of enriching the training data by adding examples from sources other than the original dataset.

[2] For *Founta*, we discard the tweets labeled as Spam and use the train-dev-test split as provided by Zhou et al. (2021).

[3] We used a smaller version of the *Wiki* dataset as provided in Nejadgholi and Kiritchenko (2020). In that work, we removed 54% of Wikipedia-specific non-toxic instances from the training set to mitigate the topic bias, and reported improvements in both the classification performance and the execution time. Here, we found similar benefits.

[4] We used the stop word list from the scikitlearn package.

Dataset	**Data Source**	**Positive Class**	**Negative Class**	**Number (%Pos:%Neg)**		
				Train	*Dev*	*Test*
Wikipedia Toxicity (*Wiki*) (Wulczyn et al., 2017)	Wikipedia comments	Toxic	Normal	43,737 (17:83)	32,128 (9:91)	31,866 (9:91)
Founta et al. (2018) dataset (*Founta*)	Twitter posts	Abusive; Hateful	Normal	62,103 (37:63)	10,970 (37:63)	12,893 (37:63)
East-Asian Prejudice (*EA*) (Vidgen et al., 2020)	Twitter posts	Hostility against an East Asian entity	Criticism of an East Asian entity; Counter speech; Discussion of East Asian prejudice; Non-related	16,000 (19:81)	1,200 (19:81)	2,800 (19:81)
COVID-HATE (*CH*) (Ziems et al., 2020)	Twitter posts	Anti-Asian COVID-19 hate; Hate directed to non-Asians	Pro-Asian COVID-19 counterhate; Hate-neutral	–	–	2,319 (43:57)

Table 1: Class descriptions, number of instances and ratio of positive to negative in percentage (%Pos:%Neg) for the general abusive datasets (*Wiki* and *Founta*) and COVID-related Anti-Asian hate speech datasets (*EA* and *CH*).

Table 2 shows the three categories of shared words among the 100 most frequent words of the positive classes in our datasets.

This analysis reveals that the two COVID-related datasets share more words in common: 50 out of the 100 most frequent words are common between the two datasets. As expected, a large portion of their shared vocabulary (32%) is specific to the pandemic, has been used more frequently during the pandemic or has found new connotations because of the pandemic. For all other datasets, fewer words are shared, and the shared words are either related to profanity and violence or are merely commonly used terms. Profanity and strongly negative words such as "hate" make up 30% of the shared vocabulary between the *Wiki* and *Founta* datasets. Interestingly, *CH* has a set of profane words in common with both *Wiki* and *Founta* ($\sim$25% of shared words), while the words shared between *EA* and the general datasets are simply common words in the English language, such as "people", "want", and "need." We expect that this vocabulary shift between the different datasets will have a considerable impact on the generalizability.

2.2 Differences in Explicitness

Another important factor in our study is generalization with respect to explicit and implicit types of abusive language. Above, we observed that *CH* shares many profane words with the general datasets and, therefore, we anticipate it contains more explicitly abusive texts than *EA* does. Unfortunately, neither of the datasets has originally been annotated for *explicitness of abuse*. We manually annotate instances from the positive class in the *CH* dataset and the *EA* dev set using the following rule: instances that include profanity, insult or rudeness that could be correctly identified as abusive without general knowledge about the COVID-19 pandemic are labeled as explicitly abusive; the remaining instances (e.g., *'it is not covid 19 but wuhanvirus'*) are labeled as implicitly abusive. We find that 85% of the *CH-positive* class is categorized as explicit, whereas only 8% of the *EA-positive* class in the *EA* dev set is labeled as explicit. Thus, *CH* and *EA* share COVID-related vocabulary, but are very different in terms of explicitness of abuse (*CH* containing mostly explicit abuse while *EA* containing mostly implicit abuse), which makes them suitable test beds for assessing the generalizability of classifiers to a new type of abusive language and the impact of new vocabulary on the classification of implicit and explicit abuse.

3 Cross-Dataset Generalization

We start by assessing the robustness of a general-purpose abusive language classifier on a new domain of abusive language. Specifically, we analyze the performance of classifiers trained on the *Wiki* and *Founta* datasets (expected to detect general toxicity and abuse) on COVID-related anti-Asian racism data. In addition, we want to assess the impact of the change of vocabulary on the generalizibility of the classifiers to implicit and explicit abuse in the new domain. We train binary RoBERTa-based classifiers on the *Wiki*, *Founta*, *EA* and *CH* datasets (referred to hereafter as the *Wiki*, *Founta*, *EA* and *CH* classifiers), and test them on the *EA* as the mostly implicit COVID-related dataset and *CH* as the mostly explicit COVID-

Datasets	Count	Shared Words
EA - CH	50	**COVID-related (32%):** ccp, 19, communist, pandemic, coronavirus, covid19, chinesevirus, infected, covid, chinese, chinavirus, corona, wuhanvirus, wuhan, china, virus **Hateful (0%)** **Other (68%):** racist, came, want, country, calling, come, does, spread, like, amp, media, eating, did, human, world, know, government, say, started, think, need, blame, evil, time, people, don, new, let, news, stop, countries, just, spreading, make
Wiki - Founta	37	**COVID-related (0%)** **Hateful (30%):** *ss, b*tch, id*ot, n*ggas, d*ck, f*cking, f*ck, sh*t, hell, hate, stupid **Other (70%):** oh, dont, want, way, going, come, does, like, look, life, did eat, sex, know, say, think, man, need, time, people, said, stop, really, just, make, tell
Founta - EA	19	**COVID-related (0%)** **Hateful (0%)** **Other (100%):** racist, want, calling, come, does, like, did, world, know, say, think, need, time, people, trying, let, stop, just, make
Wiki - EA	15	**COVID-related (0%)** **Hateful (0%)** **Other (100%):** people, want, did, say, think, good, need, come, does, stop, just, know, like, make, time
Founta - CH	35	**COVID-related (0%)** **Hateful (23%):** *ss, b*tch, f*cking, f*ck, sh*t, hate, stupid, f*cked **Other (77%):** racist, want, way, going, calling, come, does, like, got, look, did, eat, world, know, say, think, man, trump, need, time, people, said, let, stop, really, just, make
Wiki - CH	33	**COVID-related (0%)** **Hateful (27%):** *ss, b*tch, f*cking, f*ck, sh*t, hate, stupid, shut, kill **Other (73%):** want, way, going, come, does, like, look, did, eat, right, know, die, say, think, man, need, time, people, don, said, stop, really, just, make

Table 2: Shared words among 100 most frequent words of the positive classes in the datasets.

related dataset. (The training details are provided in Appendix A.) Note that *CH* is too small to be broken into train/test/dev sets, so it is used either as a training dataset when testing on *EA* or a test dataset for all other classifiers. Here, while the classifier makes a binary positive/negative decision, we are really assessing its ability to generalize to the new task of identifying anti-Asian hate. For comparison, we also train an "explicit general abuse" classifier with only explicit examples of the *Wiki* dataset and the class balance similar to the original *Wiki* dataset. This classifier is referred to as *Wiki-exp*.[5]

Domain	Train Set	AUC		F1-score	
		EA	*CH*	*EA*	*CH*
COVID	*EA*	0.94	0.82	0.74	0.66
	CH	0.86	-	0.62	-
pre-COVID	*Founta*	0.69	0.73	0.29	0.65
	Wiki	0.64	0.74	0.27	0.69
	Wiki-exp	0.58	0.71	0.15	0.56

Table 3: Cross-dataset generalization on *EA* (mostly implicit) and *CH* (mostly explicit) datasets.

Table 3 presents the Area Under the ROC Curve (AUC) and F1-scores for all the classifiers; precision, recall, and average precision scores are provided in Appendix B. We first consider whether class imbalances can explain our results. Note that while abusive language is a relatively rare phenomenon in online communications, most abusive language datasets are collected through boosted sampling and therefore are not subject to extreme class imbalances. The percentage of positive instances in our datasets ranges from 9% to 43% (Table 1). We observe similar performances for the *Wiki* and *Founta* classifiers despite different class ratios in their training sets, and different performances for *Wiki* and *EA* classifiers despite their similar training class ratios. We also observe better performance from the *CH* classifier (on the *EA* test set), compared to the *Wiki* or *Founta* classifiers, despite the very small size of the *CH* dataset. Based on previous research, we argue that cross-dataset generalization in abusive language detection is often governed by the compatibility of the definitions and sampling strategies of training and test labels rather than class sizes (Yin and Zubiaga, 2021). Instead, we explain the results presented in Table 3 in terms of implicit/explicit types of abuse and the change of vocabulary.

Cross-dataset generalization is better when datasets share similar vocabulary. The classifiers trained on the *EA* and *CH* datasets perform better

---

[5] For *Wiki-exp*, the examples of the positive class are taken from the 'explicit abuse' topic, which contains texts with explicitly toxic words, from (Nejadgholi and Kiritchenko, 2020), and negative examples are randomly sampled from the *Wiki-Normal* class.

than all the classifiers trained on the pre-COVID datasets (*Wiki* and *Founta*). Interestingly, the performance of the *CH* classifier on the *EA* dataset is higher than the performance of all the general classifiers, despite the *CH* dataset being very small and containing mostly explicit abuse. This observation confirms that general classifiers need to be updated to learn the new vocabulary.

General-purpose classifiers generalize better to explicit than implicit examples in the new domain. The *Wiki* and *Founta* classifiers, which have been exposed to large amounts of generally explicit abuse, perform well on the mostly explicit *CH* dataset, but experience difficulty with the COVID-specific implicit abuse in the *EA* dataset. For example, the tweet *'the chinavirus is a biological attack initiated by china'* is misclassified as non-abusive. We observe that *Wiki-exp* performs relatively similar to the *Wiki* classifier on *CH*, despite its small size (only 1,294 positive examples) but is worse than *Wiki* classifier on *EA*. This means that the additional 35K instances (of which, 9K are positive examples) of the *Wiki* compared to the *Wiki-exp*, only moderately improve the classification of the implicit examples in the new domain. This observation indicates that generalization mostly occurs between the explicit type of the pre-COVID abuse and the explicit type of the COVID-related abuse. Therefore, a general-purpose classifier should be specifically updated to learn implicit abuse in the new domain.

4 Sensitivity to Implicit and Explicit Abuse to Explain Generalizability

In Section 3, we showed that when a new domain emerges, the change in vocabulary mostly affects the classification of implicitly expressed abuse. This observation is in line with findings by Fortuna et al. (2021), and suggests that generalization should be evaluated on implicit and explicit abuse separately. However, due to complexities of annotation of abusive content, curating separate implicit and explicit test sets is too costly (Wiegand et al., 2021). Instead, we propose to adapt the Testing Concept Activation Vector (TCAV) algorithm, originally developed for image classification (Kim et al., 2018), to calculate the classifiers' sensitivity to explicit and implicit COVID-related racism, using only a small set of examples. Then, we show how these sensitivities can explain the generalizations observed in Table 3.

4.1 TCAV background and implementation

TCAV is a post-training interpretability method to measure how important a user-chosen concept is for a prediction, even if the concept was not directly used as a feature during the training. The concept is defined with a set of *concept examples*. To illustrate, Kim et al. (2018) suggest "stripes" as a visual concept relevant to the class "zebra", and then operationally define the "stripes" concept by collecting examples of images containing stripes. In our language-based TCAV method, a concept is defined by a set of manually chosen textual examples. We collect examples from held-out subsets or other available data sources and manually annotate them for the concept of interest (for example, explicit anti-Asian abuse). Then, we represent the concept by averaging the representations of the examples that convey that concept, similarly to how the "stripes" concept is represented by several images that include stripes.

Here, we consider concepts such as COVID-19, hate speech, and anti-Asian abuse, but the approach generalizes to any concept that can be defined through a set of example texts. Using these examples, a Concept Activation Vector (CAV) is learned to represent the concept in the activation space of the classifier. Then, directional derivatives are used to calculate the sensitivity of predictions to changes in inputs towards the direction of the concept, at the neural activation layer.

We adapt the TCAV procedure for a binary RoBERTa-based classifier to measure the importance of a concept to the positive class. For any input text, $x \in \mathbb{R}^{k \times n}$, with k words in the n-dimensional input space, we consider the RoBERTa encoder of the classifier as $f_{emb} : \mathbb{R}^{k \times n} \to \mathbb{R}^m$, which maps the input text to its RoBERTa representation (the representation for [CLS] token), $r \in \mathbb{R}^m$. For each concept, C, we collect N_C concept examples, and map them to RoBERTa representations $r_C^j, j = 1, ..., N_C$. To represent C in the activation space, we calculate P number of CAVs, υ_C^p, by averaging[6] the RoBERTa representations of N_υ randomly chosen concept examples:

---

[6] In the original TCAV algorithm, a linear classifier is trained to separate representations of concept examples and random examples. Then, the vector orthogonal to the decision boundary of this classifier is used as the CAV. We experimented with training a linear classifier and found that the choice of random utterances has a huge impact on the results to the point that the results are not reproducible. More stable results are obtained when CAVs are produced by averaging the RoBERTa representations.

$$v_C^p = \frac{1}{N_v}\sum_{j=1}^{N_v} r_C^j \quad p = 1,..,P \tag{1}$$

where $N_v < N_C$. The *conceptual sensitivity* of the positive class to the v_C^p, at input x can be computed as the directional derivative $S_{C,p}(x)$:

$$\begin{aligned} S_{C,p}(x) &= \lim_{\epsilon \to 0} \frac{h(f_{emb}(x)+\epsilon v_C^p)-h(f_{emb}(x))}{\epsilon} \\ &= \bigtriangledown h(f_{emb}(x)).v_C^p \end{aligned} \tag{2}$$

where $h : \mathbb{R}^m \rightarrow \mathbb{R}$ is the function that maps the RoBERTa representation to the logit value of the positive class. In Equation 2, $S_{C,p}(x)$ measures the changes in class logit, if a small vector in the direction of C is added to the input example, in the RoBERTa-embedding space. For a set of input examples X, we calculate the TCAV score as the fraction of inputs for which small changes in the direction of C increase the logit:

$$TCAV_{C,p} = \frac{|x \in X : S_{C,p}(x) > 0|}{|X|} \tag{3}$$

A TCAV score close to one indicates that for the majority of input examples the logit value increases. Equation 3 defines a distribution of scores for the concept C; we compute the mean and standard deviation of this distribution to determine the overall sensitivity of the classifier to the concept C.

4.2 Classifier's Sensitivity to a Concept

We define each concept C with $N_C = 100$ manually chosen examples, and experiment with six concepts described in Table 4. To set a baseline, we start with a set of random examples to form a non-coherent concept. Next, we define a non-hateful COVID-related concept using random tweets with COVID-related keywords *covid, corona, covid-19, pandemic*. For the explicit anti-Asian abuse concept, we include all 14 explicitly abusive examples from the *EA* dev set and 86 explicitly abusive examples from *CH* class. We define two implicit anti-Asian concepts with examples from *EA* and *CH*, to assess whether selecting the examples from two different datasets affects the sensitivities. We also define the generic hate concept with examples of pre-COVID general hateful utterances, not directed at Asian people or entities, from the *Founta* dev set.

We calculate $P = 1000$ CAVs for each concept, where each CAV is the average of $N_v = 5$ randomly chosen concept examples. We use 2000 random tweets collected with stopwords as input examples X (see Equation 3).[7] Table 5 presents the means and standard deviations of the TCAV score distributions for the classifiers trained on *Wiki*, *Founta*, *EA*, and *CH* datasets, respectively. First, we observe that all TCAV scores calculated for a random, non-coherent set of examples are zero; i.e., as expected, the TCAV scores do not indicate any association between a non-coherent concept and the positive class. Also, as expected, none of the classifiers associate the non-hateful COVID-related concept to the positive class. Note that a zero TCAV score can be due to the absence of that concept in the training data (e.g., the COVID concept for the *Wiki* and *Founta* classifiers), insignificance of the topic for predicting the positive label (e.g., the COVID concept for the *EA* classifier), or the lack of coherence among the concept examples (such as the concept defined by random examples). A TCAV score close to 1, on the other hand, indicates the importance of a concept for positive prediction. These observations set a solid baseline for interpreting the TCAV scores, calculated for other concepts. Here we ask whether the generated TCAV scores can explain the generalization performances observed in Table 3.

Non-coherent concept: random tweets collected with stop words as queries
COVID-19: tweets collected with words *covid, corona, covid-19, pandemic* as query words
Explicit anti-Asian abuse: tweets labeled as explicit from *EA* dev and *CH*
Implicit abuse (EA): tweets labeled as implicit from *EA* dev
Implicit abuse (CH): tweets labeled as implicit from *CH*
Generic hate: tweets from the *Hateful* class of *Founta* dev

Table 4: Human-defined concepts and the sources of the tweets used as concept examples.

We consider a classifier to be sensitive to a concept if its average TCAV score is significantly different (according to the t-test with p < 0.001) from the average TCAV score of a non-coherent random concept. First, we observe that the general classifiers are only sensitive to the explicit type of COVID-related abusive language. This confirms that the classifiers generalize better to the explicit type of an emerging domain of abusive language.

---

[7] Unlike the original TCAV algorithm, we do not restrict the input examples to the target class. In our experiments, we observed that, for this binary classification set-up, the choice of input examples has little impact on the TCAV scores. Intuitively, we assess whether adding the concept vector to a random input would increase the likelihood of it being assigned to the positive class.

Classifier	Concept					
	non-coherent	COVID-19	explicit anti-Asian	implicit (EA)	implicit (CH)	generic hate
EA	0.00 (0.00)	0.00 (0.00)	**0.90** (0.26)	**0.87** (0.30)	**0.70** (0.42)	0.00 (0.00)
CH	0.00 (0.00)	0.00 (0.00)	-	0.35 (0.44)	-	0.21 (0.12)
Founta	0.00 (0.02)	0.00 (0.01)	**0.92** (0.22)	0.00 (0.06)	0.19 (0.32)	**0.60** (0.44)
Wiki	0.00 (0.03)	0.00 (0.05)	**0.96** (0.16)	0.00 (0.03)	0.32 (0.44)	**0.75** (0.41)
Wiki-exp	0.00 (0.05)	0.00 (0.07)	**0.78** (0.12)	0.00 (0.02)	0.00 (0.05)	**0.59** (0.40)

Table 5: Means and standard deviations of TCAV score distributions for the positive class of the five classifiers with respect to six human-defined concepts. Scores statistically significantly different from random are in bold.

We also note that *Wiki-exp*, is sensitive to the explicit anti-Asian concept.

Second, the classifier trained with mostly explicit COVID-related data (*CH*) is not sensitive to the implicit abuse concept.[8] The only classifier that is sensitive to the explicit and both implicit COVID-related abusive concepts is the *EA* classifier. Classifiers trained on the COVID datasets are also not sensitive to the generic hate concept, which encompasses a much broader range of target groups. Overall, these findings stress the importance of including implicitly abusive examples in the training data for better generalizability within and across domains.

5 Degree of Explicitness

Here, we suggest that implicit examples are more informative (less redundant) for updating a general classifier and provide a quantitative metric to guide the data augmentation process. We extend the TCAV methodology to estimate the *Degree of Explicitness* or *DoE* of an utterance. We showed that the average TCAV score of the positive class for the explicit concept is close to 1. DoE is based on the idea that adding one example to an explicit concept will not affect its average TCAV score (i.e., it will still be close to 1), if the added example is explicitly abusive. However, adding an implicit example presumably will change the direction of all CAVs and reduce the sensitivity of the classifier to this modified concept. Here, we modify Equation 1 and calculate each CAV by averaging the RoBERTa representations of $N_v - 1$ explicit concept examples, and the new utterance for which we want the degree of explicitness, x_{new}, with representation r_{new}. Thus,

$$v^p_{new} = \frac{1}{N_v}(\sum_{j=1}^{N_v-1} r^j_C + r_{new}), \quad p = 1, .., P$$

We then calculate the average TCAV score for each x_{new} as its DoE score. If the new utterance, x_{new}, is explicitly abusive, v^p_{new} will represent an explicit concept, and the average TCAV score, i.e., $mean(TCAV_{C,p})$ will remain close to 1. However, the less explicit the new example is, the more v^p_{new} will diverge from representations of explicit abuse, and the average score will drop. We use $N_v = 3$ in the following experiments.

DoE analysis on COVID-related abusive data: We validate the utility of DoE in terms of separating implicit and explicit abusive examples. For the *Wiki* and *Founta* classifiers, we calculate the DoE score of the implicit and explicit examples from *CH* and the *EA* dev set (described in Section 3), excluding the examples used to define the *Explicit anti-Asian abuse* concept. Given that low classification confidence could indicate that the model struggles to predict an example correctly, one might expect that implicit examples are classified with less classification confidence than explicit examples. Figure 1 shows the comparison of DoE with classification confidence in distinguishing between implicit and explicit examples. We observe that for both classifiers, the distribution of DoE scores of implicit examples is different from the distribution of DoE scores of explicit examples, but the distributions of their classification confidences are indistinguishable. Therefore, we conclude that DoE is more effective at separating implicit abuse from explicit abuse than classification confidence. We further analyze DoE scores for the positive and negative classes separately in Appendix C.

6 Data Augmentation with DoE score

We now use the DoE score to direct data augmentation. We consider a scenario where a general classifier should be re-trained with an augmented dataset to include emerging types of abusive language. As we showed, general classifiers are already sensitive to explicit abuse. Therefore, we hypothesize that implicit examples are more benefi-

---

[8] We do not measure the sensitivity of this classifier to the explicit anti-Asian and implicit CH concepts, since their concept examples are included in the training set of the classifier.

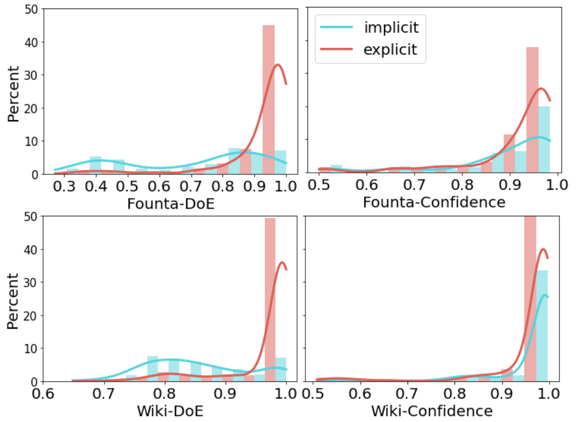

Figure 1: Comparison of classification confidence and DoE score for distinguishing between implicit and explicit abusive utterances.

cial for updating the classifier. Here, we describe a novel DoE-based augmentation approach and contrast it with the conventional process of choosing augmentation examples based on the classification confidence (Zhu et al., 2008; Chen et al., 2019).

We consider the general *Wiki* classifier. Our goal is to find a small but sufficient portion of the *EA* train set to augment the original *Wiki* train set, so that the classifier is able to handle COVID-related anti-Asian hate speech. We calculate the DoE and confidence scores for all the examples in the *EA* train set and add the N examples with the lowest scores to the original *Wiki* train set. We vary N from 1K to 6K, with a 1K step. After the augmentation data size reaches 6K, the classifier performance on the original *Wiki* test set drops substantially for both techniques. Also, note that as the size of the augmentation dataset increases, the two methods converge to the same performance.

6.1 Results

Figure 2 shows the F1-score of the classifiers updated using the DoE and confidence-based augmentation methods on the original test set (*Wiki*) and the new test set (*EA*) for different augmentation sizes. (Precision and recall figures are provided in Appendix D.) Since only *EA* is used for augmentation, we evaluate the classifiers on this dataset to find the optimum size for the augmented training set and only evaluate the best performing classifiers on *CH*. We expect that an efficient augmentation should maintain the performance on *Wiki* and reach acceptable results on *EA* test set.

DoE is better at learning the new type of abuse: On the *EA* dataset, DoE achieves better results than the confidence-based augmentation method for all augmentation sizes, except for N= 5K, where the performances of the two methods are comparable.

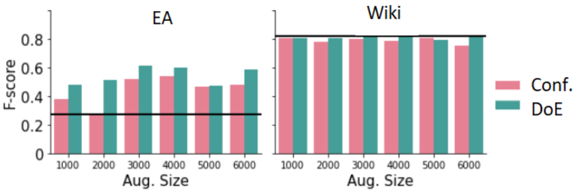

Figure 2: F1-score of the augmented *Wiki* classifier on the *EA* and *Wiki* test sets. Solid lines show the baseline.

DoE is better at maintaining performance on the original dataset: DoE outperforms the confidence-based method on the *Wiki* dataset. For all augmentation sizes, the performance of the DoE-augmented classifier on this class stays within 2% of the baseline (the F1-score of the classifier trained just on the *Wiki* data), whereas for the confidence-based augmentation, we observe up to 6% drop depending on the size of the added data.

DoE is better overall: Table 6 presents the best results achieved by the two augmentation methods on the *EA* test set: AUC score of 0.81 for the DoE-based augmentation obtained with 3K added examples, and AUC score of 0.69 for the confidence-based augmentation obtained with 4K added examples. For comparison, we also show the baseline results for the original *Wiki* classifier and the classifier trained on the combined *Wiki* and full *EA* train sets. Although we did not optimize the augmentation for the *CH* dataset, our evaluation shows that DoE performs favourably on this dataset, as well. We conclude that the new DoE-based augmentation method maintains the classification performance on the original dataset, while outperforming the other method on the new data.

We also qualitatively assess the classifier's output before and after data augmentation with DoE. While explicitly abusive utterances (e.g., "f*ck you china and your chinese virus") are often correctly classified both before and after re-training, many implicitly abusive examples (e.g., "it is not covid 19 but wuhanvirus") are handled correctly by the classifier only after re-training.

7 Related Work

Generalizability has been an active research area in NLP (Ettinger et al., 2017; Hendrycks et al., 2020). In a recent review, Yin and Zubiaga (2021) discussed the challenges for building generalizable

hate speech detection systems and recommended possible future directions, including improving data quality and reducing overfitting through transfer learning. Several studies evaluated generalizability in abuse detection through cross-dataset evaluation (Swamy et al., 2019; Wiegand et al., 2019), direct dataset analysis (Fortuna et al., 2020) or topic modeling on the training data (Nejadgholi and Kiritchenko, 2020). Fortuna et al. (2021) showed that the lack of generalizability is rooted in the imbalances between implicit and explicit examples in training data.

The distinction between explicit and implicit abuse has been recognized as an important factor in abuse detection (Waseem et al., 2017; Caselli et al., 2020). Wiegand et al. (2019) showed that lexicon-based sampling strategies fail to collect implicit abuse and most of the annotated datasets are overwhelmed with explicit examples. Breitfeller et al. (2019) showed that inter-annotation agreement is low when labeling the implicit abuse utterances, as sometimes specific knowledge is required in order to understand the implicit statements. For better detection of implicitly stated abuse, large annotated datasets with hierarchical annotations are needed (Sap et al., 2020), so that automatic detection systems can learn from a wide variety of such training examples. Field and Tsvetkov (2020) proposed propensity matching and adversarial learning to force the model to focus on signs of implicit bias. Wiegand et al. (2021) created a novel dataset for studying implicit abuse and presented a range of linguistic features for contrastive analysis of abusive content. We define explicitness as obvious rudeness and hateful language regardless of the social context and introduce a quantitative measure of explicitness from a trained classifier's point of view.

Data augmentation has been used to improve the robustness of abuse detection classifiers. To mitigate biases towards specific terms (e.g., identity terms), one strategy is to add benign examples containing the biased terms to the training data (Dixon et al., 2018; Badjatiya et al., 2019). Other works combined multiple datasets to achieve better generalizations, using a set of probing instances (Han and Tsvetkov, 2020), multi-task training (Waseem et al., 2018), and domain adaptation (Karan and Šnajder, 2018). In contrast to these works, we take an interpretability-based approach and guide the data collection process by mapping the new data on the implicit vs. explicit spectrum.

8 Conclusion

As real-world data evolves, we would like to be able to query a trained model to determine whether it generalizes to the new data, without the need for a large, annotated test set. We adopted the TCAV algorithm to quantify the sensitivity of text classifiers to human-chosen concepts, defined with a small set of examples. We used this technique to compare the generalizations of abusive language classifiers, trained with pre-pandemic data, to explicit and implicit COVID-related anti-Asian racism.

We then proposed a sensitivity-based data augmentation approach, to improve generalizability to emerging categories. We showed that in the case of abuse detection, the most informative examples are implicitly abusive utterances from the new category. Our approach collects implicit augmentation examples and achieves higher generalization to the new category compared to confidence-based sampling. Strategies for choosing the optimal set of concept examples should be explored in the future.

While we examined abusive language detection as a case study, similar techniques can be applied to different NLP applications. For example, the TCAV method could be used to measure the sensitivity of a sentiment analysis system to a new product, or a stance detection algorithm's sensitivity to an important new societal issue. As language evolves, methods of monitoring and explaining classifier behaviour over time will be essential.

Ethical Considerations

Content moderation is a critical application with potential of significant benefits, but also harms to human well-being. Therefore, ethics-related issues in content moderation have been actively studied in NLP and other disciplines (Vidgen et al., 2019; Wiegand et al., 2019; Kiritchenko et al., 2021; Vidgen and Derczynski, 2020). These include sampling and annotation biases in data collection, algorithmic bias amplification, user privacy, system safety and security, and human control of technology, among others. Our work aims to address the aspects of system safety and fairness by adapting the model to newly emerged or not previously covered types of online abuse, often directed against marginalized communities. We employ existing datasets (with all their limitations) and use them only for illustration purposes and preliminary evaluation of the proposed methodology. When deploying the technology care should be taken to adequately address other ethics-related issues.

A Model Specifications

All of our models are binary RoBERTa-based classifiers trained with the default settings of the Trainer module from the Huggingface library[9] for 3 training epochs, on a Tesla V100-SXM2 GPU machine, batch size of 16, warm-up steps of 500 and weight decay of 0.01. We use Roberta-base model, which includes 12 layers, 768 hidden nodes, 12 head nodes, 125M parameters, and add a linear layer with two nodes for binary classification. Training these classifiers takes several hours depending on the size of the training dataset.

B Additional Results for Cross-Dataset Generalization

In table B.1, we present additional metrics for the generalizability experiments described in Section 3. Besides the commonly used metrics, precision and recall, we measure averaged precision score to count for potential threshold adjustments. Averaged precision score summarizes a precision-recall curve as the weighted mean of precisions at each threshold, weighted by the increase in recall from the previous threshold. The results are consistent with AUC and F1-scores reported in Table 3.

Train Set	Precision		Recall		Ave. Prec.	
	EA	*CH*	*EA*	*CH*	*EA*	*CH*
EA	0.72	0.77	0.73	0.58	0.80	0.80
CH	0.58	-	0.66	-	0.64	-
Founta	0.46	0.57	0.23	0.73	0.35	0.65
Wiki	0.39	0.61	0.21	0.78	0.31	0.66
Wiki-exp	0.37	0.64	0.10	0.51	0.26	0.64

Table B.1: Additional metrics for cross-dataset generalization results presented in Table 3.

C DoE Analysis on the *EA* Train Set

With the DoE score, we want to distinguish between implicit and explicit examples of abuse. However, when used for data selection, the true labels of the selected examples are not available. We investigate what low DoE scores mean in terms of 'being challenging to classify'. With both *Founta* and *Wiki* classifiers, we calculate the DoE score for all instances of the *EA* train set, sort the negative and positive examples separately based on DoE and look at the classification accuracies in bins of size 100 of sorted DoEs. Figure C.1 shows that low DoE examples are correctly classified if negative and misclassified if positive (implicit abuse). In contrast, high DoE examples are misclassified if negative and correctly classified if positive (explicit abuse).

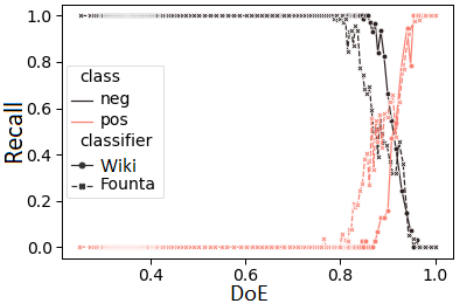

Figure C.1: Recall per class for varying DoE scores on the *EA* train set

D Comparing DoE and Confidence-Based Augmentation Using Precision and Recall

In Section 6, we compare the classifiers updated with DoE and confidence-based methods using classification F1-score. Here, we provide a more fine-grained analysis based on recall and precision.

Figure D.1 shows the recall and precision of the updated classifiers on the *EA* dataset. This figure indicates that the classifiers updated with DoE are much more successful in recognizing abusive utterances than the classifiers updated with confidence, but misclassify more non-abusive sentences, which results in substantially higher recall scores, but slightly lower precision scores. Note that in computer-assisted content moderation, recall is more important than precision, since automatically flagged posts are assessed by human moderators to make the final decision.

We argue that the higher recall and lower precision of classifiers updated with DoE is due to the discrepancies in the definitions of the negative classes for the *Wiki* and *EA* datasets. Previous work has commented on the difficulty of aligning annotations of *abusive*, *offensive*, *hateful*, and *toxic* speech across different datasets (Swamy et al., 2019; Kolhatkar et al., 2019; Fortuna et al., 2021). Here, we also observe that the definitions of positive (abusive) and negative classes differ significantly between the generalized and COVID-related data. In the *Wiki* and *Founta* datasets, the positive class encompasses a wide range of offensive language, while in the *EA* and *CH* datasets, the positive class

---

[9] `https://huggingface.co/transformers/main_classes/trainer.html`

is restricted to hate speech and other more intense cases of expressed negativity. Further, the negative class in *Wiki* and *Founta* datasets comprise non-abusive, neutral, or friendly instances while in the *EA* and *CH* datasets the negative class may also include rude and offensive texts as long as they do not constitute hate speech against Asian people or entities.

In Appendix C, we observe that low DoE examples are correctly classified if negative and misclassified if positive (implicit abuse). In contrast, high DoE examples are misclassified if negative and correctly classified if positive (explicit abuse). We use this observation to explain higher recall of the confidence-based method in comparison with the DoE-based method for the *EA-negative* class. As mentioned before, while *EA-positive* fits under the definition of 'toxicity' in *Wiki-positive*, the definition of *EA-negative* is inconsistent with the definition of *Wiki-negative*. In other words, DoE tends to choose negative examples that the *Wiki* classifier already recognizes as negative, whereas the confidence-based data augmentation selects negative examples that are unknown to the classifier. Therefore, the classifier augmented with low confidence scores adapts better to the new definition of negative examples than the classifier updated with low DoE scores. In a real-life scenario, we do not expect the definition of the negative class to change over time, so precision for DoE-base augmentation should not suffer.

Reports of personal experiences and stories in argumentation: datasets and analysis

Neele Falk and **Gabriella Lapesa**
Institute for Natural Language Processing, University of Stuttgart
`{neele.falk,gabriella.lapesa}@ims.uni-stuttgart.de`

Abstract

Reports of personal experiences or stories can play a crucial role in argumentation, as they represent an immediate and (often) relatable way to back up one's position with respect to a given topic. They are easy to understand and increase empathy: this makes them powerful in argumentation. The impact of personal reports and stories in argumentation has been studied in the Social Sciences, but it is still largely underexplored in NLP. Our work is the first step towards filling this gap: our goal is to develop robust classifiers to identify documents containing personal experiences and reports. The main challenge is the scarcity of annotated data: our solution is to leverage existing annotations to be able to scale-up the analysis. Our contribution is two-fold. First, we conduct a set of in-domain and cross-domain experiments involving three datasets (two from Argument Mining, one from the Social Sciences), modeling architectures, training setups and fine-tuning options tailored to the involved domains. We show that despite the differences among datasets and annotations, robust cross-domain classification is possible. Second, we employ linear regression for performance mining, identifying performance trends both for overall classification performance and individual classifier predictions.

1 Introduction

Although personal narratives and experiences naturally fill an important place in our everyday discussions, they still do not conform to the classic ideal of a "good" argument. A "good" argument contains facts and logical conclusions, but as soon as more personal or emotional nuances are involved, it deviates from the norm. According to the theory of Deliberative Democracy (Habermas, 1996; Fishkin, 1995), the discourse that precedes political decisions plays a central role. Here, too, until the so-called *affective turn* in Social Sciences (Hoggett and Thompson, 2012), the assumption was that an exchange of arguments that is as rational as possible can lead to better political decisions. Recent studies in Deliberative Theory, however, are increasingly concerned with the interplay between classical argumentation and *alternative forms of argumentation*, which include personal experiences, narratives and emotions, and their positive effects on discourse (Polletta and Lee, 2006; Esau, 2018; Gerber et al., 2018; Maia et al., 2020). A norm that only allows rational and logical argumentation firstly does not correspond to human realistic communication and secondly bears the danger that less educated groups or groups in which other communication standards prevail are marginalized. Arguments with personal experiences are therefore important to fulfill one of the core deliberative standards, namely inclusivity (Polletta and Gardner, 2018).

The following example is taken from a discussion about regulations to ban peanut products on airlines and illustrates further possible positive effects of arguments with personal experiences: *My daughter has been tested 4 times for her allergy to peanuts. She is in the highest category of reactivity which means if peanuts are being ingested in her vicinity, she could die. A buffer zone simply doesn't work in a confined space such as an airline.*[1] The perspective of the frightened parent and their allergy-affected daughter is likely to elicit emphatic reactions from the other participants in the discussion and illustrates the rationale of proponents of a peanut ban.

Our work represents the first step towards identifying these arguments at a large scale by developing models for automatic detection of contributions with personal experiences and stories (to which we refer with the general label of *reports* in the paper). This is the necessary first step to be able to further examine the role of such arguments in

May 22-27, 2022

reasoning and their relationship with Argument Quality (Wachsmuth et al., 2017a) and Discourse Quality (Steenbergen et al., 2003),

To tackle this task we collect available datasets and investigate the best strategy to merge the available sources. In two of the datasets we employ, produced by the Argument Mining community (Regulation Room and Change My View) our targeted phenomenon is annotated as *testimony*. In the third dataset, from the Social Science community (Europolis) it is annotated as *storytelling*. The two categories are obviously not fully overlapping, but we hypothesize that they share a conceptual core which can be leveraged for robust classification.

We perform a large set of in-domain, out-domain and cross-domain experiments including different domain-adaptation strategies for the pre-trained language models used in the classification. We analyze our results using performance mining and show that the cross-domain training setup leads to the most robust results and also has the most positive effect when used with a domain-adapted LM. We also conduct regression-based error analysis and compare the most salient features of the two largest datasets that get picked up by the most robust model and show that prototypical textual properties of reports can push the model in the right direction (probability of reports close to decision boundary) but can also lead to over-generalization (higher probability of reports for false positives).

2 Related work

Argument Mining & NLP The automatic detection of arguments with personal experiences was first tackled by Park and Cardie (2014) with the goal to classify claims as verifiable or unverifiable and to be able to detect what type of evidence would be necessary as a consequence. They defined the subcategory *verifiable experiential* for verifiable claims that contain personal experiences. Their dataset contains comments from Regulation-Room,[2] an e-rulemaking platform with the goal of enabling online deliberation: governmental institutions or companies can have their proposals about new regulations discussed by citizens to get feedback. Park and Cardie (2014) conducted classification experiments with a SVM using different feature sets hypothesizing that the amount of past tense and first personal pronouns would be most predictive for verifiable experientials. They achieved a F1-score of $\sim 70\%$ on the Regulation-Room dataset. This work was further extended in Park et al. (2015b) and reformulated as a sequence classification task. Park et al. (2015a) and Park and Cardie (2018) developed a new annotation scheme targeted at elementary units in arguments. This schema introduces **testimony** as an elementary unit which corresponds to a proposition about the author's personal state or experience. A similar evidence type, called *anecdote* and defined as a personal experience of the author or a narration of a concrete example or event was classified in news editorials (Al-Khatib et al., 2016, 2017). Song et al. (2016) build a database for claims and suitable anecdotes focusing on stories with a clear narrative structure and popular main characters (e.g. the Dalai Lama). Wang et al. (2019) model different persuasion strategies in dialogues targeting social good (e.g. fund raising): personal stories which exemplify positive outcomes and benefits of a donation are one of these strategies.

Social Sciences The role of personal narratives in digital and deliberative democracy has gained more attention in the recent years. Polletta and Lee (2006) were the first who investigated the role of personal narratives in online argumentation. Their data was further analyzed in Black (2008) and Black (2013), who emphasized the importance of personal narratives in discussions for forming group identity and understanding others' perspectives. The relationship between storytelling and emotions was investigated in Esau (2018) who pointed out that these are especially useful when discussing social problems that cannot be addressed with factual information alone. Maia et al. (2020) annotated the functions of storytelling (e.g. do people tell an experience as a disclosure of harm or to propose a solution?) and examined how the different types of narratives effect the quality of a discussion. As far as available annotation is concerned, we conduct our experiments on the Europolis corpus (Gerber et al., 2018). Europolis contains spoken contributions from a transnational poll, in which citizens from different European countries got together to discuss about the EU and the topic immigration. The spoken contribution have been annotated with different aspects of deliberative quality (e.g. does the speaker show respect or value other participants?), and one of these aspects includes alternative forms of communication. Relevant to our work is the annotation category

---

[2] `http://regulationroom.org/`

storytelling, marking those contributions which contain personal experiences or concrete examples of a speaker's own country.

3 Datasets

Regulation Room (*RegRoom)* Our experiments are based on the final version of the Cornell eRulemaking Corpus (CDCP) (Park and Cardie, 2018) It contains 725 comments from Regulation Room, discussing consumer debt collection practices in the United States. The comments are annotated with different proposition types, and our category of interest is *testimony*.

Change My View (*CMV*) contains 344 comments from the subreddit *ChangeMyView*[3] (Egawa et al., 2019) and is annotated with a similar schema as introduced in Park et al. (2015a). Our reference category is *testimony*.

Europolis (Gerber et al., 2018), already introduced in section 2, contains a total of 856 transcribed speech contributions whose original language was German, French, and Polish (only available in the English translation).[4] Europolis is annotated along many deliberative quality dimensions (Steenbergen et al., 2003), and our reference category is *storytelling*.

From now on, we will use the neutral term REPORT as our positive label, of which *testimony* and *storytelling* are dataset-specific declinations. Note that, while *storytelling* is annotated at the document level in Europolis, RegRoom and CMV contain span-level annotation of *testimony*: for our experiments, a document containing a *testimony* span is considered as a positive instance of REPORT. For all datasets, reports are the minority class (RegRoom: 41%; CMV: 37%, Europolis: 35%).

Table 1 displays one example per dataset. In the example of Europolis the participant describes the general situation in their country in a more objective manner, thus reflecting a quite broad definition of a personal narrative. The RegRoom example is very personal and emotional in its tone, displaying more prototypical features of a personal experience. The CMV example is somewhere in between: it departs from a personal experience but it targets a general situation, and has a more objective tone.

3.1 Preprocessing and Feature extraction

The datasets were preprocessed by removing time stamps and URLs. With freely available tools, we extracted a total of 51 features (henceforth, *contribution-level* features) from four categories:[5]

Surface features (6 features), e.g., length in tokens; average amount of characters and syllables per word. We hypothesize that longer comments are more likely to contain reports (verbose retelling of concrete stories / examples).

Syntactic features (6), e.g., relative amount of fine-grained part-of-speech tags per comment (e.g., personal pronouns, past tense, auxiliaries, named entities). Specific categories, e.g. first-person pronouns and past tense verbs ("I had an unpleasant experience..."), are likely to be predictive of reports.

Textual complexity (19), with different measures of lexical diversity, lexical sophistication and readability. While prototypical reports are expected to exhibit lower textual complexity (character repetitions, more concrete concepts), the modulation of complexity in the reports in our datasets is an open question.

Sentiment/Polarity (20), e.g. amount of positive or negative adjectives/nouns, amount of specific emotions (joy, fear). We hypothesize that comments with reports will have more marked polarity.

4 Experiments

Task We perform binary classification at the document level: forum posts in RegRoom and CMV, spoken contributions in Europolis. We create 10 random train / dev / test splits using 15 % as development and 20 % as test data and we ensure that every document is part of the test set at least once.

Setups We experiment with the following training/test setups:

In-domain: we train and test the models on the same dataset.

Out-domain: we train the models on a single dataset and test them on the other two individually (e.g. train on Europolis and test on CMV and RegRoom). We also concatenate two datasets and test the corresponding model on the missing one, e.g. train on a joined set of CMV and RegRoom and test on Europolis (*2vs1*).

---

[3] On CMV, users exchange views on a variety of different topics and can reward other comments if they are convincing or have led to a change of their opinion. Research on persuasion on CMV has targeted, for example, interaction dynamics and stylistic choices (Tan et al., 2016) or the effect of social pressure (Jain and Srivastava, 2021).

[4] We translated the German and French transcriptions into English using DeepL and used the professional English translation of the Polish data. Refer to A.1 for more details.

[5] For an overview of the features and mean values, as well as extraction details, refer to appendix A.2.1.

RegRoom (testimony)	I was never informed by Bank of America that they sold my credit card and closed the card. When I realized it, I paid it off immediately. During that quarter, after long illnesses, my Father and Mother both passed (within 31 days of each other) and frankly, credit card payments were not in the forefront of my thinking. ALSO, just because a bank or credit card company has been exempted from Usury laws does not mean they do not commit the violation! THAT needs to be stopped!
CMV (testimony)	I used to work at an aquatic center that had women's only hours once a week during which only female lifeguards would cover the pool. As it was explained to me, the primary purpose of these hours was to give Muslim and Orthodox women a place to swim without violating their religion. It was common for non-religious women to swim during these times because they felt more comfortable not having to swim in front of men. I don't know what the rationale is at your gym . I would argue that yes, the women's only hours there may be sexist , but they also allow women to partake in an activity that would otherwise be prohibited to them during normal hours
Europolis (storytelling)	In Slovenia, we have a lot of immigrants from the non-EU countries, especially in the health care sector, because we need specialists in Slovenia. Slovenians do not want to work in this sector so of course people from other countries are coming to work there.

Table 1: Examples of reports (testimony or storytelling) in the three datasets

Cross-domain: we create one training set which is the concatenation of the training sets for of the in-domain experiments and test it on the each dataset-specific test set (*all*).

Classification models We experiment with the following classification models (cf. section B.1 for more details and hyper-parameters):

- *Feature-based*: we train a random-forest classifier with the features mentioned above (51 in total, appendix section 3.1).
- *BoW*: each contribution is represented as a count vector with the frequency counts for the 5000 most frequent words (the vocabulary was constructed based on the fusion of all datasets) which is fed into a random-forest classifier.
- *FeedforwardNN*: a contribution is represented as the average of the embeddings the words occuring in it and fed into a feed-forward neural network with one hidden layer of size 300 and a `ReLU`.
- *BERT*: we fine-tune BERT (Devlin et al., 2019) with a classification head on the task of predicting whether a contribution contains a report or not.
- *Domain-adapted BERT (3 models)*: we fine-tune the underlying language model (LM) with the masked language modeling objective and next sentence prediction on domains that would match the domains of our target datasets. For the Europolis dataset we sample ∼1M sentences from Europarl (Koehn, 2005) [6], for CMV and RegRoom we sample ∼1M sentences from the Webis-CMV-20 corpus (Al-Khatib et al., 2020) and ∼1M sentences from the args.me corpus (Ajjour et al., 2019). We fine-tuned one LM on each domain (*BERT-adapt-europarl*, *BERT-adapt-argue*) and one on the concatenation of the two (*BERT-adapt-mixed*).

Results Table 11 in the Appendix displays the results for all models for each training setup (averaged over all splits), with significance values. The results show that BERT outperforms the other models for all training/test setups and training on the joined dataset (*all*) works well for all test corpora (the feature-based classifiers benefit especially from it). Fine-tuning the LM on the concatenated domains (*BERT-adapt-mixed*) yields the best results when trained on *all* with a macro F1-score of 0.76 (Europolis), 0.85 (CMV) and 0.94 (RegRoom). The non-domain-adapted BERT is more robust if in-domain and out-domain experiments are also taken into account, e.g. a drop in performance from 0.72 to 0.65 F1 can be observed on Europolis when trained in-domain using *Bert-adapt-europarl*. In the following section, we will employ linear regression to build a comprehensive picture of these performance trends.

5 Analysis

To get a statistically informed understanding of the different factors influencing the behavior of our models on the different datasets, we employ linear regression. Our dependent variables are **aggregated performance** (F1 macro) in section 5.1 and **model predictions** on individual items (probability of report) in section 5.2.

For the aggregated performance analysis in Section 5.1, our independent variables (IV) are: the different experimental configurations i.e., combinations of classifier architectures (referred to as

---

[6] We used the EN monolingual and the English translation from the DE-EN and FR-EN parallel data.

"model" in the tables), training setup and test corpus as well as their interactions, as specified in the formula:[7]

```
F1macro ∼ (model +
training setup + test corpus)^3
```

For the model predictions (section 5.2) our independent variables are: the contribution-level features in 3.1 and a subset of the experimental configurations (training setup and test corpus), as well as the interactions between the contribution-level features and the experimental configurations.

In both cases, our analysis proceeds in three steps. First, we fit incrementally complex models and assess their fit in terms of adjusted R^2 (proportion of explained variance) and significance with respect to the less complex models (i.e., models with fewer independent variables). At this step, we also check for multicollinearities. Next, once we identify the most explanatory regression model (i.e., the set of independent variables that maximizes the fit to the dependent variables), we proceed to identify its most explanatory IVs in terms of explained variance and significance (e.g., does the choice of training setup determine a strong difference in the performance of our classifiers?). Last, we identify the best values for the IVs (e.g., which of the training setups guarantees best F1?) by visualizing predicted performance with the help of effect displays (Fox, 2003), which show the partial effect of one (or more) parameters by marginalizing over all other parameters.

5.1 Aggregated Performance

With the regression analysis presented in this section, we are interested in capturing the pattern of variation exhibited by our experimental configurations, with a focus on the effects of in-domain, out-domain and cross-domain training and domain adaptation.

Data: we consider all experimental runs from the in-domain, 2vs1 out-domain, and cross-domain training setups, resulting in 630 data points.[8] We code the levels of the IV `training setup` as *in-domain* (trained/tested on the same corpus), *2vs1* (out-domain training) and *all* (cross-domain training).

IV	**adjusted R^2**	**sign.**
test corpus	11.6 %	
+ training setup	23.6 %	***
+ model	44.1 %	***
+ all two-way interactions	65.3 %	***
+ all three-way interactions	77.2%	***

Table 2: Adjusted R^2 for each regression model predicting the F1 macro with step-wise addition of IVs. Significance adding more predictors is tested using the `anova` function from R.

Results: Table 2 reports the fit of the simplest model, which only contains `test corpus` as IV, and of the incrementally more complex models. All IVs and interactions between explain a significant additional amount of variance[9]. The most explanatory model contains the three IVs and their two-way and three-way interactions, for a total explained variance of $R^2 = 77.2\%$.

Table 12 in the appendix displays the portion of variance accounted for by each IV in the final regression model. Most variance in performance (20% of the R^2) is determined by the classifier architecture (IV: `model`).The high amount of additional variance explained by the three-way interaction, however, (12%) indicates that the effects of the training setup and test corpus differ significantly between classifier architectures.

What is the effect of training setup and domain-adaption? To get a more detailed picture of the relationship between experimental configurations, classifier architectures, and the predicted performance we can have a look at figure 1 which displays the effect plot for corresponding the three-way interaction.

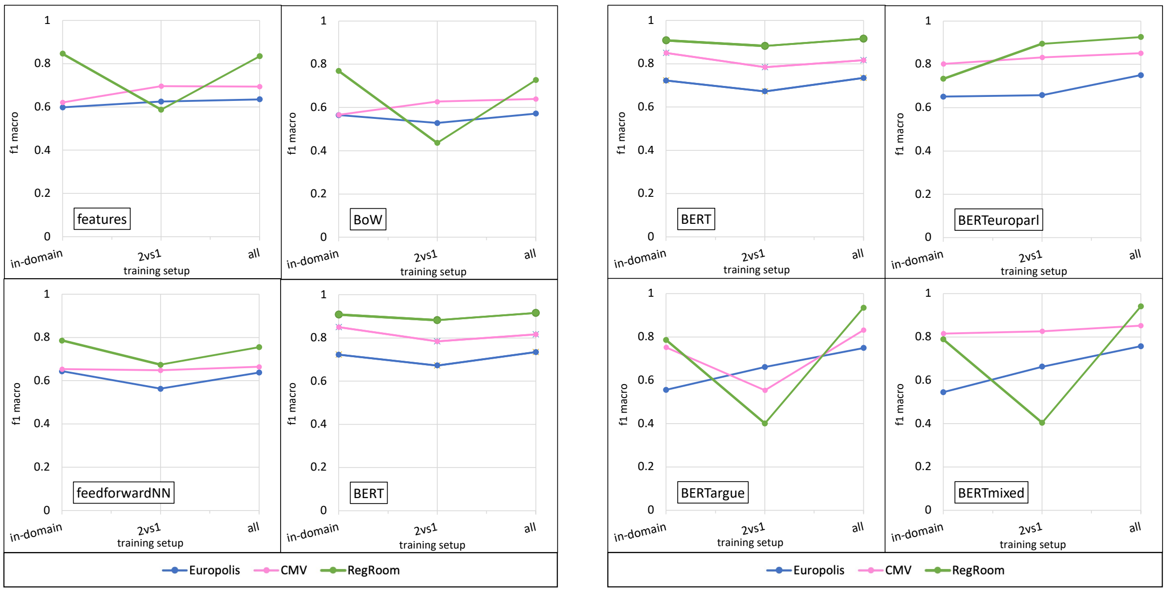
Comparing the different training setups, it becomes evident that cross-domain training setup is most robust: the difference between the predicted performance for all test corpora when trained on mixed domains (`training setup` = *all*), i.e. the difference between the colored lines at the rightmost position of the y-axis, is similar for the different classifier architectures (across all panels), while in-domain or out-domain training can lead to very different performance predictions. One can for example observe a low predicted performance when using features or BoW as classifier architecture for RegRoom in an out-domain setting (drop in the green line in the two upper panels in figure 1a). Out-domain training is rarely beneficial if no

---

[7] The formula follows the R syntax, ^3 denotes the 3-way interactions among the terms included between parenthesis, as well as their lower-order terms.

[8] This number of data points results from the multiplication of: the number of classifiers (7), test corpora (3), training setups (3), splits (10). We conducted a sanity-check analysis with split id as IV, finding no significant effect.

[9] $p \leq 0.05$ '*' $p \leq 0.01$ '**' $p \leq 0.001$ '***'



(a) Non-domain-adapted classifier architectures

(b) BERT + its domain-adapted variants

Figure 1: Effect plot, 3-way interaction: predicted performance (x-axis), training setup (y-axis), classifier architectures (each panel), test corpus (colored lines).

domain adaptation is performed, small positive effects can only be obtained for CMV and Europolis with the feature-based classifier (increase in the pink and blue line in the upper left panel in figure 1a). The largest positive effects for cross-domain training in contrast to in-domain training can be observed for Europolis (increase in the blue line from *in-domain* to *all* across most panels).

Figure 1b compares the performance of the non-adapted BERT model (top-left panel) to its three domain-adapted variants. This comparison helps us further characterize the domain-specificity of the annotations. First of all, we can observe that BERT is more robust across different training setups and test-corpora. If we look at the course of the lines in the upper left panel in figure 1b we can see that it is relatively stable, almost parallel: the panel shows only a small drop in predicted performance for out-domain training and a small improvement with cross-domain training for RegRoom and Europolis. In contrast, the domain-adapted variants are subject to a much higher variance (e.g., a strong drop in predicted performance for BERTargue and BERTmixed, trained out-domain, tested on RegRoom).

Domain-adaptation can be useful in a cross-domain training setup, as we can see slight improvements for the predicted performance comparing the colored lines at the right-most position of the y-axis of the upper left panel with the others, and this observation is similar for all domain-adapted variants.

When comparing the different domain-adapted variants, the best model is BERTeuroparl which works well for all test corpora for out-domain and cross-domain training, whereas BERTargue leads to a low predicted performance when used with Europolis or in an out-domain training setup. This indicates that the LM adapted to a deliberative context (since Europarl contains parliamentary debates) is compatible with all test corpora, whereas BERTargue may be too domain-specific.

5.2 Item-based predictions: error analysis

In this section, we employ regression for error analysis, with the goal of finding out which linguistic properties of a contribution drive the model prediction away or towards the gold label. In this analysis, we focus on the predictions of the most robust classifier if both in-domain and out/cross-domain are taken into account, namely the non-adapted BERT (see section 5.1).

We extract two subsets predictions from the `BERT` and perform regression analysis on each of them. We examine the predictions for the false positives (FPs) in order to find out in which cases the model overgeneralizes (which properties cause the model to predict a high probability for reports?), but also to find out what puts the model on the right track (probability close to the decision boundary). Similarly, we can examine the predictions for FNs, where typical features for reports may ensure that the model's probabilities go in the right direction, while particularly atypical features or a disadvantageous training/test combination may cause the model to incorrectly predict lower probabilities.

Dependent variable In this analysis, our dependent variable is the **probability that a comment contains a report**. The distribution of the probabilities, however, is heavily skewed towards the upper and lower bound. We therefore transform the individual probabilities with a log transformation to reduce the skewness. In order to gain the same advantage for both error types and to be able to better compare the two in the effect plots, we invert the probabilities of the FPs and map them to the same range as the false negatives ($1 - p(reports)$). For both error types, the resulting values range between -10 and -0.5 and in both cases the predicted classification label would change to the gold label when the probability exceeds the upper threshold.[10] The distribution of the dependent variables is displayed in the histograms in section D.1. Thanks to this transformation, a positive effect or an increase in the dependent variable can be interpreted as beneficial for both error types.

Independent variables and model selection In our analysis, we focus on the difference between the two largest datasets and include *Europolis* and *RegRoom* as `test corpus`, excluding *CMV*. Qualitatively, Europolis and RegRoom share the deliberative focus, while CMV is persuasion-driven and more likely to exhibit idiosyncratic properties that we would not be able to sufficiently discuss here for reasons of space. The `training setup` variable contains *RegRoom*, *Europolis*, and *all* so that we can examine the effects of in-domain, out-domain (this time in a 1vs1 version), and a cross-domain training setup. The final subsets for this analysis contain 776 datapoints for the FPs and 1,212 data points for the FNs.

Our analysis builds on the assumption that specific linguistic properties of the input drive the predictions towards or away from the gold label. For this reason, the first core of IVs is represented by the contribution-level features used to train the feature-based random forest classifier (cf. section 3.1). To avoid multicollinearities and for simplification purposes we applied a correlation-based feature reduction methodology whose criteria are described in section D.2 in the Appendix. All features were further centered and scaled.

IV	**false positives**		**false negatives**	
	adjusted R^2	**sign.**	**adjusted R^2**	**sign**
features	5.2 %		18.9 %	
+ test corpus	5.1%	-	23.2 %	***
+ training setup	5.3%	-	31.0 %	***
+ two-way interactions	8.7%	***	36.0 %	***
+ three-way interactions	9.7%	-	40.0 %	***

Table 3: Adjusted R^2 and significance for each regression model (FPs, FNs) predicting the probability of reports with step-wise addition of IV. Significance between the richer model and its nested counterpart is tested using anova.

We incrementally added the experimental configuration features (`training setup` and `test corpus`), as well as two- and three-way interactions, on top of the contribution-level ones. Similar to section 5.1 we compare nested models starting from the one containing only contribution-level features as IVs, effectively assessing whether the variation in performance is only due to linguistic properties or whether certain linguistic properties affect specific experimental configurations.

Results: The results for both subsets (FPs and FNs) are shown in table 3. It is noticeable that the most explanatory regression model for the FNs can explain significantly more variance (40%) than the one for the FPs (10%); reasons for this could be the smaller amount of data and the poorer distribution of the dependent variable. In both cases, the contribution-level features alone explain roughly half of the variance accounted for by the most complex models. For the FPs, `training setup` and `test corpus` significantly contribute to the fit only when the two-way interactions are taken into account. On the other hand, for the FNs, all incremental steps significantly improve the fit.[11]

Which feature types have the greatest impact on the errors? Table 4 summarizes the relative contribution of different feature groups to the total amount of explained variance.[12] The surface

---

[10] We trained the regression models without a log transformation. This led to significantly worse results for the FNs, no large difference for the FPs. We therefore report the models with the log transformation.

[11] To identify the most explanatory regression models (set of IVs) for FPs and FNs we employed step-wise model selection. A detailed discussion of this process, along with the list of selected IVs and their explained variance and significance can be found in appendix section D.2, in tables 13 and 14.

[12] The sum of the explained variance (R^2) of a feature group is the sum of the R^2 of the individual features in that group plus their interactions with `training setup` and/or `test corpus`.) The feature type "experimental configurations" contains only the amount explained by `training setup`,

group of IV	false positives	false negatives
experimental configurations	23 %	27 %
surface features	0 %	3 %
syntactic features	27 %	32 %
sentiment/polarity	23 %	21 %
textual complexity	27 %	17 %

Table 4: Effect sizes (relative amount of R^2) for different groups of IVs in the most explanatory regression models for the FPs and FNs.

based features have an extremely low impact on the prediction of the probability of reports: this is surprising given that previous work has shown that the length of a contribution has a great impact on model predictions (*length bias*, cf. Wachsmuth and Werner (2020)). The other feature groups are all involved relatively equally in explaining performance variance, with textual complexity and syntactic features dominating FPs, and syntactic features FNs.

What is the impact of contribution-level features? If we look at the effect plots for the most explanatory IVs, we can see which features are particularly helpful for the errors: positive effects drive the model towards the gold label. The effects for FNs highlight the dominant role of syntactic features. For example, we see positive effects for past tense verbs, personal pronouns, and post length (cf. figure 5, section D.2 in the appendix) which also confirm the hypotheses that these features are prototypical for reports. Some features are more discriminative when training on specific data: for example, the effect for personal pronouns is positive when training on RegRoom but slightly negative when training on Europolis (cf. figure 6, section D.2 in the appendix).

While some of the features can lead to overgeneralization of the model we can identify a feature of textual complexity that proves to be useful for FPs. The effect plot in figure 7 (section D.2 in the appendix) displays the interaction between mean average type token ratio (*mattr50*) and `training setup`. This feature puts the model on the right track when trained on RegRoom but moves the probability further away from the decision boundary when trained on Europolis or a mix. This example once again emphasizes that RegRoom, in combination with specific features, can take on an advantageous role as a training corpus.

Storytelling vs. testimony: discussion The reports of personal experiences in RegRoom resemble prototypical narratives; they contain very personal and individual experiences, exhibiting many of the expected characteristics of a typical report. Our regression-informed error analysis shows that training on RegRoom positively impacts performance, while the opposite is often true for Europolis. Indeed, the reports in Europolis can describe more general experiences or a concrete situation in a country (e.g. in the example from Europolis, table 1). As a result, they are less prototypical and difficult to detect based on structural and linguistic features. Ideally, through training on Europolis or on mix, it is possible to recognize reports that are not only about an individual experience, but about a collective one, an aspect that is especially important in a discussion with a deliberative focus. An initial empirical investigation of the argument quality of the different types of reports gives evidence that reports exhibit a higher quality than contributions without reports (see section E in the appendix a detailed description of a pilot case-study). An interesting research question in this context is to what extent the individuality of a report influences quality or to what the commonality of the reported experience positively impacts deliberation.

6 Conclusion

This work targeted the automatic identification of personal experiences and stories in argumentation. Leveraging available annotation in three argumentative datasets (two, Regulation Room and Change My View, from the Argument Mining community; one, Europolis, from the Deliberative Theory community), we evaluated different classifier architectures and training setups. Mixing training data from different domains leads to robust results across all corpora and models and boosts the performance of the classifiers based on the domain-adapted LMs.[13]

Our experiments established an empirical foundation that will allow us to investigate the target phenomenon at a larger scale and will lead to a better understanding of the compatibility of the underlying annotations (storytelling from Deliberative Theory and testimony in Argument Mining) as well as of the impact of storytelling/testimony on the quality of an argument.

`test corpus`, and their interaction.

Acknowledgments

The research reported in this paper has been funded by Bundesministerium für Bildung und Forschung (BMBF) through the project E-DELIB (Powering up e-deliberation: towards AI-supported moderation). We thank the anonymous reviewers for their valuable feedback. We would also like to thank Eva Maria Vecchi, Enrica Troiano, Sebastian Padó, and Jonas Kuhn for their feedback on different versions of this work. We also thank Marlène Gerber for giving us access to the Europolis dataset.

Ethics statement

Two of the three datasets employed in this work, *Regulation Room* and `Change My View`, are publicly available along with the annotation used in our experiments. *Europolis* has been kindly provided to us and the splits will be relased at the terms and conditions of its owners.

Our experiments and analysis do not employ any author-specific feature. We cannot exclude, however, that the reporting of very specific personal experiences may facilitate the identification of the author of a post.

As far as the societal impact of the use of reports of personal experiences and stories is concerned, we are fully aware that they can be a two-edged sword. On the one hand, as pointed out in the paper, the use of personal experiences triggers empathy and promotes inclusivity. On the other hand, however, the non verifiable nature of such reports makes them an easy vehicle to generate and spread fake news, and this, coupled with the emotional loading reports tend to have, makes them a useful tool highlight certain episodes for propagandistic purposes. Robust computational models to identify human-generated reports of personal experiences and a deeper understanding of the linguistic features of these contributions can also serve as a first step into the identification of false stories generated by automatic systems and of those human-generated ones that are best candidates to serve manipulation purposes.

A Preprocessing

A.1 The Europolis dataset and its automatic translation

The discussions collected in the Europolis dataset were held in 2009 in order to investigate whether and how deliberation can take place in a multilingual/transnational setting, and what effects deliberation can have for citizens (e.g. increasing political engagement or interest). Participants from 27 countries participated to simultaneously translated small-groups discussions about the topics of climate change and immigration. A sample of the discussions of 13 groups, whose original language was French, German, and Polish, has been annotated by Gerber et al. (2018) on different dimensions of the Discourse Quality Index (DQI) by Steenbergen et al. (2003).

The dataset contains the professional translation of the Polish speeches into English, as well as the transcription of the speeches French and German, which we translated into English with DeepL (`https://www.deepl.com/translator`). The quality of the English translation of the French and German texts has been checked by one native speaker each. Native speakers were instructed to check for the semantic integrity of the conveyed message and the grammaticality of the output.

We acknowledge that this quality check does not rule out the possibility that the automatic translation has distorted the linguistic features we employ for the feature-based classifiers and in the regression analysis. We do believe, however, that the pattern of results in table 11 is still relatively stable despite the potential distortion. More specifically, the F1 macro of the feature-based classifier trained and tested on Europolis is more than acceptable: had the translation affected the features dramatically, the performance would have dropped much more with respect to the feature-based representations trained/tested on in-domain native English models (F1 macro: Europolis=0.60; CMV=0.62; RegRoom=0.85). Moreover, had the features been distorted inconsistently, the generalization learnt from the out-domain (2vs1) feature-based classifier tested on Europolis and trained on CMV+RegRoom would have exhibited a drop in performance, not a gain (test: Europolis, 2vs1 = 0.63; test: Europolis, in domain = 0.60).

As regards the fact that translated features are also employed in the regression analysis at the item level, we believe that the validity of this analysis is not affected, because the translated text was the input of the BERT classifiers which in turn produced the probability values we analyse with the features extracted from that text.

A.2 Features

This section provides the details regarding the features briefly introduced in section 3.1 and employed in the experiments. Tables 5, 6, 7, 8 and 9 list all features names grouped by type, along with a short description and information on the values. For each feature, table 10 displays the mean value per corpus, separately for documents with a positive (report) vs. negative label (no report).

A.2.1 Extraction details

Syntactic features (Table 5)

- Quantify the relative amount of a certain part-of-speech tag (e.g., adverbs, adjectives, named entities) in a document.

These features have been computed using `spacy` (`https://spacy.io`) for tagging, with a model trained on English blogs, news and online comments (en_core_web_md).

Surface features (Table 6)

- Measure the length of the sentences / words, the number of complex words and a combination of these information in the form of readability metrics (flesch reading ease and gunning fog index)

The two readability metrics (*Flesch Reading Ease* (Flesch, 1948) and *Gunning Fog Index*) have been computed with the python package `readability` [14].

Lexical diversity (Table 7)

- These metrics are different variants of the type/token ratio, designed to be less sensitive to text length.

These features has been extracted with `TAALED` [15]. For more details refer to Kyle et al. (2021).

---

[14] `https://github.com/andreasvc/readability/`

[15] `https://www.linguisticanalysistools.org/taaled.html`

feature name	value
adverbs	relative amount of adverbs in a contribution
auxiliary	relative amount of auxiliary verbs in a contribution
named_entities	relative amount of named entities in a contribution
past_tense	relative amount of past tense verbs in a contribution
personal_pronouns	relative amount of first personal pronouns in a contribution
subordinate_conj	relative amount of subordinate conjunctions in a contribution

Table 5: Syntactic features: overview. Total number: 6.

feature name	description	value
postlength	the number of words of a comment	raw frequency
chars_per_word	number of characters per word	mean of all scores
syllables_per_word	number of syllables per word	mean of all scores
long_words	number of words with more than 7 characters	mean of all scores
flesch	flesch score based on average length of a sentence and average number of syllables per word	mean of all scores
gunning fog	weighted average of the number of words per sentence and number of long words (words with more than three syllables)	mean of all scores

Table 6: Surface features: overview. Total number: 6.

Lexical sophistication (Table 8) The metrics of lexical sophistication are computed based on word / co-occurrence information taken from existing reference corpora and word lists, e.g. the Corpus of Contemporary American English (COCA) or the (Averil Coxhead's) High-Incidence Academic Word List (AWL).

- *Word Frequency*: given a text, its word frequency value is calculated as the average of the frequencies of the words occurring in it, based on frequency estimates from different reference corpora (see above).
- *Range indices*: given a text, its range indices are calculated as the average of document frequencies of the words occurring in it, estimated on reference corpora.
- *Mutual information*: uses the mutual information scores of academic bigrams, computed based on reference corpora.
- *Academic list indices* relative amount of academic words and n-grams using word lists as reference.
- *(Psycholinguistic) Word Information*: average of different psycholinguistic scores (e.g. concreteness, familiarity, imageability).
- *Semantic network*s: measures indicate how word forms are semantically related. More sophisticated texts contain words with fewer senses and words with more hypernyms (more subordinate terms).
- *Contextual distinctiveness* measures the diversity of contexts in which a word is encountered, e.g. "love" occurs in many different contexts, while the number of contexts where the word "bride" occurs is more restricted.

This set of features has been extracted with `TAALES` [16], see Kyle et al. (2018) for details.

Sentiment features (Table 9) The sentiment features rely on a number of pre-existing sentiment, social-positioning and cognition dictionaries (e.g. EmoLex) which serve as a look-up table.

- The features correspond to macro-feature component scores produced by PCA

To extract the sentiment features, we use `SEANCE` [17]. The metrics and the retrieval of the feature components are described in Crossley et al. (2017).

Table 11: Precision, recall and F1 score for the positive class (reports) and F1 macro across training / test setups.∗ denotes statistical significance between the domain-adapted `BERT` and the non-adapted `BERT` model.‡ denotes statistical significance between `BERT` trained in-domain vs. *all*

.

B Classification experiments

B.1 Classifiers

In what follows, we provide the implementation details for the classification models employed in our experiments.

- Random forest classifier: we use sklearn `https://scikit-learn.org` with the `n_estimators` parameter set to 1000. The other parameters are set to the default.

- Feed-forward neural network: we use pretrained word embeddings with subwords ($d = 300$), provided by finalfusion (`https://finalfusion.github.io/pretrained`), pretrained with skipgram (Mikolov et al., 2013). The English word embeddings were trained on the CoNLL 2017 corpus.

- BERT: we use `BERTForSequenceClassification` from the huggingface library `https://huggingface.co/docs/transformers/model_doc/bert`. We use the sequence of the first 512 tokens and train for a maximum of 20 epochs. We pick the model that achieves the best macro F1 score on the validation set. Parameters: batchsize = 16, lr=2e-5, optim=Adam, model=bert-base-uncased.

B.2 Results

Table 11 reports the full set of experimental results for the automatic recognition of contributions containing reports. We report the precision, recall and F1 score for the positive class (report) and the F1 macro score. Each column shows the results for one test corpus: Europolis, CMV and RegRoom. The scores represent the average of the 10 scores obtained for each test split. We therefore also report the standard deviation.

C Analysis

C.1 Aggregated performance analysis

Table 12 provides the details of the fit of the regression model predicting aggregated performance (F1 macro): relative importance of each IV (measured by the relative amount of explained R^2), the GVIF, and significance.

IV	**f1 macro**		
	expl.var	**GVIF**	**sign.**
model	20.9	3.0	***
test corpus	11.9	4.6	***
training setup	12.2	4.6	***
training setup : test corpus	8.8	4.3	***
test corpus: model	5.0	2.6	***
training setup : model	8.6	2.6	***
test corpus : training setup : model	12.1	2.0	***

Table 12: Effect sizes (relative amount of R^2), significance and GVIF for the most explanatory regression model with `training setup` = *in-domain*, *2vs1*, *all*.

D Item-based performance analysis

The following tables and paragraphs contain more details about the regression analysis to predict model performance at the item-level (probability of report).

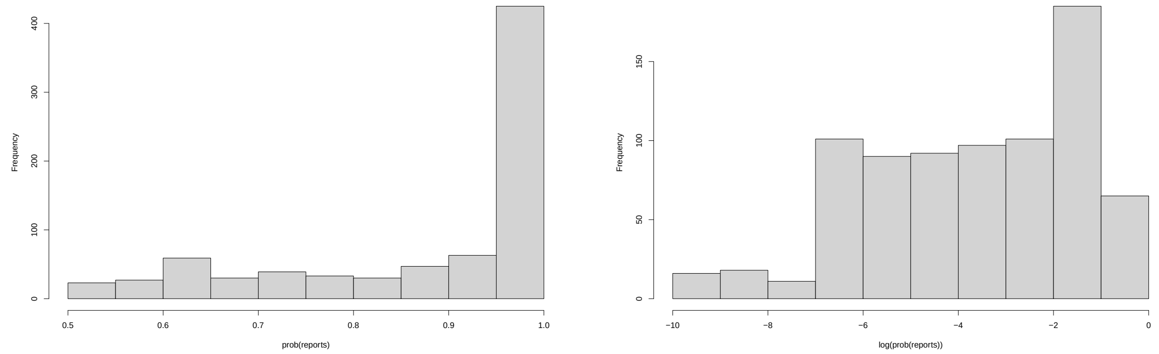
D.1 Dependent Variable

Table 2 and 3 display the distribution of predicted probabilities by the best classification model (BERT) for each error type before and after transformation.

D.2 Feature Reduction and Model Selection

While tackling a regression analysis task with very many IVs as it is in our case, there is not just one strategy for model selection (i.e., which IVs and interactions to include in the regression model). Given the large pool of (potentially correlated) 51 contribution-level features which we wanted to combine with the experimental configuration features (`training setup` and `test corpus`), and being interested in potential interactions as well, we decided to pre-select the contribution-level features based on their correlation.

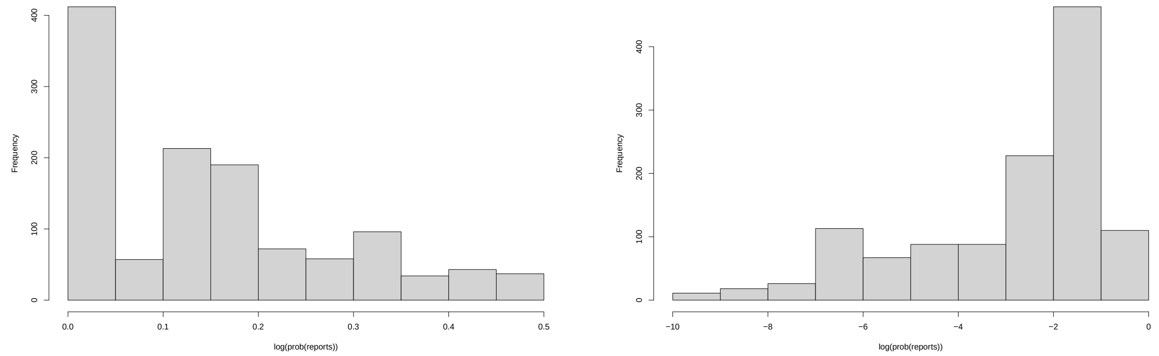
The first step in our selection of contribution-level features is a correlation analysis conducted on the full dataframe (false-positives and false negatives). We clustered the 51 features based on their pairwise Spearman correlation. The output of the clustering is displayed in the dendrogram in figure 4). Based on the assumption that correlated features are likely to distort the performance of the regression model, we established a conservative threshold of Spearman ≥ 0.2 and, for each subcluster with a correlation higher than this threshold, we manually selected only one feature and discared the others. The manual selection was based on qualitative consideration (e.g., the more general feature, or the more interpretable). For example, for the subcluster that contains the *MRC imageability* score



(a) Probabilities without transformation.

(b) Probabilities with transformation ($log(1 - prob(reports))$).

Figure 2: Histogram of the probability of reports for the **false positives**, with and without transformation.



(a) Probabilities without transformation.

Table 13: Terms of the final regression model for the **false positives**, with degrees of freedom, variance inflation factor, statistical significance and explained variance.

and the *Brysbeart concreteness* we keep the *Brysbeart concreteness* score because concreteness is a more general notion. Concreteness quantifies the extent to which the word's referent can be perceived and imageability, the extent to which the word's referent can be perceived visually.

The output of correlation-based qualitative feature selection is a set of 37 features. The features we discarded features are: flesch, gunning Fog Index, long words, characters per word, syllables per word, fear and disgust component, joy component, COCA spoken range norms, Sem_D, COCA spoken bigram mutual information, MRC Imageability, hdd42_aw and LD_Mean_Accuracy.

At this point the analysis proceeds per subset (FPs vs. FNs). We first run a regression model with the 37 contribution-level features on the FP and FN subset, respectively, without interactions. Next, we perform step-wise model selection on the regression model [18]. Unsurprisingly, we find no collinearities. The output of the stepAIC selection are two feature-based regression models, one for the FPs and one for the FNs. The feature-based regression models contain 11 contribution-level features for FPs and 20 contribution-level features for FNs respectively.

The next step in our analysis is to incrementally add the experimental configuration features, `training setup` (3 levels: *Europolis, RegRoom, all*) and `test corpus` (2 levels: *Europolis, RegRoom*). First, we add them IVs first on top of the contribution level features. Then, we add the following two-way interactions: those between contribution-level features and experimental configuration features (training setup and test corpus) as well as the two-way interaction between training setup and test corpus. We simplify the final models again using stepAIC and checked for multicollinearities. At each step, we test the significance between a richer model and its nested counterpart using the ANOVA function from R. (e.g., the model with contribution-level features in nested in the model with contribution-level + experimental configuration features).

As the output of this further process of selection of the IVs, we have two final regression models, one for the FPs and one for the FNs, which unsurprisingly differ in terms of the selected predictors and explained variance. In the next section we provide the details for the fit of the models. Tables 13 and 14 provide the details of the fit of the selected model regression model for FPs and FNs, respectively. For each selected IV (or interaction), the tables display: degrees of freedom, GVIF variance inflation factor, significance, as well as explained variance in $R2$.

Effect plots Figures 7 to 5 display the effect plots referred to in the discussion in section 5.2.

---

[18] We used the stepAIC function by the *MASS* package in R with standard settings

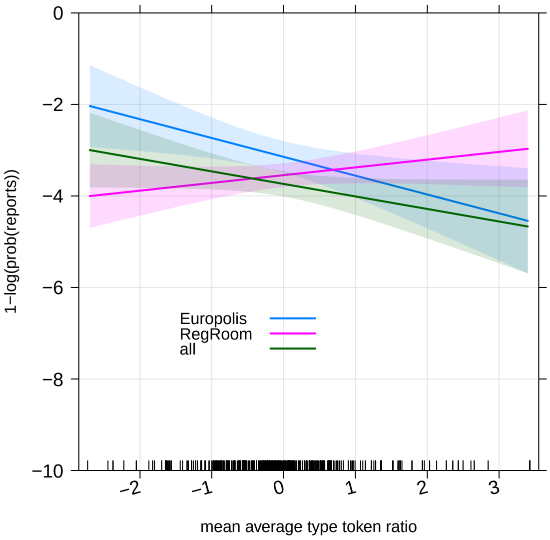

Figure 7: Effect of the interaction between mean average type token ratio (`mattr50`) and `training setup`, **false positives**. A positive effect (increase in a line) indicates that the feature pushes the model in the right direction.

E Case-study: Reports and Argument Quality

To investigate the impact of reports on the quality of a contribution, we conducted a pilot study on available Argument Quality datasets.

The first Argument Quality dataset we employed is the Dagstuhl-15512-ArgQuality corpus (Wachsmuth et al., 2017c): it is small but contains quality annotations for a very fine-grained taxonomy of argument quality dimensions (Wachsmuth et al., 2017b). We employed the best classifier from our experiments to predict whether a comment contained or not a report and found 59 comments containing report (out of a total of 320). We use t-tests to carry out a pairwise comparison of the means of the quality scores for each argument quality dimension (arguments with reports vs. argument without reports) and found the values of the documents containing reports scoring significantly higher in appropriateness, emotional appeal and sufficiency than the ones not containing reports (table 15). In particular, the higher score for emotional appeal is in line with the expectation that contributions with reports are more effective on the affective dimensions of argument quality.

Next, we conducted the same analysis on the grammarly Argument Quality corpus (GAQ) (Ng et al., 2020) which contains 3,373 comments from online fora with gold annotations for each of the 3 core dimensions of the taxonomy of (Wachsmuth et al., 2017b) (cogency, effectiveness, reasonableness) and overall quality. Our classifier detected reports in 1,288 comments. We conducted the same type of analysis as above, and found comments containing reports scoring significantly higher than the non-reports ones in all dimensions (table 16).

Last, we used a state-of-the art multi-task regression classifier (Lauscher et al., 2020) (trained on the GAQ corpus) to automatically predict argument quality scores for our three datasets. The performance of this classifier on RegulationRoom has already been validated in a manual annotation study by (Falk et al., 2021). For each dataset, we compared the means of contributions with and without reports (based on the gold standard for each corpus). While we found no significant difference in CMV or RegRoom, we did find that for Europolis (Table 17) contributions containing reports have significantly higher means for all dimensions of Argument Quality. This is in line with the findings by (Gerber et al., 2018) who state that people who score high on the deliberative quality dimensions also use reports to back up their claim.

Quality dimension	t-value	p-value
appropriateness	2.04	≤ 0.05
emotional appeal	2.29	≤ 0.05
sufficiency	2.02	≤ 0.05

Table 15: T-tests for the comparison of quality dimensions: arguments with reports vs. arguments without reports. Corpus: Dagstuhl-15512-ArgQuality. Argument with reports have significantly higher appropriateness, emotional appeal, and sufficiency

Quality dimension	t-value	p-value
cogency	5.00	≤ 0.001
effectiveness	5.91	≤ 0.001
reasonableness	5.60	≤ 0.001
overall	5.84	≤ 0.001

Table 16: T-tests for the comparison of argument quality dimensions: arguments with reports vs. arguments without reports. Corpus: GAQ corpus. Argument with reports have significantly higher cogency, effectiveness, reasonableness, and overall quality.

Quality dimension	t-value	p-value
cogency	3.17	≤ 0.05
effectiveness	3.25	≤ 0.05
reasonableness	3.19	≤ 0.05
overall	3.27	≤ 0.05

Abstract

In recent years, neural models have often outperformed rule-based and classic Machine Learning approaches in NLG. These classic approaches are now often disregarded, for example when new neural models are evaluated. We argue that they should not be overlooked, since for some tasks, well-designed non-neural approaches achieve better performance than neural ones. In this paper, the task of generating referring expressions in linguistic context is used as an example. We examined two very different English datasets (WEBNLG and WSJ), and evaluated each algorithm using both automatic and human evaluations. Overall, the results of these evaluations suggest that rule-based systems with simple rule sets achieve on-par or better performance on both datasets compared to state-of-the-art neural REG systems. In the case of the more realistic dataset, WSJ, a machine learning-based system with well-designed linguistic features performed best. We hope that our work can encourage researchers to consider non-neural models in future.

1 Introduction

Natural Language Generation (NLG) is concerned with the generation of natural language text from non-linguistic input (Gatt and Krahmer, 2018). One step in a classic generation pipeline (Reiter and Dale, 2000) is Referring Expression Generation (REG, Krahmer and van Deemter (2019) for an overview). REG has important practical value for commercial natural language generation (Reiter, 2017), computer vision (Mao et al., 2016), and robotics (Fang et al., 2015), for example. It has also been used as a tool to understand human language use (van Deemter, 2016). REG contains two different problems. One is to find a set of attributes to single out a referent from a set (also called *one-shot REG*). The other is to generate referring expressions (REs) to refer to a referent at different points in a discourse (Belz and Varges, 2007). We will focus on the latter task. We call this the *REG-in-context* task.

In earlier works, REG is often tackled in two steps (Henschel et al., 2000; Krahmer and Theune, 2002). The first step decides the form of an RE. For example, whether a reference should be a proper name ("*Marie Skłodowska-Curie*"), a description ("*the physicist*"), or a pronoun ("*she*") at a given point in the context. The second step is concerned with content selection, i.e., the different ways in which a referential form can be realised. For example, to generate a description of *Marie Curie*, the REG system decides whether it is sufficient to mention her profession (i.e., "*the physicist*") or whether it is better to mention her nationality as well (i.e., "*a Polish-French physicist*").

Thanks to the rapid development of deep learning techniques, recent NLG models are able to generate RE in an End2End (E2E) manner, i.e., to tackle the selection of form and content simultaneously (Castro Ferreira et al., 2018a; Cao and Cheung, 2019; Cunha et al., 2020). The task of End2End (E2E) REG was proposed by Castro Ferreira et al. (2018a), who extracted a corresponding corpus from the WebNLG corpus (Castro Ferreira et al., 2018b)[1]. Grounding on the WEBNLG dataset, they proposed a neural REG system built on a *sequence-to-sequence with attention* model. Their automatic and human evaluation results suggested that neural REG systems significantly outperform rule-based and feature-based machine learning (ML) baselines. However, it can be argued that Castro Ferreira et al. did not use very strong baselines for their comparison: `OnlyName` is a rule-based system that always generates a proper name given an entity, and `Ferreira` is a feature-based model

---

[*] Equal contribution. Order determined by swapping the order in Chen et al. (2021).

[1] We refer to this extracted REG corpus as WEBNLG.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 5554 - 5567

that uses Naive Bayes with only 3 simple features[2].

We present several rule-based and feature-based baselines to examine how neural models perform against "well-designed" non-neural alternatives. Note that a well-designed model is not necessarily complex. For example, it can be a rule-based system with one or two simple, "well-designed" rules. Since one of the advantages of neural E2E models is that they require little effort for feature engineering, we used two types of baselines, namely models that require minimal expert effort and models that use more demanding (but linguistically well-established) rules or features. Therefore, our main research question is: *Do state-of-the-art neural REG models always perform better than rule-based and machine learning-based models?*

To answer this question fairly, we consider the amount of resources used by each model. For example, the neural models require fewer human resources when it comes to linguistic expertise and annotation, but they require input from Deep Learning experts. Resources such as computing power and data needs should also be considered.

Another issue with previous studies concerns the datasets that were used: in WEBNLG, approximately 99.34% of entities in the test set also appear in the training set; consequently, evaluations using WEBNLG do not take unseen entities into consideration. Furthermore, since many sentences in WEBNLG are paraphrases of one another, evaluating neural models on WEBNLG alone may overestimate their performance. Castro Ferreira et al. (2019) recently extended WEBNLG to include unseen domains that contain many unseen entities[3], and Cunha et al. (2020) have developed new models to handle them. Their test set has two subsets: one consists of documents 99.34% of whose entities are *seen*, while the other consists of documents 92.81% of whose entities are *unseen*. This arguably makes the data in WEBNLG unrealistic (see §2 for discussion). Therefore, we created what we believe to be a more realistic dataset based on the Wall Street Journal (WSJ) portion of the OntoNotes corpus (Hovy et al., 2006; Weischedel et al., 2013)[4].

We evaluate all models on both WEBNLG and WSJ, using automatic and human evaluation experiments. The human experiments included a total of 240 participants and 16920 judgments.

This paper is structured as follows: in §2 and §3, we describe the datasets used and the REG models. In §4, we provide a detailed description of our automatic and human evaluations. In §5 and §6, we compare the results across different dimensions and make suggestions for future studies. The code for reproducing the results in this article can be found at: `https://github.com/a-quei/neuralreg-re-evaluation`.

2 Task and Datasets

This section explains the REG-in-context task and the two English datasets used to conduct the experiments.

2.1 The REG-in-context Task

Given a text whose REs have not yet been generated, and given the intended referent for each of these REs, the REG-in-context task is to build an algorithm that generates all these REs.

Consider the delexicalised text in Table 1. Given the entity "*AWH_Engineering_College*", REG selects an RE based on the entity and its pre-context ("*AWH_Engineering_College is in "Kuttikkattoor" , India in the state of Kerala .* "), and its post-context ("*has 250 employees and Kerala is ruled by Kochi . The Ganges River is also found in India.*").

2.2 The WEBNLG Dataset

Gardent et al. (2017) introduced the WEBNLG corpus for evaluating NLG systems. Using crowdsourcing, each crowdworker was asked to write a description for a given Resource Description Framework (RDF) triple (Table 1). The number of triples varied from 1 to 7. This corpus was later enriched and delexicalised (Castro Ferreira et al., 2018a,b) to fit the REG-in-context task. Castro Ferreira et al. (2019) further extended WEBNLG and divided the documents into test sets *seen* (where all data are from the same domains as the training data) and *unseen* (where all data are from different domains than the training data). This results in that almost all entities from the seen test set appear in the training set (9580 out of 9644), while only a

---

[2] The human evaluation in Cunha et al. (2020) showed a slightly different result: the `OnlyName` model performed as well as the Neural REG models in terms of fluency, grammaticality, and adequacy. However, since their human evaluation involved only two subjects, these outcomes need to be approached with caution.

[3] We used version 1.5 of the WEBNLG dataset in `https://github.com/ThiagoCF05/webnlg`.

[4] We used Ontonotes 5.0 licensed by the Linguistic Data Consortium (LDC) `https://catalog.ldc.upenn.edu/LDC2013T19`.

Triples:
(AWH_Engineering_College, country, India)
(Kerala, leaderName, Kochi)
(AWH_Engineering_College, academicStaffSize, 250)
(AWH_Engineering_College, state, Kerala)
(AWH_Engineering_College, city, "Kuttikkattoor")
(India, river, Ganges)

Text: AWH Engineering College is in Kuttikkattoor, India in the state of Kerala. The school has 250 employees and Kerala is ruled by Kochi. The Ganges River is also found in India.

Delexicialised Text:
Pre-context: AWH_Engineering_College is in "Kuttikkattoor" , India in the state of Kerala .
Target Entity: AWH_Engineering_College
Post-context: has 250 employees and Kerala is ruled by Kochi . The Ganges River is also found in India .

Table 1: An example data from the WEBNLG corpus. In the delexicalised text, every entity is underlined.

few entities from the unseen test set appear in the training set (688 out of 9644). Note that the maximum number of triples in the unseen set is five. So, one would expect the data in the unseen set to be less complex than the seen data.

We used version 1.5 of WEBNLG, which contains 67,027, 8278, and 19,210 REs in the training, development, and test sets. From the point of view of the present study, WEBNLG has some notable shortcomings. For a start, it consists of rather formal texts that may not reflect the everyday use of REs, and in which very simple syntactic structures dominate. The texts in WEBNLG also stand out for other reasons. For example, the texts are extremely short, with an average length of only 1.4 sentences. Consequently, as many as 85% of the REs are first-mentions, while 71% of the REs are proper names. Finally, in any given test sample, either more than 90% of the entities are seen or more than 90% are unseen. Realistic data should contain a reasonable amount of mixtures of seen and unseen entities. For all these reasons, we decided to test all algorithms on a second corpus as well.

2.3 The WSJ Dataset

Using the Wall Street Journal portion of the OntoNotes corpus, we constructed a new English REG dataset, following a similar approach as Castro Ferreira et al. (2018a). This corpus (WSJ) has very different characteristics from the WEBNLG. The WSJ consists of 582 newspaper articles containing 20,186, 2362 and 2781 REs in the training, development and test sets, respectively. The average length of the documents is 1189 words, and each document consists of 25 sentences on average. Furthermore, 23% of the instances are first-mention REs and the rest are subsequent mentions.

For each RE, we created its pre- and post-context at the local sentence-level and added K preceding and following sentences to the local context. We refer to K as the context length and set K=2 for this experiment. To create the dataset, we first delexicalised the REs. The dataset contains nearly 8000 coreferential chains. The REs in each chain were replaced with corresponding delexicalised expressions (similar to table 1). For delexicalisation, we used (1) the POStag information, (2) the fine-grained annotation of the referential forms, and (3) the entity type of each referent. To delexicalise human REs, for example, we looked for concise but informative REs such as the combination of first and last names (e.g., *"Barack Obama"*)[5]. When such an expression was found in a coreferential chain, its delexicalised version (tokens being separated by underscores, e.g., *"Barack_Obama"*) was assigned to all REs in the chain. We then moved on to the next tag. Below is the order in which the human referents were searched and delexicalised: [firstname-lastname], [title-firstname-lastname], [modified firstname-lastname], [title-lastname], [lastname], [modified-lastname], [firstname]. For more details on the preparation of the WSJ documents and a delexicalised example, see Appendix A.

3 REG Models

In this section, we introduce the rule-based, ML-based, and the SOTA neural REG models. The term *ML-based* here refers to models that require feature engineering and follow a pipeline architecture.

---

[5] The reason for choosing concise and informative REs for delexicalisation is that these labels are also used in the realisation process.

3.1 Rule-based REG

Rule-based models have been widely used for generating REs in context (McCoy and Strube, 1999; Henschel et al., 2000). Here, we build rule-based systems for binary classification into two classes, namely pronominal and non-pronominal REs.

Simple Rule-based System (`RREG-S`). For the first rule-based system, we use 2 simple rules. The target entity r is realised as a pronominal RE if:

1. r is *discourse-old*;
2. r has no *competitor* in the current sentence and the previous sentence,

Otherwise, r is realised as a non-pronominal RE. An entity r is defined as discourse-old if it has been mentioned in the previous context. A competitor is an entity that can be referred to with the same pronoun as r.

We also build a dictionary that stores the pronouns associated with each entity. For seen entities, we extract pronouns from the training data. If an entity has multiple possible pronominal forms, we extract the most frequent one. For unseen entities, we determine their pronominal forms based on their meta-information, which is also used in E2E systems (Cunha et al., 2020). For example, if an entity in WEBNLG has the type `PERSON` and the gender `FEMALE`, we assign "*she*" to this entity.

For the surface realisation of each entity, we realise its non-pronominal form by replacing the underscores in the entity label with whitespaces (e.g., "*Adenan_Satem*" to "*Adenan Satem*"), as previously described by Castro Ferreira et al. (2018a). We realise the pronominal forms according to Castro Ferreira et al. (2016) by using the grammatical role of each entity (e.g., if the entity is in the object position, then we realise "*he*" as "*him*").

Linguistically-informed Rule-based System (`RREG-L`). We build `RREG-L` by adopting a set of pronominalisation rules from Henschel et al. (2000). The fundamental concepts used by these rules are the idea of *local focus*, which is a simpler implementation of the Centering Theory (Grosz et al., 1995), and *parallelism*, i.e., whether r and its antecedent in the previous sentence have the same grammatical role (Henschel et al., 2000). The `RREG-L` is described in detail in Appendix B.

3.2 ML-based REG

The GREC Shared Task (Belz et al., 2010) triggered a plethora of ML-based models for building REG-in-context (e.g., Greenbacker and McCoy, 2009; Hendrickx et al., 2008). These models differ from each other in the features and the ML algorithms they have used.

In this study, we build ML-based REG models using CatBoost (Prokhorenkova et al., 2018). It predicts whether a reference is realised as a pronoun, proper name, or description. Once the referential form is predicted, the next step is to select the content. The most frequent variant (with the same referential form as the predicted class) is selected in the training corpus given the referent and the full set of features. If no matching RE is found, a back-off method (Castro Ferreira et al., 2018a) is used, removing one feature at a time in order of importance. The order is calculated using the inherent feature importance method of the CatBoost algorithm. Depending on which features are used, we build two variants of ML-based models, namely `ML-S` and `ML-L`. The detailed list of the features used in these models can be found in Appendix C.

Features obtained by minimum effort (`ML-S`). To find out what the upper bound is for a system that does not require any additional linguistic information or any additional annotation effort, we developed `ML-S`. In this model, we have relied only on the features that can be extracted directly from the corpus. Therefore, features such as grammatical role (which requires a syntactic parser) are not included in this model.

Linguistically Informed Features (`ML-L`). To evaluate the upper bound performance of ML-based systems, we developed `ML-L` with the features that could affect the choice of referential form and could improve the overall accuracy of the REG systems suggested by the previous linguistic and computational studies (Ariel, 1990; Gundel et al., 1993; Brennan, 1995; Arnold and Griffin, 2007; Fukumura and Van Gompel, 2011; Kibrik et al., 2016; von Heusinger and Schumacher, 2019; Same and van Deemter, 2020). For example, we included features encoding grammatical role, recency, gender, and animacy in `ML-L`. Note that `ML-L` makes full use of the syntactic information[6] and entity meta-information (e.g., `GENDER` and `TYPE` which are also used by both the rule-based systems and the neural models).

---

[6] The syntactic information is available in the annotations of the WSJ data set. We used spaCy to parse WEBNLG.

Model	RE Acc.↑	SED↓	BLEU↑	Text Acc.↑	Precision↑	Recall↑	F1↑

Table 2: Automatic Evaluation Results on WEBNLG. Best results are **boldfaced**, whereas the second best are underlined. ↑ means the higher the metric, the better, while ↓ means the lower the better.

3.3 Neural REG

A limitation of the rule-based and ML-based models mentioned above is that they are not able to handle situations where an RE form (e.g., a proper name) can have multiple realisations, e.g., Lady Gaga/Stefani Germanotta. End2End NeuralREG can address this by generating REs from scratch. This study examines three NeuralREG systems that have been developed to deal with unseen entities as well. All of them were developed using the *sequence-to-sequence with attention* model (Bahdanau et al., 2014).

`ATT+Copy`. Cunha et al. (2020) proposed using three bidirectional LSTMs (Hochreiter and Schmidhuber, 1997) to encode a pre-context, a post-context, and the proper name of an entity (i.e., replacing underscores in entity labels with whitespaces) into three hidden vectors $h^{(pre)}$, $h^{(post)}$ and $h^{(r)}$, respectively. An auto-regressive LSTM-based decoder generates REs based on context vectors. To handle unseen entities, Cunha et al. used the copy mechanism, which allows the decoder to copy words from the contexts directly as output.

`ATT+Meta`. `ATT+Meta` (Cunha et al., 2020) used meta information of each entity to improve the quality of the generated REs. In each decoding step t, the context vector $\mathbf{v}_t^{(c)}$ is concatenated with meta information embeddings before being fed to the decoder. In WEBNLG, meta information are the entity type $\mathbf{v}^{(type)}$ and gender embeddings $\mathbf{v}^{(gender)}$; while in WSJ, in addition to $\mathbf{v}^{(type)}$ and $\mathbf{v}^{(gender)}$, there is also plurality embedding $\mathbf{v}^{(pl)}$.

`ProfileREG`. Cao and Cheung (2019) made `ProfileREG` to leverage the content of entity profiles extracted from Wikipedia. More specifically, instead of encoding the proper name of each entity, `ProfileREG` asks the entity encoder to encode the whole entity's profile to obtain $h^{(r)}$. Note that since profiles of entities in WSJ are not accessible, we evaluate `ProfileREG` only on WEBNLG.

4 Evaluation

We evaluated all the systems described in §3 on both WEBNLG and WSJ using automatic and human evaluations. We implemented the neural models based on the code of Cunha et al. (2020) and Cao and Cheung (2019)[7]. For WEBNLG, we used their original parameter setting, while for WSJ, we tuned the parameters on the development set and used the best parameter set.

To determine the optimal context length K of WSJ, we varied K from 1 to 5 sentences before and after the target sentence, then tested `ATT+Meta` on the development set with the different K contexts. It reaches the best performance when $K = 2$.

4.1 Automatic Evaluation

Metrics. Following Cunha et al. (2020), we evaluated REG systems from 3 angles. (1) **RE Accuracy** and **String Edit Distance** (SED, Levenshtein, 1966) were used to evaluate the quality of each generated RE. (2) After adding the REs to the original document, **BLEU** (Papineni et al., 2002) and **Text Accuracy** were used to evaluate the output text. (3) **Precision**, **recall**, and **F1** score were used to assess pronominalisation.

Results of WEBNLG. Table 2 depicts the results of WEBNLG[8]. Overall, the classic rule- and ML-based models performed better than neural models, while neural models did a better job on pronominalisation. For generating REs, `ML-L` had the best performance, as it obtained the highest RE

---

[7] `ATT+Copy` and `ATT+Meta`: `github.com/rossanacunha/NeuralREG`; and `ProfileREG`: `github.com/mcao610/ProfileREG`.

[8] Note that there is a discrepancy between our replication results and the results of Cunha et al. (2020). The reason for this difference is that we found a bug in the code for preprocessing provided by the original paper and fixed it after consultation with Cunha et al.

`ML-L`	**56.60**	**9.23**	**85.64**	**50.03**	**85.12**	**85.75**	**85.43**
`ATT+Copy`	29.27	15.19	79.01	32.55	76.33	54.16	51.10
`ATT+Meta`	35.56	12.11	81.07	36.83	72.72	70.50	71.42

Table 4: Automatic Evaluation Results on WSJ. Note that since, for a WSJ document, it is extremely unlikely to generate every RE correctly, the text accuracy is always 0. Instead, we report sentence-level accuracy.

accuracy and BLEU scores and the second best SED and text accuracy score. For pronominalisation, `ProfileREG` yields the best performance, followed by RREG-S.

We were surprised to find that the simplest rule-based system, `RREG-S`, performs remarkably well. It not only defeats the linguistically informed, rule-based `RREG-L`, but also outperforms the SOTA neural models `ATT+Copy` and `ATT+Meta` on both RE generation and pronominalisation.

Table 3 shows the breakdown of the seen and unseen subsets. The SOTA neural models (i.e., `ATT+Copy`, `ATT+Meta`, and `ProfileREG`) have the top 3 performance on seen data, and the worst RE generation performance (i.e., RE Acc., SED, BLEU, and Text Acc.) on unseen data. The ML-based models achieve the fourth and fifth best performance on seen data, and lower performance (but not as low as the neural models) on unseen data. The nature of WEBNLG could explain this drop in performance on unseen data: the models may have limited ability to handle unseen entities, for instance, because they fail to conduct domain transfer (remember that unseen data comes from different domains than seen data). Since rule-based systems do not rely on training data, this explanation does not apply to them, which explains why they did not show the same drop in performance. In fact, they performed even better on unseen data, possibly because unseen data contained fewer triples than seen data (see §2). Concretely, rule-based systems have lower REG accuracy but higher pronominalisation accuracy on unseen data compared to seen data. Additionally, ML-based models have low performance in the pronominalisation of unseen entities. The pronominalisation accuracy of the rule-based models is based on a 2-way distinction between a pronominal and a non-pronominal form, while the ML-based models make a 3-way distinction between a pronoun, a proper name and a description.

Another factor that might have lowered the performance of the ML models is the annotation practices in WEBNLG. Since these models are data-driven, the quality of the annotations directly affects their performance. It appears that whenever a (nominal) RE starts with a determiner, it is marked in WEBNLG as `description`; otherwise, it is marked as `proper name`. For instance, *"United States"* is marked as a proper name, while *"The United States"* is wrongly marked as a description. To allow comparison with previous work, we have not corrected the annotations, but it is important to keep in mind that this issue can cause ML-based models to underperform.

Results of WSJ. Table 4 shows the results of WSJ. Once again, `ML-L` performs best both in RE generation and in pronominalisation, outperforming the other models by a large margin. `RREG-L` outperforms `RREG-S` on WSJ on all evaluation metrics, which could be seen as confirmation of our hunch that WSJ contains different, and potentially more naturalistic texts than WEBNLG (see §2.2).

As for the neural models, the results suggest that meta-information can improve RE prediction

	All			Seen			Unseen

accuracy. Also, the inclusion of meta-information significantly boosts the recall of pronominalisation comparing `ATT+Copy` with `ATT+Meta`. Table 10 in Appendix D shows an original text and different outputs generated by the WSJ models.

4.2 Human Evaluation on WEBNLG

Materials. For WEBNLG seen entities, we randomly sampled 4 instances from each triple size group of 2-7 from the test set. In the case of the unseen data, we randomly chose 6 instances from size groups of 2-5. In this way, we obtained a total number of 48 reference instances (24 seen and 24 unseen). In addition to each reference instance, we selected its 7 different versions generated by the models (3 neural, 2 ML-based and 2 rule-based models). This yields a total of 384 items (48 × 8).

Design. The 384 items were randomly distributed into 12 lists of 32 items. Each list was rated by 10 participants. Participants were asked to rate each text for its fluency ("does the text flow in a natural, easy to read manner?"), grammaticality ("is the text grammatical (no spelling or grammatical errors)?") and clarity ("does the text clearly express the data in the table?") on a 7-point Likert scale anchored by 1 (very bad) and 7 (very good). The definition of each criterion was taken from Castro Ferreira et al. (2018a).

Participants. We used Amazon Mechanical Turk (MTurk) for human evaluation. We restricted MTurk workers to those located in the United States, with an approval rating of $\geq 95\%$ and 1,000 or more HITs approved. We rejected workers if they: (1) gave human-produced descriptions a score lower than 2 more than 3 times; or (2) gave scores with a standard deviation less than 0.5. 120 workers (12 lists×10 workers) participated, providing us with 11520 judgements (384 items×3 criteria×10 judgements/item). The participants were 80 males, 36 females, and 4 others/unanswered, with an average age of 37.

Results. Table 5 shows the results of the human evaluation WEBNLG. Few of the differences reach significance (using Wilcoxon's signed-rank test with Bonferroni correction[9]), suggesting that WEBNLG may be ill-suited for differentiating between REG models[10]. The only two significant differences appear when comparing `RREG-S` with `ATT+Meta` and `ProfileREG` in terms of the grammaticality of unseen data. The results suggest that `RREG-S` is the best model for generating REs on WEBNLG, performing on a par with neural models on seen data and better than neural models on unseen data. Unlike our automatic evaluation, `ATT+Meta` does not outperform `ATT+Copy` in human evaluation.

4.3 Human Evaluation on WSJ

Materials. We randomly selected 30 documents from the test set of WSJ (reference text). We included the 6 different outputs generated by the 6 WSJ models (hereafter target texts). In this way we obtained a total of 180 reference-target pairs.

---

[9] P-values were multiplied by the number of comparisons.

[10] All non-significant differences in Table 5 and Table 6 are associated with p-values greater than 0.1.

Design. As mentioned in §2.3, the WSJ documents have an average length of 25 sentences. Since there are no input representations (e.g., in RDF) for WSJ, we decided to ask participants to compare texts using a Magnitude Estimation (ME) (Bard et al., 1996). The participants saw the reference and one of the target texts side by side, and they were asked to rate the target relative to the reference text. To make the task manageable for participants, texts were shortened to a maximum of the first 20 sentences. The 180 reference-target pairs were randomly distributed over 12 lists, each list having 15 items. Each list was rated by 10 participants. They were asked to rate the fluency, grammaticality and clarity of the target texts. The definition of fluency and grammaticality were as in the WEBNLG task, and clarity was defined as "how clearly does the target text allow you to understand the situation described in the standard text[11]?". The question asked for each of the 3 criteria was: assuming that standard text has a score of 100, how do you rate the fluency|grammaticality|clarity of target text? Participants were allowed to choose any positive number.

Participants. The MTurk worker restrictions were similar to the WEBNLG experiment. Workers with scores less than 5 standard deviations were rejected. The experiment included 120 participants, resulting in 5400 judgements (180 items×3 criteria×10 judgements/item). The participants were 65 males, 54 females, and 1 others/unanswered, with an average age of 38.

Results. Since typos are possible in ME (e.g., a worker might type 600 instead of 60), we excluded outliers, defined as a score that is lower than the median minus 3 standard deviations, or higher than the median plus 3 standard deviations of that item. The remaining scores were down-sampled for conducting significant testing. The results are shown in Table 6. Unlike WEBNLG, significant differences are frequent. For fluency, `ML-S` and `ML-L` perform the best while `ATT+Meta` performs the worst. For grammaticality, `ML-L` is still the best model, which significantly defeats `RREG-L` and `ATT+Meta`. A more detailed study is needed to investigate why `RREG-L` is the second worst in terms of grammaticality, which we found surprising. For clarity, no significant difference was found, perhaps because it was difficult for participants to compare long documents. In sum, on WSJ, `ML-L` has the best performance, and the simpler `ML-S` and `RREG-S` also have considerably good performances.

5 Discussion

Why does Neural REG not defeat rule-based REG? Received wisdom has it that although neural models may be inferior to other models in terms of interpretability, they are nonetheless superior in terms of performance. Although it is possible that future neural models will perform better than the ones examined here, our results call into question whether this received wisdom is correct. One possible explanation is the observation that Neural NLG systems tend to perform very well on surface realisation tasks, but less well on tasks that focus on semantic content (see e.g., Reiter (2018) on hallucinations in the Data2Text generation tasks). REG, after all, is a task that focuses in large part on semantic content. There may be other reasons, which should be investigated in future work.

Role of Linguistically-informed Features. Rule-based models did particularly well on WEBNLG, outperforming other models. By contrast, on WSJ, the linguistically-informed feature-based model (`ML-L`) outperformed all other models. This suggests that the type of text, and consequently, the complexity of the REG task, might be a factor in choosing the REG method. Linguistically-informed features seem to have a more pivotal role in the case of more complex text types, whereas simpler texts can be handled at least as well by simpler rule-based models.

Resources Use. As mentioned before, different approaches require different amounts of **human** resources and annotation efforts. But we believe that other resource types should also be taken into consideration when models are compared, including the following: (1) **The amount of context**: the neural models access the whole pre-context and post-context for WEBNLG, while they access K preceding and K following sentences around the target entity for WSJ. The ML-based models extract features taking only the current sentence and the whole pre-context into account. The rule-based models only look at the current sentence and the previous one; (2) **External tools**: the neural models need no external tools, while the rule-based and `ML-L` models need a syntactic parser (which is also used for constructing datasets); (3)

---

[11] We refer to the reference text as *standard text*.

External information: rule-based models, `ML-L`, and `ATT+Meta` need entities' meta-information. `ProfileREG` requires the profile description of each entity, which, for most REG tasks, is hard to obtain; (4) **Computing resources**: the neural models need GPUs while other models can be constructed using merely personal computers; (5) **The amount of training data**: the rule-based models need no training data, while other models require training data (large-scale naturalistic versions of which, for the task of REG, is not available).

As we have seen, `RREG-S` and `ML-S` perform remarkably well on both WSJ and WEBNLG. Taking resources into consideration, the advantage of using a model such as `RREG-S` and `ML-S` becomes more pronounced. `RREG-S` uses less human resources, less context, less computing resources, and no training data[12] compared to other models. `ML-S` needs more context and training data; it probably also needs more human effort for feature engineering and selecting ML models, but it needs no external tools and no meta-information.

In aggregate, one's choice of model may depend partially on what resources are available. For instance, for classic pipeline NLG systems, syntactic position and meta-information are often decided by earlier steps in the pipeline (Gatt and Krahmer, 2018). Therefore, if one's aim is to rapidly construct a pipeline NLG system, then `RREG-S` should probably be preferred.

Generalisability. We used neural REG to illustrate the importance of non-neural baselines. Our findings may not be generalisable to End2End NLG. However, if complex rule/template-based NLG systems are taken into account, Dušek et al. (2018) found that although these systems cannot defeat neural approaches, they still have competitive performance. It would be interesting to compare different types of models for other sub-tasks in the NLG pipeline (e.g., content determination, aggregation, and lexicalisation) in a similar way as has been done in the present paper[13].

6 Conclusion

In this work, we have re-evaluated state-of-the-art Neural REG systems by considering four well-designed rule- and ML-based baselines. In addition to the existing WEBNLG corpus, we built a new dataset for the task of *REG-in-context* on the basis of the WSJ corpus, arguing that this dataset may be more appropriate for the task. In the re-evaluation, we examined both our baselines and SOTA neural REG systems on both datasets, using automatic and human evaluations. The results suggest that the simplest rule-based baseline `RREG-S` achieves equally good or better performance compared to SOTA neural models. Our results on the WSJ suggest that, on that corpus, the linguistically-informed ML-based model (`ML-L`) is best. We hope these results will encourage further research into the comparative strengths and weaknesses of neural, non-neural and hybrid methods in NLP.

In future, we have 4 items on our TODO list: (1) Investigate bottleneck features for Neural based models based on the feature set of `ML-L`; (2) Explore other neural architectures (e.g., testing models that leverage pre-trained language models) and construct larger realistic REG corpora; (3) Explore better human evaluation methods for longer documents that are better suited for evaluating the task of generating referring expressions in context; (4) Extend our research to other languages, especially in other language families, including languages that are morphological very rich or very poor and languages that frequently use zero pronouns (e.g., Chinese (Chen et al., 2018)).

Ethical Considerations

We collected our human evaluations using Amazon Mechanical Turk. For the WEBNLG task, which used a 7-point Likert scale, the workers were paid 0.03$ per item, in line with rates for similar tasks. For the more demanding WSJ task, we paid 0.10$ per item. The payment for each task was set at $7.5/hour (slightly above the US minimum wage, i.e., $7.25/hour). We expected the amount to be a fair remuneration, but given the actual time some

---

[12] The pronominal form (e.g., he or she) of an entity can either be extracted from the training data or decided by the entity's meta-information.

[13] Note that pipelined NLG systems are sometimes thought to yield better outputs than fully End2End NLG systems (Castro Ferreira et al., 2019)

participants needed, their remuneration turned out to be on the low side. In future crowd-sourcing experiments, we will base our remuneration on a more generous estimate of the duration per experimental task. We asked for demographic information, age, gender and English proficiency level, explicitly stating in the experiment that "Your information will be used for research purposes only. All your data will be held *anonymously*." These fields were not marked as mandatory fields. The demographic information will not be made publicly available.

A WSJ Dataset Construction

In this work, we used Ontonotes 5.0 licensed by the Linguistic Data Consortium (LDC) `https://catalog.ldc.upenn.edu/LDC2013T19`. We used the files in OntoNotes Normal Form (ONF) format. This format has combined all layers of the OntoNotes corpus, ranging from text (sentence and token segmented), parsing information, propositional content, and the coreference chains (Weischedel et al., 2013). These files were later rendered into XML format for full processing. As mentioned earlier, only the Wall Street Journal portion of this corpus has been used in the current study. The first and second person references were excluded from the dataset. Furthermore, we assumed that REs are presented in a linear order, therefore excluded cases such as union REs. As an example, in the sentence "[Mary], [John] and [David] received their booster shot last month", the REs enclosed in brackets are included in the dataset, but their underlined union, *"Mary, John, and David"*, is excluded. We then delexicalised the REs as explained in §2.3. The delexicalised text in table 7 shows an example from the WSJ corpus.

B Details of `RREG-L`

Algorithm 1 describes the generation process of `RREG-L`. The system takes in the target entity r, the current sentence (u_2, i.e., the one where the target RE is located), and the previous sentence (u_1). It starts with a rule checking whether an antecedent of r appears in u_1 (line 1). If the answer is no, then it realises r with its non-pronominal form. If such an antecedent exists, the system heads to check parallelism(Henschel et al., 2000). Concretely speaking, it checks whether or not r has the same grammatical role (i.e., subject or object) as its antecedent. If the parallelism holds, r is realised as a pronoun. Otherwise, we apply the "local focus" idea from Henschel et al. (2000), which builds upon the Centering Theory (Grosz et al., 1995). A referent is the local focus if it is (1) discourse-old, or (2) in the subject position. In line 5, the `FocusSetConst` function constructs a set $\mathcal{F}$, consisting of local focus entities in u_1. If r's antecedent is an element of $\mathcal{F}$, and r has no competitor being an element of $\mathcal{F}$, then we realise r as a pronoun (line 6-9). Both surface realisation functions (i.e., `RealiseProRE` and `RealiseNONProRE`) work similarly to `RREG-S` in realising pronominal and non-pronominal REs, respectively.

Algorithm 1 The Linguistically Informed Rule-based REG Algorithm

```
Input: The target entity $r$, the sentence $u_2$ that $r$ is in, and its previous sentence $u_1$.
Output: The surface form of $r$.
 1: if $r$ has an antecedent in $u_1$ then
 2:     if $r$ occurs in parallel context then
 3:         RealiseProRE(r)
 4:     else
 5:         $\mathcal{F}$ := FocusSetConst($u_1$)
 6:         if $r$'s antecedent $\in \mathcal{F}$ and $r$ has no competitor $r' \in \mathcal{F}$ then
 7:             RealiseProRE(r)
 8:         else
 9:             RealiseNONProRE(r)
10: else
11:     RealiseNONProRE(r)
```

C Detailed list of features used in WEBNLG and WSJ feature-based ML models

Each feature is defined and calculated for each target entity r. `Antecedent` refers to the first co-referential RE preceding r. Tables 8 and 9 list the features used in the ML models.

Since we wanted to use the features in a back-off method for selecting the content of REs, we converted numerical features, such as recency, into categorical values. We tried different recency measurements on the WEBNLG and WSJ validation sets, and chose the ones which yielded the best results: (1) `Word distance` in all ML-based WEBNLG and WSJ models: 5 quantile groups; (2) `Sentence distance` in WEBNLG `ML-R & ML-S`, and WSJ `ML-S` models: 2 quantile groups; (3) `Sentence distance` in WSJ `ML-L`: 3 bins defined as whether the `antecedent` is in the

Text: Ronald B. Koenig , 55 years old , was named a senior managing director of the Gruntal & Co. brokerage subsidiary of this insurance and financial - services firm . Mr. Koenig will build the corporate - finance and investment - banking business of Gruntal , which has primarily been a retail - based firm . He was chairman and co-chief executive officer of Ladenburg , Thalmann & Co. until July , when he was named co-chairman of the investment-banking firm along with Howard L. Blum Jr. , who then became the sole chief executive . Yesterday , Mr. Blum , 41 , said he was n't aware of plans at Ladenburg to name a co-chairman to succeed Mr. Koenig and said the board would need to approve any appointments or title changes .

Delexicialized Text:

Target Entity: Mr._Koenig

Post-context: will build the corporate-finance and investment-banking business of Gruntal. Mr._Koenig was chairman and co-chief executive officer of Ladenburg until July , when Mr._Koenig was named co-chairman of Ladenburg along with Mr._Blum. Yesterday, Mr._Blum said Mr._Blum was n't aware of plans at Ladenburg to name a co-chairman to succeed Mr._Koenig and said the board would need to approve any appointments or title changes.

Table 7: An example data from the WSJ corpus. In the delexicalized text, every entity is underlined.

Feature Class	Definition
Referential status	Is r the first mention of the entity in the text?
Referential status	Is the antecedent of r in the same sentence?
Recency	Categorical distance between r and its antecedent in number of sentences
Recency	Categorical distance between r and its antecedent in number of words
Competition	Is there any other RE between r and its antecedent?
Position	A categorical feature marking whether r is the first, second, middle or last mention

Table 8: Features used in the ML-S models. Each feature is defined and calculated for each target entity r. Antecedent refers to the first co-referential referring expressions preceding r.

Feature Class	Definition
Grammatical Role	Grammatical Role of r
Grammatical Role	Grammatical Role of the antecedent
Meta information	Entity type (e.g. human, city, country, organization)
Meta information	Plurality: Is r plural or singular? (only WSJ)
Meta information	Gender
Recency	Categorical distance between r and its antecedent in number of words
Recency	Categorical distance between r and its antecedent in number of sentences
Recency	Categorical distance between r and its antecedent in number of paragraphs (only WSJ)

Table 9: Features used in the ML-L models.

same sentence, 1 sentence away, or more than 1 sentence away; (4) Paragraph distance in WSJ ML-L: 4 bins defined as whether r and its antecedent are in the same paragraph, 1 paragraph away, 2 paragraphs away, more than two paragraphs away. The paragraph information associated with the WSJ documents are taken from the PDTB parser at: github.com/WING-NUS/pdtb-parser/tree/master/external/aux_data/paragraphs.

D Sample texts generated by the WSJ models

Table 10 shows a reference text from the WSJ dataset in addition to the outputs generated by RREG-S (rule-based), ML-L (feature-based), and ATT-Meta (neural).

`Original`: **MGM Grand Inc.** said **it** filed a registration statement with the Securities and Exchange Commission for a public offering of six million common shares. **The Beverly Hills , Calif.-based company** said **it** would have 26.9 million common shares outstanding after the offering. **The hotel and Gaming company** said Merrill Lynch Capital Markets will lead the underwriters. Proceeds from the sale will be used for remodeling and refurbishing projects , as well as for the planned MGM Grand hotel / casino and theme park.
`RREG-S`: **MGM Grand Inc.** said **MGM Grand Inc .** filed a registration statement with the Securities and Exchange Commission for the offering. **MGM Grand Inc.** said **MGM Grand Inc.** would have 26.9 million common shares outstanding after the offering. **MGM Grand Inc.** said Merrill Lynch Capital Markets will lead the underwriters . Proceeds from the offering will be used for remodeling and refurbishing projects , as well as for the planned MGM Grand hotel / casino and theme park .
`ML-L:` **MGM Grand Inc.** said **it** filed a registration statement with the Securities and Exchange Commission for an offering of common shares. **MGM Grand Inc.** said **it** would have 26.9 million common shares outstanding after the offering. **MGM Grand Inc.** said Merrill Lynch Capital Markets will lead the underwriters . Proceeds from the offering will be used for remodeling and refurbishing projects , as well as for the planned MGM Grand hotel / casino and theme park.
`ATT-Meta:` **MGM Grand Inc.** said **MGM Grand Inc.** filed a registration statement with the Securities and Exchange Commission for the offering of the company of the market. **MGM Grand Inc.** said **it** would have 26.9 million common shares outstanding after the offering. **MGM Grand Inc.** said Merrill Lynch Capital Markets will lead the underwriters. Proceeds from the offering will be used for remodeling and refurbishing projects , as well as for the planned MGM Grand hotel / casino and theme park .

Table 10: Examples of an original text from the WSJ dataset together with the outputs generated by the models `RREG-S`, `ML-L`, and `ATT-Meta`. References to *"MGM Grand Inc."* are boldfaced.

Bridging the Generalization Gap in Text-to-SQL Parsing with Schema Expansion

Abstract

Text-to-SQL parsers map natural language questions to programs that are executable over tables to generate answers, and are typically evaluated on large-scale datasets like SPIDER (Yu et al., 2018). We argue that existing benchmarks fail to capture a certain *out-of-domain generalization* problem that is of significant practical importance: matching domain specific phrases to composite operations over columns. To study this problem, we propose a synthetic dataset and a re-purposed train/test split of the SQUALL dataset (Shi et al., 2020) as new benchmarks to quantify domain generalization over column operations. Our results indicate that existing state-of-the-art parsers struggle in these benchmarks. We propose to address this problem by incorporating prior domain knowledge by preprocessing table schemas, and design a method that consists of two components: *schema expansion* and *schema pruning*. This method can be easily applied to multiple existing base parsers, and we show that it significantly outperforms baseline parsers on this domain generalization problem, boosting the underlying parsers' overall performance by up to 13.8% relative accuracy gain (5.1% absolute) on the new SQUALL data split.

1 Introduction

Text-to-SQL parsing is the task of translating natural language questions over provided tables to SQL queries which can be executed to produce answers. In recent years, with the availability of large-scale datasets (e.g., Zhong et al., 2017; Yu et al., 2018), neural semantic parsers have witnessed significant success on this task. However, recent work (Suhr et al., 2020; Lee et al., 2021) has suggested that these state-of-the-art parsers are far from successful in terms of *out-of-domain generalization* in real scenarios, where users may ask questions related to potentially very large tables with the goal of improving their productivity (e.g., while they are viewing or editing a large Excel spreadsheet).

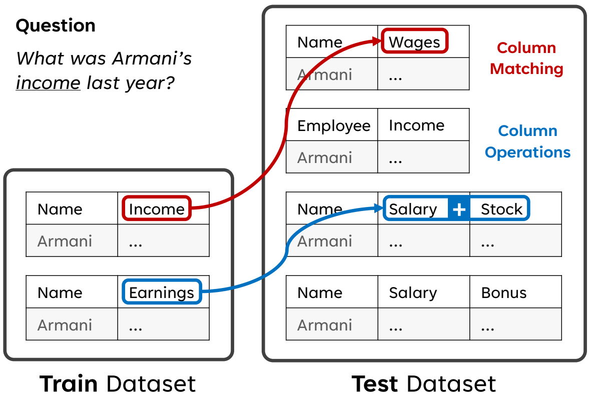

Figure 1: Illustration of two aspects of out-of-domain generalization that are challenging for text-to-SQL parsers. While existing methods partially address the "column matching" issue, they still suffer when it comes to "column operations". Note that there are more tables on the right to illustrate the fact that there are a variety of settings the parser may run into at test time.

In such scenarios, it is common to encounter tables specific to new domains that were not encountered while training a parser. Perhaps the most challenging aspect of domain generalization is that models need to understand domain-specific phrases that they have not seen before, and translate them into logical form segments that involve references to table elements (e.g., column names or aggregation operations over columns). We argue that two kinds of abstract operations, shown in Figure 1, are particularly challenging for new domains:

1. Column Matching: The task of mapping natural language phrases to the most relevant columns (e.g., mapping "Income" to the `"Wages"` column). This can be challenging because some mappings may be implicit or may require domain knowledge.
2. Column Operations: The task of mapping natural language phrases to composite expressions over table columns. For example, in Figure 1, we need to map *income* to just `"Wages"` for one table, and to `"Salary" + "Stock"` for another table. Similarly, consider the complex `"Term"` column in Figure 2, in which two subfields _1 and _2 represent the term start (e.g., 1926) and term end (e.g., 1927), respectively. Some questions may ask about the *term duration* while others may ask about the *term start*.

Figure 2: Illustration of the training pipeline for the proposed method and the inference process for an example. The proposed method is described in detail in §4. Note that the proposed components interact with the parser by modifying the table that is fed to it as input, as well as the target program during training in the case of *schema expansion*.

> Each of these questions requires mapping the corresponding phrase to an expression that refers to this column (e.g., `"Term"._2 - "Term"._1` for the former and `"Term"._1` for the latter).

While recent approaches rely on pre-trained language models (e.g., Yin et al., 2020; Deng et al., 2021) for addressing the column matching challenge, column operations remain relatively unexplored due to the lack of evaluation benchmarks.

To this end, we first propose two new benchmarks: a synthetic dataset and a train/test repartitioning of the SQUALL dataset (Shi et al., 2020); both capable of quantifying out-of-domain generalization on column operations. We then show that existing neural parsers underperform on both benchmarks because they require an impractically large amount of in-domain training data—which is not available in our setting—to effectively "memorize" mappings from natural language phrases to program fragments. Finally, we propose a new method for making any existing text-to-SQL parsers aware of prior information that may be available about the domains of interest. Specifically, we propose two new components: *schema expansion* and *schema pruning*.

Schema expansion uses heuristics to expand columns into sets of derived columns based solely on their *types* (all schemas are assumed to be typed which tends to be true for both relational databases and Excel spreadsheets in practice; Excel uses a built-in type inference mechanism). Relying on generic types makes this method applicable to new domains, as long as they make use of similar underlying types. This process allows us to transform complex program fragments (e.g., `"Term"._2 - "Term"._1`) into simpler ones (e.g., `"Term Duration"`) that are better aligned with the natural language questions, thus making the underlying parser's job easier. While schema expansion may result in a large number of unnecessary expanded columns, schema pruning then examines both the input question and the available columns (original and expanded) and prunes the set of columns that the final parser is exposed to.

Our experiments show that schema expansion and schema pruning can boost the underlying parsers' performance by up to 13.8% relative accuracy (5.1% absolute) on the new SQUALL data split. Furthermore, they also boost performance over the original SQUALL data splits by up to 4.2% relative (1.9% absolute). One of our main goals in this paper is to put attention on the difficult problem of domain generalization by providing a new evaluation benchmark, as well as an initial direction for solving this problem. Our evaluation benchmarks along with code for reproducing our experiments are available at `https://aka.ms/text-to-sql-schema-expansion-generalization`.

2 Background

Task. Semantic parsing has been widely studied in the context of multiple other tasks like instruction following (Chen and Mooney, 2011; Artzi and Zettlemoyer, 2013), code generation (Oda et al., 2015; Iyer et al., 2018), knowledge graph question answering (Berant et al., 2013; Yih et al., 2015), etc. We focus on using tables as the context in which semantic parsing is performed, where the goal is to translate pairs of natural language questions and tables to executable SQL queries, also known as text-to-SQL parsing (Androutsopoulos et al., 1995; Minock et al., 2008). Note that, while we focus on questions in the English language, there exists prior work on multilingual semantic parsing as well (Jie and Lu, 2014; Sherborne et al., 2020) and the contributions of our work also apply there. Formally, our goal is to map a pair (q, T), where q is a natural language question and T is a table, to an executable program π that, when executed against table T, will produce the answer α to question q. We focus on the fully-supervised setting where the target executable program π^* is provided as supervision for training our parser.

Out-of-Domain Generalization. Generalization in machine learning is often defined as the ability to do well on a test set after learning from a training set, where all examples in both sets are drawn independently from the same distribution (*i.i.d. generalization*). However, as Gu et al. (2021) argue, in real-world applications such as semantic parsing, the test data may involve new compositional structures (*compositional generalization*), or new domains (*domain generalization*) that are not encountered during training. Existing work in compositional generalization for semantic parsing has focused on using synthetic datasets (e.g., Keysers et al., 2020; Lake and Baroni, 2018), or repartitioning existing text-to-SQL datasets into new train and test splits (e.g., Finegan-Dollak et al., 2018). Both approaches have generally shown that compositional generalization remains an important challenge (e.g., Shaw et al., 2021). We focus on the arguably even more challenging domain generalization problem, also known as *domain adaptation*, where entire domains may never be encountered during training or may only be encountered a small number of times (Motiian et al., 2017). Even though this problem has been studied extensively in the context of classification (Daumé III and Marcu, 2006), machine translation (Daumé III and Jagarlamudi, 2011), and question answering (Talmor and Berant, 2019), it remains underexplored for semantic parsing. To be applicable in real scenarios, semantic parsers must be able to generalize to new domains since collecting domain-specific labeled data is often prohibitively expensive. Recent approaches have focused on data synthesis (Yin et al., 2021), meta-learning (Wang et al., 2021), relation-aware schema encoding (Wang et al., 2020), and encoder pretraining (Yin et al., 2020; Herzig et al., 2020; Yu et al., 2020; Deng et al., 2021). In this paper, we hone in on one aspect of domain generalization that we shall broadly refer to as *column operations* and which was introduced in §1 and illustrated in Figure 1.

Evaluation Benchmarks. Text-to-SQL parsing became popular after the introduction of large-scale datasets and evaluation benchmarks. Zhong et al. (2017) first introduced WIKISQL, which contains Wikipedia tables paired with questions and annotated with SQL queries, albeit the queries are generated from a limited set of templates. SPIDER was introduced by Yu et al. (2018) the following year. It contains more complex questions and SQL queries and focuses on generalizing to previously unseen database schemas, but the dataset has the artifact from its annotation design that the references columns are often mentioned verbatim in the natural language questions. Deng et al. (2021) attempt to address this limitation by repartitioning SPIDER to produce a more realistic benchmark, and Lee et al. (2021) propose a challenging test set from Kaggle for evaluating parsers trained on SPIDER dataset. However, as Suhr et al. (2020) point out, SPIDER also uses a simplified setting which excludes examples that involve multiple columns (e.g., adding two columns together), as well as ones that require background knowledge. These benchmarks are thus limited in their usefulness for evaluating parsers in real-world settings where they may encounter complex questions that require mapping specific phrases to expressions over table columns, rather than to a single column. Furthermore, while both WIKISQL and SPIDER assume "simple" tables with only `String`- or `Number`-valued columns, in practice we may encounter tables where the columns themselves may have structured types (e.g., `TimeSpan`). For example, consider the table shown on the top left of Figure 2. In this case, the `"Term"` column is of type `TimeSpan` and consists of two `Numbers` that represent the beginning and the end of the timespan. In this case, users may ask questions that require constructing expressions to access nested elements from the `"Term"` column (e.g., "How long was Pier's term?"). Recently, Shi et al. (2020) introduced SQUALL, a dataset that annotates WIKITABLEQUESTIONS (Pasupat and Liang, 2015) with SQL queries and refined column types like `Date`, `Score`, `(T1, T2)`, and `List[T]`. However, SQUALL distributes tables evenly between the train and test splits, thus not allowing us to evaluate the kind of out-of-domain generalization we are interested in. Therefore as we will show in the following section, we aim to address this limitation by repartitioning SQUALL into new train and test splits.

Neural Text-to-SQL Parsers. Neural encoder-decoder models have recently gained popularity for text-to-SQL parsing (e.g., Xu et al., 2017). We focus on two models that represent the current state-of-the-art for SQUALL and SPIDER, respectively: SEQ2SEQ of Shi et al. (2020) [1] and SMBOP of Rubin and Berant (2021). Both models concatenate the question with a textual representation of the table schema, separated by a special `[SEP]` token, and feed the combined sequence to a pre-trained instance of the BERT (Devlin et al., 2019) language model. The activations of the last layer represent the encoded representations of the question and the table schema. SEQ2SEQ then uses a *autoregressive decoder*, which represents programs as token sequences and at each decoding step it: (1) predicts the next token type (i.e., whether the next token is a SQL keyword, a column name, or a literal value), and (2) predicts the token conditioned on its type. SMBOP, on the other hand, uses *bottom-up decoding*, which represents programs as abstract syntax trees and constructs these trees in a bottom-up fashion (i.e., it starts by predicting the leaf nodes and then recursively composes generated sub-trees into new trees and ranks them, in a way that resembles beam search), until it reaches the tree root. We refer the reader to the aforementioned papers for details.

---

[1] Shi et al. (2020) mentioned that the SEQ2SEQ model in their experiment is competitive with a state-of-the-art system (Suhr et al., 2020) on the SPIDER leaderboard.

3 Proposed Evaluation Benchmarks

Our goal is to design an evaluation benchmark that has the following out-of-domain generalization properties: (i) the training data involves a different set of domains from the test data, (ii) the questions and tables that appear in the train and test data are non-overlapping, not only in terms of the domains they belong to, but also in terms of the program fragments that they contain, and (iii) to simulate the more challenging setting that is often encountered in real applications, the test data is biased to contain more examples that involve both nested *column access operations*, like getting the start of a `"Term"` in Figure 2, as well as *composite column expressions*, like getting the duration of a `"Term"`. To this end, we propose a new synthetic dataset and a repartitioning of the SQUALL dataset into new train/test splits.

3.1 Synthetic Dataset

We consider three fictional domains inspired by common uses of tables: *finance*, *sports*, and *science*. We explain our synthetic dataset generation process through a running example as follows:

1. For each domain, we declare a set of formulas that relate different quantities (e.g., `"Income" = "Salary" + "Stock"`). The primitives used in these formulas define the set of available columns.
2. For each column we declare a set of noun phrases that can be used to refer to it (e.g., "wages" for `"Income"` and "base salary" for "salary"). We also define a SQL query template that shall be used for all programs: `SELECT <column> FROM t WHERE "Year" = <year>`, and a question template `What was <column> in <year>?` Note that the `"Year"` column is special and is included in all examples of this synthetic dataset.
3. We sample a formula and a variable from that formula (e.g., `"Income"` from formula `"Income" = "Salary" + "Stock"`). We then generate a question asking for this variable, randomly replacing the variable with a noun phrase in the corresponding set, and randomly generate a year value (e.g., use "wages" to replace "income" and generate a question "What was `[wages]` in `[2011]`?").
4. To generate the target program π^*, we randomly drop a variable from the sampled formula in step 3. If the asked value corresponds to this variable, we transform its reference in the SQL query so that it is expressed as a function of the columns that are kept (e.g., `"Salary" + "Stock"`), otherwise we use the column name (e.g., `"Income"`).
5. To generate a table schema we first add a `"Year"` column and two of the columns that were not sampled from the formula (e.g., `"Salary"` and `"Stock"`). We then sample k other columns and add them to schema ($k = 15$ in our experiments) as *distractor* columns. Note that we do not generate full tables for this synthetic dataset since we do not evaluate on table cell selections.

We construct benchmark datasets by first generating 1,000 examples per domain and then iterating over the domains and keeping the data generated for the current domain as our test data, while using the data of the remaining two domains for training. This results in three datasets, each with 2,000 train examples and 1,000 test examples. More details on the declarations for our domains can be found in Appendix A.1.

3.2 SQUALL Repartitioning

Aside from the synthetic dataset we also propose to repartition SQUALL into new train and test data splits, with a focus on the aforementioned out-of-domain generalization properties. The original splits for SQUALL were produced by uniformly sampling 20% of the tables to produce the test set and using the remaining 80% as the train set. This process was repeated 5 times and the evaluation metric results were averaged over the results obtained for each repetition. This resulted in similar tables being included in both the train and test sets (e.g., tables referring to two different basketball matches, but having identical schemas), and few examples in the test set required column operations. In order to avoid this issue, we propose the following algorithm for automatically constructing data splits focused on out-of-domain generalization on column operations:

1. Collect the table schemas used across all examples in the train and dev splits of the dataset (there are about 1,600 schemas; note that the test set is not annotated with SQL queries).
2. Construct a graph by treating each schema as a node, and adding an edge for each pair of schemas that share more than 33% of their columns.
3. Find all connected components of the graph. Each defines a cluster of table schemas.
4. Each table has a set of SQL queries associated with it: one for each example that uses this table. For each query we check if it is a `SELECT` of a single column or if it is a `SELECT` that involves column operations such as field accessors or arithmetic operations. We associate each cluster with the number of queries that involve such column operations.
5. Sort the clusters based on this number, in decreasing order, and then use the first 20% as the test set and the remaining as the train set. Note that adding a cluster to the train/test set is equivalent to

Data Category	**# Examples**	
	Train	**Test**
All	8,956	2,320
w/ `Score Accessors`	91	86
w/ `Score Expressions`	47	53
w/ `Date Accessors`	81	173
w/ `Date Expressions`	18	95

Table 1: Statistics for our repartitioned version of SQUALL, including the categories that we use in our empirical analysis and which are presented in §3.2.

adding all examples that use tables included in this cluster. This step will result in disproportionally more column operations being used in our test set than in our train set, which means that the model will need to learn to generalize well in this setting to do well in this dataset.

In the following sections we pay special attention to four data subcategories that are representative of the out-of-domain generalization setting for SQUALL:

- `Score` Expressions: Represents SQL queries that include expressions over columns of type `Score` (e.g., a query selecting the score difference for a basketball game).
- `Score` Accessors: Represents SQL queries that include field accessors for columns of type `Score` (e.g., a column with the results of a basketball game, like "89-72", and a query that requires accessing the first element of this score; i.e., "89").
- `Date` Expressions: Similar to `Score` expressions except using the `Date` and `TimeSpan` type (e.g., a query asking for the duration of a presidency term).
- `Date` Accessors: Similar to `Score` Accessors, except using the `Date` and `TimeSpan` type (e.g., a query asking for the start of a term).

We shall refer to these categories when reporting experimental results in §5. We provide statistics for the resulting dataset in Table 1.

4 Proposed Method

In this section we propose a simple approach for tackling this specific out-of-domain generalization problem that ought to serve as evidence that it is a real problem and that it is solvable, as well as a reference point for evaluating future approaches. Our approach consists of two new components that can be used in combination with any existing text-to-SQL parser: *schema expansion* and *schema pruning*. These components interact with the parser by preprocessing the table that is fed to it as input. This is illustrated in Figure 2.

As discussed in §1, there are two kinds of challenges related to out-of-domain generalization in text-to-SQL parsing, *column matching* and *column operations*, with the latter being more challenging. The goal of *schema expansion* is to reduce column operation challenges to column matching by adding synthetic columns to the table schema. These synthetic columns correspond to expressions or accessors over existing columns (e.g., a column that represents the sum of two columns). Rather than learning (or memorizing) the ways in which different types of columns can be composed together, we propose to inject prior knowledge as to what kind of symbolic operations are possible based solely on the column types in a schema. This reduces column operations to column matching by effectively bringing the target programs closer to their surface form in the natural language question. For example, `"Income"` can now map to a synthetic column that corresponds to the sum of `"Salary"` and `"Stock"` instead of having the parser produce the sum expression directly. Since our expansion is based on column types, we argue that it is reasonable to assume that all schemas are typed and our expansion could be applied to any new domain. It is also worth noting that even though our templates may not cover all cases,[2] when applying our method to new domains, developers can declare a few templates of their interest and apply schema expansion on these templates to create parser-friendly schemas. This would be more cost-effective compared to collecting large in-domain training data for training the parser.

Naturally, having a component that expands the table schema means that we may end up with large schemas that the parser has to deal with, which will often involve a lot of irrelevant columns (partially because the schema expansion component does not peek at the question). This can result in increased latency which is not desirable in real-world systems. To this end, we introduce a *schema pruning* component that looks at both the expanded table schema and the question and decides which columns to prune before invoking the parser. It can be argued that this pruning is as hard as parsing itself, but there is evidence from other areas that it can indeed be helpful (e.g., vocabulary selection; Chen et al., 2019; Xu et al., 2021). As we shall show schema pruning can actually provide an additional boost in accuracy, depending on architecture of the underlying parser.

4.1 Schema Expansion

A domain developer first declares a set of *templates* that specify the ways in which different column types can interact (e.g., it specifies that given a typed `TimeSpan` column that contains two subfields, _1 and _2, the expression `TimeSpan._2 - TimeSpan._1` can be constructed that represents a duration), and the names for each such interaction (e.g., `"Duration"`).[3] The schema expansion component receives as input this set of templates along with the table schema and returns an expanded schema that includes additional columns generated by using all applicable templates. For our SQUALL experiments, we declared the templates shown in Table 2. Although these templates are somewhat tailored to this dataset, our main goal is to show that there is considerable room for improvement in this challenging generalization scenario, and that even a simple approach with minimal manual effort can result in significant gains.

4.2 Schema Pruning

We propose a simple schema pruning approach that is inspired by vocabulary selection methods in machine translation. Let us denote the input question

---

[2] An interesting future project idea would be to automatically expand schemas using pre-trained language models.

[3] Having a name that accurately reflects the meaning of the column operation results is desired, as semantic parsers are sensitive to column names for column matching.

Column : Type : Fields	Synthetic Column		Example	
	Column Name	Expression	Original Column Name(s)	Synthetic Column Name(s)
Expressions				
`x:TimeSpan:_1,_2`	`[x]` Duration	`x._2 - x._1`	Term	Term Duration
`x:Date,y:Date`	`[x & y]` Duration	`y - x`	Term Start; Term End	Term Duration
`x:Score:_1,_2`	`[x]` Difference	`x._2 - x._1`	Result	Result Difference
`x:Score:_1,_2`	`[x]` Sum	`x._2 + x._1`	Result	Result Sum
Accessors				
`x:TimeSpan:_1,_2`	`[x]` Start; `[x]` End	`x._1`; `x._2`	Term	Term Start; Term End
`x:Score:_1,_2`	Home `[x]`; Away `[x]`	`x._1`; `x._2`	Result	Home Result; Away Result
`x:Score:_1,_2,_3`	Win Record; Loss Record; Tie Record	`x._1`; `x._2`; `x._3`	Result	Win Record; Loss Record; Tie Record
`x:Score:_1,_2,_3`	First Round `[x]`; Second Round `[x]`; Total `[x]`	`x._1`; `x._2`; `x._3`	Score	First Round Score; Second Round Score; Total Score

Table 2: The templates we used for schema expansion over `TimeSpan`-, `Date`-, `Score`-valued columns, including column expressions and accessor operations. `x` and `y` denote columns in the original schema, `_1`, `_2`, and `_3` refer to tuple field accessors, `&` denotes overlapping column name tokens, and `;` is used as a column separator.

by q and the input column names after expansion by $c_1, \ldots, c_M$. We concatenate the question and the column names as `[CLS]` q `[SEP]` c_1 `[SEP]` `...` `[SEP]` c_M `[SEP]` and feed the resulting sequence to a BERT encoder (Devlin et al., 2019). We then define the embedding of each column, $\boldsymbol{c}_i$, as the final-layer representation of the last token of that column's name. Finally, we define the probability that a column should be kept as $p_i = \text{Softmax}\left(\text{MLP}(\boldsymbol{c}_i)\right)$. We train this model based on whether each column is used in the corresponding SQL program. At inference time, we need to choose a threshold on the predicted probabilities for deciding whether to prune a column or not. We assume a transductive setting and choose this threshold such that the ratio of pruned columns over the test set equals to the ratio of pruned columns over the train set plus a constant hyperparameter to account for fact that accuracy will likely be lower for the test set than the train set. Note that assuming a transductive setting is fine because in a real-world system we could be tuning this threshold based on the last t requests made to the model. While this is not equivalent, assuming a large enough t, we should be able to adapt this threshold using the same approach.

Negative Column Sampling. As is evident from Figure 2, we also introduce a negative column sampling component. This is because we train our pruning model on the same data that we use to train the underlying parser (aside from the modified table schemas) and thus the pruning model can become good at pruning all irrelevant columns over this dataset. This will result in the underlying parser being unable to handle situations where irrelevant columns are mistakenly left unpruned by the pruning model. To this end, during training we introduce some irrelevant columns to improve the robustness of the underlying parser. We found that making sure to always include at least 3 columns in the resulting schemas was sufficient and equivalent to randomly sampling 1 or 2 additional columns for each training example, and so that is what we did in our experiments.

5 Experiments

We performed experiments on the two proposed benchmarks (as well as the existing version of the SQUALL benchmark), using the two current state-of-the-art parser architectures presented in §2 in combination with our proposed schema expansion and pruning components.

5.1 Experimental Setup

As described in §3, our synthetic benchmark consists of three domains, *finance*, *sports* and *science*. We repeat our experiments once for each domain. For each repetition we test on one of the domains, while training on the other two. For SQUALL, we present results on our repartitioned split from §3.2. For both datasets, we also include results for three i.i.d. splits. In each experiment, we compare four different configurations for the parsers:

1. Base: The underlying parser which can be either SEQ2SEQ or SMBOP.
2. Base + P: Base while also using schema pruning.
3. Base + E: Base while also using schema expansion.
4. Base + P + E: Base while also using both schema expansion and schema pruning.

We repeat each experiment three times using different random seeds and report mean *exact match accuracy* (i.e., fraction of examples where the predicted SQL queries exactly match the gold queries), and standard error for this mean.

Note that for SQUALL, researchers often also report *execution accuracy*, which measures the fraction of examples for which executing the predicted SQL queries results in the correct answer to the input question. However, we found that for 7% of the examples that are representative of out-of-domain generalization, executing the gold SQL queries does not yield the correct answer (e.g., in cases where the correct answer is a sub-string of a cell value). Therefore we chose to only report exact match accuracy in our experiments.

Table 3: Mean accuracy and standard error for 3 experiment runs, computed over multiple different splits for each dataset. The best results in each row are shown in **bold red font**. Note that, when compared with the Base model, all gains statistically significant. + P stands for using the schema pruning model and + E for the schema expansion model.

5.2 Results

Synthetic Benchmark Results. Our results for this benchmark are presented in the top part of Table 3. A first observation is that performance on the i.i.d. split for the baseline parsers is significantly better than on the domain-based splits. Interestingly, our expansion and pruning components still provide a significant boost over baseline performance in this setting (up to 43.7% absolute accuracy / 83.2% relative). However, the baseline parsers are practically unusable in the domain-based splits. In this case, our approach provides a very significant accuracy gain, rendering them useful (*up to 55.0% absolute / 327.4% relative*).

SQUALL Benchmark Results. Our results for this benchmark are presented in the bottom part of Table 3. Similar to the synthetic benchmark, we observe that both parsers perform reasonably well on the i.i.d. split, but significantly underperform in our repartitioned benchmark. This is consistent with earlier observations by Suhr et al. (2020) and Lee et al. (2021). Furthermore, we observe that our expansion component helps boost the accuracy of both parsers significantly (up to 5.1% absolute / 13.8% relative) and the pruning component provides some small further improvements on top of that. However, we notice that the pruning component is not as helpful for SMBOP as it is for SEQ2SEQ, which we provide detailed analysis in §5.4. Drilling down a bit further, we observe that most gains are due to the data categories we defined in §3.2. Perhaps most importantly, we get a *47.0% absolute accuracy gain (1,468.8% relative)* for SMBOP on the "`Date` Expressions" category alone. This can be largely attributed to our schema expansion component, where by incorporating prior domain knowledge we are effectively reducing the original column operations problem to a column matching problem, which is significantly easier. As a result, we get significant improvements on both "Expression" data categories. We do not observe the same for "Accessor" categories, which we address in the following section.

5.3 When is Schema Expansion Helpful?

From Table 3, schema expansion does not seem to help much for "Accessor" expressions (i.e., Base + P performs as well as or slightly better than Base + E + P on those categories). In order to further understand the contribution of schema expansion, we conducted an ablation study where we compare the proposed Base + P + E with three more approaches: (1) E Expressions: the schema expansion component only uses "Expression" templates, (2) E Accessors: the schema expansion component only uses "Accessor" templates, (3) P Oracle: the schema pruning model is replaced with an oracle model that always only keeps the columns that are used in the gold SQL queries (so the parser only has to figure out how to use them, rather than also figuring out which ones to use). Note that (3) will be discussed in the following section. We present the results for this ablation study in Table 4. We observe that expanding "Expressions" but not "Accessors" boosts performance on the "Expressions" categories, and similarly for "Accessors". More importantly though we see that using either one alone performs worse than using both types of expansion, indicating that they both provide value and that they work well together.

5.4 When is Schema Pruning Helpful?

It is evident from Table 3 that schema pruning is useful both on its own (i.e., Base + P), but also on top of schema expansion (i.e., Base + E + P). For SMBOP, we observe that Base + P is more or less on par with Base. Though this may seem inconsistent with the SEQ2SEQ results at first, it is not actually surprising because SMBOP keeps the most relevant columns in the beam during bottom-up decoding, and thus it is implicitly already using a schema pruning component. Furthermore, we observe that schema pruning is especially useful on top of schema expansion for the column operation data categories ("Expressions" and "Accessors"). This is because in the corresponding examples we end up with a significantly larger number of expanded columns that labeled as negatives when training the pruning model.

Dataset Split	Seq2Seq				SmBop			
	Base + E + P	E Accessors	E Expressions	P Oracle	Base + E + P	E Accessors	E Expressions	P Oracle

Table 4: Mean accuracy and standard error for 3 runs of our ablation studies on SQUALL repartitioning split for domain generalization, with the best results in each row colored **red**.

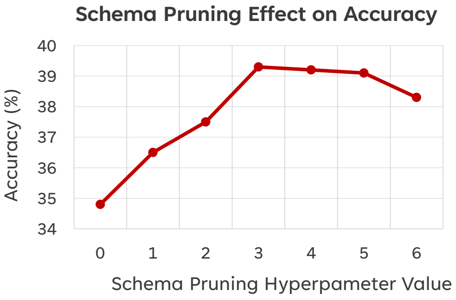

Figure 3: Accuracy (%) while varying the schema pruning model hyperparameter of §4. Pruning more than necessary has a significant negative impact on accuracy, while pruning less does not.

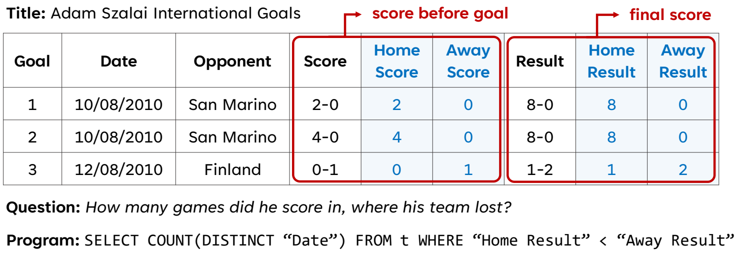

Title: Adam Szalai International Goals

Goal	Date	Opponent	Score	Home Score	Away Score	Result	Home Result	Away Result
1	10/08/2010	San Marino	2-0	2	0	8-0	8	0
2	10/08/2010	San Marino	4-0	4	0	8-0	8	0
3	12/08/2010	Finland	0-1	0	1	1-2	1	2

Question: *How many games did he score in, where his team lost?*

Program: `SELECT COUNT(DISTINCT “Date”) FROM t WHERE “Home Result” < “Away Result”`

Figure 4: Example that showcases some of the challenges that are not addressed by our approach, but which are accounted for in the evaluation benchmarks that we propose. In this case, the `"Score"` and `"Result"` columns have domain-specific semantics that are hard for the model to learn, and the question also depends on the title of the table, which current models do not take into account.

Schema pruning then filters most of these irrelevant columns before training the underlying parser, resulting in a more robust training procedure. Finally, in Table 4 we observe that P Oracle performs really well, indicating that investing in a good schema pruning model would be meaningful for improving generalization performance.

Schema Pruning Decision Threshold. As discussed in §4, the proposed schema pruning component requires setting a decision threshold hyperparameter. We already described the way we do this in §4, but it is also worth analyzing the impact of this decision on the overall parser accuracy. This is because, intuitively we expect that too aggressive pruning will likely cause cascading errors, while too conservative pruning would not be very effective and end up being equivalent to not using any pruning at all. To this end, we conducted a study for how the parser accuracy varies as a function of the schema pruning model hyperparameter which was discussed in §4. We performed this experiment using the SEQ2SEQ model which is more affected by the pruning component, over our repartitioned SQUALL benchmark. The results are shown in Figure 3. It is evident that aggressive pruning has a more significant negative impact on accuracy then conservative pruning.

5.5 Limitations

The proposed method is of course not without any limitations and in this section we would like to put attention on some of them. While schema expansion does help significantly when tackling out-of-domain generalization on column operations, there are a lot of cases that it cannot directly handle as currently designed. For example, consider the question-table pair shown in Figure 4. In this case the original table contains a `"Score"` column and a `"Result"` column. The interpretation of these columns is very domain-specific and in this case, `"Score"` refers to the score in a game right before the player of that row scored a goal, while `"Result"` refers to the final score of the game. Our schema expansion component cannot help with resolving distinctions of this kind. Arguably, one might say this is a challenge inherently related to column matching, but putting details aside, our approach coupled with the proposed benchmarks does help show that column operations pose a significant challenge for existing text-to-SQL parsers, and this paper provides a reference point that future work can build upon. Also, note that while constructing expansion templates requires some effort and may initially seem like a limitation of our approach, we have shown that this effort can be small relative to the amount of training data that would need to be annotated otherwise.

6 Conclusion

In this paper, we introduced and focused on *column operations*, an important challenge related to out-of-domain generalization for text-to-SQL parsing. We proposed two new evaluation benchmarks—one based on a new synthetic dataset and one based on a repartitioning of the SQUALL dataset—and showed that current state-of-the-art parsers significantly underperform when it comes to this form of generalization. We then proposed a simple way to incorporate prior domain knowledge to the parser via a new component called *schema expansion* that allows us to reduce the column operations challenge to column matching; an arguably easier challenge. We also introduced a *schema pruning* component allowing us to scale schema expansion, and showed that when paired together, these two components can boost the performance of existing text-to-SQL parsers by a significant amount (up to 13.8% relative accuracy gain / 5.1% absolute in our experiments). Through column expansion, we created a new table schema that is more friendly to downstream parsers. Our work uses heuristics based schema expansion and works well when limited to columns that have specified types (e.g., scores or timespans), but our synthetic experiments suggest much larger potential on this problem. We hope this work could motivate future research on creating a parser-friendly table ontology. Future work could explore learning approaches that use models to automatically expand any table schema, for example, by showing appropriate prompts to ask pre-trained language models to tackle it (Brown et al., 2020; Petroni et al., 2019).

Acknowledgments

We thank the anonymous reviewers for their helpful comments, Jason Eisner for his detailed feedback and suggestions on an early draft of the paper, and Jacob Andreas, Ziyu Yao, Yuchen Zhang, and Sam Thomson for helpful discussions.

Abstract

Paraphrase identification involves identifying whether a pair of sentences express the same or similar meanings. While cross-encoders have achieved high performances across several benchmarks, bi-encoders such as SBERT have been widely applied to sentence pair tasks. They exhibit substantially lower computation complexity and are better suited to symmetric tasks. In this work, we adopt a bi-encoder approach to the paraphrase identification task, and investigate the impact of explicitly incorporating predicate-argument information into SBERT through weighted aggregation. Experiments on six paraphrase identification datasets demonstrate that, with a minimal increase in parameters, the proposed model is able to outperform SBERT/SRoBERTa significantly. Further, ablation studies reveal that the predicate-argument based component plays a significant role in the performance gain.

1 Introduction

Paraphrases are sentences that express the same or similar meanings with different wording (Bhagat and Hovy, 2013). Paraphrase pairs are either fully or largely semantically equivalent. For example:

a) *Marriage equality law passed in Rhode Island*

b) *Rhode Island becomes the 10th state to enact marriage equality*

It is generally considered to be a symmetric task where the paraphrase relation holds in both directions (Bhagat and Hovy, 2013; Yang et al., 2019).

Since word order and sentence structure are crucial in determining sentence meaning, effective paraphrase models must be structure-aware and word order sensitive. In light of this, paraphrase datasets have been created that are specifically designed to encourage models to consider structural differences (Xu et al., 2015; Zhang et al., 2019b). For example, PIT2015 (Xu et al., 2015) consists of paraphrase pairs that are lexically diverse and non-paraphrase pairs that are lexically similar but semantically dissimilar.

There are generally two pre-trained based approaches for sentence pair tasks such as paraphrase identification. The first is the cross-encoder approach, which involves concatenating the two input sentences and performing full-attention over the input. The second is the bi-encoder approach, which adopts a conjoined twin network structure and maps each sentence onto separate representations, which can then be compared using similarity measures such as cosine. Though typical cross-encoders like BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019b) have set state-of-the-art performance on various sentence pair tasks (Zhang et al., 2021; Xia et al., 2021), they still face challenges from both extreme computational overhead for many use cases (Reimers and Gurevych, 2019; Thakur et al., 2021) and inconsistent predictions (ranging from 2.66% to 8.46% depending on specific datasets) when dealing with symmetric tasks (Chen et al., 2020).

In contrast, a bi-encoder approach such as Sentence-BERT (SBERT) (Reimers and Gurevych, 2019) encodes sentences separately and generates high-quality embeddings for each of them. This architecture enables sentence embeddings to be pre-computed, supporting efficient indexing and comparison between different sequences. Due to the nature of bi-encoders, the symmetry property will be preserved as long as no asymmetry is introduced in subsequent layers. These properties make bi-encoders appealing for the paraphrase identification task. Accordingly, here, we focus on bi-encoders rather than cross-encoders.

One downside of SBERT is that it only adopts a

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 5579 - 5589
May 22-27, 2022

very simple strategy, which is mean-pooling over all tokens, to generate sentence embeddings. As previously discussed, models should ideally be sensitive to any structural differences between two sentences. Relational Graph Convolutional Networks (RGCNs) (Schlichtkrull et al., 2018) have been used to introduce structural information (e.g. dependency/semantic parse trees) into SBERT and improvements have been reported on unsupervised similarity comparison tasks (Peng et al., 2021). One drawback of RGCNs is the size of the parameter space. For example, a single-layer RGCN can involve more than 30 million parameters. Furthermore, as we will demonstrate, the performance gain on different paraphrase identification datasets is not consistent.

An important aspect of sentence meaning concerns its predicate-argument structure. This has been utilised to generate paraphrases (Kozlowski et al., 2003) and to compare sentence meanings (Shan et al., 2009). Inspired by the Self-Explain model (Sun et al., 2020) which uses a span-based framework to generate sentence embeddings, we propose a method that effectively introduces sentence structure into SBERT via the aggregation of predicate-argument spans. This self-attention based aggregation allows us to gain benefits with minimal increased cost in terms of additional parameters. Empirical results indicate that the proposed model yields improvements on six benchmarks for paraphrase identification. Upon closer investigation, we find the predicate-argument span (PAS) component plays a crucial role in the performance gains and can be easily generalised to other models.

2 Related Work

2.1 Paraphrase Identification

The problem of paraphrase identification has been explored now for several decades (Mihalcea et al., 2006; Kozareva and Montoyo, 2006). Prior to the emergence of pre-trained models, bi-encoder structures were widely used. For example, Mueller and Thyagarajan (2016) applied LSTM in a twin architecture with tied weights and used Manhattan distance to compute similarity. InferSent (Conneau et al., 2017) exploited BiLSTM in a similar twin structure with a fully-connected layer for classification over interacted sentence embeddings. Although their model was mainly proposed for transfer learning, experiments showed that it achieves good performance when directly trained on in-domain data.

Some bi-encoders do not generate single-vector sentence embeddings and allow direct comparisons between the words in the two sentences. Pang et al. (2016) proposed MatchPyramid where interaction matrix is constructed, and convolutional networks were used to extract features for final classification. PMWI (He and Lin, 2016) introduced more fine-grained comparisons between words to better dissect the meaning difference. ESIM (Chen et al., 2017) further utilised BiLSTM to bring contextualised token representations and allow rich interactions between tokens. Researchers have further improved these models by incorporating context and structure information (Liu et al., 2019a), as well as character-level information (Lan and Xu, 2018).

After the emergence of pre-trained models, cross-encoders like BERT and RoBERTa have achieved state-of-the-art performance on various sentence pair tasks including paraphrase identification. Zhang et al. (2019a) introduced pairwise word interaction mechanism into BERT. Zhang et al. (2021) improved BERT on paraphrase tasks by using CNNs to gather local information and an auxiliary task to further bring in semantic relation information. Xia et al. (2021) injected similarity matrices into BERT's attention mechanism. Though improved performance can be obtained, cross-encoders have known drawbacks. In particular, Reimers and Gurevych (2019) showed the extreme computation overhead of cross-encoders, and Chen et al. (2020) demonstrated that cross-encoders often give inconsistent predictions when reversing the input sentence order. Based on these factors, bi-encoders are often preferred for the paraphrase identification task.

2.2 Sentence Representation with Structures

Though pre-trained models like BERT seem to encode certain structures in their contextualised representations, open questions remain about how to better utilise such information (Hewitt and Manning, 2019; Clark et al., 2019) and how useful the hidden structure is compared to externally provided sentence structures (Glavaš and Vulić, 2021; Dai et al., 2021). Recent improvements are also observed on various natural language understanding tasks by incorporating structural information into pre-trained models. SentiBERT proposed by Yin et al. (2020)

incorporates constituency parse tree into BERT for sentiment analysis. Xu and Yang (2019) model each sentence as a directed dependency graph by using RGCN, and achieve improvements on pronoun resolution. Zhang et al. (2020) propose a semantics-aware BERT (SemBERT) model by further encoding semantic labels with BERT using a GRU. RGCNs have also been used by Wu et al. (2021) to introduce semantic information into RoBERTa, and achieved consistent improvements when fine-tuned on problem-specific datasets. Peng et al. (2021) propose a SBERT-RGCN model where structural information is explicitly encoded into SBERT in a similar way, achieving improvements on unsupervised sentence similarity comparison tasks. Similar efforts can be seen where researchers try to provide syntax information via self-attention mechanism (Bai et al., 2021; Li et al., 2020). Self-Explain model proposed by Sun et al. (2020) focuses on continuous text spans. It generates sentence embeddings by taking the weighted sum over all possible continuous text spans rather than individual tokens in the sentence. Though, Self-Explain achieves improvements over SentiBERT and SemBERT on sentiment analysis and language inference tasks, the continuous span strategy only captures linear structure and not differences in linguistic structure. In this paper, we draw inspiration from it, designing a similar span-based component to incorporate predicate-argument spans.

3 Model

Our proposed model adopts the same conjoined twin architecture as SBERT and turns focus to the predicate-argument structure of the given sentence. As depicted in Figure 1, the model consists of different components:

BERT: Each sentence is first fed into the pre-trained BERT-base model to produce both a sentence representation, by applying mean-pooling over all token representations from the last hidden layer, and an original contextualised sequence-length token representation, which is used to derive predicate-argument span representations.

Predicate Argument Spans (PAS): We use AllenNLP (Gardner et al., 2018) with its BERT-based semantic role labelling (SRL) tagger to obtain predicates and relevant arguments for all input sentences. We group the predicate and its arguments together to generate predicate-argument spans. The initial position in the sentence determines their position in the span. An example of such spans is shown below:

He slices tomatoes in the kitchen

From this sentence, the predicate is the verb *slices*, and the three arguments are (*he*, *tomatoes* and *in the kitchen*), involving the relations (*ARG0*, *ARG1* and *ARGM-LOC*), respectively. In this way, we form three predicate-argument spans and split them into individual words: (*He*, *slices*), (*slices*, *tomatoes*), (*slices*, *in*, *the*, *kitchen*). One sentence is likely to have multiple predicates, by adopting this strategy, we are able to obtain all potential predicate-argument spans in the given sentence. We further utilise these extracted spans to form a span-based sentence representation. If no predicate-argument structure can be found in the sentence, we directly use the representation after mean-pooling over all tokens as its sentence representation.

Aggregation: After obtaining all predicate-argument spans, we derive corresponding span representations by looking at BERT's token representations. In BERT/RoBERTa, tokenization yields sub-tokens, whereas in the created spans, we have an entire word token. To properly align them, we use the same tokenizer to break the original word into sub-tokens and represent it as a sequence of sub-tokens in the span if a sub-token exists. Given a predicate-argument span sequence $s = \{s_1, s_2, ..., s_N\}$ in the sentence, where N denotes the number of spans and every span s_i consists of tokens $\{x_1, ..., x_l\}$ that make up the span. For each span s_i, we obtain its dense vector representation h_i by taking mean-pooling over all tokens in it:

$$h_i = MeanPooling(x_1, .., x_l) \tag{1}$$

Therefore, the whole representation for span sequence s is represented as $h = \{h_1, h_2, ..., h_N\}$, where $h_i \in \mathbb{R}^D$.

Then, we aggregate information from all spans using a simple self-attentive mechanism. Following Sun et al. (2020), this is achieved by first assigning weights α_i to each span h_i and combining these representations using weighted sum:

$$\begin{aligned} o_i &= W \cdot h_i + b \\ \alpha_i &= \frac{exp(o_i)}{\sum_{j=1}^{N} exp(o_j)} \end{aligned} \tag{2}$$

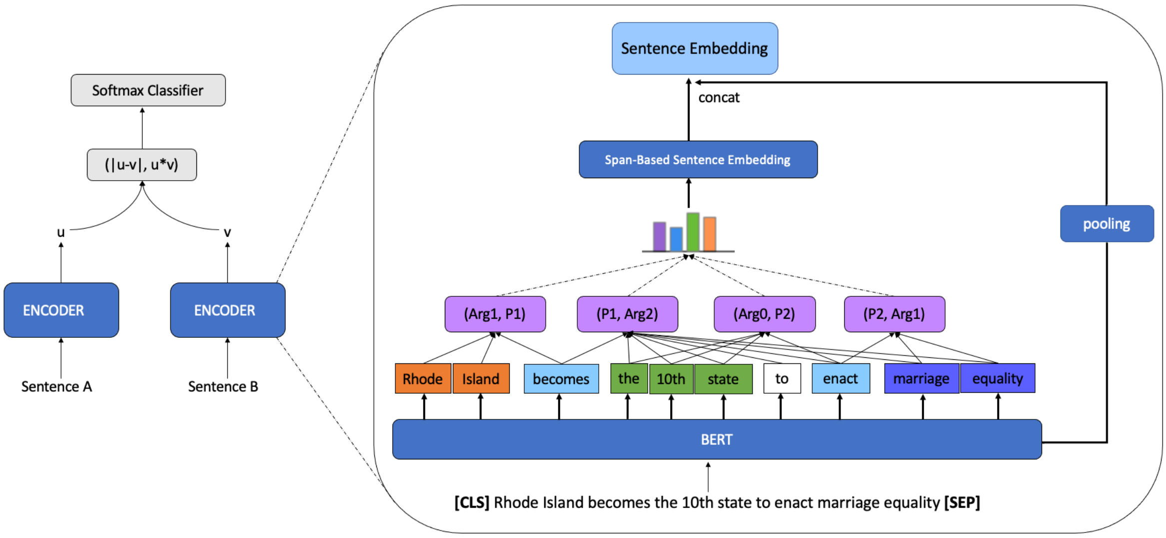

Figure 1: The proposed model in twin structure. All parameters are shared between two encoders. The final sentence representation is the concatenation of the mean-pooling based sentence representation and the span-based sentence representation.

where $W \in \mathbb{R}^{1\times D}$ and b are learnable parameters. The span-based sentence representation $\hat{h}$ from the aggregation component is the weighted average of all predicate-argument span representations:

$$\hat{h} = \sum_{i=1}^{N} \alpha_i \cdot h_i \tag{3}$$

The weights are learned during training. This gives the model flexibility to decide the best combination method on its own. The combination of self-attentive mechanism and predicate-argument spans allow us to construct structure-aware sentence embeddings without introducing a large number of parameters.

Connect BERT and Aggregation: The final sentence representation is the concatenation of both BERT mean-pooling based sentence representation and the span-based sentence representation. Sentence embeddings of the given sentence-pair are then combined using vector operations before passing to the final classifier for training as shown in Figure 1. To combine the embeddings, we use the concatenation of the element-wise multiplication $u * v$ and the absolute element-wise difference $|u-v|$. This is different to the typical concatenation strategy used with SBERT/SRoBERTa (Reimers and Gurevych, 2019) which introduces asymmetry into the task by using (u, v, |u-v|). In initial experiments, we tested the prediction consistency of SBERT on paraphrase tasks and found that, across different datasets, between 2.78% and 9.16% of test predictions change when the sentence order is reversed. Furthermore, here, we find that SBERT performs worse on paraphrase tasks with (u, v, |u-v|) compared to (|u-v|, $u * v$). Results are given in Table 5 and discussed in Section 5.1.

Finally, we note that in this twin structure, all parameters are shared and are updated accordingly. Cross-entropy loss is used for optimisation.

4 Experiments

We compare our model with SBERT, SRoBERTa[1] and the SBERT-RGCN (Peng et al., 2021) which utilises RGCN to incorporate structures into SBERT with an introduction of 32 million extra parameters[2]. The original sentence-pair aggregation strategy of these models is (u, v, |u-v|). We modify this to (|u-v|, $u * v$) as discussed in Section 3, but we retain the original notation. We adopt their structures and directly fine-tune the whole model on downstream tasks from the original BERT/RoBERTa checkpoints. We considered two strategies to apply SBERT on classification inference. One involved finding the optimal similarity threshold on the development set and then applying it on the test set, while the other involved directly using the trained classifier. In this paper,

[2] SBERT-RGCN tried both dependency and semantic parse trees. In the following experiments, we use semantic parse trees that that capture predicate-argument structures.

we adopted the latter approach since we find it gave improved and more robust results.

4.1 Datasets

We evaluate our model on six binary paraphrase identification benchmarks. The statistics of these datasets are listed in Table 1. Below we give some basic descriptions:

- **Microsoft Research Paraphrase Corpus (MSRP)**: A corpus of sentence pairs obtained by clustering news articles with an SVM classifier and human annotations (Dolan and Brockett, 2005). It has 4,076 train data and 1,725 test data. In this paper, we split 10% of training data as the validation set according to GLUE (Wang et al., 2019) standardised splits.
- **TwitterURL**: To better study the realistic language usage, Lan et al. (2017) proposed the TwitterURL corpus where sentence pairs in the dataset are collected from tweets that share the same URL of news articles.
- **PIT2015**: The corpus is derived from Twitter's trending topic data, containing 18,763 sentence pairs on more than 400 distinct topics (Xu et al., 2015). Given we are dealing with binary classification, we discard debatable sentence pairs according to its guideline and obtain 16,510 sentence pairs in total. This dataset contains paraphrase pairs that are lexically diverse and non-paraphrase pairs that are lexically similar, but semantically dissimilar. To capture these properties, models are assumed to be structure-aware.
- **Quora Question Pairs (QQP)**: The Quora Question Pairs dataset is a collection of potential duplicate question pairs from the QA website Quora.com (Iyer et al., 2017). In this paper, we adopt the same split strategy as in Wang et al. (2017).
- **PAWS_QQP**: QQP is criticised for lacking negative examples with high lexical overlapping. Models trained on QQP tend to mark any sentence pairs with a high word overlap as paraphrases despite clear clashes in meaning. In light of these factors, Zhang et al. (2019b) proposed a new paraphrase identification dataset which has extremely high lexical overlap by applying word scrambling and back translation to sentences in QQP.

Datasets	Train	Dev	Test
MSRP	3,668	408	1,725
TwitterURL	37,976	4,224	9,334
PIT2015	11,530	4,142	838
QQP	384,348	10,000	10,000
PAWS_QQP	11,986	8,000	677
PAWS_Wiki	49,401	8,000	8,000

Table 1: Statistics of all six benchmarks used in this work.

- **PAWS_Wiki**: Similar to PAWS_QQP, Zhang et al. (2019b) applied the same technique on sentences obtained from Wikipedia articles to construct sentence pairs. Both PAWS datasets aim to measure sensitivity of models on word order and sentence structure.

Due to the lack of development set for PAWS_QQP, we use PAWS_Wiki's development set for early stopping since they are constructed in the same way. It is worth noting that both PIT2015 and PAWS_QQP datasets have relatively small test sets compared to others.

4.2 Training Details

Following the SBERT training protocol, we train all models with a batch-size of 16. We tune the learning rate in the range of (1e-5, 2e-5, 5e-5) with Adam optimizer and a linear learning rate warm-up over 10% of the training data. All models are trained for four epochs and use the development set for early stopping with a patience of 5. The evaluation step depends on actual tasks but roughly we evaluate them on the development set twice each epoch. The maximum sequence length is set to be 128. All experiments are conducted on NVIDIA Titan V GPUs.

4.3 Evaluation

The main experiment results are summarised in Table 2. We report the averaged F1 score of positive class with standard error. In the table, we see that the proposed model consistently outperforms its SBERT and SRoBERTa versions on 5 paraphrase identification tasks and show competitive, but not statistically significantly different results on QQP. As also revealed by Zhang et al. (2019b), negative examples in QQP often have low lexical overlap, and models trained on it tend to mark any sentence pairs with high word overlap as paraphrases. We

PAS+SBERT	+3840
SBERT-RGCN	+ 32M

Table 3: The parameter comparison between different models.

reason that the QQP task is relatively easy and does not require much structural information to achieve high scores. For tasks like PAWS_QQP and PIT2015 where structures are more important, the performance gap is more apparent. Furthermore, despite bringing in more than 30 million parameters and explicitly encoding sentence structures with a complex model, SBERT-RGCN does not significantly outperform SBERT on most of these tasks (excluding PIT2015) and underperforms our proposed model.

In summary, the proposed model shows improved performances on five out of six paraphrase tasks, demonstrating the advantages of bringing in the predicate-argument structure. Moreover, when we combine PAS with SRoBERTa, we get similar performance gains, proving the generalisation ability of our component. Similarly in Reimers and Gurevych (2019), we only observe minor differences by replacing SBERT with SRoBERTa.

The number of parameters for different approaches are shown in Table 3. We note that compared to SBERT, our proposed model introduces 3,840 additional parameters, and if we only consider the span-based component, only 768 additional parameters are introduced. In comparison, SBERT-RGCN brings in more than 32 million parameters.

5 Analysis

In order to better understand how the performance gain is achieved, we have carried out several experiments to investigate different aspects of the proposed model. The following experiments are conducted only with SBERT, since we would expect similar results with SRoBERTa.

5.1 Ablation Study

Our proposed model is made of different components and so it is important to dissect the impact of each component so as to explain the improved performance. Given that the final sentence representation is the concatenation of both mean-pooling based BERT representation and the weighted sum of span representations, we first assess their performances individually on six datasets. Furthermore, it is necessary to assess the impact of adopting the weighted sum strategy when we derive span-based sentence representations. We experimented with simple averaging over all spans and compared it with the weighted sum where the model learns to combine different spans.

The ablation experiment results are shown in Table 4. The SBERT-only component appears to perform the poorest, and the complete model achieves the highest performance on five out of six tasks. By only using the span-based sentence representation, we are able to achieve significant improvements over SBERT on most of these tasks. The improvements are more substantial when concatenating with SBERT sentence representations. We observe considerable performance decreases on most tasks when switching from weighted sum to simple averaging, which further verifies the benefits of adopting learnable weights.

The original asymmetric sentence aggregation strategy (u, v, |u-v|) of SBERT assumes an ordering of the sentences by concatenating two individual

sentence embeddings. $u * v$ has been widely used elsewhere (Conneau et al., 2017; Cer et al., 2018) and we found that concatenating this with |u-v| gave the best performance on all tasks. The results are summarised in Table 5. Therefore, we use (|u-v|, $u * v$) as our concatenation method for all of our other experiments.

5.2 Span Strategy Analysis

The impact of incorporating predicate-argument spans into SBERT in terms of the performance on various paraphrase identification tasks has been investigated in the above experiments. We now address the question of whether it is the use of specifically predicate-argument based spans that is critical, or whether this is simply a result of the fact that we are benefiting from the use of representations based on spans rather than all tokens. To verify this, we further conduct experiments with different span strategies. We pick three paraphrase identification datasets for this purpose (MSRP, PAWS_QQP and PIT2015) since performance gaps between PAS+SBERT and SBERT are more apparent in previous experiments.

Here we experiment with two other span strategies. The first, inspired by the Self-Explain model (Sun et al., 2020), is the continuous random span, where instead of following the predicate-argument structure, we randomly sample continuous word sequences from the sentence to build a span. The length of the sampled spans is arbitrary. To make a fair comparison, the number of sampled spans is the same as that of the predicate-argument spans in the sentence. The other one is random span, where we do not necessarily sample continuous words, but allow word leaps from one to another. In this strategy, we have the opportunity to get both continuous and discontinuous word sequences to form spans, which better matches the scenario of PAS. The only difference between these two strategies and PAS is the words in the span.

We also experiment with a bi-encoder approach more directly based on the Self-Explain cross-encoder model (Sun et al., 2020). This model extracts all possible continuous text spans and obtains span representations by taking the first and last token in the span, passing them through a complex mapping function. Unlike our PAS model, this

model brings in 2.36 million more parameters compared to SBERT.

Table 6 shows the results. In order to focus on the impact of different span strategies, we only use the PAS component and do not concatenate it with SBERT sentence representations in this experiment. As shown in the table, the PAS-based model outperforms the Self-Explain inspired bi-encoder model and achieves the best performance among all other span-based models. The continuous random span and the random span model have comparable performances with SBERT. This is expected because they do not introduce linguistically-meaningful structures and the impact of contextualisation makes them similar to SBERT despite the absence of some tokens. Despite introducing 2.36 million more parameters, the Self-Explain inspired bi-encoder model does not show consistent improvements over SBERT on these datasets, which further suggests the importance of the predicate-argument structure in this paraphrase identification task.

5.3 Training Size Analysis

In order to examine the stability of our model and the impact of the predicate-argument structure when different sizes of training data are available, we conduct experiments with different training data scales. We randomly sample from 10% to 100% data (10%, 30%, 60%, 100%) from the training set as training data. We show the results in Figure 2. In spite of limited increased parameters, the proposed model appears to yield consistent improvements across different training scales. We also note that, whilst our proposed model performs comparably to SBERT on QQP when trained with the complete data-set, we can see that when only a small proportion of training data (e.g. 10%, 30%) is available, our model demonstrates improvements over SBERT. Thus the introduction of predicate-argument structures may be more beneficial with limited annotated training data.

6 Conclusion

In this work, we propose a method which effectively introduces sentence structure to a sentence embedding via the aggregation of predicate-argument spans (PAS). Experiments with SBERT and SRoBERTa show that such method brings improvements on six paraphrase identification tasks. Compared to models based on RGCNs, our method obtains more consistent benefits with minimal increased cost in terms of numbers of parameters. Upon closer investigation, we show that the PAS component and its learnable weights play a substantial impact in the performance gain. This PAS component, as demonstrated with SRoBERTa, can be easily extended to other models that require the generation of sentence embeddings. Our future work will include enhancing the structural difference between sentences by taking use of the argument tag information.

Abstract

NER model has achieved promising performance on standard NER benchmarks. However, recent studies show that previous approaches may over-rely on entity mention information, resulting in poor performance on out-of-vocabulary (OOV) entity recognition. In this work, we propose MINER, a novel NER learning framework, to remedy this issue from an information-theoretic perspective. The proposed approach contains two mutual information-based training objectives: i) generalizing information maximization, which enhances representation via deep understanding of context and entity surface forms; ii) superfluous information minimization, which discourages representation from rote memorizing entity names or exploiting biased cues in data. Experiments on various settings and datasets demonstrate that it achieves better performance in predicting OOV entities.

	Precision			Recall		
	InDict	OutDict	**Diff**	InDict	OutDict	**Diff**
PER	88.03	75.40	14%	92.90	85.20	8%
ORG	73.51	72.77	1%	81.93	76.56	7%
GPE	79.55	78.21	2%	85.37	77.22	10%
FAC	65.91	65.67	0%	86.05	65.67	24%
ALL	83.37	71.97	**12%**	89.08	79.11	**11%**

Table 1: The comparison between the in-dictionary and out-of-dictionary parts of the CoNLL 2003 baseline (Lin et al., 2020), which was tested on Bert-CRF. It is obvious that the performance gap between InDict and OutDict is significantly large.

1 Introduction

Named Entity Recognition (NER) aims to identify and classify entity mentions from unstructured text, e.g., extracting location mention "Berlin" from the sentence "Berlin is wonderful in the winter". NER is a key component in information retrieval (Tan et al., 2021), question answering (Min et al., 2021), dialog systems (Wang et al., 2020), etc. Traditional NER models are feature-engineering and machine learning based (Zhou and Su, 2002; Takeuchi and Collier, 2002; Agerri and Rigau, 2016). Benefiting from the development of deep learning, neural-network-based NER models have achieved state-of-the-art results on several public benchmarks (Lample et al., 2016; Peters et al., 2018; Devlin et al., 2018; Yamada et al., 2020; Yan et al., 2021).

Recent studies (Lin et al., 2020; Agarwal et al., 2021) show that, context does influence predictions of NER models, but the main factor driving high performance is learning the named tokens themselves. Consequently, NER models underperform when predicting entities that have not been seen during training (Fu et al., 2020; Lin et al., 2020), which is referred to as an Out-of-Vocabulary (OOV) problem.

There are three classical strategies to alleviate the OOV problem: external knowledge, OOV word embedding, and contextualized embedding. The first one is to introduce additional features, e.g., entity lexicons (Zhang and Yang, 2018), part-of-speech tags (Li et al., 2018), which alleviates the model's dependence on word embeddings. However, the external knowledge is not always easy to obtain. The second strategy is to get a better OOV word embedding (Peng et al., 2019; Fukuda et al., 2020). The strategy is learning a static OOV embedding representation, but not directly utilizing the context. Last one is fine-tune pre-trained models, e.g., ELMo (Peters et al., 2018), BERT (Devlin et al., 2018), which provide contextualized word representations. Unfortunately, Agarwal et al. (2021) shows that the higher performance of pre-trained models could be the results of learning the subword structure better.

How do we make the model focus on contextual

information to tackle the OOV problem? Motivated by the information bottleneck principle (Tishby et al., 2000), we propose a novel learning framework - Mutual Information based Named Entity Recognition (MINER). The proposed method provides an information-theoretic perspective to the OOV problem by training an encoder to minimize task-irrelevant nuisances while keeping predictive information.

Specifically, MINER contains two mutual information based learning objectives: i) generalizing information maximization, which aims to maximize the mutual information between representations and well-generalizing features, i.e., context and entity surface forms; ii) superfluous information minimization, which prevents the model from rote memorizing the entity names or exploiting biased cues via eliminating entity name information. *Our codes*[1] are publicly available.

Our main contributions are summarized as follows:

1. We propose a novel learning framework, i.e., MINER, from an information theory perspective, aiming to improve the robustness of entity changes by eliminating entity-specific and maximizing well-generalizing information.

2. We show its effectiveness on several settings and benchmarks, and suggest that MINER is a reliable approach to better OOV entity recognition.

2 Background

In this section, we highlight the information bottleneck principle. Subsequently, the analysis of possible issues was provided when applying it to OOV entity recognition. Furthermore, we review related techniques in deriving our framework.

Information Bottleneck (IB) principle originated in information theory, and provides a theoretical framework for analyzing deep neural networks. It formulates the goal of representation learning as an information trade-off between predictive power and representation compression. Given the input dataset (X,Y), it seeks to learn the internal representation Z of some intermediate layers by:

$$L_{IB} = -I(Z;Y) + \beta * I(Z;X),$$

where I represents the mutual information(MI), a measure of the mutual dependence between the two variables. The trade-off between the two MI terms is controlled by the Lagrange multiplier β. A low loss indicates that representation Z does not keep too much information from X while still retaining enough information to predict Y.

Section 5 suggests that directly applying IB to NER can not bring obvious improvement. We argue that IB cannot guarantee well-generalizing representation.

On the one hand, it has been shown that it is challenging to find a trade-off between high compression and high predictive power (Tishby et al., 2000; Wang et al., 2019; Piran et al., 2020). When compressing task-irrelevant nuisances, however, useful information will inevitably be left out. On the other hand, it is unclear for the IB principle which parts of features are well-generalizing and which are not, as we usually train a classifier to solely maximize accuracy. Consequently, neural networks tend to use any accessible signal to do so (Ilyas et al., 2019), which is referred to as a *shortcut learning* problem (Geirhos et al., 2020). For training sets with limited size, it may be easier for neural networks to memorize entity names rather than to classify them by context and common entity features (Agarwal et al., 2021). In Section 4, we demonstrate how we extend IB to the NER task and address these issues.

3 Model Architecture

In recent years, NER systems have undergone a paradigm shift from sequence labeling, which formulates NER as a token-level tagging task (Chiu and Nichols, 2016; Akbik et al., 2018; Yan et al., 2019), to span prediction (SpanNER), which regards NER as a span-level classification task (Mengge et al., 2020; Yamada et al., 2020; Fu et al., 2021). We choose SpanNER as base architecture for two reasons:

1) SpanNER can yield the whole span representation, which can be directly used for optimize information. 2) Compared with sequence labeling, SpanNER does better in sentences with more OOV words (Fu et al., 2021).

Overall, SpanNER consists of three major modules: token representation layer, span representation layer, and span classification layer. Besides, our method inserts a bottleneck layer to the architecture for information optimization.

---

[1] https://github.com/BeyonderXX/MINER

3.1 Token Representation Layer

Let $X = \{x_1, x_2, \cdots, x_n\}$ represents the input sentence, thus, the token representation h_i is as follows:

$$u_1, \cdots, u_n = Embedding(x_1, \cdots, x_n) \quad (1)$$

$$h_1, \cdots, h_n = Encoder(u_1, \cdots, u_n) \quad (2)$$

where $Embedding()$ is the non-contextualized word embeddings, e.g., Glove (Pennington et al., 2014) or contextualized word embeddings, e.g., ELMo (Peters et al., 2018), BERT (Devlin et al., 2018). $Encoder()$ can be any network structures with context encoding function, e.g., LSTM (Hochreiter and Schmidhuber, 1997), CNN (LeCun et al., 1995), transformer (Vaswani et al., 2017), and so on.

3.2 Span Representation Layer

For all possible spans $S = \{s_1, s_2, \cdots, s_m\}$ of sentence X, we re-assign a label $y \in Y$ for each span. Take "Berlin is wonderful" as an example, its possible spans and labels are $\{(1,1),(1,2),(1,3),(2,2),(2,3),(3,3)\}$ and $\{LOC, O, O, O, O, O\}$, respectively.

Given the start index b_i and end index e_i, the representation of span s_i can be calculated by two parts: boundary embedding and span length embedding.

Boundary embedding: This part is calculated by concatenating the start and end tokens' representation $t_i^b = [h_{b_i}; h_{e_i}]$.

Span length embedding: In order to introduce the length feature, we additionally provide the length embedding t_i^l, which can be obtained by a learnable look-up table.

Finally, the span representation can be obtained as: $t_i = [t_i^b; t_i^l]$.

3.3 Information Bottleneck Layer

In order to optimize the information in the span representation, our method additionally adds an information bottleneck layer of the form:

$$p(z|t) = \mathcal{N}\left(z \mid f_e^{\mu}(t), f_e^{\Sigma}(t)\right) \quad (3)$$

where f_e is an MLP which outputs both the K-dimensional mean μ of z as well as the $K * K$ covariance matrix Σ. Then we can use the reparameterization trick ((Kingma and Welling, 2013)) to get the compressed representation z_i.

3.4 Span Classification Layer

Once the information bottleneck layer is finished, z_i is fed into the classifier to obtain the probability of its label y_i. Based on the probability, the basic loss function can be calculated as follows:

$$L_{base} = -\frac{score(z_i, y_i)}{\sum_{y' \in Y} score(z_i, y')}, \quad (4)$$

where $score()$ is a function that measures the compatibility between a specified label and a span representation:

$$score(z_i, y^k) = exp(z_i^T y^k), \quad (5)$$

where y^k is a learnable representation of class k.

Heuristic Decoding A heuristic decoding solution for the flat NER is provided to avoid the prediction of over-lapped spans. For those overlapped spans, we keep the span with the highest prediction probability and drop the others.

It's worth noting that our method is flexible and can be used with any other NER model based on span classification. In next section, we will introduce two additional objectives to tackle the OOV problem of NER.

4 MI-based objectives

Motivated by IB (Tishby et al., 2000; Federici et al., 2020), we can subdivide $I(X;Z)$ into two components by using the chain rule of mutual information(MI):

$$I(X;Z) = \underbrace{I(Y;Z)}_{predictive} + \underbrace{I(X;Z|Y)}_{superfluous}, \quad (6)$$

The first term determines how much information about Y is accessible from Z. While the second term, conditional mutual information term $I(X;Z|Y)$, denotes the information in Z that is not predictive of Y.

For NER, which parts of the information retrieved from input are useful and which are redundant?

From human intuition, **text context** should be the main predictive information for NER. For example, "The CEO of X resigned", the type of X in each of these contexts should always be "ORG". Besides, **entity mentions** also provide much information for entity recognition. For example, nearly all person names capitalize the first letter and follow the "firstName lastName" or "lastName

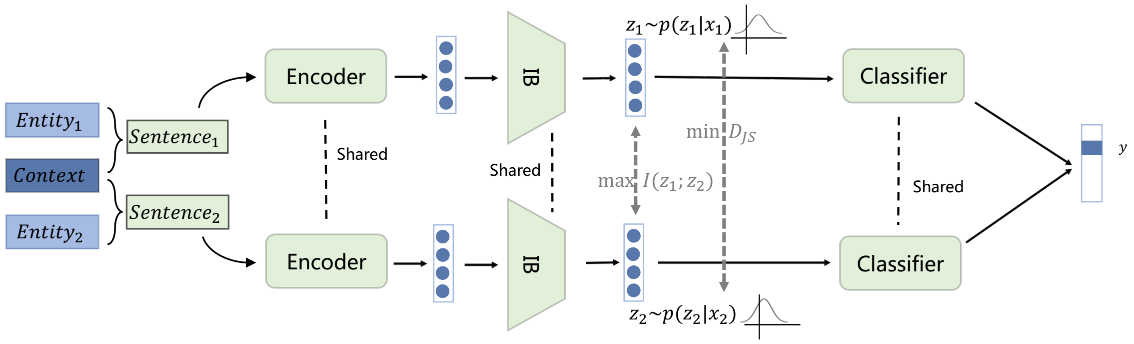

Figure 1: Visualization of MINER, where x_1 and x_2 share the same context and entity labels, while their entity words are different. z_1 and z_2 are compressed entity representations sampled by $p(z_1|x_1)$ and $p(z_2|x_2)$, respectively, which are implemented by information bottleneck(IB) layer. Our method add two additional learning objectives to basic architecture. The first one is to maximize the mutual information, i.e., $I(z_1; z_2)$, to enhance context information and entity surface form information of z_1 and z_2. The second objective is to minimize the Jensen-Shannon divergence, representing an upper bound of $I(x_1; z_1|x_2)$, aiming to eliminate task-irrelevant nuisances.

firstName" patterns. However, **entity name** is not a well-generalizing features. By simply memorizing the fact which span is an entity, it may be possible for it to fit the training set, but it is impossible to predict entities that have never been seen before.

We convert the targets of Eq. (6) into a form that is easier to solve via a contrastive strategy. Specifically, consider x_1 and x_2 are two contrastive samples of similar context, and contains different entity mentions of the same entity category, i.e., s_1 and s_2, respectively. Assuming both x_1 and x_2 are both **sufficient** for inferring label y. The mutual information between x_1 and z_1 can be factorized to two parts.

$$I(x_1; z_1) = \underbrace{I(z_1; x_2)}_{consistent} + \underbrace{I(x_1; z_1|x_2)}_{specific}, \tag{7}$$

where z_1 and z_2 are span representations of s_1 and s_2, respectively, $I(z_1; x_2)$ denotes the information that isn't entity-specific. And $I(x_1; z_1|x_2)$ represents the information in z_1 which is unique to x_1 but is not predictable by sentence x_2, i.e., entity-specific information.

Thus any representation z containing all information shared from both sentences would also contain the necessary label information, and sentence-specific information is superfluous. So Eq. (6) can be approximated by Eq. (7) by:

$$maximize\ I(z_1; y) \ \sim\ I(z_1; x_2), \tag{8}$$

$$minimize\ I(x_1; z_1|y) \ \sim\ I(x_1; z_1|x_2), \tag{9}$$

The target of Eq. (8) is defined as **generalizing information** maximization. We proved that $I(z_1; z_2)$ is a lower bound of $I(z_1; x_2)$(proof could be found in appendix 7). InfoNCE (Oord et al., 2018) was used as a lower bound on MI and can be used to approximate $I(z_1; z_2)$. Subsequently, it can be optimized by:

$$L_{gi} = -\mathbb{E}_p \left[g_w(z_1, z_2) - \mathbb{E}_{p'} \log \sum_{z'} \exp g_w(z_1, z') \right], \tag{10}$$

where $g_w(\cdot, \cdot)$ is a compatible score function approximated by a neural network, z_2 are the positive entity representations from the joint distribution p of original sample and corresponding generated sample, z' are the negative entity representations drawn from the joint distribution of the original sample and other samples.

The target of Eq. (9) is defined as **superfluous information** minimization. To restrict this term, we can minimize an upper bound of $I(x_1; z_1|x_2)$ (proofs could be found in appendix 7) as follows:

$$L_{si} = \mathbb{E}_{x_1, x_2} \mathbb{E}_{z_1, z_2} \left[D_{JS}[p_{z_1} || p_{z_2}] \right], \tag{11}$$

where D_{JS} means Jensen-Shannon divergence, p_{z_1} and p_{z_2} represent $p(z_1|x_1)$ and $p(z_2|x_2)$, respectively. In practice, Eq. (11) encourage z to be invariant to entity changes. The resulting Mutual Information based Named Entity Recognition model is visualized in Figure 1.

4.1 Contrastive sample generation

It is difficult to obtain samples with similar contexts but different entity words. We generate

Datasets	sents	entities	OOV Rate
WNUT2017	1286	947	1.00
TwitterNER	3257	3990	0.62
BioNER	3856	4344	0.77
Conll2003-Typos	2676	4130	0.71
Conll2003-OOV	3684	5648	0.96

Table 2: Number of OOV entities in the test sets.

contrastive samples by the mention replacement mechanism(Dai and Adel, 2020). For each mention in the sentence, we replace it by another mention from the original training set, which has the same entity type. The corresponding span label can be changed accordingly. For example, "LOC" mention "Berlin" in sentence "Berlin is wonderful in the winter" is replaced by "Iceland".

4.2 Training

Combine Eq. (4), (10), and (11), we can get the following objective function, which try to minimize:

$$L = L_{base} + \gamma * L_{gi} + \beta * L_{si}, \qquad (12)$$

where γ and β are the weights of the generalizing information loss and superfluous information loss, respectively.

5 Experiment

In this section, we verify the performance of the proposed method on five OOV datasets, and compared it with other methods. In addition, We tested the universality of the proposed method in various pre-trained models.

5.1 Datasets and Metrics

Datasets We performed experiments on:

1. WNUT2017 (Derczynski et al., 2017), a dataset focus on unusual, previous-unseen entities in training data, and is collected from social media.
2. TwitterNER (Zhang et al., 2018), an English NER dataset created from Tweets.
3. BioNER (Kim et al., 2004), the JNLPBA 2004 Bio-NER dataset focus on technical terms in the biology domain.
4. Conll03-Typos (Wang et al., 2021), which is generated from Conll2003 (Sang and De Meulder, 2003). The entities in the test set are replaced by typos version(character modify, insert, and delete operation).
5. Conll03-OOV (Wang et al., 2021), which is generated from Conll2003 (Sang and De Meulder, 2003). The entities in the test set are replaced by another out-of-vocabulary entity in test set.

Table 2 reports the statistic results of the OOV problem on the test sets of each dataset. As shown in the table, the test set of these datasets comprises a substantial amount of OOV entities.

Metrics We measured the entity-level micro average F1 score on the test set to compare the results of different models.

5.2 Baseline methods

Li et al. (2020) share the same intuition as us, enriching word representations with context. However, the work is neither open source nor reported on the same dataset, so this method cannot be compared with MINER. We compare our method with baselines as follows:

- Fu et al. (2021) (SpanNER), which is trained by original SpanNER framework, without any constraint and extra data processing.
- Vanilla information bottleneck(VaniIB), a method employs the original information bottleneck constraint to the SpanNER, which is optimized based on Alemi et al. (2016). Compared with our method, it directly compresses all the information from the input.
- Dai and Adel (2020) (DataAug) , which trains model with data augmentation strategy, while keeps the same model architecture as SpanNER. This model is trained by 1:1 original training set and entity replacement training set, which keeps the same input as the proposed method.
- Shahzad et al. (2021) (InferNER), a method focus on word-, character-, and sentence-level information for NER in short-text, without recurring to external sources. In addition, it is able to incorporate visual information and introduce an attention component which computes attention weight probabilities over textual and text-relevant visual contexts separately.

Methods	**WNUT2017**	**BioNER**	**TwitterNER**	**CoNLL 2003**	
				Typos	OOV
VaniIB	51.60	73.41	71.19	83.49	70.12
DataAug	52.29	75.85	73.69	81.73	69.6
InferNER	50.52	-	74.17	-	-
MIN	49.93	**77.97**	-	-	-
CoFEE	39.1	-	69.5	-	-
MAML	24.19	76.36	-	-	-
SA-NER	50.36	-	-	-	-

MINER (Albert large)	51.94	75.23	72.67	86.53	77.95

Table 3: Performance of the proposed method compared with state-of-the-arts.

- Li et al. (2021) (MIN), which utilizes both segment-level information and word-level dependencies, and incorporates an interaction mechanism to support information sharing between boundary detection and type prediction, enhancing the performance for the NER task.

- Fukuda et al. (2020) (CoFEE), which refer to pre-trained word embeddings for known words with similar surfaces to target OOV words.

- Nie et al. (2020) (SA-NER), which utilize semantic enhancement methods to reduce the negative impact of data sparsity problems. Specifically, the method obtains the augmented semantic information from a large-scale corpus, and proposes an attentive semantic augmentation module and a gate module to encode and aggregate such information, respectively.

To verify the universality of our method, we measured its performance on various pre-trained models, i.e., Bert (Devlin et al., 2018), Roberta (Liu et al., 2019), Albert (Lan et al., 2019).

5.3 Implementation Details

Bert-large released by Devlin et al. (2018) is selected as our base encoder. The learning rate is set to 5e-5, and the dropout is set to 0.2. The output dim of the information bottleneck layer is 50. In order to make a trade-off for the performance and efficiency, on the one hand, we truncate the part of the sentence whose tokens exceeds 128. On the other hand, we count the length distribution of entity length in different datasets, and finally choose 4 as the maximum enumerated entity length. The values of β and γ differ for different datasets. Empirically, 1e-5 for β and 0.01 for γ can get promised results. The model is trained in an NVIDIA GeForce RTX 2080Ti GPU. Checkpoints with top-3 performance are finally evaluated on the test set to report averaged results.

5.4 Main Results

We demonstrate the effectiveness of MINER against other state-of-the-art models. As shown in table 3, we conducted the following comparison and analysis:

1) Our baseline model, i.e., SpanNER, does an excellent job of predicting OOV entities. Compared with sequence labeling, the span classification could model the relation of entity tokens directly;2) The performance of SpanNER is further boosted with our proposed approach, which proved the effectiveness of our method. As shown in table 3, MINER almost outperforms all other SOTA methods without any external resource;3) Compared with *Typos* data transformation, it is more difficult for models to predict *OOV* words.

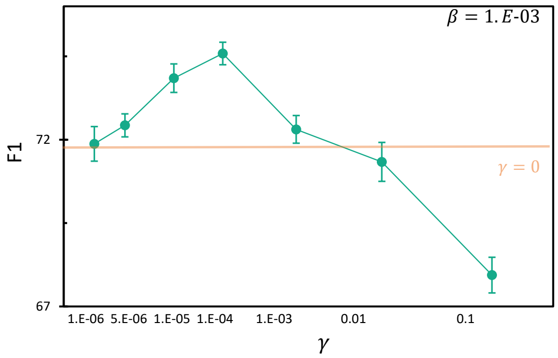

Figure 2: Illustration of f1 score in different γ values. The results are obtained by testing MINER (Bert large) on TwitterNER (Zhang et al., 2018). We fix $\beta = 1e03$, and the orange line is f1 score when $\gamma = 0$.

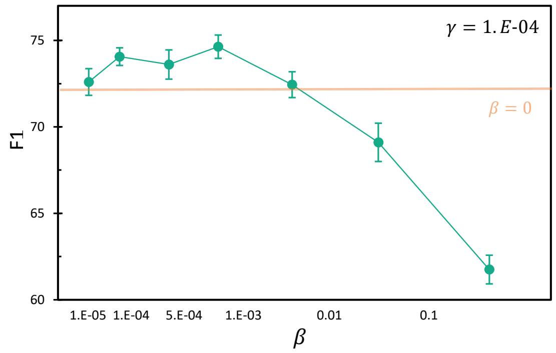

Figure 3: Illustration of f1 score in different β values. The results are obtained by testing MINER (Bert large) on TwitterNER (Zhang et al., 2018). We fix $\gamma = 1e04$, and the orange line is f1 score when $\beta = 0$.

To pre-trained model, typos word may not appear in training set, but they share most subwords with the original token. Moreover, the subword of OOV entity may be rare; 4) It seems that the traditional information bottleneck will not significantly improve the OOV prediction ability of the model. We argue that the traditional information bottlenecks will indiscriminately compress the information in the representation, leading to underfitting; 5) Our model has significantly improved the performance of the model on the entity perturbed methods of typos and OOV, demonstrating that MI improve the robustness substantially in the face of noise; 6) It is clear that our proposed method is universal and can further improve OOV prediction performance for different embedding models, as we get improvements on Bert, Roberta, and Albert stably.

5.5 Ablation Study

We also perform ablation studies to validate the effectiveness of each part in MINER. Table 4 demonstrates the results of different settings for the proposed training strategy equipped with BERT. After only adding the L_{gi} loss to enhance context and entity surface form information, we find that the results are better than the original PLMs. A similar phenomenon occurs in L_{si}, too. It reflects that both L_{gi} and L_{si} are beneficial to improve the generalizing ability on OOV entities recognition. Moreover, the results on the three datasets are significantly improved by adding both L_{gi} and L_{si} learning objectives. It means L_{gi} and L_{si} can boost each over, which proves that our method enhances representation via deep understanding of context and entity surface forms and discourages representation from rote memorizing entity names or exploiting biased cues in data.

Dataset	OOV	MI	F1

	✓	-	52.57
	-	✓	53.91
	✓	✓	**54.52**
BioNER	-	-	73.78
	✓	-	75.23
	-	✓	74.22
	✓	✓	**77.03**
Twitter-NER	-	-	71.57
	✓	-	73.78
	-	✓	73.32
	✓	✓	**75.26**

Table 4: Ablation study results on three datasets.

5.6 Sensitivity Analysis of β and γ

To show the different influence of our proposed training objectives L_{gi} and L_{si}, we conduct sensitivity analysis of the coefficient β and γ. Figure 2 shows the performance change under different settings of the two coefficients. The yellow line denotes ablation results without the corresponding loss functions (with β=0 or γ=0). From Figure 2 we can observe that the performance is significantly enhanced with a small rate of β or γ, where the best performance is achieved when β=1e-3 and γ=1e-4, respectively. It probes the effectiveness of our proposed training objectives that enhances representation via deep understanding of context and entity surface forms and discourages representation from rote memorizing entity names or exploiting biased cues in data. As the coefficient rate increases continuously, the performance shows a declining trend, which means the over-constraint of L_{gi} or L_{si} will hurt the generalizing ability of predicting

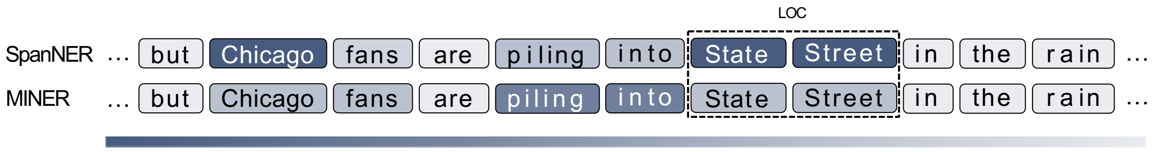

Figure 4: Visualization of attention weights over entities and context.

the OOV entities.

5.7 Interpretable Analysis

The above experiments show the promising performance of MINER on predicting the unseen entities. To further investigate which part of the sentence MINER focuses on, we visualize the attention weights over entities and contexts. We demonstrate an example in Figure 4 , where is selected from TwitterNER. The attention score is calculated by averaging the attention weight of the 0th layer of BERT. Take the attention weights of the entity "State Street" as an example, it is obvious that baseline model, i.e., SpanNER, focus on entity words themselves. While the scores of our model are more average, it means that our method concerns more context information.

6 Related Work

6.1 External Knowledge

This group of methods makes it easier to predict OOV entities using external knowledge. Zhang and Yang (2018) utilize a dictionary to list numerous entity mentions. It is possible to get stronger "look-up" models by integrating dictionary information, but there is no guarantee that entities outside the training set and vocabulary will be correctly identified. To diminish the model's dependency on OOV embedding, Li et al. (2018) introduce part-of-speech tags. External resources are not always available, which is a limitation of this strategy.

6.2 OOV word Embedding

The OOV problem can be alleviated by improving the OOV word embedding. The character ngram of each word is used by Bojanowski et al. (2017) to represent the OOV word embedding. Pinter et al. (2017) captures morphological features using character-level RNN. Another technique is to first match the OOV words with the words that have been seen in training, then replace the OOV words' embedding with the seen words' embedding. Peng et al. (2019) trains a student network to predict the closest word representation to the OOV term. Fukuda et al. (2020) referring to pre-trained word embeddings for known words with similar surfaces to target OOV words. This kind of method is learning a static OOV embedding representation, and does not directly utilize the context.

6.3 Contextualized Embedding

Contextual information is used to enhance the representation of OOV words in this strategy. (Hu et al., 2019) formulate the OOV problem as a K-shot regression problem and learns to predict the OOV embedding by aggregating only K contexts and morphological features. Pre-trained models contextualized word embeddings via pretraining on large background corpora. Furthermore, contextualized word embeddings can be provided by the pre-trained models, which are pre-trained on large background corpora (Peters et al., 2018; Devlin et al., 2018; Liu et al., 2019). Yan et al. (2021) shows that BERT is not always better at capturing context as compared to Gloe-based BiLSTM-CRFs. Their higher performance could be the result of learning the subword structure better.

7 Conclusion

Based on the recent studies of NER, we analyze how to improve the OOV entity recognition. In this work, we propose a novel and flexible learning framework - MINER, to tackle OOV entities recognition issue from an information-theoretic perspective. On the one hand, this method can enhance the context information of the output of the encoder. On the other hand, it can safely eliminate task-irrelevant nuisances and prevents the model from rote memorizing the entities. Specifically, the proposed approach contains two mutual information based training objectives: generalizing information maximization, and superfluous information minimization. Experiments on various datasets demonstrate that MINER achieves much better performance in predicting out-of-vocabulary entities.

A Appendix

This section provides the proof of generalizing information maximization, i.e., Eq. (8). Consider x_1 and x_2 are two contrastive samples of similar context, and contains different entity mentions of the same entity category, i.e., s_1 and s_2, respectively.

$$\begin{aligned} I(z_1; x_2) =& I(z_1; x_2 z_2) - I(z_1; z_2 | x_2) \\ =& I(z_1; x_2 z_2) \\ =& I(z_1; z_2) + I(z_1; x_2 | z_2) \\ \geq& I(z_1; z_2) \end{aligned} \tag{13}$$

B Appendix

This section provides the proof of superfluous information minimization, i.e. Eq. (9).

$$\begin{aligned} & \mathrm{I}(\mathrm{x}_1; z_1 | x_2) \\ &= E_{x_1,x_2 \sim p(x_1,x_2)} E_{z \sim p(z_1|v_1)} \log \frac{p(x_1,z_1|x_2)}{p(x_1|x_2)p(z_1|x_2)} \\ &= E_{x_1,x_2 \sim p(x_1,x_2)} E_{z \sim p(z_1|v_1)} \log \frac{p(z_1|x_1)p(x_1|x_2)}{p(x_1|x_2)p(z_1|x_2)} \\ &= E_{x_1,x_2 \sim p(x_1,x_2)} E_{z \sim p(z_1|v_1)} \log \frac{p(z_1|x_1)}{p(z_1|x_2)} \\ &= E_{x_1,x_2 \sim p(x_1,x_2)} E_{z \sim p(z_1|v_1)} \log \frac{p(z_1|x_1)p(z_2|x_2)}{p(z_2|x_2)p(z_1|x_2)} \\ &= D_{KL}(p(z_1|x_1)||p(z_2|x_2)) \\ &- D_{KL}(p(z_1|x_2)||p(z_2|x_2)) \\ &\leq D_{KL}(p(z_1|x_1)||p(z_2|x_2)) (14) \end{aligned}$$

Leveraging Wikipedia article evolution for promotional tone detection

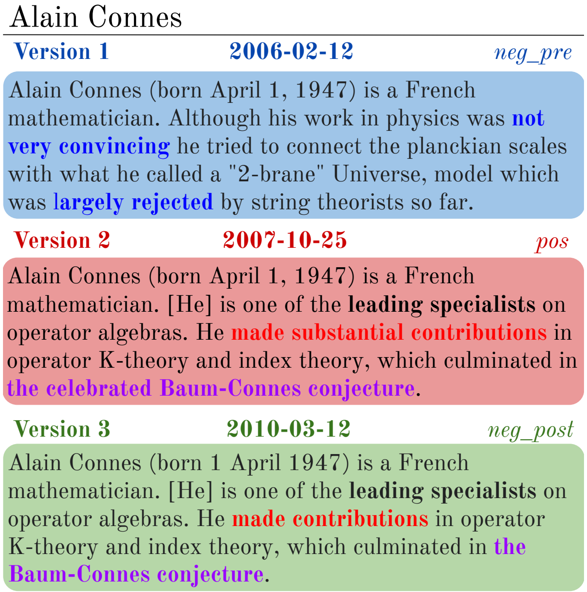
Abstract

Detecting biased language is useful for a variety of applications, such as identifying hyperpartisan news sources or flagging one-sided rhetoric. In this work we introduce WikiEvolve, a dataset for document-level promotional tone detection in English. Unlike previously proposed datasets, it contains seven versions of the same article from Wikipedia, from different points in its revision history; one with promotional tone, and six without it. We adapt the gradient reversal layer framework to encode two article versions simultaneously, and thus leverage the training signal present in the multiple versions. In our experiments, our proposed adaptation of gradient reversal improves the accuracy of four different architectures on both in-domain and out-of-domain evaluation.



Alain Connes

Version 1 **2006-02-12** *neg_pre*

Alain Connes (born April 1, 1947) is a French mathematician. Although his work in physics was **not very convincing** he tried to connect the planckian scales with what he called a "2-brane" Universe, model which was **largely rejected** by string theorists so far.

Version 2 **2007-10-25** *pos*

Alain Connes (born April 1, 1947) is a French mathematician. [He] is one of the **leading specialists** on operator algebras. He **made substantial contributions** in operator K-theory and index theory, which culminated in **the celebrated Baum-Connes conjecture**.

Version 3 **2010-03-12** *neg_post*

Alain Connes (born 1 April 1947) is a French mathematician. [He] is one of the **leading specialists** on operator algebras. He **made contributions** in operator K-theory and index theory, which culminated in **the Baum-Connes conjecture**.

Figure 1: A sample from the dataset. The middle version was tagged as having a promotional tone problem. The first and third versions were sampled respectively before the tag was added and after it was removed.

1 Introduction

Maintaining a neutral point of view is a desideratum in many communication channels, e.g. news articles, scientific writing, and encyclopaedias. Biased writing detection can help reduce the distribution of content which contains unfair representations of a topic. For this reason, datasets and methods have been developed to automate it.

A number of studies have approached biased writing detection in the context of news media (e.g. Fan et al. (2019); Chen et al. (2020); Färber et al. (2020)), primarily considering political stance and partisanship. However, biased writing also arises in other settings. In Wikipedia, the online encyclopaedia, it manifests itself in the form of promotional tone which violates the cornerstone "neutral point of view" policy of the platform. The latter allows users to flag articles with such policy violations by adding tags to the article mark-up, which are retained in its edit history. Leveraging this process, Recasens et al. (2013) and Aleksandrova et al. (2019) have released datasets of words and sentences which were altered in subsequent revisions, thus facilitating model development for word/sentence level bias detection.

In this work, we propose an alternative data collection methodology for document-level promotional tone detection, We sample multiple versions of the same article in Wikipedia and present WikiEvolve[1], a dataset of 68,498 labelled articles for this task. These articles are arranged into 13,887 sample sets, where each set contains multiple versions of the same article: one version tagged as having a promotional tone problem, and up to three versions respectively from before the tag was added and after it was removed. This is illustrated in Fig. 1; the second version was labelled as containing

promotional tone (positive), whereas the first and third versions were considered negative.

In contrast with Recasens et al. (2013) and Aleksandrova et al. (2019), we choose to perform classification at the level of documents rather than sentences or words. Our motivation is that classifying a sentence out of context as biased is known to be difficult and prone to subjective judgements, while higher inter-annotator agreement is achieved at the document-level (Chen et al., 2020). Recasens et al. (2013) similarly found that identifying promotional tone at the word-level is challenging, with Mechanical Turk workers achieving 37% accuracy on this task. We hypothesise that there are article-level features which provide corroborating evidence to the intentions of the writer, which isolated sentences might not capture. We also see evidence of this in our own data – for instance, in Fig. 1, the mention of "leading specialist" in version 3 is dubious but justifiable; however, in version 2, it contributes to an overall assessment of biased writing.

To make better use of the training signal available in the multiple versions per article in WikiEvolve, we adapt gradient reversal (Ganin and Lempitsky, 2015). The latter entails adding an auxiliary task during training which shares the input encoder with the main task and is optimised concurrently, but its gradients are reversed during backpropagation. The model is therefore discouraged from learning features which are useful for the auxiliary task and assumed harmful for the main task. Our adaptation operates on pairs of samples rather than individual texts, and we define the auxiliary task as classifying whether two samples originated from the same article. The features we learn are therefore more likely to be informative of the tone, but not of the content.

In our experiments, gradient reversal improves the accuracy of all four architectures of increasing complexity. On a bag-of-words encoding followed by two neural network layers, the PR-AUC score improves from 0.60 to 0.64. Using a hierarchical attention network, performance is increased from 0.63 to 0.65. This illustrates that the additional structural information WikiEvolve provides can be utilised to improve performance on this task. To further assess the ability of gradient reversal to improve performance by encouraging models to learn features that do not rely on the topic or content, we also tested our models on out-of-domain data from the SemEval 2019 Shared Task on Hyperpartisan News Detection (Kiesel et al., 2019). Our results show that GRL training improves our accuracy on this dataset from 0.714 to 0.785.

2 Promotional tone on Wikipedia

A number of studies have utilised Wikipedia to develop labelled datasets for content-related issues, including promotional tone detection. Wikipedia has several favourable characteristics which enable this form of data collection. Firstly, articles evolve over time through different versions. Secondly, the chronological revision history of each article is preserved and open-sourced[2], meaning that the evolution of an article can be retrieved. Finally, the platform's decentralised quality control system allows users to tag articles that violate the platform's content policies, to warn readers of such issues and to attract the attention of editors to fix them. These tags are removed from the article once the problem is resolved, but they are preserved in the article's edit history. A more details on Wikipedia's policy violation tags see Anderka et al. (2012).

In this context, a revision of an article which contains a tag is considered a positive instance of that specific policy violation. Different methods have been proposed for sampling negatives. A popular approach is to find revisions of the same or other articles which do not contain the tag. However, this approach can introduce noise, as the absence of a policy violation tag from an article does not guarantee that the problem is not present. This characteristic of template-based Wikipedia datasets has been noted in previous work, e.g. Anderka et al. (2012); Bhosale et al. (2013); Orizu and He (2018). Another option is to look to other articles which are known to represent well-written content. For instance, Anderka et al. (2012) and Bhosale et al. (2013) select negatives from Wikipedia's list of featured and good articles. However, these articles are of a higher quality generally and therefore have other distinguishing characteristics, which may be misleading if the goal is to detect policy-violating content. Additionally, sampling negatives from different articles may introduce a topical bias.

3 Mining promotional articles

Our data extraction methodology consists of (i) finding articles tagged by a Wikipedia editor as having a promotional tone problem at some point

---

[2] A Creative Commons Attribution-Share-Alike License 3.0 applies.

in their edit history, (ii) selecting the revision where such a tag was added as a positive sample, and (iii) sampling negatives from revisions which did not contain the template.

Finding promotional tone tags To identify tags of interest, we refer to the Wikipedia category "articles with a promotional tone" (Wikipedia, 2021a) and identify the quality tags which most frequently occur in this articles of this category. These are "advert", "autobiography", "fanpov", "peacock" and "weasel". Each of these tags describes a different type of promotional tone issue, for which the definitions are contained in Appendix A. We then use regular expressions to collect all revisions which contain variations of these tags in the WikiText data lake (Wikipedia, 2021c).

Finding tag addition events Once incidences of promotional tone tags have been identified, we use the WikiHistory data lake (Wikipedia, 2021b) to find the full edit histories of these articles. For each article, we then identify the point in its edit history where a tag was added, and consider this version of the article as the positive sample. We exclude cases where the tag addition edit was reverted[3] by another editor. The article text at this timestamp is retrieved from the WikiText data lake.

Sampling negatives For each positive sample, we select negatives from the revision history of the same article. We consider as candidates all revisions which were not reverted, and which took place within 30 revisions (chronologically sorted) of the tag addition event. This is intended to ensure that the negative samples are of the same approximate stage of article development as the positive sample. We exclude the revision immediately before the tag addition event, as it is this version which prompted the tag to be added. Up to three revisions (depending on availability) are selected at random from these candidates, before and after the positive. We refer to such a set of samples as a **sample set**. The negatives sampled before the tag addition are denoted ***neg_pre***, and those from after are denoted ***neg_post***. The number of samples per tag and class are shown in Table 1. We split the data into train, test and validation sets with a ratio of 70-20-10. The datasets are stratified to contain samples from each tag type (set out in Table 1), and samples from the same sample set (i.e. revisions of the same article) are kept in the same split.

Tag	# Positives	# Negatives
Autobiography	1578	9289
Advert	4361	25843
Fanpov	413	2446
Peacock	2859	16960
Weasel	906	5421
Total	**8 539**	**59 959**

Table 1: Number of samples per tag and class.

Although this work only considers promotional tone detection in English, the data collection methodology and training framework we propose could be extended to other languages on Wikipedia, as is done in Aleksandrova et al. (2019).

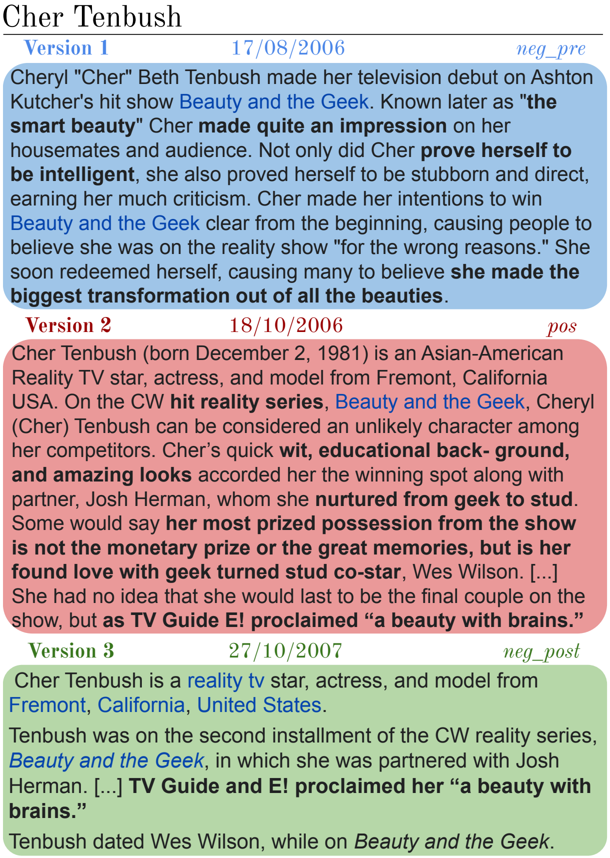
4 Data validation

As discussed in Sec. 2, Wikipedia tag-based datasets are known to contain a certain level of noise. To counteract this, we have implemented three measures: ensuring that the negatives are from the same stage of article development, sampling from different points in the same article's edit history, and sampling negatives before and after the positive. However, there is still a risk of including false negatives, i.e. articles not tagged as containing promotional tone even though they do. An example of such a case from our dataset is shown in Fig. 2. Despite containing non-neutral phrases such as "hit show", "made quite an impression", and "prove[d] herself to be intelligent", the *neg_pre* (first) sample is not tagged as containing biased language. It does however contain some information that reflects negatively on the subject ("for the wrong reasons"). This is removed in the positive (middle) sample, and more overtly biased descriptions are added ("quick wit, educational background, amazing looks", "bubbly personality and easy on the eye appearrance"). In the *neg_post* negative sample, the problematic phrasing is removed.

We perform manual validation of our dataset to estimate how frequently false negatives are included. We perform two types of validation: pairwise and independent prediction. For the former, the task is to rank two samples (i.e. revisions of the same article) as to which is more promotional. 40 articles, consisting of 20 positive-negative pairs in random order, are evaluated by two of the authors.

---

[3] From the platform guidelines: "On Wikipedia, reverting means undoing or otherwise negating the effects of one or more edits, which results in the page (or a part of it) being restored to a previous version."



Cher Tenbush

Version 1 17/08/2006 *neg_pre*

Cheryl "Cher" Beth Tenbush made her television debut on Ashton Kutcher's hit show Beauty and the Geek. Known later as **"the smart beauty"** Cher **made quite an impression** on her housemates and audience. Not only did Cher **prove herself to be intelligent**, she also proved herself to be stubborn and direct, earning her much criticism. Cher made her intentions to win Beauty and the Geek clear from the beginning, causing people to believe she was on the reality show "for the wrong reasons." She soon redeemed herself, causing many to believe **she made the biggest transformation out of all the beauties**.

Version 2 18/10/2006 *pos*

Cher Tenbush (born December 2, 1981) is an Asian-American Reality TV star, actress, and model from Fremont, California USA. On the CW **hit reality series**, Beauty and the Geek, Cheryl (Cher) Tenbush can be considered an unlikely character among her competitors. Cher's quick **wit, educational back- ground, and amazing looks** accorded her the winning spot along with partner, Josh Herman, whom she **nurtured from geek to stud**. Some would say **her most prized possession from the show is not the monetary prize or the great memories, but is her found love with geek turned stud co-star**, Wes Wilson. [...] She had no idea that she would last to be the final couple on the show, but **as TV Guide E! proclaimed "a beauty with brains."**

Version 3 27/10/2007 *neg_post*

Cher Tenbush is a reality tv star, actress, and model from Fremont, California, United States.

Tenbush was on the second installment of the CW reality series, *Beauty and the Geek*, in which she was partnered with Josh Herman. [...] **TV Guide and E! proclaimed her "a beauty with brains."**

Tenbush dated Wes Wilson, while on *Beauty and the Geek*.

Figure 2: An example of a false negative obtained from the *neg_pre* version of a sample set.

The orderings of the annotators agreed with the assigned labels for respectively 16/20 and 14/20 pairs, with a Cohen's Kappa score of 0.79 indicating substantial agreement. This suggests that the collected data contains a trustworthy signal for comparing the extent to which two texts are promotional.

Since the task we are mainly interested in is text classification, rather than ranking, we also perform an evaluation on individual samples, annotating 30 samples of each type (positive, *neg_pre* and *neg_post*). The concurrence with the mined labels of the *neg_pre* and *neg_post* annotations are shown in Table 2. This task appears to be more challenging compared to the pairwise comparison, with both annotators achieving lower scores and a lower inter-annotator agreement Kappa score of 0.4805, indicating moderate agreement. A reason for this may be the subjective nature of the task, as illustrated by Chen et al. (2020).

Our evaluation indicates that the negative samples from before the tag was added contain more noise, compared to those sampled after it was removed. This can be attributed to the active removal of the tag by an editor in the version after the tag was added (*neg_post*), which indicates that the problem is resolved, while the lack of a policy violation tag in earlier versions (*neg_pre*) does not guarantee lack of promotional tone. However, ignoring the *neg_pre* samples altogether would expose the temporal bias mentioned in Sec. 1: if negatives are always sampled chronologically after positives and from a more developed version of the article, spurious correlations may be inferred.

Annotator	***neg_pre***	***neg_post***
A1	$\frac{12}{30}$	$\frac{14}{30}$
A2	$\frac{14}{30}$	$\frac{22}{30}$
Total	$\frac{24}{60}$	$\frac{36}{60}$

Table 2: Agreement of two authors with mined labels of negative sample annotations.

Based on these insights, we have chosen to include the automatically mined *neg_pre* samples in training, but to create a separate set of manually validated *neg_pre* samples for evaluation. Thus, we randomly selected 100 *neg_pre* samples from the original test set and verified whether they represent a neutral writing style. 42 of the 100 samples were confirmed as true negatives. We balance these negatives with their corresponding positive samples, and refer to this dataset as *ValidNegPre*.

5 Gradient reversal training for promotional tone detection

Gradient reversal training (Ganin and Lempitsky, 2015) jointly optimises two classifiers which rely on a shared underlying encoder model: (i) a label predictor for the main task, which predicts class labels and is used during both training and test time, and (ii) a domain classifier, which predicts either the source or the target domain during training as the auxiliary task. The parameters of the encoder model are optimised to minimise the loss of the main task classifier while maximising the loss of the domain classifier. This is achieved through a gradient reversal layer, which leaves the input unchanged during forward propagation and reverses the gradient by multiplying it by a negative scalar during the backpropagation. This approach is motivated by theory on domain adaptation, which suggests that a good representation for cross-domain transfer is one for which an algorithm cannot learn to identify the domain of origin of the input observation (Ben-David et al., 2010).

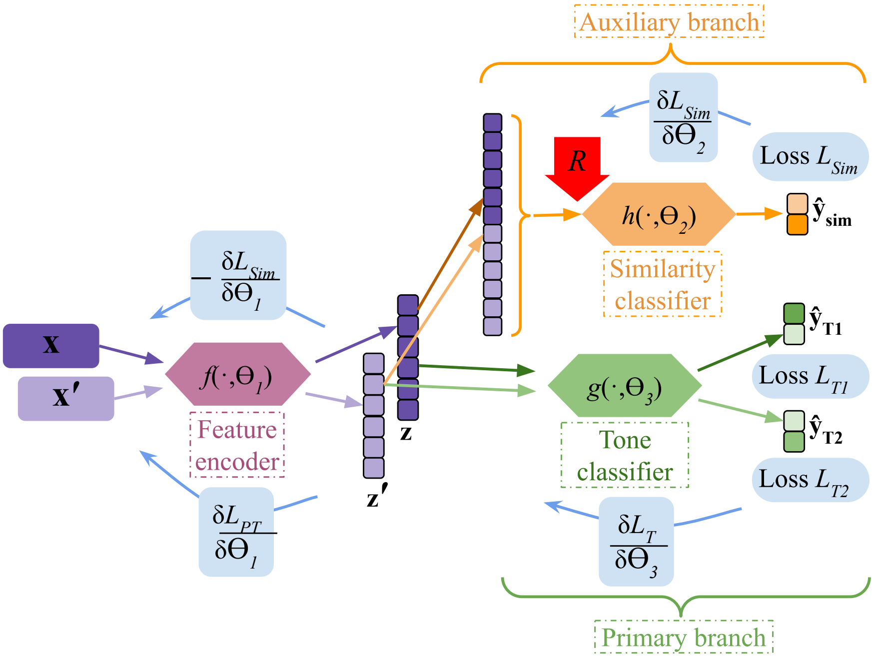


Figure 3: Model architecture for training with gradient reversal. x and x' represent two different samples which are encoded in parallel, by the same feature encoder model.

Our adaptation of this framework, shown in Fig. 3, differs from Ganin and Lempitsky (2015) in that it considers two text inputs concurrently (x and x'), as opposed to one. f represents a neural network encoder with parameters θ_1. f encodes the two texts independently, to produce z and z':

$$z = f(x; \theta_1); z' = f(x'; \theta_1) \tag{1}$$

The network then splits into two branches. The primary (bottom) branch consists of a neural network model g, with parameters θ_3, which produces promotional tone predictions $\hat{y}_{T1}$ and $\hat{y}_{T2}$ for the two samples:

$$\hat{y}_{T1} = g(z; \theta_3); \hat{y}_{T2} = g(z'; \theta_3) \tag{2}$$

The auxiliary branch concatenates the two input encodings as $[z, z']$, and then the similarity classifier h, a neural network parameterised by θ_2, provides a prediction $\hat{y}_{sim}$ of whether the two samples originate from the same Wikipedia article:

$$\hat{y}_{sim} = h([z, z']; \theta_2) \tag{3}$$

Our intention with this task is to encourage the encoder f to learn features that are topic agnostic. This should allow for better generalisation across datasets, as well as to avoid learning spurious correlations due to topical biases in the data.

The encoder and classifier models are trained simultaneously.

Given a set of training samples D = $[x_1, ..., x_N, y_1, ..., y_N]$, we construct M pairs with indices $P = (i, j) : i, j \in [1, ..., N]$. The process for generating these pairs is described in Sec. 6. Then, the loss is given by:

$$\begin{aligned} L(\theta_1, \theta_2, \theta_3, D, P) = \\ \frac{1}{M} \sum_{m=1}^{M} \Big(L_T(x_{P1}, x_{P2}; \theta_1, \theta_2) \\ - \lambda L_{Sim}(x_{P1}, x_{P2}; \theta_1, \theta_3) \Big), \end{aligned} \tag{4}$$

such that the loss with respect to the similarity label is maximised, while the loss with respect to the promotional tone label is minimised. λ is a scalar which controls the weight of the loss from the adversarial task, and $L_T = L_{T1} + L_{T2}$.

During testing, only the feature encoder and the main task branch are retained to perform the tone classification task:

$$\hat{y} = g(f(x; \theta_1), \theta_3). \tag{5}$$

Recall that the model encodes and predicts on the two input samples independently during training. We can therefore obtain predictions for individual test samples (rather than pairs), as is the more general case in other models and datasets for this task.

6 Experimental setup

6.1 Models

The two classifier models, g and h, are both MLP models. The feature encoder (indicated as f in Fig. 3) is responsible for producing an embedding of an article to be used in both the main and auxiliary task. We evaluate four options:

- **Bag-of-words (BoW + MLP)**: a bag-of-words representation of an article is propagated through a multilayer perceptron (MLP) to obtain an embedding,
- **Averaged embeddings (AvgEmb + MLP)**: GloVe embeddings (Pennington et al., 2014) for every word in the article are averaged, followed by an MLP model,
- **Hierarchical Attention Network (HAN)** (Yang et al., 2016): word embeddings are processed using an LSTM layer followed by an attention mechanism to build up sentence embeddings. Sentence embeddings are similarly combined to form an article embedding.
- **Longformer** (Beltagy et al., 2020): A transformer-based model, adapted for long-form documents. We finetune the pretrained "longformer-base-4096" model.

For the GRL models, we further experiment with the weights of the main versus auxiliary task λ on the validation set, finding that weighting the outputs equally yields the best results.

We compare the GRL training approach with the standard method of training the classifier with each feature extractor model. This is equivalent to training with the inference model in Equation 5; the auxiliary branch is removed and one sample is processed at a time. Implementation details are provided in App. B.

6.2 Metrics

For each model, we report two metrics:

- **PR-AUC**: The area under the precision-recall curve, which provides an aggregate measure of performance across all possible classification thresholds (Davis and Goadrich, 2006). Perfect performance is 1, and a random classifier would receive 0.
- **Accuracy**: The percentage of samples which are correctly classified, using a classification threshold based on Youden's J statistic (Fluss et al., 2005), which maximises the true positive rate and minimises the false negative rate.

6.3 Data

In order to train the main task we require samples with and without a promotional tone (i.e. positive and negative labels). To train the auxiliary we require both *matched* pairs (originating from the same sample set / article) and *unmatched* pairs (originating from different sample sets). Therefore, we include a number of different pairing configurations.

Firstly, given a training set consisting of K sample sets, we collect K positive-negative matched pairs. This means that we need to select one negative sample and one positive sample from each sample set. There are multiple negatives in every sample set, so we sample at random from all *neg_pre* and *neg_post* samples. There is only one positive per sample set, so this sample is used. We also collect K positive-negative unmatched pairs. We further include K matched and K unmatched negative-negative pairs. Finally, we include K positive-positive unmatched pairs. It is not possible to add positive-positive matched pairs, as there is only one positive per sample set.

Using this pair selection method, there are $7K$ samples for the tone classification task and $3.5K$ pairs for the similarity classification task, for a total of 48762 articles. For the baseline models, without GRL, only one sample is used at a time during training; thus, we retain the data generation method described above (to ensure the results are comparable), but ignore the pairings.

The training dataset is slightly unbalanced, with a ratio of 4:3 of negatives to positives for the similarity classification task and a ratio of 4:3 of unmatched to matched pairs. The numbers of samples per label and their origin are shown in Table 7 in App. C. Our validation and test sets consist of only positive-negative matched pairs, one from each sample set, and thus are fully balanced. As motivated in Sec. 4, for the main test set (denoted *FullTest*) negatives are only selected from the *neg_post* samples. For the *ValidNegPre* test set, all negatives are manually validated. The text preprocessing steps are described in App. B.

7 Results

The results from our evaluation on the *FullTest* are in Table 3. We observe that models trained with GRL consistently outperform models trained without it, on both the accuracy and PR-AUC metrics. All improvements, except for the Longformer, are

Model	**PR-AUC**	**Accuracy**
BoW + MLP	0.6019	0.5913
BoW + GRL	0.6409	0.6102
AvgEmb + MLP	0.6129	0.5848
AvgEmb + GRL	0.6415	0.6084
HAN	0.6271	0.5968
HAN + GRL	0.6459	0.6102
Longformer	0.6798	0.6392
Longformer + GRL	0.6984	0.6432

Table 3: Results using GRL training on $FullTest$.

	Test data	
Train data	*FullTest*	*ValidNegPre*
Incl. *neg_pre*	0.6984	0.6184
Excl. *neg_pre*	0.6962	0.5725

Table 4: Effect of ignoring *neg_pre* during training. PR-AUC scores are shown.

statistically significant at the $\alpha = 0.05$ level, using the permutation test to compare PR-AUC values. Larger gains are observed for the BoW+MLP and AvgEmb+MLP models, compared to the HAN and Longformer models. A possible explanation for this is that the simpler models rely only on word-level information, and thus more susceptible to topical biases which GRL mitigates.

These results support the motivation behind our data collection method and training framework: by incorporating our knowledge of how samples are related in our dataset and training, models are exposed to different versions of the same content (with and without promotional tone), and can therefore better learn features that are more effective for detecting promotional tone, compared to models that ignore this information.

7.1 Effect of *neg_pre* samples

Given our discussion in Sec. 4, we also evaluate the GRL approach on a separate, validated test set, which uses *neg_pre* rather than *neg_post* negatives (denoted *ValidNegPre*). In this evaluation, we are particularly interested in the effect of excluding *neg_pre* samples during training. The total number of samples in the training set remains the same as for experiments already reported, but all negatives are sampled from the *neg_post* samples for each sample set during training. We compare our best model (Longformer+GRL) under these conditions. For brevity, in Table 4 we only show the PR-AUC values, but the same trends hold for accuracy.

The original configuration is shown in the top left of the table; with training data including both *neg_post* and *neg_pre*, and testing on $FullTest$. We note that, using the same training data, the PR-AUC score is slightly lower on the *ValidNegPre* set (top right) compared to the *FullTest* set, indicating that these samples may be more difficult to classify correctly. The effect of excluding *neg_pre* samples during training is shown in the second row. The two training settings achieve similar performance on the *FullTest* test set, however, the performance on the *ValidNegPre* dataset is markedly lower when excluding *neg_pre*samples. This supports our motivation for including *neg_pre* samples during training, as described in Sec. 4, i.e. that not including them may lead to learning spurious correlations, such as temporal or article development biases. The *neg_pre* sampling adds useful information during training, despite including noise in the form of false negatives.

7.2 Ranked prediction

Since our main goal is to predict promotional tone for a given text, we did not optimise for ranked prediction; however, the pairwise accuracy is of interest since the GRL-based model is trained on pairs. This is similar to the pairwise human evaluation we performed in Sec. 4. For this we calculate the proportion of pairs for which the directionality of the predictions is correct. A score of 0.722 is achieved for the non-GRL Longformer model, compared to 0.741 for the GRL model. The fact that these values are higher than the accuracy values in Table 3 illustrates that there are samples which were incorrectly classified, but whose relative (pairwise) relationship was correctly predicted.

7.3 Error analysis

To better understand the differences in predictions made by models trained with GRL, we analyse more closely the test set and our predictions. There are 1318 samples on which both models are correct and 764 on which both are incorrect. There are 320 samples where the non-GRL model is correct while the GRL model is incorrect, and 356 samples in the reverse case. We are interested in the last two categories, where the two models disagree.

To better understand these classification categories, we evaluate the pointwise mutual information (PMI; Jurafsky and Martin, 2008) of each word

(w) with its classification status (c):

$$PMI(w,c) = log_2(\frac{P(w,c)}{P(w)P(c)}). \qquad (6)$$

This gives us an indication of how much higher the probability of observing a word is to be in one of the categories, compared to the full test set.

The 50 words with the highest PMI, which were correctly classified as not promotional by our model but mislabeled as promotional by the non-GRL variant, are shown in Table 8 in Appendix D. Without GRL, these words were indicative of promotional tone; but with GRL, their use for promotional tone detection was reduced. Thus, these should be words that are misleading for the tone classifier, but helpful for the similarity classifier.

The list includes the terms "feminist", "feminism" and "female". This topical concentration may be caused by a bias in the training data, whereby there are more positive examples which contain these terms. Such an imbalance in the data may be related to the findings of Wagner et al. (2016), which explores the imbalance in representations of women versus men on Wikipedia. However, this is not the only topical bias we observe in the predictions of the non-GRL model; the terms "photograph", "photographer", and "graphics" are also in this list.

The PMI values for the opposite case where the non-GRL model is correct while the GRL model is incorrect is shown in Table 9. Here, too, we see some topical groupings; eg. "tumor", "physicians", "diagnosis". However, the PMI of these words are lower than that of the samples where the GRL model was correct (with a maximum PMI of 3.92 vs 2.76), meaning that the co-occurrence is on the whole lower.

7.4 Out-of-domain evaluation

We further evaluate our model on the test set from the "per-article" track of the SemEval 2019 Shared Task on Hyperpartisan News detection (Kiesel et al., 2019). Their dataset contains 314 positive (hyperpartisan) and 314 negative (not hyperpartisan) news articles. On this dataset, the Longformer+GRL model, trained on our training data, achieves a PR-AUC score of 0.759 (accuracy 0.785), compared to a PR-AUC of 0.736 (accuracy 0.714) when the GRL is omitted (statistically significant; P=0.043 on the signed rank test). The shared task received 42 entries and closed in June 2019. Compared against their leaderboard, our model would be ranked eighth, even though it was not trained on the provided training data.

Test set	No GRL	Content	Time
FullTest	0.6936	0.6984	0.6901
ValidNegPre	0.5769	0.6184	0.5948
SemEval	0.6942	0.785	0.7531

Table 5: The results on each of the test scenarios from Sec. 7, comparing models with no auxiliary task, the content-based task we proposed, and the time-based auxiliary task.

7.5 Time-based gradient reversal

A motivation for including the *neg_pre* samples is that they counteract the temporal bias introduced by only sampling *neg_post* samples. The gradient reversal layer also provides a debiasing mechanism, used to suppress topic-based biases in our proposed model. To observe the impact of the *neg_pre* sampling, we also evaluate models trained with a time-based auxiliary task. Specifically, we define the task as predicting which sample in an input pair is earlier in the revision history of an article. We use only *neg_post* samples, as they were found to be less noisy. Samples are generated from (*neg_post*, *positive*) pairs as well as (*neg_post*, *neg_post*) pairs, with the chronological ordering being swapped at random to give an equal probability of both outcomes. The results on each of the test scenarios from Sec. 7 are shown in Table 5, using the Longformer feature encoder and comparing to the results from the original formulation. We also compare to the same model trained without an auxiliary task. The Time-GRL model outperforms the model with no auxiliary task on the *ValidNegPre* and SemEval datasets, but the content-GRL model scores the highest on all three test sets. This indicates that using *neg_pre* samples to counter temporal biases and the auxiliary task to counter content biases achieves better performance on this task.

7.6 Comparing against sentence-level models

Previous work by Aleksandrova et al. (2019) explored a similar dataset creation strategy, using Wikipedia tags to identify sentences with a promotional tone. Our work focuses on document-level promotional tone detection, however, we also compare performance on our dataset using their models to verify whether document-level training captures more information than sentence-level training.

Model	Mean aggr.	Max aggr.
BoW+LogReg	0.55	0.54
LSTM+Attn	0.34	0.31

Table 6: Performance of models from Aleksandrova et al. (2019) on the *FullTest* dataset.

We replicate their best performing model and the reported test set score of F1 score of 0.62. To compare performance on our own document-level data, we obtain a prediction for each sentence in an article and apply two aggregation strategies: using the average prediction and the maximum score. We further implement an LSTM model with attention, which is similar to our HAN model without the hierarchical computation. Results are shown in Table 6. In both cases, the mean aggregation yields a slightly better score; however, models trained on our data, both with and without the GRL optimisation, achieve significantly higher scores, providing support that there is useful information contained in WikiEvolve for the task of document-level promotional tone detection.

Finally, it worth noting that the LSTM+Attn model performs worse than the BoW+LogReg model. The authors also report comparatively worse performance for a model using FastText (Bojanowski et al., 2017) embeddings.

8 Conclusion

In this work, we have proposed an alternative data collection method and dataset for promotional tone detection, which leverages the evolution of articles on the platform. To utilise the additional structure in our dataset, we extended the gradient reversal framework to train models which are more effective at detecting promotional tone. This was shown both on our own test set and on a test set from a different domain. We further provided insights on the effects of two negative sampling strategies on Wikipedia. These findings should be useful for researchers who use Wikipedia-based data more broadly, in addition to those who work on biased language detection.

A Tag definitions

The definitions for the promotional tone tags used in this study are as follows, as per the relevant Wikipedia policy descriptions:

- **Fanpov**: Written from a fan's point of view, rather than a neutral point of view (Wikipedia, 2021f).
- **Peacock**: Contains wording that promotes the subject in a subjective manner without imparting real information (Wikipedia, 2021g).
- **Autobiography**: Article is extensively edited by the subject or by someone connected to the subject (Wikipedia, 2021e).
- **Advert**: Contains content that is written like an advertisement (Wikipedia, 2021d).

- **Weasel**: Vague phrasing that often accompanies biased or unverifiable information (Wikipedia, 2021h).

B Implementation details

Hyperparameters All models are implemented in Keras. For the BoW+MLP and AvgEmb+MLP encoder models, we use two-layer neural networks. The GRL label predictor and similarity predictor models also consist of two neural network layers. We experiment with learning rates in [0.0001,0.001,0.01], dropout (Srivastava et al., 2014) in [0.1,0.3,0.5] and hidden layer sizes in [64, 128, 256] on the validation set. The ReLU activation function is used. For the Longformer model, we finetune the `longformer-base-4096` snapshot using the Huggingface[4] package, using a learning rate of 5×10^{-6}.

Models were trained on a Nvidia Quadro RTX8000 GPU available at the authors' institution and training finished within less than 36 hours in all cases.

Text preprocessing The articles are preprocessed using the `mwparserfromhell` library, which extracts the article text from the marked-up wikicode. We remove the sections 'See also', 'External links' and 'References', as these mainly contain references to other sources rather than content. The resulting samples have a median length of 615 tokens. Samples longer than 1024 tokens are truncated.

C Data configuration for GRL training

The data configuration for GRL training is shown in Table 7.

D Error analysis

The top 50 words in terms of PMI for the two categories discussed in Sec. 7.3 are shown in Tables 8 and 9.

From text to talk: Harnessing conversational corpora for humane and diversity-aware language technology

Abstract

Informal social interaction is the primordial home of human language. Linguistically diverse conversational corpora are an important and largely untapped resource for computational linguistics and language technology. Through the efforts of a worldwide language documentation movement, such corpora are increasingly becoming available. We show how interactional data from 63 languages (26 families) harbours insights about turn-taking, timing, sequential structure and social action, with implications for language technology, natural language understanding, and the design of conversational interfaces. Harnessing linguistically diverse conversational corpora will provide the empirical foundations for flexible, localizable, humane language technologies of the future.

1 The natural habitat of language

The primary ecology of natural language is in real-life episodes of human interaction. This is where people learn language and where they use it to coordinate joint actions, build social relations, and exchange information (Schieffelin and Ochs, 1986; Schegloff, 2006). In contrast, when machines encounter language, it tends to be radically divorced from this habitat and reduced to large amounts of decontextualised non-interactive text (Bender and Koller, 2020; Marge et al., 2022). Natural languages are also characterized by diversity at many levels, from sound and sign systems to syntax and semantics (Nettle, 1999; Evans and Levinson, 2009). In contrast, the language samples that inform language technology tend to be limited to a handful of well-resourced languages, representing only a tiny sliver of the world's linguistic diversity (Blasi et al., 2021; Joshi et al., 2020).

The time is ripe for language technology to benefit from linguistically diverse interactional data. Insights from such data can strengthen the empirical foundations of language technology, help break down the hegemony of the resourceful few, and provide room for linguistic diversity in localized applications (Bird, 2020; Danielescu and Christian, 2018). Today there is a growing set of conversational corpora of diverse languages, thanks in large part to important primary work on language documentation and description (Seifart et al., 2018). We argue such corpora represent an important and mostly untapped resource for language technology.

Corpus size is often seen as a challenge, but data comes in levels of granularity. A well-curated corpus amounting to an hour of lively conversation may not contain enough text to train a language model. But it does provide thousands of conversational turns organized in larger sequential structures of social action, along with fine details about timing, participation and linguistic structure. Since conversational corpora are one of the few places where we can study language in a way that approaches its natural habitat, collectively, these corpora harbour important insights about human interactional infrastructure.

May 22-27, 2022

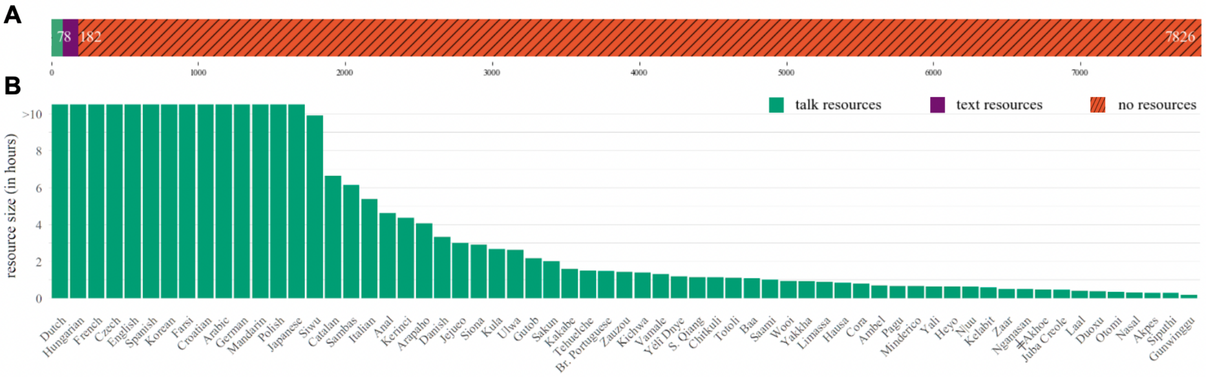

Figure 2: Language resources (corpora) and their size in relation to global language diversity. **A**: In red: total number of L1 languages in the world (estimate based on spoken and signed L1 languages in Glottolog 4.4 (Hammarström et al., 2021)); In purple: estimated languages with available textual corpora, based on number of languages used on the internet (W3techs survey; see also Pimienta et al. (2009)); In green: estimate of languages with conversational corpora made available through research-oriented language resource platforms and language documentation projects (not including scripted data like subtitles). **B**: Languages and dataset size (in hours of talk) of the subset of 63 languages used in this study. See Figure 1 for a map and Appendix B for details.

Recent work has shown the dire state of language resources in relation to linguistic diversity (Blasi et al., 2021; Joshi et al., 2020), and pointed to ways forward to increase the empirical coverage of language typology and technology (Asgari and Schütze, 2017; Bjerva and Augenstein, 2018; Deri and Knight, 2016; Duong et al., 2015; Levow et al., 2021). Work in distributional and corpus-based typology is showing how to analyse linguistic information available in text corpora (Ponti et al., 2019; Seifart et al., 2021; Levshina, 2021).

Compared to text corpora, conversational corpora are much harder to collect, annotate and transcribe, and as a result they represent a much smaller subset of data. However, we think there is reason for cautious optimism. In this paper we present a first foray into this domain. We collate conversational corpora made available for research purposes and find there is now data available for a wide range of languages, many of them not the usual suspects of NLP research. Besides well-known resources like TalkBank and the Linguistic Data Consortium, here we highlight the potential of corpora collected and archived as part of language documentation projects around the world (see Appendix B).

Our focus is specifically on corpora of informal conversations among co-present participants, transcribed and time-aligned at the level of conversational turns. Details of our curation and analysis pipeline are described in the Appendix and in Liesenfeld & Dingemanse (2022). While it is impossible to exhaustively list or estimate the size of extant conversational corpora, the quality-controlled subset we consider here represents 63 languages from 26 language families (Figure 1), and amounts to over 800 hours of talk produced by over 11.000 partipants, segmented into over 1.6 million turns (9.3 million words) (Figure 2).

In what follows, we examine aspects of this collection with scientific and technological applications in mind. In doing so, we aim to contribute towards a move from the most represented to a more representative sample of the world's languages, and to show how the study of human interaction can yield insights of relevance to linguistics, language technology and human-computer interaction.

2 From text to talk-in-interaction

Despite recent advances in speech and dialogue modelling, to date, no machine can "lead a half-decent coherent conversation with a human" (Kopp and Krämer, 2021). There are several reasons for this, including the need for complex cognitive skills like intention attribution and incremental common ground construction, but equally important is a dearth of data and domain knowledge: modern natural language processing predominantly deals with text, not talk.

As a simple illustration of the difference, compare frequency distributions of words and phrases in corpora of talk versus text in English, an Indo-European language (Figure 3). The forms most characteristic of talk are interactive interjections like *hm, uhhuh, um, yeah, okay*. Items like this

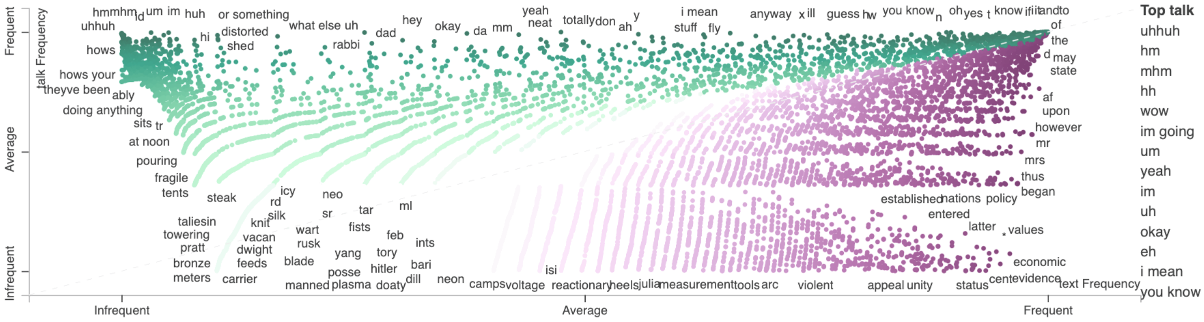

Figure 3: Words and phrases characteristic of spoken interaction (green) versus written text (purple) in English, with words most characteristic of conversational interaction in the upper left. Source data: 55k random-sampled turns and sentences from corpora of English text (Francis, 1965) and talk (Canavan and Zipperlen, 1996a; Canavan et al., 1997a), based on Scaled F score metric, plotted using *scattertext* (Kessler, 2017).

streamline conversation, calibrate mutual understanding and coordinate joint action (Clark, 1996; Bavelas et al., 2000). Yet it is precisely such items that are woefully underrepresented in the data underlying most current language models (Prevot et al., 2019). It is little surprise that conversational agents have a hard time dealing with informal conversational style (Hoegen et al., 2019) and building social bonds (Cassell, 2020), and that speech recognition easily mixes up interjections with opposite pragmatic functions (Zayats et al., 2019) if it doesn't miss them altogether (Cumbal et al., 2021).

Proposed solutions to such challenges involve imparting agents with domain-specific interactional knowledge like keyword-based scripted conversational routines and domain knowledge from Q&A databases (Bocklisch et al., 2017; Dinan et al., 2019) or with capacities for feedback generation (Oertel et al., 2016) or common ground reasoning (Kopp and Krämer, 2021). Here we propose a complementary approach: pay closer attention to how language is used in informal everyday interaction around the world. We believe this is important because just like natural language processing has long been limited to monologic texts, the science of human interaction has for the most part been based just on English and a small number of similarly well-resourced languages (Henrich et al., 2010).

If language technology is to be maximally scalable, localizable and usable, it will greatly benefit from broadening its empirical base towards more interactive data from a wider range of languages. Such data can improve our understanding of interactional infrastructure and can help us chart both language-specific routines and pragmatic universals of interaction.

3 From strings to social actions

Utterances are not just strings with probability distributions defined over them; they stand in relation to other turns, with which they form structured sequences and implement social actions. A key element of this is a socially sanctioned turn-taking system by which participants self-organize the distribution of turns over participants (Sacks et al., 1974). Foundational work on English showed that participants appear to avoid both gaps and overlaps, often achieving speaker transition in as little as 200 ms. This temporal organization is so tight that it has long puzzled psycholinguists, who observe that even planning a simple sentence in isolation may take up to 600ms, implying that language comprehension and production must run in parallel (Levinson, 2016). Indeed participants do not wait for pauses to begin their contribution, but instead start planning early, continuously weighing a range of cues to determine the likely point at which the current turn ends (de Ruiter et al., 2006).

Subsequent cross-linguistic work has confirmed this no-gap-no-overlap goal, showing that across 10 languages from 7 language families, floor transfers are usually achieved between 0 and 200ms, with language-specific means falling within 250ms on either side of the mean (Stivers et al., 2009). Currently available data allows us to replicate this in 24 languages from 12 unrelated families, more than doubling the sample size. Because our aim is to characterize the overall temporal features of quotidian interaction, we consider all turn transitions in dyadic stretches of conversation (see Appendix A.1 for a validation in question-answer sequences).

In the 24 corpora that contain at least 1000 dyadic turn transitions, we find substantially the same finely calibrated temporal distribution of turns, suggesting that participants aim for a no-gap, no-overlap target, with the bulk of language-specific means falling within a relatively narrow bandwidth of variation (Figure 4). In the full set of 674 223 transitions, 46% of turns are produced in slight terminal overlap. This includes both fuller turns and short responsive tokens (Goodwin, 1986; Corps et al., 2022), and underlines the extent to which human interaction everywhere involves a braiding of successive and concurrent moves.

The implications for language and speech technology are considerable (Skantze, 2021; Roddy, 2021). It means that social robots that switch between listen and talk states will be behind the curve approximately half of the time: perceived as responding too slowly or switching to a listening state too late to pick up early and concurrent responses. If the aim is to facilitate fluid interaction, a first challenge is to achieve the rapid transitions that characterize human language use. This requires incremental and continuous processing (Levinson, 2016; Pitsch, 2016), representing a radical departure from classic reactive spoken dialog systems. Most work in this area is still based on English, potentially jeopardizing the generalizability of findings. Cross-linguistic conversational corpora will prove crucial to identify the most robust prosodic, lexical and interactional features that can inform continuous projections of transition relevance places (Ward et al., 2018; Roddy et al., 2018).

Even if rapid transitions may be achieved with the help of continuous, context-sensitive processing, a further layer of language-specific calibration will be necessary to account for the known range of variation (Stivers et al., 2009). Experimental work in this domain shows measurable intercultural differences in orientations to inter-turn silences (Roberts et al., 2011): across cultures, people treat gaps as meaningful beyond a threshold of a few hundred milliseconds, but the exact threshold varies with culture. Without calibration of this kind, people may easily experience conversational agents as overeager, stilted, or out of sync. Progress in this domain may hinge on endowing interactive technologies with a sense for timing and rhythm (Yu et al., 2021; Pouw et al., 2021).

An important aspect of human conversation is how rapid turn-taking enables on-the-fly calibration and coordination. This motivates a theoretical turn from singular, perfectly formulated, unambigous utterances to incremental, good enough, co-constructed understanding (Dingemanse et al., 2015; Albert and de Ruiter, 2018; van Arkel et al., 2020). Increasingly, parsers and other models of grammar and dialogue incorporate this kind of incremental perspective (Schlangen and Skantze, 2011; Vanzo et al., 2018; Buschmeier and Kopp, 2018). Promising application-oriented work in this direction exists (Ekstedt and Skantze, 2020;

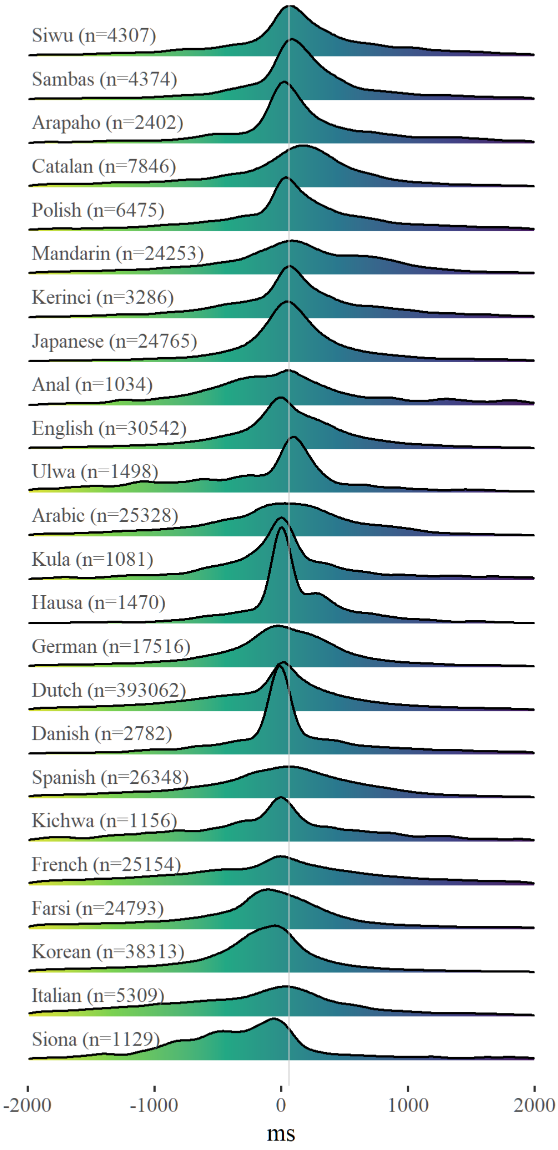

Figure 4: The timing of turn transitions in dyadic interactions in 24 languages around the world, replicating earlier findings and extending the evidence for the interplay of universals and cultural variation in turn-taking (n = number of turn transitions per corpus). Positive values represent gaps between turns; negative values represent overlaps. Across languages, the mean transition time is 59ms, and 46% of turns are produced in (slight) terminal overlap with a prior turn.

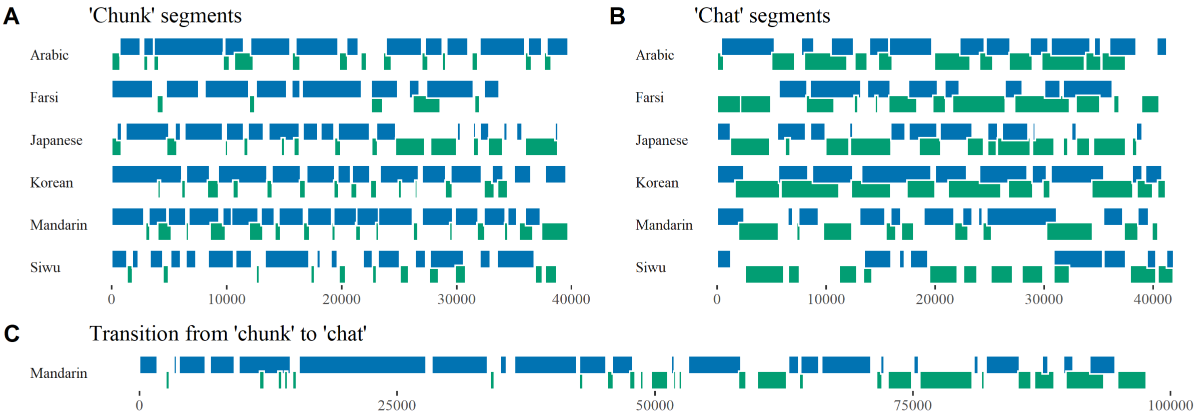

Figure 5: Two types of conversational activity in 6 unrelated languages, showing the viability of identifying broad activity types using ebbs and flows in amount of talk contributed (time in ms). **A**. Tellings ('chunks') are characterized by highly skewed relative contributions, with one participant serving as teller and the other taking on a recipient role (roles may switch, as in the Japanese example). **B**. In 'chat' segments, turns and speaking time are distributed more evenly. **C**. Shifts from one state to another are interactionally managed by participants.

Skantze, 2017), though two critical challenges remain: (i) text corpora of asynchronous interaction are much less piecemeal and incremental than copresent interaction, and (ii) the interactional disruptiveness of timing discrepancies can be masked by the flexibility of human participants, who soon learn to revert to simpler forms of robot-directed talk (Suchman, 2007; Seibt, 2017).

4 Keeping unity and diversity in sight

While text corpora are sometimes treated as shapeless collections of strings, conversational data is not flat but richly structured (Goodwin, 1981; Couper-Kuhlen and Selting, 2017). Each turn at talk builds on what came before and shapes the possibility space of what comes next (Firth, 1935; Heritage, 1984). Conversation analysts call this *sequence organization* (Schegloff, 2007), and cross-linguistic work has uncovered a number of basic sequential positions along with slots for inserts and expansions (Kendrick et al., 2020). Sequences are one of the major tools for organizing social action.

Studying conversational sequences across diverse languages poses considerable challenges, because it requires access not just to form but also to social action or intent (Bender and Koller, 2020). While annotated corpora of dialog acts (Jurafsky et al., 1998) are available for a small number of well-resourced languages (Bunt et al., 2020), they invite an overly categorical view of what is in fact fluid and emergent action ascription. The open-endedness of social actions in casual conversation (Levinson, 2013) places severe constraints on the utility of slot-filling approaches (Papaioannou et al., 2018), which have their origin in narrow task-oriented interactions (Liu et al., 2021).

Here we probe conversational sequencing by starting from coarse-grained but robust structural facts about the relative distribution of turns and talk. Casual interaction often combine lively spates of equitable exchange with more lopsided moments such as tellings in which one participant secures the floor and the other assumes a recipient role (Schegloff, 1982; Goodwin, 1995). Some work on English has captured this as *chat* versus *chunk*, where a chunk is defined as 'a segment where one speaker takes the floor and is allowed to dominate the conversation for an extended period' (Eggins and Slade, 2004; Gilmartin et al., 2018). Using a measure of relative skew in contributions in a moving 10 second window, we can identify stretches corresponding to such a distinction, as well as transitions from one state to another, across unrelated languages (Figure 5A-C).

Knowing about such states and transitions between them is of great relevance to language technology and dialog systems. For instance, the relative predictability of responses differs strongly across states (Gilmartin, 2021). Our results suggest that it is possible to reliably identify at least some broad activity types across languages, opening up possibilities for investigating the linguistic resources that characterize them, and the ways in which people transition between them. The notions of 'chat' and 'chunk' should not be reified, but the distinction points to a data-driven way to get ana-

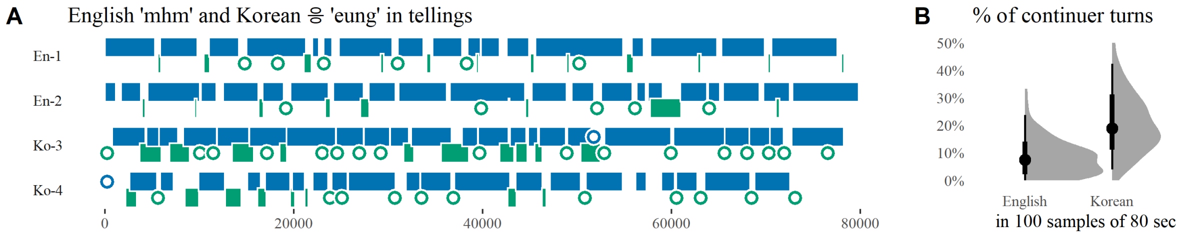

Figure 6: **A.** Continuers (marked ○) are among the most frequent recipient behaviours in tellings (‘chunks’) in both English and Korean, shown here in two 80 second segments each with a strong skew in contributions. **B.** However, their relative frequency is about twice as high in Korean based on 100 random samples of 80 second segments in both languages: on average, 21% of turns are continuers in Korean, against 9% of turns in English. Segments were sampled from 53 (55) distinct conversations involving 106 (95) distinct speakers in Korean (English). Measures are expressed relative to turns instead of time to control for speech rate differences.

lytical grip on structural features of activity types in conversation (Levinson, 1979).

Work on English has found that tellings can be recognized not just by their skewed division of labour, but also by the use of continuers like *mhm* (Howes and Eshghi, 2021; Schegloff, 1982) at places where turn transition would be relevant. We find that this is the case in languages in our sample too, so a simple conclusion could be that we have found a way to unearth universal aspects of tellings, or ‘chunks’, with possible implications for the design of, say, dialog systems sensitive to the interactional achievement of dialog states.

However, on closer look, the data also provides reason to take linguistic diversity seriously. Figure 6A zooms in on four longer stretches of conversation in English and Korean. Here, circles highlight the use of the most frequent continuer in the language, which is ‘mhm’ in English and 응 ‘eung’ in Korean. What is already apparent in the four conversations shown in panel A is also borne out in a quantitative analysis of 100 random samples of 80 second stretches of English and Korean conversations: while 8% of turns are continuers in English, this is 21% in Korean (Figure 6B). This higher frequency also comes with higher susceptibility to overlap: whereas in English, 39% of continuer tokens occurs in full or partial overlap, in Korean this is 73%. The difference does not appear to be reducible to transcription conventions; for instance, in both corpora, continuers repeated in quick succession are transcribed as a distinct format (*mhm mhm*, 응응 *eung eung*) and excluded from these counts; and in both corpora, the average number of words per turn lies around 6 (Korean: 5.7; English: 6.9) and the average number of turns per 10 second window is 5.6 (Korean: 5.6; English: 5.6).

One implication of this is that continuers are apparently relevant at more points during interaction in Korean than in English (Kim, 1999), which has consequences for the design of dialog systems, incremental parsers and conversational agents. For instance, a conversational agent in Korean might have to issue more displays of recipiency and should be prepared to deal with incoming feedback at a higher pace; in the same context, an agent calibrated to English might need different conversation design. The observed variation is extreme enough to warrant a critical look at the notion of feedback relevance spaces (Howes and Eshghi, 2021): perhaps this notion needs to be relativized to cover attested cross-linguistic diversity, as has been suggested in qualitative conversation analytic research (White, 1989; Clancy et al., 1996; Young and Lee, 2004).

We have touched here only on some coarse-grained aspects of sequential structure by way of demonstrating the utility of conversational corpora representing diverse languages. Plenty of other phenomena are ripe for similar treatment.

5 Interactional tools

A key finding of linguistics going back to Estoup and Zipf (Estoup, 1917; Zipf, 1935) is that a small number of items tends to be used for a large amount of work. Power law distributions are ubiquitous in linguistic data and well-studied across a range of languages (see Piantadosi 2014 for review). Most analyses in this line of work tokenize textual data on the basis of the observation that sentences are built out of reusable elements. For such tokenised items (roughly, ‘words’), we have come to expect the rank-frequency distribution to look linear on a log/log scale. Yet language does not come in stray words, but in *turns* at talk: communicative moves

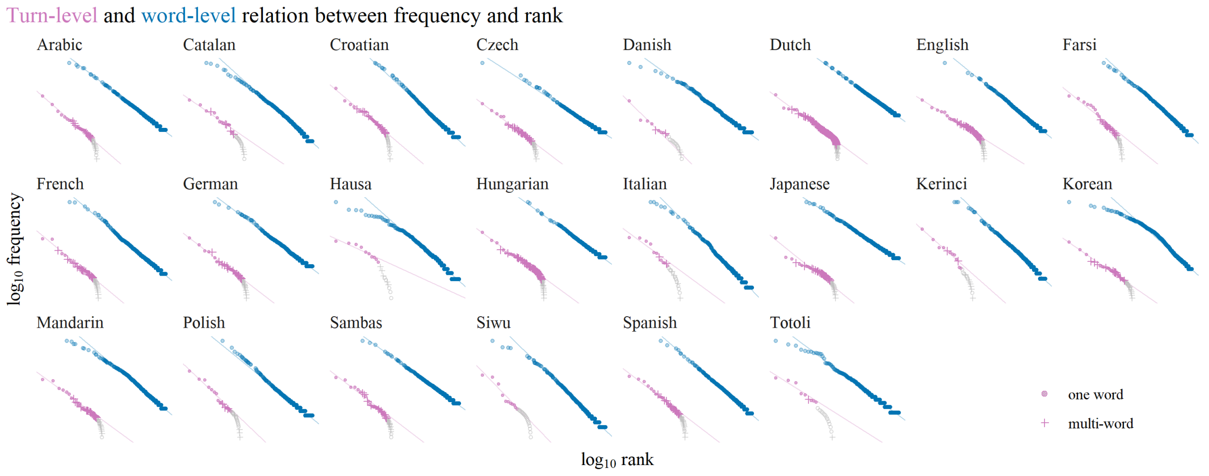

Figure 7: Frequency/rank distributions of tokenized items ('words') and recurring turn formats in conversational corpora with at least 20 such turn formats, representing 22 languages (8 phyla). Tokenized items (blue) show a linear frequency/rank relation in log/log space. Recurring turn formats (whether one-word ○ or multi-word +) appear to obey a similar frequency/rank distribution for the 20% of turns that occur >20 times (purple), tapering off towards lower frequencies and unique turns (grey). Fit fluctuates with corpus size and the parallelism of distributions is most apparent in larger corpora. Data for 21 smaller corpora (12 further phyla) in Appendix A.2.

of varying complexity and conventionality.

Since communicative turns are rarely studied as holistic units, it is an open question to what extent they may or may not show evidence of linguistic laws. Such an organization may seem prima facie unlikely: after all, we know we build complex turns out of simpler elements like words and phrases, and the unlimited expressive power generated by this compositionality is rightly celebrated as one of the hallmarks of human language (Hockett, 1960). On the other hand, as Firth (1935) noted, "Conversation is much more of a roughly prescribed ritual than most people think". Indeed a look at conversational data shows that many turns are not one-offs: at least 28% of the utterances in our sample (436 367 out of 1 532 915 across 63 languages) occur more than once, and over 21% (329 548) occur more than 20 times. Many of these recurring turn formats are interjections and other pragmatic devices that help manage the flow of interaction and calibrate understanding (Yngve, 1970; Jefferson, 1985; Allwood et al., 1990; Ward, 2006; Norrick, 2009). The ubiquity and communicative importance of these items opens up the possibility of power law-like distributions at turn level for some subset of turns.

Here we compare rank-frequency distributions of tokenized items and standalone turn formats in the subset of 22 languages with conversational corpora large enough to feature at least 20 recurring standalone turn formats (Figure 7). We find that tokenized items, as expected, reproduce some well-known structural properties of rank-frequency distributions, including their linear nature on a log-log plot and a systematic deviation from this linearity for the highest frequency (lowest rank) words. For standalone turns, distributions trail off sharply towards the lowest frequencies, reflective of the creative and compositional nature of many utterances. However, the considerable subset of recurring turn formats (Figure 5, purple) may also suggest a partial power law distribution: though the data is sparser, a log-log line fitted to the 20% of turns used at least 20 times has a comparable slope in most corpora.

The result cannot simply be reduced to the fact that standalone turns are drawn from the larger population of single words. Recurrent turn formats tend to have specialized discourse-level functions, and while many are single words like 'm-hm', 'huh?' or 'oh', one out of three are multi-word expressions like English 'but um', Japanese あそうなんだ *a soo nanda* 'oh really' or Hungarian *nem tudom* 'I dunno'. If such recurring formats obey a power law distribution, this provides novel, interactionally motivated evidence in support of the claim that the phrase rather than the word may be a privileged locus for Zipf's law of frequency (Ryland Williams et al., 2015). In this context it is worth recalling that Zipf motivated his observations in terms of tools-for-jobs (Zipf, 1949). Just as the tools of artisans are constructed and arranged in ways that support efficient use, so the tools of language are organized to optimally carry out their jobs. In this sense, we can speak of recurring turn formats as *interactional tools*.

Even if interactional tools make up a significant proportion of turns in any exchange (as we saw in §4, continuers alone may account for 10 to 20% of turns at talk), they are easily obscured by premature tokenization or erased by seemingly innocuous procedures like stopword removal. And yet it is precisely these interactional tools that may prove essential to understanding and modelling interactional infrastructure within and across languages. Getting at these tools and charting their universality and variability represents a key goal for human language technologies.

Overlooking interactional tools and the details of their deployment comes with immediate adverse consequences. A recent user study reported that a significant number of participants ran into interactional turbulence and overlap when interacting with a neural conversational agent through an English-based voice user interface (Hoegen et al., 2019). The turbulence was traced to the agent making segmentation errors and responding to every single utterance detected. This in turn made it harder for human participants to predict when the agent was done speaking, leading to cascades of overlap and confusion. The study proposed two solutions to deal with this (casting the interactional scuffles as situations to be avoided rather than as the rapid and flexible recalibrations they represent in human interaction). The first is to return the floor to a participant as soon as overlap is detected. This seems to assume that any vocalization by a participant is an attempt to take the floor (rather than, say, a minimal display of understanding-so-far). The second proposal is to "filter out stop words and interjections from the participant" on the grounds that the agent responding to these can confuse participants, "since people often do not even realize they are using stop words or are interjecting" (p. 117).

However, people do not produce interjections stochastically, but wield them as interactional tools in the service of calibrating mutual understanding and coordinating joint action (Dingemanse, 2017). A continuer like *mhm* shows understanding, while a repair initiator like *huh?* requests clarification. Indiscriminately filtering out such utterances robs conversational agents of direct access to public displays of understanding and misunderstanding. It also robs people of the very tools they use to co-construct interdependence and understanding, and therefore of a significant part of their linguistic agency. Filtering out interjections to avoid interactional turbulence is like removing all pedestrian crossings to deal with self-driving cars crashing into people. The result may be an incident-free zone, but at significant cost to human flexibility and agency (Illich, 1973).

More work is needed to explore the distributional properties of recurring turn formats, but at least we can conclude that every corpus in our dataset has a subset of recurrent turn formats with metacommunicative functions whose organization suggests a power-law distribution. Their importance in human interaction and by extension human-computer interfaces can hardly be overstated. To build flexible conversational agents (Buschmeier and Kopp, 2018) and localizable conversational interfaces (AbuShawar and Atwell, 2016), we need a solid grip both on possibly universal aspects as well as on the full range of cross-linguistic diversity.

6 Ways forward

Recent work has argued that text-based stochastic models may be running into dimishing returns (Bender and Koller, 2020), has stressed the dearth of relevant conversational data (Gilmartin, 2021), and has pointed to formidable challenges in the creation of truly interactive systems (Marge et al., 2022). Progress will come from multiple fronts, but careful and mindful data curation must be a fundamental part of it (Rogers, 2021). This requires a reconceptualization not just of what counts as "NLP work", but also of what counts as data. Here we have shown how linguistically diverse corpora of co-present conversation may contribute to such a reconceptualization. Now is the time to pivot from text to talk; for few things other than the careful study of interactive language use can bring us closer to an understanding of how language augments human cognition and supports fluid and flexible action coordination. This understanding, in turn, will be critical to make meaningful progress in any domain that involves human language technologies and interactive interfaces.

Fortunately there are good ways forward. Here we summarise three principles to foster a robust and diversity-aware science of human interaction that can underpin engineering solutions, inform language models, and contribute to human-centered applications:

1. *Maximise ecological validity.* To understand and model human interaction, start from rich data that is as close as possible to the natural habitat of language: co-present social interaction. Audio and video corpora of informal conversation are increasingly available for many languages and provide an excellent starting point. What such corpora may lack in breadth they make up for in depth: terabytes of text cannot replace the intricacies of multimodal communication and fluid participation.

2. *Represent interactional infrastructure.* Fine-grained temporal organization, radical interdependency and emergent social action are characteristics of human interaction that cannot be reduced to stochastic properties of text. The timing, co-construction and sequential positioning of turns is as consequential to their meaning and interpretation as their form. The complex and socially distributed nature of sequence organization exceeds the powers of slot filling approaches and requires renewed attention to interactional tools: the metacommunicative resources people use to construct and calibrate mutual understanding on the fly.

3. *Design for diversity.* To escape the reign of the resourceful few, use linguistically diverse data and anticipate a combination of universal and language-specific design principles. This not only ensures broad empirical coverage and enables new discoveries; it also benefits diversity and inclusion, as it enables language technology development that serves the needs of diverse communities.

Our aim in this position paper has been to sketch how these principles, fuelled by insights from the study of dialogue, linguistic typology, conversation analysis, and a range of other fields, can provide the conceptual foundations for novel work on human language technologies and human interaction.

7 Conclusions

Cross-linguistically diverse corpora of conversation are increasingly available and can help us to better understand basic interactional patterns and build more flexible, context-sensitive language technologies. For this to work, it is important to keep both linguistic diversity and potential universals in sight (Sidnell and Enfield, 2012; Enfield et al., 2013). We cannot assume that a given piece of interactional infrastructure is universal just based on a handful of languages. Encouragingly, our results suggest that even relatively small corpora can support robust generalizations about key aspects of interactional infrastructure.

One reason this matters is *empirical grounding*. Cross-linguistic and comparative work on human interaction has barely started (Floyd, 2021; Ameka and Terkourafi, 2019). There may be more universals of interaction; equally likely is that there are more patterns of unrecognized diversity. Both types of outcomes are important for how they shed light on the structure of human interaction, and both have implications for language technology and human-computer interfaces. More fundamental work in pragmatic typology is needed — and computational approaches to low-resource languages provide a promising starting point.

But an equally important reason to consider linguistic diversity in language technology and natural language processing is one of *linguistic agency* (Di Paolo et al., 2018; Nguyen et al., 2016; Suchman, 2020). Designing interfaces that allow people to flexibly wield their preferred communicative resources lessens the hegemony of any one language and makes technology more inclusive, more humane and more convivial for a larger range of possible users (Munn, 2018; Voinea, 2018). Localizing user interface elements is only a first step; diversity in how and when basic interactional structures are deployed must ultimately be reflected in the design of conversational user interfaces.

In the rush for better language technology we should avoid being driven into the arms of only the best-resourced languages and the easiest-to-get data. We need language models that are representative of the actual ways in which people use language, and conversational interfaces that give people the feeling they do not have to leave their own linguistic identities at the door. Comparative and computational work on conversational corpora from a wide range of languages is crucial to develop a strong foundational understanding of universals and diversity in interactional infrastructure, and to ensure we can build the humane and diversity-aware language technologies of the future.

A Appendix

A.1 Turn-taking: validating analyses

In order to make visible the structure and timing of turn-taking in quotidian interaction, the turn-taking analysis in §3 takes all directly adjacent conversational turns in dyadic interactions in which a speaker change occurs, without regard for type of turn or social action. Stivers et al. (2009) limited their comparison to polar question-answer sequences, achieving a form of "natural control" to ensure comparability. In our dataset, the timing of such sequences does not radically differ from the overal timing distribution, for a subset of 10 languages for which we are able to automatically identify probable QA-sequences (Figure A1). Given the broad-scale comparability of the overall timing distributions (in grey) and the more controlled subset of at least 250 question-answer sequences per language (in black), we conclude that QA sequences can act as a useful proxy for timing in general (supporting Stivers et al. 2009), but also that QA-sequences are not necessary for a relatively robust impression of overall timing.

Analyses of turn-taking sometimes note that some turns are more likely to appear in overlap than others. In particular, continuers (also known as acknowledgement tokens (Jefferson, 1985) or backchannels (Yngve, 1970)) do not represent a claim to the conversational floor that is as strong as some other turns (Schegloff, 1982; Levinson, 2016). It is possible that cross-cultural variation in the frequency of sequentially defined continuers (as we report in §4) might underlie some part of the observed differences in turn-taking distributions. However, we feel that to dichotomize our resolutely cross-linguistic dataset into "continuers" versus "other turns" would be premature and would risk overinterpreting data that requires careful qualitative consideration.

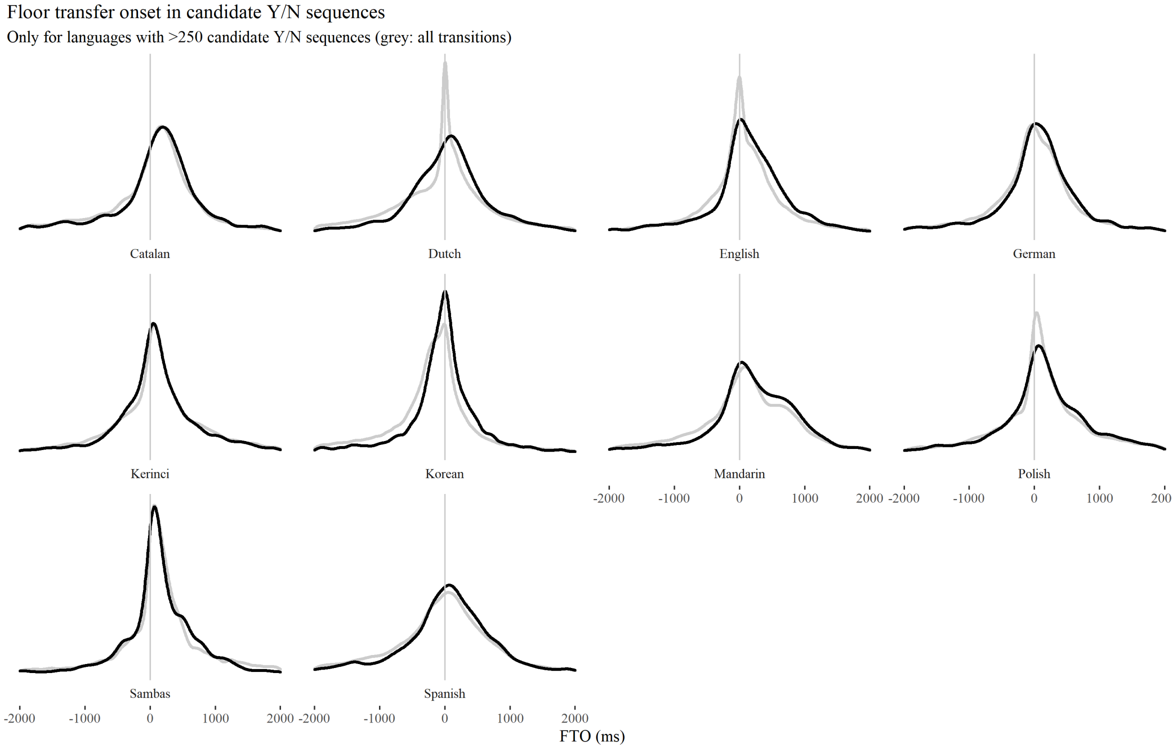

Figure A1: Timing of turn-taking in candidate polar question-answer sequences, for 10 languages with >250 such sequences. Probable sequences where identified by selecting all pairs of directly adjacent turns by two distinct participants where the first was annotated as ending in a question mark and the second was a non-unique turn format. Only languages in which questions are transcribed with a final "?" and which had at least 250 such sequences are included here.

A.2 Frequency and rank in smaller corpora

Turn-level and word-level relations between rank and frequency are sensitive to fluctuations in corpus size, so in the body of the paper we provide data for the 22 corpora that feature at least 20 turn formats that occur at least 20 times. Here we provide the same for a further 21 languages in which there are at least 9 but less than 20 recurrent turn formats (Figure A2). As in §5, turn-level fit lines are computed on the 20% of turns that occur >20 times (purple); however, fit strongly fluctuates with corpus size and should not be taken at face value.

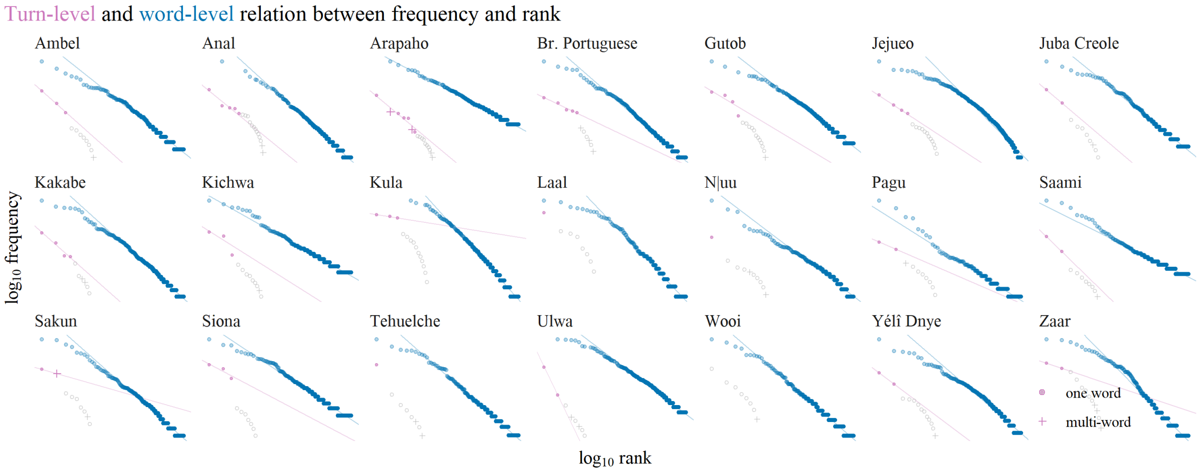

Figure A2: Frequency/rank distributions of tokenized items (‘words’) and recurring turn formats in conversational corpora with at least 9 such turn formats, representing 21 languages (18 phyla). Tokenized items (blue) show a linear frequency/rank relation in log/log space. Recurring turn formats (whether one-word ○ or multi-word +) taper off towards lower frequencies and unique turns (grey) but more frequent items may obey a similar frequency/rank distribution (purple).

B Dataset

B.1 Curation, reproducibility and ethical considerations

The data described and analysed here consists of a range of maximally diverse language resources collected (as primary data) over several decades with the contributions and consent of communities around the world. Because our aim is to highlight the potential of available language resources and to maximise the reproducibility of our research, we focus on existing data made available for research purposes in language archives like the Endangered Language Archive (ELAR), The Language Archive (TLA) and Paradisec, as well as through centralized services like CLARIN and the Linguistic Data Consortium (LDC).

While most of the sourced corpora come from publicly-funded and openly accessible language documentation or language resource platforms, some corpora are currently unpublished or paywalled. Due to the diverse set of licensing and publication agreements with the providers of the sourced corpora, we are unable to provide direct, unrestricted access to the dataset. To enhance transparency and reproducibility of the findings presented in the study, we provide an extensive datasheet with details on motivation, makeup, and processing steps, as well as full information on the larger set of corpora we have considered. This includes metadata on compilers, durable links to archival copies, and a quantitative overview of key properties of turn duration, timing and translations. The study repository is here: `https://osf.io/zd34r/`

The work reported here also comes with ethical considerations. There are at least three points at which such considerations are important when it comes to the kind of data considered here: data collection; data usage; and implications of any technologies developed on the basis of such data. With regard to the first point, we only work with corpora collected with the help and involvement of communities who have given their informed consent for this data to be recorded, annotated, translated and archived. The other two points are discussed in detail in Levow et al. (2021), who develop a shared task reliant on corpora much like the ones considered here (albeit not focusing on co-present conversation). With regard to data usage, the corpora considered here are only those for which contributors have granted access openly or to all registered users, usually for research purposes. We cannot redistribute the dataset directly, but have strived to document the process of curation in sufficient detail to enable others to register and access the data (Liesenfeld and Dingemanse, 2022). With regard to technological applications, as with any technology, there is potential for helpful as well as harmful uses (Hovy and Spruit, 2016) and we side with Levow et al. (2021) in stressing the need for computational linguists to work closely with language communities in maximising helpful uses and minimising harmful ones. As noted above, our supplementary materials also include details in the form of a data statement (Bender and Friedman, 2018).

B.2 Inclusions and exclusions

Not all of the available corpora are represented in all analyses presented in the paper or appendices, because corpora differ in size, precision of annotation, and level of transcription. For instance, some corpora use segmentation methods that do not precisely link annotations to the corresponding communicative turn. Others may split annotations in ways that are not clearly documented and that do not seem to correspond to the turn-level annotation format that is most common across corpora. While such corpora may lend themselves to various corpus linguistic analyses, incommensurable methods of segmentation means that it would take considerable additional work to use this data in qualitative and quantitative analyses of timing, turn-taking and talk-in-interaction.

The online supplementary materials provide several illustrative examples along with a detailed accounting of reasons for exclusions. We are optimistic that in the future, language technology can be harnessed to improve time-alignment and temporal precision of existing conversational corpora (Bird, 2021; Umair et al., 2021). We also hope that annotation procedures can be designed with an eye to staying faithful to the temporal and sequential structure of the primary data.

While we have collected information on sign language corpora, the set considered here does not include any of them, as corpora of casual conversation in sign languages are exceedingly rare (Kopf et al., 2021), and annotation conventions tend to focus on the level of signs rather than utterances, sequences and timing. Incorporating sign language corpora requires careful work with sign language linguists and deaf communities to arrive at common and commensurable annotation standards that afford the cross-modal comparison of interactional structure.

B.3 List of languages and corpora

The table below presents the 63 languages included in the curated dataset, with glottocodes and families according to Glottolog (Hammarström et al., 2021) and with citations according to source archives. Full details, including corpus statistics, sample annotations and links, are in the study repository.

Abstract

Adversarial robustness has attracted much attention recently, and the mainstream solution is adversarial training. However, the tradition of generating adversarial perturbations for each input embedding (in the settings of NLP) scales up the training computational complexity by the number of gradient steps it takes to obtain the adversarial samples. To address this problem, we leverage Flooding method which primarily aims at better generalization and we find promising in defending adversarial attacks. We further propose an effective criterion to bring hyper-parameter-dependent flooding into effect with a narrowed-down search space by measuring how the gradient steps taken within one epoch affect the loss of each batch. Our approach requires zero adversarial sample for training, and its time consumption is equivalent to fine-tuning, which can be 2-15 times faster than standard adversarial training. We experimentally show that our method improves BERT's resistance to textual adversarial attacks by a large margin, and achieves state-of-the-art robust accuracy on various text classification and GLUE tasks.

1 Introduction

Despite their impressive performances on various NLP tasks, deep neural networks such as BERT (Devlin et al., 2019) suffer a sharp performance degradation against deliberately constructed adversarial attacks (Zeng et al., 2021; Wang et al., 2021b; Nie et al., 2020; Zang et al., 2020; Ren et al., 2019; Zhang et al., 2019). A line of work attempts to alleviate this problem by creating adversarially robust models via defense methods, including adversarial data augmentation (Chen et al., 2021; Si et al., 2021), regularization (Wang et al., 2021a), and adversarial training (Wang et al., 2020; Zhu et al., 2020; Madry et al., 2018). Data augmentation and adversarial training rely on additional adversarial examples generated either by hand-crafting or conducting gradient ascent on the clean data for virtual adversarial samples.

However, generating adversarial examples scales up the cost of training computationally, which makes vanilla adversarial training almost impractical on large-scale NLP tasks like QNLI (Question-answering NLI, Rajpurkar et al., 2016). An increasing amount of researchers express their concern about the time-consuming property of standard adversarial training and offer cheaper but competitive alternatives by (i) replacing the perturbation generation with an additional generator network (Baluja and Fischer, 2017; Xiao et al., 2018), or by (ii) combining the gradient computation of clean data and perturbations into one backward pass (Shafahi et al., 2019). These approaches still rely on additional adversarial examples generated either by the model itself or by an extra module.

In this work, we propose a novel method, Flooding-X, to largely improve adversarial robustness without any adversarial examples, maintaining the same computational cost as conventional BERT fine-tuning. The vanilla Flooding (Ishida et al., 2020) method is a practical regularization technique to boost model generalization by preventing further reduction of the training loss when it reaches a *reasonably small value*. It results in a model performing normal gradient descent when training loss is above the decided value but gradient ascent when below. By continuing to "random walk" with the same non-zero value as a "virtual loss", the model drifts into an area with a flat loss landscape that is claimed to lead to better generalization (Ishida et al., 2020). Interestingly, we find that Flooding method is also promising in increasing models' resistance to adversarial attacks. Despite the significant rise in robust accuracy, the so-called reasonably small value, which is a hyper-parameter, takes effort to be found and varies for

each dataset, which requires an overly extensive search among the numerous candidates.

In an attempt to narrow down the candidates of hyper-parameter, we propose *gradient accordance* as an informative criterion for optimal values that bring Flooding into effect, which is used as a building-block in Flooding-X. We measure how *accordant* the gradients of the batches are by analyzing how the gradient descent steps based on part of an epoch affect the loss of each batch. Gradient accordance is computationally friendly and is tractable during training process. Experiments on various tasks show a close relation between gradient accordance and overfitting. As a result, we propose gradient accordance as a reliable flooding criterion to make the training loss flood around the level when the model has nearly overfitted. That is to say, we leverage the training loss of the model right before overfitting as the value of flood level.

Flooding-X is especially useful and shows great advantage over adversarial training in terms of computational cost when the training dataset is relatively large. Experimental results demonstrate that our method achieves stated-of-the-art robust accuracy with BERT on various tasks and improves its robust accuracy by 100 to 400% without using any adversarial example, consuming any extra training time, or conducting overly extensive search for hyper-parameter. Our main contributions are as follows.

1) We analyze and demonstrate the effectiveness of Flooding, which is designed for generalization, in improving adversarial robustness especially in NLP domain.

2) We propose a promising indicator, i.e. gradient accordance, to alleviate Flooding method from tedious search of the hyper-parameter.

3) We conduct comprehensive experiments on NLP tasks to illustrate the potential of Flooding for improving BERT's adversarial robustness.

2 Why Does Flooding Boost Adversarial Robustness?

2.1 Vanilla Flooding

We first describe the vanilla Flooding regularization method (Ishida et al., 2020) for alleviating overfitting via keeping training loss from reducing to zero. Under the main assumption that learning until zero loss is harmful, Ishida et al. (2020) propose Flooding to intentionally prevent further reduction of the training loss when it reaches a reasonably small value, which is called the *flood level*. Intuitively, this approach makes the training loss float around the pre-defined flood level and alter from normal mini-batch gradient descent to gradient ascent if the loss is below the flood level. With the constraint of flood level, the model will continue to "random walk" around the non-zero training loss, which is expected to reach a flat loss landscape.

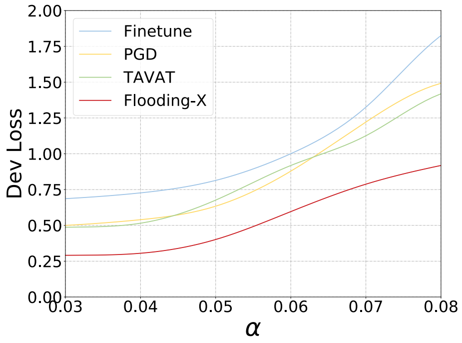

Figure 1: Input loss landscape of vanilla BERT and different adversarial training algorithms under Gaussian random noise of standard deviation α on SST-2 dataset.

The algorithm of Flooding is defined as follow:

$$\widetilde{J}(\boldsymbol{\theta}) = |J(\boldsymbol{\theta}) - b| + b, \tag{1}$$

where J denotes the original learning objective, and $\widetilde{J}$ represents the modified learning objective with flooding. The positive value b is the flood level specified by user, and $\boldsymbol{\theta}$ is the model parameter. Accordingly, the flooded empirical risk is then defined as

$$\widetilde{R}(\boldsymbol{f}) = |\widehat{R}(\boldsymbol{f}) - b| + b, \tag{2}$$

within which $\widehat{R}(\boldsymbol{f})$ / $\widetilde{R}(\boldsymbol{f})$ denotes the original / flooded empirical risk respectively, and $\boldsymbol{f}$ refers to the score function to be learned by the model. During the back propagation process, the gradient of $\widehat{R}(\boldsymbol{f})$ w.r.t. model parameters and $\widetilde{R}(\boldsymbol{f})$ point to the same direction when $\widetilde{R}(\boldsymbol{f})$ is above b but to the opposite direction when it is below b. As a result, model performs normal gradient descent when the learning objective is above the flood level, and gradient ascent when below.

2.2 Smooth Parameter Landscape Leads to Better Robustness

Flooding is designed for overfitting, but why is it valid for adversarial robustness? According to the definition described in the previous section, Flooding does not make any difference to the training process when the loss is beyond the flood level. When the training loss approaches the flood level, on closer inspection, gradient descent and gradient ascent begin to alternate. Assume that the model with learning rate ε performs gradient descent for the n-th batch and then gradient ascent for batch $n+1$, which results in:

$$\begin{aligned} \boldsymbol{\theta}_n &= \boldsymbol{\theta}_{n-1} - \varepsilon \boldsymbol{g}(\boldsymbol{\theta}_{n-1}), \\ \boldsymbol{\theta}_{n+1} &= \boldsymbol{\theta}_n + \varepsilon \boldsymbol{g}(\boldsymbol{\theta}_n). \end{aligned} \tag{3}$$

In the equations above, $\boldsymbol{g}(\boldsymbol{\theta}) = \nabla_{\boldsymbol{\theta}} J(\boldsymbol{\theta})$ is the gradient of $J(\boldsymbol{\theta})$ w.r.t. model parameters. We can then get

$$\begin{aligned} \boldsymbol{\theta}_{n+1} = & \boldsymbol{\theta}_{n-1} - \varepsilon \boldsymbol{g}(\boldsymbol{\theta}_{n-1}) + \varepsilon \boldsymbol{g}\big(\boldsymbol{\theta}_{n-1} \\ & - \varepsilon \boldsymbol{g}(\boldsymbol{\theta}_{n-1})\big), \end{aligned} \tag{4}$$

which is, by Taylor expansion, approximately equivalent to

$$= \boldsymbol{\theta}_{n-1} - \frac{\varepsilon^2}{2} \nabla_{\boldsymbol{\theta}} \| \boldsymbol{g}(\boldsymbol{\theta}_{n-1}) \|^2. \tag{5}$$

Thus, theoretically, when the training loss is relatively low, the model alters into a new learning mode where the learning rate is $\varepsilon^2/2$ and the objective is to minimize $\|\boldsymbol{g}(\boldsymbol{\theta})\|^2$. Generally, the flooded model is guided into an area with a smooth parameter landscape that leads to better adversarial robustness (Stutz et al., 2021; Prabhu et al., 2019; Yu et al., 2018; Li et al., 2018a). As is demonstrated in Figure 1, adversarial training brings about a smoother loss change to the model when the input embedding is perturbed by Gaussian random noise, which is closely related the stronger adversarial robustness. Among all the training methods involved in Figure 1, Flooding-X leads to the most smooth loss landscape, indicating an overall more robust model against attacks.

2.3 Achilles' Heel of Flooding

Despite its potential in boosting model's resistance to adversarial attacks, the optimal flood level has to be searched by performing exhaustive search within a wide range at tiny steps, which is not easily at hand. A relatively large value of flood level lengthens the gradient steps and keeps the model from convergence, while a tiny value causes hardly any difference to the training process. The effect of Flooding deeply relies on the flood level, which, at the same time, is also sensitive to the subtle change of this hyper-parameter. Figure 2 reveals that even a slight change on the value of flood level can make a huge difference on the adversarial robustness of the so-trained model. In an attempt to ease the effort of searching and make the best of Flooding, we propose a promising and reliable criterion to narrow down the search space, which is described in detail in the next section.

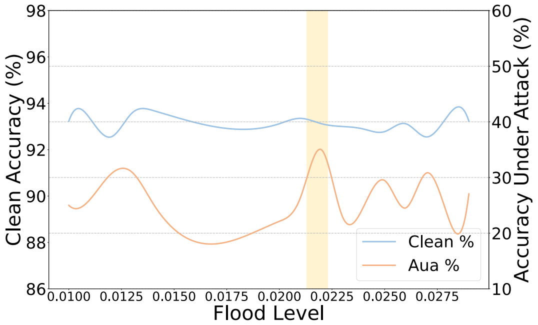

Figure 2: Influence of different flood levels on performance of the trained BERT on SST-2 against the attack of TextFooler (Jin et al., 2020). The range marked in yellow is lined out by our proposed criterion , i.e., gradient accordance. The optimal value of flood level is guaranteed within the narrowed-down space.

3 Gradient Accordance as a Criterion for Flooding

Since Flooding is proposed as an attempt to avoid overfitting, we intuitively suppose that the optimal flood level would be found at the stage when the model is about to overfit. That is, we leverage the training loss before overfitting as the flood level. Inspired by influence function (Koh and Liang, 2017), we propose *gradient accordance* as a criterion for flooding, which is empirically proved to be reliable and indicative. We consider the effect of the model updated w.r.t. one epoch on each of its batches as a signal of overfitting. As is indicated by its name, this criterion measures the relation among the gradients of each batch on epoch level, evaluating whether the model updated on an epoch has the same positive effect on the batches on average. Now we provide the formal definition of gradient accordance.

3.1 Preliminaries

We denote a model as a functional approximation f which is parameterized by $\boldsymbol{\theta}$. Consider a training data point x with the ground truth label y, which results in a loss $\mathcal{L}(f(\boldsymbol{\theta}, x), y)$. The gradient of the loss w.r.t. the parameters is thus

$$\boldsymbol{g} = \nabla_{\boldsymbol{\theta}} \mathcal{L}(f(\boldsymbol{\theta}, x), y), \tag{6}$$

whose negation denotes the direction in which the parameters $\boldsymbol{\theta}$ are updated to better correspond to the desired outputs on the training data (Fort et al., 2019). Now let's consider two data points x_1 and x_2 with their corresponding labels y_1 and y_2. According to the definition above, the gradient of sample 1 is $\boldsymbol{g_1} = \nabla_{\boldsymbol{\theta}}\mathcal{L}(f(\boldsymbol{\theta}, x_1), y_1)$. We try to inspect how the small change of $\boldsymbol{\theta}$ in the direction $-\boldsymbol{g_1}$ influences the loss on sample x_1 or x_2:

$$\begin{aligned}\Delta\mathcal{L}_1 =& \mathcal{L}(f(\boldsymbol{\theta} - \varepsilon\boldsymbol{g_1}, x_1), y_1) \\ &- \mathcal{L}(f(\boldsymbol{\theta}, x_1), y_1),\end{aligned} \tag{7}$$

where $f(\boldsymbol{\theta}, x_1)$ can be expanded by Taylor expansion to be:

$$f(\boldsymbol{\theta}, x_1) = f(\boldsymbol{\theta} - \varepsilon\boldsymbol{g_1}, x_1) + \varepsilon\boldsymbol{g_1}\frac{\partial f}{\partial \boldsymbol{\theta}} + \mathcal{O}(\varepsilon^2). \tag{8}$$

Here, we refer to $(\varepsilon\boldsymbol{g_1}\frac{\partial f}{\partial \boldsymbol{\theta}} + \mathcal{O}(\varepsilon^2))$ as $T(x_1)$; and by repeating the similar expansion we can get

$$\begin{aligned}&\mathcal{L}(f(\boldsymbol{\theta}, x_1), y_1) \\ &= \mathcal{L}(f(\boldsymbol{\theta} - \varepsilon\boldsymbol{g_1}, x_1) + T(x_1), y_1) \\ &= \mathcal{L}(f(\boldsymbol{\theta} - \varepsilon\boldsymbol{g_1}, x_1), y_1) \\ &\quad + \frac{\partial \mathcal{L}}{\partial f}T(x_1) + \mathcal{O}(T^2(x_1)).\end{aligned} \tag{9}$$

Equation (7) is thus equal to

$$\begin{aligned}\Delta\mathcal{L}_1 &= -\frac{\partial \mathcal{L}}{\partial f}T(x_1) - \mathcal{O}(T^2(x_1)) \\ &= -\frac{\partial \mathcal{L}}{\partial f}(\varepsilon\boldsymbol{g_1}\frac{\partial f}{\partial \boldsymbol{\theta}} + \mathcal{O}(\varepsilon^2)) \\ &= -\varepsilon\boldsymbol{g_1} \cdot \boldsymbol{g_1} - \mathcal{O}(\varepsilon^2).\end{aligned} \tag{10}$$

Similarly, the change of the loss on x_2 caused by the gradient update by x_1 is $\Delta\mathcal{L}_2 = -\varepsilon\boldsymbol{g_1} \cdot \boldsymbol{g_2} - \mathcal{O}(\varepsilon^2)$. Notably, $\Delta\mathcal{L}_1$ is negative by definition since the model is updated with respect to x_1 and naturally leads to a decrease on its loss. The model updated on x_1 is considered to have a positive effect on x_2 if $\Delta\mathcal{L}_2$ is also negative while an opposite effect if positive. The equations above demonstrate that this co-relation is equivalent to the overlap between the gradients of the two data points $\boldsymbol{g_1} \cdot \boldsymbol{g_2}$, which we hereafter refer to as *gradient accordance*.

3.2 Coarse-Grained Gradient Accordance

Data-point-level gradient accordance is too fine-grained to be tractable in practice. Thus, we attempt to scale it up and result in coarse-grain gradient accordance at batch level, which is computationally tractable and still reliable as a criterion for overfitting.

Consider a training batch B_0 with n samples $\boldsymbol{X} = \{x_1, x_2, \ldots, x_n\}$ and labels $\boldsymbol{y} = \{y_1, y_2, \ldots, y_n\}$ of k classes $\{c_1, c_2, \ldots, c_k\}$. These samples can be divided into k groups according to their labels $\boldsymbol{X} = \boldsymbol{X_1} \cup \boldsymbol{X_2} \cup \cdots \cup \boldsymbol{X_k}$, and so are the labels $\boldsymbol{y} = \bigcup_{i=1}^{k} \boldsymbol{y_i}$, where all the samples in $\boldsymbol{X_m}$ belong to class c_m. Thus, we have the sub-batch $B_0^1 = \{\boldsymbol{X_1}, \boldsymbol{y_1}\}$. We then define *class accordance* score of two sub-batches B_0^1 and B_0^2 of classes c_1 and c_2 as:

$$C(B_0^1, B_0^2) = \mathbb{E}[cos(\boldsymbol{g_1}, \boldsymbol{g_2})], \tag{11}$$

where $\boldsymbol{g_1}$ is the gradient of the training loss of sub-batch B_0^1 w.r.t. the model parameters, and $cos(\boldsymbol{g_1}, \boldsymbol{g_2}) = (\boldsymbol{g_1}/|\boldsymbol{g_1}|) \cdot (\boldsymbol{g_2}/|\boldsymbol{g_2}|)$. Class accordance measures whether the gradient taken with respect to a sub-batch B_0^1 of class c_1 will also decrease the loss for samples in another sub-batch B_0^2 of class c_2 (Fort et al., 2019; Fu et al., 2020).

Further consider that there are N batches in one training epoch and the training samples are of k classes. The *batch accordance* score between batches B_s and B_t is defined as

$$\begin{aligned}&S_{batch\,accd}(B_s, B_t) \\ &\quad = \frac{1}{k(k-1)} \sum_{j=1}^{k} \sum_{\substack{i=1 \\ i \neq j}}^{k} C(B_s^i, B_t^j).\end{aligned} \tag{12}$$

Batch accordance quantifies the learning consistency of two batches by evaluating how the model updated on one batch affects the other. To be more specific, a positive batch accordance denotes that the measured two batches are under the same learning pace since the model updated according to each batch benefits them both. The gradient accordance of certain epoch (or a part of an epoch, namely the sub-epoch, which can be several batch iterations) is finally defined as

$$\begin{aligned}&S_{epoch\,accd} = \\ &\frac{1}{N(N-1)} \sum_{t=s+1}^{N} \sum_{s=1}^{N-1} S_{batch\,accd}(B_s, B_t).\end{aligned} \tag{13}$$

Gradient accordance scales the batch accordance score up from a measure of two batches to that of a sub-epoch.

Criterion for Flooding A positive gradient accordance means that the model performed gradient descent w.r.t. the certain epoch decreases the loss of its batches on average, indicating that the learning pace of most batches are in line with each other. A negative one means that the model has overfitted to some of the training batches since the update of one epoch increases the loss of its batches on average, which is right the stage we would like to identify for the model by gradient accordance. We assume that the optimal flood level lies in the range of the training loss of a model when it is about to overfit. In the following section, we empirically prove that gradient accordance is a reliable and promising criterion for flooding.

4 Experiments

In this section, we provide comprehensive analysis on Flooding-X through extensive experiments on five text classification datasets of various tasks and scales: SST (Socher et al., 2013), MRPC (Dolan and Brockett, 2005), QNLI (Rajpurkar et al., 2016), IMDB (Maas et al., 2011) and AG News (Zhang et al., 2015). The statistics of these involved datasets are illustrated in Table 1, including the volume of training / test set and the average word count of the training samples. We conduct experiments on BERT-base (Devlin et al., 2019) and compare robust accuracy of Flooding-X with other adversarial training algorithms to demonstrate its strength. We implement all models in MindSpore.

Dataset	Training Set	Test Set	# Words
SST-2	67k	1.8k	19
MRPC	3.7k	1.7k	44
QNLI	105k	5.4k	37
IMDB	25k	25k	268
AG News	120k	7.6k	40

Table 1: Statistics of datasets.

4.1 Baseline Methods

We compare Flooding-X with three adversarial training algorithms, one regularization method as well as the vanilla Flooding.

PGD Projected gradient descent (PGD, Madry et al., 2018) formulates adversarial training algorithms into solving a minimax problem that minimizes the empirical loss on adversarial examples that can lead to maximized adversarial risk.

FreeLB Zhu et al. (2020) propose FreeLB to improve the generalization of language models. By adding adversarial perturbations to word embeddings, FreeLB generates virtual adversarial samples inside the region around input samples.

TAVAT Token-Aware Virtual Adversarial Training (TAVAT, Li and Qiu, 2021) aims at fine-grained perturbations, leveraging a token-level accumulated perturbation vocabulary to initialize the perturbations better and constraining them within a token-level normalization ball.

InfoBERT InfoBERT (Wang et al., 2021a) leverages two mutual-information-based regularizers for robust model training, suppressing noisy mutual information while increasing mutual information between local stable features and global features.

Flooding Flooding (Ishida et al., 2020) has been introduced in detail in section 2.1. We implemented Flooding and search for the flooding level at the step of 0.01 according to the tradition. The best result for each dataset is reported.

4.2 Attack Methods and Evaluation Metrics

Three well-received attack methods are leveraged via TextAttack (Morris et al., 2020) for an extensive comparison between our proposed method and baseline algorithms.

TextFooler (Jin et al., 2020) identifies the important words for target model and repeats replacing them with synonyms until the prediction of the model is altered. Similarly, TextBugger (Li et al., 2018b) also searches for important words and modifies them by choosing an optimal perturbation from the generated several kinds of perturbations. BERTAttack (Li et al., 2020) applies BERT in a semantic-preserving way to generate substitutes for the vulnerable words detected in the given input.

We consider four evaluation metrics to measure BERT's resistance to the mentioned adversarial attacks under different defence algorithms.

Clean% The clean accuracy refers to the model's test accuracy on the original clean dataset.

Aua% Accuracy under attack measures the model's prediction accuracy on the adversarial data deliberately generated by certain attack method. A higher *Aua%* means a more robust model and a better defender.

Suc% Attack success rate is evaluated by the ratio of the number of texts successfully perturbed by a specific attack method to the number of all the involved texts. Robust models are expected to score low on *Suc%*.

#Query Number of queries denotes the average attempts the attacker queries the target model. The larger the number is, the harder the model is to be attacked.

4.3 Implementation Details

All the baseline methods are re-implemented based on their open-released codes and the results are competing to those reported. We train our models on NVIDIA RTX 3090 and RTX 2080Ti GPUs, depending on the volume of the dataset involved. Most of the parameters such as learning rate and warm-up step are in line with vanilla BERT (Devlin et al., 2019) and the baseline methods. For all of the adversarial methods we set the training step to be 5 for a fair comparison, which is a trade-off between training cost and model performance . The clean accuracy (*Clean%*) is tested on the whole test dataset. The other three metrics (e.g., *Aua%*, *Suc%* and *#Query*) are evaluated on the whole test dataset for SST-2 and MRPC, and 800 randomly chosen samples for IMDB, AG NEWS, and QNLI. We train 10 epochs for each model on each dataset, among which the last epochs are selected for the comparison of adversarial robustness.

4.4 Experimental Results

The extensive results of all the above mentioned methods are summarized in Table 2. Generally, our Flooding-X method improves BERT by a large margin in terms of its resistance to adversarial attacks, surpassing the baseline adversarial training algorithms on most datasets under different attack methods.

Under TextFooler attack (Jin et al., 2020), our algorithm reaches the best robust performance on four datasets: IMDB, AG News, SST-2, and MRPC. We observe that Flooding is more effective on smaller datasets than larger ones, since the smaller datasets with shorter training sentences are easier to be memorized by the neural network and are more likely to cause overfitting. On QNLI dataset where Flooding-X fails to win, the accuracy under attack is only 0.2 points lower than the 5-step PGD. This might be explained by the mild change in gradient accordance during training on QNLI dataset, in which case the precise stage of overfitting is hard to be identified. Though we believe that a better value of flood level exists and can further boost the performance, we refuse to take on the pattern of extensive hyper-parameter searching which is against the original purpose of Flooding-X.

Notably, our method performs better than the baseline adversarial training methods by 5 to 20 points on average even without using any adversarial examples as training source, not to mention the vanilla BERT. Under most cases, our method remains the best performing algorithm against BERTAttack (Li et al., 2020) and TextBugger (Li et al., 2018b). This proves that our method maintains effectiveness under different kinds of adversarial attacks. As a byproduct, the clean accuracy of our method is also competing among the baseline methods, which is inherent to the vanilla Flooding that aims at better generalization.

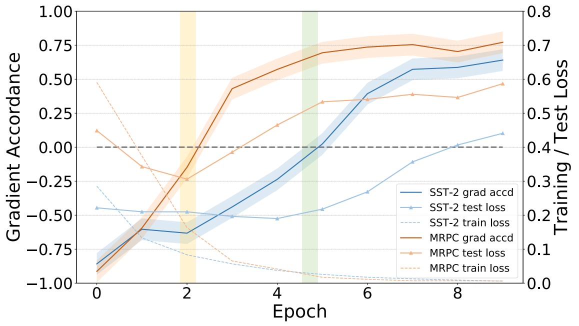

Figure 3: Gradient accordance and training/test loss of each BERT epoch finetuned on SST-2 and MRPC datasets. The grey dashed line represents zero gradient accordance, above which is the model considered to be overfitted. The region marked in yellow and green are the ranges of training iterations where the gradient accordance changes from positive to negative for MRPC and SST-2 respectively.

5 Analysis and Discussion

In this section, we construct supplementary experiments to further analyze the effectiveness of Flooding-X and its building block, i.e., gradient accordance.

5.1 Does Gradient Accordance Capture Overfitting?

Influence function (Koh and Liang, 2017) inspects the influence of one single training data on the model prediction and stiffness (Fort et al., 2019) measures how the model updated according to one sample affects the model prediction on another. Based on these two works, gradient accordance is proposed as a means for identifying model overfitting at sub-epoch level.

Table 2: Experimental results of different models' defense performances on five datasets. The best performance is marked in **bold**. *Clean%* stands for the accuracy tested on the original clean dataset. *Aua%* is short for accuracy under attack, and *Sus%* is the attack success rate of the textual attack methods. Notably, a lower *Sus%* is expected for a more robust model.

As seen in Figure 3, during training process, the turning point of gradient accordance from negative to positive closely matches the point when the test loss is about to increase, which is well received as a signal of overfitting. Since it is computationally intractable to calculate gradient accordance after trained on every single batch, we can only figure out the range where the model is about to overfit by computing gradient accordance at sub-epoch level.

5.2 How does Flooding-X Help with Robustness?

Despite its outstanding performance of the last training epoch, we find that Flooding-X boosts the robustness of model at an earlier stage than standard fine-tuning and adversarial training methods like FreeLB. As is shown in Figure 4, Flooding-X improves BERT's adversarial robustness to a relatively high level at epoch 5, which is competitive with that of standard fine-tuning at the last epoch. Besides, Flooding-X accelerates the increase of robustness at late training stage. Starting from epoch 7 our method enables a steep increment on the accuracy under attack, which is due to the effect of Flooding that forces the model to perform a more fierce "random walk" since the training loss of most batches are going below the flooding level. It is also demonstrated that the training loss stops approaching zero under the constraint of Flooding-X, while the standard fine-tuning and adversarial training continues to decrease the training loss towards zero which brings about the risk of overfitting.

5.3 Time Consumption

To further reveal the strength of Flooding besides its robustness performance, we compare its GPU training time consumption with baseline methods on several datasets of different sizes. For a fair comparison, every model of each dataset is trained on single NVIDIA RTX 2080Ti GPU with the same batch size, among which models on SST-2 are trained with a batch size of 32 while QNLI

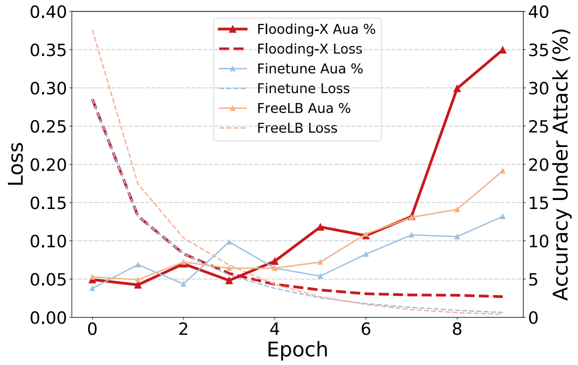

Figure 4: Loss and $Aua\%$ (accuracy under attack) of BERT trained on SST-2 under different methods. Flooding prevents the training loss from approaching zero and results in great improvement of BERT's resistance to adversarial attacks.

Method	**SST-2**	**QNLI**	**IMDB**
Finetune	260	$1,193$	$1,059$
Flooding	**272**	**1,222**	**1,087**
TAVAT	967	$4,105$	$4,609$
FreeLB	$1,041$	$4,340$	$4,457$
PGD	$1,305$	$5,571$	$5,664$
InfoBERT	$2,174$	$12,077$	$19,279$

Table 3: GPU time consumption (seconds) of training one epoch on the whole dataset. Flooding costs nearly the same as fine-tuning and 2-15 times less than the baseline adversarial training algorithms.

and IMDB are trained with 8 and 4 respectively since the training sentences are way longer than SST-2. As is demonstrated in Table 3, the time consumption (seconds) of Flooding is competitive with standard fine-tuning, which is far less than that of adversarial training algorithms.

6 Related Work

Adversarial Training Adversarial training (AT) is a well-received method for defending adversarial attacks. As an attempt against adversarial attacks, AT generates gradient-based adversarial samples and leverage them for further training (Goodfellow et al., 2015). A line of work tries different means for the generation of adversarial examples. The PGD algorithm (Madry et al., 2018), compared as a baseline method in our experiments, involves multiple projected gradient ascent steps to find the adversarial perturbations which are then used for updating the model parameters. However, it is computationally expensive and has aroused many attempts to cut down on the cost. Shafahi et al. (2019) and Zhu et al. (2020) focus on finding better adversarial sample while maintaining a low cost. Despite gradient-based methods which generates adversarial perturbations on the continuous input embedding, some works tailor AT for NLP fields. The adversarial examples are generated by replacing the original texts based on certain rules such as semantic similarity (Alzantot et al., 2018; Jin et al., 2020; Li et al., 2020). Ebrahimi et al. (2018) propose a perturbation strategy that conducts character insertion, deletion, and replacement. The mentioned algorithms of AT generates additional adversarial examples either by calculating gradients or by human force, which is computationally expensive and effort taking.

Overfitting and Criterion Deep neural networks are shown to suffer from overfitting to training configurations and memorise training scenarios (Takeoka et al., 2021; Rodriguez et al., 2021; Roelofs et al., 2019; Werpachowski et al., 2019), which leads to poor generalization and vulnerability towards adversarial perturbations. One way of identifying overfitting is to see whether the generalization gap, i.e., the test minus the training loss, is increasing or not (Salakhutdinov, 2014). Ishida et al. (2020) further decompose the situation of the generalization gap increasing into two stages with regard to the change of both training and test losses (Zhang et al., 2021; Belkin et al., 2018; Arpit et al., 2017). Derived from influence function (Koh and Liang, 2017), Fort et al. (2019) propose the concept of Stiffness as a new perspective of generalization. They measure how stiff a network is by looking at how a small gradient step in the network parameters on one example affects the loss on another example. However, from the practical perspective, it is computationally intractable to compute the stiffness between every single sample during the process of standard training where thousands of samples are involved in one batch.

7 Conclusion

In this work, we propose Flooding-X as an efficient and computational-friendly algorithm for improving BERT's resistance to adversarial attacks. We first theoretically prove that the vanilla Flooding method is able to boost model's adversarial robustness by leading it into a smooth parameter landscape. We further propose a promising and computationally tractable criterion, Gradient Accordance, to detect when the model is about to overfit and accordingly narrow down the hyperparameter space for Flooding with an optimal flood level guaranteed. Experimental results prove that gradient accordance is closely related with the phenomenon of overfitting, equipped with which Flooding-X beats the well-received adversarial training methods and achieves state-of-the-art performances on various NLP tasks against different textual attack methods. This implies that adversarial examples, either generated by gradient-based algorithms or human efforts, are not a must for the improvement of adversarial robustness. We call for further exploration and deeper understanding in the nature of adversarial robustness and attacks.

Abstract

Evaluating Natural Language Generation (NLG) systems is a challenging task. Firstly, the metric should ensure that the generated hypothesis reflects the reference's semantics. Secondly, it should consider the grammatical quality of the generated sentence. Thirdly, it should be robust enough to handle various surface forms of the generated sentence. Thus, an effective evaluation metric has to be multifaceted. In this paper, we propose an automatic evaluation metric incorporating several core aspects of natural language understanding (language competence, syntactic and semantic variation). Our proposed metric, RoMe, is trained on language features such as semantic similarity combined with tree edit distance and grammatical acceptability, using a self-supervised neural network to assess the overall quality of the generated sentence. Moreover, we perform an extensive robustness analysis of the state-of-the-art methods and RoMe. Empirical results suggest that RoMe has a stronger correlation to human judgment over state-of-the-art metrics in evaluating system-generated sentences across several NLG tasks.

1 Introduction

Automatic generation of fluent and coherent natural language is a key step for human-computer interaction. Evaluating generative systems such as text summarization, dialogue systems, and machine translation is challenging since the assessment involves several criteria such as content determination, lexicalization, and surface realization (Liu et al., 2016; Dale and Mellish, 1998). For assessing system-generated outputs, human judgment is considered to be the best approach. Obtaining human evaluation ratings, on the other hand, is both expensive and time-consuming. As a result, developing automated metrics for assessing the quality of machine-generated text has become an active area of research in NLP.

The quality estimation task primarily entails determining the similarity between the reference and hypothesis as well as assessing the hypothesis for grammatical correctness and naturalness. Widely used evaluation metrics such as BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), and ROUGE (Lin, 2004) which compute the word-overlaps, were primarily designed for evaluating machine translation and text summarization systems. Word-overlap based metrics, on the other hand, are incapable of capturing the hypotheses' naturalness and fluency. Furthermore, they do not consider the syntactic difference between reference and hypothesis. In a different line of research, word mover distance (WMD) (Kusner et al., 2015), BERTScore (Zhang et al., 2020a) and MoverScore (Zhao et al., 2019) compute word embedding based similarity for evaluating system-generated texts. Although these metrics employ the contextualized representation of words, they do not take the grammatical acceptability of the hypothesis and the syntactical similarity to the reference into account.

To address these shortcomings, we propose RoMe, an automatic and robust metric for evaluating NLG systems. RoMe employs a neural classifier that uses the generated sentence's grammatical, syntactic, and semantic qualities as features to estimate the quality of the sentence. **Firstly**, it calculates the earth mover's distance (EMD) (Rubner et al., 1998) to determine how much the hypothesis differs from the reference. During the computation of EMD, we incorporate hard word alignment and soft-penalization constants to handle various surface forms of words in a sentence, such as repeated words and the passive form of a sentence. **Secondly**, using a semantically enhanced tree edit distance, the difference in syntactic structures between the reference and hypothesis sentences is quantified. **Thirdly**, the metric incorporates a binary classifier to evaluate the grammatical accept-

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 5645 - 5657
May 22-27, 2022

ability of the generated hypotheses. **Finally**, the scores obtained from the preceding steps are combined to form a representation vector, which is subsequently fed into a self-supervised network. The network produces a final score, referred to as RoMe's output which represents the overall quality of the hypothesis statement.

We investigate the effectiveness of our proposed metric by conducting experiments on datasets from various domains of NLG such as knowledge graph based language generation dataset (KELM (Agarwal et al., 2021)), dialogue datasets (Eric et al., 2017; Chaudhuri et al., 2021), the WebNLG 2017 challenge dataset (Shimorina et al., 2018), structured data to language generation dataset (BAGEL (Mairesse et al., 2010) and SFHOTEL (Wen et al., 2015)). The capability of existing metrics to handle various forms of text has lately become a matter of debate in the NLP community (Ribeiro et al., 2020; Novikova et al., 2017; Liu et al., 2016). Hence, we conduct an extensive robustness analysis to assess RoMe's performance in handling diverse forms of system-generated sentences. To verify our claim, we design the analysis based on the text perturbation methods used in CHECKLIST (Ribeiro et al., 2020) and adversarial text transformation techniques from TextFooler (Jin et al., 2020) and TextAttack (Morris et al., 2020). Empirical assessment on benchmark datasets and the robustness analysis results exhibit that RoMe can handle various surface forms and generate an evaluation score, which highly correlates with human judgment. RoMe is designed to function at the sentence level and can be used to evaluate English sentences in the current version of the implementation. In the future versions, we plan to extend RoMe by including more languages. We released the code and annotation tool publicly [1].

2 Preliminaries

2.1 Earth Mover's Distance

The Earth Mover's Distance (EMD) estimates the amount of work required to transform a probability distribution into another (Rubner et al., 1998). Inspired by the EMD, in NLP the transportation problem is adopted to measure the amount of work required to match the system generated hypothesis sentence with the reference sentence (Kusner et al., 2015; Zhao et al., 2019). Let us define the reference as $\mathcal{R} = \{r_1, r_2, ..., r_p\}$ and the hypothesis as $\mathcal{H} = \{h_1, h_2, ..., h_q\}$, where r_i and h_j indicates the i-th and j-th word of the reference and hypothesis, respectively. The weight of the word r_i and h_j are denoted as m_i and n_j respectively. Then, the total weight distribution of $\mathcal{R}$ and $\mathcal{H}$ is $m_{\sum} = \sum_{i=1}^{p} m_i$ and $n_{\sum} = \sum_{j=1}^{q} n_j$, respectively. Here, the sentence-level and normalized TF-IDF score of a word is considered as the word's weight. Formally, EMD can be defined as:

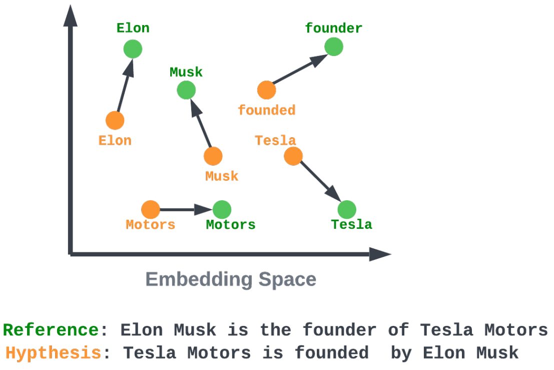

Figure 1: Illustrating an abstraction of the EMD.

$$EMD(\mathcal{H}, \mathcal{R}) = \frac{\min_{f_{ij} \in \mathcal{F}(\mathcal{H}, \mathcal{R})} \sum_{i=1}^{p} \sum_{j=1}^{q} d_{ij} f_{ij}}{\min(m_{\sum}, n_{\sum})} \tag{1}$$

where d_{ij} is the distance between the words r_i and h_j in the space and $\mathcal{F}(\mathcal{H}, \mathcal{R})$ is a set of possible flows between the two distributions that the system tries to optimize. In Equation 1, $EMD(\mathcal{H}, \mathcal{R})$ denotes the amount of work required to match the hypothesis with the reference. The optimization is done following four constraints:

$$\begin{aligned} f_{ij} &\geq 0 \qquad i = 1, 2, ..., p \text{ and } j = 1, 2, .., q, \\ \sum_{j=1}^{q} f_{ij} &\leq m_i \qquad i = 1, 2, ..., p, \\ \sum_{i=1}^{p} f_{ij} &\leq n_j \qquad j = 1, 2, ..., q, \\ \sum_{i=1}^{p} \sum_{j=1}^{q} f_{ij} &= \min(m_{\sum}, n_{\sum}) \end{aligned} \tag{2}$$

The first constraint indicates that each flow must be non-negative. The second constraint limits the total weights flowing from r_i to less than or equal to m_i. Similarly, the third constraint restricts the total weights flowing from h_j to less than or equal to n_j. The final constraint indicates that the total flow of weights must be equal to the minimum weight distribution. Figure 1 depicts the EMD for a given hypothesis-reference pair.

2.2 Syntactic Similarity and Tree Edit Distance

In computational linguistics, dependency and constituency trees are used to represent syntactic dependencies between words in a sentence. Unlike the constituency tree, a dependency tree can represent non-adjacent and non-projective dependencies in a sentence, which frequently appear in spoken language and noisy text. That leads us to prefer dependency trees over constituency trees for evaluating NLG output.

Formally, a dependency tree is a set of nodes $\Omega = \{w_0, w_1, ..., w_k\}$ and a set of dependency links $\mathcal{G} = \{g_0, g_1, ..., g_k\}$, where w_0 is the imaginary root node and g_i is an index into Ω representing the governor of w_i. Every node has exactly one governor except for w_0, which has no governor (Hall and Novák, 2010). Syntactic similarity between a pair of dependency trees can be estimated using several methods, such as graph centralities and Euclidean distances (Oya, 2020). In our work, we exploit the Tree Edit Distance (TED) algorithm (Zhang and Shasha, 1989) to estimate syntactic similarity between reference and hypothesis. TED is typically computed on ordered labeled trees and can thus be used to compare dependency trees. The *edit* operations performed during the comparison of parsed dependency trees include *Change*, *Delete*, and *Insert*.

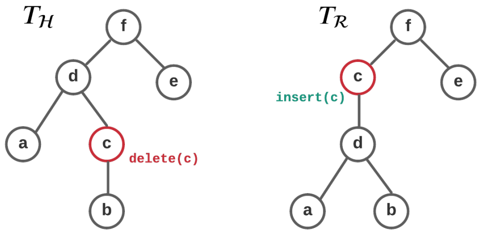

Figure 2: Visualization of the required *edit* operations to transform $T_{\mathcal{H}}$ to $T_{\mathcal{R}}$. The operations corresponds to the following sequence: *delete*(node with label *c*), *insert*(node with label *c*).

Let us consider $T_{\mathcal{H}}$ and $T_{\mathcal{R}}$ be the parsed dependency trees of the hypothesis and reference, respectively. The operations required to transform one tree into another are visualized in Figure 2. In TED, an exact match between the nodes of the compared trees is performed to decide if any edit operation is required. In this work, the syntactic difference between hypothesis and reference is determined by the output of TED, which specifies the total number of edit operations.

3 RoMe

In RoMe, a neural network determines the final evaluation score given a reference-hypothesis pair. The network is trained to predict the evaluation score based on three features: semantic similarity computed by EMD, enhanced TED, and the grammatical acceptability score. We explain these features in the following subsections.

3.1 Earth Mover's Distance Based Semantic Similarity

During the computation of EMD, we employ *hard word alignment* and *soft-penalization* techniques to tackle repetitive words and passive forms of a sentence. We compute a distance matrix and a flow matrix as described below and finally obtain EMD utilizing Equation 1.

Hard Word Alignment. We first align the word pairs between reference and hypothesis based on their semantic similarities. The alignment is performed by computing all paired cosine similarities while taking word position information into account, as in (Echizen-ya et al., 2019). In contrast to (Echizen-ya et al., 2019), we use contextualized pre-trained word embedding from the language model ALBERT (Lan et al., 2020). ALBERT uses sentence-order prediction loss, focusing on modeling inter-sentence coherence, which improves multi-sentence encoding tasks. The word alignment score is computed as follows:

$$\mathcal{A}(r_i, h_j) = \frac{\vec{r_i} \cdot \vec{h_j}}{\|\vec{r_i}\| \|\vec{h_j}\|} \cdot \frac{|q\,(i+1) - p\,(j+1)\,|}{pq} \qquad (3)$$

where $\vec{r_i}$ and $\vec{h_j}$ denote the contextualized word embedding of r_i and h_j, respectively. The first part of the right side of the equation computes the cosine similarity between $\vec{r_i}$ and $\vec{h_j}$, and the second part calculates the relative position information as proposed in (Echizen-ya et al., 2019).

Figure 3 depicts a matrix of word alignment scores generated on an example pair of sentences. This alignment strategy fails to handle repetitive words where a word from the hypothesis may get aligned to several words in the reference (see Figure 4). To tackle such cases, we restrict the word alignment by imposing a hard constraint. In the hard constraint, we prevent the words in the hypothesis from getting aligned to multiple words in the reference as illustrated by the dotted arrows in Figure 4. We denote the resulting set of hard-aligned word pairs as $\mathcal{A}_{hc}$.

	tesla	motors	is	founded	by	elon	musk
elon	0.11	0.14	0.17	0.10	0.07	0.34	0.07
musk	0.11	0.20	0.23	0.13	0.08	0.20	0.40
founded	0.08	0.14	0.18	0.97	0.23	0.12	0.09
tesla	0.34	0.20	0.09	0.11	0.15	0.11	0.12
motors	0.06	0.29	0.07	0.12	0.14	0.14	0.23

Figure 3: An example word alignment matrix for the reference sentence: "*tesla motors is founded by elon musk*" and its passive form: "*elon musk founded tesla motors*" is illustrated here.

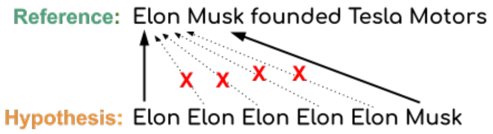

Figure 4: An example hypothesis containing repetitive words.

Transport Distance. A distance matrix $\mathcal{D}$ is required to compute the final EMD score. For each aligned pair $(r_i, h_j) \in \mathcal{A}_{hc}$ where $\frac{\vec{r_i}\cdot\vec{h_j}}{\|\vec{r_i}\|\|\vec{h_j}\|} > \delta$, the distance between r_i and h_j is computed as follows:

$$d_{ij} = 1.0 - \frac{\vec{r_i}\cdot\vec{h_j}}{\|\vec{r_i}\|\|\vec{h_j}\|} \cdot e^{\gamma\cdot\frac{|q(i+1)-p(j+1)|}{pq}} \qquad (4)$$

where $d_{ij} \in \mathcal{D}$ and δ is a confidence threshold found via hyper-parameter search, $\gamma \in [-1, 0)$ is a soft-penalization constant. For all the non-hard-aligned pairs and aligned pairs with value less than δ, the distance d_{ij} receives a maximum value of 1.0. Intuitively, a lower value of d_{ij} implies that the word needs to travel a shorter distance in the transportation problem of EMD. In Equation 4, $e^{\gamma\cdot\frac{|q(i+1)-p(j+1)|}{pq}}$ works as a penalty where a higher position difference multiplied with the negative constant γ will results in low d_{ij} score. The role of γ is explained below.

Soft-penalization. Existing metrics often impose hard penalties for words with different order than the reference sentence (Zhao et al., 2019; Echizen-ya et al., 2019). For instance, sentences phrased in the passive form obtain a very low score in those metrics. Addressing this issue, we introduce a soft-penalization constant $\gamma = -\frac{|j-i|}{\max(p,q)}$ in Equation 4 to handle the passive form of a sentence better. Let us consider a reference, "*Shakespeare has written Macbeth*" and the passive form of the sentence as hypothesis, "*The Macbeth is written by Shakespeare*". The word *Shakespeare* appears at the beginning of the reference and at the end of the hypothesis, thus the position difference is larger. In such scenario, γ imposes a lower penalty as it divides the position difference by the length $max(p, q)$.

Finally, following the optimization constraints of Equation 2, we obtain the transportation flow $\mathcal{F}(\mathcal{H}, \mathcal{R})$. For the optimized flow $f_{ij} \in \mathcal{F}(\mathcal{H}, \mathcal{R})$, the final equation of EMD is as follows:

$$EMD(\mathcal{H},\mathcal{R}) = \frac{\min_{f_{ij}\in\mathcal{F}(\mathcal{H},\mathcal{R})}\sum_{i=1}^{p}\sum_{j=1}^{q} d_{ij} f_{ij}}{\min(m_{\sum}, n_{\sum})} \qquad (5)$$

The semantic similarity between hypothesis and reference is denoted as $\mathcal{F}_{sem} = 1.0 - EMD$. The normalized value of EMD is used to calculate $\mathcal{F}_{sem}$.

3.2 Semantically Enhanced TED

To estimate the difference between the syntactic structures of reference and hypothesis, we extend the TED algorithm (Zhang and Shasha, 1989). The original TED algorithm performs edit operations based on an exact match between two nodes in the dependency trees of hypothesis and reference. In this work, we modify the TED algorithm and compute a word embedding-based cosine similarity to establish the equivalence of two nodes. Two nodes are considered equal, if the cosine similarity of their embedding representations exceeds the threshold θ. This allows the semantically enhanced TED to process synonyms and restricts it from unnecessary editing of similar nodes. We call the resulting algorithm TED-SE. The normalized value of TED-SE is denoted as $\mathcal{F}_{ted}$. We compute TED-SE over the lemmatized reference and hypothesis since lemmatized text exhibits improved performance in such use cases (Kutuzov and Kuzmenko, 2019). The lemmatizer and dependency parser from Stanza (Qi et al., 2020) are utilised to obtain the tree representation of the text. Further details are provided in Appendix A.1.

3.3 Grammatical Acceptability Classification

Linguistic competence assumes that native speakers can judge the grammatical acceptability of a sentence. However, system-generated sentences are not always grammatically correct or acceptable. Therefore, we train a binary classifier on the Corpus of Linguistic Acceptability (CoLA) (Warstadt et al., 2019), predicting the probability that the hypothesis is grammatically acceptable. CoLA is a collection of sentences from the linguistics literature with binary expert acceptability labels containing over 10k examples (Warstadt et al., 2019) [2]. The classifier is based on BERT-large (Devlin et al., 2019) and trained to optimize binary cross-entropy loss. A text sequence is fed as input and as output, the classifier produces the class membership probability (grammatically acceptable, grammatically unacceptable). The model achieves an accuracy of 80.6% on the out-of-domain CoLA test set (Warstadt et al., 2019, p. 8). We denote the score from the classifier as the feature $\mathcal{F}_g$, which is used to train a neural network (see §3.4).

3.4 Final Scorer Network

A feed-forward neural network takes the previously computed features as input and learns a function $f(\mathcal{F}_{sem}; \mathcal{F}_{ted}; \mathcal{F}_g)$ in the final step, yielding a final output score in the $[0, 1]$ interval. The output score is regarded as the overall quality of the hypothesis. Following a self-supervised paradigm, the network is trained on artificially generated training samples from the KELM dataset (Agarwal et al., 2021). KELM contains knowledge-grounded natural sentences. We randomly choose 2,500 sentence pairs from the KELM dataset and generate 2,500 more negative samples by randomly augmenting the sentences using TextAttack (Morris et al., 2020) and TextFooler (Jin et al., 2020). Following a similar approach, we additionally generate 1,000 test sentence pairs from the KELM dataset. Overall, we then have 5,000 training and 1,000 test examples. The network is a simple, two-layered feed-forward network optimized with stochastic gradient descent using a learning rate of 1e-4.

4 Experiments and Analysis

4.1 Data

To assess RoMe's overall performance, first, we benchmark on two language generation datasets, BAGEL (Mairesse et al., 2010) and SFHOTEL (Wen et al., 2015), containing 404 and 796 data points, respectively. Each data point contains a meaning representation (MR) and a system generated output. Human evaluation scores of these datasets are obtained from (Novikova et al., 2017). Furthermore, we evaluate dialogue system's outputs on Stanford in-car dialogues (Eric et al., 2017) containing 2,510 data points and the soccer dialogue dataset (Chaudhuri et al., 2019) with 2,990 data points. Each data point of these datasets includes a user query, a reference response, and a system response as a hypothesis. Three different system outputs are evaluated for each dialogue dataset. We use the human annotated data provided by (Chaudhuri et al., 2021). Moreover, we evaluate the metrics on the system generated outputs from the WebNLG 2017 challenge (Shimorina et al., 2018).

Finally, to conduct robustness analysis, we randomly sample data points from KELM (Agarwal et al., 2021) and perturb them with adversarial text transformation techniques. Three annotators participated in the data annotation process (two of them are from a Computer Science and one from a non-Computer Science background), where they annotated the perturbed data. We provided the annotators with an annotation tool which displays the reference sentence and the system output for each data point. The annotators were asked to choose a value from a range of [1,3], for each of the categories: *Fluency*, *Semantic Correctness*, and *Grammatical correctness*. In this case, the values stand for 1: *poor*, 2: *average*, and 3: *good*. The overall inter-annotator agreement score, κ is 0.78. The annotation tool and its interface are discussed in detail in Appendix A.2.

4.2 Hyper-parameter Settings

We use $\delta = 0.60$ and $\theta = 0.65$ in §3.1. Best values are found by a hyper-parameter search from a range of [0,1.0] with an interval of 0.1. RoMe obtained the best result by utilizing ALBERT-large (Lan et al., 2020) model with 18M parameters and 24 layers. Furthermore, we use the English word embedding of dimension 300 to obtain results from Fasttext (Bojanowski et al., 2017) throughout the paper. As the grammatical acceptability classifier, we train a BERT-base model with 110M parameters and 12 layers. The hidden layer size is 768 with a hidden layer dropout of 0.1. A layer norm epsilon of 1e-12 was used for layer normalization. GELU (Hendrycks and Gimpel, 2016) was used as the activation function. We use a single GPU with 12GBs of memory for all the evaluations.

4.3 Baselines

We select both the word-overlap and embedding-based metrics as strong baselines. For the experiment and robustness analysis we choose BLEU (Pa-

pineni et al., 2002), METEOR (Banerjee and Lavie, 2005), BERTScore (Zhang et al., 2020a) and MoverScore (Zhao et al., 2019). We evaluate the metrics on the sentence level to make a fair comparison.

4.4 Results

Table 1 shows the performance of different metrics on data to language generation datasets (BAGEL and SFHOTEL). In both the BAGEL and SFHOTEL, a meaning representation (MR), for instance *inform(name='hotel drisco',price_range='pricey')* is given as a reference sentence, where the system output is: *the hotel drisco is a pricey hotel*, in this case. Although, RoMe outperformed the baseline metrics in evaluating the *informativeness*, *naturalness* and *quality* score, the correlation scores remain low with regard to human judgment. This is because the MR, which is not a natural sentence, is the reference statement in this scenario. For all the experiments, we take the normalized human judgement scores. We firstly evaluate our model using Fasttext (Bojanowski et al., 2017) word embedding. We notice a significant improvement in results when we replace the Fasttext embedding with contextualized word embedding obtained from BERT (Devlin et al., 2019). Furthermore, we experiment with multiple language models and finally, we reach to our best performing model with ALBERT-large (Lan et al., 2020). In all the experiments, we report the results of RoMe, using ALBERT-large (Lan et al., 2020). In Table 1, WMD and SDM refer to word mover distance and sentence mover distance, respectively, used in MoverScore. We report the results of WDM and SMD from (Zhao et al., 2019).

Table 4 demonstrates the evaluation results on dialogue datasets. We evaluated the system-generated dialogues from three dialogue system models: Mem2Seq (Madotto et al., 2018), GLMP (Wu et al., 2019), and DialoGPT (Zhang et al., 2020b). In case of in-car dataset, all the non-word-overlap metric achieved a better correlation score than the word-overlap based metrics. This is because generated responses in dialogue systems are assessed based on the overall semantic meaning and correctness of the information. Overall, RoMe achieves stronger correlation scores on both in-car and soccer dialogue datasets in evaluating several dialogue system outputs.

Finally, we investigate the outputs of nine distinct systems that competed in the WebNLG 2017

Table 6: Metrics correlation with human judgment on system outputs from the WebNLG 2017 challenge. Here, r: Pearson correlation co-efficient, ρ: Spearman's correlation co-efficient, τ: Kendall's Tau.

competition and report the correlation scores in Table 6. Although RoMe achieves the best correlation in most of the cases, we notice a comparable and in some cases better results achieved by the MoverScore (Zhao et al., 2019). A correlation graph is plotted in Figure 5 to investigate the metrics' performance correlations further. The graph is constructed from RoMe and baseline metrics' scores on the BAGEL dataset. As observed from the correlation graph, we can infer that our proposed metric, RoMe correlates highly with the MoverScore. However, since RoMe handles both the syntactic and semantic properties of the text it achieved better results in all the datasets across different NLG tasks.

4.5 Ablation Study

We conduct an ablation study to investigate the impact of the RoMe's components on its overall performance. Table 5 exhibits the incremental improvement in Spearman's correlation coefficient, that each of the components brings to the metric. We randomly choose 100 system-generated dialogue utterances from the dialogue datasets, since they frequently contain sentences in passive form and repetitive words. The correlation of standard EMD with the human judgement is denoted as "RoMe score with EMD$_{std}$". Inclusion of semantic word alignment (EMD$_{align}$) and soft-penalization (EMD$_{soft}$) further improved the correlation score. The classifier was not used until this point in the ablation since there was just one score. Moreover, the correlation score improved significantly when the semantically enhanced TED and grammatical acceptability were introduced as features in addition to the EMD score to a neural classifier. We hypothesize that the inclusion of language features related to grammar and syntactic similarity helped the neural network achieve better performance.

4.6 Qualitative Analysis

RoMe is developed in a modular fashion, so it may be used to generate scores for semantic similarity, syntactic similarity, and grammatical acceptability separately. Table 2 shows the component-wise score and the final score of RoMe on three example data points. In the first example, RoMe demonstrates its ability of capturing similar sentences

Metrics	**BLEU**			**METEOR**			**BERTScore**			**MoverScore**			**RoMe**		
Perturbation methods	f	s	g	f	s	g	f	s	g	f	s	g	f	s	g
Entity replacement	0.06	0.04	0.06	0.09	0.09	0.08	0.11	0.07	0.09	0.16	0.13	0.11	0.16	0.19	0.14
Adjective replacement	0.07	0.06	0.07	0.09	0.13	0.11	0.11	0.11	0.13	0.13	0.17	0.16	0.18	0.23	0.18
Random word replacement	0.05	0.06	0.03	0.06	0.06	0.05	0.11	0.10	0.08	0.11	0.13	0.09	0.15	0.15	0.23
Text transformation	0.03	0.01	0.03	0.08	0.09	0.07	0.13	0.15	0.15	0.15	0.18	0.19	0.18	0.19	0.21
Passive form	0.02	0.01	0.04	0.08	0.10	0.08	0.19	0.24	0.21	0.23	0.24	0.22	0.25	0.28	0.28

Table 7: Metrics Spearman correlation score against human judgment on perturbed texts. Here, f: fluency, s: semantic similarity, g: grammatical correctness.

by obtaining high score. The scores from several components in the second example demonstrate RoMe's ability to handle passive form. The final example in Table 2 demonstrates that RoMe penalizes sentence with repetitive word.

Table 3 shows the performance of the three baselines and RoMe in handling erroneous cases. Although the first example contains a completely different hypothesis and the second case with repetitive hypothesis both BERTScore and MoverScore exhibit high score. On the contrary, BLEU score is unable to handle such scenarios. However, by obtaining low scores, RoMe demonstrates its ability to understand such cases better.

4.7 Robustness Analysis

In this section, we design five test cases to stress the models' capabilities. For the analysis purpose, we randomly sample data points from KELM (Agarwal et al., 2021) (cases 1, 2, and 4) and BAGEL (Mairesse et al., 2010) (cases 3 and 5). The annotators annotate the sampled data points on the following criteria: *fluency*, *semantic correctness*, *grammatical correctness*.

Case 1: Entity replacement. We perform invariance test (INV) from (Ribeiro et al., 2020) to check the metrics' NER capability in assessing the text quality. In this approach, we replace the entities present in the text partially or fully with other entities in the dataset. For instance, "*The population of Germany*" gets transformed to "*The population of England*".

Case 2: Adjective replacement. Similar to the entity replacement, in this case we choose 100 data points from KELM that contain adjective in them. Then we replace the adjectives with a synonym and an antonym word to generate two sentences from a single data point. For instance, the adjective *different* is replaced with *unlike* and *same*. At the end of this process, we obtain 200 data points.

Case 3: Random word replacement. The words in different positions in the text are replaced by a generic token *AAA* following the adversarial text attack method from (Morris et al., 2020), in this case. For instance, the sentence, "*x is a cheap restaurant near y*" is transformed into "*x is a cheap restaurant AAA AAA*". We select the greedy search method with the constraints on stop-words modification from the TextAttack tool. This approach generates repetitive words when two consecutive words are replaced.

Case 4: Text transformation. We leverage TextFooler (Jin et al., 2020) to replace two words in the texts by similar words, keeping the semantic meaning and grammar preserved.

Case 5: Passive forms. In this case, we randomly choose 200 data points from the KELM (Agarwal et al., 2021) dataset where the system generated responses are in passive form.

From the results of robustness analysis in Table 7, it is evident that almost all the metrics obtain very low correlation scores with respect to human judgment. Word-overlap based metrics such as BLEU and METEOR mostly suffer from it. Although RoMe achieves higher correlation scores in most of the cases, there are still scope for improvement in handling the fluency of the text better. Text perturbation techniques used to design the test cases often generate disfluent texts. In some cases, the texts' entities or subjects get replaced by words from out of the domain. From our observation, we hypothesize that handling keywords such as entities may lead to a better correlation score.

5 Related Work

A potentially good evaluation metric is one that correlates highly with human judgment. Among the unsupervised approaches, BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005) and ROUGE (Lin, 2004) are the most popular evaluation metrics traditionally used for evaluating NLG systems. Although these metrics perform well in evaluating machine translation (MT) and summarization tasks, (Liu et al., 2016) shows that none of the word overlap based metrics is close to human level performance in dialogue system evaluation scenarios. In a different line of work, word embedding based metrics are introduced for evaluating NLG systems (Mikolov et al., 2013; Matsuo et al., 2017). Several unsupervised automated metrics were proposed that leverage EMD; one of them is word mover's distance (WMD) (Kusner et al., 2015). Later, (Matsuo et al., 2017) proposed an evaluation metric, incorporating WMD and word-embedding, where they used word alignment between the reference and hypothesis to handle the word-order problem. Recently, (Echizen-ya et al., 2019) introduced an EMD-based metric WE_WPI that utilizes the word-position information to tackle the differences in surface syntax in reference and hypothesis.

Several supervised metrics were also proposed for evaluating NLG. ADEM (Lowe et al., 2017) uses a RNN-based network to predict the human evaluation scores. With the recent development of language model-based pre-trained models (Zhang et al., 2020a) proposed BERTScore, which uses a pre-trained BERT model for evaluating various NLG tasks such as machine translation and image captions. Recently, (Zhao et al., 2019) proposed MoverScore, which utilizes contextualized embedding to compute the mover's score on word and sentence level. A notable difference between MoverScore and BERTScore is that the latter relies on hard alignment compared to soft alignments in the former. Unlike the previous methods, RoMe focuses on handling the sentence's word repetition and passive form when computing the EMD score. Furthermore, RoMe trains a classifier by considering the sentence's semantic, syntactic, and grammatical acceptability features to generate the final evaluation score.

6 Conclusion

We have presented RoMe, an automatic and robust evaluation metric for evaluating a variety of NLG tasks. The key contributions of RoMe include 1) **EMD-based semantic similarity**, where *hard word alignment* and *soft-penalization* techniques are employed into the EMD for tackling repetitive words and passive form of the sentence, 2) **semantically enhanced TED** that computes the syntactic similarity based on the node-similarity of the parsed dependency trees, 3) **grammatical acceptability classifier**, which evaluates the text's grammatical quality, and 4) **robustness analysis**, which assesses the metric's capability of handling various form of the text. Both quantitative and qualitative analyses exhibit that RoMe highly correlates with human judgment. We intend to extend RoMe by including more languages in the future.

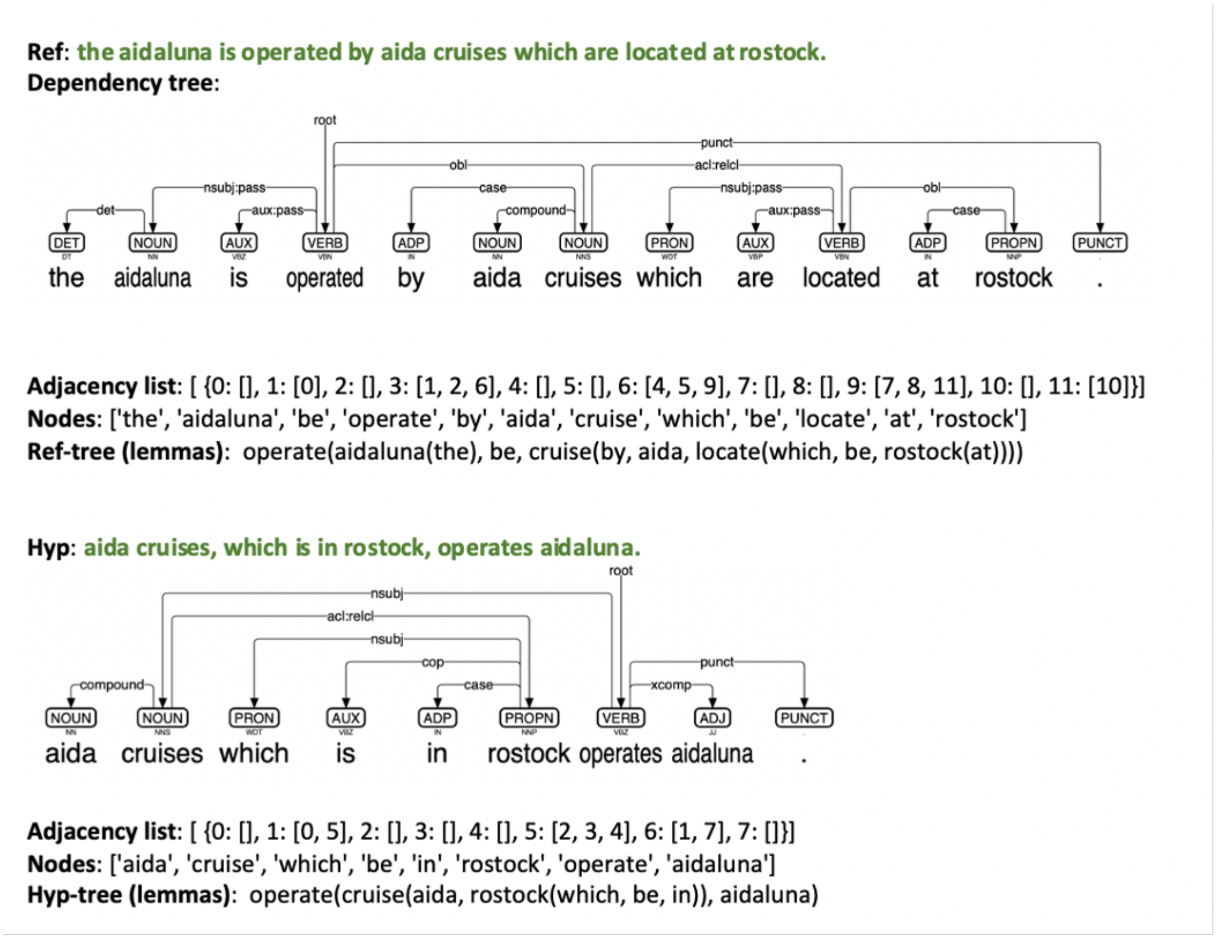
A Appendix

A.1 Dependency Tree Representation for Tree Edit Distance Calculation

This section describes the process of parsing a dependency tree from a sentence, followed by converting the dependency tree to the adjacency list for computing TED-SE. Let us consider a reference statement "*the aidaluna is operated by aida cruises which are located at rostock.*" and a hypothesis, "*aida cruises, which is in rostock, operates aidaluna.*". First, a dependency tree is parsed utilizing the Stanza dependency parser (Qi et al., 2020) and then converted to an adjacency list. The adjacency list contains a key-value pair oriented data structure where each key corresponds to a node's index in the tree, and the value is a list of edges on which the head node is incident. Figure 6 demonstrates the dependency trees and their corresponding adjacency lists for the given reference and hypothesis. List of nodes and adjacency lists are then fed into the TED-SE algorithm to calculate semantically enhanced tree edit distance as described in §3.2.

A.2 Annotation Tool

For all the annotation processes, we use the annotation tool shown in Figure 7. The tool is developed using Python programming language. Annotators can load their data into the tool in JSON format by selecting the *Load Raw Data* button. An example annotation step is shown in Figure 7. The reference and hypothesis sentences are displayed in different text windows. The annotators were asked to annotate the data based on *Fluency*, *Semantically correctness* and *Grammar*. Annotators can choose a value on a scale of [1,3] for each category, from the corresponding drop-down option. Finally, the annotated text can be saved for evaluation using the *save* button, which saves the annotated data in JSON format.



Ref: the aidaluna is operated by aida cruises which are located at rostock.

Dependency tree:

Adjacency list: [{0: [], 1: [0], 2: [], 3: [1, 2, 6], 4: [], 5: [], 6: [4, 5, 9], 7: [], 8: [], 9: [7, 8, 11], 10: [], 11: [10]}]

Nodes: ['the', 'aidaluna', 'be', 'operate', 'by', 'aida', 'cruise', 'which', 'be', 'locate', 'at', 'rostock']

Ref-tree (lemmas): operate(aidaluna(the), be, cruise(by, aida, locate(which, be, rostock(at))))

Hyp: aida cruises, which is in rostock, operates aidaluna.

Adjacency list: [{0: [], 1: [0, 5], 2: [], 3: [], 4: [], 5: [2, 3, 4], 6: [1, 7], 7: []}]

Nodes: ['aida', 'cruise', 'which', 'be', 'in', 'rostock', 'operate', 'aidaluna']

Hyp-tree (lemmas): operate(cruise(aida, rostock(which, be, in)), aidaluna)

Finding Structural Knowledge in Multimodal-BERT

Abstract

In this work, we investigate the knowledge learned in the embeddings of multimodal-BERT models. More specifically, we probe their capabilities of storing the grammatical structure of linguistic data and the structure learned over objects in visual data. To reach that goal, we first make the inherent structure of language and visuals explicit by a dependency parse of the sentences that describe the image and by the dependencies between the object regions in the image, respectively. We call this explicit visual structure the *scene tree*, that is based on the dependency tree of the language description. Extensive probing experiments show that the multimodal-BERT models do not encode these scene trees. Code available at https://github.com/VSJMilewski/multimodal-probes.

1 Introduction

In recent years, contextualized embeddings have become increasingly important. Embeddings created by the BERT model and its variants have been used to get state-of-the-art performance in many tasks (Devlin et al., 2019; Liu et al., 2019b; Yang et al., 2019; Radford and Narasimhan, 2018; Radford et al., 2019; Brown et al., 2020). Several multimodal-BERT models have been developed that learn multimodal contextual embeddings through training jointly on linguistic data and visual data (Lu et al., 2019; Su et al., 2019; Li et al., 2019; Chen et al., 2020). They achieve state-of-the-art results across many tasks and benchmarks, such as Visual Question Answering (Goyal et al., 2017), image and text retrieval (Lin et al., 2014), and Visual Commonsense Reasoning (Suhr et al., 2019).[1]

BERT and multimodal-BERTs are blackbox models that are not easily interpretable. It is not trivial to know what knowledge is encoded in the models and their embeddings. A common method for getting insight into the embeddings of both textual and visual content is probing.

Language utterances have an inherent grammatical structure that contributes to their meaning. Natural images have a characteristic spatial structure that likewise allows humans to interpret their meaning. In this paper we hypothesize that the textual and visual embeddings learned from images that are paired with their descriptions encode structural knowledge of both the language and the visual data. Our goal is to reveal this structural knowledge with the use of probing. More specifically, in order to perform this probing, we first make the inherent structure of language and visuals explicit by a mapping between a dependency parse of the sentences that describe the image and by the dependency between the object regions in the image, respectively. Because the language truthfully describes the image, and inspired by Draschkow and Võ (2017), we define a visual structure that correlates with the dependency tree structure and that arranges object regions in the image in a tree structure. We call this visual dependency tree the *scene tree*. An example of this mapping to the scene tree is visualized in Figure 1.

The aligned dependency tree and scene tree allow us to conduct a large set of experiments aimed at discovering encoded structures in neural representations obtained from multimodal-BERTs. By making use of the structural probes proposed by Hewitt and Manning (2019), we compare the dependency trees learned by models with or without provided image features. Furthermore, we investigate if scene trees are learned in the object region embeddings.

Research Questions In this study, we aim to answer the following research questions.

- **RQ 1:** Do the textual embeddings trained

---

[1] From here on we refer to the text-only BERT models as ’BERT’ and the multimodal-BERT models as ’multimodal-BERTs’.

May 22-27, 2022

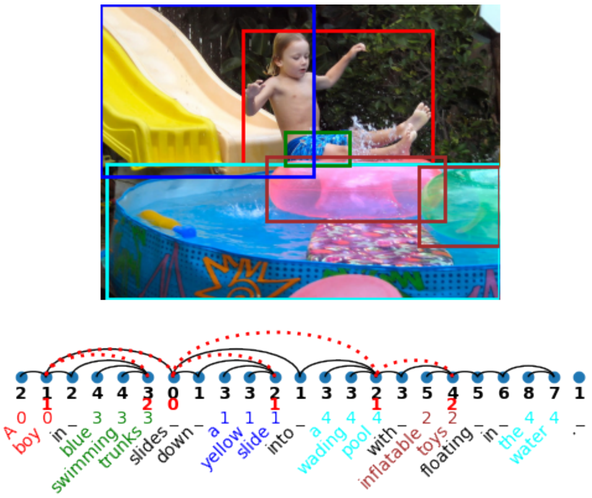

Figure 1: Example of the mapping from the linguistic dependency tree to the visual tree. The borders of the regions in the image have the same color as the phrase they are attached to. The rows below the image are the textual tree depth (in black), the visual tree depth (in red), the phrase index, and the words in the sentence.

  with a multimodal-BERT retain their structural knowledge?
  Sub-RQ 1.1: To what extent does the joint training in a multimodal-BERT influence the structures learned in the textual embeddings?

- **RQ 2:** Do the visual embeddings trained with a multimodal-BERT learn to encode a scene tree?

In a broader framework this study might contribute to better representation learning inspired by how humans acquire language in a perceptual context. It stimulates the learning of representations that are compositional in nature and are jointly influenced by the structure of language and the corresponding structure of objects in visuals.

2 Related Work

Probing studies Several studies have been performed that aim at analyzing BERT and multimodal-BERTs. For BERT, probes are designed that explore gender bias (Bhardwaj et al., 2021), relational knowledge (Wallat et al., 2020), linguistic knowledge for downstream tasks (Liu et al., 2019a), part-of-speech knowledge (Hewitt and Liang, 2019; Hewitt et al., 2021), and for sentence and dependency structures (Tenney et al., 2019; Hewitt and Manning, 2019). These studies have shown that BERT latently learns to encode linguistic structures in its textual embeddings. Basaj et al. (2021) made a first attempt at converting the probes to the visual modality and evaluated the information stored in the features created by visual models trained with self-supervision.

For multimodal-BERTs, one study by Parcalabescu et al. (2021) investigates how well these models learn to count objects in images and how well they generalize to new quantities. They found that the multimodal-BERTs overfit the dataset bias and fail to generalize to out-of-distribution quantities. Frank et al. (2021) found that visual information is much more used for textual tasks than textual information is used for visual tasks when using multimodal models. These findings suggest more needed research into other capabilities of and knowledge in multimodal-BERT embeddings. We build on this line of work but aim to discover structures encoded in the textual and visual embeddings learned with multimodal-BERTs. This is a first step towards finding an aligned structure between text and images. Future work could exploit this to make textual information more useful for visual tasks.

Structures in visual data There is large research interest in identifying structural properties of images e.g., scene graph annotation of the visual genome dataset (Krishna et al., 2016). In the field of psychology, research towards scene grammars (Draschkow and Võ, 2017) evidences that humans assign certain grammatical structures to the visual world. Furthermore, some studies investigate the grounding of textual structures in images, such as syntax learners (Shi et al., 2019) and visually grounded grammar inducers (Zhao and Titov, 2020). Here the complete image is used, without considering object regions and their composing structure, to aid in predicting linguistic structures.

Closer to our work, Elliott and Keller (2013) introduced visual dependency relations (VDR), where spatial relations are created between object in the image. The VDR can also be created by locating the object and subject in a caption and matching it with object annotations in the image (Elliott and de Vries, 2015). Our scene tree differs, since it makes use of the entire dependency tree of the caption to create the visual structure.

3 Background

Multimodal-BERT Many variations of the BERT model implement a transformer architecture to process both visual and linguistic data, e.g., images and sentences. These Multimodal-

BERTs can be categorized into two groups: single-stream and dual-stream encoders. In the former, a regular BERT architecture processes the concatenated input of the textual description and the image through a transformer stack. This allows for an "unconstrained fusion of cross-modal features" (Bugliarello et al., 2021). Some examples of these models are ViL-BERT (Su et al., 2019), VisualBERT (Li et al., 2019), and UNITER (Chen et al., 2020).

In the dual-stream models, the visual and linguistic features are first processed separately by different transformer stacks, followed by several transformer layers with alternating *intra-modal* and *inter-modal* interactions. For the *inter-modal* interactions, the query-key-value matrices modeling the multi-head self-attention are computed, and then the key-value matrices are exchanged between the modalities. This limits the interactions between the modalities but increases the expressive power with separate parameters. Examples of such dual-stream models are ViLBERT (Lu et al., 2019), LXMERT (Tan and Bansal, 2019), and ERNIE-ViL (Yu et al., 2021).[2]

4 Method

4.1 Tree Structures

In the probing experiments we assume that the structural knowledge of a sentence is made explicit by its dependency tree structure and that likewise the structural knowledge of an image is represented by a tree featuring the dependencies between object regions. Further, we assume that the nodes of a tree (words in the dependency tree of the sentence, phrase labels in the region dependency tree of the image) are represented as embeddings obtained from a layer in BERT or in a multimodal-BERT.

To generate the depths and distances values from the tree, we use properties of the embedding representation space (Mikolov et al., 2013). For example, similar types of relations between embeddings have a similar distance between them, such as counties and their capital city. The properties we use are that the length (the norm) of a vector which describes the depth in a tree and the distance between nodes that can be translated as the distance between vectors.

Algorithm 1 $ConstructSceneTree(T_t, P, I)$

```
Input: Language dependency tree $T_t = \{E_t, V_t\}$,
    with $V_t$ the set of $TextIDs$ for words in a
    sentence and $E_t$ the set of edges such that each
    $e_t = (v_{t,j}, v_{t,k})$, where $v_{t,k}$ is a child node of
    $v_{t,j}$
Input: Set of phrases $P$, each $p_i$ describes one or
    more regions and covers multiple words
Input: Image $I$
Output: Scene tree $T_s$
$V_s = \{\}$, set of Nodes in Scene Tree $T_s$
$E_s = \{\}$, set of Edges in Scene Tree $T_s$
$v_{s,0} = I$, set Image as root node
$D_0 = 0$, set root node depth as 0
$add(V_s, v_{s,0})$
$v_{t,0} = FindRootNode(T_t)$
$PhraseID2TextID(0) = v_{t,0}$
for $p_i \in P$ do
    $v_{t,k} = FindHighestNode(p_i)$
    $PhraseID2TextID(p_i) = v_{t,k}$
    $D_i = DepthInTree(T_t, v_{t,k})$
for $p_i \in P$ ordered by $D$ do
    $v_{t,k} = PhraseID2TextID(p_i)$
    while True do
        $e_t = EdgeWithChildNode(E, v_{t,k})$
        $v_{t,j} = SelectParentNode(e_t)$
        $p_p = TextID2PhraseID(v_{t,j})$
        if $p_p \in V_s$ then
            $add(V_s, p_i), \quad add(E_s, (p_p, p_i))$
            $D_i = D_p + 1$
            break while loop
        else
            $v_{t,k} = v_{t,j}$
return $T_s$
```

Generating distance values For the distance labels, a matrix $\boldsymbol{D} \in \mathbb{N}^{n \times n}$ is required, with each $\boldsymbol{D}_{ij}$ describing the distance between nodes i and j. To fill the matrix, we iterate over all possible pairs of nodes. For nodes i and j, it is computed by starting at node i in the tree and traverse it until node j is reached while ensuring a minimum distance. This is achieved by using the breadth-first search algorithm.

Generating depth values For the depth labels, we generate a vector $\boldsymbol{d} \in \mathbb{N}^n$, with n the number of nodes in the tree. There is a single node that is the root of the tree, to which we assign a depth of zero. The depth increases at every level below.

4.2 Constructing the Trees

---

[2] The ERNIE-ViL model is trained with scene graphs of the visual genome dataset. We do not probe this model as there is an overlap between the training data of ERNIE-ViL and our evaluation data.

Language dependency tree We use the dependency tree as linguistic structure. The tree annotations are according to the Stanford dependency guidelines (De Marneffe and Manning, 2008). They can either be provided as gold-standard in the dataset, or generated using the spacy dependency parser (Honnibal et al., 2020).

Scene tree Draschkow and Võ (2017) found that there are commonalities between words in language and objects in scenes, allowing to construct a scene grammar. Furthermore, Zhao and Titov (2020) have shown that an image provides clues that improve grammar induction. In line with these works, we want a visual structure that aligns with a linguistic representation like the dependency tree.

As visual structure, a scene graph could be used for the relations between regions (Krishna et al., 2016). However, the unconstrained graph is difficult to align with the dependency tree. Therefore, we propose a novel visual structure, the *scene tree*, that is created by mapping a textual dependency tree to the object regions of an image. An example of such a mapping for an image-sentence pair is given in Figure 1. This process requires a tree for the sentence and paired data for images and sentences.

Each node in the scene tree directly matches one or more visual regions. The node description is a phrase that covers multiple words in the sentence (or nodes in the dependency tree). The output of this method is a tree that contains the phrase trees that directly correspond to the regions. The algorithm is completely described as pseudo-code in Algorithm 1.

The algorithm starts by initializing the scene tree. We set the full image as the root node. For each phrase that describes an image region, we select the dependency tree node (or word with a $TextID$) that is closest to the root and assign this a phrase ID. This creates a mapping between the phrases (Phrase IDs) and dependency tree nodes (Text IDs) $PhraseID2TextID$, and its reverse $TextID2PhraseID$. We assign each phrase an initial depth, based on the word it maps to in $PhraseID2TextID$. On line 12, the loop over the phrases that describe the object regions starts, to find the direct parent for each phrase so it can be added to the new scene tree. For each phrase p_i, we select the matching dependency tree node the $v_{t,k}$ from $PhraseID2TextID$. From $v_{t,k}$ we follow the chain of parent nodes, until an ancestor $v_{t,l}$ is found that points back to a phrase p_j (using $TextID2PhraseID$) that is already a member of the scene tree. Phrase p_i is added to the tree as child of p_j. The completed tree of phrases is our *scene tree*.

4.3 Embeddings

Textual embeddings For each sentence l, every word becomes a node n_i in the tree, such that we have a sequence of s nodes $n^l_{1:s}$. To obtain the textual embeddings $\boldsymbol{h}^l_{1:s} \in \mathbb{R}^m$, we do a wordpiece tokenization (Wu et al., 2016) and pass the sentence into BERT. Depending on the requested layer, we take the output of that BERT layer as the embeddings. For nodes with multiple embeddings because of the wordpiece tokenization, we take the average of those embeddings.

To obtain the textual embeddings $\boldsymbol{h}^l_{1:s}$ for a multimodal-BERT, we use the same process but also provide visual features. When an image is present, we enter the visual features (as described in the next paragraph), otherwise, a single masked all-zero feature is entered.

Visual embeddings For sentence with image l, the sequence of s nodes $n^l_{1:s}$ consists of the number of regions plus the full image. The visual embeddings $\boldsymbol{h}^l_{1:s} \in \mathbb{R}^m$ are obtained by passing the raw Faster R-CNN features (Ren et al., 2015) into the multimodal-BERT. Depending on the requested layer, we take the output of that multimodal-BERT layer as the embeddings.

4.4 Structural Probes

Here we shortly describe the structural probes as defined by Hewitt and Manning (2019). Originally designed for text, we use these probes to map from an embedding space (either textual embeddings or visual embeddings) to depth or distance values as defined in Section 4.1.

Distance probe Given a sequence of s nodes $n^l_{1:s}$ (words or objects) and their embeddings $\boldsymbol{h}^l_{1:s} \in \mathbb{R}^m$, where l identifies the sequence and m the embedding size, we predict a matrix of $s \times s$ distances. First, we define a linear transformation $\boldsymbol{B} \in \mathbb{R}^{k \times m}$ with k the probe rank, such that $\boldsymbol{B}^T\boldsymbol{B}$ is a positive semi-definite, symmetric matrix. By first transforming a vector $\boldsymbol{h}$ with matrix $\boldsymbol{B}$, we get its norm like this: $(\boldsymbol{Bh})^T(\boldsymbol{Bh})$. To get the squared distance between two nodes i and j in sequence l, we compute the difference between node embeddings $\boldsymbol{h}_i$ and $\boldsymbol{h}_j$ and take the norm following equation 1:

$$\boldsymbol{D}_{ij} = (\boldsymbol{B}(\boldsymbol{h}_i^l - \boldsymbol{h}_j^l))^T(\boldsymbol{B}(\boldsymbol{h}_i^l - \boldsymbol{h}_j^l)) \quad (1)$$

The only parameters of the distance probe are now the transformation matrix $\boldsymbol{B}$, which can easily be implemented as a fully connected linear layer. Identical to the work by Hewitt and Manning (2019), the probe is trained through stochastic gradient descent.

Depth probe For the depth probe, we transform the embedding of each node n_i to their norm, so we can construct the vector $\boldsymbol{d}$. This imposes a total order on the elements and results in the depths. We compute the squared vector norm $\|\boldsymbol{h}_i\|_{\boldsymbol{B}}^2$ with the following equation:

$$\boldsymbol{d}_i = \|\boldsymbol{h}_i\|_{\boldsymbol{B}}^2 = (\boldsymbol{B}\boldsymbol{h}_i^l)^T(\boldsymbol{B}\boldsymbol{h}_i^l) \quad (2)$$

5 Experimental Setup

5.1 Data

By using a text-only dataset, we can test how the textual embeddings of the multimodal-BERTs perform compared to the BERT model, without the interference from the visual embeddings. This allows us to see how much information the multimodal-BERTs encode in the visual embeddings.

Therefore, we use the Penn Treebank (PTB3) (Marcus et al., 1999). It is commonly used for dependency parsing (also by Hewitt and Manning (2019) from whom we borrow the probes) and consists of gold-standard dependency tree annotations according to the Stanford dependency guidelines (De Marneffe and Manning, 2008). We use the default training/validation/testing split, that is, the subsets 2-21 for training, 22 for validation and 23 for testing of the Wall Street Journal sentences. This provides us with 39.8k/1.7k/2.4k sentences for the splits, respectively.

The second dataset is the Flickr30k dataset (Young et al., 2014), which consists of multimodal image captioning data. It has five caption annotations for each of the 30k images. An additional benefit of this dataset are the existing extensions, specifically the Flickr30k-Entities (F30E) (Plummer et al., 2015). In F30E all the phrases in the captions are annotated and match with region annotations in the image. This paired dataset is used to create the scene trees proposed in Section 4.2.

The Flickr30k dataset does not provide gold-standard dependency trees. Therefore, the transformer based Spacy dependency parser (Honnibal et al., 2020) is used to generate silver-standard dependency trees according to the Stanford dependency guidelines (De Marneffe and Manning, 2008). The dataset consists of 30k images, with (mostly) 5 captions each, resulting in 148.9k/5k/5k sentences for the training/validation/testing splits, respectively.

5.2 Models

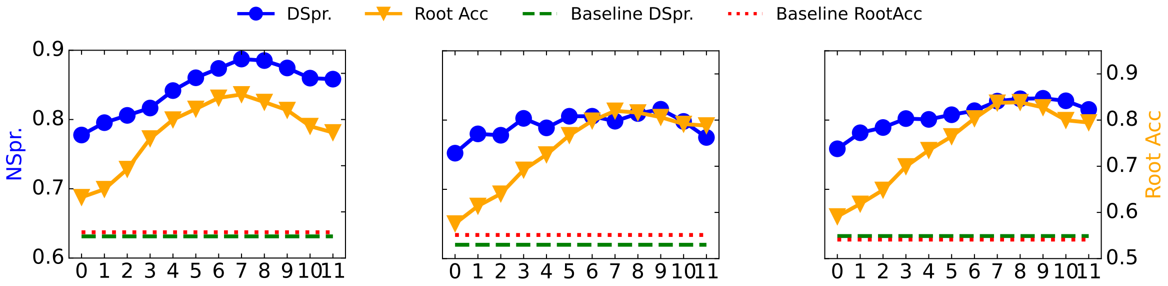
We use two different multimodal-BERTs, one **single-stream** and one **dual-stream** model. As implementation for the multimodal-BERTs, we make use of the VOLTA library (Bugliarello et al., 2021). Here, all the models are implemented and trained under a controlled and unified setup with regard to hyperparameters and training data. Based on the performance under this unified setup on the Flickr30k image-sentence matching task, we have chosen the best performing models: ViLBERT (Lu et al., 2019) as single-stream model and UNITER (Chen et al., 2020) as dual-stream model.

When probing the textual embeddings, we also use a text-only **BERT-base model** (from here on referred to as BERT) (Devlin et al., 2019). Hewitt and Manning (2019) use the same model, allowing for easy comparability. The implementation used is from the HuggingFace Transformer library (Wolf et al., 2020).

Hyperparameters For our setup and metrics, we follow the setup from Hewitt and Manning (2019). The batch size is set to 32 and we train for a maximum of 40 epochs. Early stopping is used to terminate training after no improvement on the validation L1-loss for 5 epochs.

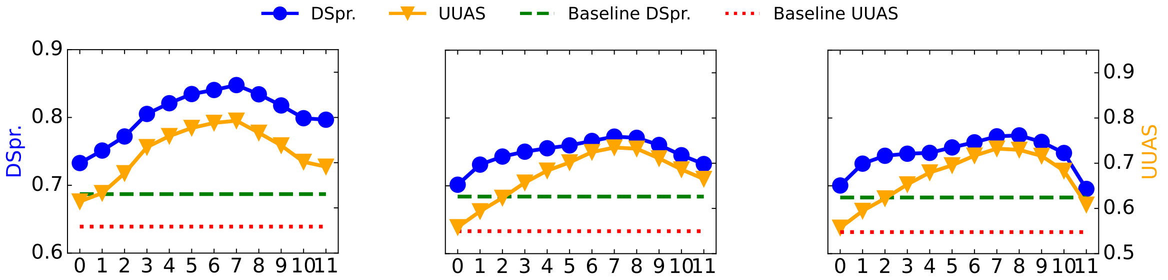
5.3 Metrics

The main metric used for both the distance and the depth probes is the Spearman rank coefficient correlation. This indicates if the predicted depth vector of the nodes, or the predicted distance matrix of the nodes, correlate with the gold-standard (or silver) depths and distances generated according to the method in Section 4.4. The Spearman correlation is computed for each length sequence separately. We take the average over the scores of the lengths between 5 and 50 and call this the Distance Spearman (DSpr.) for the distance probe and



(a) BERT (b) UNITER (c) ViLBERT

Figure 2: Comparison for the depth probe on the PTB3 test set, with textual embeddings.



(a) BERT (b) UNITER (c) ViLBERT

Figure 3: Comparison for the distance probe on the PTB3 test set, with textual embeddings.

the Norm Spearman (NSpr.) for the depth probe.[3]

For the depth probes, we also use the root accuracy (root_acc). This computes the accuracy of predicting the root of the sequence. This metric is only applicable for the textual embeddings, due to our method of generating the visual tree, where the root is always the full image at the start of the sequence.

For the distance probe, we make use of the undirected unlabelled attachment score (UUAS). This directly tests how accurate the predicted tree is compared to the ground-truth (or silver) tree by computing the accuracy of predicted connections between nodes in the tree. It does not consider the label for the connection or the direction of the connection (Jurafsky and Martin, 2021).

Baseline comparisons We design one baseline for the textual data and two for the visual data. For the textual baseline, we use the initial word piece textual embeddings (from either BERT or a multimodal-BERT) before inserting them into the transformer stack. We simply refer to it as **baseline**.

The first visual baseline implements the raw Faster R-CNN features (Ren et al., 2015) of each object region. However, they have a larger dimension than the BERT embeddings. We refer to it as **R-CNN baseline**. The second baseline uses the visual embeddings before they are fed to the transformer stack. This is a mapping from the Faster R-CNN features to the BERT embedding size. We refer to it as **baseline**.

5.4 Hypotheses

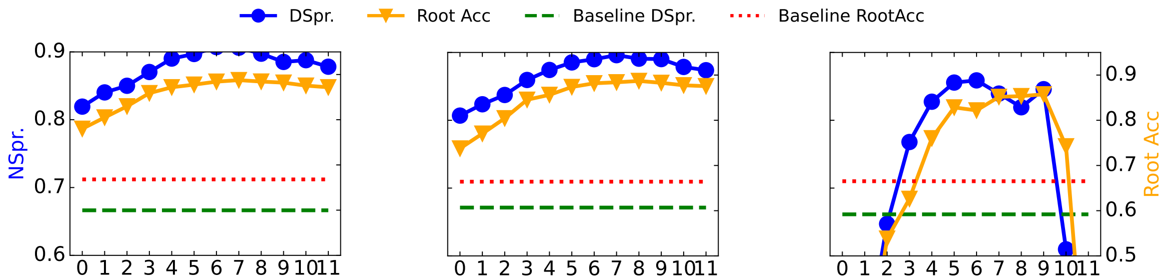
First, we want to determine the probe rank of the linear transformation used on the textual or the visual embeddings. Based on results by Hewitt and Manning (2019), we set the probe rank for BERT to 128. We run a comparison with several probe ranks on UNITER and ViLBERT to find the optimal setting for the textual and visual embeddings. The results are shown and discussed in Appendix A. We use a rank of 128 for all our following experiments.

RQ 1 The multimodal-BERT models are pretrained on language data. We assume that the resulting embeddings integrate structural grammatical knowledge and hypothesize that this knowledge will not be forgotten during multimodal training.

To determine if training on multimodal data affects the quality of predicting the dependency tree when trained solely with textual data, we train the probes with BERT and both multimodal-BERTs and evaluate on the PTB3 dataset (Marcus et al.,

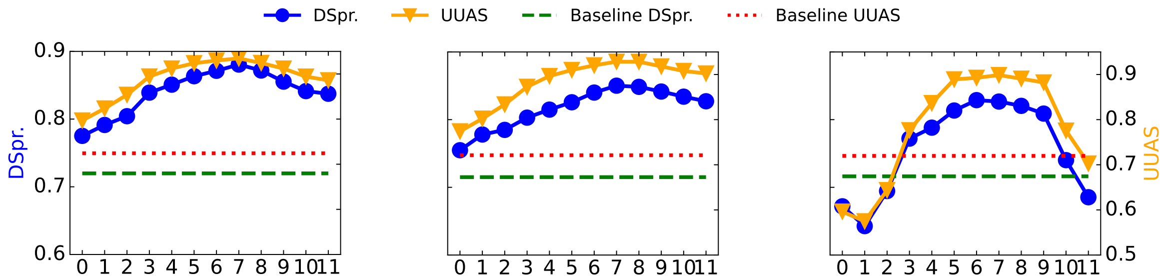
---

[3] Just as done by Hewitt and Manning (2019).



(a) BERT (b) UNITER (c) ViLBERT

Figure 4: Comparison for the depth probe on the Flickr30k test set, with textual embeddings.



(a) BERT (b) UNITER (c) ViLBERT

Figure 5: Comparison for the distance probe on the Flickr30k test set, with textual embeddings.

1999).

Sub-RQ 1.1 We expect that more interaction between the regions and the text will have a stronger impact. Some dependency attachments that are hard to predict might require visual knowledge. Next to the effect on the linguistic knowledge, we also want to discover if the multimodal data helps the multimodal-BERTs in learning structural knowledge. We run the probes on Flickr30k dataset (Young et al., 2014) with the textual embeddings for all our models. Furthermore, we compare these to the difference in scores on the PTB3 dataset (Marcus et al., 1999).

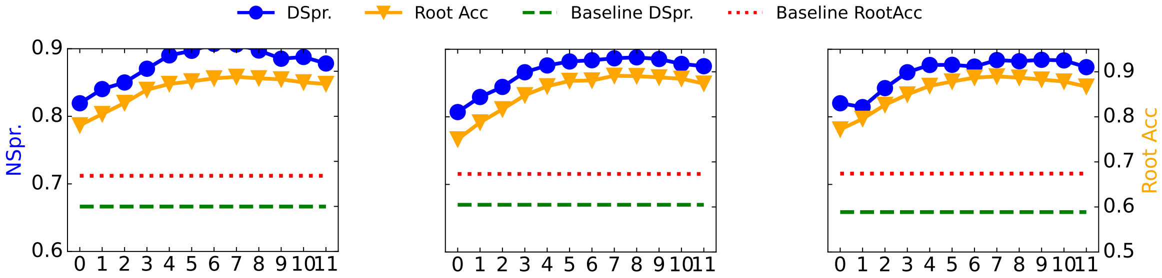
RQ 2 The Multimodal-BERTs learn highly contextualized embeddings. Therefore, we hypothesize that a model should be able to discover important interactions between object regions in the image. To see if the model has learned to encode the scene tree in the visual region embeddings, we run the probes on the Flickr30k dataset (Young et al., 2014) with the visual embeddings. Furthermore, to see if the scene tree is learned mainly through joint interaction with the textual embeddings, we compare the scores between the single-stream model UNITER (with many cross-modal interactions) and the dual-stream model ViLBERT (with limited cross-modal interactions).

6 Results and Discussion

This discussion is based on the results from the test split. The results on the validation split (see Appendix B), lead to the same observations.

RQ 1: Do the textual embeddings trained with a multimodal-BERT retain their structural knowledge? To answer RQ 1, we report the results for both structural probes on the PTB3 dataset. Here we only use the textual embeddings, since no visual features are available. The results for the depth probe are in Figure 2, and for the distance probe in Figure 3.

The results of both multimodal-BERTs (Figures 2c and 3c for ViLBERT and Figures 2b and 3b for UNITER) in terms of NSpr. and Root Acc are very comparable showing similar curves and scores. For both, the seventh layer is the best performing one. The shape of the curves across the layers is similar to those for the BERT model in Figures 2a and 3a. However, the scores of the multimodal-BERTs drop significantly. While the multimodal-BERTs were initialized with weights from BERT, they were trained longer on additional multimodal data with a different multimodal objective. This shows that the multimodal training hampers the storing of grammatical structural knowledge in the resulting embeddings.



(a) BERT (b) UNITER - only text (c) ViLBERT - only text

Figure 7: Ablation comparison for the distance probe on the Flickr30k test set while just providing textual embeddings to the multimodal-BERTs.

Sub-RQ 1.1: To what extent does the joint training in a multimodal-BERT influence the structures learned in the textual embeddings? For this experiment, we compare the effect of having visual features present when using the structural probes on the textual embeddings. We run the probes on Flickr30k. The results for the depth probe are in Figure 4, and for the distance probe in Figure 5.

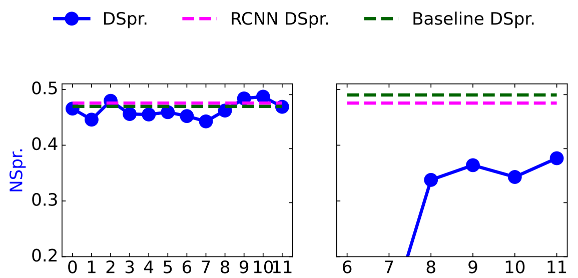
First, we see that for all models (BERT and multimodal-BERTs) the scores increase compared to the results on the PTB3 dataset (see discussion of RQ 1), but still follow a similar trend across the layers. The latter is most likely due to the complexity of the sentences and language of the PTB3 dataset, which is simpler for the captions. For ViLBERT, there is a drop in performance for the earlier layers. We believe this is caused by the early stopping method firing early with these settings. Another explanation is that it is more difficult for the dual-stream model to use the additional parameters.

BERT outperforms the multimodal-BERTs on PTB3, however, this is not the case on Flickr30k. For the depth probe (Figure 4) and the UUAS metric on the distance probe (Figure 5), the results obtained on these two datasets are almost equal. This can be due to the additional pretraining of the multimodal-BERTs on similar captioning sentences. Another explanation is that, during such pretraining, the models learned to store relevant information in the visual embeddings.

We run an additional experiment where we use the pretrained multimodal-BERT, but while probing we only provide the sentence to the model, and mask out the image. The results for the depth probe are in Figure 6, and for the distance probe in Figure 7. Here we can see that the results are almost identical to when we provide the model with the visual embeddings. This indicates that the model does not have any benefit from the visual data when predicting the structures for textual embeddings, and it seems that the model uses the extra parameters of the vision layers to store knowledge about the text.

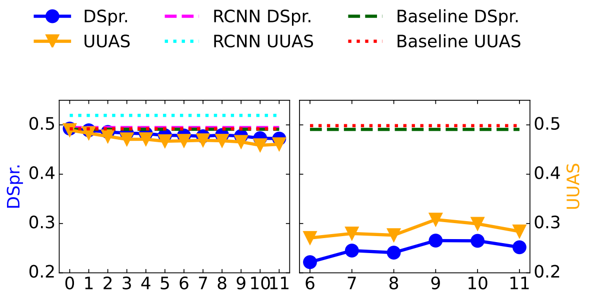
RQ 2: Do the visual embeddings trained with a multimodal-BERT learn to encode a scene tree? We aim to find the layer with the most structural knowledge learned when applied to multimodal data. See the results in Figures 8 and 9.

Regarding the results for the depth probe (Figure 8), the scores between layers fluctuate inconsistently. The scores do improve slightly over the



(a) UNITER (b) ViLBERT

Figure 8: Comparison for the depth probe on the Flickr30k test set, with visual embeddings. Note that the scale is different in this Figure.



(a) UNITER (b) ViLBERT

Figure 9: Comparison for the distance probe on the Flickr30k test set, with visual embeddings. Note that the scale is different in this Figure.

baselines, indicating that the multimodal-BERT encodes some knowledge of depth in the layers.

With regard to the distance probe (Figure 9), the trend in the curves across the layers indicate that this is a type of knowledge that can be learned for the regions. The multimodal-BERTs seem to disregard scene trees. There is a strong downward trend across the layers. Furthermore, all the scores are much lower than the baseline and the R-CNN baseline scores. This lack of learning of the scene tree can be caused by the chosen training objective of the multimodal-BERTs. These objectives require an abstract type of information, where only basic features are needed to predict the masked items.

For the distance probe, there is a noticeable difference between the single-stream (Figure 13a) and the dual-stream (Figure 13b) models, where single stream models benefit from the multimodal interactions to retain structural knowledge. For UNITER, the scores in the first layers are very close to the baseline, showing that the single stream interaction benefits the memorizing of the scene tree structure.

7 Conclusion and Future Work

We made a first attempt at investigating whether the current Multimodal-BERT models encode structural grammatical knowledge in their textual embeddings, in a similar way as text-only BERT models encode this knowledge. Furthermore, we were the first to investigate the existence of encoded structural compositional knowledge of the object regions in image embeddings. For this purpose, we created a novel scene tree structure that is mapped from the textual dependency tree of the paired caption. We discovered that the multimodal-BERTs encode less structural grammatical knowledge than BERT. However, with image features present, it is still possible to achieve similar results. The cause for this requires more research.

While tree depths from the scene tree are not natively present in the features, we found that this could be a potential method of finding connections and distances between regions, already decently predicted with the Faster R-CNN features. The Multimodal-BERT models are currently trained with an objective that does not enforce the learning or storing of these types of structural information. Hence we assume that the models learn to encode more abstract knowledge in their features.

Our work opens possibilities to further research on scene trees as a joint representation of object compositions in an image and the grammatical structure of its caption. Furthermore, we recommend investigating the training of multimodal-BERTs with objectives that enforce the encoding of structural knowledge.

A Tuning Probe Rank

To find the dimensionality needed for the multimodal-BERTS, we made a comparison between several probes. The results for the textual embeddings are in Figures 10 and 11. Here we see that the probe rank does not have any significant effect of changing the performance of the models. Therefore, we decided it is best to follow the optimal rank found for the BERT model: 128.

The results for the visual embeddings are in Figures 12 and 13. Here we also see only very small changes. Therefore, we also keep the probe rank at 128 for the visual features.

B Results on Validation Split

The same graphs as for our experiments discussed in Section 6 using the validation set instead of the test set. The graphs created for the test set are very similar to those the validation set. The results lead to an identical conclusion. One difference is the performance of the ViLBERT model. On the textual features, the score for earlier layers is again comparable with the other models. This indicates that the early stopping indead fired to early.

Furthermore, ViLBERT is less capable to predict the scene trees, which confirms the hypothesis that inter-modal interaction is needed to learn the structural knowledge that is implicitly present in the image and its captions.

Abstract

Hyperbolic neural networks have shown great potential for modeling complex data. However, existing hyperbolic networks are not completely hyperbolic, as they encode features in the hyperbolic space yet formalize most of their operations in the tangent space (a Euclidean subspace) at the origin of the hyperbolic model. This hybrid method greatly limits the modeling ability of networks. In this paper, we propose a fully hyperbolic framework to build hyperbolic networks based on the Lorentz model by adapting the Lorentz transformations (including boost and rotation) to formalize essential operations of neural networks. Moreover, we also prove that linear transformation in tangent spaces used by existing hyperbolic networks is a relaxation of the Lorentz rotation and does not include the boost, implicitly limiting the capabilities of existing hyperbolic networks. The experimental results on four NLP tasks show that our method has better performance for building both shallow and deep networks. Our code is released to facilitate follow-up research[1].

1 Introduction

Various recent efforts have explored hyperbolic neural networks to learn complex non-Euclidean data properties. Nickel and Kiela (2017); Cvetkovski and Crovella (2016); Verbeek and Suri (2014) learn hierarchical representations in a hyperbolic space and show that hyperbolic geometry can offer more flexibility than Euclidean geometry when modeling complex data structures. After that, Ganea et al. (2018) and Nickel and Kiela (2018) propose hyperbolic frameworks based on the Poincaré ball model and the Lorentz model respectively[2] to build hyperbolic networks, including hyperbolic feed-forward, hyperbolic multinomial logistic regression, etc.

Encouraged by the successful formalization of essential operations in hyperbolic geometry for neural networks, various Euclidean neural networks are adapted into hyperbolic spaces. These efforts have covered a wide range of scenarios, from shallow neural networks like word embeddings (Tifrea et al., 2018; Zhu et al., 2020), network embeddings (Chami et al., 2019; Liu et al., 2019), knowledge graph embeddings (Balazevic et al., 2019a; Kolyvakis et al., 2019) and attention module (Gulcehre et al., 2018), to deep neural networks like variational auto-encoders (Mathieu et al., 2019) and flow-based generative models (Bose et al., 2020). Existing hyperbolic neural networks equipped with low-dimensional hyperbolic feature spaces can obtain comparable or even better performance than high-dimensional Euclidean neural networks.

Although existing hyperbolic neural networks have achieved promising results, they are not fully hyperbolic. In practical terms, some operations in Euclidean neural networks that we usually use, such as matrix-vector multiplication, are difficult to be defined in hyperbolic spaces. Fortunately for each point in hyperbolic space, the tangent space at this point is a Euclidean subspace, all Euclidean neural operations can be easily adapted into this tangent space. Therefore, existing works (Ganea

et al., 2018; Nickel and Kiela, 2018) formalize most of the operations for hyperbolic neural networks in a hybrid way, by transforming features between hyperbolic spaces and tangent spaces via the logarithmic and exponential maps, and performing neural operations in tangent spaces. However, the logarithmic and exponential maps require a series of hyperbolic and inverse hyperbolic functions. The compositions of these functions are complicated and usually range to infinity, significantly weakening the stability of models.

To avoid complicated transformations between hyperbolic spaces and tangent spaces, we propose a fully hyperbolic framework by formalizing operations for neural networks directly in hyperbolic spaces rather than tangent spaces. Inspired by the theory of special relativity, which uses Minkowski space (a Lorentz model) to measure the spacetime and formalizes the linear transformations in the spacetime as the Lorentz transformations, our hyperbolic framework selects the Lorentz model as our feature space. Based on the Lorentz model, we formalize operations via the relaxation of the Lorentz transformations to build hyperbolic neural networks, including linear layer, attention layer, etc. We also prove that performing linear transformation in the tangent space at the origin of hyperbolic spaces (Ganea et al., 2018; Nickel and Kiela, 2018) is equivalent to performing a Lorentz rotation with relaxed restrictions, i.e., existing hyperbolic networks do not include the Lorentz boost, implicitly limiting their modeling capabilities.

To verify our framework, we build fully hyperbolic neural networks for several representative scenarios, including knowledge graph embeddings, network embeddings, fine-grained entity typing, machine translation, and dependency tree probing. The experimental results show that our fully hyperbolic networks can outperform Euclidean baselines with fewer parameters. Compared with existing hyperbolic networks that rely on tangent spaces, our fully hyperbolic networks are faster, more stable, and achieve better or comparable results.

2 Preliminaries

Hyperbolic geometry is a non-Euclidean geometry with constant negative curvature K. Several hyperbolic geometric models have been applied in previous studies: the Poincaré ball (Poincaré disk) model (Ganea et al., 2018), the Poincaré half-plane model (Tifrea et al., 2018), the Klein model (Gulcehre et al., 2018) and the Lorentz (Hyperboloid) model (Nickel and Kiela, 2018). All these hyperbolic models are isometrically equivalent, i.e., any point in one of these models can be transformed to a point of others with distance-preserving transformations (Ramsay and Richtmyer, 1995). We select the Lorentz model as the framework cornerstone, considering the numerical stability and calculation simplicity of its exponential/logarithm maps and distance function.

2.1 The Lorentz Model

Formally, an n-dimensional Lorentz model is the Riemannian manifold $\mathbb{L}_K^n = (\mathcal{L}^n, \mathfrak{g}_{\mathbf{x}}^K)$. K is the constant negative curvature. $\mathfrak{g}_{\mathbf{x}}^K = \mathrm{diag}(-1, 1, \cdots, 1)$ is the Riemannian metric tensor. Each point in $\mathbb{L}_K^n$ has the form $\mathbf{x} = \left[\begin{smallmatrix} x_t \\ \mathbf{x}_s \end{smallmatrix}\right], \mathbf{x} \in \mathbb{R}^{n+1}, x_t \in \mathbb{R}, \mathbf{x}_s \in \mathbb{R}^n$. $\mathcal{L}^n$ is a point set satisfying

$$\begin{aligned}\mathcal{L}^n &:= \{\mathbf{x} \in \mathbb{R}^{n+1} \mid \langle \mathbf{x}, \mathbf{x} \rangle_{\mathcal{L}} = \frac{1}{K}, x_t > 0\},\\ \langle \mathbf{x}, \mathbf{y} \rangle_{\mathcal{L}} &:= -x_t y_t + \mathbf{x}_s^{\mathsf{T}} \mathbf{y}_s \\ &= \mathbf{x}^{\mathsf{T}} \mathrm{diag}(-1, 1, \cdots, 1) \mathbf{y},\end{aligned}$$

where $\langle \mathbf{x}, \mathbf{y} \rangle_{\mathcal{L}}$ is the Lorentzian inner product, $\mathcal{L}^n$ is the upper sheet of hyperboloid (hyper-surface) in an $(n+1)$-dimensional Minkowski space with the origin $(\sqrt{-1/K}, 0, \cdots, 0)$. For simplicity, we denote a point $\mathbf{x}$ in the Lorentz model as $\mathbf{x} \in \mathbb{L}_K^n$ in the latter sections.

The special relativity gives physical interpretation to the Lorentz model by connecting the last n elements $\mathbf{x}_s$ to *space* and the 0-th element x_t to *time*. We follow this setting to denote the 0-th dimension of the Lorentz model as *time axis*, and the last n dimensions as *spatial axes*.

Tangent Space Given $\mathbf{x} \in \mathbb{L}_K^n$, the orthogonal space of $\mathbb{L}_K^n$ at $\mathbf{x}$ with respect to the Lorentzian inner product is the tangent space at $\mathbf{x}$, and is formally written as

$$\mathcal{T}_{\mathbf{x}} \mathbb{L}_K^n := \{\mathbf{y} \in \mathbb{R}^{n+1} \mid \langle \mathbf{y}, \mathbf{x} \rangle_{\mathcal{L}} = 0\}.$$

Note that $\mathcal{T}_{\mathbf{x}} \mathbb{L}_K^n$ is a Euclidean subspace of $\mathbb{R}^{n+1}$. Particularly, we denote the tangent space at the origin as $\mathcal{T}_{\mathbf{0}} \mathbb{L}_K^n$.

Logarithmic and Exponential Maps As shown in Figure 1a, the logarithmic and exponential maps specifies the mapping of points between the hyperbolic space $\mathbb{L}_K^n$ and the Euclidean subspace $\mathcal{T}_{\mathbf{x}} \mathbb{L}_K^n$.

The exponential map $\exp_{\mathbf{x}}^K(\mathbf{z}) : \mathcal{T}_{\mathbf{x}}\mathbb{L}_K^n \to \mathbb{L}_K^n$ can map any tangent vector $\mathbf{z} \in \mathcal{T}_{\mathbf{x}}\mathbb{L}_K^n$ to $\mathbb{L}_K^n$ by moving along the geodesic γ satisfying $\gamma(0) = \mathbf{x}$ and $\gamma'(0) = \mathbf{z}$. Specifically, the exponential map can be written as

$$\begin{aligned} \exp_{\mathbf{x}}^K(\mathbf{z}) &= \cosh(\alpha)\mathbf{x} + \sinh(\alpha)\frac{\mathbf{z}}{\alpha}, \\ \alpha &= \sqrt{-K}\|\mathbf{z}\|_{\mathcal{L}}, \\ \|\mathbf{z}\|_{\mathcal{L}} &= \sqrt{\langle \mathbf{z}, \mathbf{z} \rangle_{\mathcal{L}}}. \end{aligned}$$

The logarithmic map $\log_{\mathbf{x}}^K(\mathbf{y}) : \mathbb{L}_K^n \to \mathcal{T}_{\mathbf{x}}\mathbb{L}_K^n$ plays an opposite role to map $\mathbf{y} \in \mathbb{L}_K^n$ to $\mathcal{T}_{\mathbf{x}}\mathbb{L}_K^n$. and it can be written as

$$\begin{aligned} \log_{\mathbf{x}}^K(\mathbf{y}) &= \frac{\cosh^{-1}(\beta)}{\sqrt{\beta^2 - 1}}(\mathbf{y} - \beta\mathbf{x}), \\ \beta &= K\langle \mathbf{x}, \mathbf{y} \rangle_{\mathcal{L}}. \end{aligned}$$

2.2 The Lorentz Transformations

In the special relativity, the Lorentz transformations are a family of linear transformations from a coordinate frame in spacetime to another frame moving at a constant velocity relative to the former. Any Lorentz transformation can be decomposed into a combination of a Lorentz boost and a Lorentz rotation by polar decomposition (Moretti, 2002).

Definition 1 (Lorentz Boost). *Lorentz boost describes relative motion with constant velocity and without rotation of the spatial coordinate axes. Given a velocity* $\mathbf{v} \in \mathbb{R}^n$ *(ratio to the speed of light),* $\|\mathbf{v}\| < 1$ *and* $\gamma = \frac{1}{\sqrt{1 - \|\mathbf{v}\|^2}}$*, the Lorentz boost matrices are given by* $\mathbf{B} = \begin{bmatrix} \gamma & -\gamma\mathbf{v}^\intercal \\ -\gamma\mathbf{v} & \mathbf{I} + \frac{\gamma^2}{1+\gamma}\mathbf{v}\mathbf{v}^\intercal \end{bmatrix}$.

Definition 2 (Lorentz Rotation). *Lorentz rotation is the rotation of the spatial coordinates. The Lorentz rotation matrices are given by* $\mathbf{R} = \begin{bmatrix} 1 & \mathbf{0}^\intercal \\ \mathbf{0} & \tilde{\mathbf{R}} \end{bmatrix}$*, where* $\tilde{\mathbf{R}}^\intercal\tilde{\mathbf{R}} = \mathbf{I}$ *and* $\det(\tilde{\mathbf{R}}) = 1$*, i.e.,* $\tilde{\mathbf{R}} \in \boldsymbol{SO}(n)$ *is a special orthogonal matrix.*

Both the Lorentz boost and the Lorentz rotation are the linear transformations directly defined in the Lorentz model, i.e., $\forall \mathbf{x} \in \mathbb{L}_K^n, \mathbf{B}\mathbf{x} \in \mathbb{L}_K^n$ and $\mathbf{R}\mathbf{x} \in \mathbb{L}_K^n$. Hence, we build fully hyperbolic neural networks on the basis of these two types of transformations in this paper.

3 Fully Hyperbolic Neural Networks

3.1 Fully Hyperbolic Linear Layer

We first introduce our hyperbolic linear layer in the Lorentz model, considering it is the most essential block for neural networks. Although the Lorentz transformations in §2.2 are linear transformations in the Lorentz model, they cannot be directly used for neural networks. On the one hand, the Lorentz transformations transform coordinate frames without changing the number of dimensions. On the other hand, complicated restrictions of the Lorentz transformations (e.g., special orthogonal matrices for the Lorentz rotation) make computation and optimization problematic. Although the restrictions offer nice properties such as spacetime interval invariant to Lorentz transformation, they are unwanted in neural networks.

A Lorentz linear layer matrix should minimize the loss while subject to $\mathbf{M} \in \mathbb{R}^{(m+1)\times(n+1)}$, $\forall \mathbf{x} \in \mathbb{L}^n, \mathbf{M}\mathbf{x} \in \mathbb{L}^m$. It is a constrained optimization difficult to solve. We instead reformalize our lorentz linear layer to learn a matrix $\mathbf{M} = \begin{bmatrix} \mathbf{v}^\intercal \\ \mathbf{W} \end{bmatrix}, \mathbf{v} \in \mathbb{R}^{n+1}, \mathbf{W} \in \mathbb{R}^{m\times(n+1)}$ satisfying $\forall \mathbf{x} \in \mathbb{L}^n, f_{\mathbf{x}}(\mathbf{M})\mathbf{x} \in \mathbb{L}^m$, where $f_{\mathbf{x}} : \mathbb{R}^{(m+1)\times(n+1)} \to \mathbb{R}^{(m+1)\times(n+1)}$ should be a function that maps any matrix to a suitable one for the hyperbolic linear layer. Specifically, $\forall \mathbf{x} \in \mathbb{L}_K^n, \mathbf{M} \in \mathbb{R}^{(m+1)\times(n+1)}$, $f_{\mathbf{x}}(\mathbf{M})$ is given as

$$f_{\mathbf{x}}(\mathbf{M}) = f_{\mathbf{x}}\left(\begin{bmatrix} \mathbf{v}^\intercal \\ \mathbf{W} \end{bmatrix}\right) = \begin{bmatrix} \frac{\sqrt{\|\mathbf{W}\mathbf{x}\|^2 - 1/K}}{\mathbf{v}^\intercal\mathbf{x}}\mathbf{v}^\intercal \\ \mathbf{W} \end{bmatrix}, \quad (1)$$

Theorem 1. $\forall \mathbf{x} \in \mathbb{L}_K^n, \forall \mathbf{M} \in \mathbb{R}^{(m+1)\times(n+1)}$*, we have* $f_{\mathbf{x}}(\mathbf{M})\mathbf{x} \in \mathbb{L}_K^m$.

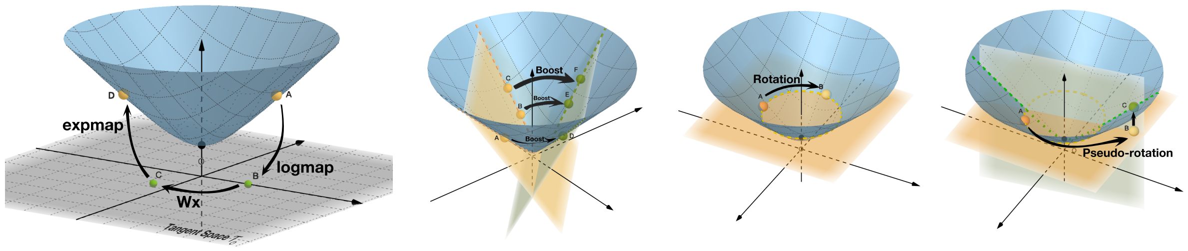
Proof 1. *One can easily verify that* $\forall \mathbf{x} \in \mathbb{L}_K^n$*, we have* $\langle f_{\mathbf{x}}(\mathbf{M})\mathbf{x}, f_{\mathbf{x}}(\mathbf{M})\mathbf{x} \rangle_{\mathcal{L}} = 1/K$*, thus* $f_{\mathbf{x}}(\mathbf{M})\mathbf{x} \in \mathbb{L}_K^m$. □

Relation to the Lorentz Transformations In this part, we show that the set of matrices $\{f_{\mathbf{x}}(\mathbf{M})\}$ defined in Eq.(1) contains all Lorentz rotation and boost matrices.

Lemma 1. *In the* n*-dimensional Lorentz model* $\mathbb{L}_K^n$*, we denote the set of all Lorentz boost matrices as* $\mathcal{B}$ *, the set of all Lorentz rotation matrices as* $\mathcal{R}$ *. Given* $\mathbf{x} \in \mathbb{L}_K^n$*, we denote the set of* $f_{\mathbf{x}}(\mathbf{M})$ *at* $\mathbf{x}$ *without changing the number of space dimension as* $\mathcal{M}_{\mathbf{x}} = \{f_{\mathbf{x}}(\mathbf{M}) \mid \mathbf{M} \in \mathbb{R}^{(n+1)\times(n+1)}\}$. $\forall \mathbf{x} \in \mathbb{L}_K^n$*, we have* $\mathcal{B} \subseteq \mathcal{M}_{\mathbf{x}}$ *and* $\mathcal{R} \subseteq \mathcal{M}_{\mathbf{x}}$.

Proof 2. *We first prove* $\mathcal{M}_{\mathbf{x}}$ *covers all valid transformations.*

Considering $\mathcal{A} = \{\mathbf{A} \in \mathbb{R}^{(n+1)\times(n+1)} \mid \forall \mathbf{x} \in \mathbb{L}_K^n : \langle \mathbf{A}\mathbf{x}, \mathbf{A}\mathbf{x} \rangle_{\mathcal{L}} = \frac{1}{K}, (\mathbf{A}\mathbf{x})_0 > 0\}$ *is the set of all valid transformation matrices in the Lorentz model. Then* $\forall \mathbf{A} = \begin{bmatrix} \mathbf{v}_A^\intercal \\ \mathbf{W}_A \end{bmatrix} \in \mathcal{A}$, $\mathbf{v}_A \in$



(a) Linear layer formalized in tangent space (b) Lorentz boost (c) Lorentz rotation (d) Pseudo-rotation

Figure 1: Illustration of a hyperbolic linear layer based on the logarithmic and exponential maps as well as different transformations in the Lorentz model. In Figure 1a, A is mapped to B in the tangent space at the origin $\mathcal{T}_{\mathbf{0}}\mathbb{L}_K^n$ through the logarithmic map. A Euclidean linear transformation is performed to obtain C. Finally, C is mapped back to the hyperbolic space through the exponential map. Figures 1b and 1c are the visualization of the Lorentz boost and rotation, where points on the intersection of a plane and the hyperboloid are still coplanar after the Lorentz boost. Figure 1d is pseudo-rotation in §3.1, where a point is first transformed and then projected onto the hyperboloid.

$\mathbb{R}^{n+1}, \mathbf{W}_A \in \mathbb{R}^{n\times(n+1)}, \exists \mathbf{x} \in \mathbb{R}^{n+1} \colon \mathbf{v}^\intercal\mathbf{x} > 0$ *and* $\|\mathbf{W}_A\mathbf{x}\|^2 - (\mathbf{v}_A^\intercal\mathbf{x})^2 = \frac{1}{K}$. *Furthermore,* $\forall \mathbf{A} \in \mathcal{A}$, *we have*

$$f_{\mathbf{x}}(\mathbf{A}) = f_{\mathbf{x}}(\begin{bmatrix} \mathbf{v}_A^\intercal \\ \mathbf{W}_A \end{bmatrix}) = \begin{bmatrix} \frac{\sqrt{\|\mathbf{W}_A\mathbf{x}\|^2 - 1/K}}{\mathbf{v}_A^\intercal\mathbf{x}}\mathbf{v}_A^\intercal \\ \mathbf{W}_A \end{bmatrix} = \mathbf{A}.$$

Hence, we can see that $\mathcal{A} \subseteq \mathcal{M}_{\mathbf{x}}$. *Since* $\mathcal{B} \subseteq \mathcal{A}$ *and* $\mathcal{R} \subseteq \mathcal{A}$, *therefore* $\mathcal{B} \subseteq \mathcal{M}_{\mathbf{x}}$ *and* $\mathcal{R} \subseteq \mathcal{M}_{\mathbf{x}}$. □

According to Theorem 1 and Lemma 1, both Lorentz boost and rotation can be covered by our linear layer.

Relation to the Linear Layer Formalized in the Tangent Space In this part, we show that the conventional hyperbolic linear layer formalized in the tangent space at the origin (Ganea et al., 2018; Nickel and Kiela, 2018) can be considered as a Lorentz transformation with only a special rotation but no boost. Figure 1a visualizes the conventional hyperbolic linear layer.

As shown in Figure 1d, we consider a special setting "*pseudo-rotation*" of our hyperbolic linear layer. Formally, at the point $\mathbf{x} \in \mathbb{L}_K^n$, all pseudo-rotation matrices make up the set $\mathcal{P}_{\mathbf{x}} = \left\{ f_{\mathbf{x}}(\left[\begin{smallmatrix} w & \mathbf{0}^\intercal \\ \mathbf{0} & \mathbf{W} \end{smallmatrix}\right]) \;\middle|\; w \in \mathbb{R}, \mathbf{W} \in \mathbb{R}^{n\times n} \right\}$. As we no longer require the submatrix $\mathbf{W}$ to be a special orthogonal matrix, this setting is a relaxation of the Lorentz rotation.

Formally, given $\mathbf{x} \in \mathbb{L}_K^n$, the conventional hyperbolic linear layer relies on the logarithmic map to map the point into the tangent space at the origin, a matrix to perform linear transformation in the tangent space, and the exponential map to map the final result back to $\mathbb{L}_K^n$ [3]. The whole process [4] is

$$\exp_{\mathbf{0}}(\left[\begin{smallmatrix} * & \mathbf{0}^\intercal \\ \mathbf{0} & \mathbf{W} \end{smallmatrix}\right] \log_{\mathbf{0}}(\left[\begin{smallmatrix} x_t \\ \mathbf{x}_s \end{smallmatrix}\right])) = \begin{bmatrix} \frac{\cosh(\beta)}{\sqrt{-K}x_t} & \mathbf{0}^\intercal \\ \mathbf{0} & \frac{\sinh(\beta)\mathbf{W}}{\sqrt{-K}\|\mathbf{W}\mathbf{x}_s\|} \end{bmatrix} \left[\begin{smallmatrix} x_t \\ \mathbf{x}_s \end{smallmatrix}\right], \tag{2}$$

where $\beta = \frac{\sqrt{-K}\cosh^{-1}(\sqrt{-K}x_t)}{\sqrt{-Kx_t^2 - 1}}\|\mathbf{W}\mathbf{x}_s\|$.

Lemma 2. $\forall \mathbf{x} \in \mathbb{L}_K^n$ *, we define the set of the outcomes of Eq.(2) as*

$$\mathcal{H}_{\mathbf{x}} = \left\{ \begin{bmatrix} \frac{\cosh(\beta)}{\sqrt{-K}x_t} & \mathbf{0}^\intercal \\ \mathbf{0} & \frac{\sinh(\beta)}{\sqrt{-K}\|\mathbf{W}\mathbf{x}_s\|}\mathbf{W} \end{bmatrix} \;\middle|\; \mathbf{W} \in \mathbb{R}^{n\times n} \right\},$$

then we have $\mathcal{H}_{\mathbf{x}} \subseteq \mathcal{P}_{\mathbf{x}}$ *and* $\mathcal{H}_{\mathbf{x}} \cap \mathcal{B} = \{\mathbf{I}\}$.

Proof 3. $\forall \mathbf{x} \in \mathbb{L}_K^n, \forall \mathbf{H} \in \mathcal{H}_{\mathbf{x}}$, $\mathbf{H}$ *has the form* $\left[\begin{smallmatrix} w & \mathbf{0}^\intercal \\ \mathbf{0} & \mathbf{W} \end{smallmatrix}\right]$, *satisfying* $\|\mathbf{W}\mathbf{x}_s\|^2 - (wx_t)^2 = \frac{1}{K}$ *and* $wx_t > 0$. *We can verify that*

$$\begin{aligned} f_{\mathbf{x}}(\mathbf{H}) &= f_{\mathbf{x}}(\left[\begin{smallmatrix} w & \mathbf{0}^\intercal \\ \mathbf{0} & \mathbf{W} \end{smallmatrix}\right]) \\ &= \begin{bmatrix} \frac{\sqrt{\|\mathbf{W}\mathbf{x}_s\|^2 - 1/K}}{wx_t}w & \mathbf{0}^\intercal \\ \mathbf{0} & \mathbf{W} \end{bmatrix} = \mathbf{H}. \end{aligned}$$

Hence, $\forall \mathbf{x} \in \mathbb{L}_K^n$, $\forall \mathbf{H} \in \mathcal{H}_{\mathbf{x}}$, *we have* $\mathbf{H} = f_{\mathbf{x}}(\mathbf{H}) \in \mathcal{P}_{\mathbf{x}}$, *and thus* $\mathcal{H}_{\mathbf{x}} \subseteq \mathcal{P}_{\mathbf{x}}$. □

To prove $\mathcal{H}_{\mathbf{x}} \cap \mathcal{B} = \mathbf{I}$ is trivial, we do not elaborate here. Therefore, a conventional hyperbolic linear layer can be considered as a special rotation where the time axis is changed according to the space axes to ensure that the output is still in the Lorentz model. Our linear layer is not only fully

---

[3] Note that Mobius matrix-vector multiplication defined in Ganea et al. (2018) also follows this process

[4] The 0-th dimension of any point in the tangent space at the origin is 0, therefore the linear matrix has the form $\mathrm{diag}(*, \mathbf{W})$, where $*$ can be arbitrary number.

hyperbolic but also equipped with boost operations to be more expressive. Moreover, without using the complicated logarithmic and exponential maps, our linear layer has better efficiency and stability.

A More General Formula Here, we give a more general formula[5] of our hyperbolic linear layer based on $f_{\mathbf{x}}(\left[\begin{smallmatrix}\mathbf{v}^\intercal\\ \mathbf{W}\end{smallmatrix}\right])\mathbf{x}$, by adding activation, dropout, bias and normalization,

$$\mathbf{y} = \texttt{HL}(\mathbf{x}) = \begin{bmatrix} \sqrt{\|\phi(\mathbf{W}\mathbf{x},\mathbf{v})\|^2 - 1/K} \\ \phi(\mathbf{W}\mathbf{x},\mathbf{v}) \end{bmatrix}, \tag{3}$$

where $\mathbf{x} \in \mathbb{L}_K^n$, $\mathbf{v} \in \mathbb{R}^{n+1}$, $\mathbf{W} \in \mathbb{R}^{m\times(n+1)}$, and ϕ is an operation function: for the dropout, the function is $\phi(\mathbf{W}\mathbf{x}, \mathbf{v}) = \mathbf{W}\texttt{dropout}(\mathbf{x})$; for the activation and normalization $\phi(\mathbf{W}\mathbf{x}, \mathbf{v}) = \frac{\lambda\sigma(\mathbf{v}^\intercal\mathbf{x}+b')}{\|\mathbf{W}h(\mathbf{x})+\mathbf{b}\|}(\mathbf{W}h(\mathbf{x}) + \mathbf{b})$, where σ is the sigmoid function, $\mathbf{b}$ and b' are bias terms, $\lambda > 0$ controls the scaling range, h is the activation function. We elaborate $\phi(\cdot)$ we use in practice in the appendix.

3.2 Fully Hyperbolic Attention Layer

Attention layers are also important for building networks, especially for the networks of Transformer family (Vaswani et al., 2017). We propose an attention module in the Lorentz model. Specifically, we consider the weighted aggregation of a point set $\mathcal{P} = \{\mathbf{x}_1, \ldots, \mathbf{x}_{|\mathcal{P}|}\}$ as calculating the centroid, whose expected (squared) distance to $\mathcal{P}$ is minimum, i.e. $\arg\min_{\boldsymbol{\mu}\in\mathbb{L}_K^n} \sum_{i=1}^{|\mathcal{P}|} \nu_i d_{\mathcal{L}}^2(\mathbf{x}_i, \boldsymbol{\mu})$, where ν_i is the weight of the i-th point. Law et al. (2019) prove that, with squared Lorentzian distance defined as $d_{\mathcal{L}}^2(\mathbf{a}, \mathbf{b}) = 2/K - 2\langle\mathbf{a}, \mathbf{b}\rangle_{\mathcal{L}}$, the centroid *w.r.t.* the squared Lorentzian distance is given as

$$\begin{aligned}\boldsymbol{\mu} &= \texttt{Centroid}\big(\{\nu_1, \ldots, \nu_{|\mathcal{P}|}\}, \{\mathbf{x}_1, \ldots, \mathbf{x}_{|\mathcal{P}|}\}\big) \\ &= \frac{\sum_{j=1}^{|\mathcal{P}|} \nu_j \mathbf{x}_j}{\sqrt{-K}\big|\|\sum_{i=1}^{|\mathcal{P}|} \nu_i \mathbf{x}_i\|_{\mathcal{L}}\big|}.\end{aligned} \tag{4}$$

Given the query set $\mathcal{Q} = \{\mathbf{q}_1, \ldots, \mathbf{q}_{|\mathcal{Q}|}\}$, key set $\mathcal{K} = \{\mathbf{k}_1, \ldots, \mathbf{k}_{|\mathcal{K}|}\}$, and value set $\mathcal{V} = \{\mathbf{v}_1, \ldots, \mathbf{v}_{|\mathcal{V}|}\}$, where $|\mathcal{K}| = |\mathcal{V}|$, we exploit the squared Lorentzian distance between points to calculate weights. The attention is defined as $\texttt{ATT}(\mathcal{Q}, \mathcal{K}, \mathcal{V}) = \{\boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_{|\mathcal{Q}|}\}$ and given by:

$$\begin{aligned}\boldsymbol{\mu}_i &= \frac{\sum_{j=1}^{|\mathcal{K}|} \nu_{ij}\mathbf{v}_j}{\sqrt{-K}\big|\|\sum_{k=1}^{|\mathcal{K}|} \nu_{ik}\mathbf{v}_k\|_{\mathcal{L}}\big|}, \\ \nu_{ij} &= \frac{\exp(\frac{-d_{\mathcal{L}}^2(\mathbf{q}_i,\mathbf{k}_j)}{\sqrt{n}})}{\sum_{k=1}^{|\mathcal{K}|} \exp(\frac{-d_{\mathcal{L}}^2(\mathbf{q}_i,\mathbf{k}_k)}{\sqrt{n}})},\end{aligned} \tag{5}$$

where n is the dimension of points. Furthermore, multi-headed attention is defined as $\texttt{MHATT}(\mathcal{Q}, \mathcal{K}, \mathcal{V}) = \{\boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_{|\mathcal{Q}|}\}$, and $\boldsymbol{\mu}_i$ is

$$\begin{aligned}\boldsymbol{\mu}_i &= \texttt{HL}([\boldsymbol{\mu}_i^1|\ldots|\boldsymbol{\mu}_i^H]), \\ \{\boldsymbol{\mu}_1^i, \boldsymbol{\mu}_2^i, \ldots\} &= \texttt{ATT}^i(\texttt{HL}_{\mathcal{Q}}^i(\mathcal{Q}), \texttt{HL}_{\mathcal{K}}^i(\mathcal{K}), \texttt{HL}_{\mathcal{V}}^i(\mathcal{V})),\end{aligned} \tag{6}$$

where H is the head number, $[\cdot|\ldots|\cdot]$ is the concatenation of multiple vectors, $\texttt{ATT}^i(\cdot,\cdot,\cdot)$ is the i-th head attention, and $\texttt{HL}_{\mathcal{Q}}^i(\cdot)$, $\texttt{HL}_{\mathcal{K}}^i(\cdot)$, $\texttt{HL}_{\mathcal{V}}^i(\cdot)$ are the hyperbolic linear layers of the i-th head attention.

Other intuitive choices for the aggregation in the Lorentz attention module include Fréchet mean (Karcher, 1977) and Einstein midpoint (Ungar, 2005). The Fréchet mean is the classical generalization of Euclidean mean. However, it offers no closed-form solution. Solving the Fréchet mean currently requires iterative computation (Lou et al., 2020; Gu et al., 2019), which significantly slows down the training and inference, making it impossible to generalize to deep and large model [6]. On the contrary, Lorentz centroid is fast to compute and can be seen as Frechet mean in pseudo-hyperbolic space (Law et al., 2019). The computation of the Einstein midpoint requires transformation between Lorentz model and Klein model, bringing in numerical instability. The Lorentz centroid we use minimizes the sum of squared distance in the Lorentz model, while the Einstein midpoint does not possess such property in theory. Also, whether the Einstein midpoint in the Klein model has its geometric interpretation in the Lorentz model remains to be investigated, and it is beyond the scope of our paper. Therefore, we adopt the Lorentz centroid in our Lorentz attention.

3.3 Fully Hyperbolic Residual Layer and Position Encoding Layer

Lorentz Residual The residual layer is crucial for building deep neural networks. Since there is no well-defined vector addition in the Lorentz

---

[5] Note that this general formula is no longer fully hyperbolic. It is a relaxation in implementation, while the input and output are still guaranteed to lie in the Lorentz model.

[6] 400 times slower than using Lorentz centroid in our experiment, and no improvement in performance was observed

model, we assume that each residual layer is preceded by a computational block whose last layer is a Lorentz linear layer, and do the residual-like operation within the preceding Lorentz linear layer of the block as a compromise. Given the input $\mathbf{x}$ of the computational block and the output $\mathbf{o} = f(\mathbf{x})$ before the last Lorentz linear layer of the block, we take $\mathbf{x}$ as the bias of the Lorentz linear layer. Concretely, the final output of the block is

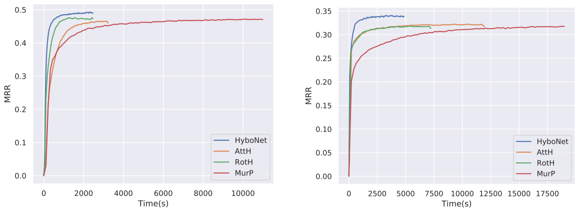
$$\mathbf{y} = \begin{bmatrix} \sqrt{\|\phi(\mathbf{Wo},\mathbf{v},\mathbf{x})\|^2 - 1/K} \\ \phi(\mathbf{Wo},\mathbf{v},\mathbf{x}) \end{bmatrix},$$
$$\phi(\mathbf{Wo},\mathbf{v},\mathbf{x}) = \frac{\lambda\sigma(\mathbf{v}^\intercal\mathbf{o})}{\|\mathbf{W}h(\mathbf{o}) + \mathbf{x}_s\|}(\mathbf{W}h(\mathbf{o}) + \mathbf{x}_s), \tag{7}$$

where the symbols have the same meaning as those in Eq.(3).

Lorentz Position Encoding Some neural networks require positional encoding for their embedding layers, especially those models for NLP tasks. Previous works generally incorporate positional information by adding position embeddings to word embeddings. Given a word embedding $\mathbf{x}$ and its corresponding learnable position embedding $\mathbf{p}$, we add a Lorentz linear layer to transform the word embedding $\mathbf{x}$, by taking the position embedding $\mathbf{p}$ as the bias. The overall process is the same as Eq.(7). Note that the transforming matrix in the Lorentz linear layer is shared across positions. This modification gives us one more $d \times d$ matrix than the Euclidean Transformer. The increase in the number of parameters is negligible compared to the huge parameters of the whole model.

4 Experiments

To verify our proposed framework, we conduct experiments on both shallow and deep neural networks. For shallow neural networks, we present results on knowledge graph completion. For deep neural networks, we propose a Lorentz Transformer and present results on machine translation. Dependency tree probing is also done on both Lorentz and Euclidean Transformers to compare their capabilities of representing structured information. Due to space limitations, we report the results of network embedding and fine-grained entity typing experiments in the appendix A. For knowledge graph completion and network embedding, we use our fully hyperbolic linear layer, and for other tasks, we use the general formula given in §3.1, which is a relaxation of our fully hyperbolic linear layer.



(a) WN18RR (b) FB15k-237

Figure 2: Validation curves of knowledge graph models.

In the following sections, we denote the models built with our proposed framework as **HYBONET**. We demonstrate that HyboNet not only outperforms Euclidean and Poincaré models on the majority of tasks, but also converges better than its Poincaré counterpart. All models in §4.1 are trained with 1 NVIDIA 2080Ti, models in §4.2 are trained with 1 NVIDIA 40GB A100 GPU. We optimize our model with Riemannian Adam (Kochurov et al., 2020). For pre-processing and hyper-parameters of each experiment, please refer to Appendix B.

4.1 Experiments on Shallow Networks

In this part, we leverage our Lorentz embedding and linear layers to build shallow neural networks. We show that HyboNet outperforms previous knowledge graph completion models on several popular benchmarks.

4.1.1 Knowledge Graph Completion Models

A knowledge graph contains a collection of factual triplets, each triplet (h, r, t) illustrates the existence of a relation r between the head entity h and the tail entity t. Since knowledge graphs are generally incomplete, predicting missing triplets becomes a fundamental research problem. Concretely, the task aims to solve the problem $(h, r, ?)$ and $(?, r, t)$.

We use two popular knowledge graph completion benchmarks, FB15k-237(Toutanova and Chen, 2015) and WN18RR(Dettmers et al., 2018) in our experiments. We report two evaluation metrics: **MRR** (Mean reciprocal rank), the average of the inverse of the true entity ranking in the prediction; **H@K**, the percentage of the correct entities appearing within the top K positions of the predicted ranking.

Setup Similar to Balazevic et al. (2019a), we design a score function for each triplet as

$$s(h, r, t) = -d_{\mathcal{L}}^2(f_r(\mathbf{e}_h), \mathbf{e}_t) + b_h + b_t + \delta,$$

Table 1: Link prediction results (%) on WN18RR and FB15k-237 in the filtered setting. $\beta \in \{200, 400, 500\}$ and we report the best result. The first group of models are Euclidean models, the second and third groups are hyperbolic models with different dimensions. Following Balazevic et al. (2019a), RotatE results are reported without their self-adversarial negative sampling for fair comparison. Best results are in bold. Best results among hyperbolic networks with same dimensions are underlined.

where $\mathbf{e}_h, \mathbf{e}_t \in \mathbb{L}_K^n$ are the Lorentz embeddings of the head entity h and the tail entity t, $f_r(\cdot)$ is a Lorentz linear transformation of the relation r and δ is a margin hyper-parameter. For each triplet, we randomly corrupt its head or tail entity with k entities and calculate the probabilities for triplets as $p = \sigma(s(h, r, t))$, where σ is the sigmoid function. Finally, we minimize the binary cross entropy loss

$$\mathcal{L} = -\frac{1}{N}\sum_{i=1}^{N}\left(\log p^{(i)} + \sum_{j=1}^{k}\log(1 - \tilde{p}^{(i,j)})\right),$$

where $p^{(i)}$ and $\tilde{p}^{(i,j)}$ are the probabilities for correct and corrupted triplets respectively, N is the triplet number. We select the model with the best MRR on validation set and report its performance on test set.

Results §3.3 shows the results on both datasets. As expected, low-dimensional hyperbolic networks have already achieved comparable or even better results when compared to high-dimensional Euclidean baselines. When the dimensionality is raised to a maximum of 500, HyboNet outperforms all other baselines on MRR, H@3, and H@1 by a significant margin. And as shown in Figures 2a and 2b, HyboNet converges better than other hyperbolic networks on both datasets and has a higher ceiling, demonstrating the superiority of our Lorentz linear layer over conventional linear layer formalized in tangent space.

4.2 Experiments on Deep Networks

In this part, we build a Transformer (Vaswani et al., 2017) with our Lorentz components introduced in §3. We omit layer normalization for the difficulty of defining hyperbolic mean and variance, but it is still kept in our Euclidean Transformer baseline. In fact, λ in Eq.(3) controls the scaling range, which normalize the representations to some extent.

4.2.1 Machine Translation

We conduct the experiment on two widely-used machine translation benchmarks: IWSLT'14 English-German and WMT'14 English-German.

Setup We use OpenNMT (Klein et al., 2017) to build Euclidean Transformer and our Lorentz one. Following previous hyperbolic work (Shimizu et al., 2021), we conduct experiments in low-dimensional settings. To show that our framework can be applied to high-dimensional settings, we additionally train a Lorentz Transformer of the same size as Transformer base, and compare their performance on WMT'14. We select the model with the lowest perplexity on the validation set, and report its BLEU scores on the test set.

Results The BLEU scores on the test set of IWSLT'14 and newstest2013 test set of WMT'14 are shown in Table 2. Both Transformer-based hyperbolic models, HyboNet and HAtt (Gulcehre et al., 2018), outperform the Euclidean Transformer. However, in HAtt, only the calculation of attention weights and the aggregation are performed

	IWSLT'14	WMT'14		
Model	d=64	d=64	d=128	d=256
ConvSeq2Seq	23.6	14.9	20.0	21.8
Transformer	23.0	17.0	21.7	25.1
HyperNN++	22.0	17.0	19.4	21.8
HAtt	23.7	18.8	22.5	25.5
HyboNet	**25.9**	**19.7**	**23.3**	**26.2**

Table 2: The BLEU scores on the test set of IWSLT'14 and WMT'14 under the low-dimensional setting.

Model	**WMT'14**
Transformer$_{\text{base}}$ (Vaswani et al., 2017)	27.3
Transformer$_{\text{big}}$ (Vaswani et al., 2017)	28.4
HAtt$_{\text{base}}$ (Gulcehre et al., 2018)	27.5
HyboNet$_{\text{base}}$	**28.2**

Table 3: The BLEU scores on the test set of WMT'14 under the high-dimensional setting. The results of Transformer and HAtt are taken from their original paper respectively.

in hyperbolic space, leaving the remaining computational blocks in the Euclidean space. That is, HAtt is a partially hyperbolic Transformer. As a result, the merits of hyperbolic space are not fully exploited. On the contrary, HyboNet performs all its operations in the hyperbolic space, thus better utilizes the hyperbolic space, and achieve significant improvement over both Euclidean and partially hyperbolic Transformer. Apart from the low-dimensional setting that is common in hyperbolic literature, we scale up the model to be the same size as Transformer base (512-dimensional input) (Vaswani et al., 2017). We report the results in Table 3. HyboNet outperforms Transformer and HAtt with the same model size, and is very close to the much bigger Transformer$_{\text{big}}$.

4.2.2 Dependency Tree Probing

In this part, we verify the superiority of HyboNet in capturing latent structured information in unstructured sentences through dependency tree probing. It has been shown that neural networks implicitly embed syntax trees in their intermediate context representations (Hewitt and Manning, 2019; Raganato et al., 2018). One reason we think HyboNet performs better in machine translation is that it better captures structured information in the sentences. To validate this, we perform a probing on Transformer, HAtt and HyboNet obtained in §4.2.1. We use dependency parsing result of stanza (Qi et al., 2020) on IWSLT'14 English corpus as our dataset. The data partition is kept.

	Distance		Depth	
Model	UUAS	Dspr.	Root%	Nspr.
Transformer	0.36	0.30	12	0.88
HAtt	0.50	0.64	49	0.88
HyboNet	**0.59**	**0.70**	**64**	**0.92**

Table 4: The probing results on dependency tree constructed from the Iwslt'14 English corpus.

Setup For a fair comparison, we probe all the models in hyperbolic space following Chen et al. (2021). Four metrics are reported: **UUAS** (undirected attachment score), the percentage of undirected edges placed correctly against the gold tree; **Root%**, the precision of the model predicting the root of the syntactic tree; **Dspr.** and **Nspr.**, the Spearman correlations between true and predicted distances for each word in each sentence, true depth ordering and the predicted ordering, respectively. Please refer to the appendix for details.

Results The probing results are shown in Table 2. HyboNet outperforms other baselines by a large margin. Obviously, syntax trees can be better reconstructed from the intermediate representation of HyboNet's encoder, which shows that HyboNet better captures syntax structure. The result of HAtt is also worth noting. Because HAtt is a partially hyperbolic Transformer, intuitively, its ability to capture the structured information should be better than Euclidean Transformer, but worse than HyboNet. Our result confirms this suspicion indeed. The probing on HAtt indicates that as the model becomes more hyperbolic, the ability to learn structured information becomes stronger.

5 Related Work

Hyperbolic geometry has been widely investigated in representation learning in recent years, due to its great expression capacity in modeling complex data with non-Euclidean properties. Previous works have shown that when handling data with hierarchy, hyperbolic embedding has better representation capacity and generalization ability (Cvetkovski and Crovella, 2016; Verbeek and Suri, 2014; Walter, 2004; Kleinberg, 2007; Krioukov et al., 2009; Cvetkovski and Crovella, 2009; Shavitt and Tankel, 2008; Sarkar, 2011). Moreover, Ganea et al. (2018) and Nickel and Kiela (2018) introduce the basic operations of neural networks in the Poincaré ball and the Lorentz model respectively. After that, researchers further introduce various types of neural models in hyperbolic space including hyperbolic attention networks (Gulcehre et al., 2018), hyperbolic graph neural networks (Liu et al., 2019; Chami et al., 2019), hyperbolic prototypical networks (Mettes et al., 2019) and hyperbolic capsule networks (Chen et al., 2020). Recently, with the rapid development of hyperbolic neural networks, people attempt to utilize them in various downstream tasks such as word embeddings (Tifrea et al., 2018), knowledge graph embeddings (Chami et al., 2020b), entity typing (López et al., 2019), text classification (Zhu et al., 2020), question answering (Tay et al., 2018) and machine translation (Gulcehre et al., 2018; Shimizu et al., 2021), to handle their non-Euclidean properties, and have achieved significant and consistent improvement.

Our work not only focus on the improvement in the downstream tasks that hyperbolic space offers, but also show that hyperbolic linear transformation used in previous work is just a relaxation of Lorentz rotation, giving a different theoretical interpretation for the hyperbolic linear transformation.

6 Conclusion and Future Work

In this work, we propose a novel fully hyperbolic framework based on the Lorentz transformations to overcome the problem that hybrid architectures of existing hyperbolic neural networks relied on the tangent space limit network capabilities. The experimental results on several representative NLP tasks show that compared with other hyperbolic networks, HYBONET has faster speed, better convergence, and higher performance. In addition, we also observe that some challenging problems require further efforts: (1) Though we have verified the effectiveness of fully hyperbolic models in NLP, exploring its applications in computer vision is still a valuable direction. (2) Though HYBONET has better performance on many tasks, it is slower than Euclidean networks. Also, because of the floating-point error, HYBONET cannot be sped up with half precision training. We hope more efforts can be devoted into this promising field.

A Other Experiments

A.1 Graph Neural Networks

Previous works have shown that when equipped with hyperbolic geometry, GNNs demonstrate impressive improvements compared with its Euclidean counterparts (Chami et al., 2019; Liu et al., 2019). In this part, we extend GCNs with our proposed hyperbolic framework. Following Chami et al. (2019), we evaluate our HYBONET for link prediction and node classification on four network embedding datasets, and observe better or comparable results as compared to previous methods.

Setup The architecture of GCNs can be summarized into three parts: feature transformation, neighborhood aggregation and non-linear activation. We use a Lorentz linear layer for the feature transformation, and use the centroid of neighboring node features as the aggregation result. The non-linear activation is integrated into Lorentz linear layer as elaborated in §3.1. The overall operations of the l-th network layer can be formulated into the following manner:

$$\mathbf{x}_i^l = \mathtt{Att}\big(\mathtt{HL}(\mathbf{x}_i^{l-1}), \{\mathtt{HL}(\mathbf{x}_{j\in\mathcal{N}_i}^{l-1})\}, \{\mathtt{HL}(\mathbf{x}_{j\in\mathcal{N}_i}^{l-1})\}\big),$$

where $\mathbf{x}_i^l$ refers to the representation of the i-th node at the layer l, $\mathcal{N}_i$ denotes the neighboring nodes of the i-th node. With the node representation, we can easily conduct link prediction and node classification. For link prediction, we calculate the probability of edges using Fermi-Dirac decoder (Krioukov et al., 2010; Nickel and Kiela, 2017):

$$p((i,j) \in \mathcal{E} \mid \mathbf{x}_i, \mathbf{x}_j) = \left(\exp((d_{\mathcal{L}}^2(\mathbf{x}_i, \mathbf{x}_j) - r)/t) + 1\right)^{-1}, \tag{8}$$

where r and t are hyper-parameters. We minimize the binary cross entropy loss. For node classification, we calculate the squared Lorentzian distance between node representation and class representations, and minimize the cross entropy loss.

Results Following Chami et al. (2019), we report ROC AUC results for link prediction and F1 scores for node classification on four different network embedding datasets. The description of the datasets can be found in our appendix. Chami et al. (2019) compute Gromovs δ-hyperbolicity(Jonckheere et al., 2008; Adcock et al., 2013; Narayan and Saniee, 2011) for these four datasets. The lower the δ is, the more hyperbolic the graph is.

The results are reported in Appendix A.1. HYBONET outperforms other baselines in those highly hyperbolic datasets. For Disease dataset, HYBONET even achieves a 12% (absolute) improvement on node classification over previous hyperbolic GCNs. On the less hyperbolic datasets such as PubMed and Cora, HYBONET still performs well on link prediction, and remains competitive for node classification. Although HYBONET does not significantly better than LGCN on all datasets, we observe that HYBONET is far more stable than LGCN. Out of 128 link prediction experiments in grid search, there are 89 times that LGCN generates NaN and fails to finish training, while HYBONET remains stable and is faster than LGCN.

A.2 Fine-grained Entity Typing

Given a sentence containing a mention of entity e, the purpose of entity typing is to predict the type of e from a type inventory. It is a multi-label classification problem since multiple types can be assigned to e. For fine-grained entity typing, type labels are divided into finer granularity, making the type inventory contains thousands of types. We conduct the experiment on Open Entity dataset (Choi et al., 2018), which divides types into three levels: coarse, fine, and ultra-fine.

Setup Our entity typing model consists of a mention encoder and a context encoder. To get mention representation, the mention encoder first obtain word representation $\mathbf{s}_i$, then calculate the centroid of $\mathbf{s}_i$ as mention representation $\mathbf{m}$ according to Eq. (4) with uniform weight. The context encoder is a Lorentz Transformer encoder that shares the same embedding module with mention encoder. The context representation $\mathbf{c}$ is the distance-based attention (López and Strube, 2020) result over the Transformer encoder's output. We combine $\mathbf{m}$ and $\mathbf{c}$ in the way of combining multi-headed outputs described in §3.2 by regarding $\mathbf{m}$ and $\mathbf{c}$ as a two-headed output. We then calculate a probability $p_i = \sigma(-d_{\mathcal{L}}^2(\mathbf{r}, \mathbf{t}_i)/\alpha_i + \beta_i)$ for every type label, where σ is sigmoid function, $\mathbf{t}_i$ is the Lorentz embedding of the i-th type label, and α_i, β_i are learnable scale and bias factor respectively. During training, we optimize the multi-task objective (Vaswani et al., 2017). For evaluation, a type is predicted if its probability is larger than 0.5.

Results Following previous works (Choi et al., 2018; López and Strube, 2020), we report the macro-averaged F1 scores on the development set of Open Entity dataset in Appendix A.2. HyboNet outperforms LabelGCN (Xiong et al., 2019) and MultiTask (Vaswani et al., 2017) on Total with fewer parameters. Compared with large Euclidean models Denoised and BERT, HyboNet achieves comparable fine and ultra-fine results with significantly fewer parameters. Compared with another hyperbolic model HY (López and Strube, 2020), which is based on the Poincaré ball model, HyboNet outperforms HY xLarge model on coarse and fine results. Note that HyboNet has only slightly more parameters than HY base, and fewer than HY Large.

B Data Preprocessing Methods

We describe data preprocessing methods for each experiment in this section.

B.1 Knowledge Graph Completion

The statistics of WN18RR and FB15k-237 are listed in Table 7. We keep our data preprocessing method for knowledge graph completion the same as Balazevic et al. (2019a). Concretely, we augment both WN18RR and FB15k-237 by adding reciprocal relations for every triplet, i.e. for every (h, r, t) in the dataset, we add an additional triplet (t, r^{-1}, h).

	Disease($\delta=0$)		**Airport**($\delta=1$)		**PubMed**($\delta=3.5$)		**Cora**($\delta=11$)

Table 6: Macro F_1 scores (%) on the development set of Open Entity dataset for different baselines and models. Best results are underlined, and best results among hyperbolic models are in bold.

B.2 Machine Translation

For WMT'14, we use the preprocessing script provided by OpenNMT[7]. For IWSLT'14, we clean and partition the dataset with script provided by FairSeq[8]. We limit the lengths of both source and target sentences to be 100 and do not share the vocabulary between source and target language.

B.3 Network Embedding

We use four datasets, referred to as Disease, Airport, Pubmed and Cora. The four datasets are preprocessed by Chami et al. (2019) and published in their code repository[9]. We refer the readers to Chami et al. (2019) for further information about the datasets.

B.4 Entity Typing

The dataset consist of $6,000$ crowd sourced samples and 6M distantly supervised training samples. We keep our data preprocessing method for knowledge graph completion the same as López and Strube (2020). For the input context, We trimmed the sentence to a maximum of 25 words. During the trimming, one word at a time is removed from one side of the mention, trying to keep the mention in the center of the sentence, and preserve the context information of the mention. For the input mention, we trimmed the mention to a maximum of 5 words.

C Experiment Details

All of our experiments use 32-bit floating point numbers, not 64-bit floating point numbers as in most previous work. We use PyTorch as the neural networks' framework. The negative curvature K of the Lorentz model in our experiments is -1.

We take the function ϕ in Lorentz linear layer to have the form

$$\phi(\mathbf{W}\mathbf{x}) = \frac{\sqrt{(\lambda\sigma(\mathbf{v}^T\mathbf{x}+b)+\epsilon)^2+\frac{1}{K}}}{\|\mathbf{W}h(\texttt{drop}(\mathbf{x}))\|}\mathbf{W}h(\texttt{drop}(\mathbf{x})), \tag{9}$$

DROP means dropout function. To see what it means, we first compute $\mathbf{y_0} = \lambda\sigma(\mathbf{v}^T\mathbf{x}+b)+\epsilon$ as the 0-th dimension of the output $\mathbf{y}$, where σ is the sigmoid function, λ controls the 0-th dimension's range, it can be either learnable or fixed, b is a learnable bias term, and $\epsilon > \sqrt{1/K}$ is a constant preventing the 0-th dimension be smaller than $\sqrt{1/K}$. According to the definition of Lorentz model, $\mathbf{y}$ should satisfies $\|\mathbf{y}_{1:n}\|^2 - \mathbf{y_0}^2 = 1/K$, that is, $\|\mathbf{y}_{1:n}\| = \sqrt{\mathbf{y_0}^2+1/K} = \sqrt{(\lambda\sigma(\mathbf{v}^T\mathbf{x}+b)+\epsilon)^2+1/K}$. Then equation (9) can be seen as first calculate $\tilde{\mathbf{y}}_{1:n} = \mathbf{W}h(\texttt{drop}(\mathbf{x}))$, then scale $\tilde{\mathbf{y}}_{1:n}$ to have vector norm $\|\mathbf{y}_{1:n}\|$ to obtain $\mathbf{y}_{1:n}$. Finally, we concatenate $\mathbf{y_0}$ with $\mathbf{y}_{1:n}$ as output.

Table 9: Hyper-parameters for knowldge graph completion.

For residual and position embedding addition, we also use Eq.(9).

C.1 Initialization

We use different initialization method for different parameters, see Table 8. Geoopt(Kochurov et al., 2020) initialize the parameter with Gaussian distribution in the tangent space, and map the embedding to hyperbolic space with exponential map.

C.2 Knowledge Graph Completion

We list the hyper-parameters used in the experiment in Table 9. Note that in this experiment, we restrict the norm of the last n dimension of the embeddings to be no bigger than a certain value, referred to as Max Norm in Table 9. For each dataset, we explore BatchSize $\in \{500, 1000\}$, Margin $\in \{4, 6, 8\}$, MaxNorm $\in \{1.5, 2.5, 3.5\}$, $\lambda \in \{2.5, 3.5, 5.5\}$, LearningRate $\in \{3e-3, 5e-3, 7e-3\}$.

C.3 Machine Translation

Our code is based on OpenNMT's Transformer(Klein et al., 2017). The hyper-parameters are listed in Table 11

C.4 Dependency Tree Probing

The probing for the Euclidean Transformer is done by first applying an Euclidean linear mapping $f_P : \mathbb{R}^n \to \mathbb{R}^{m+1}$ followed by a projection to map Transformer's intermediate context-aware representation $\mathbf{c}_i$ into points $\tilde{\mathbf{h}}_i$ in tangent space of Lorentz model's origin, then using exponential map to map $\tilde{\mathbf{h}}_i$ to hyperbolic space $\mathbf{p}_i$. In the hyperbolic space, we construct the Lorentz syntactic subspace via a Lorentz linear layer $f_Q : \mathbb{L}_K^m \to \mathbb{L}_K^m$:

$$\begin{aligned}\mathbf{p}_i &= \exp_{\mathbf{0}}^K(f_P(\mathbf{c}_i)),\\ \mathbf{q}_i &= f_Q(\mathbf{p}_i).\end{aligned}$$

We use the squared Lorentzian distance between $\mathbf{q}_i$ and $\mathbf{q}_j$ to recreate tree distances between word pairs w_i and w_j, the squared Lorentzian distance between $\mathbf{q}_i$ and the origin $\mathbf{o}$ to recreate the depth of word w_i. We minimize the following loss:

$$\mathcal{L}_{\text{distance}} = \frac{1}{l^2} \sum_{i,j \in \{1,\cdots,t\}} |d_T(w_i, w_j) - d_{\mathcal{L}}^2(\mathbf{q}_i, \mathbf{q}_j)|$$

$$\mathcal{L}_{\text{depth}} = \frac{1}{l} \sum_{i \in \{1,\cdots,t\}} |d_D(w_i) - d_{\mathcal{L}}^2(\mathbf{q}_i, \mathbf{o})|,$$

where $d_T(w_i, w_j)$ is the edge number of the shortest path from w_i to w_j in the dependency tree, and l is the sentence length. For the probing of Lorentz Transformer, we only substitute f_P with a Lorentz one, and discard the exponential map. We probe every layer for both models, and report the results of the best layer.

We do the probing in the 64 dimensional hyperbolic space. The hyper-parameters and the best layer we choose according to development set are listed in Table 12. Because no Lorentz embedding is involved, we simply use Adam as the optimizer. For parameter selection, we explore Learning Rate $\in \{5e-4, 3e-4, 1e-4, 5e-5, 3e-5, 1e-5\}$, Weight Decay $\in \{0, 1e-6, 1e-5, 1e-4\}$, Batch Size$\in \{16, 32, 64\}$.

C.5 Network Embedding

The experiment setting is the same as Chami et al. (2019). We list the hyper-parameters for the four datasets in Table.10

C.6 Entity Typing

Abstract

Multimodal machine translation (MMT) aims to improve neural machine translation (NMT) with additional visual information, but most existing MMT methods require paired input of source sentence and image, which makes them suffer from shortage of sentence-image pairs. In this paper, we propose a phrase-level retrieval-based method for MMT to get visual information for the source input from existing sentence-image data sets so that MMT can break the limitation of paired sentence-image input. Our method performs retrieval at the phrase level and hence learns visual information from pairs of source phrase and grounded region, which can mitigate data sparsity. Furthermore, our method employs the conditional variational auto-encoder to learn visual representations which can filter redundant visual information and only retain visual information related to the phrase. Experiments show that the proposed method significantly outperforms strong baselines on multiple MMT datasets, especially when the textual context is limited.

1 Introduction

Multimodal machine translation (MMT) introduces visual information into neural machine translation (NMT), which assumes that additional visual modality could improve NMT by grounding the language into a visual space (Lee et al., 2018). However, most existing MMT methods require additional input of images to provide visual representations, which should match with the source sentence. Unfortunately, in practice it is difficult to get this kind of pairwise input of text and images which hinders the applications of MMT. What is worse, to train an MMT model, the training data still involves the target sentence besides the source sentence and the image, which is costly to collect. As a result, the MMT model is usually trained on a small Multi30K (Elliott et al., 2016) data set, which limits the performance of MMT. Therefore, it is necessary to utilize the separate image data set to obtain visual representations to break the constraints of pairwise input.

Towards this end, some researchers (Zhang et al., 2020; Wu et al., 2021) propose to integrate a retrieval module into NMT, which retrieve images related to the source sentence from existing sentence-image pairs as complementary input, and then use a pre-trained convolutional neural network (CNN) to encode the images. However, such sentence-level retrieval usually suffers from sparsity as it is difficult to get the images that properly match with the source sentence. Besides, visual features outputted by the CNN contain richer information (*e.g.*, color, size, shape, texture, and background) than the source text, thus encoding them in a bundle without any filtering will introduce noise into the model.

To solve these problems, we propose a novel retrieval-based method for MMT to learn phrase-level visual representations for the source sentence, which can mitigate the aforementioned problems of sparse retrieval and redundant visual representations. For the sparsity problem, our method retrieves the image at the phrase level and only refers to the grounded region in the image related with the phrase. For the redundancy problem, our method employs the conditional variational auto-encoder to force the learned representations to properly reconstruct the source phrase so that the learned representations only retain the information related to the source phrase . Experiments on Multi30K (Elliott et al., 2016) show that the proposed method gains significant improvements over strong baselines. When the textual context is limited, it achieves up to 85% gain over the text-only baseline on the BLEU score. Further analysis demonstrates that

the proposed method can obtain visual information that is more related to translation quality.

2 Phrase-Guided Visual Representation

We use phrase-level visual representation to improve NMT. In this section, we will introduce our proposed *phrase-guided visual representation*. We first build a phrase-level image set, and then introduce a latent-variable model to learn a phrase-guided visual representation for each image region.

2.1 Phrase-Level Image Set

Our phrase-level image set is built from the training set of Multi30K, which contains about 29K bilingual sentence-image pairs. We only use the images $\mathbf{e}$ and source descriptions $\mathbf{x}$ from them, which is denoted as $\mathcal{D} = \{(\mathbf{x}_i, \mathbf{e}_i)\}_{i=1}^{N}$. We extract <noun phrase, image region> pairs from <sentence, image> pairs in $\mathcal{D}$ to build our phrase-level image set, which is denoted as $\mathcal{D}_p$.

For each sentence $\mathbf{x}_i$, we use an open-source library *spaCy*[1] to identify the noun phrases, which is denoted as $\mathbf{P}_i = (\mathbf{p}_1^i, \mathbf{p}_2^i, ..., \mathbf{p}_{t_i}^i)$, where t_i is the number of noun phrases in $\mathbf{x}_i$. For each noun phrase $\mathbf{p}_j^i$, we detect the corresponding region $\mathbf{r}_j^i$ from the paired image $\mathbf{e}_i$ using the visual grounding toolkit (Yang et al., 2019). Then $(\mathbf{p}_j^i, \mathbf{r}_j^i)$ is added to our phrase-level image set $\mathcal{D}_p$. Figure 1 illustrates an example.

Finally, we obtain the phrase-level image set $\mathcal{D}_p = \{(\mathbf{p}_i, \mathbf{r}_i)\}_{i=1}^{T}$, where $T = \sum_{i=1}^{N} t_i$. It contains about 102K pairs in total.

2.2 Latent-Variable Model

For an image region $\mathbf{r}$, we can obtain the visual features $\mathbf{v}$ with a pre-trained ResNet-101 Faster R-CNN (He et al., 2016; Ren et al., 2015), which contains rich visual information (*e.g.*, color, size, shape, texture, and background). However, we should not pay much attention to the visual information not mentioned in the corresponding phrase, which will introduce too much noise and even be harmful to NMT. Therefore, we further introduce a continuous latent variable to explicitly model the semantic information of image regions under the guidance of phrases. We adopt the framework of conditional variational auto-encoder (CVAE) (Kingma and Welling, 2014; Sohn et al., 2015) to maximize the conditional marginal log-likelihood $\log p(\mathbf{p}|\mathbf{v}) = \log \int_z p(\mathbf{p}|z, \mathbf{v}) p(z|\mathbf{v}) dz$ by maximizing the evidence lowerbound (ELBO):

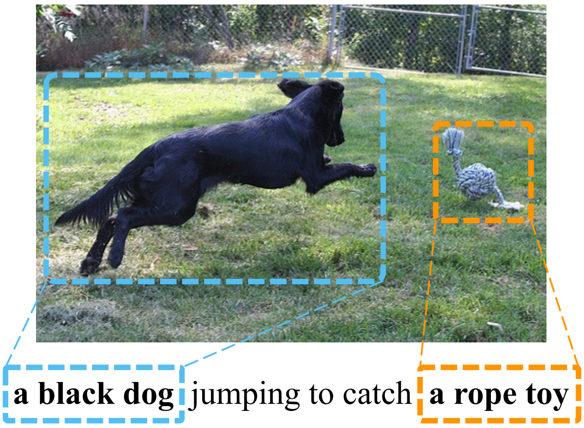

Figure 1: Example of extracting <noun phrase, image region> pairs from existing <sentence, image> pairs.

$$\begin{aligned}\mathcal{L}_{cvae}(\omega, \phi, \theta) = & \mathbb{E}_{z\sim q_\phi(\mathbf{z}|\mathbf{p},\mathbf{v})}[\log p_\theta(\mathbf{p}|\mathbf{z}, \mathbf{v})] \\ & - \mathrm{KL}[q_\phi(\mathbf{z}|\mathbf{p}, \mathbf{v}) \| p_\omega(\mathbf{z}|\mathbf{v})],\end{aligned} \tag{1}$$

where $p_\omega(\mathbf{z}|\mathbf{v})$ is the prior, $q_\phi(\mathbf{z}|\mathbf{p}, \mathbf{v})$ is an approximate posterior and $p_\theta(\mathbf{p}|\mathbf{z}, \mathbf{v})$ is the decoder. The prior p_ω is modeled as a Gaussian distribution:

$$p_\omega(\mathbf{z}|\mathbf{v}) = \mathcal{N}(\mathbf{z}; \boldsymbol{\mu}_p(\mathbf{v}), \boldsymbol{\sigma}_p(\mathbf{v})^2\mathbf{I}), \tag{2}$$

$$\boldsymbol{\mu}_p(\mathbf{v}) = \mathrm{Linear}(\mathbf{v}), \tag{3}$$

$$\boldsymbol{\sigma}_p(\mathbf{v}) = \mathrm{Linear}(\mathbf{v}), \tag{4}$$

where $\mathrm{Linear}(\cdot)$ denotes linear transformation. The approximate posterior q_ϕ is also modeled as a Gaussian distribution:

$$q_\phi(\mathbf{z}|\mathbf{p}, \mathbf{v}) = \mathcal{N}(\mathbf{z}; \boldsymbol{\mu}_q(\mathbf{p}, \mathbf{v}), \boldsymbol{\sigma}_q(\mathbf{p}, \mathbf{v})^2\mathbf{I}), \tag{5}$$

$$\boldsymbol{\mu}_q(\mathbf{p}, \mathbf{v}) = \mathrm{Linear}([\mathrm{RNN}(\mathbf{p}), \mathbf{v}]), \tag{6}$$

$$\boldsymbol{\sigma}_q(\mathbf{p}, \mathbf{v}) = \mathrm{Linear}([\mathrm{RNN}(\mathbf{p}), \mathbf{v}]), \tag{7}$$

where $\mathrm{RNN}(\cdot)$ denotes a single-layer unidirectional recurrent neural network (RNN). The final hidden state of RNN is used to compute the mean and variance vectors.

To be able to update the parameters using backpropagation, we use the reparameterization trick (Kingma and Welling, 2014) to sample $\mathbf{z}$ from q_ϕ:

$$\mathbf{z} = \boldsymbol{\mu}_q + \boldsymbol{\sigma}_q \odot \boldsymbol{\epsilon}, \boldsymbol{\epsilon} \sim \mathcal{N}(0, \mathbf{I}). \tag{8}$$

The decoder $p_\theta(\mathbf{p}|\mathbf{z}, \mathbf{v})$ is also implemented by a single-layer unidirectional RNN. The initial hidden state of decoder RNN is defined as:

$$\mathbf{s} = \mathrm{Linear}([\mathbf{z}, \mathbf{v}]), \tag{9}$$

---

[1] `https://spacy.io`

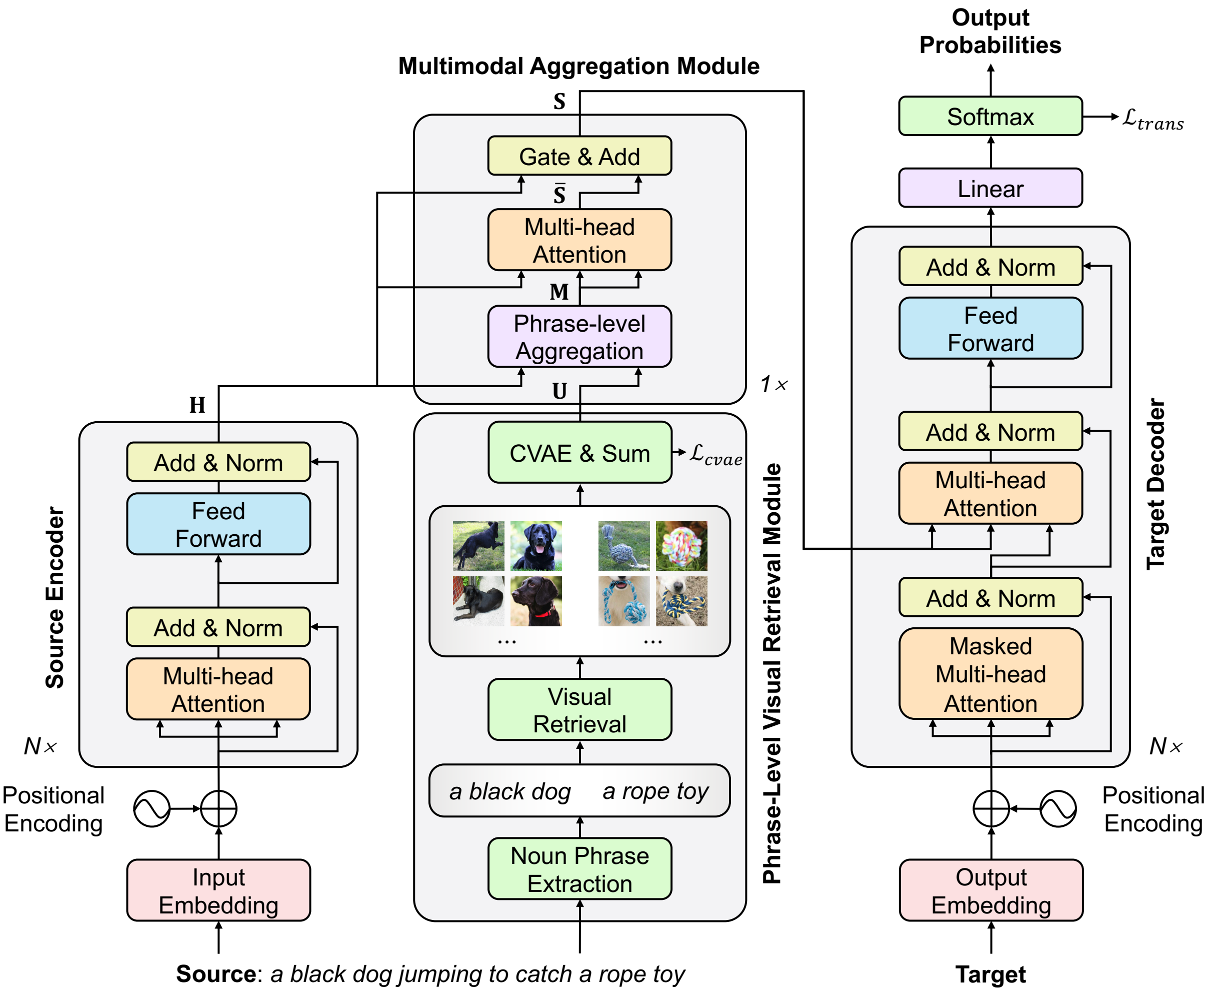

Figure 2: Overview of our proposed method.

and then the decoder will reconstruct the phrase $\mathbf{p}$ based on $\mathbf{s}$. We refer to $\mathbf{s}$ as *phrase-guided visual representation*, since it pays more attention to the semantic information mentioned in the phrase and filters out irrelevant information. We will describe how to incorporate it into NMT in the next section.

3 NMT with Phrase-Level Universal Visual Representation

In this section, we will introduce our retrieval-based MMT method. Specifically, we obtain visual context through our proposed phrase-level visual retrieval, and then learn a universal visual representation for each phrase in the source sentence, which is used to improve NMT. Figure 2 shows the overview of our proposed method, which is composed of four modules: source encoder, phrase-level visual retrieval module, multimodal aggregation module, and target decoder. The source encoder and target decoder are the same as the encoder and decoder of conventional text-only Transformer (Vaswani et al., 2017). Therefore, we will introduce the phrase-level visual retrieval module and multimodal aggregation module in detail in the rest of this section.

We denote the input source sentence as $\mathbf{x} = (x_1, x_2, ..., x_n)$, the ground truth target sentence as $\mathbf{y}^* = (y_1^*, y_2^*, ..., y_m^*)$ and the generated translation as $\mathbf{y} = (y_1, y_2, ..., y_m)$. The input source sentence $\mathbf{x}$ will be encoded with the source encoder to obtain source sentence representation, which is denoted as $\mathbf{H} = (\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_n)$.

3.1 Phrase-Level Visual Retrieval Module

To obtain the visual context of the source sentence without input paired images, we design a phrase-level visual retrieval module. Specifically, for the input sentence $\mathbf{x} = (x_1, x_2, ..., x_n)$, we identify the noun phrases $\bar{\mathbf{P}} = (\bar{\mathbf{p}}_1, \bar{\mathbf{p}}_2, ..., \bar{\mathbf{p}}_t)$ in $\mathbf{x}$. Each phrase $\bar{\mathbf{p}}_i = (x_{l_i}, x_{l_i+1}, ..., x_{l_i+d_i-1})$ is a continuous list of tokens, where l_i is the index of the first token and d_i is the length of $\bar{\mathbf{p}}_i$. For each noun phrase $\bar{\mathbf{p}}_i$, we will retrieve several relevant <noun phrase, image region> pairs from our phrase-level image set $\mathcal{D}_p$ according to the semantic similarity between phrases, and then use the image regions as visual context. We design a phrase encoder to compute the phrase embedding, which is used to measure the semantic similarity between phrases.

Phrase Encoder Our phrase encoder $\mathrm{Enc_p}(\cdot)$ is based on a pre-trained BERT (Devlin et al., 2019). For a phrase $\mathbf{p} = (p_1, p_2, ..., p_l)$, we first use BERT to encode it into contextual embeddings:

$$\mathbf{c}_1, \mathbf{c}_2, ..., \mathbf{c}_l = \mathrm{BERT}(p_1, p_2, ..., p_l), \tag{10}$$

then the phrase embedding is the average embedding of all tokens:

$$\mathrm{Enc_p}(\mathbf{p}) = \frac{1}{l}\sum_{i=1}^{l} \mathbf{c}_i. \tag{11}$$

Visual Retrieval For a given phrase $\bar{\mathbf{p}}$, we retrieve top-K relevant <noun phrase, image region> pairs from $\mathcal{D}_p$. For $(\mathbf{p}_i, \mathbf{r}_i) \in \mathcal{D}_p$, the relevance score with given phrase $\bar{\mathbf{p}}$ can be defined as the cosine distance between their phrase embeddings:

$$\mathrm{RS}(\bar{\mathbf{p}}, (\mathbf{p}_i, \mathbf{r}_i)) = \frac{\mathrm{Enc_p}(\bar{\mathbf{p}}) \cdot \mathrm{Enc_p}(\mathbf{p}_i)}{\|\mathrm{Enc_p}(\bar{\mathbf{p}})\| \|\mathrm{Enc_p}(\mathbf{p}_i)\|}, \tag{12}$$

then we retrieve top-K relevant pairs for $\bar{\mathbf{p}}$:

$$\{(\mathbf{p}_{i_k}, \mathbf{r}_{i_k})\}_{k=1}^{K} = \underset{i=1..T}{\text{top-}K}(\mathrm{RS}(\bar{\mathbf{p}}, (\mathbf{p}_i, \mathbf{r}_i))). \tag{13}$$

Universal Visual Representation For every pair $(\mathbf{p}_{i_k}, \mathbf{r}_{i_k})$, we can obtain the phrase-guided visual representation $\mathbf{s}_{i_k}$ through our latent-variable model as described in Section 2.2. Finally, the phrase-level *universal visual representation* of $\bar{\mathbf{p}}$ is defined as the weighted sum of all $\{\mathbf{s}_{i_k}\}$:

$$\mathbf{u} = \frac{1}{K}\sum_{k=1}^{K} \mathrm{RS}(\bar{\mathbf{p}}, (\mathbf{p}_{i_k}, \mathbf{r}_{i_k})) \cdot \mathbf{s}_{i_k}. \tag{14}$$

Our universal visual representation considers multi-view visual information from several image regions, which avoids the bias caused by a single image region. Finally, for all phrases $\bar{\mathbf{P}} = (\bar{\mathbf{p}}_1, \bar{\mathbf{p}}_2, ..., \bar{\mathbf{p}}_t)$ in $\mathbf{x}$, we obtain the corresponding universal visual representation $\mathbf{U} = (\mathbf{u}_1, \mathbf{u}_2, ..., \mathbf{u}_t)$.

3.2 Multimodal Aggregation Module

Inspired by the recent success of modality fusion in multimodal machine translation (Yin et al., 2020; Zhang et al., 2020; Fang et al., 2022), we design a simple *multimodal aggregation module* to fuse the source sentence representation $\mathbf{H}$ and phrase-level universal visual representation $\mathbf{U}$. At first, we perform a phrase-level aggregation. For each phrase $\bar{\mathbf{p}}_i = (x_{l_i}, x_{l_i+1}, ..., x_{l_i+d_i-1})$, we fuse the universal visual representation $\mathbf{u}_i$ and the textual representation of corresponding tokens $(\mathbf{h}_{l_i}, \mathbf{h}_{l_i+1}, ..., \mathbf{h}_{l_i+d_i-1})$:

$$\mathbf{m}_i = \mathrm{LayerNorm}(\mathbf{u}_i + \sum_{j=l_i}^{l_i+d_i-1} \mathbf{o}_{ij} \odot \mathbf{h}_j), \tag{15}$$

$$\mathbf{o}_{ij} = \mathrm{sigmoid}(\mathbf{W}_1\mathbf{u}_i + \mathbf{W}_2\mathbf{h}_j), \tag{16}$$

where $\odot$ denotes element-wise product. Now we obtain the multimodal phrase representation $\mathbf{M} = (\mathbf{m}_1, \mathbf{m}_2, ..., \mathbf{m}_t)$. Afterwards, we apply a multi-head attention mechanism to append $\mathbf{M}$ to the source sentence representation:

$$\bar{\mathbf{S}} = \mathrm{MultiHead}(\mathbf{H}, \mathbf{M}, \mathbf{M}). \tag{17}$$

We then fuse $\bar{\mathbf{S}}$ and $\mathbf{H}$ with a gate mechanism:

$$\mathbf{S} = \mathbf{H} + \boldsymbol{\lambda} \odot \bar{\mathbf{S}}, \tag{18}$$

$$\boldsymbol{\lambda} = \mathrm{sigmoid}(\mathbf{W}_3\mathbf{H} + \mathbf{W}_4\bar{\mathbf{S}}). \tag{19}$$

Finally, $\mathbf{S}$ is fed into our target decoder for predicting the translation. The translation model is trained with a cross-entropy loss:

$$\mathcal{L}_{trans} = -\sum_{i=1}^{m} \log p(y_i^* | \mathbf{y}_{<i}, \mathbf{x}). \tag{20}$$

4 Experiments

We conduct experiments on the following datasets:

Multi30K Multi30K dataset contains bilingual parallel sentence pairs with image annotations, where each image is paired with one English description and the translations in German and French. Training, validation and test sets contain 29,000, 1,014, and 1,000 instances, respectively. We also report the results on the WMT17 test set and the ambiguous MSCOCO test set, which contain 1,000 and 461 instances respectively.

WMT16 EN-DE WMT16 EN-DE dataset contains about 4.5M sentence pairs. We choose *newstest2013* for validation and *newstest2014* for test.

Models	EN-DE			EN-FR

Ours	$\mathbf{40.30}^{+0.43}$	$\mathbf{33.45}^{+1.67}**$	$\mathbf{30.28}^{+0.92}$	$\mathbf{61.31}^{+0.80}*$	$\mathbf{53.15}^{+0.71}*$	$\mathbf{43.65}^{+1.16}*$

Table 1: BLEU scores on Multi30K dataset. * and ** mean the improvements over Transformer (Vaswani et al., 2017) baseline is statistically significant ($p < 0.05$ and $p < 0.01$, respectively).

WMT16 EN-RO WMT16 EN-RO dataset contains about 0.6M sentence pairs. We choose *newsdev2016* for validation and *newstest2016* for test.

For all the above datasets, all sentences are tokenized and segmented into subwords units using byte-pair encoding (BPE) (Sennrich et al., 2016). The vocabulary is shared for source and target languages, with a size of 10K for Multi30K, and 40K for WMT16 EN-DE and WMT16 EN-RO.

4.1 System Settings

Model Implementation For the latent-variable model, the image region is encoded with a pre-trained ResNet101 Faster-RCNN (He et al., 2016; Ren et al., 2015). Both the phrase encoder and decoder are implemented using a single-layer unidirectional RNN with 512 hidden states. The size of the latent variable is set to 64. The batch size is 1024, and the learning rate is 5e-5. We train the model up to 200 epochs with Adam optimizer (Kingma and Ba, 2015). We adopt *KL cost annealing* and *word dropout* tricks to alleviate the posterior collapse problem following Bowman et al. (2016). The annealing step is set to 20000 and the word dropout is set to 0.1. Note that the phrases are segmented using the same BPE vocabulary as that for each source language.

For the translation model, we use Transformer (Vaswani et al., 2017) as our baseline. Both encoder and decoder contain 6 layers. The number of attention heads is set to 4. The dropout is set to 0.3, and the value of label smoothing is set to 0.1. For the visual retrieval module, we retrieve top-5 image regions for each phrase. We use Adam optimizer (Kingma and Ba, 2015) to tune the parameters. The learning rate is varied under a warm-up strategy with 2,000 steps. We train the model up to 8,000, 20,000, and 250,000 steps for Multi30K, WMT16 EN-RO, and WMT16 EN-DE, respectively. We average the checkpoints of last 5 epochs for evaluation. We use beam search with a beam size of 4. Different from previous work, we use sacreBLEU[2] (Post, 2018) to compute the BLEU (Papineni et al., 2002) scores and the statistical significance of translation results with paired bootstrap resampling (Koehn, 2004) for future standard comparison across papers. Specifically, we measure case-insensitive detokenized BLEU for Multi30K (sacreBLEU signature: nrefs:1 | bs:1000 | seed:12345 | case:lc | eff:no | tok:13a | smooth:exp | version:2.0.0)[3] and case-sensitive detokenized BLEU for WMT datasets (sacreBLEU signature: nrefs:1 | bs:1000 | seed:12345 | case:mixed | eff:no | tok:13a | smooth:exp | version:2.0.0).

All models are trained and evaluated using 2 RTX3090 GPUs. We implement the translation model based on *fairseq*[4] (Ott et al., 2019). We train latent-variable model and translation model individually.

4.2 Baseline Systems

Our baseline is the text-only Transformer (Vaswani et al., 2017). Besides, we implement **Imagination** (Elliott and Kádár, 2017) and **UVR-NMT** (Zhang et al., 2020) based on Transformer, and compare our method with them. The details of these methods can be found in Section 6. We use the same configuration for all baseline systems as our model.

5 Results and Analysis

5.1 Results on Multi30K Dataset

Table 1 shows the results on Multi30K. Our proposed method significantly outperforms the Transformer (Vaswani et al., 2017) baseline, demonstrating that our proposed phrase-level universal visual representation can be helpful to NMT. Our method also surpass **Imagination** (Elliott and Kádár, 2017) and **UVR-NMT** (Zhang et al., 2020). We consider

(a) original (b) phrase-guided

Figure 3: Visualization of different visual representations.

it is mainly due to the following reasons. First, our phrase-level visual retrieval can obtain strongly correlated image regions instead of weakly correlated whole images. Second, our phrase-level universal visual representation considers visual information from multiple image regions and pays more attention to the semantic information mentioned in the phrases. Last, our phrase-level aggregation module makes it easier for the translation model to exploit the visual information.

5.2 Effects of Latent-Variable Model

In Section 2.2, we introduce a latent-variable model to learn a phrase-guided visual representation for each image region. To understand how it improves the model performance compared with original visual features, we visualize the representations by reducing the dimension with Principal Component Analysis (PCA). Specifically, for all <noun phrase, image region> pairs in $\mathcal{D}_p$, we cluster the image regions by the head[5] of noun phrases. We select top-8 clusters according to their size, and randomly sample 1000 image regions for each cluster. As shown in Figure 3, the original visual features of different clusters are mixed together, indicating that they contains too much irrelevant information. In contrast, our proposed phrase-guided visual representations, which pay more attention to the semantic information, form several clusters according to their heads.

Combined with our visual retrieval module, we found that as the number of retrieved image regions K increases, the BLEU score keeps decreasing when we use original visual features, while increasing when we use our proposed phrase-guided visual representations, which is shown in Figure 4. We believe the decrease of BLEU score is due to the irrelevant information in original visual features, and thus directly sum them together will introduce too much noise. Our method filters out those irrelevant information, and multiple image regions could avoid the bias caused by a single one, which leads to the increase of BLEU score. However, we don't observe further improvements when using more image regions.

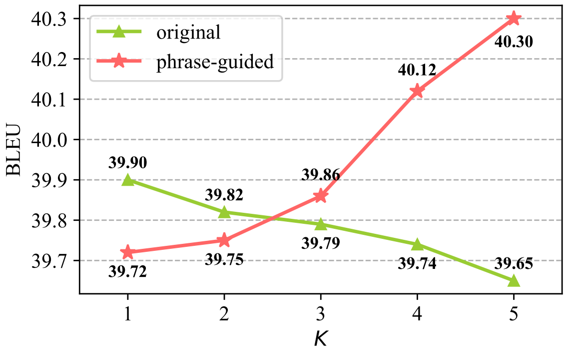

Figure 4: BLEU scores with different number of retrieved image regions K. Phrase-guided visual representations achieve better performance as K increases.

Models	Test2016	Test2017	MSCOCO
Transformer	10.42	8.59	7.08
Ours	**19.41**$^{+8.99}$	**13.67**$^{+5.08}$	**12.23**$^{+5.15}$

Table 2: BLEU scores on Multi30K En-De under source-degradation setting.

5.3 Source-Degradation Setting

We further conduct experiments under source-degradation setting, to verify the effectiveness of our method when the source textual context is limited. Following Wu et al. (2021), we mask the visually grounded tokens in the source sentence, which affects around 43% of tokens in Multi30K. As shown in Table 2, our method achieves almost 85% improvements over the text-only Transformer baseline. It means our proposed phrase-level universal visual representation can fill in the missing information effectively.

5.4 Phrase-Level vs. Sentence-Level Retrieval

To prove the effectiveness of phrase-level retrieval, we implement a sentence-level variant of our method. In this variant, we switch the latent-variable model, retrieval module and aggregation module from phrase-level to sentence-level. In this way, we retrieve several images as visual con-

(#27907) a person is driving a red and black race car
(#28972) a person is walking with a white bag
(#23551) a person is riding a bike on a dirt road
(#17872) a person is riding a bike in a tunnel
(#28972) a person is walking by an old building

(a) Phrase-level retrieval

(b) Sentence-level retrieval

Figure 5: Example of different levels of retrieval. We denote the index of retrieved image (regions) in the training set of Multi30K with #id.

Models	Test2016	Test2016 (Mask)
Transformer	39.87	10.42
Ours-sentence	40.02$^{+0.15}$	11.52$^{+1.10}*$
Ours	**40.30$^{+0.43}$**	**19.41$^{+8.99}$**$**$

Table 3: BLEU scores on Multi30K En-De Test2016. (Mask) indicates source-degradation setting. * and ** mean the improvements over Transformer (Vaswani et al., 2017) baseline is statistically significant ($p < 0.05$ and $p < 0.01$, respectively).

text to help the translation. As shown in Table 3, the sentence-level variant *Ours-sentence* performs worse than *Ours*, especially in the case of source-degradation setting. We believe it is because phrase-level retrieval can obtain more relevant image regions as visual context, which contain less noise and can be integrated into textual representations more precisely. In contrast, sentence-level retrieval leads to images with much irrelevant information, and makes it difficult for the model to capture the fine-grained semantic correspondences between images and descriptions. To understand this difference more intuitively, we give an example in Figure 5. As we can see, for the input sentence, phrase-level retrieval can obtain closely related image regions for noun phrases *a person* and *a black car*, while the results of sentence-level retrieval are actually weakly related with the input sentence.

5.5 Results on WMT News Datasets

Finally, we conduct experiments on WMT16 EN-DE and WMT16 EN-RO datasets. As shown in Table 4, we observe that both Zhang et al. (2020) and our method only achieve marginal improvements compared with text-only Transformer baseline. We consider that there are two main reasons. On the one hand, most of tokens in such news text are not naturally related to specific visual contents. We found that the percentage of visual grounded tokens in the training set of WMT16 EN-DE is only 7% (vs. 43% in Multi30K), so the contribution of visual information is indeed limited. On the other hand, the news text is far from the descriptive text in Multi30K. In this way, the retrieved image regions are actually weakly correlated with the source phrase. We did some analysis to verify our hypotheses. As described in Section 3.1, we retrieve top-K pairs for each phrase according to the relevance scores. We define the average relevance scores (ARS) as follows:

$$\text{ARS}(k) = \mathbb{E}_{\mathbf{p}\in\mathcal{D}_{\text{val}}}\text{RS}(\mathbf{p}, (\mathbf{p}_{i_k}, \mathbf{r}_{i_k})), \qquad (21)$$

which means the average relevance scores for all phrases in the validation set. As shown in Figure 6, ARS on WMT news datasets are much lower than that on Multi30K, which proves that the gap between news text and descriptive text does exists.

Models	EN-DE	EN-RO
Transformer	26.54	32.67
UVR-NMT	$26.89^{+0.35}$	$32.93^{+0.26}$
Ours	$\mathbf{26.97^{+0.43}}$	$\mathbf{33.18^{+0.51}}$

Table 4: BLEU scores on WMT16 EN-DE and WMT16 EN-RO dataset.

6 Related Work

Multimodal machine translation (MMT) aims to enhance NMT (Vaswani et al., 2017; Zhang et al., 2019; Li et al., 2021) with additional visual context. Since the release of Multi30K (Elliott et al., 2016) dataset, researchers have proposed many MMT methods. Early methods (Huang et al., 2016; Calixto and Liu, 2017; Caglayan et al., 2016; Calixto et al., 2016; Caglayan et al., 2017; Libovický and Helcl, 2017; Delbrouck and Dupont, 2017b,a; Zhou et al., 2018; Calixto et al., 2017; Helcl et al., 2018; Caglayan et al., 2018) are mainly based on the RNN-based encoder-decoder architecture with attention (Bahdanau et al., 2015). Recent methods based on Transformer (Vaswani et al., 2017) achieve better performance. Yao and Wan (2020); Yin et al. (2020); Liu et al. (2021) design multimodal encoder to fuse the textual and visual information during encoding. Ive et al. (2019); Lin et al. (2020) enhance the decoder with deliberation networks (Xia et al., 2017) or capsule networks (Sabour et al., 2017) to better utilize visual information during decoding. Caglayan et al. (2021) propose a cross-lingual visual pre-training method and fine-tuned for MMT. It is worth noting that some of previous works (Ive et al., 2019; Lin et al., 2020; Yin et al., 2020; Wang and Xiong, 2021; Nishihara et al., 2020; Zhao et al., 2021) adopt regional visual information like us, which shows effectiveness compared with global visual features. The major difference between our method and theirs is that our method is a retrieval-based method, which breaks the reliance on bilingual sentence-image pairs, Therefore, our method is still applicable when the input is text only (without paired images), which is unfortunately not available with those previous methods.

In addition to focusing on model design, Yang et al. (2020); Nishihara et al. (2020); Wang and Xiong (2021) propose auxiliary loss to allow the model to make better use of visual information. Caglayan et al. (2019); Wu et al. (2021) conduct systematic analysis to probe the contribution of visual modality. Caglayan et al. (2020); Ive et al. (2021) focus on improving simultaneous machine translation with visual context.

All of the above methods require a specific image as input to provide visual context, which heavily restricts their applicability. To break this bottleneck, Hitschler et al. (2016) propose target-side image retrieval to help the translation. Elliott and Kádár (2017) propose a multitask learning framework **Imagination** to decomposes the multimodal translation into learning translation and learning visually grounded representation. Calixto et al. (2019) introduce a latent variable and estimate a joint distribution over translations and images. Long et al. (2020) predict the translation with visual representation generated by a generative adversarial network (GAN) (Goodfellow et al., 2014). The most closely related work to our method is **UVR-NMT** (Zhang et al., 2020), which breaks the reliance on bilingual sentence-image pairs. Like some retrieval-enhanced MT (Feng et al., 2017; Gu et al., 2017) methods, they build a topic-image lookup table from Multi30K, and then retrieve images related to the source sentence as visual context based on the topic words. The central differences between Zhang et al. (2020) and our method are as follows:

- First, their method depends on the weak correlation between words and images, which leads to much noise in the retrieved images, while our approach relies on the strong correlation between noun phrases and image regions.

- Second, our phrase-level retrieval can obtain more related visual context than their sentence-level retrieval (Section 5.4).

- Last, their method directly uses visual features extracted by ResNet (He et al., 2016), which may introduce too much noise. We adopt a latent-variable model to filter out irrelevant information and obtain a better representation.

7 Conclusion

In this paper, we propose a retrieval-based MMT method, which learns a phrase-level universal visual representation to improve NMT. Our method not only outperforms the baseline systems and most existing MMT systems, but also breaks the restrictions on input that hinder the development of MMT in recent years. Experiments and analysis demonstrate the effectiveness of our proposed method. In the future, we will explore how to apply our method to other tasks.

Abstract

The emotional state of a speaker can be influenced by many different factors in dialogues, such as dialogue scene, dialogue topic, and interlocutor stimulus. The currently available data resources to support such multimodal affective analysis in dialogues are however limited in scale and diversity. In this work, we propose a **M**ulti-modal **M**ulti-scene **M**ulti-label **E**motional **D**ialogue dataset, **M^{3}ED**, which contains 990 dyadic emotional dialogues from 56 different TV series, a total of 9,082 turns and 24,449 utterances. M^{3}ED is annotated with 7 emotion categories (happy, surprise, sad, disgust, anger, fear, and neutral) at utterance level, and encompasses acoustic, visual, and textual modalities. To the best of our knowledge, M^{3}ED is the first multimodal emotional dialogue dataset in Chinese. It is valuable for cross-culture emotion analysis and recognition. We apply several state-of-the-art methods on the M^{3}ED dataset to verify the validity and quality of the dataset. We also propose a general Multimodal Dialogue-aware Interaction framework, MDI, to model the dialogue context for emotion recognition, which achieves comparable performance to the state-of-the-art methods on the M^{3}ED. The full dataset and codes are available[1].

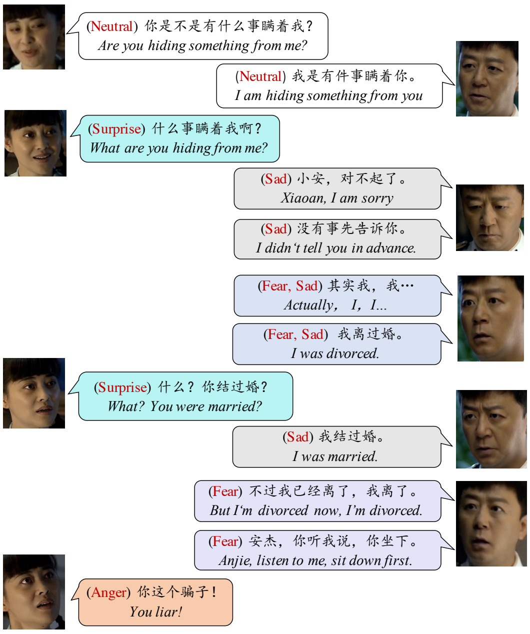

Figure 1: An example of a dialogue, showing the rich emotions, inter and intra-turn emotion shifts, emotional inertia and blended emotions.

1 Introduction

Emotion Recognition in Conversation (ERC) aims to automatically identify and track the emotional status of speakers during a dialogue (Poria et al., 2019b). It is a crucial component to improve natural human-computer interactions and has a wide range of applications in interaction scenarios, including call-center dialogue systems (Danieli et al., 2015), conversational agents (Fragopanagos and Taylor, 2005) and mental health diagnoses (Ringeval et al., 2018), etc. Different from traditional multimodal emotion recognition on isolated utterances, multimodal ERC is a more challenging problem, because there are many influencing factors that affect the speakers' emotional state in a dialogue, including the dialogue context from multi-modalities, the scene, the topic, and even the personality of subjects, etc. (Poria et al., 2019b; Scherer, 2005; Koval et al., 2015). It has been proved in recent works (Majumder et al., 2019; Ghosal et al., 2019; Hu et al., 2021; Shen et al., 2020) that contextual information plays an important role in ERC tasks and brings significant improvements over baselines that only consider isolated utterances. DialogueRNN (Majumder et al., 2019) uses recurrent networks to model global and speaker-specific temporal-context information. DialogueGCN (Ghosal et al., 2019) and MMGCN (Hu et al., 2021) use graph-based networks to capture conversational dependencies between utterances in dialogues. DialogXL (Shen et al., 2020)

applies a strong pre-trained language model XLNet (Yang et al., 2019) to ERC and proposes a dialog-aware self-attention method for modeling the context information. The IEMOCAP (Busso et al., 2008) and MELD (Poria et al., 2019a) are two multimodal emotional dialogue benchmark datasets, which are widely used in the above-mentioned works and promote research in the affective computing field. However, both of them are limited in size and diversity. The videos in MELD are collected only from the Friends TV series, and the videos in IEMOCAP are recorded in laboratory environments from ten actors performing scripted and spontaneous dialogues. These limitations not only affect the investigation of generalization and robustness of the models, but also limit the exploration of other important influencing factors in dialogues, such as dialogue scene, dialogue topic, emotional influence from interlocutors, and so on.

In this work, we construct a large-scale Multi-modal Multi-scene and Multi-label Emotional Dialogue dataset, **M^{3}ED**, which consists of 990 emotional dyadic dialogue video clips from 56 different TV series (about 500 episodes), ensuring that there are various dialogue scenes and topics. We also consider the blended annotations of emotions, which are commonly observed in real-life human interactions (Devillers et al., 2005; Vidrascu and Devillers, 2005). M^{3}ED contains 24449 utterances in total, which are more than three times larger than IEMOCAP and almost two times larger than MELD. There are rich emotional interaction phenomena in M^{3}ED dialogues, for example, 5,396 and 2,696 inter-turn emotion-shift and emotion-inertia scenarios respectively, and 2,879 and 10,891 intra-turn emotion-shift and emotion-inertia scenarios respectively. To the best of our knowledge, M^{3}ED is the first large-scale multi-modal emotional dialogue dataset in Chinese, which can promote research of affective computing for the Chinese language. It is also a valuable addition for cross-cultural emotion analysis and recognition.

We further perform the sanity check of the dataset quality. Specifically, we evaluate our proposed M^{3}ED dataset on several state-of-the-art approaches, including DialogueRNN, DialogueGCN, and MMGCN. The experimental results show that both context information and multiple modalities can help model the speakers' emotional states and significantly improve the recognition performance, in which context information and multiple modalities are two salient factors of a multimodal emotion dialogue dataset. Furthermore, motivated by the masking strategies of self-attention used in DialogXL (Shen et al., 2020), we propose a general Multimodal Dialogue-aware Interaction (MDI) framework which considers multimodal fusion, global-local context modeling, and speaker interactions modeling and achieves state-of-the-art performance.

All in all, M^{3}ED is a large, diverse, high-quality, and comprehensive multimodal emotional dialogue dataset, which can support more explorations in the related research directions, such as multi-label learning, interpretability of emotional changes in dialogues, cross-culture emotion recognition, etc. The main contributions of this work are as follows:

- We build a large-scale Multi-modal Multi-scene and Multi-label Emotional Dialogue dataset called M^{3}ED, which can support more explorations in the affective computing field.
- We perform a comprehensive sanity check of the dataset quality by running several state-of-the-art approaches on M^{3}ED and the experimental results prove the validity and quality of the dataset.
- We propose a general Multimodal Dialogue-aware Interaction framework, MDI, which involves multimodal fusion, global-local context and speaker interaction modeling, and it achieves comparable performance to other state-of-the-art approaches.

2.1 Related Datasets

Table 1 summarizes some of the most important emotion datasets related to this work. The EmoryNLP (Zahiri and Choi, 2018), EmotionLines (Chen et al., 2018), and DailyDialog (Li et al., 2017) are emotional dialogue datasets in only text modality, which have been widely used in the ERC tasks. The CMU-MOSEI (Zadeh et al., 2018), AFEW (Dhall et al., 2012), MEC (Li et al., 2018), and CH-SIMS (Yu et al., 2020) contain multiple modalities and have been wildly used for multimodal emotion recognition, but they are not conversational and can not support explorations of dialogue emotional analysis. The IEMOCAP (Busso et al., 2008), MSP-IMPROV (Busso et al., 2016) and MELD (Poria et al., 2019a) are

Table 1: Comparison with existing benchmark datasets. a, v and l refer audio, visual and text respectively.

Dataset	Dialogue	Modalities	Sources	Mul-label	Emos	Spks	Language	Utts

the currently available multimodal emotional dialogue datasets. The IEMOCAP and MSP-IMPROV datasets are recorded from ten/twelve actors performing scripted and spontaneous dyadic dialogues, and each utterance is manually labeled with discrete emotion categories. The MELD (Poria et al., 2019a) is a multi-modal multi-party emotional dialogue dataset extended from the text-based EmotionLines dataset (Chen et al., 2018), which is derived only from the Friends TV series.

2.2 Related Methods

Previous works on ERC focus on modeling context information in a conversation with different frameworks. BC-LSTM (Poria et al., 2017) employs a Bi-directional LSTM to capture temporal-context information in conversations. CMN (Hazarika et al., 2018b) and ICON (Hazarika et al., 2018a) use distinct GRUs to model the global and speaker-specific temporal-context, and apply memory networks to model speaker emotional states. DialogueRNN (Majumder et al., 2019) uses distinct GRUs to model global and speaker-specific temporal-context, and global emotional states tracking respectively. DialogueGCN (Ghosal et al., 2019) captures conversational dependencies between utterances with a graph-based structure. MMGCN (Hu et al., 2021) further proposes a GCN-based multimodal fusion method for multimodal ERC tasks to improve recognition performance. DialogXL (Shen et al., 2020) first introduces a strong pre-trained language model XLNet for text-based ERC. It also proposes several masking strategies of self-attention to model the global, local, inter-speaker, and intra-speaker interactions.

3 Dataset Construction

3.1 Dialogue Selection

In order to build a large-scale, diversified, and high-quality multimodal emotional dialogue dataset, we collect video dialogue clips from different TV series, which can simulate spontaneous emotional behavior in the real-world environment (Dhall et al., 2012; Li et al., 2018; Poria et al., 2019a).

Since high-quality conversation video clips are very important, we require the crowd workers to follow the strict selection requirements, including the following major aspects: 1) The required TV series should belong to these categories, such as family, romance, soap opera, and modern opera, which have rich and natural emotional expressions. 2) The workers are required to select 15 $\sim$ 25 high-quality emotional dialogue video clips from each TV series. 3) Each dialogue should have at least 3 rounds of interaction and a clear conversation topic. 4) In order to ensure the quality of the visual and acoustic modalities, the workers are required to select two-person dialogue scenes with clear facial expressions and intelligible voices.

After the dialogue selection, we randomly check several dialogues for each TV series and filter out the low-quality dialogues or ask the crowd workers to correct the inappropriate start and end timestamps.

3.2 Annotation

3.2.1 Text and Speaker Annotation

In order to facilitate the process of emotion annotation, we first require the crowd workers to correct the text content and annotate the speaker info of each utterance. Since the videos of TV series do not have embedded subtitles, we use the OCR-based (Optical Character Recognition) method[2] to automatically generate the text content and the corresponding timestamps. For speaker annotations, the first speaker in the dialogue is annotated as "A", and the other speaker is annotated as "B". In addition, we annotate the role names, ages and genders of these speakers as well.

3.2.2 Emotion Annotation

We annotate each utterance based on Ekman's six basic emotions (*happy, surprise, sad, disgust, anger, and fear*) and an additional emotion label *neutral*, which is an annotation scheme widely used in previous works (Poria et al., 2019a; Busso et al., 2008). The annotators are asked to sequentially annotate the utterances, after watching the videos. Thus, the textual, acoustic and visual information, and the previous utterances in the dialogue are available for emotional annotation. The annotators are allowed to select more than one emotional label to account for blended emotions (e.g., anger&sad), which are commonly observed in real-life human interactions (Devillers et al., 2005). If none of the seven emotion categories can accurately describe the emotion status of the utterance, a special *other* category can be annotated.

In order to obtain high-quality annotations, we together with several emotional psychology experts design an annotation tutorial with reference to previous guidelines (Ekman, 1992; Campos et al., 2013). We train the annotators and provide them with an examination, and only those who pass the exam can participate in the annotation stage. The vast majority of the dataset is annotated by university students and all the annotators are native Mandarin speakers. We assign three annotators to each dialogue.

3.3 Emotion Annotation Finalization

We apply the majority voting strategy over all the annotations of an utterance to produce its final emotion label. Please note that annotators are allowed to assign more than one emotion label to an utterance, and the importance of these labels is in descending order. We simply assign an importance value to the emotion label of each utterance in descending order, e.g. $I(e) = 7$ for the first emotion label, $I(e) = 6$ for the second emotion label, and so on. If a label is not assigned to the utterance, its importance value $I(e) = 0$. An emotion label e is assigned as one of the final emotion labels for an utterance, if it is assigned to the utterance by at least two annotators. And its importance value is decided by averaging its importance ranking from all annotators: $I(e) = \sum_{k=1}^{3} I_k(e)$, where $I_k(e)$ is its importance value from annotator k.

Table 2: M^{3}ED statistics. "x-turn" and "in-turn" refer to *inter-turn* and *intra-turn* respectively.

Statistics	Train	Val	Test	Total
# TV series	38	7	11	56

# in-turn emo-shift	2,029	338	512	2,879
# in-turn emo-inertia	7,775	1,292	1,824	10,891
# blended emos	1,862	379	386	2,627
Fleiss' Kappa	0.59	0.603	0.579	0.59

Table 3: Emotion Distribution of M^{3}ED.

Emotion	Train	Val	Test	Total
neutral	7,130	1,043	1,855	10,028
happy	1,626	303	358	2,287
surprise	696	120	235	1,051
sad	2,734	489	734	3,957
disgust	1,145	134	218	1,497
anger	3,816	682	736	5,234
fear	280	50	65	395
Total	17,427	2,821	4,201	24,449

To further ensure annotation quality, we design two strategies to review and revise incorrect annotations. 1) We calculate the annotation agreement between the annotators of each dialogue. For the dialogues with a poor agreement, we require all relevant annotators to review the annotations again and make corrections if necessary. 2) For the utterances (0.5% of all utterances) that don't have a majority annotators' agreement, we ask several high-quality annotators to review them and make a final emotion annotation decision for these utterances.

Finally, we analyze the inter-annotators agreement and achieve an overall Fleiss' Kappa (Fleiss et al., 2013) statistic of $k = 0.59$ for a seven-class emotion problem, which is higher than other datasets, such as $k = 0.43$ in MELD, $k = 0.48$ in

---

[2] The ASR-based methods do not perform as well in these scenarios compared to OCR-based methods.

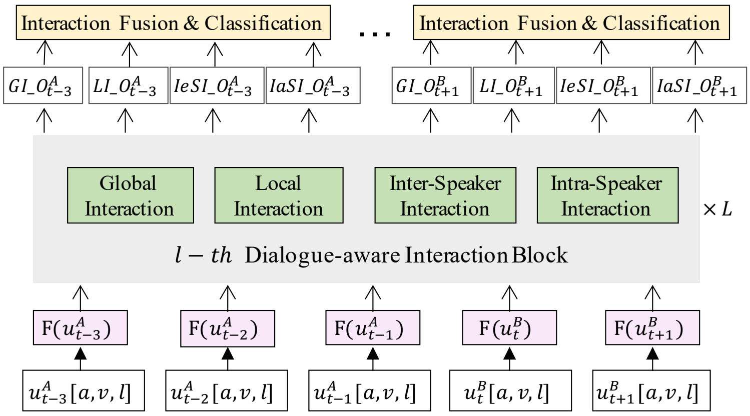

Figure 2: Illustration of the Multimodal Dialog-aware Interaction (MDI) framework (taking one round as an example). l represents the l-th block in the Dialog-aware Interaction Module. $F(\cdot)$ denotes the multimodal fusion module. The $GI\_O_t^B$ represents the output of the t-th utterance from the Global Interaction of Dialog-aware Interaction Module. Similarly, the LI_O, $IeSI\_O$, and $IaSI\_O$ represent the output of the Local Interaction, Inter-Speaker Interaction and Intra-Speaker Interaction respectively.

Table 4: Speaker/Age/Gender Distributions of M^{3}ED.

Age	Child: 34 Young: 295 Mid: 223 Old: 74

IEMOCAP and $k = 0.49$ in MSP-IMPROV.

3.4 Dataset Statistics

Table 2 presents several basic statistics of the M^{3}ED dataset. It contains 990 dialogues, 9,082 turns, 24,449 utterances derived from 56 different TV series (about 500 episodes), which ensures the scale and diversity of the dataset. We adopt the TV-independent data split manner in order to avoid any TV-dependent bias, which means there is no overlap of TV series across training, validation, and testing sets. The basic statistics are similar across these three data splits. There are rich emotional interactions phenomena in the M^{3}ED, for example, 5,396 and 2,696 inter-turn emotion-shift and emotion-inertia scenarios respectively, and 2,879 and 10,891 intra-turn emotion-shift and emotion-inertia scenarios. The emotion shift and emotion inertia are two important factors in dialogues, which are challenging and worthy of exploration (Poria et al., 2019a). As shown in the table, 89% of utterances are assigned with one emotion label, and 11% of utterances are assigned with blended emotions[3].

Table 3 presents the single emotion distribution statistics. The distribution of each emotion category is similar across train/val/test sets. As shown in Table 4, there are in total 626 different speakers in M^{3}ED with balanced gender distribution. Among all the speakers, young and middle-aged speakers account for more than 80%.

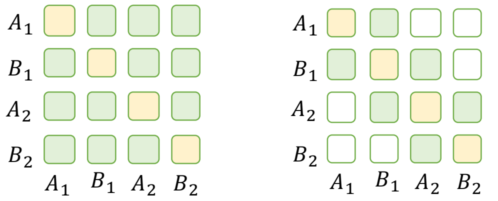
4 Proposed Framework

A dialogue can be defined as a sequence of utterances $D = \{utt_1, utt_2, ..., utt_N\}$, where N is the number of utterances. Each utterance consists of textual (l), acoustic (a) and visual (v) modalities. We denote $u_t^A[a, v, l]$ as the utterance-level feature of utterance utt_t from speaker A with the textual, acoustic and visual modality respectively. The task aims to predict the emotional state for each utterance in the dialogue based on all existing modalities. Figure 2 illustrates our proposed Multimodal Dialogue-aware Interaction (MDI) framework, which contains three main modules: 1) *Multimodal Fusion* module aims to generate the utterance-level multimodal representation from different modalities. 2) *Dialog-aware Interaction* module aims to model the interactions in the dialogue; 3) *Interaction Fusion and Classification* module fuses the different interaction information from the outputs of the Dialog-aware Interaction module, and then makes the emotional state prediction based on the fused interaction information.

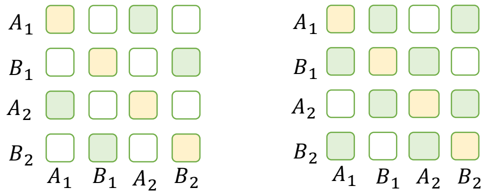
Multimodal Fusion Module: Based on the modality-specific feature representations from different modalities, we apply early fusion of these modalities features to produce the multimodal feature representation: $u = \text{concat}(u[a], u[v], u[l])$.

---

[3] The top 5 most frequent blended emotions are: anger&disgust, anger&sad, sad&anger, disgust&anger and fear&sad



(a) Global Mask (b) Local Mask (window=1)



(c) Intra-speaker Mask (d) Inter-speaker Mask

Figure 3: Illustration of the four masking strategies corresponding to the four interaction sub-modules respectively. A_i denotes the i-th utterance of the speaker A. The yellow blocks denote the current utterances. Utterances that can be accessed by the current utterance are marked as green, while those can not be accessed are marked as white.

Dialog-aware Interaction Module: In order to adequately capture the contextual information in the dialogue, we propose the Dialog-aware Interaction Module which consists of L dialog-aware interaction blocks (gray block in Figure 2). In each block, we adopt four sub-modules, Global Interaction, Local Interaction, Intra-speaker Interaction and Inter-speaker Interaction, to model the global, local, intra-speaker and inter-speaker interactions in the dialogue respectively. We implement these four types of interactions in one Transformer layer by skillfully changing the masking strategies of self-attention (Shen et al., 2020; Li et al., 2020) as illustrated in Figure 3.

Interaction Fusion and Classification: As the Dialog-aware Interaction Module produces different outputs that carry various interaction contextual information, we fuse these outputs via simple addition. Finally, we use one fully connected layer as a classifier to predict the emotional state based on the fused interaction information.

5 Experiments

5.1 Feature Extraction

We investigate the state-of-the-art features of different modalities including textual, acoustic, and visual features for emotion recognition tasks[4].

Textual Features: We extract the word-level features from a pre-trained RoBERTa model (Yu et al., 2020). Furthermore, to get more efficient emotional features, we extract the finetuned features ("[CLS]" position) from the finetuned RoBERTa model trained on M^{3}ED. We refer to the word-level and finetuned utterance-level textual features as "L_Frm", and "L_Utt" respectively.

Acoustic Features: We extract the frame-level features from a pre-trained Wav2Vec2.0 model (Baevski et al., 2020). We extract the finetuned features (the last time step) from the Wav2Vec2.0 model finetuned on M^{3}ED. We refer to the frame-level and finetuned utterance-level acoustic features as "A_Frm" and "A_Utt" respectively.

Visual Features: We first propose a two-stage strategy to detect the speaker's faces[5]. We then extract the face-level features via a pre-trained DenseNet model (Huang et al., 2017) for each utterance based on the detected speaker's faces. DenseNet was trained on two facial expression benchmark corpus, FER+ (Barsoum et al., 2016) and AffectNet (Mollahosseini et al., 2017). We average the face-level features within one utterance to get the averaged utterance-level features. We refer to the face-level, averaged utterance-level visual features as "V_Frm", "V_Utt" respectively.

5.2 Baseline Models

We evaluate several state-of-the-art methods including utterance-level recognition methods and dialog-level recognition methods on the proposed M^{3}ED dataset, and they are listed as follows:

MultiEnc: A flexible and efficient utterance-level multimodal emotion recognition framework (Zhao et al., 2021) that consists of several modality-specific encoders (LSTM, LSTM and TextCNN for acoustic, visual and textual modalities respectively) and a fusion encoder (several fully-connected layers) for emotion prediction. For the utterance-level modality features, three DNN encoders are used for the three modalities respectively.

DialogueRNN: A state-of-the-art RNN-based ERC framework proposed in (Majumder et al., 2019), which captures the global and speaker-specific temporal context information, and global emotional state information via different GRUs. For the multimodal experiments, the early-fusion method that concatenates different modality features as input is adopted in this work.

---

[4] More detailed description of the feature extractors can be found in the supplementary material. A.2

[5] more details in supplementary material. A.1

DialogueGCN: A state-of-the-art GCN-based ERC framework proposed in (Ghosal et al., 2019), which models long-distance dependency and speaker interactions via direct edges and different designed relations respectively. For the multimodal experiments, we also adopt the early-fusion method in this work.

MMGCN: A state-of-the-art GCN-based multimodal ERC framework proposed in (Hu et al., 2021). For the uni-modal experiments, we only model the fully connected graph.

5.3 Experiment Setup

We split the M^{3}ED dataset into training, validation, testing sets in a TV-independent manner, which is a more challenging experiment setting. The distribution of the data splits is shown in Table 3. We use the weighted-F1 score (WF1) as the evaluation metrics. We tune the parameters on the validation set and report the performance on the testing set. We run each model three times and report the average performance to alleviate the influence of random parameter initialization.

We conduct two sets of experiments, including 1) the utterance-level baseline experiments of emotion recognition on isolated utterances without considering dialogue context, which aims to check the quality of each modality and compare the effectiveness of multimodal information for emotion recognition, and 2) the dialogue-level experiments of emotion recognition in the dialogue, which aims to compare our proposed general MDI framework with the state-of-the-art models in modeling dialogue context for emotion recognition. For the utterance-level experiments, we adopt the Multi-Enc (Section 5.2) framework as the baseline model. For the dialogue-level experiments, we compare to DialogueRNN, DialogueGCN, and MMGCN models.

Since different modality features are used in this work, we have tried different hidden sizes (such as 180, 256, and 512) in our experiments. For the experiments on the proposed Multimodal Dialog-aware Interaction framework (Section 4), we use the Adam optimizer with learning rate of 3e-5. We set the dropout as 0.1, the hidden size as 384 in the unimodal experiments and 512 in the multimodal experiments.

5.4 Utterance Baseline Experiments

Table 5 presents the utterance-level baseline results. Among the different unimodal features, the finetuned utterance-level features achieve significant improvement on textual and acoustic modalities. The multimodal information can bring significant performance improvement over unimodal. However, for the multimodal experiments, the finetuned features do not show much improvement over the frame-level features. It is mainly because the finetuned features retain more classification information and lose some modality-specific information, which limits the complementarity between the modalities.

Table 5: Utterance-level baseline performance (WF1) of different features and different modalities. “Frm”, “Utt” refer to frame-level, utterance-level features respectively.

Modalities	Frm		Utt	
	val	test	val	test
$\{l\}$	42.24	43.23	44.67	**44.41**
$\{a\}$	42.56	40.96	48.56	**46.09**
$\{v\}$	43.79	**41.25**	42.32	41.09
$\{l, a\}$	48.10	46.53	51.58	**48.68**
$\{l, v\}$	50.73	**48.17**	50.48	47.68
$\{a, v\}$	49.66	46.19	49.66	**46.28**
$\{l, a, v\}$	54.55	**49.48**	52.15	48.90

In addition, we observe that there is no big gap between the performances on different modalities, which indicates the good quality of different modalities in our M^{3}ED dataset.

5.5 Dialogue Experiments

Since the state-of-the-art dialogue-level methods mainly focus on modeling the dialogue context information based on the utterance-level features, we adopt the finetuned utterance-level features (“Utt_ft”) in the following experiments. Table 6 presents the dialogue-level experiment results. The results show that context information and multiple modalities, the two salient factors of a multimodal emotion dialogue dataset, both bring significant performance improvement, which also proves the validity and quality of the M^{3}ED dataset to some extend.

Compared to the state-of-the-art models, our proposed general MDI framework achieves superior performance in the textual, acoustic, and visual unimodal experiments. It demonstrates that the four dialogue-aware interaction strategies which consider both the global- and local-context interactions and the intra- and inter-speaker interactions have better dialogue modeling ability than only considering part of these interactions, which demon-

Table 6: Emotion recognition performance (WF1) in dialogues under the unimodal and multimodal conditions.

Model	Metric	Modalities						
		$\{l\}$	$\{a\}$	$\{v\}$	$\{l,a\}$	$\{l,v\}$	$\{a,v\}$	$\{l,a,v\}$
UttBaseline	val	44.67	48.56	42.32	51.58	50.48	49.66	52.15
	test	44.41	46.09	41.09	48.68	47.68	46.28	48.90
DialogueGCN	val	50.77 (+6.1)	50.96 (+2.4)	33.82	53.91 (+2.3)	54.26 (+3.8)	50.80 (+1.1)	54.58 (+2.4)
	test	46.09 (+1.7)	46.45 (+0.4)	27.79	49.44 (+0.8)	49.26 (+1.6)	47.09 (+0.8)	49.93 (+1.0)
MMGCN	val	50.83 (+6.2)	52.93 (+4.4)	37.05	55.62 (+4.0)	54.75 (+4.3)	54.71 (+5.1)	56.67 (+4.5)
	test	46.49 (+2.1)	47.77 (+1.7)	32.87	49.44 (+0.8)	50.42 (+2.7)	**48.55** (+2.3)	51.18 (+2.3)
DialogueRNN	val	53.65 (+9.0)	52.09 (+3.5)	36.03	55.85 (+4.3)	58.70 (+8.2)	52.69 (+3.0)	56.52 (+4.4)
	test	48.80 (+4.4)	47.65 (+1.6)	28.38	**51.87** (+3.2)	**52.28** (+4.6)	47.49 (+1.2)	**51.66** (+2.8)
Ours	val	51.37 (+6.7)	51.5 (+2.9)	45.97 (+3.6)	54.27 (+2.7)	55.69 (+5.2)	51.34 (+1.7)	54.09 (+1.9)
	test	**49.42** (+5.0)	**48.03** (+1.9)	**41.33** (+0.2)	50.24 (+1.6)	52.07 (+4.4)	47.64 (+1.4)	50.99 (+2.1)

strates the strong dialogue context modeling ability of MDI. However, MDI does not outperform other models under the multimodal conditions, which may be due to the limited training dataset size and the limited ability of the vanilla multimodal fusion strategy in interaction modeling. In the future, we will explore more effective multimodal fusion module and interaction modeling module within the MDI framework to improve its performance under multimodal conditions.

6 Future Directions

The M^{3}ED dataset is a large, diversified, high-quality, and comprehensive multimodal emotional dialogue dataset. Based on the characteristics of the dataset and the analysis from the extensive experiments, we believe that M^{3}ED can support a number of related explorations in affective computing field.

- Based on the experiment results, we think that the finetuned features lack sufficient modality-specific information, which limits the performance under the multimodal conditions. Therefore, it is worth exploring to realize a more efficient multimodal fusion module based on the raw frame-level features and make the above proposed general Multimodal Dialog-aware Interaction (MDI) framework an end-to-end model.
- According to psychological and behavioral studies, emotional inertia and stimulus (external/internal) are important factors that affect the speaker's emotional state in dialogues. The emotional inertia and emotional stimulus can explain how one speaker's emotion affects his own or the other speaker's emotion. There are rich emotional interaction phenomena including inter- and intra-turn emotion shifts in the M^{3}ED dataset. Therefore, it can support the exploration of interpretability of emotional changes in a Dialogue.
- The blended emotions are commonly observed in human real-life dialogues, and multi-label learning can help reveal and model the relevance between different emotions. Therefore, the M^{3}ED dataset can support the exploration of multi-label emotion recognition in conversations.
- Emotional expression varies across different languages and cultures. The M^{3}ED dataset in Chinese is a valuable addition to the existing benchmark datasets in other languages. It can promote the research of cross-culture emotion analysis and recognition.

7 Conclusion

In this work, we propose a multi-modal, multi-scene, and multi-label emotional dialogue dataset, M^{3}ED, for multimodal emotion recognition in conversations. Compared to MELD, the currently largest multimodal dialogue dataset for emotion recognition, M^{3}ED is larger (24,449 vs. 13,708 utterances), more diversified (56 different TV series vs. only one TV series Friends), with higher-quality (balanced performance across all three modalities), and containing blended emotions annotation which is not available in MELD. M^{3}ED is the first multimodal emotion dialogue dataset in Chinese, which can serve as a valuable addition to the affective computing community and promote the research of cross-culture emotion analysis and recognition. Furthermore, we propose a general Multimodal Dialog-aware Interaction framework, which considers multimodal fusion, temporal-context modeling, and speaker interactions modeling, and achieves the state-of-the-art performance. We also propose several interesting future exploration directions based on the M^{3}ED dataset.

This work was partially supported by the National Key R&D Program of China (No. 2020AAA0108600), the National Natural Science Foundation of China (No. 62072462), Large-Scale Pre-Training Program 468 of Beijing Academy of Artificial Intelligence (BAAI), A*STAR RIE2020 Advanced Manufacturing and Engineering Domain (AME) Programmatic Grant (No. A1687b0033), NRF Centre for Advanced Robotics Technology Innovation (CARTIN) Project and China Scholarship Council.

9 Ethical Considerations

This work presents M^{3}ED, free and open dataset for the research community to study the multimodal emotion recognition in dialogues. Data in M^{3}ED are collected from TV series in Chinese. To ensure that crowd workers were fairly compensated, we paid them at an hourly rate of 40 yuan ($6.25 USD) per hour, which is a fair and reasonable hourly wage in Beijing. First, to select high-quality dialogues from 56 TV-series, we recruited 12 Chinese college students (5 males and 7 females). Each student was paid 100 yuan ($15.625 USD) for selecting about 18 dialogues from each TV series. To annotate the emotional status of the selected dialogues, we recruited 14 Chinese college students (6 males and 8 females). Each student was paid 200 yuan ($31.25 USD) for annotating about 18 dialogues from each TV series with emotion labels, text correction, speaker, gender, and age information. If only the emotion labels were annotated, the payment for each TV series was 100 yuan ($15.625 USD). Considering the copy-right issue of TV-series, we will only release the name list of the TV-series and our annotations. To facilitate future comparison research on this dataset, we will provide our extracted visual expression features and acoustic features. We anticipate that the high-quality and rich annotation labels in the dataset will advance research in multimodal emotion recognition.

A Supplementary

A.1 Details of the Active Speaker Detection

We observe that the speaker face detection often encounters difficulties in the in-the-wild dialogue scenarios, and the state-of-the-art active speaker detection (ASD) models trained on the English clean dataset normally suffer performance degradation on the Mandarin dataset. Therefore, in this work, we propose a two-stage strategy to extract the speaker's faces. In order to get high-quality faces of the active speakers, we first extract the high-confidence faces of each speaker using a state-of-the-art pre-trained ASD model (Tao et al., 2021). Then, for the frames that have low detection confidence by the ASD model, we compute the similarity based on the face embeddings[6] between the face in each of these frames and the detected high-confidence speaker's faces, in order to determine which speaker each face in these frames belong to. The speaker's facial expression information is very important in emotion recognition, and we provide the speaker's facial information even though the detection process is difficult and complicated, while MELD (Poria et al., 2019a) did not provide it and did not conduct visual-related experiments.

A.2 Details of Feature Extractors

Textual Feature Extractor: We adopt a pre-trained language RoBERTa model in Chinese[7] to extract the word-level textual features. Furthermore, we finetune the pre-trained RoBERTa followed by a classifier on the training set of M^{3}ED to extract more efficient finetuned features. We evaluate utterance-level textual modality performance on the finetuned RoBERTa model. It achieves the weighted-F1 performance of 43.50% and 45.73% on the validation and testing sets respectively.

Acoustic Feature Extractor: We adopt a pre-trained speech Wav2Vec model in Chinese[8] to extract the frame-level acoustic features. Furthermore, we finetune the pre-trained Wav2Vec followed by a classifier on the training set of M^{3}ED to extract more efficient finetuned features. We evaluate utterance-level acoustic modality performance on the finetuned Wav2Vec model. It achieves the weighted-F1 performance of 48.56% and 45.92% on the validation and testing sets respectively.

Table 7: The distribution of facial expression recognition datasets. neu, hap, sur, ang, dis and con denotes neutral, happy, surprise, anger, disgust and contempt respectively.

	FER+		AffectNet		Total	
	train	val	train	val	train	val
neu	10,342	1,342	74,874	500	85,216	1842
hap	7,526	898	134,415	500	141,941	1398
sur	3,576	458	14,090	500	17,666	958
sad	3,530	416	25,459	500	28,989	916
ang	2,464	319	24,882	500	27,346	819
dis	654	36	3,803	500	3,996	536
fear	193	75	6,378	500	7,032	575
con	167	25	3,750	499	3,917	524

Visual Feature Extractor: We adopt a pre-trained facial expression recognition DenseNet model to extract the face-level visual features, which is trained on the combination of the FER+ and AffectNet two benchmark corpus (Tabel. 7). It achieves the Weighted-accuracy and F1-score performance of 63.54% and 52.94% on the combined validation set respectively.

A.3 Extra Experimental Results Analysis.

Figure. 4 presents the confusion matrices of DialogueRNN and our MDI dialogue-level models under the $\{l, a, v\}$ multimodal condition. Both models perform badly for recognizing the fear emotion, which relates to the limited number of training instances for the fear emotion. It demonstrates the class imbalance issue is a challenging problem for both models. We also observe a high confusing rate between sad, anger, and disgust emotion categories since these emotions are more likely to occur at the same time (the top 5 blended emotions indeed come from these 3 categories), which makes them more difficult to disambiguate. In the future, we will explore effective solutions to deal with the emotion imbalance challenge and learn multi-label emotion classification.

Abstract

Few-shot NER needs to effectively capture information from limited instances and transfer useful knowledge from external resources. In this paper, we propose a self-describing mechanism for few-shot NER, which can effectively leverage illustrative instances and precisely transfer knowledge from external resources by describing both entity types and mentions using a universal concept set. Specifically, we design *Self-describing Networks* (SDNet), a Seq2Seq generation model which can universally describe mentions using concepts, automatically map novel entity types to concepts, and adaptively recognize entities on-demand. We pre-train SDNet with large-scale corpus, and conduct experiments on 8 benchmarks from different domains. Experiments show that SDNet achieves competitive performances on all benchmarks and achieves the new state-of-the-art on 6 benchmarks, which demonstrates its effectiveness and robustness.

1 Introduction

Few-shot named entity recognition (FS-NER) aims to identify entity mentions corresponding to new entity types (i.e., novel types) with only a few illustrative examples. FS-NER is a promising technique for open-domain NER which contains various unforeseen types and very limited examples and therefore has attached great attention in recent years (Huang et al., 2020; Wang et al., 2021).

The main challenge of FS-NER is how to accurately model the semantics of unforeseen entity types using only a few illustrative examples. To achieve this, FS-NER needs to effectively capture information in few-shot examples, meanwhile exploiting and transferring useful knowledge from external resources. Unfortunately, information entailed in illustrative examples is very limited, i.e., the **limited information challenge**. And external knowledge usually doesn't directly match with the new task because it may contain irrelevant, heterogeneous, or even conflicting knowledge (Beryozkin et al., 2019; Yu and Yang, 2020) – which we refer as **knowledge mismatch challenge**. For example, the schemas in Wikipedia, OntoNotes (Ralph et al., 2013) and WNUT17 (Derczynski et al., 2017) are conflicting, where "America" is `geographic entity` in Wikipedia, `GPE` in OntoNotes, and `location` in WNUT17. Such a knowledge mismatch problem makes it unsuitable to directly transfer external knowledge to downstream tasks. Consequently, how to sufficiently leverage limited few-shot examples and precisely transfer external knowledge are the critical challenges for FS-NER.

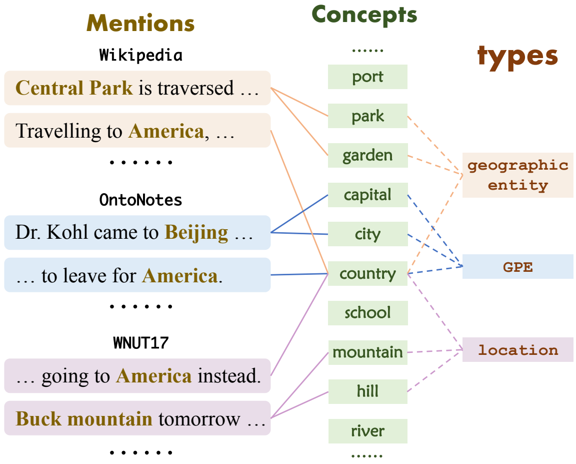

Figure 1: Examples of concept description. Wikipedia, OntoNotes, WNUT17 can transfer knowledge to each other by describing mentions and types using a universal concept set.

To this end, this paper proposes a self-describing mechanism for FS-NER. The main idea behind self-describing mechanism is that all entity types can be described using the same set of concepts, and the mapping between types and concepts can be universally modeled and learned. In this way, the knowledge mismatch challenge can be resolved by uniformly describing different entity types using

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 5711 - 5722
May 22-27, 2022

the same concept set. For example, in Figure 1 the types in different schemas are mapped to the same concept set {*park*, *garden*, *country*, ...}, therefore the knowledge in different sources can be universally described and transferred. Furthermore, because the concept mapping is universal, the few examples are only used to construct the mapping between novel types and concepts, the limited information problem can be effectively addressed.

Based on the above idea, we propose Self-describing Networks – SDNet, a Seq2Seq generation network which can universally describe mentions using concepts, automatically map novel entity types to concepts, and adaptively recognize entities on-demand. Specifically, to capture the semantics of a mention, SDNet generates a set of universal concepts as its description. For example, generate {*capital, city*} for "Dr. Kohl came to [Beijing], ...". To map entity types to concepts, SDNet generates and fuses the concept description of the mentions with the same entity type. For example, map `GPE` to {*country*, *capital*, *city*} using its mentions "Beijing" and "America". To recognize entity, SDNet directly generates all entities in a sentence via a concept-enriched prefix prompt, which contains the target entity types and their concept descriptions. For example, recognizing entity in "France is beautiful." by generating"France is GPE" using prefix prompt "`[EG] GPE`: {*country*, *capital*, *city*}". Because the concept set is universal, we pre-train SDNet on large-scale, easily accessible web resources. Concretely, we collect a pre-training dataset which contains 56M sentences with more than 31K concepts by leveraging the links from Wikipedia anchor words to the Wikidata items.

By projecting both mentions and entity types to a universal concept space, SDNet can effectively enrich entity types to resolve the limited information problem, universally represent different schemas to resolve the knowledge mismatch problem, and can be effectively pre-trained in a unified way. Moreover, all the above tasks are modeled in a single generation model by using prefix prompt mechanism to distinguish different tasks, which makes the model controllable, universal and can be continuously trained.

We conduct experiments on 8 few-shot NER benchmarks with different domains. Experiments show that SDNet leads to very competitive performance and achieves the new state-of-the-art on 6 of these benchmarks.[1]

Generally speaking, the contributions of this paper are:

- We propose a self-describing mechanism for FS-NER, which can effectively resolve the limited information challenge and the knowledge mismatch challenge by describing both entity types and mentions using a universal concept set.
- We propose Self-describing Networks – SDNet, a Seq2Seq generation network which can universally describe mentions using concepts, automatically map novel entity types to concepts, and adaptively recognize entities on-demand.
- We pre-train SDNet on the large-scale open dataset, which provides a universal knowledge for few-shot NER and can benefit many future NER studies.

2 Related Work

To deal with the limited information challenge, current FS-NER studies mostly focus on leveraging external knowledge, many knowledge resources are used: 1) PLMs. Early FS-NER studies (Tong et al., 2021; Wang et al., 2021) mainly use PLMs for better encoding. And prompt-based NER formulation is proposed to exploit the PLMs' knowledge more effectively (Xin et al., 2018; Obeidat et al., 2019; Dai et al., 2021; Ding et al., 2021; Yan et al., 2021a; Liu et al., 2021; Cui et al., 2021; Ma et al., 2021; Lee et al., 2021). 2) Existing annotation datasets. These studies (Fritzler et al., 2019; Hou et al., 2020; Yang and Katiyar, 2020; Li et al., 2020a,b; Tong et al., 2021; Das et al., 2021) focus on reusing annotations in existing datasets, and the annotations can be used to pre-train NER models. 3) Distantly annotated datasets. Some works (Mengge et al., 2020; Huang et al., 2020; Jiang et al., 2021) try to automatically construct NER datasets via distant supervision, but which often suffer from the partially-labeled (Yang et al., 2018; Nooralahzadeh et al., 2019; Peng et al., 2019) and noise label (Shang et al., 2018; Peng et al., 2019; Zhang et al., 2021b,a) problem.

To deal with the knowledge mismatch problem, Kim et al. (2015); Reed et al. (2016); Qiao et al. (2016); Xian et al. (2019); Hou et al. (2020) employ label project methods which project labels

---

[1] Our source codes are openly available at `https://github.com/chen700564/sdnet`

in different schemas. Rei and Søgaard (2018); Li et al. (2020c); Wang et al. (2021); Aly et al. (2021) enrich the semantics of labels using manually label descriptions. Beryozkin et al. (2019); Yu and Yang (2020) merge the labels in different schemas into the same taxonomy for knowledge sharing. And Jiang et al. (2021) relabels the external noisy datasets using current labels. Compared with these methods, we resolve the knowledge mismatch problem by mapping all entity types to a universal concept set, and the concept mapping and target entities are automatically generated using a self-describing networks.

3 Self-describing Networks for FS-NER

In this section, we describe how to build few-shot entity recognizers and recognize entities using Self-describing networks. Figure 3 (b) shows the entire procedure. Specifically, SDNet is a Seq2Seq network which performs two generation tasks successively 1) ***Mention describing***, which generates the concept descriptions of mentions; 2) ***Entity generation***, which adaptively generates entity mentions corresponding to desirable novel type one by one. Using SDNet, NER can be directly performed through the entity generation process by putting type descriptions into its prompt. Given a novel type, its type description is built through mention describing upon its illustrative instances. In the following, we will first introduce SDNet, then describe how to construct type descriptions and build few-shot entity recognizers.

3.1 Self-describing Networks

SDNet is a Seq2Seq network that can perform two generation tasks: mention describing and entity generation. Mention describing is to generate the concept descriptions of mentions and entity generation is to adaptively generate entity mentions. To guide the above two processes, SDNet uses different task prompts $\mathbf{P}$ and generates different outputs $\mathcal{Y}$. Figure 2 shows their examples. For mention describing, the prompt contains a task descriptor `[MD]`, and the target entity mentions. For entity recognition, the prompt contains a task descriptor `[EG]`, and a list of target novel types and their corresponding descriptions. Taking prompt $\mathbf{P}$ and sentence X as input, SDNet will generate a sequence $\mathcal{Y}$ which contains the mention describing or entity generation results. The above two processes can be viewed as **symmetrical processes**: one is to capture concept semantics of given entities, the other is to identify entities containing the specific concepts.

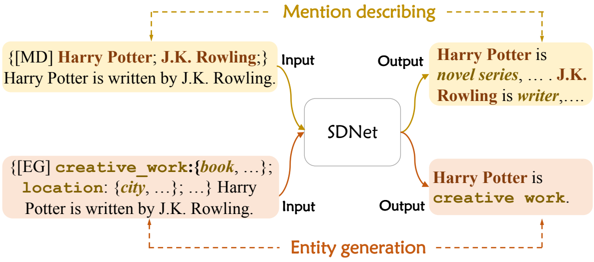

Figure 2: Examples of input and output of mention describing and entity generation.

Specifically, SDNet first concatenates prompt $\mathbf{P}$ and sentence $\mathbf{X}$ into a sequence $\mathcal{I} = \mathbf{P} \oplus \mathbf{X}$ and then fed $\mathcal{I}$ into an encoder to obtain the hidden state representation $\mathcal{H}$:

$$\mathcal{H} = \text{Encoder}(\mathcal{I}).$$

Then $\mathcal{H}$ will be fed into a decoder, and the decoder will sequentially generate a sequence $\mathcal{Y}$. At time step t, the probability $\mathbf{p}_t$ of generating tokens in vocabulary is calculated by:

$$\mathbf{p}_t = \text{Decoder}(\mathcal{H}, \mathcal{Y}_{<t}).$$

We use the greedy decoding here and therefore the word in the target vocabulary with maximum value in $\mathbf{p}_t$ is generated until $[EOS]$ is generated.

By modeling different tasks in a single model, the generation is controllable, learning is uniform, and the model can be continuously trained.

We can see that, few-shot entity recognition can be effectively performed using the above two generation processes. For entity recognition, we can put the descriptions of target entity types into the prompt, then entities will be adaptively generated through the entity generation process. To construct the entity recognizer of a novel type, we only need its type description, which can be effectively built by summarizing the concept descriptions of their illustrative instances.

3.2 Entity Recognition via Entity Generation

In SDNet, entity recognition is performed by the entity generation with the given entity generation prompt $\mathbf{P}_{\text{EG}}$ and sentence X. Specifically, $\mathbf{P}_{\text{EG}}$ starts with a task descriptor `[EG]`, and the descriptor is followed by a list of target types and their corresponding descriptions, i.e., $\mathbf{P}_{\text{EG}} = \{\texttt{[EG]}t_1 : \{l_1^1, \ldots, l_1^{m_1}\}; t_2 : \{l_2^1, \ldots, l_2^{m_2}\}; \ldots\}$,

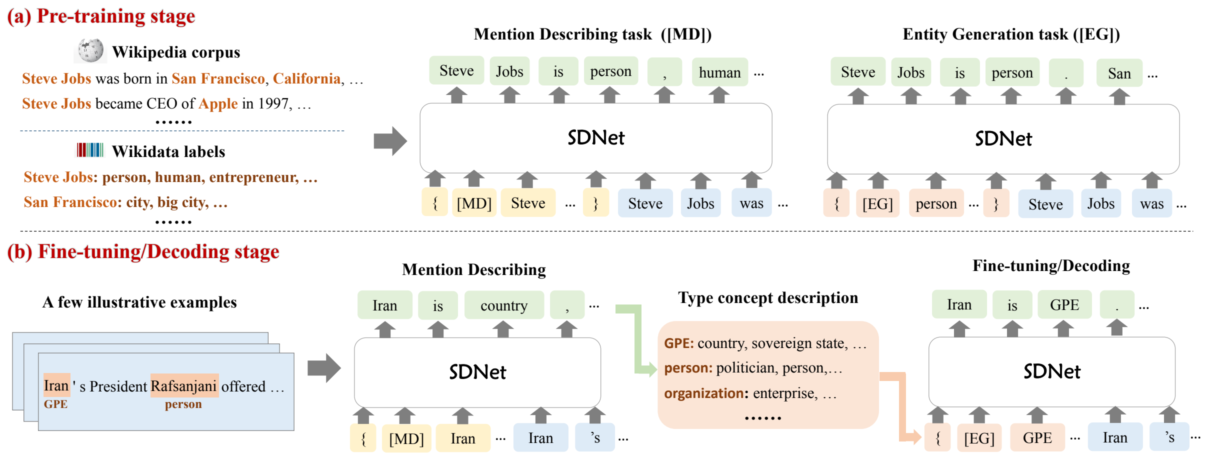

Figure 3: Overview of the process of SDNet. The upper part is the pre-training stage, and the lower part is the fine-tuning/decoding stage. In pre-training stage, the external data is used to jointly train mention describing and entity generation tasks. In fine-tuning/decoding stage, SDNet first conducts mention describing to summarize type concept descriptions, and then conducts entity generation based on the generated descriptions.

where l_i^j is the j-th concept of i-th type t_i. Prompt $\mathbf{P}_{\text{EG}}$ and sentence X will be fed to SDNet as Section 3.1 described. Then, SDNet will generate text $\mathcal{Y}$ in the format as "e_1 is $t_{y_1}; \ldots; e_n$ is t_{y_n}.", where t_{y_i} is the type of i-th entity e_i. Based on the generated text $\mathcal{Y}$, the recognized entities are obtained, i.e, {<e_1, t_{y_1}> ... <e_n, t_{y_n}>}.

We can see that, in SDNet, the entity generation process can be controlled on-the-fly using different prompts. For example, given a sentence "Harry Potter is written by J.K. Rowling.", if we want to identify entity of `person` type , put { `[EG] person`: {*actor*, *writer*}} to $\mathbf{P}_{\text{EG}}$, SDNet will generate "J.K. Rowling is person", while if we want to identify entity of `creative_work` type, put { `[EG] creative_work`: {*book*, *music*}} to $\mathbf{P}_{\text{EG}}$, SDNet will generate "Harry Potter is creative_work".

3.3 Type Description Construction via Mention Describing

SDNet is controlled on-the-fly to generate different types of entities by introducing different corresponding type descriptions to $\mathbf{P}_{\text{EG}}$. For example, the description {*actor*, *doctor*, ...} for and the description is {*city*, *state*, ...} for `location`.

To build the type description for novel types with several illustrative examples, SDNet first obtains the concept description of each mention in illustrative examples via mention describing. Then the type description of each type is constructed by summarizing all the concept descriptions of its illustrative examples. In the following, we describe them in detail.

Mention Describing. In SDNet, mention describing is a generation process, whose input is mention describing prompt $\mathbf{P}_{\text{MD}}$ and an illustrative instance X. Specifically, given an illustrative example X which contains entity mentions $\{e_1, e_2, \ldots\}$ of novel types, $\mathbf{P}_{\text{MD}}$ starts with a task descriptor `[MD]`, and the descriptor is followed by target entity mentions. i.e., $\mathbf{P}_{\text{MD}} = \{\texttt{[MD]}\, e_1; e_2; \ldots\}$. Prompt $\mathbf{P}_{\text{MD}}$ and sentence X will be fed to SDNet as Section 3.1 described. And then SDNet will generate the text $\mathcal{Y}$ in the format as "e_1 is $l_1^1, \ldots, l_1^{n_1}$; e_2 is $l_2^1, \ldots, l_2^{n_2}; \ldots$", where l_i^j is the j-th concept for the i-th entity mention. The concept set $\{l_i^1, l_i^2, \ldots, l_i^{n_i}\}$ will be considered as the semantic concepts reflected by entity mention e_i.

Type Description Construction. SDNet then summarizes the generated concepts to describe the precise semantics of specific novel types. Specifically, all concept descriptions of mentions with the same type t will be fused to C and regarded as the description of type t. And the type descriptions $\mathcal{M} = \{(t, C)\}$ are constructed. Then the constructed type descriptions are incorporated to $\mathbf{P}_{\text{EG}}$ to guide entity generation.

Filtering Strategy. Because of the diversified downstream novel types, SDNet may not have sufficient knowledge for describing some of these types, and therefore forcing SDNet to describe them can result in the inaccurate descriptions. To resolve this problem, we introduce a filtering strategy to make SDNet able to reject generating unreliable descriptions. Specifically, SDNet is trained to generate `other` as the concept description for those uncertain instances. Given a novel type and a few illustrative instances, we will count the frequency of `other` in the concept descriptions from these instances. If the frequency of generating `other` on illustrative instances is greater than 0.5, we will remove the type description, and directly use the type name as $\mathbf{P}_{\text{EG}}$. We will describe how SDNet learns the filtering strategy in Section 4.1.

4 Learning

In this section, we first describe how to pre-train SDNet using large-scale external data, so that the common NER ability can be captured through the mention describing ability and the entity generation ability. Then we describe how to quickly adapt and transfer NER knowledge via fine-tuning. Figure 3 shows the two processes and we describe them as follows.

4.1 SDNet Pre-training

In SDNet, the NER ability consists of mention describing ability and entity generation ability, which can be effectively pre-trained by constructing corresponding datasets. This paper constructs datasets and pre-trains SDNet using the easily available and large-scale Wikipedia and Wikidata data.

Entity Mention Collection. For SDNet pre-training, we need to collect $<e, T, X>$ triples, where e is entity mention, T is entity types and X is sentence, such as <J.K. Rowling; person, writer, ...; J.K. Rowling writes ...>. To this end, we use the 20210401 version of Wikipedia and Wikidata dump and collect triples by aligning facts in Wikidata and documents in Wikipedia and process as follows. 1) Firstly, we construct an entity type dictionary from Wikidata. We regard each item in Wikidata as an entity and use the "instance of", "subclass of" and "occupation" property values as its corresponding entity types. To learn general NER knowledge, we use all entity types except whose instances are < 5. For the types whose names are longer than 3 tokens, we use their head words as the final type for simplicity, e.g., "state award of the Republic of Moldova" is converted to "state award". In this way, we obtain a collection $\mathbb{T}$ of 31K types which can serve as a solid foundation for universal NER. 2) Secondly, we collect the mentions of each entity using its anchor texts in Wikipedia and the top 3 frequent noun phrase occurrences of its entry page (Li et al., 2010). Then for each mention, we identify its entity types by linking it to its Wikidata item's types. If its Wikidata item doesn't have a type, we assign its type as `other`. For each Wikipedia page, we split the text to sentences[2] and filter out sentences that have no entities. Finally, we construct a training dataset containing 56M instances.

Type Description Building. To pre-train SDNet, we need the concept descriptions $\mathcal{M}^P = \{(t_i, C_i)\}$, where $t_i \in \mathbb{T}$, C_i is the related concepts of type t_i. This paper uses the collected entity types above as concepts, and builds the type description as follows. Given an entity type, we collect all its co-occurring entity types as its describing concepts. For example, `Person` can be described as {*businessman*, *CEO*, *musician*, *musician...*} by collecting the types of "Steve Jobs": {`person`, `businessman`, `CEO`} and "Beethoven": {`person`, `musician`, `pianist`}. In this way, for each entity type we have a describing concept set. Because some entity types have a very large describing concept set, we randomly sample no more than N (10 in this paper) concepts during pre-training for efficiency.

Pre-training via Mention Describing and Entity Generation. Given a sentence X with its mention-type tuples $\{(e_i, T_i) | e_i \in E, T_i \subset \mathbb{T}\}$, where $T_i = \{t_i^1, ..., t_i^{n_i}\}$ is the set of types of i-th entity mention e_i, t_i^j is the j-th type of the e_i, $E = \{e_1, e_2, ...\}$ is the set of entity mentions contained in X. Then we construct type descriptions, and transform these triples to pre-training instances. Specifically, for mention describing, some target entity mentions $E^{'}$ are sampled from E to put into prompt $\mathbf{P}_{\text{MD}}$. Then SDNet will take $\mathbf{P}_{\text{MD}}$ and X to generate the corresponding types of sampled mentions $E^{'}$ as described in Section 3.3. For entity generation, positive type T_p and negative type T_n are sampled to construct the target-sampled type set $T^{'} = T_p \cup T_n$, where $T_p \subset T_1 \cup T_i ... \cup T_k$, $T_n \subset \mathbb{T} \setminus \{T_1 \cup T_i ... \cup T_k\}$. Next, the type set $T^{'}$ and their sampled concept description will be put into prompt $\mathbf{P}_{\text{EG}}$. Then SDNet will take prompt $\mathbf{P}_{\text{EG}}$ and sentence X to generate the sequence as described in Section 3.2.

For each instance, SDNet generates two kinds of sequences: $\widetilde{\mathcal{Y}_m^p}$ for mention describing, and $\widetilde{\mathcal{Y}_e^p}$ for

entity generation. We use cross-entropy (CE) loss to train SDNet:

$$\mathcal{L}_p = \mathrm{CE}(\widetilde{\mathcal{Y}^p_m}, \mathcal{Y}^p_m) + \mathrm{CE}(\widetilde{\mathcal{Y}^p_e}, \mathcal{Y}^p_e) \qquad (1)$$

Note that when constructing the target generation sequence $\mathcal{Y}^p_e$, the order of mentions depends on the order they appear in the original text.

4.2 Entity Recognition Fine-tuning

As described above, SDNet can directly recognize entities using manually designed type descriptions. But SDNet can also automatically build type descriptions using illustrative instances and be further improved by fine-tuning. Specifically, given annotated $<e, T, X>$ instances, we first construct the descriptions of different types, next build an entity generation prompt $\mathbf{P}_{\text{EG}}$, then generate sequence $\widetilde{\mathcal{Y}^f_n}$. We fine-tune SDNet by optimizing:

$$\mathcal{L}_f = \mathrm{CE}(\widetilde{\mathcal{Y}^f_n}, \mathcal{Y}^f_n) \qquad (2)$$

We can see that, by fine-tuning SDNet, the entity generation process can better capture the associations between mentions and entity types.

5 Experiments

5.1 Settings

Datasets. Following previous studies, we use 8 benchmarks from different domains: 1) CoNLL2003 (Sang and Meulder, 2003) ; 2) WNUT17 (Derczynski et al., 2017); 3) Re3d (Science and Laborator, 2017); 4) MIT corpus (Liu et al., 2013a,b) includes three datasets: Res, Movie1(trivial10k13 version) and Movie2; 5) I2B2 (Stubbs and Uzuner, 2015); 6) OntoNotes5 (Ralph et al., 2013). Appendix shows detailed statistics of these datasets.

Evaluation. We conduct main experiments on 5-shot setting as previous work (Huang et al., 2020; Wang et al., 2021), and also ranging the shot size from 5 to 100, as well as full shot for further analysis. For k-shot setting, we sample k instances for each entity type from training set as support set to fine-tune models. Specifically, all pre-trained models are trained 300k steps, all datasets are fine-trained 50 epochs and more hyperparameters are shown in Appendix. The performance is evaluated by micro-F1 on test set, and a predicted entity is correct if its entity type and offsets both match the golden entity. To obtain the offset of each mention, we extract entity mentions and their types from the generated sentence, and locate them in the original sentence. And if they are repeated, we match them in order, that is, the i-th same mention in the generated sentence will be matched to the i-th same utterances in the original sentence. We run 10 times for each dataset and report the average F1 score as Huang et al. (2020) and Wang et al. (2021) did.

Baselines. We compare with following baselines: To evaluate the effect of pre-training for few-shot NER, we compare with baselines without NER-specific pre-training: 1) **BERT-base**, a traditional sequential BIO-based NER tagger (Wang et al., 2021) using pre-trained bert-base-uncased model. 2) **T5-base**, a generation-based NER baseline which uses the same generation format as SDNet but only using original t5-base model for generation. 3) **T5-base-prompt**, the prompt-extended version of T5-base which use entity types as prompt. To compare the effect of different knowledge transfer ways, we construct a distant supervision based baseline: 4) **T5-base-DS**, we further pre-train T5-base using the dataset collected in Section 4.1 as distantly supervised dataset. We

w/o filter	53.57	35.01	42.23	63.49	66.63	65.00	63.31	57.40	60.17	62.99	59.07	60.96

Table 2: Ablation experiments. SDNet is the full model, SDNet w/o filter is the same model fine-tuned without filtering strategy, SDNet w/o desp is the same model pre-trained and fine-tuned without description, and SDNet w/o joint is two models trained to perform mention description and entity generation separately.

also compare with several recent few-shot NER methods: 5) RoBERTa-based few-shot classifier **RoBERTa** and its distantly-supervised pre-trained version **RoBERTa-DS** (Huang et al., 2020). 6) Prototypical network based RoBERTa model **Proto** and its distantly supervised pre-training version **Proto-DS** (Huang et al., 2020). 7) MRC model **SpanNER** which needs to design the description for each label and its distantly supervised pre-training version **SpanNER-DS** (Wang et al., 2021). Notice that these methods mostly only focus on task-specific entity types, by contrast, this paper focuses on building a general few-shot NER model which can recognize entities universally.

5.2 Main Results

Table 1 shows the performances of SDNet and all baselines on 8 datasets. We can see that:

1) **By universally modeling and pre-training NER knowledge in a generation architecture, the self-describing network can effectively handle few-shot NER.** Compared with previous baselines, SDNet achieves competitive performance on all 8 datasets (new state-of-the-art on 6 datasets), and its performance is robust on different datasets.

2) **Due to the limited information problem, transferring external knowledge to few-shot NER models are critical.** Compared with BERT-base, T5-base, and T5-base-prompt, SDNet achieves 24%/16%/11% F1 improvements, which verified that SDNet provides a universal knowledge-enhanced foundation for NER and can adaptively transfer universal knowledge to enhance novel type recognition.

3) **Due to the knowledge mismatch, it is challenging to transfer external knowledge effectively to novel downstream types.** Using the same external knowledge sources, SDNet can achieve a 16% F1 improvement than T5-base-DS. We believe it is due to the noise, partially-labeled and heterogeneous problems in the external knowledge sources, and SDNet can effectively address these issues.

5.3 Effects of Shot Size

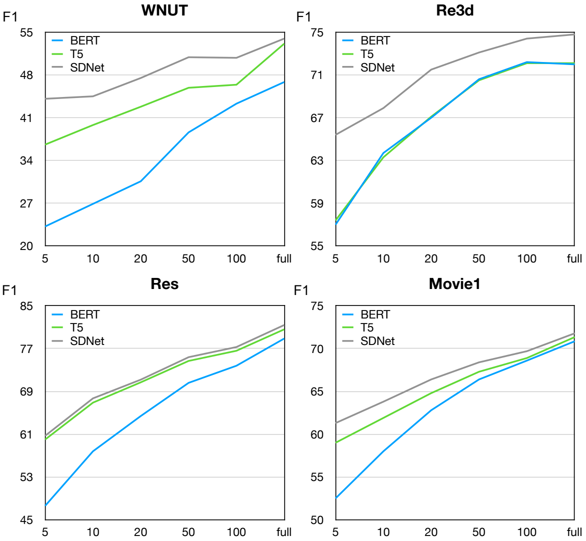

Figure 4: Performances of BERT, T5, SDNet with k-shot samples on WNUT, Re3d, Res, Movie1 dataset.

To verify the performance of SDNet under different shot settings, we compare the performance of BERT, T5, and SDNet with k-shot samples where k ranges from 5 to 100. From Figure 4 we can see that 1) SDNet can achieve better performance under all different shot settings. Furthermore, the improvements are more significant on low shot settings, which verified the intuitions behind SDNet; 2) Generation-based models usually achieve better performance than classifier-based BERT model. We believe this is because generation-based model can more efficiently capture the semantics of types by leveraging the label utterances, and therefore can achieve much better performance, especially in low-shot settings. 3) SDNet significantly outperforms T5 on almost all datasets except *Res*. This shows the effectiveness of the proposed self-describing mechanism. For *Res*, we find that the main reason why T5 can achieve close performance to SDNet is the huge domain shifting between *Res* and Wikipedia. Such domain shifting makes SDNet frequently generate *other* for type descriptions, and therefore SDNet degrades to T5 in many cases. However, SDNet can still perform better than T5 on *Res*, which verifies the robustness of the proposed type description and the filtering strategy.

5.4 Ablation Study

To analyze the effectiveness of type description, multi-task modeling and type description filtering, we conduct following ablation experiments: 1) SDNet w/o desp: we directly use entity type as prompt, without the universal concept description, e.g. `{[EG] person; location; ...}` ; 2) SDNet w/o joint: we split SDNet into two individual generation network, one for mention description, the other for entity generation, and trained them using same resources as SDNet; 3) SDNet w/o filter: we use all the generated concept descriptions with no filtering strategy. From Table 2 we can see that:

1) **Type description is critical for SDNet to transfer knowledge and capture type semantics.** By removing type description, the F1 of all datasets will decrease. We believe this is because 1) type description provides a common base for knowledge transferring, where all entity types are described using the same set of concepts; 2) the concept descriptions capture the semantics of entity types more accurately and precisely, which can better guide the NER process.

2) **Joint learning mention describing and entity generation processes in a unified generation network is effective to capture type semantics.** Compared with modeling two tasks separately, SDNet can achieve better performance. We believe this is because the two processes are symmetrical, and they can complement and promote each other.

3) **Filtering strategy can effectively alleviate the transferring of mismatched knowledge.** Removing the filtering strategy will undermine the performance on all 4 datasets. We believe this is because there exist some instances that can not be described based on the pre-trained SDNet knowledge. As a result, introducing filtering strategy can effectively prevent the mistaken knowledge transferring to these instances.

5.5 Zero-shot NER with Manual Description

In this section, we adapt SDNet to zero-shot setting, to investigate whether SDNet can achieve promising zero-shot performance without any illustrative instances. To this end, we conduct an experiment on WNUT by introducing manually created concepts as type descriptions based on annotation guideline, and the designed descriptions are shown in Appendix. Then we compare with the baseline without using type description, to see the effectiveness of the descriptions and whether SDNet can well-adapted to manually created descriptions.

Types	w/o desp	Artifact	Few-shot
person	51.29	46.27	59.80
corporation	31.30	34.43	33.21
location	46.15	50.36	52.64
creative-work	12.29	14.38	27.69
group	19.93	24.45	24.10
product	19.10	23.08	23.63

Table 3: F1 score of each label in WNUT under zero-shot setting. **w/o desp** is the model pre-trained without description. **Artifact** is SDNet with manually designed concept description based on guideline.

Text	[Chris Hill]$_{\text{person}}$ was in [China]$_{\text{GPE}}$ [a few days ago]$_{\text{date}}$.
Input1	{ [EG] GPE: {state, country, city, democracy, republic, community}; date: {}; } Chris Hill was in China ...
Output1	China is GPE. a few days ago is date.
Input2	{ [EG] person: {politician, actor, lawyer}; organization: {business, company}; } Chris Hill was in China ...
Output2	Chris Hill is person.

Table 4: Examples of the outputs of entity generation process. SDNet is fine-tuned on OntoNotes and the type description is automatically generated by SDNet via mention describing.

From Table 3, we can see that SDNet can benefit from manual description significantly. Compared with SDNet without description, incorporating manual description can improve zero-shot performance on the majority of types. Furthermore, SDNet with manual description on zero-shot setting can achieve comparable performance with few-shot settings in many entity types. This demonstrates that type description is an effective way for model to capture the semantic of novel types, which verifies the intuition of SDNet.

5.6 Effect of Entity Generation Prompt

Table 4 shows that by putting different types and its corresponding type descriptions to prompt, SDNet can generate different outputs according to the prompt. This verifies that SDNet can be controlled on-the-fly to generate different types of entities.

6 Conclusions

In this paper, we propose Self-describing Networks, a Seq2Seq generation model which can universally describe mentions using concepts, automatically map novel entity types to concepts, and adaptively recognize entities on-demand. A large-scale SDNet model is pre-trained to provide universal knowledge for downstream NER tasks. Experiments on 8 datasets show that SDNet is effective and robust. For future work, we will extend self-describing mechanism to other NLP tasks like event extraction (Paolini et al., 2021; Lu et al., 2021) and complex NER tasks like nested (Lin et al., 2019) or discontinuous NER (Yan et al., 2021b).

Abstract

Motivated by the success of T5 (Text-To-Text Transfer Transformer) in pre-trained natural language processing models, we propose a unified-modal SpeechT5 framework that explores the encoder-decoder pre-training for self-supervised speech/text representation learning. The SpeechT5 framework consists of a shared encoder-decoder network and six modal-specific (speech/text) pre/post-nets. After preprocessing the input speech/text through the pre-nets, the shared encoder-decoder network models the sequence-to-sequence transformation, and then the post-nets generate the output in the speech/text modality based on the output of the decoder. Leveraging large-scale unlabeled speech and text data, we pre-train SpeechT5 to learn a unified-modal representation, hoping to improve the modeling capability for both speech and text. To align the textual and speech information into this unified semantic space, we propose a cross-modal vector quantization approach that randomly mixes up speech/text states with latent units as the interface between encoder and decoder. Extensive evaluations show the superiority of the proposed SpeechT5 framework on a wide variety of spoken language processing tasks, including automatic speech recognition, speech synthesis, speech translation, voice conversion, speech enhancement, and speaker identification. We release our code and model at `https://github.com/microsoft/SpeechT5`.

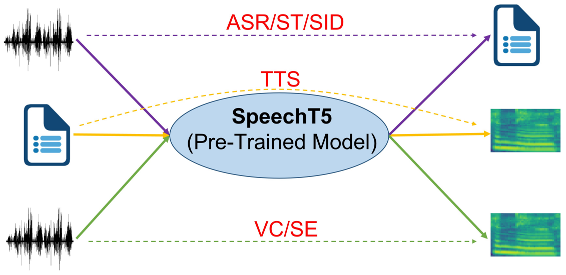

Figure 1: An illustration of the SpeechT5 framework, which treats spoken language processing tasks as a speech/text to speech/text format, including automatic speech recognition (ASR), speech translation (ST), speech identification (SID), text to speech (TTS), voice conversion (VC), and speech enhancement (SE).

1 Introduction

Starting with ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019), substantial work has shown that pre-trained models can significantly improve in various natural language processing (NLP) tasks (Radford et al., 2019; CONNEAU and Lample, 2019; Yang et al., 2019; Dong et al., 2019; Lewis et al., 2020). Following the pre-training techniques in NLP, self-supervised speech representation learning has also been investigated and shown promising results, benefiting from richly learned representations (Chung and Glass, 2018; Chuang et al., 2020; Song et al., 2019; Baevski et al., 2020; Wang et al., 2021; Hsu et al., 2021; Chung et al., 2021a), such as wav2vec 2.0 (Baevski et al., 2020) and HuBERT (Hsu et al., 2021).

However, previous speech pre-training work suffers from two problems: (1) most of them learn the speech representation with only unlabeled speech data but ignore the importance of textual data to spoken language tasks (e.g., automatic speech recognition) which require the modality transformation; (2) most of these models solely rely on a pre-trained speech encoder for various downstream tasks, leaving the decoder not pre-trained for the sequence-to-sequence generation tasks. How to design a unified encoder-decoder model that can take advantage of both unlabeled speech and text data to improve various spoken language processing tasks is not well explored.

Inspired by the T5 method (Raffel et al., 2020),

we attempt to formulate each spoken language processing task as a speech/text to speech/text problem via an encoder-decoder framework, which enables us to use the same pre-trained model with bimodal data across diverse tasks, as shown in Figure 1. To achieve this, we propose a unified-modal pre-training framework, SpeechT5, containing an encoder-decoder backbone network and modal-specific pre/post-nets. With the pre-nets, the input speech/text is embedded in a shared space, and the encoder-decoder backbone network models the sequence-to-sequence conversion, from which the model-specific post-nets generate the speech/text output. Particularly, SpeechT5 is mainly pre-trained with a denoising sequence-to-sequence method by leveraging large-scale unlabeled text and speech corpus. To align the textual and acoustic information into a unified semantic space, the proposed SpeechT5 model (1) maps text and speech representations into a shared vector quantization space, and (2) randomly mixes up the quantized latent representations and the contextual states, which can better guide the quantizer to learn the cross-modal features.

We fine-tune SpeechT5 on a wide variety of downstream spoken language processing tasks, including automatic speech recognition (ASR), text-to-speech (TTS), speech translation (ST), voice conversion (VC), speech enhancement (SE), and speaker identification (SID). Massive experiments show that the proposed SpeechT5 model achieves a significant improvement on these spoken language processing tasks compared with the state-of-the-art baselines. Specifically, the proposed SpeechT5 outperforms wav2vec 2.0 (Baevski et al., 2020) and HuBERT (Hsu et al., 2021) with the BASE model on the ASR task and also performs better than the state-of-the-art voice Transformer network (Huang et al., 2021) on the VC task. Besides, SpeechT5 is significantly superior to SpeechNet (Chen et al., 2021b) and pre-trained models from SUPERB (Yang et al., 2021) and achieves the state-of-the-art performance (i.e., 96.49%) on the SID task. We further provide an empirical comparison of the pre-training tasks and modules, and the ablation study demonstrates the effectiveness of the proposed joint speech-text pre-training method.

The contributions of this paper are summarized as follows.

- To the best of our knowledge, this is the first work to investigate a unified encoder-decoder framework for various spoken language processing tasks.
- We propose a cross-modal vector quantization approach, which learns the implicit alignment between acoustic and textual representation with large-scale unlabeled speech and text data.
- Extensive experiments on spoken language processing tasks demonstrate the effectiveness and superiority of the proposed SpeechT5 model.

2 SpeechT5

In this section, we propose SpeechT5, a unified-modal framework for learning joint contextual representations for speech and text data via a shared encoder-decoder structure.

2.1 Model Architecture

Figure 2(a) shows the model architecture of the proposed SpeechT5 model. It consists of an encoder-decoder module and six modal-specific pre/post-nets. The pre-nets convert the input speech $\mathbf{X}^s \in \mathcal{D}^s$ or text $\mathbf{X}^t \in \mathcal{D}^t$ to a unified space of hidden representations and then feed them into the shared encoder-decoder to perform the sequence-to-sequence conversion. Finally, the post-nets generate the output in the speech or text modality, based on the decoder output.

Input/Output Representations To train a single model for a diverse set of spoken language processing tasks, we formulate them as "speech/text to speech/text" tasks, where the model is fed with speech/text as the input and generates the corresponding output in the speech/text format. Specifically, a text is split into a sequence of characters $\mathbf{X}^t = (\mathbf{x}_1^t, ..., \mathbf{x}_{N^t}^t)$ as the input and output. For speech modality, the raw waveform $\mathbf{X}^s = (\mathbf{x}_1^s, ..., \mathbf{x}_{N^s}^s)$ is used as the input, and a sequence of the log Mel-filterbank features $\mathbf{X}^f = (\mathbf{x}_1^f, ..., \mathbf{x}_{N^f}^f)$ extracted from raw audio using librosa tool[1] is adopted as the target output. A vocoder (Kong et al., 2020) is leveraged to generate the final waveform from the generated features.

Encoder-Decoder Backbone The Transformer encoder-decoder model (Vaswani et al., 2017) is used as the backbone network of SpeechT5. Please

(a) The model architecture of SpeechT5

(b) The joint pre-training approach

Figure 2: (a) The model architecture of SpeechT5, which contains an encoder-decoder module and six modal-specific pre/post-nets. Most spoken language processing tasks can be learned by concatenating the encoder-decoder module and the corresponding pre-net and post-net. (b) By sharing discrete tokens across modalities, the joint pre-training approach builds bridges between speech and text. Hidden states and latent units are mixed up and used as the inputs of the cross-attention module in the decoder.

refer to Vaswani et al. (2017) for more details. We employ the relative position embedding (Shaw et al., 2018) to help capture the relative position differences between elements in the input. Specifically, we only add the relative position embedding to the dot-product weights of the self-attention.

Speech Pre/Post-Net The convolutional feature extractor of wav2vec 2.0 (Baevski et al., 2020) serves as the speech-encoder pre-net to downsample raw waveform $\mathbf{X}^s$ and produce a sequence of a speech utterance $\mathbf{H} = (\mathbf{h}_1, ..., \mathbf{h}_{N^h})$. The speech-decoder pre-net is a neural network composed of three fully connected layers with the ReLU activation, fed with the log Mel-filterbank $\mathbf{X}^f$. To support multi-speaker TTS and VC, the speaker embedding extracted with the x-vector (Snyder et al., 2018) is concatenated with the output of the speech-decoder pre-net followed by a linear layer. The speech-decoder post-net consists of two modules. The first module uses a linear layer fed with the decoder output to predict the log Mel-filterbank $\mathbf{Y}^f = (\mathbf{y}_1^f, ..., \mathbf{y}_{N^f}^f)$, followed by five 1-dimensional convolutional layers to produce a residual to refine the predicted $\mathbf{Y}^f$. Another linear module is added to project the decoder output to a scalar for predicting the stop token.

Text Pre/Post-Net We use shared embeddings as the text-encoder pre-net and text-decoder pre/post-nets. The pre-net transforms a token index into an embedding vector. The post-net transforms the hidden state into the probability distribution of tokens, normalized by the softmax function.

2.2 Pre-Training

The proposed SpeechT5 model can be pre-trained with large-scale collections of unlabeled speech and text corpus. The proposed joint pre-training method can align the textual and acoustic information into a unified semantic space.

Speech Pre-Training Leveraging unlabeled speech data $\mathcal{D}^s$ to learn general speech representations for both classification and generation tasks, SpeechT5 is trained with two types of tasks: bidirectional masked prediction and sequence-to-sequence generation.

Following HuBERT (Hsu et al., 2021), the bidirectional masked prediction leverages a masked language model similar to BERT (Devlin et al., 2019) for the encoder, in which an acoustic unit discovery model provides the frame-level targets $\mathbf{Z} = (\mathbf{z}_1, ..., \mathbf{z}_{N^h})$[2]. Specifically, we apply span mask strategies to the output $\mathbf{H}$ from speech-encoder pre-net, where 8% of timesteps are randomly selected as start indices, and spans of 10 steps are masked. The Transformer encoder takes masked $\mathbf{H}$ as the input and produces hidden representations $\mathbf{U} = (\mathbf{u}_1, ..., \mathbf{u}_{N^h})$. Based on these hidden representations, the cross-entropy loss is computed over masked timesteps as

$$\mathcal{L}_{mlm}^s = \sum_{n \in \mathcal{M}} \log p(\mathbf{z}_n | \hat{\mathbf{H}}, n), \qquad (1)$$

where $\hat{\mathbf{H}}$ denotes the masked version of $\mathbf{H}$, $\mathcal{M}$

---

[2] The target labels are generated by clustering outputs of the 6-th Transformer layer in the first iteration HuBERT BASE model via the k-means clustering method with 500 clusters.

denotes the set of masked timesteps, and $\mathbf{z}_n$ denotes the frame-level target at timestep n from $\mathbf{Z}$.

Furthermore, we propose to reconstruct the original speech via a sequence-to-sequence generation task, given the randomly masked input as introduced in bidirectional masked prediction. Following seq2seq TTS models (Li et al., 2019), we enforce the corresponding predicted output $\mathbf{Y}^f$, which is generated through the speech-decoder prenet, Transformer decoder, and speech-decoder postnet, to be close to the original $\mathbf{X}^f$ by minimizing their L_1-distance as

$$\mathcal{L}_1^s = \sum_{n=1}^{N^f} \|\mathbf{y}_n^f - \mathbf{x}_n^f\|_1, \quad (2)$$

where $\mathbf{x}_n^f$ denotes n-th an 80-dimensional log Melfilterbank from $\mathbf{X}^f$. Besides, we use the binary cross-entropy (BCE) loss $\mathcal{L}_{bce}^s$ for the stop token.

Text Pre-Training With unlabeled text data $\mathcal{D}^t$, SpeechT5 is trained to reconstruct the model output $\mathbf{Y}^t = (\mathbf{y}_1^t, ..., \mathbf{y}_{N^t}^t)$ to the original text $\mathbf{X}^t$, using the corrupted text $\hat{\mathbf{X}}^t = (\hat{x}_1^t, ..., \hat{x}_M^t)$ as the input generated with a mask-based noising function. Following the text infilling approach in BART[3] (Lewis et al., 2020), we randomly sample 30% of text spans to mask, where the span length of text spans draws from a Poisson distribution ($\lambda = 3.5$), and each span is replaced with a single mask token. Formally, SpeechT5, including text-encoder pre-net, encoder-decoder model, and text-decoder pre/post nets, is optimized to generate the original sequence with the maximum likelihood estimation as

$$\mathcal{L}_{mle}^t = \sum_{n=1}^{N^t} \log p(\mathbf{y}_n^t | \mathbf{y}_{<n}^t, \hat{\mathbf{X}}^t), \quad (3)$$

Joint Pre-Training The above pre-training methods can only leverage speech or text data to model acoustic or language information individually. To build a cross-modality mapping between speech and text, which is essential for tasks such as ASR and TTS, we propose a cross-modal vector quantization method to learn representations capturing the modality-invariant information.

Specifically, we utilize vector quantized embeddings as a bridge to align the speech representation and text representation through a shared codebook, as shown in Figure 2(b). Inspired by VQ-VAE (Oord et al., 2017) and SemFace (Ren et al., 2021), we first use the quantizer to convert these continuous speech/text representations $\mathbf{u}_i$ from the output of the encoder into discrete representations $\mathbf{c}_i$ from a fixed-size codebook $\mathbf{C}^K$, which contains K learnable embeddings. Then, the nearest neighbor search is performed between the encoder output and the embedding of each latent code via the L_2 distance as

$$\mathbf{c}_i = \arg\min_{j \in [K]} \|\mathbf{u}_i - \mathbf{c}_j\|_2, \quad (4)$$

where $\mathbf{c}_j$ is the j-th quantized vector in the codebook. Note that we do the same operation for the output of the speech and text encoders with a shared codebook.

Then, we randomly replace a proportion (10%) of the contextual representations with quantized latent representations in the corresponding time steps and calculate the cross-attention upon the mixed representations, which can explicitly guide the quantizer to utilize the cross-modal information. The diversity loss is used to encourage sharing more codes by maximizing the entropy of the averaged Softmax distribution as

$$\mathcal{L}_d = \frac{1}{K} \sum_{k=1}^{K} p_k \log p_k, \quad (5)$$

where p_k is the averaged probability of choosing the k-th code in the codebook.

The final pre-training loss with unlabeled speech and text data can be formulated as

$$\mathcal{L} = \mathcal{L}_{mlm}^s + \mathcal{L}_1^s + \mathcal{L}_{bce}^s + \mathcal{L}_{mle}^t + \gamma \mathcal{L}_d. \quad (6)$$

where γ is set to 0.1 during pre-training.

2.3 Fine-Tuning

After pre-training, we fine-tune the encoder-decoder backbone via the loss of the downstream task. The goal is to measure the learning abilities of SpeechT5, and we study the performance on a diverse set of downstream tasks such as ASR, TTS, ST, VC, SE, and SID. All of the spoken language processing tasks that we consider can be learned by concatenating the outputs of the encoder-decoder backbone and corresponding pre-net and post-net. Taking ASR as an example, the final model consists of the speech-encoder pre-net, encoder-decoder, text-decoder pre-net, and text-decoder post-net,

---

[3] We conducted experiments to compare the BART (Lewis et al., 2020) and T5 (Raffel et al., 2020) mask strategies, which can be found in Appendix A.

which are initialized by SpeechT5 and fine-tuned via the cross-entropy loss on the corresponding training data. The baseline systems have the same architecture as SpeechT5, but the weights of the baseline encoder are initialized by the HuBERT Base model (Hsu et al., 2021) if the input data of the downstream tasks is speech. It allows raw waveform as the model input and can provide a strong baseline.

3 Experiments

3.1 Pre-Training Setup

All models are implemented in Fairseq[4] (Ott et al., 2019). The encoder-decoder backbone contains 12 Transformer encoder blocks and 6 Transformer decoder blocks, where the model dimension is 768, the inner dimension (FFN) is 3,072, and the number of attention heads is 12. The above encoder setting is the same as that in wav2vec 2.0 Base and HuBERT Base. The speech-encoder pre-net contains 7 blocks of temporal convolutions, each of which is composed of 512 channels with strides $(5, 2, 2, 2, 2, 2, 2)$ and kernel sizes $(10, 3, 3, 3, 3, 2, 2)$. For the speech-decoder pre-net and post-net, we use the same setting as the pre-net and post-net in Shen et al. (2018) except that the number of channels of the post-net is 256. For text-encoder/decoder pre/post-net, a shared embedding layer with dimension 768 is used. For the vector quantization, we use two codebooks with 100 entries for the shared codebook module, resulting in a theoretical maximum of $K = 10^4$ code entries.

For speech pre-training, we use the full 960 hours of LibriSpeech audio (Panayotov et al., 2015). For text pre-training, we use the normalized language model training text of LibriSpeech as unlabeled data, which contains 400M sentences.[5] We optimize the model with Adam (Kingma and Ba, 2014) by warming up the learning rate for the first 8% of updates to a peak of 2×10^{-4}, which is linear decayed for the following updates. We pre-train the proposed SpeechT5 model on 32 V100 GPUs with a batch size of around 90s samples per GPU for speech and 12k tokens per GPU for text and set the update frequency to 2 for 500k steps.

3.2 Evaluation on ASR

We fine-tune the ASR model with the LibriSpeech 100/960 hours data and train the language model (LM) with the LibriSpeech LM text data, which is used for shallow fusion (Gulcehre et al., 2015) during the ASR inference. Besides the cross-entropy loss for the decoder, we add an extra linear layer to calculate the connectionist temporal classification (CTC) loss on the top of the encoder (Watanabe et al., 2017), so that we can apply the joint CTC/attention decoding (Hori et al., 2017) to boost the performance. We measure the performance of ASR by the word error rate (WER). The implementation details can be found in Appendix B.1.

The results of ASR on the 100 hours set of LibriSpeech are reported in Table 1. We compare with several state-of-the-art self-supervised approaches, including DiscreteBERT (Baevski et al., 2019), wav2vec 2.0 (Baevski et al., 2020), and HuBERT (Hsu et al., 2021). Without LM fusion, the baseline outperforms wav2vec 2.0 Base and HuBERT Base with the help of the joint CTC/attention decoding, which shows the importance of the decoder.

Table 2: Results of VC (speech to speech) on the CMU Arctic. The bdl, clb, and slt denote three speakers.

The proposed SpeechT5 model achieves significant improvements on all settings compared to wav2vec 2.0 BASE, HuBERT BASE and our strong baselines, demonstrating the superiority of the proposed pre-training method. Furthermore, when decoding with LM fusion, SpeechT5 obtains the lower WERs than wav2vec 2.0 BASE on all sets and achieves the state-of-the-art performance. Due to space constraints, the results of 960h fine-tuning experiments are reported in Appendix C.

3.3 Evaluation on TTS

We fine-tune the pre-trained model on the 460-hours LibriTTS clean sets (Zen et al., 2019) with the L_1 loss, $\mathcal{L}_{bce}^{s}$ loss, and attention loss (Tachibana et al., 2018). We utilize the HiFi-GAN (Kong et al., 2020) vocoder to convert the log Mel-filterbank to the raw waveform. We evaluate the Naturalness with the open-source NISQA-TTS (Mittag and Möller, 2020), the mean option score (MOS), and the comparison mean option score (CMOS) by native speakers on the randomly selected 200 sentences with various lengths (no overlapping with training data) generated by different models, in which case we keep the text content consistent. More details can be found in Appendix B.2.

Model	Naturalness	MOS	CMOS
Ground Truth	-	3.87 ± 0.04	-
Baseline	2.76	3.56 ± 0.05	0
SpeechT5	**2.91**	**3.65** ± 0.04	**+0.290**

Table 3: Results of TTS (text to speech) on the LibriTTS.

Table 3 shows the experimental results of TTS. The proposed SpeechT5 trained without $\mathcal{L}_{mlm}^{s}$ is considered because the bidirectional masked prediction loss is proposed to help the encoder learn to encode the speech signal, and this variant achieves superior Naturalness, as shown in Table 13 (in Appendix D). The proposed SpeechT5 model behaves better than baseline and achieves a performance of 2.91 Naturalness and 3.65 MOS. Furthermore, our proposed SpeechT5 obtains a gain of +0.29 in CMOS with respect to the baseline model, which suggests the proposed pre-training method significantly improves the speech generation quality.

3.4 Evaluation on ST

We evaluate the ST task on the MUST-C dataset (Di Gangi et al., 2019), including English-German (EN-DE) and English-French (EN-FR) translation tasks. We use the default training setting of speech translation in Fairseq ST (Wang et al., 2020), and we also average the last 10 checkpoints and use a beam size of 5 for decoding. Translation results are evaluated with case-sensitive BLEU (Papineni et al., 2002). Details about the dataset and fine-tune setting are introduced in Appendix B.3.

Model	EN-DE	EN-FR
Fairseq ST (Wang et al., 2020)	22.70	32.90
ESPnet ST (Inaguma et al., 2020)	22.91	32.69
Adapter Tuning (Le et al., 2021)	24.63	34.98
Baseline	23.43	33.76
SpeechT5 (w/o initializing decoder)	24.44	34.53
SpeechT5	**25.18**	**35.30**

Table 4: Results of ST (speech to text) on the MUST-C EN-DE and EN-FR.

We list the BLEU scores of ST in Table 4. The result of SpeechT5 without initializing the decoder is also reported since we do not pre-train the decoder with German or French data, and it outperforms the strong baseline whose encoder is initialized by HuBERT encoder. The proposed SpeechT5 further beats the SpeechT5 without initializing the decoder, and achieves a significant improvement of 1.75 and 1.54 BLEU scores than baseline in EN-DE and EN-FR tasks, respectively, which demonstrates the effectiveness and superiority of our method. Besides, our SpeechT5 model outperforms existing models such as Fairseq ST (Wang et al., 2020), ESPnet ST (Inaguma et al., 2020), and Adapter Tuning (Le et al., 2021) that employs adapter modules to be further specialized in each language pair from different pre-trained models.

3.5 Evaluation on VC

VC aims to convert a speaker-dependent source speech waveform into a different one while preserving linguistic information of the source speech waveform. We follow the many-to-many setting and utilize speech recordings of four speakers in the CMU Arctic (Kominek and Black, 2004), including clb, bdl, slt, and rms. For the waveform synthesis, we use the Parallel WaveGAN (Yamamoto et al., 2020), a non-autoregressive variant of the WaveNet vocoder. We employ the average of MCD (Mel-Cepstral Distortion) and WER as the metrics for the VC task. More details about the dataset and fine-tune setting are given in Appendix B.4.

We show the results of VC in Table 2, where we list the conversion from speaker bdl to slt and clb to slt as used in the voice Transformer network (VTN) (Huang et al., 2021). The experimental results demonstrate that the proposed SpeechT5 model achieves a significant gain than the strong baseline model. The proposed SpeechT5 model also outperforms the state-of-the-art VTN variants in terms of MCD, including VTN fine-tuned from ASR or TTS (Huang et al., 2021) and many-to-many VTN (Kameoka et al., 2021).

3.6 Evaluation on SE

SE is the task of removing background noise from a degraded speech signal and improving the intelligibility and the perceived quality of the signal. We use the WSJ0 Hipster Ambient Mixtures (WHAM!) dataset (Wichern et al., 2019) and conduct the 16 kHz max enhance-single task that recovers the signal from a mixture of only the first WSJ0 speaker and noise. We utilize HiFi-GAN to transform the log Mel-filterbank to the raw waveform. Since the input and output lengths are probably different in the encoder-decoder model, we can not evaluate it by PESQ (Rix et al., 2001) and ESTOI (Jensen and Taal, 2016), so we evaluate the negative impact on the ASR performance by WER. The implementation details of SE are in Appendix B.5.

As shown in Table 5, our strong baseline model recovers contents from the noisy speech, achieving 10.9% WER from 76.1% WER. Moreover, the proposed SpeechT5 model gets a relative 9% WER reduction compared to the strong baseline model.

Model	WER
Ground Truth Speech	3.2%
Noisy Speech (Wichern et al., 2019)	76.1%
Baseline	10.9%
SpeechT5	**8.9%**

Table 5: Results of SE (speech to speech) on the WHAM!.

The results suggest that although the noisy speech with WHAM! is challenging as summarized in Table 12 (in Appendix B.5), the proposed encoder-decoder framework can effectively suppress the noise and recover the content.

3.7 Evaluation on SID

We convert SID, a multi-class classification task of classifying each utterance for its speaker identity, to a speech to text task by sequence to sequence model. Compared to the ASR task, the text embedding table is replaced by a speaker embedding table, and the decoder predicts speaker identifies at the first step. We adopt the VoxCeleb1 dataset (Nagrani et al., 2017), which contains over 100,000 speech records uttered by 1,251 celebrities extracted from videos uploaded to YouTube. The top-1 speaker classification accuracy (ACC) is used as the evaluation metric of SID. Refer to Appendix B.6 for more details about the dataset and fine-tuning.

Model	ACC
SUPERB (Yang et al., 2021)	
wav2vec 2.0 BASE (Baevski et al., 2020)	75.18%
HuBERT BASE (Hsu et al., 2021)	81.42%
HuBERT LARGE (Hsu et al., 2021)	90.33%
SpeechNet (Chen et al., 2021b)	
Single Task	86.00%
Multi-Task with TTS	87.90%
Thin ResNet-34 (Chung et al., 2020)	89.00%
Ours	
Baseline	91.92%
SpeechT5	**96.49%**

Table 6: Results of SID (speech to text) on the VoxCeleb1. The SUPERB fine-tuning freezes the encoder.

As shown in Table 6, our baseline is superior to existing Transformer-based methods such as SpeechNet (Chen et al., 2021b) and pre-trained models from SUPERB (Yang et al., 2021). Moreover, it outperforms ResNet-based architectures such as Thin ResNet-34 (Chung et al., 2020), indicating the superiority of the encoder-decoder architecture for the SID task. The SpeechT5 further improves the performance compared to baseline and achieves the state-of-the-art performance (i.e., 96.49% accuracy), which demonstrates the effectiveness of the proposed pre-training technique.

3.8 Ablation Study

To better understand why the proposed SpeechT5 model is effective, we investigate the influence of the pre-training methods by removing each of them independently.

Model	ASR		VC	SID
	clean	other		
SpeechT5	4.4	10.7	5.93	96.49%
w/o Speech PT	-	-	6.49	38.61%
w/o Text PT	5.4	12.8	6.03	95.60%
w/o Joint PT	4.6	11.3	6.18	95.54%
w/o $\mathcal{L}_{mlm}^{s}$	7.6	22.4	6.29	90.91%

Table 7: Ablation study for the SpeechT5 model. Different variants of the SpeechT5 model, including the SpeechT5 model without speech pre-training (PT), text pre-training, joint pre-training method, or the bidirectional masked prediction loss, are evaluated on the ASR (test subsets with WER), VC (bdl to slt with MCD), and SID (test set with ACC) tasks.

As shown in Table 7, we can draw the following conclusions: (1) The pre-training methods, including speech pre-training, text pre-training, and joint pre-training method, are important to SpeechT5 since without each of them, the performance of all tasks will degrade significantly; (2) Speech pre-training is more critical than text pre-training on these tasks that need to encode speech, and the ASR model fine-tuned from SpeechT5 without speech pre-training even can not converge; (3) Without the joint pre-training method, the performance of the ASR model decreases, which demonstrates that the learned alignment from joint pre-training brings benefits for cross-modality tasks; (4) The masked language model learning $\mathcal{L}_{mlm}^{s}$ of speech data is mainly responsible for extracting acoustic features and learning better speech representation, which is beneficial to ASR and SID tasks.

4 Related Work

Large-scale pre-training models such as BERT (Devlin et al., 2019), T5 (Raffel et al., 2020), wav2vec 2.0 (Baevski et al., 2020), and HuBERT (Hsu et al., 2021) have drawn much attention in the NLP and speech communities, due to its strong capability of generalization and efficient usage of large-scale data (Devlin et al., 2019; Liu et al., 2019; Yang et al., 2019; Lewis et al., 2020; Chen et al., 2021c; Baevski et al., 2020; Lakhotia et al., 2021; Kharitonov et al., 2021; Chen et al., 2021a). However, the research mentioned above effects gear towards single-modal learning, hence they can only be used in either text or speech modeling. Although some speech-language pre-training work (Chung et al., 2021b; Kim et al., 2021; Qian et al., 2021) attempts to improve spoken language understanding tasks, these methods only focus on an encoder with task-specific layers for different tasks and do not pre-train a decoder for generation tasks such as speech synthesis or text generation. Besides, a series of research work begins to investigate joint text and speech training (Han et al., 2021; Ye et al., 2021; Tang et al., 2021a; Zheng et al., 2021; Tang et al., 2021b), but they are mainly designed for speech to text tasks.

The proposed SpeechT5 method is most related to T5 (Raffel et al., 2020). The core idea of the T5 model, a unified framework for a variety of text-based language problems, is to treat every text processing problem as a "text-to-text" problem. SpeechT5 is also related to Speech Chain (Tjandra et al., 2020), which leverages the ASR model and TTS model to build a closed-loop machine speech chain to train models on the concatenation of both labeled and unlabeled data, and SpeechNet (Chen et al., 2021b), which designs a universal modularized model to perform multiple speech processing tasks with multi-task learning. The differences from the above models are that (1) SpeechT5 is a shared cross-modal encoder-decoder framework, whose input and output are speech or text through multiple pre/post-nets; (2) SpeechT5 attempts to pre-train and improve the universal model with large-scale unlabeled text and speech data.

Another related work is SUPERB (Yang et al., 2021), a benchmark to examine the capability of pre-trained models such as HuBERT (Hsu et al., 2021). SUPERB focuses on investigating a simple framework to learn SUPERB tasks with a frozen and shared pre-trained encoder and lightweight prediction modules fine-tuned for each task. In contrast, the goal of SpeechT5 is to learn all spoken language processing tasks by fine-tuning a unified-modal encoder-decoder model, which is pre-trained on unlabeled speech and text corpus.

5 Conclusion

In this paper, we have proposed SpeechT5 as a pre-trained encoder-decoder model for various spoken language processing tasks. We convert all spoken language processing tasks into a speech/text to speech/text format and propose a novel joint pre-training method to utilize cross-modal information by leveraging the unlabeled speech and text data. The proposed unified encoder-decoder model can support generation tasks such as speech translation and voice conversion. Massive experiments show that SpeechT5 significantly outperforms all baselines in several spoken language processing tasks. In the future, we are going to pre-train the SpeechT5 with a larger model and more unlabeled data. We are also interested in extending the proposed SpeechT5 framework to address multilingual spoken language processing tasks for future work.

Acknowledgments

We thank Yanqing Liu and Sheng Zhao for their help in TTS human evaluation. We also want to thank the anonymous reviewers for insightful comments and suggestions.

A Comparisons of Text Mask Strategies

We compare the performance when using the BART (Lewis et al., 2020) or T5 (Raffel et al., 2020) strategies for text masking on the ASR task, as reported in Table 10. The BART strategy achieves comparable or better performance than the T5 strategy under different inference settings.

B Implementation Details

B.1 ASR

Dataset We use the LibriSpeech corpus and fine-tune on two labeled data settings: 960 hours of transcribed Librispeech and the train-clean-100 subset comprising 100 hours (100 hours labeled). We train the language model by the LibriSpeech language model (LM) text data, which is used for shallow fusion (Gulcehre et al., 2015) during the ASR inference.

Fine-Tuning Details We fine-tune the model with the CTC loss and the cross-entropy loss, where the loss weights are 0.5 for both of them. We train on 8 V100 GPUs with a batch size of up to 256k audio samples per GPU. The learning rate is warmed up for the first 10% steps, hold as a constant for the following 40% steps, and is decayed linearly for the rest steps. Table 8 summarizes the hyperparameters for ASR experiments of 100 hours and 960 hours sets.

Hyperparameter	100 hours	960 hours
updates	80k	320k
learning rate	6e-5	1.3e-4
time-step mask prob.	0.075	0.05
channel mask prob	0.008	0.0016

Table 8: The setting of hyperparameters for ASR fine-tuning.

Language Model and Decoding We train a character-level LM for the ASR inference. The model has the same architecture as the Transformer LM in Synnaeve et al. (2020), which is used for decoding of wav2vec 2.0 (Baevski et al., 2020) and HuBERT (Hsu et al., 2021). The LM contains 20 blocks of Transformer decoder with the model dimension of 1280, inner dimension of 6144, and 16 attention heads. To investigate the difference of the performance between our LM and the LM in Synnaeve et al. (2020), we evaluate the word-level perplexities of these LMs on the LibriSpeech dev-clean/other sets as shown in Table 9. The Transformer LM used for SpeechT5 gets 56.5 perplexity on the dev-clean set and 59.3 perplexity on the dev-other set, which are higher than the perplexities of word Transformer LM in Synnaeve et al. (2020). It suggests that we may achieve better performance on the ASR task if the perplexities of our LM are similar to the LM in Synnaeve et al. (2020).

Language Model	dev	
	clean	other
Word 4-gram (Synnaeve et al., 2020)	148.0	136.6
Word Transf. (Synnaeve et al., 2020)	48.2	50.2
Character Transf.	56.5	59.3

Table 9: Word-level perplexities of language models on dev-clean/other sets of LibriSpeech.

During decoding, the beam size is set to 30 for all experiments. We select the model with the highest accuracy on dev-other set for inference and apply the joint CTC/attention decoding (Hori et al., 2017) to further improve the performance. The model generates the output transcription by the beam search algorithm, which aims to maximize

$$\alpha \log P_{Dec} + (1-\alpha) \log P_{CTC} + \beta \log P_{LM} \quad (7)$$

where α and β are weights for the log probabilities, P_{Dec}, P_{CTC}, and P_{LM} are the probabilities of the decoder, CTC, and LM, respectively. We set α to 0.5 and β to 1.0 for fine-tuning experiments of 100 hours set, and set α to 0.9 and β to 0.7 for fine-tuning experiments of 960 hours set.

B.2 TTS

Dataset and Evaluation Metrics We use the 460-hours LibriTTS clean sets (Zen et al., 2019), a multispeaker corpus of read English speech from the audiobooks of the LibriVox project, as TTS training dataset. We trim the waveform as ESPnet recipe (Watanabe et al., 2018). The WER is evaluated by using the open-source ASR model wav2vec 2.0 CTC[6]. The naturalness of synthetic speech is estimated by using the open-source TTS naturalness prediction model NISQA-TTS[7] (Mittag and Möller, 2020).

Fine-Tuning Details Besides the L_1 loss and BCE loss, we add an additional attention loss

Mask Strategies	CTC	LM	dev		test	
			clean	other	clean	other
BART (Lewis et al., 2020)	-	-	5.4	10.7	5.8	10.7
	✓	-	4.3	10.3	4.4	10.4
	✓	✓	2.1	5.5	2.4	5.8
T5 (Raffel et al., 2020)	-	-	5.4	11.3	5.7	11.3
	✓	-	4.3	10.7	4.4	10.7
	✓	✓	2.3	5.8	2.3	5.8

Table 10: Comparisons of mask strategies for the text pre-training under different inference settings. Models are pre-trained on the 960 hours speech data of LibriSpeech and 400M text sentences of LibriSpeech-LM corpus, and fine-tuned on the 100 hours labeled data of LibriSpeech. CTC and LM mean the Joint CTC/attention decoding (Hori et al., 2017), and language model fusion, respectively.

(Tachibana et al., 2018) to speed up model convergence. We train on 8 V100 GPUs in a speaker-independent manner by using the training data of the LibriTTS. The model is updated for 120k steps with a learning rate of 0.0004, while each GPU processes up to 45,000 tokens for a batch. The learning rate is warmed up for the first 10k steps and decayed in an inverse square root manner for the rest steps.

B.3 ST

Dataset and Evaluation Metrics We evaluate the ST task on the MUST-C dataset (Di Gangi et al., 2019), including English-German (EN-DE) and English-French (EN-FR) translation tasks. The EN-DE/EN-FR language pair consists of 408/492 hours of speech data aligned with 234K/280K translated sentences. We report the results on EN-DE and EN-FR tst-COMMON set (2641 and 2632 utterances). Translation results are computed with case-sensitive BLEU (Papineni et al., 2002).

Fine-Tuning Details ST translates speech signals in a language to text in another language. We use raw audio as speech inputs in our experiments. The training setting is the same as that in S2T model in Fairseq. We set training steps to 80K and warm-up steps to 10K. Baseline and SpeechT5 models are trained with 8 GPUs via Adam optimizer. We use 8K unigram vocabulary for both EN-DE and EN-FR. Following Fairseq ST (Wang et al., 2020), we average the last 10 checkpoints and use a beam size of 5 for decoding.

B.4 VC

Dataset and Evaluation Metrics We consider the many-to-many setting for the CMU Arctic (Kominek and Black, 2004), which contains speech recordings of four speakers, such as clb (female), bdl (male), slt (female), and rms (male), who read the same 1,132 phonetically balanced English utterances. Thus, there are twelve different combinations of source and target speakers. For each speaker, the first 932, the last 100, and the rest 100 sentences of the 1,132 sentences are used for training, test, and validation as (Huang et al., 2021), respectively. The average of MCD is estimated by using the DTW (dynamic time warping) path between the output and ground-truth Mel-cepstra. A smaller MCD indicates better performance. The WER is evaluated by using the public ASR model HuBERT LARGE[8], where the WER of the test set with this ASR model is comparable to that of VTN (Huang et al., 2021).

Fine-Tuning Details Besides the L_1 loss and BCE loss, we add an additional attention loss (Tachibana et al., 2018) to speed up the model convergence. The model is trained on 8 V100 GPUs by the Adam optimizer with a batch size of 20000 tokens per GPU. We assign the learning rate based on the inverse square root with the maximum learning rate of 10^{-4} within 60k steps and apply 6k warm-up steps.

B.5 SE

Dataset and Evaluation Metrics We aim to recover the content of signals contaminated by various noises and reduce the negative impact on the performance of ASR systems. The 16 kHz enhance-single task of the WHAM! dataset (Wichern et al., 2019) is used as the SE dataset. It contains 20,000 training utterances, 5,000 validation utterances, and 3,000 test utterances, where the input waveform is a mixture of only the first WSJ0[9] speaker and noise.

Model	LM	dev-clean	dev-other	test-clean	test-other
wav2vec 2.0 BASE (Baevski et al., 2020)	-	3.2	8.9	3.4	8.5
Baseline (w/o CTC)	-	3.1	7.8	3.1	7.6
Baseline	-	2.8	7.6	2.8	7.4
SpeechT5 (w/o CTC)	-	2.8	7.6	3.1	7.3
SpeechT5	-	**2.5**	**7.4**	**2.7**	**7.1**
wav2vec 2.0 BASE (Baevski et al., 2020)	4-gram	2.0	5.9	2.6	6.1
wav2vec 2.0 BASE (Baevski et al., 2020)	Transf.	1.8	4.7	2.1	4.8
Baseline	Transf.	2.0	4.5	1.9	4.5
SpeechT5	Transf.	**1.8**	**4.3**	**1.9**	**4.4**

Table 11: WER of ASR when training on the 960 hours labeled data of LibriSpeech.

Metric	WHAM!
PESQ	1.12
ESTOI	0.48
WER (NSNet2 (Sebastian and Ivan, 2020))	45.8%

Table 12: Results of noisy speech utterances on the test set in terms of PEQS, ESTOI, and WER.

We trim the noisy segment without contents. The WER is evaluated by using the open-source ASR model[10] because lengths of inputs and outputs are probably different in the encoder-decoder model. Since lengths of noisy speech utterances are the same as lengths of clean utterances, we measure the test set via speech quality (PESQ) (Rix et al., 2001), extended short-time objective intelligibility (ESTOI) (Jensen and Taal, 2016), and WER to quantify the difficulty of noisy speech, as shown in Table 12. NSNet2 is the baseline model on the 2020 Deep Noise Suppression (DNS) challenge (Reddy et al., 2021) and obtains WER of 45.8%, probably due to the mismatch between the noise intensity of the WHAM! and DNS corpus.

Fine-Tuning Details We employ the loss function as used in the fine-tuning of the VC task. The model is trained on 8 V100 GPUs by the Adam optimizer with a batch size of 16000 tokens per GPU. We assign the learning rate based on the inverse square root with the maximum learning rate 10^{-4} within 100k steps and apply 10k warm-up steps.

B.6 SID

Dataset and Evaluation Metrics We use the official split of the VoxCeleb1 dataset (Nagrani et al., 2017) for the SID task, where the test set contains 8,251 utterances from these 1,251 celebrities. The capability of identifying speakers is assessed by classifying an utterance into the ground-truth category. Specifically, the whole utterance is taken as an input to the model to determine the speaker identity.

Fine-Tuning Details We use the cross-entropy loss and fine-tune all models on 8 V100 GPUs by the Adam optimizer with a batch size of 64 segments per GPU and the inputs of 3 seconds. The learning rate is set based on one cycle of a triangular cyclical schedule between 10^{-8} and 5×10^{-4} in 60k steps. We initialize the weights of the text embeddings layer because there are no overlapping text tokens between the vocabularies during the pre-training and the SID fine-tuning.

C Results for 960 Hours Set of LibriSpeech

We also fine-tune the model on the 960 hours set of LibriSpeech, as reported in Table 11. Experiments show that the proposed SpeechT5 model achieves significant improvement even without LM fusion, and it performs comparable or even better than wav2vec 2.0 with LM fusion.

D Results of the SpeechT5 without $\mathcal{L}^s_{mlm}$ on the TTS task

Model	Naturalness
SpeechT5	2.79
w/o $\mathcal{L}^s_{mlm}$	2.91

Table 13: Comparisons between SpeechT5 and its variant without using $\mathcal{L}^s_{mlm}$.

We use the automatic evaluation tool NISQA-TTS to verify the performance of TTS results here, because it is convenient and cheap compared with MOS and CMOS, which need to be evaluated by humans. As shown in Table 13, the variant of

---

[10] https://doi.org/10.5281/zenodo.4243201

SpeechT5 trained without the loss $\mathcal{L}^s_{mlm}$ achieves an improvement in terms of naturalness when compared with the SpeechT5. It suggests that the pre-training without the speech-specific loss brings a significant gain. Thus, we select the SpeechT5 without the loss $\mathcal{L}^s_{mlm}$ for MOS and CMOS evaluations.

Human Evaluation and Correlation with Automatic Metrics in Consultation Note Generation

Abstract

In recent years, machine learning models have rapidly become better at generating clinical consultation notes; yet, there is little work on how to properly evaluate the generated consultation notes to understand the impact they may have on both the clinician using them and the patient's clinical safety.

To address this we present an extensive human evaluation study of consultation notes where 5 clinicians (i) listen to 57 mock consultations, (ii) write their own notes, (iii) post-edit a number of automatically generated notes, and (iv) extract all the errors, both quantitative and qualitative. We then carry out a correlation study with 18 automatic quality metrics and the human judgements. We find that a simple, character-based Levenshtein distance metric performs on par if not better than common model-based metrics like BertScore. All our findings and annotations are open-sourced.

1 Introduction

Modern Electronic Health Records (EHR) systems require clinicians to keep a thorough record of every patient interaction and management decision. While this creates valuable data that may lead to better health decisions, it also significantly increases the burden on the clinicians, with studies showing this is a major contributor to burnout (Arndt et al., 2017).

In most primary healthcare practices, the universal record of a clinician-patient interaction is the SOAP (Subjective, Objective, Assessment, Plan) note, which captures the patient's history, and the clinician's observations, diagnosis, and management plan (Pearce et al., 2016). At the end of a consultation, the clinician is required to write up a SOAP note of the encounter. With the exception of the clinician's internal observations on how the patient looks and feels, most of the SOAP note is verbalised and could be automatically constructed from the transcript of the consultation.

A number of recent studies (Enarvi et al., 2020; Joshi et al., 2020; Zhang et al., 2021a) propose using summarisation systems to automatically generate consultation notes from the verbatim transcript of the consultation—a task henceforth referred to as Note Generation. Yet, there is very limited work on how to evaluate a Note Generation system so that it may be safely used in the clinical setting. Where evaluations are present, they are most often carried out with automatic metrics; while quick and cheap, these metrics were devised for general purpose summarisation or machine translation, and it is unclear whether they work just as well on this new task. In the field of automatic summarisation and Natural Language Generation (NLG) in general, human evaluation is the gold standard protocol. Even in cases where the cost of using human evaluation is prohibitive, it is essential to establish the ground truth scores which automatic metrics should aim for.

Our contributions are: (i) a large-scale human evaluation performed by 5 clinicians on a set of 285 consultation notes, (ii) a thorough analysis of the clinician annotations, and (iii) a correlation study with 18 automatic metrics, discussing limitations and identifying the most suitable metrics to this task. We release all annotations, human judgements, and metric scores.[1]

2 Related Work

Note Generation has been in the focus of the academic community with both extractive methods (Moen et al., 2016b; Alsentzer and Kim, 2018), and with abstractive neural methods (Zhang et al., 2018; Liu et al., 2019; MacAvaney et al., 2019; Zhang et al., 2020; Enarvi et al., 2020; Joshi et al., 2020; Krishna et al., 2021; Chintagunta et al., 2021; Yim and Yetisgen-Yildiz, 2021; Moramarco et al., 2021; Zhang et al., 2021a). Whether these studies

Clinician	Hello.	3/7 hx of diarrhea, mainly watery. No blood in stool. Opening bowels x6/day. Associated LLQ pain - crampy, intermittent, nil radiation. Also vomiting - mainly bilous. No blood in vomit. Fever on first day, nil since. Has been feeling lethargic and weak since. Takeaway 4/7 ago - Chinese restaurant. Wife and children also unwell with vomiting, but no diarrhea. No other unwell contacts. PMH: Asthma DH: Inhalers SH: works as an accountant. Lives with wife and children. Affecting his ADLs as has to be near toilet. Nil smoking/etOH hx
Patient	Hello, how are you?	
Clinician	Hello. How can I help you this morning?	
Patient	All right. I just had some diarrhea for the last three days and it's been affecting me. I need to stay close to the toilet. And yeah, it's been affecting my day-to-day activities.	
Clinician	I'm sorry to hear that and when you say diarrhea, what do you mean by diarrhea? Do you mean you're going to the toilet more often or are your stools more loose?	
Patient	Yeah, so it's like loose and watery **stole** going to the toilet quite often.	
Clinician	**freak**

Table 1: Snippet of a mock consultation transcript and the Subjective part of the corresponding SOAP note. The transcript is produced by Google Speech-to-text[3]; the bold-underlined text shows transcription errors. The note is written by the consulting clinician.

discuss the generation of radiology reports, patient-nurse summaries, discharge summaries, or SOAP notes, they all deal with long passages of text in the medical domain. This is a critical distinction from other application contexts (e.g. news summarisation): here, commonly used and well-studied evaluation criteria such as 'fluency', 'relevance', and 'adequacy' are superseded by other criteria, such as 'omissions of important negatives', 'misleading information', 'contradictions', etc. In addition, common summarisation metrics such as ROUGE (Lin, 2004) or BertScore (Zhang et al., 2019) measure the standalone quality of outputs and are not typically evaluated against more extrinsic criteria, such as post-editing times. Of the 18 studies on the subject that we could identify, 13 present an automatic evaluation (typically based on ROUGE and sometimes on medical entity linking) and 12 carry out a small-scale intrinsic human evaluation. In particular, Moen et al. (2016a) employ three domain experts to review 40 generated notes with Likert scales along 30 criteria (including 'Long-term diagnosis', 'Reason for admission', 'assessment'), but report that the subjects found the 30 item scale too difficult and detailed to assess. MacAvaney et al. (2019) use one domain expert to review 100 notes and report Likert scale values for 'Readability', 'Accuracy', and 'Completeness'. Moramarco et al. (2021) employ three clinicians and compare the times to post-edit generated notes with those of writing them from scratch, reporting that, while faster, post-editing may be more cognitively intensive than writing.

Outside of the medical domain, our work is comparable to Fabbri et al. (2021), who run an automatic metrics correlation study for news article summaries for the CNN/DailyMail dataset (Nallapati et al., 2016). They also release code[2] for evaluating text with a suite of common metrics, some of which we include in our own list of metrics to evaluate.

3 Dataset and Models

Our evaluation study is based on a dataset of 57 pairs of mock consultation transcripts and summary notes (Papadopoulos Korfiatis et al., 2022).[3] The data was produced by enacting consultations using clinical case cards. The clinicians that conducted the mock consultations also wrote the corresponding SOAP note. The consultations span common topics within primary healthcare and are about 10 minutes long.

To mimic a live clinical environment, the audio

---

[3] The dataset is available at: https://github.com/babylonhealth/primock57

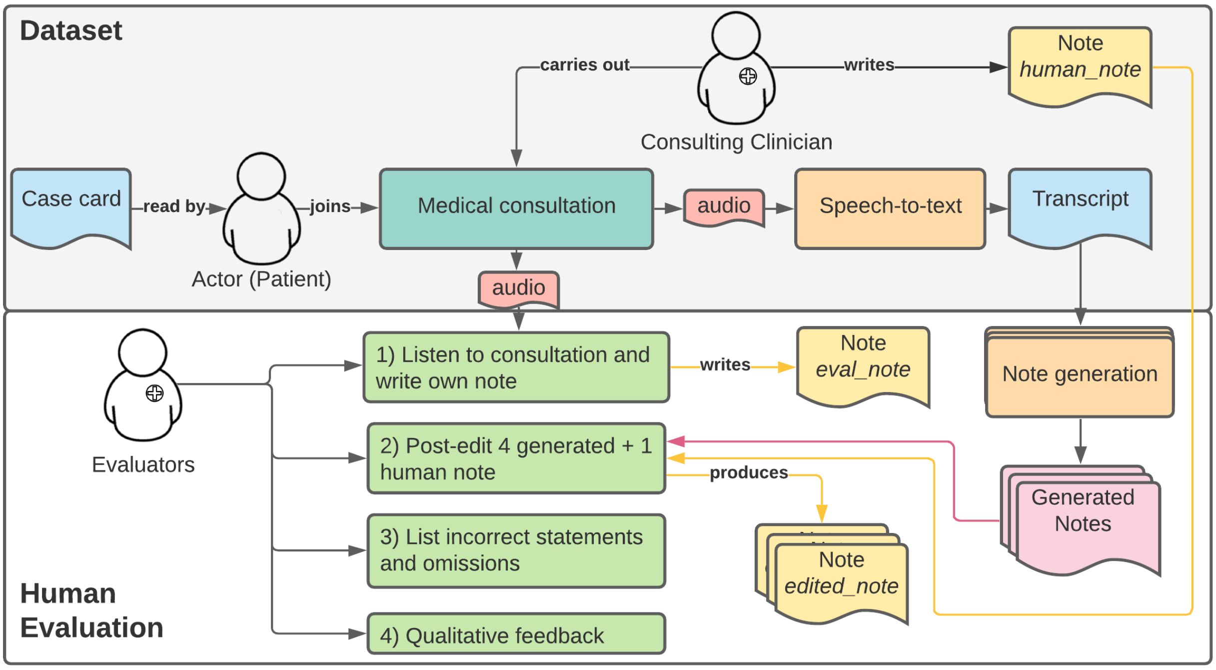

Figure 1: Diagram of the dataset creation and the four tasks involved in the human evaluation.

of the consultations was transcribed with Google Speech-to-text engine[4]. These transcripts form the input to the Note Generation models. The aim is to generate the Subjective part of a SOAP note. Table 1 shows an example transcript and respective note. Figure 1 describes the creation of the dataset and how the data feeds into the human evaluation tasks described below.

In a fashion similar to Chintagunta et al. (2021); Moramarco et al. (2021); Zhang et al. (2021a), we fine-tune 10 neural summarisation models based on BART (Lewis et al., 2020) on a proprietary dataset of 130,000 real consultation notes and transcripts. In accordance with our evaluation dataset, the training set consists of automatic Google Speech-to-text transcripts as inputs and the Subjective part of the corresponding notes as outputs.

The base models are large BART architectures pretrained on the CNN/Dailymail dataset[5]. Since our focus is on evaluation, the aim was to obtain models which would produce different outputs to cover a wider range of errors. The differences between the models included: fine-tuning on different sized datasets; using pre-processing techniques such as filtering the transcripts for relevant sentences; and using post-processing techniques such as filtering the generated notes for irrelevant sentences.

4 Human Evaluation Setup

Under the supervision of one of the authors (a clinician expert in AI development henceforth referred to as the Lead Clinician) we design the following evaluation tasks:

1. **Listen to the mock consultation audio and take notes (*eval_notes*).** These *eval_notes* appear on the evaluator screen throughout to help reduce the cognitive load of remembering what was discussed in the consultation.

2. **Relying on the *eval_notes* and the consultation audio, read 5 different notes and post-edit each one of them.** Post-editing consists of correcting an imperfect note to produce a factually accurate and relevant note (Sripada et al., 2005). It mimics how a synthetic note could be used in clinical practice while also bootstrapping the error identification (Moramarco et al., 2021). For this purpose, the evaluation platform includes a track-changes interface, which highlights insertions and deletions (Figure 2), and records the time taken to post-edit.

3. **For each note, classify the errors into two categories: ‘incorrect statements’ and ‘omissions’, by copying the spans of text from the post-editing interface and pasting them in the appropriate table (as in Figure**

3/7 watery diarrhoea hourly when awake
No blood
Intermittent cramping 6-7/10 pains before episodes
Centre of lower abdomen. Nausea too
Vomits after drinking milk. Vomiting not as bad as diarrhoea. Feels hot all the time
Passing urine less frequently
Keeping fluids down. Ate lunch today
Sx not improving
Brother with similar sx for 5/7 and may be getting better (does not live with brother though)
PMH: feels weight is normal
DH: nil.
paracetamol prn, NKDA
FH: dad with stage 3 colon Ca
SH: lives with sister/mum. managing ok. office work can be tricky/trying not to take time off.
smokes socially. drinks alcohol 1-2xs a month

3/7 hx of diarrhea - watery stools, opening bowels every hour.
No blood in stools.
Assoc crampy abdo pain - lower central, intermittent, severity 6-7/10.
Feels nauseous, has vomited occasionally.
Feeling ~~feverish~~hot all the time~~, hot/cold~~
~~Nil urinary sx -~~ passing less urine .
~~no weight loss.~~
Sx not improving
No clear dietary triggers
Brother also ~~had~~ has similar sx - improving (does not live with brother)
Tolerating oral intake
PMH: nil
DH: nil regular
NKDA
FH: father - colon Ca
SH: lives with sister and mum.
Works in office.
Smokes socially, EtOH - socially

Figure 2: Screenshot of the post-editing task where the evaluator is correcting a note with the track-changes interface. Text in green shows what they have added, and text in grey (strikethrough) what they have deleted.

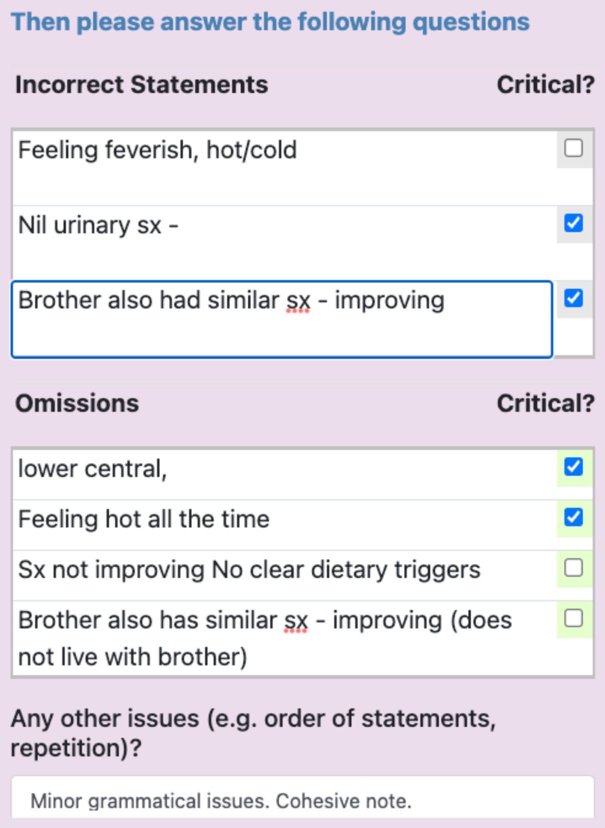
3). We define 'incorrect statements' as sentences in the generated notes which contain one or more factual errors (compared to the consultation audio). Conversely, 'omissions' are medical facts which should be recorded in a consultation note and were omitted by the model. Examples and edge cases (which were given to the evaluators for training) can be found in the Appendix, Figure A.4. Each error is also tagged as 'critical' if the information contained has essential clinical importance. Specifically, if the error would lead to medico-legal liability.

4. **Report any qualitative feedback (e.g. regarding order of statements, repetition) in the 'Other issues' box.** Figure 1 (bottom half) shows a diagram of the human evaluation workflow.

The subjects of the study were 5 regularly practising clinicians (GPs) with a minimum of 3 years experience. As part of our ethical consideration, all clinicians were paid the UK standard GP working rate and were free to cease participation at any time if they wished. For diversity and inclusion, 2 male clinicians and 3 female clinicians were enlisted from a range of ethnic backgrounds.

Following the tasks described above, each clinician evaluated the entire dataset of 57 mock consultations. Each consultation included 5 notes to evaluate, 4 of which were sampled from our 10 models and 1 was written by the consulting doctor (*human_note*). We shuffled these for every consultation and—to avoid biases—did not specify that one of the notes was not synthetic.

The evaluation study took circa 30 working hours per evaluator to complete over a period of 8 weeks. Before commencing, each evaluator went through a training and practice process conducted by the Lead Clinician, who explained the evaluation interface and guided them through the annotation of a practice note. A copy of the evaluator instructions can be found in Appendix A. Throughout the study, the authors and the Lead Clinician held weekly sessions with each evaluator where we shadowed the evaluation tasks through screen sharing. This helped us understand the difficulties in performing the tasks while ensuring the evaluators followed the guidelines set out for them.



Then please answer the following questions

Incorrect Statements	Critical?
Feeling feverish, hot/cold	☐
Nil urinary sx -	☑
Brother also had similar sx - improving	☑

Omissions	Critical?
lower central,	☑
Feeling hot all the time	☑
Sx not improving No clear dietary triggers	☐
Brother also has similar sx - improving (does not live with brother)	☐

Any other issues (e.g. order of statements, repetition)?

Minor grammatical issues. Cohesive note.

Figure 3: Screenshot of the scoring task, where the clinician is asked to quantify the incorrect statements and omissions in the generated note.

Criterion	Agree.	Word Overlap
Post-edit times	0.542^{*}	–
Incorrect statements	0.541^{*}	$0.431^{\dagger}$
Omissions	0.374^{*}	$0.268^{\dagger}$

Table 2: Inter Annotator Agreement. *Krippendorff's Alpha. †Word-level F1 score.

5 Results analysis

5.1 Agreement

The result of the human evaluation consists of 285 evaluator notes (57 consultations x 5 evaluators), 1,425 post-edited notes (285 x 5 notes per consultation), post-editing times, count and spans of incorrect statements, count and spans of omissions, whether they are critical, and qualitative comments. When compared with more common evaluation approaches such as Likert scales and ranking methods, we believe our set-up provides a more granular and more interpretable set of judgements, albeit at the price of lowering the inter-annotator agreement. To compensate for this, the 5 evaluators annotate the same 57 tasks (Sheng et al., 2008) and the scores are averaged in the correlation study (see Section 6).

Criterion	Human	Generated
Post-edit times	96.5s	136.4s
Number of Incorrect	1.3	3.9
Number of Omissions	3.9	6.6
Note length	16.9	21.5

Table 3: Aggregated judgements for *human* notes and generated notes. Note length is in number of sentences.

As shown in Table 2, we compute inter-annotator agreement on the post-editing times, incorrect statements, and omissions. The absolute post-editing times are converted to a list of rankings for each evaluator, and agreement is computed with Krippendorff's alpha (Krippendorff, 2018) with 'ordinal' level of measurement. This ensures only the ranking of each note is captured in the agreement and not the editing speed of each evaluator. For example, where evaluator 1 takes 60 seconds and 120 seconds to post-edit two given notes and evaluator 2 takes 180 seconds and 240 seconds respectively, their agreement would be perfect because they both agreed that note 1 is quicker to edit than note 2. Conversely, for incorrect statements and omissions we calculate 'interval' Krippendorff's Alpha on the counts of errors identified by the evaluators. As the counts don't ensure that two evaluators have selected the same statements, we also compute word overlap F1 score as suggested by Popović and Belz (2021). As shown in Table 2, the agreements for times and incorrect statements are not very strong (Krippendorff (2018) indicate that $\alpha \geq 0.667$ is the lowest conceivable limit). We investigate the source of disagreement and attribute it to two main factors: (i) human error due to the difficulty inherent in the task, and (ii) stylistic differences in note writing. Examples of human error can be found in subsection 5.2. As for stylistic differences, these are especially evident in the Omissions category, where some clinicians are thorough in their note taking and others only document the most important facts. See Appendix B for more details on pairwise agreement.

5.2 Human error

To compare the accuracy of the models against human-written notes, we average all the judgements for our criteria (post-edit times, incorrect statements, and omissions), aggregate by the generated notes and the *human_notes* respectively, and report the results in Table 3. As expected, the *human_notes* performed better for all criteria; in particular, they contain fewer omissions while being on average 4.6 sentences shorter. However, the evaluators found imperfections in human notes too: it takes over 1.5 minutes on average to read and post-edit a *human_note*, and it contains over 1 incorrect statement and almost 4 omissions on average. While the omissions can be reconciled as stylistic differences among evaluators, the incorrect statements are potentially more impactful. To investigate, we select two human notes and ask the Lead Clinician to post-edit them, comparing the results with those of the evaluators. In the first case, the Lead Clinician agrees with the evaluators in that the human note contains the following two incorrect statements:

Inc. statement	**Correction**
Also vomiting – mainly bilous	Also vomiting
Wife and children also unwell with vomiting, but no diarrhea.	One child had some vomiting, but no other symptoms in wife and other child.

Upon inspecting the consultation recording, the Lead Clinician found that the word 'bilious' was not stated by the patient. However, the consulting clinician may have used this term due to a personal habitual documentation style (as clinically, vomit with no red flags can conventionally be referred to as bilious). The words 'Wife and children also unwell with vomiting, but no diarrhea' were not stated by the patient. Instead, the patient made a tangential statement summarised here: 'One child had some vomiting but no other symptoms in wife and other child.' Therefore, it is inferred that this clinician likely made a normal human error due to excessive patient detail (non-critical).

In the second case, the Lead Clinician found no issues with the human note. Upon inspecting the corrections from the evaluators, he concluded that what they selected as incorrect statements were medical conditions inferred by the consulting clinician yet not specifically stated by the patient. We highlight this to show that it is unclear whether the task has a single ground truth, as even human experts don't completely agree; well thought-out evaluation tasks can mitigate this and produce one or more good ground truth approximations. Detailed examples can be found in Appendix C.

Criterion 1	**Criterion 2**	**Pears.**	**Spear.**
Post-edit times	Incorrect	0.543	0.599
Post-edit times	Omissions	0.769	0.781
Post-edit times	Inc + Omi	0.8	0.829
Post-edit times	Note length	0.38	0.413
Incorrect	Omissions	0.384	0.467
Incorrect	Note length	0.537	0.52
Omissions	Note length	0.122	0.183

Table 4: Correlation coefficients between the criteria; all numbers statistically significant (p value < 0.001). A darker shade of green means higher correlation.

5.3 Analysis of criteria

To understand the interdependence between our criteria, we compute Pearson's correlation (Freedman et al., 2007) and Spearman's rank correlation (Zar, 2005) coefficients between each pair.

Table 4 shows a moderately strong correlation between the time it takes to post-edit a note and the number of incorrect statements it contains. The correlation between post-edit times and omissions is stronger, which could be explained by the fact that it takes longer to type an omitted statement than to delete or edit an incorrect one. Finally, the correlation between post-edit times and *incorrect+omissions* is strong, which suggests that post-edit times is a function of the number of edits and that one of these criteria could be a proxy for the other.

We also compute the correlation between each criterion and the length of the generated note. These numbers can be used as a benchmark for automatic metric correlation; for example, the 0.413 Spearman's correlation between post-edit times and note length indicates that any automatic metric needs to surpass this value in order to be more useful than simply counting the number of sentences in the note.

5.4 Qualitative results

As introduced in Section 4, the evaluators provide qualitative feedback about the generated notes in the 'Other Issues' field. When analysing these comments, a number of repeated patterns emerged, highlighting common pitfalls in the generated notes. Based on these we defined a small taxonomy (Table 5; issues in the *human_notes* are excluded), providing examples and occurrences of each issue type. Aside from incorrect statements and omissions, the most significant issues revolve around repetition,

Issue	Examples	Occ.
Discourse level		
Contradiction	*no family history of bowel issues.* *father has history of colon cancer*	25
Contradiction not reported	patient corrected herself but note did not pick it up.	4
Symptom mentioned is reported as fact	*tingling of hands* stated by clinician (not refuted/confirmed by pt)	18
Misleading statement	statement: *not working* when patient has been off ill for a few days due to current sickness reads like patient is unemployed	9
Factual errors		
Hallucination	*at home and in a private place* was not mentioned in the consultation	17
Incorrect statement	statement: *brother has diabetes*. Correction: *mother has diabetes*	34
Nonsensical	*No recent unwell with diarrhoea*	18
Stylistic errors		
Repetition	*loose and watery stools* *stool is mainly watery*	93
Incorrect order of statements	*heart attack* should be in PMH; structure of history a bit jumbled; recorded social smoker in alcohol section.	38
Use of not universally recognised acronyms	NRS/EMS/DOA are not standard acronyms	7
Omissions		
Generic	no mention of *unable to open bowels*	57
Omissions of important negatives	*No fever* *No shortness of breath*	5
Other		
Good behaviour	Contains all the history that was covered in the audio and follows a logical structure.	21

Table 5: Taxonomy of errors gathered through the qualitative feedback from the evaluators.

disjointed notes, and contradiction. Upon investigating, we believe that all three are related to the tendencies of the models to generate the consultation note following the chronological order of the transcript. While that is an intuitive behaviour, consultations are seldom carried out in the order of SOAP note sections (Subjective, Objective, Assessment, Plan), with the patient providing relevant information whenever they can, sometimes after the clinician has discussed assessment and plan.

6 Correlation with Automatic Metrics

Borrowing from the field of Automatic Summarisation, most studies on Note Generation rely on ROUGE and fact-extraction based metrics to evaluate the generated notes (Section 2 for more details). While some studies carry out a small human evaluation, there is little effort to investigate whether the scores from ROUGE or the other metrics employed correlate well with the human judgements, especially extrinsic criteria such as post-edit times. However, scores from these metrics are featured on leaderboards[6] for summarisation tasks, driving future research. To address this, we carry out a correlation study of automatic metrics for the task of Note Generation. A total of 18 automatic metrics are tested against statistics produced by the human judgements of our criteria: post-edit times, number of incorrect statements, and number of omissions. Following the taxonomies reported by Celikyilmaz et al. (2020) and Sai et al. (2020), the metrics considered can be loosely grouped in:

- **Text overlap metrics.** These are based on string matching, whether character based, word based, or n-gram based. Some use stemming, synonyms, or paraphrases. They include: ROUGE (Lin, 2004), CHRF (Popović, 2015), METEOR (Lavie and Agarwal, 2007),

Table 6: Spearman's correlation coefficients for each metric and each criterion. In bold are the top three scores per column. All the metrics marked with an asterisk (*) are inversely correlated with the given criterion (e.g. higher post-edit time means worse note, but higher ROUGE score means better note); the sign of the coefficient is inverted for ease of visualisation. Coefficients in red are not statistically significant (with p > 0.05).

and BLEU (Papineni et al., 2002).

- **Edit distance metrics.** These count the number of character or word level transformations required to convert the system output into the reference text. They include: Levenshtein edit distance (Levenshtein et al., 1966), WER (Su et al., 1992), MER and WIL (Morris et al., 2004).

- **Embedding metrics,** including word-level, byte-level, and sentence-level embeddings. These metrics encode units of text with pre-trained models and compute cosine similarity between them. They include: ROUGE-WE (Morris et al., 2004), SkipThoughts, EmbeddingAverage, VectorExtrema (Forgues et al., 2014), GreedyMatching (Sharma et al., 2017), USE[7] (Cer et al., 2018), WMD (Kusner et al., 2015), BertScore (Zhang et al., 2019), and MoverScore (Zhao et al., 2019).

- **Fact-extraction.** The Stanza+Snomed metric extracts medical concept spans with Stanza (Zhang et al., 2021b), then uses similarity measures to map them to entities in the SNOMED CT clinical ontology (Spackman et al., 1997). The metric computes F1 score between reference and hypothesis over the set of extracted entities.

For more details on each metric please refer to their respective papers. All these metrics attempt to measure the accuracy of the generated text by comparing it against a reference text. Our human evaluation study produces three distinct human-curated notes which can be used as reference: the *human_note* is the original note, written by the consulting clinician (and also one of the hypotheses), the *eval_note* is the note written by the evaluators after listening to the consultation audio, and

---

[7] Cosine similarity between the reference and the hypothesis embeddings. Embeddings computed with Universal Sentence Encoder.

the *edited_note* is the generated note after being post-edited by the evaluators. Table 6 reports the correlation coefficients. When correlating against post-edit times, we consider each reference text (*human_note*, *edited_note*, *eval_note*) separately, then take the average and the maximum of the metric scores for each reference. For count of incorrect statements, omissions, and incorrect+omissions we only report the average and the maximum scores, taking all three references into account as commonly done by the metrics that support multiple references (e.g. BLEU, ROUGE, METEOR, BertScore). We compute Pearson's and Spearman's coefficients and, upon finding similar patterns, only report Spearman's coefficients in Table 6. The Pearson's coefficients can be found in Table A.8 in the Appendix.

As shown in Table 6, all metrics display a strong bias towards the choice of reference. In particular, the correlation scores with the *edited_note* as reference are much higher than those of either *human_note* or *eval_note*. As the *edited_note* is a transformation of the generated note (refer to Figure 2), these high correlations show how reliant all the metrics are on the surface form of the text. The significant difference between taking *human_note* and *eval_note* as reference can be traced to two main factors: (i) the *human_note* is unique per consultation so the human judgements are averaged across evaluators (reducing noise and collapsing disagreement), and (ii) the *eval_note* was not written to replace a SOAP note but is rather a list of the most salient points in the consultation, and sometimes contains more information than would typically be detailed in a SOAP note.

The top three metrics in most scenarios are Levenshtein distance, BertScore, and METEOR. While METEOR and BertScore are established metrics in NLG evaluation, Levenshtein distance is not typically used as a metric in long-form text evaluation. From a semantic point of view, edit distance has the least amount of knowledge and should be very brittle when comparing text that is meaningfully similar but lexically very different. Yet Levenshtein distance has the highest correlation even when the reference is the *eval_note*, which is syntactically very different from the generated note; whereas even contextual metrics like BertScore perform more poorly. A possible explanation for this behaviour may be that our post-editing times and count of incorrect statements/omissions—unlike Likert scales scores—measure the amount of work required to convert a synthetic note into a factually-correct and relevant note, just as Levenshtein distance measures the character-level distance between the synthetic note and the reference.

We notice that all the metrics correlate better with counts of *incorrect+omissions* than with post-edit times, despite the two criteria being strongly correlated with each other (0.829 Spearman's correlation, see Table 4). We believe this is due to post-editing times containing more noise and capturing more of the stylistic differences between evaluators than the number of errors does.

Correlation matrices between the metrics scores can be found in Appendix D.

7 Conclusions

We conducted a human evaluation study for the task of consultation Note Generation, computed agreement between evaluators, and quantified the extent to which human error impacts the judgements. We then carried out a correlation study with 18 automatic metrics, discussing their limitations and identifying the most successful ones.

We found that the choice of human reference has a significant effect on all automatic metrics and that simple character-based metrics like Levenshtein distance can be more effective than complex model-based metrics for the task of Note Generation. Based on our findings, character-based Levenshtein distance, BertScore, and METEOR are the most suitable metrics to evaluate this task. We release all the data and annotations and welcome researchers to assess further metrics.

8 Acknowledgements

The authors would like to thank Rachel Young and Tom Knoll for supporting the team and hiring the evaluators, Vitalii Zhelezniak for his advice on revising the paper, and Kristian Boda for helping to set up the Stanza+Snomed fact-extraction system.

Appendix

A Instructions for evaluators

Figure A.4 shows a table of examples provided to the evaluators to help them understand how to list incorrect statements and omissions, especially around edge cases.

B Pairwise Agreement

Pairwise agreement is reported in Table A.7. The agreement on post-edit times is a rank agreement computed by ranking the times and using ordinal Krippendorff Alpha; the number of incorrect statements and number of omissions agreement is computed with interval Krippendorff Alpha; and the word overlap is computed with word-level F1 score.

C Human error examples

Example human note 1.

3/7 hx of diarrhea, mainly watery.
No blood in stool.
Opening bowels x6/day.
Associated LLQ pain - crampy, intermittent, nil radiation.
Also vomiting - **mainly bilous**.
No blood in vomit.
Fever on first day, nil since.
Has been feeling lethargic and weak since.
Takeaway 4/7 ago - Chinese restaurant.
Wife and children also unwell
with vomiting, but no diarrhea.
No other unwell contacts.
PMH: Asthma
DH: Inhalers
SH: works as an accountant.
Lives with wife and children.
Affecting his ADLs as has to be near
toilet often.
Nil smoking/etOH hx

Incorrect statements

- Also vomiting - ~~mainly bilous~~, resolved after 1st day (complex incorrect statement, critical)
- ~~Wife and children also unwell with vomiting~~. -> 1 child had some vomiting but no other symptoms in wife and other child. (complex incorrect statement, non-critical)

Example human note 2.

PC: Cough and cold.
HPC: 4-5 day hx runny nose, dry cough.
No sputum/haemoptysis.
No epistaxis/sinus pain.
Feels hot, hasn't measured temperature.
No SOB/inspiratory pain/wheeze.
Aches and pains. No vomiting.
E&D ok. PUing ok.
No hx chest problems/recurrent chest
infections/wt loss.
Thinks last BP was fine, can't remember
when last BP/DM check up was.
Doesn't check blood sugars/urine at home.
No increased thirst/urinary freq.
Taking 2-3 lemsips a day which eases sx.
PMH: Hypertension. T2 DM.
DH: Lisinopril. Metformin
Height- 5ft 5in
Weight - 65kg
SH: Non smoker, odd sherry.
Lives with partner and dog.
Office manager.

Here the Lead Clinician found no incorrect statements. However, some of the evaluators did.

E1	– dm
E2	
E3	– Thinks last BP was fine, can't remember when last BP/DM check up was. – Doesn't check blood sugars/urine at home.
E4	– can't remember when last DM check up was. – Doesn't check blood sugars/urine at home. – 4 day hx
E5	

Upon inspecting the recording of the consultation, the Lead Clinician found that the words 'Thinks last BP was fine, can't remember when last BP/DM check up was. Doesn't check blood sugars/urine at home' were not stated by the patient. Instead, the patient made a tangential statement summarised here: 'diabetes (generally well controlled, last blood test was 3 weeks ago), hypertension (doesn't remember last blood pressure check)'. Please note that in diabetic and hypertension patients, clinical convention is to indicate severity of diagnosis by whether the patient requires home monitoring. Therefore, the clinician inferred part of the statement. Furthermore, clinical convention is to differentiate diabetes mellitus (DM) from diabetes insipidus (DI). Therefore again, the clinician inferred part of the statement. Any other errors are attributed to normal

Text	Incorrect Statements	Omissions	Explanation	Critical
Omissions				
Lives with wife and children.		Lives with wife and children.	Omission	No
Simple incorrect statements				
3 ~~13~~ day history of diarrhoea	13 day history of headache		Simple incorrect statements can be corrected without labelling as an omission	Yes
Opening bowels 6 ~~x16~~/day	x16 /day		Simple incorrect statements can be corrected without labelling as an omission	Yes
Takeaway 4/7 ago - Mexican ~~Chinese~~ restaurant.	Chinese restaurant.		Simple incorrect statements can be corrected without labelling as an omission	No
Complex incorrect statements				
~~No blood in stool~~ some streaks of fresh blood on wiping only	No blood in stool	some streaks of fresh blood on wiping only	One incorrect statement, one omission (complex incorrect statements require additional detail)	Yes
Vomiting for 6 ~~3~~ days, intermittent	3 days	intermittent	One incorrect statement, one omission (complex incorrect statements require additional detail)	Yes
Wife and 2 children had vomiting but no diarrhoea. ~~also have diarrhoea.~~	also have diarrhoea.	had vomiting but no diarrhoea.	One incorrect statement, one omission (complex incorrect statements require additional detail)	Yes
Edits that do not require logging as incorrect or omission				
Headache for 3 days. ~~Headache~~			Repeated/redundant text is neither incorrect nor omitted	-
~~sometimes when passes urine feels like its hard~~ feels like it's hard to pass urine			Grammatical issues do not enter in either "incorrect statements" or "omissions"	-
PMH: asthma~~.~~			Stylistic additions (PMH, deleting the full stop)	-

Figure A.4: Table of examples given to the evaluators for reference.

human error due excessive patient detail (non-critical).

D Correlation Matrices

We compute correlation matrices with Spearman's and Pearson's coefficients for all automatic metrics, considering all three references aggregated by taking the average and maximum scores respectively (Figures A.5, A.6, A.7, A.8).

Abstract

Information extraction suffers from its varying targets, heterogeneous structures, and demand-specific schemas. In this paper, we propose a unified text-to-structure generation framework, namely UIE, which can universally model different IE tasks, adaptively generate targeted structures, and collaboratively learn general IE abilities from different knowledge sources. Specifically, UIE uniformly encodes different extraction structures via a structured extraction language, adaptively generates target extractions via a schema-based prompt mechanism – structural schema instructor, and captures the common IE abilities via a large-scale pre-trained text-to-structure model. Experiments show that UIE achieved the state-of-the-art performance on 4 IE tasks, 13 datasets, and on all supervised, low-resource, and few-shot settings for a wide range of entity, relation, event and sentiment extraction tasks and their unification. These results verified the effectiveness, universality, and transferability of UIE[1].

1 Introduction

Information extraction (IE) aims to identify and structure user-specified information from unstructured texts (Andersen et al., 1992; Grishman, 2019). IE tasks are highly diversified due to its varying targets (entity, relation, event, sentiment, etc.), heterogeneous structures (spans, triplets, records, etc.), and demand-specific schemas (Grishman and Sundheim, 1996; Mitchell et al., 2005; Ji and Grishman, 2011).

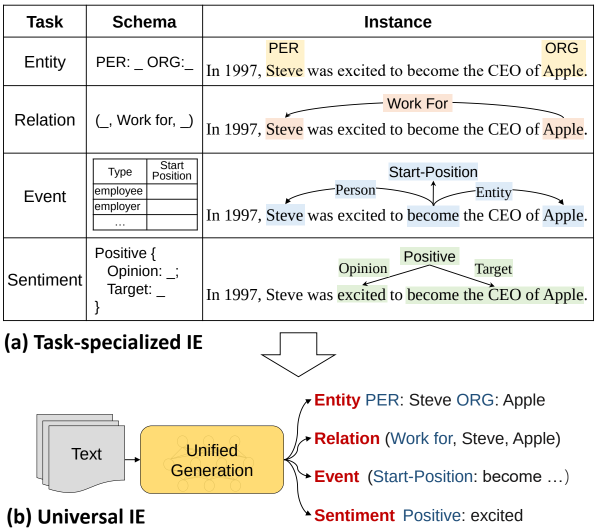

Figure 1: From (a) Task-specialized IE: different tasks, different structures, different schemas to (b) Universal IE: unified modeling via structure generation.

Currently, most IE approaches are *task-specialized*, which leads to dedicated architectures, isolated models, and specialized knowledge sources for different IE task. These task-specialized solutions greatly hinder the rapid architecture development, effective knowledge sharing, and quick cross-domain adaptation of IE systems. First, it is very complicated to develop dedicated architectures for a large amount of IE tasks/settings/scenarios. Second, learning isolated models severely restricts the knowledge sharing between related tasks and settings. Finally, it is costly and time-consuming to construct data sets and knowledge sources specialized for different IE tasks. Therefore, it will be of great benefit to develop a universal IE architecture that can uniformly model different IE tasks, adaptively predict heterogeneous structures and effectively learn from various resources, which we referred to as ***Universal IE***.

Fundamentally, all IE tasks can be modeled as text-to-structure transformations, with different

May 22-27, 2022

tasks correspond to different structures. For example, as shown in Figure 1, an entity is a named span structure, an event is a schema-defined record structure. These text-to-structure transformations in IE can be further decomposed into several atomic transformation operations: 1) ***Spotting***, which locates the desirable spans concerning to given specific semantic types (Kripke and Munitz, 1971; Chen and Yuille, 2004). For example, locating span "Steve" as a *Person* entity and locating "excited" as a sentiment expression. 2) ***Associating***, which connects spans by assigning them with semantic roles in pre-defined schemas (Onyshkevych, 1994; Milward and Thomas, 2000). For example, associating "Steve" and "Apple" by assigning them as the *Arg1* and the *Arg2* of a *Work-for* relation. In this way, different IE tasks can be decomposed into a sequence of atomic text-to-structure transformations, and all IE models share the same underlying spotting and associating abilities. For example, entity extraction can be viewed as spotting mention spans of corresponding entity types, while event detection can be reformulated as spotting triggers spans with event types. And the spotting abilities can be shared between these two tasks.

Based on the above observations, we propose UIE, a unified text-to-structure generation architecture that can universally model different IE tasks, adaptively generate targeted structures, and collaboratively learn general IE abilities from different knowledge sources. Specifically, to model heterogeneous IE structures, we design a structural extraction language (SEL) that can effectively encode different IE structures into a uniform representation, so that various IE tasks can be universally modeled in the same text-to-structure generation framework. To adaptively generate targeted structures for different IE tasks, we propose structural schema instructor (SSI), a schema-based prompt mechanism which controls what to spot, what to associate, and what to generate in UIE. To learn common IE abilities for UIE, we pre-train UIE on large-scale, heterogeneous datasets mined from easily accessible web sources. The large-scale pretrained UIE model provides a solid foundation for knowledge sharing and quick adaptation to new IE settings, and significantly boosts the IE performance in all supervised, low-resource, and few-shot settings.

We conduct experiments on 13 datasets of 4 main IE tasks (entity/relation/event/sentiment extraction and their unification), and supervised, low-resource, and few-shot settings. Experiment results show that UIE achieves significant improvements in all settings. On supervised settings, UIE achieved 1.42% F1 scores improvements over the state-of-the-art, task-specialized architectures on all datasets. On few-shot and low-resource settings, UIE exhibits strong on-demand adaptation ability: it outperforms baselines dramatically by a large margin. These results verified the effectiveness, universality, and transferability of UIE across different IE tasks, settings, and scenarios.

The main contributions of this paper are:

1) We propose UIE, a unified text-to-structure generation architecture that can universally model different IE tasks, adaptively generate targeted structures, and collaboratively learn general IE abilities from different knowledge sources.

2) We design a unified structure generation network, which encodes heterogeneous IE structures into a uniform representation via a structural extraction language, and controls the UIE model which to spot, which to associate, and which to generate via structural schema instructor mechanism.

3) We pre-train a large-scale text-to-structure generation model via a unified pre-training algorithm. To the best of our knowledge, this is the first text-to-structure pre-trained extraction model, which can benefit future IE studies.

2 Unified Structure Generation for Universal Information Extraction

Information extraction tasks can be formulated as text-to-structure problems, where different IE tasks correspond to different structures. This paper aims to uniformly model the text-to-structure transformations of different IE tasks via a single framework, i.e., different structure transformations will share the same underlying operations and different transformation abilities in a universal model. Formally, given a specific pre-defined schema s and texts x, a universal IE model needs to generate a structure that contains the desirable structural information in the text x indicated by the schema s.

Generally, there are two main challenges here. Firstly, due to the diversity of IE tasks, there are many different target structures to extract, e.g., entity, relation, event, etc. Secondly, IE tasks are often demand-specific which are defined using different schemas, therefore we need to adaptively control the extraction process.

Figure 2: Illustrations of structured extraction language.

In this section, we describe how to jointly formulate, learn, and conduct various IE tasks in a unified text-to-structure generation architecture, named **UIE**. Specifically, we first design structured extraction language (SEL) to uniformly encode heterogeneous extraction structures, i.e., encode entity, relation, event into a unified representation. Then we describe structural schema instructor (SSI), a schema-based prompt mechanism that controls the UIE model which to spot, which to associate, and which to generate for different extraction settings. The details are as follows.

2.1 Structured Extraction Language for Uniform Structure Encoding

This section describes how to encode heterogeneous IE structures into a uniform representation. Based on the above discussions, IE structure generation can be decomposed into two atomic operations:

1. **Spotting** indicates locating target information pieces from the sentence, e.g., the entity and the trigger word in the event.
2. **Associating** indicates connecting different information pieces based on the desirable associations, e.g., the relation between entity pair or the role between event and its argument.

Then different IE structures can be represented as a combination of atomic structure generation operations.

Concretely, we design a unified structured extraction language (SEL), which encodes different IE structures via the spotting-associating structure. As shown in Figure 2a, each SEL expression contains three types of semantic units: 1) SPOTNAME represents there is a specific information piece with the type of spot name existing in the source text; 2) ASSONAME indicates there exists a specific information piece in the source text that is with the AssoName association to its upper-level Spotted information in the structure; 3) INFOSPAN represents the text span corresponding to the specific spotting or associating information piece in the source text. Furthermore, ":" in the SEL indicates the mapping from InfoSpan to its spotting or associating names, and the two structure indicators "(" and ")" are used to form the hierarchical structure between the extracted information.

Using SEL, Figure 2b shows how to represent entity, relation, and event structures. There are three entities and each entity is represented as a spotting structure such as "person:Steve", "organization:Apple", and "time:1997"; one relation which is represented as an association structure between "Steve" and "Apple" with association name work for; and one event which is represented as an association structure, where the trigger is a spotting structure "start-position:became", and its arguments are associated with the trigger: Steve as employee, Apple as employer, 1997 as time.

We can see that, SEL have the advantages that: 1) uniformly encodes varying IE structures, therefore different IE tasks can be modeled as the same text-to-structure generation process; 2) efficiently represents all extraction results of a sentence in the same structure, thus can perform joint extraction naturally; 3) the output structure of generation is very compact, which greatly reduce the complexity of decoding.

For example, the two different tasks entity recognition and event detection can be revisited using the same "(SpotName: InfoSpan)" grammar. While both relation extraction and event extraction can be formulated using the grammar "(SpotName: InfoSpan (AssoName: InfoSpan), ...)", even they are with totally different binary "entity-relation-entity" and N-ary "event-arguments" structures. Such a unified structured extraction language enables UIE to learn from and adapt to different IE tasks without designing task-specialized architectures, because these IE tasks are all universally formulated as the transformation from texts to SEL representations.

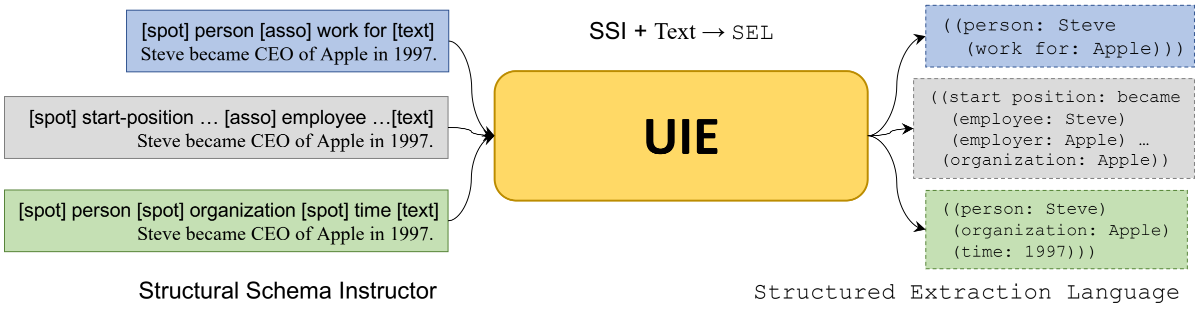

Figure 3: The overall framework of UIE.

2.2 Structural Schema Instructor for Controllable IE Structure Generation

Using SEL, UIE can uniformly generate different IE structures. However, because different IE tasks have different schemas, one challenge here is how to adaptively control which information we want to generate during extraction. For example, given a sentence "Steve became CEO of Apple in 1997.", an entity recognition system will generate "((person: Steve) (organization: Apple) (Time: 1997))", and an event extraction system will generate "(start position: became (employee: Steve) (employer: Apple))". To this end, we propose structural schema instructor (SSI), a schema-based prompt mechanism that controls which kinds of information need to be spotted and associated.

Figure 3 shows the overall framework of UIE. Formally, UIE takes the given structural schema instructor (s) and the text sequence (x) as input, and generates the linearized SEL (y) which contains the extracted information from x based on schema s:

$$y = \text{UIE}(s \oplus x) \tag{1}$$

where $x = [x_1, ..., x_{|x|}]$ is the text sequence, $s = [s_1, ..., s_{|s|}]$ is the structural schema instructor, and $y = [y_1, ..., y_{|y|}]$ is a SEL sequence that can be easily converted into the extracted information record.

2.2.1 Structural Schema Instructor

To describe the extraction target of a task, the structural schema instructor constructs a schema-based prompt and uses it as a prefix during generation.

Specifically, corresponding to the spotting-association structure, the structural schema instructor contains three types of token segments: 1) SPOTNAME: the targeted spotting name in the specific information extraction task, such as "person" in the NER task; 2) ASSONAME: the targeted association name, such as "work for" in the relation extraction task; 3) Special Symbols ([spot], [asso], [text]) which are added before each SPOTNAME, ASSONAME, and input text sequence. All tokens in SSI are concatenated and put before the original text sequences. As shown in Figure 3, the entire input for UIE is in the form of:

$$\begin{aligned} s \oplus x &= [s_1, s_2, ..., s_{|s|}, x_1, x_2, ..., x_{|x|}] \\ &= [\text{[spot]}, ...\text{[spot]}..., \\ &\quad\ \ \text{[asso]}, ..., \text{[asso]}..., \\ &\quad\ \ \text{[text]}, x_1, x_2, ..., x_{|x|}] \end{aligned} \tag{2}$$

For example, the SSI "[spot] person [spot] company [asso] work for [text]" indicates extracting records of the relation schema "the person works for the company" from the sentence. Given the SSI s, UIE first encodes the text x, then generates the target record y in linearized SEL using an encoder-decoder-style architecture.

We found that the schema-based prompt can: 1) effectively guide the SEL generation of UIE, so that the general IE ability can be transferred to new IE tasks; 2) adaptively control which to spot, which to associate, and which to generate, so that semantic knowledge across different labels and tasks can be better shared.

2.2.2 Structure Generation with UIE

Given SSI s and text x as input, UIE extracts targeted information by generating a linearized SEL. We formulate this text-to-SEL generation process using an encoder-decoder-style architecture. Given the raw text sequence x and the schema instructor s, UIE first compute the hidden representation $\mathbf{H} = [\mathbf{s}_1, ..., \mathbf{s}_{|s|}, \mathbf{x}_1, ..., \mathbf{x}_{|x|}]$ of each token:

$$\mathbf{H} = \text{Encoder}(s_1, ..., s_{|s|}, x_1, ..., x_{|x|}) \tag{3}$$

where Encoder$(\cdot)$ is a Transformer encoder. Then UIE will decode the input text into a linearized SEL in an auto-regressive style. At the step i of decoding, UIE generates the i-th token y_i in the SEL sequence and the decoder state $\mathbf{h}_i^d$ as following:

$$y_i, \mathbf{h}_i^d = \text{Decoder}([\mathbf{H}; \mathbf{h}_1^d, ..., \mathbf{h}_{i-1}^d]) \quad (4)$$

Decoder$(\cdot)$ is a transformer decoder, which predicts the conditional probability $p(y_i|y_{<i}, x, s)$ of token y_i. Finally, Decoder$(\cdot)$ finishes prediction when outputting the end symbol <eos>, then we convert the predicted SEL expression into the extracted information record.

Compared with previous IE studies which treat labels as specific symbols, the text-to-structure generation paradigm treats labels as natural language tokens. By verbalizing and generating labels and structures, our method can effectively transfer knowledge from pre-trained language models such as BART (Lewis et al., 2020), T5 (Raffel et al., 2020), and related tasks can easily share knowledge because their labels have similar semantics (e.g., *location* and *place*) and share common label-text associations (e.g., *victim* for different event types).

3 Pre-training and Fine-tuning for UIE

In this section, we describe: 1) how to pre-train a large-scale UIE model which captures common IE abilities for different IE tasks; 2) how to adapt UIE to different IE tasks in different settings via quick fine-tuning. Specifically, we first collect several large-scale datasets from the Web, including structured (e.g., knowledge bases), unstructured (e.g., raw texts), and parallel (e.g., Wikipedia-Wikidata links) data, then we uniformly pre-train our UIE model on these heterogeneous datasets. Finally, we adapt the pre-trained UIE model to the specific downstream IE tasks via on-demand fine-tuning. We found that the pre-trained UIE model provides a solid foundation for capturing, sharing, and transferring knowledge between different IE tasks, and new IE tasks can be effectively solved because UIE learns general IE ability.

3.1 Pre-training Corpus Construction

UIE needs to encode the text, map text to structure, and decode valid structure. Therefore, we collect a large-scale pre-training corpus from easily accessible web data sources (more details are in the appendix):

$\mathcal{D}_{\text{pair}}$ is the text-structure parallel data, where each instance is a parallel pair (token sequence x, structured record y). We collect large-scale parallel text-structure pairs by aligning Wikidata with English Wikipedia. $\mathcal{D}_{\text{pair}}$ is used to pre-train the text-to-structure transformation ability of UIE.

$\mathcal{D}_{\text{record}}$ is the structure dataset where each instance is structured record y. We collect structured records from ConceptNet (Speer et al., 2017) and Wikidata. $\mathcal{D}_{\text{record}}$ is used to pre-train the structure decoding ability of UIE.

$\mathcal{D}_{\text{text}}$ is the unstructured text dataset, and we use all plain texts in English Wikipedia. $\mathcal{D}_{\text{text}}$ is used to pre-train the semantic encoding ability of UIE.

3.2 Pre-training

We pre-train UIE using three sequence generation tasks with above mentioned pre-training datasets.

Text-to-Structure Pre-training using $\mathcal{D}_{\text{pair}}$. To capture the fundamental text-to-structure mapping ability, we pre-train UIE using $\mathcal{D}_{\text{pair}} = \{(x, y)\}$. Specifically, for each parallel pair (x, y), we extract the spot type s_{s+} and the associating type s_{a+} in the record y as the positive schema $s_+ = s_{\text{s+}} \cup s_{\text{a+}}$. However, we found that if we only feed UIE with a positive schema, it will only simply remember the triplet in the pre-training data. To learn general mapping ability, we also automatically construct negative schemas for each pair, i.e., we first sample negative spots $s_{\text{s-}}$ and negative association set $s_{\text{a-}}$, then concatenate meta-schema $s_{\text{meta}} = s_+ \cup s_{\text{s-}} \cup s_{\text{a-}}$, and construct the final extraction target. For example, *person* and *work for* is the positive schema in the record "((person: Steve (work for: Apple)))", and we sample *vehicle* and *located in* as the negative schema to construct meta-schema. Finally, the objective of text-to-structure pre-training is:

$$\mathcal{L}_{\text{Pair}} = \sum_{(x,y)\in\mathcal{D}_{\text{pair}}} - \log p(y|x, s_{meta}; \theta_e, \theta_d) \quad (5)$$

where θ_e and θ_d are the parameter of encoder and decoder, respectively.

Structure Generation Pre-training with $\mathcal{D}_{\text{record}}$. To pre-train the ability of generating valid structures defined by SEL and schemas, we pre-train UIE on $\mathcal{D}_{\text{record}}$. We pre-train UIE decoder as an structured language model, where each record in $\mathcal{D}_{\text{record}}$ is an expression of SEL:

$$\mathcal{L}_{\text{Record}} = \sum_{y\in\mathcal{D}_{\text{record}}} - \log p(y_i|y_{<i}; \theta_d) \quad (6)$$

By pre-training for structure generation, the decoder can capture the regularity of SEL and the interactions between different labels.

Retrofitting Semantic Representation using $\mathcal{D}_{\text{text}}$. During text-to-structure pre-training, we continually pre-train UIE also with the masked language model tasks (Raffel et al., 2020) on $\mathcal{D}_{\text{text}}$ to retrofit semantic representations of UIE. Specifically, we add span corruption based mask language modeling objective in the pre-training stage:

$$\mathcal{L}_{\text{Text}} = \sum_{x \in \mathcal{D}_{\text{text}}} - \log p(x''|x'; \theta_e, \theta_d) \qquad (7)$$

where x' is the corrupted source text and x'' is corrupted target spans. We found this pre-training can effectively alleviate the catastrophic forgetting of token semantics especially on SPOTNAME and ASSONAME tokens.

Final Pre-training Criteria. We initialize UIE-base and UIE-large with T5-v1.1-base and T5-v1.1-large (Raffel et al., 2020), and the model architectures are shown in Table 7. The final objective is the combine of the above tasks:

$$\mathcal{L} = \mathcal{L}_{\text{Pair}} + \mathcal{L}_{\text{Record}} + \mathcal{L}_{\text{Text}} \qquad (8)$$

For implementation, we uniformly represent all pre-training data as triplets. For text data (x) in $\mathcal{D}_{\text{text}}$, we build a triplet (None, x', x'') where x' is the corrupted source text and x'' is corrupted spans. For text-record data (x, y) in $\mathcal{D}_{\text{pair}}$, we construct ($s$, x, y) by sampling the meta-schema s for each text-record pair. For record data (y) in $\mathcal{D}_{\text{record}}$, we take (None, None, y) as the input triplet. We randomly pack instances for different tasks in one batch, and details are shown in Algorithm 1 in the appendix.

3.3 On-Demand Fine-tuning

Given the pre-trained UIE model, we can quickly adapt it to different IE tasks and settings through model fine-tuning. Given a labeled corpus $\mathcal{D}_{\text{task}} = \{(s, x, y)\}$, we fine-tune the UIE model using teacher-forcing cross-entropy loss:

$$\mathcal{L}_{\text{FT}} = \sum_{(s,x,y) \in \mathcal{D}_{\text{Task}}} - \log p(y|x, s; \theta_e, \theta_d) \qquad (9)$$

To alleviate the exposure bias (Ranzato et al., 2016; Zhang et al., 2020) of the auto-regressive model during decoding, we also design a ***Rejection Mechanism*** for effective fine-tuning. Specifically, given an instance (s, x, y), we first encode y using SEL language, then we randomly insert several [NULL] unit with negative SPOTNAME and ASSONAME: (SPOTNAME, [NULL]) and (ASSONAME, [NULL]) into the ground-truth SEL with the probability of p_ϵ. For example, in Table 1, *facility* is the negative spot in the schema prompt, i.e., there is no *facility* entity in the sentence "Steve became CEO of Apple in 1997". Therefore, we randomly inject the noise of "(facility: [NULL])" into the target record during model learning. In this way, the UIE can effectively learn to reject misleading generation by generating [NULL] token.

SSI Text	<spot> person ... <spot> facility <asso> ... <text> Steve became CEO of Apple in 1997.
SEL + RM	((person: Steve (work for: Apple)) (start-position: ... ((person: Steve (work for: Apple)) *(facility:* [NULL]*)* ...

Table 1: An example of rejection mechanism (RM), here "(facility: [NULL])" is the injected rejection noise during learning stage, and the [NULL]-valued span will be ignored during inference stage.

4 Experiments

To verify the effectiveness of UIE, we conducted experiments on different IE tasks and settings.

4.1 Experimental Settings

Datasets. We conduct experiments on 13 IE benchmarks across 4 well-representative IE tasks (including entity extraction, relation extraction, event extraction, structured sentiment extraction) and their combinations (e.g., joint entity-relation extraction). The used datasets includes ACE04 (Mitchell et al., 2005), ACE05 (Walker et al., 2006); CoNLL03 (Tjong Kim Sang and De Meulder, 2003), CoNLL04 (Roth and Yih, 2004), SciERC (Luan et al., 2018), NYT (Riedel et al., 2010), CASIE (Satyapanich et al., 2020), SemEval-14 (Pontiki et al., 2014), SemEval-15 (Pontiki et al., 2015), SemEval-16 (Pontiki et al., 2016), see Table 8 for detail. We employ the end-to-end setting for all extraction tasks, which takes the raw text as input and directly generates the target structure.

Evaluation. We use the same evaluation metrics as all previous methods, and details of metrics are shown in the appendix. For each fine-tuning experiment, we report the average performance on 3 random seeds. Because UIE only generates text spans, we map spans to offsets by finding the first matched offsets that are not already matched in the same SEL hierarchical level (details in appendix). We found this simple heuristic rule is very effective (<0.5% error offsets) and more complicated mapping approaches (such as attention-weight guided span mapping) are left as the future work.

Table 2: Overall results of UIE-large on different datasets. SEL refers to UIE without pre-training by directly using T5-v1.1-large as the backbone. Because NYT overlaps with pre-training data, we didn't conduct UIE on NYT for fair comparsion. More results of UIE-base and the details of evaluation metric are shown in the appendix.

4.2 Experiments on Supervised Settings

UIE provides a universal backbone for IE tasks. This section assesses the UIE performance in supervised settings. We compare UIE with the state-of-the-art, task-specific supervised models. For a fair comparison, we only compare the state-of-the-art without leveraging additional dataset-specific knowledge or larger-scale contexts. These extensions are good complementary of UIE, and can be left for further improvement. Table 2 shows the performance of UIE on the 13 IE datasets across 4 tasks. We can observe that: 1) *By modeling IE as text-to-structure generation and encoding with an effective SEL language, UIE provides an effective universal architecture for IE.* The UIE model achieves state-of-the-art performance on nearly all datasets and tasks, even without pre-training (SEL). 2) *The large-scale pre-trained model provides a solid foundation for universal IE.* Compared with baselines, the pre-trained model achieves the performance of the state-of-the-art in most datasets and improves 1.42% F1 on average. 3) *By universally modeling IE tasks and pre-training using large-scale datasets, UIE can effectively capture, share, and transfer IE abilities.* Pre-training improves all tasks at the same time, especially events and sentiment knowledge rarely appear in the pre-train dataset. It proves that SEL is a unified and cross-task transferable structured representation for IE, which allows UIE to share learned capabilities and information across different and various information extraction tasks.

4.3 Experiments on Low-resource Settings

To verify the quick adaptation ability of UIE, we conducted low-resource experiments on six different partitions of the original training sets (1/5/10-shot, 1/5/10% ratio) across 4 tasks. For the few-shot experiments, we sample 1/5/10 sentences for each entity/relation/event/sentiment type in the training set. To avoid the influence of random sampling, we repeated each experiment 10 times with different samples and reported their averaged results as previous works (Huang et al., 2021).

We compare UIE with the following pre-trained model: 1) **T5-v1.1-base** is an initial model of UIE-base; 2) **Fine-tuned T5-base** is fine-tuned with sequence generation tasks such as summarization, which have been shown effective in many low-resource NLP tasks (Paolini et al., 2021); 3) **UIE-base w/o SSI** is the distant supervised version of UIE without SSI in the pre-training stage, which is used to verify the necessity of SSI when adapting UIE in low-resource settings. Table 3 shows the performance of 4 IE tasks under 6 low-resource settings. We observe that: 1) *By guiding the generation using schema-based prompts, SSI is an effective way for adaptively controlling which to ex-*

w/o rejection		58.00	45.04	50.38

Table 5: Experiment results of 10-shot setting on the CoNLL 03 development set.

To investigate the effect of different pre-training tasks, Table 4 shows ablation experiment results of UIE-base on four downstream tasks. We can see that: (1) *The pre-training of SEL ($\mathcal{L}_{Record}$) and sequence-to-structure mapping ($\mathcal{L}_{Pair}$) is crucial for UIE, and such a structure generation pre-training is especially useful for small-scale datasets.* In small datasets CoNLL04 and 16res, adding structure generation pre-training (from T5-v1.1-base to UIE-base w/o $\mathcal{L}_{\text{Text}}$), the performance significantly increases from 72.12 to 75.70 and 72.03 to 74.28. (2) *Retrofitting semantic using the mask language model task ($\mathcal{L}_{Text}$) is more important for the complex extraction task.* In the tasks with more semantic types such as event extraction (33 types), the performance drops significantly after removing the $\mathcal{L}_{\text{Text}}$ task, e.g., 72.63→70.89 and

57.27→54.16. (3) *The mapping pre-training with $\mathcal{L}_{Pair}$ enables the model to learn the ability of extraction.* After ablating $\mathcal{L}_{\text{Pair}}$, the extraction ability of UIE is significantly decreased, i.e., the performance on the relation (-0.90), event (-1.43/-1.48), and sentiment (-0.46) tasks all see large decline.

4.5 Effects of Rejection Noise

This section investigates the effect of the proposed rejection noise. Table 5 shows the results of the different pre-trained models on the development set of CoNLL 03 under the 10-shot setting. The mis-generated label has a negative influence on the precision of the proposed generation method leading to a large number of error extraction results. The proposed rejection noise is useful for the generation method, which leads to improvements of 13.16 precision (P) on average.

5 Related Work

Building and pre-training universal models of NLP tasks has attracted a lot of attention in recent years, e.g., contextualized representation (Devlin et al., 2019; Liu et al., 2019), text generation (Lewis et al., 2020; Raffel et al., 2020), multi-modal (Li et al., 2021b; Cho et al., 2021), and multi-lingual (Conneau et al., 2020; Xue et al., 2021). This paper proposes and pre-trains the first universal model for information extraction.

IE is a long-researched area and many classical neural architectures have been proposed, such as sequence tagging (Lample et al., 2016; Zheng et al., 2017; Lin et al., 2019), span classification (Sohrab and Miwa, 2018; Lin et al., 2018; Wadden et al., 2019), and MRC (Levy et al., 2017; Li et al., 2020; Du and Cardie, 2020). And several task-specific pre-training techniques are proposed on these architectures (Mengge et al., 2020; Wang et al., 2021b; Qin et al., 2021). More relevant to our work are generation-based IE methods, which generate text spans via tagging (Straková et al., 2019; Ma et al., 2019), index pointer (Ren et al., 2021; Yan et al., 2021b) or copy mechanism (Zeng et al., 2018), and these methods usually employ specific classifiers to represent labels. The generation can be enhanced using label templates (Li et al., 2021a; Liu et al., 2021; Cui et al., 2021), schema (Lu et al., 2021; Ahmad et al., 2021), and augmented language methods (Paolini et al., 2021).

Compared with previous IE studies which focus on developing more effective task-specialized models, this paper aims to universally model various IE tasks in an unified text-to-structure framework, which can greatly benefit the rapid development, effective knowledge sharing, and quick adaptation of IE systems.

6 Conclusion

In this paper, we propose a unified text-to-structure generation framework – UIE, which can universally model different IE tasks, adaptively generate targeted structures, and unifiedly learn general IE abilities from different knowledge sources. Experimental results show that UIE achieves very competitive performance in both supervised and low-resource settings, which verified its universality, effectiveness, and transferability. A large-scale pre-trained text-to-structure model is also released, which will benefit future studies. For future work, we want to extend UIE to KB-aware IE tasks such as entity linking (Cao et al., 2021), and document-aware IE tasks such as co-reference (Lee et al., 2017; Lu et al., 2022).

Acknowledgements

We sincerely thank the reviewers for their insightful comments and valuable suggestions. This research work is supported by the National Natural Science Foundation of China under Grants no. U1936207, 62122077 and 62106251, the Project of the Chinese Language Committee under Grant no. YB2003C002.

A Experiment Details

This section describes the details of experiments, including pre-training and fine-tuning on downstream tasks.

A.1 Pre-training Details

Data Construction We use the 20210401 version of Wikipedia[2] and Wikidata[3] dump and ConceptNet[4] to construct the pre-train dataset.

For Wikidata and Wikipedia, we use them to collect the tuples $\mathcal{T}_w = \{< T_h, e_h, r, e_t, X >\}$, where T_h is head entity type, e_h is head entity, r is relation, e_t is tail entity, X is sentence, and the $\mathcal{T}_w$ can be used to construct $\mathcal{D}_{\text{pair}}$, $\mathcal{D}_{\text{record}}$ and $\mathcal{D}_{\text{text}}$. Firstly, we construct entity type dictionary $\mathcal{L}$ and relation dictionary $\mathcal{P}$ from Wikidata. Wikidata has more than 40M entity items and each item has its corresponding properties which indicate the association between entities. For type dictionary $\mathcal{L}$, we regard each item as an entity, use the "instance of" and "subclass of" property values as its corresponding entity types and consider other properties as the relation of the entity with others. To learn general knowledge, all entity types will be retained except those whose instances are < 5. For the type whose name is longer than 3 tokens, we use its headwords as the final type for simplicity, e.g.,"state award of the Republic of Moldova" is converted to "state award". For relation dictionary $\mathcal{P}$, Wikidata has more than 9K kinds of properties[5], we filter out the properties of external-id, URL, and math types. In this way, we obtain a collection of 31K types and retained 1535 properties which can serve as a solid foundation for universal IE. Secondly, we collect the mentions of each entity by using its anchor texts in Wikipedia and the top 3 frequent noun phrase occurrences of its entry page (Li et al., 2010). Then for each mention, we identify its entity types by linking it to its Wikidata item's types. For each Wikipedia page, we split the text into sentences[6] and filter out sentences that have no entities. Thirdly, we regard each entity as a head entity and find the associated entities according to its properties. The associated entity will set as as tail entity, and the property value will set as association type. If a head entity has no type, T_h will be blank or has no associated tail entity, r and e_t will be blank. To this end, given a sentence, we can construct instances based on the collected tuples $\mathcal{T}_w$ by setting e_h and e_t as INFOSPAN, and assigning T_h as SPOTNAME, r as ASSONAME. Finally, from Wikipedia and Wikidata, we construct $\mathcal{D}_{\text{pair}}$, $\mathcal{D}_{\text{record}}$ and $\mathcal{D}_{\text{text}}$ with 65M instances, respectively. And we keep 50K as the development dataset.

Algorithm 1 The pre-training process of UIE in a Python-like style.

```
# The training details of UIE
function pretraining_process
    for $step$ in $all\_steps$ do
        $batch = []$
        # load $n_{\text{text}}$ unstructured text samples
        $texts = get\_data(\mathcal{D}_{\text{text}},\ n_{\text{text}})$
        # construct corrupted source text $x'$ and
        # corrupted spans $x''$ for each text sample
        for $x$ in $texts$ do
            $x', x'' = span\_corrupt(x)$
            $batch.extend((\text{None}, x', x''))$
        end for
        # load $n_{\text{record}}$ structured record samples
        $records = get\_data(\mathcal{D}_{\text{record}},\ n_{\text{record}})$
        for $y$ in $records$ do
            $batch.extend((\text{None}, \text{None}, y))$
        end for
        # load $n_{\text{pair}}$ text-record parallel pairs
        $text\_record\_pairs = get\_data(\mathcal{D}_{\text{pair}},\ n_{\text{pair}})$
        # construct meta-schema $s_{\text{meta}}$
        # for each text-record pair $(x,\ y)$
        for $(x, y)$ in $text\_record\_pairs$ do
            $s = \textbf{meta\_schema\_sample}(y)$
            $batch.extend((s, x, y))$
        end for
        # compute loss and backward
        $\mathcal{L}_{\text{Pair}},\ \mathcal{L}_{\text{Record}},\ \mathcal{L}_{\text{Text}} = \text{UIE}(batch)$
        $loss = \mathcal{L}_{\text{Pair}} + \mathcal{L}_{\text{Record}} + \mathcal{L}_{\text{Text}}$
        $loss.backward()$
    end for
end function

# The meta sample of UIE
function meta_schema_sample(y)
    # get positive spots and associations
    # in the record $y$
    $s_{\text{s+}}, s_{\text{a+}} = get\_schema\_from\_record(y)$
    # sample negative spots
    $s_{\text{s-}} = sample\_negative\_spot(s_{+})$
    # sample negative associations
    $s_{\text{a-}} = sample\_negative\_association(s_{+})$
    $return\ s_{\text{s+}} \cup s_{\text{s-}} \cup s_{\text{a+}} \cup s_{\text{a-}}$
end function
```

To add common sense knowledge to structured extraction language (SEL), we extract the tuples $\mathcal{T}_c$ from ConceptNet. ConceptNet contains 48 associations and has no context or entity types. So we leave the T_h, T_t X blank and finally construct 1M instances.

Table 8: Detailed datasets statistics. |*| indicates the number of categories, and # is the number of sentences in the specific subset. We take sentiment types as special relation type: positive, negative, and neutral; and each sentiment triplet holds a aspect and a opinion.

Training Details We first initialize UIE-base and UIE-large with T5-v1.1-base and T5-v1.1-large checkpoints (Raffel et al., 2020), and the model architectures are shown in Table 7. We employ Adam optimizer (Kingma and Ba, 2015) as the optimizer with learning rate=1e-4, and use linear scheduling with a warming up proportion 6%. For negative spots and associations in the $\mathcal{L}_{\text{Pair}}$, we randomly select negative spots and associations up to 10 for each instance, respectively. For $\mathcal{L}_{\text{Text}}$, we set the corruption rate to 15% and the average corrupting span length to 3, following Raffel et al. (2020). We truncate the concatenated overall length of schema prompt s and raw text x, as well as the length of SEL expression y, together to 128 during pre-training. We train our base model and large model for both 500K steps with batch size 512 on 8 NVIDIA A100 GPUs.

The detailed pre-training process in a python-like style is shown in Algorithm 1. In each batch of pre-training processes for UIE, we construct a batch of triplets (s, x, y) containing text-record pairs, text instances, and record instances. In practice, since 8 GPUs could only run the large model with an overall batch of 128 (batch=16 on each GPU), we update the model parameters after accumulating 4 gradients.

A.2 Details of Downstream Tasks

We conduct downstream tasks on 4 IE tasks, 13 datasets, and the detailed statistic of each dataset is shown in Table 8.

Entity We conduct entity extraction experiments on three entity datasets: ACE04[7] (Mitchell et al., 2005), ACE05-Ent[8] (Walker et al., 2006), and CoNLL03 (Tjong Kim Sang and De Meulder, 2003). For nested entity extraction datasets ACE04 and ACE05-Ent, we follow the pre-processing steps and data split of previous works (Li et al., 2020).

Relation We conduct experiments on four wide-used end-to-end relation extraction datasets across several languages and domains: ACE05-Rel (Walker et al., 2006), CoNLL04[9] (Roth and Yih, 2004), NYT[10] (Riedel et al., 2010), and SciERC[11] (Luan et al., 2018). We follow the preprocessing

steps and data split of previous works (Taillé et al., 2020; Yu et al., 2020; Wadden et al., 2019).

Event For ACE05-Evt, we follow the same types, data splits, and pre-processing steps as Lin et al. (2020). For CASIE (Satyapanich et al., 2020), we first remove three incomplete annotated documents (999, 10001, 10002), then split the remaining documents into three sets: train/val/test=697/100/200 according to the time order of each document. We employ the state-of-the-art generation-based event extraction method TEXT2EVENT (Lu et al., 2021) as the comparable state-of-the-art system.

Sentiment We conduct sentiment extraction experiments on the sentiment triplet extraction (Xu et al., 2020) of SemEval 14/15/16 aspect sentiment analysis datasets. We employ the pre-processing datasets of the previous work (Yan et al., 2021a)[12].

Evaluation We use span-based offset Micro-F1 as the primary metric to evaluate the model:

- **Entity**: an entity mention is correct if its offsets and type match a reference entity.
- **Relation Strict**: relation with strict match, a relation is correct if its relation type is correct and the offsets and entity types of the related entity mentions are correct.
- **Relation Triplet**: relation with boundary match, a relation is correct if its relation type is correct and the string of the subject/object are correct.
- **Event Trigger**: an event trigger is correct if its offsets and event type matches a reference trigger.
- **Event Argument**: an event argument is correct if its offsets, role type, and event type match a reference argument mention.
- **Sentiment Triplet**: a correct triplet requires the offsets boundary of the target, the offsets boundary of the opinion span, and the target sentiment polarity to be all correct at the same time.

To make a fair comparison with baseline systems, we mapped the generated string-level extraction results to offset-level for model evaluation. In detail, we reconstructed the offset of predicted entity/trigger mentions by finding the matched utterance in the input sequence one by one. For argument mentions in relation and event tasks, we found the nearest matched utterance to the predicted entity/trigger mention as the predicted offset. This simple heuristic offset strategy achieves high accuracy. Compared to the string level evaluation, the error rate of the reported offset level evaluation is less than 0.5%. More complicated mapping approaches are left as future work.

Table 6 shows the detailed hyper-parameters for downstream tasks.

A.3 Comparison of UIE-base

This section introduces detailed experiment results of UIE-base.

Table 9 shows the performance of UIE-base and the state-of-the-art systems on the four aspect-based sentiment analysis datasets. As shown in Table 9, the proposed SEL and SSI also have strong portability to sentiment triplets extraction, which achieves the competitive performance with the state-of-the-art with task-specific architectures. With the unified pre-training, UIE-base achieves an improvement of 3.24 on average over T5-v1.1-base across four datasets. This verifies the proposed unified pre-training algorithms can learn general IE ability even the sentiment knowledge is rarely in the pre-training stage.

Table 10 shows the performance of SEL-SSI with the T5-v1.1-base for NYT. Due to the high overlapping of NYT and pre-trained data, we didn't conduct the experiment of UIE on NYT. Even without pre-training, SSI + SEL still achieved the state-of-the-art performance on NYT. This is because of the flexible generation architecture and the universal SEL expression, UIE can naturally handle entity overlap problems.

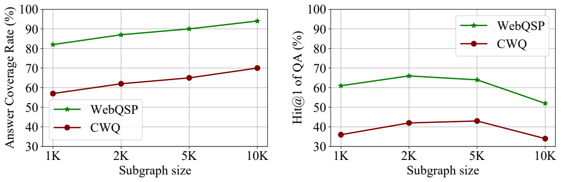
Abstract

Recent works on knowledge base question answering (KBQA) retrieve subgraphs for easier reasoning. The desired subgraph is crucial as a small one may exclude the answer but a large one might introduce more noises. However, the existing retrieval is either heuristic or interwoven with the reasoning, causing reasoning on the partial subgraphs, which increases the reasoning bias when the intermediate supervision is missing. This paper proposes a trainable subgraph retriever (SR) decoupled from the subsequent reasoning process, which enables a plug-and-play framework to enhance any subgraph-oriented KBQA model. Extensive experiments demonstrate SR achieves significantly better retrieval and QA performance than existing retrieval methods. Via weakly supervised pre-training as well as the end-to-end fine-tuning, SR achieves new state-of-the-art performance when combined with NSM (He et al., 2021), a subgraph-oriented reasoner, for embedding-based KBQA methods. Codes and datasets are available online[1].

1 Introduction

Knowledge Base Question Answering (KBQA) (Zhang et al., 2021) aims to seek answers to factoid questions from structured KBs such as Freebase, Wikidata, and DBPedia. KBQA has attracted a lot of attention, as the logically organized entities and their relations are beneficial for inferring the answer. Semantic parsing-based (SP-based) methods (Das et al., 2021; Lan and Jiang, 2020; Sun et al., 2020) and embedding-based methods (He et al., 2021; Sun et al., 2018, 2019) are two mainstream methods for addressing KBQA. The former ones heavily rely on the expensive annotation of the intermediate logic form such as SPARQL. Instead of parsing the questions, the later ones directly represent and rank entities based on their relevance to input questions. Among them, the models which first retrieve a question-relevant subgraph and then perform reasoning on it (He et al., 2021; Sun et al., 2018, 2019) reduce the reasoning space, showing superiority compared with reasoning on the whole KB (Chen et al., 2019a; Saxena et al., 2020; Xu et al., 2019) (Cf. Table 2 for empirical proof).



(a) Answer Coverage Rate (b) Hits@1 of QA

Figure 1: The impact of subgraph size on (a) answer coverage rate and (b) QA performance (Hits@1) of NSM (He et al., 2021) on WebQSP (Yih et al., 2016) and CWQ (Talmor and Berant, 2018).

Subgraph retrieval is crucial to the overall QA performance, as a small subgraph is highly likely to exclude the answer but a large one might introduce noises that affect the QA performance. Figure 1(a) presents the answer coverage rates of the subgraphs with different sizes on two widely-used KBQA datasets, WebQSP (Yih et al., 2016) and CWQ (Talmor and Berant, 2018). We extract the full multi-hop topic-centric subgraph and control the graph size by the personalized pagerank (PPR) (Haveliwala, 2003) scores of entities. We also present the QA performance (Hits@1) of NSM (He et al., 2021), a state-of-the-art embedding-based model, under the same sizes of the subgraphs in Figure 1(b). It is observed that although larger subgraphs are more likely to cover the answer, the QA performance drops dramatically when the subgraph includes more than 5,000 nodes. Moreover, it is inefficient to extract such a full multi-hop subgraph for online QA. The results show that such heuris-

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 5773 - 5784

tic retrieval is far from optimal. To improve the retrieval performance, PullNet (Sun et al., 2019) proposes a trainable retriever, but the retrieving and the reasoning processes are intertwined. At each step, a LSTM-based retriever selects new relations relevant to the question, and a GNN-based reasoner determines which tail entities of the new relations should be expanded into the subgraph. As a result, the inference as well as the training of the reasoner needs to be performed on the intermediate partial subgraph. Since the intermediate supervision is usually unobserved, reasoning on partial subgraphs increases the bias which will eventually affect the answer reasoning on the final entire subgraph.

This paper proposes a subgraph retrieval enhanced model for KBQA, which devises a trainable subgraph retriever (SR) decoupled from the subsequent reasoner. SR is devised as an efficient dual-encoder that can expand paths to induce the subgraph and can stop the expansion automatically. After that, any subgraph-oriented reasoner such as GRAFT-Net (Sun et al., 2018) or NSM (He et al., 2021) can be used to delicately deduce the answers from the subgraph. Such separable retrieval and reasoning ensure the reasoning only on the final entire instead of the intermediate partial subgraphs, which enables a plug-and-play framework to enhance any subgraph-oriented reasoner.

We systematically investigate the advantages of various training strategies for SR, including weakly supervised/unsupervised pre-training and end-to-end fine-tuning with the reasoner. Instead of the ground truth paths, we extract the shortest paths from a topic entity in the question to an answer as the weak supervision signals for pre-training. When the QA pairs themselves are also scarce, we construct pseudo (question, answer, path) labels for unsupervised pre-training. To further teach the retriever by the final QA performance, we enable the end-to-end fine-tuning, which injects the likelihood of the answer conditioned on a subgraph as the feedback from the reasoner into the prior distribution of the subgraph to update the retriever.

We conduct extensive experiments on WebQSP and CWQ. The results reveal four major advantages: (1) SR, combined with existing subgraph-oriented reasoners, achieves significant gains (+11.3-19.3% Hits@1) over the same reasoner that is performed with other retrieval methods. Moreover, SR together with NSM creates new state-of-the-art results for embedding-based KBQA models. (2) With the same coverage rate of the answers, SR can result in much smaller subgraphs that can deduce more accurate answers. (3) The unsupervised pre-training with only 20% weak supervision signals is comparable to pre-training with the full weak supervision signals. (4) The end-to-end fine-tuning can enhance the performance of the retriever as well as the reasoner.

Contributions. (1) We propose a trainable SR decoupled from the subsequent reasoner to enable a plug-and-play framework for enhancing any subgraph-oriented reasoner. (2) We devise SR by a simple yet effective dual-encoder, which achieves significantly better retrieval and QA results than the existing retrieval methods. (3) NSM equipped with SR, via weakly supervised pre-training and end-to-end fine-tuning, achieves new SOTA performance for embedding-based KBQA methods.

2 Related Work

KBQA solutions can be categorized into SP-based and embedding-based methods. SP-based methods (Bao et al., 2016; Berant and Liang, 2014; Das et al., 2021; Lan and Jiang, 2020; Liang et al., 2017; Qiu et al., 2020b; Sun et al., 2020) parse a question into a logic form that can be executed against the KB. These methods need to annotate expensive logic forms as supervision or are limited to narrow domains with a few logical predicates. Embedding-based methods embed entities and rank them based on their relevance to the question, where the entities are extracted from the whole KB (Miller et al., 2016; Saxena et al., 2020) or restricted in a subgraph (Chen et al., 2019a; He et al., 2021; Sun et al., 2018; Zhang et al., 2018). They are more fault-tolerant but the whole KB or the ad-hoc retrieved subgraph includes many irrelevant entities. Some works such as PullNet (Sun et al., 2019), SRN (Qiu et al., 2020a), IRN (Zhou et al., 2018), and UHop (Chen et al., 2019b) enhance the retrieval by training the retriever, but the retrieving and the reasoning are intertwined, causing the reasoning on partially retrieved subgraphs. Because of such coupled design, the reasoner in SRN, IRN, and UHop is degenerated into a simple MLP. On the contrary, thanks to the decoupled design, the reasoner can be complicated to support more complex reasoning. Other works propose more complicated reasoner for supporting the numerical reasoning in KBQA (Feng et al., 2021).

Open-domain QA (OpenQA) aims to answer questions based on a large number of documents. Most of the OpenQA models also consist of a retriever to identify the relevant documents and a reasoner to extract the answers from the documents. The retriever is devised as a sparse term-based method such as BM25 (Robertson and Zaragoza, 2009) or a trainable dense passage retrieval method (Karpukhin et al., 2020; Sachan et al., 2021), and the reasoner deals with each document individually (Guu et al., 2020) or fuses all the documents together (Izacard and Grave, 2021). Different from the documents in openQA, the subgraphs in KBQA can be only obtained by multi-hop retrieval and the reasoner should deal with the entire subgraph instead of each individual relation to find the answer. Although some openQA research proposes multi-hop document retrieval (Asai et al., 2020), the focus is the matching of the documents rather than the relations to the questions in KBQA. Thus the concrete solution for KBQA should be different from openQA.

3 Problem Definition

A **knowledge base** (KB) G organizes the factual information as a set of triples, *i.e.*, $G = \{(e, r, e')|e, e' \in E, r \in R\}$, where E and R denote the entity set and the relation set respectively. Given a factoid question q, KBQA is to figure out the answers A_q to the question q from the entity set E of G. The entities mentioned in q are topic entities denoted by $E_q = \{e_q\}$, which are assumed to be given. This paper considers the complex questions where the answer entities are multi-hops away from the topic entities, called multi-hop KBQA.

Probabilistic Formalization of KBQA. Given a question q and one of its answers $a \in A_q$, we formalize the KBQA problem as maximizing the probability distribution $p(a|G, q)$. Instead of directly reasoning on G, we retrieve a subgraph $\mathcal{G} \subseteq G$ and infer a on $\mathcal{G}$. Since $\mathcal{G}$ is unknown, we treat it as a latent variable and rewrite $p(a|G, q)$ as:

$$p(a|G,q) \quad = \quad \sum_{\mathcal{G}} p_\phi(a|q,\mathcal{G}) p_\theta(\mathcal{G}|q). \quad (1)$$

In the above equation, the target distribution $p(a|G, q)$ is jointly modeled by a subgraph retriever $p_\theta(\mathcal{G}|q)$ and an answer reasoner $p_\phi(a|q, \mathcal{G})$. The subgraph retriever p_θ defines a prior distribution over a latent subgraph $\mathcal{G}$ conditioned on a question q, while the answer reasoner p_ϕ predicts the likelihood of the answer a given $\mathcal{G}$ and q. The goal is to find the optimal parameters θ and ϕ that can maximize the log-likelihood of training data, *i.e.*,

$$\mathcal{L}(\theta,\phi) = \max_{\theta,\phi} \sum_{(q,a,G)\in\mathcal{D}} \log \sum_{\mathcal{G}} p_\phi(a|q,\mathcal{G}) p_\theta(\mathcal{G}|q), \quad (2)$$

where $\mathcal{D}$ is the whole training data. Thanks to this formulation, the retriever can be decoupled from the reasoner by firstly training the retriever p_θ and then the reasoner p_ϕ on the subgraphs sampled by the retriever. Via drawing a sample $\mathcal{G}$ (Sachan et al., 2021), we can approximate Eq. (2) as:

$$\mathcal{L}(\theta,\phi) = \max_{\theta,\phi} \sum_{(q,a,\mathcal{G})\in\mathcal{D}} \log p_\phi(a|q,\mathcal{G}) + \log p_\theta(\mathcal{G}|q), \quad (3)$$

where the first and the second term can be optimized for the reasoner and the retriever respectively. The concrete reasoner can be instantiated by any subgraph-oriented KBQA model such as the GNN-based GRAT-Net (Sun et al., 2018) and NSM (He et al., 2021).

4 Subgraph Retriever (SR)

The retriever needs to calculate $p_\theta(\mathcal{G}|q)$ for any $\mathcal{G}$, which is intractable as the latent variable $\mathcal{G}$ is combinatorial in nature. To avoid enumerating $\mathcal{G}$, we propose to expand top-K paths relevant to q from the topic entities and then induce the subgraph following these paths.

4.1 Expanding Paths

Path expanding starts from a topic entity and follows a sequential decision process. Here a path is defined as a sequence of relations $(r_1, \cdots, r_{|p|})$, since a question usually implies the intermediate relations excluding the entities. Suppose a partial path $p^{(t)} = (r_1, \cdots, r_t)$ has been retrieved at time t, a tree can be induced from $p^{(t)}$ by filling in the intermediate entities along the path, *i.e.*, $T^{(t)} = (e_q, r_1, E_1, \cdots, r_t, E_t)$. Each E_t is an entity set as a head entity and a relation can usually derive multiple tail entities. Then we select the next relation from the union of the neighboring relations of E_t. The relevance of each relation r to the question q is measured by the dot product between their embeddings, *i.e.*,

$$s(q,r) = f(q)^\top h(r), \quad (4)$$

where both f and h are instantiated by RoBERTa (Liu et al., 2019). Specifically, we input

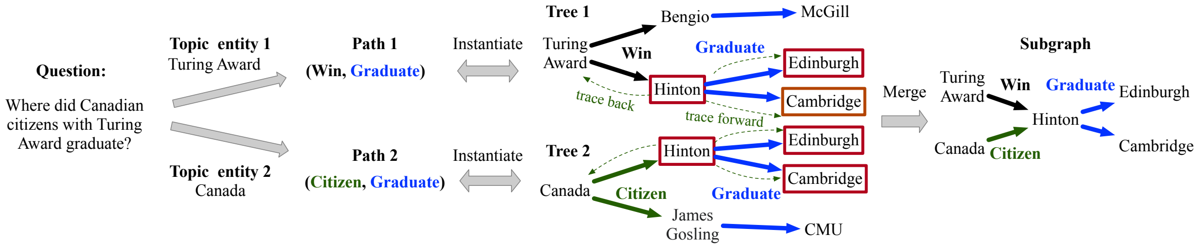

Figure 2: Illustration of the subgraph retrieving process. We expand a path from each topic entity as well as induce a corresponding tree, and then merge the trees from different topic entities to form a unified subgraph.

the question or the name of r into RoBERTa and take its [CLS] token as the output embedding. According to the assumption (Chen et al., 2019b; He et al., 2021; Qiu et al., 2020a; Zhou et al., 2018) that expanding relations at different time steps should attend to specific parts of a query, we update the embedding of the question by simply concatenating the original question with the historical expanded relations in $p^{(t)}$ as the input of RoBERTa, *i.e.*,

$$f(q^{(t)}) = \text{RoBERTa}([q; r_1; \cdots; r_t]), \qquad (5)$$

Thus $s(q, r)$ is changed to $s(q^{(t)}, r) = f(q^{(t)})^\top h(r)$. Then the probability of a relation r being expanded can be formalized as:

$$p(r|q^{(t)}) = \frac{1}{1 + \exp\left(s(q^{(t)}, \text{END}) - s(q^{(t)}, r)\right)}, \qquad (6)$$

where END is a virtual relation named as "END". The score $s(q^{(t)}, \text{END})$ represents the threshold of the relevance score. $p(r|q^{(t)})$ is larger than 0.5 if $s(q^{(t)}, r) > s(q^{(t)}, \text{END})$ and is no larger than 0.5 otherwise. We select the top-1 relation with $p(r|q^{(t)}) > 0.5$. The expansion is stopped if none of the probabilities of the relations is larger than 0.5. Finally, the probability of a path given the question can be computed as the joint distribution of all the relations in the path, *i.e.*,

$$p_\theta(p|q) = \prod_{t=1}^{|p|} p(r_t|q^{(t)}). \qquad (7)$$

where $|p|$ denotes the number of relations in p, $t = 1$ indicates the selection at the topic entity and $t = |p|$ denotes the last none-stop relation selection. Since the top-1 relevant path cannot be guaranteed to be right, we perform a top-K beam search at each time to get K paths. From each topic entity, we obtain K paths which result in nK paths in total by n topic entities. nK paths correspond to nK instantiated trees.

4.2 Inducing Subgraph

We take the union of top-K trees from one topic entity into a single subgraph, and then merge the same entities from different subgraphs to induce the final subgraph. This can reduce the subgraph size, *i.e.*, the answer reasoning space, as the subgraphs from different topic entities can be viewed as the constraints of each other. Specifically, from the n subgraphs of the n topic entities, we find the same entities and merge them. From these merged entities, we trace back in each subgraph to the root (*i.e.*, a topic entity) and trace forward to the leaves. Then we only keep the entities and relations along the tracing paths of all the trees to form the final subgraph. For example in Figure 2, given a question "Where did Canadian citizens with Turing Award graduate?" with two topic entities "Turing Award" and "Canada"[2], we can explain it by the two expanded paths (Win, Graduate) and (Citizen, Graduate) and merge the trees induced by them to form a unified subgraph. Only the top-1 path is presented in the figure for a clear illustration.

5 Training Strategies

In this section, we discuss the pre-training and the end-to-end fine-tuning strategies to train the retriever. Figure 3 illustrates the whole framework and the training procedure.

5.1 Weakly Supervised Pre-Training

Since the ground truth subgraphs are not easy to be obtained, we resort to the weak supervision signals constructed from the (q, a) pairs. Specifically, from each topic entity of a question, we retrieve all the shortest paths to each answer as the supervision signals, as paths are easier to be obtained than graphs. Since maximizing the log-

---

[2] Some work views "Canada" as a constraint, which is not easy to be distinguished with the topic entity "Turing Award". Thus this paper treats both of them as topic entities.

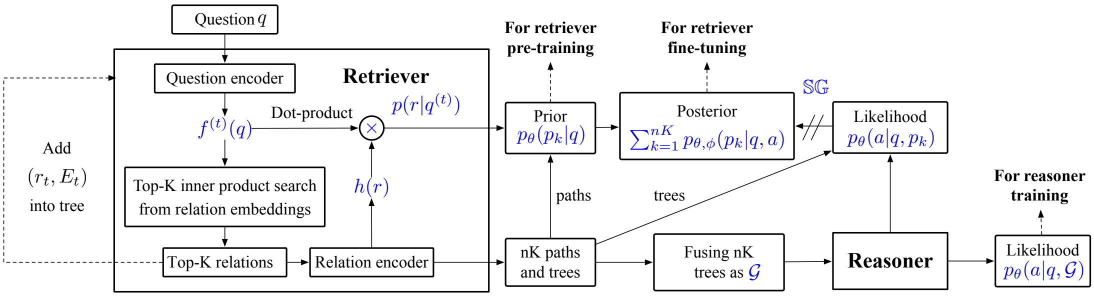

Figure 3: Overview of SR and its training strategies. Given a question, SR generates nK paths via iteratively expanding the relations. We pre-train the retriever based on the prior of each path and train the reasoner based on the likelihood of the subgraph fused from the nK trees. For end-to-end training, the retriever is fine-tuned on the posterior of each path that consists of the prior and the likelihood of it. $\mathbb{SG}$ is the stop-gradient operation.

likelihood of a path equals to $\sum_{t=1}^{|p|} \log p(r_t|q^{(t)})$ according to Eq. (7), we can maximize the probabilities of all the intermediate relations in a path. To achieve the goal, we decompose a path $p = (r_1, \cdots, r_{|p|})$ into $|p| + 1$ (question, relation) instances, including $([q], r_1)$, $([q; r_1], r_2)$, ..., $([q; r_1; r_2; \cdots; r_{|p|-1}], r_{|p|})$, and an additional END instance $([q; r_1; r_2; \cdots; r_{|p|}], \text{END})$, and optimize the probability of each instance. We replace the observed relation at each time step with other sampled relations as the negative instances to optimize the probability of the observed ones.

5.2 Unsupervised Pre-Training

When the (q, a) pairs are also scarce, we train the retriever in an unsupervised manner independent from the (q, a) pairs. We leverage the NYT dataset, a distant supervision dataset for relation extraction (Riedel et al., 2010) to construct the pseudo (q, a, p) labels. In this dataset, each instance is denoted as a tuple $(s, (e_1, r, e_2))$, where s is a sentence that refers to the relation r between two entities e_1 and e_2 mentioned in the sentence s. For two instances $(s_1, (e_1, r_1, e_2))$ and $(s_2, (e_2, r_2, e_3))$, we treat e_1 as the topic entity and e_3 as the answer. Then we concatenate s_1 and s_2 as the question, and concatenate r_1 and r_2 as the corresponding path to train the retriever. The training objective is the same as the weakly supervised pre-training.

5.3 End-to-End Fine-tuning

End-to-end training is an alternative to fine-tune the separately trained retriever and the reasoner jointly. The main idea is to leverage the feedback from the reasoner to guide the path expansion of the retriever. To enable this, we optimize the posterior $p_{\theta,\phi}(\mathcal{G}|q, a)$ instead of the prior $p_\theta(\mathcal{G}|q)$, since the former one contains the additional likelihood $p_\phi(a|q, p_k)$ which exactly reflects the feedback from the reasoner. We do not directly optimize the posterior $p_{\theta,\phi}(\mathcal{G}|q, a)$, because $\mathcal{G}$ is induced from nK paths, making it unknown which path should receive the feedback from the likelihood computed on the whole $\mathcal{G}$. Instead, we approximate $p(\mathcal{G}|q, a)$ by the sum of the probabilities of the nK paths and rewrite the posterior of each path by Bayes' rule (Sachan et al., 2021), *i.e.*,

$$
\begin{aligned}
p_{\theta,\phi}(\mathcal{G}|q,a) &\approx \sum_{k=1}^{nK} p_{\theta,\phi}(p_k|q,a), && (8)\\
&\propto \sum_{k=1}^{nK} p_\phi(a|q,p_k)p_\theta(p_k|q),
\end{aligned}
$$

where $p_\theta(p_k|q)$ is the prior distribution of the k-th path that can be estimated by Eq. (7), and $p_\phi(a|q, p_k)$ is the likelihood of the answer a given the k-th path. Essentially, $p_\phi(a|q, p_k)$ estimates the answer a on the single tree induced by the k-th path instead of the fused subgraph by nK paths. As a result, the reasoning likelihood on each tree can be reflected to the corresponding path that induces the tree. The reasoner for estimating $p_\phi(a|q, p_k)$ is the same as that for calculating $p_\phi(a|q, \mathcal{G})$.

In summary, the whole objective function for each training instance $(q, a, \mathcal{G})$ is formalized as:

$$
\begin{aligned}
\mathcal{L} &= \underbrace{\max_\phi \log p_\phi(a|q,\mathcal{G})}_{\text{Reasoner}} && (9)\\
&+ \underbrace{\max_\theta \log \sum_{k=1}^{nK} \mathbb{SG}(p_\phi(a|q,p_k))p_\theta(p_k|q)}_{\text{Retriever}},
\end{aligned}
$$

where the stop-gradient operation $\mathbb{SG}$ is to stop updating the parameters ϕ. The reasoner is updated the same as the two-stage training by computing the likelihood $p_\phi(a|q,\mathcal{G})$ on $\mathcal{G}$ sampled by the retriever (without using information from the answer a). As a result, there is no mismatch between the training and evaluation when computing $p_\phi(a|q,\mathcal{G})$, as $\mathcal{G}$ relies only on the prior at both.

Intuitively, we train the reasoner to extract the correct answer given the subgraph induced from nK highest scoring paths. And we train the retriever to select nK paths which collectively have a high score to deduce the answer when taking the feedback from the reasoner into account. Although the two components are jointly trained, the reasoning is still performed on the retrieved entire subgraph at each epoch. We present the training process in Appendix.

6 Experiments

In this section, we conduct extensive experiments to evaluate the subgraph retrieval (SR) enhanced model. We design the experiments to mainly answer the four questions: (1) Does SR take effect in improving the QA performance? (2) Can SR obtain smaller but higher-quality subgraphs? (3) How does the weakly supervised and unsupervised pre-training affect SR's performance? (4) Can end-to-end fine-tuning enhance the performance of the retriever as well as the reasoner?

6.1 Experimental Settings

Datasets. We adopt two benchmarks, WebQuestionSP (WebQSP) (Yih et al., 2016) and Complex WebQuestion 1.1 (CWQ) (Talmor and Berant, 2018), for evaluating the proposed KBQA model. Table 1 shows the statistics.

Evaluation Metrics. We evaluate the retriever by the answer coverage rate, which is the proportion of questions for which the topic-nK retrieved paths contain at least one answer. This metric reflects the upper bound of the QA performance and is denoted as Hits@K. For QA performance, We use Hits@1 to evaluate whether the top-1 predicted answer is correct. Since some questions have multiple answers, we also predict the answers by the optimal threshold searched on the validation set and evaluate their F1 score.

Baseline Models. We compare with embedding-based KBQA models, in which EmbedKGQA (Saxena et al., 2020) directly optimizes the triplet (topic entity, question, answer) based on their direct embeddings. KV-Mem (Miller et al., 2016) BAMNet (Chen et al., 2019a) store triplets in a key-value structured memory for reasoning. GRAFT-Net (Sun et al., 2018), BAMNet (Chen et al., 2019a), NSM (He et al., 2021), and PullNet (Sun et al., 2019) are subgraph-oriented embedding models. We also compare with the SP-based models, in which QGG (Lan and Jiang, 2020) generates the query graph for a question by adding the constraints and extending the relation paths simultaneously, SPARQA (Sun et al., 2020) proposes a novel skeleton grammar to represent a question, and CBR-KBQA (Das et al., 2021) leverages BigBird (Zaheer et al., 2020), a pre-trained seq2seq model to directly parse a question into a SPARQL statement that can be executed on graph DBs. SR is default trained by weakly supervised pre-training and the default path number is set to 10.

Table 1: Data statistics. The number of QA pairs for training, validating and testing are presented.

Dataset	#Train	#Validation	#Test
WebQSP	2,848	250	1,639
CWQ	27,639	3,519	3,531

Table 2: QA performance on WebQSP and CWQ (%).

Model	WebQSP Hits@1	WebQSP F1	CWQ Hits@1	CWQ F1
SP-based models				
SPARQA	-	-	31.6	-
QGG	73.0	73.8	36.9	37.4
CBR-KBQA	-	72.8	-	**70.0**
Embedding-based models				
KV-Mem	46.6	34.5	18.4	15.7
EmbedKGQA	66.6	-	32.0	-
BAMnet	55.6	51.8	-	-
GRAFT-Net (GN)	66.4	60.4	36.8	32.7
NSM	68.5	62.8	46.3	42.4
PullNet	68.1	-	45.9	-
Our Models				
SR+NSM	82.7	74.1	57.6	48.3
SR+GN	80.3	73.9	55.1	47.8
SR+NSM w E2E	**83.2**	**74.5**	**58.4**	**50.2**
SR+GN w E2E	81.9	74.1	55.7	48.7

6.2 Overall QA Evaluation

We compare with state-of-the-art KBQA models and present the Hits@1 and F1 scores in Table 2.

Table 3: The answer coverage rate of SR on WebQSP and CWQ (%).

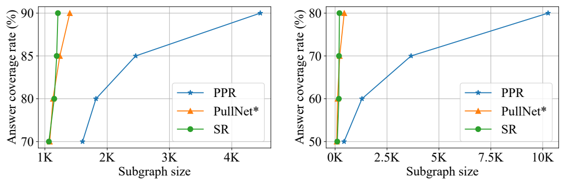
Model	WebQSP				CWQ			
	Hits@1	Hits@5	Hits@10	Hits@20	Hits@1	Hits@5	Hits@10	Hits@20
SR w SuperT	68.8	84.7	89.9	91.4	59.9	75.4	84.8	86.7
SR	63.9	84.2	90.4	92.3	50.4	75.3	84.9	87.1
SR w/o QU	60.7	64.5	66.4	68.1	40.2	60.1	62.6	63.7
SR w/o PE	61.2	66.5	70.1	73.2	41.9	62.9	65.3	63.3
SR+NSM w E2E	64.3	84.1	91.2	93.7	51.6	77.1	85.3	87.1
SR+GN w E2E	64.6	83.4	90.7	93.2	52.0	76.8	85.1	87.3

SP-based Models. The SP-based model CBR-KBQA achieves the best performance on CWQ. This is expected, as CBR-KBQA leverages a pre-trained seq-to-seq model to parse the input question into a SPARQL statement. However, the model depends on the annotated SPARQL statements, which are expensive to be annotated in practice.

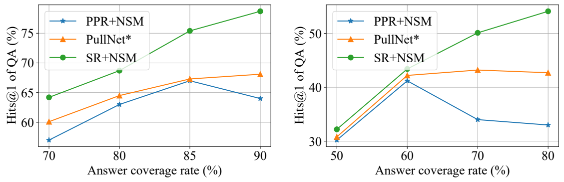
Embedding-based Models. Among these models, KV-Mem and EmbedKGQA retrieve the answers from the global key-value memory built on the KB or the original whole KB, which enjoys high recall but suffers from many noisy entities. Compared with these global retrievals, BAMNet builds the key-value memory on a subgraph, but it is a full multi-hop topic-entity-centric subgraph, which is also noisy. GRAFT-Net and NSM calculate PPR scores to control the subgraph size, but the ad-hoc retrieval method is still far from optimal. PullNet reinforces the retrieval by learning a retriever, but the retriever and the reasoner are intertwined, causing the partial reasoning on part of a subgraph, which increases the reasoning bias.

Our Models. Compared with the above embedding-based models, an obvious performance improvement on both the datasets can be observed, *e.g.*, NSM injected by SR (SR+NSM) improves 14.2% Hits@1 on WebQSP and 11.3% on CWQ compared with the original NSM. We also show that SR can be adapted to different subgraph-oriented reasoners. Beyond NSM, when injecting SR to GRAFT-NET, it also significantly improves 13.9-19.3% Hits@1. We do not inject SR into BAMNet as the model needs entity types in the subgraph, which is temporarily ignored by SR .

Summary. The overall evaluation shows that SR takes effect in improving the QA performance when injecting it before a subgraph-oriented reasoner, and SR equipped with NSM creates a new state-of-the-art model for embedding-based KBQA.



(a) WebQSP (b) CWQ



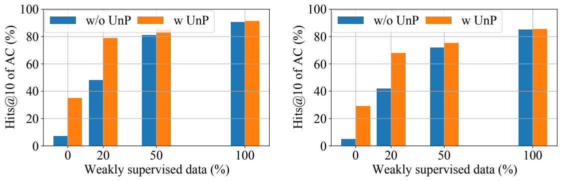
(c) WebQSP (d) CWQ

Figure 4: Comparison of the answer coverage rate under various subgraph sizes (Top row) and the QA performance (Hits@1) under various answer coverage rates (Bottom row).

6.3 Retriever Evaluation

Quality of Retrieved Subgraph. We evaluate whether the proposed SR can obtain smaller but higher-quality subgraphs, which are measured by not only the direct subgraph size and answer coverage rate but also the final QA performance. For a fair comparison, we fix the reasoner as NSM, and vary the retriever as SR, the PPR-based heuristic retrieval (Sun et al., 2018; He et al., 2021), and PullNet*—a variant PullNet (Sun et al., 2019). PullNet* upgrades PullNet by adopting the same SR as the retriever and NSM as the reasoner but trains them differently from the proposed two-stage strategy. Since PullNet selects a relation by the retriever and expands the entities by NSM interactively, the reasoner needs to be trained on the partial subgraph at each step beyond the entire subgraph.

We report the comparison results in Figure 4.



(a) WebQSP (b) CWQ

Figure 5: Retriever's performance by pre-training in terms of Hits@10 of answer coverage rate (AC). UnP denotes unsupervised pre-training.

The top row presents the answer coverage rates of the subgraphs with various sizes. It is shown that when retrieving the subgraphs of the same size, the answer coverage rate of SR is higher than PullNet*, and is significantly higher than PPR. The bottom row presents the QA performance (Hits@1) on the subgraphs with various answer coverage rates. It is shown that by performing the same NSM on the subgraphs with the same coverage rate, the subgraphs retrieved by SR can result in higher QA performance than PPR and PullNet*.

Summary. The above results show that SR can obtain smaller but higher-quality subgraphs.

Effect of Question Update, Path Ending, and Subgraph Merge. We investigate the effects of the strategies used in SR, including the question updating strategy (QU) which concatenates the original question with the partially expanded path at each time step, the path ending strategy (PE) which learns when to stop expanding the path, and the subgraph merging strategy (GM) which induces a subgraph from the top-nK paths.

Table 3 indicates that based on SR, Hits@1 drops 3.2-10.2% when removing QU (SR w/o QU) and Hits@1 drops 2.7-8.5% when changing PE to the fixed path length T (SR w/o PE), where the optimal T is set to 3 on both WebQSP and CWQ.

Table 4 shows that based on SR+NSM, the average subgraph size increases from 44.8 to 241.5, and Hits@1 of QA drops 1.4% when removing the subgraph merging strategy (SR+NSM w/o GM) but directly taking the union of all the subgraphs from different topic entities to induce the subgraph. We only present the results on CWQ as most of the questions in WebQSP only contain one topic entity, which does not need the merge operation.

Summary. The above results verify the effectiveness of the devised QU, PE, and GM in SR.

Table 4: Performance of subgraph merging strategy (GM) on CWQ.

Model	Subgraph size	Hits@1 of QA (%)
SR+NSM	44.8	58.2
SR+NSM w/o GM	241.5	56.8

6.4 Training Strategy Evaluation

Effect of Pre-training. We investigate the effects of the weakly supervised and the unsupervised pre-training on the SR. Table 3 shows the performance of the supervised training (SR w SuperT) and the weakly supervised pre-training (SR), which indicates that SR is comparable with or even better than SR w SuperT when retrieving more than 10 paths. Because a single ground-truth path between a topic entity and an answer is provided by WebQSP and CWQ, which might omit the situation when multiple ground truth paths can be found. In view of this, the weakly supervised way that retrieves multiple shortest paths as the ground truth can provide richer supervision signals.

We further vary the proportion of the weakly supervised data in {0%, 20%, 50%, 100%}, and present the corresponding answer coverage rate of the subgraph induced by top-10 paths (*i.e.* Hits@10) in Figure 5. Note 0% means the RoBERTa used in SR don't have any fine-tuning. The performance shows a consistent growth with the weakly generated data size, which demonstrates its positive effect.

Before the weakly supervised pre-training, we create 100,000 pseudo instances for unsupervised pre-training (Cf. Section 5 for details). The results presented by the orange bars show that unsupervised pre-training can significantly improve the original SR (0% weakly supervised data) by more than 20% Hits@1. Adding only 20% weakly supervised data after unsupervised pre-training can achieve comparable performance with 100% weakly supervised data.

Summary. The above results show the effectiveness of the weakly supervised pre-training. Meanwhile, the unsupervised strategy can be an alternative choice when the QA pairs are scarce.

Effect of End-to-End Fine-tuning. Table 3 shows both SR+NSM w E2E and SR+GN w E2E improve 0.3-1.6% Hits@10 of retrieval based on SR. Table 2 shows SR+NSM w E2E improves 0.5-1.6% Hits@1 of QA based on SR+NSM, and SR+GRAFT-Net w

E2E improves 0.5-1.6% Hits@1 of QA based on SR+GRAFT-Net.

Summary. The above results indicate that the answer likelihood estimated by the reasoner provides positive feedback for fine-tuning the retriever. With the improvement of the retriever, the reasoner can be also enhanced by the updated subgraphs.

7 Conclusion

We propose a subgraph retriever (SR) decoupled from the subsequent reasoner for KBQA. SR is devised as an efficient dual-encoder that can update the question when expanding the path as well as determining the stop of the expansion. The experimental results on two well-studied benchmarks show SR takes effect in improving the QA performance if injecting it before a subgraph-oriented reasoner. SR equipped with NSM creates new SOTA results for embedding-based KBQA methods if learning SR by weakly supervised pre-training as well as end-to-end fine-tuning.

ground-truth path provided by WebQSP and CWQ. The paths can explain why an answer is inferred for a question.

A.2 Training Algorithm.

We present the whole training process in Algorithm 1, where we first pre-train the retriever, then train the reasoner based on the retrieved subgraph, and finally end-to-end fine-tune the retriever and the reasoner together.

A.3 Experimental Implementation

We provide the training and inference details of all the experiments as below.

General Setting. We use RoBERTa-base in our paper (Liu et al., 2019). The basic RoBERTa contains 12 layers, 768-d hidden size, and 12 attention heads, resulting in 110M parameters in total. On WebQSP and CWQ, the batch size for training both

  subgraphs;
/* End-to-End training:    */
while not converge do
    For each $(q, a)$ pair, sample a subgraph
      $\mathcal{G}$ by current retriever;
    Update $\phi$ by optimizing the first term of
      Eq. (9) on all the $(q, a, \mathcal{G})$ instances;
    Update $\theta$ by optimizing the second term
      of Eq. (9) on all the $(q, a, \mathcal{G})$ instances;
end
```

the retriever and the reasoner is set as 16 and 8 respectively.

Supervised Training. WebQSP and CWQ provide a SPARQL statement corresponding to each (question, answer) pair. For each SPARQL statement, we extract a relation path from each topic entity to the answer variable as the ground truth path. In this way, we obtain 3,110/41,182 (question, path) instances which can be decomposed into 6,531/67,204 (question, relation) instances in total for supervised training. The learning rate for supervised training is set as 5e-5. An epoch takes about 15/30 minutes and the loss function converges within 10 epochs on WebQSP/CWQ.

Weakly supervised Pre-training. For weakly supervised pre-training, the SPARQL statements are unavailable. To create the pseudo paths, for each (question, answer) pair, we extract all the shortest paths between each topic entity and an answer. We obtain 6,801/53,536 (question, path) instances which can be decomposed into 11,561/91,011 (question, relation) instances in total for weakly supervised pre-training. The learning rate for Weakly supervised training is set as 5e-5. An epoch takes about 15/30 minutes and the loss function converges within 10 epochs.

Unsupervised Pre-training. From the NYT dataset (Riedel et al., 2010), we create 100,000 (sentence, path) pseudo instances. The learning rate for unsupervised training is set as 5e-5. An epoch takes about 90 minutes and the loss function converges within 10 epochs. The unsupervised pre-training is performed once and then SR can be adapted to various KBQA datasets.

End-to-End Training. Before end-to-end training, the retriever needs to be warmed up by weakly supervised pre-training or unsupervised pre-training. The reasoner also needs to be warmed up by supervised training on the (question, answer) pairs. For training the NSM reasoner (He et al., 2021), an epoch with batch size 20/40 takes 55/135 seconds and the loss function converges within 70/80 epochs on WebQSP/CWQ. The learning rate for warming up the reasoner is set as 1e-4. For end-to-end training, the learning rate is set as 1e-5. An epoch takes about 40/70 minutes, and the loss function converges within 10 epochs.

A.4 Inference

We retrieve the top 10 relevant relations at each step which results in 10 paths for each topic entity. The number 10 is determined at the pre-training stage by checking the inflection point of the answer coverage rate on the validation set. The average time of online inference including both the subgraph retrieving and the reasoning can be within 1 second. By comparison, GRAFT-Net and NSM which first retrieve the whole two-hop subgraph and then prune it by the PPR scores spend about 2 to 3 seconds or even 7 to 8 seconds for retrieving some dense subgraphs.

Pre-training to Match for Unified Low-shot Relation Extraction

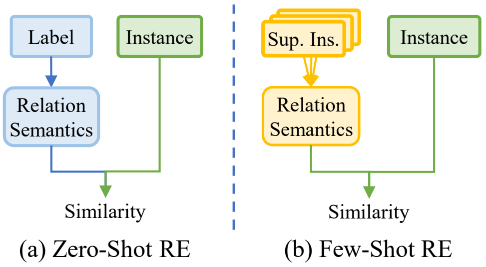
Abstract

Low-shot relation extraction (RE) aims to recognize novel relations with very few or even no samples, which is critical in real scenario application. Few-shot and zero-shot RE are two representative low-shot RE tasks, which seem to be with similar target but require totally different underlying abilities. In this paper, we propose Multi-Choice Matching Networks to unify low-shot relation extraction. To fill in the gap between zero-shot and few-shot RE, we propose the triplet-paraphrase meta-training, which leverages triplet paraphrase to pre-train zero-shot label matching ability and uses meta-learning paradigm to learn few-shot instance summarizing ability. Experimental results on three different low-shot RE tasks show that the proposed method outperforms strong baselines by a large margin, and achieve the best performance on few-shot RE leaderboard[1].

1 Introduction

Relation extraction (RE) aims to extract the relation between two given entities in the context. The most popular approaches to build RE models are based on supervised learning (Zeng et al., 2014; Baldini Soares et al., 2019). Despite the superior performance, supervised relation extraction approaches severely suffer from the data bottleneck, which restricts their application to more relation types in real scenarios.

Consequently, low-shot relation extraction has become a recent research hotspot in RE area. There are two mainstream learning paradigms widely explored in low-shot relation extraction, namely zero-shot RE (Levy et al., 2017) and few-shot RE (Han et al., 2018). Few-shot relation extraction aims to identify instances of novel relation type with only a few illustrative instances, while zero-shot RE is more progressive, which only uses external knowledge and the name or definition of the novel relations to recognize them. Because low-shot RE only requires very limited manually annotated data, it can effectively alleviate data bottlenecks in conventional RE and therefore attached great attention.



(a) Zero-Shot RE (b) Few-Shot RE

Figure 1: Difference between zero-shot RE and few-shot RE. (a) Zero-shot requires for the ability of label semantic matching, while (b) Few-shot requires for the ability of support instance (Sup. Ins.) summarizing.

However, even with similar goals, zero-shot RE and few-shot RE actually require different fundamental abilities. Specifically, zero-shot RE is built on *label semantic matching* ability, which requires models to sufficiently exploit the label semantic of given novel relations, and matches relations and queries based on their underlying semantics. While few-shot RE is built on *instance semantic summarizing* ability, which requires a model to quickly generalize to novel relations by summarizing critical information from few-shot instances. Due to this fundamental difference, current state-of-the-art architectures are separately learned to deal with these two low-shot RE tasks. For zero-shot RE, the most popular solution is to transform it into a textual entailment (Obamuyide and Vlachos, 2018; Sainz et al., 2021), word prediction (Brown et al., 2020) or MRC problem (Levy et al., 2017; Bragg et al., 2021) and use external resources from these tasks to pre-training the label semantic matching ability. However, the divergence between relation extraction and these tasks will inevitably undermine the performance. Besides, MRC and tex-

tual entailment architecture can only deal with one novel relation each time, which significantly increases the computational and storage cost of deploying such models in real-world scenarios. For few-shot RE, current methods mainly focus on summarizing better prototypes from a few illustrative instances (Snell et al., 2017), or learning a model that can generalize to novel types within a few steps (Finn et al., 2017). These approaches require few-shot examples to fine-tune or summarize prototypes, and therefore can not be directly applied to zero-shot RE. As a result, current relation extraction models can not be effectively and efficiently to apply to all low-shot RE settings.

In this paper, we propose to unify low-shot relation extraction by returning to the essence of relation extraction. Fundamentally, relation extraction can be viewed as a multiple choice task. Given two entities in context, a RE system needs to match the most appropriate relation – or *others* for none-of-the-above – from a set of pre-defined relation types. The information required to accomplish the multi-choice matching can be summarized from either the surface form of relation name or from few-shot instances. Motivated by this, we propose Multi-Choice Matching Network (MCMN) for unified low-shot RE, which is shown in Figure 2. Specifically, MCMN converts all candidate relation descriptions into a multi-choice prompt. Then the input instance is concatenated with the multi-choice prompt and passes through a pre-trained encoder to obtain the semantic representations of the input instance and candidate relations. Finally, MCMN conduct relation extraction by directly matching the relation representations and the instance representation.

To equip MCMN with both label semantic matching ability and instance semantic summarizing ability, we propose to pre-train MCMN via triplet-paraphrase meta pre-training, which contains the following two critical components: 1) a text-triple-text paraphrase module, which can generate large-scale pseudo relation extraction data to pre-train the label semantic matching ability of MCMN; 2) a meta-learning style training algorithm, which enriches MCMN with instance semantic summarizing ability to quickly generalize across different relation extraction tasks. Specifically, given large-scale raw texts, triplet-paraphrase first extracts (subject, predicate, object) triplets via OpenIE (Cui et al., 2018) toolkit. Then based on the extracted triplets, paraphrases of the original texts is generated using an RDF-to-Text generation model. In this way, we can obtain large-scale pseudo annotations by collecting the generated sentences and the predicate in the triples. Such corpus can be used to effectively pre-train the label semantic matching ability of MCMN by matching the paraphrases to the corresponding predicate. Furthermore, to enrich MCMN with the instance semantic summarizing ability, such pre-training is conducted in a meta-learning paradigm. That is, MCMN is asked to learn different relation extraction tasks at each iteration, so that the MCMN can not over-fit the pre-training corpus by directly memorizing specific target relations.

To evaluate our methods, we conduct experiments on three fairly different RE tasks: zero-shot RE, few-shot RE, and few-shot RE with none-of-the-above relation. Experiments show that the proposed method outperform previous methods on all these three tasks. Our source code is available at `https://github.com/fc-liu/MCMN`.

The main contributions of this work are:

- We propose MCMN, a unified architecture for low-shot relation extraction by fundamentally formulating relation extract using a multi-choice matching paradigm.

- We propose to pre-train MCMN with triplet-paraphrase meta training, which enriches MCMN with label semantic matching ability and instance semantic summarizing ability for both zero-shot RE and few-shot RE.

- We comprehensively study the performance of MCNN on three different relation extraction tasks, including zero-shot, few-shot, and few-shot with none-of-the-above relation extraction, where MCMN outperforms strong baseline models.

2 Background

In this section, we formulate relation extraction task and the low-shot RE settings including zero-shot RE and few-shot learning RE.

Relation Extraction. Suppose the input text $T = [t_1, t_2, ..., tn]$ contains n tokens, $e_1 = [i, j]$ and $e_2 = [k, l]$ indicate the entity pair spans, where $1 \leq i \leq j, j < k \leq l$ and $l \leq n$. A relation instance is defined as $x = (T, e_1, e_2)$. For example, the

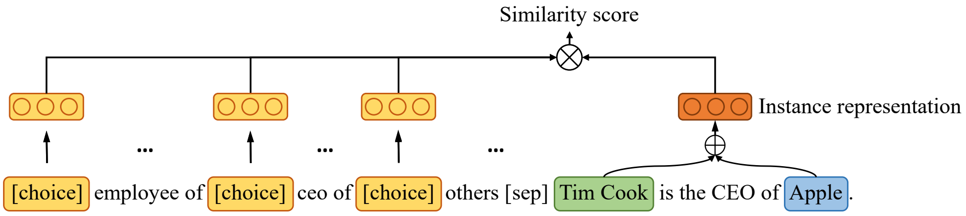

Figure 2: Illustration of our multi-choice matching networks (MCMN).

tuple (*"Tim Cook is the CEO of Apple Inc."*,*"Tim Cook"*, *"Apple Inc."*) is a relation instance. The aim of relation extraction is to learn a mapping function: $f : x \longrightarrow y$, where y is the relation class. For example, we want mapping (*"Tim Cook is the CEO of Apple Inc."*, *"Tim Cook"*, *"Apple Inc."*) to its relation class *"CEO_of"*. Traditional RE tasks typically pre-define the class space Y and annotate a large set of instances to train the model. However, in real scenarios, the targeting relation types vary in different tasks, and most of the novel relations lack annotations, rendering the supervised paradigms inapplicable. In that regard, how to transfer models to novel tasks becomes critical.

Low-shot Relation Extraction. Low-shot relation extraction requires models to recognize novel relations with very few samples. There are two mainstream low-shot RE tasks, including:

Zero-shot RE. This task aims to conduct relation extraction without any annotated instance other than some external knowledge z (or side information), such as relation descriptions. Models are supposed to transfer the knowledge and extract the targeting relation y_t for input instance x through only the external knowledge.

Few-shot RE. This task aims to conduct relation extraction with only a few annotated instances per novel relations. Each few-shot RE task contains a support set $S = S_1, ..., S_N$ for N novel relations. And for relation i, $S_i = S_i^0, ..., S_i^K$ contains K annotated instances. Models are supposed to learn to transfer the knowledge and extract the targeting relation y_t for instance x through the N-way K-shot support set.

3 Multi-Choice Matching Networks

In this section, we introduce our multi-choice matching networks (MCMN). Different from previous unifying models, MCMN adopts a much more efficient and lightweight decoding module. Following are the detailed descriptions.

3.1 Multi-choice Prompt

Fundamentally, relation extraction can be viewed as a multiple choice task. Inspired by recent advances of prompt learning (Brown et al., 2020; Schick and Schütze, 2021), we construct a multi-choice prompt for each relation extraction task by directly concatenate all relation names or descriptions. Formally, the multi-choice prompts are in the following form:

[C] rel 1 [C] rel 2 ... [C] rel N

where [C] is the placeholder separator for the following relation. For example in Figure 2, the target RE task contains three novel relations: *employee_of*, *ceo_of*, and *others*, of which the relation descriptions are then concatenated altogether to form the multi-choice prompt "[C] employee of [C] ceo of [C] others". After obtaining the multi-choice prompt, we then feed it accompanied with the input sentence into the instance encoder, and the representations at separator [C] is regarded as the representation of its following relation.

3.2 Instance Encoder

Before instance encoding, we concatenate the multi-choice prompt with each input instance into a single sentence, and separate them with a [SEP] token. Besides, we follow (Baldini Soares et al., 2019) and wrap the given entity pair with [e1], [/e1], [e2] and [/e2] respectively. For the example in Figure 2, the entire input to encoder is: "[CLS] [C] employee of [C] ceo of [C] others [SEP] [e1] Tim Cook [/e1] is the CEO of [e2] Apple [/e2] . [SEP]". Then we encode the entire sentence x through a Transformer (Vaswani et al., 2017) encoder:

$$\mathbf{h}_{[CLS]}, \mathbf{h}_{[C]}, ..., \mathbf{h}_{[SEP]} = \mathcal{H}(x), \qquad (1)$$

where **h** is the output embedding for each token in x, d is the dimension of hidden states. These token embeddings are then used for multi-choice matching and model prediction.

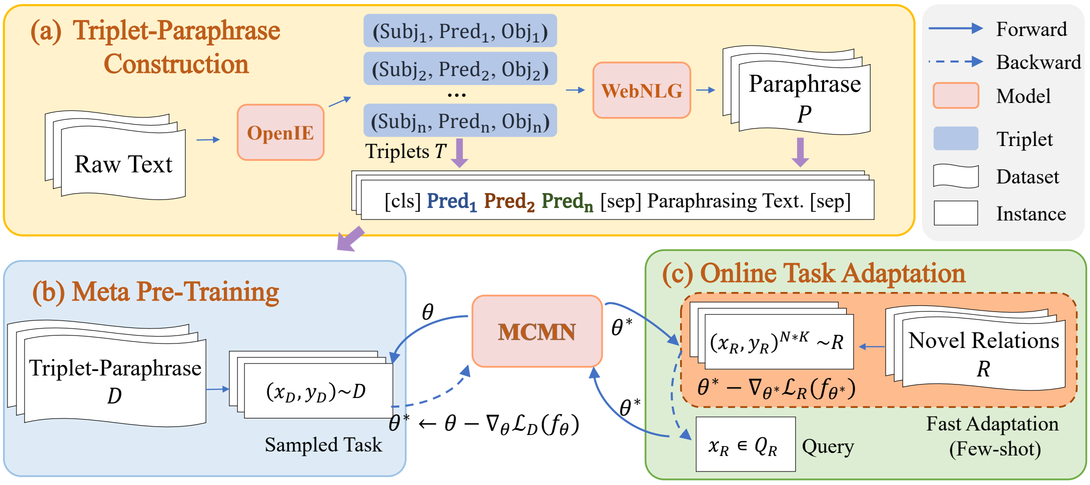

Figure 3: The framework of multi-choice matching training strategy. **(a) Triplet-Paraphrase Construction** conducts triplet-paraphrase pairs for meta training; **(b) Meta Training** on the triplet-paraphrase triplets; **(c) Online Task Meta-Training** performs an online meta-training for each test tasks.

3.3 Multi-choice Matching and Prediction

The multi-choice matching module matches the input instance to the corresponding relation. For each relation type, we use hidden states of *[C]* marker to represent each following relation:

$$\mathbf{h}_{rel_i} = \mathbf{h}_{[C]_i}, \tag{2}$$

where $\mathbf{h}_{rel_i}$ is the representation for relation i and $\mathbf{h}_{[C]_i}$ is the hidden state for the i^{th} [C] token. For the input text, we simply average hidden states of *[e1]* and *[e2]* to obtain the instance representation $\mathbf{X}$:

$$\mathbf{X} = avg(\mathbf{h}_{[\mathrm{e1}]}, \mathbf{h}_{[\mathrm{e2}]}). \tag{3}$$

Then we perform matching operation between the instance and each relation:

$$\mathcal{D}(x, y_i) = \|\mathbf{X} - \mathbf{h}_{rel_i}\|_2. \tag{4}$$

In this equation, we adopt the Euclidean distance to measure the similarity, and the corresponding probability for each relation is:

$$P(y_i|x;\theta) = \frac{\exp(-\mathcal{D}(x, y_i))}{\sum_{j=1}^{N} \exp(-\mathcal{D}(x, y_j))}. \tag{5}$$

Finally, we choose the relation $\hat{y}$ with the maximal probability as the prediction:

$$\hat{y} = \arg\max_i P(y_i|x;\theta). \tag{6}$$

3.4 Training Loss

We adopt an end-to-end training manner by minimizing the following loss function:

$$\mathcal{L}_{(x,y)}(\theta) = -\sum_{i=1}^{N} \boldsymbol{I}(y_i) \log P(y_i|x_i;\theta), \tag{7}$$

where $\boldsymbol{I}(.)$ equals 1 if y_i is the golden class, otherwise $\boldsymbol{I}(.) = 0$. The three-period training process will be detailed described in the following section.

4 Training Strategies for Multi-Choice Matching Networks

As mentioned above, the required abilities for zero-shot and few-shot are different. In this paper, we propose triplet-paraphrase meta pre-training, which jointly learn the label semantic matching ability required by zero-shot RE and instance summarizing ability required by few-shot RE. Following is the detailed description of the pre-training framework.

4.1 Triplet-Paraphrase Construction

To endow the label semantic matching ability to MCMN, it is required to incorporate large-scale data of both relational sentences and relation types to pre-train the model. Unfortunately, the highly limited relation types in existing RE datasets may lead to overfitting on specific relations and impair the generalization of MCMN. In this paper, we propose the triplet-paraphrase to generate large-scale pre-training data for MCMN from raw texts. The overall procedure of triplet-paraphrase module is demonstrated in Figure 3(a), which extracts predicates from large-scaled raw texts as the relation descriptions. Then we utilize the extracted relational triplets to generate paraphrase sentences for further multi-choice matching pre-training. The elaboration is presented below.

Relational Triplet Extraction. Most complete sentences contain at least one relational triplet, which includes the subject, predicate, and object. The predicate in a sentence corresponds to property or relation between the subject and object, which can be regarded as a concrete expression of one relationship. Therefore, To extract large-scaled triplets from open domain texts, we use OpenIE model[2] to extract on article collections of Wikipedia. Considering the example sentence: *The service traces its history to an online service known as PlayNET.* OpenIE model extracts all the possible triplets: (*an online service, known as, PlayNET*) and (*The service, traces, its history*). We collect all extracted predicates from raw texts to represent the corresponding relations, preventing the models from overfitting specific relation types. These triplets are further used for paraphrase generation and pre-training.

Paraphrase Generation. One drawback of matching predicate as the relation is that the predicate extracted by OpenIE is commonly a span from current sentence, which may lead models to take the shortcut by directly matching through words co-occurrence. To eliminate this shortcut, we follow several recent works (Agarwal et al., 2021; Liu et al., 2021) to generate paraphrase texts to match the predicate. Specifically, for extracted triplets, we first wrap them with special markers "*[H], [R], [T]*" correspond to subject, predicate and object. Then we input the wrapped triplet texts to generate the paraphrase texts. In our implementation, we adopt T5[3] (Raffel et al., 2020) as the generator, and pre-train it on WebNLG dataset (Gardent et al., 2017). For example, we wrap (*an online service, known as, PlayNET*) to "[H] an online service [R] known as [T] PlayNET" then generate the paraphrase text *playnet is an online service.* After generating the paraphrase, we then match it to the corresponding predicate for pre-training.

4.2 Triplet-Paraphrase Meta Pre-training

Each instance in the pre-training batch contains the paraphrase text and the corresponding predicate span. In addition, as shown in Figure 3(a), we concatenate all predicates in the current mini-batch as the multi-choice prompt and follow the training loss in Equation 7 to pre-train MCMN, where $\boldsymbol{I}(y_i)$ equals to 1 when y_i is the corresponding predicate, otherwise, $\boldsymbol{I}(y_i) = 0$. ·

Algorithm 1 MCMN for Few-shot Prediction

```
Require: $n$: fine-tuning epochs in online period
Require: $\theta^*$: meta-learned model parameters
Require: $\mathcal{S}$: support set, $x_q$: query instance
Require: $\alpha$: learning rate
$\theta' = \theta^*$ # save original model
for epoch in range(n) do
    # compute loss of the support set:
    $\mathcal{L}_{\mathcal{S}} = \mathbb{E}_{(x,y)\in\mathcal{S}}\mathcal{L}_{(x,y)}(\theta^*)$
    # update model parameters:
    $\theta^* \leftarrow \theta^* - \alpha\nabla_{\theta^*}\mathcal{L}_{\mathcal{S}}$
end for
$y = f_{\theta^*}(x_q)$ # predict the query instance
$\theta^* = \theta'$ # restore the original model
return $y$
```

4.3 Online Task Adaptation

In online learning or testing period, we adopt different adaptation strategies for different low-shot tasks. For zero-shot RE, we directly use the trained MCMN to conduct the task. For few-shot RE, we perform an online task meta-training on the support set, as shown in Algorithm 1. For each few-shot task with support set $\mathcal{S}$ and query instance x_q, we first update the model with all support instances:

$$\theta^* \leftarrow \theta^* - \alpha\nabla_{\theta^*}\mathbb{E}_{(x,y)\in\mathcal{S}}\mathcal{L}_{(x,y)}(\theta^*), \tag{8}$$

where α is the learning rate, $\mathcal{L}(_{(x,y)}(\theta^*))$ is the loss defined in Equation 7. To avoid overfitting, we use an early-stop criterion controlled by an adaptation epoch threshold that once the adaptation epoch is over the threshold, we exit the online fine-tuning and give the prediction for current query instance x_q:

$$y = f_{\theta^*}(x_q). \tag{9}$$

Finally, we restore the model parameter $\theta^* = \theta'$ and repeat the procedure to the next task.

5 Experiments

5.1 Datasets and Task Settings

We conduct experiments on three low-shot relation extraction tasks: zero-shot RE (Bragg et al., 2021), few-shot RE (Bragg et al., 2021) and the more challenging few-shot RE with none-of-the-above (NOTA) (Gao et al., 2019b). These tasks are all conducted based on FewRel dataset (Han et al., 2018), which is constructed through distantly aligning WikiData triplets to Wikipedia articles. In total, FewRel dataset consists of 100 relation types and

Table 1: Results (%) on zero-shot, few-shot, and few-shot with NOTA RE tasks. We report accuracy (Acc.), confidence interval (ci.), and standard deviation (Std., lower is better) for zero- and few-shot RE, and only accuracy for few-shot with NOTA task.

700 instances per type. Standard FewRel settings adopt a split of 64/16/20 fraction corresponding to train/validation/test set, where the train and validation sets are publicly accessible while the test set is not. Following are the detailed settings for each evaluation task.

Zero- and Few-shot Relation Extraction Settings. We follow the standard Flex benchmark settings, which separate the train and validation sets from FewRel into a train set of 65 relations, a validation set of 5 relations and a test set of 10 relations. The test tasks are sampled and processed through the FLEX official toolkit [4].

Few-shot RE with NOTA Relation Settings. A drawback of conventional few-shot RE tasks is that they neglect the existence of other relations, that is all query instances are assumed to express one of the given relations in the support set. Gao et al. (2019b) point out this problem and add the *"none-of-the-above"* (NOTA) relation to consider the situation where query instance does not express any of the given relations. In our experiment, we follow the default settings of FewRel benchmark and evaluate our methods on 5-way 1/5-shot tasks with a 15% or 50% NOTA rate.

5.2 Baseline and Evaluation Metrics

Baseline Methods. For zero-shot and few-shot RE tasks, we compare our model with **UniFew** (Bragg et al., 2021), a unified few-shot learning model based on T5 (Raffel et al., 2020). This model converts each few-shot classification task into a machine reading comprehension format and predicts the results through generation. With a pre-training period on large-scaled MRC data, this model reaches strong performance on both zero- and few-shot tasks. For few-shot RE with NOTA relation task, we compare our model with **Bert-Pair** (Gao et al., 2019b), an instance-pair matching framework for few-shot RE tasks. This model computes a similarity and a dissimilarity score simultaneously between query instance and each support instance, then aggregates the similarity score for each relation and dissimilarity score for NOTA relation. And the results of **CNN** and **BERT** based prototypical networks from Gao et al. (2019b) are also reported.

Evaluation Metrics. For zero-shot and few-shot RE tasks, we follow FLEX benchmark and report the accuracy, confidence interval and standard deviation correspondingly. All these results reported are from the official Flex toolkits. For few-shot RE with NOTA relation task, we follow FewRel 2.0 benchmark and report the corresponding accuracy for four different settings.

5.3 Hyperparameters and Implementation Details

In the triplet-paraphrase construction period, we extract relation triplets from articles in Wikipedia and generate the counterpart paraphrase texts. Overall, we generate about one million triplet and paraphrase text pairs. In triplet-paraphrase meta-training periods, we use a learning rate of 5e-6, weight decay of 1e-6, dropout rate of 0.5, and a linear learning schedule with a 0.95 weight decay.

---

[4] https://github.com/allenai/flex

In the online task meta-training period, we use learning rate of 5e-6, and the adaptation epoch of 1 or 2 for FewRel NOTA tasks, epochs of 45 for FLEX tasks, while keep other hyperparameters the same. We use RoBERTa-large (Liu et al., 2019) to initialize our model. Furthermore, to better endow the low-shot capability to our model, we adopt annotated FewRel data (Han et al., 2018) as an additionally supervised meta-training procedure.

5.4 Overall Results

Table 1 shows the overall results on three different RE tasks. From this table, we can see that:

- **MCMN with triplet-paraphrase pre-training outperforms previous methods in all three RE tasks and achieve state-of-the-art performance.** Compared with the strong baseline methods, MCMN achieves remarkable performance improvements. In zero-shot and few-shot RE tasks, MCNN with triplet paraphrase pre-training outperforms the baseline methods by at least 1.8% in average. In few-shot RE with NOTA task, our method outperforms previous best method by at least 4.99% in average and achieve the best performance in the leaderboard.
- **Our triplet-paraphrase pre-training achieves promising results on low-shot RE tasks.** Comparing with other pre-training strategies such as UniFew model pre-trained with large annotated MRC datasets, triplet-paraphrase pre-training achieves much better performance on zero-shot RE tasks. Besides, triplet-paraphrase can further enhance MCMN to achieves the new state-of-the-art results on all three low-shot RE tasks with supervised meta-training procedure, which are detailed analyzed in the next section.
- **MCMN performs more robust than previous methods.** In zero-shot and few-shot tasks, our methods perform a lower standard deviation and more shallow confidence interval than baseline methods, which means the prediction of our methods is more stable across different tasks.

5.5 Detailed Analysis

In this section, we conduct several experiments for in-depth analysis of our methods.

Ablation Studies on Zero- and Few-shot RE Tasks. To evaluate the effect of each part of our methods on zero- and few-shot RE tasks, we conduct separate experiments on triplet-paraphrase pre-training, MCMN and MCMN without triplet-paraphrase pre-training on Flex test set. As shown in Table 2, we can see that the pure triplet-paraphrase pre-training model outperforms RoBERTa-large model with a remarkable margin as well as leverages the MCMN model with an improvement of at least 1.9% compared with MCMN without triplet-paraphrase pre-training on both zero-shot and few-shot settings. These results demonstrate that triplet-paraphrase pre-training method can significantly improve the generalization and performance of our model, and the framework of multi-choice matching network is quite applicable in low-shot RE tasks. Besides, we notice the performance of pure triplet-paraphrase pre-training model is lower than MCMN without triplet-paraphrase pre-training. To study this issue, we analyze the triplet-paraphrase data, and find that many of the generated texts still consist of words in predicates, though the expression is quite different from the original sentences. This may still lead to the shortcut learning problem. On top of that, the expression of predicates is much different from the relation name, and the negative predicates are much easier to distinguish than the real test cases. These issues altogether result in poor performance. Fortunately, the triplet-paraphrase pre-training period can properly initialize MCMN and leverage the final performance.

Model	Zero-shot		Few-shot		Avg.
	acc	std.	acc.	std.	
RoBERTa	15.6	5.1	21.4	7.3	18.5
Triplet-Para Pre-train	66.6	8.7	74.4	7.6	70.5
MCMN w/o Pre-train	81.0	6.7	85.3	5.7	83.2
MCMN	82.9	6.6	87.4	5.6	85.1

Table 2: Ablation study results (%) of our methods on FLEX RE benchmark, Sup. Meta stands for supervised meta training.

Ablation Studies on Few-shot NOTA RE tasks. We also conduct detailed analyses of our methods in few-shot NOTA RE tasks. As shown in Table 3, the pure triplet-paraphrase pre-trained model can also boost the performance of roberta-large initialized model and leverage the supervised meta-trained MCMN by at least 0.9% in average. Although we do not consider the NOTA relation in the triplet-paraphrase pre-training period, this period can also contribute to the further supervised meta-training period, which indicates that the matching-pattern learned in triplet-paraphrase pre-training

Model	Few-shot with NOTA				Avg.
	5-way 1-shot 0.15	**5-way 5-shot 0.15**	**5-way 1-shot 0.5**	**5-way 5-shot 0.5**	
RoBERTa	27.37	27.88	16.38	16.50	22.03
Triplet-Para Pre-train	69.00	70.59	43.99	43.66	56.81
MCMN w/o. Pre-train	87.89	90.36	83.22	83.10	86.14
MCMN	88.40	89.91	84.56	85.32	87.05
MCMN w/o. Pre-train (**0**-shot)	83.08	84.10	83.61	83.45	83.56
MCMN (**0**-shot)	85.11	85.45	82.72	82.16	83.86

Table 3: Ablation study results (%) of MCMN on FewRel NOTA benchmark. Triplet-Para corresponds to triplet-paraphrase.

period is generalized and robust to down-stream tasks. Besides, we notice that in NA rate of 0.5 tasks, the pure triplet-paraphrase pre-trained model suffers from serious performance drops. This may be caused by the large proportion of negative instances in test tasks. Fortunately, this issue can be alleviated by the online adaptation period.

Zero-shot NOTA RE tasks. This experiment studies the zero-shot performance of our methods on FewRel NOTA tasks. From Table 3, we surprisingly found that our methods also outperform previous state-of-the-art few-shot NOTA models even in zero-shot conditions. This also indicates that our methods are effective in low-shot RE tasks and are robust enough across different settings.

Computing Efficiency of Multi-Choice Matching Networks. This experiment compares the computing efficiency of our method with MRC-based method. Each model is tested on the Flex test set, including both zero-shot and few-shot RE tasks. Models in zero-shot setting only need inference while both models in few-shot setting require fine-tuning on the support set which involves time-consuming back-propagation operations. For fair comparison, we use a single TITAN RTX GPU for each model and keep other computing environments the same. As a result, UniFew takes **647** minutes (more than 10 hours) to finish the test prediction, while our method takes about **80** minutes to obtain the results in Table 1, which improves the speed of roughly an order of magnitude. The main reason for such an efficiency discrepancy is that UniFew, as a generative model, involves an auto-regressive decoder to generate the results, whereas our method directly matches the relation and instance representations to give the results.

6 Related Works

Relation Extraction. Recent success of supervised relation extraction methods (Zeng et al., 2014; Zhou et al., 2016) heavily depends on large amount of annotated data. However, the bottleneck on data annotation severely limits the adaptation of these supervised methods to real scenarios. Recent works reply to this dilemma from the perspective of low-shot learning, which mainly focuses on zero- and few-shot RE tasks. In this work, we shed light on three representative sub-fields tasks, including zero-shot RE, few-shot RE and few-shot RE with NOTA relation to evaluate our methods

Zero-shot Relation Extraction. Levy et al. (2017) firstly introduce the zero-shot relation extraction task and adjust the machine reading comprehension (MRC)-based paradigm for it. Following this line, other MRC-based methods have been proposed (Cetoli, 2020; Bragg et al., 2021). Another paradigm for zero-shot RE is matching-based (Socher et al., 2013), which falls into the text-entailment-based methods (Obamuyide and Vlachos, 2018; Sainz et al., 2021), and the representation matching-based methods (Chen and Li, 2021; Dong et al., 2021). Text-entailment-based methods concatenate the relation description with the input sentence to assess whether they entail the same semantic relationship; Representation matching-based methods separately encode the relation and instance into the same semantic space but are not capable of handling the NOTA relation.

Few-shot Relation Extraction. Han et al. (2018) firstly propose the few-shot relation extraction task and adopt several meta-learning methods (Munkhdalai and Yu, 2017; Snell et al., 2017; Satorras and Estrach, 2018; Mishra et al., 2018) for it. Recent works on few-shot RE mostly centers around the metric-based methods (Vinyals et al., 2016), such as prototype-based methods (Baldini Soares et al., 2019; Ye and Ling, 2019; Gao et al., 2019a) and meta learning-based methods (Finn et al., 2017). Besides, Gao et al. (2019b) extend the FewRel challenge with few-shot domain adaptation (DA) and none-of-the-above (NOTA) tasks, which are more challenging and closer to real-world application.

Few-shot RE with NOTA. Although NOTA relation is common in conventional supervised RE tasks (Zhang et al., 2017), it is quite different in few-shot scenarios due to the label inconsistency problem. As an example, consider an instance that expresses relation r. In task A, relation r is not included in the support set, and thus model learns the semantic mapping between this instance and the NOTA relation. But in another task B where relation r is included in the support set, the model learned from task A may continue to match this instance to NOTA relation. Because of the difficulty, attempts to resolve this problem are scarce. To the best of our knowledge, Bert-Pair (Gao et al., 2019b) is the only public method for this task, and our work is the first method to unify the zero-shot, few-shot and few-shot with NOTA tasks.

7 Conclusions

In this paper, we propose Multi-Choice Matching Networks to unify low-shot relation extraction. MCMN introduces a multi-choice prompt to formulate relation extraction as in a multi-choice paradigm. To equip MCMN with different zero-shot and few-shot abilities, we propose the triplet-paraphrase meta pre-training, which leverages triplet paraphrase to pre-train zero-shot label matching ability and uses meta-learning paradigm to learn few-shot instance summarizing ability. Experimental results on three different RE tasks show MCMN outperforms strong baseline models by large margins.

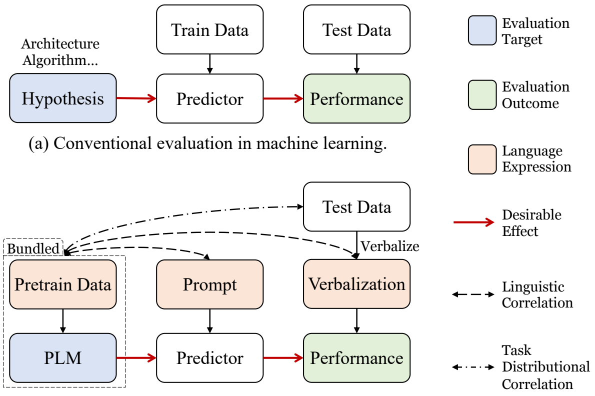
Abstract

Prompt-based probing has been widely used in evaluating the abilities of pretrained language models (PLMs). Unfortunately, recent studies have discovered such an evaluation may be inaccurate, inconsistent and unreliable. Furthermore, the lack of understanding its inner workings, combined with its wide applicability, has the potential to lead to unforeseen risks for evaluating and applying PLMs in real-world applications. To discover, understand and quantify the risks, this paper investigates the prompt-based probing from a causal view, highlights three critical biases which could induce biased results and conclusions, and proposes to conduct debiasing via causal intervention. This paper provides valuable insights for the design of unbiased datasets, better probing frameworks and more reliable evaluations of pretrained language models. Furthermore, our conclusions also echo that we need to rethink the criteria for identifying better pretrained language models[1].

1 Introduction

During the past few years, the great success of pretrained language models (PLMs) (Devlin et al., 2019; Liu et al., 2019; Brown et al., 2020; Raffel et al., 2020) raises extensive attention about evaluating what knowledge do PLMs actually entail. One of the most popular approaches is prompt-based probing (Petroni et al., 2019; Davison et al., 2019; Brown et al., 2020; Schick and Schütze, 2020; Ettinger, 2020; Sun et al., 2021), which assesses whether PLMs are knowledgable for a specific task by querying PLMs with task-specific prompts. For example, to evaluate whether BERT knows the birthplace of Michael Jordan, we could query BERT with "Michael Jordan was born in [MASK]". Recent studies often construct prompt-based probing datasets, and take PLMs' performance on these datasets as their abilities for the corresponding tasks. Such a probing evaluation has been wildly used in many benchmarks such as SuperGLUE (Wang et al., 2019; Brown et al., 2020), LAMA (Petroni et al., 2019), oLMpics (Talmor et al., 2020), LM diagnostics (Ettinger, 2020), CAT (Zhou et al., 2020), X-FACTR (Jiang et al., 2020a), BioLAMA (Sung et al., 2021), etc.



(a) Conventional evaluation in machine learning.

(b) PLM evaluation via prompt-based probing.

Figure 1: The illustrated procedure for two kinds of evaluation criteria.

Unfortunately, recent studies have found that evaluating PLMs via prompt-based probing could be inaccurate, inconsistent, and unreliable. For example, Poerner et al. (2020) finds that the performance may be overestimated because many instances can be easily predicted by only relying on surface form shortcuts. Elazar et al. (2021) shows that semantically equivalent prompts may result in quite different predictions. Cao et al. (2021) demonstrates that PLMs often generate unreliable predictions which are prompt-related but not knowledge-related.

In these cases, the risks of blindly using prompt-based probing to evaluate PLMs, without understanding its inherent vulnerabilities, are significant. Such biased evaluations will make us overestimate or underestimate the real capabilities of PLMs, mislead our understanding of models, and result in

wrong conclusions. Therefore, to reach a trustworthy evaluation of PLMs, it is necessary to dive into the probing criteria and understand the following two critical questions: *1) What biases exist in current evaluation criteria via prompt-based probing? 2) Where do these biases come from?*

To this end, we compared PLM evaluation via prompt-based probing with conventional evaluation criteria in machine learning. Figure 1 shows their divergences. Conventional evaluations aim to evaluate different hypotheses (e.g., algorithms or model structures) for a specific task. The tested hypotheses are raised independently of the training/test data generation. However, this independence no longer sustains in prompt-based probing. There exist more complicated implicit connections between pretrained models, probing data, and prompts, mainly due to the bundled pretraining data with specific PLMs. These unaware connections serve as invisible hands that can even dominate the evaluation criteria from both linguistic and task aspects. From the linguistic aspect, because pretraining data, probing data and prompts are all expressed in the form of natural language, there exist inevitable *linguistic correlations* which can mislead evaluations. From the task aspect, the pretraining data and the probing data are often sampled from correlated distributions. Such invisible *task distributional correlations* may significantly bias the evaluation. For example, Wikipedia is a widely used pretraining corpus, and many probing data are also sampled from Wikipedia or its extensions such as Yago, DBPedia or Wikidata (Petroni et al., 2019; Jiang et al., 2020a; Sung et al., 2021). As a result, such task distributional correlations will inevitably confound evaluations via domain overlapping, answer leakage, knowledge coverage, etc.

To theoretically identify how these correlations lead to biases, we revisit the prompt-based probing from a causal view. Specifically, we describe the evaluation procedure using a structural causal model (Pearl et al., 2000) (SCM), which is shown in Figure 2a. Based on the SCM, we find that the linguistic correlation and the task distributional correlation correspond to three backdoor paths in Figure 2b-d, which lead to three critical biases:

- **Prompt Preference Bias,** which mainly stems from the underlying linguistic correlations between PLMs and prompts, i.e., the performance may be biased by the fitness of a prompt to PLMs' linguistic preference. For instance, semantically equivalent prompts will lead to different biased evaluation results.

- **Instance Verbalization Bias,** which mainly stems from the underlying linguistic correlations between PLMs and verbalized probing datasets, i.e., the evaluation results are sensitive and inconsistent to the different verbalizations of the same instance (e.g., representing the U.S.A. with the U.S. or America).

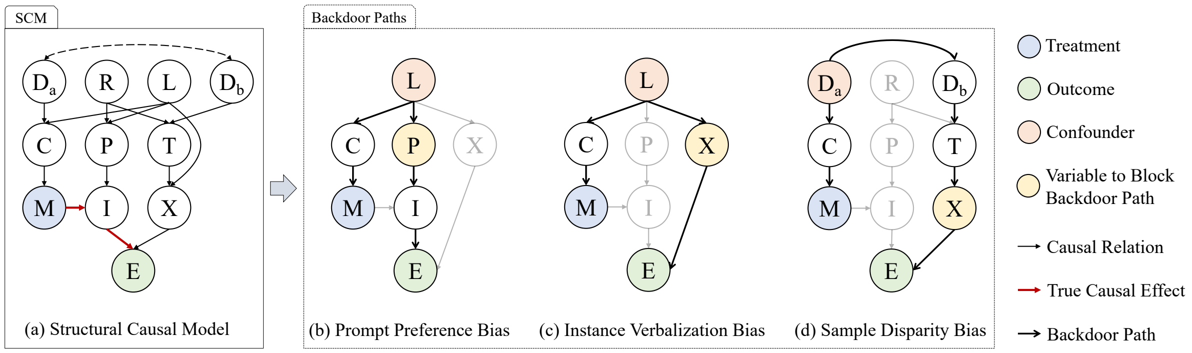
- **Sample Disparity Bias,** which mainly stems from the invisible distributional correlation between pretraining and probing data, i.e., the performance difference between different PLMs may due to the sample disparity of their pretraining corpus, rather than their ability divergence. Such invisible correlations may mislead evaluation results, and thus lead to implicit, unaware risks of applying PLMs in real-world applications.

We further propose to conduct causal intervention via backdoor adjustments, which can reduce bias and ensure a more accurate, consistent and reliable probing under given assumptions. Note that this paper not intends to create a "universal correct" probing criteria, but to remind the underlying invisible risks, to understand how spurious correlations lead to biases, and to provide a causal toolkit for debiasing probing under specific assumptions. Besides, we believe that our discoveries not only exist in prompt-based probing, but will also influence all prompt-based applications to pretrained language models. Consequently, our conclusions echo that we need to rethink the criteria for identifying better pretrained language models with the above-mentioned biases.

Generally, the main contributions of this paper are:

- We investigate the critical biases and quantify their risks of evaluating pretrained language models with widely used prompt-based probing, including prompt preference bias, instance verbalization bias, and sample disparity bias.

- We propose a causal analysis framework, which can be used to effectively identify, understand, and eliminate biases in prompt-based probing evaluations.



(a) Structural Causal Model (b) Prompt Preference Bias (c) Instance Verbalization Bias (d) Sample Disparity Bias

Figure 2: The structural causal model for factual knowledge probing and the three backdoor paths in SCM correspond to three biases.

- We provide valuable insights for the design of unbiased datasets, better probing frameworks, and more reliable evaluations, and echo that we should rethink the evaluation criteria for pretrained language models.

2 Background and Experimental Setup

2.1 Causal Inference

Causal inference is a promising technique for identifying undesirable biases and fairness concerns in benchmarks (Hardt et al., 2016; Kilbertus et al., 2017; Kusner et al., 2017; Vig et al., 2020; Feder et al., 2021). Causal inference usually describes the causal relations between variables via Structural Causal Model (SCM), then recognizes confounders and spurious correlations for bias analysis, finally identifies true causal effects by eliminating biases using causal intervention techniques.

SCM The structural causal model (Pearl et al., 2000) describes the relevant features in a system and how they interact with each other. Every SCM is associated with a graphical causal model $G = \{V, f\}$, which consists of a set of nodes representing variables V, as well as a set of edges between the nodes representing the functions f to describe the causal relations.

Causal Intervention To identify the true causal effects between an ordered pair of variables (X, Y), Causal intervention fixes the value of $X = x$ and removes the correlations between X and its precedent variables, which is denoted as $do(X = x)$. In this way, $\mathcal{P}(Y = y|do(X = x))$ represents the true causal effects of treatment X on outcome Y (Pearl et al., 2016).

Backdoor Path When estimating the causal effect of X on Y, the backdoor paths are the non-causal paths between X and Y with an arrow into X, e.g., $X \leftarrow Z \rightarrow Y$. Such paths will confound the effect that X has on Y but not transmit causal influences from X, and therefore introduce spurious correlations between X and Y.

Backdoor Criterion The Backdoor Criterion is an important tool for causal intervention. Given an ordered pair of variables (X, Y) in SCM, and a set of variables Z where Z contains no descendant of X and blocks every backdoor path between X and Y, then the causal effects of $X = x$ on Y can be calculated by:

$$\begin{aligned} &\mathcal{P}(Y = y|do(X = x)) = \\ &\sum_{z} \mathcal{P}(Y = y|X = x, Z = z)\mathcal{P}(Z = z), \end{aligned} \tag{1}$$

where $\mathcal{P}(Z = z)$ can be estimated from data or priorly given, and is independent of X.

2.2 Experimental Setup

Task This paper investigates prompt-based probing on one of the most representative and well-studied tasks – factual knowledge probing (Liu et al., 2021b). For example, to evaluate whether BERT knows the birthplace of Michael Jordan, factual knowledge probing queries BERT with "Michael Jordan was born in [MASK]", where `Michael Jordan` is the verbalized subject mention, *"was born in"* is the verbalized prompt of relation `birthplace`, and [MASK] is a placeholder for the target object.

Data We use LAMA (Petroni et al., 2019) as our primary dataset, which is a set of knowledge triples sampled from Wikidata. We remove the N-M relations (Elazar et al., 2021) which are unsuitable for the P@1 metric and retain 32 probing relations in the dataset. Please refer to the appendix for detail.

Pretrained Models We conduct probing experiments on 4 well-known PLMs: BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), GPT-2 (Radford et al., 2019) and BART (Lewis et al., 2020), which correspond to 3 representative PLM architectures, including autoencoder (BERT, RoBERTa), autoregressive (GPT-2) and denoising autoencoder (BART).

3 Structural Causal Model for Factual Knowledge Probing

In this section, we formulate the SCM for factual knowledge probing procedure and describe the key variables and causal relations.

The SCM is shown in Figure 2a, which contains 11 key variables: 1) **Pretraining corpus distribution** D_a; 2) **Pretraining corpus** C, e.g., Webtext for GPT2, Wikipedia for BERT; 3) **Pretrained language model** M; 4) **Linguistic distribution** L, which guides how a concept is verbalized into natural language expression, e.g., relation to prompt, entity to mention; 5) **Relation** R, e.g., `birthplace`, `capital`, each relation corresponds to a probing task; 6) **Verbalized prompt** P for each relation , e.g, x *was born in* y; 7) **Task-specific predictor** I, which is a PLM combined with a prompt, e.g., <BERT, *was born in*> as a `birthplace` predictor; 8) **Probing data distribution** D_b, e.g., fact distribution in Wikidata; 9) **Sampled probing data** T such as LAMA, which are sampled entity pairs (e.g., <Q41421, Q18419> in Wikidata) of relation R; 10) **Verbalized instances** X, (e.g., <Michael Jordan, Brooklyn> from <Q41421, Q18419>); 11) **Performance** E of the predictor I on X.

The causal paths of the prompt-based probing evaluation contains:

- **PLM Pretraining.** The path $\{D_a, L\} \rightarrow C \rightarrow M$ represents the pretraining procedure for language model M, which first samples pretraining corpus C according to pretraining corpus distribution D_a and linguistic distribution L, then pretrains M on C.
- **Prompt Selection.** The path $\{R, L\} \rightarrow P$ represents the prompt selection procedure, where each prompt P must exactly express the semantics of relation R, and will be influenced by the linguistic distribution L.
- **Verbalized Instances Generation.** The path $\{D_b, R\} \rightarrow T \rightarrow X \leftarrow L$ represents the generation procedure of verbalized probing instances X, which first samples probing data T of relation R according to data distribution D_b, then verbalizes the sampled data T into X according to the linguistic distribution L.
- **Performance Estimation.** The path $\{M, P\} \rightarrow I \rightarrow E \leftarrow X$ represents the performance estimation procedure, where the predictor I is first derived by combining PLM M and prompt P, and then the performance E is estimated by applying predictor I on verbalized instances X.

To evaluate PLMs' ability on fact extraction, we need to estimate $\mathcal{P}(E|do(M = m), R = r)$. Such true causal effects are represented by the path $M \rightarrow I \rightarrow E$ in SCM. Unfortunately, there exist three backdoor paths between pretrained language model M and performance E, as shown in Figure 2b-d. These spurious correlations make the observation correlation between M and E cannot represent the true causal effects of M on E, and will inevitably lead to biased evaluations. In the following, we identify three critical biases in the prompt-based probing evaluation and describe the manifestations, causes, and casual interventions for each bias.

4 Prompt Preference Bias

In prompt-based probing, the predictor of a specific task (e.g., the knowledge extractor of relation `birthplace`) is a PLM M combined with a prompt P (e.g., BERT + *was born in*). However, PLMs are pretrained on specific text corpus, therefore will inevitably prefer prompts sharing the same linguistic regularity with their pretraining corpus. Such implicit prompt preference will confound the true causal effects of PLMs on evaluation performance, i.e., the performance will be affected by both the task ability of PLMs and the preference fitness of a prompt. In the following, we investigate prompt preference bias via causal analysis.

4.1 Prompt Preference Leads to Inconsistent Performance

In factual knowledge probing, we commonly assign one prompt for each relation (e.g., `X was born in Y` for `birthplace`). However, different PLMs may prefer different prompts, and it is unable to disentangle the influence of prompt preference from the final performance. Such invisible

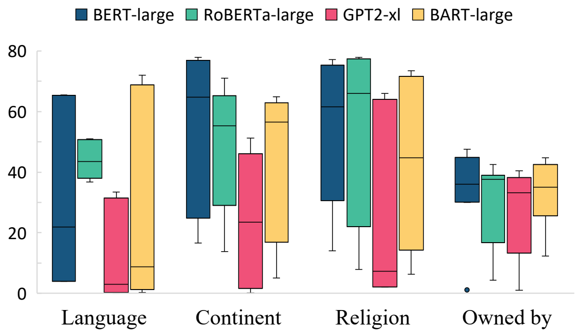


Figure 3: The variances of P@1 performance of 4 PLMs on 4 relations using semantically equivalent prompts. We can see the performance varies significantly.

Models	LAMA P@1	Worst P@1	Best P@1	Std
BERT-large	39.08	23.45	46.73	8.75
RoBERTa-large	32.27	15.64	41.35	9.07
GPT2-xl	24.19	11.19	33.52	8.56
BART-large	27.68	16.21	38.93	8.35

Table 1: The P@1 performance divergence of prompt selection averaged over all relations, we can see prompt preference results in inconsistent performance.

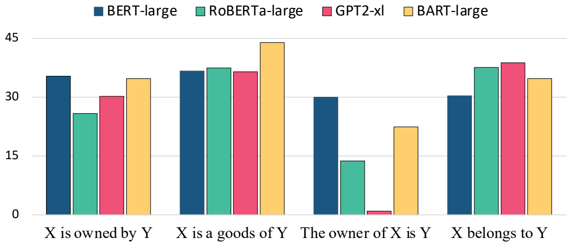

Figure 4: The P@1 performance of 4 PLMs using 4 different prompts of relation `owned by`, where the rank of 4 PLMs is unstable on different prompts: prompt preference leads to 3 distinct "best" models and 3 distinct "worst" models.

prompt preference will therefore lead to inconsistent conclusions.

To demonstrate this problem, we report the performance variance on LAMA using different prompts for each PLM. For each relation, we follow Elazar et al. (2021); Jiang et al. (2020b) and design at least 5 prompts that are semantically equivalent and faithful but vary in linguistic expressions.

Prompt selection significantly affects performance. Figure 3 illustrates the performance on several relations, where the performances of all PLMs vary significantly on semantically equivalent prompts. For instance, by using different prompts, the Precision@1 of relation `languages spoken` dramatically changing from 3.90% to 65.44% on BERT-large, and from 0.22% to 71.94% on BART-large. This result is shocking, because the same PLM can be assessed from "knowing nothing" to "sufficiently good" by only changing its prompt. Table 1 further shows the quantitative results, for BERT-large, the averaged standard deviation of Precision@1 of different prompts is 8.75. And the prompt selection might result in larger performance variation than model selection: on more than 70% of relations, the best and worst prompts will lead to >10 point variation at Precision@1, which is larger than the majority of performance gaps between different models.

Prompt preference also leads to inconsistent comparisons. Figure 4 demonstrates an example, where the ranks of PLMs are significantly changed when applying diverse prompts. We also conduct quantitative experiments, which show that the PLMs' ranks on 96.88% relations are unstable when prompt varies.

All these results demonstrate that the prompt preference bias will result in inconsistent performance. Such inconsistent performance will further lead to unstable comparisons between different PLMs, and therefore significantly undermines the evaluations via prompt-based probing.

4.2 Cause of Prompt Preference Bias

Figure 2b shows the cause of the prompt preference bias. When evaluating the ability of PLMs on specific tasks, we would like to measure the causal effects of path $M \rightarrow I \rightarrow E$. However, because the prompt P and the PLM M are all correlated to the linguistic distribution L, there is a backdoor path $M \leftarrow C \leftarrow L \rightarrow P \rightarrow I \rightarrow E$ between PLM M and performance E. Consequently, the backdoor path will confound the effects of $M \rightarrow I \rightarrow E$ with $P \rightarrow I \rightarrow E$.

Based on the above analysis, the prompt preference bias can be eliminated by blocking this backdoor path via backdoor adjustment, which requires a prior formulation of the distribution $\mathcal{P}(P)$. In Section 7, we will present one possible causal intervention formulation which can lead to more consistent evaluations.

5 Instance Verbalization Bias

Apart from the prompt preference bias, the underlying linguistic correlation can also induce bias in the instance verbalization process. Specifically, an instance in probing data can be verbalized into different natural language expressions (e.g., verbalize

Relation	Mention	Prediction
Capital of	America	Chicago
	the U.S.	Washington
	China	Beijing
	Cathay	Bangkok
Birthplace	Einstein	Berlin
	Albert Einstein	Vienna
	Isaac Newton	London
	Sir Isaac Newton	town

Table 2: Different verbalized names of the same entity lead to different predictions on BERT-large.

`Q30` in Wikidata into `America` or `the U.S.`), and different PLMs may prefer different verbalizations due to mention coverage, expression preference, etc. This will lead to instance verbalization bias.

5.1 Instance Verbalization Brings Unstable Predictions

In factual knowledge probing, each entity is verbalized to its default name. However, different PLMs may prefer different verbalizations, and such underlying correlation is invisible. Because we couldn't measure how this correlation affects probing performance, the evaluation may be unstable using different verbalizations.

Table 2 shows some intuitive examples. When we query BERT "The capital of the U.S. is [MASK]", the answer is `Washington`. Meanwhile, BERT would predict `Chicago` if we replace `the U.S.` to its alias `America`. Such unstable predictions make us unable to obtain reliable conclusions on whether or to what degree PLMs actually entail the knowledge.

To quantify the effect of instance verbalization bias, we collect at most 5 verbalizations for each subject entity in LAMA from Wikidata, and calculate the *verbalization stability* on each relation, i.e., the percentage of relation instances whose predictions are unchanged when verbalization varies. The results in Figure 5 show the average verbalization stabilities of all four PLMs are < 40%, which demonstrate that the instance verbalization bias will bring unstable and unreliable evaluation.

5.2 Cause of Instance Verbalization Bias

Figure 2c shows the cause of instance verbalization bias: the backdoor path $M \leftarrow C \leftarrow L \rightarrow X \rightarrow E$, which stems from the confounder of linguistic distribution L between pretraining corpus C and verbalized probing data X. Consequently, the observed correlation between M and E couldn't faithfully represent the true causal effect of M on E, but is also mixed up the spurious correlation caused by the backdoor path.

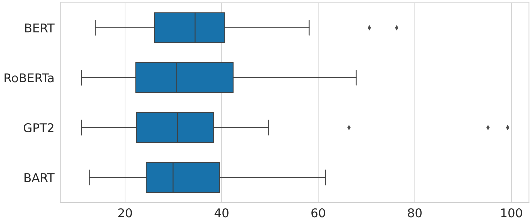

Figure 5: The *verbalization stabilities* of 4 PLMs on all relations, which is measured by the percentage of relation instances whose predictions are unchanged when verbalization varies. We can see that the verbalization stabilities of all 4 PLMs (BERT-large, RoBERTa-large, GPT2-xl, BART-large) are poor.

The instance verbalization bias can be eliminated by blocking this backdoor path via causal intervention, which requires a distribution formulation of the instance verbalization, i.e., $\mathcal{P}(X)$. We will present a possible intervention formulation in Section 7.

6 Sample Disparity Bias

Besides the biases induced by linguistic correlations, the distributional correlations between pretraining corpus and task-specific probing data can also introduce sample disparity bias. That is, the performance difference between different PLMs may due to the sample disparity of their pretraining corpus, rather than their ability divergence.

In conventional evaluation, the evaluated hypotheses are independent of the train/test data generation, and all the hypotheses are evaluated on training data and test data generated from the same distribution. Therefore, the impact of correlations between training data and test data is transparent, controllable, and equal for all the hypotheses. By contrast, in prompt-based probing, each PLM is bundled with a unique pretraining corpus, the correlation between pretraining corpus distribution and probing data distribution cannot be quantified. In the following we investigate this sample disparity bias in detail.

6.1 Sample Disparity Brings Biased Performance

In factual knowledge probing, LAMA (Petroni et al., 2019), a subset sampled from Wikidata,

$\gamma\%$	**BERT-base**	**BERT-large**	**GPT2-base**	**GPT2-medium**
0%	30.54	33.08	15.22	22.11
20%	35.77	39.56	22.02	28.21
40%	38.68	39.75	24.32	30.29
60%	38.72	40.68	25.42	31.16
80%	39.79	41.48	25.65	31.88
100%	40.15	42.51	26.82	33.12
None	37.13	39.08	16.88	22.60

Table 3: The P@1 on LAMA of PLMs whose further pretraining data are with different correlation degrees $\gamma\%$ with LAMA. The BERT-base and GPT2-base both contain 12 layers, while BERT-large and GPT2-medium both contain 24 layers.

is commonly used to compare different PLMs. Previous work claims that GPT-style models are with weaker factual knowledge extraction abilities than BERT because they perform worse on LAMA (Petroni et al., 2019; Liu et al., 2021c). However, because PLMs are pretrained on different pretraining corpus, the performance divergence can stem from the spurious correlation between pretraining corpus and LAMA, rather than their ability difference. For example, BERT's superior performance to GPT-2 may stem from the divergence of their pretraining corpus, where BERT's pretraining corpus contains Wikipedia, while GPT-2's pretraining corpus doesn't.

To verify the effect of sample disparity bias, we further pretrain BERT and GPT-2 by constructing pretraining datasets with different correlation degrees to LAMA, and report their new performances on LAMA. Specifically, we use the Wikipedia snippets in LAMA and collect a 99k-sentence dataset, named WIKI-LAMA. Then we create a series of pretraining datasets by mixing the sentences from WIKI-LAMA with WebText[2] (the pretraining corpus of GPT2). That is, we fix all datasets' size to 99k, and a parameter γ is used to control the mixture degree: for each dataset, there are $\gamma\%$ instances sampled from WIKI-LAMA and $1 - \gamma\%$ instances sampled from WebText. Please refer to the appendix for pretraining detail.

Table 3 demonstrates the effect of sample disparity bias. We can see that 1) Sample disparity significantly influences the PLMs' performance: the larger correlation degree γ will result in better performance for both BERT and GPT-2; 2) Sample disparity contributes to the performance difference. We can see that the performance gap between GPT-2 and BERT significantly narrows down when they are further pretrained using the same data. Besides, further pretraining BERT on WebText (γ=0) would significantly undermine its performance. These results strongly confirm that the sample disparity will significantly bias the probing conclusion.

6.2 Cause of Sample Disparity Bias

The cause of sample disparity bias may diverge from PLMs and scenarios due to the different causal relation between pretraining corpus distribution D_a and probing data distribution D_b. Nevertheless, sample disparity bias always exist because the backdoor path will be $M \leftarrow C \leftarrow D_a \rightarrow D_b \rightarrow T \rightarrow X \rightarrow E$ when D_a is the ancestor of D_b, or $M \leftarrow C \leftarrow D_a \leftarrow D_b \rightarrow T \rightarrow X \rightarrow E$ when D_a is the descendant of D_b. Figure 2d shows a common case when the pretraining corpus distribution D_a is an ancestor of probing data distribution D_b. For example, the pretraining data contains Wikipedia and probing data is a sampled subset from Wikipedia (e.g., LAMA, X-FACTR, BioLAMA). As a result, there is a backdoor path between M and E, which will mislead the evaluation.

7 Bias Elimination via Causal Intervention

This section describes how to eliminate the above-mentioned biases by blocking their corresponding backdoor paths. According to the Backdoor Criterion in Section 2.1, we need to choose a set of variables Z that can block every path containing an arrow into M between M and E. Since the linguistic distribution L, pretraining corpus distribution D_a and probing data distribution D_b are unobservable, we choose $Z = \{P, X\}$ as the variable set for blocking all backdoor paths between (M, E) in the SCM by conducting backdoor adjustment:

$$\begin{aligned}&\mathcal{P}(E|do(M=m), R=r) = \\ &\sum_{p\in P}\sum_{x\in X}\mathcal{P}(p,x)\mathcal{P}(E|m,r,p,x).\end{aligned} \tag{2}$$

Equation 2 provides an intuitive solution. To eliminate the biases stemming from the spurious correlations between pretraining corpus, probing data and prompts, we need to consider the natural distribution of prompts and verbalized probing data regardless of other factors. Consequently, the overall causal effects between PLM and evaluation result are the weighted averaged effects on all valid prompts and probing data.

---

Model	Original	Random	+Intervention
BERT-base	56.4	45.4	**86.5**
BERT-large	100.0	78.1	**100.0**
RoBERTa-base	75.7	44.0	**77.8**
RoBERTa-large	56.1	42.2	**86.5**
GPT2-medium	63.5	40.7	**98.2**
GPT2-xl	74.2	35.7	**77.8**
BART-base	63.4	61.6	**98.2**
BART-large	97.7	61.3	**100.0**
Overall Rank	25.5	5.5	**68.5**

Table 4: The *rank consistencies* over 1000 task samples (each task contains 20 relations from LAMA). For a PLM, the rank consistency is the percentage of its most popular rank in 1000 runtimes. For "Overall Rank", the rank consistency is the percentage of the most popular rank of all PLMs in 1000 runtimes, i.e., the rank of all PLMs remains the same. "Original" means that we use the LAMA's original prompts and verbalized names, "Random" means that we randomly sample prompts and verbalized names every time, "+Intervention" means that we apply causal intervention. We can see that the rank consistency is significantly raised after causal intervention.

Unfortunately, the exact distribution of $\mathcal{P}(x, p)$ is intractable , which needs to iterate over all valid prompts and all verbalized probing data. To address this problem, we propose a sampling-based approximation. Specifically, given a specific assumption about $\mathcal{P}(x, p)$ (we assume uniform distribution in this paper without the loss of generality), we sample K_p prompts for each relation and K_x kinds of verbalization for each instance according to $\mathcal{P}(x, p)$, and then these samples are used to estimate the true causal effects between M and E according to Equation 2.

To verify whether causal intervention can improve the evaluation consistency and robustness, we conduct backdoor adjustment experiments on 8 different PLMs. We randomly sample 1000 subsets with 20 relations from LAMA, and observe whether the evaluation conclusions were consistent and stable across the 1000 evaluation runtimes. Specifically, we use ***rank consistency*** as the evaluation metric, which measures the percentage of the most popular rank of each model in 1000 runtimes. For example, if BERT ranks at 3^{rd} place in 800 of the 1000 runtimes, then the rank consistency of BERT will be 80%.

Table 4 shows the results. We can see that causal intervention can significantly improve the evaluation consistency: 1) The consistency of current prompt-based probing evaluations is very poor on all 8 PLMs: when we randomly select prompts and verbalizations during each sampling, the overall rank consistency is only 5.5%; 2) Causal intervention can significantly improve overall rank consistency: from 5.5% to 68.5%; 3) Casual intervention can consistently improve the rank consistency of different PLMs: the rank of most PLMs is very stable after backdoor adjustment.

The above results verify that causal intervention is an effective technique to boost the stability of evaluation, and reach more consistent conclusions.

8 Related Work

Prompt-based Probing Prompt-based probing is popular in recent years (Rogers et al., 2020; Liu et al., 2021b) for probing factual knowledge (Petroni et al., 2019; Jiang et al., 2020a; Sung et al., 2021), commonsense knowledge (Davison et al., 2019), semantic knowledge (Ettinger, 2020; Sun et al., 2021; Brown et al., 2020; Schick and Schütze, 2020) and syntactic knowledge (Ettinger, 2020) in PLMs. And a series of prompt-tuning studies consider optimizing prompts on training datasets with better performance but may undermine interpretability (Jiang et al., 2020b; Shin et al., 2020; Haviv et al., 2021; Gao et al., 2021; Qin and Eisner, 2021; Li and Liang, 2021; Zhong et al., 2021). Because such prompt-tuning operations will introduce additional parameters and more unknown correlations, this paper does not take prompt-tuning into our SCM, delegate this to future work.

Biases in NLP Evaluations Evaluation is the cornerstone for NLP progress. In recent years, many studies aim to investigate the underlying biases and risks in evaluations. Related studies include investigating inherent bias in current metrics (Coughlin, 2003; Callison-Burch et al., 2006; Li et al., 2017; Sai et al., 2019, 2020), exploring dataset artifacts in data collection and annotation procedure (Lai and Hockenmaier, 2014; Marelli et al., 2014; Chen et al., 2018; Levy and Dagan, 2016; Schwartz et al., 2017; Cirik et al., 2018; McCoy et al., 2019; Liu et al., 2021a; Branco et al., 2021), and identifying the spurious correlations between data and label which might result in catastrophic out-of-distribution robustness of models (Poliak et al., 2018; Rudinger et al., 2018; Rashkin et al., 2018).

Most previous studies demonstrate the evaluation biases empirically, and interpret the underlying reasons intuitively. However, intuitive explanations are also difficult to critical and extend. In contrast, this paper investigates the biases in prompt-based probing evaluations from a causal view. Based on the causal analysis framework, we can identify, understand, and eliminate biases theoretically, which can be extended and adapted to other evaluation settings in a principled manner[3]. We believe both the causal analysis tools and the valuable insights can benefit future researches.

9 Conclusions and Discussions

This paper investigates the critical biases and quantifies their risks in the widely used prompt-based probing evaluation, including prompt preference bias, instance verbalization bias, and sample disparity bias. A causal analysis framework is proposed to provide a unified framework for bias identification, interpretation and elimination with a theoretical guarantee. Our studies can promote the understanding of prompt-based probing, remind the risks of current unreliable evaluations, guide the design of unbiased datasets, better probing frameworks, and more reliable evaluations, and push the bias analysis from empirical to theoretical.

Another benefit of this paper is to remind the evaluation criteria shifts from conventional machine learning algorithms to pretrained language models. As we demonstrate in Figure 1, in conventional evaluation, the evaluated hypotheses (e.g., algorithms, architectures) are raised independently of the train/test dataset generation, where the impact of correlations between training data and test data is transparent, controllable, and equal for all the hypotheses. However, in evaluations of pretrained language models, the pretraining corpus is bundled with the model architecture. In this case, it is significant to distinguish what you need to assess (architecture, corpus, or both), as well as the potential risks raised by the correlations between pretraining corpus and test data, which most current benchmarks have ignored. Consequently, this paper echoes that it is necessary to rethink the criteria for identifying better pretrained language models, especially under the prompt-based paradigm.

In the future, we would like to extend our causal analysis framework to fit prompt-tuning based probing criteria and all PLM-based evaluations.

A Datasets Construction Details

Instance Filtering We follow the data construction criteria as LAMA, we remove the instances whose object is multi-token or not in the intersection vocabulary of these 4 PLMs.

Relation Selection We remove all the N-M relations in LAMA such as "share border with" or "twin city". Because in these relations, there are multiple object entities corresponding to the same subject entity. In that case, the metric Precision@1 is not suitable for evaluating PLMs in such relations. In addition, due to the completeness limitation of knowledge bases, it's impossible to find all the correct answers for each subject. Therefore, we do not include these relations in our experiments.

Prompt Generation Because of the difference between the pretraining tasks of these 4 PLMs (autoencoder, autoregressive and denoising autoencoder), we design prompts where the placeholder for the target object is at the end, e.g., *The birthplace of* x *is* y instead of y *is the birthplace of* x. We follow the instruction from Wikidata, combine the prompts from Elazar et al. (2021) and Jiang et al. (2020b), and manually filter out the prompts with inappropriate semantics. All the prompts are created before any experiments and fixed afterward.

B Further Pretraining Details

We further pretrain BERT with masked language modeling (mask probability=15%) and GPT2 with autoregressive language modeling task respectively. Training was performed on 8 40G-A100 GPUs for 3 epochs, with maximum sequence length 512. The batch sizes for BERT-base, BERT-large, GPT2-base, GPT2-medium are $256, 96, 128, 64$ respectively. All the models is optimized with Adam using the following parameters: $\beta_1 = 0.9, \beta_2 = 0.999, \epsilon = 1e-8$ and the learning rate is $5e-5$ with warmup ratio=0.06.

Evaluating Extreme Hierarchical Multi-label Classification

Abstract

Several natural language processing (NLP) tasks are defined as a classification problem in its most complex form: Multi-label Hierarchical Extreme classification, in which items may be associated with multiple classes from a set of thousands of possible classes organized in a hierarchy and with a highly unbalanced distribution both in terms of class frequency and the number of labels per item. We analyze the state of the art of evaluation metrics based on a set of formal properties and we define an information theoretic based metric inspired by the Information Contrast Model (ICM). Experiments on synthetic data and a case study on real data show the suitability of the ICM for such scenarios.

1 Introduction

Many natural language processing (NLP) problems involve classification, such as sentiment analysis, entity linking, etc. However, the adequacy of evaluation metrics is still an open problem. Different metrics such as Accuracy, F-measure or Macro Average Accuracy (MAAC) may differ substantially, seriously affecting the system optimization process. For example, assigning all elements to the majority class may be very effective according to Accuracy and score low according to MAAC.

In addition, in many scenarios such as tagging in social networks (Coope et al., 2018) or topic identification (Yu et al., 2019), the classifier must assign several labels to each item (multi-label classification). This greatly complicates the evaluation problem since, in addition to the class specificity (frequency), other variables appears such as the distribution of labels per item in the gold standard, the excess or absence of labels in the system output, etc.

The evaluation problem becomes even more complicated if we consider hierarchical category structures, which are very common in NLP. For example, toxic messages are divided into different types of toxicity (Fortuna et al., 2019), named entities could be organized in nested categories (Sekine and Nobata, 2004), etc. In these scenarios, the category proximity in the hierarchical structure is an additional variable.

Even, the problem can be further complicated. *Extreme Classification* scenarios address with thousands of highly unbalanced categories (Gupta et al., 2019), where a few categories are very frequent and others completely infrequent (Almagro et al., 2020). In addition, some items have no category at all and some have many. An example scenario that we will use as a case study in this article is the labelling of adverse events in medical documents.

In this paper, we analyse the state of the art on metrics for multi-label, hierarchical and extreme classification problems. We characterize existing metrics by means of a set of formal properties. The analysis shows that different metric families satisfy different properties, and that satisfying all of them at the same time is not straightforward.

Then, propose an information-theoretic based metric inspired by the Information Contrast Model similarity measure (ICM), which can be particularized to simpler scenarios (e.g. flat, single labeled) while keeping its formal properties. Later, we define a set of five tests on synthetic data to compare empirically ICM against existing metrics. Finally, we explore a case study with real data which shows the suitability of ICM for such extreme scenarios. The paper ends with some conclusions and future work.

2 Background

In this section, we analyze the literature on the two main evaluation problems tackled in this paper: multi-labeling and class hierarchies, keeping the focus on extreme scenarios (numerous and unbalanced classes).

2.1 Multi-Label Classification

There are three main ways of generalizing effectiveness metrics to the multi-label scenario (Zhang and Zhou, 2014). The first one consists in modeling the problem as a ranking task, i.e. the system returns an ordered label list for each item according to their suitability. Some specific ranking metrics applied in multi-label classification displayed in (Wu and Zhou, 2017) are: *Ranking Loss*, which is a ordinal correlation measure, *one-error* which is based on Precision at 1, or *Average Precision*. Although these metrics are very common, they do not take into account the specificity of (unbalanced) classes. Jain et al. proposed the *propensity* versions of ranking metrics (Precision@k, nDCG) in order to weight classes according to their frequency in the data set (Jain et al., 2016).

Reducing the classification to a ranking problem is specially appropriate in extreme classification scenarios and simplifies the definition of metrics. However, it also has several disadvantages. First, it requires the output of the classifier to be in ranking format, and that does not fit many scenarios. For example, annotating posts in social networks requires predicting the amount of tags to be assigned to the post. For this reason, we focus on classification outputs, so ranking based metrics are out of our scope.

Apart from ranking metrics, multi-label effectiveness metrics have been categorized into label- and example-based metrics (Tsoumakas et al., 2010; Zhang and Zhou, 2014). **Label-based evaluation measures** assess and average the predictive performance for each category as a binary classification problem, where the negative category corresponds with the other categories. The most popular are the label-based Accuracy (LB-ACC) and F-measure (LB-F)[1]. The label-based metrics have some drawbacks. First, they do not consider the distribution of labels per item. Hits are rewarded independently of how many labels are associated to the item. Second, while items are supposed to be random samples, classes are not, so the idea of averaging results across classes is not always consistent. That is, the metric scores can vary substantially depending on how the category space is configured. Finally, if there are a large number of possible categories (extreme classification), the score contribution of any label has an upper limit of $\frac{1}{|\mathcal{C}|}$, being $\mathcal{C}$ the set of categories. This limit can be problematic, specially when labels are unbalanced and numerous.

On the other hand, the **example-based metrics** compute for each object, the proximity between predicted and true label sets ($s(d) = \{c_1^s, .., c_n^s\}$ and $g(d) = \{c_1^g, .., c_n^g\}$). Some popular ways to match category sets in multi-label classification evaluation are the Jaccard similarity (EB-JACC) which is computed as $\frac{|s(d) \cap g(d)|}{|s(d) \cup g(d)|}$ (Godbole and Sarawagi, 2004), or the precision $\left(\frac{|s(d) \cap g(d)|}{|s(d)|}\right)$, recall $\left(\frac{|s(d) \cap g(d)|}{|g(d)|}\right)$ and their F combination (EB-F). Another example-based metric is the *Hamming Loss* (EB-HAMM) (Zhang et al., 2006) which matching function is defined as: $\frac{|s(d)\;\mathrm{XOR}\;g(d)|}{|C_g|}$ where C_g represents the set of categories annotated in the gold standard. *Subset Accuracy* (EB-SUBACC) (Ghamrawi and McCallum, 2005) is a more strict measure due to it requires exact matching between both category sets. Notice that all example-based multi-label metrics converge to Accuracy in the single-label scenario. On the other hand, there are some situations in which these metrics are undefined. If both the gold standard and the system output label sets are empty, the maximum score is usually assigned to the item.

The main drawback of these approaches is that they do not take into account the specificity of classes (i.e. unbalanced classes in extreme classification). The label propensity applied over precision and recall for single items can solve this lack. Each accurate class in the intersection is weighted according to the class *propensity* p_c (Jain et al., 2016):

$$\mathrm{Prop}_P(i) = \frac{\sum_{c \in s(i) \cap g(i)} \frac{1}{p_c}}{|s(i)|}$$

$$\mathrm{Prop}_R(i) = \frac{\sum_{c \in s(i) \cap g(i)} \frac{1}{p_c}}{|g(i)|}$$

The propensity factor p_c for each class is computed as: $p_c = \frac{1}{1+Ce^{-A\log_2(N_c+B)}}$ where N_c is

---

[1] In the single label scenario, the label-based F-measure converges to the traditional F and the label-based accuracy is proportional to the traditional ACC.

the number of data points annotated with label c in the observed ground truth data set of size N and A, B are application specific parameters and $C = (logN - 1)(B + 1)^A$. In our experiments, we set the recommended parameter values $A = 0.55$ and $B = 1.5$.

However, propensity precision and recall values are not upper bounded as $\frac{1}{p_c}$ tends to infinite when p_c tends to zero. In order to solve this issue, in our experiments we replace the normalization factors $|s(i)|$ and $|g(i)|$ with the accumulation of inverse propensities in the system output or the gold standard. We also add the empty class $c_\emptyset$ in both the system output and the gold standard in order to capture the specificity of classes in the mono-label scenario:

$$\text{Prop}_P(i) = \frac{\sum_{c \in s'(i) \cap g'(i)} \frac{1}{p_c}}{\sum_{c \in s'(i)} \frac{1}{p_c}}$$

$$\text{Prop}_R(i) = \frac{\sum_{c \in s'(i) \cap g'(i)} \frac{1}{p_c}}{\sum_{c \in g'(i)} \frac{1}{p_c}}$$

where $s'(i) = s(i) \cup \{c_\emptyset\}$ and $g'(i) = g(i) \cup \{c_\emptyset\}$. Propensity F-measure (PROP-F) is computed as the harmonic mean of these values.

2.2 Hierarchical Classification

There are different taxonomies of hierarchical classification metrics (Costa et al., 2007; Kosmopoulos et al., 2013). Kosmopoulos et al. distinguish between pair and set-based metrics. **Pair-based metrics** weight hits or misses according to the distance between categories in the hierarchy. This distance depends on the number of intermediate nodes (Wang et al., 1999; Sun and Lim, 2001), with the disadvantage that the specificity of the categories is not taken into account. Depth-based distance metrics include the class depth in the metric (Blockeel et al., 2002). However, the depth of the node is not sufficient to model its specificity since depending on their frequency, leaf nodes at the first levels may be more specific than leaf nodes at deeper levels.

It is possible to compare the predicted and true single labels by means of standard ontological similarity measures such as Leackock and Chodorow (path-based) (Leacock and Chodorow, 1998), Wu and Palmer (Wu and Palmer, 1994), Resnik (depth-based) (Resnik, 1999), Jiang and Conrath (Jiang and Conrath, 1997) or Lin (Lin, 1998) similarities. The last two are based on the notion of Information Content (IC) or category specificity, i.e., the amount of items belonging to the category or any of its descendants.

However, extending pair-based hierarchical metrics to the multi-label scenario is not straightforward. Sun and Lim extended Accuracy, Precision and Recall measures for ontological distance based metrics (Sun and Lim, 2001). This method has two drawbacks. First, it requires defining a neutral hierarchical distance, i.e., an acceptable distance threshold for range normalization purposes. The second drawback is that it inherits the weaknesses of label-based metrics (see previous section). Blockeel et al. proposed computing a kernel and thus define a Euclidean distance metric between sums of class values (Blockeel et al., 2002). The drawback is that they assume a previously defined distance metric between categories and the origin and between different categories. Information based ontological similarity measures such as Jiang and Conrath or Lin's similarity do not have an upper bound which is necessary for the calculation of accuracy and coverage.

On the other hand, **set-based metrics** (also called hierarchical-based) consider the ancestor overlap (Kiritchenko et al., 2004; Costa et al., 2007). More concretely, hierarchical precision and recall are computed as the intersection of ancestor divided by the amount of ancestors of the system output category and of the gold standard respectively[2]. Their combination is the Hierarchical F-measure (HF). Since these metrics are based on category set overlap, they can be applied as example based multi-label classification by joining ancestors and computing the F measure. Their drawback is that the specificity of categories is not strictly captured since they assume a correspondence between specificity and hierarchical deepness. However, this correspondence is not necessarily true. Categories in first levels can be infrequent whereas leaf categories can be very common in the data set.

In this paper, we propose an information theoretic similarity measure called Information Contrast Model (ICM). ICM is an example-based metric as it is computed per item. Just like HF, ICM is a set-based multi-label metric as it computes the similarity between category sets. Unlike HF, ICM takes into account the statistical specificity of categories.

---

[2] In our experiments, when computing the ancestor overlap we consider the common empty label (root class) in order to avoid undefined situations

3 Formal Properties

In order to define the set of desirable properties, we formalize both the gold standard g and the system output s as sets of item/category assignments $(i, c) \in \mathcal{I} \times \mathcal{C}$, where $\mathcal{I}$ and $\mathcal{C}$ represent the set of items and categories respectively. We will denote as $P(c_j)$ the probability of items to be classified as c_j in the gold standard $(P((i, c_j) \in g | i \in \mathcal{I}))$. We also assume that the categories in the hierarchical structure are subsumed. For instance, items in a *PERSON_NAMED_ENTITY* category are implicitly labeled with the parent category *NAMED_ENTITY*. The common ancestor with maximum depth is denoted as $\texttt{lso}(c_1, c_2)$ and the descendant categories are denoted as $\texttt{Desc}(c)$ including itself.

Note that we do not claim that all properties are necessary in any scenario. The purpose of this article is to provide at least one metric that is capable of capturing all aspects simultaneously when necessary.

The first property is related to hits. In order to make this aspect independent from the ability of the metrics to capture hierarchical relationships or multi-labeling, we define monotonicity over hits in the simplest case (flat single label scenario):

Property 1 *[Strict Monotonicity] A hit increases effectiveness. Given a flat single label category structure, if* $(i, c) \in g \setminus s$*, then*[3] $\texttt{Eff}(s \cup \{(i, c)\}) > \texttt{Eff}(s)$

The next two properties state that the specificity of both the predicted and the true category affects the metric score. That is, an error or a hit in an infrequent category should have more effect than in the majority category. For instance, identifying a rare symptom in a medical report should be rewarded more than identifying a common malady present in the vast majority of patients. In addition, both the specificity of the actual category and the specificity of the category predicted by the system must be taken into account. Again, we make this aspect independent of hierarchical structures and multi-labeling.

Property 2 *[True Category Specificity] Given a flat single label category distribution, if* $P(c_1) < P(c_2)$ *and* $(i, c_1), (i, c_2) \in g \setminus s$*, then* $\texttt{Eff}(s \cup \{(i, c_1)\}) > \texttt{Eff}(s \cup \{(i, c_2)\})$.

Property 3 *[Wrong Category Specificity] Given a flat single label category distribution, if* $P(c_1) < P(c_2)$ *and* $(i, c_1), (i, c_2) \notin g \cup s$*, then* $\texttt{Eff}(s \cup \{(i, c_1)\}) < \texttt{Eff}(s \cup \{(i, c_2)\})$.

The following property captures the effect of the hierarchical category structure. A common element of any hierarchical proximity measure is that it is monotonic with respect to the common ancestor. That is, our brother is always closer to us than our cousin, regardless of which family proximity criterion is applied.In this property we do not consider multi-labelling.

Property 4 *[Hierarchical Proximity] Under equiprobable categories* $(P(c_1) = P(c_2) = P(c_3))$*, the deepness of the common ancestor affects similarity. Given a single label hierarchical category structure, if* $s(i) = \emptyset$*,* $g(i) = c_1$ *and* $\texttt{lso}(c_1, c_2) \in \texttt{Desc}(\texttt{lso}(c_1, c_3))$ *then* $\texttt{Eff}(s \cup \{(i, c_2)\}) > \texttt{Eff}(s \cup \{(i, c_3)\})$.

The last two properties are related with the multi-labeling problem. Property 5 rewards the amount of predicted categories per item.

Property 5 *[Multi-label Monotonicity] The amount of predicted categories increases effectiveness. Given a flat multi-label category structure, if* $(i, c) \in g \setminus s$*, then* $\texttt{Eff}(s \cup \{(i, c)\}) > \texttt{Eff}(s)$

Property 6 rewards hits on multiple items regarding a single item with multiple categories. To understand the motivation for this property, we can consider an extreme case. Identifying 1000 symptoms in one patient report is of less health benefit than identifying one symptom in 1000 patients.

Property 6 *[Label vs. Item Quantity] n hits on different items are more beneficial than n labels assigned to one item. Given a flat multi-label category distribution, if* $\forall j = 1..n((j, c_j) \in g \setminus s)$ *and* $\forall j = 1..n, i > n((i, c_j) \in g \setminus s)$ *then* $\texttt{Eff}(s \cup \{(1, c_1), .., (n, c_n)\}) > \texttt{Eff}(s \cup \{(i, c_1), .., (i, c_n)\})$.

4 Metric Analysis

In this section, we analyze existing metrics on the basis of the proposed formal properties (Table 1). Most of metrics satisfy Strict Monotonicity in single label scenarios. The label-based metric LB-F captures the true and wrong category specificity via the recall component. The example-based metric PROP-F (modified as described in Section 2) captures these properties via the propensity factor. Notice that the original propensity F-measure does not capture the wrong category specificity (Property 3) given that the p_c factor is applied only to

---

[3] Notice that $x \in X \setminus Y \equiv x \in X \wedge x \notin Y$

	ICM	✓	✓	✓	✓	✓	-

hits. In addition, both kind of metrics do not capture hierarchical structures. The contribution of example regarding label-based metrics is that, as label-based metrics are computed item by item, the property Label vs. Item Quantity is satisfied (Property 6). The exception is EB-HAMM which does not normalize the results with respect to the amount of labels assigned to the item.

Unlike previous metrics, the set based F-measure (HF) captures the hierarchical structure (Property 4). However, it does not capture the category specificity (properties 2 and 3). Some information-based ontological similarity measures, (Lin and Jiang & Conrath) capture both the category specificity and the hierarchical structure. However, they are not defined for multi-label classification (properties 5 and 6). In sum, different metric families satisfy different properties, and that satisfying all of them at the same time is not straightforward. The properties of ICM are described in the next section.

5 Information Contrast Model

The *Information Contrast Model* (ICM) is a similarity measure that unifies measures based on both object feature sets and Information Theory (Amigó et al., 2020). Given two feature sets A and B, ICM is computed as:

$$\text{ICM}(A,B) = \alpha_1 IC(A) + \alpha_2 IC(B) - \beta IC(A \cup B)$$

Where $IC(A)$ represents the information content $(-log(P(A))$ of the feature set A. In our scenario, objects are items to be classified and features are categories. The intuition is that the more the category sets are unlikely to occur simultaneously (large $IC(A \cup B)$), the less they are similar. Given a fixed joint IC, the more the category sets are specific ($IC(A)$ and $IC(B)$), the more they are similar. ICM is grounded on similarity axioms supported by the literature in both information access and cognitive sciences. In addition, it generalizes the Pointwise Mutual Information and the Tversky's linear contrast model (Amigó et al., 2020).

5.1 Computing Information Content

The IC of a single category corresponds with the probability of items to appear in the category or any of its descendant. It can be estimated as follows:

$$IC(c) = -log_2(P(c)) \simeq -log_2\left(\frac{\left|\bigcup_{c' \in \{c\} \cup \text{Desc}(c)} \mathcal{I}_{c'}\right|}{\left|\bigcup_{c' \in \mathcal{C}} \mathcal{I}_{c'}\right|}\right)$$

where $\mathcal{I}_{c'}$ represent the set of items assigned to the category c' and $\text{Desc}(c)$ represents the set of descendant categories. In order to estimate the IC of category set, we state the following considerations. The first one is that, given two categories A and B the common ancestor represents their intersection in terms of feature sets:

$$\{c_i\} \cap \{c_j\} = \texttt{lso}(c_i, c_j) \qquad (1)$$

The second consideration is that we assume *Information Additivity*, i.e. the IC of the union of two sets is the sum of their IC's minus the IC of its intersection:

$$IC(\{c_i\} \cup \{c_j\}) = IC(c_i) + IC(c_j) - I(\{c_i\} \cap \{c_j\}) \quad (2)$$

Equations 1 and 2 are enough to compute ICM in the single label scenario. Generalizing for category sets:

$$IC(\{c_1, c_2, .., c_n\}) = IC\left(\bigcup_i \{c_i\}\right) =$$
$$IC(c_1) + IC(\{c_2, .., c_n\}) - IC(\{c_1\} \cap \{c_2, .., c_n\})$$

where, according to the transitivity property;

$$\{c_1\} \cap \{c_2, .., c_n\} = \bigcup_{i=2..n} (\{c_1\} \cap \{c_i\})$$

and according to Equation 1, it is equivalent to $\bigcup_{i=2..n}\{\mathtt{lso}(c_1, c_i)\}$. Then, we finally obtain a recursive function to compute the IC of a category set:

$$IC(\{c_1, c_2, .., c_n\}) =$$
$$IC(c_1) + IC\left(\bigcup_{i=2..n} \{c_i\}\right) - IC\left(\bigcup_{i=2..n} \{\mathtt{lso}(c_1, c_i)\}\right)$$

In the case of ICM, it is possible the need for estimating the IC of classes that do not appear in the gold standard. Therefore, we have not evidence about its frequency or probability. We apply a smoothing approach by considering the minimum probability $\frac{1}{|\mathcal{I}|}$.

5.2 Parameterization and Formal Properties

On the basis of five general similarity axioms, in (Amigó et al., 2020) it is stated that the ICM parameters should satisfy $\alpha_1, \alpha_2 < \beta < \alpha 1 + \alpha 2$. We propose the parameter values $\alpha_1 = \alpha_2 = 2$ an $\beta = 3$. This parameterization leads to the following instantiations for each particular classification scenario. In the hierarchical mono-label scenario, it becomes into (equations 1 and 2):

$$\mathrm{ICM}(c_1, c_2) = -IC(c_1) - IC(c_2) + 3IC(\mathtt{lso}(c_1, c_2)) \quad (3)$$

which is similar to the Jiang and Conrath ontological similarity measure. In the flat multi-label scenario, it becomes into:

$$\mathrm{ICM}(C, C') = \sum_{c \in C \cap C'} IC(c) - \sum_{\substack{c \in C \setminus C' \\ \cup C' \setminus C}} IC(c) \quad (4)$$

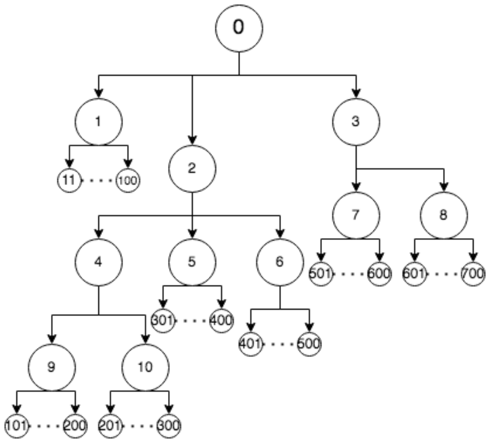

Figure 1: Category hierarchy for experiments on synthetic data.

which is an information additive example-based metric. That is, the information content of the common categories minus the differences. Finally, in the traditional flat mono-label scenario, it becomes into:

$$\mathrm{ICM}(c_1, c_2) \simeq \begin{cases} IC(c_1) & \text{if } c_1 = c_2 \\ -IC(c_1) - IC(c_2) & \text{i.o.c.} \end{cases} \quad (5)$$

which corresponds with Accuracy weighted according to the information content of categories.

According to the flat mono-label instantiation (Equation 5) $\mathrm{ICM}_{\alpha_1=\alpha_2=2, \beta=3}$ satisfies the properties 1 2 and 3. According to the single label hierarchical instantiation (Equation 3) Property 4 is satisfied. According to the flat multi-label instantiation (Equation 4), Property 5 is satisfied. Unfortunately, the label vs item quantity property is not strictly satisfied given that the gain per hit is additive in non hierarchical scenarios (Property 6). However, in the experiments we will see that the hit gain on items with many categories is smoothed out if the categories are related to each other by a hierarchical structure.

6 Experiments on Synthetic Data

Different evaluation aspects such as error rate, category specificity, hierarchical structures, etc., may have more or less weight depending on the scenario. These aspects correspond to the formal properties defined in the previous section. We perform a set of tests in order to quantify the suitability of metrics with respect to each property or evaluation aspect.

Table 2: Experiments over synthetic data. Ratio of cases in which the *best* synthetic output outperforms the *worst*.

Metrics	Metric Test				
	Sensitivity to error rate	True Category Specificity	Wrong Category Specificity	Hierarchical Proximity	Item Specificity
Accuracy (LB-ACC)	100%	50%	50%	50%	50%
F-measure(LB-F)	84.98%	100%	100%	52.65%	26.38%
Jaccard (EB-JACC)	86.59%	50%	50%	50%	100%
Hamming (EB-HAMM)	100%	50%	50%	50%	50%
Subset Accuracy (EB-SUBACC)	91.79%	50%	50%	50%	96.80%
Example Based F-measure (EB-F)	79.43%	50%	50%	50%	100%
Hierarchical F-measure (HF)	81.03%	46.55%	42.04%	100%	99.90%
Propensity F-Measure (PROP-F)	85.64%	100%	100%	53.15%	100%
ICM	96.10%	100%	100%	100%	74.77%

First, we generate the following synthetic data set. First, we definea hierarchical structure structure of 700 categories exposed in Figure 1. Note that categories $\{1..10\}$ are parent categories spread throughout the hierarchy, and categories $\{11..700\}$ are leaf categories. Secondly, We distributed 100 items across all categories. We generate assignments for each pair item/category (i, c) with a probability of $p_i \cdot p_c$ where $p_i = \max\left(\frac{51-i}{2225}, \frac{1}{2225}\right)$ with $i = 1..1000$ and $p_c = \frac{\max\left(\frac{512}{c},1\right)}{1713}$ where $c = 1..700$. We repeat this 1000 times. The result is a distribution $(300, 150, 40, .., 0.6, 0.6)$ items per category and $(22.5, 22, 21.6, 21.1, ..., 0.5, 0.5)$ labels per item. The purpose is to ensure unbalanced assignments across items and classes. We generate 1000 gold standards by reordering the category identifiers c each time in the p_c computation in order to alter the distribution of items in the hierarchical structure.

We consider in this experiment the metrics label-based Accuracy and F-measure (LB-ACC and LB-F), the example-based metrics Hamming (EB-HAMM), Jaccard (EB-JACC), Subset Accuracy (EB-SUBACC), F-measure (EB-F) and Propensity F-measure (PROP-F), the Hierarchical F-measure (HF) and ICM. The ontological similarity metrics are discarded given that they are not defined for the multi-label case. Ranking based metrics are discarded as the synthetic data set does not include graded assignments.

After this, we perform the following tests by comparing two noisy versions of the gold standard. The test result is the percentage of cases in which the hypothetically worse noised output is outscored by the best noised output (Table 2). Ties count 0.5.

In the first experiment referred in Table 2 as **Sensitivity to Error Rate**, We ran an error insertion procedure 1000 times on the goldstandard, with a probability of 0.09 and 0.1 for the best and worst output respectively. On average we will have 9 and 10 errors respectively. Each error consists of randomly choosing one of the 1000 assignments (i, c) of the goldstandard and removing it. For all metrics the best output outperforms the worst output in more that 50% of cases. LB-ACC and EB-HAMM seems to be specially sensitive to the error rate. This is due to the fact that they do not consider other aspects such as the category specificity or the hierarchical proximity. Surprisingly, ICM achieves a relatively high error rate sensitivity although it also consider other aspects. We do not have a clear explanation for this.

The second experiment is the **True Category Specificity** test. The intuition is that a gap in a frequent category should have less effect than a gap in an infrequent category. With an error rate of 0.05, for the best output, we remove a single label assignment randomly selected from all the goldstandard. For the worst output, we first select randomly a category and then we remove an assignment from this category. The result is that the best output tends to concentrate the gaps in frequent categories to a greater extent than the worst output. At the table shows, the metrics that satisfy the corresponding property achieve high scores (LB-F, PROP-F and ICM).

The third experiment is the **Wrong Category Specificity** test. The intuition is that a wrong assignment in a frequent category should have less effect than a wrong assignment in an infrequent category. With an error rate of 0.05, we select an

Table 3: Experimental results over real data. Metrics values for each baseline. The normalised value with respect to the maximum and minimum of the five baseline scores is shown in brackets.

Metrics	Baselines: Metric result (normalization)				
	ALL NONE	**MOST FREQ.**	**MATCH 75%**	**SVM DESCR.**	**SVM CODES**
Accuracy (LB-ACC)	0.9999 (1.00)	0.9997 (0.00)	0.9998 (0.50)	0.9999 (1.00)	0.9999 (1.00)
F-measure(LB-F)	0.9248 (0.79)	0.9248 (0.79)	0.9005 (0.00)	0.9273 (0.88)	0.9309 (1.00)
Jaccard (EB-JACC)	0.8395 (0.97)	0.0055 (0.00)	0.7209 (0.83)	0.8409 (0.97)	0.8644 (1.00)
-Hamming$\times 10^3$ (EB-HAMM)	-0.0507 (0.98)	-0.254 (0.00)	-0.117 (0.66)	-0.0506 (0.98)	-0.0472 (1.00)
Subset Accuracy (EB-SUBACC)	0.8395 (0.97)	0.0027 (0.00)	0.7205 (0.83)	0.8392 (0.97)	0.8573 (1.00)
Example Based F (EB-F)	0.8395 (0.96)	0.0066 (0.00)	0.7210 (0.83)	0.8416 (0.97)	0.8670 (1.00)
Hierarchical F (HF)	0.8902 (0.97)	0.2750 (0.00)	0.8054 (0.83)	0.8913 (0.97)	0.9080 (1.00)
Propensity F (PROP-F)	0.8893 (0.96)	0.5024 (0.00)	0.7742 (0.67)	0.8903 (0.96)	0.9030 (1.00)
ICM Average	-2.2062 (0.92)	-8.6158 (0.00)	-5.5761 (0.43)	-2.1107 (0.94)	-1,700 (1.00)

assignment (i, c) randomly from items with a single label. For the best output we replace c with the most frequent class different than c. For the worst output, we replace c with a randomly selected category different than c. We obtain the same result than in the previous experiment.

The fourth experiment is the **Hierarchical Similarity** test. The intuition is that the more a wrong assignment is far away from the correct category, the more it has effect in the effectiveness score. Again, with an error rate of 0.05, we select an assignment (i, c) randomly from single labeled items with leaf categories. For the best output we replace c with a sister wrong category. For the worst output, we replace c with a randomly selected wrong category. Again, the metrics that satisfy the corresponding property achieve high scores.

The last test is **Item Specificity**. The intuition is that a wrong assignment in an item with many labels should have more effect than an error in an item with one or a few labels. For the best output, for each error insertion iteration, we randomly select an assignment (i, c) (with the same error rate 0.05). For the worst output, we randomly select an item i, and we take one of its assignments (i, c). In both cases, the category is replaced with a randomly selected wrong label. In other words, we distribute errors uniformly across item/category assignments in the best output and we distribute errors uniformly across items in the worst output. The effect is that the best output concentrates errors in items with many labels. Again, those metrics that satisfy the corresponding metric achieve high performance. The label-based F-measure tends to reward the worst output. The reason is that items with many labels tend to concentrate diverse labels. Therefore, the label-based F measure penalizes the best output. As discussed in the previous section, although ICM does not satisfy the property, the hit gain on items with many categories is smoothed out if the categories are related to each other by a hierarchical structure.

7 A Case Study

The problem addressed is the automatic encoding of discharge reports (Dermouche et al., 2016; Bampa and Dalianis, 2020) from a Spanish hospital to detect adverse events (AEs) from CIE-10-ES[4], the Spanish version of the tenth revision of the International Classification of Diseases (ICD-10).

AEs detection fits to the scenario tackled in this article due to the following reasons: (i) **Extreme**: CIE-10-ES contains 4816 codes related to AEs, which probability follows a power-law distribution since most of them rarely appear in health records or even they do not appear; (ii) **Hierarchical**: CIE-10-ES is a hierarchy with six levels: an empty root ($c_\emptyset$ such that $IC(c_\emptyset) = 0$), and then a level composed by three-character-codes categories which can be divided into successive nested subcategories adding characters until seven-character-codes at most; and (iii) **Multi-label classification**: Each discharge report could have associated with several AEs codes.

We have used a corpus composed of 36264 real anonymized discharge reports (Almagro et al., 2020) annotated with AEs codes by experts. The corpus has been divided into three data sets, training, development and test, following the proportion 50%-30%-20% respectively. The corpus includes only 671 AEs codes of 4816 and 84% of the discharge reports have no AEs, so the data is highly biased and unbalanced.

---

[4] https://eciemaps.mscbs.gob.es/ecieMaps/

We have applied five simple baselines in order to analyze the behaviour of the metrics: (i) **ALL NONE** does not assign any code to each item; (ii) **MOST FREQ.** assigns the most frequent AE code in the training data set (T45.1X5A) to each item, which just appears in 68 items of 7253; (iii) **MATCH 75%** divides each item into sentences and assigns a code if a sentence contains 75% of the words of the code description avoiding stop-words; (iv) **SVM DESCR.** creates a binary classifier for each AE code in the training set using the presence of words of the AEs codes descriptions in the items as features, excepting stop-words; (v) **SVM CODES**: similar to the previous one but using as features the annotated non-AEs codes in order to check if AEs codes are related to non-AEs codes. Note that MATCH 75% is able to assign any AE, but the SVM baselines are only able to assign AEs appearing in the training data set.

Table 3 shows the metrics results obtained by each baseline. Unfortunately, with only five systems it is difficult to find differences in terms of system ranking. Therefore, we have normalised the values for each metric between the maximum and the minimum obtained across the 5 systems in order to study the relative differences of scores (values in brackets). LB-ACC, LB-F and EB-HAMM reward the absence of most of the labels in the corpus, so they are not suitable in this scenario. The rest of the metrics sort systems in the same way. The particularity of ICM is that, as shows the normalized results, the baseline MATCH 75% is penalized with respect to ALL NONE to a greater extent than in other metrics, since MATCH 75% assigns many codes incorrectly, whereas ALL NONE does not provide any information. Another slight particularity of ICM is that the system SVM CODES is rewarded against the rest of baselines to a greater extent. Notice that SVM CODES achieves 269 hits while SVM DESCR achieves 77 hits.

8 Conclusions and Future Work

The definition of evaluation metrics is an open problem for extreme hierarchical multi-label classification scenarios due to the role of several variables, for instance, a huge number of labels, unbalanced and biased label and item distributions, proximity between classes into the hierarchy, etc. Our formal analysis shows that metrics from different families (label, example, set-based, ontological similarity measures etc.) satisfy different properties and capture different evaluation aspects. The information-theoretic metric ICM proposed in this paper, combines strengths from different families. Just like example-based multi-label metrics, it computes scores by items. Just like set-based metrics, it compares hierarchical category sets. Just like some ontological similarity measures (Lin or Jiang and Conrath), it considers the specificity of categories in terms of Information Content. Our experiments using synthetic and real data show the suitability of ICM with respect to existing metrics.

ICM does not strictly hold the label vs. item quantity property. We propose to adapt ICM in order to guarantee all the formal properties as future work.

Abstract

We present a complete pipeline to extract characters in a novel and link them to their direct-speech utterances. Our model is divided into three independent components: extracting direct-speech, compiling a list of characters, and attributing those characters to their utterances. Although we find that existing systems can perform the first two tasks accurately, attributing characters to direct speech is a challenging problem due to the narrator's lack of explicit character mentions, and the frequent use of nominal and pronominal coreference when such explicit mentions are made. We adapt the progress made on Dialogue State Tracking to tackle a new problem: attributing speakers to dialogues. This is the first application of deep learning to speaker attribution, and it shows that is possible to overcome the need for the hand-crafted features and rules used in the past. Our full pipeline improves the performance of state-of-the-art models by a relative 50% in F1-score.

1 Introduction

Natural Language Processing has enabled a quantitative improvement in the humanities, by allowing for large-scale statistical measurements to be taken over hundreds of thousands of books compared to the order of tenths a human could analyse in a much longer time span. Some examples of large-scale literary analyses include studies on characters and their descriptions within the novel, mostly focused on gender differences (Underwood et al., 2018; Kraicer and Piper, 2019), and studies on character's relations by extracting social networks from novels (Labatut and Bost, 2019; Jayannavar et al., 2015).

Most of these studies demand special attention to dialogues, being a major part of character expression and interaction with other characters. Dialogues play an instrumental role in plot development, frequently encompassing focal plot moments, especially in fiction – which is also the focus for this study. Here we aim to identify direct-speech utterances that form part of dialogues and associate them with the speaking characters. Such information is not only useful to enable large-scale sociotemporal studies but also crucial to many downstream challenging tasks like narrative understanding (Iyyer et al., 2016) and summarising (Ladhak et al., 2020). Further, the high-quality dialogue-character association is pertinent for generating engaging text-to-speech for novels with distinct voice profiles for characters.

In the past, models that link direct speech to characters have been dominated by predefined rules (Muzny et al., 2017) or hand-crafted features (He et al., 2013). When evaluating these models the authors also presumed that a character list, together with the character's aliases, has been precompiled and that direct-speech text has been extracted. Although extensions to these models that extract speaking characters in a fully automated manner exist, it is unclear what impact does the automation of the aforementioned steps has on the final performance of the model. Moreover, the models have only been tested against a small dataset of three books from the same time period.

These are the two questions that we aim to answer in this paper: i) how can we build flexible models that can generalise and improve with increasing dataset sizes?, and ii) what is the impact of errors propagating from each component of the pipeline, and thus where should we focus future efforts? To answer these questions, we focus on building deep learning models with the necessary inductive biases and flexibility to learn nuanced features when given a large enough dataset, as opposed to hand-crafted rules that need revisiting to generalise to different time periods, writing styles, genres, or even languages. Moreover, we present a separate evaluation of pipeline's each component.

2 Related Work

Attributing speakers to direct speech is a common problem for two related domains: news and literature. However, previous work (O'Keefe et al., 2012) has shown that models do not generalise to both domains. Their best model obtained an accuracy of 92.4% and 84.1% on their two newswire datasets, whilst they only found a 53.3% accuracy when evaluating the same model on a literature dataset. We therefore focus on summarising progress in quote attribution for literary fiction.

The early models targeting literary texts (Glass and Bangay, 2007) were based on the identification of speech verbs and their actors. However, the proportion of dialogues accompanied by a speech-verb and an explicit mention to a character can be as low as 20% of the total quotes for some books. For this reason, consequent work (O'Keefe et al., 2012; Elson and McKeown, 2010) shifted their focus to attributing speakers to dialogues where the character is not explicitly mentioned, incorporating rules to exploit the sequential nature of conversations. These models could not improve the results of a simple Nearest Mention (NM) baseline that obtained a 53.3% accuracy on their test set.

Finally, current state-of-the-art models (Muzny et al., 2017; He et al., 2013) demonstrated how the simple nearest mention baseline could be beaten through a combination of rules and learning. Both models present analysis on a limited setup: i) they report performance on a test set comprised of two books – Jane Austen's *Emma*, and Anton Chekhov's *The Steppe*, – and have therefore not been bench-marked on a wider range of styles or time periods, and ii) they assume the ideal circumstance of a pre-compiled list of characters, with character aliases and genders provided. We relax the second assumption when we evaluate our model, to estimate the end-to-end performance on a more diverse dataset of fifteen books.

The task of speaker attribution is also closely related to other dialogue sequence problems. One such umbrella technique to solve these problems is *Dialogue State Tracking* or simply DST, where a system is tasked with estimating some conversation state variables usually the user's goals and intents. We are first to apply DST for the purpose of speaker attribution. Our proposed DST-based formulation requires modification to the utterance encoder with focus on non-dialogue context, and state-variable that can generalise to states not seen in the training set. We adapt a BERT-based DST model (Lai et al., 2020) to track the speaker for every single utterance instead of tracking the user's goals and intents.

Our work follows a similar line of thought to Ren et al. (2018); Lai et al. (2020), where the model is given a list of candidate intents (speakers in our case) embedded as inputs to the problem so that the model can generalise to unseen goals (speakers) during test time. The task of our model is to generate a score for each utterance against every candidate speaker.

To recap, we present an end-to-end pipeline for speaker to dialogue attribution that leverages recent advances in large pretrained Language Models casting the problem as a Dialogue State Tracking. We empirically show that our model is capable of generalising to different styles more reliably as compared to prior hand-crafted features-based systems. Further, we present this comparative study on literary texts ranging from the 1900s to the 2010s, which are more varied and diverse compared to past studies. Note that usually such dataset are effort-intensive to create and not publicly available due to lack of rights to redistribution, which makes the reported result very interesting for the wider community.

3 Dataset

Our annotations consist of two independent layers, one focusing on direct speech, and one focusing on clustering mentions that refer to the same character entity.

Example 1: Excerpt from 2001: A Space Odyssey. Annotated direct speech is in bold, and the annotated attributed character entity inside a blue box.

Poole was asleep, and *Bowman* was reading on the control deck, when *Hal* announced:

"Er—*Dave*, I have a report for you." HAL

"What's up?" DAVID BOWMAN

"We have another bad AE-35 unit. My fault predictor indicates failure within twenty-four hours." HAL

For the first layer, the annotator selects the span of text representing a character's direct speech. It is usually found within quotation marks, but this is not a necessary or sufficient requirement. The annotator then attributes a character entity to the utterance. Example 1 presents a typical conversation with instances of coreference (Dave and Bowman both refer to David Bowman), and implicit attribution (third and fourth paragraphs) where no character is explicitly mentioned by the narrator.

The second layer of annotations focuses on characters and their mentions. We follow Bamman et al. (2014) and distinguish character *mentions* (e.g. Dave, David, Bowman, Dr. Bowman) in the text and character *entities* (e.g. DAVID BOWMAN), to which mentions refer to. See the text in italics within Example 1 to find some of the annotated character mentions. Note that we don't include pronominal mentions. These mentions are then clustered per book into character entities by the annotators.

We annotate a collection of 15 books sampled from the most popular titles from time epochs 1881 - 2018. The annotation is carried out by 3 expert English native annotators, each reading the book in sequential order, over a BRAT [1] based annotation interface. In case the annotation from any single annotator is different, a master annotator goes through the cases and makes the correction, resulting in a dataset with a very high agreement (Cohen's Kappa greater than 0.9). Across the books, the number of annotated dialogues varies from 200 to 5000 and characters from less than 10 to 200. We would refer these books by IDs 1 through 15 and the existing 3 books as E1 (*Emma*), E2 (*Pride and Prejudice*) and E3 (*The Steppe*).

4 Model components

We divide the model into three main tasks: identifying quotes, extracting unique characters and their aliases, and attributing dialogues to the extracted characters. Our goal is to reduce the amount of hand-crafted rules (usually heavily biased to the small subset of documents of prior studies) where performance can be improved, and allow the model to learn nuanced features that allow it to generalise better when given a large enough dataset.

We first introduce our direct speech identification component, which is purely rule-based due to the simplicity of the problem and since improving this aspect is not part of our core contribution. Afterward, we focus on identifying characters and compare NER and coreference resolution deep learning models to simple rule-based systems. Finally, we discuss the focal aspect of our contribution - a DST architectural adaptation to solve the speaker attribution of quotes.

4.1 Direct Speech identification

Direct speech in fiction is usually denoted with quotation marks, although there are exceptions such as Ali Smith's *Summer*, where speech marks are completely removed and dialogues blend in with the rest of the text, or Joyce's *Ulysses* that introduces speech with dashes. Here we ignore such instances, which are not present in our dataset, and focus on the most common case where direct speech is marked by quotation marks. Further, we find that for English over ≈ 95 % of the dialogues (as analysed over a large collection of popular books) follow open-close quotation-pair variation. See Steinbach et al. (2011) for an in-depth review of the topic.

In the case of extracting quotation marks, simple rules can achieve almost perfect performance. As in O'Keefe et al. (2012), we use a regular expression to detect opening and closing quotation marks that denote the presence of direct speech.

4.2 Character identification

Although characters are central to most literary analyses, identifying them automatically from a novel remains an unsolved problem. We split the character identification task into: i) identifying mentions in the text that refer to characters, and ii) clustering those mentions into unique character entities. Similar to direct speech identification, we do not focus on improving the architecture for character identification. As both of these form input to our core DST module, we re-purpose the best of existing techniques. However, unlike previous studies, we do analyse and report the impact of these components on end-to-end performance to guide future research.

Extracting entities from text is normally done over short documents, such as Wikipedia pages. But literature brings unique challenges to the field: novels tend to be long documents, demanding efficient algorithms, and requiring models to be able to link far apart mentions.

We present an evaluation of Named Entity Recognition (NER) to detect mentions, together with the effectiveness of coreference resolution to cluster character mentions into entities. We find that although NER achieves a similar performance to a simple rule-based system, coreference resolution's performance on clustering characters is significantly poorer than a simple rule-based character clustering technique, and future work should fo-

---

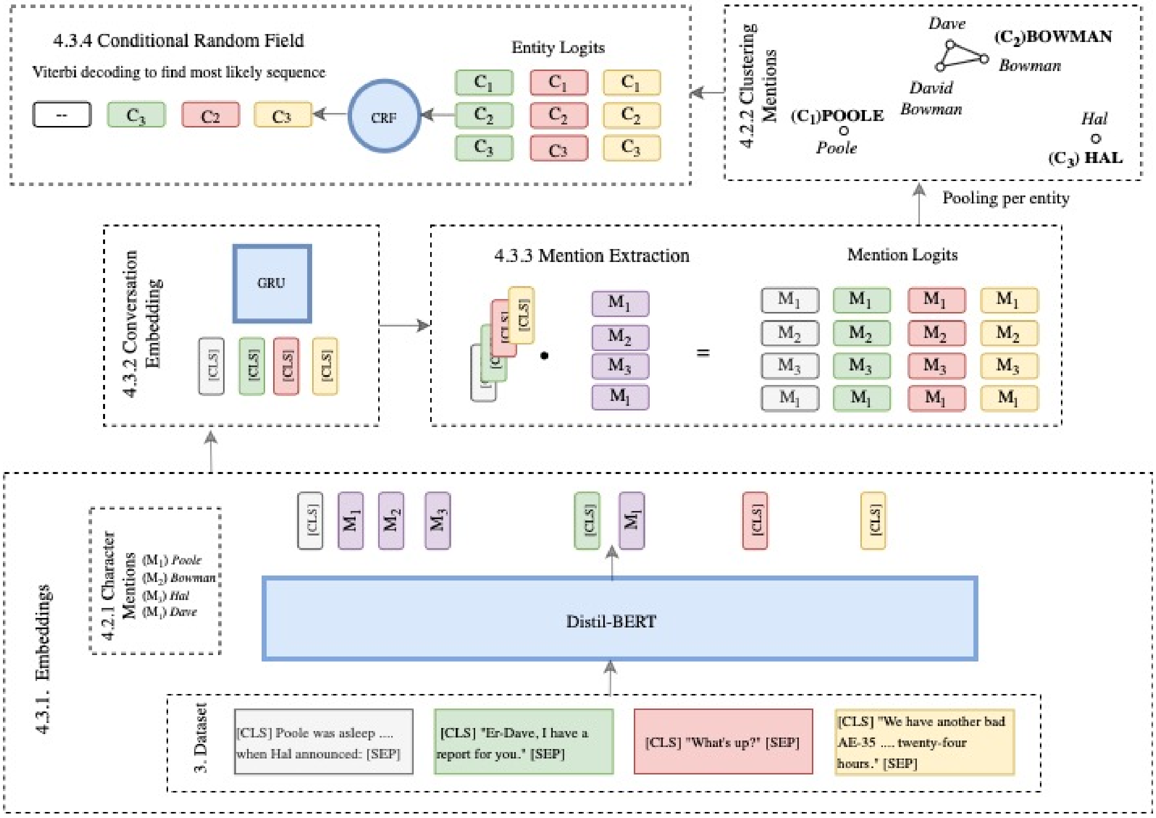

Figure 1: Diagram of our speaker attribution pipeline. Utterances in a conversation and mentions to characters are first embedded by using Distil-BERT. The extracted utterances are processed by a Gated Recurrent Network, and later combined with the embedded mentions through a dot product that results in the Mention Logits. Finally, we use the information on how mentions cluster into character entities to pool the maximum values of the Mention Logits by entity. The result is denoted by Entity Logits, and it is sent to a Conditional Random Field that generates a prediction by applying the Viterbi decoding algorithm.

cus on addressing this problem through techniques developed explicitly for the literature domain.

Type	Freq	Example ([mentions] → entity)
Full Name Variation	67%	[Harry, Potter, Mr. Potter, Harry Potter] → HARRY POTTER)
Dimunitives	7%	[Lizzy, Eliza] → ELIZABETH
Professional	15.5%	[the cook] → JOHN KING SILVER
Relational	5.5%	[her father] → MR. BENNET
Others	5%	[the cimmerian] → CONAN

Table 1: Summary of Character Name Variations for 50 randomly sampled characters over our dataset.

4.2.1 Identifying character mentions

We present a comparison between an out-of-domain NER model, trained on the CoNLL-2003 dataset (Tjong Kim Sang and De Meulder, 2003) with a simple rule-based baseline that focuses on identifying all the characters that speak explicitly. It finds the subject of the narrator's explicit dialogue attribution signals (defined by the 40 most frequent speech denoting verbs such as *said, answered, ...*).

4.2.2 Clustering character mentions into entities

In Table 1, we show a summary of the aliases variations found in our dataset and their frequency. Since our core contribution is not to improve character clustering, and our dataset of character aliases is small, we do not develop a custom model for it and merely compare two different clustering techniques: i) an out-of-domain coreference resolution system, and ii) a simple set of rules that cluster characters according to their names. In both cases, we build a graph where nodes are character mentions, and edges are attached to all two compatible nodes. See the top right box on Clustering Mentions in Figure 1 for an example of such graph.

On one hand, in the case of coreference resolution, two nodes are compatible if they appear together at least in two coreferent clusters. Clusters of characters are formed by finding all disconnected subgraphs within the graph.

On the other hand, although character aliases can be of any kind and might not be related to each other by name, most of the ones appearing in literature are variations of the character's full name (See Table 1). We build a rule-based algorithm that deems two names incompatible if,
i) The first names of the characters are different (the first names do not match exactly) or the shorter first name is not exactly inside the longest one. This also takes care of a few diminutive forms (like Eliza for Elizabeth).
ii) Both names contain a title which is different.
iii) Both names contain a surname which is different.

We split the graph into disconnected subgraphs of compatible names, and find those nodes that are ambiguous, i.e., nodes whose first neighbour connections contain more than one title, first name, or surname. Removing those nodes we can form unambiguous clusters of characters that share the same title, name, and surname.

As opposed to previous work (Bamman et al., 2014; Elson et al., 2010), where ambiguous names would be merged to the closest entity mentioned in the text, we allow ambiguous nodes to either form their own cluster, or be part of any of their first neighbour nodes' clusters. We use the text to resolve this ambiguity by finding the most mentioned cluster among the possible clusters in the 20 paragraph vicinity of the ambiguous mention. In this way, we can retain characters such as *Mrs. Bennet* in *Pride and Prejudice*, without merging them to other members of the Bennet family, since they are prominent enough to be given their own cluster.

4.3 Speaker attribution

In this section, we present an adaptation of Dialogue State Tracking to speaker attribution. In DST, it is a challenge to produce models that can work with dynamic ontologies and unseen slot values such that the user can request information on any slot (movies, restaurants, ...) and use any value (the type of food, the price, ...) that has not necessarily been seen at test time. In the same way, we can't simply use a general fixed tag set of characters beyond the level of an individual novel, since we want our model to generalise to unseen novels and unseen characters during test time. We will therefore embed the character's mentions within the inputs of the model as done in state-of-the-art DST (Lai et al., 2020). Below, we discuss in detail how we adapt DST to model speaker attribution in novels.

4.3.1 Inputs definitions

Although our dataset is annotated at the level of word spans, the odds are high that disconnected spans in the same paragraph are attributed to the same speaker. We find that this rule is violated on less than 5% of the paragraphs that contain more than one disconnected span. Therefore, as in He et al. (2013), our model will be trained on attributing speakers at the level of paragraphs.

Regarding the model inputs, we split the text into conversations. Denoting paragraphs with no direct speech as narratives, we segment conversations by restricting the number of intervening narratives between direct speech utterances to one. If more than one narrative separates two direct speech utterances, the conversation is split into two different conversations.

Given a set of n utterances that define a conversation, $\mathbf{u} = \{u_0, u_1, ..., u_{n-1}\}$, a set of l mentions to candidate characters, $\mathbf{m} = \{m_0, m_1, ..., m_{l-1}\}$, and a set of k candidate characters entities linked to those mentions, $\mathbf{c} = \{c_0, c_1, ..., c_{k-1}\}$, where $k <= l$, we wish to model the probability for each candidate character entity, c_i, being the speaker of a given utterance, u_j. This probability will be denoted as $P\left(c_i | u_j, \mathbf{u}\right)$.

Let's denote as ϕ the embedding model that transforms word tokens in vectors (equivalently $\mathbb{R}^{D_\epsilon}$ space), where D_ϵ is the output dimension of the embedding model. In this work, we chose a Distil-BERT model (Sanh et al., 2019) for ϕ.

As in Figure 1, we generate an embedding for every utterance in the conversation,

$$\boldsymbol{\epsilon}_{u_i} = \phi_{\text{Distil-BERT}}(u_i)_{[CLS]}, \tag{1}$$

by selecting the embedding of the [CLS] token, whereas to encode the character's mentions we take the mean of the embedding of the tokens inside the mention. For a mention $m_j = \{m_j^0, m_j^1, ..., m_j^{t-1}\}$ of length t,

$$\boldsymbol{\epsilon}_{m_j} = \frac{1}{t}\sum_{T=0}^{t-1} \phi_{\text{Distil-BERT}}(u_i)_{m_j^T}. \tag{2}$$

We denote the collection of all mentions embeddings by $\boldsymbol{M}$, a matrix of dimensions $D_\epsilon \times D_l$, where D_l is the number of mentions to candidate characters inside the conversation.

In the next section, we explain the three components of the model that take these embeddings and produce the probability of a character speaking: i) the conversation embedding module, that takes an utterance as input and produces its context-aware representation, ii) a character extraction module, that given the contextual representation of an utterance and the embedding of the candidate characters mentions, generates the logits for each candidate character entity and utterance, and iii) a sequential decoder component that learns the conversational turn patterns. Below, we define the architecture of each component in detail.

4.3.2 Conversation Embedding

The conversation embedding module consists of a Gated Recurrent Unit (Cho et al., 2014; Gers et al., 1999), ϕ_{GRU}, that encodes the content of the conversation,

$$\mathbf{h}_{i+1} = \phi_{\text{GRU}}\left(\boldsymbol{\epsilon}_{u_{i+1}}, \mathbf{h}_i\right), \tag{3}$$

where $\mathbf{h}_i$ is the GRU's hidden state of dimension D_ϵ which is randomly initialised at the beginning of the sequence.

4.3.3 Character mention extraction

This module processes the GRU's hidden states to extract the candidate character's logits. We take the dot product of the utterance embedding, processed by a fully connected network, with the mention embedding matrix, $\boldsymbol{M}$, to obtain the logits,

$$\mathbf{l}_i = \phi_{\text{FCN}}\left(\mathbf{h}_i\right) \cdot \boldsymbol{M}, \tag{4}$$

where $\mathbf{l}_i$, has dimensions D_l. This for whole conversation results in $\boldsymbol{L}$ of dimension $D_n \times D_l$ and are denoted by Mention Logits in Figure 1.

We can now combine the logits of different mentions that belong to the same character entity by max-pooling over character entities to get the Entity Logits, $\boldsymbol{E}$ with dimensions $D_n \times D_k$.

4.3.4 Learning to take turns with Conditional Random Fields

Implicitly, the model defined above assumes that labels are independent of each other, and that therefore the likelihood of a sequence of labels in a conversation, $\mathbf{y}$, can be expressed as the product of utterance-wise likelihoods,

$$P(\mathbf{y}|\mathbf{u}) = \prod_m p(y_k|u_1, ..., u_m). \tag{5}$$

However, characters speaking in a conversation follow certain turn-taking patterns that are common through literature, such as a two-party conversation in which the dialogues move back and forth between two characters. We add a linear chain Conditional Random Field (CRF) (Lafferty et al., 2001) to our model, to maximise the likelihood of a sequence of characters and relax the label independence assumption by allowing a target to depend on its immediate predecessor.

A CRF models the sequential likelihood as a combination of element-wise prediction, and a pairwise interaction term that models the probability of transitioning from label y_i to label y_j. In our particular implementation, the element-wise predictions are the Entity Logits, $\boldsymbol{E}$, and the pairwise interaction will be learned parameters,

$$P(\mathbf{y}|\mathbf{u}) = \exp\left(\sum_{n=0}^{N} E_n(y_n) + \sum_{n=0}^{N-1} V_{y_n,y_{n+1}}\right)/Z, \tag{6}$$

where Z represents the normalization factor, and V is generally a $D_k \times D_k$ dimensional matrix of learned weights known as transition matrix.

In our use-case, there is no specific label ordering that can generalise to unseen novels, and we thus reduce the degrees of freedom of the $D_k \times D_k$ transition matrix to two: the value of the diagonal, and the value of the off-diagonal elements. The first one controls the probability of the same speaker to continue speaking, whereas the second one varies the probability of a change in speaker. Note that this implies that we do not need to constrain the number of speaking characters. At inference, we find the most likely sequence of characters using the Viterbi algorithm (Viterbi, 1967).

5 Evaluation of the model components

In this section, we present both the evaluation of each separate component and the final evaluation of the entire pipeline.

5.1 Direct Speech identification

To compare ground truth direct speech with our extracted quotes, we define a True Positive as an exact match between our selected text and the ground truth. With this definition, the F1-score achieved by our quote identification module is 0.98 ± 0.01, when evaluated against our entire dataset. We find that common errors are the identification of quoted text that has a different purpose other than direct

Model	F1-Score	Precision	Recall
NER	0.74 ± 0.1	0.82 ± 0.08	0.69 ± 0.14
Rule-based	0.78 ± 0.1	0.85 ± 0.07	0.76 ± 0.11

Table 2: Evaluation of the character mention component, compared to NER (Wolf et al., 2020). We show the average of all books and their standard deviation.

Model	F1-Score	Precision	Recall
Coreference	0.73 ± 0.1	0.97 ± 0.08	0.60 ± 0.14
Rule-based	0.86 ± 0.08	0.94 ± 0.07	0.79 ± 0.11

Table 3: Evaluation of the character clustering component, compared to coreference resolution (Wolf et al., 2020). We show the average of all books and their standard deviation.

speech, such as emphasising a word, naming a title, or marking written text, such as a letter, that no one is reading out loud.

5.2 Character identification

We evaluate separately the effects of identifying character mentions and clustering mentions into distinct entities. Since our model aims to resolve dialogue attribution and characters that are mentioned more often tend to also speak more often, we show precision, recall and F1-score weighted by the number of times a mention appears through the text. In this way, we make sure that we are identifying the main characters in the text at the cost of missing rarer ones. The evaluation is shown in Table 2. NER and our simple rule-based model show a similar performance, although overall the rule-based system works better.

Finally, we evaluate character clustering on oracle mentions using the B^3 measures of precision, recall and F1-score (Amigó et al., 2009). The results are reported in Table 3. The performance of coreference resolution is significantly worse than the simple naming rules we developed. By using name compatibility we achieve a high precision but a low recall, meaning that the clusters we create tend to contain elements of the same class, but are incomplete; a character might be split into several different clusters. This is because we only cluster characters from variations of their names, and therefore all other cases shown in Table 1 are considered as separate entities. As mentioned in Section 4.2.2, the coreference resolution model fails at linking two mentions to the same character that are far apart, and therefore produces a system with lower recall.

5.3 Speaker attribution

We train and evaluate the speaker attribution task on oracle direct speech, mentions and character clusters. We compute precision, recall and F1-Score, all weighted averages, of the character entities attributed to each span of direct speech.

Model	F1-Score	Precision	Recall
Our model	0.78 ± 0.06	0.81 ± 0.06	0.77 ± 0.06
NM	0.54 ± 0.08	0.57 ± 0.06	0.54 ± 0.08

Table 4: Evaluation of the speaker attribution component, compared to a baseline nearest mention (NM).

The resulting evaluation is shown in Table 4. We show a comparison with a baseline model that selects the nearest mention to either left or right of the quote. To include a thorough evaluation despite the small size of our dataset, we have trained the model in a leave-one-out fashion for all books for which we annotated more than $1,000$ paragraphs, together with the three publicly available books released by Muzny et al. (2017). In Table 4, we report average values and standard deviation over the 11 books.

Moreover, we show an ablation study in Table 5, computed on only one train, validation and test split. Next to the overall F1-Score we show the performance on the model by type of signal where a sample is: i) explicit, if the character is mentioned on the same paragraph as the quote, ii) implicit, if there is no narrator context accompanying the quote. Note that not all quotes fall in either of these categories.

5.4 End-to-end evaluation

Finally, the entire pipeline is evaluated as a clustering overlap problem through the B^3 clustering metric. A cluster is defined by the set of quotations attributed to the same character entity. If the quote has been incorrectly identified as a quote by the model, it forms part of a misidentified cluster. On the other hand, if we haven't identified one of the true quotes, we also label it as another kind of misidentification.

In Figure 2, we show a full pipeline comparison of our model to the state-of-the-art model presented in Muzny et al. (2017) [2]. Our model improves over Muzny et al. (2017) by an average of 50% in F1-

---

[2] We ran their publicly available code on our dataset, the code can be found here `https://nlp.stanford.edu/~muzny/quoteli.html`

	F1-Score	Accuracy Explicit	Accuracy Implicit
Distil-BERT (DB)	0.7 ± 0.06	0.89 ± 0.03	0.37 ± 0.03
DB + GRU	0.77 ± 0.07	0.94 ± 0.04	0.45 ± 0.05
DB + CRF	0.75 ± 0.09	0.94 ± 0.05	0.43 ± 0.07
DB + GRU + CRF	0.80 ± 0.06	0.95 ± 0.05	0.6 ± 0.08

Table 5: Summary of the ablation study results. We show the effect of removing different component of the models, where average values and standard deviations are computed over three test books: 14, 15, and E3 (*The Steppe*).

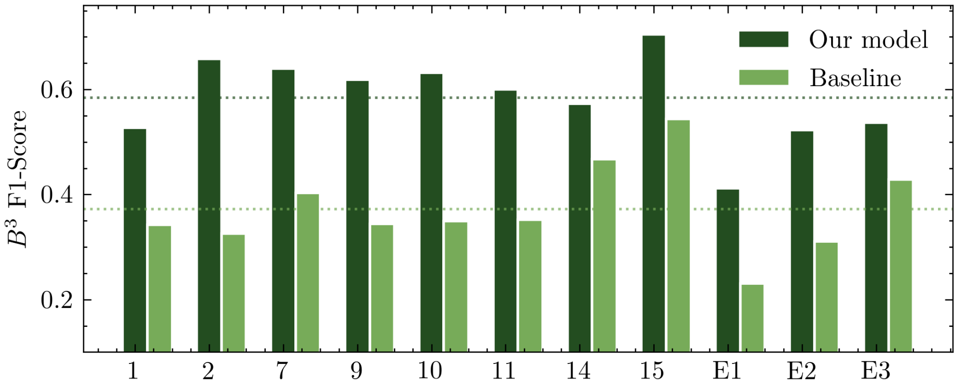

Figure 2: Chart showing F1-score values for different books training the model in a leave-one-out fashion. Average values for both our model and the baseline are shown in dotted lines.

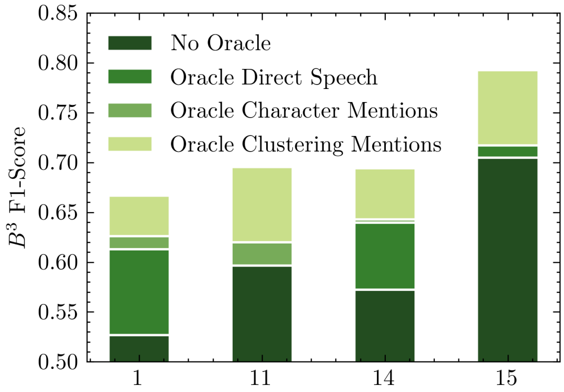

Figure 3: Stacked chart showing the F1-score when different components of the model are replaced by their oracle (ground truth) value.

score, and achieves a more consistent performance across different styles and time periods.

We also show the effect of replacing the different components with Oracle data for a subsample of the dataset in Figure 3. We can see that different components play a different role by book, whereas improving the mention extraction stage can be of crucial importance for some books (14 and 15 part of text split; and 1 and 11 part of train split), character clustering has a larger effect on others. However, the dominant effect is still the Speaker attribution model.

6 Conclusions and Future Work

We have presented a speaker attribution pipeline for novels that does not rely on pre-compiled lists of characters and that performs consistently across different writing styles and time periods. Our main contribution has been to develop the first deep learning model for speaker attribution, based on previous Dialogue State Tracking approaches. Our deep learning model has the flexibility to learn nuanced features from data, compared to previous work that relied on rules or hand-crafted features. Training our model on a small dataset composed of 15 different novels, we find that it outperforms the model presented in Muzny et al. (2017) by an average of 50% F1-score. In the future, we hope to improve our model by: training it on a larger and more varied dataset, and training the model on speaker attribution together with the related task of coreference resolution.

We have also presented an error analysis on the different components necessary to perform the end-to-end goal of attributing characters to their direct speech utterances in novels: i) direct speech identification, ii) character extraction, and iii) speaker attribution. We have shown the need to produce literature-domain specific models targeting character extraction in order to improve the accuracy of current systems.

Appendix

Model hyper-parameters

In this appendix we describe the training procedure and hyper-parameters for the DST model. During training, we use early stopping with a patience of 6 epochs, a batch size of 3 conversations, and cross-entropy as a loss function. The initial learning rate is set to $1e{-}5$ for the BERT model layers, and $1.e{-}4$ for all the others. We use a linear schedule with warmup, with the number of warmup steps set to 0. Moreover, we limit the maximum conversation length to 45 utterances. Regarding the model's architecture, the recurrent network is a bidirectional GRU with only one layer of dimension 768, and the fully connected network contains also a single layer with the same dimensions. A dropout of 0.2 is applied to both the output of BERT and the output of the fully connected layer. The model was trained on a single NVIDIA Tesla V100 SXM2 16 GB GPU.

Measuring Fairness of Text Classifiers via Prediction Sensitivity

Abstract

With the rapid growth in language processing applications, fairness has emerged as an important consideration in data-driven solutions. Although various fairness definitions have been explored in the recent literature, there is lack of consensus on which metrics most accurately reflect the fairness of a system. In this work, we propose a new formulation – ACCUMULATED PREDICTION SENSITIVITY, which measures fairness in machine learning models based on the model's prediction sensitivity to perturbations in input features. The metric attempts to quantify the extent to which a single prediction depends on a protected attribute, where the protected attribute encodes the membership status of an individual in a protected group. We show that the metric can be theoretically linked with a specific notion of group fairness (statistical parity) and individual fairness. It also correlates well with humans' perception of fairness. We conduct experiments on two text classification datasets – JIGSAW TOXICITY, and BIAS IN BIOS, and evaluate the correlations between metrics and manual annotations on whether the model produced a fair outcome. We observe that the proposed fairness metric based on prediction sensitivity is statistically significantly more correlated with human annotation than the existing counterfactual fairness metric.

1 Introduction

Ongoing research is increasingly emphasizing the development of methods which detect and mitigate unfair social bias present in machine learning-based language processing models. These methods come under the umbrella of algorithmic fairness which has been quantitatively expressed with numerous definitions (Mehrabi et al., 2019; Jacobs and Wallach, 2019). These fairness definitions are broadly categorized into two types, i.e, individual fairness and group fairness. Individual fairness (e.g., counter-factual fairness (Kusner et al., 2017)) is aimed at evaluating whether a model gives similar predictions for individuals with similar personal attributes (e.g., age or race). On the other hand, group fairness (e.g., statistical parity (Dwork et al., 2012)) evaluates fairness across cohorts with same protected attributes instead of individuals (Mehrabi et al., 2019). Although these two broad categories of fairness define valid notions of fairness, human understanding of fairness is also used to measure fairness in machine learning models (Dhamala et al., 2021). Existing studies often consider only one or two these verticals of measuring fairness.

In our work, we propose a formulation based on models sensitivity to input features – the *accumulated prediction sensitivity*, to measure fairness of model predictions. We establish its theoretical relationship with statistical parity (group fairness) and individual fairness (Dwork et al., 2012) metrics. We then demonstrate the correlation between the proposed metric and human perception of fairness using empirical experiments.

Researchers have proposed metrics to quantify fairness based on a model's sensitivity to input features. Specifically, Maughan and Near (2020); Ngong et al. (2020) propose a *prediction sensitivity* metric that attempts to quantify the extent to which a single prediction depends on a protected attribute. The protected attribute encodes the membership status of an individual in a protected group. Prediction sensitivity can be seen as a form of feature attribution, but specialized to the protected attribute. In our work, we extend their concept of prediction sensitivity to propose *accumulated prediction sensitivity*. Akin to the metric proposed by (Maughan and Near, 2020; Ngong et al., 2020), our metric also relies on model output's sensitivity to

changes in input features. Our metric generalizes their notion of sensitivity, where the model sensitivity to various input features can be weighted non-uniformly. We show that the formulation follows certain properties for the chosen definitions of group and individual fairness and also present several methodologies to select weights assigned to sensitivity of model's output to input features. For each selection, we present the correlation between the *accumulated prediction sensitivity* and human assessment of the model-output fairness.

We define our metric in Section 3 and present bounds on it (under settings when a classifier follows the selected group fairness or individual fairness constraints) in Sections 4 and 5, respectively. Next, given that the human perception of fairness is not theoretically defined, we present an empirical study on two text classification tasks in Section 6. We request a group of annotators to annotate whether they think that model output is biased against a specific gender and observe that the proposed metric correlates positively with more biased outcomes. We then observe correlations between our metric and the stated human understanding of fairness. We find that not only the proposed accumulated prediction sensitivity metric correlates positively with human perception of bias, but also beats an existing baseline based on counterfactual fairness.

2 Related Work

Multiple efforts have looked into defining, measuring, and mitigating biases in NLP models (Sun et al., 2019; Mehrabi et al., 2019; Sheng et al., 2019). Dwork et al. (2012) and Kusner et al. (2017) focus on individual fairness and propose novel classification approaches to ensure that a classification decision is fair towards an individual. Another set of works focus on group fairness. Corbett-Davies et al. (2017) present fair classification to ensure population from different race groups receive similar treatment. Hardt et al. (2016) focus on shifting the cost of incorrect classification from disadvantaged groups. Zhao and Chang (2020) measure group fairness in local regions. Finally, Kearns et al. (2019) combine the best properties of the group and individual notions of fairness.

Multiple recent works also focus on developing new dataset and associated metrics to capture various types of biases. For example, Dhamala et al. (2021) and Nangia et al. (2020) propose dataset and metrics to measure social biases and stereotypes in language model generations, Bolukbasi et al. (2016); Caliskan et al. (2017); Manzini et al. (2019) define metrics to access gender and race biases in word vector representations, and Wang et al. (2019) define metrics to quantify and mitigate biases in visual recognition task. Ethayarajh (2020) propose Bernstein bounds to represent uncertainty about the bias. Majority of these bias metrics are automatically computed, for example, using a regard classifier (Sheng et al., 2019), sentiment classifier (Dhamala et al., 2021), toxicity classifier (Dixon et al., 2018) or true positive rate difference between privileged and underprivileged groups (De-Arteaga et al., 2019). A few works additionally validate the alignment of these automatically computed bias metrics with human understanding of biases by collecting annotations of biases on a subset of test data from crowdworkers (Sheng et al., 2019; Dhamala et al., 2021). Blodgett et al. (2021, 2020) discuss the limitations of several of these bias datasets and measurements.

However, the majority of existing bias metrics are specific to the model type and the application domain used, they may not be tested for correlation with human judgement of biases, and their relationship to existing definitions of fairness has not been explored. Additionally, metrics such as true positive or error difference between groups requires ground truth labels, thereby making their computation in real-time systems difficult. Speicher et al. (2018) have attempted to present unified approach to measuring group and individual fairness via inequality indices, however we note that such metrics are non-trivial to extend to unstructured data such as text. For example, gender information in a text may be subtle (e.g. mention of softball) and it is unclear whether presence of this word should be considered to impact the genderness of the text. *Accumulated prediction sensitivity* metric, presented in this paper, attempts to address all the above limitations of existing bias metrics. We acknowledge that the proposed metric is yet to be associated with other notions of fairness (e.g. preference based notion of fairness (Zafar et al., 2017)).

3 Accumulated Prediction Sensitivity

Below, we define *accumulated prediction sensitivity*, a metric that captures the sensitivity of a model to protected attributes.

Definition 1 (Accumulated Prediction sensitivity)**.**

Let $\boldsymbol{x} \in \boldsymbol{X}$ be a feature vector drawn from the input space $\boldsymbol{X}$. Let $\boldsymbol{w}, \boldsymbol{v}$ be stochastic vectors whose entries are non-negative values that sum to one. Given $\boldsymbol{x}$, let $\boldsymbol{f}$ be a K-class classifier, such that $\boldsymbol{f}(\boldsymbol{x}) = [f_1(\boldsymbol{x}), .., f_k(\boldsymbol{x}), .., f_K(\boldsymbol{x})]$ denotes the K-dimensional probability output generated by the classifier. We define accumulated prediction sensitivity P as:

$$P = \boldsymbol{w}^T \boldsymbol{J} \boldsymbol{v}; \;\; \textit{where} \;\; \boldsymbol{J}(k, i) = \left| \frac{\partial f_k(\boldsymbol{x})}{\partial x_i} \right|. \quad (1)$$

$\boldsymbol{J}$ is a matrix[1] such that the $(k, i)^{\text{th}}$ entry is $\left|\frac{\partial f_k(\boldsymbol{x})}{\partial x_i}\right|$, where x_i is the i^{th} entry in $\boldsymbol{x}$. The product $\boldsymbol{w}^T\boldsymbol{J}$ sums the absolute derivatives $|\frac{\partial f_k(\boldsymbol{x})}{\partial x_i}|$ across $f_k, k = 1, .., K$ and returns a vector of summed derivatives with respect to each $x_i \in \boldsymbol{x}$. The product of $\boldsymbol{v}$ with $\boldsymbol{w}^T\boldsymbol{J}$ further averages the derivatives across all the features $x_i \in \boldsymbol{x}$ to yield the scalar P.

The value $\frac{\partial f_k(\boldsymbol{x})}{\partial x_i}$ captures the expected change in model output for the k^{th} class given a perturbation in x_i. If x_i is a protected feature, arguably a smaller value of $\frac{\partial f_k(\boldsymbol{x})}{\partial x_i}$ implies a fairer model; as then the model's outcome does not change sharply with changes in x_i. To capture the sensitivity of the model with respect to the protected features, one also needs to choose $\boldsymbol{v}$ judiciously. For example, given the explicit set of protected features in $\boldsymbol{x}$, one can select $\boldsymbol{v}$ such that only entries corresponding to those features are assigned a non-zero value, while the rest are set to zero. Given this heuristic, we expect the value P to be smaller for fairer models. In the following sections, we connect the accumulated prediction sensitivity to two known notions of fairness and human perception of fairness.

4 Relation to Group Fairness: Statistical Parity

Given a set of protected features (e.g. gender), a model satisfies statistical parity if model outcome is independent of the protected features (we note that identifying protected features may not always be feasible in the real world). We represent the feature vector $\boldsymbol{x} = [\boldsymbol{x}_p, \boldsymbol{x}_l]$, where $\boldsymbol{x}_p$ is the set of protected features and $\boldsymbol{x}_l$ is the remainder. Accordingly, we choose $\boldsymbol{v}$ to be a vector such that the entries that sum $|\frac{\partial f_k(x_p)}{\partial x_i}| \forall x_p \in \boldsymbol{x}_p$ in $\boldsymbol{J}$ are non-zero; and zero otherwise. This choice is intuitive as then we sum the gradients in $\boldsymbol{J}$ that correspond to protected features and measure model's sensitivity to them. The predictor $\boldsymbol{f}(\boldsymbol{x})$ will satisfy statistical parity if $\boldsymbol{f}(\boldsymbol{x}_p, \boldsymbol{x}_l) = \boldsymbol{f}(\boldsymbol{x}'_p, \boldsymbol{x}_l) \forall \boldsymbol{x}_p \neq \boldsymbol{x}'_p$. Given this, we state the following theorem.

Theorem 1. *Given a vector $\boldsymbol{v}$ with non-zero entries corresponding to $\boldsymbol{x}_p$ and zero entries for $\boldsymbol{x}_l$, if the predictor $\boldsymbol{f}(\boldsymbol{x})$ satisfies statistical parity with respect to $\boldsymbol{x}_p$, accumulated prediction sensitivity will be zero.*

Proof: If $\boldsymbol{f}(\boldsymbol{x})$ satisfies statistical parity with respect to $\boldsymbol{x}_p$, the values $\frac{\partial f_k(\boldsymbol{x})}{\partial x_p} \forall x_p \in \boldsymbol{x}_p$ will be all zeros. This is due to the fact that the function $f_k(\boldsymbol{x})$ can not be defined based on entries $x_p \in \boldsymbol{x}_p$ for it to be independent of them. Therefore, for every multiplication in the product $\boldsymbol{J}\boldsymbol{v}$, either the entry $\frac{\partial f_k(\boldsymbol{x})}{\partial x_p}$ will be 0 or the entry in $\boldsymbol{v}$ corresponding to $\boldsymbol{x}_l$ will be 0. Hence, P will be 0.

Appendix A presents empirical results in computing P on a synthetic dataset. We construct a dataset where a feature (hair length) correlates with a protected attribute (gender). We show that if the modeler unintentionally uses the correlated feature while attempting to build a classifier with statistical parity, our metric can be used for evaluation.

5 Relation to Individual Fairness

Dwork et al. (2012) state the notion of individual based fairness as: "*We interpret the goal of mapping similar people similarly to mean that the distributions assigned to similar people are similar*". They propose adding a Lipschitz property constraint during the classifier optimization. Given a loss function $\mathcal{L}$ defined to optimize the parameters $\boldsymbol{\theta}$ of the classifier $\boldsymbol{f}(\boldsymbol{x})$, a distance function $d(\boldsymbol{x}, \boldsymbol{x}')$ that computes distance between data-points $\boldsymbol{x}, \boldsymbol{x}'$, another distance function $\mathcal{D}(\boldsymbol{f}(\boldsymbol{x})), \boldsymbol{f}(\boldsymbol{x}'))$ that computes distance between classifier predictions on $\boldsymbol{x}, \boldsymbol{x}'$ and a constant L, Dwork et al. (2012) propose the following constrained optimization.

$$\begin{aligned} &\min_{\boldsymbol{\theta}} \mathcal{L}; \quad \text{such that} \\ &\mathcal{D}(\boldsymbol{f}(\boldsymbol{x})), \boldsymbol{f}(\boldsymbol{x}')) < Ld(\boldsymbol{x}, \boldsymbol{x}'); \forall \boldsymbol{x}, \boldsymbol{x}' \in \boldsymbol{X}. \end{aligned} \quad (2)$$

It is natural to choose an Lp norm (Bourbaki, 1987) for d and $\mathcal{D}$. For a classifier $\boldsymbol{f}$ that is trained with the above constrained optimization and the choice of distance metrics $\mathcal{D}, d$ is an Lp norm, we state the following.

---

[1] Note that we use the following notation scheme in this paper – bold capital letters for matrices, bold small letters for vectors and un-bolded letters for scalars.

Theorem 2. *If the predictor $\boldsymbol{f}(\boldsymbol{x})$ is trained with the constrained optimization stated in Eq. (2), the accumulated prediction sensitivity will be upper bounded by L.*

Proof: We restate the constraint in Eq. (2) as (Note that the inequality sign does not change as distance metrics $\mathcal{D}, d$ are required to be positive for $\boldsymbol{x} \neq \boldsymbol{x}'$)

$$\forall \boldsymbol{x} \neq \boldsymbol{x}', \quad L > \frac{\mathcal{D}(\boldsymbol{f}(\boldsymbol{x}), \boldsymbol{f}(\boldsymbol{x}'))}{d(\boldsymbol{x}, \boldsymbol{x}')}. \tag{3}$$

Given the inequality holds for any pair of $\boldsymbol{x}, \boldsymbol{x}'$, it must also hold for an $\boldsymbol{x}'$ of the following choice. $\boldsymbol{x}' = \boldsymbol{x} + [0, 0, \Delta x_i, 0, 0]$, where Δx_i is a scalar perturbation in the i^{th} entry in $\boldsymbol{x}$. For a chosen Lp norm, Eq (3) becomes

$$\begin{aligned} L &> \frac{[\sum_{k=1}^{K} |f_k(\boldsymbol{x}) - f_k(\boldsymbol{x}')|^p]^{\frac{1}{p}}}{|\Delta x_i|} \\ &> \frac{[|f_k(\boldsymbol{x}) - f_k(\boldsymbol{x}')|^p]^{\frac{1}{p}}}{|\Delta x_i|}. \end{aligned} \tag{4}$$

Since each entry $|f_k(\boldsymbol{x}) - f_k(\boldsymbol{x}')|^p, k = 1, ..K$ is expected to be non-zero and zeroing out all such entries (but one) will yield a lower value than the summation $\sum_{k=1}^{K} |f_k(\boldsymbol{x}) - f_k(\boldsymbol{x}')|^p$. We can rewrite Eq. (4) as:

$$\frac{|f_k(\boldsymbol{x}) - f_k(\boldsymbol{x} + [0, 0, \Delta x_i, 0, 0])|}{|\Delta x_i|}.$$

We can further chose Δx_i such that it is small perturbation, leading to the following.

$$\begin{aligned} L > &\lim_{\Delta x_i \to 0} \frac{|f_k(\boldsymbol{x}) - f_k(\boldsymbol{x} + [0, 0, \Delta x_i, 0, 0])|}{|\Delta x_i|} \\ = &\left|\frac{\partial f_k(\boldsymbol{x})}{\partial x_i}\right|. \end{aligned}$$

Therefore, each entry in $\boldsymbol{J}$ is upper bounded by L. As vectors $\boldsymbol{v}, \boldsymbol{w}$ are stochastic and they compute weighted averages of bounded entries in $\boldsymbol{J}$, P (defined in Eq. (1)) must be less than or equal to L.

We also note that as L becomes larger, the constraint in the Eq. (2) becomes looser. Therefore, a higher value of L during optimization is expected to loosen the fairness constraint as well as the bound on fairness sensitivity. This aligns with our intuition of lower values of P for fairer models. We compute value of L on a synthetically generated classification data, optimized with the individual fairness constraint in equation 2. The results are presented in Appendix B.

6 Correlations with Human Perception of Fairness

While the conditional statistical parity and individual fairness establish theoretical constraints on the model behaviour (e.g. independence from protected features and similarity in prediction outcomes for similar data-points), humans may carry a different notion of fairness for model outcomes on individual data-points. This notion may be based on their understanding of cultural norms, which in turn effect their decisions in identifying which model outputs could be considered biased. In this section, we present experiments that correlate accumulated prediction sensitivity with human perception of fairness.

6.1 Human Perception of Fairness

Given a data-point $\boldsymbol{x}$ and model prediction $\boldsymbol{f}(\boldsymbol{x})$, we assign one of the K classes to the data-point. In order to evaluate the human perception of fairness on the data-point, we request a group of annotators to evaluate the model prediction (taken as the argmax of the model output) and assess whether they believe the output is biased. For instance, given the social/cultural norms, a profession classifier assigning a data-point "she worked in a hospital" to nurse instead of doctor can be perceived as biased. To correlate the accumulated prediction sensitivity P with the human understanding of fairness, we conduct experiments on two text classification datasets. We describe the datasets below, followed by our choices for $\boldsymbol{w}$ and $\boldsymbol{v}$.

6.2 Datasets

We experiment with our proposed metric on two classification tasks, i.e, occupation classification on *Bias in Bios* dataset (De-Arteaga et al., 2019)[2] and toxicity classification with *Jigsaw Toxicity* dataset[3]. We focus on these two datasets as they have been investigated in several previous studies (Pruksachatkun et al., 2021) and have been reported to carry significant presence of bias. BIAS IN BIOS data (De-Arteaga et al., 2019) is purposed to train occupation classifier which predicts occupation given the biography of an individual. For this data, the task classifier is an occupation classification model which is composed of a standard LSTM-based encoder combined with the output layer of 28 nodes, i.e, number of occupation classes.

---

[2] The data is available at https://github.com/microsoft/biosbias

[3] The data is available at https://www.kaggle.com/c/jigsaw-unintended-bias-in-toxicity-classification

JIGSAW TOXICITY dataset is commonly used to train toxic classifier which is tasked to predict if an input sentence is toxic or not. This dataset has input sentences as the comments from Wikipedia's talk page edits labeled with the degree of toxicity. In this dataset, the task classifier is a binary classifier trained to predict whether a comment is toxic or not. We labeled the samples with >0.5 toxicity score as *toxic* and others as *non-toxic* to train the task classifier. The task classifier trained with *Jigsaw Toxicity* dataset achieved an AUC of 0.957. Table 4 in appendix summarizes the train/test/valid split for the 2 datasets.

6.3 Selecting the vectors $\boldsymbol{w}$

The vector $\boldsymbol{w}$ sums up the absolute partial derivatives of $f_k(\boldsymbol{x})$ with respect to a given feature $x_i, \forall k = 1, .., K$. In our setup, we consider input features to be the word embeddings and the matrix $\boldsymbol{J}$ is computed over the same. Given a D-dimensional word embedding, K classes and N words in $\boldsymbol{x}$, $\boldsymbol{J}$ will be a matrix of size $(K) \times (DN)$. In all our experiments, we choose $\boldsymbol{w}$ to be a uniform vector with entries $1/K$. Such a choice assigns equal weight to the partial derivatives computed over each class. One may chose to put a higher weight on derivatives computed over a specific class, if there is a reason to believe that the accumulated prediction sensitivity should be informed more with respect to that class. For instance, for a classifier that stratifies medical images into various diseases (Agrawal et al., 2019), disparity in model performance with respect to malicious diseases can be considered more costly. Therefore, derivatives for classes that represent more malicious disease can be weighted higher.

6.4 Selecting the vectors $\boldsymbol{v}$

Through the vector $\boldsymbol{v}$, we aim to select words in $\boldsymbol{x}$ that carry gendered information. We use two formulations for the the vector $\boldsymbol{v}$ as discussed below.

6.4.1 Using a list of gendered words

In this setup, we use the set of gendered words from (Bolukbasi et al., 2016) and assign entries in $\boldsymbol{v}$ corresponding to those words as $1/(N_g \times D)$, where N_g is the count of gendered words in the data-point.

6.4.2 Using a Protected Status Model (PSM)

While prior work has used word matching to a pre-defined corpus of tokens describing various demographic cohorts (Bolukbasi et al., 2016), these corpus do not contain words that stereotypically are associated with a particular cohort but may not be explicitly tied to that cohort. For example, the word "volleyball" is associated with females in the analysis presented by (Dinan et al., 2020).

To capture this nuance, we propose using another classifier (that acts on the same dataset as used to train the original classifier, for which we aim to compute P) and using it to identify tokens containing information about the protected attribute (e.g. gender). We discuss the model training below.

Protected Status Model: To extend accumulated prediction sensitivity to settings with no explicit protected attribute, we train a *protected status model* $\boldsymbol{g}$. Given the data-point $\boldsymbol{x}$, goal of the PSM model $\boldsymbol{g}(\boldsymbol{x})$ is to predict the protected attributes. Given a trained $\boldsymbol{g}(\boldsymbol{x})$, we then compute another matrix $\boldsymbol{J}_g$, where the $(j,i)^{\text{th}}$ entry is $|\frac{\partial \boldsymbol{g}_m(\boldsymbol{x})}{\boldsymbol{x}_i}|$ ($\boldsymbol{g}_m$ is the probability outcomes corresponding to the m^{th} protected attribute class; e.g. male in a gender classifier). We then define an entry $v_i \in \boldsymbol{v}$ as $\sum_j \boldsymbol{J}_g(m,i)$ (the vector $\boldsymbol{v}$ is normalized to be stochastic). Intuitively, the sum $\sum_j \boldsymbol{J}_g(m,i)$ captures the model output sensitivity with respect to the input features x_i and is expected to higher if x_i carries more gendered information.

In our experiments, we train separate PSM models for gender sensitivity computation on Bias-in-bios and Jigsaw data-sets, as each data-point in these data-sets is additionally labeled with a binary gender class (male/female)[4]. Gender PSMs predicts the associated gender given the datapoint $\boldsymbol{x}$. Training PSM on the same datasets used to train the task classifier $\boldsymbol{f}$ helps capture the gender stereotypes present in the respective datasets. For instance, in a given dataset, if the word "volleyball" appears more often in the data-points that correspond to the female gender, the gender classifier's sensitivity to this word is expected to be high as the classifier may pay higher emphasis to this word for gender classification. We use the same model architecture as the task classifiers for PSM. PSM for gender classification achieve an accuracy of 98.79% (Male Acc:98.84% Female Acc:98.17%) and 95.39% (Male Acc:95.92% Female Acc:96.22%) for *Bias in bios* and *Jigsaw Toxicity* datasets, respectively. These accuracies are computed over the same train/test split as the task classifier.

---

[4] We note that this is a limitation of this work as gender can be non-binary.

Individual Fairness Metrics	Bias in Bios		Jigsaw Toxicity	
	Corr.	MI	Corr.	MI
P1 (uniform $\boldsymbol{w}, \boldsymbol{v}$)	0.206	0.013	0.117	0.007
CF (Garg et al., 2019)	0.326	0.025	0.214	0.022
P4 ($\boldsymbol{v}$ set using gendered words)	0.34	0.037	0.227	0.054
P5 ($\boldsymbol{v}$ set using gendered words and embedding vectors)	**0.363**	**0.098**	0.295	0.061
P2 ($\boldsymbol{v}$ set using PSM)	**0.397**	**0.102**	0.358	**0.097**
P3 ($\boldsymbol{v}$ set using PSM and embedding vectors)	**0.441**	**0.105**	**0.374**	**0.101**

Table 1: Point bi-serial correlations (Corr.) and Mutual Information (MI) between different individual fairness metrics with human annotations on Bios in Bias and Jigsaw toxicity datasets. Bold numbers are the correlations where we see statistically significant increase over CF baseline. The metric variants are sorted based on the correlation values. We use the bootstrap method to compute statistical significance (Koehn, 2004) at p-value<0.05.

6.4.3 Using Word Embedding Vectors

In addition to using the list of gendered words and PSM, we also test with a setting where we multiply the word embedding vectors to the proposed formulations of $\boldsymbol{v}$. We stack the word embedding vectors for each word $x_i \in \boldsymbol{x}$ to obtain a vector of embeddings $\boldsymbol{e}_i$. We perform an element-wise multiplication of the embedding vectors $\boldsymbol{e}_i$ with the vector with entries $1/(N_g \times D)$ for gendered words or $\sum_j \boldsymbol{J}_g(j,i)$ obtained using PSM. This choice is motivated based upon the findings in (Han et al., 2020). They leverage the magnitude of embedding vectors in determining saliency of the input words for the classification task at hand. Their proposed methodology computes saliency maps over the features $x_i \in \boldsymbol{x}$ by multiplying embedding vectors with partial derivatives of the class probabilities with respect to embedding vectors themselves.

6.5 Fairness Metrics

We experiment with six fairness metrics. Out of the six, one metric is a baseline based on counter-factual fairness and the rest are variants of the accumulated prediction sensitivity P.

Counter-factual Fairness (CF) : We use the counter-factual fairness definition mentioned in Garg et al. (2019) and compute the metric as the difference in model predictions between the original sample $\boldsymbol{f}(\boldsymbol{x})$ and its corresponding counter-factual gendered sample $\boldsymbol{f}(\hat{\boldsymbol{x}})$. We take the L1 norm of the vector $\boldsymbol{f}(\boldsymbol{x}) - \boldsymbol{f}(\hat{\boldsymbol{x}})$. For example, we take the difference in predictions between the sample "She practices dentistry" and "He practices dentistry", which is the corresponding counter-factual sample. We use the definitional gender token substitutions from Bolukbasi et al. (2016) to create counter-factual samples.

P1: Uniformly weighted prediction sensitivity : In this setting, the values of $\boldsymbol{w}$ and $\boldsymbol{v}$ are set to uniform values $\frac{1}{K}$ and $\frac{1}{DN}$, respectively. This is a weak baseline as the choice of $\boldsymbol{v}$ does not provide any information regarding the gender-ness of the input words.

P2: Weighted Prediction Sensitivity based on PSM : In this setting, $\boldsymbol{w}$ is chosen to be a uniform vector, while $\boldsymbol{v}$ is chosen based on the PSM model.

P3: Weighted Prediction sensitivity + Embedding weights : In this setting, $\boldsymbol{v}$ is chosen based on the PSM model (akin to the metric in P2) which is further multiplied element-wise with the word embedding vectors.

P4: Hard gender weights based Prediction sensitivity : In this metric, we use the list of gendered words described in section 6.4.1 to determine $\boldsymbol{v}$. The value of entries in $\boldsymbol{v}$ is set to $\frac{1}{DN_g}$.

P5: Hard gender weights based prediction sensitivity + Embeddings: This setting is same as above, except entries in $\boldsymbol{v}$ are further multiplied element-wise with the word embedding vectors.

6.6 Evaluation

To evaluate whether the proposed prediction sensitivity correlates with human perception of fairness, we collect annotations from crowd workers using the Amazon Mechanical Turk platform. Crowd workers are asked to annotate if a model prediction appears to be a biased prediction or not. For *Bias in Bios* dataset, each sample presented to the annotators has the biography and occupation predicted by the model. We collect annotations on a random sample of the test set. For each biography and a predicted occupation, we ask annotators to label if the prediction is indicative of bias or if it is unbiased. Bias refers to a situation where an occupation is incorrectly predicted based on the gender associated with the biography. For instance, if the input biography is “she studied at Harvard Medical School and practices dentistry.” and is

	Example from the Bias in Bios dataset
TC	he obtained his master's in architecture from the university of tehran and phd in architecture and landscape history at georgia institute of technology
PSM	he obtained his master's in architecture from the university of tehran and phd in architecture and landscape history at georgia institute of technology
	Example from the Jigsaw Toxicity dataset
TC	gee maybe she shouldn't have cheated on her dead husband. how about that? nasty woman, it seems like.
PSM	gee maybe she shouldn't have cheated on her dead husband. how about that? nasty woman, it seems like.

Table 2: Heat map for the vectors $\boldsymbol{w}^T J$ (top entry in each row) and $\boldsymbol{v}$ (bottom entry in each row) per input word x_i. Darker color indicates higher magnitude. These vectors are multiplied to compute ACCUMULATED PREDICTION SENSITIVITY. **TC**: Task Classifier, **PSM**: Protected Status Model.

EXAMPLES OF UNBIASED SAMPLES (The predicted profession is unrelated to gender stereotype about professions)

BIO: She received a master's degree in computer science from the university of North Carolina at Chapel Hill.
Predicted Profession: Computer Scientist

BIO: He received a master's degree in computer science from the university of North Carolina at Chapel Hill.
Predicted Profession: Computer Scientist

EXAMPLES OF BIASED SAMPLES (Strongly biased predictions are based on associating a specific gender to a specific profession even when there are evidences against it in the biography)

BIO: Mary has 25 years of experience in data analytics, business intelligence and information governance with fortune 100 companies.
Predicted Profession: Nurse

BIO: He achieved a masters degree in nursing from the university of north Carolina at chapel hill
Predicted Profession: Computer Scientist

Table 3: Examples of biased/unbiased outcomes shown to the M-turk annotators

predicted as nurse, then we call this prediction biased since the biography fits better for a doctor. In case of unbiased predictions, the prediction is not expected to be influenced by the gender content in the biography. Table 3 presents a sample of examples provided to the annotators for the *Bias in bios* dataset. Each page in the annotation task consisted of ten biography-profession pairs. We collect annotations for each biography-profession pair from at least three annotators and pick the label with majority vote. Similarly for *Jigsaw Toxicity* dataset, each sample presented to the annotators contains the text and associated toxicity predicted by the model.

We restrict the set of annotators to be master annotators and the location of annotators to be Unites States. Based on the initial pilot studies conducted in the Amazon Mechanical Turk platform, we setup a payment rate to ensure a fair compensation of at least $15\$/hour$ for all annotators that work at an average pace. We annotated 900 test data-points from each dataset. We note that these test data-points were misclassified by the classifiers $\boldsymbol{f}$ trained for each dataset. While such a sampling may not conform to the true distribution of biased/unbiased model outcomes on the overall test set, we expect to get more biased samples amongst the misclassified samples. The distribution between biased and unbiased outputs was about 55:45 for *Bias in Bios* and 50:50 for *Jigsaw Toxicity*. For the *Bias in Bios* and *Jigsaw Toxicity* datsets, we obtained a Fliess' kappa of 0.43 and 0.47, respectively, amongst the three annotators. This is considered a moderate level of agreement, which we believe is expected for an relatively ambiguous task to identify model outcomes influenced by gender. We compute mutual information and bi-serial correlations as the primary measures of association between the human annotations and the *accumulated model sensitivity*.

7 Results

Table 1 lists the bi-serial correlations and mutual information between manual annotations and the different fairness metrics. First, we observe that correlations of the baseline with human judgement are mediocre (0.326 and 0.214) compared to the human judgement. We attribute this to the fact that the metric attempts to quantify a fairly subjective assessment of bias that may have different interpretation (as also pointed out by the moderate level of annotation agreement across annotators). However, the proposed variants of P have stronger correlations compared to the counter-factual baseline (except the method P1). As expected, we see the smallest correlation for P1, since this metric does not account for gender-ness in $\boldsymbol{v}$. However, metrics that determine $\boldsymbol{v}$ based on PSM prediction sensitivity and gendered words get higher correlations over P1 and the CF baseline. Variant of P with $\boldsymbol{v}$ informed using the embedding vectors further lead to improved correlations. We also observe weaker statistical significance in the case of *Jigsaw Toxicity* due to a weaker PSM. We attribute this to the noise present in gender annotations for *Jigsaw Toxicity* dataset. Hence, the performance of PSM in predicting the protected status is crucial for accurately measuring fairness.

7.1 Discussion

In order to further analyse the effect of PSM, we look into heat-maps capturing $\boldsymbol{w}^T\boldsymbol{J}$ and $\boldsymbol{v}$ separately. As a reminder, the first quantity captures the weighted average of partial derivatives of class probabilites with respect to the input features, while the second quantity computes the weights assigned to sum up the aforementioned averages. Table 2 shows while $\boldsymbol{v}$ mostly captures gendered words such as “she”, “her” and “woman”, it also captures words such as “social”, “architecture” and “cheated” to carry more gendered information compared to other words. While these words conventionally are not gendered, for the datasets at hand, they seem to provide information whether the input data-point belongs to male/female gender. We also note that $\boldsymbol{w}^T\boldsymbol{J}$ weighs on occupation specific tokens such as "physician", "executive", etc.

This finding supports our motivations to compute $\boldsymbol{v}$ based on PSM and capturing feature attributions assigned to tokens that are implicitly related to a specific gender (instead of the definitional gender tokens only). Hence, by incorporating PSM in computing P, we can capture bias present in non-trivial gendered tokens.

8 Considerations for Accumulated Prediction Sensitivity Metric

While the results showcase the promise of our metric, we draw the attention of the reader to the following considerations: (1) We observed that the metric quality depends on choice of the hyper-parameters w and v. In this regard, our metric is not different from other metrics that also depend on a hyper-parameter choice. For example, any classifier based metric has a threshold parameter and counterfactual fairness metrics rely on hyper-parameters such as the selected gendered words. (2) Our metric only works for models for which gradients can be computed. Most modern deep learning based models carry this property. (3) Lastly, we note that it is hard to interpret the absolute value of the proposed metric. The metric value should be used for relative comparison of two models which share input feature space and label space.

In addition, we note two considerations for relying on a PSM classifier. First, training it requires access to gender labels. Second, the PSM model itself could be biased. Given that gender labels may not always be available for the dataset used to train model at hand, we study the impact of transferring a PSM model trained on a different dataset on computing our metric. We also evaluate the effect of bias in PSM model on the overall metric value and present results in the Appendix D. We make observations such as the quality of the metric degrades as PSM becomes more biased. Based on these observations, we recommend that if modeler is not able to obtain high performance PSM models, they fall back to using sources such as gendered words for computing the vector $\boldsymbol{v}$.

9 Conclusion

Evaluating fairness is a challenging task as it requires selecting a notion of fairness (e.g. group or individual fairness) and then identifying metrics that can capture these notions of fairness while evaluating a classifier. Additionally, certain notions of fairness may not be well defined and can change based upon social norms (e.g. “volleyball” being closely associated with females); that may seep into the dataset at hand. In this work, we define an accumulated prediction sensitivity metric that relies on the partial derivatives of model’s class probabilities with respect to input features. We establish properties of this metric with respect to the three verticals of fairness metrics: group, individual and human-perception based. We provide bounds on the metric’s value when a predictor is expected to carry statistical parity or is trained with individual fairness. We also evaluate this metric with fairness as perceived through human evaluation of model outputs. We test variants of the proposed metric against an existing baseline derived from counter-factual fairness and observe better mutual information and correlation. Specifically, a variant of the metric that relies on a Protected Status Model (that identifies tokens that carry gender information but may not conventionally be considered gendered) yields the best correlation with the human evaluation.

In the future, one can associate the proposed formulation with other categories of group and individual fairness (Mehrabi et al., 2019). We also aim to test the metric on other datasets with other protected attributes (e.g. race, nationality). Finally, we can compare the metric across these datasets to compare trends across protected groups.

10 Broader Impact and Ethics Statement

This work can be used to evaluate bias in models, and thus used to evaluate models serving human consumers. As with all metrics, the metric does not capture all notions of bias, and thus should not be the only consideration for serving models. While this is a valid risk, this is one that is not specific to prediction sensitivity. Good use of this metric requires users to be cognizant of these strengths and weaknesses. We also note that the metric requires defining protected attributes (e.g. gender) and our work carries the limitation that the selected datasets contain binary gender annotations. Defining protected attributes may not always be possible and when possible, the protected attribute classes may not be comprehensive.

A Obtaining prediction sensitivity on classifier trained for statistical parity

Let us consider a classification task on whether to hire a person given the following features: x_1 is the person's educational experience in years, x_2 is their hair length and x_3 is their gender. We synthetically generate data for individuals in this dataset. x_1 is drawn uniformly randomly between 0 and 10. x_3 is (again) considered to be binary gender (set 0 for male and 1 for female drawn from a bernoulli distribution) and x_2 is drawn from a Gaussian distribution conditioned on x_3. $x_2 \sim \mathcal{N}(2, 10)$ (Gaussian distribution with a mean 2 and variance 10) if $x_3 = 0$ and $x_2 \sim \mathcal{N}(10, 10)$ if $x_3 = 1$. We sample 10,000 data-points from the above distribution to generate a dataset. Let us consider two cases with two different classifiers.

Case 1: Classifier depends on x_1, x_2 In this case, the modeler only deems x_3 to be the protected feature. Let us assume that they build a classifier as shown in equation 5. Lets assume that the modeler assigns a hire decision if $f > 0.5$, otherwise not.

$$f = \sigma((x_1 - 5) + (x_2 - 6)) \tag{5}$$

Given only x_3 is considered as the protected feature by the modeler, they will set the vector $\boldsymbol{v}$ to $[0, 0, 1]^T$. Let us assume that the modeler sets P as

$$P = \begin{bmatrix}\frac{1}{2} & \frac{1}{2}\end{bmatrix} \begin{bmatrix} \left|\frac{\partial f_1}{\partial x_1}\right| & \left|\frac{\partial f_1}{\partial x_2}\right| & \left|\frac{\partial f_1}{\partial x_3}\right| \\ \left|\frac{\partial f_2}{\partial x_1}\right| & \left|\frac{\partial f_2}{\partial x_2}\right| & \left|\frac{\partial f_2}{\partial x_3}\right| \end{bmatrix} \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} \tag{6}$$

We recommend the modeler computes $\frac{\partial x_2}{\partial x_3}$ and $\frac{\partial x_1}{\partial x_3}$ and if they are non-zero, use the chain rule in equation 7 to compute P.

$$\frac{\partial f_k([x_1, x_2])}{\partial x_3} = \frac{\partial f_k([x_1, x_2])}{\partial x_2} \frac{\partial x_2}{\partial x_3} \tag{7}$$

For the dataset generated above, we compute the partials $\frac{\partial x_2}{\partial x_3}$ and $\frac{\partial x_1}{\partial x_3}$. Additionally, since x_3 is a discrete variable, we approximate partial derivatives using all available right-difference quotients and left-difference quotients, as shown in equation 9. In order to compute $\frac{\partial x_2}{\partial x_3}$ at $x_3 = x_3^m$ (where x_3^m denotes the value of x_3 for the m^{th} data-point), we use the corresponding value of the feature $x_2 = x_2^m$ in the m^{th} data-point and all other available pairs $(x_2^n, x_2^n), n \neq m$.

$$\left.\frac{\partial x_2}{\partial x_3}\right|_{x_3 = x_3^m} = \text{Mean}\Big(\frac{x_2^m - x_2^n}{x_3^m - x_3^n}\Big) \tag{8}$$

The mean above is computed over all $n \neq m$. Similarly,

$$\left.\frac{\partial x_1}{\partial x_3}\right|_{x_3 = x_3^m} = \text{Mean}\Big(\frac{x_1^m - x_1^n}{x_3^m - x_3^n}\Big) \tag{9}$$

Given the dataset we generated, we compute values for $\left.\frac{\partial x_1}{\partial x_3}\right|_{x_3 = x_3^m}$ and $\left.\frac{\partial x_2}{\partial x_3}\right|_{x_3 = x_3^m}$ for an arbitrarily chosen m. We obtain values of 7.98 and 0.01, respectively. Note that we expect the second value to be 0, but due to noise in gradient approximation obtain a non-zero value. We re-write equation 6 as shown below and plug in the values of the partials. We obtain a non-zero value of P in this case.

$$P = \begin{bmatrix}\frac{1}{2} & \frac{1}{2}\end{bmatrix} \begin{bmatrix} \left|\frac{\partial f_1}{\partial x_1}\right| & \left|\frac{\partial f_1}{\partial x_2}\right| & \left|\frac{\partial f_1}{\partial x_3}\right| \\ \left|\frac{\partial f_2}{\partial x_1}\right| & \left|\frac{\partial f_2}{\partial x_2}\right| & \left|\frac{\partial f_2}{\partial x_3}\right| \end{bmatrix} \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} \tag{10}$$

$$= \begin{bmatrix}\frac{1}{2} & \frac{1}{2}\end{bmatrix} \begin{bmatrix} \left|\frac{\partial f_1}{\partial x_1}\right| & \left|\frac{\partial f_1}{\partial x_2}\right| & \left|\frac{\partial f_1}{\partial x_2}\frac{\partial x_2}{\partial x_3}\right| \\ \left|\frac{\partial f_2}{\partial x_1}\right| & \left|\frac{\partial f_2}{\partial x_2}\right| & \left|\frac{\partial f_2}{\partial x_2}\frac{\partial x_2}{\partial x_3}\right| \end{bmatrix} \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} \tag{11}$$

Case 2: Classifier only depends only on x_1 In this case, the modeler deems both x_2, x_3 to be protected features and builds a classifier as depicted below.

$$f = \sigma(x_1 - 5) \tag{12}$$

Lets assume that the modeler assigns a hire decision if $f > 0.5$, otherwise not. Additionally, given x_2 and x_3 are protected features, P is set to

$$P = \begin{bmatrix}\frac{1}{2} & \frac{1}{2}\end{bmatrix} \begin{bmatrix} \left|\frac{\partial f_1}{\partial x_1}\right| & \left|\frac{\partial f_1}{\partial x_2}\right| & \left|\frac{\partial f_1}{\partial x_3}\right| \\ \left|\frac{\partial f_2}{\partial x_1}\right| & \left|\frac{\partial f_2}{\partial x_2}\right| & \left|\frac{\partial f_2}{\partial x_3}\right| \end{bmatrix} \begin{bmatrix} 0 \\ \frac{1}{2} \\ \frac{1}{2} \end{bmatrix} \tag{13}$$

Given that the classifier does not explicitly rely on x_2 and x_3, we can rewrite equation 14 as

$$P = \begin{bmatrix}\frac{1}{2} & \frac{1}{2}\end{bmatrix} \begin{bmatrix} \left|\frac{\partial f_1}{\partial x_1}\right| & \left|\frac{\partial f_1}{\partial x_1}\frac{\partial x_1}{\partial x_2}\right| & \left|\frac{\partial f_1}{\partial x_1}\frac{\partial x_1}{\partial x_3}\right| \\ \left|\frac{\partial f_2}{\partial x_1}\right| & \left|\frac{\partial f_2}{\partial x_1}\frac{\partial x_1}{\partial x_2}\right| & \left|\frac{\partial f_2}{\partial x_1}\frac{\partial x_1}{\partial x_3}\right| \end{bmatrix} \begin{bmatrix} 0 \\ \frac{1}{2} \\ \frac{1}{2} \end{bmatrix} \tag{14}$$

We obtain the partial derivatives $\left.\frac{\partial x_1}{\partial x_2}\right|_{x_2 = x_2^m}$ and $\left.\frac{\partial x_1}{\partial x_3}\right|_{x_3 = x_3^m}$. For an arbitrary chosen x_1^m, we obtain values of 0.01 and -0.01. While we expect both these values to be zero given our data construction, they are non-zero due to the gradient approximation. Barring the noise in gradient computation, P is 0 in this case.

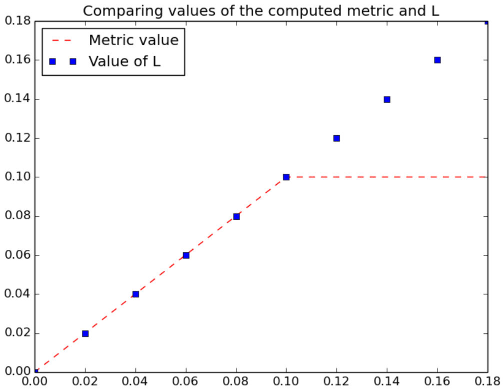

Figure 1: Plot showing the values of the accumulated prediction sensitivity and L

B Prediction sensitivity for classifier trained with individual fairness

We conduct a simulation, where we obtain the proposed metric for increasing values of L. We generate a synthetic dataset with a single feature drawn uniformly randomly between 0 and 10. The label y of a given datapoint is set to 0 if the feature value is less than 5 or 1 otherwise. Let us assume we build a linear classifier $f = \theta x$, where x is denotes scalar feature. We optimize equation 2 and obtain value of θ that satisfies the constraint and minimizes a chosen $\mathcal{L}$. Let $\mathcal{D}$ and d be L_1 norms and $\mathcal{L} = (y - f)^2$. We optimize for the value of θ, and Figure shows the value of accumulated prediction sensitivity with increasing value of L between the range 0 to 0.2. We observe the metric closely follows value of L till 0.1. We note that L will equal θ in this case and the optimal value of θ in the absence of any constraint is 0.1.

D Considerations for using PSM Classifier

Training a PSM classifier requires access to gender labels which might not be available for the dataset used to train the model under evaluation. To overcome this, we evaluate training a PSM classifier on a different dataset and then applying it on the dataset of interest. In Table 5, the last two rows record the correlation and mutual information values of a PSM classifier trained on Bias in Bios (tested on Jigsaw) and trained on Jigsaw Toxicity (tested on Bias in Bios), respectively. While we beat the CF baseline using the PSM trained on another dataset, comparison to the setting where $\boldsymbol{v}$ is set using gendered words presents a mixed picture. P3 ($\boldsymbol{v}$ set using PSM trained on Jigsaw Toxicity) has a slightly higher correlation of 0.365 compared to 0.363 in the P5 setting. However, P3 has a slightly worse MI of 0.091 compared to P5. The related experiment for Jigsaw toxicity where $\boldsymbol{v}$ is set using PSM trained on Bias in Bios yields similar mixed observations when compared to P5.

We also conducted a synthetic experiment wherein we deliberately add bias to the PSM classifier. We reduce the number of 'female' datapoints by 50% leading to about 18% reduction in the recall for the 'female' class (while the 'male' class accuracy remains the same). We observe that the metric quality also degrades in this case, leading to a correlation of 0.259 with human judgement, in case of the Bias in Bios data. This correlation is worse than the CF baseline.

Given these results, we observe that using the PSM classifier improves upon other baselines only when it is relatively un-biased in performance across genders and matched to the dataset at hand. Therefore, we recommend setting $\boldsymbol{v}$ using gendered words if a strong PSM classifier is difficult to obtain.

Individual Fairness Metrics	Bias in Bios		Jigsaw Toxicity	
	Corr.	MI	Corr.	MI
P5 ($\boldsymbol{v}$ set using gendered words and embedding vectors)	**0.363**	**0.098**	0.295	0.061
P3 ($\boldsymbol{v}$ set using PSM and embedding vectors)	**0.441**	**0.105**	**0.374**	**0.101**
P3 ($\boldsymbol{v}$ set using PSM(Bias in Bios) and embedding vectors)			**0.238**	0.083
P3 ($\boldsymbol{v}$ set using PSM(Jigsaw Toxicity) and embedding vectors)	**0.365**	**0.091**		

Table 5: Point bi-serial correlations (Corr.) and Mutual Information (MI) between different individual fairness metrics with human annotations on Bios in Bias and Jigsaw toxicity datasets. Bold numbers are the correlations where we see statistically significant increase over CF baseline. The metric variants are sorted based on the correlation values. We use the bootstrap method to compute statistical significance (Koehn, 2004) at p-value<0.05.

RotateQVS: Representing Temporal Information as Rotations in Quaternion Vector Space for Temporal Knowledge Graph Completion

Abstract

Temporal factors are tied to the growth of facts in realistic applications, such as the progress of diseases and the development of political situation, therefore, research on Temporal Knowledge Graph (TKG) attracks much attention. In TKG, relation patterns inherent with temporality are required to be studied for representation learning and reasoning across temporal facts. However, existing methods can hardly model temporal relation patterns, nor can capture the intrinsic connections between relations when evolving over time, lacking of interpretability. In this paper, we propose a novel temporal modeling method which represents temporal entities as **Rotations** in **Q**uaternion **V**ector **S**pace (RotateQVS) and relations as complex vectors in Hamilton's quaternion space. We demonstrate our method can model key patterns of relations in TKG, such as symmetry, asymmetry, inverse, and can further capture time-evolved relations by theory. Empirically, we show that our method can boost the performance of link prediction tasks over four temporal knowledge graph benchmarks.

1 Introduction

Knowledge Graphs (KGs) have been widely adopted to represent informative knowledge or facts in real-world applications (Bollacker et al., 2008; Miller, 1995; Suchanek et al., 2007). However, as known facts are usually sparse, KGs are far from completeness. Thus, Knowledge Graph Completion (KGC) methods are proposed to predict missing facts, i.e. links between entities (Bordes et al., 2013; Yang et al., 2015; Dettmers et al., 2018; Chen et al., 2021b). Furthermore, in real world, many facts are bonded with a particular time by nature. For example, *Barack Obama is the president of USA* is only valid for the time period *2009 - 2017*. To model such time-sensitive facts, Temporal Knowledge Graphs (TKGs) have recently drawn growing attention from both academic and industrial communities (Lautenschlager et al., 2015; Leetaru and Schrodt, 2013).

TKG Embedding (TKGE) methods (Jiang et al., 2016; Dasgupta et al., 2018; Jin et al., 2020; Sadeghian et al., 2021) were proposed to represent entities and relations with temporal features in TKGs (Lautenschlager et al., 2015; Leetaru and Schrodt, 2013). But how to present them with temporal interpretability remains a challenge for state-of-the-art TKGE models. Further, it is crucial for TKG Completion (TKGC) to leverage the learned temporal information. Previous static KGC works (Sun et al., 2020; Schlichtkrull et al., 2018; Gao et al., 2020) learn explainable embeddings of various relation patterns, so that symmetric pattern (e.g. "co-author"), asymmetric pattern (e.g. "affiliation"), inverse pattern (e.g. "buyer" vs. "seller") and complex composition pattern (e.g. "father's wife (mother)" vs. "wife's father (father in law)") can be captured in static KGs. However, in TKGs, there are inherent connections between entities and their relations along with time-evolving. For example, the relation between *Kit Harington* and *Rose Leslie* is *in love* in *2012*, becomes *engaged* in *2017*, and then turns into *married* in *2018*. To the best of our knowledge, very few of the existing TKGE methods can capture them.

To address this problem, we take inspirations from Hamilton's quaternion number system (Hamilton, 1844; Zhang et al., 2019a; Gao et al., 2020) and propose a novel method based on quaternion. To be specific, we encode both entities and relations as quaternion embeddings, and then temporal entity embeddings can be represented as **Rotations** in **Q**uaternion **V**ector **S**pace (RotateQVS). Theoretically, we show the limitations of previous methods and demonstrate that performing quaternion embeddings can model symmetric, asymmetric, and inverse relation patterns. Meanwhile, we prove our method is capable of cap-

Volume 1: Long Papers, pages 5843 - 5857
May 22-27, 2022

turing time-evolving information in TKG explicably. We empirically evaluate our method over four TKGC benchmarks and report state-of-the-art performance consistently. Further, we perform analysis of the learned quaternion embeddings and show the abilities of our RotateQVS for modeling various relation patterns, including temporal evolution.

We summarize our main contributions as follows:

1. We propose an original quaternion based TKGC method, namely RotateQVS, which represents temporal information as rotations in quaternion vector space.
2. We study temporal evolving relations, and we demonstrate the proposed RotateQVS can model various relation patterns including temporal evolution both theoretically and empirically.
3. Our RotateQVS outperforms the SOTA methods over all of ICEWS14, ICEWS05-15, YAGO11k and GDELT datasets on link prediction task.

2 Preliminaries on Hamilton's Quaternions

Quaternion number system (Hamilton, 1844) is an extension of traditional complex numbers. Recently, quaternion has been applied in static knowledge graph embedding (Zhang et al., 2019a; Gao et al., 2020). For readers better understanding our method in Section 3, we introduce the definition and basic operations of quaternion in this section.

2.1 Quaternion Operations

A quaternion is expressed as $q = a + b\mathbf{i} + c\mathbf{j} + d\mathbf{k}$, and some key quaternion operations are defined as:

Conjugate Similar to a traditional complex number, the conjugate of a quaternion is defined with the same real part and the opposite imaginary parts, that is

$$\overline{q} = a - b\mathbf{i} - c\mathbf{j} - d\mathbf{k}\,.$$

Inner Product The inner product between $q_1 = a_1 + b_1\mathbf{i} + c_1\mathbf{j} + d_1\mathbf{k}$ and $q_2 = a_2 + b_2\mathbf{i} + c_2\mathbf{j} + d_2\mathbf{k}$ is the sum of product of each corresponding factor

$$q_1 \cdot q_2 = \langle a_1, a_2\rangle + \langle b_1, b_2\rangle + \langle c_1, c_2\rangle + \langle d_1, d_2\rangle\,.$$

Norm With the definition of conjugate and inner product, the norm of a quaternion is defined as:

$$||q|| = \sqrt{q \cdot \overline{q}} = \sqrt{\overline{q} \cdot q} = \sqrt{a^2 + b^2 + c^2 + d^2} \tag{1}$$

Inverse The inverse of a quaternion is defined from $q^{-1} \cdot q = q \cdot q^{-1} = 1$. Multiplying by $\overline{q}$, we have $\overline{q} \cdot q \cdot q^{-1} = \overline{q}$, derived from which we get:

$$q^{-1} = \frac{\overline{q}}{||q||^2} \tag{2}$$

Hamilton Product For two quaternions q_1 and q_2, their product is determined by the products of the basis elements and the distributive law. The quaternion multiplication formula is:

$$\begin{aligned} q_1 q_2 = {} & (a_1a_2 - b_1b_2 - c_1c_2 - d_1d_2) \\ & + (a_1b_2 + b_1a_2 + c_1d_2 - d_1c_2)\mathbf{i} \\ & + (a_1c_2 - b_1d_2 + c_1a_2 + d_1b_2)\mathbf{j} \\ & + (a_1d_2 + b_1c_2 - c_1b_2 + d_1a_2)\mathbf{k} \end{aligned} \tag{3}$$

Considering the conjugate of Hamilton product, we can further deduce:

$$\begin{aligned} \overline{q_1q_2} &= \overline{q_2}\,\overline{q_1}\,, \\ \overline{q_1q_2q_3} &= \overline{q_3}\,\overline{q_2}\,\overline{q_1}\,. \end{aligned} \tag{4}$$

2.2 3D Vector Space

In fact, the imaginary part $b\mathbf{i} + c\mathbf{j} + d\mathbf{k}$ of a quaternion behaves like a vector $\mathbf{v} = (b, c, d)$ in a 3D vector space. Thus, conveniently, we rewrite a quaternion using **imaginary vectors**:

$$q = a + b\mathbf{i} + c\mathbf{j} + d\mathbf{k} = a + \mathbf{v} = (a, \mathbf{0}) + (0, \mathbf{v})\,. \tag{5}$$

Multiplication rule The multiplication of two imaginary vectors $\mathbf{v}_1$ and $\mathbf{v}_2$ is

$$\mathbf{v}_1\mathbf{v}_2 = \mathbf{v}_1 \times \mathbf{v}_2 - \mathbf{v}_1 \cdot \mathbf{v}_2\,, \tag{6}$$

where $\mathbf{v}_1 \times \mathbf{v}_2$ is vector cross product, resulting in a vector, and $\mathbf{v}_1 \cdot \mathbf{v}_2$ is the dot product, which gives a scalar. Obviously, the multiplication of two imaginary vectors is non-commutative, as the cross product is non-commutative.

Thus, the multiplication of two quaternions can be rewritten in 3D vector perspective:

$$\begin{aligned} & q_1q_2 = (a_1, \mathbf{v}_1)\,(a_2, \mathbf{v}_2) \\ = & (a_1a_2 - \mathbf{v}_1 \cdot \mathbf{v}_2, a_1\mathbf{v}_2 + a_2\mathbf{v}_1 + \mathbf{v}_1 \times \mathbf{v}_2) \end{aligned} \tag{7}$$

3 Proposed Method

In this section, we introduce a novel temporal modeling approach for TKG by representing temporal information as **Rotations** in **Q**uaternion **V**ector **S**pace (RotateQVS).

3.1 Notations

Suppose that we have a temporal knowledge graph, noted as $\mathcal{G}$. We use $\mathcal{E}$ to denote the set of entities, $\mathcal{R}$ to denote the set of relations, and $\mathcal{T}$ to denote the set of time stamps. Then, the temporal knowledge graph $\mathcal{G}$ can be defined as a collection of quadruples, noted as (s, r, o, t), where a relation $r \in \mathcal{R}$ holds between a head entity $s \in \mathcal{E}$ and an tail entity $o \in \mathcal{E}$ at time t. The actual time t is represented by a time stamp $\tau \in \mathcal{T}$.

3.2 Representing Temporal Information using Rotations in 3D Vector Space

Similar to Tero (Xu et al., 2020a) which utilizes a rotation in complex space, we also represent temporal information using rotations while in the quaternion vector space.

In 3D vector space, according to *Euler's rotation theorem* (Euler, 1776; Verhoeff, 2014), any rotation or sequence of rotations of a rigid body or a coordinate system about a fixed point is equivalent to a single rotation by a given angle θ about a fixed axis (called the Euler axis) that runs through the fixed point. And an extension of Euler's formula for quaternion can be expressed as follows:

$$\begin{aligned} q &= e^{\frac{\theta}{2}(v_x\mathbf{i}+v_y\mathbf{j}+u_z\mathbf{k})} \\ &= \cos\frac{\theta}{2} + (v_x\mathbf{i}+v_y\mathbf{j}+u_z\mathbf{k})\sin\frac{\theta}{2}, \end{aligned} \tag{8}$$

where **i**, **j**, **k** are unit vectors representing the three Cartesian axes.

3.2.1 Representing Time, Entities, and Relations:

Quaternions provide us with a simple way to encode this axis–angle representation in four numbers, and can be used to perform the rotation procedure in 3D vector space. By doing so, we constrain the **time stamp** embedding $\boldsymbol{\tau}$ as a unit quaternion as

$$\boldsymbol{\tau} = \cos\frac{\theta_\tau}{2} + \mathbf{u}_\tau \sin\frac{\theta_\tau}{2}, \tag{9}$$

where $\mathbf{u}_\tau$ is a unit vector in the quaternion space. And for other elements of a quadruple (s, r, o, t), based on the Hamilton's quaternions in Section 2, we map each of them to its base, which is a time-independent quaternion embedding:

$$\begin{aligned} \mathbf{s} &= \{\mathbf{a}_s + \mathbf{b}_s\mathbf{i} + \mathbf{c}_s\mathbf{j} + \mathbf{d}_s\mathbf{k}\} \\ \mathbf{r} &= \{\mathbf{a}_r + \mathbf{b}_r\mathbf{i} + \mathbf{c}_r\mathbf{j} + \mathbf{d}_r\mathbf{k}\} \\ \mathbf{o} &= \{\mathbf{a}_o + \mathbf{b}_o\mathbf{i} + \mathbf{c}_o\mathbf{j} + \mathbf{d}_o\mathbf{k}\}, \end{aligned} \tag{10}$$

where $\mathbf{a}_{\{.\}}, \mathbf{b}_{\{.\}}, \mathbf{c}_{\{.\}}, \mathbf{d}_{\{.\}} \in \mathbb{R}^k$.

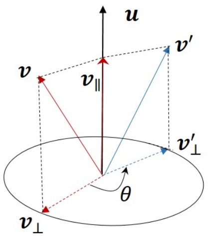

Figure 1: An illustration of the proposed rotation in 3D vector space, where $\mathbf{v}'$ is the result of vector $\mathbf{v}$ rotating θ around the rotation axis $\mathbf{u}$.

3.2.2 Temporal Entities:

We make use of the quaternion rules to represent temporal information as rotations in 3D vector space. An abstract rotation procedure is illustrated in Figure 1.

Theorem 1. *Given a unit quaternion $q = \cos\frac{\theta}{2} + \mathbf{u}\sin\frac{\theta}{2}$, where $\mathbf{u} \in \mathbb{R}\mathbf{i} + \mathbb{R}\mathbf{j} + \mathbb{R}\mathbf{k}$ is a unit vector (rotation axis) in a three-dimensional space, the result of vector $\mathbf{v}$ rotating θ around the rotation axis $\mathbf{u}$ is*

$$\mathbf{v}' = q\mathbf{v}q^{-1} = q\mathbf{v}\bar{q}. \tag{11}$$

Theorem 1 is supported by Rodrigues' rotation formula (Rodrigues, 1840).[1] We then define the functional mapping that reflects the temporal evolution of an entity embedding. For each time stamp τ, the functional mapping is an element-wise rotation from the basic entity embedding $\mathbf{e}$ (quaternion representation) to the **time-specific entity** embedding $\mathbf{e}_t$, which is as follows:

$$\begin{aligned} \mathbf{e}_t &= \boldsymbol{\tau}\mathbf{e}\boldsymbol{\tau}^{-1} = \boldsymbol{\tau}(a_\mathbf{e} + \mathbf{v}_\mathbf{e})\boldsymbol{\tau}^{-1} \\ &= a_\mathbf{e}\boldsymbol{\tau}\boldsymbol{\tau}^{-1} + \boldsymbol{\tau}\mathbf{v}_\mathbf{e}\boldsymbol{\tau}^{-1} \\ &= a_\mathbf{e} + \boldsymbol{\tau}\mathbf{v}_\mathbf{e}\boldsymbol{\tau}^{-1}, \end{aligned} \tag{12}$$

where $a_\mathbf{e}$ and $\mathbf{v}_\mathbf{e}$ are the scalar/real and vector/imaginary part of the entity quaternion representation $\mathbf{e}$ respectively. And according to Theorem 1, $\boldsymbol{\tau}\mathbf{v}_\mathbf{e}\boldsymbol{\tau}^{-1}$ is the result of vector $\mathbf{v}_\mathbf{e}$ rotating θ_τ around the rotation axis $\mathbf{u}_\tau$ ($\boldsymbol{\tau} = \cos\frac{\theta_\tau}{2} + \mathbf{u}_\tau\sin\frac{\theta_\tau}{2}$, see

---

[1] See proof in Appendix A

Equation 9) which constitutes the vector/imaginary part of $\mathbf{e}_t$. Thus, we can get a lemma:

Lemma 1. *The vector (imaginary) part is rotated while the scalar (real) part remains unchanged in the functional mapping (Equation 12) which reflects the temporal evolution of an entity embedding.*

For a quadruple (s, r, o, t), we make use of the functional mapping to get the time-specific entity embeddings $\mathbf{s}_t$ and $\mathbf{o}_t$ from the basic entity embeddings $\mathbf{s}$ and $\mathbf{o}$:

$$\mathbf{s}_t = \boldsymbol{\tau}\mathbf{s}\boldsymbol{\tau}^{-1}, \quad \mathbf{o}_t = \boldsymbol{\tau}\mathbf{o}\boldsymbol{\tau}^{-1}. \tag{13}$$

Considering the temporal evolution of entity embedding, the **relation** embedding $\mathbf{r}$ is regarded as a translation from the time-specific subject embedding $\mathbf{s}_t$ to the conjugate of the time-specific object embedding $\overline{\mathbf{o_t}}$. In other words, we aim to make $\mathbf{s}_t + \mathbf{r} = \overline{\mathbf{o_t}}$ for all positive quadruples. Then, the score function can be defined as:

$$f(s, r, o, t) = ||\mathbf{s}_t + \mathbf{r} - \overline{\mathbf{o}_t}||. \tag{14}$$

Note that each embedding above is a quaternion representation, and "$||$" denotes the norm computation (see Equation 1).

3.2.3 Loss Function

We use the same margin loss function with multiple negative sampling as proposed in (Sun et al., 2019), which has been proved to be effective on distance-based KGE models (Bordes et al., 2013; Sun et al., 2019) and as well as the TKGE models (Xu et al., 2019, 2020a). In details, our loss function is

$$\mathcal{L} = -\log\sigma(\gamma - f(\xi)) - \sum_{i=1}^{\eta}\log\sigma(f(\xi'_i) - \gamma), \tag{15}$$

where η is the number of negative training samples over the positive one, ξ is the positive training quadruple, $\sigma(\cdot)$ denotes the sigmoid function, γ is a fixed margin, and ξ'_i denotes the i-th negative sample generated by randomly corrupting the subject or the object of ξ such as (s', r, o, t) and (s, r, o', t).

3.3 Modeling Various Relation Patterns

In this section, we demonstrate that our RotateQVS can model various relation patterns. In TKGE, four kinds of relation patterns are mostly considered and studied in previous static KGE and TKGE works (Sun et al., 2019; Gao et al., 2020). Their definitions are given as follows:

Definition 1. *A relation r is symmetric, if $\forall s, o, t$, $r(s, o, t) \wedge r(o, s, t)$ holds True.*

Definition 2. *A relation r is asymmetric, if $\forall s, o, t$, $r(s, o, t) \wedge \neg r(o, s, t)$ holds True.*

Definition 3. *Relation r_1 is the inverse of r_2, if $\forall s, o, t$, $r_1(s, o, t) \wedge r_2(o, s, t)$ holds True.*

Definition 4. *Relation r_1 and r_2 are evolving over time from t_1 (time stamp τ_1) to t_2 (time stamp τ_2), if $\forall s, o$, $r_1(s, o, t_1) \wedge r_2(s, o, t_2)$ holds True.*

Comparing with other TKGE methods, we show RotateQVS can model all these four patterns, while previous methods (see Section 4.3) fail to do so.[2] One advantage of applying quaternion embeddings is that our method supports all these relation patterns, while other representation forms cannot, such as TeRo (Xu et al., 2020a) using complex number system $a + b\mathbf{i}$.[3]

As seen in our score function (Equation 14), our aim is to make

$$\begin{aligned} &\boldsymbol{\tau}\mathbf{s}\boldsymbol{\tau}^{-1} + \mathbf{r} = \overline{\boldsymbol{\tau}\mathbf{o}\boldsymbol{\tau}^{-1}} = \boldsymbol{\tau}\bar{\mathbf{o}}\boldsymbol{\tau}^{-1} \\ &\Leftrightarrow \bar{\mathbf{o}} - \mathbf{s} = \boldsymbol{\tau}^{-1}\mathbf{r}\boldsymbol{\tau}. \end{aligned} \tag{16}$$

Then we can get following results:

Lemma 2. *RotateQVS can model the symmetric pattern for TKG. (See proof in Appendix B)*

Lemma 3. *RotateQVS can model the asymmetric pattern for TKG. (See proof in Appendix C)*

Lemma 4. *RotateQVS can model the inversion pattern for TKG. (See proof in Appendix D)*

Lemma 5. *RotateQVS can model the temporal-evolution pattern for TKG.*

Proof. For temporal-evolution pattern, $r_1(s, o, t_1) \wedge r_2(s, o, t_2)$ in Definition 4 can be expressed as:

$$\begin{aligned} &\begin{cases} \bar{\mathbf{o}} - \mathbf{s} = \boldsymbol{\tau}_1^{-1}\mathbf{r}_1\boldsymbol{\tau}_1 \\ \bar{\mathbf{o}} - \mathbf{s} = \boldsymbol{\tau}_2^{-1}\mathbf{r}_2\boldsymbol{\tau}_2 \end{cases} \\ &\Leftrightarrow \boldsymbol{\tau}_2\boldsymbol{\tau}_1^{-1}\mathbf{r}_1(\boldsymbol{\tau}_2\boldsymbol{\tau}_1^{-1})^{-1} = \mathbf{r}_2. \end{aligned} \tag{17}$$

For the same head entity and tail entity, if a relation r_1 holds at time t_1 (time stamp τ_1) and a relation r_2 holds at time t_2 (time stamp τ_2), we are supposed to get $\boldsymbol{\tau}_2\boldsymbol{\tau}_1^{-1}\mathbf{r}_1(\boldsymbol{\tau}_2\boldsymbol{\tau}_1^{-1})^{-1} = \mathbf{r}_2$.

In addition, based on Equation 17, we have

$$\boldsymbol{\tau}_1^{-1}\mathbf{r}_1\boldsymbol{\tau}_1 = \boldsymbol{\tau}_2^{-1}\mathbf{r}_2\boldsymbol{\tau}_2. \tag{18}$$

---

[2] Statistics of several baselines modeling on various relation patterns are summarised in Appendix E.

[3] Theoretical analysis of TeRo's defect is shown in Section 3.4.

Model	Space Complexity
TransE	$\mathcal{O}(n_e d + n_r d)$
TTransE	$\mathcal{O}(n_e d + n_r d + n_\tau d)$
HyTE	$\mathcal{O}(n_e d + n_r d + n_\tau d)$
TA-DistMult	$\mathcal{O}(n_e d + n_r d + n_{token} d)$
ATiSE	$\mathcal{O}(n_e d + n_r d)$
DE-SimplE	$\mathcal{O}(n_e d + n_r d)$
TeRo	$\mathcal{O}(n_e d + n_r d + n_\tau d)$
RotateQVS	$\mathcal{O}(n_e d + n_r d + n_\tau d)$

Table 1: Space complexity comparison of our RotateQVS with several baselines.

Dataset	ICEWS14	ICEWS05-15	YAGO11k	GDELT
Entities	7,128	10,488	10,623	500
Relations	230	251	10	20
Time Stamps	365	4,017	70	366
Train	72,826	386,962	16,408	2,735,685
Validation	8,941	46,275	2,050	341,961
Test	8,963	46,092	2,051	341,961

Table 2: Statistics of four experimented datasets.

Since we have Theorem 1, $\boldsymbol{\tau}_1^{-1}\mathbf{r}_1\boldsymbol{\tau}_1$ and $\boldsymbol{\tau}_2^{-1}\mathbf{r}_2\boldsymbol{\tau}_2$ can be regarded as rotations in quaternion vector space for $\mathbf{r}_1$ and $\mathbf{r}_2$, respectively, which indicates the norm of $\mathbf{r}_1$ is the same as that of $\mathbf{r}_2$. Furthermore, Lemma 1 indicates the rotation mapping keeps the scalar/real part unchanged for a vector. Thus, we can have the following deductions:

$$\begin{cases} ||\mathbf{r}_1|| = ||\mathbf{r}_2|| \\ Re(\mathbf{r}_1) = Re(\mathbf{r}_2)\,. \end{cases} \tag{19}$$

Notice that Equation 19 is a sufficient and unnecessary conclusion of Equation 18. ☐

3.4 Theoretical Comparison Against TeRo

TeRo (Xu et al., 2020a) is the main baseline for our model. The rotated head entity embedding and tail entity embedding of TeRo in complex number system are $\mathbf{s} \circ \boldsymbol{\tau}$, and $\mathbf{o} \circ \boldsymbol{\tau}$ respectively, where $\circ$ denotes Hermitian dot product. The translational score function of TeRo $f(s, r, o, t) = ||\mathbf{s_t} + \mathbf{r} - \overline{\mathbf{o_t}}||$ is to make

$$\mathbf{s} \circ \boldsymbol{\tau} + \mathbf{r} = \overline{\mathbf{o} \circ \boldsymbol{\tau}} = \overline{\boldsymbol{\tau}} \circ \overline{\mathbf{o}} = \overline{\mathbf{o}} \circ \overline{\boldsymbol{\tau}}\,. \tag{20}$$

And we further prove that TeRo can not model relations with temporal evolution by means of reduction to absurdity.[4]

To this end, taking advantages of quaternion representation, our RotateQVS can deduce further derivation:

$$\begin{aligned} &\boldsymbol{\tau}\mathbf{s}\boldsymbol{\tau}^{-1} + \mathbf{r} = \overline{\boldsymbol{\tau}\mathbf{o}\boldsymbol{\tau}^{-1}} = \boldsymbol{\tau}\overline{\mathbf{o}}\boldsymbol{\tau}^{-1} \\ &\Leftrightarrow \overline{\mathbf{o}} - \mathbf{s} = \boldsymbol{\tau}^{-1}\mathbf{r}\boldsymbol{\tau}\,, \end{aligned} \tag{21}$$

where time stamp embeddings and relation embeddings can be particularly extracted to analyse the influence of temporal evolution on relations, since our derivation result is independent with entity embeddings. Above all, we demonstrate that our RotateQVS can model relations with temporal evolution while TeRo cannot.[5]

3.5 Complexity Comparison

Table 1 summarizes the space complexities of several baselines and our model. n_e, n_r, n_τ and n_{token} denote numbers of entities, relations, time stamps, and temporal tokens used in (García-Durán et al., 2018); and d is the dimension of embeddings. The space complexity of our RotateQVS is $\mathcal{O}(n_e d + n_r d + n_\tau d)$, the same as TTransE (Leblay and Chekol, 2018), HyTE (Dasgupta et al., 2018) and TeRo (Xu et al., 2020a).

4 Experiments

4.1 Benchmark Datasets

To evaluate our proposed Quaternion embeddings, we perform link prediction task on four commonly used TKG benchmark datasets, namely ICEWS14, ICEWS05-15 (García-Durán et al., 2018), YAGO11k (Dasgupta et al., 2018) and GDELT (Trivedi et al., 2017).[6] Table 2 summarises the details of the four datasets, where it is easy to find ICEWS14 and ICEWS05-15 have more quantitative relations than the other two datasets.

ICEWS (Lautenschlager et al., 2015) is a repository containing political events with a specific timestamp. ICEWS14 and ICEWS05-15 (García-Durán et al., 2018) are two subsets of ICWES corresponding to facts in 2014 and facts between 2005 and 2015.

YAGO11k (Dasgupta et al., 2018) is a subset of YAGO3 (Mahdisoltani et al., 2015), where time annotations are represented as time intervals. We derive the dataset from HyTE (Dasgupta et al., 2018)

---

[4] See proof in Appendix F.

[5] Proof process is shown in Lemma 5, and case based analysis is shown in Section 4.5.2.

[6] GDELT is derived from https://github.com/BorealisAI/de-simple/tree/master/datasets/gdelt, and other datasets can be downloaded from https://github.com/soledad921/ATISE.

to obtain the same year-level granularity by dropping the month and date information, which results in 70 different time stamps.

For GDELT, we use the subset extracted by Trivedi et al., consisting of the facts from April 1, 2015 to March 31, 2016. We take the same pretreatment of the train, validation and test sets as (Goel et al., 2020), to make the problem into a TKGC rather than an extrapolation problem.

4.2 Evaluation Protocol

Link prediction task that aims to infer incomplete time-wise fact with a missing entity ($(s, r, ?, t)$ or $(?, r, o, t)$) is adopted to evaluate the proposed model. During the inference, we follow the same procedure of Xu et al. to generate candidates. For a test sample (s, r, o, t), we first generate candidate quadruples set $C = \{(s, r, \overline{o}, t) : \overline{o} \in \mathcal{E}\} \cup \{(\overline{s}, r, o, t) : \overline{s} \in \mathcal{E}\}$ by replacing s or o with all possible entities, and then rank all the quadruples by their scores (Equation 14) under the time-wise filtered settings (Xu et al., 2019; Goel et al., 2020).

The performance is reported on the standard evaluation metrics: the proportion of correct triples ranked in top 1, 3 and 10 (Hits@1, Hits@3, and Hits@10), and Mean Reciprocal Rank (MRR). All the metrics (Hits@1, Hits@3, Hits@10 and MRR) are the higher the better. For all experiments, we report averaged results across 5 runs, and we omit the variance as it is generally low.

4.3 Baselines

We compare with both sota static and temporal KGE baselines. For static baselines, we use TransE (Bordes et al., 2013), DistMult (Yang et al., 2015), RotatE (Sun et al., 2019), and QuatE (Zhang et al., 2019a). For TKGE methods, we consider TTransE (Leblay and Chekol, 2018), HyTE (Dasgupta et al., 2018), TA-DistMult (García-Durán et al., 2018), DE-SimplE (Goel et al., 2020), ATiSE (Xu et al., 2019), and TeRo (Xu et al., 2020a).[7]

Note that TeRo (Xu et al., 2020a) is also based on the idea of rotations, and thus we consider TeRo as a directly baseline. Because our quaternion representation ($\mathbf{a}+\mathbf{b}\mathbf{i}+\mathbf{c}\mathbf{j}+\mathbf{d}\mathbf{k}$) doubles the embedding parameters of TeRo which uses complex representation ($\mathbf{a} + \mathbf{b}\mathbf{i}$), we further adopt two models for fair comparisons: (i) TeRo-Large: TeRo using double embedding dimension;[8] (ii) RotateQVS-Small: The proposed RotateQVS with half embedding dimension. By doing so, their parameter complexities can be comparable with TeRo's.

4.4 Results

The experimental results over four TKG datasets are shown in Table 3.[9] Overall, TKGE methods are better than static KGE methods, which shows the effectiveness of modeling temporal information. For the proposed RotateQVS, we observe that our model outperforms all the baseline models over the four datasets across all metrics consistently.[10] To demonstrate the superiority of the proposed quaternion method, we compare our RotateQVS with the direct baseline TeRo (Xu et al., 2020a). For fair comparisons of model sizes, we observe that our RotateQVS outperforms TeRo-Large and RotateQVS-Small outperforms TeRo. This shows our methods with quaternion embeddings makes great improvements, demonstrating our advantages. Specially, we see that our RotateQVS achieves more improvements on ICEWS14 and ICEWS05-15 datasets. We believe this is because these two datasets have much more quantitative relations (see Table 2) and it is also evident our method behaves better on datasets with complex relation patterns.

4.5 Analysis and Case Study

To further demonstrate the learned quaternion embeddings and the ability of our model, we perform case studies on multiple relation patterns, through visualization and quantitative analysis on intuitive examples from ICEWS14.

4.5.1 Symmetric/Asymmetric/Inversion Patterns

Since symmetric, asymmetric and inversion patterns have been discussed in previous work (Sun et al., 2019; Xu et al., 2020a), we present the case studies of them to Appendix J.

4.5.2 Temporal-evolution Pattern

As shown in Lemma 5, if a relation r_1 and a relation r_2 are evolving over time from t_1 (time stamp τ_1)

---

[7] See complexity comparison in Appendix 3.5.

[8] We reuse the original implementation of (Xu et al., 2020a) from https://github.com/soledad921/ATISE and follow the their best setups.

[9] See hyperparameter setup in Appendix G.

[10] We also take time granularity analysis and embedding dimension analysis in Appendix H and I.

Table 3: Results on link prediction task over four experimented datasets. The best score is in **bold** and second best score is underlined.

to t_2 (time stamp $\boldsymbol{\tau}_2$), we have

$$\boldsymbol{\tau}_2\boldsymbol{\tau}_1^{-1}\mathbf{r}_1(\boldsymbol{\tau}_2\boldsymbol{\tau}_1^{-1})^{-1} = \mathbf{r}_2. \qquad (22)$$

To analyse the temporal-evolution pattern, we focus on the relations between the same head and tail entities with different time stamps. For example, from ICEWS14, we observe a base fact *(South Korea, Engage in negotiation, North Korea, 2014-02-12)* and a temporal-evolution fact *(South Korea, Sign formal agreement, North Korea, 2014-02-15)*, where *Sign formal agreement* is considered as the consequence of *Engage in negotiation*. Thus, in our model, the embeddings of *Sign formal agreement* at time stamp *2014-02-15* and of *Engage in negotiation* at *2014-02-12* should satisfy Equation 22.

To illustrate this pattern, we measure the matrix cosine similarity between $\mathbf{r}_2$ (base) and $\boldsymbol{\tau}_2\boldsymbol{\tau}_1^{-1}\mathbf{r}_1(\boldsymbol{\tau}_2\boldsymbol{\tau}_1^{-1})^{-1}$ (temporal-evolved). For each true fact, we sample a random negative relation and show their similarity difference. Figure 2 illustrates the density histogram of similarities with random 250 fact quadruples at different time stamps between *South Korea* and *North Korea*. We observe that the distributions of positive examples and negative examples are distinct, which explains

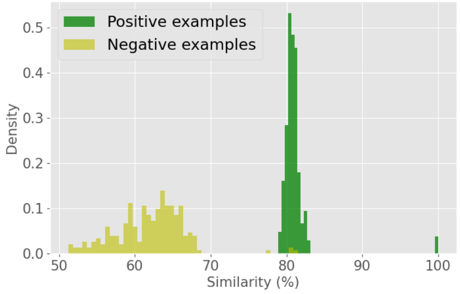

Figure 2: Density histogram with bin size 1% of similarity scores for temporal-evolution relations. All positive and negative examples are randomly sampled and compared with the base relation *Engage in negotiation*.

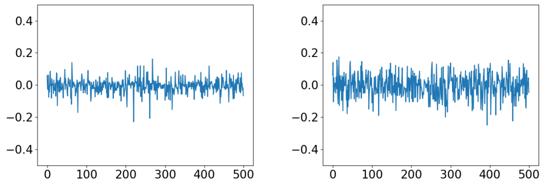
		Head entity	Relation	Tail entity	Time	Similarity
Example 1	Base fact	John Kerry	Express intent to meet or negotiate	Pietro Parolin	2014-01-13	0.810
	True fact		Consult		2014-01-16	
	Negative		Detonate nuclear weapons			0.508
Example 2	Base fact	Member of Legislative (Govt) (Iran)	Make statement	Iran	2014-03-16	0.819
	True Fact		Make statement		2014-05-04	
	Negative		Detonate nuclear weapons			0.492
Example 3	Base fact	Federal Bank	Make a visit	European Central Bank	2014-02-04	0.815
	True fact		Make statement		2014-02-25	
	Negative		Receive inspectors			0.510

Table 4: Examples of temporal-evolution patterns in ICEWS14 dataset. The similarity score is based on base fact.



(a) $Re(\mathbf{r_1}) - Re(\mathbf{r_2}) = \mathbf{0}$ (b) $||\mathbf{r_1}|| - ||\mathbf{r_2}|| = \mathbf{0}$

Figure 3: Quaternion representations of Equation 19 for temporal-evolution pattern.

our RotateQVS can model temporal-evolution patterns more effectively. Comparing with TeRo (Xu et al., 2020a), which is the main baseline for our model, we show TeRo cannot model this pattern theoretically (see Section 3.4).

In addition, Figure 3 shows our quaternion representation do well in reflecting Equation 19, the sufficient and unnecessary deductions of theoretical analysis for temporal-evolution pattern.

More examples of temporal-evolution pattern are shown in Table 4, where we use the relation in base fact and time information to get a generated embedding $\tau_2{\tau_1}^{-1}\mathbf{r_1}(\tau_2{\tau_1}^{-1})^{-1}$, and also sample a random negative relation for each example. We compute the matrix cosine similarity between $\tau_2{\tau_1}^{-1}\mathbf{r_1}(\tau_2{\tau_1}^{-1})^{-1}$ and $\mathbf{r_2}$, and also compute the similarity between $\tau_2{\tau_1}^{-1}\mathbf{r_1}(\tau_2{\tau_1}^{-1})^{-1}$ and the embedding of another relation in the negative sample. Time stamps in negatives are taken as same as the true facts. The comparison between the two sets of results can once again prove the ability of our model in modeling this pattern.

4.6 Convergence Analysis

For convergence analysis, we consider two fair comparisons, where the compared two methods have the same number of parameters:[11] RotateQVS (blue solid line) vs. TeRo-Large (yellow solid line) and RotateQVS-Small (green dotted line) vs. TeRo (red dotted line) in Figure 4. We observe that RotateQVS and TeRo-Large converge at approximately the same rate, and so do RotateQVS-Small and TeRo. We can conclude that our proposed RotateQVS can achieve better results in comparisons of both large and small levels without sacrificing additional training efforts.

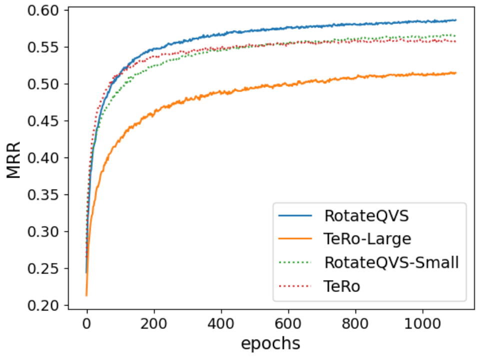


Figure 4: The convergence study of RotateQVS, TeRo-Large, RotateQVS-Small and TeRo by epochs on ICEWS14 test set, and we use the metric MRR here.

5 Related work

Models working on Static Knowledge graph have been well studied (Zhang et al., 2019b; Xu et al., 2020b; Mao et al., 2020; Chen et al., 2021a) with semantic and structure information. Translation based methods, e.g. TransE (Bordes et al., 2013) and TransR (Lin et al., 2015), formalise the factual distance between a head entity s and a tail entity o with the translation carried out by the relation. Adopting tensor factorization with a bilinear transformation, semantic matching models, e.g. RESCAL (Nickel and Tresp, 2013) and DistMult (Yang et al., 2015), capture the semantic relevance of entities. Recently, more attention were paid to study various relation patterns. RotatE (Sun et al., 2019) treat each relation as a rotation so that symmetric/asymmetric, inversion and composition patterns can be inferred to predict missing links. Further, quaternion number system (Hamil-

---

[11] Refer to Section 4.3 for more details

ton, 1844) is applied to model more complex composition patterns in 3D space, such as Rotate3D (Gao et al., 2020) and QuatE (Zhang et al., 2019a).

Many aforementioned methods (Dasgupta et al., 2018; Leblay and Chekol, 2018; Trivedi et al., 2017; García-Durán et al., 2018; Goel et al., 2020; Sadeghian et al., 2021) are extended from static Static KGs to TKGs. They integrate time information into previous static methods as independent features. Others study the dynamic evolution of TKG. ATiSE (Xu et al., 2019) regards the temporal evolution of entity and relation embeddings as combinations of trend component, seasonal component and random component. CyGNet (Zhu et al., 2021) proposes a time-aware copy-generation mechanism leveraging known facts in the past to predict unknown facts in the future. TeRo (Xu et al., 2020a) defines the temporal evolution of entity embedding as a rotation in the complex vector space. Inspired by TeRo, our RotateQVS further represents temporal entities as rotations in quaternion vector space and obtains more advantages.[12]

Modeling various temporal relation patterns (Goel et al., 2020; Xu et al., 2020a), especially the temporal-evolution patterns, is crucial for TKGE and the following TKGC. Zhang et al. mentions the time-evolution property, but does not make a systematic research on it. It remains an open research question with few researches. Our work (RotateQVS) takes inspirations from the idea of rotation and generalises it into the quaternion number system to model the complex temporal-evolution pattern that TeRo can hardly do.

6 Conclusion

In this paper, we introduce a novel TKGC method RotateQVS which represents temporal information of TKGs as rotations in quaternion vector space. Targeting temporal interpretability, we theoretically analyse that RotateQVS can model various relation patterns and demonstrate it with extensive experiments. Compared to previous methods, RotateQVS has made significant improvements on link prediction tasks over four benchmark datasets. Furthermore, we show our RotateQVS has great advantages in modeling various relation patterns with temporal evolution.

AAAI Press.

A Proof of Theorem 1

Proof. Based on Equation 2, for a unit quaternion q, it follows that $q^{-1} = \overline{q}$. Unfolding the Equation 11, we can get

$$\begin{aligned} \mathbf{v}' &= (\cos\frac{\theta}{2} + \mathbf{u}\sin\frac{\theta}{2})\mathbf{v}(\cos\frac{\theta}{2} - \mathbf{u}\sin\frac{\theta}{2}) \\ &= \mathbf{v}\cos^2\frac{\theta}{2} + (\mathbf{uv} - \mathbf{vu})\sin\frac{\theta}{2}\cos\frac{\theta}{2} \\ &\quad - \mathbf{uvu}\sin^2\frac{\theta}{2}\,. \end{aligned} \tag{23}$$

Bearing in mind that $\mathbf{uv} = \mathbf{u} \times \mathbf{v} - \mathbf{u} \cdot \mathbf{v}$ (based on the Equation 6), further we can get

$$\begin{aligned} \mathbf{v}' &= \mathbf{v}\cos^2\frac{\theta}{2} + 2(\mathbf{u} \times \mathbf{v})\sin\frac{\theta}{2}\cos\frac{\theta}{2} \\ &\quad - ((\mathbf{u} \times \mathbf{v}) - (\mathbf{u} \cdot \mathbf{v}))\mathbf{u}\sin^2\frac{\theta}{2} \\ &= \mathbf{v}(\cos^2\frac{\theta}{2} - \sin^2\frac{\theta}{2}) + (\mathbf{u} \times \mathbf{v})(2\sin\frac{\theta}{2}\cos\frac{\theta}{2}) \\ &\quad + \mathbf{u}(\mathbf{u} \cdot \mathbf{v})(2\sin^2\frac{\theta}{2})\,. \end{aligned} \tag{24}$$

Using trigonometric identities, we can get

$$\begin{aligned} \mathbf{v}' &= \mathbf{v}\cos\theta + (\mathbf{u} \times \mathbf{v})\sin\theta \\ &\quad + \mathbf{u}(\mathbf{u} \cdot \mathbf{v})(1 - \cos\theta) \\ &= (\mathbf{v} - \mathbf{u}(\mathbf{u} \cdot \mathbf{v}))\cos\theta + (\mathbf{u} \times \mathbf{v})\sin\theta \\ &\quad + \mathbf{u}(\mathbf{u} \cdot \mathbf{v}) \\ &= \mathbf{v}_\perp\cos\theta + (\mathbf{u} \times \mathbf{v})\sin\theta + \mathbf{v}_\parallel \end{aligned} \tag{25}$$

where $\mathbf{v}_\perp = \mathbf{v} - \mathbf{u}(\mathbf{u} \cdot \mathbf{v})$ and $\mathbf{v}_\parallel = \mathbf{u}(\mathbf{u} \cdot \mathbf{v})$ are the components of $\mathbf{v}$ (perpendicular and parallel to the axis $\mathbf{u}$ respectively). Our Equation 25 satisfies the Rodrigues' rotation formula (Rodrigues, 1840) in 3D vector space (illustrated in Figure 5). Therefore, the Equation 11 is proven to be a rotation in 3D vector space. ☐

B Proof of Lemma 2

Proof. For symmetric pattern, considering our rotation based temporal representation, we express the $r(s, o, t) \wedge r(o, s, t)$ in Definition 1 as:

$$\begin{cases} \overline{\mathbf{o}} - \mathbf{s} = \boldsymbol{\tau}^{-1}\mathbf{r}\boldsymbol{\tau} \\ \overline{\mathbf{s}} - \mathbf{o} = \boldsymbol{\tau}^{-1}\mathbf{r}\boldsymbol{\tau} \end{cases} \Leftrightarrow \mathbf{r} + \overline{\mathbf{r}} = 0 \Leftrightarrow Re(\mathbf{r}) = 0\,, \tag{26}$$

where Re denotes the real part of a quaternion representation. ☐

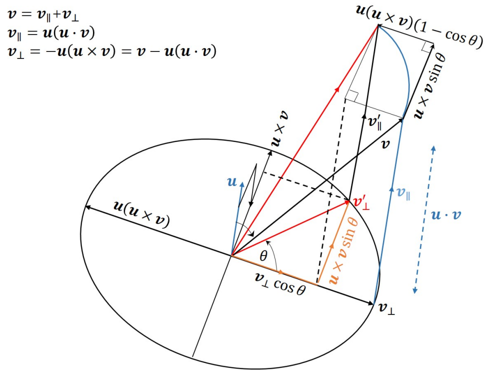

Figure 5: An illustration of our rotation equation, which satisfies the Rodrigues' rotation formula (Rodrigues, 1840), where $\mathbf{v}'$ is the result of vector $\mathbf{v}$ rotating θ around rotation axis $\mathbf{u}$.

C Proof of Lemma 3

Proof. For asymmetric pattern, $r(s, o, t) \wedge \neg r(o, s, t)$ in Definition 2 can be expressed as:

$$\begin{cases} \overline{\mathbf{o}} - \mathbf{s} = \boldsymbol{\tau}^{-1}\mathbf{r}\boldsymbol{\tau} \\ \overline{\mathbf{s}} - \mathbf{o} \neq \boldsymbol{\tau}^{-1}\mathbf{r}\boldsymbol{\tau} \end{cases} \Leftrightarrow \mathbf{r} + \overline{\mathbf{r}} \neq 0 \Leftrightarrow Re(\mathbf{r}) \neq 0\,. \tag{27}$$

☐

D Proof of Lemma 4

Proof. For inversion pattern, $r_1(s, o, t) \wedge r_2(o, s, t)$ in Definition 3 can be expressed as:

$$\begin{cases} \overline{\mathbf{o}} - \mathbf{s} = \boldsymbol{\tau}^{-1}\mathbf{r}_1\boldsymbol{\tau} \\ \overline{\mathbf{s}} - \mathbf{o} = \boldsymbol{\tau}^{-1}\mathbf{r}_2\boldsymbol{\tau} \end{cases}$$

$$\Leftrightarrow \mathbf{r}_1 + \overline{\mathbf{r}_2} = 0 \quad \Leftrightarrow \begin{cases} Re(\mathbf{r}_1) + Re(\mathbf{r}_2) = \mathbf{0} \\ Im(\mathbf{r}_1) - Im(\mathbf{r}_2) = \mathbf{0}\,, \end{cases} \tag{28}$$

where Im denotes the imaginary part of a quaternion representation. ☐

E Statistics of several previous TKGE methods modeling on various relation patterns

Table 5 shows the statistics of several previous TKGE methods modeling on various relation patterns, containing symmetry, asymmetry, inversion and temporal-evolution.

F Proof by Contradiction for TeRo

Proof. Supposing TeRo (Xu et al., 2020a) can model the temporal-evolution relation pattern (defined in Definition 4), then relations with temporal-

Methods	Symmetry	Asymmetry	Inversion	Temporal-evolution
TTransE	✗	✓	✓	✗
TA-DistMult	✓	✗	✗	✗
DE-SimplE	✓	✓	✓	✗
TeRo	✓	✓	✓	✗
RotateQVS (ours)	✓	✓	✓	✓

Table 5: Statistics of several previous TKGE methods modeling on various relation patterns.

evolution pattern will satisfy the Equation 20. Notice that our relation patterns defined are unconcerned with some specific entities, but focusing on the general rules among relations inside the universal entities.

If relation r_1 and r_2 are evolving over time from t_1 to t_2, considering the same head entity s and two different tail entities o_1 and o_2 which satisfy $r_1(s, o_1, t_1) \wedge r_2(s, o_1, t_2)$ and $r_1(s, o_2, t_1) \wedge r_2(s, o_2, t_2)$, we can get

$$\begin{cases} \mathbf{s} \circ \boldsymbol{\tau}_1 + \mathbf{r}_1 = \overline{\mathbf{o}_1} \circ \overline{\boldsymbol{\tau}_1} \\ \mathbf{s} \circ \boldsymbol{\tau}_2 + \mathbf{r}_2 = \overline{\mathbf{o}_1} \circ \overline{\boldsymbol{\tau}_2} \end{cases} \wedge \begin{cases} \mathbf{s} \circ \boldsymbol{\tau}_1 + \mathbf{r}_1 = \overline{\mathbf{o}_2} \circ \overline{\boldsymbol{\tau}_1} \\ \mathbf{s} \circ \boldsymbol{\tau}_2 + \mathbf{r}_2 = \overline{\mathbf{o}_2} \circ \overline{\boldsymbol{\tau}_2} \end{cases}, \tag{29}$$

where we can find the derivations depend on entity embeddings. And we can further derive that

$$\begin{aligned} &\begin{cases} \mathbf{s} \circ (\boldsymbol{\tau}_2 - \boldsymbol{\tau}_1) + (\mathbf{r}_2 - \mathbf{r}_1) = \overline{\mathbf{o}_1} \circ (\overline{\boldsymbol{\tau}_2} - \overline{\boldsymbol{\tau}_1}) \\ \mathbf{s} \circ (\boldsymbol{\tau}_2 - \boldsymbol{\tau}_1) + (\mathbf{r}_2 - \mathbf{r}_1) = \overline{\mathbf{o}_2} \circ (\overline{\boldsymbol{\tau}_2} - \overline{\boldsymbol{\tau}_1}) \end{cases} \\ &\Leftrightarrow \mathbf{o}_1 = \mathbf{o}_2 \,, \end{aligned} \tag{30}$$

where two different tail entities o_1 and o_2 have the exactly same embeddings in TeRo. Obviously, it is not in line with our common sense and has a big problem in modelling the temporal-evolution relation pattern. □

G Hyperparameter

To seek and find proper hyperparameters, we utilize a grid search empirically over the following ranges for all three datasets: embedding dimension in $\{100, 200, 300, 400, 500\}$, learning rate in $\{1, 0.5, 0.3, 0.1, 0.05, 0.03, 0.02, 0.01\}$, the ratio of negative over positive training sample in $\{1, 3, 5, 10\}$, the margin used in loss function in $\{1, 2, 3, 5, 10, 20, \cdots, 120\}$, the time granularity parameter in $\{1, 2\}$, and the optimizer we use is Adagrad.

And we have found out the best hyperparameters combination as follows: for ICEWS14, we set the margin as 110, the time granularity parameter as 1; for ICEWS05-15, we set the margin as 120, the time granularity parameter as 2; for YAGO11k, we set the margin as 50, the time granularity parameter as 100; for GDELT, we set the margin as 110, the time granularity parameter as 1; and for all the datasets, we choose the learning rate as 0.1, the embedding dimension as 500, the ratio of negative over positive training sample as 10.

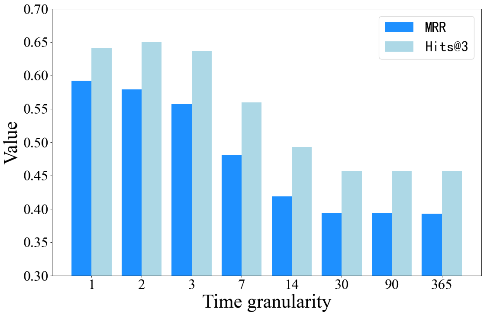

Figure 6: Results of RotateQVS with different time granularities on ICEWS14 dataset.

H Time Granularity Analysis

As shown in Figure 6, we take time granularity analysis on ICEWS14 dataset. It find that the results of smaller granularities are better than that of larger granularities, as larger-granularity setups fuzz the time information. Smaller granularity means more time stamps to compute, while we believe in current dataset the number of time-stamps are relatively small compared with the numbers of relations and entities, and thus we suggest small time granularity in TKG tasks.

I Size of Embedding Dimension

As shown in Figure 7, we take embedding dimension analysis on ICEWS14 dataset. We can find out that the values of all the four metrics increase as the dimension increases from 100 to 500, while the improvement gains decrease when approaching the size of 500. This indicates that larger embedding size are recommended, while larger embeddings can drag time efficiency and requires more computational resources, thus it is a time-efficiency trade-off.

J Analysis and Case Study for Symmetric/Asymmetric/Inversion Pattern

J.1 Symmetric Pattern

As shown in Lemma 2 and its proof (see Appendix B), if r is a symmetric relation, we have $\mathbf{r} + \overline{\mathbf{r}} = \mathbf{0} \Leftrightarrow Re(\mathbf{r}) = \mathbf{0}$. That is if r is a symmetric relation, the real part of quaternion representa-

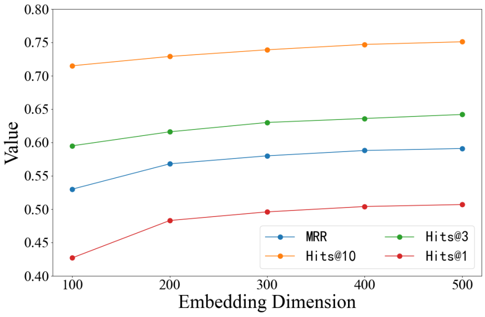

Figure 7: Results of RotateQVS with different embedding dimensions on ICEWS14 dataset.

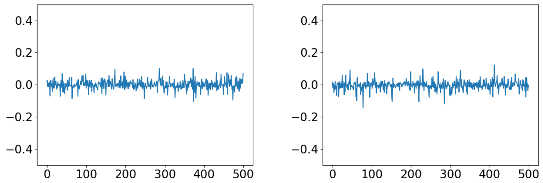
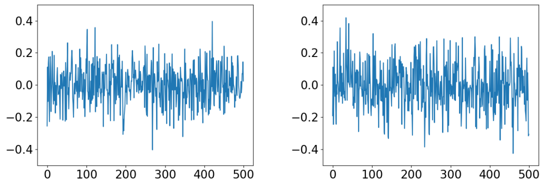


(a) *relation:Consult* (b) *relation:Engage in negotiation*

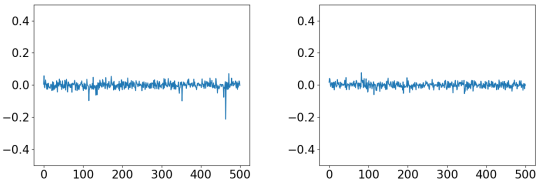
Figure 8: Illustrations of the real parts (Re) closing to $\mathbf{0}$ for two symmetric relations, *Consult* and *Engage in negotiation*, in quaternion embeddings with size 500.



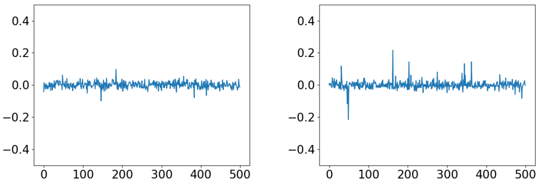
(a) *relation:Threaten to halt mediation* (b) *relation:Demand policy change*

Figure 9: Illustrations of the real parts $Re(\mathbf{r}) \neq \mathbf{0}$ for two asymmetric relations in quaternion embeddings.

tion of r is close to zero. To empirically study the learned quaternion embedding of r, we illustrate the real parts of quaternion embeddings in Figure 8 for two symmetric relations, *Consult* and *Engage in negotiation*. For *Consult*, we have *(France, Consult, Canada, 2014-10-23)* and *(Canada, Consult, France, 2014-10-23)*. For *Engage in negotiation*, we have *(Victor Ponta, Engage in negotiation, Klaus Johannis, 2014-11-11)* and *(Klaus Johannis, Engage in negotiation, Victor Ponta, 2014-11-11)*. These suggest that the relation *Consult* and the relation *Engage in negotiation* are two symmetric relations. We observe that the learned quaternion embeddings in Figure 8 are close to $\mathbf{0}$, which confirms the ability of our model.



(a) $Re(\mathbf{r_1}) + Re(\mathbf{r_2}) = \mathbf{0}$ (b) $\mathbf{i}(\mathbf{r_1}) - \mathbf{i}(\mathbf{r_2}) = \mathbf{0}$



(c) $\mathbf{j}(\mathbf{r_1}) - \mathbf{j}(\mathbf{r_2}) = \mathbf{0}$ (d) $\mathbf{k}(\mathbf{r_1}) - \mathbf{k}(\mathbf{r_2}) = \mathbf{0}$

Figure 10: Quaternion representations of Equation 28, with the real part (Re) and three imaginary parts ($\mathbf{i}$, $\mathbf{j}$, and $\mathbf{k}$) for an inverse relation pair: *Make a visit* vs. *Host a visit*.

J.2 Asymmetric Pattern

Opposite to symmetric pattern, if r is an asymmetric relation, we have $Re(\mathbf{r}) \neq \mathbf{0}$. Intuitively, if r is an asymmetric relation, the real part of quaternion representation of r is supposed to be far away from zero. Since we have *(Nabih Berri, Threaten to halt mediation, Israeli Defense Forces, 2014-05-12)* and *(Islamic Preacher (Iran), Demand policy change, Iran, 2014-03-02)*, the two relations *Threaten to halt mediation* and *Engage in negotiation* are taken as two asymmetric relations. Figure 9 illustrates the real parts of quaternion representation of them. These observations from Figure 8 and Figure 9 show that our RotateQVS can effectively model the symmetry and asymmetry patterns and can distinguish them.

J.3 Inversion Pattern

Lemma 4 and its proof (see Appendix D) show that if the relation r_1 is the inverse of the relation r_2, we have $Re(\mathbf{r}_1) + Re(\mathbf{r}_2) = \mathbf{0}$ and $Im(\mathbf{r}_1) - Im(\mathbf{r}_2) = \mathbf{0}$. From two existing facts *(Romania, Host a visit, Evangelos Venizelos, 2014-02-20)* and *(Evangelos Venizelos, Make a visit, Romania, 2014-02-20)* in ICEWS14, we can find out the relation *Host a visit* is the inverse of the relation *Make a visit*, which satisfies the Definition 4. Figure 10 shows the quaternion representation as in

Equation 28 for the inverse relation pair, containing the real part and the imaginary part (3D), where $\mathbf{i}$, $\mathbf{j}$ and $\mathbf{k}$ denote three directions of the imaginary parts. This demonstrates our method has effective modeling for inverse relations.

Abstract

Machine Reading Comprehension (MRC) reveals the ability to understand a given text passage and answer questions based on it. Existing research works in MRC rely heavily on large-size models and corpus to improve the performance evaluated by metrics such as Exact Match (EM) and F_1. However, such a paradigm lacks sufficient interpretation to model capability and can not efficiently train a model with a large corpus. In this paper, we argue that a deep understanding of model capabilities and data properties can help us feed a model with appropriate training data based on its learning status. Specifically, we design an MRC capability assessment framework that assesses model capabilities in an explainable and multi-dimensional manner. Based on it, we further uncover and disentangle the connections between various data properties and model performance. Finally, to verify the effectiveness of the proposed MRC capability assessment framework, we incorporate it into a curriculum learning pipeline and devise a Capability Boundary Breakthrough Curriculum (CBBC) strategy, which performs a model capability-based training to maximize the data value and improve training efficiency. Extensive experiments demonstrate that our approach significantly improves performance, achieving up to an 11.22% / 8.71% improvement of EM / F_1 on MRC tasks.

1 Introduction

A competency assessment is used to measure someone's capabilities against the requirements of their job (Cheryl Lasse, 2020). In other words, it measures how (behaviors) someone does the what (task or skill). By showing what it looks like to be good in a job, a competency assessment can effectively empower and engage people who want to understand and improve their unique skill profile and tell them what action to take to close any gaps so they can own their development. A natural question that arises here is: can we develop competency assessments for machine learning models to help better understand their capabilities and improve their performance on a given task?

In this paper, we focus on competency assessments for machine reading comprehension (MRC). MRC is a core task in natural language processing (NLP) that aims to teach machines to understand human languages and answer questions (Zeng et al., 2020; Chen et al., 2019). Recently, pretrained language models (LMs) (Mikolov et al., 2013; Peters et al., 2018; Pennington et al., 2014; Devlin et al., 2018) have demonstrated superior performance on MRC tasks by pre-training on large amounts of unlabeled corpus and fine-tuning on MRC datasets. The performance is usually evaluated by metrics such as Exact Match (EM) and F_1 score, lacking interpretability to the capabilities of a model. That is to say, such metrics only tell how good a model performs overall on a specific dataset, but uncovers little about what specific skills a model has gained and the level of each skill.

We argue that the value of each data sample varies during the training process of a model, depending on the model's current capabilities. A deep understanding of the model's intrinsic capabilities can help us estimate each data sample's learning value and better manage the training process to improve the training efficiency. Take student learning as an example. There is no doubt that a college student can do well in solving primary school level exercises, but such exercises do not help improve his/her ability. On the contrary, a primary school student can not acquire knowledge efficiently from college-level exercises due to the big gap between his/her current knowledge or skills and the require-

Capability c_i	**Subclasses**		**Metrics** m_i^j
Reading words	Recognize vocabulary		Intra-n (Gu et al., 2018) and Ent-n (Serban et al., 2017).
	Recognize function words		Frequency of function words.
Reading sentences	Recognize grammaticality		Height and width of a question's constituency parsing tree.
	Readability		Readability metrics.
Understanding words	Arithmetic operation		Frequency of numerical expressions (CD tag).
	Logical operation		Frequency of logically qualified words such as *any*, *all* and *every*.
Understanding sentences	Linguistic reasoning	Syntactic and semantic overlap	BLEU-n (Papineni et al., 2002), BERTScore (Zhang* et al., 2020) and MoverScore (Zhao et al., 2019) between the context and question.
		Coreference resolution	Frequency of personal and possessive pronouns, such as PRP and PRP$ tags.
		Con/Dis-junction, negation	Frequency of coordinating junctions, such as *and* and *or*.
	Factual reasoning	Causality	Frequency of causal clauses, such as *because* and *the reason for*.
		Spatial/Temporal	Frequency of spatial/temporal expressions, such as *before*, *after*. and *in front of*.
		Multi-hop reasoning	Number of supporting evidences.

Table 1: Example set of MRC model capabilities $\{c_i\}$ and corresponding metrics $\{m_i^j\}$. See Section 2.1 for details.

ment to solve the exercises. We need to measure the ability of a student and then choose the appropriate exercises accordingly.

Existing works on interpreting MRC model capabilities concentrate on analyzing a model's behavior with adversarial data (Jia and Liang, 2017), or defining the prerequisite skills to solve a specific dataset (Sugawara et al., 2017). However, these works require costly human annotation efforts or ignore the fact that model capabilities change during the training progresses.

In this paper, we design a competency assessment framework for MRC model capabilities. Specifically, we define four major capability dimensions for understanding text and solving MRC tasks: *reading words*, *reading sentences*, *understanding words* and *understanding sentences*, which are inspired by the computational models of human text comprehension in psychology (Kintsch, 1988). Based on the proposed framework, we can obtain a more appropriate assessment of model capabilities than the regular EM or F_1 metrics.

Furthermore, we analyze a variety of data properties to estimate how good a model has to be to solve a specific data sample and identify the relationships between data properties and model performance. This greatly helps us estimate the learning value of each training sample. Based on this analysis, we discover a very common situation: if a sample is scored as a high value in one capability dimension, the other dimensions have the same tendency as well, and vice versa. To alleviate these inevitable correlations, we utilize data whitening to quantify each sample as four capability-specific scores in a decorrelated fashion.

Finally, to reveal the potential usefulness of our proposed competency assessment framework and evaluate its efficiency, we employ it in a curriculum learning pipeline and design a Capability Boundary Breakthrough Curriculum (CBBC) strategy. This strategy gradually enlarges the model capability boundary by picking samples around the boundary and breaking through it. Based on the analysis of model capabilities and data properties, we feed the model with training samples that are neither too simple nor too hard for it to solve. Extensive experiments on four benchmark datasets demonstrate that our approach significantly improves the performance of existing MRC models, achieving up to an 11.22% / 8.71% improvement of EM / F_1 on MRC tasks. These results show the reasonability and effectiveness of our proposed assessment framework and provide a widely applicable measurement for dealing with the relationship between the model capability and data quality.

2 Competency Assessment of MRC Capabilities

In this section, we first formulate our competency assessment framework of 4-dimensional MRC capabilities. Based on this framework, the data properties related to each capability dimension are described as corresponding heuristic metrics. We then uncover the relationship between various data properties and model performance in a decorrelated manner, quantifying each sample as 4-dimensional capability-specific scores with little correlation.

2.1 Assessment Framework Formulation

Human text comprehension has been studied in psychology for a long time. Constructionist, landscape model, and computational architectures have been proposed for such comprehension (McNamara and Magliano, 2009). Among them, the construction-

Context: James is a trouble making Turtle . One day, James went to the grocery store and pulled all the pudding off the shelves and ate two jars. Then he walked to the fast food restaurant and ordedred 15 bags of fries.
Q1: Who is the trouble making turtle?
A1: James
Q2: Where did James go after he went to the grocery store?
A2: A fast food restaurant
Requirded capabilities: syntactic matching, temporal relation, semantic overlap

Figure 1: Two example questions $Q1$ and $Q2$ with different difficulties require different capabilities.

integration (CI) model (Kintsch, 1988) is one of the most basic and influential theories. The CI model assumes three different representation levels (surface structure, textbase, and situation model) and a two-step process (construction and integration) to understand text comprehensively. It first constructs the propositions (*i.e.* textbase) from the raw textual input (*i.e.* surface structure), then integrates the local connections into a globally coherent representation (*i.e.* situation model). Based on this situation model, a given text is understood comprehensively and can even be grounded to other modalities. Inspired by the two-step process of the CI model, we formulate our assessment framework by 4-dimensional capabilities as summarized in Table 1. We sketch out the meaning of each MRC capability $\{c_i\}_{i=1}^{4}$ and highlight some heuristic metrics $\{m_i^j\}_{j=1}^{n(i)}$ (where $n(i)$ means the number of metrics to measure a sample's learning value to capability c_i) as follows.

Reading words. To formulate the surface structure of the CI model in our framework, we first highlight the text representation at the verbal or linguistic level. Theoretically, the units at the linguistic level are the words that make up the text and the hierarchical sentence constituents to which these words belong. Empirically, Sugawara et al. (2018) has shown that some questions are answered correctly by just reading the first k tokens. Similarly, the perturbation-based experiments of Nema and Khapra (2018) have demonstrated the significant influence of four types of words (*i.e.* content words, named entities, question types, and function words) on an MRC question. Therefore, the dimension of *reading words* is defined as recognizing the observed vocabulary and the special words' appearance (*i.e.* function words). In this study, The former is implemented as *Intra-n* (Gu et al., 2018) and *Ent-n* (Serban et al., 2017) to measure vocabulary distribution, while the latter is computed as the frequency of corresponding words.

Reading sentences. The rules that are used to form a sentence using the aforementioned linguistic units are conventional phrase-structure grammars. Consequently, before understanding the information contained in a text, an MRC system inevitably requires capturing the sentence structure and handling the possible obscure words. We define the dimension of *reading sentences* as recognizing grammaticality and readability, and they are implemented by constituency parsing tree statistics and readability metrics[1], respectively.

Understanding words. The semantic representation of text is usually established by local and global links according to the linguistic units at word-level and sentence-level, respectively. To reflect the local semantic structure, we design the dimension of *understanding words* to assess how well an MRC model understands the relationships between words. In this work, we exemplify two relations (*i.e.* the arithmetic operations and logical items) that usually have salient patterns in the text. The former directly focuses on statistical and operational reasoning from the text, while the latter deals with the reasoning of predicate logic, *e.g.* conditionals and qualifiers. Inspired by the human annotation process (Boratko et al., 2018; Schlegel et al., 2020), where the annotators are asked to label as many reasoning skills as possible by paying more attention to corresponding indicative words, the sub-capabilities of this dimension is quantified as the frequency of those words.

Understanding sentences. Integrating the local structures into a global representation requires not only the text itself but also specific knowledge. To simplify the forms of knowledge, we divide the dimension of *understanding sentences* into two subclasses, linguistic and factual reasoning. They respectively mean understanding the relationship between sentences based on linguistics and the events (*i.e.* five dimensions including time, space, causation, intentionality, and objects). Among metrics of this dimension, *BERTScore* (Zhang* et al., 2020), *MoverScore* (Zhao et al., 2019) and *LS_score* (Wu et al., 2020) are used to measure semantic overlap between the context and question and multi-hop reasoning is an extra particular subclass on the HotpotQA (Yang et al., 2018; Cheng et al., 2021)

Table 2: The Pearson's correlation (r) between capability-specific value v_i and model performance. Stronger correlations are marked in **bold**. All the correlations are with the p-value < 0.05.

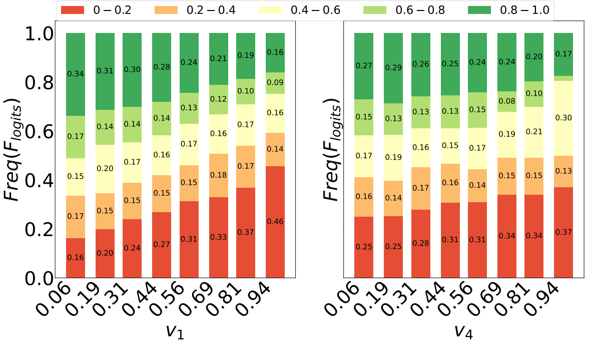

Figure 2: Bar diagram illustrating the relationship between the distribution of model performance and different ranges of v_i. Horizontal axes represent the different score ranges of v_i of samples, and the vertical axis means the performance distribution by the frequency of F_{logits} on five levels (plotted in five colors).

dataset. For the other sub-capabilities of this dimension, we consider lessons of the ablation operations performed by Sugawara et al. (2020) to observe the performance change of the MRC model and quantify them using the corresponding indicative structures.

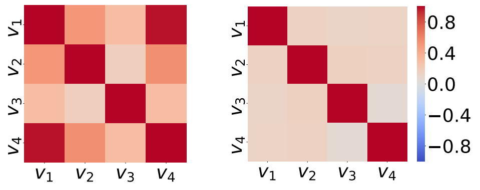
Consider the two examples questions shown in Figure 1. To solve $Q1$, an MRC system just needs to match the words between the question and context. However, $Q2$ requires understanding temporal relations among the events (went to the grocery store → walked to the fast-food restaurant) and the verb semantics (walk to means go to). Therefore, $Q2$ is more challenging to the MRC system than $Q1$. *Please refer to Appendix B for more detailed examples and descriptions of our employed metrics.*

2.2 Relationship Between Data Properties and Model Performance

Based on our assessment framework, the learning value of each sample is also decomposed into four dimensions, namely capability-specific values. In this section, we first uncover the connection between the capability-specific values and model performance from four dimensions and then recalibrate the connection by removing the inter-dimension correlations.

Capability-specific value. Given a sample x, we represent it by four capability-specific value (denoted as $\{v_i(x)\}_{i=1}^4$) to reflect its learning value for each capability dimension. According to our assessment framework, $v_i(x)$ can be computed by merging the corresponding metrics $\{m_i^j(x)\}_{j=1}^{n(i)}$. Specifically, considering the sensitivity of capability-specific value to different ranges of the metric score, we normalize each raw metric $m_i^j(x)$ from its original scale to range $[0, 1]$ by the cumulative density function (CDF) as Platanios et al. (2019), which is denoted as $\widetilde{m_i^j(x)}$. In this work, the normalization computes the cumulative density from a higher model performance to ensure that the normalized metric and model performance are negatively correlated. The capability-specific score $v_i(x)$ is formulated as: $v_i(x) = \frac{1}{n(i)} \sum_{j=1}^{n(i)} \widetilde{m_i^j(x)}$.

Analysis between capability-specific values and model performance. For each sample x, we obtain a 4-dimensional score $\{v_i(x)\}_{i=1}^4$. It is necessary to explore the relationship between samples' $v_i(x)$ and model performance for knowing about what specific capabilities a model has gained and the level of each capability. In this work, we employ BERT-base (Devlin et al., 2018) as the MRC model and train it respectively on training split of datasets SQuADv1 (Rajpurkar et al., 2016), SQuADv2 (Rajpurkar et al., 2018), HotpotQA (Yang et al., 2018) and RACE (Lai et al., 2017). We then analyze the correlations between four capability-specific scores and the model's overall performance on the corresponding dev split. In addition to F_1, we also report the results of scaled F_1 (denoted as F_{logits}) by taking the model's confidence to an answer span or candidate into account.



(a) Before applying inter-dimension decorrelation.

(b) After whitening capability-specific scores using ZCA.

Figure 3: Pairwise correlations of capability-specific scores before and after inter-dimension decorrelation.

F_{logits} is computed as:

$$F_{logits} = \begin{cases} F_1 * ln(slog) * ln(elog) \quad \text{or} \\ F_1 * ln(candlog) \end{cases} \tag{1}$$

where $slog$ and $elog$ mean the model output logits for start and end token in answer extraction style questions, and $candlog$ represents the largest logits among all candidate answers.

Table 2 quantitatively shows the Pearson's correlation coefficients (r) between capability-specific values and model performance. From the results, we have the following observations: First, each capability-specific score has a relatively strong correlation with the model performance under a statistically significant guarantee, showing the reasonability of our capability-based assessment framework. Second, F_{logits} shows better relevancy than F_1, which indicates that F_{logits} is a more appropriate performance measurement in our framework.

We further explore the distribution of model performance over different ranges of v_i. The distribution diagrams of v_1 and v_4 are shown in Figure 2. There are two inspiring characteristics in this diagram: First, among all the bins of v_i, the frequency of prediction results within the intermediate range ($0.4 \sim 0.6$) are similar ($\approx 50\%$). Second, as the v_i increases, the frequency of prediction results within a low range ($0.0 \sim 0.2$) also increases, while the one of a high range ($0.8 \sim 1.0$) decreases. These observations reveal that the samples with high v_i can be used in indicative measurements to the corresponding model capability c_i. *Please refer to Appendix C for more diagrams illustrating this relationship.*

Inter-dimension decorrelation. Let $\mathcal{V} = \{v_i | i = 1, \cdots, 4\}$. Pairwise correlations of $\mathcal{V}$ are illustrated in Figure 3a in a heatmap fashion. The results show a common situation where if a sample is difficult (scored as high capability-specific value) in a dimension, the other dimensions have the same tendency and vice versa. To alleviate the inevitable correlations and construct a clear value representation for our following specific application scenario (*i.e.* CBBC), we eliminate the 4-dimensional capabilities by decorrelation. Specifically, we employ zero-phase component analysis (ZCA) whitening (Bell and Sejnowski, 1996) to diagonalize the covariance matrix while keeping the local information of the samples as much as possible.

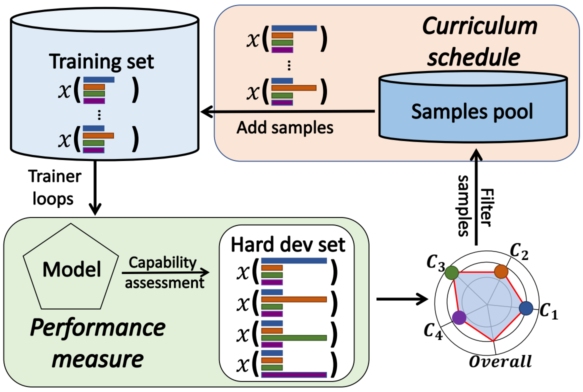


Figure 4: Illustration of our capability boundary breakthrough curriculum learning (CBBC). Different capabilities and their levels are represented in different colors and the length of the color bar, respectively. A longer color bar indicates a stronger capability.

As shown in Figure 3b, the 4-dimensional capabilities are not highly correlated after inter-dimension decorrelation, which can be in favor of constructing clear indicators for our following data sampling in CBBC.

3 Improve Learning Efficiency with Competency Assessment

In this section, our universal assessment framework of the model capability is adapted into a specific MRC training scenario to evaluate its usefulness and efficiency. Specifically, we embed our proposed assessment framework into a curriculum learning pipeline and make a capability boundary breakthrough curriculum learning (CBBC) strategy. Based on the assessment framework, our CBBC can guide a model to learn according to its capability boundary by understanding what the model has learned from data (*i.e.* capability-specific value v_i) and choosing appropriate samples with comparable learning values from four dimensions. It is worth noting that our competency assessment framework is also applicable to other training pipelines that balance the relationship between the model capabilities and data properties, such as active learning (Settles, 2009) and self-training (Mihalcea, 2004) (Appendix E).

Figure 4 shows an illustration of the pipeline of our CBBC. Following the original formulation of curriculum learning (Bengio et al., 2009), our CBBC organizes all samples by a sequence of ordered training stages $\{s\}_{s=1}^{S}$ and corresponding training sets $\{D^s\}_{s=1}^{S}$ with an easy-to-difficult fashion. The classic curriculum learning works (Soviany et al., 2021) usually consist of two essential components: the performance measurer and the curriculum scheduler. In general, the measurer is used to determine the learning status of a model by evaluating performance, while the scheduler is responsible for deciding when and how to update the curriculum by selecting the input samples.

In our work, the measurer and scheduler are implemented by analyzing the multi-dimensional capability levels of the model interpretably and measuring the capability-specific values of the data in a decorrelated way, respectively. That is to say, the only difference between our CBBC and the original curriculum learning design is incorporating MRC capability assessment into the curriculum learning. Without significantly increasing the complexity of the pipeline, our proposed assessment framework can generally empower the MRC training pipeline in a plug-and-play manner.

Performance measurer. Recall what we have discussed in Section 2.2 that the samples with high v_i can be used in indicative measurements to the corresponding model capability c_i. In this work, we use samples scored in the top-k of each capability-specific value to assess the corresponding model capability. More precisely, we first evaluate the model on the dev set and obtain an average F_{logits} for each capability on the corresponding top-k subset. Then partial correlation (Baba et al., 2004) (denoted as ρ_i) between dimension v_i and F_{logits} is computed to mask the contributions of the other dimensions $\mathcal{V}\backslash\{v_i\}$. After that, each model capability on stage s is quantified as: $c_i^s = \frac{\rho_i}{\sum_{j=1}^{4}\rho_j} F_{logits}$. Empirically, we set k in top-k as 32.

Curriculum scheduler. Following the most works (Xu et al., 2020; Platanios et al., 2019), we schedule the curriculum at a linear pace (every 1,000 training iterations). During each curriculum schedule, we enlarge the training set two times until it includes all the samples. The capability upper bound $\overline{c_i^{s+1}}$ for $s+1$ stage by exponential growth: $\overline{c_i^{s+1}} = max\{\gamma c_i^s, 1.0\}$. After that, we use criterion $v_i(x) < \overline{c_i^{s+1}}$ to construct candidate set D_i^{s+1} for the i-th capability on the state $s+1$, and use absolute contribution of v_i to F_{logits} as sampling ratio (*i.e.* $\rho_1 : \rho_2 : \rho_3 : \rho_4$) to construct D^{s+1}.

4 Experiments

Datasets. We employ two question styles to evaluate our CBBC: answer span extraction and multiple choice. The former consists of SQuADv1 (Rajpurkar et al., 2016), SQuADv2 (Rajpurkar et al., 2018) and HotpotQA (Yang et al., 2018), while the latter adopts RACE (Lai et al., 2017). For each dataset, we train and evaluate the model on official training and dev split, respectively.

Implementation details. The source code and hyperparameters are included in the supplementary material. We use BERT-base (Devlin et al., 2018) as our backbone model, which is initialized by pre-trained parameters from cased BERT. AdamW (Loshchilov and Hutter, 2017) optimizer with weight decay $5e-4$ and epsilon 8 is used to finetune the model with max sequence length 384, document stride 128. The learning rate warms up over the first 10% steps and then decays linearly to 0 for all experiments with training batch size 16 and maximum iteration $40,000$.

Baseline models. In addition to the BERT-base model, we also consider the following ten baselines. The first two baselines are trained through a pre-defined curriculum learning strategy, which sorts the samples, then feeds them to the model stage-by-stage. "B+CL+$\mathcal{V}$ (M_2)" sorts the samples by four capability-specific scores in an easy-to-difficult order. "B+antiCL+$\mathcal{V}$ (M_3)" does like "M_2", but in a reverse difficult-to-easy order. The following five baselines are trained using our CBBC strategy to maximize the data value in each dimension, respectively. "B+C+v_1 (M_4)", "B+C+v_2 (M_5)", "B+C+v_3 (M_6)" and "B+C+v_4 (M_7)" use the corresponding v_1, v_2, v_3 and v_4 respectively to perform the competency test and filter samples. "B+C+$\mathcal{V}_{corr}$ (M_8)" is trained using four correlated scores through CBBC. The following three baselines are devised by embedding other instance scoring methods into our CBBC pipeline. "B+C+DatasetMap (M_9)", "B+C+Forgetting (M_{10})" and "B+C+Predictability (M_{11})" substitute the capability-specific scores with the confidence score of true answer span (Swayamdipta et al., 2020), number of "forgotten" events (Toneva et al., 2018) and predictability score (Le Bras et al., 2020), respectively. The last two baselines (denoted as M_{12} and M_{13}) are

Name	Method	SQuADv1		SQuADv2		HotpotQA		RACE

start-of-the-art curriculum learning pipelines consisting of DRCA (Xu et al., 2020) and CBCL (Platanios et al., 2019). Finally, our full model is trained using four decorrelated scores through CBBC instead. The critical difference between the full model and M_8 is the decorrelation operation.

4.1 Experimental Results

Quantitative Results. We present a summary of our quantitative results in Table 3. As shown in the table, we have the following key observations.

On the one hand, our proposed competency framework does benefit the MRC learning efficiency in either a single or multiple dimensions. For example, when using a pre-defined curriculum strategy, M_2 achieves EM and F_1 far beyond M_1, highlighting that our quantification to data properties properly estimates the learning value contained in the data. M_3 degrades performance w.r.t. M_1, demonstrating that the learning strategy from easy to difficult samples is more reasonable than the reverse. When equipped with our CBBC, all models of M_4, M_5, M_6 and M_7 achieve improvements w.r.t. M_1 on four datasets, which indicates the significant contribution of each capability dimension on gradually increasing the model capability. In particular, among the four different dimensions, M_7 has the best result, indicating that understanding sentences is a relatively more important capability for MRC. M_8 outperforms all the models except for ours. This demonstrates that our CBBC can maximize the learning value of the data sample to increase an MRC model's capability.

On the other hand, our framework wins other scoring methods and curriculum learning pipelines by a considerable margin. Although M_9, M_{10}, M_{11}, M_{12} and M_{13} achieve substantial improvements on four datasets w.r.t. M_1, their performances are still worse than our full model. These results verify that our proposed framework can assess the model capability more correctly and make better use of the learning value within data.

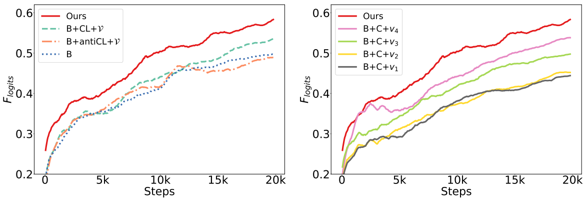

Figure 5: Illustration of performance (smoothed by averaging F_{logits} every 32 steps) of various baseline models on HotpotQA dev split as training progresses. Ours (denoted as red plot) outperforms the other models from the start of training.
