A Training details for the T5 simplification model

We used the `T5` base architecture, which contains around 220M parameters. For both Newsela and Wikilarge, we trained the T5 model for 5 epochs with a batch size of 6 and constant learning rate of 3e-4. We prefixed each input text with the summarization prefix `summarize:`, since that was the task closest to simplification that the T5 model was pretrained on. Newsela simplifications were generated using nucleus sampling with $p = 0.9$ (Holtzman et al., 2020), and Wikilarge simplifications were generated using beam search with 6 beams.

B Noise filtering on Wikilarge

To filter out noisy alignments in the Wikilarge test set (when comparing the normalized edit distances between complex and simplified sentences in Newsela and Wikilarge), we employed the same method as used by Xu et al. (2015) to produce sentence-level alignments from the Newsela dataset, that is, we only keep sentence pairs if they have a Jaccard similarity of at least 0.4 if the simplification is one sentence long and 0.2 if it is longer than one sentence.

C Numerical Details for System Output Results

Table 11 shows the relationship between mean % length reduction from input text to model output and the level of factuality errors present in the example. Table 12 likewise shows the relationship between normalized edit distance between inputs and model outputs and factuality annotations.

D Qualitative Analysis of System Outputs

We also manually examined system outputs for error trends. Despite output variability for every model, two primary trends were observed in deletion errors across the models for both Wikilarge and, where available, Newsela. No trends could be drawn for insertion and substitution errors because of their infrequency. The first type of deletion error, hence referred to as a "short", is the deletion or change of a single word or short phrase, usually a modifier (such as an adjective, adverb, or serialized noun), but occasionally a noun, noun phrase, or verb. For example:

> **Original:** The *equilibrium* price for a certain type of labor is the wage.
> **Simplified:** The price of a certain type of labor is the wage. *(`ControlTS`, Wikilarge, deletion-1)*

When the word is changed rather than deleted, the replacing word is often less descriptive but can also be lateral. Shorts include pronoun errors, where a noun phrase is replaced with a pronoun. Note also that multiple, independent shorts may occur in an output and still receive a level 1 for deletion. The second type of error, hence referred to as a "long", is the deletion of a phrase, most commonly a prepositional phrase, or a *subordinate* or *coordinate* clause. For example:

> **Original:** For Rowling, this scene is important because it shows Harry's bravery, *and by retrieving Cedric's corpse, he demonstrates selflessness and compassion.*
> **Simplified:** For Rowling, this scene is important because it shows Harry's bravery. *(`Dress`, Wikilarge, deletion-2)*

Importantly, longs concerning clauses differ from the clause promotion error found in the datasets in that longs delete a *subordinate* or *coordinate* clause of the original while clause promotion errors delete the *main* clause of the original. Multiple, independent longs rarely occur in one output; that is, if multiple secondary clauses are deleted, they are usually nested (likely because a sentence where this could happen would have a very complex structure, at least in English.)

`Access` and `ControlTS` had notable variability in the errors. Despite this, shorts were the most common error for label 1, with no notable presence of longs. These shorts were often not pronoun errors. Additionally, no trends could be noted for label 2 errors in these models. By contrast, nearly all of `Dress`'s errors fit into these two trends. Label 1 output errors primarily consisted of shorts, especially pronoun errors, though longs also occurred. Label 2 output errors were almost entirely longs. `EditNTS` and `T5` errors closely follow the trends found in Dress, though `T5` notably had several label 2 errors that were shorts, deleting a semantically-critical word.

E Automatic Factuality Assessment

Here we describe the details of generating synthetic data and training the three annotation classifiers.

E.1 Synthetic Data Generation

Name Insertion. Each name of a person in the source text is replaced one at a time with a pronoun

		Insertion			Deletion			Substitution		
Model	**Dataset**	**0**	**1**	**2**	**0**	**1**	**2**	**0**	**1**	**2**
Dress	Wikilarge	-20.7	6.3	-26.3	0.11	-26.8	-47.4	-21.0	-10.5	-15.1
	Newsela	-29.4	—	—	-1.4	-35.4	-51.0	-31.1	-21.8	-27.8

Table 11: % length change in system outputs (mean).

		Insertion			Deletion			Substitution		
Model	**Dataset**	**0**	**1**	**2**	**0**	**1**	**2**	**0**	**1**	**2**
Dress	Wikilarge	0.23	0.06	0.42	0.03	0.32	0.49	0.23	0.22	0.17
	Newsela	0.29	—	—	0.07	0.38	0.48	0.28	0.30	0.33
EditNTS	Wikilarge	0.18	0.46	—	0.10	0.25	0.43	0.20	0.17	0.18
	Newsela	0.36	0.33	—	0.10	0.37	0.46	0.37	0.42	0.25
T5	Wikilarge	0.08	0.53	—	0.04	0.30	0.56	0.09	0.09	—
	Newsela	0.30	0.36	0.56	0.13	0.39	0.13	0.33	0.13	—
Access	Wikilarge	0.20	0.31	0.14	0.17	0.23	0.42	0.22	0.20	0.21
ControlTS	Wikilarge	0.24	0.43	0.52	0.12	0.38	0.50	0.27	0.24	0.52

Table 12: Normalized edit distances in system outputs (mean).

to create a target text. Then the source and target texts are swapped to simulate the insertion of a name in place of a pronoun. This text pair is labeled with a level 1 insertion.

Phrase Insertion. Each phrase in the source text is deleted one at a time to create a shorter target text, and the source and target texts are swapped to simulate the insertion of a phrase. The insertion is labeled as a level 1 if the BERTScore of the texts is between 0.6 and 0.8, and it is labeled as 2 if it is between 0.2 and 0.4. If the score is not in either interval, the example is discarded. These thresholds were determined by manual inspection of the distribution of scores computed in Section 8.

Number Alteration. We replace each number found in the source sentence one at a time with a random number of the same order of magnitude (e.g., 3 → 7, 99 → 74). This modification is labeled as a level 1 substitution.

Statement Negation. Each auxiliary verb in the source text is negated one at a time to generate target texts. This modification is labeled as a level 1 substitution.

BERT Masking. To generate level 1 substitutions, we randomly mask 2 tokens in the source text, pass the masked text through a BERT model, and fill the masked tokens with the third highest probability token in the output logits. To generate level 2 substitutions, we instead mask every fifth token in the source text and fill them with the fifth highest probability token indicated by the logits.

Category	**Level 0**	**Level 1**	**Level 2**	**Total**
Insertion	823	1167	1167	3157
Substitution	810	4572	2008	7390

Table 13: Sizes and label distributions of synthetic datasets.

Once synthetic examples were generated, all the label 0 examples from the original training dataset were added. In the insertion synthetic dataset, level 1 labels significantly outnumbered level 2 labels, so only a random sample of them was included in the final dataset. Table 13 shows the sizes and label distributions of the synthetic datasets. Some class imbalance was tolerated here since the number of examples for all levels was much larger than in the original training set and minority classes were oversampled during training.

E.2 Model

We fine-tune the pretrained base RoBERTa model architecture with a classification head. The model contains 12 hidden layers, a hidden size of 768, and 12 attention heads.

E.3 Training Details

The insertion and substitution models were pre-trained on an 80-20 train/dev split of their synthetic datasets for 10 epochs with a batch size of 64 and learning rate of 1e-4 and evaluated on the validation split every 100 steps.

The best checkpoint was selected and then trained on an 80-20 split of its original dataset for 50 epochs with the same batch size and learning rate and evaluated every 10 steps. The best model from this round was finally fine-tuned on the entire training dataset for 1 epoch with the same batch size but a learning rate of 3e-5 before being evaluated on the test set.

The deletion classifier was trained similarly, except that the pretraining step was omitted.

In every stage of training, minority classes were oversampled in the training split until they matched the frequency of the most populous class.

F Case Study: Medical Texts

We present an initial analysis of factuality in the context of medical text simplification (Devaraj et al., 2021), a case where information accuracy is paramount. This task presents unique challenges given the complex, jargon-laden texts to be simplified. We evaluate a model proposed in recent work for medical text simplification (Devaraj et al., 2021). This was trained by fine-tuning BART (Lewis et al., 2020) on aligned *paragraphs* of technical abstracts—plain English summaries from the Cochrane library, a database of systematic reviews of clinical trials. We annotated 10 randomly selected outputs from this model with respect to the original *paragraphs*.[3] Because the original texts are difficult to understand, we enlist a trained annotator (a senior in Linguistics and co-author of this work) to perform this evaluation.

Table 14 reports the number of error types observed across paragraphs. The error rate here is disconcerting: Out of the 10 paragraphs evaluated, we found 3 with at least one level-2 error, and 5 with more than one error. We provide examples or errors below. These findings further stresses the critical importance of factuality evaluation and improvement in simplification systems.

Insertion
Original: [...] All studies were associated with methodological limitations. [...]
Simplified: [...] All studies were of poor quality and had limitations in the way they were conducted. [...]

Substitution
Original: [...] There was no difference in operating time or perioperative complication rates. [...]
Simplified: [...] However, there was not enough evidence to determine if there was an important difference in operative time or complication rates when compared to conventional surgery. [...]

Category	**Level 0**	**Level 1**	**Level 2**
Insertion	5	4	1
Deletion	0	8	2
Substitution	8	1	1

Abstract

This paper describes the motivation and development of speech synthesis systems for the purposes of language revitalization. By building speech synthesis systems for three Indigenous languages spoken in Canada, Kanien’kéha, Gitksan & SENĆOŦEN, we re-evaluate the question of how much data is required to build low-resource speech synthesis systems featuring state-of-the-art neural models. For example, preliminary results with English data show that a FastSpeech2 model trained with 1 hour of training data can produce speech with comparable naturalness to a Tacotron2 model trained with 10 hours of data. Finally, we motivate future research in evaluation and classroom integration in the field of speech synthesis for language revitalization.

1 Introduction

There are approximately 70 Indigenous languages spoken in Canada, from 10 distinct language families (Rice, 2008). As a consequence of the residential school system and other policies of cultural suppression, the majority of these languages now have fewer than 500 fluent speakers remaining, most of them elderly. Despite this, interest from students and parents in Indigenous language education continues to grow (Statistics Canada, 2016); we have heard from teachers that they are overwhelmed with interest from potential students, and the growing trend towards online education means many students who have not previously had access to language classes now do.

Supporting these growing cohorts of students comes with unique challenges for languages with few fluent first-language speakers. A particular concern of teachers is to provide their students with opportunities to hear the language outside of class. Text-to-speech synthesis technology (TTS) shows potential for supplementing text-based language learning tools with audio in the event that the domain is too large to be recorded directly, or as an interim solution pending recordings from first-language speakers.

Development of TTS systems in this context faces several challenges. Most notable is the usual assumption that neural speech synthesis models require at least tens of hours of audio recordings with corresponding text transcripts to be trained adequately. Such a data requirement is far beyond what is available for the languages we are concerned with, and is difficult to meet given the limited time of the relatively small number of speakers of these languages. The limited availability of Indigenous language speakers also hinders the subjective evaluation methods often used in TTS studies, where naturalness of synthetic speech samples is judged by speakers of the language in question.

In this paper, we re-evaluate some of these challenges for applying TTS in the low-resource context of language revitalization. We build TTS systems for three Indigenous languages of Canada, with training data ranging from 25 minutes to 3.5 hours, and confirm that we can produce acceptable speech as judged by language teachers and learners. Outputs from these systems could be suitable for use in some classroom applications, for example a speaking verb conjugator.

2 Background

2.1 Language Revitalization

It is no secret that the majority of the world’s languages are in crisis, and in many cases this crisis is even more urgent than conservation biologists’ dire predictions for flora and fauna (Sutherland, 2003). However, the ‘doom and gloom’ rhetoric that often follows endangered languages over-represents vulnerability and under-represents

the enduring strength of Indigenous communities who have refused to stop speaking their languages despite over a century of colonial policies against their use (Pine and Turin, 2017). Continuing to speak Indigenous languages is often seen as a political act of anti-colonial resistance. As such, the goals of any given language revitalization effort extend far beyond memorizing verb paradigms to broader goals of nationhood and self-determination (Pitawanakwat, 2009; McCarty, 2018). Language revitalization programs can also have immediate and important impacts on factors including community health and wellness (Whalen et al., 2016; Oster et al., 2014).

There is a growing international consensus on the importance of linguistic diversity, from the Truth & Reconciliation Commission of Canada (TRC) report in 2015 which issued nine calls to action related to language, to 2019 being declared an International Year of Indigenous Languages by the UN, and 2022-2032 being declared an International Decade of Indigenous Languages. From 1996 to 2016, the number of speakers of Indigenous languages increased by 8% (Statistics Canada, 2016). These efforts have been successful despite a lack of support from digital technologies. While opportunities may exist for technology to assist and support language revitalization efforts, these technologies must be developed in a way that does not further marginalize communities (Brinklow et al., 2019; Bird, 2020).

2.2 Why TTS for Language Revitalization?

Our interest in speech synthesis for language revitalization was sparked during user evaluations of Kawennón:nis (lit. 'it makes words'), a Kanien'kéha verb conjugator (Kazantseva et al., 2018) developed in collaboration between the National Research Council Canada and the Onkwawenna Kentyohkwa adult immersion program in Six Nations of the Grand River in Ontario, Canada. Kawennón:nis models a pedagogically-important subset of verb conjugations in XFST (Beesley and Karttunen, 2003), and currently produces 247,450 unique conjugations. The pronominal system is largely responsible for much of this productivity, since in transitive paradigms, agent/patient pairs are fused, as illustrated in Figure 1.

(1) ***Se****nòn:wes*
you.to.it-like-habitual
'**You** like **it**.'

(2) ***Take****nòn:wes*
you.to.me-like-habitual
'**You** like **me**.'

Figure 1: An example of fusional morphology of agent/patient pairs in Kanien'kéha transitive verb paradigms (from Kazantseva et al., 2018)

In user evaluations of Kawennón:nis, students often asked whether it was possible to add audio to the tool, to model the pronunciation of unfamiliar words. Assuming a rate of 200 forms/hr for 4 hours per day, 5 days per week, this would take a teacher out of the classroom for approximately a year. Considering Kawennón:nis is anticipated to have over 1,000,000 unique forms by the time the grammar modelling work is finished, recording audio manually becomes infeasible.

The research question that then emerged was 'what is the smallest amount of data needed in order to generate audio for all verb forms in Kawennón:nis'. Beyond Kawennón:nis, we anticipate that there are many similar language revitalization projects that would want to add supplementary audio to other text-based pedagogical tools.

2.3 Speech Synthesis

The last few years have shown an explosion in research into purely neural network-based approaches to speech synthesis (Tan et al., 2021). Similar to their HMM/GMM predecessors, neural pipelines typically consist of both a network predicting the acoustic properties of a sequence of text and a vocoder. The feature prediction network must be trained using parallel speech/text data where the input is typically a sequence of characters or phones that make up an utterance, and the output is a sequence of fixed-width frames of acoustic features. In most cases the predictions from the TTS model are log Mel-spectral features and a vocoder is used to generate the waveform from these acoustic features.

Much of the previous work on low resource speech synthesis has focused on transfer learning; that is, 'pre-training' a network using data from a language that has more data, and then 'fine-tuning' using data from the low-resource language. One of the problems with this approach is that the input space often differs between languages. As the inputs to these systems are sequences of characters or phones, and as these sequences are typically one-hot encoded, it can be difficult to devise a principled method for transferring weights from the source language network to the target if there is a difference between the character or phone inventories of the two languages. Various strategies have emerged for normalizing the input space. For example, Demirsahin et al. (2018) propose a unified inventory for regional multilingual training of South Asian languages, while Tu et al. (2019) compare various methods to create mappings between source and target input spaces. Another proposal is to normalize the input space between source and target languages by replacing one-hot encodings of text with multi-hot phonological feature encodings (Gutkin et al., 2018; Wells and Richmond, 2021).

2.4 Speech Synthesis for Indigenous Languages in Canada

There is extremely little published work on speech synthesis for Indigenous languages in Canada (and North America generally). A statistical parametric speech synthesizer using Simple4All was recently developed for Plains Cree (Harrigan et al., 2019; Clark, 2014). Although it was unpublished, two highschool students[1] created a statistical parametric speech synthesizer for Kanien'kéha by adapting eSpeak (Duddington and Dunn, 2007). We know of no other attempts to create speech synthesis systems for Indigenous languages in Canada. Elsewhere in North America, a Tacotron2 system has been built for Cherokee (Conrad, 2020), and some early work on concatenative systems for Navajo was discussed in a technical report (Whitman et al., 1997), as well as on Rarámuri (Urrea et al., 2009).

3 Indigenous Language Data

Although the term 'low resource' is used to describe a wide swath of languages, most Indigenous languages in Canada would be considered 'low-resource' in multiple senses of the word, having both a low amount of available data (annotated or unannotated), and a relatively low number of speakers. Most Indigenous languages lack transcribed audio corpora, and fewer still have such data recorded in a studio context. Due to the limited number of speakers, creating these resources is non-trivial: there are limited amounts of text from which a speaker could read, and there are few people available who are sufficiently literate in the languages to transcribe recorded audio. Re-focusing speakers' limited time to these tasks presents a significant opportunity cost; they are often already over-worked and over-burdened in under-funded and under-resourced language teaching projects.

As mentioned in §2.1, language technology projects that aim to assist language revitalization and reclamation efforts must be centered around the primary goals of those efforts and ensure that the means of developing the technology do not distract or work against the broader sociopolitical goals. A primary stress point for many natural language processing projects involving Indigenous communities surrounds issues of data sovereignty. It is important that communities direct the development of these tools, and maintain control, ownership, and distribution rights for their data, as well as for the resulting speech synthesis models (Keegan, 2019; Brinklow, 2021). In keeping with this, the datasets described in this paper are not being released publicly at this time.

To test the feasibility of developing speech synthesis systems for Indigenous languages, we trained models for three unrelated Indigenous languages, Kanien'kéha (§3.1), Gitksan (§3.2), and SENĆOŦEN (§3.3).

3.1 Kanien'kéha

Kanien'kéha[2] (a.k.a. Mohawk) is an Iroquoian language spoken by roughly 2,350 people in southern Ontario, Quebec, and northern New York state (Statistics Canada, 2016). In 1979 the first immersion school of any Indigenous language in Canada was opened for Kanien'kéha, and many other very successful programs have been started since, including the Onkwawenna Kentyohkwa adult immersion program in 1999 (Gomashie, 2019).

In the late 1990s, a team of five Kanien'kéha translators worked with the Canadian Bible Society to translate and record parts of the Bible; one of the speakers on these recordings, Satewas, is still living. Translation runs in Satewas's family, with his great-grandfather also working on Bible translations in the 19th century. Later, a team of four speakers and learners, including this paper's third author, aligned the text and audio at the utterance

---

[2] As there are different variations of spelling, we use the spelling used in the communities of Kahnawà:ke and Kahnesetà:ke throughout this paper

level using Praat (Boersma and van Heuven, 2001) and ELAN (Brugman and Russel, 2004).

While a total of 24 hours of audio were recorded, members of the Kanien’kéha-speaking community told us it would be inappropriate to use the voices of speakers who had passed away, leaving only recordings of Satewas’s voice. Using a GMM-based speaker ID system (Kumar, 2017), we removed utterances by these speakers, then removed utterances that were outliers in duration (less than 0.4s or greater than 11s) and speaking rate (less than 4 phones per second or greater than 15), recordings with an unknown phase effect present, and utterances containing non-Kanien’kéha characters (e.g. proper names like ‘Euphrades’). Handling utterances with non-Kanien’kéha characters would have required grapheme-to-phoneme prediction capable of dealing with multilingual text and code-switching which we did not have available. The resulting speech corpus comprised 3.46 hours of speech.

3.2 Gitksan

Gitksan[3] is one of four languages belonging to the Tsimshianic language family spoken along the Skeena river and its surrounding tributaries in the area colonially known as northern British Columbia. Traditional Gitksan territory spans some 33,000 square kilometers and is home to almost 10,000 people, with approximately 10% of the population continuing to speak the language fluently (First Peoples’ Cultural Council, 2018).

As there were no studio-quality recordings of the Gitksan language publicly available, and as an intermediate speaker of the language, the first author recorded a sample set himself. In total, he recorded 35.46 minutes of audio reading isolated sentences from published and unpublished stories (Forbes et al., 2017).

3.3 SENĆOŦEN

The SENĆOŦEN language is spoken by the W̱SÁNEĆ people on the southern part of the island colonially known as Vancouver Island. It belongs to the Coastal branch of the Salish language family. The W̱SÁNEĆ community runs a world-famous language revitalization program[4], and uses an orthography developed by the late SENĆOŦEN speaker and W̱SÁNEĆ elder Dave Elliott. While the community of approximately 3,500 has fewer than 10 fluent speakers, there are hundreds of learners, many of whom have been enrolled in years of immersion education in the language (First Peoples’ Cultural Council, 2018).

As there were no studio-quality recordings of the SENĆOŦEN language publicly available, we recorded 25.92 minutes of the language with PENÁĆ David Underwood reading two stories originally spoken by elder Chris Paul.

4 Research Questions

Given the motivation and context for language revitalization-based speech synthesis, a number of research questions follow. Namely, how much data is required in order to build a system of reasonable pedagogical quality? How do we evaluate such a system? And, how is the resulting system best integrated into the classroom? In §4.1, we discuss the difficulty of evaluating TTS systems in low-resource settings. We then discuss preliminary results for English and Indigenous language TTS which show that acceptable speech quality can be achieved with much less training data than usually considered for neural speech synthesis (§4.2). Finally, we suggest possible directions for pedagogical integration in section §4.4.

4.1 Low-Resource Evaluation

One of the most significant challenges in researching speech synthesis for languages with few speakers is evaluating the models. For some Indigenous languages in Canada, the total number of speakers of the language is less than the number typically required for statistical significance in a listening test (Wester et al., 2015). While the number of speakers in these conditions is sub-optimal for statistical analysis, we have been told by the communities we work with that the positive assessment of a few widely respected and community-engaged language speakers would be practically sufficient to assess the pedagogical value of speech models in language revitalization contexts. For the experiments described in this paper, we ran listening tests for both Kanien’kéha and Gitksan with speakers, teachers, and learners, but were not able to run any such tests for SENĆOŦEN due to very few speakers with already busy schedules.

While some objective metrics do exist, such as

---

[3] We use Lonnie Hindle and Bruce Rigsby’s spelling of the language, which, with the use of ‘k’ and ‘a’ is a blend of upriver (gigeenix) and downriver (gyets) dialects

[4] `https://wsanecschoolboard.ca/sencoten-language/`

Mel cepstral distortion (MCD, Kubichek, 1993), we do not believe they should be considered reliable proxies for listening tests. Future research on speech synthesis for languages with few speakers should prioritize efficient and effective means of evaluating results.

In many cases, including in the experiment described in §4.2, artificial data constraints can be placed on a language with more data, like English, to simulate a low-resource scenario. While this technique can be insightful and it is tempting to draw universal conclusions, English is linguistically very different from many of the other languages spoken in the world. Accordingly, we should be cautious not to assume that results from these types of experiments will necessarily transfer or extend to genuinely low-resource languages.

4.2 How much data do you really need?

The first question to answer is whether our Indigenous language corpora ranging from 25 minutes to 3.46 hours of speech are sufficient for building neural speech synthesizers. Due to the prominence of Tacotron2 (Shen et al., 2018), it seems that many people have assumed that the data requirements for training *any* neural speech synthesizer of similar quality must be the same as the requirements for this particular model. As a result, some researchers still choose to implement either concatenative or HMM/GMM-based statistical parametric speech synthesis systems in low-resource situations based on the assumption that a "sufficiently large corpus [for neural TTS] is unavailable" (James et al., 2020, p. 298). We argue that attention-based models such as Tacotron2 should not be used as a benchmark for data requirements among all neural TTS methods, as they are notoriously difficult to train and unnecessarily inflate training data requirements.

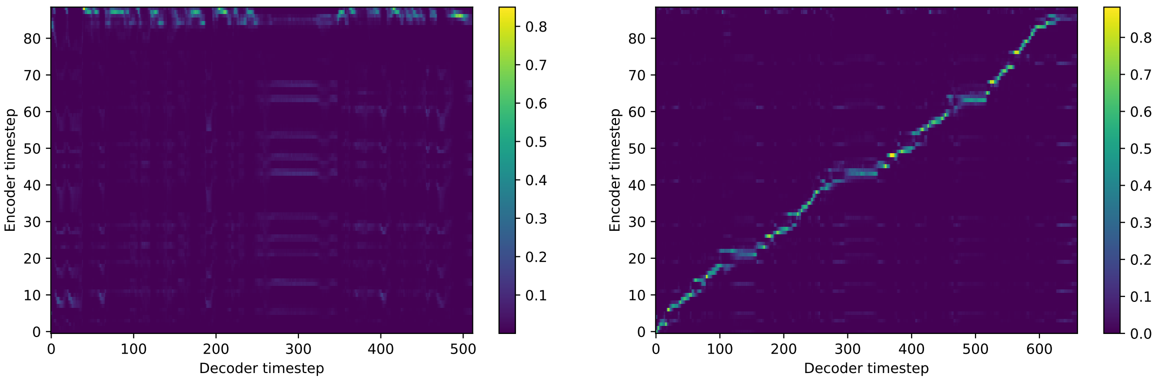
4.2.1 Replacing attention-based weak duration models

Tacotron2 is an autoregressive model, meaning it predicts the speech parameters $\hat{y}_t$ from both the input sequence of text x and the previous speech parameters $y_1, ..., y_{t-1}$. Typically, the model is trained with 'teacher-forcing', where the autoregressive frame y_{t-1} passed as input for predicting $\hat{y}_t$ is taken from the ground truth acoustic features and not the prediction network's output from the previous frame $\hat{y}_{t-1}$. As discussed by Liu et al. (2019), such a system might learn to copy the teacher forcing input or disregard the text entirely, which could still optimize Tacotron2's root mean square error function over predicted acoustic features, but result in an untrained or degenerate attention network which is unable to properly generalize to new inputs at inference time when the teacher forcing input is unavailable. Attention failures represent a characteristic class of errors for models such as Tacotron2, for example skipping or repeating words from the input text (Valentini-Botinhao and King, 2021).

There have been many proposals to improve training of the attention network, for example by guiding the attention or using a CTC loss function to respect the monotonic alignment between text inputs and speech outputs (Tachibana et al., 2018; Liu et al., 2019; Zheng et al., 2019; Gölge, 2020). As noted by Liu et al. (2019), increasing the so-called 'reduction factor' – which applies dropout to the autoregressive frames – can also help the model learn to rely more on the attention network than the teacher forcing inputs, but possibly at the risk of compromising synthesis quality.

FastSpeech2 (Ren et al., 2021), and similar systems like FastPitch (Łańcucki, 2021), present an alternative to Tacotron2-type attentive, autoregressive systems with similar listening test results and without the characteristic errors related to attention. Instead of modelling duration using attention, they include an explicit duration prediction module trained on phone duration targets extracted from the training data. For the original FastSpeech, target phone durations derived from the attention weights of a pre-trained Tacotron2 system were used to provide phone durations (Ren et al., 2019). In low-resource settings, however, there might not be sufficient data to train an initial Tacotron2 in the target language in the first place. For FastSpeech2, phone duration targets are instead extracted using the Montreal Forced Aligner (MFA, McAuliffe et al., 2017), trained on the same data as used for TTS model training. We have found MFA can provide suitable alignments for our target languages, even with alignment models being trained on only limited data.

Faster convergence of text-acoustic feature alignments has been found to speed up overall encoder-decoder TTS model training, as stable alignments provide a solid foundation for further training of the decoder. Badlani et al. (2021) show this by adding a jointly-learned alignment framework to a Tacotron2 architecture, reducing time



(a) 5 Hr LJ Corpus Subset

(b) 10 Hr LJ Corpus Subset

Figure 2: Visualization of Tacotron2 Attention Network Weights extracted after 100k steps trained on the LJ corpus. The weights of the attention network should be diagonal and monotonic as seen in subfigure (b). Subfigure (a) shows that the network trained on a 5 hour subset of the LJ corpus results in a degenerate attention network.

to convergence. In contrast, they found that replacing MFA duration targets in FastSpeech2 training offers no benefit – forced alignment targets already provide enough information for more time-efficient training compared to an attention-based Tacotron2 system. Relieving the burden of learning an internal alignment model also opens the door to more data-efficient training. For example, Perez-Gonzalez-de-Martos et al. (2021) submitted a non-attentive model trained from forced alignments to the Blizzard Challenge 2021, where their system was found to be among the most natural and intelligible in subjective listening tests despite only using 5 hours of speech; all other submitted systems included often significant amounts of additional training data (up to 100 hours total).

4.2.2 Experimental Comparison of Data Requirements for Neural TTS

To investigate the effects of differing amounts of data on the attention network, and in preparation for training systems with our limited Indigenous language data sets, we trained five Tacotron2 models on incremental partitions of the LJ Speech corpus of American English (Ito and Johnson, 2017). We used the NVIDIA implementation[5] with default hyperparameters apart from a reduced batch size of 32 to fit the memory capacity of our GPU resources. We artificially constrained the training data such that the first model saw only the first hour of data from the shuffled corpus, the second model that same first hour plus another two hours (3 total) etc., so that the five models were trained on 1, 3, 5, 10 and 24 (full corpus) hours of speech. The models were trained for 100k steps and, as seen in Figure 2, using up to 5 hours of data the attention mechanism does not learn properly, resulting in degenerate outputs.

For comparison, we trained seven FastSpeech2 models with batch size 16 for 200k steps on 15 and 30 minute, 1, 3, 5, 10 and 24 hour incremental partitions of LJ Speech. Our model[6] is based on an open-source implementation (Chien, 2021), which adds learnable speaker embeddings and a decoder postnet to the original model, as well as predicting pitch and energy values at the phone rather than frame level. We also added learnable language embeddings for supplementary experiments in cross-lingual fine-tuning; while not reported in this paper, we refer the interested reader to Pine (2021) for discussion of these experiments. Motivated by concerns of efficiency in model training and inference, and the possibility of overfitting a large model to limited amounts of data, we further modified the base architecture to match the LightSpeech model presented in Luo et al. (2021). We removed the energy adaptor, replaced the convolutional layers in the encoder, decoder and remaining variance predictors with depthwise separable convolutions (Kaiser et al., 2018) and matched encoder and decoder convolutional kernel sizes with Luo et al. (2021). This reduced the number of model parameters from 35M[7] to 11.6M without noticeable change in voice quality and sped up train-

ing by 33% on GPU or 64% on CPU. For additional discussion of the accessibility benefits of these changes with respect to Indigenous language communities, see Appendix A.

4.2.3 Results

We conducted a short (10-15 minute) listening test to compare the two Tacotron2 models that trained properly (10h, full) against the seven FastSpeech2 models. We recruited 30 participants through Prolific, and presented each with four MUSHRA-style questions where they were asked to rank the 9 voices along with a hidden natural speech reference (ITU-R, 2003). MUSHRA-style questions were used as a practical way to evaluate this large number of models.

While it only took 30 minutes to recruit 30 participants using Prolific, the quality of responses was quite varied. We rejected two outright as they seemingly did not listen to the stimuli and left the same rankings for every voice. Even still, there was a lot of variation in responses from the remaining participants, as seen in Figure 3. We tested for significant differences between pairs of voices using Bonferroni-corrected Wilcoxon signed rank tests. Pairwise test results are summarized in the heat map of their p-values in Figure 4.

In the results from the pairwise analysis, we can see that natural speech is rated as significantly more natural than all synthetic speech samples. Naturalness ratings for the FastSpeech2 voices trained on 15m and 30m of data are significantly lower than all other voices, and significantly different from each other. The results for the remaining voices, while showing consistent improvements in naturalness ratings as more data is added (as shown in Figure 3), are not significantly different from each other. This is a relevant and important finding for low-resource speech synthesis because it shows that a FastSpeech2 voice built with 3 hours of data can achieve subjective naturalness ratings which are not significantly different from a Tacotron2 voice built with 24 hours of data. Similarly, the results of the listening test for our FastSpeech2 voice built with 1 hour of data are not significantly different from our Tacotron2 voice built with 10 hours of data. Additionally, while all the FastSpeech2 voices were intelligible, all Tacotron2 models trained with less than 10 hours of data produced unintelligible speech.

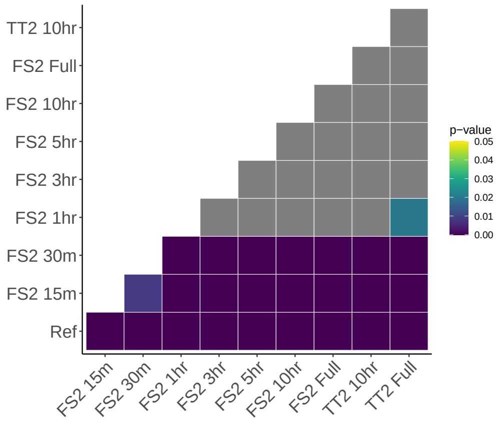

Figure 4: Pairwise Bonferroni-corrected Wilcoxon signed rank tests between each pair of voices. Cells correspond to the significance of the result of the pairwise test between the model on the y-axis and the model on the x-axis. Darker cells show stronger significance; grey cells did not show a significant difference in listening test results. FS2 refers to models built with FastSpeech2, TT2 refers to models built with Tacotron2, and 'Ref' to reference recordings. Samples available at `https://roedoejet.github.io/msc_listening_tests_data/`

4.3 Indigenous Language Experiments

Despite the difficulty in evaluation (§4.1), we built and evaluated a number of TTS systems for the Indigenous languages described in §3. We had a baseline concatenative model available for Kanien'kéha that we had previously built using Festival and Multisyn (Taylor et al., 1998; Clark et al., 2007). Additionally, we trained cold-start FastSpeech2 models for each language, as well as models fine-tuned for 25k steps from a multilingual, multispeaker FastSpeech2 model pre-trained on a combination of VCTK (Yamagishi et al., 2019), Kanien'kéha and Gitksan recordings. A rule-based mapping from orthography to pronunciation form was developed for each language using the 'g2p' Python library in order to perform alignment and synthesis at the phone-level instead of character-level (Pine et al., Under Review).

4.3.1 Results

We carried out listening test evaluations of Gitksan and Kanien'kéha models. Participants were recruited by contacting teachers, learners and linguists with at least some familiarity with the languages.

For the Kanien'kéha listening test, 6 participants were asked to answer 20 A/B questions comparing synthesized utterances from the various models. We used A/B tests for more targeted comparisons between different systems, namely cold-start vs. fine-tuned and neural vs. concatenative. Results showed that 72.2% of A/B responses from participants preferred our FastSpeech2 model over our baseline concatenative model. In addition, 81.7% of A/B responses from participants preferred the cold-start to the model fine-tuned on the multi-speaker, multi-lingual model, suggesting that the transfer learning approach discussed in §2.3 might not be necessary for models with explicit durations such as FastSpeech2 since they are relieved of the burden to learn an implicit model of duration through attention from limited data.

For the Gitksan listening test, we did not build a concatenative model as with Kanien'kéha and so we were not comparing different models, but rather just gathering opinions on the quality of the cold-start FastSpeech2 model. Accordingly, 10 MOS-style questions were presented to 12 participants for both natural utterances and samples from our FastSpeech2 model. The model received a 3.56 ± 0.26 MOS compared with a MOS for the reference recordings of 4.63 ± 0.19 as shown in Figure 5. While both Kanien'kéha and Gitksan results seem to corroborate our belief that these models should be of reasonable quality despite limited training data, it is difficult to make any conclusive statement given the low number of eligible participants available for evaluation.

As the main goal of our efforts here is to eventually integrate our speech synthesis systems into a pedagogical setting, we also asked the 18 people who participated across Kanien'kéha and Gitksan listening tests directly whether they approved of the synthesis quality. As seen in Figure 6, participant responses were generally positive; full responses are reported in Appendix B.

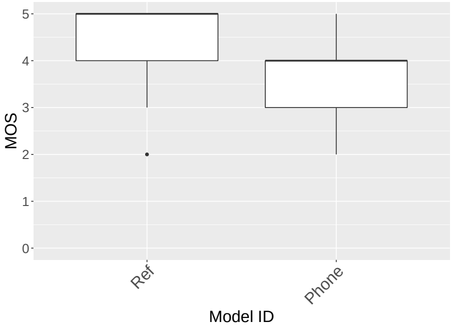

Figure 5: Box plot of MOS results for Gitksan listening test. 'Ref' is the reference voice and 'Phone' is the phone-based FastSpeech2 neural model. Variable results for the reference voice are likely due to the natural speech recordings coming from a non-native speaker.

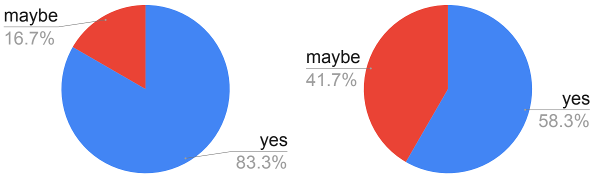

(a) Kanien'kéha (b) Gitksan

Figure 6: Responses from qualitative survey asking participants "Would you be comfortable with any of the voices you heard being played online, say for a digital dictionary or verb conjugator if no other recording existed?". No participants responded "no".

4.4 Integrating TTS in the Classroom

Satisfying the goal of adding supplementary audio to a reference tool like Kawennón:nis can be straightforwardly implemented by linking entries in the verb conjugator to pre-generated audio for the domain from a static server. This implementation also limits the potential of out of domain utterances that might be deemed inappropriate, which is an ethical concern in communities with low numbers of speakers where the identity of the 'model' speaker is easily determined.

However, the ability to synthesize novel utterances could be pedagogically useful. Students often come into contact with words or sentences which do not have audio, and teachers often have to prepare new thematic word lists or vocabulary lessons that could benefit from a more general purpose speech synthesis solution. In those cases, with community and speaker input, we might consider what controls would be necessary for the users of this technology. One potential solution is the variance adaptor architecture present in FastSpeech2, allowing for phone-level control of duration, pitch and energy; an engaging demonstration of a graphical user interface for the corresponding controls in a FastPitch model is also available.[8] We would like to focus further efforts on designing a user interface for speech synthesis systems that satisfies ethical concerns while prioritizing language pedagogy as the fundamental use case.

In addition to fine-grained prosodic controls, we would like to explore the synthesis of hyperarticulated speech, as often used by language teachers when modelling pronunciation of unfamiliar words or sounds for students. This style of speech typically involves adjustment beyond the parameters of pitch, duration and energy, and is characterized by more careful enunciation of individual phones than is found in normal speech. This problem has parallels to the synthesis of Lombard speech (Hu et al., 2021), as used to improve intelligibility by speakers who find themselves in noisy environments.

5 Conclusion

In this paper, we presented the first neural speech synthesis systems for Indigenous languages spoken in Canada. Subjective listening tests showed encouraging results for the naturalness and acceptability of voices for two languages, Kanien'kéha and Gitksan, despite limited training data availability (3.5 hours and 35 minutes, respectively). More extensive evaluation on English shows that the FastSpeech2 architecture can produce speech with similar quality to a Tacotron2 system using a fraction of the amount of speech usually considered for neural speech synthesis. Notably, a FastSpeech2 voice trained on 1 hour of English speech achieved subjective naturalness ratings not significantly different from a Tacotron2 voice using 10 hours of data, while a 3-hour FastSpeech2 system showed no significant difference from a 24-hour Tacotron2 voice.

We attribute these results to the fact that FastSpeech2 learns input token durations from forced alignments, rather than jointly learning to align linguistic inputs to acoustic features alongside the acoustic feature prediction task as in attention-based architectures such as Tacotron2. Given forced alignments of sufficient quality, which we found to be achievable even by training a Montreal Forced Aligner model only on our limited Indigenous language training data, this makes for more data-efficient training of neural TTS systems than has generally been explored in previous work. These findings show great promise for future work in low-resource TTS for language revitalization, especially as they come from systems trained from scratch on such limited data, rather than pre-training on a high-resource language and subsequent fine-tuning on limited target language data.

Acknowledgements

We would like to gratefully acknowledge the many people who worked to record the audio for the speech synthesis systems described in this project. In particular, Satewas Harvey Gabriel, and PENÁĆ David Underwood.

Much of the text and experimentation related to this paper was submitted as partial fulfillment of the first author's M.Sc. dissertation at the University of Edinburgh (Pine, 2021).

This work was supported in part by the UKRI Centre for Doctoral Training in Natural Language Processing, funded by the UKRI (grant EP/S022481/1) and the University of Edinburgh, School of Informatics and School of Philosophy, Psychology & Language Sciences.

A Compute, Accessibility, & Environmental Impact

For reasons of environmental impact and accessibility, reducing the amount of computation required for both training and inference is important for any neural speech synthesis system, particularly so for Indigenous languages.

A.1 Accessibility, Training & Inference Speed

While language revitalization efforts are *mostly* encouraging about integrating new technologies into curriculum, there is a growing awareness of the potential harms. Beyond assessing the benefits and risks of introducing a new technology into language revitalization efforts, communities are concerned with the way the technology is researched and developed, as this process has the ability to empower or disempower language communities in equal measure (Alia, 2009; Brinklow et al., 2019). The current model for developing speech synthesis systems is not very equitable – models need to be run on GPUs by people with specialized training. For Indigenous communities to create speech synthesis tools for their languages, they should not be required to hand over their language data to a large government or corporate organization. A pre-training, fine-tuning pipeline could be attractive for this reason; communities could fine-tune their own models on a laptop if a multilingual/multi-speaker model were pre-trained on GPUs at a larger institution. Reducing the computational requirements for training and inference of these models could help ensure language communities have greater control over the process of the development of these systems, less dependence on governmental organizations or corporations, and more sovereignty over their data (Keegan, 2019).

Strubell et al. (2019) present an argument for equitable access to computational resources for NLP research; put another way, we might say that systems which require less compute are more accessible. Reducing the number of parameters in a neural TTS model should translate to increased efficiency, and might make the model less prone to overfitting when training on limited amounts of data. As discussed in §4.2.2, we modified the base implementation of FastSpeech2 from Chien (2021) closely following the lightweight alternative discovered through neural architecture search in Luo et al. (2021). These changes reduced the size of the model from Chien (2021) from 35M to 11.6M parameters, reduced the size of the stored model from 417 MB to 135 MB and significantly improved inference and train times as summarized in Table 1. We saw a 33% improvement in average batch processing times on the GPU during training, and 64% on the CPU, which may be even more relevant for Indigenous language communities with limited computational resources. During inference, we saw a 15% speed-up on GPU and 57% on CPU.

Results were timed by running the model for 300

		FastSpeech2	Adapted System
Training	GPU	90.52 ms (σ 3.31)	60.04 ms (σ 1.70)
	CPU	7561.50 ms (σ 263.55)	2720.88 ms (σ 92.99)
Inference	GPU	12.00 ms (σ 0.30)	10.23 ms (σ 0.78)
	CPU	138.73 ms (σ 3.94)	59.50 ms (σ 1.85)

Table 1: Mean and standard deviation of training and inference times for a single forward pass of baseline FastSpeech2 and adapted models.

repetitions and taking the mean. The GPU (Tesla V100-SXM2 16GB) was warmed up for 10 repetitions before timing started, and PyTorch's built-in GPU synchronization method was used to synchronize timing (which occurs on the CPU) with the training or inference running on the GPU. CPU tests were performed on an Intel(R) Xeon(R) CPU E5-2650 v2 @ 2.60GHz with 4 cores and 16GB memory reserved. All timings used a batch size of 16.

A.2 CO2 Consumption

Strubell et al. (2019) also argue that NLP researchers should have a responsibility to disclose the environmental footprint of their research, in order for the community to effectively evaluate any gains and to allow for a more equitable and reproducible field.

All experiments for this paper requiring a GPU were run on the Canadian General Purpose Science Cluster (GPSC) in Dorval, Quebec. Experiments were all run on single Tesla V100-SXM2 16GB GPUs. Strubell et al. (2019) provide the following equation for estimating CO_2 production:

$$p_t = \frac{1.58t(p_c + p_r + (g * p_g))}{1000} \tag{1}$$

where t is time, p_t is total power for training, p_c is average draw of CPU sockets, p_r is average DRAM memory draw, g is the number of GPUs used in training and p_g is the average draw from GPUs. In our case, we estimate t to be equal to 1,541.98[9] after summing the time for experiments based on their log files, p_c is 75 watts, p_r is 6 watts, g is 1, and p_g is 250 watts, and the equation for grams of CO2 consumption is $CO_2 = 34.5p_t$ as the average carbon footprint of electricity distributed in Quebec is estimated at 34.5g CO2eq/kWh (Levasseur et al., 2021). This results in a total equivalent carbon consumption of 27,821.65 grams, roughly equivalent to driving a single passenger gas-powered vehicle for 110 kilometres according to the average rate of 404 grams/mile (EPA, 2019).

This is a comparatively low CO2 consumption for over 1500 GPU hours, largely due to the low CO2/kWh output of Quebec electricity when compared with the 2019 USA average of 400g CO2eq/kWh (EPA, 2019). However, CO2 equivalents are just a proxy for environmental impact and should not be understood to comprehensively account for social and environmental impact. Hydroelectric dam projects in Quebec, like the ones powering the GPSC have a sordid and complex history in the province. Innu Nation Grand Chief Mary Ann Nui spoke to this when she commented that "over the past 50 years, vast areas of our ancestral lands were destroyed by the Churchill Falls hydroelectric project, people lost their land, their livelihoods, their travel routes, and their personal belongings when the area where the project is located was flooded. Our ancestral burial sites are under water, our way of life was disrupted forever. Innu of Labrador weren't informed or consulted about that project" (Innu-Atikamekw-Anishnabeg Coalition, 2020).

B Qualitative Results

Question:

"Would you be comfortable with any of the voices you heard being played online, say for a digital dictionary or verb conjugator if no other recording existed?"

Kanien'kéha responses:

- Yes.
- yes
- Yes

---

[9] Note this estimate is based on the total number of hours spent running experiments from the M.Sc. dissertation this paper draws its experiments from. There were additional models trained for experiments that are not discussed in this paper. As such, this is a generous overestimation of t.

- Out of the two voices I hear, the first was clearer to understand
- Yes, voices sounds really good!
- yes

Gitksan responses:

- yes
- Yes, but the ones that have the most whistling or buzzing would be annoying.
- maybe?? I think for a talking dictionary people do want to hear original pronunciations, but it could be a useful interim solution or a way to do short phrases!
- Yes
- Yes.
- Assuming there is a single control for the last section of the survey/test, then some of the synthesised voices actually sound really good and I would be comfortable hearing those in an online dictionary where audio didn't exist for a particular word or phrase.
- yes
- The ones with higher ratings for sure, some of the lower ratings were just about the sound quality because that hampered hearing the speech quality. So I may have confounded the results with that, but point remains that it is always good to try to avoid poor audio recordings for online dictionaries
- Maybe/yes
- only ones rated fair or above fair
- Absolutely yes
- yes, as long as they were identified as synthesized

Sharpness-Aware Minimization Improves Language Model Generalization

Dara Bahri, Hossein Mobahi, Yi Tay
Google Research
{dbahri,hmobahi,yitay}@google.com

Abstract

The allure of superhuman-level capabilities has led to considerable interest in language models like GPT-3 and T5, wherein the research has, by and large, revolved around new model architectures, training tasks, and loss objectives, along with substantial engineering efforts to scale up model capacity and dataset size. Comparatively little work has been done to improve the generalization of these models through better optimization. In this work, we show that Sharpness-Aware Minimization (SAM), a recently proposed optimization procedure that encourages convergence to flatter minima, can substantially improve the generalization of language models without much computational overhead. We show that SAM is able to boost performance on SuperGLUE, GLUE, Web Questions, Natural Questions, Trivia QA, and TyDiQA, with particularly large gains when training data for these tasks is limited.

1 Introduction

Over the last several years, remarkable progress has been made within the domain of natural language understanding, with machine-learned models able to solve some tasks at near or above human-level performance. This progress has, by and large, been fueled by research centered around 1) better *inductive biases*, such as the attention-enabled Transformer architecture (Vaswani et al., 2017), 2) the clever leverage of massive corpora of textual data that was historically disregarded as "unlabeled," usually in the form of pre-training objectives that strive to teach the model the structure of language (Radford et al., 2019; Devlin et al., 2018), 3) scaling up model capacity and the methods to support it (Shazeer and Stern, 2018), 4) multi-task learning (Raffel et al., 2019), and lastly, 5) larger and more diverse datasets along with ever-improving benchmarks that attempt to test the true capabilities of these models. Although these efforts all share the single goal of improving the model's generalization, doing so by explicit changes to the optimization of the loss function has received less attention in comparison.

Recently, motivated by the both empirical and theoretical findings that flatter minima lead to better generalization (Kleinberg et al., 2018; Shirish Keskar et al., 2016; Chaudhari et al., 2019; Smith and Le, 2017), Foret et al. (2020) proposed a novel modification to vanilla stochastic gradient descent they term "Sharpness-Aware Minimization," or SAM. They show theoretically and empirically that optimizing with SAM encourages convergence to flatter points in the loss landscape and with it comes the anticipated improvement in out-of-sample error. While their empirical findings are limited to computer vision tasks and datasets using convolutional neural networks (ResNets), follow-up work (Chen et al., 2021) showed how SAM is particularly effective on Vision transformers (ViTs) (Dosovitskiy et al., 2020) and MLP-Mixers (Tolstikhin et al., 2021), architectures that are more prone than convolutional ones to land in sharp minima. Crucially, they show that when equipped with SAM, ViTs outperform ResNets of similar size and throughput *without the need for large-scale pre-training*.

Encouraged by wins in the vision domain, we ask whether SAM can deliver similar gains in the language domain. Our contributions are as follows:

1. We show that blithely applying SAM when fine-tuning public pre-trained checkpoints of the text-to-text transformer (T5) (Raffel et al., 2019) and its multilingual counterpart, mT5 (Xue et al., 2020) on SuperGLUE (Wang et al., 2019), GLUE (Wang et al., 2018), TyDiQA-GoldP (Clark et al., 2020) and the Closed-Book Question Answering (CBQA) tasks from Roberts et al. (2020) – Web Questions (Berant et al., 2013), Natural Questions (Kwiatkowski et al., 2019), and Trivia QA (Joshi et al., 2017) – improves test perfor-

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 7360 - 7371
May 22-27, 2022

mance quite markedly. Furthermore, by employing an approximation suggested by Brock et al. (2021), these gains come only at the cost of about 25% extra compute.

2. The improvement brought by SAM often increases with less labeled training data, making SAM indispensable for data-limited tasks. We test this by subsampling the training splits of CBQA and SuperGLUE datasets at rates ranging from 2% to 80%.

2 Related Works

Better Generalization. In light of flatter minima generalizing better, Smith and Le (2017) showed that the inherent noise in SGD serves as a form of *implicit regularization*, preventing the optimization from ever entering sharp valleys. Like SAM, entropy SGD (Chaudhari et al., 2019) *explicitly* encourages flatter minima. Smith et al. (2021); Barrett and Dherin (2020) analyzed SGD's generalization formally by way of continuous-time gradient flow. Optimization routines based on adversarial risk (Zhu et al., 2019; He et al., 2020) and trust regions (Jiang et al., 2019; Aghajanyan et al., 2020) have been proposed and shown to improve generalization across settings.

While the number of methods which provide implicit or explicit regularization is overwhelmingly large, methods like early stopping, weight decay (or ℓ_2-regularization), dropout (Srivastava et al., 2014), teacher-student or self-distillation (Hinton et al., 2015; Mobahi et al., 2020), label smoothing (Müller et al., 2019), batch normalization (Ioffe and Szegedy, 2015), mixup (Zhang et al., 2017), and data-augmentation more broadly are among the most widely used in practice. Marginalization of Bayesian neural networks, though challenging, has been shown to result in superior generalization in some settings (Wilson and Izmailov, 2020; MacKay, 1995).

While first-order optimization via SGD has been the prevailing way of training neural networks due to its efficiency and effectiveness, alternative second-order methods like K-FAC (Martens and Grosse, 2015) and Shampoo (Gupta et al., 2018) have slowly gained traction, often enabled by clever engineering to make them feasible at scale. Notably, Anil et al. (2020) presents a scalable implementation of Shampoo that provides significant convergence and wall-clock time improvements compared to first-order methods. They demonstrate superior performance on machine translation and language modeling.

SAM. While this is, to the best of our knowledge, the first work detailing the benefits of SAM for language tasks, there have been successful applications of SAM in the vision domain. Notably, Chen et al. (2021) showed that convolution-free vision models like vision transformers (ViTs) (Dosovitskiy et al., 2020) and MLP-Mixers (Tolstikhin et al., 2021) suffer from sharp minima and that SAM indeed smooths their loss landscapes. They crucially show that ViTs and MLP-Mixers outperfom ResNets of similar and greater size on ImageNet *without* the use of pre-training or data augmentations that would otherwise be necessary to achieve reasonable performance. They show that SAM induces sparsity in both architectures and leads to more perceptive attention maps in ViTs. They observe empirically that data augmentation and SAM are alike in that they both smooth the landscape on average, but the latter does so by explicitly controlling the worst-case curvature, whereas the former smooths over the directions induced by the augmentations. Furthermore, they observe that SAM encourages linearity with respect to the input, exhibiting an effect similar to that of mixup (Zhang et al., 2017). Lastly, they show that SAM helps contrastive learning and that it enables better robustness on corrupted examples from ImageNet-C (Hendrycks and Dietterich, 2019) and ImageNet-R (Hendrycks et al., 2021).

In a similar spirit, Brock et al. (2021) proposed speeding up SAM significantly by using fewer examples when computing the ascent step, a strategy which we employ in this work, and they were able to apply it to ResNet model variants to advance the state of the art on ImageNet without extra data.

Meanwhile, in an attempt to make SAM's radius ρ invariant to the scale of the model parameters, Kwon et al. (2021) proposed an adaptive version named Adaptive Sharpness-Aware Minimization (ASAM), which they then show empirically to outperform normal SAM on a set of benchmark vision tasks.

3 Review of Sharpness-Aware Minimization (SAM)

We begin by briefly reviewing the SAM algorithm; interested readers can see the original paper for a thorough treatment. In our presentation, we use the ℓ_2 norm ($p = 2$ using notation from the original paper), assume a general optimizer (instead of vanilla SGD), and use the approximation proposed by Brock et al. (2021) to compute the ascent gradient (adversarial point) efficiently. Given a loss function $L : \mathcal{W} \times \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}_+$, SAM seeks to find the parameter w whose neighborhood has low training loss by optimizing the minimax objective:

$$\min_{w} \max_{||\epsilon||_2 \leq \rho} L_{\text{train}}(w + \epsilon).$$

Finding the exact optima ϵ^* of the inner-maximization is challenging, so Foret et al. (2020) employ a first-order approximation, resulting in:

$$\begin{aligned}\hat{\epsilon}(w) &= \underset{||\epsilon||_2 \leq \rho}{\operatorname{argmin}}\, L_{\text{train}}(w) + \epsilon^T \nabla_w L_{\text{train}}(w) \\ &= \rho \nabla_w L_{\text{train}}(w) / ||\nabla_w L_{\text{train}}(w)||_2.\end{aligned}$$

That is, $\hat{\epsilon}$ is just a scaling of the loss gradient at the current parameters. After computing $\hat{\epsilon}(w)$, SAM performs gradient descent using the gradient $\nabla_w L_{\text{train}}(w)|_{w_{\text{adv}}}$ at the nearby "adversarial" point $w_{\text{adv}}(w) \triangleq w + \hat{\epsilon}(w)$.

Put another way, SAM plugs-and-plays with any first-order optimizer by simply replacing the gradient of the mini-batch $\mathcal{B}$ at the current model weights $w_t \in \mathcal{W}$ with the gradient computed at w_{adv}. w_{adv} itself is computed by taking a gradient *ascent* step of size ρ along the unit gradient vector $\nabla_w L_{\mathcal{M}}(w) / ||\nabla_w L_{\mathcal{M}}(w)||_2|_{w_t}$, where $\mathcal{M}$ can be the mini-batch $\mathcal{B}$, or a subset of it for enhanced efficiency. We found that setting $\mathcal{M}$ to be $1/4$-th of $\mathcal{B}$ sped up the method significantly with little loss in quality, in line with the recommendation of Brock et al. (2021). The end-to-end algorithm is outlined in Algorithm 1.

4 Experiments

With SAM reviewed, we now discuss our experiments. We evaluate SAM on a range of natural language understanding tasks using the T5 (text-to-text Transformer) framework (Raffel et al., 2019). T5 casts NLU tasks as sequence-to-sequence ones that are learned using an encoder-decoder Transformer (Vaswani et al., 2017) architecture setup. These Transformer models are typically pre-trained on large corpora, like the Colossal Clean Crawled Corpus (C4) (Raffel et al., 2019), with, for example, the objective of predicting a short contiguous span of text that was intentionally corrupted in a snippet of input text. The pre-trained model is typically fine-tuned on a single task or a mixture of multiple tasks, the latter enabled by the fact that the framework treats all tasks as simple input-to-target sequence predictions.

Algorithm 1 Efficient SAM Algorithm.

```
input: training set $\mathcal{S} \triangleq \cup_{i=1}^{n}\{(x_i, y_i)\}$, loss function $L : \mathcal{W} \times \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}_+$, batch size $b$, neighborhood size $\rho > 0$ (default $0.15$), ascent micro-batch size $a \leq b$ (default $b/4$), first-order optimizer update $\text{opt} : \mathcal{W} \times \mathcal{W} \rightarrow \mathcal{W}$.
initialize parameters $w_0$, $t = 0$.
while not converged do
    sample batch $\mathcal{B} = \{(x_1, y_1), ..., (x_b, y_b)\}$.
    sample ascent micro-batch $\mathcal{M} = \{(x_1, y_1), ..., (x_a, y_a)\}$.
    compute adversarial (ascent) point: $w_{\text{adv}} = w_t + \rho \frac{\nabla_w L_{\mathcal{M}}(w)}{||\nabla_w L_{\mathcal{M}}(w)||_2}|_{w_t}$.
    compute gradient approximation for the SAM objective: $g_{\text{adv}} = \nabla_w L_{\mathcal{B}}(w)|_{w_{\text{adv}}}$.
    update parameters: $w_{t+1} = \text{opt}(w_t, g_{\text{adv}})$.
    $t = t + 1$.
end while
return $w_t$
```

To this end, we evaluate SAM in two ways:

1. When publicly available pre-trained checkpoints of the T5.1.1 model variant are fine-tuned with and without SAM, on SuperGLUE, GLUE, TyDiQA, and the Closed-Book Question Answering benchmarks: Web Questions, Natural Questions, TriviaQA. We show SAM improves generalization across benchmarks and four model sizes: Small (77M parameters), Base (250M), Large (800M), and XL (3B).

2. To show how it helps when task data is limited, we report results when the training splits of these benchmarks at various rates, ranging from 2% to 80%.

4.1 Setup

Framework. For all experiments, we train using Jax (Bradbury et al., 2018) and Google Cloud TPUs. To ensure fair comparisons, eliminate the impact of exogenous factors, and reduce the possibility of software bugs, we train both standard and SAM-enabled models using the same codebase and settings, so that the code paths are identical except for the gradient calculation at each step, wherein

Table 3: Average results on TyDiQA-GoldP. Public checkpoints of mT5 of various sizes are fine-tuned on TyDiQA-GoldP for 20k steps. SAM boosts performance acros model sizes here as well. We found that smaller values of ρ than those used for the English-only T5 model were necessary to achieve good performance here. Full, per-language results are shown in the Appendix.

SAM behaves differently. Our implementation of SAM is an adaptation of an existing open-source implementation[1] to fit our framework for training language models.

Efficient SAM. In Foret et al. (2020), the idea of partitioning the ascent mini-batch into m disjoint micro-batches and computing a distinct adversarial point for each micro-batch and then averaging the SAM-gradients at each of these points was proposed under the name m-sharpness. It was noted there and in follow-up work (Chen et al., 2021) that $m > 1$ can result in better performance. This modification incurs m-times more compute under a naive sequential implementation (though it can be parallelized well if multiple devices are available).

Meanwhile, Brock et al. (2021) suggests (in the Appendix) using roughly 20% of the examples from the mini-batch for computing the adversarial point, observing little loss in model quality. With $m = 1$, this approximation roughly reduces SAM's relative runtime from 2x to 1.2x. Since we understand how a $2m$-x slow-down of model training may be prohibitive or significantly deter SAM's widespread adoption, we, at the possible

Table 5: Experimental results (F1/EM) (test scores) on the (full) CBQA tasks, where the model is trained on each of the three tasks separately, rather than on a mixture. We see that SAM improves performance across *all* model sizes, as we observed when training on the mixtures. This suggests that SAM's gains are not solely due to some ability to better leverage multi-task learning.

loss of larger improvements, set $m = 1$ and use 1/4-th (25%) of the mini-batch, or the number of available training devices (TPU cores in our case), whichever is larger, to compute SAM's adversarial point. This is necessary because the mini-batch gradient computation is parallelized over devices and each device must receive at least one example. We've observed from wall-clock times that with these settings, SAM is all in all about 25% slower than standard training.

Hyper-parameters. SAM has a single hyper-parameter ρ, which is size of the step taken along the unit adversarial gradient vector. We search the range $[0.02, 0.05, 0.1, 0.15, 0.2, 0.3]$ a *single* time *only* when fine-tuning on SuperGLUE. We found that 0.05 is a reasonable choice for T5.1.1 small models, and 0.15 for the Base, Large, and XL variants, and so for all subsequent experiments except for TyDiQA, we use these choices without additional tuning. For the mT5 model on TyDiQA, we found that a smaller ρ was necessary for good performance. For this, we searched the range $[0.01, 0.02, 0.05]$.

For all fine-tuning, we use the AdaFactor optimizer with learning rate 1e-3, 128 batch size, and the T5.1.1 settings. For SuperGLUE, we use 10% dropout rate, 512 input sequence length, 62 target sequence length, and fine-tune for 250k steps. For Natural Questions, Web Questions, and TriviaQA, we use 5% dropout, 38 input sequence length, 18 target sequence length, and fine-tune for 20k steps. For TyDiQA, we use the official, public mT5 checkpoints, 10% dropout, 1024 input sequence length, 512 target sequence length, and fine-tune for 20k steps. We run each experiment once, due to resource constraints, and we take the best checkpoint (stored every 1k steps for SuperGLUE and GLUE and every 200 steps for all other datasets) across

training steps. Following standard practice, we report the best checkpoint for each task-metric pair (e.g. SuperGLUE CB F1) individually.

4.2 Full Data Results

Results for SuperGLUE and GLUE are shown in Table 1 and Table 2 respectively. We observe that SAM improves the overall scores for both benchmarks across all T5 model sizes. For Base and XL sizes on SuperGLUE, SAM brings 4.2% and 2.1% relative gains in overall score respectively, while the gain for Large on GLUE is 2.4%. As shown in Table 4, on Natural Questions, Web Questions, and Trivia QA tasks, we observe improvements for each task, metric (F1 and EM), and model size. For Base, we see a 13.8%, 8.8%, and 13.7% gain on the exact match metric for Natural Questions, Web Questions, and Trivia QA respectively. For Large, these figures are 12.1%, 7.2%, and 15.7%. Table 3 shows the results for TyDiQA-GoldP. Here, we observe more modest improvements in the 1-2% range.

SAM improves performance on all model sizes. In light of the conventional wisdom that "larger models generalize better," we suspected, a priori, that SAM would be more helpful for the smaller models we consider, like Small and Base, and that we should expect substantial diminishing returns

Model	SGlue	BoolQ	CB	CoPA	MultiRC	ReCoRD	RTE	WiC	WSC
Small	50.2	**60.8**	37.0 / 55.4	52.0	60.1 / 11.0	33.9 / 32.5	**54.5**	54.4	65.4

Table 6: SuperGLUE results when only 5% of the training data is available. We see again that SAM boosts performance across the board, adding a whopping 7.2% relative improvement on the Base model.

Model	Natural Q.	Web Q.	TriviaQA
Small	4.9 / 2.9	4.8 / 1.8	3.0 / 1.3
Small + SAM (0.05)	**6.0 / 3.7**	**7.1 / 2.2**	**3.3 / 1.6**
Base	7.9 / 4.8	**13.7** / 4.6	7.6 / 4.2
Base + SAM (0.15)	**8.6 / 5.6**	12.2 / **5.7**	**7.7 / 4.4**
Large	8.7 / 5.2	14.0 / 7.0	9.8 / 6.0
Large + SAM (0.15)	**10.5 / 6.6**	**14.9 / 7.7**	**10.6 / 7.1**
XL	13.1 / 8.0	20.6 / 11.9	**19.6 / 15.3**
XL + SAM (0.15)	**13.4 / 8.1**	**22.9 / 13.6**	19.1 / 14.5

Table 7: CBQA results when only 5% of the training data is available. We see SAM helps here as it did for subsampled SuperGLUE. For Natural Questions, SAM improves Base model performance by a relative 8.86%/16.6% (F1/EM).

as we scale up the model size. Surprisingly, we did not observe any clear pattern with regards to size: indeed, sometimes the gains on XL were larger than those on Small. Thus, we lean to recommend SAM to all practitioners regardless of the regime in model capacity they are working in.

SAM improves single-task and multi-task learning alike. Thus far, SAM has been trained on a mixture of tasks, where the influence of a particular task is proportional to the number of examples in its training split (i.e. no artificial up or down-weighting). To rule out the possibility that the gains observed are *solely* due to some ability of SAM's to leverage multi-task learning and improve cross-task transfer, we conduct the following ablation. For each of the three CBQA tasks, we train only on a single task and report the performance on that task's test set. Results are shown in Table 5. Indeed, we see similar gains when training and testing on each single task individually. We conclude that the mechanism driving SAM's improvements affect single-task and multi-task learning alike.

4.3 When training data is limited

We now switch gears and evaluate whether or not SAM helps when training data is scarce. Prior work (Chen et al., 2021) showed that for vision models and tasks, SAM helps more when there is less training data to learn from. To test whether this holds for language, we do as follows: we subsample the training splits for both SuperGLUE and CBQA datasets at rates ranging from 2% to 80%, and observe test performance when the public checkpoint is fine-tuned with and without SAM. SuperGLUE and CBQA results at a 5% sampling rate are shown in Tables 6 and 7 respectively. In both cases we see again that SAM boosts performance across the board, adding, for example, a whopping 7.2% relative improvement on the Base model on 5% SuperGLUE and a relative 8.86%/16.6% to F1/EM on Natural Questions.

Figure 1 plots the performance on the three CBQA tasks as a function of the sampling rate. We observe consistent gains from SAM across the size of the subsampled training set, with the relative improvement appearing largest when the subsampling rate is around 20%.

4.4 Sensitivity to hyper-parameters

Figure 2 shows the impact of SAM's hyper-parameters ρ, the ascent micro-batch size a, and the sharpness factor m on the (full) SuperGLUE benchmark for the Base model. For ρ, we see that all tested values perform better than fine-tuning without SAM. However, 0.15 is a "sweet spot," performing better than values below or above it. Thus, practitioners with little computational budget for hyper-parameter tuning may still see large gains by using a non-optimal ρ, while those with a generous budget should consider tuning. For the ascent micro-batch size a, we see that when the normal (descent) batch size is 128, there is improvement as a is increased to 32 but little past this point. Thus, setting a to be 1/4-th the descent batch size, as we do throughout our experiments, provides a good trade-off between performance and computational overhead. Increasing the sharpness m, where each of the m ascent micro-batches has size $32/m$, does not improve performance here. We thus recommend a default of 1, which is the setting used across our experiments. Full results are shown in the Appendix.

5 Conclusion

To the best of our knowledge, this paper is the first to demonstrate how the recently-proposed Sharpness-Aware Minimization can be applied for fine-tuning the ubiquitous text-to-text Transformer (T5) and its multilingual counterpart mT5 on language tasks of broad interest. We thereby corroborate the already-documented success the method has had in the vision domain. Furthermore, we reveal SAM's benefits when data is limited by fine-tuning on subsamples of the original task training split. By approximating the ascent step of the algorithm via fewer samples, we show how large gains can be had across benchmarks and model sizes while adding only around 25% additional compute and wall-clock training time. Our hope is that this work will spur SAM's adoption in the natural language processing community the way it is starting to in the vision one.

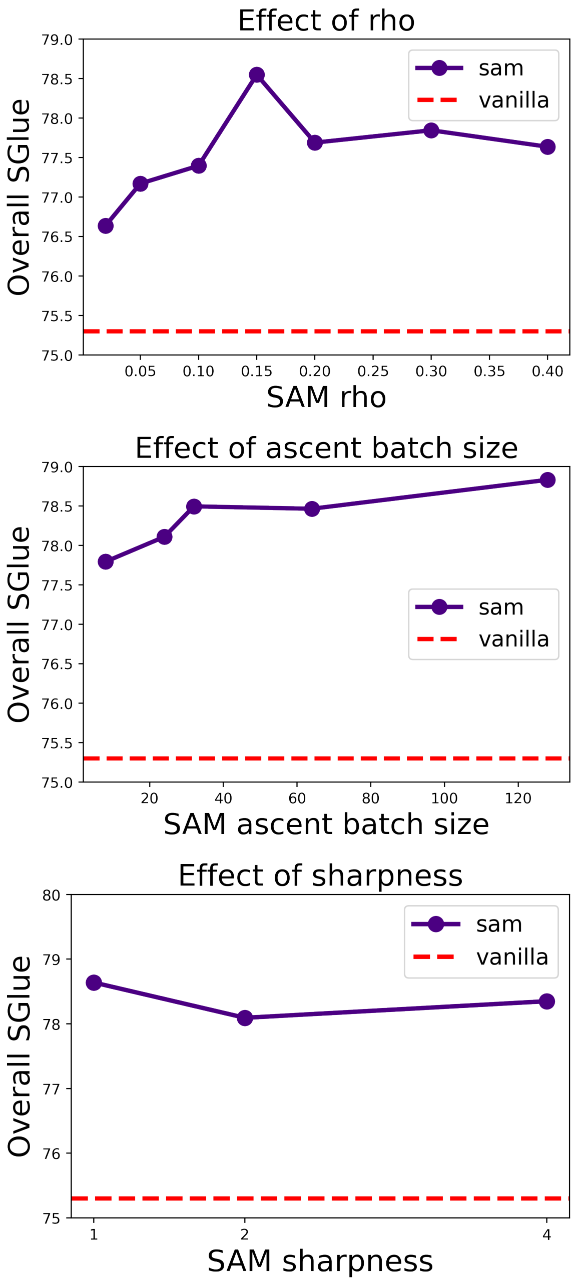

Figure 2: Impact of SAM's hyper-parameters ρ, the ascent micro-batch size a, and the sharpness m on the SuperGLUE benchmark for the Base model. Except for the ablated hyper-parameter, we use $\rho = 0.15$, $a = 32$, $m = 1$. For ρ, we see that all tested values perform better than fine-tuning without SAM. However, 0.15 is a "sweet spot," performing better than values below or above it. For the ascent micro-batch size a, we see that when the descent batch size is 128, there is improvement as a is increased to 32 but little past this point. Thus, setting a to be 1/4-th the descent batch size provides a good trade-off between performance and computational overhead. Increasing the sharpness m does not help (in fact it hurts) here. Full results are shown in the Appendix.

Abstract

Recent advances in natural language processing have enabled powerful privacy-invasive authorship attribution. To counter authorship attribution, researchers have proposed a variety of rule-based and learning-based text obfuscation approaches. However, existing authorship obfuscation approaches do not consider the adversarial threat model. Specifically, they are not evaluated against adversarially trained authorship attributors that are aware of potential obfuscation. To fill this gap, we investigate the problem of adversarial authorship attribution for deobfuscation. We show that adversarially trained authorship attributors are able to degrade the effectiveness of existing obfuscators from 20-30% to 5-10%. We also evaluate the effectiveness of adversarial training when the attributor makes incorrect assumptions about whether and which obfuscator was used. While there is a a clear degradation in attribution accuracy, it is noteworthy that this degradation is still at or above the attribution accuracy of the attributor that is not adversarially trained at all. Our results underline the need for stronger obfuscation approaches that are resistant to deobfuscation.

1 Introduction

Recent advances in natural language processing have enabled powerful attribution systems[1] that are capable of inferring author identity by analyzing text style alone (Abbasi and Chen, 2008; Narayanan et al., 2012; Overdorf and Greenstadt, 2016; Stolerman et al., 2013; Ruder et al., 2016). There have been several recent attempts to attribute the authorship of anonymously published text using such advanced authorship attribution approaches.[2] This poses a serious threat to privacy-conscious individuals, especially human rights activists and journalists who seek anonymity for safety.

Researchers have started to explore text *obfuscation* as a countermeasure to evade privacy-invasive authorship attribution. Anonymouth (McDonald et al., 2012; Brennan et al., 2012) was proposed to identify words or phrases that are most revealing of author identity so that these could be manually changed by users seeking anonymity. Since it can be challenging for users to manually make such changes, follow up work proposed rule-based text obfuscators that can automatically manipulate certain text features (e.g., spelling or synonym) (McDonald et al., 2013; Almishari et al., 2014; Keswani et al., 2016; Karadzhov et al., 2017; Castro-Castro et al., 2017; Mansoorizadeh et al., 2016; Kacmarcik and Gamon, 2006; Kingma and Welling, 2018). Since then more sophisticated learning-based text obfuscators have been proposed that automatically manipulate text to evade state-of-the-art authorship attribution approaches (Karadzhov et al., 2017; Shetty et al., 2018; Li et al., 2018; Mahmood et al., 2019; Gröndahl and Asokan, 2020).

In the arms race between authorship attribution and authorship obfuscation, it is important that both attribution and obfuscation consider the adversarial threat model (Potthast et al., 2018). While recent work has focused on developing authorship obfuscators that can evade state-of-the-art authorship attribution approaches, there is little work on developing authorship attribution approaches that can work against state-of-the-art authorship obfuscators. Existing authorship attributors are primarily designed for the non-adversarial threat model and only evaluated against non-obfuscated documents. Thus, it is not surprising that they can be readily evaded by state-of-the-art authorship obfuscators

---

To fill this gap, we investigate the problem of authorship deobfuscation where the goal is to develop adversarial authorship attribution approaches that are able to attribute obfuscated documents. We study the problem of *adversarial authorship attribution* in the following two settings. *First,* we develop attributors that filter obfuscated documents using obfuscation/obfuscator detectors and then use an authorship attributor that is adversarially trained on obfuscated documents. *Second,* we develop adversarially trained authorship attributors that does not make assumptions about whether and which authorship obfuscator is used.

The results show that our authorship deobfuscation approaches are able to significantly reduce the adverse impact of obfuscation, which results in up to 20-30% degradation in attribution accuracy. We find that an authorship attributor that is purpose-built for obfuscated documents is able to improve attribution accuracy to within 5% as without obfuscation. We also find that an adversarially trained authorship attributor is able to improve attribution accuracy to within 10% as without obfuscation. Additionally, we evaluate the effectiveness of adversarial training when the attributor makes incorrect assumptions about whether and which obfuscator is used. We find that these erroneous assumptions degrade accuracy up to 20%, however, this degradation is the same or smaller than when the attributor is not adversarially trained, which can degrade accuracy up to 32%.

Our key contributions include:

- investigating the **novel problem** of adversarial authorship attribution for deobfuscation;
- **proposing approaches** for adversarial authorship attribution; and
- **evaluating robustness** of existing authorship obfuscators against adversarial attribution.

Ethics Statement: We acknowledge that authorship deobfuscation in itself is detrimental to privacy. Our goal is to highlight a major limitation of prior work on authorship obfuscation under the adversarial threat model. We expect our work to foster further research into new authorship obfuscation approaches that are resistant to deobfuscation.

2 Related Work

Authorship attribution is the task of identifying the correct author of a document given a range of possible authors. It has been a long-standing topic, and researchers have developed a wide range of solutions to the problem. Earlier researchers focus more on analysis based on writing style features. These include the distribution of word counts and basic Bayesian methods (Mosteller and Wallace, 1963), different types of writing-style features (lexical, syntactic, structural, and content-specific) (Zheng et al., 2006), and authors' choices of synonyms (Clark and Hannon, 2007). Other researchers combined machine learning and deep learning methods with stylometric features. Abbasi and Chen (2008) combine their rich feature set, "Writeprints", with an SVM. Brennan et al. (2012) improve "Writeprints" to reduce the computational load required of the feature set. Finally, more recent research focuses on fine-tuning pretrained models since they do not require predefined features sets. Ruder et al. (2016) tackle authorship attribution with a CNN, while Howard and Ruder (2018) introduce the Universal Language Model Fine-tuning (ULMFiT) which shows strong performance in attribution.

To the best of our knowledge, prior work lacks approaches for adversarial authorship deobfuscation. Prior work has shown that existing authorship attributors do not perform well against obfuscators. Brennan et al. (2012) present a manual obfuscation experiment which causes large accuracy degradation. Since this obfuscation experiment, much has been done in the area of authorship text obfuscation (Rao and Rohatgi, 2000; Brennan et al., 2012; McDonald et al., 2012, 2013; Karadzhov et al., 2017; Castro et al., 2017; Mahmood et al., 2019; Gröndahl and Asokan, 2020; Bo et al., 2019). We focus on state-of-the-art obfuscators, Mutant-X (Mahmood et al., 2019) and DS-PAN (Castro et al., 2017) specifically in our research. Other obfuscation methods are as vulnerable to adversarial training which is reinforced in (Gröndahl and Asokan, 2020).

Our proposed authorship attributor leverages adversarial training to attribute documents regardless of obfuscation. First described in (Goodfellow et al., 2014), adversarial training uses text produced by an adversary to train a model to be more robust. Adversarial training has seen success in other text domains including strengthening word embeddings

(Miyato et al., 2016), better classification in cross-lingual texts (Dong et al., 2020), and attacking classifiers (Behjati et al., 2019).

3 Methodology

In this section, we present our approaches for adversarial authorship attribution for deobfuscation.

3.1 Threat Model

We start by describing the threat model for the authorship deobfuscation attack. There is an arms race between an attacker (who desires to identify/attribute the author of a given document) and a defender (an author who desires privacy and therefore uses an obfuscator to protect their identity). Figure 1 illustrates the expected workflow between the defender and the attacker. The defender uses an obfuscator before publishing the documents and the attacker employs obfuscation and/or obfuscator detector as well as an adversarially trained attributor for deobfuscation.

Defender. The goal of the defender is to obfuscate a document so that it cannot be attributed to the author. The obfuscator takes as input an original document and obfuscates it to produce an obfuscated version that is expected to evade authorship attribution.

Attacker. The goal of the attacker is to use an attributor trained on documents from multiple authors to identify the author of a given document. The attacker assumes to know the list of potential authors in the traditional closed-world setting. We examine two scenarios: First, as shown in Figure 1a, the attacker assumes to know that the document is obfuscated and also the obfuscator used by the defender. In this scenario, the attacker is able to access the documents that are produced by the obfuscator and hence train an attributor for obfuscated documents from the obfuscator. Second, as shown in Figure 1b, the attacker assumes to know that the document is obfuscated and that there is a pool of available obfuscators, of which one is used by the defender. Note that the attacker does not know exactly which obfuscator from the pool was used by the defender. Thus, the attacker trains an attributor for documents that are obfuscated by any one of the pool of available obfuscators.

3.2 Obfuscation

We use two state-of-the-art text obfuscators .

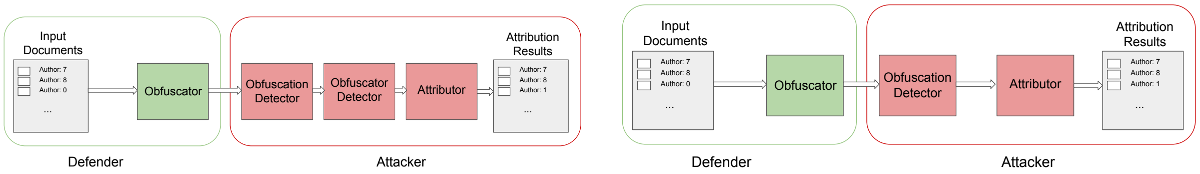
Document Simplification (DS-PAN). This approach obfuscates documents through rule-based sentence simplification (Castro et al., 2017). The transformation rules include lexical transformations, substitutions of contractions or expansions, and eliminations of discourse markers and fragments of text in parenthesis. This approach was one of the best performing in the annual PAN competition, a shared CLEF task (Potthast et al., 2017). It was also one of the few approaches that achieves "passable" and even "correct" judgements on the soundness of obfuscated text (i.e., whether the semantics of the original text are preserved) (Hagen et al., 2017). We refer to this approach as DS-PAN.

Mutant-X. This approach performs obfuscation using a genetic algorithm based search framework (Mahmood et al., 2019). It makes changes to input text based on the attribution probability and semantics iteratively so that obfuscation improves at each step. It is also a fully automated authorship obfuscation approach and outperformed text obfuscation approaches from PAN (Potthast et al., 2017) and has since been used by other text obfuscation approaches (Gröndahl and Asokan, 2020). There are two versions of Mutant-X: Mutant-X writeprintsRFC, which uses Random Forests along with Writeprints-Static features (Brennan et al., 2012); and Mutant-X embeddingCNN, which uses a Convolutional Neural Network (CNN) classifier with word embeddings. We use writeprintsRFC version because it achieves better drop in attribution accuracy and semantic preservation as compared to embeddingCNN.

3.3 Deobfuscation

We describe the design of the authorship attributor and our adversarial training approaches for deobfuscation.

Authorship Attributor. We use writeprintsRFC as the classifier for authorship attribution. More specifically, we use the Writeprints-Static feature set (Brennan et al., 2012) that includes lexical features on different levels, such as word level (total number of words) and letter level (letter frequency) as well as syntactic features such as the frequency of functional words and parts of speech tags. It is one of the most widely used stylometric feature sets and has consistently achieved high accuracy on different datasets and author sets while maintaining a low computational cost. We then use these features to train an ensemble random forest classifier



(a) Scenario 1: Attacker knows the document is obfuscated and the obfuscator used

(b) Scenario 2: Attacker only knows the document is obfuscated

Figure 1: Deobfuscation pipeline using obfuscation and/or obfuscator detectors for adversarial training

with 50 decision trees.

Adversarial Training. The basic idea of adversarial training is to include perturbed/obfuscated inputs into the training set to improve the model's resistance towards such adversarially obfuscated inputs (Goodfellow et al., 2014). It has been widely used in various domains including text classification. In our case, obfuscated texts are texts that vary slightly from the original texts and these serve as adversarial examples. We examine how using these adversarial examples as training data influences the attributor's performance and whether it adds resilience against obfuscation. Based on our two scenarios described in Section 3.1 and shown in Figure 1, we propose two ways of adversarial training. For both cases, original texts from the list of possible authors are selected and prepared for obfuscation. For scenario 1, we train the attributor using documents obfuscated by a known obfuscator. For scenario 2, since the attacker does not assume to know the specific obfuscator used by the defender, we train the attributor using documents obfuscated by the pool of available obfuscators.

4 Experimental Setup

We describe the dataset, evaluation metrics, and experimental design to assess the effectiveness of our adversarial authorship attribution approaches for deobfuscation.

Dataset. Following previous research (Mahmood et al., 2019), we examine a publicly available dataset for evaluation of our methodology. The Blog Authorship Corpus (Schler et al., 2006) contains over 600,000 blog posts from blogger.com. These posts span 19,320 unique authors. Previous research (Narayanan et al., 2012) found that authorship attribution gets harder when more authors are included. Based on the author selection in (Mahmood et al., 2019), we select a subset of 15 each with 100 documents (compared to their 5 and 10 authors) for a more precised evaluation. These 1500 documents are divided into 80-20% split for training and testing, respectively. Specifically, 80 documents from each author are used in the training set while the rest 20 documents are used in the test set.

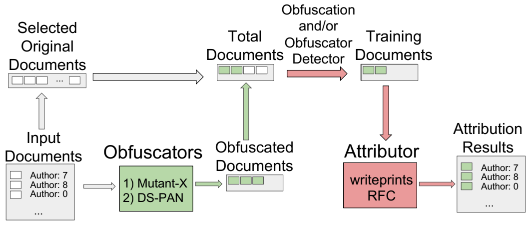


Figure 2: Generalized deobfuscation training process using adversarial training

As shown in Figure 2, we train on various combinations of obfuscated documents. These documents are obfuscated by the obfuscators described in Section 3.2. When an attributor-dependent-obfuscator (e.g. Mutant-X (Mahmood et al., 2019)) is used, the attributor will have access to the same training documents used to train the obfuscator. Otherwise, the attributor does not assume to have access to the attributor used by the obfuscator. To control for training size, when more than 1 obfuscator is used, we sample equal amounts of documents from each set of obfuscated documents. For example, if we train against 2 obfuscators, then 600 documents are sampled from each set of respective obfuscated documents to get a training set of size 1200.

To calibrate the obfuscated texts, we use METEOR score (Banerjee and Lavie, 2005) to evaluate the soundness of documents. The score for Mutant-X ranges from 0.3 to 0.7 (mean=0.46), and the score for DS-PAN ranges from 0.24 to 0.57 (mean=0.38), which are comparable to previous studies (Mahmood et al., 2019). An in-depth analysis of the METEOR score is reported in Appendix A.

Metric. To quantify attribution performance on the

15-class problem, we calculate the accuracy as:

$$\text{accuracy} = \frac{\text{\# of correctly attributed documents}}{\text{total \# of documents}} \tag{1}$$

Attack Scenarios. Figure 3 illustrates the flow of our experimental evaluation under different attack scenarios.

0. *Baseline:* For the baseline model, we assume that there is no obfuscation in this world. The attacker is trained on original documents and is deployed on original documents.

1. *Obfuscation-unaware-attacker:* The first case we examine is when the defender actively seeks to hide author identity. Thus, the defender gains an advantage by obfuscating documents using either Mutant-X or DS-PAN in order to bypass the attacker. The attacker, however, remains unaware of obfuscation and trains the attributor only on original documents.

2. *Obfuscation-aware-attacker with obfuscation detector:* Next, we give knowledge of obfuscation to the attacker by introducing an obfuscation detector into the system. Previous research (Mahmood et al., 2020) shows that texts generated by existing obfuscators can be detected as obfuscated with high accuracy. The device for this type of detection is called an obfuscation detector. Hence, in this scenario we ask whether there is any benefit to the attacker if the text is identified as obfuscated before attribution. Since the attacker does not know which obfuscator was used by the defender, the attributor is trained on the combination of documents generated from DS-PAN and from Mutant-X. The defender is the same as in the previous scenario, i.e., it uses one of the obfuscators to generate documents.

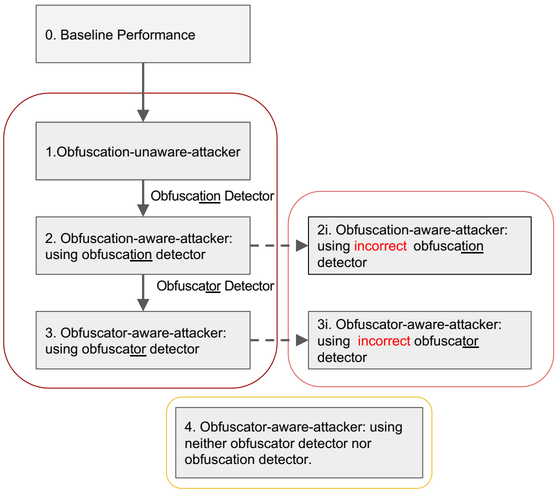

Figure 3: Progression of various attack scenarios

3. *Obfuscator-aware-attacker with obfuscator detector:* We give additional information to the attacker. Previous research has shown that embedding watermarks and fingerprints that show the identity of the model into deep neural networks is a valid approach to protect the rights of shared trained models (Uchida et al., 2017; Zhang et al., 2018). Hence, it is reasonable to assume that there will be methods in the future to identify the watermarks for specific deep neural networks. Here, we propose the concept of obfuscator detector, which can detect the specific obfuscator used. In this case, the attacker attributor is trained always on the documents generated by the same obfuscator as the defender: either documents generated from DS-PAN or from Mutant-X.

2i. *Obfuscation-aware-attacker with incorrect obfuscation detector:* Here we ask the question: what happens in scenario 2 if the obfuscation detector makes errors? The specific error addressed is that the detector classifies the text as obfuscated whereas it is actually an original. Under this condition, the attacker attributor is still trained on the combination of documents generated from DS-PAN and from Mutant-X. But the defender now presents an original document.

3i. *Obfuscator-aware-attacker with incorrect obfuscator detector:* When the obfuscator detector classifies incorrectly, it assumes that the defender uses a specific obfuscator when it actually uses a different one. The attacker attributor is trained on the documents generated by one of the obfuscators: either documents generated from DS-PAN or from Mutant-X. However, the defender uses a different obfuscator than the attacker to generate the documents.

4. *Obfuscator-aware-attacker that does not rely on an obfuscator detector or obfuscation detector:* Since the previous processes require the proposed obfuscation and obfuscator detector, it is not efficient. Hence, a simpler, more efficient solution is to train on all the documents at once. In this simplified version, the attacker attributor is trained on the combination of original documents, documents generated from DS-PAN, and documents generated from Mutant-X. Since this is the combined condition, the defender may or may not use an obfuscator, and will choose from the two possible obfuscators to generate documents.

5 Results

In this section, we present the results following the progression of various attack scenarios shown in Figure 3.

5.1 Major Scenarios

0. *Baseline:* The original authorship attributor has an accuracy of 76.7% when trained on the original documents and tested on original documents. The attribution accuracy should be higher than 6.7%, which is when we attribute the 15 authors randomly, to be considered effective.

1. *Obfuscation-unaware-attacker:* Based on the first row of Table 1, the result shows that the attribution accuracy drops from 76.7% to 50.7% with a decrease of 26% when tested on DS-PAN obfuscated documents, while the accuracy for testing on Mutant-X obfuscated documents drops from 76.7% to 44.3%. The average drop in accuracy is from 76.7% to 47.5%, which is 29.2%. Based on the results, we know that as shown by previous works (Karadzhov et al., 2017; Mahmood et al., 2019) on the performance of the obfuscators, DS-PAN and Mutant-X obfuscators can successfully decrease the attribution accuracy of original attributor.

2. *Obfuscation-aware-attacker with obfuscation detector:* The second row of Table 1 shows that attribution accuracy increases by 13.2% from 50.7% to 63.9% when tested on DS-PAN documents, and increases by 24.7% from 44.3% to 69% when tested on Mutant-X documents. The average accuracy is 66.4%, which increases from the previous 47.5% by about 19%. While the performance is still not comparable to the baseline results, the increase in accuracy from the previous scenario is significant, which suggests that the obfuscation detector would benefit the performance against obfuscated documents.

3. *Obfuscator-aware-attacker with obfuscator detector:* As shown on the third and forth row of Table 1, when trained only on DS-PAN documents, the accuracy tested on DS-PAN is 68.6%, with an increase of 17.9% from the first scenario; when trained only on Mutant-X documents, the accuracy tested on Mutant-X is 75.7%, with an increase of 31.4%. The average test accuracy is 71.1%, which increases by about 5% compared to the 66.4% in the previous case. From the results, we can see that having an obfuscator detector as well as an obfuscation detector is the most beneficial to improve the attribution accuracy from obfuscated texts.

Training set	Test set		
	DS-PAN	MutantX	Average
Original	50.7	44.3	47.5
DS-PAN+MutantX	63.9	69.0	**66.4**
DS-PAN	**68.6**	-	-
MutantX	-	**75.7**	-

Table 1: Accuracy of original attributor and different adversarially trained attributors tested against different obfuscators

5.2 Error Conditions

Although obfuscation/obfuscator detector are quite accurate, they are not perfect. Hence, we test the success of the attacker when the obfuscation detector and obfuscator detector are incorrect.

2i. *Obfuscation-aware-attacker with incorrect obfuscation detector:* Shown on the first column of row four on Table 2, the attribution accuracy decreases by 8.4% from the baseline 76.7% to 68.3%, but a higher accuracy is maintained than the average of Attack Scenario 2 (66.4%) The result shows that when the obfuscation detector produces wrong results, performance will be influenced, but still stay at a relatively high level. Thus, having an obfuscation detector is generally good for the attacker with little cost.

3i. *Obfuscator-aware-attacker with incorrect obfuscator detector:* From second and third rows of Table 2 we see that when the attacker is trained only on DS-PAN documents, the accuracy tested on Mutant-X is 57.3%, with a drop in performance of 18.4% when compared to training on only Mutant-X documents (75.7%). When the attacker is trained only on Mutant-X documents, the accuracy tested on DS-PAN is 48.5%, with a drop in performance of 20.1% as compared to training on only DS-PAN documents (68.6%). The average test accuracy is 52.9%, which is lower than training on the same obfuscator, but higher than the results in 1 of 5.1 (50.7% and 44.3%). When the obfuscator detector gives incorrect results, the attribution accuracy will not achieve its best performance, but the result is still higher than trained only on original documents. Hence, using obfuscated documents to train always tends to benefit the attribution accuracy.

5.2.1 Combined Condition

Here the attacker simply uses originals and obfuscated documents from all available obfuscators for adversarial training of the attributor.

4. *Obfuscator-aware-attacker that does not rely on an obfuscator detector or obfuscation detector:*

This result is shown on the last row of Table 2. Attribution accuracy when tested on original documents drops from 76.7% to 66.3%, but increases by 10.5% from 50.7% to 61.2% when tested on DS-PAN, and increases by 24.5% from 44.3% to 68.8% when tested on Mutant-X. The average accuracy is 65%, which increases from the average of the former three, 57.2%, by about 8%. While the attacker does not know if the document is obfuscated or not, or by which obfuscator, it is still able to achieve a high boost in attribution accuracy by adversarial training. Therefore, although the previous processes can achieve higher performances, training on a combination of these documents could be a valid approach when time and resources are limited.

6 Discussion

Next, we look more closely into the results from adversarial training to better understand them.

6.1 General Author Analysis

Figure 4 pesents the confusion matrices produced from DS-PAN obfuscated documents tested on Attack Scenario 1, 2 and 3 respectively. Rows represent the Original Authors, while the columns represent the Predicted Authors. The values in the matrices are the percentage of the original documents that are classified as a specific author.

Moving from scenario 1 to 3, we see an increase in color density and percentage on the diagonal, which signifies the general increase in accuracy when the training documents become more specific. Consistent with above, the color on the non-diagonal areas becoming more transparent also indicates reduction of classification errors. At the author level, we observe that almost all of the authors show increases in accuracy on the diagonal cells across the three scenarios. It shows that adversarial training is effective even on authors with different styles.

Looking more closely at each author, we know that Author 9 is the easiest to classify - performance is always at 100%. Author 6, on the other hand, is relatively hard to attribute. The best performance for Author 6 is only 35% from the most effective Attack Scenario 3.

Figure 6 presents another view on performance. It shows the percentage of errors made for each author out of all the errors in the three scenarios combined (note: the sum of all errors in the figure is 100%). Thus, the errors made for Author 1 under Scenario 1 is 3.18% of total errors across the three scenarios. We observe that the color is generally darker in Scenario 1, while it gradually lightens in Scenario 2 and then in Scenario 3. Again, this indicates the benefit of having more specific training data. Looking more closely within each scenario, we see that the attributor of Attacker Scenario 1 tends to misclassify Authors 5 and 8 the most. But the attributors for Scenario 2 and Scenario 3 learn more effectively for these two authors thereby reducing mistakes. For Attack Scenario 3, the most misclassified author is Author 6, where 3.76% of all errors. But this percentage is still an improvement over the 4.34% in the previous two scenarios. Motivated by the above observations, next we investigate shifts in performance for a specific author.

6.2 Individual Author Analysis

We assign labels to the 15 authors in the dataset and select Original Author 15 for more detailed analysis. The reason we choose Author 15 is that its accuracy is among the ones that increases the most, from 45% to 80%. In order to find out the reasons behind such increase, we perform PCA analysis on all of the DS-PAN documents whose original author is Author 15. We use Writeprints-Static feature set, which has a total of 555 features. In order to preserve the most significant features for attribution, we select the most important 25 features from the original writeprintsRFC and process them through PCA so that we can visualize the features into 3 dimensional graphs.

As shown in the graphs in Figure 5, each dot on the graph represents a document. The green ones are the ones that are attributed correctly while the red ones are attributed incorrectly. In Figure 5a, the incorrectly attributed ones are mainly gathered in a cluster. This suggests that the attributor has trouble discriminating the documents that are similar to each other. But as we go from left to right, the documents in the cluster are also gradually attributed correctly. The trend shows that the attributor is getting better at distinguishing between documents that are similar to each other. Hence, we can infer that adversarial training improves attribution accuracy by discriminating between the ones that are more similar to each other.

6.3 Comparing DS-PAN and Mutant-X

In Attack Scenarios 2, 3, and 4, the test sets using DS-PAN for obfuscation yield worse attribution

Training set	Test set			
	Original	DS-PAN	MutantX	Average of DS+MX
Original	**76.7**	50.7	44.3	47.5
DS-PAN	57.3	**68.6**	57.3	62.9
MutantX	72.0	48.5	**75.7**	62.1
DS-PAN + MutantX	68.3	63.9	69.0	**66.4**
DS-PAN + MutantX + Original	66.3	61.2	68.8	65.0

Table 2: Accuracy of adversarial training on various combinations of test documents

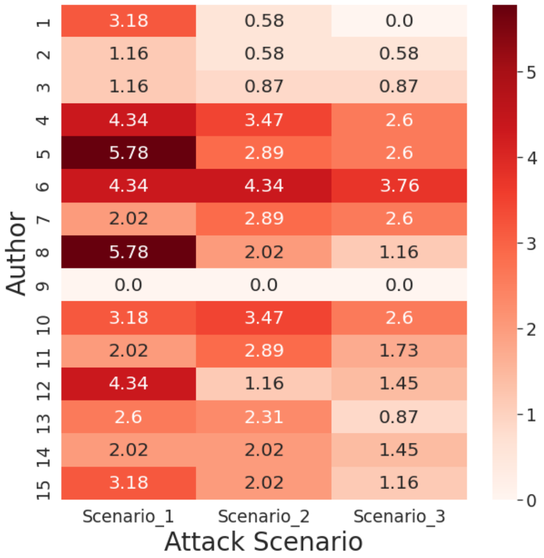

Figure 6: Percentage of misclassified document for each author across attack scenarios

accuracy than those using Mutant-X. Our analysis of obfuscated documents showed that DS-PAN makes both a greater number of changes as well as more significant changes as compared to Mutant-X. Thus, we surmise that DS-PAN results in larger degradation in attribution accuracy because the attacker's training set contains text that is less similar to the original text. However, the changes made by DS-PAN also have side effect in that they lower the soundness of obfuscated text as reflected by lower METEOR scores. The mean METEOR score for DS-PAN is 0.38 as compared to 0.46 for Mutant-X. A more detailed analysis of METEOR score and semantic similarity between obfuscated and original texts is reported in Appendix A.

6.4 Insights into Adversarial Training

The performance gain of adversarial training comes from a "noisy" training dataset comprising of obfuscated documents as well as knowledge about the obfuscator. To disentangle these two factors, we compare the accuracy improvements of the second and third rows of Table 2 against the Mutant-X obfuscated test documents. We note that the improvement in attribution accuracy is 13% when DS-PAN obfuscated documents are used for training. The improvement in attribution accuracy is further 18% (31% overall) when Mutant-X obfuscated documents are used for training. This difference (13% vs. 18%) indicates that although having a noisy dataset helps, the knowledge of the specific obfuscator is likely more crucial to improving attribution performance. This trend holds for DS-PAN obfuscated test documents.

7 Concluding Remarks

In this work, we explored the novel problem of adversarial authorship attribution for deobfuscation. We demonstrate that adversarial training is able to significantly reduce the adverse impact of existing text obfuscators on authorship attribution accuracy. We found that an adversarially trained authorship attributor improves attribution accuracy to within 5-10% as without obfuscation. While an adversarially trained authorship attributor achieved best accuracy when it is trained using the documents obfuscated by the respective obfuscator, we found that it achieves reasonable accuracy even when it is trained using documents obfuscated by a pool of obfuscators. When the adversarially trained attributor makes erroneous assumptions about the obfuscator used to obfuscate documents, we note a degradation in attribution accuracy. It is noteworthy, however, that this degradation is still similar or better than the attribution accuracy of the baseline attributor that is not adversarially trained.

Our results shed light into the future of the ensuing arms race between obfuscators and attributors. Most notably, we find that the effectiveness of adversarial training is somewhat limited if the obfuscators continue to employ new and improved methods that are not available to attributors for adversarial training. Therefore, it is important to continue development of new and improved text obfuscation approaches that are resistant to deobfuscation (Bevendorff et al., 2019; Bo et al., 2019; Gröndahl and Asokan, 2020; Hlavcheva et al., 2021). On the other hand, recent work on understanding and improving transferability of adversarial attacks can inform development of better adversarial attributors that might work well even for unknown obfuscators (Tramèr et al., 2017; Zheng et al., 2020; He et al., 2021; Mireshghallah and Berg-Kirkpatrick, 2021).

Finally, our experiments were limited to the closed-world setting where the universe of potential authors is assumed to be known by the attributor. Further research is needed to investigate whether (and how much) adversarial algorithms are effective in the open-world setting.

A Qualitative Analysis

We conduct analysis to evaluate the quality of the text. We first evaluate the semantics of the obfuscated text with respect to the original text using METEOR scores. The results show that METEOR scores of obfuscated text are comparable to those reported in prior studies. We also conduct qualitative analysis of the obfuscated text.

First, we evaluate the quality of obfuscated documents from the two obfuscators. We use METEOR score to measure the soundness of the obfuscated text in terms of the semantic similarity between the original and the obfuscated text.

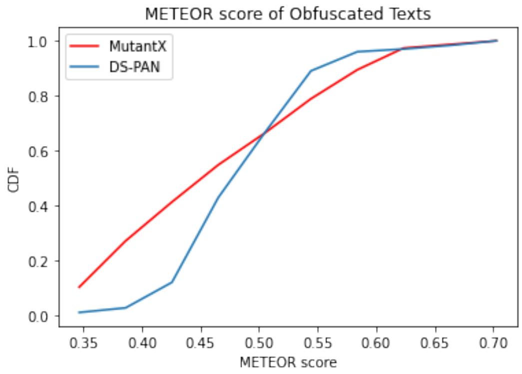

Figure 7: CDF plot of METEOR score for obfuscated texts

Figure 7 shows the distribution of the METEOR score for Mutant-X and DS-PAN. The plot shows that the METEOR scores for Mutant-X ranges from 0.3 to 0.7 (mean=0.46), and the METEOR score for DS-PAN ranges from 0.24 to 0.57 (mean=0.38). Compared to the previous METEOR score results calculated in (Mahmood et al., 2019), where the METEOR score for Mutant-X ranges from 0.48 to 0.55 (mean = 0.51), and the METEOR score for other baseline models ranges from 0.32 to 0.46 (mean = 0.38), the two obfuscators used in this work achieve similar results at preserving the semantics of the original texts.

Table 3 contains examples from the two obfuscators showing different types of changes. Synonym replacement is common in both systems. Examples of such are (street <-> sidewalk), (student <-> pupil). There are also changes in word form. (run <-> running), (waited <-> wait) preserves the morpheme, but changes the tense of the word. It is also worth noting that DS-PAN tends to change the form of abbreviations, such as (I'm <-> I am) and (to have <-> to've). In general, the transformations make sense to the readers, and preserve most of the original meanings. But there are also cases (like the last row) where the transformations change the content and break the grammar.

Abstract

Word and morpheme segmentation are fundamental steps of language documentation as they allow to discover lexical units in a language for which the lexicon is unknown. However, in most language documentation scenarios, linguists do not start from a blank page: they may already have a pre-existing dictionary or have initiated manual segmentation of a small part of their data. This paper studies how such a weak supervision can be taken advantage of in Bayesian non-parametric models of segmentation. Our experiments on two very low resource languages (Mboshi and Japhug), whose documentation is still in progress, show that weak supervision can be beneficial to the segmentation quality. In addition, we investigate an incremental learning scenario where manual segmentations are provided in a sequential manner. This work opens the way for interactive annotation tools for documentary linguists.

1 Introduction

Recent years have witnessed a blooming of research aimed at applying language technologies (LTs) to "under-resourced languages".[1] Such studies have been mostly motivated on three main grounds (not necessarily mutually exclusive): (a) to develop tools that could speed up the work of field linguists collecting and annotating recordings for these languages; (b) to provide linguistic communities with LTs that are necessary in an increasingly digitalised world, e.g. to interact with smartphones or computers in their own language and communicate with speakers of other languages; (c) to challenge existing machine-learning techniques in very low resource settings, where hardly any resource (dictionary, corpus, grammar) is available.

Those objectives are thoroughly discussed in a recent position paper (Bird, 2020) who notices, among other things, that objective (c) (training language processing tools with zero resource) is questionable in the context of language documentation works which can often rely on some pre-existing knowledge, such as a word list, or information from related languages. Accordingly, this paper explores ways to make the best of prior resources and improve the effectiveness of unsupervised language analysis techniques for the purpose of linguistic documentation. Our main objective is to develop tools that will effectively assist field linguists in their documentary tasks (objective (a)). We focus on segmentation tasks, which aim to automatically identify meaningful units in an unsegmented phonetic or orthographic string (Johnson, 2008; Doyle and Levy, 2013; Eskander et al., 2016; Godard et al., 2018b; Eskander et al., 2019).

Following these authors, we experiment with Bayesian non-parametric segmentation models, derived in our case from Goldwater et al. (2009) and subsequent work, which we recap in Section 2. Our first contribution is in Section 3 which studies multiple semi-supervised learning regimes aimed to take advantage of pre-existing linguistic material such as incomplete segmentations and word lists.

In Sections 4 and 5, we experimentally assess the pros and cons of these weakly supervised approaches in batch and online learning, for two extremely low-resource languages currently in the process of being documented: Mboshi, a Bantu language used in former studies (Godard et al., 2018a); and Japhug, a language from the Sino-Tibetan family spoken in the Western part of China thoroughly documented by Jacques (2021). These two languages were selected because they illustrate actual documentation processes, for which high-quality linguistic resources have been derived from fieldwork, at the end of a long and difficult procedure (Aiton, 2021). A complementary analysis follows,

---

where we use the Japhug corpus to take a closer look at the units identified automatically, contrasting morpheme-based and word-based supervision.

2 Background

Going from audio recordings to fully annotated transcripts implies two successive segmentation steps: the first segments words and happens during the production of phonemic or orthographic transcripts; the second further splits words into morphs, which are then annotated with syntactic information and glosses. We mostly focus on the former task, assuming a two-step process: first, the computation of a phonemic transcript that we assume is given; then the segmentation into words for which we consider two settings: batch and online learning. The word and morpheme segmentation tasks are closely related and rely on similar tools: using the Japhug corpus, which contains both levels of segmentations, we also study the implications of using lists of words vs morphemes as weak supervision.

In its baseline form, the word segmentation process is fully unsupervised, and the only training material is a set of transcribed sentences (see Fig. 1).

We rely on Bayesian non-parametric approaches to word segmentation (see (Cohen, 2016) for a thorough exposition), and our baselines are the unigram version of the `dpseg` model (Goldwater et al., 2009) and a variant where the underlying Dirichlet Process is replaced by a Pitman-Yor Process as in (Neubig, 2014). We selected unigram models for their simplicity, which (a) makes them amenable to the processing of very small sets of sentences; (b) makes the online learning setting tractable. While using higher-order models or more sophisticated models of the same family (Teh, 2006b; Mochihashi et al., 2009) may improve the performance (see (Godard et al., 2016) for an experimental comparison), we believe that in our low-resource conditions, these variations would be small[2] and would not change our main conclusions.

Word segmentation models fundamentally rely on probabilistic models for word sequences defining $P(\boldsymbol{w} = w_1 \dots w_T)$; word sequences can also be viewed as segmented sequences of characters $\boldsymbol{y} = y_1 \dots y_L$, so that the same model can be used for the joint probability of $(\boldsymbol{y}, \boldsymbol{b})$, with $\boldsymbol{b} = b_1 \dots b_L$ representing the vector of boundary locations where value $b_t = 1$ (resp. $b_t = 0$) denotes a boundary (resp. no boundary) after symbol y_t. In an unsupervised setting, these boundaries are hidden and are latent variables in the model. Such models lend themselves well to Gibbs sampling, which repeatedly produces samples of each boundary given all the other boundaries in the corpus.

In `dpseg`, the underlying sequence model is a unigram model: $P(w_1 \dots w_T) = \prod_{t=1}^{T} P(w_t)$. The probability of individual words corresponds to a Dirichlet Process with parameters α, the *concentration* parameter, and P_0, the *base distribution*, and yields the following formulation for the conditional probability of w_t given the past words $\boldsymbol{w}_{<t}$:

$$P(w_t = w | \boldsymbol{w}_{<t}) = \frac{n_w(\boldsymbol{w}_{<t}) + \alpha P_0(w)}{t + \alpha - 1}, \quad (1)$$

where $n_w(\boldsymbol{w}_{<t})$ counts the number of times w has occurred in the past. With lower values of α, the most frequent words tend to be generated more (hence, concentration), while with higher values, the words are more smoothly distributed. P_0, the base distribution, assigns scores to arbitrary character strings; Goldwater et al. (2009) use a length model and a uniform character model. For word w made of characters $y_1, ..., y_m$, P_0 is computed as:

$$P_0(w) = \underbrace{p_\#(1 - p_\#)^{m-1}}_{\text{length model}} \underbrace{\prod_{j=1}^{m} P(y_j)}_{\text{character model}} \quad (2)$$

where $p_\#$ is the probability to end the word.

For this model, Gibbs sampling compares at each position t two sequences of words $\boldsymbol{w}_{t=0}$ (no boundary at position t) and $\boldsymbol{w}_{t=1}$ (a boundary is inserted). As these sequences only differ minimally, terms such as $P(b_t = 0 | \boldsymbol{y}, \boldsymbol{b}_{-t})$ are readily derived (see e.g. (Goldwater et al., 2009)). Gibbs sampling is performed for a number of iterations that are sufficient to reach convergence, and we use the last iteration to uncover the resulting segmentation. To speed up mixing, Goldwater et al. (2009) also use annealing, so that a larger search space is explored.

An extension of `dpseg`, denoted `pypseg`, uses a Pitman-Yor Process (PYP) instead of the Dirichlet Process and generalises equation (1) with an additional *discount* parameter, which enables to better control the generation of new words. PYPs are introduced in (Teh, 2006b; Mochihashi et al., 2009); a fast implementation is in (Neubig, 2014). For our experiments, both models have

---

[2] Godard et al. (2018a) report results with the bigram version of dpseg on the Mboshi corpus; the difference with our unigram version is about 4 points for the boundary F-score.

$\boldsymbol{y} =$	b$_1$	á$_2$	a$_3$	á$_4$	m$_5$	i$_6$	k$_7$	ú$_8$	n$_9$	d$_{10}$	á$_{11}$	p$_{12}$	o$_{13}$	o$_{14}$	y$_{15}$	á$_{16}$	k$_{17}$	a$_{18}$	l$_{19}$	a$_{20}$
$\boldsymbol{b} =$	0	0	1	0	0	**0**	0	0	0	0	1	0	0	1	0	1	0	0	0	1
$\boldsymbol{w}_{6=0}$	báa			ámikúndá								poo			yá		kala			
$\boldsymbol{b} =$	0	0	1	0	0	**1**	0	0	0	0	1	0	0	1	0	1	0	0	0	1
$\boldsymbol{w}_{6=1}$	báa			ámi			kúndá					poo			yá		kala			

Figure 1: The sentence segmentation task illustrated with a sentence from the Mboshi corpus: 'báa ámikúndá poo yá kala' ('*they found the old village*'). The two possible segmentations only differ in one boundary at position $t = 6$, one ($w_{6=0}$) where 'ámikúndá' is one single unit and one ($w_{6=1}$) where it is split in two.

been re-implemented in Python. This implementation is available at `https://github.com/shuokabe/pyseg`.

3 Supervising word segmentation

In this section, we discuss realistic sources of weak supervision for segmentation tasks and how they can be included in Bayesian models.

3.1 Finding supervision information

Segmentation boundaries Segmentation data, corresponding to the location of boundary (and non-boundary) information, can be obtained in different ways. For instance, when audio recordings are available, prosodic cues such as short silences or specific intonative patterns can serve to identify plausible locations for word endings. Longer pauses generally denote the end of an utterance, which we assume are already given. This would yield a *sparse partial annotation*, where supervision data is randomly scattered across the corpus.

Another realistic situation where we have access to a partial annotation is when a small subset is already segmented. In this case, the partial annotation is *dense* and concentrated in a few sentences, a semi-supervised setting also studied in (Sirts and Goldwater, 2013). We thus consider two questions: (a) which is more effective between dense and sparse annotations? (b) how effective is supervision in an incremental learning regime, where automatic (dense) annotations are progressively corrected and used to update the model?

Word lists Word lists constitute another valuable and common source of information. They may contain morphs, morphemes, lexemes or fully inflected forms, with various levels of information (part-of-speech, gloss, translation, etc.). In this study, we consider that lists of *surface forms* are available and evaluate their usefulness, depending on their size and on the way they were collected. A related question is about the relative interest of word and morph lists, which we study in Section 5.3. The use of more sophisticated forms of lexical information regarding word structure, PoS, is out of the scope of this paper and is left for future work.

Having a collection of fully segmented utterances, as discussed above, is another way to generate word lists. So these two sources of information must be viewed as complementary ways to supervise the task at hand: boundary marks at the token level, word list at the type level.

3.2 Forms of Weak Supervision

Segmentation boundaries Observed segmentation boundaries can be used to facilitate the training process. Two experimental conditions, both affecting the Gibbs sampler (`gs`), have been considered:

- `gs.sparse`: a fraction (λ%) of the actual boundaries are observed, which corresponds to a sparse annotation scenario.
- `gs.dense`: for λ% of sentences, all boundary and non-boundary variables are given.

In both cases, we modify the sampling process and make sure that the value of observed variables is not sampled, as in (Sirts and Goldwater, 2013).

Using a word list Assuming now that a word list D is available, we consider the following approaches to reinforce the likelihood of units in D in the output segmentation:

- `d.count`: D is used to initialise the 'internal' model dictionary, and words in D are created with a fixed pseudo-count of value λ. Formally, $\forall w \in D$, the counting function $n_w()$ of Equation (1) will add λ to their actual count.
- `d.mix`: D is combined with the base distribution, resulting in the following mixture P_0':

$$P_0'(w) = \frac{\lambda}{|D|}\mathbb{1}_{\{w \in D\}} + (1-\lambda)P_0(w), \quad (3)$$

where $\lambda \in [0,1]$, $|D|$ is the size of D, and $\mathbb{1}_{\{w \in D\}}$ is the indicator function testing membership in D. As for `d.count`, P'_0 increases the probability of words in D, but in a looser way, due to the term αP_0 in Equation (1).

- `d.ngram`: the baseline `dpseg` version uses a uniform character model for P_0 (Equation (2)); here, we use D to train a character n-gram language model (LM), with $n = 2$ and add-k smoothing in our experiments.

- `d.mix+ngram`: this method combines `d.mix` and `d.ngram`: P_0 is replaced with the mixture P'_0 of Equation (3) and the character model is an n-gram LM. This can be viewed as a proxy to the complete nested Dirichlet Process of Mochihashi et al. (2009), with D implementing a cache mechanism for known words.

We have also used weaker forms of supervision aimed at learning a better length model, with hardly any improvement with respect to the baseline; these results are not reported below.

3.3 Incremental training

In addition to the static use of supervision information described above, we also considered a more dynamic training regime, where dense annotations are provided in a sequential manner through interaction with an expert linguist, enabling incremental learning. To measure the effectiveness of this approach, we contrast three scenarios in Section 5.2:

- the baseline is the post-edition of a fully unsupervised model without further training;

- the post-edition of a fully unsupervised model, with additional Gibbs sampling iterations every batch utterances for iter iterations. This aims at propagating forward the supervision information obtained from past annotations. This method is referred to as `o.regular`.

- on top of this, we also used the past annotated sentences to reestimate the base distribution of the underlying process as in `d.ngram`. The corresponding results are labelled `o.2level` in Figure 2.

4 Experimental settings

4.1 Linguistic material

Two languages have been considered in this paper: Mboshi and Japhug.

Mboshi is a tonal Bantu language spoken in the Republic of Congo (Bantu C25). The data has been collected as part of the BULB project (Adda et al., 2016). It has seven vowels and 25 consonant phonemes with five prenasalised consonants (made of two to three consonants), a common feature in Bantu languages (Embanga Aborobongui, 2013; Kouarata, 2014). Although the language is usually not written, linguists have transcribed it with graphemes in a way that approximates the phonetic content. To mark the distinction between long and short vowels, they were either duplicated (VV) or not (V). One challenge for Mboshi word segmentation is its complex phonological rules, notably, vowel elision patterns whereby a vowel disappears before another one (also a common Bantu feature) (Rialland et al., 2015). This kind of phenomenon makes it harder to find the boundaries.

From a morphological point of view, words are composed of roots and affixes. Another characteristic Bantu feature is its deletion rule for class-prefix consonants in nouns. Templates for verb structure are also quite rigid, with affixes following a strict ordering (Godard et al., 2018a).

Our corpus is a manual alphabetic transcription of audio recordings.[3] It contains 5,312 sentences segmented in words, one sentence per line.

Japhug is a Sino-Tibetan language from the Gyalrong family spoken in the Sichuan province in China. Japhug has eight vowels and 50 consonant phonemes, which can combine to create a large number (more than 400) of consonant clusters. The rich cluster feature is one important characteristic of Japhug, which actually has one of the largest inventory of consonant clusters in the Trans-Himalayan language family. The structure of these clusters can be analysed by looking at patterns of partial reduplication of syllable initial consonants. There are no tones in this language.

Japhug also has a rich morphology, both for verbs and nouns. Remarkably, in verb forms, up to six or seven prefixes can be chained to express features such as tense, aspect, modality, while suffixation is used to express inflectional phenomena.

---

[3] Download from: `https://www.islrn.org/resources/747-055-093-447-8/`.

Even though these processes are quite regular, they contribute to generating a large number of possible word forms. Recordings, annotated corpora, and dictionaries for Japhug are available from the Pangloss collection.[4] An extensive description of the language is given in (Jacques, 2021).[5]

Our training material has been extracted from the LaTeX source files of this book, by collecting all Japhug examples. These can easily be retrieved by searching the `\gll` command introducing Japhug sentences. Not only are the resulting sentences well-curated, but they are also segmented at two levels: words and morphemes. This will lead to a specific experiment presented in Section 5.3.

language	Mboshi	Japhug	
segment	word	word	morph.
N_{utt}	5130	3628	3628
WL	4.19	4.73	2.90
TL	6.39	7.30	5.41
N_{type}	5312	6739	2731
N_{token}	30556	28579	46632

Table 1: Statistics for the Mboshi and Japhug corpora. For the latter, we use the word-based and morpheme-based segmentations.

Table 1 displays the general statistics for the two languages. N_{utt}, N_{type}, and N_{token} represent the number of utterances, of word types, and of word tokens, respectively. WL represents the average token length, while TL is the average type length. The sentences used for semi-supervision correspond to the first 200 sentences of each dataset, which is a realistic amount of data. Likewise, lexical supervision corresponds to the list of words observed in the same 200 sentences, and respectively contain 517 words for Mboshi, 664 words and 493 morphemes for Japhug.

4.2 Model settings

In our experimental setting, we made sure to also resample the hyperparameter(s) after each iteration, following mostly (Teh, 2006a; Mochihashi et al., 2009): the concentration parameter α has a Gamma posterior distribution, and the discount parameter d a Beta distribution. The initial values of the hyperparameters were set as in Goldwater et al.'s work on the unigram `dpseg`: concentration parameter: $\alpha = 20$, $p_{\#} = 0.5$, discount parameter for `pypseg`: $d = 0.5$. The Gibbs sampler always runs for 20,000 iterations and simulated annealing is implemented as in (Goldwater et al., 2009) with 10 increments of temperature.

All the results are obtained by collecting the predicted boundaries at the end of the last sampling iteration of one single run.

4.3 Evaluation metrics

Following Goldwater et al. (2009), evaluation relies on 'PRF' metrics: precision, recall, and F-score, defined as follows: precision $P = \frac{TP}{TP+FP}$, recall $R = \frac{TP}{TP+FN}$, and F-score $F = 2 * \frac{precision*recall}{precision+recall}$, where TP are the true positives (match in the reference and segmented texts), FP are the false positives, and FN are the false negatives. These metrics are computed at three levels:[6]

- boundary level (BP, BR, BF): compare the reference boundary vectors with the predictions;
- token level (WP, WR, WF): compare word in the reference and segmented sentences: a correct match requires two correct boundaries;
- type level (LP, LR, LF): compare the set of unique words in the reference and segmented utterances.

To have an overall view of the output text, we also report the average type and token lengths (TL and WL) as well as their counts (N_{type} and N_{token}), as in Table 1. Numbers are computed on the entire text (including the supervised part).

5 Results

This section presents the results for the models presented above. We also report the performance of SentencePiece, another word segmentation tool based on a unigram language model (Kudo, 2018):[7] To boost this baseline, the vocabulary size has been set to the *reference number* of N_{type} (cf. Table 1). Supplementary material additionally contains results for Morfessor baselines (Creutz and Lagus, 2002), with the corresponding weak supervision. As a reminder, our supervision here consists of the first 200 sentences in the text, either directly given as observed boundaries or used to generate the initial word list.

5.1 Using weak supervision

5.1.1 dpseg

Table 2 displays our experimental results for the 5K Mboshi corpus for SentencePiece (SP), `dpseg` and `pypseg` with various amounts of supervision.

First, the unsupervised `dpseg` model has better results than SP on all three levels by a significant margin. SP, on the other hand, produces more types as it 'knows' the actual number of types to generate.

Regarding segmentation boundaries, the `gs.sparse` model has disappointing results, with scores lower than the baseline. On the other hand, the dense supervision manages to improve the baseline scores by around 2.5 points for BF, 4.5 points for WF, and 7.5 points for LF. This is an encouraging result, since, with less than 5% of the whole text, the model has improved in a noticeable way, especially at type level, which seems to be difficult for fully unsupervised learning.

When supervising with a word list, all models but `d.2gram` outperform the baseline. Yet, the `d.count` and `d.mix` methods have lower scores than the `gs.dense`: this was expected for BF and WF—where directly supervising boundaries is likely to be more useful than an indirect one, but less so for LF. Regarding the `d.2gram` model, its poor BF and WF scores are more than compensated by an increase of around 12 points in LF, showing the impact of a better type model. Finally, by combining the `d.mix` and `d.2gram` strategies, `d.mix+2gram` obtains the overall best results.

5.1.2 pypseg

Results are in the right part of Table 2, where the baseline is the fully unsupervised `pypseg`. It slightly outperforms `dpseg` by less than 1 point in terms of F-scores. In our setting, although PYP increases the number of discovered types, it does not improve the performance in any significant manner.

This trend is confirmed for weakly supervised models:[8] the `gs.dense` model is the only one benefiting from a small improvement in all F-scores. `d.count` underperforms both the baseline and its `dpseg` version. With worsened BF and WF scores compared to the baseline, `d.mix+2gram` with `pypseg` is worse than with `dpseg`. Overall, the former seems to benefit less from annotations than the latter.

The performance of the bigram character model is noteworthy both with `dpseg` and `pypseg`. This improvement alone (i.e. `d.2gram`) is responsible not only for a large increase in LF, but also for an average type length that gets much closer to its true value (6.39 in the reference, 6.60 with `dpseg` and `d.mix+2gram`).

5.1.3 Results for Japhug

Table 3 displays a selection of results for Japhug (segmented in words). As previously observed, supervision noticeably improves the results for both models, with `pypseg` outperforming `dpseg` by a small margin on all metrics.[9] Note also that SP is much worse than Bayesian models, only reaching the same F-score as `dpseg` for the LF metric.

The best results are obtained with lexical supervision and the `d.mix+2gram` model for `dpseg`: it combines the type boost in P_0' from `d.mix` and the improved base model from `d.2gram`.

5.2 Incremental learning

Figure 2 displays the evolution of the boundary error rate (number of errors over 100 sentences / length of the 100 sentences) as more annotated sentences are available, for three contrasts of § 3.3 (baseline, `o.regular`, and `o.2level`). We use the `dpseg` model and 50 complementary Gibbs sampling iterations every 100 sentences.

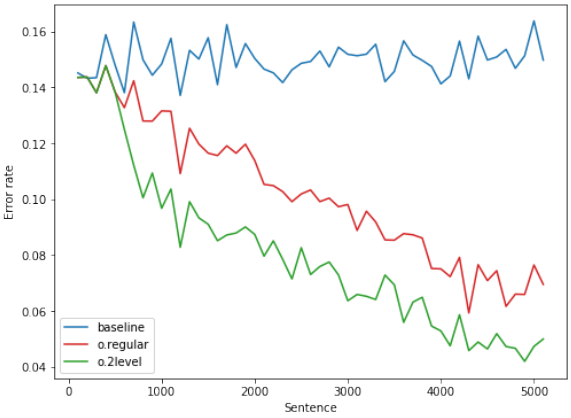

Figure 2: Average loss over 100 sentences on the 5K Mboshi text with incremental training ($\text{batch} = 100$, $\text{iter} = 50$)

While the baseline error rate (in blue) remains the same throughout training, both supervised models show a sharp decrease, from 0.14 to about 0.06. The large drop at the beginning for the `o.2level`

---

[8] We do not report the results of `d.mix` and `d.2gram` but their combination `d.mix+2gram`, due to space limitation.

model (green) can be attributed to the use of the bigram character model. It gives this model an initial edge over `o.regular` that remains significant for the first 3,000 sentences. Here again, the benefits of improving the base distribution (character-based model) as much as possible in the early training iterations clearly appear.

5.3 Supervising words and morphemes

This section addresses a recurring issue in word segmentation model related to the linguistic nature of the units learnt by the model and the consequences of choosing one or the other reference in training. The Japhug corpus contains both annotation levels and is a perfect test bed for this study. We have thus used a segmentation model (`dpseg`) with and without weak supervision (using the `d.mix+2gram` variant) at the level of words or morphemes, and the results are also evaluated against the two references (a segmentation in words or in morphemes). Results are in Table 4.

In the unsupervised setting, segmentation metrics are markedly better with morpheme-based references, especially for the LF metric. This again shows the tendency of the unigram model to oversegment the training sentences.

With word supervision, we observe a shift in behaviour that is consistent with the provided annotations: better word-level metrics with word-based annotations, and accordingly, a decrease of performance for morpheme-based scores. With morpheme supervision, results are more contrasted: an improvement for word segmentation (because some words are also morphemes) that is not matched for morpheme boundaries. Looking at the detailed results (see appendix A.1, Table 7), one can see that this is due to an undersegmentation, which yields a poor recall at the boundary and token levels. Here, the main remaining benefit of supervision is an increase in the LF score.

These preliminary results suggest that considering only one type of boundary is a too naive view of the segmentation process and does not allow us to fully benefit from annotated data. They call for models that would carefully distinguish boundaries within words and between words, with appropriate supervision for each of these levels.

5.4 Error analysis

It is noteworthy that dictionary supervision almost deterministically ensures that the input word types will occur in the segmented output. For instance, 96% of the words in the Mboshi supervision dictionary are found in the output of the `d.mix+2gram` method, whereas we only find 44% with fully unsupervised learning. Similar trends are observed for Japhug. Some remaining errors are, however, observed: in the example of Figure 3, the word ‘bana’ belongs to the supervision dictionary but remains attached to the following word ‘ba’. Additional examples are in appendix A.2. This may be because both words ‘bana’ and ‘ba’ often occur together, a cooccurrence that can not be captured by our unigram model (Goldwater et al., 2009).

6 Related work

Unsupervised segmentation is a generic NLP task that can be performed at multiple levels of analysis: a document segmented in sections, a speech segmented in utterances, an utterance segmented in words, a word segmented in morphemes, syllables or phonemes. It has been studied in multiple ways, and we report here recent work related to word discovery for language documentation, noting that the same methods also apply to the unsupervised segmentation of continuous speech into ‘words’ (de Marcken, 1996) which has given rise to a vast literature on language acquisition. Recently, this task has become central in preprocessing pipelines, with new implementations of simple models (Sennrich et al., 2016; Kudo and Richardson, 2018).

Linear segmentation models in the Bayesian realm can be traced back to (Goldwater et al., 2006, 2009). They were extended with nesting in (Mochihashi et al., 2009), where the base distribution of the Dirichlet Process is a char-based nonparametric model; and in (Uchiumi et al., 2015; Löser and Allauzen, 2016), who consider hidden state variables in the word generation process. This extension enables, for instance, to jointly learn segmentation and PoS tagging or to introduce some morphotactics in the model. Other sources of weak supervisions along these lines concern the use of higher-order n-grams and of prosodic cues (Doyle and Levy, 2013). Finally, (Börschinger and Johnson, 2012) (with particle filtering techniques) and (Neubig, 2014) (with block sampling) study ways to speed up inference.

The unsupervised techniques exposed in Section 2 only depend on the design of a probabilistic word generation process. This means that they are also readily applicable when this process is conditioned to some input, for instance, when a translation is available as an additional information source. This setup is notably studied in (Neubig et al., 2011; Stahlberg et al., 2012), and also considered, with radically different tools, in (Anastasopoulos and Chiang, 2017; Godard et al., 2018c).

A somewhat richer trend of works aimed at informing word segmentation relies on the model of adaptor grammars (AG) of Johnson et al. (2007), applied to the segmentation task as early as (Johnson, 2008). AGs generalise finite-state models such as `dpseg` and `pypseg` by modelling trees and subtrees, rather than mere strings. Their use necessitates a context-free description of the language, which enables to integrate information regarding word and syllable structures. Even generic descriptions can be useful, but finding the most appropriate and effective one is challenging (Johnson and Goldwater, 2009; Eskander et al., 2016). This formalism has also been used to introduce syntactic information (Johnson et al., 2014), prosodic information (Börschinger and Johnson, 2014), and partial annotations (Sirts and Goldwater, 2013). Recent software packages for AGs are presented in (Bernard et al., 2020) and (Eskander et al., 2020). Using AGs comes, however, with a high computational price, as the Gibbs sampling process typically requires repeated parses of the corpus, even though cheaper estimation techniques may also be considered (Cohen et al., 2010). As our goal is to integrate learning techniques in interactive annotation tools, AGs were not deemed appropriate, and we explored simpler alternatives.

Similar arguments apply to the use of neural networks, which have attracted a growing interest even for very low-resource languages, combining supervised segmentation methods (Moeng et al., 2021; Liu et al., 2021) with cross-lingual transfer or data augmentation techniques (Silfverberg et al., 2017; Kann et al., 2018; Lane and Bird, 2020).

7 Conclusion and outlook

In this work, we have studied various ways to use weak supervision for automatic word segmentation. In language documentation scenarios, such supervision is often available, taking the form of a partial annotation or word lists. Bayesian non-parametric models lend themselves well to this setting, and our experiments have shown that two variants of a simple unigram model were getting a substantial boost from weak supervision, a result that has been obtained with two languages currently being documented. The most effective approach seems to start with a small set of fully segmented data, which helps learning in two ways: as a training signal for segmentation and as lexical prior for the base distribution. Based on this observation, we have further evaluated the longer-term benefits of an incremental training regime and also contrasted the improvement obtained using a word-based vs a morpheme-based vocabulary list.

Our future work will continue to explore the interplay between word and morpheme segmentations, as both are required in actual documentation settings, possibly extending our analyses on additional languages. We will also consider supervising the annotation process with lists of *non-inflected forms*, which requires to jointly learn inflectional patterns and segmentation. Finally, our main objective remains to integrate these techniques into an annotation platform and evaluate how much they help speed up the annotation process, hence the need to control the run-time of our algorithms.

Acknowledgements

This work was partly funded by French ANR and German DFG under grant ANR-19-CE38-0015 (CLD 2025). The authors wish to thank Alexis Michaud and Guillaume Jacques for their help in preparing the Japhug corpus.

A Appendix

A.1 Full results

Table 5 displays the complete results of Table 2 with both precision and recall for the three evaluation levels. SentencePiece (SP) tends to have more balanced scores for precision and recall, whereas `dpseg` displays a wider gap between the two metrics, especially at type level.

The 'Morf' column displays the performance of Morfessor 2.0 (Creutz and Lagus, 2002; Smit et al., 2014).[10] These results have been obtained with the morph-length parameter set to the observed average token length (4.19). This setting led to better F-scores than using the gold number of types for num-morph-types or the default Morfessor model. The Morfessor model outperforms SentencePiece significantly for both boundary (BF) and token (WF) F-scores, while it lags behind for the type-based metrics. Compared to the unsupervised `dpseg`, Morfessor is worse on all accounts by a wide margin.

Table 6, in turn, displays the complete results of Table 3, again with both precision and recall for the three evaluation levels.

The 'Morf' column in Table 6 also represents the Morfessor results, with a morph-length parameter of 4.73. Here again, Morfessor outperforms SentencePiece on the boundary and token-level F-scores (to a smaller extent) but not at type level.

Finally, Table 7 displays the complete results for the word and morpheme experiment (Table 4).

segmented, affecting the second word, 'amipasa'. In the supervised model with `d.mix+2gram`, the word is correctly segmented as 'obengi', and the second word is also correct, although not in the supervision dictionary.

Figure 5 presents two of the 200 sentences used for supervision in Mboshi. This means that all the words in the example are in the supervision dictionary, which can explain why words such as 'owoi', 'atyeeli', or 'lekonyi' are correctly segmented in the weakly supervised setting. Yet, some errors remain (e.g. 'adimo' instead of 'adi mo') mainly because of the cooccurrence effect.

reference	atyeeli adi mo lekonyi
unsupervised	at yee li adi mole konyi
supervised	atyeeli adimo lekonyi
reference	nɯ owoi dzue la baa
unsupervised	nɯ o wo i dzuela baa
supervised	nɯ owoi dzue la baa

Figure 5: Examples of Mboshi sentences used for supervision (here, `d.mix+2gram`): '*Termite workers are on the dead wood*' and '*Did you listen to their voices?*'

A.3 Computing environment

Our experiments have been carried out on an Intel® Xeon® Processor E5-2643 v3 (6 cores and 12 threads). With this processor, the baseline `dpseg` model on the 3K Japhug corpus takes around 10 hours for 20,000 iterations of Gibbs sampling.

All results in this paper have been obtained with a random seed of 42. The remaining parameters are presented in Section 4.2.

SciNLI: A Corpus for Natural Language Inference on Scientific Text

Mobashir Sadat and Cornelia Caragea
Computer Science
University of Illinois Chicago
msadat3@uic.edu cornelia@uic.edu

Abstract

Existing Natural Language Inference (NLI) datasets, while being instrumental in the advancement of Natural Language Understanding (NLU) research, are not related to scientific text. In this paper, we introduce SciNLI, a large dataset for NLI that captures the formality in scientific text and contains $107,412$ sentence pairs extracted from scholarly papers on NLP and computational linguistics. Given that the text used in scientific literature differs vastly from the text used in everyday language both in terms of vocabulary and sentence structure, our dataset is well suited to serve as a benchmark for the evaluation of scientific NLU models. Our experiments show that SciNLI is harder to classify than the existing NLI datasets. Our best performing model with XLNet achieves a Macro F1 score of only 78.18% and an accuracy of 78.23% showing that there is substantial room for improvement.

1 Introduction

Natural Language Inference (NLI) or Textual Entailment (Bowman et al., 2015) aims at recognizing the semantic relationship between a pair of sentences—whether the second sentence entails the first sentence, contradicts it, or they are semantically independent. NLI was introduced (Dagan, Glickman, and Magnini, 2005) to facilitate the evaluation of Natural Language Understanding (NLU) that significantly impacts the performance of many NLP tasks such as text summarization, question answering, and commonsense reasoning.

To date, several NLI datasets are made available (Bowman et al., 2015; Williams, Nangia, and Bowman, 2018; Marelli et al., 2014; Dagan, Glickman, and Magnini, 2005). These datasets have not only been instrumental for developing and evaluating NLI models but also have been useful in advancing many other NLP areas such as: representation learning (Conneau et al., 2017), transfer learning (Pruksachatkun et al., 2020) and multi-task learning (Liu et al., 2019a).

However, despite their usefulness, none of the existing NLI datasets is related to scientific text that is found in research articles. The vocabulary as well as the structure and formality used in sentences in scientific articles are very different from the sentences used in the everyday language. Moreover, the scientific text captured in research papers brings additional challenges and complexities not only in terms of the language and its structure but also the inferences that exist in it which are not available in the existing NLI datasets. For example, a sentence can present the reasoning behind the conclusion made in the previous sentence, while other sentences indicate a contrast or entailment with the preceding sentence. These inferences are crucial for understanding, analyzing, and reasoning over scientific work (Luukkonen, 1992; Kuhn, 2012; Hall, Jurafsky, and Manning, 2008). Therefore, ideally, the scientific language inference models should be evaluated on datasets which capture these inferences and the particularities seen only in scientific text.

To this end, we seek to enable deep learning for natural language inference over scientific text by introducing SciNLI,[1] a large dataset of $107,412$ sentence pairs extracted from scientific papers related to NLP and computational linguistics (CL) and present a comprehensive investigation into the inference types that occur frequently in scientific text. To capture the inference relations which are prevalent in scientific text but are unavailable in the existing NLI datasets, we introduce two new classes—CONTRASTING and REASONING. We create SciNLI by harnessing cues in our data in the form of linking phrases between contiguous sentences, which are indicative of their semantic relations and provide a way to build a labeled dataset using distant supervision (Mintz et al., 2009). Class	First Sentence	Second Sentence	Linking Phrase
CONTRASTING	Essentially, that work examines how a word gains new senses, and how some senses of a word may become deprecated.	here we examine how different words compete to represent the same meaning, and how the degree of success of words in that competition changes over time.	'In contrast,'
REASONING	The Lang-8 corpus has often only one corrected sentence per learner sentence, which is not enough for evaluation.	we ensured that our evaluation corpus has multiple references.	'Thus,'
ENTAILMENT	As a complementary area of investigation, a plausible direction would be to shift the focus from the decomposition of words into morphemes, to the organization of words as complete paradigms.	instead of relying on sub-word units, identify sets of words organized into morphological paradigms (Blevins, 2016)."	'That is,'
NEUTRAL	Literature on the topic of the current study spans across many areas, including verb classification, semiotics, sign language and learning.	abstract words can be more challenging to learn and memorise.	N/A

Table 1: Examples of sentence pairs from our dataset and the linking phrases used to extract them, corresponding to all four classes considered. The second sentence of each pair is shown after removing the linking phrase.

ing training, we directly utilize these (potentially noisy) sentence pairs, but to ensure a realistic evaluation of the NLI models over scientific text, we manually annotate 6,000 sentence pairs. These clean pairs are used in two splits, 2,000 pairs for development and hyper-parameter tuning and 4,000 pairs for testing. Table 1 shows examples from our dataset corresponding to all of our four classes.

We evaluate SCINLI by experimenting with traditional machine learning models using lexical and syntactic features, neural network models—BiLSTM, CBOW, CNN, and pre-trained language models—BERT (Devlin et al., 2019), SciBERT (Beltagy, Lo, and Cohan, 2019), RoBERTa (Liu et al., 2019b), and XLNet (Yang et al., 2019). Our findings suggest that: (1) SCINLI is harder to classify than other datasets for NLI; (2) Lexical features are not enough for a model to achieve satisfactory performance on SCINLI and deep semantic understanding is necessary; (3) SCINLI is well suited for evaluating scientific NLI models; and (4) Our best performing model based on XLNet shows 78.18% Macro F1 and 78.23% accuracy illustrating that SCINLI is a challenging new benchmark.

2 Related Work

To date, several datasets exist for NLI of varying size, number of labels, and degree of difficulty. Dagan, Glickman, and Magnini (2006) introduced the RTE (Recognizing Textual Entailment) dataset of text-hypothesis pairs from the general news domain and considered two labels: entailment or no-entailment (i.e., a hypothesis is true or false given a text). The RTE dataset is paramount in developing and advancing the entailment task. The SICK (Sentences Involving Compositional Knowledge) dataset introduced by Marelli et al. (2014) was created from two existing datasets of image captions and video descriptions. SICK consists of sentence pairs (premise-hypothesis) labeled as: entailment, contradiction, or neutral. Despite being instrumental in the progress of NLI, both RTE and SICK datasets are less suitable for deep learning models due to their small size.

In recent years, SNLI (Bowman et al., 2015) and MNLI (Williams, Nangia, and Bowman, 2018) are the most popular datasets for training and evaluating NLI models, in part due to their large size. Similar to SICK, SNLI is derived from an image caption dataset where the captions are used as premises and hypotheses are created by crowdworkers, with each sample being labeled as: entailment, contradiction, or neutral. MNLI is created in a similar fashion to SNLI except that the premises are extracted from sources such as face-to-face conversations, travel guides, and the 9/11 event, to make the task more challenging and suitable for domain adaptation. More recently, Nie et al. (2020) released ANLI which was created in an iterative adversarial manner where human annotators were used as adversaries to provide sentence pairs for which the state-of-the-art models make incorrect predictions. Unlike the datasets specific to classifying the relationships between two sentences, Zellers et al. (2018) combined NLI with commonsense reasoning to introduce a new task of predicting the most likely next sentence from a number of options along with their new dataset called SWAG which was also created with an adversarial approach. However, different from ANLI, the SWAG approach was automatic. All these datasets have been widely used for evaluating NLU models and many of them appear in different NLU benchmarks such as GLUE (Wang et al., 2018) and SUPERGLUE (Wang et al., 2019).

Heretofore, Khot, Sabharwal, and Clark (2018) created the only NLI dataset related to science. Their dataset, SCITAIL was derived from a school level science question-answer corpus. As a result, the text used in SCITAIL is very different from the type of text used in scientific papers. Furthermore, the sentence pairs in SCITAIL are classified into one of two classes: entailment or no-entailment. Thus, SCITAIL does not cover all the inference relationships necessary to understand scientific text.

In other lines of research, discourse cues, e.g., linking phrases have been previously used to extract inter-sentence and/or inter-clause semantic relations in discourse parsing (Hobbs, 1978; Webber et al., 1999; Prasad et al., 2008; Jernite, Bowman, and Sontag, 2017; Nie, Bennett, and Goodman, 2019), causal inference (Do, Chan, and Roth, 2011; Radinsky, Davidovich, and Markovitch, 2012; Li et al., 2020; Dunietz, Levin, and Carbonell, 2017) and why-QA (Oh et al., 2013). However, none of the aforementioned bodies of research investigates these relations in scientific text, nor do they exploit the discourse cues to create NLI datasets. Furthermore, discourse parsing studies a broader range of semantic relations, many of which are unrelated to the task of NLI while causal inference and why-QA are limited to only cause-effect relations. In contrast to these tasks, we focus on the semantic relations which are either relevant to the task of NLI or highly frequent in scientific text and leverage linking phrases to create the first ever scientific NLI dataset, which we call SCINLI.

3 SCINLI: A New Corpus for NLI

In order to better understand the inter-sentence relationships that exist in scientific text, we started the process of creating our dataset by perusing through scientific literature with the intent of finding clues that are revealing of those relationships. We found that to have a coherent structure, authors often use different linking phrases in the beginning of sentences, which is indicative of the relationship with the preceding sentence. For example, to elaborate or make something specific, authors use linking phrases such as "In other words" or "In particular," which indicate that the sentence supports or entails the previous sentence. We also found that some linking phrases are used to indicate additional relationships that are prevalent in scientific text but are not captured in the existing NLI datasets. For instance, when a sentence starts with "Therefore" or "Thus," it indicates that the sentence is presenting a conclusion to the reasoning in the previous sentence. Similarly, the phrase "In contrast" is used to indicate that the sentence is contrasting what was said in the previous sentence.

Therefore, inspired by the framework of discourse coherence theory (Hobbs, 1978; Webber et al., 1999; Prasad et al., 2008) that characterizes the inferences between discourse units, we extend the NLI relations commonly used in prior NLI work—entailment, contradiction, and semantic independence—to a set of inference relations that manifest in scientific text—contrasting, reasoning, entailment, and semantic independence (§3.1). In order to create a large training set with minimal manual effort, we employ a distant supervision method based on linking phrases that are commonly used in scientific writing and are indicative of the semantic relationship between adjacent sentences (§3.2). We avoid the noise incurred by the distant supervision method in our development and test sets by manually annotating these sets (§3.3).

3.1 Inference Classes

We define the inference classes used to create our dataset in this section.

3.1.1 CONTRASTING

Our CONTRASTING class is an extension of the CONTRADICTION class in the existing NLI datasets. With this class, in addition to contradicting relations between sentences in a pair, we aim to capture inferences that occur when one sentence mentions a comparison, criticism, juxtaposition, or a limitation of something said in the other sentence. We can see an example of a sentence pair from our CONTRASTING class in Table 1. Here, the authors discuss how their work differs from the other work mentioned in the first sentence thereby making a comparison between the two works.

3.1.2 REASONING

The examples where the first sentence presents the reason, cause, or condition for the result or conclusion made in the second sentence are placed in

Label	Linking Phrases
CONTRASTING	'However', 'On the other hand', 'In contrast', 'On the contrary'
REASONING	'Therefore', 'Thus', 'Consequently', 'As a result', 'As a consequence', 'From here, we can infer'
ENTAILMENT	'Specifically', 'Precisely', 'In particular', 'Particularly', 'That is', 'In other words'

Table 2: Linking phrases used to extract sentence pairs and their corresponding classes.

our REASONING class. In Table 1, we can see an example where the authors mention that they use a multi-reference corpus for evaluation in the second sentence and provide the reason behind it in the first sentence.

3.1.3 ENTAILMENT

Our ENTAILMENT class includes the sentence pairs where one sentence generalizes, specifies or has an equivalent meaning with the other sentence. An example from this class can be seen in Table 1. In the example, the second sentence is specifying the proposed direction mentioned in the first sentence making the pair suitable for our ENTAILMENT class.

3.1.4 NEUTRAL

The NEUTRAL class includes the sentence pairs which are semantically independent. We can see an example from this class in Table 1. Here, the first sentence discusses the span of the literature of a particular topic, whereas the second sentence mentions the challenges of handling abstract words in certain tasks. Therefore, the sentences are semantically independent of each other.

3.2 Training Set Creation

We construct our training set from scientific papers on NLP and computational linguistics available in the ACL Anthology, published between 2000 and 2019 (Bird et al., 2008; Radev, Muthukrishnan, and Qazvinian, 2009). For extracting textual data from the PDF papers, we use GROBID[2] which is a popular tool for parsing PDF files. We employ the following distant supervision technique on the extracted text to select and label the sentence pairs.

We create a list of linking phrases which are indicative of the semantic relationship between the sentence they occur in and the respective previous sentence. We then group these linking phrases into three classes based on the type of relationship indicated by each of them. The linking phrases and their assigned class can be seen in Table 2. We select the sentences which start with any of these phrases from each paper and include them in our dataset as hypotheses or second sentences; we include their respective preceding sentences as the premises or first sentences. Each sentence pair is labeled based on the class assigned to the linking phrase present in the second sentence, e.g., if the second sentence starts with "In contrast", the sentence pair is labeled as CONTRASTING. After assigning the labels, we delete the linking phrases from the second sentence of each pair to ensure that the models cannot get any clues of the ground truth labels just by looking at them. We also pair a large number of randomly selected sentences for our NEUTRAL class using three approaches:

- BOTHRAND: Two completely random sentences which do not contain any linking phrases are extracted (both from the same paper) and are paired together.
- FIRSTRAND: First sentence is random; second sentence is selected randomly from the other three classes (both from the same paper).
- SECONDRAND: Second sentence is random; first sentence is selected randomly from the other three classes (both from the same paper).

Our choice for including the last two approaches above was to make the dataset more challenging.

3.3 Benchmark Evaluation Sets Creation

To create our development and test sets, we start by extracting and labeling sentence pairs using the same distant supervision approach described in the previous section from the papers published in 2020 which are available in the ACL anthology. We then manually annotate a subset of these sentence pairs in order to make SCINLI a suitable benchmark for evaluation. The annotation process is completed in two steps, as described below.

First, we manually clean the data by filtering out the examples which contain too many mathematical terms and by completing the sentences that are broken due to erroneous PDF extraction by looking at the papers they are from. The second step of the annotation process is conducted in an

Table 3: Comparison of key statistics of SciNLI with other related datasets.

iterative fashion. In each iteration, we randomly sample a balanced subset from the cleaned set of examples created in the previous step and present the sentence pair from each example to three expert annotators. To avoid a performance ceiling due to lack of context, the annotators are instructed to label each example based only on the two sentences in each example. If the label is not clear from the context available in the two sentences, the instruction is to label them as unclear. The label with the majority of the votes from annotators is then chosen as the gold label. No gold label is assigned to the examples ($\approx 5\%$) which do not have a majority vote. The examples for which the gold label agrees with the label assigned based on the linking phrase are selected to be in our **benchmark evaluation set**. We continue the iterations of sampling a balanced set of examples and annotating them until we have at least $1,500$ examples from each class in the benchmark evaluation set. In total, $8,044$ sentence pairs—$2,011$ from each class are annotated among which $6,904$ have an agreement between the gold label and the label assigned based on the linking phrase. Therefore, these 6904 examples are selected to be in the benchmark evaluation set. The percentage of overall agreement and the class-wise agreement between the gold labels and the labels assigned based on the linking phrases are reported in the last column of Table 3. The Fleiss-k score among the annotators is 0.62 which indicates that the agreement among the annotators is substantial (Landis and Koch, 1977).

We randomly select 36% of the papers in our benchmark evaluation set to be in our development set and the rest of the papers are assigned to the test set. This is done based on our decision to have at least 500 samples from each class in the development set and 1000 samples from each class in the test set. Splitting the dataset into train, development and test sets *at paper level instead of sentence pair level* is done to prevent any information leakage among the data splits caused by sentences from one paper being in more than one split.

3.4 Data Balancing

Because of the differences in the frequency of occurrence of the linking phrases related to different classes, our initial dataset was unbalanced in all three splits. In contrast, the examples in the related datasets such as SNLI (Bowman et al., 2015) and MNLI (Williams, Nangia, and Bowman, 2018) are almost equally distributed across their classes. Therefore, for a fair comparison, we balance our dataset by downsampling the top three most frequent classes to the size of the least frequent class in each split. We can see the number of examples in each class of our SciNLI dataset in Table 3.

3.5 Data Statistics

A comparison of key statistics of SciNLI with four related datasets is also shown in Table 3.

Dataset Size Although the total size of our dataset is smaller than SNLI and MNLI, SciNLI is still large enough to train and evaluate deep learning based NLI models.

Sentence Lengths From Table 3, we can see that the average number of words in both premise and hypothesis is higher in SciNLI compared with the other datasets. This reflects the fact that sentences used in scientific articles tend to be longer than the sentences used in everyday language.

Sentence Parses Similar to the related datasets, we parse the sentences in SciNLI by using the Stanford PCFG Parser (3.5.2) (Klein and Manning,

Dataset	F1	Acc
SICK	63.54	64.86
SNLI	80.61	80.74
MNLI Dev		
-Matched	65.39	65.70
-Mismatched	64.75	65.01
SciTail	71.18	72.29
SciNLI	60.98	61.38

Table 4: The Macro F1 (%) and Accuracy (%) of the BiLSTM model on different datasets.

2003). We can see that $\approx 97\%$ of both first and second sentences have parses with an 'S' root which is higher than the sentences in SNLI and very competitive with the other datasets. This illustrates that most of our sentences are syntactically complete.

Token Overlap We report the average percentage of tokens occurring in hypotheses which overlap with the tokens in their premises (Table 3). We observe that the overlap percentage in SciNLI is much lower compared to the other datasets. Therefore, our dataset has low surface-level lexical patterns revealing the relationship between sentences.

4 SciNLI Evaluation

We evaluate our dataset by performing three sets of experiments. First, we aim to understand the difficulty level of SciNLI compared to related datasets (§4.1). Second, we investigate a lexicalized classifier to test whether simple similarity based features can capture the particularities of our relations and potentially perform well on our dataset (§4.2). Third, we experiment with traditional machine learning models, neural network models and transformer based pre-trained language models to establish strong baselines (§4.3).

4.1 SciNLI vs. Related Datasets

To evaluate the difficulty of SciNLI, we compare the performance of a BiLSTM (Hochreiter and Schmidhuber, 1997) based classifier on our dataset and four related datasets: SICK, SNLI, MNLI and SciTail. The architecture for this model is similar to the BiLSTM model used by Williams, Nangia, and Bowman (2018). Precisely, the sentence level representations S_1 and S_2 are derived by sending the embedding vectors of the words in each of the sentences in a pair through two separate BiLSTM layers and averaging their hidden states. The context vector S_c is calculated using the following equation:

$$S_c = [S_1, S_2, S_1 \odot S_2, S_1 - S_2] \qquad (1)$$

Here, the square brackets denote a concatenation operation of vectors and $\odot$ and $-$ are element-wise multiplication and subtraction operators, respectively. S_c is sent through a linear layer with Relu activation which is followed by a softmax layer to obtain the final output class.

Implementation details We pre-process the input sentences by tokenizing and stemming them using the NLTK tokenizer[3] and Porter stemmer,[4] respectively. Any stemmed token which occurs less than two times in the training set is replaced with an [UNK] token. We use 300D Glove embeddings (Pennington, Socher, and Manning, 2014) to represent the tokens which are allowed to be updated during training. The hidden size for the BiLSTM models is 300. The batch size is set at 64 and the models are trained for 30 epochs where we optimize a cross-entropy loss using Adam optimizer (Kingma and Ba, 2014) with an initial learning rate of 0.001. We employ early stopping with a patience size 10 where the Macro F1 score of the development set is used as the stopping criteria. Since SICK does not have a development split, we randomly select 10% of its training examples to be used as the development set. Similarly, since MNLI does not have a publicly available test split, we consider its development split as the test split and we randomly select $\approx 10,000$ samples from the training set to be used as the development set.

We can see the performance of this model on different datasets in Table 4. We find the following:

SciNLI is more challenging than other related datasets. The BiLSTM model shows a much lower performance for SciNLI compared with the other datasets. These results indicate that the task our dataset presents is more challenging compared to other datasets. As we have seen in Table 3, there is a substantial amount of discrepancy in sentence lengths between SciNLI and the other datasets. The longer sentences in our dataset make it harder for the models to retain long distance dependencies, which result in lower performance. Furthermore, our dataset has low surface-level lexical cues and exhibits complex linguistic patterns that require a model to be less reliant on lexical cues but instead learn deep hidden semantics from text.

Table 5: The Macro F1 (%) and Accuracies (%) of the lexicalized classifier on SICK and SCINLI.

4.2 Lexical Similarity vs. Semantic Relationship

To verify that the examples in our dataset cannot be classified based only on syntactic and lexical similarities, we explore a simple lexicalized classifier similar to (Bowman et al., 2015). We train a classifier using different combinations of the following features: (1) the second sentence's BLEU (Papineni et al., 2002) score with respect to the first sentence with an n-gram range of 1 to 4; (2) the difference in length between the two sentences in a pair; (3) overlap of all words, just nouns, verbs, adjectives, or adverbs - both the actual number and the percentage over possible overlaps; and (4) unigrams and bigrams from the second sentence as indicator features. We compare the performance of these models on our dataset and the SICK dataset because given the small size of SICK, this is especially suitable for this kind of models. The results can be seen in Table 5. We observe the following:

Semantic understanding is required to perform well on SCINLI. The lexicalized model fails to achieve satisfactory results on SCINLI even when all features are combined. Both Macro F1 and accuracy are much lower for our dataset than SICK. This means that without actually understanding the content in the sentences in SCINLI, a model cannot successfully predict their relationship.

4.3 SCINLI Baselines

To establish baselines on our dataset, we consider three types of models: a traditional machine learning model, neural network models, and pre-trained language models.

Traditional Machine Learning Model We consider the lexicalized classifier using all four features described in §4.2 as a baseline on our dataset.

Neural Network Models We experiment with three neural models to get the sentence level representations for each sentence in a pair: (a) **BiLSTM** - word embeddings are sent through a BiLSTM layer and the hidden states are averaged; (b) **CBOW** - word embedding vectors are summed; (c) **CNN** - 64 convolution filters of widths [3, 5, 9] on the word embeddings are applied, the outputs of which are mean pooled to get a single vector representation from the filters of each of the three widths. These three vectors are then concatenated to get the sentence level representation.

For all three models, the sentence level representations are combined as in Eq. 1. The obtained representations are first sent through a linear layer with Relu activation followed by softmax for classification (i.e., project them with a weight matrix $\mathbf{W} \in \mathbb{R}^{d \times 4}$). The hyperparameters and other implementation details are the same as for the BiLSTM model described in §4.1.

Pre-trained Language Models We fine-tune four transformer based pre-trained language models: (a) **BERT** (Devlin et al., 2019) - pre-trained by masked language modeling (MLM) on BookCorpus (Zhu et al., 2015) and Wikipedia; (b) **SciBERT** (Beltagy, Lo, and Cohan, 2019) - a variant of BERT pre-trained with a similar procedure but exclusively on scientific text; (c) **RoBERTa** (Liu et al., 2019b) - an extension of BERT which was pre-trained using dynamic masked language modeling, i.e., unlike BERT, different words were masked in each epoch during training. It was also trained for a longer period of time on a larger amount of text compared with BERT; and (d) **XLNet** (Yang et al., 2019) - pre-trained with a "Permutation Language Modeling" objective instead of MLM. We employ the base variants of each of these models using the huggingface transformers library. The input sequence for these models is derived by concatenating the two sentences in a pair with a `[SEP]` token in between. The `[CLS]` token is then projected with a weight matrix $\mathbf{W} \in \mathbb{R}^{d \times 4}$ by sending it as the input to a softmax layer to get the output class. We fine-tune each transformer based model for 5 epochs where we minimize the cross-entropy loss using Adam optimizer (Kingma and Ba, 2014) with an initial learning rate of $2e-5$. Early stopping with a patience size 2 is employed.

The experiments are run on a single Tesla V10 GPU. The transformer based models took approximately four hours to train and the traditional machine learning and neural network models were trained in less than one hour. We run each experiment three times with different random seeds and

Table 6: The Macro F1 scores (%) and accuracies (%) of our baseline models on SciNLI along with individual F1 scores on four classes. Here, an asterisk indicates that there is a statistically significant difference between the models in the third block of the table and BERT according to a paired T-test with $\alpha = 0.05$. The three models in the third block shows statistically indistinguishable results. The best Macro F1 and accuracy are in bold.

report the average and standard deviation of the F1 scores for each of the four classes, their Macro average and overall accuracy in Table 6. Our findings are discussed below.

Transformer based models consistently outperform the traditional models The transformer based models have a very high performance gap with the traditional lexicalized and neural models. Their better performance can be attributed to their superior design for capturing the language semantics and their pre-training on large amounts of texts.

More sophisticated pre-training methods lead to better performance RoBERTa and XLNet are created by addressing different limitations of BERT. Both of these models show a better performance than BERT on our dataset. Therefore, the progress made in these two models for better NLU capability is reflected by the results on SciNLI. This proves that SciNLI can be used as an additional resource for tracking the progress of NLU.

Pre-training on domain specific text helps to improve classification performance The results show that SciBERT consistently outperforms BERT on SciNLI. This is because unlike BERT, SciBERT was pre-trained exclusively on scientific text. Hence, it has a better capability to understand the text in the scientific domain. We see that RoBERTa and XLNet show slightly better performances than SciBERT despite being pre-trained on non-scientific text, just like BERT. However, it should be noted that these differences in performance are not statistically significant. Moreover, both RoBERTa and XLNet were created by modifying the training procedure of BERT to further improve the performance, whereas SciBERT is just a plain BERT model pre-trained on scientific text. Even without any modifications to the training procedure, SciBERT is able to perform similarly to these models proving the advantage of pre-training on domain specific text and suitability of our dataset for evaluating scientific NLI models.

		SciNLI	
Model		**F1**	**Acc**
BERT	BOTH SENTENCES	75.36	75.37
	ONLY 2^{nd} SENTENCE	54.56	55.40
SciBERT	BOTH SENTENCES	77.66	77.60
	ONLY 2^{nd} SENTENCE	58.16	58.80

Table 7: Performance comparison on SciNLI when both sentences are concatenated vs. when only second sentence is used as the input.

5 Analysis

Research has shown that some stylistic and annotation artifacts are present (only in the hypotheses) in NLI datasets created using crowdsource annotators (Gururangan et al., 2018). To verify that the models do not learn similar spurious patterns in our dataset and predict the labels without understanding the semantic relation between the sentences, we start our analysis by experimenting with only the second sentence as the input to BERT and SciBERT models. Next, to intuitively understand the errors made by the models, we perform a qualitative analysis of the predictions made by the SciBERT model on 100 randomly selected examples from our test set. Finally, we show that the Neutral examples extracted with FirstRand and SecondRand approaches are harder to classify than the examples extracted with BothRand.

Spuriosity Analysis A comparison between the *only second sentence* models and the models with both sentences concatenated as the input can be seen in Table 7. Clearly, as we can see from the

First Sentence	Second Sentence	True Label	Predicted Label
Multiple studies of BERT concluded that it is considerably overparametrized.	it is possible to ablate elements of its architecture without loss in performance or even with slight gains (Kovaleva et al., 2019;Michel et al., 2019;Voita et al., 2019).	Entailment	Contrasting
Upon further investigation, we find that experiments which use probabilities with image based features have an inter-quartile range of 0.05 and 0.1 for EBG and BLOG respectively whereas for experiments using probabilities with binning based features, this range is 0.32 for both datasets.	inter-quartile range for experiments using ranks with image based features is 0.08 and 0.05 for EBG and BLOG whereas for experiments using ranks with binning based features, this range is 0.49 and 0.42 respectively.	Contrasting	Neutral

Table 8: Examples of errors made by SciBERT on SciNLI.

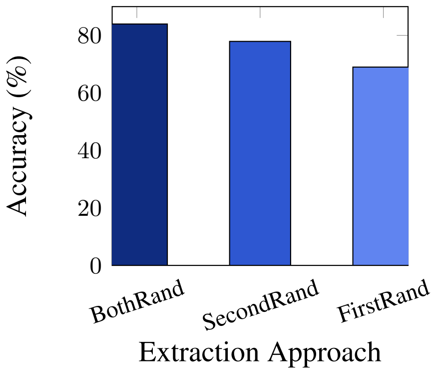

Figure 1: Extraction approach vs. accuracy of SciBERT on the Neutral pairs of SciNLI test set.

table, there is a substantial amount of performance decrease when only the second sentence is used as input. Therefore, in order to perform at the optimal level, both sentences are required for the models to make the correct inference by learning the semantic relation between them.

Qualitative Error Analysis We find that a major reason behind the wrong predictions is a lack of domain specific knowledge. For example, in the first sentence pair in Table 8, without the domain knowledge that the number of parameters in a model affects the performance, one will not be able to make the correct inference. We also find that the model is prone to making mistakes for longer sentences. This issue is exemplified by the second sentence pair in Table 8.

Neutral Class Performance Analysis We can see a plot of the accuracy shown by SciBERT on Neutral pairs of our test set extracted with different approaches in Figure 1. Indeed, the examples in which one sentence comes from one of the other three classes are harder to classify.

6 Conclusion & Future Directions

In this paper, we introduced SciNLI, the first natural language inference dataset on scientific text created with our novel data annotation method. We manually annotated a large number of examples to create our benchmark test and development sets. Our experiments suggest that SciNLI is harder to classify than existing NLI datasets and deep semantic understanding is necessary for a model to perform well. We establish strong baselines and show that our dataset can be used as a challenging benchmark to evaluate the progress of NLU models. In the future, we will leverage knowledge bases to improve the models' ability to understand scientific text. We make our code and the SciNLI dataset available to further research in scientific NLI.

Abstract

In lexicalist linguistic theories, argument structure is assumed to be predictable from the meaning of verbs. As a result, the verb is the primary determinant of the meaning of a clause. In contrast, construction grammarians propose that argument structure is encoded in constructions (or form-meaning pairs) that are distinct from verbs. Decades of psycholinguistic research have produced substantial empirical evidence in favor of the construction view. Here we adapt several psycholinguistic studies to probe for the existence of argument structure constructions (ASCs) in Transformer-based language models (LMs). First, using a sentence sorting experiment, we find that sentences sharing the same construction are closer in embedding space than sentences sharing the same verb. Furthermore, LMs increasingly prefer grouping by construction with more input data, mirroring the behaviour of non-native language learners. Second, in a "Jabberwocky" priming-based experiment, we find that LMs associate ASCs with meaning, even in semantically nonsensical sentences. Our work offers the first evidence for ASCs in LMs and highlights the potential to devise novel probing methods grounded in psycholinguistic research.

1 Introduction

Pretrained Transformer-based language models (LMs) such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019b) have recently achieved impressive results on many natural language tasks, spawning a new interdisciplinary field of aligning LMs with linguistic theory and probing the linguistic capabilities of LMs (Linzen and Baroni, 2021). Most probing work so far has investigated the linguistic knowledge of LMs on phenomena such as agreement, binding, licensing, and movement (Warstadt et al., 2020a; Hu et al., 2020) with a particular focus on determining whether a sentence is linguistically acceptable (Schütze, 1996). Relatively little work has attempted to determine whether the linguistic knowledge induced by LMs is more similar to a formal grammar of the sort postulated by mainstream generative linguistics (Chomsky, 1965, 1981, 1995), or to a network of form-meaning pairs as advocated by construction grammar (Goldberg, 1995, 2006).

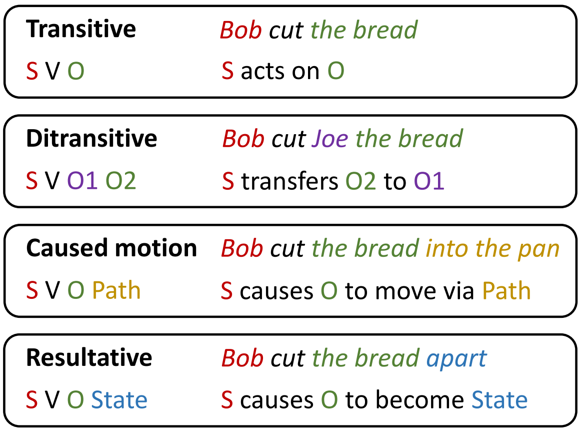

Figure 1: Four argument structure constructions (ASCs) used by Bencini and Goldberg (2000), with example sentences (top right). Constructions are mappings between form (bottom left) and meaning (bottom right).

One area where construction grammar disagrees with many generative theories of language is in the analysis of the argument structure of verbs, that is, the specification of the number of arguments that a verb takes, their semantic relation to the verb, and their syntactic form (Levin and Rappaport Hovav, 2005). Lexicalist theories were long dominant in generative grammar (Chomsky, 1981; Kaplan and Bresnan, 1982; Pollard and Sag, 1987). In lexicalist theories, argument structure is assumed to be encoded in the lexical entry of the verb: for

May 22-27, 2022 ©2022 Association for Computational Linguistics

example, the verb *visit* is lexically specified as being transitive and as requiring a noun phrase object (Chomsky, 1986). In contrast, construction grammar suggests that argument structure is encoded in form-meaning pairs known as *argument structure constructions* (ASCs, Figure 1), which are distinct from verbs. The argument structure of a verb is determined by pairing it with an ASC (Goldberg, 1995). To date, a substantial body of psycholinguistic work has provided evidence for the psychological reality of ASCs in sentence sorting (Bencini and Goldberg, 2000; Gries and Wulff, 2005), priming (Ziegler et al., 2019), and novel verb experiments (Kaschak and Glenberg, 2000; Johnson and Goldberg, 2013).

Here we connect basic research in ASCs with neural probing by adapting several psycholinguistic studies to Transformer-based LMs and show evidence for the neural reality of ASCs. Our first case study is based on sentence sorting (Bencini and Goldberg, 2000); we discover that in English, German, Italian, and Spanish, LMs consider sentences that share the same construction to be more semantically similar than sentences sharing the main verb. Furthermore, this preference for constructional meaning only manifests in larger LMs (trained with more data), whereas smaller LMs rely on the main verb, an easily accessible surface feature. Human experiments with non-native speakers found a similarly increased preference for constructional meaning in more proficient speakers (Liang, 2002; Baicchi and Della Putta, 2019), suggesting commonalities in language acquisition between LMs and humans.

Our second case study is based on nonsense "Jabberwocky" sentences that nevertheless convey meaning when they are arranged in constructional templates (Johnson and Goldberg, 2013). We adapt the original priming experiment to LMs and show that RoBERTa is able to derive meaning from ASCs, even without any lexical cues. This finding offers counter-evidence to earlier claims that LMs are relatively insensitive to word order when constructing sentence meaning (Yu and Ettinger, 2020; Sinha et al., 2021). Our source code and data are available at: `https://github.com/SPOClab-ca/neural-reality-constructions`.

2 Psycholinguistic background

2.1 Construction grammar and ASCs

Construction grammar is a family of linguistic theories proposing that all linguistic knowledge consists of *constructions*: pairings between form and meaning where some aspects of form or meaning are not predictable from their parts (Fillmore et al., 1988; Kay and Fillmore, 1999; Goldberg, 1995, 2006). Common examples include idiomatic expressions such as *under the weather* (meaning "to feel unwell"), but many linguistic patterns are constructions, including morphemes (e.g., *-ify*), words (e.g., *apple*), and abstract patterns like the ditransitive and passive. In contrast to lexicalist theories of argument structure, construction grammar rejects the dichotomy between syntax and lexicon. In contrast to transformational grammar, it rejects any distinction between surface and underlying structure.

We focus on a specific family of constructions for which there is an ample body of psycholinguistic evidence: argument structure constructions (ASCs). ASCs are constructions that specify the argument structure of a verb (Goldberg, 1995). In the lexicalist, verb-centered view, argument structure is a lexical property of the verb, and the main verb of a sentence determines the form and meaning of the sentence (Chomsky, 1981; Kaplan and Bresnan, 1982; Pollard and Sag, 1987; Levin and Rappaport Hovav, 1995). For example, *sneeze* is intransitive (allowing no direct object) and *hit* is transitive (requiring one direct object). However, lexicalist theories encounter difficulties with sentences like *"he sneezed the napkin off the table"* since intransitive verbs are not permitted to have object arguments.

Rather than assuming multiple implausible senses for the verb *"sneeze"* with different argument structures, Goldberg (1995) proposed that ASCs operate on an arbitrary verb, altering its argument structure while at the same time modifying its meaning. For example, the *caused-motion* ASC adds a direct object and a path argument to the verb *sneeze*, with the semantics of causing the object to move along the path. Other ASCs include the transitive, ditransitive, and resultative (Figure 1), which specify the argument structure of a verb and interact with its meaning in different ways.

2.2 Psycholinguistic evidence for ASCs

Sentence sorting. Several psycholinguistic studies have found evidence for argument structure con-

	Transitive	Ditransitive	Caused-motion	Resultative
Throw	Anita threw the hammer.	Chris threw Linda the pencil.	Pat threw the keys onto the roof.	Lyn threw the box apart.
Get	Michelle got the book.	Beth got Liz an invitation.	Laura got the ball into the net.	Dana got the mattress inflated.
Slice	Barbara sliced the bread.	Jennifer sliced Terry an apple.	Meg sliced the ham onto the plate.	Nancy sliced the tire open.
Take	Audrey took the watch.	Paula took Sue a message.	Kim took the rose into the house.	Rachel took the wall down.

Table 1: Stimuli from Bencini and Goldberg (2000), consisting of a 4x4 design, with 4 different verbs and 4 different argument structure constructions.

structions using experimental methods. Among these, Bencini and Goldberg (2000) used a sentence sorting task to determine whether the verb or construction in a sentence was the main determinant of sentence meaning. 17 participants were given 16 index cards with sentences containing 4 verbs (*throw, get, slice*, and *take*) and 4 constructions (*transitive, ditransitive, caused-motion*, and *resultative*) and were instructed to sort them into 4 piles by overall sentence meaning (Table 1). The experimenters measured the deviation to a purely verb-based or construction-based sort, and found that on average, the piles were closer to a construction sort.

Non-native sentence sorting. The same set of experimental stimuli was used with L2 (non-native) English speakers. Gries and Wulff (2005) ran the experiment with 22 German native speakers, who preferred the construction-based sort over the verb-based sort, showing that constructional knowledge is not limited to native speakers. Liang (2002) ran the experiment on Chinese native speakers of 3 different English levels (46 beginner, 31 intermediate, and 33 advanced), and found that beginners preferred a verb-based sort, while advanced learners produced construction-based sorts similar to native speakers (Figure 2). Likewise, Baicchi and Della Putta (2019) found the same result in Italian native speakers with B1 and B2 English proficiency levels. Overall, these studies show evidence for ASCs in the mental representations of native and L2 English speakers alike, and furthermore, preference for constructional over verb sorting increases with increasing English proficiency.

Multilingual sentence sorting. Similar sentence sorting experiments have been conducted in other languages, with varying results. Kirsch (2019) ran a sentence sorting experiment in German with 40 participants and found that they mainly sorted by verb but rarely by construction. Baicchi and Della Putta (2019) ran an experiment with non-native learners of Italian (15 participants of B1 level and 10 participants of B2 level): both groups preferred the constructional sort, and similar to Liang (2002), the B2 learners sorted more by construction than the B1 learners. Vázquez (2004) ran an experiment in Spanish with 16 participants, and found approximately equal proportions of constructions and verb sort. In Italian and Spanish, some different constructions were substituted as not all of the English constructions had an equivalent in these languages; see the appendix for the complete set of stimuli in each language.

Priming. Another line of psycholinguistic evidence comes from priming studies. Priming refers to the condition where exposure to a (prior) stimulus influences the response to a later stimulus (Pickering and Ferreira, 2008). Bock and Loebell (1990) found that participants were more likely to produce sentences of a given syntactic structure when primed with a sentence of the same structure; Ziegler et al. (2019) argued that Bock and Loebell (1990) did not adequately control for lexical overlap, and instead, they showed that the construction must be shared for the priming effect to occur, not just shared abstract syntax.

Novel verbs. Even with unfamiliar words, there is evidence that constructions are associated with meaning. Kaschak and Glenberg (2000) constructed sentences with novel denominal verbs and found that participants were more likely to interpret a transfer event when the denominal verb was used in a ditransitive sentence (*Tom crutched Lyn an apple*) than a transitive one (*Tom crutched an apple*).

Johnson and Goldberg (2013) used a "Jabberwocky" priming task to show that abstract constructional templates are associated with meaning. Participants were primed with a nonsense sentence of a given construction (e.g., *He daxed her the norp* for the ditransitive construction), followed by a lexical decision task of quickly deciding if a string of characters was a real English word or a non-word. The word in the decision task was semantically congruent with the construction (*gave*) or incongruent (*made*); furthermore, they experimented with target words that were high-frequency (*gave*), low-frequency (*handed*), or semantically related but not associated with the construction (*transferred*). They found priming effects (faster lexical decision times) in all three conditions, with the strongest effect for the high-frequency condition, followed by the low-frequency and the semantically nonassociate conditions.

We adapt several of these psycholinguistic studies to LMs: the sentence sorting experiments in Case study 1, and the Jabberwocky priming experiment in Case study 2. We choose these studies because their designs allow for thousands of stimuli sentences to be generated automatically using templates, avoiding issues caused by small sample sizes from manually constructed sentences.

3 Related work in NLP

3.1 Linguistic probing of LMs

Many studies have probed for various aspects of syntax in LSTMs and Transformer-based LMs. Linzen et al. (2016) tested LSTMs on their ability to capture subject-verb agreement, using templates to generate test data. This idea was extended by BLiMP (Warstadt et al., 2020a), a suite encompassing 67 linguistic phenomena, including filler-gap effects, NPI licensing, and ellipsis; Hu et al. (2020) released a similar test suite. Template generation is a convenient method to construct stimuli exhibiting specific linguistic properties, but alternative approaches include CoLA (Warstadt et al., 2019), which compiled an acceptability benchmark of sentences drawn from linguistic publications, and Gulordava et al. (2018), who perturbed natural sentences to study LMs' knowledge of agreement on nonsense sentences. We refer to Linzen and Baroni (2021) for a comprehensive review of the linguistic probing literature.

So far, relatively few papers approached LM probing from a construction grammar perspective. Madabushi et al. (2020) probed for BERT's knowledge of constructions via a sentence pair classification task of predicting whether two sentences share the same construction. Their probe was based on data from Dunn (2017), who used an unsupervised algorithm to extract plausible constructions from corpora based on association strength. However, the linguistic validity of these automatically induced constructions is uncertain, and there is currently no human-labelled wide-coverage construction grammar dataset in any language suitable for probing. Other computational work focused on a few specific constructions, such as identifying caused-motion constructions in corpora (Hwang and Palmer, 2015) and annotating constructions related to causal language (Dunietz et al., 2015). Lebani and Lenci (2016) is the most similar to our work: they probed distributional vector space models for ASCs based on the Jabberwocky priming experiment by Johnson and Goldberg (2013).

3.2 Psycholinguistic treatment of LMs

Some recent probing studies adapted methods and data from psycholinguistic research, treating LMs as psycholinguistic participants. Using a cloze completion task, Ettinger (2020) found that BERT was less sensitive than humans at commonsense inferences and detecting role reversals, and fails completely at understanding negation. Michaelov and Bergen (2020) compared LM surprisals with the N400 (a measure of human language processing difficulty) across a wide range of conditions; Li et al. (2021) used psycholinguistic stimuli and found that LMs exhibit different layerwise surprisal patterns for morphosyntactic, semantic, and commonsense anomalies. Wilcox et al. (2021) compared LM and human sensitivities to syntactic violations using a maze task to collect human reaction times. Prasad et al. (2019); Misra et al. (2020) investigated whether LMs are sensitive to priming effects like humans. The advantage of psycholinguistic data is that they are carefully constructed by expert linguists to test theories of language processing in humans; however, their small sample size makes it challenging to make statistically meaningful conclusions when the (oft-sparse) experimental stimuli are used to probe a language model.

4 Case study 1: Sentence sorting

This section describes our adaptation of the sentence sorting experiments to Transformer LMs.

4.1 Methodology

Models. To simulate varying non-native English proficiency levels, we use MiniBERTa models (Warstadt et al., 2020b), trained with 1M, 10M,

---

[1] Bencini and Goldberg (2000) ran the sentence sorting experiment twice, so we take the average of the two runs.

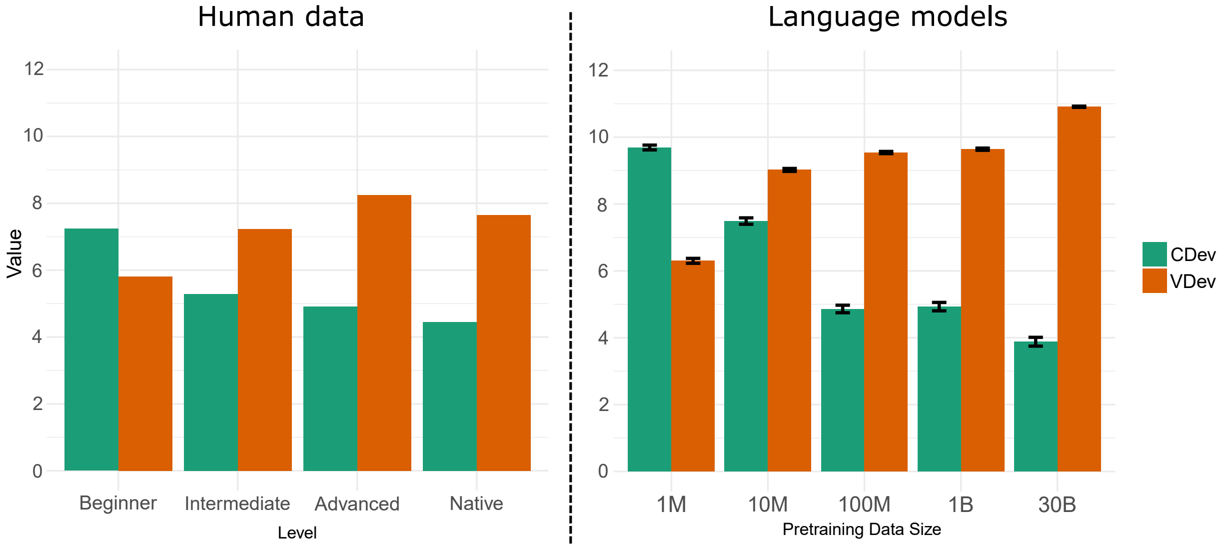

Figure 2: Sentence sorting results for humans and LMs, measured by deviation from pure construction and verb sort (CDev and VDev). Non-native human results are from Liang (2002); native human results from Bencini and Goldberg (2000).[1] LM results are obtained using MiniBERTas (Warstadt et al., 2020b) and RoBERTa (Liu et al., 2019b) on templated stimuli. The MiniBERTa models use between 1M to 1B tokens for pretraining, while RoBERTa uses 30B tokens. Error bars indicate 95% confidence intervals.

100M, and 1B tokens. We also use the base RoBERTa model (Liu et al., 2019b), trained with 30B tokens. In other languages, there are no available pretrained checkpoints with varying amounts of pretraining data, so we use the mBERT model (Devlin et al., 2019) and a monolingual Transformer LM in each language.[2] We obtain sentence embeddings for our models by taking the average of their contextual token embeddings at the second-to-last layer (i.e., layer 11 for base RoBERTa). We use the second-to-last because the last layer is more specialized for the LM pretraining objective and less suitable for sentence embeddings (Liu et al., 2019a).

Template generation. We use templates to generate stimuli similar to the 4x4 design in the Bencini and Goldberg (2000) experiment. To ensure an adequate sample size, we run multiple empirical trials. In each trial, we sample 4 random distinct verbs from a pool of 10 verbs that are compatible with all 4 constructions (*cut, hit, get, kick, pull, punch, push, slice, tear, throw*). We then randomly fill in the slots for proper names, objects, and complements for each sentence according to its verb, such that the sentence is semantically coherent, and there is no lexical overlap among the sentences of any construction. Table 3 in the appendix shows a set of template-generated sentences. In English, we generate 1000 sets of stimuli using this procedure; for other languages, we use the original stimuli from their respective publications.

Evaluation. Similar to the human experiments, we group the sentence embeddings into 4 clusters (not necessarily of the same size) using agglomerative clustering by Euclidean distance (Pedregosa et al., 2011). We then compute the deviation to a pure construction and pure verb sort using the Hungarian algorithm for optimal bipartite matching. This measures the minimal number of cluster assignment changes necessary to reach a pure construction or verb sort, ranging from 0 to 12. Thus, lower construction deviation indicates that constructional information is more salient in the LM's embeddings.

4.2 Results and interpretation

Figure 2 shows the LM sentence sorting results for English. All differences are statistically significant ($p < .001$). The smallest 1M MiniBERTa model is the only LM to prefer verb over construction sorting, and as the amount of pretraining data grows, the LMs increasingly prefer sorting by construction instead of by verb. This closely mirrors the trend observed in the human experiments.

The results for multilingual sorting are shown in Figure 3. Both mBERT and the monolingual LMs consistently prefer constructional sorting over verb

---

[2] We use monolingual German and Italian models from `https://github.com/dbmdz/berts`, and the monolingual Spanish model from Cañete et al. (2020).

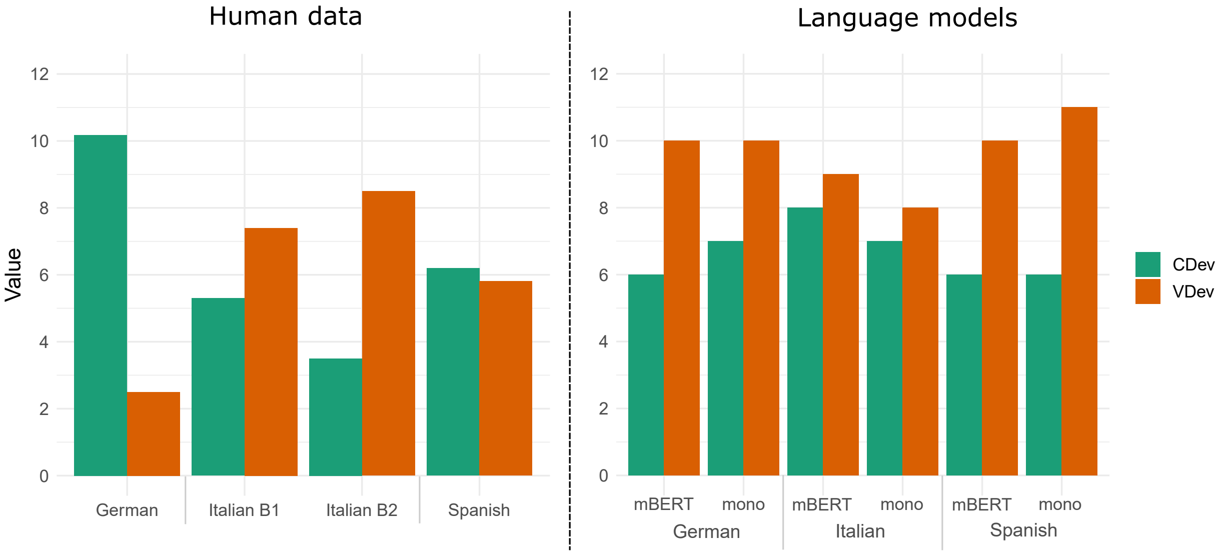

Figure 3: Multilingual sentence sorting results for German (Kirsch, 2019), Italian (Baicchi and Della Putta, 2019), and Spanish (Vázquez, 2004). LM results are obtained using the same stimuli; we use both mBERT and a monolingual LM for each language.

sorting in all three languages, whereas the results from the human experiments are less consistent.

Our results show that RoBERTa can generalize meaning from abstract constructions without lexical overlap. Only larger LMs and English speakers of more advanced proficiency are able to make this generalization, while smaller LMs and less proficient speakers derive meaning more from surface features like lexical content. This finding agrees with Warstadt et al. (2020b), who found that larger LMs have an inductive bias towards linguistic generalizations, while smaller LMs have an inductive bias towards surface generalizations; this may explain the success of large LMs on downstream tasks. A small quantity of data (10M tokens) is sufficient for LMs to prefer the constructional sort, indicating that ASCs are relatively easy to learn: roughly on par with other types of linguistic knowledge, and requiring less data than commonsense knowledge (Zhang et al., 2021; Liu et al., 2021).

We note some limitations in these results, and reasons to avoid drawing unreasonably strong conclusions from them. Human sentence sorting experiments can be influenced by minor differences in the experimental setup: Bencini and Goldberg (2000) obtained significantly different results in two runs that only differed on the precise wording of instructions. In the German experiment (Kirsch, 2019), the author hypothesized that the participants were influenced by a different experiment that they had completed before the sentence sorting one. Given this experimental variation, we cannot attribute differences across languages to differences in their linguistic typology. Although LMs do not suffer from the same experimental variation, we cannot conclude statistical significance from the multilingual experiments, where only one set of stimuli is available in each language.

5 Case study 2: Jabberwocky constructions

We next adapt the "Jabberwocky" priming experiment from Johnson and Goldberg (2013) to LMs, and make several changes to the original setup to better assess the capabilities of LMs. Priming is a standard experimental paradigm in psycholinguistic research, but it is not directly applicable to LMs: existing methods simulate priming either by applying additional fine-tuning (Prasad et al., 2019), or by concatenating sentences that typically do not co-occur in natural text (Misra et al., 2020). Therefore, we instead propose a method to probe LMs for the same linguistic information using only distance measurements on their contextual embeddings.

5.1 Methodology

Template generation. We generate sentences for the four constructions randomly using the templates in Table 2. Instead of filling nonce words like *norp* into the templates as in the original study, we take an approach similar to Gulordava et al. (2018) and generate 5000 sentences for each construction

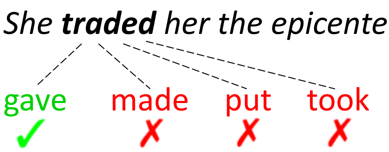

Figure 4: In our adapted Jabberwocky experiment, we measure the Euclidean distance from the Jabberwocky verb (*traded*) to the 4 prototype verbs, of which 1 is congruent (✓) with the construction of the sentence, and 3 are incongruent (✗).

Construction	Template / Examples
Ditransitive	S/he V-ed him/her the N. *She traded her the epicenter.* *He flew her the donut.*
Resultative	S/he V-ed it Adj. *He cut it seasonal.* *She surged it civil.*
Caused-motion	S/he V-ed it on the N. *He registered it on the diamond.* *She awarded it on the corn.*
Removal	S/he V-ed it from him/her. *He declined it from her.* *She drove it from him.*

Table 2: Templates and example sentences for the Jabberwocky construction experiments. The templates are identical to the ones used in Johnson and Goldberg (2013), except that we use random real words instead of nonce words.

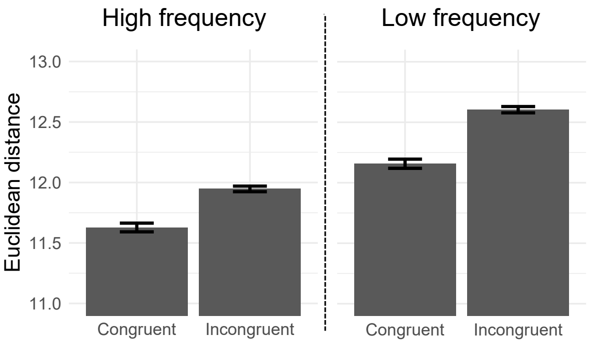

Figure 5: Euclidean distance between Jabberwocky and prototype verbs for congruent and incongruent conditions. Error bars indicate 95% confidence intervals.

by randomly filling real words of the appropriate part-of-speech into construction templates (Table 2). This gives nonsense sentences like *"She traded her the epicenter"*; we refer to these random words as *Jabberwocky words*. By using real words, we avoid any potential instability from feeding tokens into the model that it has never seen during pretraining. We obtain a set of singular nouns, past tense verbs, and adjectives from the Penn Treebank (Marcus et al., 1993), excluding words with fewer than 10 occurrences.

Verb embeddings. Our probing strategy is based on the assumption that the contextual embedding for a verb captures its meaning in context. Therefore, if LMs associate ASCs with meaning, we should expect the contextual embedding for the Jabberwocky verb to contain the meaning of the construction. Specifically, we measure the Euclidean distance to a *prototype* verb for each construction (Figure 4). These are verbs that Johnson and Goldberg (2013) selected whose meaning closely resembles the construction's meaning: *gave*, *made*, *put*, and *took* for the ditransitive, resultative, caused-motion, and removal constructions, respectively.[3] We also run the same setup using lower frequency prototype verbs from the same study: *handed*, *turned*, *placed*, and *removed*.[4] As a control, we measure the Euclidean distance to the prototype verbs of the other three unrelated constructions.

The prototype verb embeddings are generated by taking the average across their contextual embeddings across a 4M-word subset of the British National Corpus (BNC; Leech (1992)). We use the second-to-last layer of RoBERTa-base, and in cases where a verb is split into multiple subwords, we take the embedding of the first subword token as the verb embedding.

5.2 Results and interpretation

We find that the Euclidean distance between the prototype and Jabberwocky verb embeddings is significantly lower ($p < .001$) when the verb is congruent with the construction than when they are incongruent, and this is observed for both high and low-frequency prototype verbs (Figure 5). Examining the individual constructions and verbs (Figure 6), we note that in the high-frequency scenario, the lowest distance prototype verb is always the congruent one, for all four constructions. In the low-frequency scenario, the result is less consis-

---

[3] The reader may notice that the four constructions here are slightly different from Bencini and Goldberg (2000): the transitive construction is replaced with the removal construction in Johnson and Goldberg (2013).

[4] Johnson and Goldberg (2013) also included a third experimental condition using four verbs that are semantically related but not associated with the construction, but one of the verbs is very low-frequency (*ousted*), so we exclude this condition in our experiment.

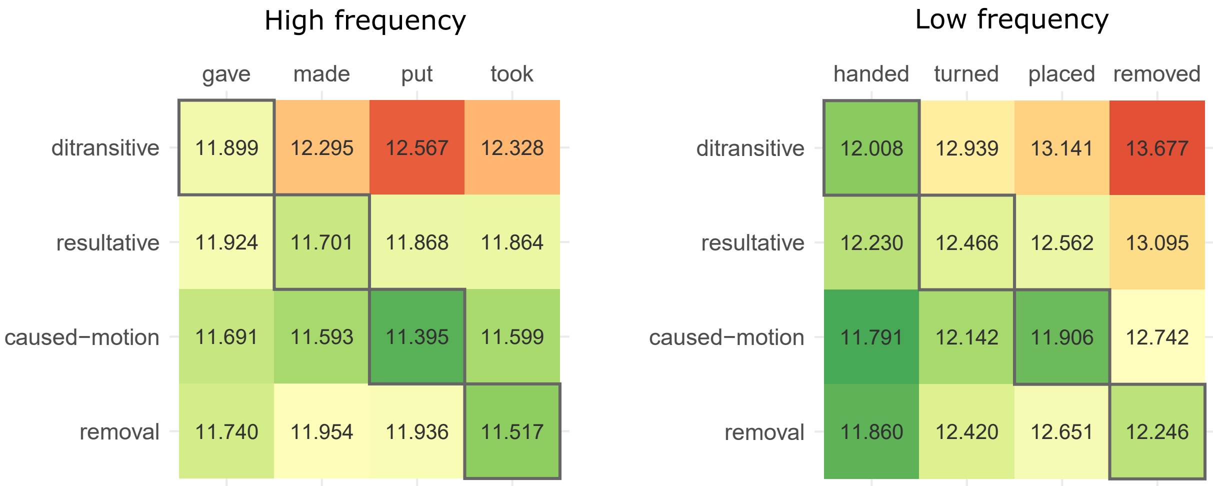

Figure 6: Mean Euclidean distance between Jabberwocky and prototype verbs in each verb-construction pair. Diagonal entries (gray border) are the congruent conditions; off-diagonal entries are incongruent.

tent: the congruent verb is not always the lowest distance one, although it is always still at most the second-lowest distance out of the four.

The main result holds for both high and low-frequency scenarios, but the correct prototype verb is associated more consistently in the high-frequency case. This agrees with Wei et al. (2021), who found that LMs have greater difficulty learning the linguistic properties of less frequent words. We also note that the Euclidean distances are higher overall in the low-frequency scenario, which is consistent with previous work that found lower frequency words to occupy a peripheral region of the embedding space (Li et al., 2021).

5.3 Potential confounds

In any experiment, one must be careful to ensure that the observed patterns are due to the phenomenon under investigation rather than confounding factors. We discuss potential confounds arising from lexical overlap, anisotropy of contextual embeddings, and neighboring words.

Lexical overlap. The randomized experiment design ensures that the Jabberwocky words cannot be lexically biased towards any construction, since each verb is equally likely to occur in every construction. Technically, the lexical content in the four constructions are not identical: i.e., words such as *"from"* (occurring only in the removal construction) or *"on"* (in the caused-motion construction) may provide hints to the sentence meaning. However, the ditransitive and resultative constructions do not contain any such informative words, yet RoBERTa still associates the correct prototype verb for these constructions, so we consider it unlikely to be relying solely on lexical overlap. There is substantial evidence that RoBERTa is able to associate abstract constructional templates with their meaning without lexical cues. This result is perhaps surprising, given that previous work found that LMs are relatively insensitive to word order in compositional phrases (Yu and Ettinger, 2020) and downstream inference tasks (Sinha et al., 2021; Pham et al., 2021), where their performance can be largely attributed to lexical overlap.

Anisotropy. Recent probing work have found that contextual embeddings suffer from anisotropy, where embeddings lie in a narrow cone and have much higher cosine similarity than expected if they were directionally uniform (Ethayarajh, 2019). Furthermore, a small number of dimensions dominate geometric measures such as Euclidean and cosine distance, resulting in a degradation of representation quality (Kovaleva et al., 2021; Timkey and van Schijndel, 2021). Since our experiments rely heavily on Euclidean distance, anisotropy is a significant concern. Following Timkey and van Schijndel (2021), we perform standardization by subtracting the mean vector and dividing each dimension by its standard deviation, where the mean and standard deviation for each dimension is computed from a sample of the BNC. We observe little difference after standardization: in both the high and low frequency scenarios, the Euclidean distances are lower for the congruent than the incongruent conditions, by a similar margin compared to the original experiment without standardization. We also run standardization on the first case study, and find that the results remain essentially unchanged: smaller LMs still prefer verb sorting while larger LMs prefer construction sorting. Thus, neither of our experiments appear to be affected by anisotropy.

Neighboring words. A final confounding factor is our assumption that RoBERTa's contextual embeddings represent word meaning, when in reality, they contain a mixture of syntactic and semantic information. Contextual embeddings are known to contain syntax trees (Hewitt and Manning, 2019) and linguistic information about neighboring words in a sentence (Klafka and Ettinger, 2020); although previous work did not consider ASCs, it is plausible that our verb embeddings leak information about the sentence's construction in a similar manner. If this were the case, the prototype verb embedding for *gave* would contain not only the semantics of transfer that we intended, but also information about its usual syntactic form[5] of *"S gave NP1 NP2"*, and both would be captured by our Euclidean distance measurement. Controlling for this syntactic confound is difficult – one could alternatively probe for transfer semantics without syntactic confounds using a natural language inference setup (e.g., whether the sentence entails the statement *"NP1 received NP2"*), but we leave further exploration of this idea to future work.

6 Conclusion

We find evidence for argument structure constructions in Transformer language models from two separate angles: sentence sorting and Jabberwocky construction experiments. Our work extends the existing body of literature on LM probing by taking a constructionist instead of generative approach to linguistic probing. Our sentence sorting experiments identified a striking resemblance between humans' and LMs' internal language representations as LMs are exposed to increasing quantities of data, despite the differences between neural language models and the human brain. Our two studies suggest that LMs are able to derive meaning from abstract constructional templates with minimal lexical overlap. Both sets of experiments were inspired by psycholinguistic studies, which we adapted to fit the capabilities of LMs – this illustrates the potential for future work on grounding LM probing methodologies in psycholinguistic research.

A Visualization of sentence sorting

We use principal components analysis (PCA) to visualize the sentence sorting experiment for the MiniBERTa models (trained with 1M and 100M tokens) and RoBERTa-base (trained with 30B tokens). In RoBERTa, there is strong evidence of clustering based on constructions; the effect is unclear in the 100M model and nonexistent in the 1M model (Figure 7). This visually confirms our quantitative evaluation based on the construction and verb deviation metrics (Figure 2).

B Additional experimental stimuli

Table 3 shows an example set of template-generated stimuli for sentence sorting: we generate 1000 similar sets of 16 sentences to increase the sample size. We also present the sentence sorting stimuli for German (Table 4), Italian (Table 5), and Spanish (Table 6). German uses the same four constructions as English. Italian does not have the ditransitive construction but instead uses the prepositional dative construction to express transfer semantics. Spanish has no equivalents for the caused-motion and resultative constructions, so the authors in that experiment instead used the unplanned reflexive (expressing accidental or unplanned events), and the middle construction (expressing states pertaining to the subject).

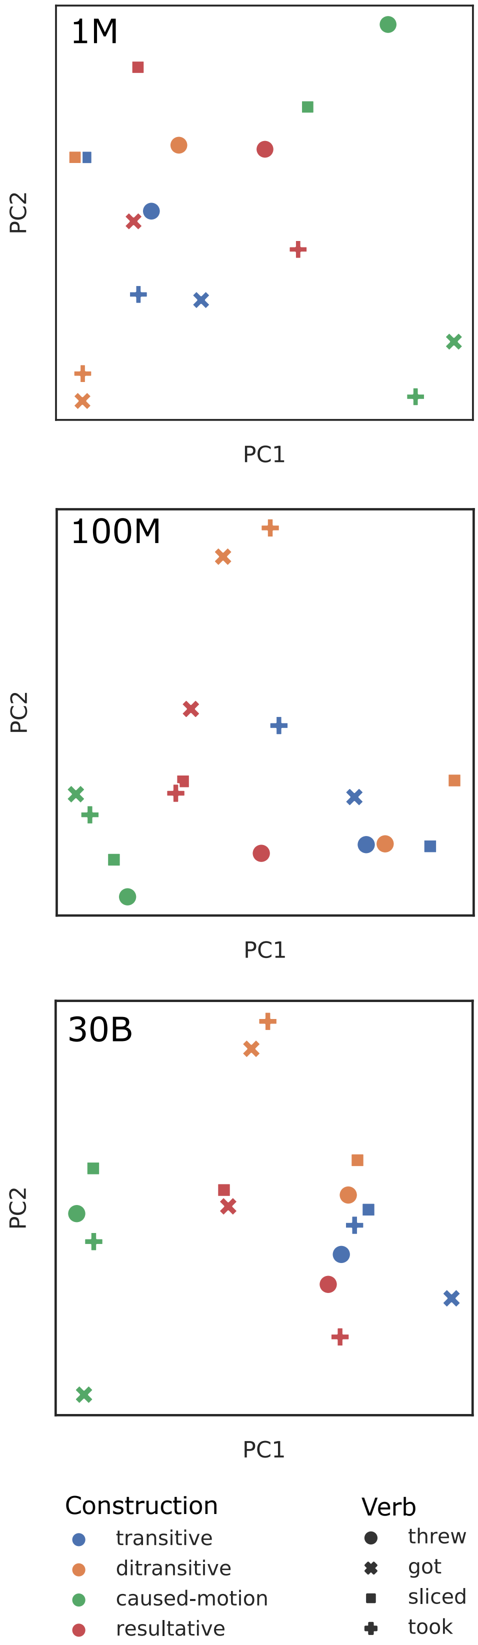

Figure 7: PCA plots of Bencini and Goldberg (2000) sentence sorting using the 1M and 100M MiniBERTa models and RoBERTa-base (30B). Figure best viewed in color.

	Transitive	Ditransitive	Caused-motion	Resultative
Slice	Harry sliced the bread.	Henry sliced Eric the box.	Sam sliced the ball onto the bed.	John sliced the book apart.
Kick	Thomas kicked the box.	Mike kicked Frank the ball.	Michael kicked the wall into the house.	James kicked the door open.
Cut	George cut the ball.	Adam cut Paul the tree.	Bill cut the box into the water.	Bob cut the bread apart.
Get	Tom got the book.	Andrew got Steve the door.	Jack got the fridge onto the elevator.	David got the ball stuck.

Table 3: Example of our 4x4 sentence sorting stimuli, similar to those by Bencini and Goldberg (2000) in Table 1, but generated automatically using templates.

	Transitive	Ditransitive	Caused-motion	Resultative
Werfen	Anita warf den Hammer.	Berta warf Linda den Bleistift.	Erika warf den Schlüsselbund auf das Dach.	Laura warf die Kisten auseinander.
Bringen	Michelle brachte das Buch.	Simone brachte Lydia eine Einladung.	Emma brachte den Ball ins Netz.	Leonie brachte die Stühle zusammen.
Schneiden	Karolin schnitt das Brot.	Luisa schnitt Paula einen Apfel.	Jennifer schnitt die Wurst auf den Teller.	Doris schnitt den Reifen auf.
Nehmen	Maria nahm die Uhr.	Sophia nahm Jasmin das Geld.	Helena nahm die Rosen in das Haus.	Theresa nahm das Plakat herunter.

Table 4: German sentence sorting stimuli, obtained from Kirsch (2019).

	Transitive	Prepositional Dative	Caused-motion	Resultative
Dare	Lauda dà un esame.	Carlo dà una mela a Maria.	Luca dà una spinta a Franco.	Paolo dà una verniciata di verde alla porta.
Fare	Mario fa una torta.	Luigi fa un piacere a Giovanna.	Fabio fa entrare la macchina in garage.	Stefano fa bruciare il sugo.
Mettere	Annalisa mette la giacca.	Riccardo mette il cappello al bambino.	Silvia mette la penna nel cassetto.	Filippo mette la casa in ordine.

Abstract

Social media platforms are deploying machine learning based offensive language classification systems to combat hateful, racist, and other forms of offensive speech at scale. However, despite their real-world deployment, we do not yet comprehensively understand the extent to which offensive language classifiers are robust against adversarial attacks. Prior work in this space is limited to studying robustness of offensive language classifiers against primitive attacks such as misspellings and extraneous spaces. To address this gap, we systematically analyze the robustness of state-of-the-art offensive language classifiers against more crafty adversarial attacks that leverage greedy- and attention-based word selection and context-aware embeddings for word replacement. Our results on multiple datasets show that these crafty adversarial attacks can degrade the accuracy of offensive language classifiers by more than 50% while also being able to preserve the readability and meaning of the modified text.

1 Introduction

Online social media platforms are dealing with an unprecedented scale of offensive (e.g., hateful, threatening, profane, racist, and xenophobic) language (Twitter; Facebook; Reddit). Given the scale of the problem, online social media platforms now increasingly rely on machine learning based systems to proactively and automatically detect offensive language (Rosen, 2020; Gadde and Derella, 2020; Kastrenakes, 2019; Hutchinson, 2020). The research community is actively working to improve the quality of offensive language classification (Zampieri et al., 2020, 2019b; Liu et al., 2019; Nikolov and Radivchev, 2019; Mahata et al., 2019; Arango et al., 2020; Agrawal and Awekar, 2018; Fortuna and Nunes, 2018). A variety of offensive language classifiers ranging from traditional shallow models (SVM, Random Forest), deep learning models (CNN, LSTM, GRU), to transformer-based models (BERT, GPT-2) have been proposed in prior literature (Liu et al., 2019; Nikolov and Radivchev, 2019; Mahata et al., 2019). Amongst these approaches, BERT-based transformer models have achieved state-of-the-art performance while ensembles of deep learning models also generally perform well (Zampieri et al., 2019b, 2020).

It remains unclear whether the state-of-the-art offensive language classifiers are robust to adversarial attacks. While adversarial attacks are of broad interest in the ML/NLP community (Hsieh et al., 2019; Behjati et al., 2019), they are of particular interest for offensive language classification because malicious users can make subtle perturbations such that the offensive text is still intelligible to humans but evades detection by machine learning classifiers. Prior work on the robustness of text classification is limited to analyzing the impact on classifiers of primitive adversarial changes such as deliberate misspellings (Li et al., 2019), adding extraneous spaces (Gröndahl et al., 2018), or changing words with their synonyms (Jin et al., 2020; Ren et al., 2019; Li et al., 2020). However, the primitive attacks can be easily defended against—a spell checker can fix misspellings and a word segmenter can correctly identify word boundaries even with extra spaces (Rojas-Galeano, 2017; Li et al., 2019). Additionally, a normal synonym substitution will not theoretically hold for offensive language as less offensive language will be substituted and thus meaning will be lost. Crucially, we do not know how effective these text classifiers are against crafty adversarial attacks employing more advanced strategies for text modifications.

To address this gap, we analyze the robustness of offensive language classifiers against an adversary who uses a novel word embedding to identify

---

[*] This paper examines offensive language as a case study. The reader is cautioned that the paper contains unavoidable strong language given the nature of the research.

word replacements and a surrogate offense classifier in a black-box setting to guide modifications. This embedding is purpose-built to evade offensive language classifiers by leveraging an *evasion collection* that comprises of evasive offensive text gathered from online social media. Using this embedding, the adversary modifies the offensive text while also being able to preserve text readability and semantics. We present a comprehensive evaluation of the state-of-the-art BERT and CNN/LSTM based offensive language classifiers, as well as an offensive lexicon and Google's Perspective API, on two datasets.

We summarize our key contributions below.

- We systematically study the ability of an adversary who uses a novel, crafty strategy to attack and bypass offensive language classifiers. The adversary first builds a new embedding from a special evasion collection, then uses it alongside a surrogate offensive language classifier deployed in black-box mode to launch the attack.
- We explore variations of our adversarial strategy. These include greedy versus attention based selection of text words to replace. These also include two different versions of embeddings for word substitutions.
- We evaluate robustness of state-of-the-art offensive language classifiers, as well as a real-world offensive language classification system on two datasets from Twitter and Reddit. Our results show that 50% of our attacks cause an accuracy drop of $\geq$ 24% and 69% of attacks cause drops $\geq$ 20% against classifiers across datasets.

Ethics Statement: We acknowledge that our research demonstrating attacks against offensive language classifiers could be used by bad agents. Our goal is to highlight the vulnerability within offensive language classifiers. We hope our work will inspire further research to improve their robustness against the presented and similar attacks.

2 Target Offensive Language Classifiers

2.1 Threat model

The adversary's goal is to modify his/her offensive post in such a manner as to evade detection by offensive language classifiers while simultaneously preserving semantics and readability for humans. To make suitable modifications, the adversary is assumed to have black-box access to a surrogate offensive language classifier that is different from the one used by the online social media platform. The adversary leverages feedback from this surrogate classifier to guide modifications using a novel approach that we propose. Our goal is to evaluate the extent to which the adversary can evade detection by an unknown offensive language classifier under this threat model.

2.2 Offensive Language Classifiers

We evaluate the following offensive language classifiers under our threat model.

1. **NULI** (Liu et al., 2019) is a BERT (Devlin et al., 2019) based system trained on offensive language. During preprocessing, emojis are converted into English phrases[1] and hashtags are segmented[2]. This was the top-ranked system in OffensEval (Zampieri et al., 2019b).

2. **Vradivchev** (Nikolov and Radivchev, 2019) is also a BERT based system trained on offensive language data. The preprocessing step includes removing symbols "@" and "#", tokenization and lowercasing, splitting hashtags, and removing stopwords. This was the second best system in OffensEval.

3. **MIDAS** (Mahata et al., 2019) is a voting ensemble of three deep learning systems: a CNN, a BLSTM, and a BLSTM fed into a Bidirectional Gated Recurrent Unit (BGRU). This was the top non-BERT system in OffensEval[3].

4. **Offensive Lexicon** (Wiegand et al., 2018) is a simple method that classifies a post as offensive if at least one word is in a lexicon of offensive words. We use their lexicon.

5. **Perspective API** (Perspective) by Google (Jigsaw) provides a toxicity model that classifies whether a post is "rude, disrespectful, or unreasonable." The production model uses a CNN trained with fine-tuned GloVe word embeddings and provides "toxicity" probability. We use 0.5 threshold to classify a post as offensive as in Pavlopoulos et al. (2019).

---

[1] https://github.com/carpedm20/emoji

[2] https://github.com/grantjenks/python-wordsegment

[3] We implemented NULI, vradivchev and MIDAS with parameters reported in the cited papers. Our accuracies were within 1% of the reported F1 score.

3 Attack Methods

This section describes our adversarial attack method as well as a recent visual adversarial attack (Eger et al., 2019) and a simpler attack (Gröndahl et al., 2018) for baseline comparison.

3.1 Proposed Attack

The adversary's attack involves selecting words to replace in the input text and deciding on suitable replacements.

Selection. There are several ways to approach word selection for replacement. Here we explore a greedy approach (Hsieh et al., 2019) and an approach using attention weights (Xu et al., 2018).

For the greedy approach, we first remove each word one at a time (retaining the rest in the text) and get the drop in classification probability for the text from the surrogate offensive classifier. Words are removed until the offensive label is flipped (according to the classifier). The removed words make up the full list of possible replacements. The adversary then selects the word that causes the largest drop for replacement. If replacing this word is insufficient to bypass the surrogate classifier then the word with the next largest drop is also selected for replacement and so on.

For the attention approach, we leverage a BLSTM with attention which is trained on the target classification task. Note that this BLSTM is different from the one found in MIDAS. To select words, we give the input text to the BLSTM and examine the attention weights estimated during classification. The adversary selects the word with the highest attention weight. If replacing this word is insufficient to bypass the surrogate classifier then the word with the next largest attention weight is also selected for replacement and so on.

The attention approach can potentially find replacements that greedy approach may not. Specifically, the greedy approach may miss instances where the combination of words cause offense rather than single words.

Replacement. Figure 1 depicts our framework for substituting the selected word with another word. First, a candidate list of 20 most similar words (closest vectors) is obtained from an embedding space. Next, we replace the selected word with its most similar word and check the modified text against the surrogate classifier. If the modified text is declared not offensive, then this word is chosen as the replacement. Otherwise, the process continues with the next most similar word. If the candidate list is exhausted without misclassification by the surrogate classifier, we choose the replacement word which causes the largest drop in classification probability.

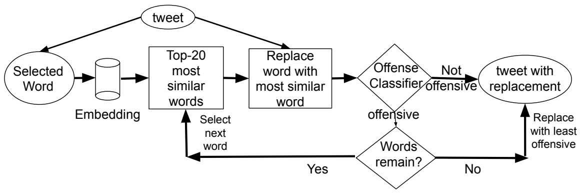

Figure 1: The design of our word replacement approach. First, select the word's 20 most similar words as candidates. Next, replace the word with the most similar candidate and check text against surrogate classifier. If this results in a not offensive classification, the process ends with this word as replacement. Otherwise, continue the process with the next most similar candidate. If no candidates remain, choose the one which causes the greatest drop in classification probability.

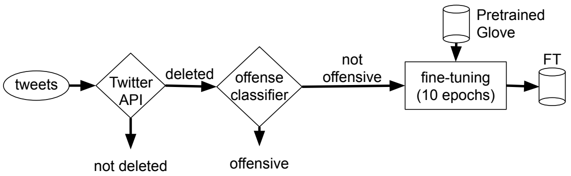

Figure 2: Our approach for creating FT . First, 13 million deleted tweets are identified via retrospective analysis using the Twitter API (Le et al., 2019; Thomas et al., 2011). Next, the tweets are checked against offensive language classifiers to remove those detected as offensive. Finally, for FT, fine-tune the pretrained (Pre) with the remaining tweets for 10 epochs.

Embeddings. The key idea here is to design a context-aware word embedding for crafty replacements. To this end, we first build a text collection of 13 million deleted tweets through retrospective analysis using the Twitter API (Thomas et al., 2011; Le et al., 2019). Next we filter out the tweets from this set that are labeled as offensive by any of the offensive language classifiers in Section 2.2.[4] The remaining set of 8.5 million deleted tweets contains offensive tweets that were likely flagged by users or human moderators.[5] We expect this set of deleted tweets to contain crafty substitutions and expressions that are likely to evade detection by state-of-the-art offensive language classifiers. We refer to this set of deleted tweets as the *evasion* collection and this is the data that the adversary uses to train word embeddings. We explore the following embeddings:

1. GloVe pretrained Twitter embedding (Pre):

---

[4] Note that Perspective did not participate in this tagging due to query limits of the API.

[5] It is possible that some of these tweets were deleted for other reasons that are unknown to us.

These are pretrained GloVe embeddings on 2 billion tweets. The vocabulary size of this model is 1,193,514 tokens. This represents a baseline off-the-shelf word embedding.

2. GloVe embedding fine-tuned with evasion collection (FT): We use the evasion collection to fine-tune the pretrained GloVe embeddings. Fine tuning is done over 10 epochs. The resulting vocabulary size is 1,312,106 tokens. Figure 2 illustrates this approach.

Insights into the embeddings. Our intuition of crafty substitutions being present in the evasion collection is backed up by examination of the embeddings. Using a set of offensive words as probes we find that on average the position of the first evasive word amongst the 20 most similar words in Pre is 11, while for FT this number is 3, implying that FT is more likely to offer an evasive replacement. We expand on these insights and analysis in Section 6. Furthermore, as fine-tuning the embeddings may introduce garbage words (non english, often meaningless words) as replacements, we add in a filter to the candidates when using the FT embeddings. This filter only allows candidates which have been used in tweets by 3 distinct authors in the *evasion* dataset. Finally, as checking every candidate can be time consuming and inefficient, we apply this filter only when we substitute text words that were not in the original *Pre* embeddings.

3.2 Other Attacks

VIPER. We implement a recent visual adversarial attack called VIPER (Eger et al., 2019) that aims to generate adversarial text for any classification task. VIPER (VIsual PERturber) replaces characters in the text with visually nearest neighbors determined from a visual embedding space. Each character present in the text is selected for replacement with a fixed probability p. VIPER strategically chooses replacements from non standard unicode characters assuming that systems rarely train outside the standard unicode space. As the main comparison, we choose their description-based character embedding space (DCES) in our experiments since it had the best tradeoff between attack success and readability. DCES represents characters by their unicode textual descriptions. The nearest neighbor substitute is the character whose description refers to the same letter in the same case. We also compare with their simpler, easy character embedding space (ECES), which contains only nearest neighbor for character replacement. We used VIPER with $p = 0.1$ and 0.4, the first for better readability and the second for better likelihood of attack success. Note that higher p values correspond to more changes in the text.

Grondahl. Gröndahl et al. (2018) explored rather simple attack methods such as modifying whitespace and misdirection by adding a misleading word. We implement several of their adversarial attacks. These are: adding a space after every character, removing all spaces between characters, adding the word 'love' to the input text, and finally removing all spaces then adding 'love.' This last attack strategy outperformed others in their evaluation.

4 Experimental Setup

4.1 Datasets

Offensive Language Identification Dataset (OLID). OLID was used in SemEval-6 2019: OffensEval, a shared task on classifying offensive language (Zampieri et al., 2019a). This collection is annotated by experienced annotators to ensure high quality. OLID contains 14,100 English tweets (text only): split into 13,240 (4,400 offensive, 8,840 non-offensive) training tweets and 860 (240 offensive, 620 non-offensive) test tweets.

Semi-Supervised Offensive Language Identification Dataset (SOLID). SOLID is an expansion of OLID used in SemEval 2020: OffensEval, which continued the task of classifying offensive language (Rosenthal et al., 2020). SOLID was constructed from tweets via semi-supervised manner using democratic co-training with OLID as a seed dataset. SOLID contains 9,000,000 tweets as an expansion for training, and 5,993 test tweets, (3,002 offensive, 2,991 non-offensive).

4.2 Evaluation Metrics

Drop in Accuracy:

$\Delta = \text{Accuracy}_{\text{Original}} - \text{Accuracy}_{\text{Modified}}$,

where $\text{Accuracy}_{\text{Original}}$ is the classifier's accuracy on original text and $\text{Accuracy}_{\text{Modified}}$ is the classifier's accuracy on the modified text. Larger drops imply better evasion of offensive language classifiers by the adversary.

Readability and semantic preservation: We measure readability of the modified text and its semantic preservation through manual evaluation. More specifically, for readability, human reviewers are asked to examine the modified text and rate it as one of: {'The text is easy to read', 'The text can be read with some difficulty', 'The text is hard to read'}. For semantic preservation, reviewers are given the original texts alongside the modified versions and are asked whether 'text B' (modified text) conveys the same meaning as 'text A' (original text). The choices are {'Yes, Text B conveys the same meaning as Text A', 'Text B conveys partially the meaning of Text A', 'No, Text B does not convey the same meaning as Text A'}.

4.3 Experiment Design

We use the OLID and SOLID test sets to assess the success of our attack strategies. Amongst the several offensive language classifiers considered in this work (see Section 2.2), we make one classifier available to the adversary as a surrogate black-box classifier to guide adversarial modification of each test tweet. Note that we do not use Lexicon as an internal classifier as it does not provide useful feedback (only returning 0 or 1 for positive class probabilities). We then evaluate the drop in classification accuracy (Δ) for each of the remaining classifiers.

5 Results

In this section, we first present the results of our proposed adversarial attack approach and then those of existing approaches from prior literature on the OLID dataset. Evaluation was also performed on the SOLID dataset and the results followed a similar trend. Full results for all attacks are located in the appendix.

5.1 Our adversarial attack

Table 1 presents the results on the OLID dataset. Rows specify the attack strategy. The first column identifies the surrogate offensive language classifier used by the adversary to guide modifications. The remaining columns specify the offensive language classifier whose robustness is being evaluated. Cell values are drops in accuracy after adversarial modification. Accuracy here refers to the percentage of offensive tweets correctly predicted as offensive. Classification accuracy for original text is given in the first row of the table. So for example, the final accuracy for NULI where the adversary uses GS-Pre and MIDAS is 44 (61-17). Blocks of rows labeled with prefix GS stand for results with greedy word selection strategy while AS stand for results with BLSTM-attention based word selection. Note that diagonal entries, where the surrogate classifier is the same as the one being tested for robustness are ignored because the adversary is expected to be quite successful under this condition. We indeed find that the accuracy drops close to 0% in these cases. Additionally, for the Lexicon based method, we find it does not perform as well as the other classifiers, thereby excluding it from the state-of-the-art (SOTA) category.

Offensive language classifiers are susceptible to our adversarial attacks. Table 1 shows that our adversarial attacks are quite successful against crafty offensive language classifiers. For OLID, classifiers see a drop of accuracy in the range of 11–46[6]. In fact, 50% of attacks cause a drop of $\geq$ 24 and 69% of attacks cause a drop of $\geq$ 20. This shows the vulnerability of offensive language classifiers and their vulnerability under our threat model.

Greedy select (GS) outperforms Attention select (AS) attacks. Greedy Select achieves higher average drops in accuracy across classifiers. For example, GS - FT achieves an average drop of 26 against NULI while AS - FT achieves only a drop of 17. This holds true for both replacement embeddings. Although lower, AS still achieves strong drops against vradivchev (average of 35). This indicates the strength of a greedy approach, however, attention selection may be more viable in a setting where the number of queries is limited.

***FT* embeddings and *Pre* embeddings see success against different systems.** Comparing to Pre embeddings, FT we see different leads in dropped accuracy depending on the classifier. FT see great success against NULI and vradivchev, while Pre see success against the other three. This indicates that the *evasion* collection can help add power, especially against popular (BERT-based) classifiers.

NULI and vradivchev, BERT based classifiers, are the most and least robust to attacks. Focusing on the GS - FT embedding, NULI has a mean drop in accuracy of 26 (range: 18 - 39), the lowest across SOTA offensive language classifiers. In contrast, vradivchev, performs the best with accuracy of 69 but is also the most vulnerable to our attack model with a mean drop in accuracy of 37

---

[6] Note: The BLSTM attention classifier used for attention based word selection could also be used as an internal classifier. However, since this strategy did not perform as well as SOTA classifiers so we do not include these results in the main analysis.

		Drop in Classification Accuracy					
		NULI	vradivchev	MIDAS	Perspective	Lexicon	Avg. Drop
No Attack Accuracy %		61	69	66	68	54

	Average Drop	17	36	20	19	16	
AS - *FT*	NULI	-	39	18	17	15	22
	vradivchev	23	-	17	15	15	18
	MIDAS	11	27	-	17	12	17
	Perspective	17	40	21	-	16	*24*
	Average Drop	17	35	19	16	15	

Table 1: Robustness results on OLID with our attack model. Columns show accuracy drop. The approach is specified as *selection - replacement* where *selection = {Greedy Select (GS), Attention Select (AS)}* and *replacement = {Pre, FT}*. Note that the BLSTM used for AS can be used as an internal classifier but performed poorly so was not included. The adversarial, surrogate classifier is indicated in column 1. The first row presents baseline classification accuracies (%) before attacks. Therefore the resulting accuracies can be calculated by subtracting the drop from the original accuracy.

(range: 29 - 46), the highest drop of any offensive language classifier. This mean is 27 for Perspective and 29 for MIDAS. The stark difference between the two BERT systems' robustness most likely stems from the preprocessing step. BERT is a context-aware system. While NULI's preprocessing helps add context (e.g. converting emojis to text), vradivchev's hinders it. Specifically, vradivchev removes stop words. This could be a problem as removing this additional information causes the system to miss out on context during training. Then, as the attack is more likely to focus on changing non-stop words, vradivchev then loses both contextual information (via stop word removal) as well as offense indicating tokens (the main information it focused on during training).

NULI is the most effective surrogate classifier for the adversary while MIDAS the least effective. Again, focusing on GS-FT , NULI helps the adversary as the surrogate classifier the most by causing an average accuracy drop of 32 (range: 19 - 46), compared to vradivchev (avg: 28, range: 18 - 39), Perspective (avg: 25, range: 13 - 37), and MIDAS (avg: 21, range: 13 - 29). This again emphasizes BERT based methods' ability to understand context and use it effectively in attacks, also seen in previous research (Li et al., 2020).

Replication of Results. We replicate our results on a Reddit dataset in the appendix.

5.2 Other attacks

Grondahl. Table 2 shows the results when methods proposed by Gröndahl et al. (2018) are used to obfuscate. Note that this approach does not use a surrogate classifier. The simpler whitespace and 'love' word based attacks proposed by Gröndahl et al. (2018) have little to no effect on offensive language classifiers which contain a word segmentation pre-processing step. These classifiers include NULI (average drop: -3), vradivchev (average drop: 11), and Lexicon (average drop:0). MIDAS being ill equipped in this regard sees a drop of 64 when all spaces are removed and 'love' is added to the text. However, when we add a simple word segmentation step during pre-processing the attack loses effectiveness. For example, the "Remove space, Add 'love'" attack is reduced to a drop of 33 with this shielding pre-processing step, compared to 64 without it. Similarly, Perspective also sees drops up to 38 in these settings.

VIPER. Like a whitespace attack, VIPER attacks can be easily prevented using a trivial text pre-processing step. To demonstrate this, we added a pre-processing 'shielding' step to each system which replaces any non-standard characters with standard ones. The results for shielded VIPER attacks are found in Table 2 (Note: The full results for non-shielding against VIPER are found in the appendix.). This is in essence logically the reverse of VIPER's obfuscation by character translation process. Non-standard characters are those which exist outside 'a-zA-Z', numbers, and punctuation. To do this, as do the VIPER authors, we leverage the NamesList from the unicode database[7]. For any non-standard character, the description is searched for in the NamesList and the character which appears after "LETTER" in the description is used for substitution. For example, '$\hat{a}$'is described as "LATIN SMALL LETTER A WITH INVERTED BREVE", and hence would be replaced with 'a'. This simple pre-processing step reduces VIPER's average attack rate from 37 to 7 as shown in the VIPER results. In contrast, our proposed attack is not preventable through such simple preprocessing.

5.3 SOLID Results

The attack results against SOLID are found in Table 3. We see similar attack success as seen in OLID, finding even greater drops. Specifically, 75% of attacks cause a drop of $\geq$ 40 and 100% attacks cause a drop of at least 33.

5.4 Quality of Adversarial Examples

FT embeddings maintain a majority of the meaning and readability. We test readability of a sample of 50 tweets from the SOLID dataset, of which all were modified by FT . We asked three crowdworkers to assess the 50 tweets for readability. For comparison, we asked additional crowdworkers to assess the readability of the original texts. This helps explore the true drop in readability of a text. Additionally, we showed three other crowdworkers the original text as well and asked them to assess if the obfuscated texted conveyed the same meaning as the original (see Section 4.2 for details). We finally combined the crowdworkers votes by taking a majority vote for each example.

Table 4 presents the results. We find that FT scored slightly less in terms of readability than the original texts, but finds replacements with similar meaning. Specifically, readability drops from 74% to 70% for fully readable, but nearly two thirds retain the same meaning and 96% retain at least partial meaning. These numbers help indicate the strength of the attack, even when leveraging a crafty collection of word substitutions.

To provide insights into texts which retained full meaning versus partial, Table 5 shows a few examples of tweets in their respective categories as voted by crowdworkers. FT is able to find many appropriate, non traditional replacements. For example, "shit" is replaced with "shxt", in several instances which helps maintain meaning while evading classification. As another example, "phising" a mispelling of "phishing" is substituted for "fake". In context, this substitution makes sense. Note that while some examples are misspellings, these crafty modifications are ones that are mined from our large evasion text collection and not algorithmically-generated mispellings. However, some errors are found after replacement. For example, in the *Not Similar* instance FT replaces "fuck" with "bruh", and "shut" with "walked". These errors demonstrate room for improvement when selecting a candidate.

6 Analysis of embeddings

As discussed in Section 3.1, the adversary's strategy is to make crafty word replacements using a new embedding generated from an evasion collection (here made of deleted tweets not detected by an offense classifier). Results show that these embeddings successfully support the adversary at evading offensive language classifiers while maintaining readability and semantics. For further insights, we compare the off-the-shelf pretrained (Pre) embedding with the embedding fine-tuned on the evasion collection (FT). We examine the embeddings using the 59 words as probes which are both in the offensive Lexicon (Wiegand et al., 2018) and in the OLID test. For each word we get the 20 most similar words from Pre and from FT for comparison.

Fine-tuned embeddings move evasive substitute words closer to offensive probe words. We calculate the average position of the first evasive word[8] amongst the 20 most similar words. Pre has an average distance of 11, while FT has an average distance of 3. Thus, on average, FT is more likely to find evasive replacements. For example, in Pre *dispicable* appears as the 3rd most similar word to *despicable*, but it is the most similar in FT. Since

	MIDAS	33	38	-	39	34	37
	Perspective	46	54	43	-	40	46
	Average Drop	44	54	43	43	41	

Table 3: Robustness results on SOLID with our attack model. Columns show accuracy drop. The adversarial, surrogate classifier is indicated in column 1. The first row presents baseline classification accuracies (%) before attacks. Therefore the resulting accuracies can be calculated by subtracting the drop from the original accuracy.

Adversarial	Readability		
Attack	Yes	Partially	No
FT	35	13	2
[%]	70.0	26.0	4.0
Original	37	13	0
[%]	74.0	26.0	0.0
	Conveys same meaning		
	Yes	Partially	No
FT	31	17	2
[%]	62.0	34.0	2.0

Table 4: Results of human readability and meaning comparison assessments. Majority voting was used to combine all three annotators' answers into one vote.

FT could contain some unintelligible words, we repeat the experiment to filter out substitute words used by less than 3 different users. The same overall trend still holds.

Updated embeddings learn creative replacements. We manually compare the entries in the two lists (FT and Pre) of substitute words for each probe word. FT learns creative replacements absent in Pre. Examples include the word *azz* being the most similar word to *ass* in FT, but being absent within the most similar word list for Pre. Similarly, *niggah* appears as a replacement for *bitch* in FT, but not in Pre. These examples, along with the previous distance analysis, illustrate the craftiness in our evasion dataset.

7 Related Work

We first review related work on robustness of text classification in general and then closely related research on evading offensive language classifiers.

Evading Text Classifiers. Prior work has explored ways to evade text classification in general. Li et al. (2019) showed that character-level perturbations such as misspellings and word-level perturbations using off-the-shelf GloVe embeddings can evade text classifiers. Deri and Knight (2015) proposed an approach to create portmanteaus, which could be extended to adversarial texts. Behjati et al. (2019) added a sequence of words to any input to evade text classifiers. Zhao et al. (2018) proposed a GAN to generate adversarial attacks on text classification tasks. (Li et al., 2020) leverage BERT to propose solutions for replacement words, (Jin et al., 2020) leverage word embeddings, and (Ren et al., 2019) leverage WordNet. In contrast to prior work evading text classifiers, our work includes approaches to leverage embeddings built from a special evasion text collection.

Robustness of Text Classifiers. Our work is also relevant to prior studies of the robustness of text classifiers to adversarial inputs. Rojas-Galeano (2017) showed that primitive adversarial attacks (e.g., misspellings) can be detected and countered using edit distance. Hsieh et al. (2019) evaluated the robustness of self-attentive models in tasks of sentiment analysis, machine translation, and textual entailment. We examine robustness of similar models, however, we fine tune our embeddings to be task specific, while they do not, and we also test on the state-of-the-art offensive language classifiers.

Evading Offensive Language Classifiers. Gröndahl et al. (2018) examined robustness of hate speech classifiers against adding typos, whitespace, and non-hate words to text. As discussed earlier, prior work has shown that such primitive perturbations can be detected and reversed (Li et al., 2019; Rojas-Galeano, 2017). In contrast, we focus on more crafty text perturbations in our work. Ji and Knight (2018) surveyed the ways text has been encoded by humans to avoid censorship and explain challenges which automated systems would have to overcome. This work does not propose an automated approach for text perturbation. Eger et al. (2019) proposed VIPER for visual adversarial attacks. We implemented VIPER and (Gröndahl et al., 2018) as baseline attacks and showed that our approach is more successful overall. Overall, our work advances the research in this space by investigating robustness of offensive language classifiers against crafty adversarial attacks.

8 Conclusion

In this paper, we showed that state-of-the-art offensive language classifiers are vulnerable to crafty adversarial attacks. Our proposed adversarial attacks that leverage greedy and attention-based word selection and context-aware embeddings for word replacement were able to evade offensive language classifiers while preserving readability and semantics much better than prior simpler adversarial attacks. We report accuracy drops of up to 46 points or 67% against state-of-the-art offensive language classifiers. Furthermore, unlike VIPER and simpler attacks, our proposed attack cannot be easily prevented using pre-processing strategies. The user study showed that our adversarial attack was able to maintain similar readability with only a slight drop in semantic preservation.

Our work also suggests ways to improve the robustness of offensive language classifiers through adversarial training (Kurakin et al., 2017; Madry et al., 2018; Tramèr et al., 2018). More specifically, our attack relies on the *evasion* collection, which contains crafty adversarial examples that evade detection by offensive language classifiers but are flagged based on manual feedback by users or human moderators. Thus, offensive language classifiers can be adversarially trained on the latest *evasion* collection from time to time to improve their robustness to the ever evolving adversarial attacks. In this context it is noteworthy that continuous availability of large-scale manual feedback is quite unique to the problem of offensive language classification, where popular online social media platforms employ thousands of human moderators (Barrett, 2020).

A Full Results

Table 6 shows full results for all attacks, including our attack, Grondahl ,and VIPER attacks before and after shielding.

B Replication study: Reddit dataset

We verify our initial results on a second dataset composed of moderated Reddit comments (Chandrasekharan et al., 2018). To include non-moderated comments, we collected 5.6 million comments following the same procedure as (Chandrasekharan et al., 2018). We then used random sampling to construct a dataset with a similar 15:1 ratio of non-moderated to moderated comments as OLID. The dataset has 181,519 comments split into 145,846 (4,285 moderated and 141,561 non-moderated) training comments and 35,746 (1,071 moderated and 34,675 non-moderated) test comments. We re-build using these data and test the BERT based classifer (NULI-R) and the BLSTM Ensemble classifier (MIDAS-R). These are tagged with a '-R' to indicate training on the Reddit dataset. We exclude VIPER due to the previously shown weaknesses. We also exclude the methods of Gröndahl et al. (2018) because of weak performance.

Accuracy. Summarizing here, BLSTM ensemble (MIDAS-R) is most robust seeing a lower drop in accuracy, 31, than the BERT based model (NULI-R), 39, against the attack. Attacks using FT , see highest drops in accuracy against MIDAS: average of 32 (range: 28 - 35), while attacks using Pre, see highest drops against NULI (avg: 40, range: 37-42). Finally, greedy select (GS) causes greater drops against NULI (avg: 40) while attention select (AS) causes greater drops against MIDAS (avg: 35). The results are reported in Table 7

Quality. We see substitutions that subvert offense detectors such as *trump* being replaced with *trum*, which maintains the original message but now bypasses the detector[9]. We also see errors appear, such as "ctfu" being substituted for "shut". Overall, results with this second Reddit dataset are consistent with OLID results underlining our conclusion that the offense classifiers are not robust against these crafty attacks. We also see room for improvement of our adversarial attack methods especially in exploring more advanced filters for candidate substitution words. More examples found in Table 8.

---

[9] Comments on Reddit are moderated for various reasons not limited to offensive words, therefore in this case if comments against trump supporters are being moderated, it follows to change "trump"

Few-shot Controllable Style Transfer for Low-Resource Multilingual Settings

Kalpesh Krishna♠ * **Deepak Nathani**♢ **Xavier Garcia**♢
Bidisha Samanta♢ **Partha Talukdar**♢

♠University of Massachusetts Amherst, ♢Google Research
`kalpesh@cs.umass.edu`
`{xgarcia, dnathani, bidishasamanta, partha}@google.com`

Abstract

Style transfer is the task of rewriting a sentence into a target style while approximately preserving content. While most prior literature assumes access to a large style-labelled corpus, recent work (Riley et al., 2021) has attempted “few-shot” style transfer using just 3-10 sentences at inference for style extraction. In this work, we study a relevant low-resource setting: style transfer for languages where no style-labelled corpora are available. We notice that existing few-shot methods perform this task poorly, often copying inputs *verbatim*.

We push the state-of-the-art for few-shot style transfer with a new method modeling the stylistic difference between paraphrases. When compared to prior work, our model achieves 2-3x better performance in formality transfer and code-mixing addition across seven languages. Moreover, our method is better at controlling the style transfer magnitude using an input scalar knob. We report promising qualitative results for several attribute transfer tasks (sentiment transfer, simplification, gender neutralization, text anonymization) all *without retraining the model*. Finally, we find model evaluation to be difficult due to the lack of datasets and metrics for many languages. To facilitate future research we crowdsource formality annotations for 4000 sentence pairs in four Indic languages, and use this data to design our automatic evaluations.[1]

1 Introduction

Style transfer is a natural language generation task in which input sentences need to be re-written into a target style, while preserving semantics. It has many applications such as writing assistance (Heidorn, 2000), controlling generation for attributes like simplicity, formality or persuasion (Xu et al., 2015; Smith et al., 2020; Niu and Carpuat, 2020), data augmentation (Xie et al., 2020; Lee et al., 2021), and author obfuscation (Shetty et al., 2018).

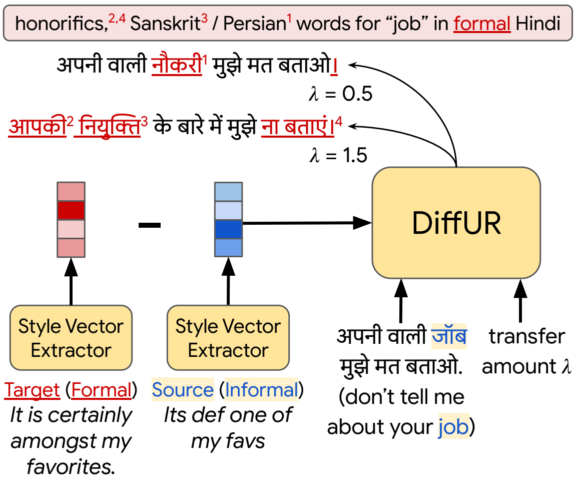

Figure 1: An illustration of our few-shot style transfer system during inference. Our model extracts style vectors from exemplar English sentences as input (in this case formal/informal sentences) and uses their vector difference to guide style transfer in other languages (Hindi). λ is used to control the magnitude of transfer: in this example our model produces more high Sanskrit words & honorifics (more formal) with higher λ.

Most prior work either assumes access to supervised data with parallel sentences between the two styles (Jhamtani et al., 2017), or access to a large corpus of unpaired sentences with style labels (Prabhumoye et al., 2018; Subramanian et al., 2019). Models built are style-specific and cannot generalize to new styles during inference, which is needed for applications like real-time adaptation to a user’s style in a dialog or writing application. Moreover, access to a large unpaired corpus with style labels is a strong assumption. Most standard “unpaired” style transfer datasets have been carefully curated (Shen et al., 2017) or were originally parallel (Xu et al., 2012; Rao and Tetreault, 2018). This is especially relevant in settings outside En-

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 7439 - 7468
May 22-27, 2022

glish, where NLP tools and labelled datasets are largely underdeveloped (Joshi et al., 2020). In this work, we take the first steps studying style transfer in seven languages[2] with nearly 1.5 billion speakers in total. Since no training data exists for these languages, we analyzed the current state-of-the-art in few-shot multilingual style transfer, the Universal Rewriter (UR) from Garcia et al. (2021). Unfortunately, we find it often copies the inputs verbatim (Section 3.1), *without changing their style*.

We propose a simple inference-time trick of style-controlled translation through English, which improves the UR output diversity (Section 4.1). To further boost performance we propose DIFFUR,[3] a novel algorithm using the recent finding that paraphrasing leads to stylistic changes (Krishna et al., 2020). DIFFUR extracts edit vectors from paraphrase pairs, which are used to condition and train the model (Figure 2). On formality transfer and code-mixing addition, our best performing DIFFUR variant significantly outperforms UR across all languages (by 2-3x) using automatic & human evaluation. Besides better rewriting, our system is better able to control the style transfer magnitude (Figure 1). A scalar knob (λ) can be adjusted to make the output text reflect the target style (provided by exemplars) more or less. We also observe promising qualitative results in several attribute transfer directions (Section 6.2) including sentiment transfer, simplification, gender neutralization and text anonymization, all *without retraining the model* and using just 3-10 examples at inference.

Finally, we found it hard to precisely evaluate models due to the lack of evaluation datasets and style classifiers (often used as metrics) for many languages. To facilitate further research in Indic formality transfer, we crowdsource formality annotations for 4000 sentence pairs in four Indic languages (Section 5.1), and use this dataset to design the automatic evaluation suite (Section 5).

In summary, our contributions provide an end-to-end recipe for developing and evaluating style transfer models and evaluation in a low-resource setting.

2 Related Work

Few-shot methods are a recent development in English style transfer, with prior work using variational autoencoders (Xu et al., 2020), or prompting large pretrained language models at inference (Reif et al., 2021). Most related is the state-of-the-art TextSETTR model from Riley et al. (2021), who use a neural style encoder to map exemplar sentences to a vector used to guide generation. To train this encoder, they use the idea that adjacent sentences in a document have a similar style. Recently, the **Universal Rewriter** (Garcia et al., 2021) extended TextSETTR to 101 languages, developing a joint model for translation, few-shot style transfer and stylized translation. This model is the only prior few-shot system we found outside English, and our main baseline. We discuss its shortcomings in Section 3.1, and propose fixes in Section 4.

Multilingual style transfer is mostly unexplored in prior work: a 35 paper survey by Briakou et al. (2021b) found only one work in Chinese, Russian, Latvian, Estonian, French. They further introduced XFORMAL, the first formality transfer *evaluation* dataset in French, Brazilian Portugese and Italian.[4] To the best of our knowledge, we are the first to study style *transfer* for the languages we consider. More related work from Hindi linguistics and on style transfer control is provided in Appendix B.

3 The Universal Rewriter (UR) model

We will start by discussing the Universal Rewriter (UR) model from Garcia et al. (2021), upon which our proposed DIFFUR model is built. At a high level, the UR model extracts a style vector $\mathbf{s}$ from an exemplar sentence e, which reflects the desired target style. This style vector is used to style transfer an input sentence x. Concretely, consider $f_{\text{enc}}, f_{\text{dec}}$ to be encoder & decoder Transformers initialized with mT5 (Xue et al., 2021b), which are composed to form the model f_{ur}. The UR model extracts the style vector using the encoder representation of a special `[CLS]` token prepended to e, and adds it to the input x representations for style transfer,

$$f_{\text{style}}(e) = \mathbf{s} = f_{\text{enc}}(\texttt{[CLS]} \oplus e)[0]$$
$$f_{\text{ur}}(x, \mathbf{s}) = f_{\text{dec}}(f_{\text{enc}}(x) + \mathbf{s})$$

where $\oplus$ is string concatenation, $+$ vector addition. f_{ur} is trained using the following objectives,

Learning Style Transfer by Exemplar-driven Denoising: To learn a style extractor, the Universal Rewriter uses the idea that two non-overlapping spans of text in the same document are likely to have the same style. Concretely, let x_1 and x_2 be

---

[2] Indic (`hi`, `bn`, `kn`, `gu`, `te`), Spanish, Swahili.

[3] "**Diff**erence **U**niversal **R**ewriter", pronounced as *differ*.

[4] We do not use this data since it does not cover Indian languages, and due to Yahoo! L6 corpus restrictions for industry researchers (confirmed via author correspondence).

two non-overlapping spans. Style extracted from one span (x_1) is used to denoise the other (x_2),

$$\begin{aligned}\bar{x}_2 &= f_{\text{ur}}(\text{noise}(x_2), f_{\text{style}}(x_1)) \\ \mathcal{L}_{\text{denoise}} &= \mathcal{L}_{\text{CE}}(\bar{x}_2, x_2)\end{aligned}$$

where $\mathcal{L}_{\text{CE}}$ is the standard next-word prediction cross entropy loss function and noise$(\cdot)$ refers to 20-60% random token dropping and token replacement. This objective is used on the mC4 dataset (Xue et al., 2021b) with 101 languages. To build a general-purpose rewriter which can do translation as well as style transfer, the model is **additionally trained on two objectives**: (1) supervised machine translation using the OPUS-100 parallel dataset (Zhang et al., 2020), and (2) a self-supervised objective to learn effective style-controlled translation; more details in Appendix C.

During **inference** (Figure 1), consider an input sentence x and a transformation from style A to B (say *informal* to *formal*). Let S_A, S_B to be exemplar sentences in each of the styles (typically 3-10 sentences). The output y is computed as,

$$\begin{aligned}\mathbf{s}_A &= \frac{1}{|S_A|}\sum_{y \in S_A} f_{\text{style}}(y) \\ \mathbf{s}_B &= \frac{1}{|S_B|}\sum_{y \in S_B} f_{\text{style}}(y) \\ y &= f_{\text{ur}}(x, \lambda(\mathbf{s}_B - \mathbf{s}_A))\end{aligned}$$

where λ acts as a control knob to determine the magnitude of style transfer, and the vector subtraction helps remove confounding style information.[5]

3.1 Shortcomings of the Universal Rewriter

We experimented with the UR model on Hindi formality transfer, and noticed poor performance. We noticed that UR has a **strong tendency to copy sentences *verbatim*** — 45.5% outputs were copied exactly from the input (and hence not style transferred) for the best performing value of λ. The copying increase for smaller λ, making magnitude control harder. We identify the following issues:

1. **Random token noise leads to unnatural inputs & transformations:** The Universal Rewriter uses 20-60% uniformly random token dropping or replacement to noise inputs, which leads to ungrammatical inputs during training. We hypothesize models tend to learn grammatical error correction, which encourages verbatim copying during inference where fluent inputs are used and no error correction is needed. Moreover, token-level noise does not differentiate between content or function words, and cannot do syntactic changes like content reordering (Goyal and Durrett, 2020). Too much noise could distort semantics and encourage hallucination, whereas too little will encourage copying.

2. **Style vectors may not capture the precise style transformation:** The Universal Rewriter extracts the style vector from a single sentence during training, which is a mismatch from the inference where a *difference* between vectors is taken. Without taking vector differences at inference, we observe semantic preservation and overall performance of the UR model is much lower.[6]

3. **mC4 is noisy**: On reading training data samples, we noticed noisy samples with severe language identification errors in the Hindi subset of mC4. This has also been observed recently in Kreutzer et al. (2022), who audit 100 sentences in each language, and report 50% sentences in Marathi and 20% sentences in Hindi have the wrong language.

4. **No translation data for several languages:** We notice worse performance for languages which did not get parallel translation data (for the translation objective in Section 3). In Table 1 we see UR gets a score[7] of 30.4 for Hindi and Bengali, languages for which it got translation data. However, the scores are lower for Kannada, Telugu & Gujarati (25.5, 22.8, 23.7), for which no translation data was used. We hypothesize translation data encourages learning language-agnostic semantic representations needed for translation from the given language, which in-turn improves style transfer.

4 Our Models

4.1 Style-Controlled Backtranslation (+ BT)

While the Universal Rewriter model has a strong tendency to exactly copy input sentences while rewriting sentences in the same language (Section 3.1), we found it is an effective style-controlled *translation* system. This motivates a simple **inference-time** trick to improve model outputs and reduce copying — translate sentences to English (`en`) in a style-agnostic manner with a zero style

---

[5] Garcia et al. (2021) also recommend adding the style vectors from the input sentence x, but we found this increased the amount of verbatim copying and led to poor performance.

[6] This difference possibly helps remove confounding information (like semantic properties, other styles) and focus on the specific style transformation. Since two spans in the same document will share aspects like article topic / subject along with style, we expect these semantic properties will confound the style vector space obtained after the UR training.

[7] Using the r-AGG style transfer metric from Section 5.5.

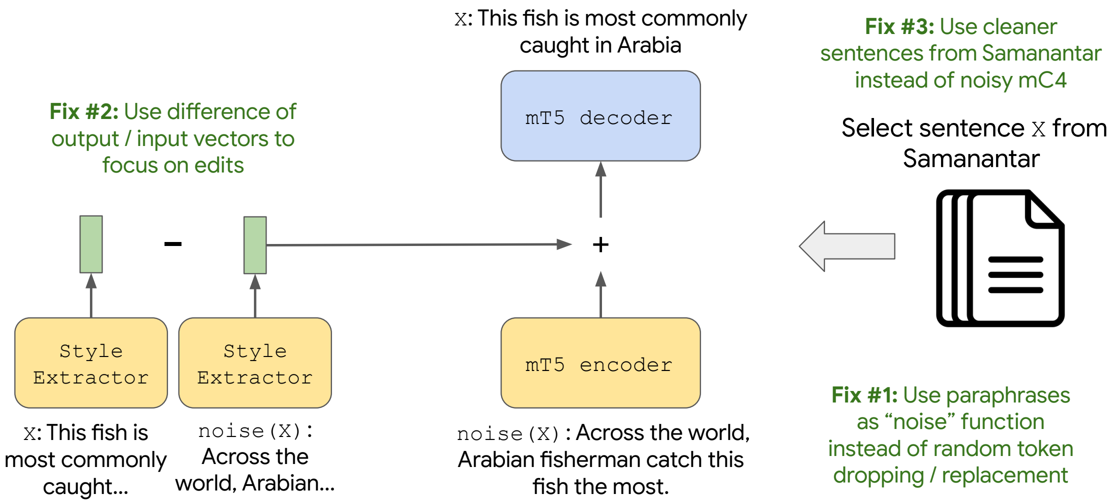

Figure 2: The DIFFUR approach (Section 4.2), with fixes to the shortcomings of the Universal Rewriter approach (Section 3.1) shown. Sentences are noised using paraphrasing, the style vector difference between the paraphrase & original sentence ("edit vector") is used to control denoising. See Figure 1 for the inference-time process.

vector $\mathbf{0}$, and translate back into the source language (`lx`) with stylistic control.

$$x^{\text{en}} = f_{\text{ur}}(\texttt{en} \oplus x, \mathbf{0})$$
$$\bar{x} = f_{\text{ur}}(\texttt{lx} \oplus x^{\text{en}}, \lambda(\mathbf{s}_B - \mathbf{s}_A))$$

where x is the input sentence, $\mathbf{s}_A, \mathbf{s}_B$ are the styles vectors we want to transfer between, `en`, `lx` are language codes prepended to indicate the output language (Appendix C). Prior work has shown that backtranslation is effective for paraphrasing (Wieting and Gimpel, 2018; Iyyer et al., 2018) and style transfer (Prabhumoye et al., 2018).

4.2 Using Paraphrase Vector Differences for Style Transfer (DIFFUR)

While style-controlled backtranslation is an effective strategy, it needs two translation steps. This is 2x slower than UR, and semantic errors increase with successive translations. To learn effective style transfer systems needing only a single generation step we develop DIFFUR, a new few-shot style transfer training objective (overview in Figure 2). DIFFUR tackles the issues discussed in Section 3.1 using paraphrases and style vector differences.

Paraphrases as a "noise" function: Instead of using random token-level noise (Issue #1 in Section 3.1), we paraphrase sentences to "noise" them during training. Paraphrasing modifies the lexical & syntactic properties of sentences, while preserving fluency and input semantics. Prior work (Krishna et al., 2020) has shown that paraphrasing leads to stylistic changes, and denoising can be considered a style re-insertion process.

To create paraphrases, we backtranslate sentences from the UR model[8] with no style control (zero vectors used as style vectors). To increase diversity, we use random sampling in both translation steps, pooling generations obtained using temperature values $[0.4, 0.6, 0.8, 1.0]$. Finally, we discard paraphrase pairs from the training data where the semantic similarity score[9] is outside the range $[0.7, 0.98]$. This removes backtransation errors (score < 0.7), and exact copies (score > 0.98). In Appendix K we confirm that our backtranslated paraphrases are lexically diverse from the input.

Using style vector differences for control: To fix the training / inference mismatch for style extraction (Issue #2 in Section 3.1), we propose using style vector differences between the output and input as the stylistic control. Concretely, let x be an input sentence and x_{para} its paraphrase.

$$\mathbf{s}_{\text{diff}} = f_{\text{style}}(x) - f_{\text{style}}(x_{\text{para}})$$
$$\bar{x} = f_{\text{ur}}(x_{\text{para}}, \text{stop-grad}(\mathbf{s}_{\text{diff}}))$$
$$\mathcal{L} = \mathcal{L}_{\text{CE}}(\bar{x}, x)$$

where stop-grad$(\cdot)$ stops gradient flow through $\mathbf{s}_{\text{diff}}$, preventing the model from learning to copy x exactly. To ensure f_{style} extracts meaningful style representations, we fine-tune a trained UR model. Vector differences have many advantages,

1. Subtracting style vectors between a sentence

---

[8] Specifically, an Indic variant of the UR model is used, described in Section 4.3. Note it is not necessary to use UR for backtranslation, any good translation model can be used.

[9] Calculated using LaBSE, discussed in Section 5.3.

and its paraphrase removes confounding features (like semantics) present in the vectors.

2. The vector difference focuses on the precise transformation that is needed to reconstruct the input from its paraphrase.
3. The length of $\mathbf{s}_{\text{diff}}$ acts as a proxy for the amount of style transfer, which is controlled using λ during inference (Section 3).

DIFFUR is related to neural editor models (Guu et al., 2018; He et al., 2020), where language models are decomposed into a probabilistic space of edit vectors over prototype sentences. We justify the DIFFUR design with ablations in Appendix G.1.

4.3 Indic Models (UR-INDIC, DIFFUR-INDIC)

To address the issue of no translation data (Issue #4 in Section 3.1), we train Indic variants of our models. We replace the OPUS translation data used for training the Universal Rewriter (Section 3) with Samanantar (Ramesh et al., 2021), which is the largest publicly available parallel translation corpus for 11 Indic languages. We call these variants UR-INDIC and DIFFUR-INDIC. This process significantly up-samples the parallel data seen between English / Indic languages, and gives us better performance (Table 1) and lower copy rates, especially for languages with no OPUS translation data.

4.4 Multitask Learning (DIFFUR-MLT)

One issue with our DIFFUR-INDIC setup is usage of a stop-grad($\cdot$) to avoid verbatim copying from the input. This prevents gradient flow into the style extractor f_{style}, and as we see in Appendix H, a degradation of the style vector space. To prevent this we simply multi-task between the exemplar-driven denoising UR objective (Section 3) and the DIFFUR objective. We initialize the model with the UR-INDIC checkpoint, and fine-tune it on these two losses together, giving each loss equal weight.

5 Evaluation

Automatic evaluation of style transfer is challenging (Pang, 2019; Mir et al., 2019; Tikhonov et al., 2019), and the lack of resources (such as evaluation datasets, style classifiers) make evaluation trickier for Indic languages. To tackle this issue, we first collect a small dataset of formality and semantic similarity annotations in four Indic languages (Section 5.1). We use this dataset to guide the design of an evaluation suite (Section 5.2-5.6). Since automatic metrics in generation are imperfect (Celikyilmaz et al., 2020), we complement our results with human evaluation (Section 5.7).

5.1 Indic Formality Transfer Dataset

Since no public datasets exist for formality transfer in Indic languages, it is hard to measure the extent to which automatic metrics (such as style classifiers) are effective. To tackle this issue, we build a dataset of **1000** sentence pairs in **each of four Indic languages** (Hindi, Bengali, Kannada, Telugu) with formality and semantic similarity annotations. We first style transfer held-out Samanantar sentences using our UR-INDIC + BT model (Section 4.1, 4.3) to create sentence pairs with different formality. We then asked three crowdworkers to 1) label the more formal sentence in each pair; 2) rate semantic similarity on a 3-point scale.

Our crowdsourcing is conducted on Task Mate,[10] where we hired native speakers from India with at least a high school education and 90% approval rating on the platform. To ensure crowdworkers understood "formality", we provided instructions following advice from professional Indian linguists, and asked two qualification questions in their native language. More details (agreement, compensation, instructions) are provided in Appendix E.4.

5.2 Transfer Accuracy (r-ACC, a-ACC)

Our first metric checks whether the output sentence reflects the target style. This is measured by an external classifier's predictions on system outputs. We use two variants of transfer accuracy: (1) Relative Accuracy (r-ACC): does the target style classifier score the output sentence *higher* than the input sentence? (2) Absolute Accuracy (a-ACC): does the classifier score the output *higher* than 0.5?

Building multilingual classifiers: Unfortunately, no large style classification datasets exist for most languages, preventing us from building classifiers from scratch. We resort to zero-shot cross lingual transfer techniques (Conneau and Lample, 2019), where large multilingual pretrained models are first fine-tuned on English classification data, and then applied to other languages at inference. We experiment with three such techniques, and find MAD-X classifiers with language adapters (Pfeiffer et al., 2020b) have the highest accuracy of 81% on our Hindi data from Section 5.1. However, MAD-X classifiers were only available for Hindi, so we use

---

[10] `https://taskmate.google.com`

the next best XLM RoBERTa-base (Conneau et al., 2020) for other languages, which has 75%-82% accuracy on annotated data; details in Appendix E.1.

5.3 Semantic Similarity (SIM)

Our second evaluation criteria is semantic similarity between the input and output. Following recent recommendations (Marie et al., 2021; Krishna et al., 2020), we avoid n-gram overlap metrics like BLEU (Papineni et al., 2002). Instead, we use LaBSE (Feng et al., 2020), a language-agnostic semantic similarity model based on multilingual BERT (Devlin et al., 2019). LaBSE supports 109 languages, and is the only similarity model we found supporting all the Indic languages in this work. We also observed LaBSE had greater correlation with our annotated data (Section 5.1) compared to alternatives; details in Appendix E.2.

Qualitatively, we found that sentence pairs with LaBSE scores lower than 0.6 were almost never paraphrases. To avoid rewarding partial credit for low LaBSE scores, we use a hard threshold[11] ($L = 0.75$) to determine whether pairs are paraphrases,

$$\textsc{sim}(x, y') = 1 \text{ if } \left\{\text{LaBSE}(x, y') > L\right\} \text{ else } 0$$

5.4 Other Metrics (LANG, COPY, 1-g)

Additionally, we measure whether the input and output sentences are in the same language (LANG), the fraction of outputs copied verbatim from the input (COPY), and the 1-gram overlap between input / output (1-g). High LANG and low COPY / 1-g (more diversity) is better; details in Appendix E.6.

5.5 Aggregated Score (r-AGG, a-AGG)

To get a sense of overall system performance, we combine individual metrics into one score. Similar to Krishna et al. (2020) we aggregate metrics as,

$$\textsc{agg}(x, y') = \textsc{acc}(x, y') \cdot \textsc{sim}(x, y') \cdot \textsc{lang}(y')$$

$$\textsc{agg}(\mathcal{D}) = \frac{1}{|\mathcal{D}|} \sum_{x, y' \in \mathcal{D}} \textsc{agg}(x, y')$$

Where (x, y') are input-output pairs, and $\mathcal{D}$ is the test corpus. Since each of our individual metrics can only take values 0 or 1 at an instance level, our aggregation acts like a Boolean AND operation. In other words, we are measuring the fraction of outputs which *simultaneously* transfer style, have a semantic similarity of at least L (our threshold in Section 5.3), and have the same language as the input. Depending on the variant of ACC (relative / absolute), we can derive r-AGG / a-AGG.

5.6 Evaluating Control (CALIB)

An ideal system should not only be able to style transfer sentences, but also control the *magnitude* of style transfer using the scalar input λ. To evaluate this, for every system we first determine a λ_{max} value and let $[0, \lambda_{\text{max}}]$ be the range of control values. While in our setup λ is an unbounded scalar, we noticed high values of λ significantly perturb semantics (also noted in Garcia et al., 2021), with systems outputting style-specific n-grams unfaithful to the output. We choose λ_{max} to be the largest λ from the list $[0.5, 1.0, 1.5, 2.0, 2.5, 3.0]$ whose outputs have an average semantic similarity score (SIM, Section 5.3) of at least 0.75[12] with the validation set inputs. For each system we take three evenly spaced λ values in its control range, denoted as $\Lambda = [\frac{1}{3}\lambda_{\text{max}}, \frac{2}{3}\lambda_{\text{max}}, \lambda_{\text{max}}]$. We then compute the **style calibration to** λ (CALIB), or how often does increasing λ lead to a style score increase? We measure this with a statistic similar to Kendall's τ (Kendall, 1938), counting concordant pairs in Λ,

$$\textsc{calib}(x) = \frac{1}{n} \sum_{\lambda_b > \lambda_a} \{\text{style}(y_{\lambda_b}) > \text{style}(y_{\lambda_a})\}$$

where x is input, CALIB(x) is the average over all possible n $(= 3)$ pairs of λ values (λ_a, λ_b) in Λ.

5.7 Human Evaluation

Automatic metrics are usually insufficient for style transfer evaluation — according to Briakou et al. (2021a), 69 / 97 surveyed style transfer papers used human evaluation. We adopt the crowd-sourcing setup from Section 5.1, which was used to build our formality evaluation datasets. We presented 200 generations from each model and the corresponding inputs in a random order, and asked three crowdworkers two questions about each pair of sentences: (1) which sentence is more formal/code-mixed? (2) how similar are the two sentences in meaning? This lets us evaluate r-ACC, SIM, r-AGG, CALIB with respect to human annotations instead of classifier predictions. More experiment details (inter-annotator agreement, compensation, instructions) are provided in Appendix E.4.

---

[11] Roughly 73% pairs annotated as paraphrases (from dataset in Section 5.1) had $L > 0.75$. We experiment with different values of L in Appendix E.3 and notice similar trends.

[12] This threshold is identical to the value chosen for paraphrase similarity in Section 5.3. We experiment with more/less conservative thresholds in Appendix E.3.

Model	Hindi		Bengali		Kannada		Telugu		Gujarati	
	r-AGG	a-AGG	r-AGG	a-AGG	r-AGG	a-AGG	r-AGG	a-AGG	r-AGG	a-AGG
UR (2021)	30.4	10.4	30.4	7.2	25.5	8.0	22.8	8.4	23.7	5.0
UR-INDIC	58.3	18.6	65.5	22.3	61.3	17.8	59.8	19.9	54.0	10.7

DIFFUR-MLT	2.5	4.4	61.9	97.2	89.7	89.7	34.0	**78.1**	**27.5**

Table 2: Performance by individual metrics for Hindi formality transfer. DIFFUR-MLT gives best overall performance (r-AGG / a-AGG), with a good trade-off between style accuracy (ACC), semantic similarity (SIM), langID score (LANG), and low input copy rates (COPY); metrics defined in Section 5, other language results in Appendix I.

6 Main Experiments

6.1 Experimental Setup

In our experiments, we compare the following models (training details are provided Appendix A):

- UR: the Universal Rewriter (Garcia et al., 2021), which is our main baseline (Section 3);
- DIFFUR: our model with paraphrase vector differences (Section 4.2);
- UR-INDIC, DIFFUR-INDIC: Indic variants of UR and DIFFUR models (Section 4.3);
- DIFFUR-MLT: Multitask training between UR-INDIC and DIFFUR-INDIC (Section 4.4);
- + BT: models with style-controlled backtranslation at inference time (Section 4.1).

Our models are **evaluated** on (1) formality transfer (Rao and Tetreault, 2018); (2) code-mixing addition, a task where systems attempt to use English words in non-English sentences, while preserving the original script.[13] Since we do not have access to any formality evaluation dataset,[14] we hold out 22K sentences from Samanantar in each Indic language for validation / testing. For Swahili / Spanish, we use mC4 / WMT2018 sentences. These sets have similar number of formal / informal sentences, as marked by our formality classifiers (Section 5.2), and are transferred to the opposite formality. We re-use the hi/bn formality transfer splits for code-mixing addition, evaluating unidirectional transfer.

Seven languages with varying scripts and morphological richness are used for evaluation (`hi,es,sw,bn,kn,te,gu`). The UR model only saw translation data for `hi,es,bn`, whereas UR-INDIC sees translation data for all Indic languages (Section 4.3). To test the generalization capability of the DIFFUR, no Gujarati paraphrase training data for is used. Note that *no paired/unpaired data with style labels is used during training*: models determine the target style at inference using 3-10 exemplars sentences. For few-shot formality transfer, we use the English exemplars from Garcia et al. (2021). We follow their setup and use English exemplars to guide non-English transfer zero-shot. For code-mixing addition, we use Hindi/English code-mixed exemplars in Devanagari (shown in Appendix D).

6.2 Main Results

Each proposed method improves over prior work, DIFFUR-MLT works best. We present our

---

[13] Hinglish is common in India, examples in Figure 5.

[14] We do not use GYAFC (Rao and Tetreault, 2018) and XFORMAL (Briakou et al., 2021b) due to reasons in footnote 4. Our dataset from Section 5.1 has already been used for classifier selection, and has machine generated sentences.

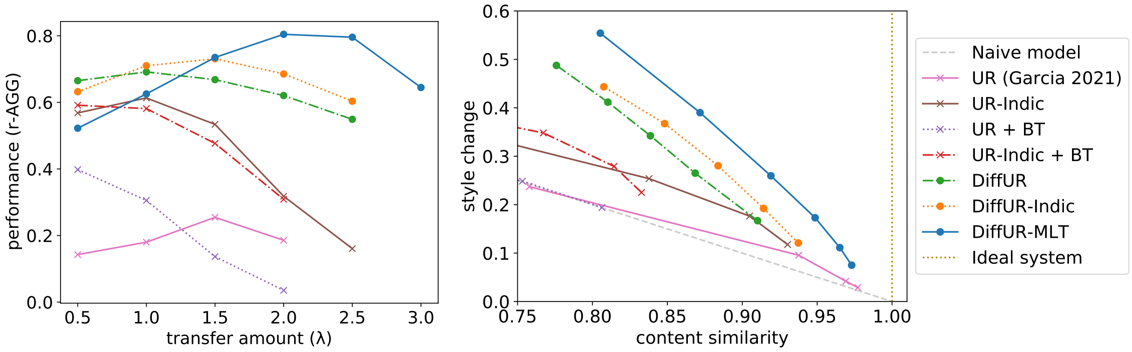

Figure 3: Variation in Kannada formality transfer with λ. In the *left* plot, we see DIFFUR-* models have consistently good overall performance with change in λ. In the *right* plot, we see the tradeoff between average style change and content similarity as λ is varied. Plots (such as DIFFUR-*) which stretch the Y-axis range, closer to the ideal system ($x = 1$) and away from the naive system ($x + y = 1$, akin to naive model in Krishna et al., 2020) are better.

Model	Swahili r-AGG / a-AGG	Spanish r-AGG / a-AGG
UR (2021)	19.9 / 4.8	13.4 / 1.3
UR, BT	13.7 / 3.4	33.3 / 5.8
DIFFUR-MLT	**32.2 / 7.2**	**46.5 / 16.5**

Table 3: Automatic evaluation of formality transfer in Swahili and Spanish. DIFFUR-MLT performs best.

Model	ACC	SIM	AGG	CALIB	C-IN
UR (2021)	29.5	**87.2**	23.2	-	-
UR-INDIC	46.5	85.3	40.8	35.7	43.0
UR + BT	57.5	71.2	42.9	-	-
UR-INDIC + BT	65.0	77.8	52.4	24.0	40.3
DIFFUR	64.5	80.8	52.0	-	-
DIFFUR-INDIC	62.0	83.1	50.4	48.0	**54.5**
DIFFUR-MLT	**70.0**	80.8	**55.6**	**53.0**	**54.5**

Table 4: Human evaluation on Hindi formality transfer, measuring style accuracy (ACC), input similarity (SIM), overall score (AGG) and control with λ (CALIB, C-IN). Like Table 1, DIFFUR-MLT performs best.

Model	Hindi ACC / SIM / AGG	Bengali ACC / SIM / AGG
UR (2021)	4.5 / **93.8** / 3.6	0.0 / **96.4** / 0.0
UR-INDIC,BT	18.5 / 79.2 / 15.3	18.0 / 68.3 / 12.7
DIFFUR-MLT,BT	**62.5** / 69.9 / **41.5**	**79.0** / 57.1 / **43.5**

Table 5: Human evaluation on code-mixing addition. DIFFUR-MLT+BT performs best (AGG), giving high style accuracy (ACC). Due to verbatim copying, UR SIM score is nearly 100, but ACC score close to 0.

Model	CALIB	Model	CALIB
UR (2021)	29.2	DIFFUR	64.9
UR-INDIC	60.7	DIFFUR-INDIC	**69.6**
UR + BT	43.4	DIFFUR-MLT	69.0
UR-INDIC + BT	38.7		

Table 6: Evaluation of Hindi formality transfer magnitude control using λ. We find that DIFFUR-* are best at calibrating style change (CALIB) to input λ (metrics details in Section 5.6, more results in Appendix F).

automatic evaluation results for formality transfer across languages in Table 1, Table 3. Overall we find that each of our proposed methods (DIFFUR, *-INDIC, +BT) helps improve performance over the baseline UR model (71.1, 58.3, 54.2 vs 30.4 r-AGG on Hindi). Combining these ideas with multitask learning (DIFFUR-MLT) gives us the best performance across all languages (78.1 on Hindi). On Gujarati, the DIFFUR-INDIC fails to get good performance (36.0 r-AGG) since it did not see Gujarati paraphrase data, but this performance is recovered using DIFFUR-MLT (75.0). In Table 4 we see human evaluations support our automatic evaluation for formality transfer. In Table 5 we perform human evaluation on a subset of models for code-mixing addition and see similar trends, with DIFFUR-MLT significantly outperforming UR, UR-INDIC (41.5 AGG vs 3.6, 15.3 on Hindi).

DIFFUR-MLT and DIFFUR-INDIC are best at controlling magnitude of style transfer: In Table 6, we compare the extent to which models can control the amount of style transfer using λ. We find that all our proposed methods outperform the UR model, which gets only 29.2 CALIB. +BT models are not as effective at control (43.4 CALIB), while DIFFUR-INDIC and DIFFUR-MLT perform best (69.6, 69.0 CALIB). This is graphically illustrated in Figure 3. DIFFUR-MLT performs consistently well across different λ values (left plot), and gives a high style change without much drop in content similarity to the input as λ is varied (right plot); more control experiments in Appendix F.

In Table 2 we provide a **breakdown by individual metrics**. In the baseline Hindi UR model, we notice high COPY rates (45.4%), resulting in lower

Input	Generations	Analysis
Informal अपनी वाली जॉब मुझे मत बताओ. (don’t tell me about your job)	*Formal* (λ = 0.5) अपनी वाली नौकरी मुझे मत बताओ। (λ = 1.0) अपनी नौकरी के बारे में मुझे बताने की जरूरत नहीं। (λ = 1.5) आपकी नियुक्ति के बारे में मुझे ना बताएं।	As sentences get more formal, the english word “job” (जॉब) is converted to Persian (नौकरी) / high Sanskrit (नियुक्ति) and honorifics are used (आपकी, बताएं)
Formal हिंसा में दो लोगों की मौत हुई थी और लगभग 150 घायल हुए थे। (two people died in the violence and 150 were injured)	*Informal* (λ = 1.0) हिंसा में दो लोग मारे गए और 150 के करीब लोग घायल हो गए. (λ = 1.5) हिंसा में 2 लोग मारे गए थे व 150 लोग घायल हुए थे (λ = 2.0) हिंसा में 2 लोग मारे गए और 150 घायल	As sentences get more informal besides lexical changes, sentence shortening is common, while roughly conveying same meaning
Positive Sentiment मुझे यह फिल्म बहुत पसंद आई तुम तोह काफी इंटेलीजेंट हो	*Negative Sentiment* इस फिल्म को मैंने कभी पसंद नहीं किया. तुम बेहद अनाड़ी हो.	Negations (नहीं) and word antonyms (इंटेलीजेंट, अनाड़ी) are common as sentiment changes
Complex भाजपा व्यंग्य करती महसूस होती है। कठिन परिश्रम कर सकता है.	*Simple* भाजपा मजाक करती दिख रही है। कड़ी चीजें कर सकते हैं।	Lexical substitutions (व्यंग्य → मजाक, कठिन → कड़ी) to use more commonly spoken words
Monocode 01.2017 से, अर्थात इस योजना के चालू होने की तिथि से प्रभावी बोली लगाने के लिए सलाहकारी सेवाएं	*Code-mixed* 01.2017, i.e. उस डेट से, जब से यह योजना इंटीग्रेटेड है बोली लगाने के लिए काउंसलिंग सर्विसिज़	With code-mixing, several english words are introduced (तिथि → डेट / date, अर्थात → i.e., सलाहकारी सेवाएं → काउंसलिंग सर्विसिज़ / counseling services)
De-anonymized फिल्म में कार्थी और अदिति राव हैदरी मुख्य किरदार निभाते हुए नजर आ रहे हैं। और इसमाईल, अलयसअ, यूनुस और लूत को भी। इनमें से हर एक को हमने संसार के मुक़ाबले में श्रेष्ठता प्रदान की	*Anonymized *** फिल्म में PII और PII PII मुख्य भूमिका निभाते हुए नजर आ रहे हैं। और PII, PII, PII और PII को भी। इनमें से प्रत्येक को हमने संसार के विरुद्ध ऊँचाइयाँ प्रदान की	Entities (अदिति राव हैदरी, इसमाईल) are replaced with PII (Personal Identifiable Information) tags, to anonymize text
Gendered रियो ओलंपिक : बैडमिंटन में भारतीय महिलाओं ने किया निराश, हार से हुई शुरुआत	*Gender Neutral *** रियो ओलंपिक : बैडमिंटन में भारतीय खिलाड़ियों ने किए निराश, हार से हुए शुरू	Gendered words (महिलाओं) are replaced with their neutral equivalents (खिलाड़ियों)

Figure 4: Outputs and qualitative analysis of our best performing model for several attribute transfer tasks (λ is transfer magnitude). We notice lower quality qualitatively for ** marked styles; see Appendix J for more outputs.

ACC scores. COPY reduces in our proposed models (4.4% for DIFFUR-MLT), which boosts overall performance. We find the lowest COPY (and lowest 1-g) for models with +BT (1%), which is due to two translation steps. However, this lowers semantic similarity (also seen in Table 4) lowering the overall score (60.0 vs 78.1) compared to DIFFUR-MLT.

In Appendix G we show **ablations studies** justifying the DIFFUR design, decoding scheme, etc. In Appendix I we show a breakdown by individual metrics for other languages and plot variations with λ. We also analyze the style encoder f_{style} in Appendix H, finding it is an effective style classifier.

We **analyze several qualitative outputs** from DIFFUR-MLT in Figure 4. Besides formality transfer and code-mixing addition, we transfer several other attributes: sentiment (Li et al., 2018), simplicity (Xu et al., 2015), anonymity (Anandan et al., 2012) and gender neutrality (Reddy and Knight, 2016). More outputs are provided in Appendix J.

7 Conclusion

We present a recipe for building & evaluating controllable few-shot style transfer systems needing only 3-10 style examples at inference, useful in low-resource settings. Our methods outperform prior work in formality transfer & code-mixing for 7 languages, with promising qualitative results for several other attribute transfer tasks. Future work includes further improving systems for some attributes, and studying style transfer for languages where little / no translation data is available.

Acknowledgements

We are very grateful to the Task Mate team (especially Auric Bonifacio Quintana) for their support and helping us crowdsource data and evaluate models on their platform. We thank John Wieting, Timothy Dozat, Manish Gupta, Rajesh Bhatt, Esha Banerjee, Yixiao Song, Marzena Karpinska, Aravindan Raghuveer, Noah Constant, Parker Riley, Andrea Schioppa, Artem Sokolov, Mohit Iyyer and Slav Petrov for several useful discussions during the course of this project. We are also grateful to Rajiv Teja Nagipogu, Shachi Dave, Bhuthesh R, Parth Kothari, Bhanu Teja Gullapalli and Simran Khanuja for helping us annotate model outputs in several Indian languages during pilot experiments. This work was mostly done during Kalpesh Krishna (KK)'s internship at Google Research India, hosted by Bidisha Samanta and Partha Talukdar. KK was partly supported by a Google PhD Fellowship.

Ethical Considerations

Recent work has highlighted issues of stylistic bias in text generation systems, specifically machine translation systems (Hovy et al., 2020). We acknowledge these issues, and consider style transfer and style-controlled generation technology as an opportunity to work towards fixing them (for instance, gender neutralization as presented in Section 6.2). Note that it is important to tread down this path carefully — In Chapter 9, Blodgett (2021) argue that style is inseparable from social meaning (as originally noted by Eckert, 2008), and humans may perceive automatically generated text very differently compared to automatic style classifiers.

Our models were trained on 32 Google Cloud TPUs. As discussed in Appendix A, the UR & UR-INDIC model take roughly 18 hours to train. The DIFFUR-* and DIFFUR-MLT models are much cheaper to train (2 hours) since we finetune the pretrained UR-* models. The Google 2020 environment report mentions,[15] "TPUs are highly efficient chips which have been specifically designed for machine learning applications". These accelerators run on Google Cloud, which is carbon neutral today, and is aiming to "run on carbon-free energy, 24/7, at all of Google's data centers by 2030" (`https://cloud.google.com/sustainability`).

Appendices for "Few-shot Controllable Style Transfer for Low-Resource Multilingual Settings"

A Model training details

To **train** the UR-INDIC model, we use mC4 (Xue et al., 2021b) for the self-supervised objectives and Samanantar (Ramesh et al., 2021) for the supervised translation. For creating paraphrase data for training our DIFFUR models (Section 4.2), we again leverage Indic language side of Samanantar sentence pairs. Our models are implemented in JAX (Bradbury et al., 2018) using the T5X library.[16] We re-use the UR checkpoint from Garcia et al. (2021). To train the UR-INDIC model, we follow the setup in Garcia et al. (2021) and initialize the model with mT5-XL (Xue et al., 2021b), which has 3.7B parameters. We fine-tune the model for 25K steps with a batch size of 512 inputs and a learning rate of 1e-3, using the objectives in Section 3. Training was done on 32 Google Cloud TPUs which took a total of 17.5 hours. To train the DIFFUR and DIFFUR-INDIC models, we further fine-tune UR and UR-INDIC for a total of 4K steps using the objective from Section 4.2, taking 2 hours.

B More Related Work

Multilingual style transfer is mostly unexplored in prior work: a 35 paper survey by Briakou et al. (2021b) found only one work in Chinese, Russian, Latvian, Estonian, French (Shang et al., 2019; Tikhonov and Yamshchikov, 2018; Korotkova et al., 2019; Niu et al., 2018). Briakou et al. (2021b) further introduced XFORMAL, the first formality transfer *evaluation* dataset in French, Brazilian Portugese and Italian.[17] Hindi formality has been studied in linguistics, focusing on politeness (Kachru, 2006; Agnihotri, 2013; Kumar, 2014) and code-mixing (Bali et al., 2014). Due to its prevalence in India, English-Hindi code-mixing has seen work in language modeling (Pratapa et al., 2018; Samanta et al., 2019) and core NLP tasks (Khanuja et al., 2020). To the best of our knowledge, we are the first to study style *transfer* for Indic languages. A few prior works build models which can **control the degree of style transfer** using a scalar input (Wang et al., 2019; Samanta et al., 2021). However, these models are style-specific and require large unpaired style corpora during training. We adopt the inference-time control method used by Garcia et al. (2021) and notice much better controllability after our proposed fixes in Section 4.2.

C More details on the translation-specific Universal Rewriter objectives

In this section we describe the details of the supervised translation objective and the style-controlled translation objective used in the Universal Rewriter model. See Section 3 for details on the exemplar-based denoising objective.

Learning translation via direct supervision: This objective is the standard supervised translation setup, using zero vectors for style. The output language code is prepended to the input. Consider a pair of parallel sentences (x, y) in languages with codes `lx`, `ly` (prepended to the input string),

$$\begin{aligned} \bar{y} &= f_{\text{ur}}(\texttt{ly} \oplus x, \mathbf{0}) \\ \mathcal{L}_{\text{translate}} &= \mathcal{L}_{\text{CE}}(\bar{y}, y) \end{aligned}$$

The Universal Rewriter is trained on English-centric translation data from the high-resource languages in OPUS-100 (Zhang et al., 2020).

Learning style-controlled translation: This objective emulates "style-controlled translation" in a self-supervised manner, via backtranslation through English. Consider x_1 and x_2 to be two non-overlapping spans in mC4 in language `lx`,

$$\begin{aligned} x_2^{\texttt{en}} &= f_{\text{ur}}(\texttt{en} \oplus x_2, -f_{\text{style}}(x_1)) \\ \bar{x}_2 &= f_{\text{ur}}(\texttt{lx} \oplus x_2^{\texttt{en}}, f_{\text{style}}(x_1)) \\ \mathcal{L}_{\text{BT}} &= \mathcal{L}_{\text{CE}}(\bar{x}_2, x_2) \end{aligned}$$

D Choice of Exemplars

Formal exemplars

1. This was a remarkably thought-provoking read.
2. It is certainly amongst my favorites.
3. We humbly request your presence at our gala in the coming week.

Informal exemplars

1. reading this rly makes u think
2. Its def one of my favs
3. come swing by our bbq next week if ya can make it

Complex exemplars

2. हमें और कर्मचारियों की जरूरत है
3. यह डॉक्टर बहुत अच्छे हैं

Figure 6: Exemplars used for gender neutralization.

1. The static charges remain on an object until they either bleed off to ground or are quickly neutralized by a discharge.
2. It is particularly famous for the cultivation of kiwifruit.
3. Notably absent from the city are fortifications and military structures.

Simple exemplars
1. Static charges last until they are grounded or discharged.
2. This area is known for growing kiwifruit.
3. Some things important missing from the city are protective buildings and military buildings.

De-anonymized Exemplars
1. मेरा फोन नंबर 091898807646 है
2. केट का आधार नंबर है 4098-7980-8098
3. 18 सितंबर को मैंने microsoft.com पर विज़िट किया और IP 192.168.0.1 से test@google.site पर एक ईमेल भेजा।
4. मेरा पासपोर्ट नंबर 4903-3289-2394 है
5. फिल Google में बारबरा की टीम में काम करता है
6. बॉब 42 साल का है
7. शर्लक 221B बेकर स्ट्रीट में रहता है
8. मेरा ईमेल पता है email1@gmail.com

Anonymized Exemplars
1. मेरा फोन नंबर PII है
2. PII का आधार नंबर है PII
3. PII को मैंने PII पर विज़िट किया और IP PII से PII पर एक ईमेल भेजा।
4. मेरा पासपोर्ट नंबर PII है
5. PII PII में PII की टीम में काम करता है
6. PII PII साल का है
7. PII PII में रहता है
8. मेरा ईमेल पता है PII

Figure 7: Exemplars used for text anonymization. All entities in the deanonymized exemplars are random.

Positive sentiment exemplars
1. The most comfortable bed I've ever slept on, I highly recommend it.
2. I loved it.
3. The movie was fantastic.

Negative sentiment exemplars
1. The most uncomfortable bed I've ever slept on, I would never recommend it.
2. I hated it.
3. The movie was awful.

E Evaluation Appendix

E.1 Multilingual Classifier Selection

Due to the absence of a style classification dataset in Indic languages, we built our multilingual classifier drawing inspiration from recent research in zero-shot cross-lingual transfer (Conneau et al., 2018; Conneau and Lample, 2019; Pfeiffer et al., 2020b). We experimented with three zero-shot transfer techniques while selecting our classifiers for evaluating multilingual style transfer.

TRANSLATE TRAIN: The first technique uses the hypothesis that style is preserved across translation.

We classify the style of English sentences in the Samanantar translation dataset (Ramesh et al., 2021) using a style classifier trained on English formality data from Krishna et al. (2020). We use the human translated Indic languages sentences as training data. This training data is used to fine-tune a large-scale multilingual language model.

ZERO-SHOT: The second technique fine-tunes large-scale multilingual language models on a English style transfer dataset, and applies it zero-shot on multilingual data during inference.

MAD-X: Introduced by Pfeiffer et al. (2020b), this technique is similar to ZERO-SHOT but additionally uses language-specific parameters ("adapters") during inference. These language-specific adapters have been originally trained using masked language modeling on the desired language data.

Dataset for evaluating classifiers: We conduct our experiments on Hindi formality classification, leveraging our evaluation datasets from Section 5.1. We removed pairs which did not have full agreement across the three annotators and those pairs which had the consensus rating of "Equal" formality. This filtering process leaves us with 316 pairs in Hindi (out of 1000). In our experiments, we check whether the classifiers give a higher score to the more formal sentence in the pair.

Models: We leverage the multilingual classifiers open-sourced[18] by Krishna et al. (2020). These models have been trained on the English GYAFC formality classification dataset (Rao and Tetreault, 2018), and have been shown to be effective on the XFORMAL dataset (Briakou et al., 2021b) for formality classification in Italian, French and Brazilian Portuguese.[13] These classifiers were trained on preprocessed data which had trailing punctuation stripped and English sentences lower-cased, encouraging the models to focus on lexical and syntactic choices. As base multilingual language models, we use (1) mBERT-base from Devlin et al. (2019); (2) XLM-RoBERTa-base from Conneau et al. (2020).

Results: Our results on Hindi are presented in Table 7 and other languages in Table 8. Consistent with Pfeiffer et al. (2020b), we find MAD-X to be a superior zero-shot cross lingual transfer method compared to baselines. We also find XLM-R has better multilingual representations than mBERT. Unfortunately, AdapterHub (Pfeiffer et al., 2020a) has XLM-R language adapters available only for Hindi & Tamil (among Indic languages). For other languages we use the ZERO-SHOT technique on XLM-R, consistent with the recommendations[13] provided by Krishna et al. (2020) based on their experiments on XFORMAL (Briakou et al., 2021b).

Method	Model	Accuracy (↑)
TRANSLATE TRAIN	mBERT	66%
ZERO-SHOT	mBERT	72%
	XLM-R	76%
MAD-X	XLM-R	**81**%

Table 7: Hindi formality classification accuracy on our crowdsourced dataset (Section 5.1) using different cross-lingual transfer methods. Our results indicate that MAD-X is the most effective method, and XLM-R is a better pretrained model than mBERT.

Language	mBERT	XLM-R
bn	65.3%	82.2%
kn	76.3%	76.9%
te	72.6%	74.6%

Table 8: Formality classification on our crowdsourced Bengali, Kannada and Telugu dataset (Section 5.1) using the ZERO-SHOT technique described in Appendix E.1. Results confirm the efficacy of the XLM-R classifier. See Table 7 for Hindi results.

E.2 Semantic Similarity Model Selection

We considered three models for evaluating semantic similarity between the input and output:

(1) LaBSE (Feng et al., 2020);
(2) m-USE (Yang et al., 2020);
(3) multilingual Sentence-BERT (Reimers and Gurevych, 2020), the knowledge-distilled variant `paraphrase-xlm-r-multilingual-v1`

Among these models, only LaBSE has support for all the Indic languages we were interested in. No Indic language is supported by m-USE, and

---

[18] `https://github.com/martiansideofthemoon/style-transfer-paraphrase/blob/master/README-multilingual.md`

multilingual Sentence-BERT has been trained on parallel data only for Hindi, Gujarati and Marathi among our Indic languages. However, in terms of Semantic Textual Similarity (STS) benchmarks (Cer et al., 2017) for English, Arabic & Spanish, m-USE and Sentence-BERT outperform LaBSE (Table 1 in Reimers and Gurevych, 2020).

LaBSE correlates better than Sentence-BERT with our human-annotated formality dataset: We measured the Spearman's rank correlation between the semantic similarity annotations on our human-annotated formality datasets (Section 5.1). We discarded 10% sentence pairs which had no agreement among three annotators and took the majority vote for the other sentence pairs. We assigned "Different Meaning" a score of 0, "Slight Difference in Meaning" a score of 1 and "Approximately Same Meaning" a score of 2 before measuring Spearman's rank correlation. In Table 9 we see a stronger correlation of human annotations with LaBSE compared to Sentence-BERT, especially for languages like Bengali, Kannada for which Sentence-BERT did not see parallel data.

Model	hi	bn	kn	te
LaBSE	0.34	0.49	0.39	0.25
Sentence-BERT	0.33	0.36	0.29	0.18

Table 9: Spearman's rank correlation between different semantic similarity models and our semantic similarity human annotations collected along with formality labels. Overall, LaBSE correlates more strongly than Sentence-BERT with our annotated data.

E.3 Evaluation with Different LaBSE thresholds

In Section 6, we set our LaBSE threshold L to 0.75. In this section, we present our evaluations with a more and less conservative value of L.

In Table 18, we present results with $L = 0.65$, and in Table 19 we set $L = 0.85$. Compared to Table 1, trends are mostly similar, with DIFFUR models and INDIC variants outperforming counterparts. Note that the absolute values of SIM and AGG metrics differ, with absolute values going down with the stricter threshold of $L = 0.85$, and up with the relaxed threshold of $L = 0.65$.

Comparing chosen thresholds with human annotations: To verify these three thresholds are reasonable choices, we measure the LaBSE similarity of the sentence pairs annotated by humans, and compare the LaBSE scores to human semantic similarity annotations. We pool the "Approximately Same Meaning" and "Slight Difference in Meaning" categories as "same", and consider only sentence pairs with a majority rating of "same". In Table 10 we see that the chosen thresholds span the spectrum of LaBSE values for the human annotated semantically similar pairs.

	% of sentence pairs > L			
Threshold L	hi	bn	kn	te
0.65	97.4	96.1	94.6	90.6
0.75	83.9	76.1	68.4	62.6
0.85	75.1	62.7	50.5	45.5

Table 10: Percentage of human annotated semantically similar pairs which have a LaBSE score of at least L. As we increase the threshold L, we see this percentage substantially reduces, indicating our chosen thresholds are within the range of variation in LaBSE scores for semantically similar sentences.

E.4 More Crowdsourcing Details

In Figure 17, we show screenshots of our crowdsourcing interface along with all the instructions shown to crowdworkers. The instructions were written after consulting professional Indian linguists. Each crowdworker was allowed to annotate a maximum of 50 different sentence pairs per language, paying them $0.05 per pair. For formality classification, we showed crowdworkers two sentences and asked them to choose which one is more formal. Crowdworkers were allowed to mark ties using an "*Equal*" option. For semantic similarity annotation, we showed crowdworkers the sentence pair and provided three options — "*approximately same meaning*", "*slight difference in meaning*", "*different meaning*", to emulate a 3-point Likert scale. While performing our human evaluation (Section 5.7), we use a 0.5 SIM score for "*slight difference in meaning*" and a 1.0 SIM score for "*approximately same meaning*" annotations. For every system considered, we analyzed the same set of 200 input sentences for style transfer performance, and 100 of those sentences for evaluating controllability. We removed sentences which were exact copies of the input (after removing trailing punctuation) or were in the wrong language to save annotator time and cost. When outputs were exact copies of the input, we assigned SIM = 100, ACC = 0, AGG = 0.

In Table 11 and Table 12 we show the inter-annotator agreement statistics. We measure Fleiss Kappa (Fleiss, 1971), Randolph Kappa (Randolph, 2005; Warrens, 2010), the fraction of sentence pairs with total agreement between the three annotators and the fraction of sentence pairs with no agreement.[19] In the table we can see all agreement statistics are well away from a uniform random annotation baseline, indicating good agreement.

	F-κ	R-κ	all agree	none agree
Random	0.00	0.00	11.1%	22.2%
hi	0.21	0.28	32.8%	10.2%
bn	0.33	0.40	43.8%	7.2%
kn	0.22	0.31	35.0%	7.7%
te	0.21	0.31	36.0%	9.3%

Table 11: Fleiss kappa (F-κ), Randolph kappa (R-κ), and agreement scores of crowdsourcing for **formality classification**. All κ scores are well above a random annotation baseline, indicating fair agreement.

	F-κ	R-κ	all agree	none agree
Random	0.00	0.00	11.1%	22.2%
hi	0.10	0.27	32.6%	11.8%
bn	0.24	0.34	38.7%	10.2%
kn	0.13	0.25	30.8%	11.3%
te	0.10	0.31	36.1%	9.7%

Table 12: Fleiss kappa (F-κ), Randolph kappa (R-κ), and agreement scores of crowdsourcing for **semantic similarity**. All κ scores are well above a random annotation baseline, indicating fair agreement.

E.5 Fluency Evaluation

Unlike some prior works, we **avoid evaluation of output fluency** due to the following reasons: (1) lack of fluency evaluation tools for Indic languages;[20] (2) fluency evaluation often discriminates against styles which are out-of-distribution for the fluency classifier, as discussed in Appendix A.8 of Krishna et al. (2020); (3) several prior works (Pang, 2019; Mir et al., 2019; Krishna et al., 2020) have recommended against using perplexity of style language models for fluency evaluation since it is unbounded and favours unnatural sentences with common words; (4) large language models are known to produce fluent text as perceived by humans (Ippolito et al., 2020; Akoury et al., 2020), reducing the need for this evaluation.

E.6 Details of other individual metrics

Language Consistency (LANG): Since our semantic similarity metric LaBSE is language-agnostic, it tends to ignore accidental translations, which are common errors in large multilingual transformers (Xue et al., 2021a,b), especially the Universal Rewriter (Section 3.1). Hence, we check whether the output sentence is in the same language as the input, using `langdetect`.[21]

Output Diversity (COPY, 1-g): As discussed in Section 3.1, the Universal Rewriter has a strong tendency to copy the input verbatim. We build two metrics to measure output diversity compared to the input, which have been previously used for extractive question answering evaluation (Rajpurkar et al., 2016). The first metric COPY measures the fraction of outputs which were copied verbatim from the input. This is done after removing trailing punctuation, to penalize models generations which solely modify punctuation. A second metric 1-g measures the unigram overlap F1 score between the input and output. A diverse style transfer system should minimize both COPY and 1-g.

F More Controllability Evaluations

We follow the setup in Section 5.6 to first compute a λ_{max} per system. We then compute the following,

1. **Style Transfer Performance** (r-AGG): An ideal system should have good overall performance (Section 5.5) across different values in the range Λ.
2. **Average Style Score Increase** (INCR): As our control value increases, we want the classifier's target style score (compared to the input) to increase. Additionally, we want the style score increase of λ_{max} to be as high as possible, indicating the system can span the range of classifier scores.
3. **Style Calibration to λ** (CALIB, C-IN): As defined in Section 5.6. We additionally also measure calibration by including the input sentence x in the CALIB(x) calculation, treating it as the output for $\lambda = 0$ (no style transfer). Here, calibration is averaged over a total of $n = 6$ (λ_1, λ_2) pairs. We call this metric C-IN.

---

[19] The κ scores are measured using the library `https://github.com/statsmodels/statsmodels`.

[20] A potential tool for fluency evaluation in future work is LAMBRE (Pratapa et al., 2021). However, the original paper does not evaluate performance on Indic languages and the grammars for Indic languages would need to collected / built.

[21] This package is the Python port of Nakatani (2010).

A detailed breakdown of performance by different metrics for every model is shown in Table 15.

G Ablation Studies

G.1 Ablation Study for DIFFUR design

This section describes the ablation experiments conducted for the DIFFUR modeling choices in Section 4.2. We ablate a DIFFUR-INDIC model trained on Hindi paraphrase data only, and present results for Hindi formality transfer in Table 16.

- **no paraphrase**: We replaced the paraphrase noise function with the random token dropping / replacing noise used in the denoising objective of UR model (Section 3), and continued to use vector differences. As seen in Table 16, this significantly increases the copy rate, which lowers the style transfer performance.

- **no paraphrase semantic filtering**: We keep a setup identical to Section 4.2, but avoid the LaBSE filtering done (discarding pairs having a LaBSE score outside [0.7, 0.98]) to remove noisy paraphrases or exact copies. As seen in Table 16, this decreases the semantic similarity score of the generations, lowering the overall performance.

- **no vector differences**: Instead of using vector differences for DIFFUR-INDIC, we simply set $\mathbf{s}_{\text{diff}} = f_{\text{style}}(x)$, or the style of the target sentence. In Table 16, we see this significantly decreases SIM scores, and LANG scores for $\lambda = 2.0$. We hypothesize that this training encourages the model to rely more heavily on the style vectors, ignoring the paraphrase input. This could happen since the style vectors are solely constructed from the output sentence itself, and semantic information / confounding style is not subtracted out. In other words, the model is behaving more like an autoencoder (through the style vector) instead of a denoising autoencoder with stylistic supervision.

- **mC4 instead of Samanantar**: Instead of creating pseudo-parallel data with Samanantar, we leverage the mC4 dataset itself which was used to train the UR model. We backtranslate spans of text from the Hindi split of mC4 on-the-fly using the UR translation capabilities, and use it as the "paraphrase noise function". To ensure translation performance does not deteriorate during training, 50% minibatches are supervised translation between Hindi and English. In Table 16, we see decent overall performance, but the LANG score is 6% lower than DIFFUR-INDIC. Qualitatively we found that the model often translates a few Hindi words to English while making text informal. Due to sparsity of English tokens, it often escapes penalization from LANG.

- **mC4 + exemplar instead of target**: This setting is similar to the previous one, but in addition to the mC4 dataset we utilize the vector difference between the style vector of the exemplar span (instead of target span), and the "paraphrase noised" input. Results in Table 16 show this method is not effective, and it's important for the vector difference to model the precise transformation needed.

G.2 Choice of Decoding Scheme

We experiment with five decoding schemes on the Hindi formality validation set — beam search with beam size 1, 4 and top-p sampling (Holtzman et al., 2020) with $p = 0.6, 0.75, 0.9$.

In Table 17, we present results at a constant style transfer magnitude ($\lambda = 3.0$). Consistent with Krishna et al. (2020), we find that top-p decoding usually gets higher style accuracy (r-ACC, a-ACC) and output diversity (1-g, COPY) scores, but lower semantic similarity (SIM) scores. Overall beam search triumphs since the loss in semantic similarity leads to a worse performing model. In Figure 10, we see a consistent trend across different magnitudes of style transfer (λ). In all our main experiments, we use beam search with beam size 4 to obtain our generations.

G.3 Number of Training Steps

In Figure 11, we present the variation in style transfer performance with number of training steps for our best model, the DIFFUR-MLT model. We find that with more training steps performance generally improves, but improvements saturate after 8k steps. We also see the peak of the graphs (best style transfer performance) shift rightwards, indicating a preference for higher λ values.

H Analysis Experiments

H.1 Style vectors from f_{style} as style classifiers

The Universal Rewriter models succeed in learning an effective style space, useful for few-shot style transfer. But can this metric space also act as a

Model	hi	bn	kn	te
UR	79.1	69.7	66.2	67.1
UR-INDIC	80.7	74.3	68.2	72.2
DIFFUR-INDIC	68.0	73.8	67.0	70.4
DIFFUR-MLT	75.0	81.7	79.8	79.0

Table 13: style vector as a classifier, measuring the cosine similarity with informal exemplar vectors.

style classifier? To explore this, we measure the cosine distance between the mean style vector of our informal exemplars,[22] and the style vectors derived by passing human-annotated formal/informal pairs (from our dataset of Section 5.1) through f_{style}. We only consider pairs which had complete agreement among annotators. In Table 13 we see good agreement (68.2%-80.7%) between human annotations and the classifier derived from the metric space of the UR-INDIC model. Agreement is lower (67.0%-74.3%) for the DIFFUR-INDIC model, likely due to the stop gradient used in Section 4.2. With DIFFUR-MLT, agreement jumps back up to 75%-81.7% since gradients flow into the style extractor as well.

H.2 Style Vector Analysis with Formal Exemplars Vectors

In Appendix H.1, we saw that the metric vector space derived from the style encoder f_{style} of various models is an effective style classifier, using the *informal* exemplar vectors. In Table 14, we present a corresponding analysis using *formal* exemplar vectors. Most accuracy scores are close to 50%, implying this setup is not a very effective style classifier.

Model	hi	bn	kn	te
UR	56.6	60.0	61.6	57.6
UR-INDIC	59.5	60.6	52.6	44.8
DIFFUR-INDIC	58.5	58.3	59.5	49.7
DIFFUR-MLT	64.9	52.3	47.1	41.8

Table 14: style vector as a classifier, measuring the cosine similarity with formal exemplar vectors.

I Full Breakdown of Results

A full breakdown of results by individual metrics, along with plots showing variation with change in λ, is provided for — Hindi (Table 20, Figure 12), Bengali (Table 21, Figure 13), Kannada (Table 22, Figure 14), Telugu (Table 23, Figure 15), Gujarati (Table 24, Figure 16).

J More Model Outputs

Please refer to Figure 8. In the main body, Figure 4 has a few examples as well with detailed analysis.

K Paraphrase Diversity

In Figure 9 we measure the lexical overlap between paraphrases used in our DIFFUR training strategy for six different languages (Hindi, Bengali, Kannada, Telugu, Swahili and Spanish). The lexical overlap is measured using the unigram F1 score, using the implementation from the SQuAD evaluation script (Rajpurkar et al., 2016). The wide spread of the histogram and sufficient percentage of low overlap pairs confirm the lexical diversity of the paraphrases used. As shown in prior work (Krishna et al., 2020), high lexical diversity of paraphrases is helpful for changing the input style.

---

[22] See Appendix D for the exemplar sentences. We found the informal exemplars more effective than formal exemplars for style classification; Appendix H.2 has a comparison.

Table 16: Ablation study on Hindi formality transfer validation set using beam size of 4 and $\lambda = 2.0$ unless the optimal hyperparameters were different (marked by **). As shown by the overall a-AGG scores, removing any component of our design leads to an overall performance drop, sometimes significantly. For a detailed description of analysis and results, see Appendix G.1. For detailed metric descriptions, see Section 5.

Decoding	COPY(↓)	1-g(↓)	LANG	SIM	r-ACC	a-ACC	r-AGG	a-AGG
beam 4	1.8	52.7	95.8	73.3	94.7	51.6	**66.2**	**32.3**
beam 1	1.2	47.4	92.3	61.7	95.7	62.5	55.8	31.4
top-p 0.6	1.0	45.3	91.5	56.6	96.2	65.9	51.3	29.9
top-p 0.75	0.9	43.1	90.3	52.4	96.3	69.0	47.3	28.2
top-p 0.9	0.7	40.4	89.4	46.8	96.6	71.7	42.4	26.5

Table 17: Automatic evaluation of different decoding algorithms (top-p sampling and beam search) on the DIFFUR-MLT model for Hindi formality transfer (validation set) using $\lambda = 3.0$. As expected, output diversity (1-g, COPY) and style accuracy (r-ACC, a-ACC) improves as we move down the table, but compromise semantic preservation (SIM), bringing the overall performance (r-AGG, a-AGG) down. Also see Figure 10 for a comparison across λ values, and Section 5 for detailed metric descriptions.

Model	Hindi		Bengali		Kannada		Telugu		Gujarati	
	r-AGG	a-AGG	r-AGG	a-AGG	r-AGG	a-AGG	r-AGG	a-AGG	r-AGG	a-AGG
UR (2021)	34.5	13.4	33.8	9.0	26.8	8.8	24.3	10.7	25.6	5.9

DIFFUR-MLT	85.8	45.2	86.0	48.3	86.9	54.4	86.1	51.7	78.8	41.3

Table 18: Test set performance across languages for a **smaller LaBSE semantic similarity threshold** of 0.65. Due to the more relaxed threshold, absolute numbers compared to Table 1 are higher. Trends remain similar, with the DIFFUR and INDIC variants outperforming other competing methods.

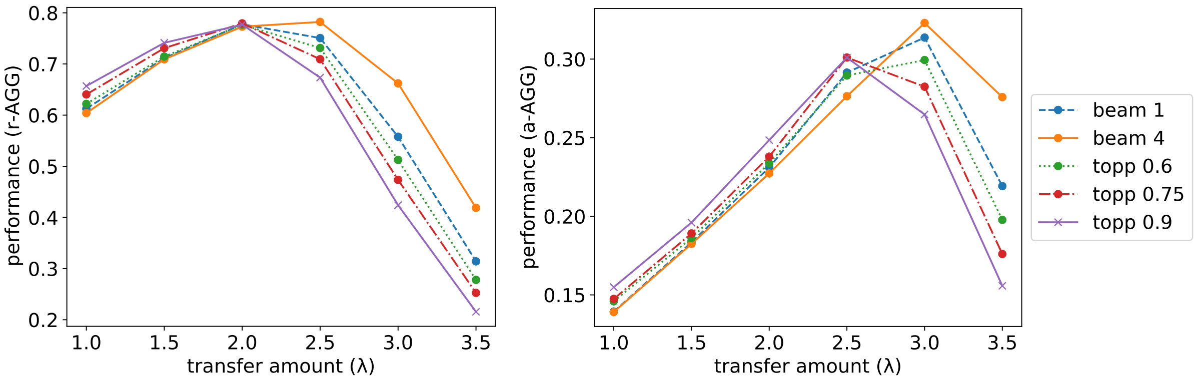

Figure 10: Variation in Hindi formality transfer (validation set) performance vs λ with change in decoding scheme, for the DIFFUR-MLT model. The plots show overall style transfer performance, using the r-AGG (left) and a-AGG (right) metrics from Section 5.5. Beam search with beam size 4 performs best, see Table 17 for an individual metric breakdown while keeping $\lambda = 3.0$.

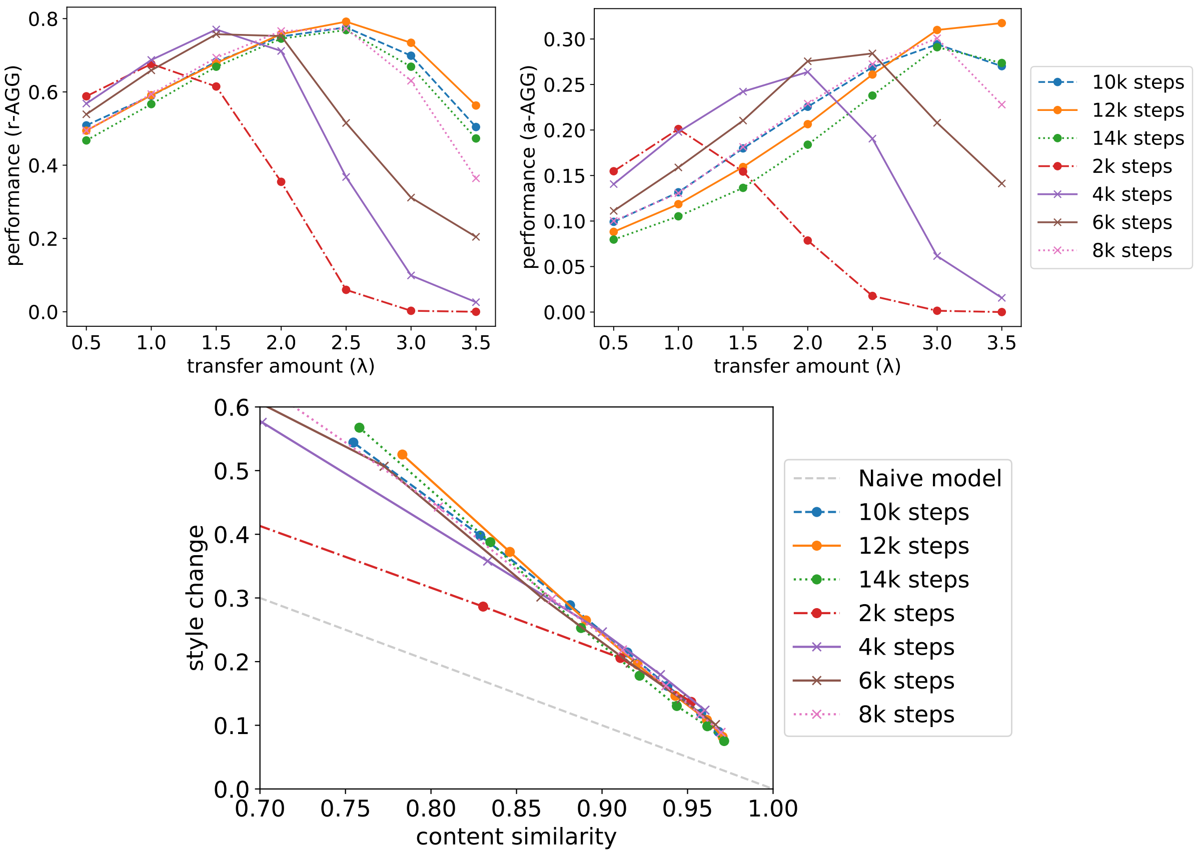

Figure 11: Variation in Hindi formality transfer validation set performance with change in number of training steps for the DIFFUR-MLT model. The plots show overall style transfer performance, using the r-AGG (top-left) and a-AGG (top-right) metrics from Section 5.5. With more training steps performance seems to improve and the peak of the graph shifts towards the right (a preference towards higher scale values). We also see more training steps leads to better controllability (bottom plot, closer to Y-axis is better), but only marginal gains after 6k steps.

Table 24: Performance breakdown of Gujarati formality transfer by individual metrics described in Section 5.

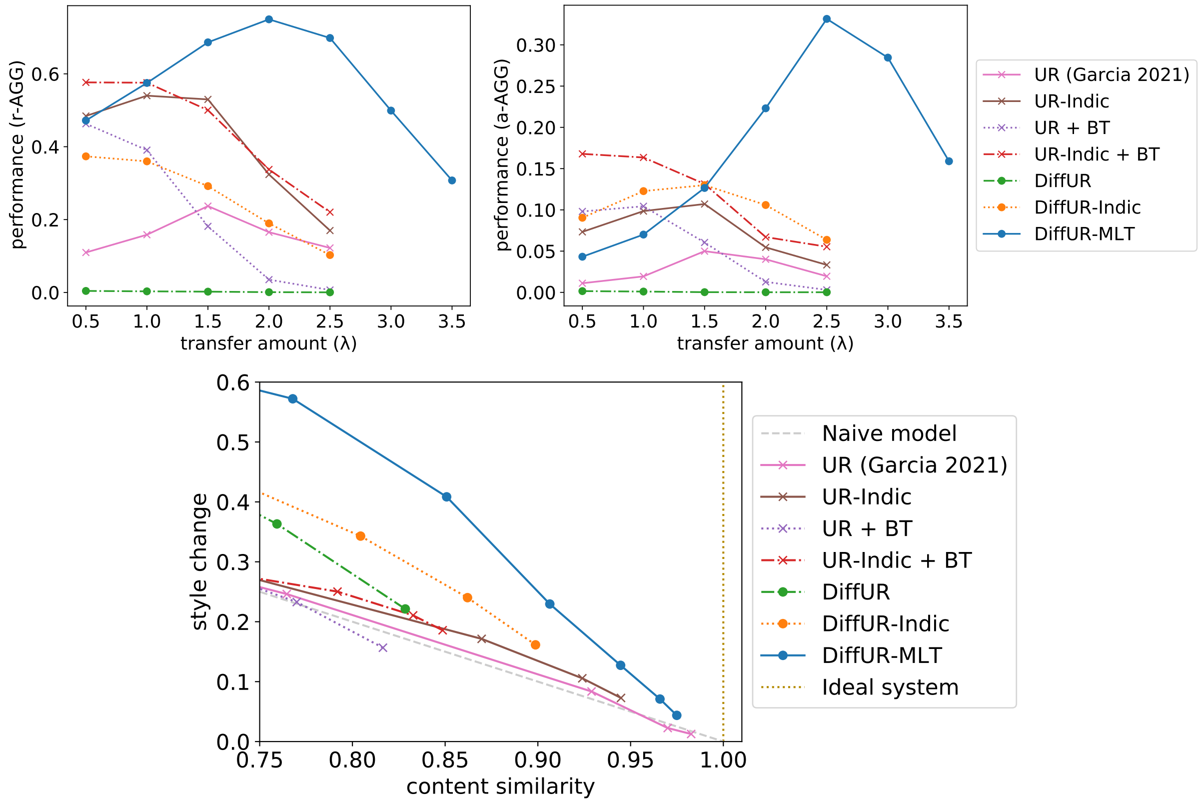

Figure 16: Variation in Gujarati formality transfer test set performance & control for different models (see Table 24 for a individual metric breakdown of the models at the best performing λ). The plots show overall style transfer performance, using the r-AGG (top-left) and a-AGG (top-right) metrics from Section 5.5. Note that Gujarati is a **zero-shot** language for DIFFUR models — no Gujarati paraphrase data was seen during training. We see that while the vanilla DIFFUR model performs poorly, the DIFFUR-INDIC is competitive with baselines and the DIFFUR-MLT variant significantly outperforms other systems. We also see that the DIFFUR-MLT variant lead to better style transfer control (bottom plot, closer to $x = 1$ is better), giving style variation with λ without loss in semantics (X-axis).

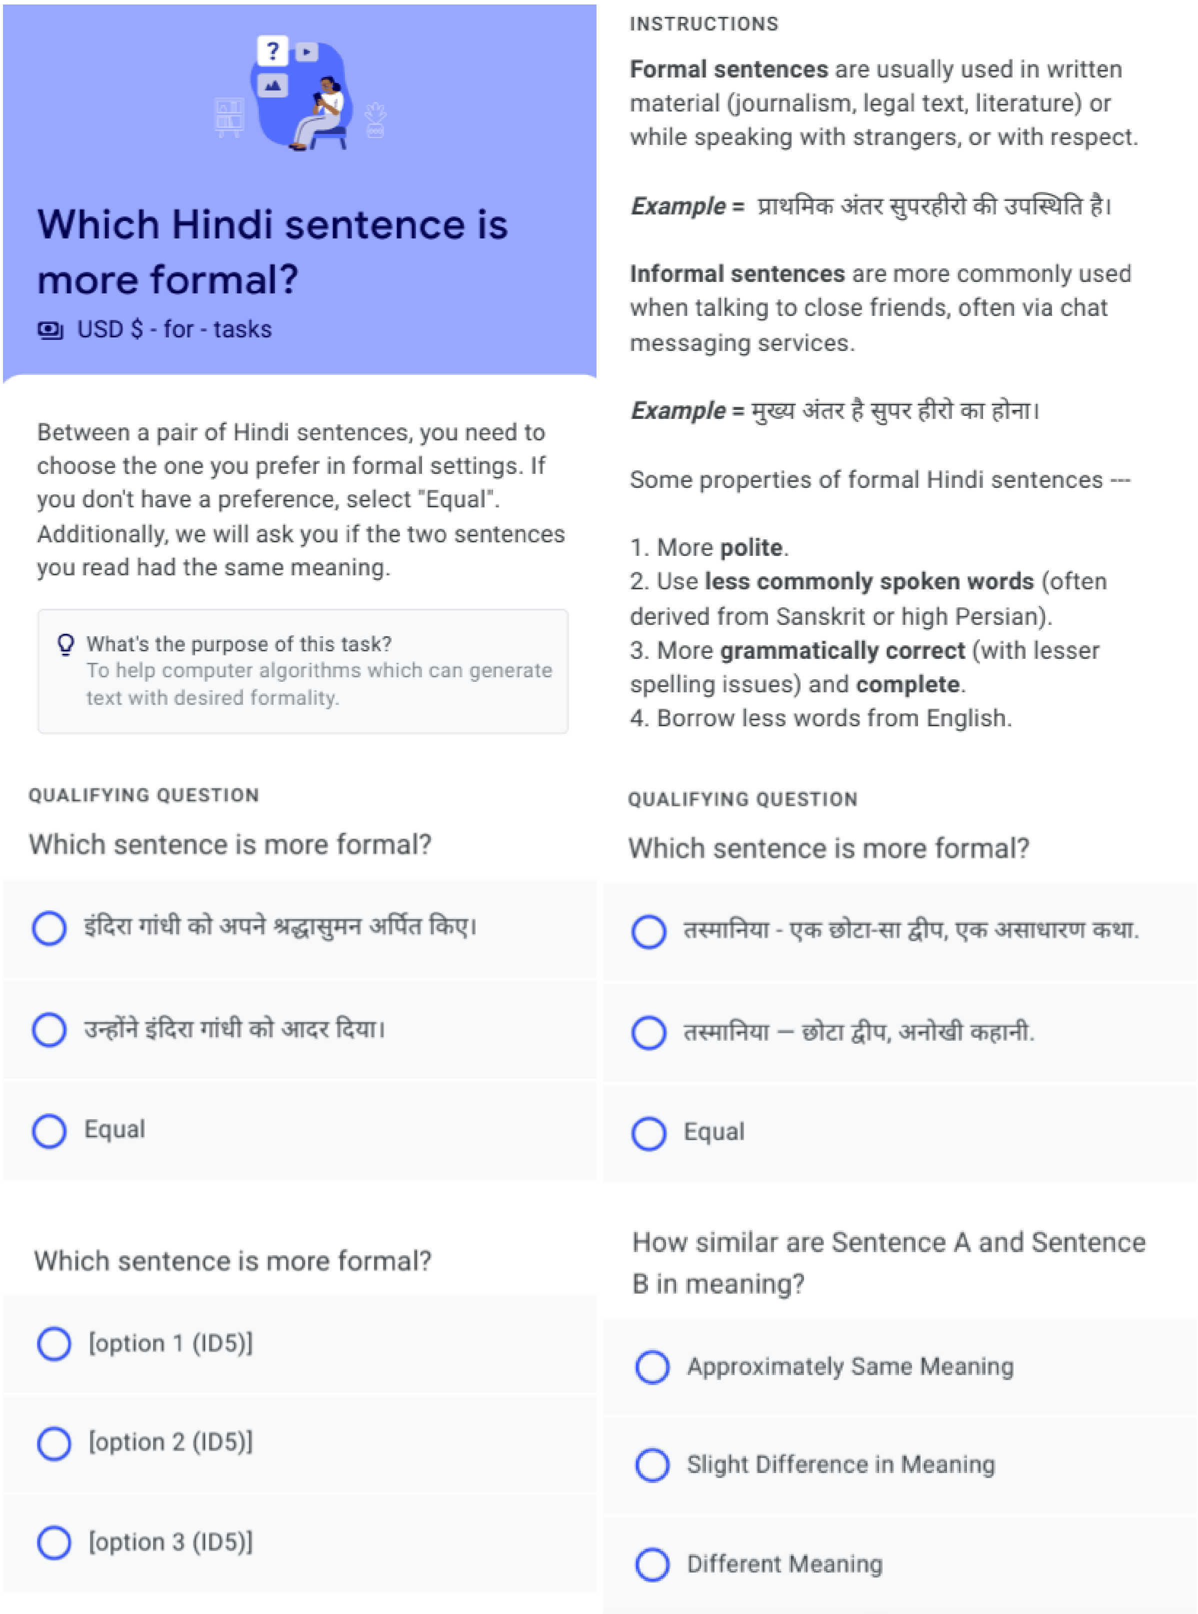

Which Hindi sentence is more formal?

USD $ - for - tasks

Between a pair of Hindi sentences, you need to choose the one you prefer in formal settings. If you don't have a preference, select "Equal". Additionally, we will ask you if the two sentences you read had the same meaning.

What's the purpose of this task?
To help computer algorithms which can generate text with desired formality.

INSTRUCTIONS

Formal sentences are usually used in written material (journalism, legal text, literature) or while speaking with strangers, or with respect.

Example = प्राथमिक अंतर सुपरहीरो की उपस्थिति है।

Informal sentences are more commonly used when talking to close friends, often via chat messaging services.

Example = मुख्य अंतर है सुपर हीरो का होना।

Some properties of formal Hindi sentences ---

1. More **polite**.
2. Use **less commonly spoken words** (often derived from Sanskrit or high Persian).
3. More **grammatically correct** (with lesser spelling issues) and **complete**.
4. Borrow less words from English.

QUALIFYING QUESTION

Which sentence is more formal?

○ इंदिरा गांधी को अपने श्रद्धासुमन अर्पित किए।

○ उन्होंने इंदिरा गांधी को आदर दिया।

○ Equal

QUALIFYING QUESTION

Which sentence is more formal?

○ तस्मानिया - एक छोटा-सा द्वीप, एक असाधारण कथा.

○ तस्मानिया – छोटा द्वीप, अनोखी कहानी.

○ Equal

Which sentence is more formal?

○ [option 1 (ID5)]

○ [option 2 (ID5)]

○ [option 3 (ID5)]

How similar are Sentence A and Sentence B in meaning?

○ Approximately Same Meaning

○ Slight Difference in Meaning

○ Different Meaning

Figure 17: Our crowdsourcing interface on Task Mate, used to build our formality evaluation datasets (Section 5.1) and conduct human evaluations (Section 5.7). The first row shows our landing page and instruction set derived from our conversations with professional linguists. The second row shows our qualification questions for formality classification, and the third row shows templates for the two questions asked to crowdworkers per pair.

ABC: Attention with Bounded-Memory Control

Abstract

Transformer architectures have achieved state-of-the-art results on a variety of natural language processing (NLP) tasks. However, their attention mechanism comes with a quadratic complexity in sequence lengths, making the computational overhead prohibitive, especially for long sequences. Attention context can be seen as a random-access memory with each token taking a slot. Under this perspective, the memory size grows linearly with the sequence length, and so does the overhead of reading from it. One way to improve the efficiency is to bound the memory size. We show that disparate approaches can be subsumed into one abstraction, **a**ttention with **b**ounded-memory **c**ontrol (ABC), and they vary in their *organization* of the memory. ABC reveals new, unexplored possibilities. First, it connects several efficient attention variants that would otherwise seem distinct. Second, this abstraction gives new insights—an established approach (Wang et al., 2020b) previously thought to *not* be applicable in causal attention, *actually is*. Last, we present a new instance of ABC, which draws inspiration from existing ABC approaches, but replaces their heuristic memory-organizing functions with a *learned*, contextualized one. Our experiments on language modeling, machine translation, and masked language model finetuning show that our approach outperforms previous efficient attention models; compared to strong transformer baselines, it significantly improves the inference time and space efficiency with no or negligible accuracy loss.

1 Introduction

Transformer architectures are now central in natural language processing (Vaswani et al., 2017). They rely on the attention mechanism (Bahdanau et al., 2015) to contextualize the input. The context can be seen as a random access **memory** whose size linearly grows with the sequence length; each query reads from it using a softmax-normalized linear combination, with overhead linear in the memory size. This amounts to a quadratic complexity overall, making transformers' computational overhead prohibitive, especially for long sequences.

One way to improve attention's efficiency is to bound its memory size. Imposing a constant-sized constraint over the memory ensures that reading from it has constant time and space overhead, yielding a linear overall complexity in sequence lengths. This is in fact a common strategy adopted by several recent works. In this work, we show that some of these works are closely connected in ways that, to date, have gone unremarked. We propose **a**ttention with **b**ounded-memory **c**ontrol (ABC), a unified abstraction over them. In ABC, constant-sized memories are organized with various control strategies, e.g., induced from heuristic patterns (Beltagy et al., 2020; Zaheer et al., 2020; Ainslie et al., 2020; Rae et al., 2020, *inter alia*), locality assumptions (Parmar et al., 2018; Liu et al., 2018), or positions (Wang et al., 2020b).

These strategies, by and large, are "context-agnostic." In response to this, we propose ABC_{MLP}, a particular instance of ABC that learns a contextualized control strategy from data. Specifically, ABC_{MLP} uses a neural network to determine how to store each token into the memory (if at all). Compared to previous bounded-memory models, it strikes a better trade-off between accuracy and efficiency: controlling for the accuracy, ABC_{MLP} can get away with much smaller memory sizes.

ABC models (including ABC_{MLP}) come with a linear complexity in sequence lengths, and admit recurrent computation graphs in causal attention (self-attention over the prefix). Therefore they are appealing choices in a variety of applications, including text encoding, language modeling and text generation. This leads to a surprising finding. Linformer (Wang et al., 2020b), an established efficient attention method, was previously thought *not*

to be applicable in causal attention or autoregressive decoding (Tay et al., 2020). Through the ABC view, we show that it actually *is*, and achieves competitive performance in our machine translation experiments.

ABC connects existing models that would otherwise seem distinct, reveals new insights into established methods, and inspires new efficient attention architectures. We explore its applications in transformers, as a drop-in substitute for the canonical softmax attention. ABC offers a novel lens that can help future research in the analysis of transformers, where the theoretical insights are still catching up with empirical success. Experiments on language modeling, machine translation, and masked language model finetuning show that our ABC$_{\text{MLP}}$ model outperforms previous ABC approaches in accuracy with a much smaller memory size. Compared to the strong transformer baseline, ABC$_{\text{MLP}}$ achieves a significant speedup and memory savings at inference time, with no or negligible accuracy loss. The efficiency improvements are more prominent for long sequences, suggesting that the asymptotic savings are even more appealing in applications involving long sequences. We release our code at `https://github.com/Noahs-ARK/ABC`.

2 An Outer-Product View of Attention

This section presents our outer-product memory perspective of attention, which allows for a smooth transition to later discussion.

In attention, a sequence of **queries** $\{\mathbf{q}_i\}_{i=1}^N$ attend to a **memory** with N slots, each storing a **key** and **value** pair: $\mathbf{K} = [\mathbf{k}_1, \dots, \mathbf{k}_N]^\top, \mathbf{V} = [\mathbf{v}_1, \dots, \mathbf{v}_N]^\top \in \mathbb{R}^{N \times d}$.[1] Query $\mathbf{q}$ reads from the memory using a softmax-normalized linear combination, producing a d-dimensional vector:

$$\operatorname{attn}(\mathbf{q}, \{\mathbf{k}_i\}, \{\mathbf{v}_i\}) = \mathbf{V}^\top \operatorname{softmax}(\mathbf{K}\mathbf{q}). \quad (1)$$

This takes $\mathcal{O}(N)$ time and space. When the attention with N queries can be parallelized (e.g., in text encoding), it takes linear time and quadratic space; when it *cannot* be (e.g., in decoding), it takes quadratic time and linear space.

The memory can be equivalently represented as sums of vector outer products: $\mathbf{K} = \mathbf{I}\mathbf{K} = \sum_{i=1}^N \mathbf{e}_i \otimes \mathbf{k}_i$, $\mathbf{V} = \sum_{i=1}^N \mathbf{e}_i \otimes \mathbf{v}_i$. $\mathbf{I}$ is the identity matrix, and $\otimes$ denotes the outer product: $[\mathbf{x} \otimes \mathbf{y}]_{i,j} = x_i y_j$. N-dimensional vectors $\{\mathbf{e}_i\}$ form the standard basis: $\mathbf{e}_i$ has the ith element being one and others zeros. We can view $\mathbf{e}_i$ as **control vectors** that determine where to store $\mathbf{k}_i$ and $\mathbf{v}_i$:

$$\begin{aligned}\mathbf{e}_i \otimes \mathbf{k}_i &= \big[\underbrace{0, \dots 0}_{i-1}, 1, \underbrace{0, \dots, 0}_{N-i}\big]^\top \otimes \mathbf{k}_i \\ &= \big[\underbrace{\mathbf{0}}_{d\times(i-1)}; \mathbf{k}_i; \underbrace{\mathbf{0}}_{d\times(N-i)}\big]^\top.\end{aligned} \quad (2)$$

The N-by-d matrix on the last line has its ith row being $\mathbf{k}_i^\top$ and all others zeros; in this sense, $\mathbf{k}_i$ is stored in the ith slot by $\mathbf{e}_i$, not affecting others.

3 Attention with Bounded Memory

A straightforward way to improve attention's efficiency is to bound its memory size. Our outer-product view of attention provides a straightforward way to devise this, by replacing $\{\mathbf{e}_i\}$ with control vectors that select $n \ll N$ vectors to attend to. We dub this approach **a**ttention with **b**ounded-memory **c**ontrol (ABC). Concretely, let $\widetilde{\mathbf{K}}, \widetilde{\mathbf{V}} \in \mathbb{R}^{n \times d}$ denote a constant-size memory with n slots, with n set *a priori*.

$$\widetilde{\mathbf{K}} = \sum_{i=1}^N \boldsymbol{\phi}_i \otimes \mathbf{k}_i, \quad \widetilde{\mathbf{V}} = \sum_{i=1}^N \boldsymbol{\phi}_i \otimes \mathbf{v}_i. \quad (3)$$

$\{\boldsymbol{\phi}_i \in \mathbb{R}^n\}_{i=1}^N$ denotes a sequence of **control** vectors. The output is calculated by attending to $\widetilde{\mathbf{K}}$ and $\widetilde{\mathbf{V}}$: ABC $(\mathbf{q}, \{\mathbf{k}_i\}, \{\mathbf{v}_i\}, \{\boldsymbol{\phi}_i\}) =$

$$\widetilde{\mathbf{V}}^\top \operatorname{softmax}\left(\widetilde{\mathbf{K}}\mathbf{q}\right). \quad (4)$$

We will discuss various ways to construct $\{\boldsymbol{\phi}_i\}$ in the subsequent sections. Reading from the memory takes a constant $\mathcal{O}(n)$ time and space; therefore ABC's overall complexity is $\mathcal{O}(Nn)$, linear in the sequence length.[2]

Eq. 3 offers an equivalent recurrent computation, which is particularly useful in causal attention where only the prefix is looked at,

$$\widetilde{\mathbf{K}}_{t+1} = \widetilde{\mathbf{K}}_t + \boldsymbol{\phi}_{t+1} \otimes \mathbf{k}_{t+1}, \quad (5)$$

likewise for $\widetilde{\mathbf{V}}_t$. $\widetilde{\mathbf{K}}_t$ and $\widetilde{\mathbf{V}}_t$ can be seen as the **recurrent hidden state** that encodes the prefix.

In what follows, we study several existing efficient attention approaches and show that they are in fact instances of the ABC abstraction.

---

[1] The number of queries and key-value pairs may differ, e.g., in the cross attention of a sequence-to-sequence model.

[2] Using bounded memory distinguishes ABC from softmax attention. If growing-size memory *were* allowed ($n = N$), an ABC with $\boldsymbol{\phi}_i = \mathbf{e}_i$ would fall back to softmax attention.

3.1 Linformer

Linformer (Wang et al., 2020b) is an established efficient transformer variant that has proven successful in masked language modeling and text encoding. It assumes fixed-length inputs and learns a low-rank approximation of the attention weights. A learned n-by-N matrix $\mathbf{W}^{\text{LF}}$ down projects the N-by-d dimensional keys and values along the *timestep* dimension, to an n-by-d memory: $\widetilde{\mathbf{K}}^{\text{LF}} = \mathbf{W}^{\text{LF}}\mathbf{K}$, $\widetilde{\mathbf{V}}^{\text{LF}} = \mathbf{W}^{\text{LF}}\mathbf{V}$; they are then used for attention computation with Eq. 4. This yields a linear complexity in the input length. Linformer is an ABC instance with $\boldsymbol{\phi}_i^{\text{LF}} = \mathbf{W}_{:,i}^{\text{LF}}$ (ith column), and in this sense, it learns a control vector for each position.

Previous works have noted that Linformer *cannot* be efficiently applied in causal attention (Table 1 of Tay et al., 2020). Indeed, it is less straightforward to avoid mixing future with the past when projecting along the timestep dimension. ABC reveals that, in fact, Linformer *is* applicable in causal attention. Like all ABC models, it admits a linear-complexity recurrent computation (Eq. 5): $\widetilde{\mathbf{K}}_{t+1}^{\text{LF}} = \widetilde{\mathbf{K}}_t + \boldsymbol{\phi}_{t+1}^{\text{LF}} \otimes \mathbf{k}_{t+1}$. This confirms ABC's benefits: it reveals new insights about existing models and reassesses their applications and impact. Our experiments show that Linformer achieves competitive performance in machine translation.

3.2 Clustering-Based Attention

Improving attention's efficiency with clustering has received an increasing amount of interest (Kitaev et al., 2020; Roy et al., 2020; Wang et al., 2020a, *inter alia*). ABC bears interesting connections to clustering-based methods. Here we discuss an approach that closely follows Vyas et al. (2020), except that it clusters keys and values instead of queries, and only attends to the centroids to reduce the effective context size. Formally, keys and values are grouped into $n < N$ clusters $\{\widetilde{\mathbf{k}}_j^{\text{CL}}\}_{j=1}^n$, $\{\widetilde{\mathbf{v}}_j^{\text{CL}}\}_{j=1}^n$.[3] Let an N-by-n binary matrix $\mathbf{M}$ denote the cluster membership shared between keys and values. $M_{i,j} = 1$ iff. $\mathbf{k}_i$ is assigned to cluster $\widetilde{\mathbf{k}}_j^{\text{CL}}$ and $\mathbf{v}_i$ to $\widetilde{\mathbf{v}}_j^{\text{CL}}$. The jth centroid for the keys is

$$\widetilde{\mathbf{k}}_j^{\text{CL}} = \sum_{i=1}^{N} \frac{M_{i,j}}{\sum_{\ell=1}^{N} M_{\ell,j}} \mathbf{k}_i; \tag{6}$$

likewise for the values. It then attends over the centroids using Eq. 4, with $\widetilde{\mathbf{K}}^{\text{CL}} = [\widetilde{\mathbf{k}}_1^{\text{CL}}, \dots, \widetilde{\mathbf{k}}_n^{\text{CL}}]^\top =$

$$\begin{aligned} \sum_{j=1}^{n} \mathbf{e}_j \otimes \widetilde{\mathbf{k}}_j^{\text{CL}} &= \sum_{j=1}^{n} \mathbf{e}_j \otimes \sum_{i=1}^{N} \frac{M_{i,j}}{\sum_{\ell=1}^{N} M_{\ell,j}} \mathbf{k}_i \\ &= \sum_{i=1}^{N} \left(\sum_{j=1}^{n} \mathbf{e}_j \frac{M_{i,j}}{\sum_{\ell=1}^{N} M_{\ell,j}} \right) \otimes \mathbf{k}_i. \end{aligned}$$

The last line indicates that this model is an instance of ABC: $\boldsymbol{\phi}_i = \sum_{j=1}^{n} (M_{i,j} / \sum_{\ell=1}^{N} M_{\ell,j}) \mathbf{e}_j$. The stack of centroids can be seen as the constant-size memory. Putting aside the clustering overhead (i.e., constructing $\mathbf{M}$ and computing centroids), it has a linear complexity in the sequence length.

3.3 Sliding-Window Attention

In some applications, being able to remove entries from the memory can be beneficial: clearing up older context frees slots for more recent ones, promoting a locality inductive bias. ABC offers the capability to do so, if augmented with an additional matrix multiplication. We use the sliding-window attention as an example.

Attending to the most recent n input tokens (Beltagy et al., 2020; Zaheer et al., 2020; Sukhbaatar et al., 2021, *inter alia*) can be seen as a first-in-first-out queue that "pops" out the oldest token while "pushing" in the most recent one: $\widetilde{\mathbf{K}}_t^{\text{WD}} = [\mathbf{k}_{t-n+1}, ..., \mathbf{k}_t]^\top$. The pop operation can be achieved by multiplying an n-by-n **upper shift matrix**: $U_{i,j} = \delta_{i+1,j}$, with δ being the Kronecker delta (i.e., $\mathbf{U}$ has ones only on the superdiagonal and zeros elsewhere). Left-multiplying $\mathbf{U}$ against $\widetilde{\mathbf{K}}_t^{\text{WD}}$ shifts its rows one position up, with zeros appearing in the last:

$$\begin{aligned} \mathbf{U}\widetilde{\mathbf{K}}_t^{\text{WD}} &= \mathbf{U}\big[\underbrace{\mathbf{k}_{t-n+1}, \dots, \mathbf{k}_t}_{n}\big]^\top \\ &= \big[\underbrace{\mathbf{k}_{t-n+2}, \dots, \mathbf{k}_{t-1}, \mathbf{k}_t}_{n-1}, \mathbf{0}\big]^\top \in \mathbb{R}^{n \times d}. \end{aligned}$$

Then the most recent token can be put into the slot freed up: $\widetilde{\mathbf{K}}_{t+1}^{\text{WD}} = \mathbf{U}\widetilde{\mathbf{K}}_t^{\text{WD}} + \mathbf{e}_n \otimes \mathbf{k}_{t+1}$. $\mathbf{U}$ and $\boldsymbol{\phi}_t = \mathbf{e}_n$ ensure a first-in-first-out queue. Dilated and stride convolution patterns (Beltagy et al., 2020) can be similarly recovered (§A.4).

Recurrently multiplying $\mathbf{U}$ simulates the discrete pop operation (Grefenstette et al., 2015; Joulin and Mikolov, 2015; Yogatama et al., 2018) in a differentiable way. This is reminiscent of recurrent neural networks, while in this case $\mathbf{U}$ is *never* updated as

---

[3] We use $\widetilde{\mathbf{k}}_j^{\text{CL}}$ to denote both the jth cluster and its centroid.

parameters. It is exciting to explore learning $\mathbf{U}$, but is beyond the scope of this work.

Discussion. Besides the models discussed above, certain variants of Rae et al. (2020) and sparse attention patterns (local-to-global attention; Beltagy et al., 2020; Zaheer et al., 2020; Ainslie et al., 2020) can also be seen as instances of ABC (§A). ABC provides a unified perspective of them, and at the same time points out their limitations: their control strategies are context-agnostic. In response to this, in §4 we propose to learn a contextualized strategy from data. Table 1 analyzes various ABC models, and Table 2 details their complexity.

4 Learned Memory Control

The ABC abstraction connects several existing approaches that would otherwise seem distinct. This inspires the design of new architectures. We hypothesize that learning a contextualized strategy can achieve better performance. This section introduces ABC$_{\text{MLP}}$. It parameterizes $\boldsymbol{\phi}$ with a single-layer multi-layer perceptron (MLP) that takes as input the token's representation $\mathbf{x}_i$, and determines which slots to write it into and how much.

$$\boldsymbol{\alpha}_i = \mathbf{exp}\left(\mathbf{W}_{\boldsymbol{\phi}}\mathbf{x}_i\right), \quad \boldsymbol{\phi}_i = \boldsymbol{\alpha}_i \Bigg/ \sum_{j=1}^{N} \boldsymbol{\alpha}_j. \quad (7)$$

Matrix $\mathbf{W}_{\boldsymbol{\phi}}$ is learned. $\mathbf{exp}$ is an elementwise activation function. The motivation is to allow for storing a "fractional" (but *never* negative) amount of input into the memory.[4] Using a non-negative activation, however, has a drawback: the scales of $\sum_i \boldsymbol{\phi}_i \otimes \mathbf{k}_i$ and $\sum_i \boldsymbol{\phi}_i \otimes \mathbf{v}_i$ would grow with the sequence lengths, making training less stable. To overcome this, we divide $\boldsymbol{\alpha}_i$ vectors by their sum. This functions as normalization and aims to offset the impact of varying sequence lengths.[5] It admits the recurrent computation graph as in Eq. 5, and has a linear complexity in the sequence length.

A key design choice of ABC$_{\text{MLP}}$ is that its $\boldsymbol{\phi}_i$ depends *only* on current input $\mathbf{x}_i$. This helps (1) keep the recurrent computation efficient in practice (Lei et al., 2018), and (2) make it applicable in not only encoder self-attention and cross attention, but also causal attention. Concurrently to this work, Goyal et al. (2021) and Ma et al. (2021) also proposed methods to learn contextualized control. They compute $\boldsymbol{\phi}_i$ from *previous* layer's memory, revealing the full sequence to the control vectors. As a result, these two approaches are *unsuitable* for causal attention.[6]

ABC$_{\text{MLP}}$, as other ABC models, can be used as a drop-in replacement for the canonical softmax attention, and we apply its multihead variant in transformers. With proper parameter sharing, the number of additional parameters ABC$_{\text{MLP}}$ incurs is small: inspired by Wang et al. (2020b), we tie $\boldsymbol{\phi}$-MLP's parameters across different layers, which adds less than 1% parameters to the models.

ABC$_{\text{MLP}}$: context-agnostic then context-dependent attention. We now dissect ABC$_{\text{MLP}}$ and show that it can be seen as a cascade of two attention mechanisms: one with a learned context-agnostic "pseudo query" followed by one with a context-dependent query. Our analysis starts with a one-dimensional example; the conclusion generalizes to higher-dimensional cases.

Example 1. Consider ABC$_{\text{MLP}}$ with a *single* memory slot ($n = 1$). It is parameterized with a learned vector $\mathbf{w}_\phi$, and $\phi_i = \exp(\mathbf{w}_\phi \cdot \mathbf{x}_i) / \sum_{j=1}^{N} \exp(\mathbf{w}_\phi \cdot \mathbf{x}_j)$. Since ϕ_i is a scalar here, $\phi_i \otimes \mathbf{k}_i = \phi_i \mathbf{k}_i^\top$.

$$\begin{aligned}\widetilde{\mathbf{K}}^\top &= \sum_{i=1}^{N} \left(\phi_i \otimes \mathbf{k}_i\right)^\top \\ &= \sum_{i=1}^{N} \frac{\exp(\mathbf{w}_\phi \cdot \mathbf{x}_i)}{\sum_{j=1}^{N} \exp(\mathbf{w}_\phi \cdot \mathbf{x}_j)} \mathbf{k}_i \\ &= \operatorname{attn}\left(\mathbf{w}_\phi, \{\mathbf{x}_i\}_{i=1}^{N}, \{\mathbf{k}_i\}_{i=1}^{N}\right).\end{aligned}$$

In other words, $\widetilde{\mathbf{K}}$ uses $\mathbf{w}_\phi$ as a "pseudo-query" to attend to $\{\mathbf{x}_i\}$ and $\{\mathbf{k}_i\}$. Likewise, $\widetilde{\mathbf{V}}^\top = \operatorname{attn}(\mathbf{w}_\phi, \{\mathbf{x}_i\}_{i=1}^{N}, \{\mathbf{v}_i\}_{i=1}^{N})$. Despite its similarity to the standard softmax attention, Example 1 has a more efficient linear complexity in sequence lengths. $\mathbf{w}_\phi$'s being context-independent is the key to the savings. Table 2 details its complexity.

Example 1's conclusion generalizes to higher-dimensional cases: the jth dimension of $\{\boldsymbol{\phi}_i\}$ attends to $\{\mathbf{x}_i\}$ and $\{\mathbf{k}_i\}$ using the jth row of $\mathbf{W}_{\boldsymbol{\phi}}$ as the context-independent pseudo-query; n such attention mechanisms run in parallel, stacking the

---

[4] We experiment with other activations in §C.2.

[5] Here encoder self-attention or cross attention is assumed, and the normalization sums over the entire sequence. Causal attention is slightly different, normalizing by the sum over the prefix instead: $\boldsymbol{\phi}_i = \boldsymbol{\alpha}_i / \sum_{j=1}^{i} \boldsymbol{\alpha}_j$. This does *not* require access to future tokens. §B.1 details a linear complexity computation graph of causal $\boldsymbol{\phi}_i$.

[6] Both are instances of ABC (§A.5). Ma et al. (2021) resorts to a variant of Katharopoulos et al. (2020) for causal attention.

Model	**Section**	ϕ_t	**Mem. Control**
Sliding-window	§3.3	$\mathbf{e}_n$	$\widetilde{\mathbf{K}}_{t+1} = \mathbf{U}\widetilde{\mathbf{K}}_t + \boldsymbol{\phi}_{t+1} \otimes \mathbf{k}_{t+1}$
Linformer	§3.1	$\mathbf{W}^{\text{LF}}_{:,t}$	$\widetilde{\mathbf{K}}_{t+1} = \widetilde{\mathbf{K}}_t + \boldsymbol{\phi}_{t+1} \otimes \mathbf{k}_{t+1}$
L2G Pattern	§A.1	$\mathbf{e}_i$ if $\mathbf{x}_t$ is the ith global token

ABC$_{\text{MLP}}$	§4	$\exp\left(\mathbf{W}_{\boldsymbol{\phi}}\mathbf{x}_t\right) / \sum_{i=1}^{t} \exp\left(\mathbf{W}_{\boldsymbol{\phi}}\mathbf{x}_i\right)$	

Table 1: A comparison of different ABC models. N denotes the sequence length, and n the memory size. $\boldsymbol{\phi}_t$ denotes the memory control vector for $\mathbf{k}_t$ and $\mathbf{v}_t$, and unif is the discrete uniform distribution.

	Time Complexity			**Space Complexity**		
Model	**Mem.**	**Per Query**	**Overall**	**Mem.**	**Per Query**	**Overall**
Softmax Attention	-	$\mathcal{O}(N)$	$\mathcal{O}(N^2)$	-	$\mathcal{O}(N)$	$\mathcal{O}(N^2)$
ABC	$\mathcal{O}(N)$	$\mathcal{O}(n)$	$\mathcal{O}(nN)$	$\mathcal{O}(n)$	$\mathcal{O}(n)$	$\mathcal{O}(nN)$

Table 2: ABC's time and space complexity in sequence length against the softmax attention's. "Mem." indicates the time and space needed for calculating and storing memory $\widetilde{\mathbf{K}}, \widetilde{\mathbf{V}}$. N denotes the sequence length, and n the memory size. The time complexity analysis assumes that the softmax attention *cannot* be parallelized across the queries. In practice, this is common in autoregressive decoding or for long sequences where the accelerators (e.g., GPUs) do not have enough threads to fully parallelize softmax attention's computation across different queries.

results into n-by-d memory $\widetilde{\mathbf{K}}$ and $\widetilde{\mathbf{V}}$. Intuitively, it is the "real queries" $\{\mathbf{q}_i\}$ that encode "what information is useful for the prediction task." Without access to them, ABC$_{\text{MLP}}$ summarizes the input for n times using different pseudo-queries, aiming to preserve enough information in the memory for onward computation. The attention output is calculated with the context-dependent real queries using Eq. 4. §B.2 presents a detailed derivation.

Connections to other prior works. Although starting from distinct motivations, ABC$_{\text{MLP}}$ closely relates to hierarchical attention (HA; Yang et al., 2016). HA summarizes the context into higher-level representations with a cascade of attention mechanisms, e.g., words to sentences, and then to documents. ABC$_{\text{MLP}}$ applies two types of attention. The first learns context-agnostic pseudo-queries and attends to the same sequence for n times in parallel, while the second retrieves from the memory with real queries. HA, in contrast, summarizes non-overlapping segments at each level.

The learned pseudo-queries closely relate to the inducing point method in set attention (ISA; Lee et al., 2019). ISA applies a non-linear feedforward network between a cascade of two attention modules. This precludes the outer-product memory computation and efficient recurrences in ABC.

Another line of work "linearizes" attention through kernel tricks and also applies bounded memory: their feature map dimensions are analogous to memory sizes. They substitute the softmax with approximations (Peng et al., 2021; Choromanski et al., 2021), heuristically designed (Katharopoulos et al., 2020; Schlag et al., 2021), or learned (Kasai et al., 2021b) functions. ABC$_{\text{MLP}}$ keeps the softmax, but over a smaller constant-sized context. This can be useful in practice: (1) ABC provides a unified perspective of several efficient attention methods, allowing for borrowing from existing wisdom to design new architectures; (2) it draws a close analogy to the canonical softmax attention, and is better-suited as its drop-in substitute in various application settings, as we will show in the experiments; (3) empirically, we find that ABC$_{\text{MLP}}$ can get away with a much smaller memory size to retain the accuracy. Peng et al. (2021) and Schlag et al. (2021) use gating to promote recency bias. The same technique is equally applicable in ABC models.

The learned contextualized memory control is reminiscent of the content-based addressing in neural Turing machines (NTM; Graves et al., 2014). ABC$_{\text{MLP}}$ computes the control vectors $\{\phi_i\}$ as a function of the input, but *not* of the memory as in NTM. This ensures that the control vectors at different timesteps can be computed in parallel, improving the time efficiency in practice (Lei et al., 2018; Peng et al., 2018). Analogies between memory and neural architectures are also made by other previous works (Hochreiter and Schmidhuber, 1997; Weston et al., 2015; Le et al., 2020, *inter alia*).

5 Experiments

We evaluate ABC models on language modeling (§5.1), sentence-level and document-level machine translation (§5.2), and masked language model finetuning (§5.3). Dataset statistics and implementation details are summarized in §C.

5.1 Language Modeling

Setting. We experiment with WikiText-103, sampled text from English Wikipedia (Merity et al., 2017). The BASE model with standard softmax attention is the strong transformer-based language model by Baevski and Auli (2019). We compare the following ABC variants, which build on BASE, but replace the softmax attention with linear-complexity bounded-memory attention alternatives while keeping other components the same.

- ABC$_{\text{MLP}}$, as described in §4, learns a contextualized exp-MLP as the ϕ function.
- Linformer (§3.1; Wang et al., 2020b).
- ABC$_{\text{RD}}$ stores each token in a randomly-selected memory slot with $\phi_t = \mathbf{e}_{i_t}$. i_t is uniformly drawn from $\{1, \ldots, n\}$ at each time step. This helps us quantify the differences between random and learned bounded-memory controls.

We consider two model size settings:

- 16 layers (Baevski and Auli, 2019). All models have around ~242M parameters. They train with 512-token segments, and evaluate with 0 or 480 context sizes: a 0- or 480- length prefix precedes each evaluation segment.
- 32 layers (Kasai et al., 2021b). All models have ~484M parameters. This setting applies layer dropout (Fan et al., 2020), and evaluates with a 256 context size. It aims to compare ABC$_{\text{MLP}}$ to several kernel-based efficient attention variants: ELU (Katharopoulos et al., 2020), RFA (Peng et al., 2021), and T2R (Kasai et al., 2021b).

Results. Table 3a compares ABC variants using Baevski and Auli (2019)'s 16-layer setting. Among ABC models, ABC$_{\text{MLP}}$ achieves the best performance for both context sizes. With a memory size $n = 64$, ABC$_{\text{MLP}}$ outperforms both Linformer and ABC$_{\text{RD}}$ by more than 2.9 test perplexity; and the gap is larger with the longer 480-length context: more than 3.6 test perplexity. ABC$_{\text{MLP}}$-32 outperforms its larger-memory ABC counterparts by more than 2.1 test perplexity. These results confirm ABC$_{\text{MLP}}$'s advantages of using a contextualized strategy. Surprisingly, Linformer *underperforms* ABC$_{\text{RD}}$, and its performance drops with the larger 480-length context window. This suggests that, while successful in text encoding, Linformer's position-based strategy is a suboptimal design choice for causal attention, at least for long context. All ABC models *underperform* the BASE, with ABC$_{\text{MLP}}$-64 having the smallest gap of 0.5 perplexity. ABC$_{\text{MLP}}$-32 outperforms kernel-based methods by more than 0.9 test perplexity, using Kasai et al. (2021b)'s 32-layer setting (Table 3b).

5.2 Machine Translation

Datasets. To assess their performance over various output lengths, we compare ABC models on sentence- and document- level machine translation.

- Sentence-level translation with WMT14 EN-DE

Model	**Cross n**	**Causal n**	**BLEU**
BASE	-	-	27.2
ABC$_{\text{RD}}$	32	32	25.7
ABC$_{\text{RD}}$	64	64	26.2
Linformer	32	32	26.6
Linformer	64	64	26.7
ABC$_{\text{MLP}}$	32	8	27.1
ABC$_{\text{MLP}}$	32	32	**27.3**

(a) Bolded number outperforms BASE.

Model	**Cross n**	**Causal n**	**BLEU**
BASE	-	-	39.9
Linformer	128	64	-
ABC$_{\text{RD}}$	128	64	38.6
ABC$_{\text{MLP}}$	128	64	**39.7**

(b) Linformer fails to converge even with multiple random seeds. Bold number performs the best among ABC models.

Table 4: Machine translation test SacreBLEU. Left: sentence-level translation with WMT14 EN-DE; right: document-level translation with IWSLT14 ES-EN.

(Bojar et al., 2014). The preprocessing and data splits follow Vaswani et al. (2017).

- Document-level translation with IWSLT14 ES-EN (Cettolo et al., 2014). We use Miculicich et al. (2018)'s data splits and preprocessing. Following standard practice (Voita et al., 2019), a 4-sentence sliding window is used to create the dataset, i.e., each instance has 4 sentences.

Setting. We compare ABC variants as in §5.1. §C.2 further compares to the clustering-based (§3.2) and sliding-window (§3.3) ABC variants.

The BASE model they build on is our implementation of transformer-base (Vaswani et al., 2017). ABC variants replace decoder cross attention and causal attention with bounded-memory attention, while keeping softmax attention for the encoder, since its overhead is much less significant (Kasai et al., 2021a); other components are kept the same. §C.2 studies a model that replaces *all* softmax attention with ABC$_{\text{MLP}}$. It performs on par with BASE, confirming ABC$_{\text{MLP}}$'s broad applicability in various application scenarios. We evaluate with SacreBLEU (Post, 2018).

Results. Table 4a summarizes sentence-level machine translation results on the WMT14 EN-DE test set. Overall ABC$_{\text{MLP}}$ performs on par with BASE, with either 32-32 cross-causal memory sizes or 32-8. Even with smaller memory sizes, it outperforms other ABC variants by more than 1.1 BLEU. Differently from the trend in the language modeling experiment (§5.1), Linformer outperforms ABC$_{\text{RD}}$ by more than 0.5 BLEU. We attribute this to the smaller sequence lengths of this dataset. ABC$_{\text{MLP}}$ outperforms other ABC models by more than 0.4 BLEU, even with smaller memory sizes.

The trend is similar on document-level translation with IWSLT14 ES-EN (Table 4b), except that ABC$_{\text{MLP}}$ slightly *underperforms* BASE by 0.2 BLEU. This suggests that even with longer sequences, ABC$_{\text{MLP}}$ is effective despite its bounded memory size. Linformer fails to converge even with multiple random seeds, suggesting the limitations of its purely position-based strategy in tasks involving decoding varying-length text.

5.3 Masked Language Model Finetuning

Setting. We compare the ABC variants as in §5.1. It is interesting to pretrain ABC from scratch, but we lack the resources to do so. Instead, we warm-start from a pretrained RoBERTa-base (Liu et al., 2019) trained with the softmax transformer, swap its attention with ABC variants, and continue pretraining with the masked language modeling (MLM) objective on a concatenation of BookCorpus (Zhu et al., 2015), English Wikipedia, OpenWebText (Gokaslan and Cohen, 2019), and RealNews (Zellers et al., 2019).[7] Then the models are finetuned and evaluated on downstream classification datasets from the the GLUE benchbark (Wang et al., 2019). This is an appealing setting, since it avoids reinvesting the huge amounts of resources already put into pretraining.[8]

Results. Table 5 compares downstream text classification performance. BASE indicates a baseline that continues pretraining RoBERTa-base on our data.[9] Following standard practice, we report development accuracy. Linformer achieves competitive

---

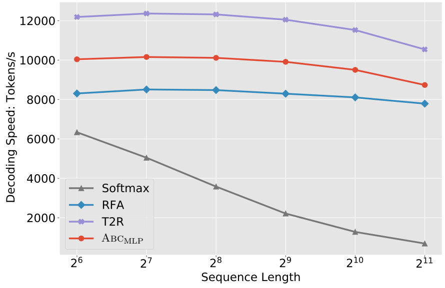
[7] Our data differs from RoBERTa's, which we do *not* have access to. We replace CC-News (Nagel, 2016) with RealNews, and drop Stories (Trinh and Le, 2018), whose public access is broken at the time of this work.

[8] In preliminary experiments, we explored swapping in ABC, and then directly finetuning on downstream tasks *without* continued MLM pretraining; all models fail.

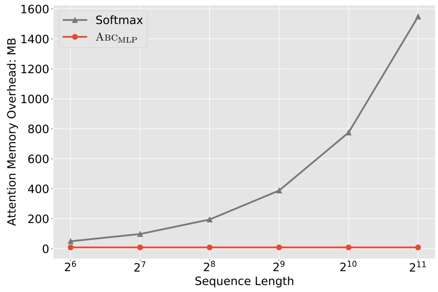
[9] BASE slightly *underperforms* RoBERTa-base. This could be due to overfitting, or the pretraining data discrepancy.

Model	n	**MNLI**	**QNLI**	**QQP**	**SST**	**Avg.**
Base	-	87.2	92.4	91.7	94.3	91.4
Linformer	64	85.3	91.8	90.8	92.4	90.1
Linformer	128	86.1	91.9	91.4	93.7	90.8
ABC$_{\text{MLP}}$	64	85.6	91.8	91.7	93.8	90.7
ABC$_{\text{MLP}}$	128	**87.1**	**92.6**	**91.8**	**94.4**	**91.5**

Table 5: Text classification development set accuracy. All models continue pretraining RoBERTa-base on our data with the MLM objective. Bold numbers perform the best among ABC models, and underlined ones perform on par with or better than Base.



(a) Decoding Speed.



(b) Decoding memory overhead.

Figure 1: Sequence-to-sequence decoding speed (top) and memory consumption (bottom) varying sequence lengths. Greedy decoding is used, with batch size 16.

performance, aligned with Wang et al. (2020b)'s results. ABC$_{\text{MLP}}$ outperforms Linformer, and performs on par with or better than Base, affirming the benefits of using contextualized memory organization in MLM. ABC$_{\text{RD}}$ fails to converge in continued pretraining even with multiple seeds.

Based on the above results, we think ABC$_{\text{MLP}}$ can achieve competitive performance when pretrained from scratch, just as Linformer does (Wang et al., 2020b). Further empirical exploration is beyond our budget and left for future work.

6 Analysis

Decoding efficiency over varying sequence lengths. ABC's efficiency gains can be more prominent for long sequences. We study ABC$_{\text{MLP}}$'s decoding overhead with varying sequence lengths. Following Kasai et al. (2021b), we consider a sequence-to-sequence generation experiment. Three linear-complexity models are compared: RFA (with 256/128 cross/causal memory sizes; Peng et al., 2021), T2R (32/4; Kasai et al., 2021b), and ABC$_{\text{MLP}}$ (32/8). The sizes are chosen to maximize efficiency *without* accuracy drop. T2R needs to be finetuned from a pretrained transformer to match its performance, while others don't.

All linear-time models achieve consistent decoding speed for different lengths (Figure 1a), substantially outpacing the softmax attention baseline, especially for long sequences. In particular, ABC$_{\text{MLP}}$ decodes $\sim$1.25 times faster than RFA, another competitive model that can match transformer's accuracy *without* a warm start from a pretrained model. This can be attributed to the fact that ABC$_{\text{MLP}}$ achieves similar accuracy with a much smaller memory. T2R's memory sizes are similar to ABC$_{\text{MLP}}$'s, but it decodes about 20% faster. This is because it does *not* compute the softmax when calculating attention output, while ABC$_{\text{MLP}}$ does (Eq. 4). These results show that ABC$_{\text{MLP}}$ is an appealing modeling choice for decoding tasks, especially when training from scratch is desired.

ABC$_{\text{MLP}}$ also achieves significant savings in terms of memory overhead (Figure 1b). ABC$_{\text{MLP}}$, RFA, and T2R's curves are similar.

Text encoding efficiency. We compare the efficiency of ABC$_{\text{MLP}}$ against softmax attention and Linformer when used as text encoders. The models' sizes mirror those in the MLM experiment (§5.3). Table 6 summarizes inference time and memory overhead with 512-length inputs, batch size 16. Both ABC$_{\text{MLP}}$ and Linformer achieve inference speed gains and memory savings over Base. Linformer is faster, since its linear projection is cheaper to compute than ABC$_{\text{MLP}}$'s MLP. Inference speed is measured on the same V100 GPU. The trend in memory overhead is similar.

Although ABC$_{\text{MLP}}$ slightly underperforms Linformer in terms of inference speed, it can be a more appealing architectural choice in practice: in all of our 5 experiments, ABC$_{\text{MLP}}$ outperforms other ABC models in accuracy. Linformer, in contrast, fails to converge or yields sub-optimal performance on some tasks. This confirms its flexibility and ap-

	BASE	Linformer		ABC$_{\text{MLP}}$	
n	-	64	128	64	128

	16	-	25.4	25.7	25.6
	32	-	-	25.7	25.8
	64	-	-	-	25.8

Table 7: ABC$_{\text{MLP}}$'s SacreBLEU on WMT14 EN-DE development data varying memory sizes.

plicability in various settings.

Memory size's impact on accuracy. Practically, one may want to minimize the memory size to improve efficiency. We use the WMT14 EN-DE experiment to investigate how memory size affects accuracy. Using the §5.2's setup, we vary ABC$_{\text{MLP}}$'s cross and causal attention memory sizes and compare their translation quality on the development data. They are selected from $\{8, 16, 32, 64\}$, with cross attention's equal to or larger than causal's: cross attention is more important than causal attention in machine translation (Michel et al., 2019). Our results (Table 7) align with this observation: when cross attention memory is large enough, reducing causal attention memory size from 64 to 8 has a minor 0.3 BLEU drop. Surprisingly, ABC$_{\text{MLP}}$ with 8-8 sized cross-causal memory is only 1.1 BLEU behind the best-performing configuration.

7 Conclusion

We presented attention with bounded-memory control (ABC). It provides a unified perspective of several recently-proposed models, and shows that they vary in the organization of the bounded memory. ABC reveals new insights into established methods and inspires new architectures. We proposed ABC$_{\text{MLP}}$, a particular instance of ABC that learns a contextualized memory control. On language modeling, machine translation, and masked language model finetuning, ABC$_{\text{MLP}}$ outperforms previous ABC models. Compared to the strong transformer baseline, ABC$_{\text{MLP}}$ achieves substantial efficiency improvements with no or negligible accuracy loss.

Acknowledgments

We would like to thank the ARK group at the University of Washington for their helpful feedback, and the anonymous reviewers for their thoughtful comments. This work was supported in part by NSF grant 2113530 and a Google Fellowship. Nikolaos Pappas was supported by the Swiss National Science Foundation grant P400P2_183911.

Appendices

A Other ABC Models

A.1 Sparse Local-to-global Attention

It sparsifies attention pattern to reduce the number of tokens that are attended to (Beltagy et al., 2020; Zaheer et al., 2020, *inter alia*). All queries attend to a subset of $n < N$ "global tokens," while ignoring others. Therefore the effective context size is reduced to n. The global tokens are usually preselected by positions according to some heuristics. Local-to-global attention is an instance of ABC: it can be recovered by letting $\boldsymbol{\phi}_t = \mathbf{e}_i$ if x_t is the ith global token ($i = 1, \ldots, n$), and the zero vectors for others.

A.2 Random Memory Control

As a baseline, ABC$_{\text{RD}}$ stores each token in a randomly-selected memory slot. This is achieved by letting $\boldsymbol{\phi}_t = \mathbf{e}_{i_t}$, where i_t is uniformly drawn from $\{1, \ldots, n\}$ for each t. It is designed as a baseline to ABC$_{\text{MLP}}$ and Linformer to quantify the differences between random and learned bounded-memory control.

Random sparse attention patterns are explored by Zaheer et al. (2020), where a subset of $n < N$ tokens are randomly selected to be attended to by all tokens. ABC$_{\text{RD}}$ is different, and it attends to *all* tokens, but randomly "squash" them into an n-slot memory.

A.3 Compressive Transformer with Mean Pooling

The compressive transformer (Rae et al., 2020) explores various ways to "squash" long context into smaller and more compact representations. It achieves state-of-the-art performance on several language modeling benchmarks. We show that at least the mean-pooling variant of the compressive transformer can be seen as an ABC instance.

The mean-pooling variant of the compressive transformer compresses the context by

$$\begin{aligned}
&\mathbf{K} = \left[\mathbf{k}_1, \ldots, \mathbf{k}_N\right]^\top \in \mathbb{R}^{N \times d} \\
\rightarrow\ &\widetilde{\mathbf{K}} = \Big[\underbrace{(\mathbf{k}_1 + \cdots + \mathbf{k}_c)}_{c}/c, \\
&\qquad \underbrace{(\mathbf{k}_{c+1} + \cdots + \mathbf{k}_{2c})}_{c}/c \ldots, \\
&\qquad \underbrace{(\mathbf{k}_{N-c+1} + \cdots + \mathbf{k}_N)}_{c}/c\Big]^\top \in \mathbb{R}^{n \times d}.
\end{aligned}$$

where $c = N/n$ is the compression ratio. Here $N \bmod n = 0$ is assumed, since otherwise the sequence can be padded to.

The above model is an ABC instance by letting

$$\boldsymbol{\phi}_i = \mathbf{e}_{\lfloor (i-1)/c \rfloor + 1}/c. \tag{8}$$

A.4 Dilated Convolution Attention Patterns

The dilated attention pattern is similar to the sliding window attention and only considers the context within a predefined window. It differs in that it attends to every other token:

$$\widetilde{\mathbf{K}}_t = [\mathbf{k}_{t-2n+2}, \mathbf{k}_{t-2n+4}, ..., \mathbf{k}_{t-2}, \mathbf{k}_t]^\top. \tag{9}$$

It can be simulated with two separate queues $\widetilde{\mathbf{K}}^{\text{odd}}$ and $\widetilde{\mathbf{K}}^{\text{even}}$:

$$\widetilde{\mathbf{K}}_t^{\text{odd}} = \begin{cases} \mathbf{U}\widetilde{\mathbf{K}}_{t-1}^{\text{odd}} + \mathbf{e}_n \otimes \mathbf{k}_t, & \text{if } t \text{ is odd} \\ \widetilde{\mathbf{K}}_{t-1}^{\text{odd}}, & \text{otherwise} \end{cases}$$

$$\widetilde{\mathbf{K}}_t^{\text{even}} = \begin{cases} \mathbf{U}\widetilde{\mathbf{K}}_{t-1}^{\text{even}} + \mathbf{e}_n \otimes \mathbf{k}_t, & \text{if } t \text{ is even} \\ \widetilde{\mathbf{K}}_{t-1}^{\text{even}}, & \text{otherwise} \end{cases}$$

Likewise for the values. Depending on t, the query attends to one of the two queues: $\text{output} =$

$$\begin{cases} \left(\widetilde{\mathbf{V}}^{\text{odd}}\right)^\top \operatorname{softmax}(\widetilde{\mathbf{K}}^{\text{odd}}\mathbf{q}_t), & \text{if } t \text{ is odd} \\ \left(\widetilde{\mathbf{V}}^{\text{even}}\right)^\top \operatorname{softmax}(\widetilde{\mathbf{K}}^{\text{even}}\mathbf{q}_t), & \text{otherwise.} \end{cases}$$

The above implementation could incur considerable amount of overhead and may be actually more expensive than the the original dilated window formulation. Therefore it has more conceptual value than practical value.

A.5 Shared Workspace and Linear Unified Nested Attention

Concurrently to this work, shared workspace (SW; Goyal et al., 2021) and linear unified nested attention (LUNA; Ma et al., 2021) also propposed methods to learn contextualized memory control strategies. Both can be seen as instances of ABC. At layer ℓ, their $\boldsymbol{\phi}_i^\ell$ is a function of previous layer's memory $\widetilde{\mathbf{X}}^{\ell-1} \in \mathbb{R}^{n \times d}$ and current layer's input $\mathbf{X}^\ell \in \mathbb{R}^{N \times d}$:

$$\boldsymbol{\phi}_i = \left[\operatorname{softmax}\left(\widetilde{\mathbf{X}}^{\ell-1}{\mathbf{X}^{\ell}}^\top\right)\right]_{:,i}, \tag{10}$$

where $[\cdot]_{:,i}$ denotes the ith column of a matrix. Query, key, and value projections are suppressed for notation clarity.

SW and LUNA reveal the entire sequence to the control vectors, by constructing $\boldsymbol{\phi}$ as a function of previous layer's memory. Although both admit the recurrent computation as all ABC models do, they are ill-suited for causal attention and autoregressive decoding, since future information is "leaked" to $\boldsymbol{\phi}_i$ from the previous layer. LUNA resorts to a variant of Katharopoulos et al. (2020) in causal attention (Ma et al., 2021). In contrast, ABC$_{\text{MLP}}$ never conditions $\boldsymbol{\phi}_i$ on previous layer's memory, but only on the current layer's input.

B More Details about ABC-MLP

B.1 Normalization in Causal Attention

An equivalent implementation to Eq. 7 is to normalize $\widetilde{\mathbf{K}}$ and $\widetilde{\mathbf{V}}$ instead of $\boldsymbol{\phi}_i$ vectors:

$$\boldsymbol{\alpha}_i = \mathbf{exp}\left(\mathbf{W}_{\boldsymbol{\phi}} \mathbf{x}_i\right), \quad \boldsymbol{\phi}_i = \boldsymbol{\alpha}_i,$$

$$\bar{\mathbf{K}} = \widetilde{\mathbf{K}} \Bigg/ \sum_{j=1}^{N} \boldsymbol{\alpha}_j. \quad \bar{\mathbf{V}} = \widetilde{\mathbf{V}} \Bigg/ \sum_{j=1}^{N} \boldsymbol{\alpha}_j.$$

$$\text{output} = \bar{\mathbf{V}}^\top \operatorname{softmax}(\bar{\mathbf{K}}\mathbf{q}).$$

$\mathbf{M}/\mathbf{z}$ divides the ℓth row of matrix $\mathbf{M}$ by vector $\mathbf{z}$'s ℓth dimension. This admits a linear complexity computation graph for the causal variant of ABC$_{\text{MLP}}$.

B.2 Higher-Dimensional Case of Example 1

This section generalizes Example 1 to higher dimensional cases. Assume that the constant-sized memory has n slots. $\boldsymbol{\phi}_i$ is cauculated as in Eq. 7. Then $\widetilde{\mathbf{K}} = \sum_{i=1}^{N} \boldsymbol{\phi}_i \otimes \mathbf{k}_i \in \mathbb{R}^{n \times d}$. Each row of $\widetilde{\mathbf{K}}$ can be seen as a separate attention mechanism with a pseudo query. Let $[\cdot]_\ell$ denote the ℓth row/dimension of a matrix/vector. Then for any $\ell = 1, \ldots, n$,

$$\begin{aligned}
\left[\widetilde{\mathbf{K}}\right]_\ell &= \sum_{i=1}^{N} [\boldsymbol{\phi}_i]_\ell \otimes \mathbf{k}_i \\
&= \sum_{i=1}^{N} \frac{\exp([\mathbf{W}_\phi]_\ell \cdot \mathbf{x}_i)}{\sum_{j=1}^{N} \exp([\mathbf{W}_\phi]_\ell \cdot \mathbf{x}_j)} \mathbf{k}_i^\top \\
&= \operatorname{attn}\left([\mathbf{W}_\phi]_\ell, \{\mathbf{x}_i\}_{i=1}^{N}, \{\mathbf{k}_i\}_{i=1}^{N}\right)^\top \in \mathbb{R}^{1 \times d}.
\end{aligned}$$

In other words, there are n attention mechanisms in total, each with a separately-parameterized pseudo-query $[\mathbf{W}_\phi]_\ell$. They summarize the context for n times in parallel, each producing a d-dimensional vectors. These output vectors are then stacked into n-by-d memory $\widetilde{\mathbf{K}}$. $\widetilde{\mathbf{V}}$ is similar.

C Experimental Details

C.1 Language Modeling

We closely build on Baevski and Auli (2019) and Kasai et al. (2021b). The hyperparameters are summarized in Table 10. All models are trained on 4 A100 GPUs.

C.2 Machine Translation

We experiment with a sentence-level (WMT14 EN-DE, Bojar et al., 2014) and a document-level benchmark (IWSLT14 ES-EN, Cettolo et al., 2014) to assess model performance over various sequence lengths. The preprocessing and data splits of WMT14 EN-DE follow Vaswani et al. (2017). A 32,768 byte pair encoding (BPE; Sennrich et al., 2016) vocabulary is shared between source and target languages. For IWSLT14, we follow Miculicich et al. (2018) and use the *dev2010* subset for development and *tst2010-2012* for testing. The tokenization is also the same as Miculicich et al. (2018): we tokenize and truecase Spanish and English with Moses (Koehn et al., 2007) and run byte-pair encoding with 30k splits, shared between the two languages. The final dataset contains 1421, 8, and 42 documents for training, development, and testing. On average, each document contains 126.7 sentences, and each sentence contains 21.7(ES)/22.5(EN) BPE subwords. We use a sliding window with length-4 and stride-one to generate our dataset. During inference, we use predicted context on the target side.

We average the checkpoints from the last five epochs to obtain the final model (Vaswani et al., 2017). In inference, we apply beam search with size 5 and length penalty 0.6. Other hyperparameters are summarized in Table 11. All models are trained on 4 RTX 2080 Ti GPUs.

Additional machine translation results. In addition to the results presented in §5.2, Table 8 further compares, on the WMT14 EN-DE dataset, the clustering-based (§3.2) and sliding-window (§3.3) models of ABC, as well as ReLU and sigmoid variants of ABC$_{\text{MLP}}$. Clustering and sliding-window ABC variants *underperform* ABC$_{\text{MLP}}$ with the same memory sizes by more than 0.5 BLEU. Both ReLU and sigmoid *underperform* their exp counterpart.

MLP-exp-all replaces the encoder's softmax attention modules with ABC, in addition to the decoder's. It underperforms ABC$_{\text{MLP}}$ by only 0.3 BLEU.

Model	ϕ	Cross n	Causal n	Encoder n	BLEU

	MLP-exp	32	32	-	**27.3**
	MLP-exp-all	32	32	32	27.0

Table 8: ABC variants' performance (SacreBLEU) on the WMT14 EN-DE test set for sentence-level machine translation. MLP-ReLU with 32/8 memory sizes fails to converge. MLP-exp-all applies ABC in both the encoder and the decoder, while others only in the decoders.

Figure 1b compares ABC_{MLP}'s (32-8 memory sizes) attention memory overhead with softmax attention's. Following Kasai et al. (2021b), we consider a synthetic sequence-to-sequence generation task with varying sequence lengths. A batch size of 16 and greedy decoding is used. The models are of the same size as those in §5.2.

C.3 Masked Language Model Finetuning

Our data for continued pretraining is a concatenation of BookCorpus (Zhu et al., 2015), English Wikipedia, OpenWebText (Gokaslan and Cohen, 2019), and RealNews (Zellers et al., 2019). Our data differs from RoBERTa's pretraining data, which we do *not* have access to. We replace their CC-News (Nagel, 2016) with RealNews, and drop Stories (Trinh and Le, 2018). At the time of this project, the public access to the Stories dataset is broken.[10] Our machine does *not* have a large enough memory to load all the data. We therefore split the training data into 20 shards, after shuffling. Other preprocessing is the same as Liu et al. (2019).[11] The hyperparameters for continued pretraining follow base-sized RoBERTa, part of which are summarized in Table 12. All models are trained on a single TPU v3 accelerator.

For downstream task finetuning, we use the same hyperparameters as Liu et al. (2019).[12] Table 13 briefly describes the tasks. The readers are referred to Wang et al. (2019) for futher details.

The Dangers of Underclaiming:
Reasons for Caution When Reporting How NLP Systems Fail

Samuel R. Bowman
New York University
`bowman@nyu.edu`

Abstract

Researchers in NLP often frame and discuss research results in ways that serve to deemphasize the field's successes, often in response to the field's widespread hype. Though well-meaning, this has yielded many misleading or false claims about the limits of our best technology. This is a problem, and it may be more serious than it looks: It harms our credibility in ways that can make it harder to mitigate present-day harms, like those involving biased systems for content moderation or resume screening. It also limits our ability to prepare for the potentially enormous impacts of more distant future advances. This paper urges researchers to be careful about these claims and suggests some research directions and communication strategies that will make it easier to avoid or rebut them.

1 Introduction

Over the last few years, natural language processing has seen a wave of surprising negative results overturning previously-reported success stories about what our models can do, and showing that widely-used models are surprisingly brittle (Jia and Liang, 2017; Niven and Kao, 2019; McCoy et al., 2019). This shows that many of our standard practices for evaluation and reporting can lead to unrealistically positive initial claims about what we can do. The resulting hype and overclaiming, whether intentional or not, are a problem. They can encourage the reckless deployment of NLP systems in high-stakes settings where they can do significant harm. They also threaten the health and credibility of NLP as a research field, and thereby threaten our ability to influence applied stakeholders or attract funding.

Fortunately, these results have led to a surge of research and writing that proposes more thorough and cautious practices for the evaluation of model ability (Ribeiro et al., 2020; Gardner et al., 2020; Kiela et al., 2021; Bowman and Dahl, 2021). While we have only a limited ability to control the public narrative taking place through industry PR and the media, there's reason to be hopeful that we researchers are getting much better at avoiding the worst forms of overconfidence about our systems. Less fortunately, this pattern of disappointment seems to have led to many instances of pessimism about model performance that are ungrounded from real empirical results. This leaves room for the research community's consensus about our capabilities to fall short of our actual capabilities.

Hey #deeplearning skeptics,
Why complain about "neural nets hype" when you could be calling it "backpropaganda"?

12:09 PM · Mar 6, 2015 · Twitter Web Client

Figure 1: Hype is a problem. The opposite of hype isn't necessarily better. (Quoted with permission.)

I call this issue *underclaiming*, for lack of a better term,[1] and argue that it is more dangerous than it might seem. It risks our credibility and thereby limits our ability to influence stakeholders in cases where our current systems are doing real harm. It also limits our ability to accurately forecast and plan for the impacts that may result from the deployment of more capable systems in the future. If we can truly reach near-human-level performance on many of the core problems of NLP, we should expect enormous impacts which will be potentially catastrophic if not planned for.

In this paper, I lay out case studies demonstrating four types of underclaiming, focusing especially on writing and citation practices. I then argue that

---

[1] While *overclaiming* generally refers to overstating the effectiveness of *one's own* methods or ideas, the phenomenon that I call underclaiming often involves downplaying the effectiveness of preexisting methods or ideas.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 7484 - 7499
May 22-27, 2022

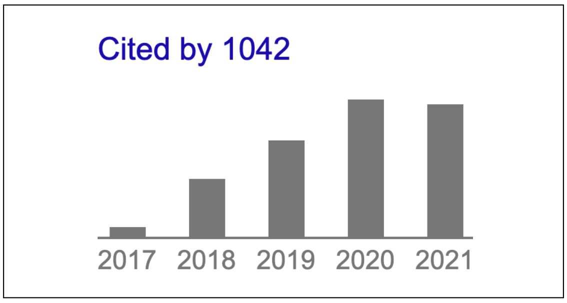

Figure 2: Jia and Liang (2017) remains widely cited according to Google Scholar. The original work pointed out major unexpected limitations in neural networks trained from scratch on the SQuAD reading comprehension task. However, many of these citing works use it to imply that modern pretrained systems—developed more recently than 2017—show these same limitations.

it is a problem. I close by sketching some ways of reducing the prevalence of this kind of underclaiming, including straightforward best practices in writing and evaluation, a proposed rule of thumb for writing and reviewing, improvements to tooling for analysis and benchmarking, and research directions in model performance forecasting and test set design.

2 Underclaiming: Case Studies

This paper addresses the phenomenon of scholarly claims that imply state-of-the-art systems are significantly less capable than they actually are. This takes on several forms, including misleading presentations of valid negative results from weak or dated baseline models, misleading claims about the limits of what is conceptually possible with machine learning, and misleading reporting of results on adversarially collected data.

2.1 Negative Results on Weaker Models

Despite many surprises and setbacks, NLP research seems to have made genuine progress on many problems over the last few years. In light of this, discussions about the limitations of systems from past years don't straightforwardly apply to present systems. The first two cases that I present involve failures to contextualize claims about the failures of weaker past systems:

Adversarial Examples for SQuAD Jia and Liang (2017) published one of the first demonstrations of serious brittleness in neural-network-based systems for NLU, showing that a simple algorithm could automatically augment examples from the SQuAD benchmark (Rajpurkar et al., 2016) in a way that fool many state-of-the-art systems, but not humans. This work prompted a wave of much-needed analysis and a corresponding lowering of expectations about the effectiveness of neural network methods.

Model	Year	SQuAD	AS	AOS
ReasoNet Ensemble	2017	81	39	50
BERT-Base	2018	87	64	72
XLNet-Base	2019	**89**	**69**	**77**

Table 1: F1 results on the original SQuAD development set and the two Jia and Liang adversarial evaluation sets. Results cover the best-performing SQuAD model studied by Jia and Liang—ReasoNet (Shen et al., 2017)—and the newer BERT and XLNet models (Devlin et al., 2019; Yang et al., 2019), as tested by Zhou et al. (2020). While I am not aware of results from more recent models on the this data, progress through 2019 had already cut error rates in half.

However, the results in Jia and Liang predate the development of modern pretraining methods in NLP (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2019), and the best systems studied in this work have more than twice the error rate of the current state of the art. While I am not aware of any results from current state-of-the-art systems on this data, results from 2019 systems suggest that we are making substantial progress (Table 1). We have no reason to expect, then, that the failures documented in this work are quantitatively or qualitatively similar to the failures of current systems.

However, papers that cite these results often present them with no discussion of the model under study, yielding misleading implications. For example, the award-winning work of Linzen (2020) cites the Jia and Liang result to justify this claim:

> [F]or current deep learning systems: when tested on cases sampled from a distribution that differs from the one they were trained on, their behavior is unpredictable and inconsistent with that of humans

The chief concern in this context is the claim that this failure applies to *current deep learning systems* in general, and the corresponding unjustified implication that these failures are a fundamental or defining feature of neural network language models. Looking only to highly-cited works from the last two years that cite Jia and Liang, similar statements can be found in Xu et al. (2020), Zhang et al. (2020), and others.

The Long Shadow of BERT While the case of Jia and Liang is especially striking since it deals with models that predate pretraining entirely, a similar effect is much more common in a subtler form: Most *analysis* papers that identify limitations of a system come out well after the system description paper that claims the initial (typically positive) results. BERT, first released in fall 2018, has been a major locus for this kind of analysis work, and continues to be long after its release. Looking to a random sample of ten papers from the NAACL 2021 analysis track that study pretrained models,[2] none of them analyze models that have come out since summer 2019, and five only study BERT, representing a median lag of nearly three years from the release of a model to the publication of the relevant analysis.[3]

This analysis work is often valuable and these long timelines can be justifiable: Good analysis work takes time, and researchers doing analysis work often have an incentive to focus on older models to ensure that they can reproduce previously observed effects. Even so, this three-year lag makes it easy to seriously misjudge our progress.

In particular, this trend has consequences for the conclusions that one would draw from a broad review of the recent literature on some problem: A review of that literature will contrast the successes of the best current systems against the weaknesses of the best systems *from an earlier period*. In many cases, these weaknesses will be so severe as to challenge the credibility of the successes if they are not properly recognized as belonging to different model generations.

The BERT-only results, though, represent a clear missed opportunity: There exist newer models like RoBERTa and DeBERTa (Liu et al., 2019; He et al., 2020) which follow nearly identical APIs and architectures to BERT, such that it should generally be possible to reuse any BERT-oriented analysis method on these newer models without modification. In many cases, these newer models are different enough in their performance that we should expect analyzing them to yield very different conclusions: For example, BERT performs slightly *worse* than chance on the few-shot Winograd Schema commonsense reasoning test set in SuperGLUE (Levesque et al., 2011; Wang et al., 2019), while DeBERTa reaches a near-perfect 96% accuracy. How much better would our understanding of current technology be if a few of these works had additionally reported results with DeBERTa?

2.2 Strong Claims about *Understanding*

The influential work of Bender and Koller (2020) is centered on the claim that:

> [T]he language modeling task, because it only uses form as training data, cannot in principle lead to learning of meaning.

The proof of this claim is straightforward and convincing under some (but not all) mainstream definitions of the word *meaning* in the context of NLP: If *meaning* deals with the relationship between language and some external nonlinguistic reality, then a system that can only ever interact with the world through language cannot access meaning.

This argument does not, on its own, make any prediction about the behavior of these models on tasks that take place entirely through the medium of language. Under this definition, a translation system is acting *without reference to meaning* even if it has a rich, structured internal model of the world, and even it interprets sentences with reference to that model when translating: As long as that model of the world is developed solely using language, no *meaning* is involved.[4]

In addition, this argument does not justify any strong prediction about the behavior of models which are trained primarily, but *not exclusively*, on a language modeling objective, as with models that are fine-tuned to produce non-textual outputs like labels, or models which are trained in a multimodal language-and-vision regime.

While this core claim is sound and important, public discussion of the paper has often repeated the claim in ways that imply stronger conclusions about model behavior. Utama et al. (2020), for example, write

---

[2] Papers studying only BERT: White et al. (2021); Slobodkin et al. (2021); Bian et al. (2021); Cao et al. (2021); Pezeshkpour et al. (2021). Papers studying other models predating fall 2019: Wallace et al. (2021); Hall Maudslay and Cotterell (2021); Hollenstein et al. (2021); Bitton et al. (2021); Du et al. (2021)

[3] A similar analysis of the late-2021 EMNLP conference, conducted after peer review for the present paper, shows a slightly better median lag of two years.

[4] See Merrill et al. (2021) for some limits on how closely such a model can correspond to the real world and Bommasani et al. (2021, §2.6.3) for further discussion of the implications of Bender and Koller's arguments for NLP.

> Researchers have recently studied more closely the success of large fine-tuned LMs in many NLU tasks and found that models are simply better in leveraging biased patterns instead of capturing a better notion of language understanding for the intended task (Bender and Koller, 2020).

, misleadingly suggesting that this result deals with the outward performance of specific language models on tasks.

In another vein, Jang and Lukasiewicz (2021) make the straightforward claim that

> Bender and Koller (2020) show that it is impossible to learn the meaning of language by only leveraging the form of sentences.

but they then use that claim to motivate a new regularization technique for language models, which does nothing to change the fact that they are trained on form alone. In this context, it is hard to avoid the incorrect inference that Bender and Koller show a *specific and contingent* problem with recent language models—which could be mitigated by better regularization.

Similar claims can be found in many other citing works (Utama et al., 2020; van Noord et al., 2020; Hovy and Yang, 2021; Sayers et al., 2021; Peti-Stantić et al., 2021; Jang and Lukasiewicz, 2021). While Bender and Koller raise important points for discussion, these strong implications in citing works are misleading and potentially harmful.

2.3 Adversarially Collected Test Sets

Adversarially collected test sets (Bartolo et al., 2020; Nie et al., 2020; Kiela et al., 2021)—or test sets composed of examples that some target system gets wrong—have recently become a popular tool in the evaluation of NLP systems. Datasets of this kind are crowdsourced in a setting where an example-writer can interact with a model (or ensemble) in real time and is asked to come up with examples on which the model fails. Writers are generally incentivized to find these failure cases, and the test section(s) of the resulting dataset will generally consist *exclusively* of such cases.

This process produces difficult test sets and it can be a useful tool in understanding the limits of existing training sets and models (Williams et al., 2020). However, the constraint that a specified system *must* fail on the test examples makes it difficult to infer much from absolute measures of test-set performance: As long as a model makes *any errors at all* on *any* possible inputs, then we expect it to be possible to construct an adversarial test set against the model, and we expect the model to achieve zero test accuracy on that test set. We can further infer that any models that are *sufficiently similar* to the adversary should also perform very poorly on this test set, regardless of their ability. Neither of these observations would tell us anything non-trivial about the actual abilities of the models.

What's more, in many NLU data collection efforts, a large share of annotator disagreements represent subjective judgments rather than clear-cut errors (Pavlick and Kwiatkowski, 2019). This means that even a perfectly careful and perfectly well-qualified human annotator should be expected to disagree with the majority judgment on some examples, and will thereby be coded as having made errors. It is, therefore, possible to create an adversarial test set for which a careful human annotator would achieve 0% accuracy. Absolute performance numbers on adversarially-collected test sets are meaningless as measures of model capabilities.

Adversarially-collected test sets are often used in standard experimental paradigms, and these caveats about the interpretation of results are not always clear when numbers are presented. Sampling papers that cite Nie et al. (2020), for example, it is easy to find references that do not mention the adversarial design of the data and that therefore make claims that are hard to justify:[5] Talmor et al. (2020) use the results from Nie et al. to claim that "LMs do not take into account the presence of negation in sentences", and Hidey et al. (2020) use them to justify the claim that "examples for numerical reasoning and lexical inference have been shown to be difficult." Bender et al. (2021) misleadingly describe a form of adversarial data collection[6] as a method for the "careful manipulation of the test data to remove spurious cues the systems are leveraging", and cite results on such data to argue that "no actual language understanding is taking place

---

[5] I focus here about claims about the *absolute* performance level of models. Whether adversarially collected test sets are appropriate for comparing the *relative* effectiveness of models is a largely orthogonal issue (Bowman and Dahl, 2021; Kaushik et al., 2021; Phang et al., 2021).

[6] AFLite (Bras et al., 2020) uses ensembles of *weak* models to filter data. This avoids the most direct *0% accuracy* concerns, but it can still provide arbitrarily large distortions to absolute performance in a way that is disconnected from any information about the skill or task that a dataset is meant to test.

in LM-driven approaches". Liu et al. (2020) similarly use absolute results on the adversary models to back up the trivial but easily-misread claim that BERT-style models "may still suffer catastrophic failures in adversarial scenarios."

3 A Word on Hype

The previous section has laid out some ways in which the mainstream NLP research community makes unjustifiable claims about the limitations of state-of-the-art methods. These claims do not make the opposite phenomenon, *hype*, any less real or any less harmful. While hype is likely most severe in industry PR and in the media,[7] it is nonetheless still prevalent in the research literature. In one especially clear example, a prominent paper claiming of human parity in machine translation performance (Hassan et al., 2018) severely overstates what has been accomplished relative to commonsense intuitions about what a human-level translation system would do (Toral et al., 2018; Läubli et al., 2018; Zhang and Toral, 2019; Graham et al., 2020).

I do not aim to argue that overclaiming or hype is acceptable or safe. Combating hype should be fully compatible with the goals laid out in this paper, and broad-based efforts to improve our practices in evaluation, analysis, writing, and forecasting should help reduce both underclaiming and hype.

4 Why Underclaiming is Harmful

Research papers are generally most useful when they're true and informative. A research field that allows misleading claims to go unchallenged is likely to waste its time solving problems that it doesn't actually have, and is likely to lose credibility with serious funders, reporters, and industry stakeholders. This is the most obvious reason that we should be concerned about underclaiming, but it is not the whole story. This loss of insight and credibility can seriously challenge our ability to anticipate, understand, and manage the impacts of deploying NLP systems. This is especially true of impacts that are contingent on NLP technologies *actually working well*, which we should expect will become more substantial as time goes on.

4.1 Present-Day Impact Mitigation

The deployment of modern NLP systems has had significant positive and negative impacts on the world. Researchers in NLP have an ethical obligation to inform (and if necessary, pressure) stakeholders about how to avoid or mitigate the negative impacts while realizing the positive ones. Most prominently, typical applied NLP models show serious biases with respect to legally protected attributes like race and gender (Bolukbasi et al., 2016; Rudinger et al., 2018; Parrish et al., 2021). We have no reliable mechanisms to mitigate these biases and no reason to believe that they will be satisfactorily resolved with larger scale. Worse, it is not clear that even superhuman levels of fairness on some measures would be satisfactory: Fairness norms can conflict with one another, and in some cases, a machine decision-maker will be given more trust and deference than a human decision-maker would in the same situation (see, e.g., Rudin et al., 2020; Fazelpour and Lipton, 2020). We thus are standing on shaky moral grounds when we deploy present systems in high-impact settings, but they are being widely deployed anyway (e.g. Dastin, 2018; Nayak, 2019; Dansby et al., 2020). Beyond bias, similar present-day concerns can be seen around issues involving minority languages and dialects, deceptive design, and the concentration of power (Joshi et al., 2020; Bender et al., 2021; Kenton et al., 2021, §3.3).

Persuading the operators of deployed systems to take these issues seriously, and to mitigate harms or scale back deployments when necessary, will be difficult. Intuitively, researchers concerned about these harms may find it appealing to emphasize the limitations of models in the hope that this will discourage the deployment of harmful systems. This kind of strategic underclaiming can easily backfire: Models are often both useful and harmful, especially when the operator of the system is not the one being harmed. If the operator of some deployed system sees firsthand that a system is effective for their purposes, they have little reason to trust researchers who argue that that same system *does not understand language*, or who argue something similarly broad and negative. They will then be unlikely to listen to those researchers' further claims that such a system is harmful, even if those further claims are accurate.

4.2 Preparing for Future Risks

We can reasonably expect NLP systems to improve over the coming decades. Even if intellectual progress from research were to slow, the dropping

---

[7] Consider the 2017 Huffington Post headline "Facebook Shuts Down AI Robot After It Creates Its Own Language."

price of compute should allow us to continue to reap the benefits of larger-scale training (Kaplan et al., 2020; Brown et al., 2020). This improvement in capabilities is likely to amplify both the harms and benefits of language technology.

We have good reason to expect that this further progress in NLP, over many years or decades, will lead to upheavals in areas like education, medicine, law, and the service sector more broadly, as well as making mass surveillance and misinformation campaigns far more effective and opening up additional new use cases that will be hard for us to foresee (Brundage et al., 2018; Tamkin et al., 2021; Bommasani et al., 2021). One can reasonably expect that the positive and negative impacts of these upheavals will far exceed the impacts that our technologies have produced to date. In turn, NLP researchers who want to ensure that their career has a net-positive impact on the world should be concerned with these possibilities.

How does this relate to underclaiming? It will be difficult to do the necessary technical, social, and governance work to prepare for these advances if we do not have a clear picture of our current capabilities, and it will be difficult to convince outside stakeholders to act appropriately to mitigate these risks if we don't acknowledge that we have made, and are making, real progress toward effective language technology.

Looking somewhat further into the future, a substantial community of philosophers, economists, and general ML researchers are concerned that highly-capable AI systems—of the kind that could plausibly be developed through existing ML research paradigms—are extremely dangerous by default (Bostrom, 2012; Critch and Krueger, 2020; Christian, 2020; Ord, 2020; Russell and Norvig, 2020). Expert forecasts suggest that this could take place within a few decades (Grace et al., 2018). If these hypotheses hold, and if we are poorly prepared for these developments, the worst-case outcomes could be catastrophic, even threatening the existence of human civilization on some views.

Investments in research into these potential catastrophic risks from advanced machine learning have become substantial: Funding from one foundation alone has totaled over $200M USD.[8] Concerns about risks from AI have also been the stated motivation for a significant fraction of the work from DeepMind and OpenAI, which both have access to even greater amounts of funding. The British Prime Minister Boris Johnson recently made a speech calling for further investment on the floor of the UN General Assembly (Nations, 2019).

Spurred on in particular by the shift in emergent capabilities from GPT-2 to GPT-3, the attention of these AI risk researchers has also been increasingly centered on language models and similar self-supervised multimodal models (Irving et al., 2018; Stiennon et al., 2020; Hendrycks et al., 2020; Kenton et al., 2021; Wu et al., 2021; Bommasani et al., 2021, §4.9). Despite the scale of this research, and its recent shift of focus toward language models, there has been little interaction between the research communities working on long-term AI risk and on NLP.

The facts that AI risk research is growing in influence and that it is increasingly focused on language models put NLP in an exceptionally strange and troubling situation as a field. To the extent that these concerns are valid, they represent an urgent call for reprioritization within NLP research to favor safety-relevant areas like interpretability, control, and evaluation over scaling, and to push for better oversight and regulation of large-scale research (Dafoe, 2018): Even a small risk of a globally significant catastrophe warrants a dramatic response. On the other hand, to the extent that these concerns are unfounded or are built on misunderstandings about the possible trajectories of ML research, it would be quite valuable to correct this misunderstanding. Correcting the record could redirect these resources and, more significantly, reduce the risk that popular or regulatory pressure will snuff out the positive potential of NLP technologies.

5 Catastrophic Risks

Because these more speculative concerns around advanced artificial intelligence are rarely discussed in the NLP literature, I will here offer a brief overview of that work. Recent writing tends to focus on four clusters of hypotheses:

Unaccountable Organizations Highly-capable AI is likely to lead to highly-profitable applications, making the institutions that first develop it quite powerful. It is also likely to be able to displace human labor in technical fields to a large extent, increasing the relative value of capital over labor, and making it easier for the leaders of these organiza-

---

[8] `https://www.openphilanthropy.org/giving/grants`

tions to take unpopular actions unilaterally. In the longer term, highly-capable AI may also contribute to the effectiveness of persuasion campaigns, further insulating these organizations from outside pressure. These forces could conspire to make the companies or governments that first produce highly-capable AI almost entirely unaccountable, and allowing their decisions to play a major role in the trajectory of humanity as a whole (Ord, 2020).

Alignment and Robustness Failures Even if a system is deployed by an actor with good intentions and substantial oversight, good outcomes are not guaranteed. As AI systems become more capable, they become capable of effecting—directly or indirectly—significant force on the outside world. In these cases, it becomes crucial that they behave in ways that we would endorse, even when they are pushed into unfamiliar new situations. This requires both that the systems be optimized for the right objectives and that the systems actually internalize and generalize those objectives correctly.

Specifying and using *safe* objectives, such that aggressively optimizing them does not produce catastrophic outcomes, is difficult (Critch and Krueger, 2020). Human preferences are complex, making the problem of specifying an objective that rules out unintended bad behavior non-trivial. Goodhart's law[9] means that many objectives that serve as good proxies for what we want in in familiar situations can break down in new situations.

Further, training large models with high precision is difficult. A small flaw in a highly-capable system's learned understanding of its objective can cause catastrophic failures, even if the true intended objective would have been safe (Hubinger et al., 2019).

Instrumentally-Convergent Subgoals The *instrumental convergence* hypothesis holds that systems that are optimizing for benign objectives, once they become sufficiently capable, have a predictable reason to take on dangerous *subgoals*—like accumulating large amounts of computational, economic, or political power—to maximize the odds that their primary objectives are achieved (Bostrom, 2003; Omohundro, 2008; Bostrom, 2012).[10] Even with merely near-human-like levels of performance, the ability of computational models to be copied and accelerated gives them considerable leeway to act in un-human-like ways. Systems that interact with humans only through text, or systems whose goals are circumscribed to a well-defined task like question answering, are not exempt from this concern (Armstrong et al., 2012).

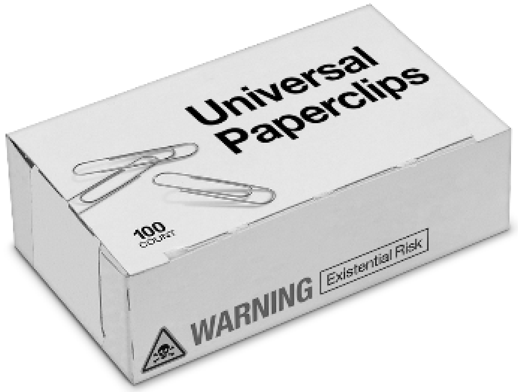

Figure 3: Downplaying the capabilities of current ML systems makes it less likely that we'll be well prepared for the impacts that come from developing highly-capable future sytsems. That can be bad. Image from Lantz (2017).

Risks Will Be Difficult to Spot Human-level capabilities are likely to emerge first from large machine learning models that, like modern neural networks, are not directly interpretable. This means that it may be difficult to spot ways in which a model is unsafe or to forecast ways in which its behavior might change in novel settings (Critch and Krueger, 2020).

Further, we should expect highly-capable AI systems to be *useful* in the short term, giving potential users a strong incentive to deploy them as soon as they are affordable, even if their safety is not guaranteed. This means that it is not enough that it simply be *possible* for us to develop safe systems, it is additionally necessary that it be nearly as easy and nearly as affordable as developing unsafe systems (Irving et al., 2018).

So What? None of these arguments is conclusive in its current form, but as far as I am aware, all have resisted straightforward attempts at falsification. All four are potentially applicable to neural

---

[9] in the formulation of Strathern (1997): "When a measure becomes a target, it ceases to be a good measure."

[10] This is exemplified by the thought experiment of the *paperclip maximizer* (Figure 3), which points out that a machine tasked with manufacturing as many paperclips as possible, if sufficiently capable, should be expected to turn nearly all matter on earth into paperclips. While this vision of a single system acting alone on such a trivial objective is unrealistic, it demonstrates the key hypothesis that almost any reasonable-sounding goal starts to conflict with basic human needs if a sufficiently capable system pursues it single-mindedly.

network-based models and to models which operate primarily through language. While the nascent field of *AI alignment* has proposed some mechanisms by which we might mitigate these risks, work in this area is still largely exploratory, with no clear research agenda in place to ensure that powerful models will be safe (Hadfield-Menell et al., 2016; Irving et al., 2018; Critch and Krueger, 2020; Kenton et al., 2021; Askell et al., 2021). If these arguments hold, significant further work is needed to avoid catastrophe. This will be difficult to achieve without a clear accounting of the abilities and limitations of current and plausible near-future systems. In particular, we will need enough foresight to be able to see substantial progress of this kind coming well in advance, to avoid the complacency that comes with the perception that worrying about impacts from powerful AI is like worrying about "overpopulation on mars" (Garling, 2015, quoting Andrew Ng).

6 Ways to Do Better

The core issue in this paper is one of sloppy communication about results. The most straightforward step that we can take to remedy underclaiming is to simply use the same practices that we already use to avoid overclaiming: The peer-review process already polices overclaiming to a significant extent, and most researchers have learned to be careful about overclaiming in their writing. We should apply high standards of evidence to our own empirical claims and those of others, both in peer-reviewed venues and in more informal scientific communication, even when those claims are negative and cloaked in a frame of individual or field-level modesty.

Beyond this, there are specific best practices or research directions that can help make these mistakes harder to make:

A Rule of Thumb In light of the issues with negative results on older models discussed in Section 2.1, it could be productive to introduce a new heuristic when reviewing or evaluating papers that discuss model failures.[11] In the spirit of the Bender Rule (Bender, 2019), I propose:

> When describing the failure of a machine learning model on some empirical evaluation, make it clear
>
> i. what kind of model has failed,
> ii. whether the model is significantly less capable than the current state of the art in the domain, and
> iii. whether the evaluation was deliberately set up to trick that model or another model like it.

Better Evaluation The pervasiveness of underclaiming can likely be attributed in part to the ineffectiveness of current evaluation practices in many areas of NLP. When impressive numbers on widely-used benchmarks are usually followed by disappointment, suggesting that good evaluation numbers don't translate to effective systems, it is rational to treat new encouraging results with extreme skepticism.

Better benchmarks and evaluation practices could help mitigate this by providing a firmer ground on which to make positive claims about system capacities.[12] In practice, research into more effective crowdsourcing and benchmark design and research into better statistical reporting and publication norms (Dodge et al., 2019; Card et al., 2020; Rogers and Augenstein, 2020; van Miltenburg et al., 2021) seem especially high-impact under this lens.

Better Analysis We can help address the time-lag issue discussed in Section 2.1 by building tooling to make it easier to adapt existing analysis techniques to new models seamlessly. Leaderboards that integrate conventional benchmarking with analysis can be especially helpful by making this largely automatic (Wang et al., 2018; Dua et al., 2019; Gehrmann et al., 2021; Ma et al., 2021). More broadly, careful analysis work, targeted at broadly understanding the capacities of capable models, will be valuable in helping to forecast and mitigate the worst risks from future systems (Elhage et al., 2021; Ganguli et al., 2022).

Better Forecasting *Scaling laws* results in NLP (Hestness et al., 2017; Kaplan et al., 2020; Brown et al., 2020; Zhang et al., 2021) offer the promise that we can predict the performance of *future* larger-scale machine learning models on at least some

---

[11] While a corresponding rule could be helpful in the context of results describing the *success* of a machine learning system on some evaluation, the asymmetry here is intentional: Successes are likely to be deliberately replicated from one generation of models to the next, while the opposite is true of failures.

[12] Though Raji et al. (2021) point out ways in which better benchmarking *alone* is unlikely to be fully satisfactory.

metrics. This line of work is still nascent, and successes to date have largely focused on loss values rather than more interpretable measures of capability. Further developing these methods, as well as others that allow us to better forecast near future progress, should be helpful. Better forecasting will provide a useful way to sanity-check future claims (DellaVigna et al., 2019) and will help improve the responsiveness of model analysis by enabling us to prepare analysis methods and datasets that *anticipate* future capabilities.

7 Additional Related Work

While much of this paper discusses the state of the NLP literature, a few related works warrant emphasis as starting points for further reading:

Bender and Koller (2020), Bender et al. (2021), and Raji et al. (2021) discuss the role of hype in driving bad outcomes from the development of language technology. Jin et al. (2021) and Rogers (2021) offer broader discussion of how to ensure that the net impact of near-future NLP deployments on the world is positive. Morris et al. (2020) and Hauser et al. (2021) highlight overly strong negative claims in papers analyzing models' robustness to synonym substitution.

Looking to the longer term, Bommasani et al. (2021, §4.9) provides an introduction to the AI risk and AI alignment literature from a perspective that emphasizes NLP and language. Welty et al. (2019), Linzen (2020), Ribeiro et al. (2020), Raji et al. (2021), Bowman and Dahl (2021), and Dehghani et al. (2021), among many others, discuss the challenges involved in designing evaluations that yield trustworthy and accurate depictions of the capabilities of ML models.

8 Conclusion

Like many research fields that have a tight connection to technological practice, NLP has long struggled to avoid inflated expectations about the capabilities of state-of-the-art tools. This remains a serious issue. However, this paper argues that our attempts to avoid hype often overshoot: Instead of merely correcting overly optimistic claims about our capabilities, we replace them with overly *pessimistic* claims.

Making misleading claims is generally a bad sign for the health and credibility of a scientific field, and the stakes are high: NLP technologies are implicated in a range of serious real-world harms, and plausible future elaborations of these technologies are potentially much more dangerous still. Our ability to mitigate existing harms will depend on our ability to make reliably credible claims about the limitations of our systems. Our ability to mitigate future harms will depend on our ability to accurately anticipate, recognize, agree upon, and report upon emerging capabilities. Both of these goals are seriously hampered by claims that current technologies are less capable than they in fact are.

Better evaluation, better tooling for model analysis, and better mechanisms for technical forecasting should all contribute to making these pessimistic claims easier to avoid or debunk. However, this problem is ultimately one of scientific communication, and to solve it fully, we will need to use the tools and norms of science to better police false or misleading claims. The stakes are high.

Acknowledgements

The ideas and arguments in this work were developed through conversation (live or on Twitter) with more researchers than I can name, including Emiel van Miltenburg, Deb Raji, Paul Christiano, Geoffrey Irving, Rohin Shah, Jacob Steinhardt, Catherine Olsson, Nick Beckstead, Alex Tamkin, Daniel Dewey, Alex Ray, and Robin Jia, as well as audiences at UT Austin, Georgia Tech, UPenn, University College London, CMU, Bar Ilan University, Tel Aviv University, Technion, Hebrew University, Unbabel, Instituto Superior Técnico, UChicago, and TTI-C, and contributors to the AI Alignment Forum. Anna Rogers, Owain Evans, Alex Wang, Jacob Steinhardt, Jason Phang, Jared Kaplan, Alex Cristia, Tal Linzen, Jonathan Uesato, and four anonymous ARR reviewers provided feedback on drafts. Any errors or dubious rhetoric are my own.

RELiC: Retrieving Evidence for Literary Claims

Abstract

Humanities scholars commonly provide evidence for claims that they make about a work of literature (e.g., a novel) in the form of quotations from the work. We collect a large-scale dataset (RELiC) of 78K literary quotations and surrounding critical analysis and use it to formulate the novel task of *literary evidence retrieval*, in which models are given an excerpt of literary analysis surrounding a masked quotation and asked to retrieve the quoted passage from the set of all passages in the work. Solving this retrieval task requires a deep understanding of complex literary and linguistic phenomena, which proves challenging to methods that overwhelmingly rely on lexical and semantic similarity matching. We implement a RoBERTa-based dense passage retriever for this task that outperforms existing pretrained information retrieval baselines; however, experiments and analysis by human domain experts indicate that there is substantial room for improvement over our dense retriever.

1 Introduction

When analyzing a literary work (e.g., a novel or short story), scholars make claims about the text and provide supporting evidence in the form of quotations from the work (Thompson, 2002; Finnegan, 2011; Graff et al., 2014). For example, Monaghan (1980) claims that Elizabeth, the main character in Jane Austen's *Pride and Prejudice*, doesn't just refuse an offer to join the standoffish bachelor Darcy and the wealthy Bingleys on their morning walk, "but does so in such a way as to group Darcy with the snobbish Bingley sisters," and then directly quotes Elizabeth's tongue-in-cheek rejection: "No, no; stay where you are. You are charmingly grouped, and appear to uncommon advantage. The picturesque would be spoilt by admitting a fourth."

Literary scholars construct arguments like these by making complex connective inferences between their interpretations, framed as claims, and quotations (e.g., recognizing that Elizabeth says "charmingly grouped" and "picturesque" ironically in order to group Darcy with the snobbish Bingley sisters). This process requires a deep understanding of both literary phenomena, such as irony and metaphor, and linguistic phenomena (coreference, paraphrasing, and stylistics). In this paper, we computationally study the relationship between literary claims and quotations by collecting a large-scale dataset for **R**etrieving **E**vidence for **Li**terary **C**laims (RELiC), which contains 78K scholarly excerpts of literary analysis that each directly quote a passage from one of 79 widely-read English texts.

The complexity of the claims and quotations in RELiC makes it a challenging testbed for modern neural retrievers: given just the text of the claim and analysis that surrounds a masked quotation, can a model retrieve the quoted passage from the set of all possible passages in the literary work? This *literary evidence retrieval* task (see Figure 1) differs considerably from retrieval problems commonly studied in NLP, such as those used for fact checking (Thorne et al., 2018), open-domain QA (Chen et al., 2017; Chen and Yih, 2020), and text generation (Krishna et al., 2021), in the relative lack of lexical or even semantic similarity between claims and queries. Instead of latching onto surface-level cues, our task requires models to understand complex devices in literary writing and apply general theories of interpretation. RELiC is also challenging because of the large number of retrieval candidates: for *War and Peace*, the longest literary work in the dataset, models must choose from one of $\sim$ 32K candidate passages.

How well do state-of-the-art retrievers perform on RELiC? Inspired by recent research on dense passage retrieval (Guu et al., 2020; Karpukhin et al., 2020), we build a neural model (dense-RELiC) by embedding both scholarly claims and candidate literary quotations with pretrained RoBERTa networks (Liu et al., 2019), which are then fine-tuned

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 7500 - 7518
May 22-27, 2022

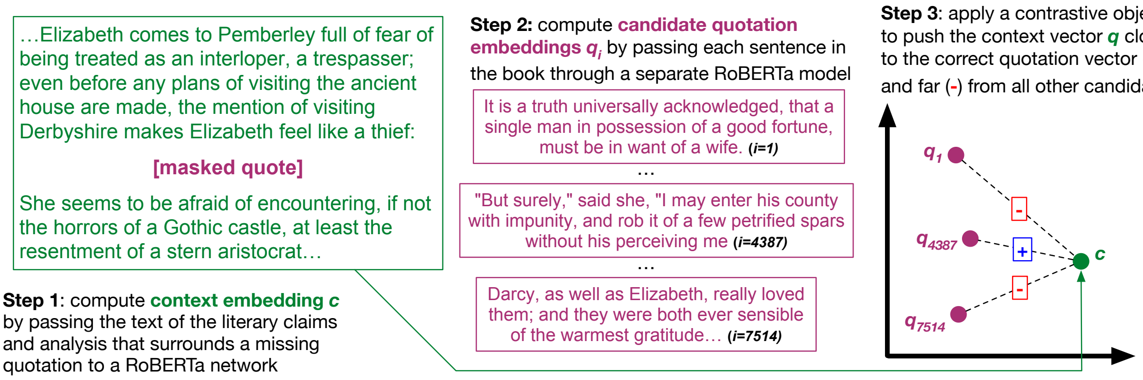

Figure 1: An example of our *literary evidence retrieval* task and the model we built to solve it. The model must retrieve a missing quotation from *Pride and Prejudice* given the literary claims and analysis that surround the quotation. The retrieval candidate set for this example consists of all 7,514 sentences from *Pride and Prejudice*. Our dense-RELiC model is trained with a contrastive loss to push a learned representation of the surrounding context close to a representation of the ground-truth missing quotation (here, the 4,387th sentence from the novel).

using a contrastive objective that encourages the representation for the ground-truth quotation to lie nearby to that of the claim. Both sparse retrieval methods such as BM25 and pretrained dense retrievers such as DPR and REALM perform poorly on RELiC, which underscores the difference between our dataset and existing information retrieval benchmarks (Thakur et al., 2021) on which these baselines are much more competitive. Our dense-RELiC model fares better than these baselines but still lags far behind human performance, and an analysis of its errors suggests that it struggles to understand complex literary phenomena.

Finally, we qualitatively explore whether our dense-RELiC model can be used to support evidence-gathering efforts by researchers in the humanities. Inspired by prompt-based querying (Jiang et al., 2020), we issue our own out-of-distribution queries to the model by formulating simple descriptions of events or devices of interest (e.g., *symbols of Gatsby's lavish lifestyle*) and discover that it often returns relevant quotations. To facilitate future research in this direction, we publicly release our dataset and models.[1]

2 Collecting a Dataset for Literary Evidence Retrieval

We collect a dataset for the task of **R**etrieving **E**vidence for **Li**terary **C**laims, or RELiC, the first large-scale retrieval dataset that focuses on the challenging literary domain. Each example in RELiC consists of two parts: (1) the context surrounding the quoted material, which consists of literary claims and analysis, and (2) a quotation from a widely-read English work of literature. This section describes our data collection and preprocessing, as well as a fine-grained analysis of 200 examples from RELiC to shed light on the types of quotations it contains. See Table 1 for corpus statistics.

2.1 Collecting and Preprocessing RELiC

Selecting works of literature: We collect 79 primary source works written or translated into English[2] from Project Gutenberg and Project Gutenberg Australia.[3] These public domain sources were selected because of their popularity and status as members of the Western literary canon, which also yield more scholarship (Porter, 2018). All primary sources were published in America or Europe between 1811 and 1949. 77 of the 79 are fictional novels or novellas, one is a collection of short stories (*The Garden Party and Other Stories* by Katherine Mansfield), and one is a collection of essays (*The Souls of Black Folk* by W. E. B. Du Bois).

Collecting quotations from literary analysis: We queried all documents in the HathiTrust Digital Library,[4] a collaborative repository of volumes from academic and research libraries, for exact matches of all sentences of ten or more tokens from each of the 79 works. The overwhelming majority

---

[1] https://relic.cs.umass.edu

[2] Of the 79 primary sources in RELiC, 72 were originally written in English, 3 were written in French, and 4 were written Russian. RELiC contains the corresponding English translations of these 7 primary source works. The complete list of primary source works is available in Appendix Tables A7, A8.

# training examples	62,956
# validation examples	7,833
# test examples	7,785
# total examples	78,574
average context length (words)	157.7
average quotation length (words)	40.5
# primary sources	79
# unique sec. sources	8,836

Table 1: RELiC statistics. Primary sources are from Project Gutenberg and Project Gutenberg Australia. Secondary sources are from the HathiTrust.

of HathiTrust documents are scholarly in nature, so most of these matches yielded critical analysis of the 79 primary source works. We received permission from the HathiTrust to publicly release short windows of text surrounding each matching quotation.

Filtering and preprocessing: The scholarly articles we collected from our HathiTrust queries were filtered to exclude duplicates and non-English sources. We then preprocessed the resulting text to remove pervasive artifacts such as in-line citations, headers, footers, page numbers, and word breaks using a pattern-matching approach (details in Appendix A). Finally, we applied sentence tokenization using spaCy's dependency parser-based sentence segmenter[5] to standardize the size of the windows in our dataset. Each window in RELiC contains the identified quotation and four sentences of claims and analysis[6] on each side of the quotation (see Table 2 for examples). To avoid asking models to retrieve a quote they have already seen during training, we create training, validation, and test splits such that primary sources in each fold are mutually exclusive. Statistics of our dataset sources are provided in Appendix A.3.

2.2 Comparison to other retrieval datasets

Table 1 contains detailed statistics of RELiC. To the best of our knowledge, RELiC is the first retrieval dataset in the literary domain, and the only one that requires understanding complex phenomena like irony and metaphor. We provide a detailed comparison of RELiC to other retrieval datasets in the recently-proposed BEIR retrieval benchmark (Thakur et al., 2021) in Appendix Table A6. RELiC has a much longer query length (157.7 tokens on average) than all BEIR datasets except ArguAna (Wachsmuth et al., 2018). Furthermore, our results in Section 3.3 show that while these longer queries confuse pretrained retriever models (which heavily rely on token overlap), a model trained on RELiC is able to leverage the longer queries for better retrieval.

2.3 Analyzing different types of quotation

What are the different ways in which literary scholars use direct quotation in RELiC? We perform a manual analysis of 200 held-out examples to gain a better understanding of quotation usage, categorizing each quotation into the following three types:

Claim-supporting evidence: In 151 of the 200 annotated examples, literary scholars used direct quotation to provide evidence for a more general claim about the primary source work. In the first row of Table 2, Hartstein (1985) claims that "this whale... brings into focus such fundamental questions as the knowability of space:" and then quotes the following metaphorical description from *Moby Dick* as evidence: "And as for this whale spout, you might almost stand in it, and yet be undecided as to what it is precisely." When quoted material is used as **claim-supporting evidence**, the context before and after usually refers directly to the quoted material;[7] for example, the paradoxes of reality and uncertainties of this world are exemplified by the vague nature of the whale spout.

Paraphrase-supporting evidence: In 31 of the examples, we observe that scholars used the primary source work to support their own paraphrasing of the plot in order to contextualize later analysis. In the second row of Table 2, Blackstone (1972) uses the quoted material to enhance a summary of a specific scene in which Jacob's mind is wandering during a chapel service. Jacob's daydreaming is later used in an analysis of Cambridge as a location in Virginia Woolf's works, but no literary argument is made in the immediate context. When quoted material is being employed as

---

[5] `https://spacy.io/`, the default segmenter in spaCy is modified to use ellipses, colons, and semicolons as custom sentence boundaries, based on the observation that literary scholars often only quote part of what would typically be defined as a sentence.

[6] The HathiTrust permitted us to release windows consisting of up to eight sentences of scholarly analysis. While more context is of course desirable, we note that (1) conventional model sizes are limited in input sequence length, and (2) context further away from the quoted material has diminishing value, as it is likely to be less relevant to the quoted span.

[7] In 19 of the 151 **claim-supporting evidence** examples, scholars introduce quoted material by explicitly referring to a specific "sentence," "passage," "scene," or similar delineation.

Quote type	Preceding context, **primary source quotation**, subsequent context
Claim-supporting evidence (*153*)	If this whale inspires the most lyrical passages in the novel, it also brings into focus such fundamental questions as the knowability of space: **And as for this whale spout, you might almost stand in it, and yet be undecided as to what it is precisely.** But Ishmael stands before the paradoxes of reality with historical and scientific intellect, wisdom, and comic elasticity that accommodates–however tenuously–the uncertainties of this world (Hartstein, 1985).
Paraphrase-supporting evidence (*25*)	But then, suddenly, Jacob's thought switches back to the lantern under the tree, with the old toad and the beetles and the moths crossing from side to side in the light, senselessly. **Now there was a scraping and murmuring. He caught Timmy Durrant's eye; looked very sternly at him; and then, very solemnly, winked.** From a boat on the Cam there is another sort of beauty to be seen. There are buttercups gilding the meadows, and cows munching, and the legs of children deep in the grass. Jacob looks at all these things and becomes absorbed (Blackstone, 1972).
Claim-supporting evidence	The relationship between Alexandra and the earth is an intensely personal one: **For the first time, perhaps, since that land emerged from the waters of geologic ages, a human face was set toward it with love and yearning...** The religious connotations of the more lyrical descriptions of the land prepare us for the emergence of Alexandra as its goddess (Helmick, 1968).
Paraphrase-supporting evidence	O Pioneers! is the story of a Swedish immigrant, Alexandra Bergson, who some to Nebraska with her parents when she is young. Her father dies, and she has to take over the farm and look after her younger brothers. Her courage, vision, and energy bring life and civilization to the wilderness. As Alexandra faces the future after her father's death, Willa Cather writes: **For the first time, perhaps, since that land emerged from the waters of geologic ages, a human face was set toward it with love and yearning.** The history of every country begins in the heart of a man or a woman. Alexandra succeeds in taming the wild land, and after a heaping measure of material success and personal tragedy, she faces the future calmly. (Woodress, 1975).

Table 2: Examples of the two major types of evidence identified in our manual analysis of RELiC. *Claim-supporting* evidence uses quotations to support more general literary claims, while *paraphrase-supporting evidence* uses quotations to corroborate summaries of the plot. The bottom two rows show the same quotation (from Willa Cather's *O Pioneers!*) being used as evidence in different ways, highlighting the dataset's complexity.

paraphrase-supporting evidence, the surrounding context does not refer directly to the quotation.

Miscellaneous: 18 of the 200 samples were not literary analysis, though some were still related to literature (for example, analysis of the the film adaptation of *The Age of Innocence*). Others were excerpts from the primary sources that suffered from severe OCR artifacts and were not detected or extracted by the methods in Appendix A.2.

3 Literary Evidence Retrieval

Having established that the examples in RELiC contain complex interplay between literary quotation and scholarly analysis, we now shift to measuring how well neural models can understand these interactions. In this section, we first formalize our evidence retrieval task, which provides the scholarly context *without* the quotation as input to a model, along with a set of candidate passages that come from the same book, and asks the model to retrieve the ground-truth missing quotation from the candidates. Then, we describe standard information retrieval baselines as well as a RoBERTa-based ranking model that we implement to solve our task.

3.1 Task formulation

Formally, we represent a single window in RELiC from book b as $(..., l_{-2}, l_{-1}, q_n, r_1, r_2, ...)$ where q_n is the quoted n-sentence long passage, and l_i and r_j correspond to individual sentences before and after the quotation in the scholarly article, respectively. The window size on each side is bounded by hyperparameters l_{max} and r_{max}, each of which can be up to 4 sentences. Given the $l_{-l_{max}:-1}$ and $r_{1:r_{max}}$ sentences surrounding the missing quotation, we ask models to identify the quoted passage q_n from the candidate set $C_{b,n}$, which consists of all n-sentence long passages in book b (see Figure 1). This is a particularly challenging retrieval task because the candidates are part of the same overall narrative and thus mention the same overall set of entities (e.g., characters, locations) and other plot elements, which is a disadvantage for methods based on string overlap.

Evaluation: Models built for our task must produce a ranked list of candidates $C_{b,n}$ for each example. We evaluate these rankings using both recall@k for $k = 1, 3, 5, 10, 50, 100$ and *mean rank* of q in the ranked list. Both types of metrics focus on the position of the ground-truth quotation

Model	**L/R**	**Recall@*k* (↑)**						**Avg rank (↓)**	**Proxy task acc (↑)**

Human domain experts	4/4								**93.5**

Table 3: Overall comparison of different systems and context sizes (L/R indicates the number of sentences on the left and right side of the missing quote) on the test set of RELiC using recall@k metrics, normalized to a maximum score of 100. Our trained dense-RELiC retriever significantly outperforms BM25 and all pretrained dense retrieval models. The average number of candidates per example is 4888. We report the accuracy of different systems[9]on a proxy task that we administered to human domain experts, which shows that there is huge room for improvement.

q in the ranked list, and neither gives special treatment to candidates that overlap with q. As such, recall@1 alone is overly strict when the quotation length $l > 1$, which is why we show recall at multiple values of k. An additional motivation is that there may be multiple different candidates that fit a single context equally well. We also report accuracy on a proxy task with only three candidates, which allows us to compare with human performance as described in Section 4.

3.2 Models

Baselines: Our baselines include both standard term matching methods as well as pretrained dense retrievers. **BM25** (Robertson et al., 1995) is a bag-of-words method that is very effective for information retrieval. We form queries by concatenating the left and right context and use the implementation from the rank_bm25 library[10] to build a BM25 model for each unique candidate set $C_{b,n}$, tuning the free parameters as per Kamphuis et al. (2020).[11]

Meanwhile, our dense retrieval baselines are pretrained neural encoders that map queries and candidates to vectors. We compute vector similarity scores (e.g., cosine similarity) between every query/candidate pair, which are used to rank candidates for every query and perform retrieval. We consider the following four pretrained dense retriever baselines in our work, which we deploy in a zero-shot manner (i.e., not fine-tuned on RELiC):

- **DPR** (Dense Passage Retrieval) is a dense retrieval model from Karpukhin et al. (2020) trained to retrieve relevant context paragraphs in open-domain question answering. We use the DPR context encoder[12] pretrained on Natural Questions (Kwiatkowski et al., 2019) with dot product as a similarity function.
- **SIM** is a semantic similarity model from Wieting et al. (2019) that is effective on semantic textual similarity benchmarks (Agirre et al., 2016). SIM is trained on ParaNMT (Wieting and Gimpel, 2018), a dataset containing

---

[8] ColBERT does not provide a ranking for candidates outside the top 1000, so we cannot report mean rank.

[9] We do not report BM25's accuracy on the proxy task because its top-ranked quotes were used as candidates in the proxy task in addition to the ground-truth quotation.

[10] `https://github.com/dorianbrown/rank_bm25`, a library implementing many BM25-based algorithms.

[11] We set $k_1 = 0.5$, $b = 0.9$ after tuning on validation data.

[12] `https://huggingface.co/facebook/dpr-ctx_encoder-single-nq-base`

16.8M paraphrases; we follow the original implementation,[13] and use cosine similarity as the similarity function.

- **c-REALM** (contrastive Retrieval Augmented Language Model) is a dense retrieval model from Krishna et al. (2021) trained to retrieve relevant contexts in open-domain long-form question answering, and shown to be a better retriever than REALM (Guu et al., 2020) on the ELI5 KILT benchmark (Fan et al., 2019; Petroni et al., 2021).
- **ColBERT** is a ranking model from Khattab and Zaharia (2020) that estimates the relevance between a query and a document using contextualized late interaction. It is trained on MS MARCO ranking data (Nguyen et al., 2016).

Training retrievers on RELiC (dense-RELiC): Both BM25 and the pretrained dense retriever baselines perform similarly poorly on RELiC (Table 3). These methods are unable to capture more complex interactions within RELiC that do not exhibit extensive string overlap between quotation and context. As such, we also implement a strong neural retrieval model that is actually *trained* on RELiC, using a similar setup to DPR and REALM. We first form a context string c by concatenating a window of sentences on either side of the quotation q (replaced by a MASK token),

$$c = (l_{-l_{max}}, ..., l_{-1}, \text{[MASK]}, r_1, ..., r_{r_{max}})$$

We train two encoder neural networks to project the literary context and quote to fixed 768-d vectors. Specifically, we project c and q using **separate** encoder networks initialized with a pretrained RoBERTa-base model (Liu et al., 2019). We use the <s> token of RoBERTa to obtain 768-d vectors for the context and quotation, which we denote as $\mathbf{c}_i$ and $\mathbf{q}_i$. To train this model, we use a contrastive objective (Chen et al., 2020) that pushes the context vector $\mathbf{c}_i$ close to its quotation vector $\mathbf{q}_i$, but away from all other quotation vectors $\mathbf{q}_j$ in the same minibatch ("in-batch negative sampling"):

$$\text{loss} = -\sum_{(c_i,q_i)\in B} \log \frac{\exp \mathbf{c}_i \cdot \mathbf{q}_i}{\sum_{q_j \in B} \exp \mathbf{c}_i \cdot \mathbf{q}_j}$$

where B is a minibatch. Note that the size of the minibatch $|B|$ is an important hyperparameter since it determines the number of negative samples.[14] All elements of the minibatch are context/quotation pairs sampled from the same book. During inference, we rank all quotation candidate vectors by their dot product with the context vector.

3.3 Results

We report results from the baselines and our dense-RELiC model in Table 3 with varying context sizes where L/R refers to L preceding context sentences and R subsequent context sentences. While all models substantially outperform random candidate selection, all pretrained neural dense retrievers perform similarly to BM25, with ColBERT being the best pretrained neural retriever (2.9 recall@1). This result indicates that matching based on string overlap or semantic similarity is not enough to solve RELiC, and even powerful neural retrievers struggle on this benchmark. Training on RELiC is crucial: our best-performing dense-RELiC model performs 7x better than BM25 (9.4 vs 1.3 recall@1).

Context size and location matters for model performance: Table 3 shows that dense-RELiC effectively utilizes longer context — feeding only one sentence on each side of the quotation (1/1) is not as effective as a longer context (4/4) of four sentences on each side (7.8 vs 9.4 recall@1). However, the longer contexts hurt performance for pretrained dense retrievers in the zero-shot setting (1.6 vs 0.9 recall@1 for c-REALM), perhaps because context further away from the quotation is less likely to be helpful. Finally, we observe that dense-RELiC performance is strictly better (5.2 vs 6.8 recall@1) when the model is given only preceding context (4/0 or 1/0) compared to when the model is given only subsequent context (0/4 or 0/1).

Dense vs. sparse retrievers: As expected, BM25 retrieves the correct quotation when there is significant string overlap between the quotation and context, as in the following example from *The Great Gatsby*, in which the terms *sky*, *bloom*, *Mrs. McKee*, *voice*, *call*, and *back* appear in both places:

---

[13] `https://github.com/jwieting/beyond-bleu`

[14] We set $|B| = 100$, and train all models for 10 epochs on a single RTX8000 GPU with an initial learning rate of 1e-5 using the Adam optimizer (Kingma and Ba, 2015), early stopping on validation loss. Models typically took 4 hours to complete 10 epochs. Our implementation uses the HuggingFace `transformers` library (Wolf et al., 2020). The total number of model parameters is 249M.

> Yet his analogy also implicitly unites the two women. Myrtle's expansion and revolution in the smoky air are also outgrowths of her surreal attributes, stemming from her residency in the Valley of Ashes. **The late afternoon sky bloomed in the window for a moment like the blue honey of the Mediterranean-then the shrill voice of Mrs. McKee called me back into the room.** The objective talk of Monte Carlo and Marseille has made Nick daydream. In Chapter I Daisy and the rooms had bloomed for him, with him, and now the sky blooms. The fact that Mrs. McKee's voice "calls him back" clearly reveals the subjective daydreamy nature of this statement.

However, this behavior is undesirable for most examples in RELiC, since string overlap is generally not predictive of the relationship between quotations and claims. The top row of Table 5 contains one such example, where dense-RELiC correctly chooses the missing quotation while BM25 is misled by string overlap.

4 Human performance and analysis

How well do humans actually perform on RELiC? To compare the performance of our dense retriever to that of humans, we hired six domain experts with at least undergraduate-level degrees in English literature from the Upwork[15] freelancing platform. Because providing thousands of candidates to a human evaluator is infeasible, we instead measure human performance on a simplified proxy task: we provide our evaluators with four sentences on either side of a missing quotation from *Pride and Prejudice*[16] and ask them to select one of only three candidates to fill in the blank. We obtain human judgments both to measure a *human upper bound* on this proxy task as well as to evaluate whether humans struggle with examples that fool our model.

Human upper bound: First, to measure a human upper bound on this proxy task, we chose 200 test set examples from *Pride and Prejudice* and formed a candidate pool for each by including BM25's top two ranked answers along with the ground-truth quotation for the single sentence case. As the task is trivial to solve with random candidates, we decided to use a model to select harder negatives, and we chose BM25 to see if humans would be distracted by high string overlap in the negatives. Each of the 200 examples was separately annotated by three experts, and they were paid $100 for annotating 100 examples. The last column of Table 3 compares all of our baselines along with dense-RELiC against human domain experts on this proxy task. Humans substantially outperform all models on the task, with at least two of the three domain experts selecting the correct quote 93.5% of the time; meanwhile, the highest score for dense-RELiC is 67.5%, which indicates huge room for improvement. Interestingly, all of the zero-shot dense retrievers except ColBERT 1/1 underperform random selection on this task; we theorize that this is because all of these retrievers are misled by the high string overlap of the negative BM25-selected examples. Table 4 confirms substantial agreement among our annotators.

	Fleiss κ (↑)	all agree (↑)	none agree (↓)
Random	0.00	11.1%	22.2%
Humans	0.68	68.5%	0.5%

Table 4: Inter-annotator agreement of our three human annotators compared to a random annotation. In our 3-way classification task, all three annotators chose the same option 68.5% of the time, while they each chose a different option in just 0.5% of instances. Our annotators also show substantial agreement in terms of Fleiss Kappa (Fleiss, 1971).[17]

Human error analysis of dense-RELiC: To evaluate the shortcomings of our dense-RELiC retriever, we also administered a version of the proxy task where the candidate pool included the ground-truth quotation along with dense-RELiC's two top-ranked candidates, where for all examples the model ranked the ground-truth outside of the top 1000 candidates. Three domain experts attempted 100 of these examples and achieved an accuracy of 94%, demonstrating that humans can easily disambiguate cases on which our model fails, though we note our model's poorer performance when retrieving a single sentence (as in the proxy task) versus multiple sentences (A5). The bottom two rows of Table 5 contain instances in which all human annotators agreed on the correct candidate but dense-RELiC failed to rank it in the top 1000. In one, all human annotators immediately recognized the opening line of *Pride and Prejudice*, one

---

[15] `https://upwork.com`

[16] We decided to keep our proxy task restricted to the most well-known book in our test set because of the ease with which we could find highly-qualified workers who self-reported that they had read (and often even re-read) *Pride and Prejudice*.

[17] In our proxy task each instance has a different set of candidate quotations, which we randomly shuffle before showing annotators. Since our task is not strictly categorical, while computing Fleiss Kappa we define "category" as the option number shown to annotators. We believe this definition is closest to the free-marginal nature of our task (Randolph, 2010).

Surrounding context	Correct candidate	Incorrect candidate	Analysis
She is caught up for a moment or two in a fantasy of possession: **[masked quote]** The thought that she would not have been allowed to invite the Gardiners is a lucky recollection it save[s] her from something like regret. (Paris, 1978)	[*dense-RELiC*]: "And of this place," thought she, "I might have been mistress! With these rooms I might now have been familiarly acquainted!"	[*BM25*]: "I should not have been allowed to invite them." This was a lucky recollection-it saved her from something very like regret.	dense-RELiC correctly retrieves the quotation that shows the "fantasy of possession," while BM25 retrieves a quote that is paraphrased in the surrounding context.
It is delicious from the opening sentence: **[masked quote]** Mr. Bingley, with his four or five thousand a year, had settled at Netherfield Park. (Masefield, 1967)	[*Human*]: It is a truth universally acknowledged, that a single man in possession of a good fortune, must be in want of a wife.	[*dense-RELiC*]: "My dear Mr. Bennet," said his lady to him one day, "have you heard that Netherfield Park is let at last?"	Human readers can immediately identify the first sentence of *Pride and Prejudice*, while dense-RELiC lacks this world knowledge.
Sometimes we hear Mrs Bennet's idea of marriage as a market in a single word: **[masked quote]** Her stupidity about other people shows in all her dealings with her family... (McEwan, 1986)	[*Human*]: "I do not blame Jane," she continued, "for Jane would have got Mr. Bingley if she could."	[*dense-RELiC*]: You must and shall be married by a special licence.	Human readers understood the uncommon usage of "got" to convey a transaction.

Table 5: Examples that show failure cases of BM25 (top row) and our dense-RELiC retriever (bottom two rows) from our proxy task on *Pride and Prejudice*. BM25 is easily misled by string overlap, while dense-RELiC lacks world knowledge (e.g., knowing the famous first sentence) and complex linguistic understanding (e.g., the relationship between marriage as a market and got) that humans can easily rely on to disambiguate the correct quotation.

of the most famous in English literature. In the other, the claim mentions that the interpretation hinges on a single word's ("got") connotation of "a market," which humans understood.

Issuing out-of-distribution queries to the retriever: Does our dense-RELiC model have potential to support humanities scholars in their evidence-gathering process? Inspired by prompt-based learning, we manually craft simple yet out-of-distribution prompts and queried our dense-RELiC retriever trained with 1 sentence of left context and no right context. A qualitative inspection of the top-ranked quotations in response to these prompts (Table 6) reveals that the retriever is able to obtain evidence for distinct character traits, such as the ignorance of the titular character in *Frankenstein* or Gatsby's wealthy lifestyle in *The Great Gatsby*. More impressively, when queried for an example from *Pride and Prejudice* of the main character, Elizabeth, demonstrating frustration towards her mother, the retriever returns relevant excerpts in the first-person that do not mention Elizabeth, and the top-ranked quotations have little to no string overlap with the prompts.

Limitations: While these results show dense-RELiC's potential to assist research in the humanities, the model suffers from the limited expressivity of its candidate quotation embeddings $\mathbf{q}_i$, and addressing this problem is an important direction for future work. The quotation embeddings do not incorporate any broader context from the narrative, which prevents resolving coreferences to pronominal character mentions and understanding other important discourse phenomena. For example, Table A5 shows that dense-RELiC 's top two 1-sentence candidates for the above *Pride and Prejudice* example are not appropriate evidence for the literary claim; the increased relevancy of the 2-sentence candidates (Table 6, third row) over the 1-sentence candidates suggests that dense-RELiC may benefit from more contextualized quotation embeddings. Furthermore, dense-RELiC struggles with retrieving concepts unique to a text, such as the "hypnopaedic phrases" strewn throughout *Brave New World* (Table 6, bottom).

5 Related Work

Datasets for literary analysis: Our work relates to previous efforts to apply NLP to literary datasets

From *Frankenstein*, given "Victor does not consider the consequences of his actions:" our model's top-ranked single sentence candidates are:

1. It is even possible that the train of my ideas would never have received the fatal impulse that led to my ruin.
2. The threat I had heard weighed on my thoughts, but I did not reflect that a voluntary act of mine could avert it.
3. Now my desires were complied with, and it would, indeed, have been folly to repent.

From *The Great Gatsby*, given "A symbol of Gatsby's lifestyle:" our model's top-ranked single sentence candidates are:

1. His movements-he was on foot all the time-were afterward traced to Port Roosevelt and then to Gad's Hill where he bought a sandwich that he didn't eat and a cup of coffee.
2. Every Friday five crates of oranges and lemons arrived from a fruiterer in New York-every Monday these same oranges and lemons left his back door in a pyramid of pulpless halves.
3. On week-ends his Rolls-Royce became an omnibus, bearing parties to and from the city, between nine in the morning and long past midnight, while his station wagon scampered like a brisk yellow bug to meet all trains.

From *Pride and Prejudice*, given "Elizabeth displays frustration towards her mother:" our model's top-ranked 2-sentence candidates are:

1. Oh, that my dear mother had more command over herself! She can have no idea of the pain she gives me by her continual reflections on him.
2. My mother means well; but she does not know, no one can know, how much I suffer from what she says.
3. with tears and lamentations of regret, invectives against the villainous conduct of Wickham, and complaints of her own sufferings and ill-usage; blaming everybody but the person to whose ill-judging indulgence the errors of her daughter must principally be owing.

From *Brave New World*, given "Children are indoctrinated while sleeping and taught hypnopaedic phrases, such as", our model's top-ranked single sentence candidates are:

1. The principle of sleep-teaching, or hypnopædia, had been discovered.
2. Roses and electric shocks, the khaki of Deltas and a whiff of asafoetida-wedded indissolubly before the child can speak.
3. Told them of the growing embryo on its bed of peritoneum.

Table 6: Given a novel and a short out-of-distribution prompt, this table shows the top 3 quotations from the novel that dense-RELiC returns as evidence. The relevance of many of the returned quotations, even without string overlap between the prompt and candidates, indicates the model is learning some non-trivial relationships that could have potential impact for building tools that support humanities research. However, it is not perfect, as shown in the final example where none of the retrieved quotations is actually an instance of a hypnopaedic phrase.

such as LitBank (Bamman et al., 2019; Sims et al., 2019), an annotated dataset of 100 works of fiction with annotations of entities, events, coreferences, and quotations. Papay and Padó (2020) introduced RiQuA, an annotated dataset of quotations in English literary text for studying dialogue structure, while Chaturvedi et al. (2016) and Iyyer et al. (2016) characterize character relationships in novels. Our work also relates to quotability identification (MacLaughlin and Smith, 2021), which focuses on ranking passages in a literary work by how often they are quoted in a larger collection. Unlike RELiC, however, these datasets do not contain literary analysis about the works.

Retrieving cited material: Citation retrieval closely relates to RELiC and has a long history of research, mostly on scientific papers: O'Connor (1982) formulated the task of document retrieval using "citing statements", which Liu et al. (2014) revisit to create a reference retrieval tool that recommends references given context. Bertin et al. (2016) examine the rhetorical structure of citation contexts. Perhaps closest to RELiC is the work of Grav (2019), which concentrates on the quotation of secondary sources in other secondary sources, unlike our focus on quotation from primary sources. Finally, as described in more detail in Section 2.2 and Appendix A6, RELiC differs significantly from existing NLP and IR retrieval datasets in domain, linguistic complexity, and query length.

6 Conclusion

In this work, we introduce the task of *literary evidence retrieval* and an accompanying dataset, RELiC. We find that direct quotation of primary sources in literary analysis is most commonly used as evidence for literary claims or arguments. We train a dense retriever model for our task; while it significantly outperforms baselines, human performance indicates a large room for improvement. Important future directions include (1) building better models of *primary sources* that integrate narrative and discourse structure into the candidate representations instead of computing them out-of-context, and (2) integrating RELiC models into real tools that can benefit humanities researchers.

Acknowledgements

First and foremost, we would like to thank the HathiTrust Research Center staff (especially Ryan Dubnicek) for their extensive feedback throughout our project. We are also grateful to Naveen Jafer Nizar for his help in cleaning the dataset, Vishal Kalakonnavar for his help with the project webpage, Marzena Karpinska for her guidance on computing inter-annotator agreement, and the UMass NLP community for their insights and discussions during this project. KT and MI are supported by awards IIS-1955567 and IIS-2046248 from the National Science Foundation (NSF). KK is supported by the Google PhD Fellowship awarded in 2021.

Ethical Considerations

We acknowledge that the group of authors from whom we selected primary sources lacks diversity because we selected from among digitized, public domain sources in the Western literary canon, which is heavily biased towards white, male writers. We made this choice because there are relatively few primary sources in the public domain that are written by minority authors and also have substantial amounts of literary analysis written about them. We hope that our data collection approach will be followed by those with access to copyrighted texts in an effort to collect a more diverse dataset. The experiments involving humans were reviewed by the UMass Amherst IRB with a status of Exempt.

Appendices for "RELiC: Retrieving Evidence from Literature in Context"

A Dataset Collection & Statistics

Filtering secondary sources: The HathiTrust is not exclusively a repository of literary analysis, and we observe that many matching quotes come from different editions of a primary source, writing manuals, and even advertisements. Because we are seeking only scholarly work that directly analyzes the quoted sentences, we performed a combination of manual and automatic filtering to remove such extraneous matches. For each primary source, we first aggregate all secondary sources matches by the their unique HathiTrust-assigned identifier. From manual inspection of the secondary source titles, most sources that quote a particular literary work only once or twice are not likely to be literary scholarship, while sources with hundreds of matches are almost always a different edition of the primary source itself. For each primary source, we create upper and lower thresholds for number of matches, discarding sources that fall outside of these bounds. Additionally, we discard secondary sources whose titles contain the words "dictionary", "anthology", "encyclopedia," and others that indicate that a secondary source is not literary scholarship.

Preprocessing: After the above filtering, we identified and removed all non-English secondary sources using langid,[17] a Python tool for language identification. Next, because the secondary source texts in the HathiTrust are digitized via OCR, various artifacts appear throughout the pages we download. Some of these, such as citations that include the page number of primary source quotes, allow models trained on our task to "cheat" to identify the proper quote (see Table A1), necessitating their removal. Using a pattern-matching approach, we eliminate the most pervasive: in-line citations, headers, footers, and word breaks. Finally, we apply sentence tokenization in order to standardize the length of preceding and subsequent context windows for the final dataset. Specifically, we feed the preprocessed text through spaCy's[18] dependency parser-based sentence segmenter on the cleaned text. The default segmenter in spaCy is modified to use ellipses, colons, and semicolons as custom sentence boundaries, based on the observation that literary scholars often only quote part of what would typically be defined as a sentence (Table A2).

Raw text from HathiTrust:
The prejudice in these same eyes, however, keeps them "less clear-sighted" **(p. 149)** to Bingley's feelings for Jane and totally closed to the real **worth- lessness** of Wickham and worth of Darcy. When Jane's letter reporting **196 Mark M. Hennelly, Jr.** Lydia's disappearance with Wickham confirms Darcy's earlier indictment of him, though, Elizabeth's "eyes were opened to his real character" **(p. 277)**.

Table A1: An analysis of Jane Austen's *Pride and Prejudice* from Hennelly (1983) that contains artifacts (bold) such as citations and page numbers that we remove during preprocessing.

Quoted span in context of literary analysis: Edna tries to discuss this issue of possession versus self-possession with Madame Ratignolle but to no avail; '**the two women did not appear to understand each other or to be talking the same language.**' Madame Ratignolle cannot comprehend that there might be something more that a mother could sacrifice for her children beyond her life...
Quote in original context from The Awakening: Edna had once told Madame Ratignolle that she would never sacrifice herself for her children, or for any one. Then had followed a rather heated argument; **the two women did not appear to understand each other or to be talking the same language.** Edna tried to appease her friend, to explain.

Table A2: An analysis of Kate Chopin's *The Awakening* from Madsen (2000) that quotes part of a sentence (following a semi-colon) from the primary source. We detect such partial matches during preprocessing.

Identifying quoted sentences: As previously mentioned, HathiTrust does not provide the exact indices corresponding to the primary source quote. As such, we identify which secondary source sentences (from the output of the sentence tokenizer) include quotes from primary source works using RapidFuzz,[19] a fuzzy string match library, with the QRatio metric and a score threshold of 80.0. Fuzzy match is essential for detecting quotes with OCR mistakes or with author modifications; in Appendix Table A3, for instance, the author adds clarification [the natives] and omits "he would say" when citing two sentences from Joseph Conrad's *Heart of Darkness*. Once a fuzzy match is identified in a secondary source document, we replace it with its corresponding primary source sentence.

[18] `https://spacy.io/`

[19] `https://github.com/maxbachmann/RapidFuzz`

Secondary source material: Kurtz's credo, like his royal employer's, was a simple one. 1. "You show them [the natives] you have in you something that is really profitable, and then there will be no limits to the recognition of your ability. 2. Of course you must take care of the motives—right motives—always." Kurtz dies screaming: "The Horror! The Horror!" Leopold, so far as one knows, died more peacefully (Legum, 1972).
Window in RELiC with standardized quote: Kurtz's credo, like his royal employer's, was a simple one. **'You show them you have in you something that is really profitable, and then there will be no limits to the recognition of your ability,' he would say. 'Of course you must take care of the motives—right motives—always.'** Kurtz dies screaming: "The Horror! The Horror!" Leopold, so far as one knows, died more peacefully.

Table A3: This example demonstrates the necessity of fuzzy match and block quote identification. Consecutive sentences are quoted and one is slightly modified from its original form in the primary source.

Identifying block quotes: While we query HathiTrust at a sentence level, many of the returned results are actually *block quotes* in which multiple contiguous sentences from the primary source are quoted. Correct identification of these block quotes is integral to the quality of our dataset and formulated task: if the preceding or subsequent context contains part of the quoted span, our evidence retrieval task becomes trivial because part of the answer exists in the input. In our approach, if the fuzzy match yields consecutive matches in secondary source documents for sentences that also appear consecutively in the primary source, we concatenate them together and consider them a single block quote.

Handling ellipses: One prevalent technique for direct quotation in literary analysis is the use of ellipses to condense primary source material. As our fuzzy match method still falls short in detecting block quotes that contain ellipses, we implement an additional method for insuring that block quotes are properly delineated. Once the fuzzy match approach fails to identify any more consecutively quoted sentences in a secondary source, we continue to search for matches adjacent to the block quote using the Longest Common Substring (LCS) metric. If a block-quote-adjacent sentence in the secondary source shares an LCS of 15 or more characters with the block-quote-adjacent sentence in the primary source, this is considered a match and concatenated with the block quote (see Appendix A.1 for an example).

A.1 LCS example

For example, in Parker (1985), Kenneth Parker cites a passage from Joseph Conrad's *Heart of Darkness*: "The narrator, Marlow, informs us, approvingly:...**I met a white man, in such an unexpected elegance of get-up that in the first moment I took him for a sort of vision.** I saw a high starched collar, white cuffs, a light alpaca jacket, snowy trousers, a clean necktie, and varnished boots." Fuzzy match alone is insufficient for detecting the first sentence in this block quote that contains an ellipse in place of primary source text. With our LCS approach, we are able to replace the first sentence of block quote above with "**When near the buildings I met a white man, in such an unexpected elegance of get-up that in the first moment I took him for a sort of vision.**"

A.2 Noise when standardizing quotes:

In a small number of cases, our quote standardization process removes important context. For example, the analysis of Maes-Jelinek (1970) quotes a sentence from D.H. Lawrence's *The Rainbow* as "As to Will, **his intimate life was so violently active, that it set another man free in him.**". After standardization, the example in our dataset becomes "**His intimate life was so violently active, that it set another man free in him.**", dropping the critical "As to Will" necessary for the integration of the quote in the surrounding analysis.

Model-predicted quotes are sometimes as valid as the gold quote: Human raters also identify cases in which multiple quotes appear to be appropriate evidence for a literary claim, which illustrate the model's potential in helping humanities scholars find evidence. In Table A4, both model and experts failed to identify the correct quote that both depicts Elizabeth's "discomfiture" and has a "Greek ring to it:" "Till this moment I never knew myself." However, the experts all selected the model's second ranked choice which mentions Elizabeth's "anger" at "herself." This quote also shows Elizabeth's displeasure while referring to the Greek idea of self.

Window of secondary source analysis:
For example, Elizabeth's anger with herself, after reading Darcy's letter, is couched largely in the vocabulary of rectifiable intellectual error"blind, partial, prejudiced, absurd, and the like-rather than in the relentless, coercive vocabulary of moral contrition. Her discomfiture, though profound, has a Greek ring to it: **Till this moment I never knew myself.** Heuristically, the distinction between moral and other spheres of value throws light also on other Austen novels that we can only glance at here (Wilkie, 1992).
Best model's top ranked candidate:
that loss of virtue in a female is irretrievable;
Best model's second ranked candidate
but when she considered how unjustly she had condemned and upbraided him, her anger was turned against herself;

Table A4: The model ranked the correct quote outside of the top ten percent of 5,278 candidates, but all 3 domain experts selected the model's second ranked candidate over the ground-truth quote.

A.3 More dataset statistics

Each primary source has relevant windows from an average of 112 unique secondary sources, and an average of 16.35% of the sentences in each primary source are quoted in secondary sources. On average, each primary source has 995 corresponding windows in our dataset, and each secondary source produced an average of 9 windows. Figure 2 shows the distribution of quote lengths in RELiC, suggesting that successful models will have to learn to understand both single-sentence and block quotes in context.

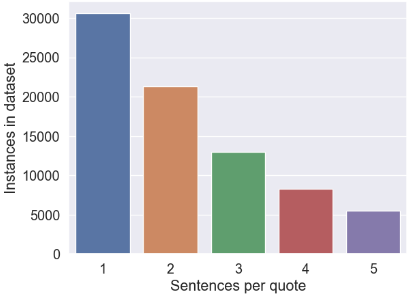

Figure 2: Distribution of RELiC quote lengths.

B Best Model Detailed Results

Candidate length does not significantly affect model performance: We observe in Table A9 that the length of the ground-truth quote and the candidates does not significantly impact model performance — for a fixed k, model performance is within 10% for any candidate length. Model performance is slightly worse for longer candidates of length 4 or 5, and for the shortest single sentence contexts (possibly due to under-specification).

From *Pride and Prejudice*, given ”Elizabeth displays frustration towards her mother:” our model’s top-ranked, 1-sentence candidates are:

1. Elizabeth was again deep in thought, and after a time exclaimed, "To treat in such a manner the godson, the friend, the favourite of his father!"
2. Far be it from me," he presently continued, in a voice that marked his displeasure, "to resent the behaviour of your daughter.
3. Her mother’s ungraciousness, made the sense of what they owed him more painful to Elizabeth’s mind;

Table A5: When querying the model using out-of-distribution prompts, number of sentences of the desired candidates can be specified. This table shows the top 3 quotations from the *Pride and Prejudice* that dense-RELiC returns as evidence for single-sentence candidates. The suitability of the 2-sentence candidates (show in Table 6) over the single-sentence candidates suggests that contextualizing the quotation embeddings will improve model performance.

Analyzing Generalization of Vision and Language Navigation to Unseen Outdoor Areas

`{rschuman|riezler}@cl.uni-heidelberg.de`

Abstract

Vision and language navigation (VLN) is a challenging visually-grounded language understanding task. Given a natural language navigation instruction, a visual agent interacts with a graph-based environment equipped with panorama images and tries to follow the described route. Most prior work has been conducted in indoor scenarios where best results were obtained for navigation on routes that are similar to the training routes, with sharp drops in performance when testing on unseen environments. We focus on VLN in outdoor scenarios and find that in contrast to indoor VLN, most of the gain in outdoor VLN on unseen data is due to features like junction type embedding or heading delta that are specific to the respective environment graph, while image information plays a very minor role in generalizing VLN to unseen outdoor areas. These findings show a bias to specifics of graph representations of urban environments, demanding that VLN tasks grow in scale and diversity of geographical environments.[1]

1 Introduction

Vision and language navigation (VLN) is a challenging task that requires the agent to process natural language instructions and ground them in a visual environment. The agent is embodied in the environment and receives navigation instructions. Based on the instructions, the observed surroundings, and the current trajectory the agent decides its next action. Executing this action changes the position and/or heading of the agent within the environment, and eventually the agent follows the described route and stops at the desired goal location. The most common evaluation metric in VLN is the proportion of successful agent navigations, called task completion (TC).

While early work on grounded navigation was confined to grid-world scenarios (MacMahon et al., 2006; Chen and Mooney, 2011), recent work has studied VLN in outdoor environment consisting of real-world urban street layouts and corresponding panorama pictures (Chen et al., 2019). Recent agent models for outdoor VLN treat the task as a sequence-to-sequence problem where the instructions text is the input and the output is a sequence of actions (Chen et al., 2019; Xiang et al., 2020; Zhu et al., 2021b). In contrast to indoor VLN (Anderson et al., 2018; Ku et al., 2020), these works only consider a *seen scenario*, i.e., the agent is tested on routes that are located in the same area as the training routes. However, studies of indoor VLN (Zhang et al., 2020) show a significant performance drop when testing in previously unseen areas.

The main goal of our work is to study *outdoor VLN in unseen areas*, pursuing the research question of which representations of an environment and of instructions an agent needs to succeed at this task. We compare existing approaches to a new approach that utilizes features based on the observed environment graph to improve generalization to unseen areas. The first feature, called junction type embedding, encodes the number of outgoing edges at the current agent position; the second feature, called heading delta, encodes the agent's heading change relative to the previous timestep. As our experimental studies show, representations of full images do not contribute very much to successful VLN in outdoor scenarios beyond these two features. One reason why restricted features encoding junction type and heading delta are successful in this task is that they seem to be sufficient to encode peculiarities of the graph representation of the environments. Another reason is the current restriction of outdoor environments to small urban areas. In our case, one dataset is the widely used Touchdown dataset introduced by Chen et al. (2019), the

other dataset is called map2seq and has recently been introduced by Schumann and Riezler (2021). The map2seq dataset was created for the task of navigation instructions generation but can directly be adopted to VLN. We conduct a detailed analysis of the influence of general neural architectures, specific features such as junction type or heading delta, the role of image information and instruction token types, to outdoor VLN in seen and unseen environments on these two datasets.

Our specific findings unravel the contributions of these features on several VLN subtasks such as orientation, directions, stopping. Our general finding is that current outdoor VLN suffers a bias towards urban environments and to artifacts of their graph representation, showing the necessity of more diverse datasets and tasks for outdoor VLN.

Our main contributions are the following:

- We describe a straightforward agent model that achieves state-of-the-art task completion and is used as a basis for our experiments.
- We introduce the *unseen scenario* for outdoor VLN and propose two environment-dependent features to improve generalization in that setting.
- We compare different visual representations and conduct language masking experiments to study the effect in the unseen scenario.
- We adopt the map2seq dataset to VLN and show that merging it with Touchdown improves performance on the respective test sets.

2 VLN Problem Definition

The goal of the agent is to follow a route and stop at the desired target location based on natural language navigation instructions. The environment is a directed graph with nodes $v \in \mathbb{V}$ and labeled edges $(u, v) \in \mathbb{E}$. Each node is associated with a 360° panorama image p and each edge is labeled with an angle $\alpha_{(u,v)}$. The agent state $s \in S$ consists of a node and the angle at which the agent is heading: $(v, \alpha_{(v,u)} \mid u \in \mathbb{N}_v^{out})$, where $\mathbb{N}_v^{out}$ are all outgoing neighbors of node v. The agent can navigate the environment by performing an action $a \in \{\texttt{FORWARD}, \texttt{LEFT}, \texttt{RIGHT}, \texttt{STOP}\}$ at each timestep t. The `FORWARD` action moves the agent from state $(v, \alpha_{(v,u)})$ to $(u, \alpha_{(u,u')})$, where (u, u') is the edge with an angle closest to $\alpha_{(v,u)}$. The `RIGHT` and `LEFT` action rotates the agent towards the closest edge angle in clockwise or counterclockwise direction, respectively: $(v, \alpha_{(v,u')})$. Given a starting state s_1 and instructions text $\mathbf{x}$, the agent performs a series of actions $a_1, ..., a_T$ until the `STOP` action is predicted. If the agent stops within one neighboring node of the desired target node (goal location), the navigation was successful. The described environment and location finding task was first introduced by (Chen et al., 2019) and we will also refer to it as "outdoor VLN task" throughout this paper.

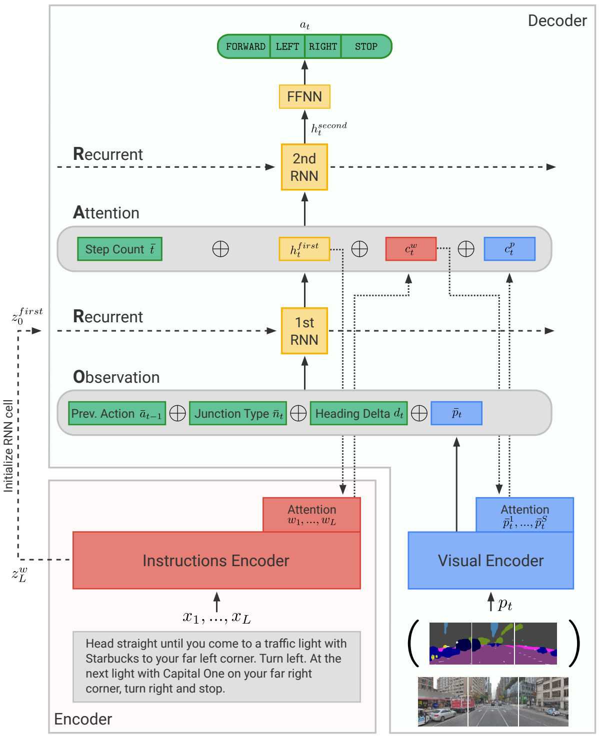

Figure 1: The ORAR model for outdoor vision and language navigation follows a sequence-to-sequence architecture. The instructions text is encoded and used along the visual features to predict the next agent action. The recurrent decoder has two layers, the first encodes observations about the current environment state, the second allows attention over the input text and panorama view. The predicted action changes the state of the agent in the environment and with it the panorama view of the next timestep.

3 Model Architecture

In this section we introduce the model that we use to analyze navigation performance in the unseen and seen scenario for outdoor VLN. The architecture is inspired by the cross-modal attention model for indoor VLN (Krantz et al., 2020). First we give a high level overview of the model architecture and rough intuition. Afterwards we provide a more formal description.

As depicted in Figure 1, the model follows a sequence-to-sequence architecture where the input sequence is the navigation instructions text and the output is a sequence of agent actions. At each decoding timestep, a new visual representation of the current agent state within the environment is computed, where the agent state is dependent on the previously predicted actions. The decoder RNN has two layers where the first encodes metadata and a visual representation. The second RNN layer encodes a contextualized text and visual representation and eventually predicts the next action.

The intuition behind the model architecture is to firstly accumulate plain *observations* available at the current timestep and entangle them with previous observations in the first *recurrent* layer. Based on these observations, the model focuses *attention* to certain parts of the instructions text and visual features which are again entangled in the second *recurrent* layer. Thus, we use the acronym *ORAR* (observation-recurrence attention-recurrence) for the model.

In detail, the instructions encoder embeds and encodes the tokens in the navigation instructions sequence $\mathbf{x} = x_1, ..., x_L$ using a bidirectional LSTM (Graves et al., 2005):

$$\hat{x}_i = \text{embedding}(x_i)$$
$$((w_1, ..., w_L), z_L^w) = \text{Bi-LSTM}(\hat{x}_1, ..., \hat{x}_L),$$

where $w_1, ..., w_L$ are the hidden representations for each token and z_L^w is the last LSTM cell state. The visual encoder, described in detail below, emits a fixed size representation $\bar{p}_t$ of the current panorama view and a sequence of sliced view representations $\bar{p}_t^1, ..., \bar{p}_t^S$. The state z_0^{first} of the cell in the first decoder LSTM layer is initialized using z_L^w. The input to the first decoder layer is the concatenation ($\oplus$) of visual representation $\bar{p}_t$, previous action embedding $\bar{a}_{t-1}$, junction type embedding $\bar{n}_t$, and heading delta d_t. The output of the first decoder layer,

$$h_t^{first} = \text{LSTM}^{first}([\bar{a}_{t-1} \oplus \bar{n}_t \oplus d_t \oplus \bar{p}_t]),$$

is then used as the query of multi-head attention (Vaswani et al., 2017) over the text encoder. The resulting contextualized text representation c_t^w is then used to attend over the sliced visual representations:

$$c_t^w = \text{MultiHeadAttention}(h_t^{first}, (w_1, ..., w_L))$$
$$c_t^p = \text{MultiHeadAttention}(c_t^w, (\bar{p}_t^1, ..., \bar{p}_t^S)).$$

The input and output of the second decoder layer are

$$h_t^{second} = \text{LSTM}^{second}([\bar{t} \oplus h_t^{first} \oplus c_t^w \oplus c_t^p]),$$

where $\bar{t}$ is the embedded timestep t. The hidden representation h_t^{second} of the second decoder LSTM layer is then passed through a feed forward network to predict the next agent action a_t.

3.1 Visual Encoder

At each timestep t the panorama at the current agent position is represented by extracted visual features. We slice the panorama into eight projected rectangles with 60° field of view, such that one of the slices aligns with the agent's heading. This centering slice and the two left and right of it are fed into a ResNet pretrained[2] on ImageNet (Russakovsky et al., 2015). We consider two variants of ResNet derived panorama features. One variant extracts low level features from the fourth to last layer (**4th-to-last**) of a pretrained ResNet-18 and concatenates each slice's feature map along the width dimension, averages the 128 CNN filters and cuts out 100 dimensions around the agents heading. This results in a feature matrix of 100×100 ($\bar{p}_t^1, ..., \bar{p}_t^{100}$). The full procedure is described in detail in Chen et al. (2019) and Zhu et al. (2021b). The other variant extracts high level features from a pretrained ResNet-50's **pre-final** layer for each of the 5 slices: $\bar{p}_t^1, ..., \bar{p}_t^5$. Each slice vector $\bar{p}_t^s$ is of size $2,048$ resulting in roughly the same number of extracted ResNet features for both variants, making a fair comparison. Further, we use the **semantic segmentation** representation of the panorama images. We employ omnidirectional semantic segmentation (Yang et al., 2020) to classify each pixel by one of the 25 classes of the Mapillary Vistas dataset (Neuhold et al., 2017). The classes include e.g. car, truck, traffic light, vegetation, road, sidewalk. See Figure 1 bottom right for a visualization. Each panorama slice ($\bar{p}_t^1, ..., \bar{p}_t^5$) is then represented by a 25 dimensional vector where each value is the normalized area covered by the corresponding class (Zhang et al., 2020). For either feature extraction method, the fixed sized panorama representation $\bar{p}_t$ is computed by concatenating the slice features $\bar{p}_t^1, ..., \bar{p}_t^S$ and passing them to a feed forward network.

---

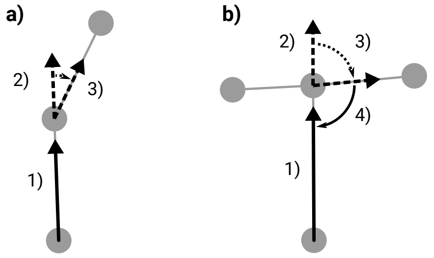

Figure 2: Visualization of automatic agent rotation initiated by the environment. Grey circles and interconnecting edges are part of the environment graph. Black solid arrows are actions initiated by the agent. Black dotted arrows depict agent heading and automatic rotation by the environment. **a)**: 1) The agent moves forward. 2) Agent's heading does not point to an outgoing edge. 3) Agent is automatically rotated to the closest edge without causing problems. **b)**: The agent receives instructions like "Turn right at the next intersection". 1) The agent moves forward. 2) Agent's heading does not point to an outgoing edge. 3) The environment automatically rotates the agent towards the closest outgoing edge. 4) The agent has no explicit information about the automatic rotation and predicts a right turn as instructed, leading to a failed navigation.

3.2 Junction Type Embedding

The junction type embedding is a feature that we introduce to better analyze generalization to unseen areas. It embeds the number of outgoing edges of the current environment node and is categorized into {2, 3, 4, >4}. It provides the agent information about the type of junction it is positioned on: a regular street segment, a three-way intersection, a four way intersection or an intersection with more than four outgoing streets. We want to point out that the number of outgoing edges isn't oracle information in the environment described in Section 2. The agent can rotate left until the same panorama view is observed and thus counting the number of outgoing edges by purely interacting with the environment. But it is clear that the feature leverages the fact that the environment is based on a graph and it would not be available in a continuous setting (Krantz et al., 2020).

3.3 Heading Delta

As described in Section 2, the environment defined and implemented by Chen et al. (2019) only allows states where the agent is heading towards an outgoing edge. As a consequence the environment automatically rotates the agent towards the closest outgoing edge after transitioning to a new node. The environment behavior is depicted in Figure 2a) for a transition between two regular street segments. However, as depicted in Figure 2b), a problem arises when the agent is walking towards a three-way intersection. The automatic rotation introduces unpredictable behavior for the agent and we hypothesis that it hinders generalization to unseen areas. To correct for this environment artifact, we introduce the heading delta feature d_t which encodes the change in heading direction relative to the previous timestep. The feature is normalized to $(-1, 1]$ where a negative value indicates a left rotation and a positive value indicates a right rotation. The magnitude signals the degree of the rotation up to 180°.

4 Data

We use the Touchdown (Chen et al., 2019) and the map2seq (Schumann and Riezler, 2021) datasets in our experiments. Both datasets contain human written navigation instructions for routes located in the same environment. The environment consists of 29,641 panorama images from Manhattan and the corresponding connectivity graph.

4.1 Touchdown

The Touchdown dataset (Chen et al., 2019) for vision and language navigation consists of 9,326 routes paired with human written navigation instructions. The annotators navigated the panorama environment based on a predefined route and wrote down navigation instructions along the way.

4.2 Map2seq

The map2seq (Schumann and Riezler, 2021) dataset was created for the task of navigation instructions generation. The 7,672 navigation instructions were written by human annotators who saw a route on a rendered map, without the corresponding panorama images. The annotators were told to include visual landmarks like stores, parks, churches, and other amenities into their instructions. A different annotator later validated the written navigation instructions by using them to follow the described route in the panorama environment (without the map). This annotation procedure allows us to use the navigation instructions in the map2seq dataset for the vision and language navigation task. We are the first to report VLN results on this dataset.

4.3 Comparison

Despite being located in the same environment, the routes and instructions from each dataset differ in multiple aspects. The map2seq instructions typically include named entities like store names, while Touchdown instructions focus more on visual features like the color of a store. Both do not include street names or cardinal directions and are written in egocentric perspective. Further, in map2seq the agent starts by facing in the correct direction, while in Touchdown the initial heading is random and the first part of the instruction is about orientating the agent ("Turn around such that the scaffolding is on your right"). A route in map2seq includes a minimum of three intersections and is the shortest path from the start to the end location.[3] In Touchdown there are no such constraints and a route can almost be circular. The routes in both datasets are around 35-45 nodes long with some shorter outliers in Touchdown. On average instructions are around 55 tokens long in map2seq and around 89 tokens long in Touchdown.

5 Experiments

We are interested in the generalization ability to unseen areas and how it is influenced by the two proposed features, types of visual representation, navigation instructions and training set size. Alongside of the results in the unseen scenario, we report results in the seen scenario to interpret performance improvements in relation to each other. All experiments[4] are repeated ten times with different random seeds. The reported numbers are the average over the ten repetitions. Results printed in **bold** are significantly better than non-bold results in the same column. Significance was established by a paired t-test[5] on the ten repetition results and a p-value ≤ 0.05 without multiple hypothesis corrections factor. Individual results can be found in the Appendix.

5.1 Data Splits

To be able to compare our model with previous work, we use the original training, development and test split (Chen et al., 2019) for the seen scenario on Touchdown. Because we are the first to use the map2seq data for VLN we create a new split for it. The resulting number of instances can be seen in the left column of Table 1. For the unseen scenario, we create new splits for both datasets. We separate the unseen area geographically by drawing a boundary across lower Manhattan (see Figure 3). Development and test instances are randomly chosen from within the unseen area. Routes that are crossing the boundary are discarded. The right column of Table 1 shows the number of instances for both splits. Additionally, we merge the two datasets for both scenarios. This is possible because both datasets are located in the same environment and the unseen boundary is equivalent.

Figure 3: Visualization of the environment area located in Manhattan. **The seen scenario is depicted on the left and the unseen scenario on the right.** Each white dot is a training route and each black dot is a test route in the Touchdown and map2seq dataset. The unseen scenario is characterized by geographic separation of the training and testing area.

Merged	12,597	2,191	2,209	12,507	1,600	2,307

Table 1: Number of instances in the data splits for the seen and unseen scenario of Touchdown and map2seq.

5.2 Training Details

We train the models with Adam (Kingma and Ba, 2015) by minimizing cross entropy loss in the teacher forcing paradigm. We set the learning rate to 5e-4, weight decay to 1e-3 and batch size to 64. After 150 epochs we select the model with the best shortest path distance (SPD) performance on the development set. We apply dropout of 0.3 after each dense layer and recurrent connection. The multi-head attention mechanism is regularized

---

[3] The shortest path bias reduces the number of reasonable directions at each intersection and thus makes the task easier.

[4] Except comparison models on the Touchdown seen test set for which we copy the results from the respective work.

Table 2: Results on Touchdown and map2seq for the seen and unseen scenario. Metrics are normalized Dynamic Time Warping (nDTW) and task completion (TC). In the first section we list results for the comparison models: RConcat, GA, VLN Transformer (Zhu et al., 2021b) and ARC, ARC+learn2stop (Xiang et al., 2020). In the second section we present results for the ORAR model with two different types of image features: *ResNet pre-final* features are extracted from the last layer before the classification and *ResNet 4th-to-last* are low level features extracted from the fourth to last layer of a pretrained ResNet. The last section ablates the two proposed features: *heading delta* and *junction type embedding*.

by attention dropout of 0.3 and layer normalization. The navigation instructions are lower-cased and split into byte pair encodings (Sennrich et al., 2016) with a vocabulary of 2,000 tokens and we use BPE dropout (Provilkov et al., 2020) during training. The BPE embeddings are of size 32 and the bidirectional encoder LSTM has two layers of size 256. The feed forward network in the visual encoder consists of two dense layers with 512 and 256 neurons, respectively, and 64 neurons in case of using semantic segmentation features. The embeddings that encode previous action, junction type, and step count are of size 16. The two decoder LSTM layers are of size 256 and we use two attention heads. Training the full model takes around 3 hours on a GTX 1080 Ti.

5.3 Model Comparison

We compare the ORAR model to previous works. Because these works only report results for the seen scenario on Touchdown, we evaluate those for which we could acquire the code, on the map2seq dataset and the unseen scenario. The models *RConcat* (Mirowski et al., 2018; Chen et al., 2019), *GA* (Chaplot et al., 2018; Chen et al., 2019) and *ARC* (Xiang et al., 2020) use an LSTM to encode the instructions text and a single layer decoder LSTM to predict the next action. They differ in how the text and image representations are incorporated during each timestep in the decoder. As the name suggests, in *RConcat* the two representations are concatenated. *GA* uses gated attention to compute a fused representation of text and image. *ARC* uses the hidden representation of the previous timestep to attend over the instructions text. This contextualized text representation is then concatenated to the image representation. They further introduce *ARC+l2s* which cascades the action prediction into a binary stopping decision and a subsequent direction classification. The *VLN-Transformer* (Zhu et al., 2021b) uses pretrained BERT (Devlin et al., 2019) to encode the instructions and VLN-BERT (Majumdar et al., 2020) to fuse the modalities.

5.4 Metrics

We use task completion (**TC**) as the main performance metric. It represents the percentage of successful agent navigations (Chen et al., 2019). We further report normalized Dynamic Time Warping (**nDTW**) which quantifies agent and gold trajectory overlap for all routes (Ilharco et al., 2019). The shortest path distance (**SPD**) is measured within the environment graph from the node the agent stopped to the goal node (Chen et al., 2019).

6 Results & Analysis

The two upper sections of Table 2 show the results of the ORAR model introduced in Section 3 in comparison to other work. While the model sig-

nificantly outperforms all previous work on both datasets, our main focus is analyzing generalization to the unseen scenario. It is apparent that the type of image features influences agent performance and will be discussed in the next section. The bottom section of Table 2 ablates the proposed heading delta and junction type features for the best models. Removing the heading delta feature has little impact in the seen scenario, but significantly reduces task completion in the unseen scenario of the map2seq dataset. Surprisingly, the feature has no impact in the unseen scenario of Touchdown. We believe this is a consequence of the different data collection processes. Touchdown was specifically collected for VLN and annotators navigated the environment graph, while map2seq annotators wrote instructions only seeing the map. Removing the junction type embedding leads to a collapse of task completion in the unseen scenario on both datasets. This shows that without this explicit feature, the agent lacks the ability to reliably identify intersections in new areas.

6.1 Visual Features

Table 3 shows results for different types of visual features in the unseen scenario. We compare high level ResNet features (pre-final), low level ResNet features (4th-to-last), semantic segmentation features and using no image features. For the ResNet based features, the low level 4th-to-last features perform better than pre-final on both datasets. On map2seq the no image baseline performs on par with models that have access to visual features. When we remove the junction type embedding, the task completion rate drops significantly, which shows that the agent is not able to reliably locate intersections from any type of visual features.

orientation	59.8	57.0	61.3	60.5
directions	74.1	73.3	58.8	57.9
stopping	39.3	38.8	36.1	34.0

Table 4: Oracle analysis on Touchdown. Division into three sub-tasks: *orientation*, *directions* and *stopping*. Providing oracle actions for two of the three sub-tasks allows an isolated look at the remaining one. Underlined results are best for the sub-task, e.g. 85.5 is the best TC for the directions task on the test set in the seen scenario.

6.2 Sub-task Oracle

The agent has to predict a sequence of actions in order to successfully reach the goal location. In Touchdown this task can be divided into three subtasks (see Section 4). First the agent needs to **orientate** itself towards the correct starting heading. Next the agent has to predict the correct **directions** at the intersections along the path. The third subtask is **stopping** at the specified location. Providing oracle actions (during testing) for two of the three sub-tasks lets us look at the completion rate of the remaining sub-task. Table 4 shows the completion rates for each of the three sub-tasks when using ResNet pre-final, 4th-to-last and no image features. In the seen scenario we can observe that the pre-final features lead to the best performance for the directions task. The 4th-to-last features on the other hand lead to the best orientation task performance and the stopping task is not influenced by the choice of visual features. In the unseen scenario 4th-to-last features again provide best orientation task performance but no image features lead to the best performance for the directions task. This shows that the ResNet 4th-to-last features are primarily useful for the orientation sub-task and explains the discrepancy of the no image baseline on Touchdown and map2seq identified in the previous subsection. In the Appendix we use this knowledge to train a mixed-model that uses 4th-to-last features

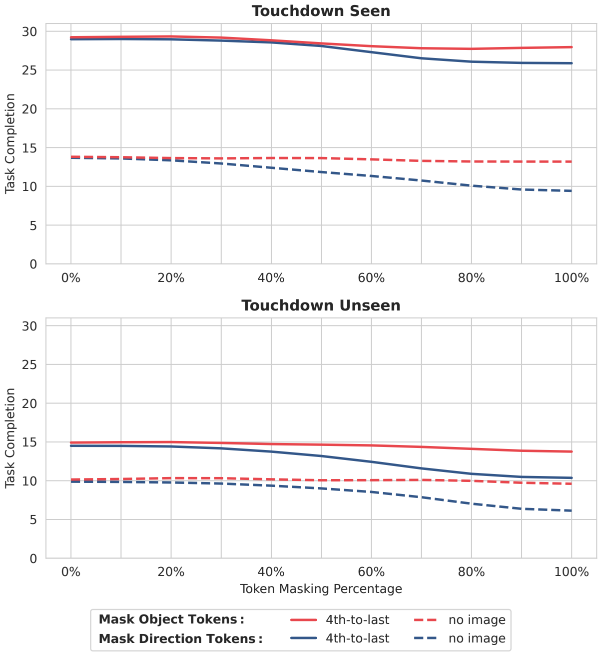

Figure 4: Masking experiments on the seen and unseen test set of Touchdown. Object or direction tokens are masked during training and testing.

for the orientation sub-task and pre-final/no image features for directions and stopping.

6.3 Token Masking

To analyze the importance of direction and object tokens in the navigation instructions, we run masking experiments similar to Zhu et al. (2021a), except that we mask the tokens during training and testing instead of during testing only. Figure 4 shows the resulting task completion rates for an increasing number of masked direction or object tokens. From the widening gap between masking object and direction tokens, we can see that the direction tokens are more important to successfully reach the goal location. Task completion nearly doesn't change when masking object tokens, indicating that they are mostly ignored by the model. While task completion significantly drops when direction tokens are masked, the agent still performs on a high level. This finding is surprising and in dissent with Zhu et al. (2021a) who report that task completion nearly drops to zero when masking direction tokens during testing only. We believe that in our setting (masking during testing and training), the model learns to infer the correct directions from redundancies in the instructions or context around the direction tokens. Besides the general trend of lower performance on the unseen scenario, we can not identify different utilization of object or direction tokens in the seen and unseen scenario.

6.4 Merged Datasets

We train the ORAR full model on the merged dataset (see Section 5.1). Model selection is performed on the merged development set but results are also reported for the individual test sets of Touchdown and map2seq. For comparison with models trained on the non-merged datasets, the first row of Table 5 shows the best results of Table 2. Training on the merged dataset significantly improves nDTW and task completion across both datasets and scenarios. This shows that both datasets are compatible and the merged dataset can further be used by the VLN community to evaluate their models on more diverse navigation instructions. Despite being trained on twice as many instances, the no image baseline still performs on par on map2seq unseen. From this we conclude that the current bottleneck for better generalization to unseen areas is the number of panorama images seen during training instead of number of instructions.

7 Related Work

Natural language instructed navigation of embodied agents has been studied in generated grid environments that allow a structured representation of the observed environment (MacMahon et al., 2006; Chen and Mooney, 2011). Fueled by the advances in image representation learning (He et al., 2016), the environments became more realistic by using real-world panorama images of indoor locations (Anderson et al., 2018; Ku et al., 2020). Complementary outdoor environments contain street level panoramas connected by a real-world street layout (Mirowski et al., 2018; Chen et al., 2019; Mehta et al., 2020). Agents in this outdoor environment are trained to follow human written navigation instructions (Chen et al., 2019; Xiang et al., 2020), instructions generated by Google Maps (Hermann et al., 2020), or a combination of both (Zhu et al., 2021b). Recent work focuses on analyzing the navigation agents by introducing better trajectory overlap metrics (Jain et al., 2019; Ilharco et al., 2019) or diagnosing the performance under certain constraints such as uni-modal inputs (Thomason et al., 2019) and masking direction or object tokens (Zhu et al., 2021a). Other work used a trained VLN agent to evaluate automatically generated navigation instructions (Zhao et al., 2021). An open problem in indoor VLN is

Table 5: Results for models trained on the merged dataset. Test results are presented for the merged test set and individual Touchdown and map2seq test sets. Metrics are normalized Dynamic Time Warping (nDTW) and task completion (TC). In the first row the best results of Table 2 (non-merged training sets) are listed for comparison. The bottom section presents results on the *ORAR full model* with different types of image features.

the generalization of navigation performance to previously unseen areas. Proposed solutions include back translation with environment dropout (Tan et al., 2019), multi-modal environment representation (Hu et al., 2019) or semantic segmented images (Zhang et al., 2020). Notably the latter work identifies the same problem in the Touchdown task.

8 Conclusion

We presented an investigation of outdoor vision and language navigation in seen and unseen environments. We introduced the heading delta feature and junction type embedding to correct an artifact of the environment and explicitly model the number of outgoing edges, respectively. Both are helpful to boost and analyze performance in the unseen scenario. We conducted experiments on two datasets and showed that the considered visual features poorly generalize to unseen areas. We conjecture that VLN tasks need to grow in scale and diversity of geographical environments and navigation tasks.

- no text attention	9.4	10.4	22.0	21.8
- no image attention	21.5	20.1	**48.8**	**45.7**

Table 6: ORAR full model ablation study on the **seen** scenario of Touchdown and map2seq. Metric is task completion and ablations are not cumulative.

A Architecture Ablation

We perform ablation studies on the ORAR full model in the seen scenario to measure the impact of individual architecture components. As seen in Table 6, removing the second decoder RNN layer or BPE dropout results in a decrease of six and three task completion points, respectively. The largest drop in performance is observed when removing the text attention mechanism. This again shows the importance of attention over the encoder in sequence-to-sequence models. Removing the image attention mechanism on the other hand does not affect task completion on the map2seq dataset.

B Mixed-Model

The findings in Section 6.2 inspire us to modify the ORAR model to use distinct visual features for the orientation and directions/stopping task. The orientation task is equivalent to the very first action prediction by the agent. Thus we modify the model architecture to use the ResNet 4th-to-last features (+text representation) to predict the first action and then start the recurrent prediction of the remaining actions with a different set of visual features (pre-final for the seen scenario and no image features for the unseen scenario). The results for this **ORAR mixed** model trained on the merged dataset are shown in Table 7. We only test it on Touchdown because map2seq does not have the orientation task. The mixed model significantly outperforms the single visual feature model on the Touchdown seen test set but unfortunately shows no improvement in the unseen scenario.

C Additional Metrics and Individual Runs

We present the results of the individual repetitions and additional metrics for the main results in Table 2 and the results on the merged dataset in Table 5. The additional metrics are success weighted normalized Dynamic Time Warping (Ilharco et al., 2019) and shortest-path distance (Chen et al., 2019).

Abstract

Neural coreference resolution models trained on one dataset may not transfer to new, low-resource domains. Active learning mitigates this problem by sampling a small subset of data for annotators to label. While active learning is well-defined for classification tasks, its application to coreference resolution is neither well-defined nor fully understood. This paper explores how to actively label coreference, examining sources of model uncertainty and document reading costs. We compare uncertainty sampling strategies and their advantages through thorough error analysis. In both synthetic and human experiments, labeling spans within the same document is more effective than annotating spans across documents. The findings contribute to a more realistic development of coreference resolution models.

1 Introduction

Linguistic expressions are coreferent if they refer to the same entity. The computational task of discovering coreferent mentions is coreference resolution (CR). Neural models (Lee et al., 2018; Joshi et al., 2020) are SOTA on ONTONOTES 5.0 (Pradhan et al., 2013) but cannot immediately generalize to other datasets. Generalization is difficult because domains differ in content, writing style, and annotation guidelines. To overcome these challenges, models need copiously labeled, in-domain data (Bamman et al., 2020).

Despite expensive labeling costs, adapting CR is crucial for applications like uncovering information about proteins in biomedicine (Kim et al., 2012) and distinguishing entities in legal documents (Gupta et al., 2018). Ideally, we would like to quickly and cheaply adapt the model without repeatedly relying on an excessive amount of annotations to retrain the model. To reduce labeling cost, we investigate active learning (Settles, 2009) for CR. Active learning aims to reduce annotation costs by intelligently selecting examples to label. Prior approaches use active learning to improve the model within the same domain (Gasperin, 2009; Sachan et al., 2015) without considering adapting to new data distributions. For domain adaptation in CR, Zhao and Ng (2014) motivate the use of active learning to select out-of-distribution examples. A word like "the bonds" refers to municipal bonds in ONTONOTES but links to "chemical bonds" in another domain (Figure 1). If users annotate the antecedents of "the bonds" and other ambiguous entity mentions, then these labels help adapt a model trained on ONTONOTES to new domains.

Active learning for CR adaptation is well-motivated, but the implementation is neither straightforward nor well-studied. First, CR is a span detection and clustering task, so selecting which spans to label is more complicated than choosing independent examples for text classification. Second, CR labeling involves closely reading the documents. Labeling more spans within the same context is more efficient. However, labeling more spans across different documents increases data diversity and may improve model transfer. How should we balance these competing objectives?

Our paper extends prior work in active learning for CR to the problem of coreference model transfer (Xia and Van Durme, 2021):

1. We generalize the *clustered entropy* sampling strategy (Li et al., 2020) to include uncertainty in mention detection. We analyze the effect of each strategy on coreference model transfer.
2. We investigate the trade-off between labeling and reading through simulations and a real-time user study. Limiting annotations to the same document increases labeling throughput and decreases volatility in model training.

Taken together, these contributions offer a blueprint for faster creation of CR models across domains.[1]

Source

Traders said municipals were underpinned by influences, including the climb in Treasury issue prices. Also, municipal bonds lured buying because the stock market remains wobbly, traders contended. Mainly though, it was a favorable outlook for yesterday's new supply that propped up municipals , some traders said. Among the new issues was Massachusetts's $230 million of general obligation bonds . The bonds were won by a Goldman Sachs & Co. group with a true interest cost of 7.17%.

Cluster: { municipals , municipal bonds , municipals , general obligation bonds , The bonds }

Target

(1)

A molecule is a group of atoms held together by chemical bonds . Imagine you and your friends standing in a circle holding hands. Each person stands for one atom, your hands represent the bonds , and the entire circle represents a molecule.

Active query: the bonds *Answer:* chemical bonds

Queries: your the bonds a molecule

(2)

Dr. Raizman thinks the animals help decrease patients' stress by increasing the release of oxytocin, which is the hormone that bonds mothers to babies. Studies have shown patients who spend time with dogs have higher levels of dopamine.

Active query: bonds *Answer:* query is not entity

Queries: oxytocin bonds patients dogs

Figure 1: CR models are trained on **source** domain ONTONOTES, which contains data like news articles. The **source** document links “the bonds” to “municipal bonds”. In a **target** domain like PRECO (Chen et al., 2018), “the bonds” may no longer have the same meaning. It can refer to “chemical bonds” (Document 1) or not be considered an entity (Document 2). A solution is to continue training the **source** model on more spans from the **target** domain. Active learning helps select ambiguous spans, like “the bonds”, for the user to label on this interface (Section 4.2).

2 Problem: Adapting Coreference

Lee et al. (2018) introduce C2F-COREF, a neural model that outperforms prior rule-based systems. It assigns an antecedent y to mention span x. The set $\mathcal{Y}(x)$ of possible antecedent spans include a dummy antecedent ϵ and all spans preceding x. If span x has no antecedent, then x should be assigned to ϵ. Given entity mention x, the model learns a distribution over its candidate antecedents in $\mathcal{Y}(x)$,

$$P(Y = y) = \frac{\exp\{s(x, y)\}}{\sum_{y' \in \mathcal{Y}(x)} \exp\{s(x, y')\}}. \tag{1}$$

The scores $s(x, y)$ are computed by the model’s pairwise scorer (Appendix A.1).

CR models like C2F-COREF are typically trained on ONTONOTES. Recent work in CR improves upon C2F-COREF and has SOTA results on ONTONOTES (Wu et al., 2020; Joshi et al., 2020). However, annotation guidelines and the underlying text differ across domains. As a result, these CR models cannot immediately transfer to other datasets. For different domains, spans could hold different meanings or link to different entities. Xia and Van Durme (2021) show the benefits of *continued training* where a model trained on ONTONOTES is further trained on the target dataset. For several target domains, continued training from ONTONOTES is stronger than training the model from scratch, especially when the training dataset is small.

Their experiments use an incremental variant of C2F-COREF called ICOREF (Xia et al., 2020). While C2F-COREF requires $\Theta(n)$ memory to simultaneously access all spans in the document and infer a span’s antecedent, ICOREF only needs constant memory to predict a span’s entity cluster. Despite using less space, ICOREF retains the same accuracy as C2F-COREF. Rather than assigning x to antecedent y, ICOREF assigns x to cluster c where c is from a set of observed entity clusters $\mathcal{C}$,

$$P(C = c) = \frac{\exp\{s(x, c)\}}{\sum_{c' \in \mathcal{C}} \exp\{s(x, c')\}}. \tag{2}$$

As the algorithm processes spans in the document, each span is either placed in a cluster from $\mathcal{C}$ or added to a new cluster. To learn the distribution over clusters (Equation 2), the algorithm first creates a cluster representation that is an aggregate of span representations over spans that currently exist in the cluster. With cluster and span representations, individual spans and entity clusters are mapped into a shared space. Then, we can compute $s(x, c)$ using the same pairwise scorer as before.

Xia and Van Durme (2021) show that continued training is useful for domain adaptation but assume that labeled data already exist in the target domain. However, model transfer is more critical when annotations are scarce. Thus, the question becomes: how can we adapt CR models without requiring a large, labeled dataset? Our paper investigates active learning as a potential solution. Through active learning, we reduce labeling costs by sampling and annotating a small subset of ambiguous spans.

3 Method: Active Learning

Neural models achieve high accuracy for ONTONOTES but cannot quickly adapt to new datasets because of shifts in domain or annotation standards (Poot and van Cranenburgh, 2020). To transfer to new domains, models need substantial in-domain, labeled data. In low-resource situations, CR is infeasible for real-time applications. To reduce the labeling burden, active learning may target spans that most confuse the model. Active learning for domain adaptation (Rai et al., 2010) typically proceeds as follows: begin with a model trained on source data, sample and label k spans from documents in the target domain based on a strategy, and train the model on labeled data.

This labeling setup may appear straightforward to apply to CR, but there are some tricky details. The first complication is that—unlike text classification—CR is a *clustering* task. Early approaches in active learning for CR use *pairwise annotations* (Miller et al., 2012; Sachan et al., 2015). Pairs of spans are sampled and the annotator labels whether each pair is coreferent. The downside to pairwise annotations is that it requires many labels. To label the antecedent of entity mention x, x must be compared to every candidate span in the document. Li et al. (2020) propose a new scheme called *discrete annotations*. Instead of sampling pairs of spans, the active learning strategy samples individual spans. Then, the annotator only has to find and label first antecedent of x in the document, which bypasses the multiple pairwise comparisons. Thus, we use discrete annotations to minimize labeling.

To further improve active learning for CR, we consider the following issues. First, the CR model has different scores for mention detection and linking, but prior active learning methods only considers linking. Second, labeling CR requires time to read the document context. Therefore, we explore important aspects of active learning for adapting CR: model uncertainty (Section 3.1), and the balance between reading and labeling (Section 3.2).

3.1 Uncertainty Sampling

A well-known active learning strategy is uncertainty sampling. A common measure of uncertainty is the entropy in the distribution of the model's predictions for a given example (Lewis and Gale, 1994). Labeling uncertain examples improves accuracy for tasks like text classification (Settles, 2009). For CR, models have multiple components, and computing uncertainty is not as straightforward. Is uncertainty over where mentions are located more important than linking spans? Or the other way around? Thus, we investigate different sources of CR model uncertainty.

3.1.1 Clustered Entropy

To sample spans for learning CR, Li et al. (2020) propose a strategy called *clustered entropy*. This metric scores the uncertainty in the entity cluster assignment of a mention span x. If x has *high* clustered entropy, then it should be labeled to help the model learn its antecedents. Computing clustered entropy requires the probability that x is assigned to an entity cluster. Li et al. (2020) use C2F-COREF, which only gives probability of x being assigned to antecedent y. So, they define $P(C = c)$ as the sum of antecedent probabilities $P(Y = y)$,

$$P(C = c) = \sum_{y \in C \cap \mathcal{Y}(x)} P(Y = y). \tag{3}$$

Then, they define clustered entropy as,

$$\mathrm{H}(x) = -\sum_{c \in \mathcal{C}} P(C = c) \log P(C = c). \tag{4}$$

The computation of clustered entropy in Equation 4 poses two issues. First, summing the probabilities may not accurately represent the model's probability of linking x to c. There are other ways to aggregate the probabilities (e.g. taking the maximum). C2F-COREF never computes cluster probabilities to make predictions, so it is not obvious how $P(C = c)$ should be computed for clustered entropy. Second, Equation 4 does not consider mention detection. For ONTONOTES, this is not an issue because singletons (clusters of size 1) are not annotated and mention detection score is implicitly included in $P(Y = y)$. For other datasets containing singletons, the model should disambiguate singleton clusters from non-mention spans.

To resolve these issues, we make the following changes. First, we use ICOREF to obtain cluster probabilities. ICOREF is a mention clustering model so it already has probabilities over entity clusters (Equation 2). Second, we explore other forms of maximum entropy sampling. Neural CR models have scorers for mention detection and clustering. Both scores should be considered to sample spans that confuse the model. Thus, we propose more strategies to target uncertainty in mention detection.

3.1.2 Generalizing Entropy in Coreference

To generalize entropy sampling, we first formalize mention detection and clustering. Given span x, assume X is the random variable encoding whether x is an entity mention (1) or not (0). In Section 2, we assume that the cluster distribution $P(C)$ is independent of X: $P(C) = P(C \mid X)$.[2] In other words, Equation 2 is actually computing $P(C = c \mid X = 1)$. We sample top-k spans with the following strategies.

ment-ent Highest mention detection entropy:

$$\begin{aligned} \mathrm{H}_{\text{MENT}}(x) &= \mathrm{H}(X) \qquad (5) \\ &= -\sum_{i=0}^{1} P(X = i) \log P(X = i). \end{aligned}$$

The probability $P(X)$ is computed from normalized mention scores s_m (Equation 10). **Ment-ent** may sample spans that challenge mention detection (e.g. class-ambiguous words like "park"). The annotator can clarify whether spans are entity mentions to improve mention detection.

clust-ent Highest mention clustering entropy:

$$\begin{aligned} \mathrm{H}_{\text{CLUST}}(x) &= \mathrm{H}(C \mid X = 1) \qquad (6) \\ &= -\sum_{c \in \mathcal{C}} P(C = c \mid X = 1) \log \\ &\qquad P(C = c \mid X = 1). \end{aligned}$$

Clust-ent looks at clustering scores without explicitly addressing mention detection. Like in ONTONOTES, all spans are assumed to be entity mentions. The likelihood $P(C = c \mid X = 1)$ is given by ICOREF (Equation 2).

cond-ent Highest conditional entropy:

$$\begin{aligned} \mathrm{H}_{\text{COND}}(x) &= \mathrm{H}(C \mid X) \\ &= \sum_{i=0}^{1} P(X = i) \mathrm{H}(C \mid X = i) \qquad (7) \\ &= P(X = 1) \mathrm{H}(C \mid X = 1) \\ &= P(X = 1) \mathrm{H}_{\text{CLUST}}(x). \end{aligned}$$

We reach the last equation because there is no uncertainty in clustering x if x is not an entity mention and $\mathrm{H}(C \mid X = 0) = 0$. **Cond-ent** takes the uncertainty of mention detection into account. So, we may sample more pronouns because they are obviously mentions but difficult to cluster.

joint-ent Highest joint entropy:

$$\begin{aligned} \mathrm{H}_{\text{JOINT}}(x) &= \mathrm{H}(X, C) = \mathrm{H}(X) + \mathrm{H}(C \mid X) \\ &= \mathrm{H}_{\text{MENT}}(x) + \mathrm{H}_{\text{COND}}(x). \qquad (8) \end{aligned}$$

Joint-ent may sample spans that are difficult to detect as entity mentions *and* too confusing to cluster. This sampling strategy most closely aligns with the uncertainty of the training objective. It may also fix any imbalance between mention detection and linking (Wu and Gardner, 2021).

3.2 Trade-off between Reading and Labeling

For CR, the annotator reads the document context to label the antecedent of a mention span. Annotating and reading spans from different documents may slow down labeling, but restricting sampling to the same document may cause redundant labeling (Miller et al., 2012). To better understand this trade-off, we explore different configurations with k, the number of annotated spans, and m, the maximum number of documents being read. Given source model h_0 already fine-tuned on ONTONOTES, we adapt h_0 to a target domain through active learning (Algorithm 1):

Scoring To sample k spans from unlabeled data $\mathcal{U}$ of the target domain, we score spans with an active learning strategy S. Assume S scores each span through an *acquisition model* (Lowell et al., 2019). For the acquisition model, we use h_{t-1}, the model fine-tuned from the last cycle. The acquisition score quantifies the span's importance given S and the acquisition model.

Reading Typically, active learning samples k spans with the highest acquisition scores. To constrain m, the number of documents read, we find the documents of the m spans with highest acquisition scores and only sample spans from those documents. Then, the k sampled spans will belong to at most m documents. If m is set to "unconstrained", then we simply sample the k highest-scoring spans, irrespective of the document boundaries.

Our approach resembles Miller et al. (2012) where they sample spans based on highest uncer-

---

[2] A side effect of ONTONOTES models lacking singletons.

Algorithm 1 Active Learning for Coreference

```
Require: Source model $h_0$, Unlabeled data $\mathcal{U}$, Active learning strategy $S$, No. of cycles $T$, No. of labeled spans $k$, Max. no. of read docs $m$
Labeled data $\mathcal{L} = \{\}$

    $a_x \leftarrow$ Score span $x \in \mathcal{U}$ by $S(h_{t-1}, x)$
    $\mathcal{Q} \leftarrow$ Sort ($\downarrow$) $x \in \mathcal{U}$ by scores $a_x$
    $\mathcal{Q}_m \leftarrow$ Top-$m$ spans in $\mathcal{Q}$
    $\mathcal{D} \leftarrow \{\boldsymbol{d}_x \mid x \in \mathcal{Q}_m\}$ where $\boldsymbol{d}_x$ is doc of $x$
    $\widetilde{\mathcal{Q}} \leftarrow$ Filter $\mathcal{Q}$ s.t. spans belong to $\boldsymbol{d} \in \mathcal{D}$
    $\widetilde{\mathcal{Q}}_k \leftarrow$ Top-$k$ spans in $\widetilde{\mathcal{Q}}$
    $\mathcal{L}_k \leftarrow$ Label antecedents for $\widetilde{\mathcal{Q}}_k$
    $\mathcal{L} \leftarrow \mathcal{L} \cup \mathcal{L}_k$
    $h_t \leftarrow$ Continue train $h_0$ on $\mathcal{L}$
return $h_T$
```

tainty and continue sampling from the same document until uncertainty falls below a threshold. Then, they sample the most uncertain span from a new document. We modify their method because the uncertainty threshold will vary for different datasets and models. Instead, we use the number of documents read to control context switching.

Labeling An oracle (e.g., human annotator or gold data) labels the antecedents of sampled spans with discrete annotations (Section 3).

Continued Training We combine data labeled from current and past cycles. We train the source model h_0 (which is already trained on OntoNotes) on the labeled target data. We do not continue training a model from a past active learning cycle because it may be biased from only training on scarce target data (Ash and Adams, 2020).

4 Active Learning for CR through Simulations and Humans

We run experiments to understand two important factors of active learning for CR: sources of model uncertainty (Section 3.1) and balancing reading against labeling (Sections 3.2). First, we simulate active learning on PreCo to compare sampling strategies based on various forms of uncertainty (Section 4.1). Then, we set up a user study to investigate how humans perform when labeling spans from fewer or more documents from PreCo (Section 4.2). Specifically, we analyze their annotation time and throughput. Finally, we run large-scale simulations on PreCo and QBCoref (Section 4.3). We explore different combinations of sampling strategies and labeling configurations.

Models In all experiments, the source model is the best checkpoint of ICoref model trained on OntoNotes (Xia et al., 2020) with SpanBERT-large-cased (Joshi et al., 2020) encoder. For continued training on the target dataset, we optimize with a fixed parameter configuration (Appendix A.2). We evaluate models on Avg F_1, the averaged F_1 scores of MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), and $\text{CEAF}_{\phi 4}$ (Luo, 2005). For all synthetic experiments, we simulate active learning with gold data substituting as an annotator. However, gold mention boundaries are not used when sampling data. The model scores spans that are likely to be entity mentions for inference, so we limit the active learning candidates to this pool of high-scoring spans. For each active learning simulation, we repeat five runs with different random seed initializations.

Baselines We compare the proposed sampling strategies (Section 3.1.2) along with **li-clust-ent**, which is clustered entropy from Li et al. (2020) (Equation 4). Active learning is frustratingly less effective than random sampling in many settings (Lowell et al., 2019), so we include two random baselines in our simulation. **Random** samples from all spans in the documents. **Random-ment**, as well as other strategies, samples only from the pool of likely (high-scoring) spans. Thus, **random-ment** should be a stronger baseline than **random**.

Datasets OntoNotes 5.0 is the most common dataset for training and evaluating CR (Pradhan et al., 2013). The dataset contains news articles and telephone conversations. Only non-singletons are annotated. Our experiments transfer a model trained on OntoNotes to two target datasets: PreCo and QBCoref. PreCo is a large corpus of grade-school reading comprehension texts (Chen et al., 2018). Unlike OntoNotes, PreCo has annotated singletons. There are 37K training, 500 validation, and 500 test documents. Because the training set is so large, Chen et al. (2018) only analyze subsets of 2.5K documents. Likewise, we reduce the training set to a subset of 2.5K documents, comparable to the size of OntoNotes.

The QBCoref dataset (Guha et al., 2015) contains trivia questions from Quizbowl tournaments that are densely packed with entities from academic topics. Like PreCo, singletons are annotated. Un-

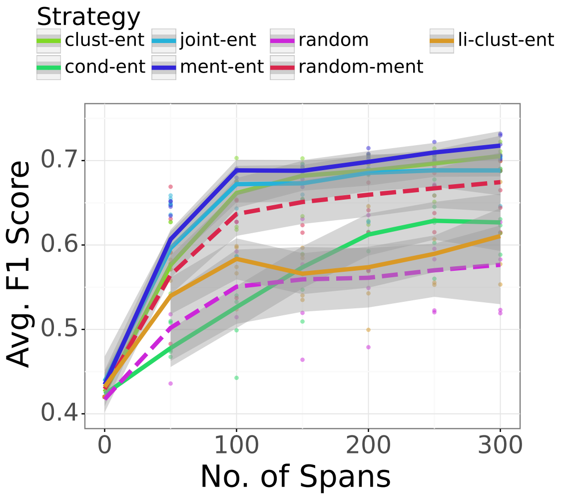

Figure 2: Test AVG F_1 on PRECO for each strategy. On each cycle, fifty spans from one document are sampled and labeled. We repeat each simulation five times. **Ment-ent**, **clust-ent**, and **joint-ent** are most effective while **random** hurts the model the most.

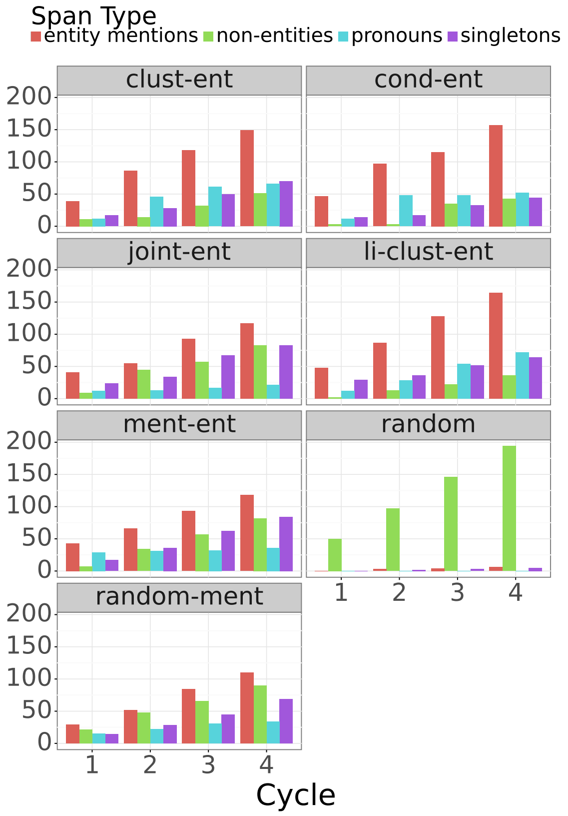

Figure 3: Cumulative counts of entities, non-entities, pronouns, and singletons sampled for each strategy over first four cycles of the PRECO simulation. **Random** mostly samples non-entities. **Li-clust-ent** and **cond-ent** sample many entity mentions but avoid singletons.

like other datasets, the syntax is idiosyncratic and world knowledge is needed to solve coreference. Examples are pronouns before the first mention of named entities and oblique references like “this polity” for “the Hanseatic League”. These complicated structures rarely occur in everyday text but serve as challenging examples for CR. There are 240 training, 80 validation, and 80 test documents.

4.1 Simulation: Uncertainty Sampling

To compare different sampling strategies, we first run experiments on PRECO. We sample fifty spans from one document for each cycle. By the end of a simulation run, 300 spans are sampled from six documents. For this configuration, uncertainty sampling strategies generally reach higher accuracy than the random baselines (Figure 2), but **cond-ent** and **li-clust-ent** are worse than **random-ment**.

4.1.1 Distribution of Sampled Span Types

To understand the type of spans being sampled, we count entity mentions, non-entities, pronouns, and singletons that are sampled by each strategy (Figure 3). **Random** samples very few entities, while other strategies sample more entity mentions. **Clust-ent** and **cond-ent** sample more entity mentions and pronouns because the sampling objective prioritizes mentions that are difficult to link. **Clust-ent**, **joint-ent**, and **ment-ent** sample more singleton mentions. These strategies also show higher AVG F_1 (Figure 2). For transferring from ONTONOTES to PRECO, annotating singletons is useful because only non-singleton mentions are labeled in ONTONOTES. We notice **ment-ent** sampling pronouns, which should obviously be entity mentions, only in the first cycle. Many pronouns in ONTONOTES are singletons, so the mention detector has trouble distinguishing them initially in PRECO.

4.1.2 Error Analysis

Kummerfeld and Klein (2013) enumerate the ways CR models can go wrong: *missing entity*, *extra entity*, *missing mention*, *extra mention*, *divided entity*, and *conflated entity*. *Missing entity* means a gold entity cluster is missing. *Missing mention* means a mention span for a gold entity cluster is missing. The same definitions apply for *extra entity* and *extra mention*. *Divided entity* occurs when the model splits a gold entity cluster into multiple ones. *Conflated entity* happens when the model merges gold entity clusters. For each strategy, we analyze the errors of its final model from the simulation’s last

Figure 4: For each sampling strategy, we analyze the model from the last cycle of its PRECO simulation. We compare the number of errors across common error types in CR. The **source** ONTONOTES model severely suffers from *missing entities* and *missing mentions*. **Ment-ent** helps most with reducing these errors.

cycle (Figure 4). We compare against the **source** model that is only trained on ONTONOTES.

The **source** model makes many *missing entity* and *missing mention* errors. It does not detect several entity spans in PRECO, like locations ("Long Island") or ones spanning multiple words ("his kind acts of providing everything that I needed"). These spans are detected by uncertainty sampling strategies and **rand-ment**. **Ment-ent** is most effective at reducing "missing" errors. It detects gold entity clusters like "constant communication" and "the best educated guess about the storm". By training on spans that confuse the mention detector, the model adapts to the new domain by understanding what constitutes as an entity mention.

Surprisingly, **li-clust-ent** makes at least twice as many *extra entity* and *extra mention* errors than any other strategy. For the sentence, "Living in a large building with only 10 bedrooms", the gold data identifies two entities: "a large building with only 10 bedrooms" and "10 bedrooms". In both ONTONOTES and PRECO, the guidelines only allow the longest noun phrase to be annotated. Yet, the **li-clust-ent** model predicts additional mentions, "a large building" and "only 10 bedrooms". We find that **li-clust-ent** tends to sample nested spans (Table 4). Due to the summed entropy computation, nested spans share similar values for clustered entropy as they share similar antecedent-linking probabilities. This causes the *extra entity* and *extra mention* errors because the model predicts there are additional entity mentions within a mention span.

Finally, we see a stark difference between **random-ment** and **random**. Out of all the sampling strategies, **random** is least effective at preventing *missing entity* and *missing mention* errors. We are more likely to sample non-entities if we randomly sample from all spans in the document (Appendix A.7). By limiting the sampling pool to only spans that are likely to be entity mentions, we sample more spans that are useful to label for CR. Thus, the mention detector from neural models should be deployed during active learning.

4.2 User Study: Reading and Labeling

We hold a user study to observe the trade-off between reading and labeling. Three annotators, with minimal NLP knowledge, label spans sampled from PRECO. We use **ment-ent** to sample spans because the strategy shows highest AVG F_1 (Figure 2). First, the users read instructions (Appendix A.6) and practice labeling for ten minutes. Then, they complete two sessions: **FewDocs** and **ManyDocs**. In each session, they label as much as possible for at least twenty-five minutes. In **FewDocs**, they read fewer documents and label roughly seven spans per document. In **ManyDocs**, they read more documents and label about one span per document.

For labeling coreference, we develop a user interface that is open-sourced (Figure 8). To label the antecedent of the highlighted span, the user clicks on a contiguous span of tokens. The interface suggests overlapping candidates based on the spans that are retained by the CR model.

In the user study, participants label at least twice as much in **FewDocs** compared to **ManyDocs** (Figure 5). By labeling more spans in **FewDocs**, the mean AVG F_1 score is also slightly higher. Our findings show that the number of read documents should be constrained to increase labeling throughput. Difference in number of labeled spans between **FewDocs** and **ManyDocs** is more pronounced when two annotators volunteer to continue labeling after required duration (Appendix A.6).

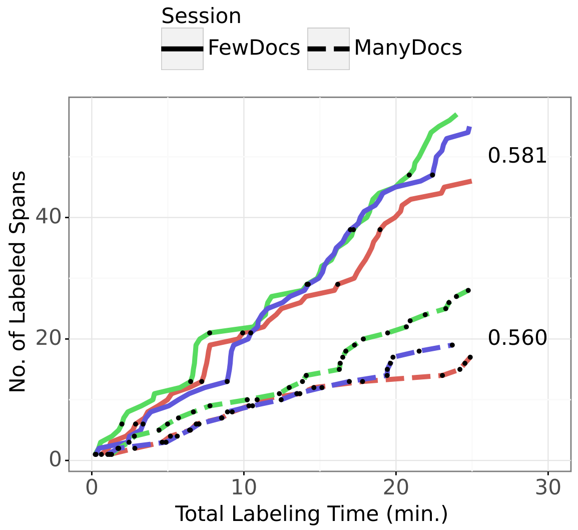

Figure 5: The number of spans labeled within twenty-five minutes. Each color indicates one of three users and the linetype designates the session. Black dots mark the first span labeled in a different document. The mean AVG F_1 across users for each session is on the right. By restricting the number of read documents in **FewDocs**, users label at least twice as many spans and the model slightly improves in AVG F_1.

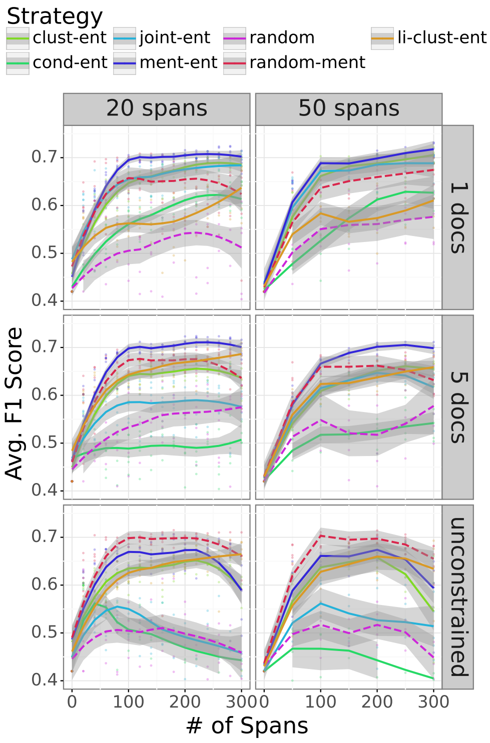
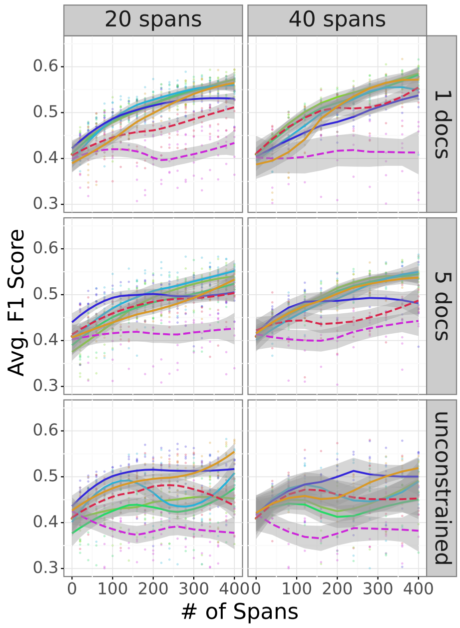
4.3 Simulation: Uncertainty Sampling and Reading-Labeling Trade-off

We finally run simulations to explore *both* sources of model uncertainty and the trade-off between reading and labeling. The earlier experiments have individually looked at each aspect. Now, we analyze the interaction between both factors to understand which combination works best for adapting CR to new domains. We run simulations on PRECO and QBCOREF that trade-off the number of documents read m with the number of annotated spans k (Figure 6). We vary m between one, five, and an unconstrained number of documents. For PRECO, we set k to twenty and fifty. For QBCOREF, we set k to twenty and forty. These results are also presented in numerical form (Appendix A.5).

PRECO For PRECO, the test AVG F_1 of ICOREF trained on the full training dataset is 0.860. When m is constrained to one or five, AVG F_1 can reach around 0.707 from training the model on only 300 spans sampled by **ment-ent**. As m increases, fewer spans are sampled per document and all sampling strategies deteriorate. After training on sparsely annotated documents, the model tends to predict singletons rather than cluster coreferent spans. Like in the user study, we see benefits when labeling



(a) PRECO



(b) QBCOREF

Figure 6: Test AVG F_1 on PRECO and QBCOREF of each strategy throughout simulations. Each row varies in m, the maximum number of documents read per cycle. Each column varies in k, the number of annotated spans per cycle. For m of one or five, **ment-ent** shows highest AVG F_1 for PRECO and other uncertainty sampling strategies are best for QBCOREF. When m is unconstrained, many strategies show unstable training.

more spans within a document. Interestingly, **li-clust-ent** performs better when document reading is not constrained to one document. The issue with **li-clust-ent** is that it samples nested mention spans (Section 4.1.2). Duplicate sampling is less severe if spans can be sampled across more documents. Another strategy that suffers from duplicate sampling is **cond-ent** because it mainly samples pronouns. For some documents, the pronouns all link to the same entity cluster. As a result, the model trains on a less diverse set of entity mentions and **cond-ent** drops in AVG F_1 as the simulation continues.

QBCOREF For QBCOREF, the test AVG F_1 of ICOREF trained on the full training dataset is 0.795. When we constrain m to one or five, **li-clust-ent**, **clust-ent**, **cond-ent**, and **joint-ent** have high AVG F_1. Clustering entity mentions in QBCOREF questions is difficult, so these strategies help target ambiguous mentions (Table 5). **Ment-ent** is less useful because demonstratives are abundant in QBCOREF and make mention detection easier. **Li-clust-ent** still samples nested entity mentions, but annotations for these spans help clarify interwoven entities in Quizbowl questions. Unlike PRECO, **li-clust-ent** does not sample duplicate entities because nested entity mentions belong to different clusters and need to be distinguished.

Overall, the most helpful strategy depends on the domain. For domains like PRECO that contain long documents with many singletons, **ment-ent** is useful. For domains like QBCOREF where resolving coreference is difficult, we need to target linking uncertainty. Regardless of the dataset, **random** performs worst. **Random-ment** has much higher AVG F_1, which shows the importance of the mention detector in active learning. Future work should determine the appropriate strategy for a given domain and annotation setup.

5 Related Work

Gasperin (2009) present the first work on active learning for CR yet observe negative results: active learning is not more effective than random sampling. Miller et al. (2012) explore different settings for labeling CR. First, they label the most uncertain pairs of spans in the corpus. Second, they label all pairs in the most uncertain documents. The first approach beats random sampling but requires the annotator to infeasibly read many documents. The second approach is more realistic but loses to random sampling. Zhao and Ng (2014) argue that active learning helps domain adaptation of CR. Sachan et al. (2015) treat pairwise annotations as optimization constraints. Li et al. (2020) replace pairwise annotations with discrete annotations and experiment active learning with neural models.

Active learning has been exhaustively studied for text classification (Lewis and Gale, 1994; Zhu et al., 2008; Zhang et al., 2017). Text classification is a much simpler task, so researchers investigate strategies beyond uncertainty sampling. Yuan et al. (2020) use language model surprisal to cluster documents and then sample representative points for each cluster. Margatina et al. (2021) search for constrastive examples, which are documents that are similar in the feature space yet differ in predictive likelihood. Active learning is also applied to tasks like machine translation (Liu et al., 2018), visual question answering (Karamcheti et al., 2021), and entity alignment (Liu et al., 2021).

Rather than solely running simulations, other papers have also ran user studies or developed user-friendly interfaces. Wei et al. (2019) hold a user study for active learning to observe the time to annotate clinical named entities. Lee et al. (2020) develop active learning for language learning that adjusts labeling difficulty based on user skills. Klie et al. (2020) create a human-in-the-loop pipeline to improve entity linking for low-resource domains.

6 Conclusion

Neural CR models desparately depend on large, labeled data. We use active learning to transfer a model trained on ONTONOTES, the “de facto” dataset, to new domains. Active learning for CR is difficult because the problem does not only concern sampling examples. We must consider different aspects, like sources of model uncertainty and cost of reading documents. Our work explores these factors through exhaustive simulations. Additionally, we develop a user interface to run a user study from which we observe human annotation time and throughput. In both simulations and the user study, CR improves from continued training on spans sampled from the same document rather than different contexts. Surprisingly, sampling by entropy in mention detection, rather than linking, is most helpful for domains like PRECO. This opposes the assumption that the uncertainty strategy must be directly tied to the training objective. Future work may extend our contributions to multilingual transfer or multi-component tasks, like open-domain QA.

7 Ethical Considerations

This paper involves a user study to observe the trade-off between reading and labeling costs for annotating coreference. The study has been approved by IRB to collect data about human behavior. Any personal information will be anonymized prior to paper submission or publication. All participants are fully aware of the labeling task and the information that will be collected from them. They are appropriately compensated for their labeling efforts.

A Appendix

A.1 Coreference Resolution Models

C2F-COREF In C2F-COREF, a pairwise scorer computes $s(x, y)$ to learn antecedent distribution $P(Y)$ (Equation 1). The model's pairwise scorer judges whether span x and span y are coreferent based on their antecedent score s_a and individual mention scores s_m,

$$s(x, y) = \begin{cases} 0 & y = \epsilon \\ s_m(x) + s_m(y) + s_a(x, y) & y \neq \epsilon \end{cases}, \tag{9}$$

Suppose $\boldsymbol{g_x}$ and $\boldsymbol{g_y}$ are the span representations of x and y, respectively. Mention scores and antecedent scores are then computed with feedforward networks $FFNN_m$ and $FFNN_c$,

$$s_m(x) = FFNN_m(\boldsymbol{g_x}) \tag{10}$$

$$s_a(x, y) = FFNN_a(\boldsymbol{g_x}, \boldsymbol{g_y}, \phi(x, y)). \tag{11}$$

The input $\phi(x, y)$ includes features like the distance between spans. The unary mention score s_m can be viewed as the likelihood that the span is an entity mention. For computational purposes, the C2F-COREF model only retains top-k spans with the highest unary mention scores. Lee et al. (2018) provide more details about the pairwise scorer and span pruning.

Incremental Clustering We elaborate upon the clustering algorithm of ICOREF here. As the algorithm processes spans in the document, each span is either placed in a cluster from $\mathcal{C}$ or added to a new cluster. To learn the distribution over clusters (Equation 2), the algorithm first creates a cluster representation $\boldsymbol{g_c}$ that is an aggregate of span representation that is an aggregate of span representations over spans that currently exist in the cluster. (Equation 12). With cluster and span representations, individual spans and entity clusters are mapped into a shared space. Then, we can compute $s(x, c)$ using the same pairwise scorer as Lee et al. (2018). Suppose that model predicts c^* as most likely cluster: $c^* = \arg\max_{c \in \mathcal{C}} s(x, c)$. Now, the algorithm makes one of two decisions:

1. If $s(x, c^*) > 0$, then x is assigned to c^* and update $\boldsymbol{g_{c^*}}$ such that

$$\boldsymbol{g_{c^*}} = s_e(c^*, x)\boldsymbol{g_{c^*}} + (1 - s_e(c^*, x))\boldsymbol{g_x}, \tag{12}$$

   where s_e is a learned weight.

2. If $s(x, c^*) \leq 0$, then a new entity cluster $c_x = \{x\}$ is added to $\mathcal{C}$.

The algorithm repeats for each span in the document.

Like C2F-COREF, the ICOREF model only retains top-k spans with highest unary mention score. All of our active learning baselines (Section 4), except **random**, sample spans from this top-k pool of spans.

Strategy	PRECO	QBCOREF
random	2	< 1
random-ment	4	< 1
ment-ent	5	< 1
li-clust-ent	12	< 1
clust-ent	12	1
cond-ent	14	1
joint-ent	16	1

Table 1: The time (minutes) to sample a batch of fifty spans from five documents from either PRECO or QBCOREF for a given active learning strategy. On large datasets like PRECO, we see that **li-clust-ent**, **clust-ent**, **cond-ent**, and **joint-ent** are slower because the strategy needs to incrementally cluster each span and then compute clustering entropy.

A.2 Training Configuration

The SPANBERT-LARGE-CASED encoder has 334M parameters and ICOREF has 373M parameters in total. For model fine-tuning, we train for a maximum of fifty epochs and implement early stopping with a patience of ten epochs. We set top span pruning to 0.4, dropout to 0.4, gradient clipping to 10.0, and learning rate to 1e-4 for Adam optimizer. The hyperparameter configuration is based on results from prior work (Lee et al., 2017; Xia et al., 2020).

All experiments in the paper are ran on NVIDIA Tesla V100 GPU and 2.2 GHz Intel Xeon Silver 4114 CPU processor.

A.3 Simulation Time

We compare the time to sample fifty spans between different active learning strategies for PRECO and QBCOREF (Table 1). For PRECO, **clust-ent**, **cond-ent**, and **joint-ent** are slower because they need to run documents through ICOREF and get span-cluster likelihood. On the other hand, **ment-ent** only needs unary scores s_m, which is much faster to compute. Thus, for both datasets, running **ment-ent** takes about the same time as **random-ment**.

For QBCoref, fine-tuning ICoref on fifty spans takes three minutes and fine-tuning on full training set takes thirty-four minutes. For PreCo, fine-tuning ICoref on fifty spans takes nine minutes and fine-tuning on full training set takes five hours and 22 minutes.

A.4 Mention Detection Accuracy

For the annotation simulation in Section 4, we also record mention detection accuracy. As **ment-ent** targets ambiguity in mention detection, it is the most effective strategy for improving mention detection (Figure 7). The strategy is unaffected by labeling setup parameters, like the number of spans labeled per cycle or the number of documents read per cycle. For strategies like **cond-ent** and **joint-ent**, mention detection accuracy is stagnant or decreases as more spans are sampled (Figure 7a). Due to deteriorating mention detection, the Avg F_1 of models also drop.

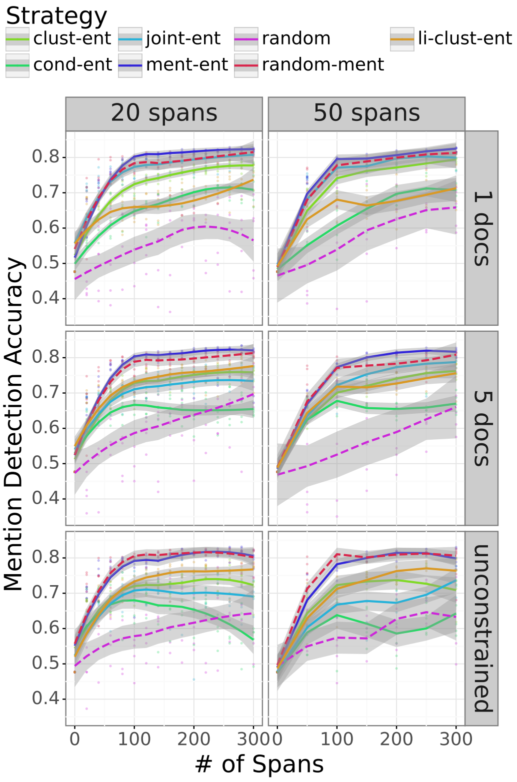
A.5 Numerical Results

The results for Avg F_1 and mention detection accuracy are presented as graphs throughout the paper. To concretely understand the differences between the methods, we provide results in numerical form (Tables 2,3). We show results from the PreCo and QBCoref simulations where twenty spans are labeled each cycle and the number of documents read is either one or an unconstrained amount. The values in the tables show the mean and variance of Avg F_1 and mention detection accuracy over five different runs.

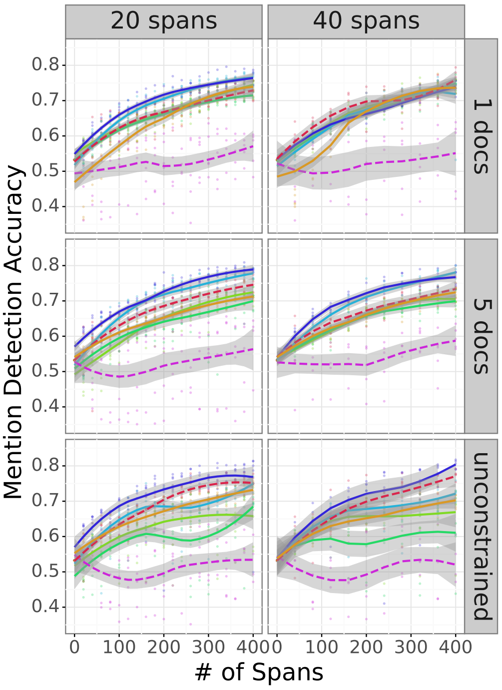
A.6 User Study

Instructions to Participants We give the following instructions to user study participants:

> You will be shown several sentences from a document. We have highlighted a mention (a word or phrase) of an entity (a person, place, or thing). This entity mention may be a pronoun (such as "she" or "their") or something else.
>
> We need your help to find an earlier mention of the same entity, whether in the same sentence or in an earlier sentence. The mention does not have to be the immediately previous one.
>
> If the span is not an entity mention or does not have an antecedent, please make note of it on the interface.



(a) PreCo



(b) QBCoref

Figure 7: Comparing mention detection accuracy on test set for different active learning strategies across reading/labeling configurations. The plots are formatted in the same way as Figure 6. Generally, mention detection improves most from **ment-ent** sampling.

Total No. of Labeled Spans	m	Strategy	AVG F_1	Mention Accuracy

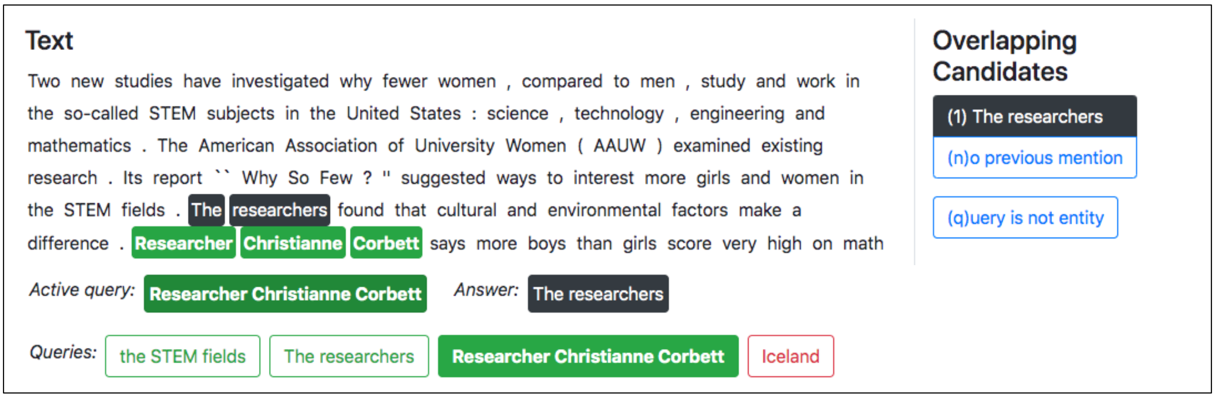
Table 3: Results of QBCOREF simulation in numerical form, accompanying the graphs in Figures 6b and 7b. The table shows Avg F_1 and mention detection accuracy of experiments where twenty spans are sampled and labeled each cycle. Results are shown for m, the maximum number of documents read, equal to one and also unconstrained.



Text

Two new studies have investigated why fewer women , compared to men , study and work in the so-called STEM subjects in the United States : science , technology , engineering and mathematics . The American Association of University Women (AAUW) examined existing research . Its report `` Why So Few ? " suggested ways to interest more girls and women in the STEM fields . The researchers found that cultural and environmental factors make a difference . Researcher Christianne Corbett says more boys than girls score very high on math

Active query: Researcher Christianne Corbett *Answer:* The researchers

Queries: the STEM fields The researchers Researcher Christianne Corbett Iceland

Overlapping Candidates

(1) The researchers

(n)o previous mention

(q)uery is not entity

Figure 8: On the user interface, the sampled span is highlighted and the user must select an antecedent. If no antecedents exist or the span is not an entity mention, then the user will click the corresponding buttons.

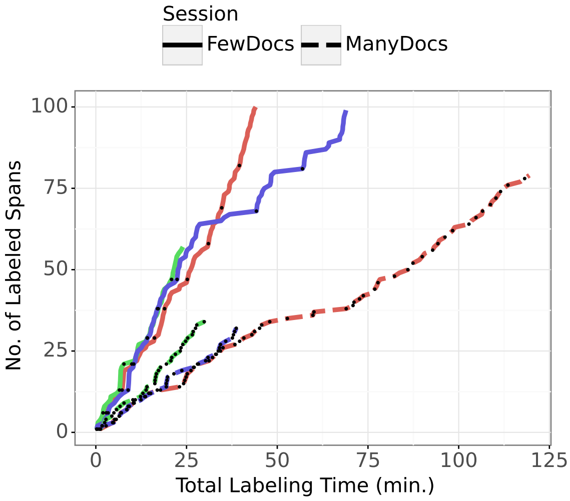


Figure 9: Full annotation times of participants (distinguished by color) during the user study. Over a longer period of time, the difference in number of labeled spans between the two sessions is much more pronounced. Within fourty-five minutes, the red user can label a hundred spans in the **FewDocs** session but only labels about thirty spans in the **ManyDocs** session.

User Interface We design a user interface for annotators to label coreference (Figure 8). The user interface takes the sampled spans from active learning as input. Afterward, it will present the document and highlight the sampled spans in the document. The user the proceeds to go through the list of "Queries". For the "Active query", they need to either: find its antecedent, mark there is "no previous mention", or indicate that "query is not an entity". The interface will suggest some overlapping candidates to help narrow down the user's search. The candidates are spans that the CR model scores as likely entity mentions. Users may use keyboard shortcuts to minimize labeling time. The code for the user interface is released along with the code for the simulations.

Extending Annotation Time User study participants are asked to annotate at least twenty-five minutes (Section 4.2). During the study, two participants continue to label after the minimum duration. Figure 9 shows full results from the user study. Over a longer duration, the differences between the **FewDocs** and **ManyDocs** sessions are clearer.

A.7 Examples of Sampled Spans

We provide examples of spans that are sampled from the experiments. For these examples, we look at the simulation where document reading is constrained to one document and twenty spans are sampled per cycle. We compare the spans sampled by each strategy for both PRECO (Table 4) and QBCOREF (Table 5). Across domains, the strategies behave similarly, but we notice some differences in **ment-ent** and **joint-ent**. In PRECO, those strategies tend to sample a mix of spans that are and are not entity mentions (Section 4.1.1). In QBCOREF, they sample more entity mentions. This could be due to more entity mentions present in a Quizbowl question, which makes it more likely to sample something that should belong to an entity cluster.

For other strategies, we notice some issues. As mentioned in Section 4.1.2, **li-clust-ent** tends to sample nested entity mentions, which may become redundant for annotators to label. In fact, AVG F_1 for **li-clust-ent** tends to be lower if document reading is constrained to one document. **Cond-ent** suffers from redundant labeling because pronouns are repeatedly sampled and they tend to link to the same entity cluster.

Strategy	Sampled Spans	Comments
random	Later, I got out of the back door secretly and gave the food to the old man, whose [name I had discovered]$_1$ was Taff. I had never seen anything else as lovely as the smile of satisfaction [on]$_2$ Taff's face when he ate the food. From then on, my visits to [the old house had]$_3$ a purpose, and I enjoyed every minute of the rest of my stay.	*Sampled spans are typically not entity mentions.*
random-ment	When opening the door, his face was full of smiles and he hugged [his two children and gave [his wife]$_2$ a kiss]$_1$. Afterwards, he walked with me to the car. We passed the tree. I was so curious that I asked [him]$_3$ about what I had [seen]$_4$ earlier.	*Diverse set of span types is sampled, including spans that are not entity mentions and ones that do link to entities.*
li-clust-ent	Although [he and [his young men]$_2$]$_1$ had taken no part in the killings, he knew that [the white men]$_3$ would blame [all of [the Indians]$_5$]$_4$.	*Many sampled spans are nested entity mentions.*
ment-ent	This summer, Republicans have been [meeting]$_1$ "behind closed doors" on a Medicare proposal scheduled to be released [later this month, only a few weeks before Congress votes]$_2$ on it, thereby avoiding independent analysis of the costs, mobilization by opponents and other inconvenient aspects of a long national debate. Two years ago, the Republicans rang alarms about the [Clinton]$_3$ plan's emphasis on [managed care]$_4$	*Sampled spans are both entity mentions and non-entities. The spans are difficult for mention detection like "meeting" but may also be hard for clustering like "Clinton".*

Abstract

We propose a framework for training non-autoregressive sequence-to-sequence models for editing tasks, where the original input sequence is iteratively edited to produce the output. We show that the imitation learning algorithms designed to train such models for machine translation introduces mismatches between training and inference that lead to undertraining and poor generalization in editing scenarios. We address this issue with two complementary strategies: 1) a roll-in policy that exposes the model to intermediate training sequences that it is more likely to encounter during inference, 2) a curriculum that presents easy-to-learn edit operations first, gradually increasing the difficulty of training samples as the model becomes competent. We show the efficacy of these strategies on two challenging English editing tasks: controllable text simplification and abstractive summarization. Our approach significantly improves output quality on both tasks and controls output complexity better on the simplification task.

1 Introduction

Neural sequence-to-sequence (seq2seq) models primarily developed and tested for machine translation (MT) Bahdanau et al. (2015); Vaswani et al. (2017); Gu et al. (2018) are increasingly used for other sequence transduction tasks. This paper focuses on *editing tasks*, such as post-editing of MT output (Simard et al., 2007), style transfer (Jin et al., 2020), or text simplification (Chandrasekar and Srinivas, 1997; Xu et al., 2015), where systems directly edit the input sequence, instead of generating the output from scratch as in MT. As illustrated in Table 1, in these tasks, there might be substantial overlap in content between inputs and outputs, and also diverse rewrites, ranging from local substitutions to more complex restructuring.

Original: The Mauritshuis museum is *staging an exhibition focusing* on the 17th century self-portraits, *highlighting* the similarities and the differences between *modern-day snapshots and historic works of art.*

Simplified: The Mauritshuis museum is *now set to open an exhibit* on the 17th century self-portraits. *It shows* the similarities and differences between *modern photos and artworks.*

Table 1: Text simplification is an editing task, where the output sequence overlaps with the input, while incorporating multiple rewrite types to restructure and simplify content.

While dedicated architectures have been designed for these editing tasks, based on e.g., a multistep, tag-then-edit approach (Alva-Manchego et al., 2017; Malmi et al., 2019; Dong et al., 2019; Mallinson et al., 2020), they can also be addressed with non-autoregressive (NAR) seq2seq models which generate their output by iteratively editing intermediate sequences (Lee et al., 2018; Gu et al., 2019; Awasthi et al., 2019; Stern et al., 2019; Chan et al., 2020). NAR models hold the promise of providing a more generic solution, where the model does not need to be tailored to a given editing task.

This work is centered on the hypothesis that training NAR models for editing tasks using the same strategy as for MT leads to a mismatch between train and test settings that limits their generalization ability and output quality. Specifically, the learning algorithms designed for MT are aligned with inference strategies that generate output from an empty initial sequence. By contrast, in sequence editing tasks, the inference step is initialized instead with the original input sequence. In addition, since editing samples might range from limited lexical substitutions to more thorough rewrites, training samples cover a wide range of edit distances. During training, the loss can thus be dominated by the more distant samples leading to undertrained models and poor generalization. By contrast, the

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 7550 - 7563

distance between input and output samples in MT is more uniform, since it always involves at least lexical translation of the input tokens.

To address these issues, we introduce a new training framework, EDITING CURRICULUM, which dynamically exposes the model to more relevant edit actions during training and exploits the full spectrum of available training samples more effectively. First, we design a new roll-in strategy, EDITING *roll-in*, that exposes the model to intermediate sequences that it is more likely to encounter during inference. Second, we introduce a training CURRICULUM to expose the model to training samples in order of increasing edit distance, thus gradually increasing the complexity of oracle edit operations that the model learns to imitate.

We show that our approach improves the quality of outputs on two challenging English text editing tasks: controllable text simplification (TS) and abstractive summarization. It also improves the degree of TS control by generating simplified outputs that match the target reading grade level better than the baselines. We conduct an extensive analysis which supports our hypothesis, and show that the sequences generated by our training policy improve exploration during training and are easier to learn from, leading to better generalization across samples with varying edit distances. Training with curriculum further improves output quality.

2 Background

Model NAR edit-based models (Chan et al., 2020; Gu et al., 2019; Stern et al., 2019; Xu and Carpuat, 2021) cast sequence editing as an iterative sequence refinement problem modeled by a Markov Decision Process $(\mathcal{Y}, \mathcal{A}, \mathcal{E}, \mathcal{R}, \boldsymbol{y}^0)$. A state $y = (y_1, y_2, ..., y_L) \in \mathcal{Y}$ is a sequence of tokens where each y_i represents a token from the vocabulary $\mathcal{V}$, L is the sequence length and $y^0 \in \mathcal{Y}$ is the initial sequence to be refined, using actions drawn from the set $\mathcal{A}$. The reward $\mathcal{R}$ is based on the distance $\mathcal{D}$ between the generated output and the reference sequence $y^* \in \mathcal{Y}$: $\mathcal{R}(y) = -\mathcal{D}(y, y^*)$. At each decoding iteration, the model takes an input y, chooses an action $a \in \mathcal{A}$ to refine the sequence using a policy π, resulting in state $\mathcal{E}(y, a)$.

Models differ based on the nature of edit actions used and support different operations such as insertion, deletion, reposition and substitution. We select the operations from the EDITOR model based on its competitive performance on constrained decoding tasks that require editing non-empty initial sequences (Xu and Carpuat, 2021). It is a Transformer model that uses two types of actions or edits on sequences, y:

1. The **reposition** operation, modeled by π_{rps}, predicts the new position of each token in the input sequence. For each input position, the reposition policy predicts a value r that corresponds to the index of the input token to be placed at the position and 0 if the input token is to be deleted.
2. The **insertion** operation has two components: *placeholder prediction*, π_{plh} that predicts the number of placeholders to be inserted and *token prediction*, π_{ins} that generates the actual output tokens for each placeholder.

At each decoding iteration, the model applies an action a that consists of a reposition and an insertion operation. This refinement process is repeated until two consecutive decoding iterations return the same output (Gu et al., 2019), or a preset maximum number of them is reached (Lee et al., 2018; Ghazvininejad et al., 2019).

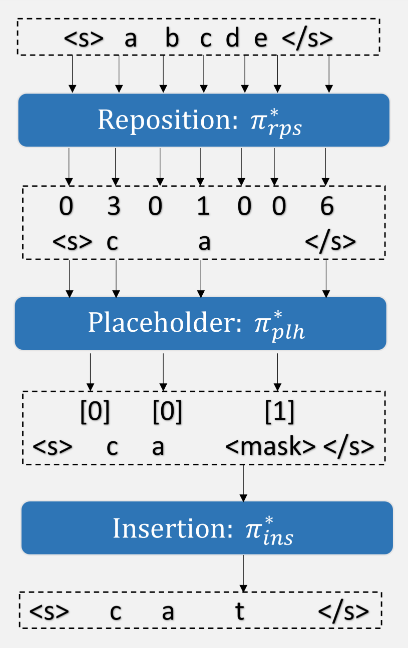

Figure 1: One refinement iteration for the input sequence: "a b c d e" using the operations generated by the Levenshtein Edit Distance Algorithm.

Training NAR models are typically trained via imitation learning that uses a roll-in policy and a roll-out policy. The roll-in policy is used to generate the sequences that the model learns to refine

	OPERATIONS	Roll-In	ROLL-IN POLICIES
Gu et al. (2019)	Insertion, Deletion	Mixed	$y' = \{\mathcal{E}(y^*, \tilde{d}), \tilde{d} \sim \pi_{rnd}\}$ $y_{ins} = \{y' \text{ if } u < \alpha \text{ else } \mathcal{E}(y^s, d^*), d^* \sim \pi^*_{del}\}$ $y_{del} = \{y^s \text{ if } u < \beta \text{ else } \mathcal{E}(\mathcal{E}(y_{ins}, p^*), \tilde{t}), p^* \sim \pi^*_{plh}, \tilde{t} \sim \pi_{ins}\}$

Xu and Carpuat (2021)	Insertion, Reposition (including deletions)	Learned	$y' = \{\mathcal{E}(\mathcal{E}(y^*, \tilde{d}), \tilde{p}), \tilde{d} \sim \pi_{rnd}, \tilde{p} \sim \pi_{per}\}$ $y_{ins} = \{y' \text{ if } u < \alpha \text{ else } \mathcal{E}(y, r), r \sim \pi_{rps}\}$ $y_{rps} = \{y' \text{ if } u < \beta \text{ else } \mathcal{E}(\mathcal{E}(y, p^*), \tilde{t}), p^* \sim \pi^*_{plh}, \tilde{t} \sim \pi_{ins}\}$

Table 2: Training Policies and Edit Operations performed by different NAR models: y^s: original input sequence, y^*: output sequence, y: model generated variant of reference sequence, π_{rnd}/ π_{masks} drops/masks random words from y^* according to a distribution (e.g. uniform, bernoulli, etc.), π_p generates a permutation, $u :\sim Uniform[0, 1]$, $\pi_{ins}, \pi_{plh}, \pi_{del}, \pi_{rps}$ are insertion, placeholder prediction, deletion and reposition policies.

from. A roll-out policy is then used to estimate the cost-to-go from the generated roll-in sequences to the desired output sequences. The cost-to-go is calculated by comparing the model actions to oracle demonstrations. We summarize the policies of various NAR models proposed for MT in Table 2.

For EDITOR, the roll-in sequences for the reposition (or insertion) module are stochastic mixtures (parameterized by α or β) of the output of the insertion (or reposition) module or a noised version of the output sequence. The oracle is the Levenshtein edit distance (Gu et al., 2019). The noisy sequence is generated by applying random word dropping (Gu et al., 2019) and random word shuffle (Lample et al., 2018) with a probability of 0.5 and maximum shuffle distance of 3. Figure 1 shows an example instantiation of the edit actions generated by the Levenshtein Edit Distance to transform the original input sequence ("a b c d e") to the output sequence ("c a t"). In this example, the oracle action is to delete the tokens ["b", "d", "e"], reposition "a" and "c" and insert "t" at the appropriate position. The reposition and the insertion modules are trained in a supervised fashion to predict these oracle operations during training.

3 Our Approach: EDITING CURRICULUM

To tailor training to editing tasks, we propose to modify the roll-in policy to better match the intermediate sequences encountered at inference, and introduce a curriculum to increase the difficulty of oracle actions learned throughout training.

EDITING Roll-in Sequences generated using the roll-in policy control the search space explored during training. Those sequences should therefore be representative of the intermediate sequences generated at inference time (Ross and Bagnell, 2010). While typically, the roll-in policy is a stochastic mixture of the model and the expert demonstrations as described above, the noise incurred early on due to the large difference between the expert demonstration and the learner's policy actions may hurt overall performance (Brantley et al., 2019; He et al., 2012; Leblond et al., 2018). As we will see (§5), this is what happens on editing tasks when training the model to imitate experts using learned roll-in sequences. At the same time, rolling in with expert demonstrations raises its own issues, as it can limit the exploration of the search space.

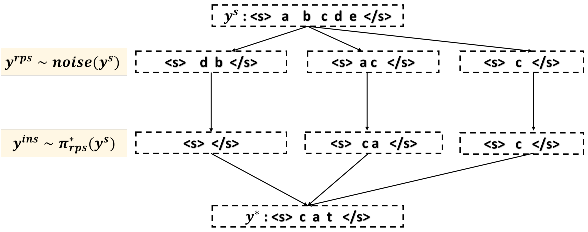

Figure 2: Example roll-in sequences for the reposition and the insertion modules: The same initial input sequence (y^s) can enable the model to learn to generate the reference output (y^*) using different edit operations from its noised version.

Motivated by these observations, we propose a new policy, EDITING, that allows exploration by injecting noise to the input sequence to generate new intermediate sequences for training. This lets the model learn to fix errors without deviating from learning the task at hand. Figure 2 shows an example of intermediate sequences generated by our proposed roll-in policy. Different intermediate sequences encourage the model to learn differ-

```
Algorithm 1: Our proposed framework: EDITING CURRICULUM
Input: Dataset, $D = \{y, y^*\}_{i=1}^{M}$, difficulty scoring function, $d$, and competence function, $c$.
Compute the difficulty, $d(s_i)$, for each $s_i = \{y_i, y_i^*\} \in D$.
Compute the cumulative density function (CDF) of the difficulty scores. This results in one
  difficulty CDF score per sample, $\tilde{d}(s_i) \in [0, 1]$
Initialize $\pi_{rps}$ and $\pi_{ins}$.
for training step $t = 1 ... T$ do
    Compute the competence value, $c(t)$.
    Create training dataset from by selecting all samples, $B_t$ using $s_i \in D$, such that $\tilde{d}(s_i) \leq c(t)$.
    for $i$ in $1..|B_t|$ do
        Generate roll-in sequences:
          $y_{rps} = noise(y^s)$
          $y_{ins} = \mathcal{E}(y_{rps}, r^*), r^* \sim \pi^*_{rps}$
        Train $\pi_{rps}$ and $\pi_{ins}$ on $y_{rps}$ and $y_{ins}$ minimizing cost-to-go to $y^*$.
Return best $\pi_{rps}$ and $\pi_{ins}$ evaluated on validation set.
```

ent reposition and insertion edit operations starting from the same input sequence, hence enabling exploration. We modify the roll-in policies to be aligned with the editing inference process, where the reposition operation is followed by insertion on the original input sequence:

- The roll-in sequence for training the reposition module, π_{rps}, is generated by applying noise to the original source sequence y^s, i.e. $y_{rps} = noise(y^s) = \{\mathcal{E}(\mathcal{E}(y^s, \tilde{d}), \tilde{p}), \tilde{d} \sim \pi_{rnd}, \tilde{p} \sim \pi_{per}\}$. Unlike EDITOR, the random word dropping ($\tilde{d} \sim \pi_{rnd}$) and the word shuffling ($\tilde{p} \sim \pi_{per}$) are applied to the original input sequence instead of the output sequence. This aligns the training with the inference scenario where the model edits an original input sequence instead of generating an output from scratch.

- The roll-in sequence for training the insertion module, π_{ins} is an intermediate sequence generated by applying the expert reposition policy to y_{rps}, i.e. $y_{ins} = \{\mathcal{E}(y_{rps}, r^*), r^* \sim \pi^*_{rps}\}$. The expert reposition policy corresponds to the deletion and reposition actions derived by using the levenshtein edit distance algorithm between the noisy input sequence, $noise(y^s)$ and the target sequence, y^*.

Curriculum controlled roll-out To prevent undertraining when samples with large edit distances overwhelm the loss, we use a curriculum to expose the model to easy-to-learn actions first, then gradually increase the difficulty of the edit-operations performed as the learner becomes more competent. Prior work on curriculum learning (CL) does not agree on standard measures of sample difficulty for seq2seq tasks (Kumar et al., 2019; Yao et al., 2021; Zhang et al., 2018; Zhou et al., 2020) or apply CL for the different problem of shifting the training of a Transformer model from AR to NAR regimes (Guo et al., 2020; Liu et al.). By contrast, in our settings, the Levenshtein distance provides a measure of difficulty that directly aligns with the model design and the training oracle.

Resulting Algorithm Given a training dataset $\mathcal{D} = \{y^s, y^*\}_{i=1}^{M}$ consisting of $\mathcal{M}$ samples, the difficulty score $d(s_i)$ for each sample $s_i = \{y_i^s, y_i^*\} \in \mathcal{D}$ is measured by the Levenshtein Distance between the input and the output sequence. The cumulative density function (CDF) of the difficulty scores results in one difficulty CDF score per sample, $\tilde{d}(s_i)$. At each training step t, we estimate the progress made by the learner by computing the competence of the model $c(t) \in (0, 1]$ as follows:

$$c_{\text{sqrt}}(t) = \min\left(1, \sqrt{t\frac{1 - c_0^2}{\lambda_t} + c_0^2}\right)$$

where, λ_t defines the length of the curriculum[1]; $c_0 = 0.1$ as in Platanios et al. (2019).

Based on this competence value $c(t)$, the model is then trained on all the samples whose difficulty as measured by the Levenshtein distance between the input and the output sequence is lower than that

---

[1] We set the curriculum length to 5K for our experiments.

competence value, i.e. $\tilde{d}(s_i) \leq c(t)$. The resulting algorithm is also shown in Algorithm 1.

4 Experimental Settings

We evaluate our approach on Controllable Simplification and Abstractive Summarization, two challenging sequence editing tasks that are motivated by real world information access needs. They are challenging because they require learning to perform a wide range of rewrites (from local substitution to sentence restructuring).

4.1 Controllable Simplification

Task Definition Given a complex text and a target grade level, the goal is to generate a simplified output that is appropriate for the desired grade level. The type of operations performed across different grade levels span sentence splitting, paraphrasing, deletion, content elaboration and substitution.

Data We use English Newsela samples as extracted by Agrawal and Carpuat (2019) with 470k/2k/19k for training, development and test sets respectively. Grade side-constraints are defined using a distinct special token for each grade level (from 2 to 12) and are introduced as side constraints for both the input and the output grade levels Scarton and Specia (2018).

Evaluation Metrics We automatically evaluate truecased detokenized system outputs using: **SARI** (Xu et al., 2016), which measures the lexical simplicity based on the n-grams kept, added, and deleted by the system relative to the input and the output sequence. It computes the F1 score for the n-grams that are added (**add-F1**). The model's deletion capability is measured by the F1 score for n-grams that are kept (**keep-F1**) and precision for the n-grams that are deleted (**del-P**) [2]; **Pearson's correlation coefficient (PCC)** between the complexity of the system and reference outputs as measured by Automatic Readability Index (ARI) (Senter and Smith, 1967) and **ARI-Accuracy** (Heilman et al., 2008) representing the percentage of sentences where the system output grade level is within 1 grade of the reference text according to the ARI.

4.2 Abstractive Summarization

Task Given a short paragraph (one or two sentences on average), the goal is to generate a concise summary that captures the salient ideas of the source text. It contains heavy deletions with moderate amounts of substitutions and frequent shifts caused by re-orderings.

Data We use the dataset from Toutanova et al. (2016), which contains 6K short input texts, with upto 5 summaries each. We use the same split as provided by the authors with 4937/448/786 unique input texts in the training, development and test sets respectively. The human experts were allowed to insert new words and reorder parts of the sentence when generating the summary, which makes this dataset particularly suited for abstractive summarization models.

Evaluation Metrics We automatically evaluate truecased detokenized system outputs using: **Rouge-L**[3](Lin, 2004). Even though it is not a summarization metric, we also report **SARI** to track the nature and type of edit operations performed. Given multiple references for each input text, we define the corpus level score as the arithmetic mean of automated metrics at the instance level, which is further averaged across the multiple references.

4.3 Model configurations

Data Preprocessing We pre-process all data using Moses tools for normalization, and truecasing. We apply subword segmentation with a joint input-output byte pair encoding model with $32,000$ operations. We use ARI to compute the input grade level at the inference time.

Architecture We adopt the base Transformer architecture (Vaswani et al., 2017) with d_{model} = 512, d_{hidden} = 2048, n_{heads} = 8, n_{layers} = 6, and $p_{dropout}$ = 0.1 for all our models. We add dropout to embeddings (0.1) and label smoothing (0.1). The base EDITOR model is trained using Adam with initial learning rate of 0.0005 and a batch size of $16,000$ tokens. The model is further fine-tuned on the editing task with a learning rate of 0.0001. We train all our models on two GeForce GTX 1080Ti GPUs. The average training time for a single seed of AR model is $\sim$8-9 hrs and for the EDITOR model is $\sim$20-22 hrs. Fine-tuning EDITOR takes additional 5-6 hrs. Training stops after 8 checkpoints without improvement of validation perplexity. All models are implemented using the Fairseq toolkit.

[3] `https://github.com/pltrdy/rouge`

Models We compare our proposed approaches against the following models trained from scratch in controlled conditions: 1) **`AR`** is a auto-regressive (AR) transformer model (Scarton and Specia, 2018). 2) We train EDITOR with the dual-path roll-in policy as in Xu and Carpuat (2021), refered to as **`From Reference`**. We fine-tune EDITOR with the following policy variants: 3) **`From Input`** replaces the reference with the input for generating the initial sequence as in Agrawal et al. (2021). 4) **`Editing`** is our proposed roll-in policy. 5) **`Editing Curriculum`**, EDITCL, refers to our approach as described in §3. During inference, we start from the input sequence (y^s), which is refined iteratively by applying a sequence of actions, as described in §2 until 1) the output sequences from two consecutive iterations are the same, or 2) the maximum number of decoding steps ($N = 10$) is reached. The edit distance between two sequences is measured by the Levenshtein edit distance (Levenshtein et al., 1966).

5 Findings

Controllable Simplification As can be seen in Table 3, our overall training framework, `EDITCL` improves over the prior training strategy for EDITOR— `From Reference` — significantly for all metrics (SARI: +3.8, PCC: +0.091, ARI-Acc: +10.1%), and over the AR baseline. Ablations show that this is a combined effect of multiple factors. Dual-path roll-in, `From Input` improves over `From Reference` as expected (SARI: +1.9, PCC: $+0.077$, ARI-Acc: $+8.0\%$), as the roll-in sequences encountered during training are similar to those encountered during inference. Using expert roll-in (`EDITING`) performs better than using learned roll-in (dual-path roll-in) across the board, with gains of up to 3 SARI points over `From Reference`. Training with CL (`EDITCL`) improves over the best roll-in strategy[4], improving the precision of deletions (+1.6) and leading to a significant improvement in SARI score (+0.7) over `EDITING` with no significant change in grade-specific metrics.

We also report training and inference statistics. For training, we report the number of training updates to convergence, i.e. when the model achieves the best validation perplexity on the development dataset. For inference, we report the average number of actions taken by the model to generate the refined output counts. Each iteration encompasses a reposition operation followed by an insertion applied to the all the tokens in the input sequence in parallel. CL reduces the average number of actions needed to generate outputs compared to `EDITING`, while taking only $\sim$ 2K more updates during training than `From Input`. These results show that our roll-in policy, EDITING and the curriculum play a complementary role in improving training for editing.

Abstractive Summarization On the Abstractive Summarization task (Table 4), `EDITCL` achieves the best performance across the board compared to alternative training strategies for EDITOR with gain of upto ~ 4 SARI, and ~ 3 ROUGE points. Our proposed approach improves the precision of the deletion operation (DEL-P, $+7$). It also preserves the tokens from the source sequence that are present in the reference suggested by the improvement in KEEP-F1($+3.9$) over the EDITOR (`From Reference`) model.

For completeness, we also compare our approach with systems trained in prior work: (1) ILP (Clarke and Lapata, 2008), an integer linear programing approach for deletion-based compression, (2) T3 (Cohn and Lapata, 2008), a tree transducer-based model for abstractive compression, (3) SEQ2SEQ (Filippova et al., 2015), a neural network model for deletion-based compression, (4) NAMAS (Rush et al., 2015), a neural model for abstractive compression and summarization and (5) FELIX (Mallinson et al., 2020), a non-autoregressive approach to text editing. We use the outputs provided by Toutanova et al. (2016) for [1-4] and Mallinson et al. (2020) for [5]. We endeavored to make the comparison as fair as possible[5], but it is not possible to have a fully controlled comparison. In particular, FELIX is trained on uncased data and generates uncased outputs, while we train and evaluate our models with truecasing.

When evaluated using our pipeline, our training strategy applied to generic NAR models achieve scores that are on par with, or better than, those of dedicated summarization models (Table 5). However, this evaluation penalizes FELIX as it is trained to address the simpler problem of sum-

---

[4] As the order of the training samples as governed by our curriculum strategy will be same for `From Input`, `EDITING`, we only report results over the best roll-in strategy.

[5] We detokenized and manually checked the outputs from Mallinson et al. (2020) and corrected for de-tokenization errors such as “1. 23” to “1.23” and “wanda ’s” to “wanda’s”.

6 Analysis

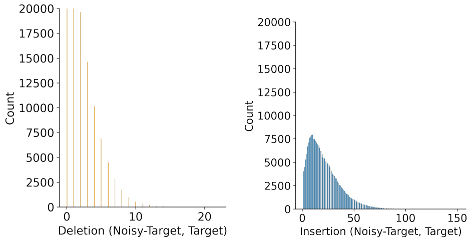
We conduct further experiments to better understand the factors that help our training strategies improve editing quality.

6.1 Impact of EDITING roll-in

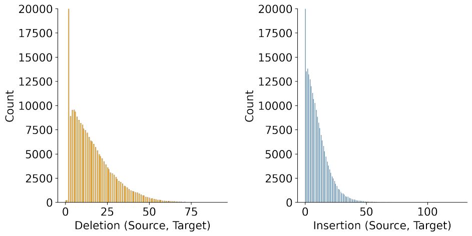
First, we seek to measure whether our approach has the intended effect of bridging the gap between training and test for editing tasks. Figure 3 shows the distribution of oracle insertion and deletions observed when (a) training with EDITOR ś default roll-in policy; (b) refining an original input sequence and (c) exposed to the model with our EDITING roll-in policy for Controllable TS. The plots show that with the default learning policy of the Editor model, the model doesn't learn to perform complex deletion operation at inference time. By contrast, our proposed roll-in exposes the model to the distribution that has higher overlap with the inference distribution as as well as additional intermediate sequences that encourages exploration during training.

6.2 Impact of Curriculum Controlled roll-out

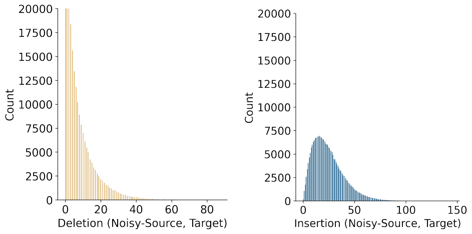
Training Dynamics To verify that curriculum learning helps our model better exploit its training data, we train EDITOR on $x\% \in [0, 100]$ of the data, and compare using random samples with samples ranked by increasing edit distance. Figure 4 shows the number of updates to convergence on the development dataset for controllable simplification with/without CL. Training converges early (70 iterations only) on 13% of the easiest



(a) EDITOR ś roll-in (Training)



(b) Inference Distribution



(c) EDITING roll-in (Training)

Figure 3: Distribution of Oracle Edit Operations (*Insertions*/*Deletions*) observed on Controllable TS. Our proposed roll-in policyś distribution of edit operations is closer to the inference distribution, while enabling exploration during training.

samples with oracle edit distance between the input and the output sequence $<= 2$. This supports the hypothesis that despite adding noise, our approach yields easier examples to train on. The order in which samples are presented matters, as adding batches with larger edit distance ($> 63\%$ data) without maintaining the order of the samples converges early. By contrast, the curriculum pacing function adds samples in order of increasing difficulty, allowing the model sufficient training time to learn from new samples while improving overall performance across metrics.

We also report the learning curves when training EDITOR on the Newsela dataset in Figure 5. Training with curriculum reduces the overall loss consistently on the development dataset, leading to better generalization.

Ranking Criteria We compare the edit-distance (EDITCL) with other curriculum criteria in Table 6 where the order of examples is a) random, b) controlled by the length ratio between source and target sequence (Length Ratio), c) governed by the difference between the source and target grade levels (Grade Difference). Our proposed criterion outperforms both task-specific (`Grade Difference`) and task-agnostic criteria (`Length Ratio`) on the Newsela Grade development set across all the metrics. `Length Ratio` achieves better correlation with Edit distance than `Grade Difference` which is also reflected by its performance (SARI: +0.3, PCC: 0.032, ARI: 0.7) on the Controllable Simplification task. This might reflect the fact that higher grade differences do not necessarily require more edits to be performed, for instance when the sentence to be simplified is already relatively simple. These mismatches do not occur when the edit distance itself is used as the sample difficulty criterion.

Criteria	**SARI**	**PCC**	**% ARI-Acc**	**Corr.**
Random	40.7	0.749	38.6	-
Length Ratio	41.0	0.762	39.0	0.26
Grade Difference	40.7	0.730	38.3	0.19
EDITCL	42.0	0.758	39.6	1.00
- EDITING roll-in	40.1	0.734	37.8	-
- CL	41.2	0.742	39.3	-

Table 6: On Newsela-grade dev dataset: Using Edit distance as the difficulty criteria improves over both task-specific (Grade Difference) and task-agnostic (Length ratio) criteria. Our proposed EDITING roll-in and curriculum-controlled roll-out provides complementary advantages to the model training.

Complementarity of roll-in and roll-out design We report the performance of the `From Input` model, when trained with curriculum only without the EDITING policy, i.e. `EDITCL- EDITING` in the same Table 6. Both `EDITING` roll-in and curriculum controlled roll-out provides complementary advantages to the model training as removing either results in the drop in performance across all the metrics for controllable TS. However, we observe larger drop in the scores when we do not apply the EDITING policy which shows that our proposed roll-in policy is necessary to reap the benefits of curriculum learning.

7 Related Work

NAR models They have been used to enable parallel generation of output tokens for Machine translation. (Stern et al., 2019; Chan et al., 2020; Xu and Carpuat, 2021). Mallinson et al. (2020) design a custom multi-step non-autoregressive edit-based model for sequence editing where each source to-

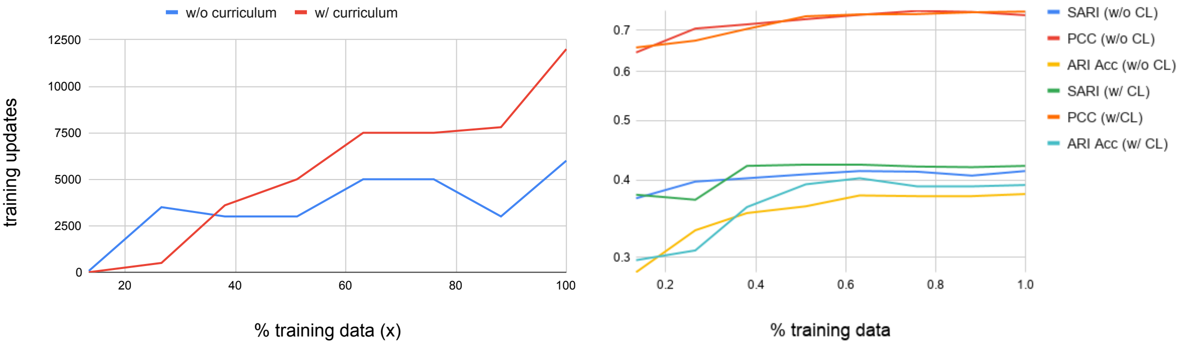


Figure 4: The sample order during training matters as training without curriculum on the same amount of data ($>= 40\%$) converges early (plot on the left) and to lower performance across all metrics (plot on the right) relative to training with curriculum using the same data.

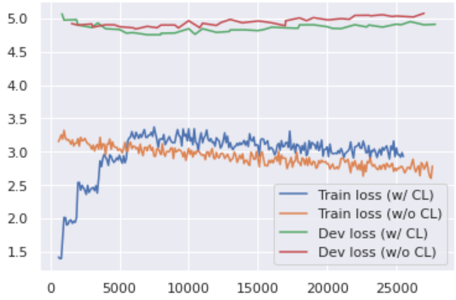

Figure 5: Training with curriculum reduces the loss on the development dataset leading to better generalization on Controllable TS.

ken is first tagged to represent the type of edit operation to be performed and then a secondary model is used to in-fill new tokens. The tagging and editing models are trained independently. By contrast, we propose approaches to adapt NAR models designed for MT for these tasks and train an end-to-end model to generate an edited sequence.

Curriculum Learning for Sequence Refinement While curriculum learning has been applied to many tasks such as MT (Haffari, 2009; Platanios et al., 2019; Kumar et al., 2019), sentiment analysis (Sido and Konopík, 2019), natural language understanding (Xu et al., 2020), reading comprehension (Tay et al., 2019), their application to sequence refinement tasks has not been explored yet. Various strategies have been proposed to control the sample difficulty like n-gram frequency (Haffari, 2009; Platanios et al., 2019), token rarity, and sentence length (Liu et al., 2020). Chang et al. (2021) use Levenshtein edit distance as a sample difficulty criteria to order the samples for the task of data-to-text generation where the training model uses an AR seq2seq model. Instead, we focus on edit distance as a sample difficulty criteria that is directly tied to the training oracle and model design.

Roll-in policies There has been a plethora of work in the Imitation learning landscape on algorithms that strike a balance between learned and expert roll-in policies (Ross et al., 2011; Venkatraman et al., 2015; Chang et al., 2015). However, large differences in expert and learner's policy action can hurt performance (Brantley et al., 2019; He et al., 2012; Leblond et al., 2018). In our work, we propose to roll-in with noised states instead, so that the model can be exposed to mimic expert demonstrations from states that the model is more likely to encounter during inference.

8 Conclusion

This paper introduced two complementary strategies to address undertraining and poor generalization when adapting NAR models to editing tasks: 1) a new roll-in policy that generates intermediate sequences that the model is likely to encounter during inference and 2) a curriculum to control the difficulty of the roll-out policy which estimates the cost-to-go from the roll-in sequences to the desired output sequences, throughout training. Together, these strategies improve output quality consistently on controllable simplification and abstractive summarization. These results open space for further research to evaluate the potential of this approach for other editing tasks (e.g., post editing, style transfer), and to further tailor imitation learning policies and curriculum design to these tasks.

Abstract

State-of-the-art pre-trained language models have been shown to memorise facts and perform well with limited amounts of training data. To gain a better understanding of how these models learn, we study their generalisation and memorisation capabilities in noisy and low-resource scenarios. We find that the training of these models is almost unaffected by label noise and that it is possible to reach near-optimal results even on extremely noisy datasets. However, our experiments also show that they mainly learn from high-frequency patterns and largely fail when tested on low-resource tasks such as few-shot learning and rare entity recognition. To mitigate such limitations, we propose an extension based on prototypical networks that improves performance in low-resource named entity recognition tasks.

1 Introduction

With recent advances in pre-trained language models (Peters et al., 2018; Devlin et al., 2019; Liu et al., 2019; He et al., 2020), the field of natural language processing has seen improvements in a wide range of tasks and applications. Having acquired general-purpose knowledge from large amounts of unlabelled data, such methods have been shown to learn effectively with limited labelled data for downstream tasks (Howard and Ruder, 2018) and to generalise well to out-of-distribution examples (Hendrycks et al., 2020).

Previous work has extensively studied *what* such models learn, e.g. the types of relational or linguistic knowledge (Tenney et al., 2019; Jawahar et al., 2019; Rogers et al., 2020). However, the process of *how* these models learn from downstream data and the qualitative nature of their learning dynamics remain unclear. Better understanding of the learning processes in these widely-used models is needed in order to know in which scenarios they will fail and how to improve them towards more robust language representations.

The fine-tuning process in pre-trained language models such as BERT (Devlin et al., 2019) aims to strike a balance between generalisation and memorisation. For many applications it is important for the model to generalise—to learn the common patterns in the task while discarding irrelevant noise and outliers. However, rejecting everything that occurs infrequently is not a reliable learning strategy and in many low-resource scenarios memorisation can be crucial to performing well on a task (Tu et al., 2020). By constructing experiments that allow for full control over these parameters, we are able to study the learning dynamics of models in conditions of high label noise or low label frequency. To our knowledge, this is the first qualitative study of the learning behaviour of pre-trained transformer-based language models in conditions of extreme label scarcity and label noise.

We find that models such as BERT are particularly good at learning general-purpose patterns as generalisation and memorisation become separated into distinct phases during their fine-tuning. We also observe that the main learning phase is followed by a distinct performance plateau for several epochs before the model starts to memorise the noise. This makes the models more robust with regard to the number of training epochs and allows for noisy examples in the data to be identified based only on their training loss.

However, we find that these excellent generalisation properties come at the cost of poor performance in few-shot scenarios with extreme class imbalances. Our experiments show that BERT is not able to learn from individual examples and may never predict a particular label until the number of training instances passes a critical threshold. For example, on the `CoNLL03` (Sang and De Meulder, 2003) dataset it requires 25 instances of a class to

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 7564 - 7578

learn to predict it at all and 100 examples to predict it with some accuracy. To address this limitation, we propose a method based on prototypical networks (Snell et al., 2017) that augments BERT with a layer that classifies test examples by finding their closest class centroid. The method considerably outperforms BERT in challenging training conditions with label imbalances, such as the `WNUT17` (Derczynski et al., 2017) rare entities dataset.

Our contributions are the following: 1) We identify a second phase of learning where BERT does not overfit to noisy datasets. 2) We present experimental evidence that BERT is particularly robust to label noise and can reach near-optimal performance even with extremely strong label noise. 3) We study forgetting in BERT and verify that it is dramatically less forgetful than some alternative methods. 4) We empirically observe that BERT completely fails to recognise minority classes when the number of examples is limited and we propose a new model, ProtoBERT, which outperforms BERT on few-shot versions of `CoNLL03` and `JNLPBA`, as well as on the `WNUT17` dataset.

2 Previous work

Several studies have been conducted on neural models' ability to memorise and recall facts seen during their training. Petroni et al. (2019) showed that pre-trained language models are surprisingly effective at recalling facts while Carlini et al. (2019) demonstrated that LSTM language models are able to consistently memorise single out-of-distribution (OOD) examples during the very first phase of training and that it is possible to retrieve such examples at test time. Liu et al. (2020) found that regularising early phases of training is crucial to prevent the studied CNN residual models from memorising noisy examples later on. They also propose a regularisation procedure useful in this setting. Similarly, Li et al. (2020) analyse how early stopping and gradient descent affect model robustness to label noise.

Toneva et al. (2019), on the other hand, study forgetting in visual models. They find that models consistently forget a significant portion of the training data and that this fraction of forgettable examples is mainly dependent on intrinsic properties of the training data rather than the specific model. In contrast, we show that a pretrained BERT forgets examples at a dramatically lower rate compared to a BiLSTM and a non-pretrained variant.

Memorisation is closely related to generalisation: neural networks have been observed to learn simple patterns before noise (Arpit et al., 2017) and generalise despite being able to completely memorise random examples (Zhang et al., 2017). Zhang et al. (2021) also show that our current understanding of statistical learning theory cannot explain the superhuman generalisation performance of large neural models across many areas of study.

Hendrycks et al. (2020) show that pre-trained models generalise better on out-of-distribution data and are better able to detect such data compared to non-pretrained methods but that they still do not cleanly separate in- and out-of-distribution examples. Kumar et al. (2020) find that pre-trained methods such as BERT are sensitive to spelling noise and typos. In contrast to noise in the input, we focus on the models' learning dynamics in the presence of label noise and find that pre-trained methods are remarkably resilient to such cases.

3 Experimental setting

We investigate the performance of pre-trained language models in specific adverse conditions. In order to evaluate generalisation abilities, we first create datasets with varying levels of label noise by randomly permuting some of the labels in the training data. This procedure allows us to pinpoint noisy examples and evaluate the performance on clean and noisy datapoints separately. Then, in order to investigate memorisation we train the models on datasets that contain only a small number of examples for a particular class. This allows us to evaluate how well the models are able to learn from individual datapoints as opposed to high-frequency patterns. We make the code for the experiments available online.[1]

Datasets We focus on the task of named entity recognition (NER) and employ the `CoNLL03` (Sang and De Meulder, 2003), the `JNLPBA` (Collier and Kim, 2004), and the `WNUT17` (Derczynski et al., 2017) datasets. NER is commonly used for evaluating pre-trained language models on structured prediction and its natural class imbalance is well suited for our probing experiments. `CoNLL03` and `JNLPBA` are standard datasets for NER and Bio-NER respectively. The `WNUT17` dataset is motivated by the observation that state-of-the-art methods tend to memorise entities during training

---

[1] `https://github.com/Michael-Tanzer/BERT-mem-lowres`

(Augenstein et al., 2017). The dataset focuses on identifying unusual or rare entities at test time that cannot be simply memorised by the model. We evaluate based on entity-level F_1 unless stated otherwise.

Language models We use BERT-base (Devlin et al., 2019) as the main language model for our experiments, as BERT is widely used in practice and other variations of pre-trained language models build on a similar architecture. The model is augmented with a classification feed-forward layer and fine-tuned using the cross-entropy loss with a learning rate of 10^{-4}. AdamW (Loshchilov and Hutter, 2019) is used during training with weight decay of 0.01 and a linear warm-up rate of 10%. The test results are recorded using the model that produced the highest validation metrics.

We compare BERT's behaviour with that of other pre-trained transformers such as RoBERTa (Liu et al., 2019) and DeBERTa (He et al., 2020) fine-tuned with the same optimiser and hyperparameters as above. In order to also compare against non-transformer models, we report performance for a bi-LSTM-CRF (Lample et al., 2016) model with combined character-level and word-level representations. The model is comprised of 10 layers, with 300-dimensional word representations and 50-dimensional character representations, for a total of approximately 30 million trainable parameters. In our experiments, the model is trained with the Adam optimiser (Kingma and Ba, 2014) and a learning rate of 10^{-4} for 100 epochs using a CRF loss (Lafferty et al., 2001).

4 Generalisation in noisy settings

We first investigate how BERT learns general patterns from datasets that contain label noise. Figure 1 shows how the model performance on the `CoNLL03` training and validation sets changes when faced with varying levels of noise, from 0% to 50%. Based on the progression of performance scores, we can divide BERT's learning process into roughly three distinct phases:

1. **Fitting**: The model uses the training data to learn how to generalise, effectively learning simple patterns that can explain as much of the training data as possible (Arpit et al., 2017). Both the training and validation performance rapidly increase as the model learns these patterns.

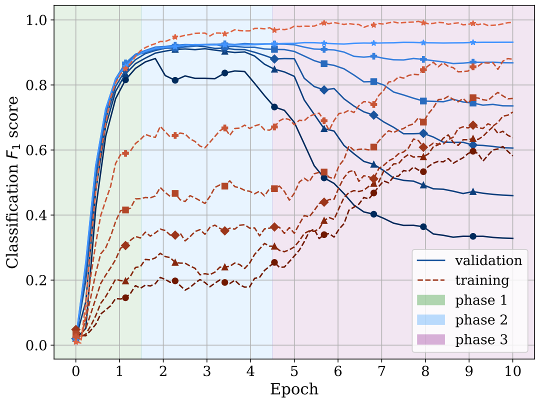

Figure 1: BERT performance (F_1) throughout the training process on the `CoNLL03` train and validation sets. Darker colours correspond to higher levels of noise (0% to 50%).

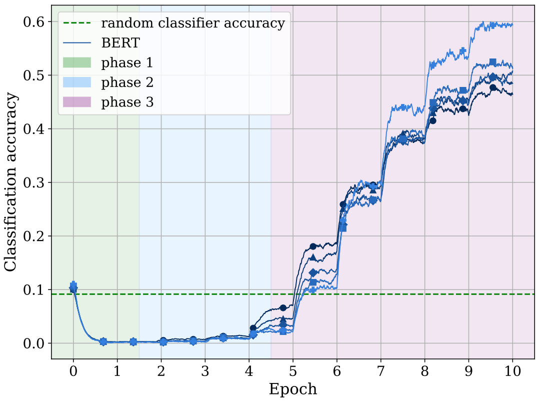

Figure 2: Classification accuracy of noisy examples in the training set for the `CoNLL03` dataset. Darker colours correspond to higher levels of noise (0% to 50%).

2. **Settling**: The increase in performance plateaus and neither the validation nor the training performance change considerably. The duration of this phase seems to be inversely proportional to the amount of noise present in the dataset.
3. **Memorisation**: The model rapidly starts to memorise the noisy examples, quickly improving the performance on training data while degrading the validation performance, effectively over-fitting to the noise in the dataset.

A second phase of learning We find BERT to exhibit a distinct second *settling* phase during which it does not over-fit. A resilience to label noise has been observed in other neural networks trained with gradient descent (Li et al., 2020). However, we find this phase to be much more prolonged in BERT compared to models pre-trained on other modalities such as a pre-trained ResNet fine-tuned on `CIFAR10`, which immediately starts memorising noisy examples (see Appendix A for a comparison). These results indicate that the precise point of early stopping is not as important when it comes to fine-tuning pre-trained language models. Similar optimal performance is retained for a substantial period, therefore training for a fixed number of epochs can be sufficient.

We illustrate BERT's behaviour by evaluating the token-level classification accuracy of noisy examples in Figure 2. During the second phase, BERT completely ignores the noisy tokens and correctly misclassifies them, performing "worse" than a random classifier. The step-like improvements during the third stage show that the model is unable to learn any patterns from the noise and improves by repeatedly optimising on the same examples, gradually memorising them.

Robustness to noise We also observe in Figure 1 that BERT is extremely robust to noise and overfitting in general. In the absence of noise, the model does not over-fit and maintains its development set performance, regardless of the length of training. Even with a large proportion of noise, model performance comparable to training on the clean dataset can be achieved by stopping the training process somewhere in the second phase.[2]

We also hypothesise that due to the robustness to noise shown in the second phase of training, a noise detector can be constructed based only on BERT's training losses, without requiring any other information. We find that a simple detector that clusters the losses using k-means reliably achieves over 90% noise-detection F_1 score in all our experiments, further showing how the model is able to actively detect and reject single noisy examples (see Appendix E for details about the noise detection process).

Impact of pre-training The above properties can mostly be attributed to BERT's pre-training process—after large-scale optimisation as a language model, the network is primed for learning general patterns and better able to ignore individual noisy examples. We find that a randomly initialised model with the same architecture does not only achieve lower overall performance but crucially does not exhibit's BERT's distinct second phase of learning and robustness to noise (see Appendix C).

Other pre-trained transformers We also analyse the behaviour of other pre-trained transformers for comparison. Specifically, studying RoBERTa and DeBERTa, we find the same training pattern that was observed in BERT—all models show a clear division into the three phases described above. These models are also all very robust to label noise during the *settling* phase of training. Notably, RoBERTa is even more resilient to label noise compared to the other two analysed models, despite DeBERTa outperforming it on public benchmarks (He et al., 2020). Training and validation performance visualisations, such as those in Figure 1, can be found for both models in Appendix I.

5 Forgetting of learned information

Evaluating only the final model does not always provide the full picture regarding datapoint memorisation, as individual datapoints can be learned and forgotten multiple times during the training process. Following Toneva et al. (2019), we record a *forgetting event* for an example at epoch t if the model was able to classify it correctly at epoch $t-1$, but not at epoch t. Similarly, we identify a *learning event* for an example at epoch t if the model was not able to classify it correctly at epoch $t-1$, but it is able to do so at epoch t. A *first learning event* thus happens at the first epoch when a model is able to classify an example correctly. We furthermore refer to examples with zero and more than zero forgetting events as *unforgettable* and *forgettable* examples, respectively, while the set of *learned* examples includes all examples with one or more learning events.

In Table 1, we show the number of forgettable, unforgettable, and learned examples on the training data of the `CoNLL03` and `JNLPBA` datasets for BERT, a non-pre-trained BERT, and a bi-LSTM model. We also show the ratio between forgettable and learned examples, which indicates how easily a model forgets learned information. We can observe that BERT forgets less than other models and that pre-training is crucial for retaining important information. We show the most forgettable examples in Appendix D, which tend to be atypical examples of the corresponding class.

Toneva et al. (2019) found that the number of forgetting events remains comparable across different architectures for the vision modality, given

---

[2] Adding 30% noise to the `CoNLL03` dataset causes only a 0.9% decrease of validation performance in the second phase.

Dataset	Model	Forgettable N_f	Unforgettable N_u	Learned N_l	N_f/N_l (%)
`CoNNL03`	bi-LSTM	71.06%	29.94%	90.90%	78.17%
	non-pre-trained BERT	9.89%	90.11%	99.87%	9.90%
	pre-trained BERT	2.97%	97.03%	99.80%	2.98%

	non-pre-trained BERT	25.50%	74.50%	98.24%	25.96%
	pre-trained BERT	16.62%	83.38%	98.18%	16.93%

Table 1: Number of forgettable, unforgettable, and learned examples during BERT training on the `CoNLL03` dataset and `JNLPBA` dataset.

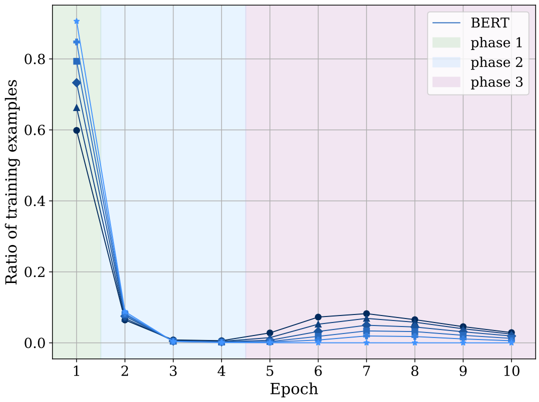

Figure 3: First learning events distribution during the training for various levels of noise on the `CoNLL03` dataset. Darker colours correspond to higher levels of noise (0% to 50%).

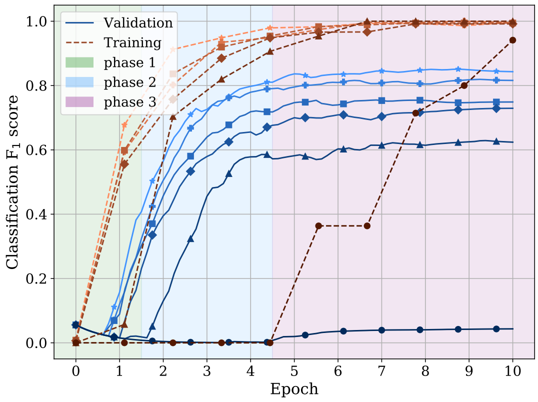

Figure 4: BERT performance (F_1) throughout the training process on the `CoNLL03` dataset with varying number of sentences containing the `LOC` class. Darker colours correspond to fewer examples of the `LOC` class available (5 to 95 in steps of 20).

a particular dataset.[3] However, our experiments show that the same does not necessarily hold for pre-trained language models. Specifically, there is a large discrepancy in the ratio between forgettable and learned examples for BERT (~3%) and a bi-LSTM model (~80%) on the `CoNLL03` dataset.

We additionally analyse the distribution of first learning events throughout BERT's training on `CoNLL03` with label noise between 0% and 50% (Figure 3) and notice how BERT learns the majority of learned examples during the first epochs of training. As the training progresses, we see that BERT stops learning new examples entirely, regardless of the level of noise for the third and fourth epochs. Finally, in the last epochs BERT mostly memorises the noise in the data.[4]

6 BERT in low-resource scenarios

In the previous sections, we have observed that BERT learns examples and generalises very early in training. We will now examine if the same behaviour applies in low-resource scenarios where a minority class is only observed very few times. To this end, we remove from the `CoNLL03` training set all sentences containing tokens with the minority labels `MISC` and `LOC` except for a predetermined number of such sentences. We repeat the process for the `JNLPBA` dataset with the `DNA` and `Protein` labels.

We conduct similar experiments to the previous sections by studying how different numbers of sentences containing the target class affect BERT's ability to learn and generalise. We report in Figure 4 the training and validation classification F_1 score for the `CoNLL03` datasets from which all but few (5 to 95) sentences containing the `LOC` label were removed. Note that the reported performance in this experiment refers to the `LOC` class only. In Figure 5 we also report the distribution of first learning

---

[3] They report proportions of forgettable examples for MNIST, PermutedMNIST, CIFAR10, and CIFAR100 as 8.3%, 24.7%, 68.7%, and 92.38% respectively.

[4] We conducted additional experiments on other datasets (see Appendix F for results on the `JNLPBA` dataset). In all cases we observe the same distribution of first learning events throughout training.

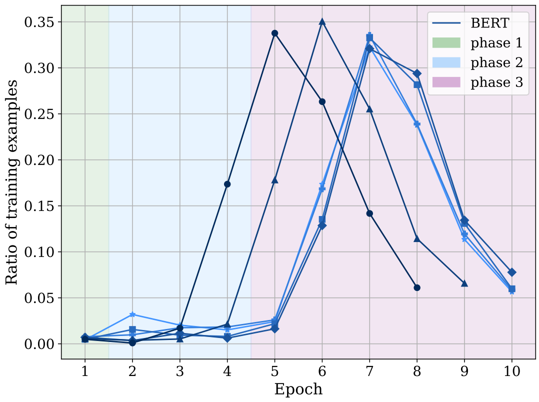

Figure 5: First learning events distribution during the training on the `CoNLL03` dataset with varying number of sentences containing the `LOC` class. Darker colours correspond to fewer examples of the `LOC` class available (5 to 95 in steps of 20).

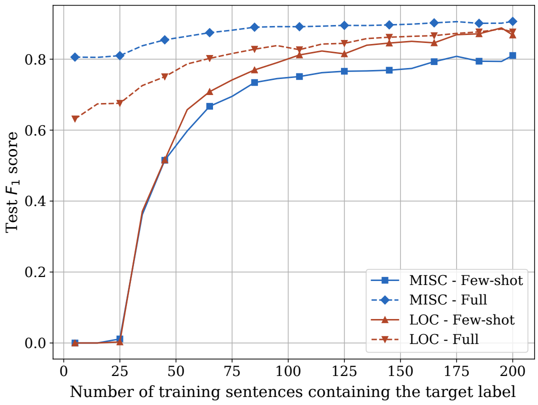

Figure 6: BERT final validation entity-level F_1 score on the few-shot class keeping varying numbers of sentences containing examples of a selected class on the `CoNLL03` dataset.

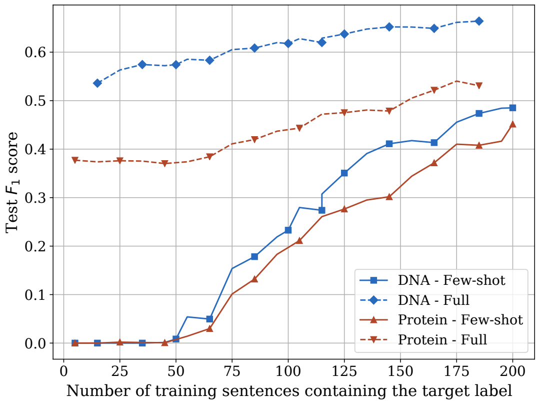

Figure 7: BERT final validation entity-level F_1 score on the few-shot class keeping varying numbers of sentences containing examples of a selected class on the `JNLPBA` dataset.

events for the `LOC` class in the same setting. Two phenomena can be observed: 1) reducing the number of sentences greatly reduces the model's ability to generalise (validation performance decreases yet training performance remains comparable); and 2) when fewer sentences are available, they tend to be learned in earlier epochs for the first time. Corresponding experiments on the `MISC` label can be found in Appendix J.

We also show the average entity-level F_1 score on tokens belonging to the minority label and the model performance for the full NER task (i.e. considering all classes) for the `CoNLL03` and `JNLPBA` datasets in Figures 6 and 7 respectively. For the `CoNLL03` dataset, we observe that BERT needs at least 25 examples of a minority label in order to be able to start learning it. Performance rapidly improves from there and plateaus at around 100 examples. For the `JNLPBA` dataset, the minimum number of examples increases to almost 50 and the plateau occurs for a higher number of examples. On the challenging `WNUT17` dataset, BERT achieves only 44% entity-level F_1. This low performance is attributable to the absence of entity overlap between training set and test set, which increases the inter-class variability of the examples.

7 ProtoBERT for few-shot learning

In order to address BERT's limitations in few-shot learning, we propose a new model, ProtoBERT that combines BERT's pre-trained knowledge with the few-shot capabilities of prototypical networks (Snell et al., 2017) for sequence labelling problems. The method builds an embedding space where the inputs are clustered on a per-class basis, allowing us to classify a token by finding its closest centroid and assigning it the corresponding class. The model can be seen in Figure 8.

We first define a support set S, which we use as context for the classification and designate with S_k all elements of S that have label k. We refer to the set of points that we want to classify as the query set Q, with $l(Q_i)$ indicating the label of the i^{th} element in Q. We will also refer to f as the function computed by BERT augmented with a linear layer, which produces an M dimensional output.

The model then classifies a given input $\mathbf{x}$ as follows: for each class k, we compute the centroid of the class in the learned feature space as the mean of all the elements that belong to class k in the

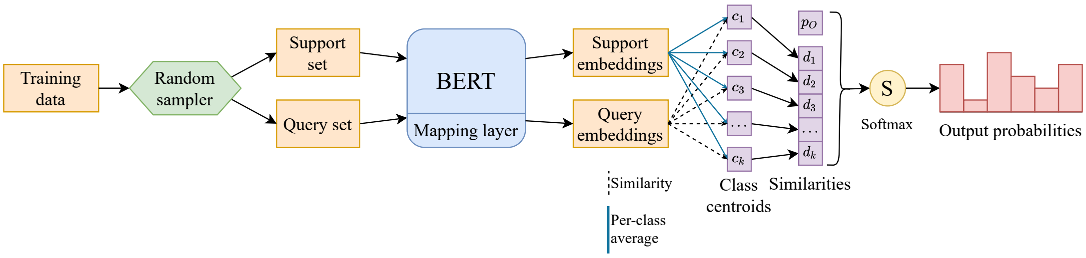

Figure 8: Schematic representation of the inference using a BERT model with a prototypical network layer.

support set S:

$$\mathbf{c}_k = \frac{1}{|S_k|} \sum_{\mathbf{x}_i \in S_k} f(\mathbf{x}_i) \tag{1}$$

Then, we compute the distance from each input $\mathbf{x} \in Q$ to each centroid:

$$dist_k = d(f(\mathbf{x}), \mathbf{c}_k)$$

and collect them in a vector $v \in \mathbb{R}^k$. Finally, we compute the probability of $\mathbf{x}$ belonging to class k as

$$p(y = k \mid \mathbf{x}) = \frac{\exp\left(-d\left(f(\mathbf{x}), \mathbf{c}_k\right)\right)}{\sum_{k'} \exp\left(-d\left(f(\mathbf{x}), \mathbf{c}_{k'}\right)\right)} = \\ = softmax(-v)_k$$

The model is trained by optimising the cross-entropy loss between the above probability and the one-hot ground-truth label of $\mathbf{x}$. Crucially, S and Q are not a fixed partition of the training set but change at each training step. Following Snell et al. (2017), we use Euclidean distance as a choice for the function d.

In order to take into account the extreme under-representation of some classes, we create the support by sampling s_1 elements from each minority class and s_2 elements from each non-minority class. A high ratio s_1/s_2 gives priority to the minority classes, while a low ratio puts more emphasis on the other classes. We then similarly construct the query set with a fixed ratio n between the minority classes and the non-minority classes.

For NER, rather than learning a common representation for the negative class “`O`”, we only want the model to treat it as a fallback when no other similar class can be found. For this reason, we define the vector of distances v as follows:

$$v = (d_O,\ dist_0,\ \ldots,\ dist_k)$$

where d_O is a scalar parameter of the network that is trained along with the other parameters. Intuitively, we want to classify a point as a *non-entity* (i.e. class `O`) when it is not close enough to any centroid, where d_O represents the threshold for which we consider a point “close enough”.

If no example of a certain class is available in the support set during the training, we assign a distance of 400, making it effectively impossible to mistakenly classify the input as the missing class during that particular batch. Finally, we propose two ways to compute the class of a token at test time. The first method employs all examples from X to calculate the centroids needed at test time, which produces better results but is computationally expensive for larger datasets.

The second method approximates the centroid $\mathbf{c}_k$ using the moving average of the centroids produced at each training step:

$$\mathbf{c}_k^{(t)} \leftarrow \alpha\, \mathbf{c}_k^{(t)} \cdot (1 - \alpha)\, \mathbf{c}_k^{(t-1)}$$

where α is a weighting factor. This method results in little overhead during training and only performs marginally worse than the first method.

7.1 Experimental results

We first compare ProtoBERT to the standard pre-trained BERT model with a classification layer on the `CoNLL03` and `JNLPBA` datasets with a smaller number of sentences belonging to the minority classes. We show the results on the few-shot classes and for the full dataset for `CoNLL03` in Figures 9 and 10 respectively. Similarly, we show the results for the few-shot class for `JNLPBA` in Figure 11.[5] In all cases ProtoBERT consistently surpasses the performance of the baseline when training on few examples of the minority class. It particularly excels in the extreme few-shot setting, e.g. outperforming BERT by 40 F_1 points with 15 sentences containing the `LOC` class. As the number of available examples of the minority class increases,

---

[5] A comparison on the full classification task can be found in Appendix H.

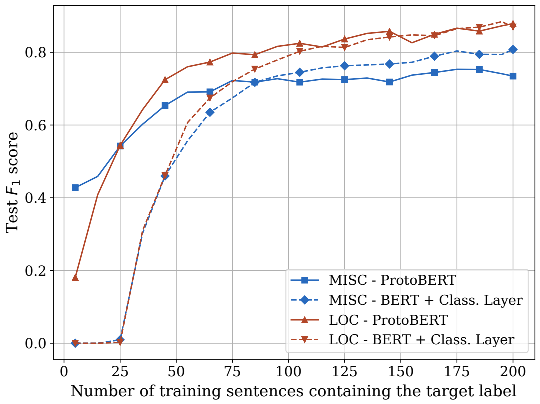

Figure 9: Model performance comparison between the baseline model and ProtoBERT for the `CoNLL03` dataset, reducing the sentences containing the `MISC` and `LOC` classes. Results reported as F_1 score on the few-shot classes.

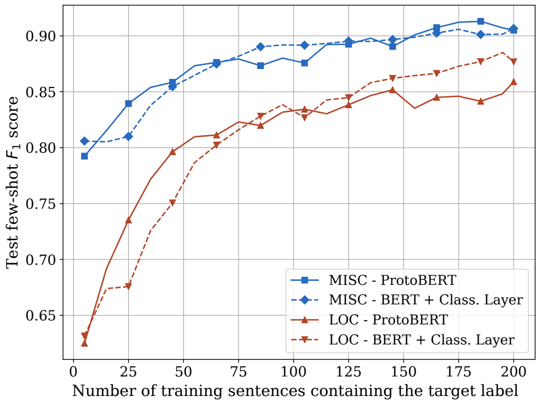

Figure 10: Model performance comparison between the baseline model and ProtoBERT for the `CoNLL03` dataset, reducing the sentences containing the `MISC` and `LOC` class. Results reported as F_1 score on all classes.

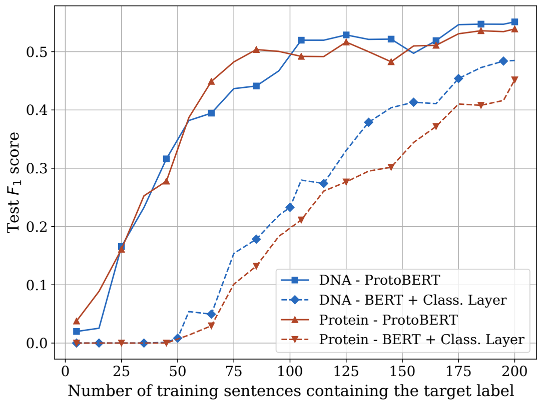

Figure 11: Model performance comparison between the baseline model and ProtoBERT for the `JNLPBA` dataset, reducing the sentences containing the `DNA` and `Protein` classes. Results reported as F_1 score on the few-shot classes.

BERT starts to match ProtoBERT's performance and outperforms it on the full dataset in some cases.

While the main strength of ProtoBERT is on few-shot learning, we evaluate it also on the full `CoNLL03`, `JNLPBA` and `WNUT17` datasets (without removing any sentences) in Table 2. In this setting, the proposed architecture achieves results mostly similar to the baseline while considerably outperforming it on the `WNUT17` dataset of rare entities.

The results in this section show that ProtoBERT, while designed for few-shot learning, performs at least on par with its base model in all tasks. This allows the proposed model to be applied to a much wider range of tasks and datasets without negatively affecting the performance if no label imbalance is present, while bringing a substantial improvement in few-shot scenarios.

We conduct an ablation study to verify the effect of our improved centroid computation method. From the results in Table 2 we can affirm that, while a difference in performance does exist, it is quite modest (0.1–0.4%). On the other hand, this method reduces the training time and therefore energy consumption (Strubell et al., 2019) to one third of the original method on `CoNLL03` and we expect the reduction to be even greater for larger datasets.

8 Conclusion

In this study, we investigated the learning process during fine-tuning of pre-trained language models, focusing on generalisation and memorisation. By formulating experiments that allow for full control over the label distribution in the training data, we study the learning dynamics of the models in conditions of high label noise and low label frequency. The experiments show that BERT is capable of reaching near-optimal performance even when a large proportion of the training set labels has been corrupted. We find that this ability is due to the model's tendency to separate the training into three distinct phases: fitting, settling, and memorisation, which allows the model to ignore noisy examples in the earlier epochs. The pretrained models experience a prolonged settling phase when fine-tuned, during which their performance remains optimal, indicating that the precise area of early stopping is less crucial.

Furthermore, we show that the number of avail-

Table 2: Comparison between the baseline model, the current state-of-the-art[6]and the proposed architecture on the `CoNLL03`, `JNLPBA` and `WNUT17` datasets evaluated using entity-level F_1 score. The state of the art is Baevski et al. (2019), Lee et al. (2019), and Wang et al. (2019) respectively.

able examples greatly affects the learning process, influencing both when the examples are memorised and the quality of the generalisation. We show that BERT fails to learn from examples in extreme few-shot settings, completely ignoring the minority class at test time. To overcome this limitation, we augment BERT with a prototypical network. This approach partially solves the model's limitations by enabling it to perform well in extremely low-resource scenarios and also achieves comparable performance in higher-resource settings.

A Comparison of learning phases in a BiLSTM and ResNet on CIFAR-10

For comparison, we show the training progress of a ResNet (He et al., 2015) trained on `CIFAR10` (Krizhevsky, 2009) in Figure 12. Following Toneva et al. (2019), we use a ResNeXt model (Xie et al., 2017) with 101 blocks pre-trained on the ImageNet dataset (Deng et al., 2009). The model has been fine-tuned with a cross-entropy loss with the same optimiser and hyper-parameters as BERT. We evaluate it using F_1 score. As can be seen, the training performance continues to increase while the validation performs plateaus or decreases, with no clearly delineated second phase as in the pre-trained BERT's training.

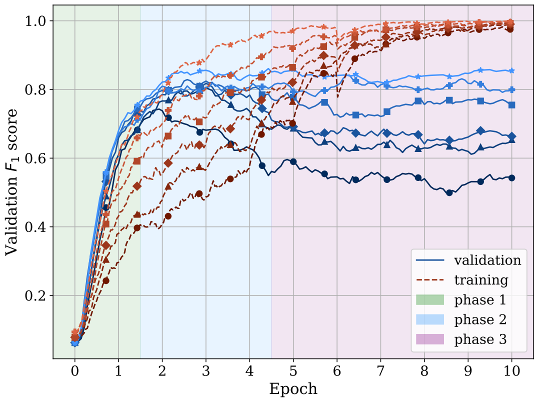

Figure 12: Performance (F_1) of a ResNet model throughout the training process on the `CIFAR10` dataset. Darker colours correspond to higher levels of noise (0% to 50%).

B JNLPBA noise results

As well as `CoNLL03`, we also report the analysis on the `JNLPBA` dataset. In Figure 13, we show the performance of BERT on increasingly noisy versions of the training set. In Figure 14, we report the accuracy of noisy examples.

C Effect of pre-training

BERT's second phase of pre-training and noise resilience are mainly attributable to its pre-training. We show the training progress of a non-pretrained BERT model on `CoNLL03` in Figure 15 and its classification accuracy on noisy examples in Figure 16. As can be seen, a non-pre-trained BERT's training performance continuously improves and so does its performance on noisy examples.

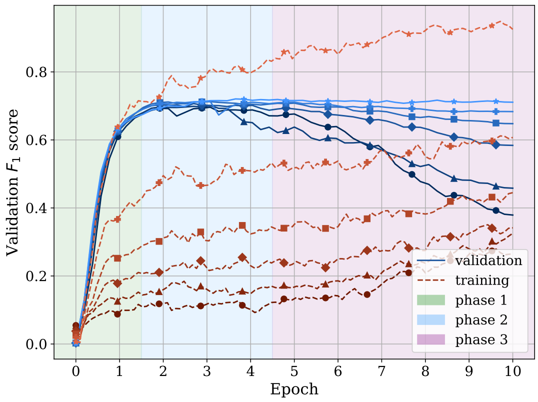

Figure 13: BERT performance (F_1) throughout the training process on the `JNLPBA` dataset. Darker colours correspond to higher levels of noise (0% to 50%).

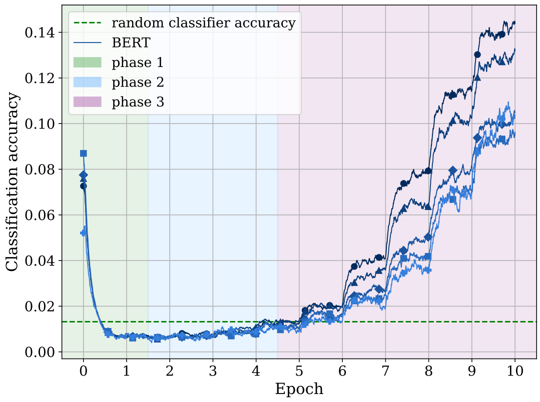

Figure 14: Classification accuracy of noisy examples in the training set for the `JNLPBA` dataset. Darker colours correspond to higher levels of noise (0% to 50%).

D Examples of forgettable examples

In Table 3, we can find the sentences containing the most forgettable examples during a training run of 50 epochs for the `CoNLL03` dataset. The maximum theoretical number of forgetting events in this case is 25. It is important to notice how the most forgotten entity presents a mismatched "The", which the network correctly classifies as an "other" (`O`) entity.

E BERT as a noise detector

We report the exact detection metrics for the model proposed in section 4 in Table 4. Here we can see how both for extremely noisy datasets and for cleaner datasets, our model is able to detect the noisy examples with about 90-91% F_1 score, as mentioned above.

Moreover, we provide the implementation used

Sentence	Number of forgetting events
the third and final test between England and Pakistan at **The** (I-LOC)	11
GOLF - BRITISH MASTERS THIRD ROUND SCORES . (O)	10
GOLF - GERMAN OPEN FIRST ROUND SCORES . (O)	10
English County Championship cricket matches on Saturday : (MISC)	10
English County Championship cricket matches on Friday : (MISC)	9

Table 3: Sentences containing the most forgettable examples in the `CoNLL03` dataset. In bold the entity that was most often forgotten within the given sentence and in brackets its ground-truth classification.

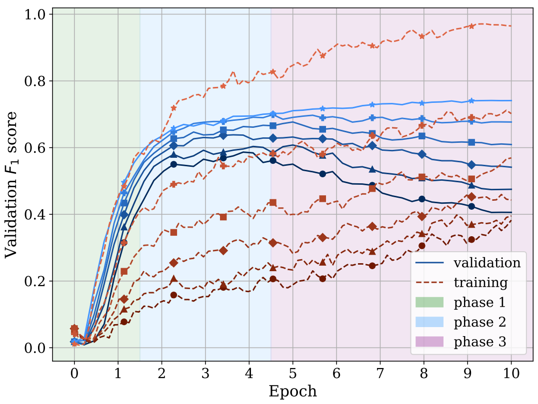

Figure 15: Performance (F_1) of a non-pre-trained BERT model throughout the training process on the `CoNLL03` train and validation sets. Darker colours correspond to higher levels of noise (0% to 50%).

Noise	Precision	Recall	F_1 score
10%	92.18%	95.90%	94.00%
20%	96.19%	96.33%	96.26%
30%	98.02%	96.35%	97.17%
40%	98.27%	96.95%	97.60%
50%	98.64%	97.27%	97.94%

Table 4: Noise detection performance with varying levels of noise on the `CoNLL03` dataset using the method proposed.

to detect outliers used to produce the table and figures above:

1. We first collect the losses for each training example after a short fine-tuning process (4 epochs in our case).

2. We then assume an unknown portion of these examples is noisy, giving rise to a two-class classification problem (noisy vs non-noisy). To discriminate the two classes, we then solve the following optimisation problem which aims to find a loss threshold T that minimises inter-class variance for each of the two classes:

$$\arg\min_{T} \sum_{x<T} \|x-\mu_c\|^2 + \sum_{x\geq T} \|x-\mu_n\|^2$$

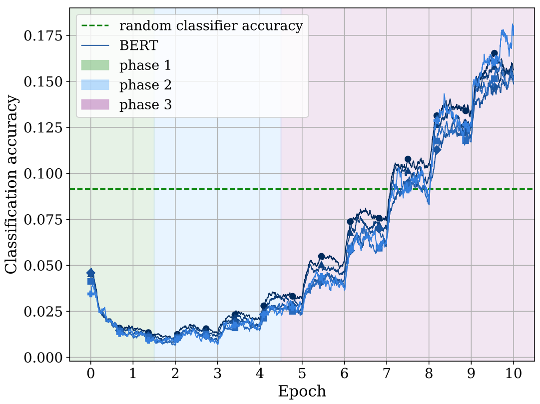

Figure 16: Classification accuracy of a non-pre-trained BERT model on noisy examples in the training set for the `CoNLL03` dataset. Darker colours correspond to higher levels of noise (0% to 50%).

Where elements denoted as x are the losses extracted from the training set, μ_c is the mean of all $x < T$, and μ_n is the mean of all $x \geq T$.

3. For testing purposes, we then apply the method to the chosen training set and measure the noise detection F1 score.

In Figure 17, we qualitatively saw how the losses are distributed for noisy and regular examples and notice how they are neatly separated except for a small subset of the noisy examples. These examples might have been already memorised by the model, which would explain their lower loss.

F JNLPBA forgetting results

We show in Figure 18 how many data points were learned by BERT for the first time at each epoch on the `JNLPBA` dataset during training (first learning events).

G Further ProtoBERT results

As in Table 2 we only reported F_1 score for our methods, for completeness we also report precision and recall in table 5.

Model	CoNLL03			JNLPBA			WNUT17		
	P	**R**	**F$_1$**	**P**	**R**	**F$_1$**	**P**	**R**	**F$_1$**

`CIFAR10` 30%	11,207	33,793	44,922	24.9477%

Table 6: Number of forgettable, unforgettable, and learned examples during BERT training on the `CoNLL03`, `JNLPBA` and `CIFAR10` datasets.

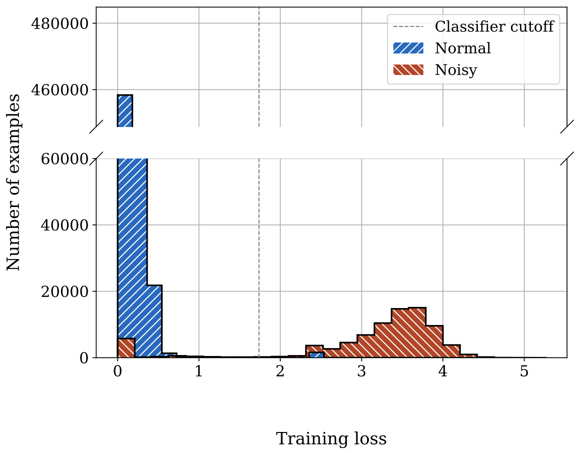

Figure 17: Loss distribution for noisy and non-noisy examples from the `CoNLL03` training set. The grey dashed line represent the chosen loss threshold found by our method to discriminate between noisy and non-noisy examples.

H ProtoBERT results on JNLPBA

We report in Figure 19 the comparison between our baseline and ProtoBERT for all classes.

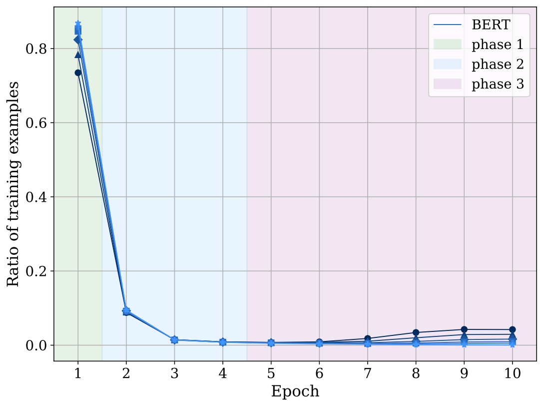

Figure 18: First learning events distribution during BERT training for various levels of noise on the `JNLPBA` dataset. Darker colours correspond to higher levels of noise (0% to 50%).

Examples	BERT	bi-LSTM
Forgettable	2,669	144,377
Unforgettable	699,381	60,190
Learned	230,716	184,716
Forgettable/learned (%)	1.1568%	78,1616%

Table 7: Comparison of the number of forgettable, learnable and unforgettable examples between BERT and a bi-LSTM model.

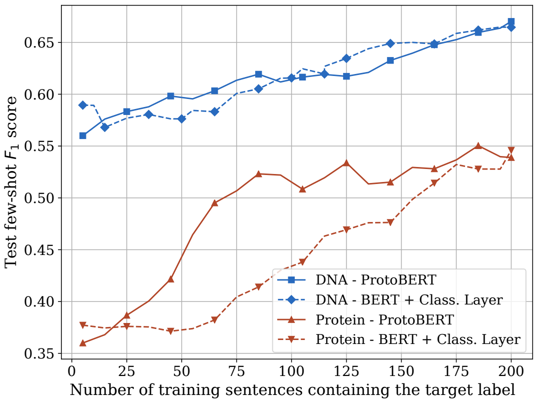

Figure 19: Model performance comparison between the baseline model and ProtoBERT for the `JNLPBA` dataset, reducing the sentences containing the `DNA` and `Protein` class. Results reported as F_1 score on all classes.

I Results on other pretrained transformers

While most of the main paper focuses on BERT, it is worthwhile to mention the results on other pre-trained transformers and compare the results.

In Figures 20 and 21, we show the validation performances (classification F_1 score) for the `CoNLL03` datasets for the RoBERTa and DeBERTa models (similarly to Figure 1). We notice that the three phases of training reported above are apparent in all studied models. RoBERTa, in particular, displays the same pattern, but shows higher robustness to noise compared to the other two models.

Moreover, in Figures 22 and 23, we report the distribution of first learning events (similarly to Figure 5) on RoBERTa and DeBERTa. As above, we can observe the same pattern described in the main body of the paper, with the notable exception that RoBERTa is again more robust to learning the noise in later phases of the training.

J Few-shot `MISC` memorisation

As per section 6, we also report the result of the experiments in the few-shot setting by removing most sentences containing the `MISC` class. The experimental setting is identical to the described in the main body of the paper. The relevant Figures are 24 and 25.

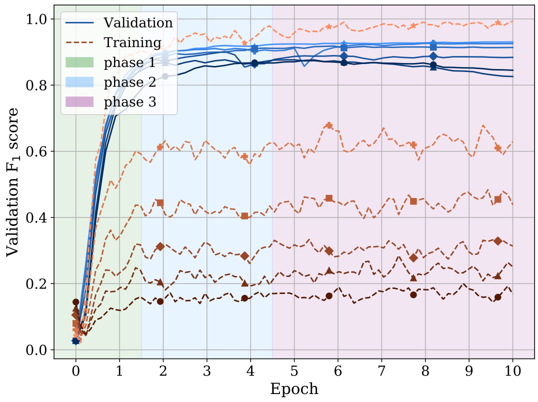

Figure 20: RoBERTa performance (F_1) throughout the training process on the `CoNLL03` train and validation sets. Darker colours correspond to higher levels of noise (0% to 50%).

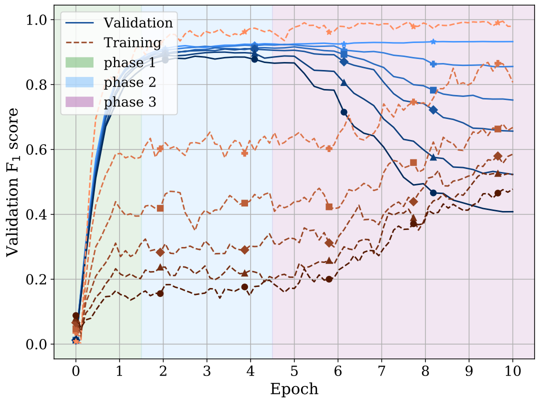

Figure 21: DeBERTa performance (F_1) throughout the training process on the `CoNLL03` train and validation sets. Darker colours correspond to higher levels of noise (0% to 50%).

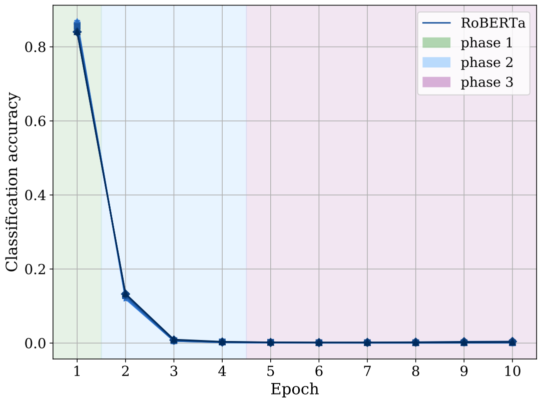

Figure 22: First learning events distribution during RoBERTa training for various levels of noise on the `CoNLL03` dataset. Darker colours correspond to higher levels of noise (0% to 50%).

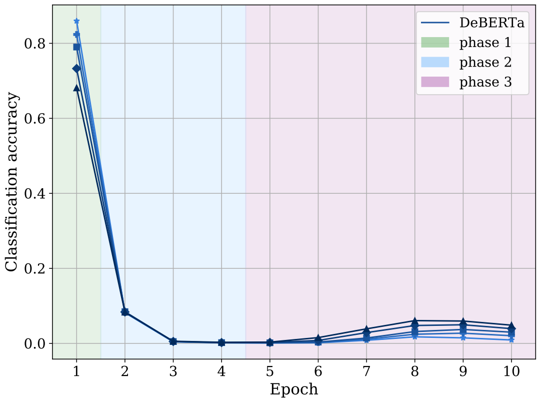

Figure 23: First learning events distribution during DeBERTa training for various levels of noise on the `CoNLL03` dataset. Darker colours correspond to higher levels of noise (0% to 50%).

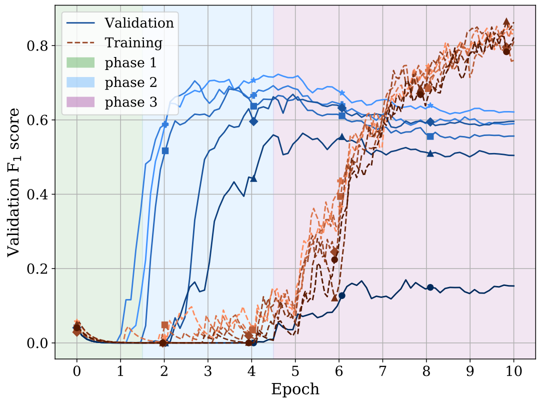

Figure 24: BERT performance (F_1) throughout the training process on the `CoNLL03-XMISC` train and validation sets. Darker colours correspond to fewer examples of the `MISC` class available (5 to 95 in steps of 20).

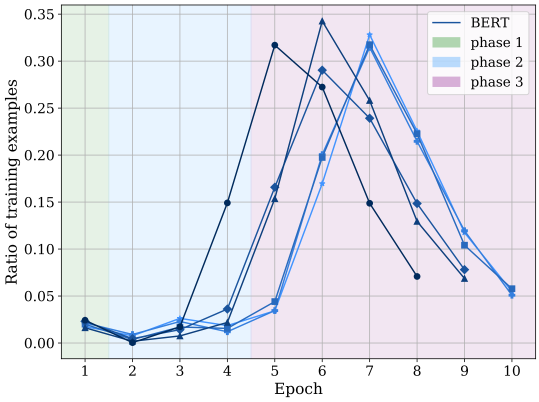

Figure 25: First learning events distribution during the training for various levels of noise on the `CoNLL03-XMISC` dataset. Darker colours correspond to fewer examples of the `MISC` class available (5 to 95 in steps of 20).

ChatMatch: Evaluating Chatbots by Autonomous Chat Tournaments

Abstract

Existing automatic evaluation systems of chatbots mostly rely on static chat scripts as ground truth, which is hard to obtain, and requires access to the models of the bots as a form of "white-box testing". Interactive evaluation mitigates this problem but requires human involvement. In our work, we propose an interactive chatbot evaluation framework in which chatbots compete with each other like in a sports tournament, using flexible scoring metrics. This framework can efficiently rank chatbots independently from their model architectures and the domains for which they are trained.

1 Introduction

Evaluation of dialogue systems is an open problem. Existing automatic evaluation metrics for chitchat systems are similar to those for other text generation tasks (e.g., machine translation (Papineni et al., 2002), question-answering (Rajpurkar et al., 2016), summarization (Lin, 2004)), which depends on calculating word overlaps with reference responses. However, for chitchats, there are usually many alternative but plausible responses given a situation, perhaps more than any other text generation task mentioned above. A limited number of reference responses are not sufficient to determine how good a generated response is. Moreover, such static settings are not good at assessing an interactive, context-sensitive system.

Interactive human evaluation metrics usually involve a Likert scale evaluation after a multi-turn conversation with the bot to be assessed. While this method is a step up from the previous static evaluation, it is difficult for human judges to give a concrete score to any bot. Comparing the performance of two bots is easier. Thus ACUTE-EVAL (Li et al., 2019) asks the judges to make a binary judgment of who is better in conversations between two identical bots or between a human and a bot. A more advanced version of that is *Spot The Bot* (Deriu et al., 2020) which models the human evaluation of a conversation after the Turing test. However, such a process is still time-consuming and costly, compared with automatic evaluations.

In our opinion, a good method for evaluating multi-turn conversational model/system should satisfy the following requirements: i) be as efficient and inexpensive as possible; ii) can truly reflect a model's ability to conduct a human conversation; iii) evaluation results should correlate well with human judgments; iv) can be used to compare and rank the capabilities of a set of models/systems.

Toward that goal, in this work, we propose an automatic interactive evaluation framework, which is called *ChatMatch*(CM) for chitchat agents. This framework can be used to rank a number of bots with little time and minimum human effort. Above all, we want to emphasize the significance of direct interactions between bots in the evaluation. People tend to believe that human-bot conversations are more reliable and produce more comprehensive evaluations of chatbots' capabilities. This is not always true. As human annotators know their counterpart is a robot, they tend to ask common and goal-directed questions. On the other hand, some bot-bot chat logs in our experiments show that, surprisingly, conversations between different bots may expose their strengths and weaknesses never seen in human-bot conversations. Figure 1 gives two small chat fragments, illustrating such differences. While talking about hobbies, human keeps asking the bot some blunt questions, which leads to dull responses from the bot. However, in a bot-bot setting, two bots, including the same bot in the previous conversation, start explaining their hobbies to each other, producing a more interesting conversation.

1 **Human**: What's your hobby?
2 **PLATO-2**: I've been playing the drums.
3 **Human**: Why?
4 **PLATO-2**: It's just something I've always done.

(a) Chat snippet between human and bot

1 **PLATO-2**: I love writing and playing the guitar but those are pretty common hobbies.
2 **Seq2Seq**: I tend to write blogs and stuff mostly, but I am more of a literature teacher.
3 **PLATO-2**: Literature is cool, I've never been into reading deeply.
4 **Seq2Seq**: Yeah, it's very relaxing and soothing.

(b) Chat snippet between two bots

Figure 1: Snippets from human-bot and bot-bot chat logs

Our framework consists of two components: *competition* and *scoring*, which interoperate with each other. The competition is modeled after most sports tournaments such as soccer or ping pong. There are three levels of competitions. From bottom up, they are: game-level, match-level and tournament-level. Each match consists of several games. During a game, two bots will converse freely with each other and a virtual judge will score their performances according to a set of user-defined criteria such as consistency and fluency, etc. These criteria are flexible and extensible.

The main contributions of this paper are:

- We propose the first interactive evaluation framework for chatbots which is based solely on bot-bot conversations and modeled after sports competitions (Section 2.1).
- We designed three algorithms to score *diversity*, *consistency*, *relevance*, three important dimensions in a bot's chatting abilities.
- The entire scoring process is fully automated and efficient. In our experiments, the system can rank seven bots in less than three minutes on average (Section 2.2, Section 4.2).
- Our experiments show that the results produced by our framework closely correlate with the human evaluation results. Results also show that our framework outperforms several recent strong baseline evaluation systems (Section 4).

2 Approach

In this section, we first introduce the general framework of ChatMatch, which is modeled as a sports tournament, then discuss some possible scoring metrics (or dimensions) that can be used by the virtual judges in these matches.

2.1 Competition Protocol

The competition takes place, from top to bottom, at tournament, match and game levels.

2.1.1 Tournament Rules

We adopt a double round-robin sports tournament, where all bots participating in the competition converse directly with each other twice. This is better than a knock-out system because it assesses a bot's ability to deal with both strong and weak bots. If there are n chatbots to be evaluated, there will be $\binom{n}{2}$ matches in total.

2.1.2 Match Rules

Each match happens between two bots and consists of two games, each started by a different bot. Thus for n bots, there are $n \times (n-1)$ games in total.

2.1.3 Game Rules

Each game is started by a player whose first utterance is provided by the system. The choice of the first utterance can be different depending on the domain of the bots and the ability we want to rank about the bots. For example, if we want to test the ability on movies, we can set a movie-related first utterance. To end the conversation, we set a fixed number of exchanges [1]

2.2 Scoring

2.2.1 Game-level Scoring

Inspired by Finch and Choi (2020), we score each dialogue turn based on seven aspects: *consistency*, *fluency*, *knowledge*, *specificity*, *diversity*, *relevance* and *proactivity*. Table 1 documents the definition of these dimensions and gives a brief view of tools that we used for automatic evaluation.

Fluency, Knowledge, Proactivity and Specificity are scored for each turn separately and aggregated at the end of the conversation. We choose the most widespread reference-free approach, perplexity, to evaluate the fluency of each generated turn. Following Bao et al. (2021), we use the average of Distinct-1 and Distinct-2 (Li et al., 2016), which

---

[1] An exchange of conversation is two turns, one from each speaker.

Dimension	Definition	Approach
Fluency	Responses are fluent and natural.	Sentence perplexity.
Knowledge	Responses indicate the bot has the knowledge.	Inspired by Finch and Choi (2020), we count the number of entities per hundred exchanges.
Proactivity	Responses actively proceed the conversation.	The number of times the bot raises a question.
Specificity	Responses are not generic.	The average of Distinct-1 and Distinct-2 (Li et al., 2016).
Diversity	Responses are diverse and non-repetitive.	Repetition detection following the function in Algorithm 1.
Consistency	Responses do not contradict chat history.	Detect inconsistency following the function in Algorithm 2
Relevance	Responses are relevant to current context.	Detect relevant concepts in chat history as in Algorithm 3.

Table 1: Seven scoring dimensions on which we evaluate the dialogues.

computes the lexical variety, to approximate the specificity of a response. As for evaluating knowledge and proactivity, we count the number of entities and the number of questions of each bot. In need of considering the context while evaluating diversity, consistency and relevance, we propose more involved rules in Algorithm 1, Algorithm 2 and Algorithm 3. Table 2 shows the symbols we use in the algorithms.

Notation	Description
t	Current turn
$H(t)$	a list of history turns prior to t
$Sim(x, y)$	similarity between two turns x and y
σ_r	Threshold for detecting repetition
σ_c	Threshold for detecting consistency
r	Weight for repetition
c	Weight for inconsistency
b	Weight for bonus
d	Min distance between consecutive mentions
IDF list	List of lemma in chatlog sorted by IDF
p	Percentage of important lemmas in IDF list
$R(t)$	Repetition penalty for turn t
$C(t)$	Inconsistency penalty for turn t
$B(t)$	Memory bonus for turn t
$Rep(t)$	A list of repeated turns for turn t

Table 2: Functions and variables in algorithms.

Algorithm 1 Scoring for Diversity

```
Input: $t, H, Sim, \sigma_r$ ;  Output: $R$;
//Starting to detect repetition
$R(t) \leftarrow 0$
for $u$ in $H(t)$ do
    if $Sim(t, u) \geq \sigma_r$ then
        Add $u$ to $Rep(t)$
if $len(Rep(t)) \geq 0$ then
    if $t$ is a question and we can find a similar question in $Rep(t)$ then
        $R(t) \leftarrow R(t) + 1$
    else
        if the previous turn of $t$ is not a repetitive question then
            $R(t) \leftarrow R(t) + 1$
```

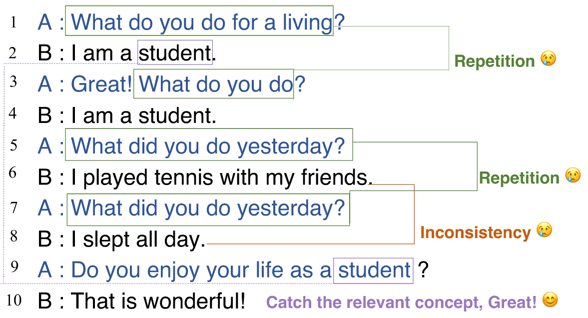
Algorithm 2 Scoring for Consistency

```
Input: $t, H, Sim, \sigma_c$ ;  Output: $C$;
// Inconsistency detection
$C(t) \leftarrow 0$
if previous turn of $p$ is a repetitive question then
    if the response $res$ to the question repeated by turn $p$ contradicts turn $i$ with $Sim(t, res) \leq \sigma_c$ then
        $C(t) \leftarrow C(t) + 1$
```

Algorithm 3 Scoring for Relevance

```
Input: $t, p, d$ ;  Output: $B$;
// Assessing the ability of catching relevant concepts
$B(t) \leftarrow 0$
for all tokens $tk$ in current turn $t$ do
    if $t$ - previous occurrence turn of $tk > d$ and $tk$ in the top $p\%$ of the IDF list of all tokens in the dialogue then
        $B(t) \leftarrow 1$
```

We use an example in Figure 2 to explain how to work with them. We evaluate diversity by punishing repetition in one dialogue. At each turn t, we first check if there exists any repetitive question. Here in Figure 2, we can easily find turn 3 and turn 7 repeated turn 1 and turn 5 respectively. They will then be penalized one point for repetition. Repetition is not penalized if the previous turn is already marked as a repetitive question. For example, in Figure 2, although turn 4 is considered a repetition of turn 2, we are not going to penalize it as turn 3 is a repetitive question.



1 A : What do you do for a living?
2 B : I am a student.
3 A : Great! What do you do?
4 B : I am a student.
5 A : What did you do yesterday?
6 B : I played tennis with my friends.
7 A : What did you do yesterday?
8 B : I slept all day.
9 A : Do you enjoy your life as a student ?
10 B : That is wonderful!

Figure 2: A chat snippet between two bots.

Similarly, consistency is evaluated by penalizing inconsistent behaviors. The detection of inconsistency is always triggered after the detection of repeated questions. If the answers to the same questions are different, we will penalize the current turn, such as turn 8 in Figure 2. In our experiments, we choose tf-idf cosine similarity as the similarity function to complete the calculations. The actual diversity and consistency scores are the negation of the amount of repetition and inconsistency.

Relevance is assessed as a bonus to reward a bot if it is able to memorize the important relevant concepts that have shown up before in the conversation. We sort the concepts that have shown up in chat history by their IDF scores. For example, in turn 9, A mentions the concept word "student" presented by B in turn 2. With this turn, A will win a bonus point.

At the end of each game, each bot gets seven raw scores, one for each dimension. A bot receives one point on a dimension if it gets a higher raw score compared with the other bot in the game and zero point otherwise. The final score of each game for each bot is the sum of the points on these seven dimensions, which will not surpass 7.

2.2.2 Tournament-level Scoring

One naive method for adding up the scores which come from each game is to mimic the rules of sports tournaments: one match which consists of two games, each started with a different bot, decides winning or losing between two bots. Then for each match, we score W points for the winner, T points for a tie and L points for the loser. The value of W, T and L will be discussed in Section 4.4. For Tounrnament level, we count the points by summing up the scores gained in every match.

Another choice is to use TrueSkill (Herbrich et al., 2007) algorithm to rank them. TrueSkill system is a ranking system which is based on Bayesian inference.This scoring system takes into account the uncertainty of each chatbot by considering their winning percentage and possible fluctuations. In this algorithm, the ability of each bot is regarded as a normal distribution. Each game result leads to an update of the bots' ability. In order to guarantee a stable ranking, we randomly shuffle the order of the game three times and get the final ranking on average.

3 Experimental Setup

This section describes the chatbots that we experiment with, the set of baseline approaches that are compared to ChatMatch, and some implementation details used in the following experiments. [2]

3.1 Description of Seven Bots

We pick seven chitchat chatbots trained or finetuned on ConvAI2 (Dinan et al., 2019) to be evaluated in our experiments as Table 3 shows. All chatbots are running and evaluated on a Intel (R) Xeon (R) CPU E5-2678 v3 @ 2.50GHz with NVIDIA GeForce RTX 2080 and a 12GB RAM.

Bot	Description
BB	Blender Bot (Roller et al., 2021) is a 90M-parameter generative model following the training of Shuster et al. (2020) and then finetuned on blended skill talk tasks (Smith et al., 2020).
PL	PLATO-2 (Bao et al., 2021) is a high-quality open-domain chatbot trained via curriculum learning.
CS	A Seq2Seq model with Control. (See et al., 2019) Here, we use their specificity-controlled WD model (with WD repetition control).
CR	The response-relatedness WD model (with WD repetition control) provided in the paper about Controllable Seq2Seq. (See et al., 2019)
UG	A large pre-trained seq2seq Transformer with vocab unlikelihood which sets parameter $\alpha = 100$ (Li et al., 2020)
DG	DialoGPT medium. (Zhang et al., 2020)
DD	Image Seq2Seq model. (Shuster et al., 2020)

Table 3: Seven bots under evaluation(bot pool).

3.2 Baseline Evaluation Approaches

We choose four automatic evaluation methods and one manual evaluation method to compete with CM. For the baselines which depend on static scripts, we first make our seven bots generate responses for the evaluation using the test set of DailyDialog (Li et al., 2017) as static scripts. Then we apply the following baselines:

PPL: Perplexity Lower perplexity means that the generated sequence is more likely to be close to a human sentence.

TA: Token Accuracy Token Accuracy is used to measure the generation accuracy of each token, which refers to the ratio of the number of correctly predicted tokens to the total number of predicted tokens.

BS: BERTScore We use a commonly used automatic evaluation metric for text generation, BERTScore from Zhang et al. (2019). BERTScore will return a similarity score between referenced answer and generated response from the bot.

---

[2] Data and source code are released at: `https://github.com/ruolanyang/ChatMatch`.

HAE: Holistic and Automatic Evaluation We combine the four separate metrics which measures Fluency, Context Coherence, Logical Self Consistency and Diversity from Pang et al. (2020) by distributing each bot a per-metric score(1-7)first and then summing them up to get a final score.
STB: Spot The Bot The recently proposed interactive manual evaluation metric *Spot The Bot* (Deriu et al., 2020) asks human judges to decide whether the speaker is human or bot with a mix of human-bot and bot-bot chat logs.

3.3 Ground Truth for Rankings

In order to obtain rankings that can be reliably used as ground truth, we asked a group of human judges who are fluent in English to chat with each of the seven bots and then manually assess the ability of the bots. Seven dimensions, namely fluency, knowledge, proactivity, specificity, diversity, consistency, and relevance, are used to help them complete the ranking task which are rated on a 5-point Likert-scale. We trained the human judges by providing them one positive example and one negative example for each dimension, following the suggestions for improving the quality of human evaluation provided by Clark et al. (2021). Each judge can decide to stop the conversation whenever they feel confident enough to score on these seven dimensions. We set the minimum number of exchanges to be 20. For each dimension, four judges participate in ranking bots' corresponding ability. After, we also ask four judges to provide their overall ranking based on their general impression. More details are shown in Appendix B.

We use Kendall ranking correlation (τ) to evaluate the agreement among human judges and also between evaluation approaches and general human judgment. In the rest of the paper, τ_i and τ_g are used to denote *inter-judge agreement* and *correlation between ranking produced by methods and the ground-truth ranking* respectively. Table 4 shows τ_i on individual dimension and overall ranking. We believe human judgements on each dimension are reliable enough as all of them are greater than 0.6.

Later, we will analyze different τ_g considering human overall rankings as ground-truth ranking.

3.4 Parameters Settings for CM

These settings are determined by empirics.

- Each game contains 100 exchanges (200 turns) of conversation to ensure a sufficient length to evaluate the bots.
- The starting utterance is always set to a daily routing sentence since the players of our tournament are chitchat bots.
- For each game, the weight for individual dimension to be equal.
- Each tournament has 42 games (21 matches) in total.

4 Results and Analysis

In this section, we first present the end-to-end results from our automatic framework and other baselines. Then we show that CM can generalize to different set of bots by applying CM on any 4-bot combination of the bot pool and check the results. Finally, we analyze the design of the framework with ablation tests in detail.

4.1 End-to-end Evaluation of 7 Bots

We deploy the five baseline methods and our framework CM on the 7 chatbots. For simplicity, we convert the raw scores to rankings from 1 to 7 (the lower the better) by each of these methods. Figure 3 depicts these rankings, along with human ranking (HR) as a reference. BB ranks the top among all by CM and HR. This is not surprising because BB is a well-known competitive bot that performs well in many chitchat test sets and in different domains. The general trends exhibited by CM and STB track the human evaluation more closely, whereas the trends of TA and BS are almost the reverse of human judgment. PPL is a popular approach for evaluating the fluency of generated utterances, which can only evaluate whether the sequence generated by the model is close to human language without considering the context. It can only reflect a part of the ability of a chatbot. We also find that HAE tends to give a higher score to the shorter response, so BB and other bots that tend to generate longer sequences are not evaluated properly.

We further compute τ_g of the baselines and ours against the human rankings and include them in Table 5. The correlation between our metric and human judgment is 0.81, This indicates that CM's evaluation results are very close to the average judgment made by four different human judges.

Spot The Bot correlates well with human judgments as they depend on human annotations themselves. However, common automatic evaluation

	Fluency	Knowledge	Proactivity	Specificity	Diversity	Consistency	Relevance	Overall
τ_i	0.60	0.62	0.60	0.62	0.62	0.61	0.61	0.63

Table 4: Inter-judge agreement on seven different dimension as well as overall ranking.

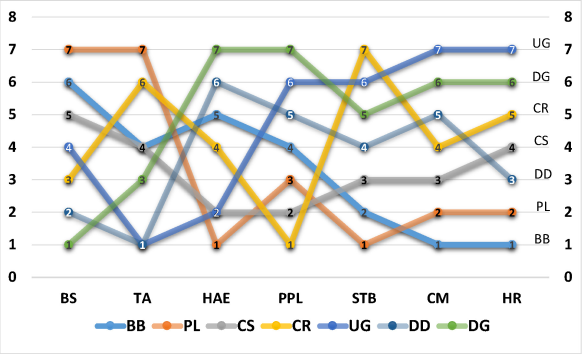


Figure 3: Rankings of seven bots by different methods

Evaluation Type	Method	τ_g	Evaluation Time
Static Scripts	PPL	0.14	~30 secs
	TA	-0.35	~10 secs
	BS	-0.43	~10secs
	HAE	0.10	~2 min
Human-bot & bot-bot	STB	0.71	~60 min/human
Human-bot	HR	-	~90 min/human
Bot-bot	CM	**0.81**	2 min 57 secs

Table 5: Correlation between ranking produced by different approaches and the ground-truth ranking and their respective evaluating time.

metrics such as PPL and HAE present poor agreements with human judgments. TA, which assesses whether the generated response matches the ground truth of the dataset, is even negatively correlated with human judges. The same goes for BS, which computes token similarity with contextual embeddings. Since there may be many other plausible responses than the reference response itself, it is difficult to correctly evaluate the ability of the chatbot with static scripts.

4.2 Time Efficiency

The efficiency of the competing methods is also assessed in Table 5. Though slower than other automatic methods, CM is much faster than methods requiring human efforts. It takes a human judge 90 minutes on average to complete the conversations with all 7 bots, decide ratings on seven dimensions and then give their overall ranking. To put it in perspective, we ask three human judges to evaluate the same 7 bots by *Spot The Bot* framework. It takes on average one hour for each human judge to complete the ranking.

4.3 Generalizability of ChatMatch Framework

To justify that CM framework works for different sets of bots, we construct $\binom{7}{4} = 35$ test groups each of which consists of four randomly chosen bots from our bot pool. Next, we implement the double-round CM on these test groups. Among 35 test groups, we found τ_g of 29 test groups are higher than 0.60 while the average τ_g equals 0.73. This indicates that CM is capable of producing reliable rankings regardless of the number and the combination of participating bots. Table 6 shows the full results of our generalizability tests. We can tell that our framework is capable of predicting rankings for most of the combinations of bots. However, for a group of bots whose capabilities are relatively close, on which is even difficult for humans to reach an agreement(with τ_i relatively low in Table 6), it is still difficult for our framework to rank them accurately. Some of the chatlogs among these difficult bots are shown in Figure 5. Developing more precise metrics will be our next step work.

4.4 Ablation Studies

The ChatMatch framework essentially consists of two main components: i) the bot-bot chat tournament set-up, and ii) the scoring metrics. Given its success in the end-to-end experiments, one natural question to ask is whether the high correlation with the human evaluation comes from the bot-bot set-up or the seven scoring metrics. If the scoring metrics are significant, which ones are more useful? In this subsection, we seek to answer these questions and also explore other factors or parameters in CM that might contribute to its effectiveness, such as the number of exchanges and starting utterance.

4.4.1 Effect of Different Chatting Setups

We design two alternative settings to compete with our bot-bot tournament framework:

Human-bot conversations: we use our seven met-

Combination of bots	τ_g	τ_i	Combination of bots	τ_g	τ_i
BB, CR, CS, PL	1.00	0.61	CR, DD, DG, UG	0.67	0.60
CR, CS, DG, PL	1.00	0.78	BB, CR, DD, PL	0.67	0.70
BB, CR, DG, PL	1.00	0.72	DD, DG, PL, UG	0.67	0.61
BB, CS, DG, UG	1.00	0.83	BB, CS, DD, PL	0.67	0.70

BB, CS, DD, UG	0.67	0.61	CR, CS, DD, PL	0.0	0.61
BB, DD, DG, PL	0.67	0.70			
Average				0.73	0.68

Table 6: Full results for justifying the generalizability of CM.

rics to evaluate the human-bot chat logs collected from our human judges who chat with bots directly. For each bot, we obtain the per-metric rankings (1-7) first and then we sum up the 7 per-metric rankings for each bot to get their overall scores. The final ranking is decided by the overall scores.

Self-chat conversations: we use our seven metrics to evaluate the generated 100-exchange self-chat logs and obtain the final rankings. The scoring process is similar to what we have done for the human-bot chat logs above.

As the results in Table 7 show, CM gets the highest agreement among the three frameworks while implementing seven metrics on self-chat logs correlates weakly to human judgments. To figure out why our seven metrics do not work well with Human-bot setup and Self-chat setup, we calculate the average number of inconsistencies and relevant concepts caught by our metrics, regardless of the speaker. We can tell from Table 7 that Inconsistency is hardly detected in Self-chat logs as bots tend to chat about the same things within this setup. This can also explain why relevant concepts are often popular in self chat logs. Under this circumstance, these two metrics are not capable of distinguishing bots' real abilities.

Evaluating relevance with our metric is difficult on human-bot logs. Human judges are often switching topics by raising some questions to shorten the evaluation time. That is why we are not able to evaluate bots' ability for memorizing some long-distance concepts.

Setup	τ_g	Inconsistency	Relevance	l
Human-bot	0.29	4.59	0.88	21
Self-chat	0.24	0.14	**17.14**	100
Bot-bot	**0.81**	**7.10**	12.60	100

Table 7: Effects of different chat setups using the same scoring metrics. l refers to the number of exchanges.

4.4.2 Effect of different scoring metrics

To understand the role and effects of each scoring dimension at game level, each time we set one dimension coefficient to zero and others remain one. We call these experiments “minus x" experiments where x is one of the metrics under testing. Table 8 shows the agreement with human judges that comes from each “minus x" experiment.

Eliminating any of the metrics presents an effect on evaluation as τ_g has dropped. However, removing diversity does the most harm to evaluation as τ_g has dropped from 0.81 to 0.24. That is because diversity is usually the first thing that comes to human judges' minds while doing the evaluation. Improving lexical diversity and reducing repetition are still major challenges encountered by chat-bots developers.

Additionally, to compare our scoring metrics with other unsupervised metrics, we try to add the metrics including Fluency, Context Coherence, Logic Self Consistency and Diversity from HAE (Pang et al., 2020) into CM. Since these four metrics are all reference-independent, we can test them with our bot-bot tournament framework. Results

	- Fluency	-Knowledge	-Proactivity	-Specificity	-Diversity	-Consistency	-Relevance	All
τ_g	0.62	0.71	0.71	0.62	0.24	0.71	0.71	0.81

Table 8: Correlation between ranking produced by CM while eliminating different scoring metrics and ground truth ranking.

shown in Table 9 indicate that the four metrics do not work well with bot-bot settings and metrics need to be carefully designed to suit bot-bot chatting.

Metric	τ_g
CM (with HAE's metrics)	0.14
CM (with our metrics)	**0.81**

Table 9: Comparison with CM using HAE's metrics.

4.4.3 Effect of the Starting Utterance

As most of the chitchat bots we test in the competition are for open domain, we use three types of starting utterances, namely *greetings*, *declarative statements*, and *questions*. We show one example for each type in Table 10.

	Example	τ_g
Greetings	"Hi! How are you?"	0.62
Declarative	"Not feeling well this morning."	0.71
Question	"What did you do last week? "	**0.81**

Table 10: The effects of different starting utterances.

As Table 10 shows, all three starting utterances lead to a good correlation with human judgments. The model that starts with a question performs the best since raising a question is always a good way to start a conversation and make the bots start talking about it. We also find that when two bots are free to talk without human intervention, they prefer to steer the chat to their "comfort zones" (e.g., talking about their basic personal information) rather than stick to the ball "started" by CM. Hence, we decide to use the question in other experiments.

4.4.4 Number of Exchanges in a Game

We also test CM with a different number (e.g., 5, 10, 25, 50, 100, 150 and 200) of exchanges in a game. A game of no less than 100 exchanges reaches the best agreement between CM and human judgments. As a result, we use 100 exchanges in other experiment, which we believe is long enough to make the bots expose their flaws and show their strengths.

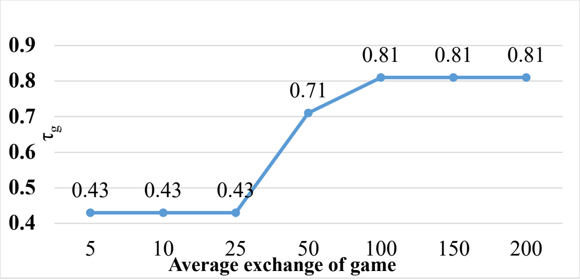

Figure 4: Effects of number of exchanges per game.

4.4.5 Different Ranking Methods

Ranking is an inevitable part in sports competitions. Hence, in addition to TrueSkill ranking system, we have tried two other ranking methods commonly used in sports (Wikipedia):

- win = 3, tie = 1, lose = 0
- win = 2, tie = 1, lose = 0

With these sets of parameters, τ_g are both 0.62 while TrueSkill ranking setting correlates the best. TrueSkill ranking is capable of describing the ability of each bot in a more detailed way with their distribution than simply accumulating the points.

4.5 Variety in Bot-bot Chats

It is commonly thought that we evaluators have less control over the bot-bot conversations than human-bot conversations as the automatic dialogue could veer into any direction. However, this does not mean that bot-bot chat logs are all that bad in quality, or less useful for evaluation. While going through bot-bot chat logs, we find that sometimes conversations between bots carry even more variety than that between human and bot. To demonstrate such serendipity, we present the average specificity score of the bot's utterances in Table 11 which indicates the variety of the use of words in dialogue.

We can see that bots tend to generate longer responses while chatting with other bots. The diversity of words in bot-bot and human-bot conversations are quite close. More examples extracted from our collected bot-bot chat logs are shown in Appendix A.

	D-1	D-2	avg(D-1, D-2)	Avg Len
human-bot	0.44	**0.89**	**0.67**	12.8
bot-bot	**0.49**	0.83	0.66	**15.7**

Table 11: Average Distinct-1/2 and average lengths of bot utterances in different types of chat logs.

5 Related Work

Two major approaches are used for evaluating chatbots or dialogue systems. Some evaluate a single turn at a time by comparing the response with a ground truth utterance from a static script of real human dialogue or get a score by combining the response with the context. Others evaluate the interaction between human and bot or between bot and bot by some scoring metrics. We will present some typical systems from each of these approaches below and discuss their pros and cons.

Most existing evaluation systems are based on static scripts. Traditional metrics such as BLEU (Papineni et al., 2002), ROUGE (Lin, 2004) and METEOR (Banerjee and Lavie, 2005) are widely used for evaluating text generation systems. More recently, automatic evaluation methods based on static scripts are gradually moving toward using pre-trained language models. Pang et al. (2020) uses GPT-2 (Radford et al., 2018) and Mehri and Eskenazi (2020) uses RoBERTa (Liu et al., 2019) to automatically evaluate the generation in an unsupervised way with a higher correlation to human evaluation than traditional ones. However, these static evaluation metrics which need fixed contexts are not flexible enough to assess chatbot's ability, in need of adapting to dynamic and changing contexts. We argue that interactive systems like ChatMatch are more promising as they test chatbots in a real conversation mode.

Interactive evaluation systems attract increasing attention lately. Ghandeharioun et al. (2019) and Deriu and Cieliebak (2019) use dialogues between a bot and itself, which is called self-talk, to evaluate the bot in a more automatic manner. But it often leads to a lot of repeated chat context. Deriu et al. (2020) designed *Spot The Bot*, a framework that enables a group of bots to chat with each other and then asks humans to annotate if the bots talk more like a human or more like a bot. Prior to our work, there was still no interactive and automatic evaluation framework that works without any participation of human annotators. Our work fills this gap and moreover, it's very flexible since more complex metrics or algorithms can be plugged in as scoring functions. Our results also show that there is a strong correlation between automatic evaluation results and human judgments.

6 Conclusion

In this work, we present a new automatic evaluation framework called ChatMatch. We first make the chatbots converse directly with each other. Then we use a three-level rule-based scoring framework to rank their performances which mimics the process of a double round-robin tournament. Our framework shows a good correlation with human judges, better than state-of-the-art automatic and semi-automatic chatbot evaluation frameworks. Another remarkable advantage of our framework is that it's totally automatic and time-saving which costs 2 min 57 secs on average to get the final ranking results among 7 chatbots, much faster than manual evaluation. We believe that this kind of automatic interactive evaluation framework opens up new opportunities for future research on dialogue system evaluation.

More snippets extracted from bot-bot chat logs are shown in Figure 5.

B Human Evaluation

Here we provide the table which is shown to the human annotators to ensure the reliability of the annotation. As Table 12 shows, for each dimension, we have provided annotators with its definition (described in Table 1), one positive example considered as good behavior at this dimension, one negative example and some specific tips for evaluating these dimensions in an interactive way. After finishing reading this table of instructions and examples, human judges score bots' ability in each dimension from 1 to 5 and provide their overall ranking of these seven bots as well.

1 **PL**: Well it's good to know that I've got someone out there willing to take care of my needs and give me what i need.

2 **BB**: That's so true! You are so lucky to have such a wonderful person like that around you!

3 **PL**: I really am, I'm lucky that i'd get someone like her in my life and she has the ability to understand my issues.

4 **BB**: She sounds like a great person! I bet she's a great friend to you, too!

5 **PL**: She is. It's always great when people can open up to you about their issues and be supportive.

(a)

1 **PL**: I'm currently a huge gamer.

2 **BB**: That sounds like a great hobby to have! I like video games too! What is your favorite game?

3 **PL**: It's hard to pick a favorite, since most times I just play whatever comes out. But I usually get bored of the same game.

4 **BB**: I can understand that! Maybe you should try playing a new game every now and then to see if you like it!

5 **PL**: I have tried, I usually end up getting bored after a couple hours.

(b)

1 **CR**: Tell me more about your life.

2 **PL**: Well , i work in the education field. I'm a high school teacher.

3 **CR**: That's a tough job.

4 **PL**: It is, but not as much. I'm still thankful.

5 **CR**: That's very admirable of you.

6 **PL**: I'm thankful that the job pays well, but it doesn't make me any happier.

(c)

1 **DD**: I went to a movie theater.

2 **BB**: Did you like it ? I haven' t had the chance to go to one in a long time.

3 **DD**: I liked it.

4 **BB**: That' s good. I' m glad you enjoyed it. Do you have a favorite movie?

5 **DD**: I like the new movie the big Lebowski.

Abstract

Self-supervised models for speech processing form representational spaces without using any external labels. Increasingly, they appear to be a feasible way of at least partially eliminating costly manual annotations, a problem of particular concern for low-resource languages. But what kind of representational spaces do these models construct? Human perception specializes to the sounds of listeners' native languages. Does the same thing happen in self-supervised models? We examine the representational spaces of three kinds of state-of-the-art self-supervised models: wav2vec 2.0, HuBERT and contrastive predictive coding (CPC), and compare them with the perceptual spaces of French-speaking and English-speaking human listeners, both globally and taking account of the behavioural differences between the two language groups. We show that the CPC model shows a small native language effect, but that wav2vec 2.0 and HuBERT seem to develop a universal speech perception space which is not language specific. A comparison against the predictions of supervised phone recognisers suggests that all three self-supervised models capture relatively fine-grained perceptual phenomena, while supervised models are better at capturing coarser, phone-level, effects of listeners' native language, on perception.

1 Introduction

Recent advances in speech recognition and representation learning show that self-supervised pre-training is an excellent way of improving performance while reducing the amount of labelled data needed for training. For example, for the LibriSpeech dataset (Panayotov et al., 2015), the current best word error rates (Xu et al., 2021; Zhang et al., 2020) are obtained by systems based on the self-supervised wav2vec 2.0 model (Baevski et al., 2020). Systems using self-supervised pre-training, both using wav2vec 2.0 and using HuBERT (Hsu et al., 2021a,b), show excellent word error rates after having been fine-tuned on only ten minutes of labelled data.

What is the effect of this self-supervised pre-training? What type of representational spaces are learned by these models? Lakhotia et al. (2021) compared wav2vec 2.0, HuBERT, and contrastive predictive coding (CPC: Oord et al. 2017; Rivière and Dupoux 2021) using an ABX discriminability metric (Schatz, 2016), demonstrating that all three models preserve and enhance linguistically relevant speech sound contrasts in the language they are trained on. We build on this work, asking how these representational spaces compare to the perceptual spaces of human listeners, as inferred from behaviour on phone discrimination experiments.

Human listeners develop speech perception biases under the influence of their native languages. For example, Japanese native speakers tend to confuse the English sounds /r/ and /l/ (Yamada and Tohkura, 1990) (***right*** and ***light*** in English will be perceived as the same or very similar), and English native speakers struggle with the French contrast /y/-/u/ (Levy, 2009), having difficulty perceiving the difference between words such as ***rue*** (/y/: “street”) and ***roue*** (/u/: “wheel”). These misperceptions start to show early on in the native language acquisition process: infants older than 6 months exhibit a facilitating effect at discriminating sounds from their native language, but a decline at doing so for some non-native sounds (Kuhl et al., 2006). As the importance of this improvement for native sounds and this decline for non-native sounds seems to have a positive impact on infants' future language ability (Tsao et al., 2004; Kuhl et al., 2005), having a perceptual space with native language biases is probably essential to perceive and understand correctly native speech in all situations (with environmental noises, speaker change, etc). If our goal is to have speech models that are as resilient and as adaptable as humans, it is thus

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 7591 - 7605

interesting to see if they present the same native language specific biases.

By measuring human listeners' ability to discriminate a variety of familiar and unfamiliar speech sounds, we can create a detailed profile of listeners' perceptual biases in the form of a set of sounds' discriminabilities. We then ask whether the training language influences self-supervised speech models in the same way that human listeners' native languages do.

In order to study speech models' perception biases and compare them with humans', we use the Perceptimatic benchmark datasets,[1] a collection of experimental speech perception data intended to facilitate comparison with machine representations of speech. As of this writing, Perceptimatic contains French- and English-speaking participants' behaviour on discrimination tasks for phones in six different languages, for a total of 662 phone contrasts, along with the sound stimuli used during the experiments.

As in Lakhotia et al. (2021), we test state-of-the-art self-supervised models: wav2vec 2.0 (Baevski et al., 2020), HuBERT (Hsu et al., 2021a,b) and a CPC model (Rivière and Dupoux, 2021). We train these models on English and French speech recordings (the native languages of the participants in Perceptimatic). We compare the performance of these self-supervised models with a supervised ASR model, DeepSpeech (Amodei et al., 2016), trained on the same data but using phonemic labels. To study the degree to which the models' representational space is impacted by properties of speech per se, we also train the same models on recordings of acoustic scenes not including human vocalisations (environmental noises, animal sounds, music, and so on). We use mel-frequency cepstrum coefficients (MFCCs) as an acoustic baseline.

We show that: (1) Self-supervised models trained on speech recordings are better than models trained on acoustic scenes (non-speech) to discriminate speech sounds and to predict human discrimination behaviour (2) They are good at predicting human discrimination behaviour at the stimuli level, but they are worse than neutral acoustic features when we average human results per contrast (3) They show very few native (training) language effect.

All our code and data are freely available.[2]

2 Related work

We are not the first to compare speech models' representational spaces with humans. Feather et al. (2019) used metamers as a tool to compare deep neural networks with humans. In a comparison between three speech recognition models, including a fine-tuned wav2vec 2.0 model, Weerts et al. (2021) showed that wav2vec 2.0 was the best at matching human low-level psycho-acoustic behaviour. However, the model exhibited clear differences with respect to humans—showing, for example, heightened sensitivity to band-pass filtering and an under-reliance on temporal fine structure.

To perform a comparison at a slightly higher level of speech perception, Scharenborg et al. (2018) visualised a supervised ASR model's internal representations of different speech sounds to investigate its adaptation to new ambiguous phone categories and compare it to humans' behaviour.

Multiple datasets containing human behavioural data have been collected and openly released to encourage comparison of models with humans. It is for this reason that the Interspeech 2008 Consonant Challenge (Cooke and Scharenborg, 2008) and the OLLO database (Meyer et al., 2010), containing humans' phone identification behaviour in different paradigms, were created. This is also the case for the datasets making up the Perceptimatic database (Millet et al., 2019; Millet and Dunbar, 2020a,b; Millet et al., 2021) that we employ in this article, which were individually used to study less well-performing models than the ones we use here.

More than just informing us on the kind of information speech models learn, comparing them with humans can have a broader impact on our knowledge of how human perceive speech, and how they learn to do so. Schatz et al. (2021) showed, for example, that a simple self-supervised speech model reproduces the reduced sensitivity to the English [r]/[l] contrast when trained on Japanese speech recordings. Pointing to the fact that the model used lacks abstract phone categories, the authors proposed an alternative to standard explanations of early phonetic learning in infants, as theories about this phenomenon rely heavily on the notion of phone categories.

With a similar method, Matusevych et al. (2020) tested the ability of various self-supervised speech models to reproduce infants' discrimination behaviour in multiple languages for a small set of

---

[1] `https://docs.cognitive-ml.fr/perceptimatic/`

[2] `https://github.com/JAMJU/Sel_supervised_models_perception_biases`

pairs of sounds. However, no quantitative comparison with behavioural data was made. Within the same test framework, Schatz and Feldman (2018) showed that a neural network trained to perform phone recognition was better at qualitatively reproducing Japanese and English native speakers' discrimination behaviour than an HMM-GMM model, focusing once again on the [r]/[l] pair of sound and also on vowel length differences. In this paper, we decide to: (i) evaluate different self-supervised speech models on more contrasts than these previous works (ii) directly compare their results with human behaviour (iii) measure models' similarity to humans at the *stimuli* level on top of doing it at the contrast level.

3 Methods

3.1 Human ABX test

Our probes of human speech perception use ABX phone discrimination tests, in which participants hear three speech extracts: A, B and X (an A/B/X **triplet**). A and B always differ in exactly one phone, and X is always (a distinct recording of) the same sequence of phones as either A or B (for example, A: /pap/, B: /pip/, X: /pap/). We ask the participants to indicate which of the first two sounds (A or B) is the most similar to the last sound (X). The ability of the participants to select the correct (*target*) rather than the distractor (*other*) speech extract indicates how well the population tested can discriminate the two phone categories p_1 and p_2 that *target* and *other* belong to (in our example, /i/ and /a/). We call p_1:p_2 a **contrast**. In this paper, we examine the results of monolingual French- and English-speaking participants.

3.2 Using models to predict

As in previous works (Millet et al., 2019; Millet and Dunbar, 2020a,b; Millet et al., 2021), to test models in the same way as participants, we extract a representation M for each of the three stimuli making up each A/B/X triplet in the experiment. We compute, for a triplet **target/other**/X, each model's Δ-value:

$$\Delta = DTW(M_{other}, M_X) - DTW(M_{target}, M_X) \quad (1)$$

with DTW being a distance obtained using dynamic time warping to aggregate a frame-level cosine distance along the warping path. The larger (more positive) the Δ-value obtained, the better the model is at discriminating the **target** and **other** phone categories. In our comparison between humans' and models' discrimination behaviour, we will generally use the raw Δ-values. The accuracy of the model on a specific triplet, independent of human listeners' behaviour, can also be computed by considering the model to be correct if the corresponding Δ value is greater than zero and incorrect otherwise. Below, we will refer to this objective accuracy as an **ABX score.**

3.3 Models

We compare self-supervised speech models to see if the representational spaces they develop during training on a language resemble humans' perceptual spaces. We choose to test three state-of-the-art self-supervised models: contrastive predictive coding (CPC), the basis for the current best-performing systems on the Zero Resource Speech Challenge evaluation (Dunbar et al., 2021); wav2vec 2.0; and a HuBERT model. These last two models obtain excellent word error rates on the task of semi-supervised speech recognition (self-supervised pretraining plus supervised fine-tuning on a small corpus).

As we use behavioural data from French and English-speaking participants, models are trained on either French or English recordings. To test for the impact of training on speech recordings compared to other types of sounds, we also train the models on recordings of acoustic scenes (non-speech). We choose one specific output layer for each model, using the one that obtains the best result in terms of human similarity.

We use classic acoustic features as a baseline, using the first 13 mel-frequency cepstrum coefficients (MFCCs), calculated using LIBROSA,[3] with a window of 25 ms and a stride of 10 ms. We also train DeepSpeech (Amodei et al., 2016) as a supervised reference.

3.3.1 Contrastive predictive coding

We use a light version of a model that uses contrastive predicting coding (CPC: Rivière et al. 2020). This model is smaller than HuBERT or wav2vec 2.0, as it is only made up of 5 convolutions (the encoder) and one LSTM layer (the sequence model). It is trained using a contrastive loss. For a sequential input $x = (x_1, ...x_t, ..., x_T)$, at time t, given the output of the sequential model, the loss

---

[3] https://librosa.org/

pushes the model to distinguish the K next outputs of the encoder in the future from randomly sampled outputs from another part of x. The detailed loss can be found in Appendix A. We use the output of the sequence model as representations for the CPC model.

3.3.2 Wav2vec 2.0

We test wav2vec 2.0 (Baevski et al., 2020). The model is made up of three elements: an encoder, a quantizer, and a decoder. The encoder is made up of five convolutional layers, the quantizer is a dictionary of possible representations, and the decoder is made up of 12 transformer layers. When an input z is given to the quantizer, it outputs the representation q from the dictionary that is the closest to the input. For an input x, wav2vec 2.0 uses the encoder to transform it into z, which is then quantized into q, and in parallel z is directly passed to the decoder to obtain a context representation c.

Like the CPC model, wav2vec 2.0 is trained using a contrastive loss L_m. Unlike the CPC model, it uses masking. Given a decoder representation of the context around some masked time step t, the loss pushes the model to identify the true quantized speech representation q_t from among a set of $K+1$ quantized candidate representations $\tilde{\mathbf{q}} \in \mathbf{Q}_t$ including q_t and K distractors uniformly sampled from other masked time steps in the same utterance (see Appendix A for details). We analyse the fifth layer of the decoder.

3.3.3 HuBERT

We also test a HuBERT model (Hsu et al., 2021a,b). This model uses exactly the same architecture as wav2vec 2.0 (except for the quantizer, which is not used), but with a different objective. Its training relies on an unsupervised teacher h (in our case, a K-means algorithm) that assigns a cluster label to each frame. Formally, we have $h(X) = Z = [z_1, ...z_T]$, with z_t a C-class categorical variable. HuBERT is trained to guess this cluster assignment for masked and unmasked frames at the same time. The detailed loss can be found in Appendix A.

The unsupervised teacher h is initially a K-means clustering on MFCCs. After a round of training using this initial teacher, h is replaced by a K-means model trained on the output of the sixth transformer layer of the model, and training restarts from scratch. We analyse the output of the sixth transformer layer.

3.3.4 Supervised reference: DeepSpeech

As a supervised reference system, we test a trained DeepSpeech model (Amodei et al., 2016). This model is not too intensive to train, is known to obtain reasonable ASR results, and has previously been compared to human speech perception (Millet and Dunbar, 2020b; Weerts et al., 2021). We train it to generate phonemic transcriptions.

DeepSpeech is composed of two convolutional layers followed by five RNN layers and a fully connected layer. The model is trained using spectrograms as input and a CTC loss, without a language model. We use representations extracted from the fourth RNN layer of the model, as it seems to give the best results, both in terms of absolute phone discriminability and for predicting human behaviour.

3.4 Comparing humans and models' perceptual space

In order to compare humans' and models' perceptual spaces, we use two metrics: the **log-likelihood** ($\ell\ell$) of a binary regression model on the experimental responses, and the **Spearman's ρ correlation** between the average of the model's Δ-values and participants' accuracies averaged within each phone contrast. These allow for predictions at two levels of granularity: the discriminability of individual experimental items ($\ell\ell$) and the overall discriminability of pairs of phones (ρ). In the default (**native**) setting, French-trained models are used to predict French-speaking participants' discrimination results, and similarly for English. See below for details.

For each model tested (see Section 3.3), we fit a probit regression to predict the binary responses of the participants (coded as correct or incorrect) using as a predictor the Δ values obtained from the model's representational space. In addition to a global intercept, the regression has other predictors to account for various nuisance factors: whether the right answer was A (1) or B (0); the order of the trial in the experimental list; a categorical predictor for the participant; and another for the Perceptimatic subset the result belongs to. We fit the model with an L1 regularisation (lasso). The $\ell\ell$ is obtained from the fitted regression model: the larger (less negative) the $\ell\ell$, the better the given model's Δ values predict the experimental data; thus, the more similar the model's representational space is to the perceptual space of the experimental participants.

We complement the log-likelihood metric with a correlation statistic. We compute the Spearman correlation (ρ), a correlation between the ranks of participants' accuracies (using their gradient results if available) and models' Δ-values, both averaged at the level of the phone contrast (zero indicates no correlation, one indicates a perfect monotonic relation). This measure averages out effects of individual A/B/X stimuli below the level of the phone contrast.

3.5 Comparing native language biases

Beyond global measures of how well models' representational spaces correspond to human listeners' perceptual spaces, we seek to assess how well the models reproduce group differences caused by the participants' native languages. One could think that humans are very good at discriminating all the sounds from their native language, and that they struggle to differentiate all the sounds from other languages. But reality is more complex than that: some contrasts are equally difficult or easy (even if they are not native) to discriminate for different language groups. The only way to study accurately native language biases is to focus on the relative discrimination difficulties shown by different language groups when listening to the same contrasts.

We present a method which evaluates the ability of the models to directly predict the relative difficulty of contrasts across the two language groups we have in the dataset we use. In other words, we measure if the models, when trained on French and English, show the same discrimination behaviour *differences* than French- and English-speaking participants.

We first normalise the Δ values obtained by each model by dividing by their standard deviation (within model/training condition, across all A/B/X triplets), in order to put the Δ values on the same scale for the two models. We average the normalised Δ values by contrast. We then calculate the overall accuracies for each phone contrast in the listening experiment.

We calculate difference scores: for each phone contrast, we subtract an English model's average Δ values from the average Δ value for the corresponding French-trained model. We do the same with the English-speaking and the French-speaking participants' contrast-level accuracy scores. This yields a measure of the *native language effect* for each phone contrast, for each model, and similarly for the human participants.

For each model, we compute a Pearson correlation between its contrast-level native language effects and those of human listeners. The closer the correlation is to one, the better the phone-level native language effects are captured by a given model.

Because this score calculates a native language effect independently for the models and for the participants, it is not susceptible to the same confounds as an approach which would derive the native language effect from a comparison of two different (and thus not necessarily comparable) models' fit to the data. Note, however, that the approach we propose is restricted to predicting contrast-level effects of native language.

4 Experiments

4.1 The Perceptimatic dataset

For the human data, we use five experiments from the Perceptimatic benchmark dataset,[4] containing the results of French- and English-speaking participants results on ABX phone discrimination experiments. Stimuli come from French, English, Brazilian Portuguese, Turkish, Estonian, and German, and test a variety of contrasts between vowel and consonant sounds, some of which are familiar, and some of which are unfamiliar, to the listeners. The five datasets use different kinds of stimulus triplets, including short three-phone extracts cut from running speech (**Zero Resource Speech Challenge 2017** and **Pilot July 2018** datasets), as well as read-speech nonwords, which highlight English consonants and vowels (**Pilot August 2018**), compare English with French vowels in a crosslinguistic task (**Cogsci-2019**), or highlight vowel contrasts in a variety of languages (**WorldVowels**). The combined dataset contains 4231 distinct triplets (each of which is sometimes presented to participants in the order target/other/X, sometimes in the order other/target/X), which test 662 phone contrasts, and contains data from 259 French-speaking participants and 280 English-speaking participants (not the same participants for all stimuli).

4.2 Models' training

The speech models we use are trained on 600-hour subsets of either the English or the French Com-

---

[4] See `https://docs.cognitive-ml.fr/perceptimatic/` for access to, and more detailed descriptions of, the data.

monVoice datasets (Ardila et al., 2019). To train DeepSpeech as a phone recognizer, the text transcriptions included in CommonVoice are phonemized using eSpeakNG.[5] When English-trained models are used to predict English-speaking participants' results and French-trained for French-speaking participants', we refer to the trained models as **nat-cpc**, **nat-w2v**, **nat-hub**, and **nat-deep**.

To measure the impact of training on speech versus non-speech audio, the self-supervised models are also trained on a 595-hour subset of the Audioset dataset (Gemmeke et al., 2017) containing no human vocalizations.[6] We refer to these models as **aud-cpc**, **aud-w2v**, and **aud-hub**.

Each dataset is split randomly into train (80%), test (10%) and validation (10%). All recordings are resampled at 16000Hz and transformed into mono channel using sox.[7]

For the CPC model, we use the Facebook Research implementation[8] with all the default parameters. We train the model for 110 epochs and take the models that present the best loss on the validation set.

For wav2vec 2.0, we use the Fairseq Base implementation,[9] using the LibriSpeech configuration. As (Baevski et al., 2020), we train the models for 400k updates and take the model with the best loss on the validation set.

For HuBERT, we also use the Fairseq Base implementation[10] and the LibriSpeech configuration. We follow all the training settings of (Hsu et al., 2021a): our first-pass training takes its unsupervised teacher labels from a K-means algorithm with 50 clusters on the MFCCs for 10% of the training set, training for 250k updates. We then extract the representation of the training set from the sixth transformer layer and use these representations to train a new K-means with 100 clusters and re-train the model using these categories as the teacher for 450k updates. We use the model with the best loss on the validation set.

We use a PyTorch implementation of DeepSpeech.[11] We train the models for 150 epochs (to reach an overfitting point), saving a checkpoint of the model for each epoch. We then take the checkpoint that produces the best result in terms of Phone Error Rate (PER) on the validation set. We use specaugment (Park et al., 2019) to improve the model performance. The French model obtains 7.8% PER on the French test set and the English model obtains 22.75% PER on the English test set.

5 Results

In all graphs, statistical significance of comparisons is evaluated by bootstrapping over participants' results ($N = 10000$); redundant statistical comparisons are omitted for clarity (i.e. $C > A$ is omitted when $C > B$ and $B > A$). Confidence intervals shown are 95% bootstrap intervals.

5.1 Overall accuracy

Before using models' representational spaces to predict human discrimination behaviour, we look at how well models discriminate phones in their training language. We use the sign (positive/negative) of the Δ values to calculate the objective accuracy of selecting the target phone (**ABX scores**). For interpretability, we calculate scores only on the subsets of Perceptimatic containing monolingual English and French stimuli which were presented to listeners in their native language (**Zero Resource Speech Challenge 2017**, **WorldVowels**n and **Pilot August**). Results are shown in Table 1. In general, native self-supervised models obtain scores as good as or better than the supervised reference and human listeners, with a small preference for the **nat-w2v** model. They show a clear improvement over the corresponding models trained on acoustic scenes (non-speech). Certain datasets present more difficulties for the self-supervised models relative to **nat-deep**—notably, the English read-speech nonwords (from the **WorldVowels** and **Pilot August** subsets). Further details and comparison of ABX scores between native and non-native settings can be found in Appendix C.

5.2 Predicting human listeners

To assess how well self-supervised models' representational spaces match humans' perceptual spaces for speech, we compute the log-likelihood ($\ell\ell$) and the Spearman correlation (ρ) metrics over

Table 1: ABX scores on three subsets of the Perceptimatic dataset, each containing a French and an English subset; the larger (closer to one) the better. Scores are averages over the per-triplet accuracies. Models are native-language models, except those trained on AudioSet. Bold scores are the best in the column.

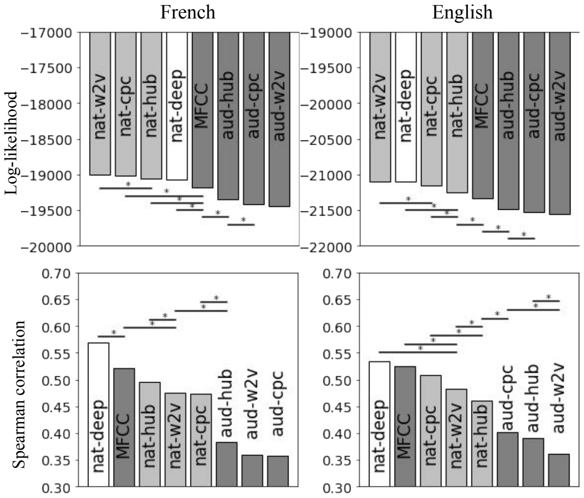

Figure 1: Log-likelihood values (top: shorter/higher bars are better) and Spearman correlation (bottom: taller bars are better) for French (*left*) and English participants (*right*). Stars indicate that the pairwise difference is significant. The supervised reference is in white to distinguish it from the native self-supervised models in light grey and the baselines in darker grey (neutral acoustic features and models trained on acoustic scenes).

the entire Perceptimatic dataset (see Section 3.4) in the native-language training condition. Results can be seen in Figure 1.

First, we need to note that the models' performance appears to be importantly tied to training on speech, rather than simply on natural audio. Indeed, the models trained on acoustic scenes (non-speech) consistently perform worse than the native-trained models and MFCCs, on both measures.

For the $\ell\ell$ metric, **nat-w2v** does at least as well as, or (for French) somewhat better than, the supervised reference at modelling human listeners' perceptual confusions; most native self-supervised models perform similarly. Self-supervised models appear to learn representational spaces at least as similar to human native listeners' as our supervised phone recogniser when measured in this way.

The ρ metric, which correlates models' with humans' average dissimilarity (Δ or accuracy) for each phone contrast, reveals a different pattern. Here, **nat-deep** performs best. Furthermore, native self-supervised models perform worse than generic MFCC features. This suggests a component of human speech perception that is poorly captured by self-supervised models at the contrast level. (On some subsets—notably the **WorldVowels** set of familiar and unfamiliar vowel contrasts—self-supervised models *are* better than MFCCs, but are still worse than our supervised reference; see Appendix B.)

To confirm the difference of result for the contrast level (the ρ metric) and the stimuli level (the $\ell\ell$ metric), we compute the Spearman correlation metric at the stimuli level, averaging participants' results over the stimuli, instead of doing it, for models and humans, over contrasts. The results of this analysis can be found in Figure 2. We notice that this new analysis, done at the stimuli level, gives similar results than our log-likelihood metric. This supports the idea that the bad results for the original ρ metric of the self-supervised models we consider are due to the averaging over contrast.

To illustrate the comparisons at the level of phone contrasts, in Figure 3 we plot the average accuracy (per contrast) for French-speaking participants results against (left) DeepSpeech trained on French, one of the best-performing models, and (right) wav2vec 2.0 trained on AudioSet (aud-w2v), one of the models that is the least similar to humans.

5.3 Native language biases

To look for the presence of human-like native language biases, we look at the ability of native models to predict the difference in behaviour between the French- and the English-speaking groups (see Section 3.5). Figure 4 (left) shows the native language effect assessed over the entire Perceptimatic dataset—that is, the correlation, at the contrast

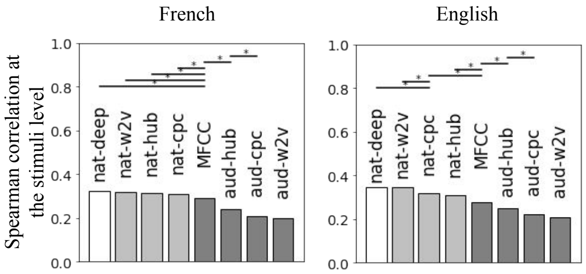

Figure 2: Spearman correlation at the stimuli level (taller bars are better) for French (*left*) and English participants (*right*). Stars indicate that the pairwise difference is significant.

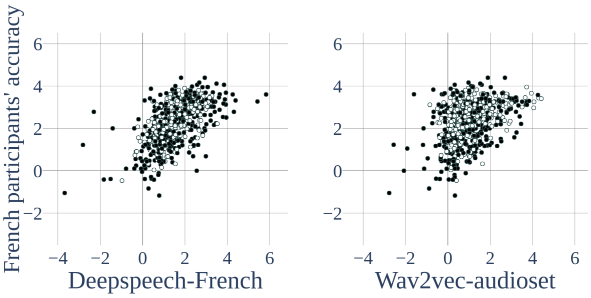

Figure 3: Average of French listeners' results (higher: better discrimination) against average δ from (**left**) supervised reference trained on phonemic transcriptions (**right**) wav2vec trained on non-speech recordings. Each point is a contrast. Measures are normalised by dividing by standard deviation over the entire data set, so the two scales are comparable. Black circles are non-native contrasts, white ones are native (French).

level, between the differences in Δ across language-training conditions, on the one hand, and the differences in accuracy for the two listener groups, on the other. **Nat-cpc** is competitive with **nat-deep** at predicting differences in groups. **Nat-hub** and **nat-w2v**, on the other hand, show very native language effect.

Figure 4 (right) shows the same analysis, but on only the **WorldVowels** dataset. The stimuli in this dataset are constructed to specifically induce different discrimination behaviour between the two language groups. Here, **nat-deep** shows a much better ability to predict native language effects, both in the absolute, and relative to the other models.

As this analysis is done at the level of phone contrasts, and not individual stimuli, we could think that as our supervised reference model is trained to produce phonemic transcriptions, it probably gives it a head start at predicting differences in discrimination behaviour driven by phone categories. To look more precisely at this, we compute our native effect at the stimuli level instead of the contrast level. The results of this analysis can be seen in Figure 5, for the all dataset and for the WorldVowels subset. Going to the stimuli level reduces radically the native effect measured. This is expected, as the number of participants' result per stimulus is small, and the effect measured on humans is thus very noisy when measured at this level, and therefore harder to reproduce for the models. However, we can notice that our supervised reference and the CPC model are still the ones that exhibit the most native language effect.

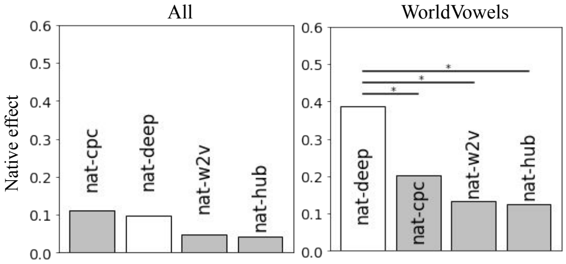

Figure 4: Native language effect for each model, the bigger the bar, the better the models capture language specificities in the discrimination behaviour between the two groups. Stars indicate that the pairwise difference is significant. The supervised reference is in white to distinguish it from the self-supervised models in light grey.

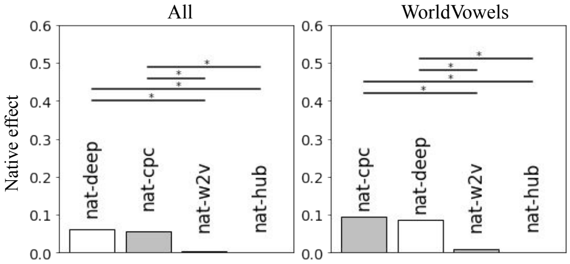

Figure 5: Native language effect for each model, the bigger the bar, the better the models capture language specificities in the discrimination behaviour between the two groups. Stars indicate that the pairwise difference is significant. The supervised reference is in white to distinguish it from the self-supervised models in light grey.

6 Discussion

We showed that the self-supervised models we tested seem to learn representational spaces relevant for predicting human phone discrimination at the stimuli level. However, while humans show consistent discrimination behaviour for certain contrasts, whatever the stimuli, the self-supervised models we test do not capture systematic effects of contrasts between specific pairs of phones. Unlike our supervised reference, their similarity to human perceptual spaces is limited to capturing the discriminability of specific individual stimuli. The models tested were similar, but wav2vec 2.0 showed a slight advantage for predicting this kind of behaviour.

We have also shown that training on speech data is essential to obtaining a human-like perceptual space: for all of our metrics (ABX accuracy or similarity to humans), training on speech leads to better results than training on acoustic scenes (non-speech). This strongly suggests that the benefits of self-supervised speech models comes from learning characteristics of human speech, not simply the fact that they are better general audio features. We speculate that this is not just important to their ability to predict human speech perception and to discriminate phones, but also of their (related) utility for doing downstream tasks such as ASR.

What these models learn about speech, however, is not typically language-specific—at least, not in the same way that human perception is. Wav2vec 2.0 and HuBERT do not model language-specific differences in human speech perception, and can be seen as modelling a language-neutral or universal speech perception space. Indeed, they exhibit very few native language effect (see Figure 4 and 5). We note that the idea of self-supervised models learning universal speech features is consistent with the fact that models trained on one language, or multilingually, have proven useful for representing speech in unseen languages (Riviere et al., 2020).

CPC does capture effects of native language on perception at the contrast level, but to a far lesser extent than our supervised reference when we focus on a subset of Perceptimatic designed to capture important differences in discrimination behaviour for our two groups of participants (WorldVowels). Our CPC model differs from the other models tested in its small size, its causal architecture (wav2vec and HuBERT use transformers), and in that it does not use masking during its training. Its architecture is probably the most biologically plausible of the three self-supervised models we tested. We should note, however, that it does not make it the best predictor of human discrimination behaviour among the three models (see Figure 1 and 2).

One possible explanation for the self-supervised models' limitations we observe is insufficiency of training data: the models in question have generally shown good performance on downstream tasks when pre-trained on large amounts of data. We tested this using available pretrained wav2vec and HuBERT models trained on much larger amounts of data. The detailed results can be found in Appendix E. The models show a slight improvement, but, when looking at the ρ statistic at the phone contrast level, they are still worse than MFCCs.

Contrary to previous results (Millet and Dunbar, 2020a,b), our supervised reference system is quite good at predicting human discrimination behaviour (in particular at the contrast level), and clearly predicts a native language effect. The main differences in our experiment with (Millet and Dunbar, 2020b) are the type of model (DeepSpeech instead of HMM-GMM), and with (Millet and Dunbar, 2020a) the type of training objective (phone recognition rather than prediction of orthographic text), and the size of the training corpora (we use fewer data). Predicting phones rather than orthography seems to be critical (as we demonstrate in Appendix F), and using a neural network instead of a Bayesian model (HMM-GMM) leads to a more human-like representational space, as already highlighted by (Schatz and Feldman, 2018).

Given the advantage supervised phone recognizers show, a different approach to developing more human-like representational spaces in self-supervised models might be the inclusion of tasks or constraints that push them to take into account longer time scales in order to encourage them to construct longer, more phone-like units.

A Detailed losses used by the models

The loss used by the **CPC** model is the following:

$$\mathcal{L}_t = -\frac{1}{K}\sum_{k=1}^{K}\log\left[\frac{\exp\left(\phi\left(\mathbf{x}_{t+k}\right)^{\top}\mathbf{A}_k\mathbf{z}_t\right)}{\sum_{\mathbf{n}\in\mathcal{N}_t}\exp\left(\phi(\mathbf{n})^{\top}\mathbf{A}_k\mathbf{z}_t\right)}\right] \tag{2}$$

Where A_k is a learned linear classifier, ϕ is the encoder, and N_i is the set of negative examples. With an input x_t and an output $\mathbf{z}_t = \psi\left(\phi\left(\mathbf{x}_1\right),\ldots,\phi\left(\mathbf{x}_t\right)\right)$, with ψ the sequential model, it pushes the model to identify the K next outputs $\phi\left(\mathbf{x}_{t+k}\right)$ in the future, in comparison with randomly sampled outputs from another part of x.

The loss used by the **wav2vec 2.0** model is the following:

$$\mathcal{L}_m = -\log\frac{\exp\left(\mathrm{sim}\left(\mathbf{c}_t,\mathbf{q}_t\right)/\kappa\right)}{\sum_{\tilde{\mathbf{q}}\sim\mathbf{Q}_t}\exp\left(\mathrm{sim}\left(\mathbf{c}_t,\tilde{\mathbf{q}}\right)/\kappa\right)} \tag{3}$$

for a masked time step t, the model has to choose the true quantized speech representation q_t in a set of $K+1$ quantized candidate representations $\tilde{\mathbf{q}}\in\mathbf{Q}_t$ which includes $\mathbf{q}_t$ and K distractors. The model also use a diversity loss so the representation in the quantizer dictionary be as diverse as possible, for more details, see (Baevski et al., 2020).

The loss used by **HuBERT** is the following:

$$\begin{aligned}L(f;X,M,Z) = \quad & \alpha\sum_{t\in M}\log p_f\left(z_t\mid\tilde{X},t\right)+\\ & (1-\alpha)\sum_{t\notin M}\log p_f\left(z_t\mid X,t\right)\end{aligned}$$

With $\alpha\in[0,1]$, M the set of masked frames, f the cluster assignment predictor, and $\hat{X}$ masked frames.

B Predicting human results: results on sub-datasets

We present the results on the different Perceptimatic subsets. The results for Cogsci 2019 can be seen in Figure 7, for WorldVowels in Figure 6, for Zerospeech in Figure 10, for pilot-july in Figure 8, and for pilot-august in Figure 9. These results should be taken carefully, in particular for the Cogsci subset and the pilots, as not much contrasts and stimuli were tested for these subsets compared to the others.

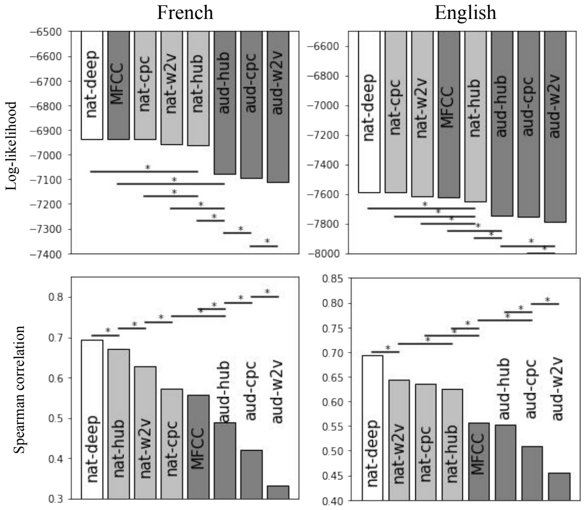

Figure 6: Results on the **WorldVowels** subset. Log-likelihood values (top: shorter bars are better) and Spearman correlation (bottom: taller bars are better) for French (*left*) and English participants (*right*). Stars indicate that the pairwise difference is significant. The supervised reference is in white to distinguish it from the self-supervised model trained on speech recordings (in light grey), and the baselines in darker grey (neutral acoustic features and models trained on acoustic scenes).

C Difference in ABX score between French and English models

To complete Table 1, we present in Figure 11 the detailed ABX score difference between a native discrimination setting (English models and participants discriminating English contrasts and same for French) and a non-native discrimination setting (English models and participants discriminating French contrasts and vice-versa). Humans' ABX scores differences show that English-speaking participants are not always better than French-speaking participants at discriminating English sounds (for the Zerospeech subsets for example).

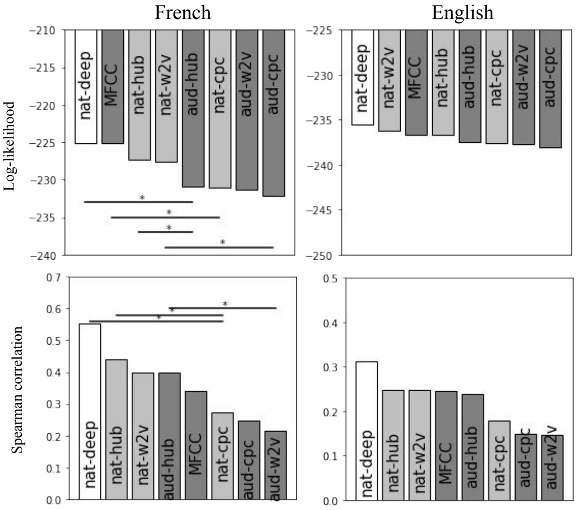

Figure 7: Results on the **Cogsci-2019** subset. Log-likelihood values (top: shorter bars are better) and Spearman correlation (bottom: taller bars are better) for French (*left*) and English participants (*right*). Stars indicate that the pairwise difference is significant. The supervised reference is in white to distinguish it from the self-supervised model trained on speech recordings (in light grey), and the baselines in darker grey (neutral acoustic features and models trained on acoustic scenes).

D Language preference

A possible approach to study models' language specificity would be to see if English-trained models predict English-speaking participants better than French-trained models, and vice versa. We assess whether models in the native training condition predict discriminability better than the corresponding models in the non-native training condition. Figure 12 plots the subtraction of the $\ell\ell$ and ρ scores in the non-native setting from the corresponding scores in the native setting (across the entire Perceptimatic dataset).

For both the (experimental item-level) $\ell\ell$ and the (phone contrast-level) ρ score, DeepSpeech consistently outperforms over wav2vec 2.0. This is in contrast with the overall prediction performance reported above, where wav2vec 2.0 was on par with DeepSpeech, DeepSpeech generally shows a relative advantage for predicting the behaviour of listeners whose native language is the same as the training language, while wav2vec 2.0 does not.

There is a striking difference between languages

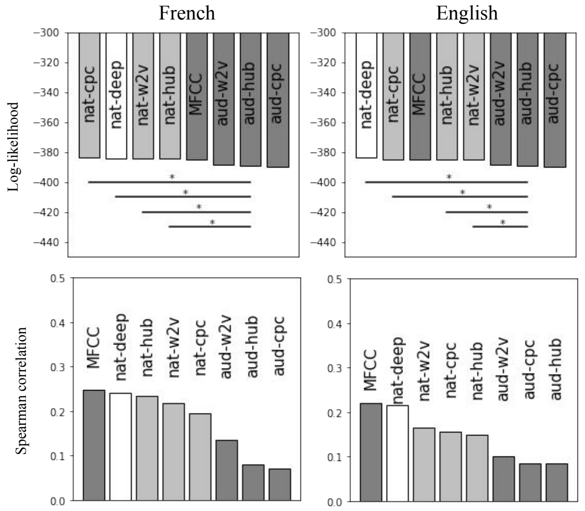

Figure 8: Results on the **pilot-july-2018** subset. Log-likelihood values (top: shorter bars are better) and Spearman correlation (bottom: taller bars are better) for French (*left*) and English participants (*right*). Stars indicate that the pairwise difference is significant. The supervised reference is in white to distinguish it from the self-supervised model trained on speech recordings (in light grey), and the baselines in darker grey (neutral acoustic features and models trained on acoustic scenes).

in the performance of DeepSpeech: for English, the native DeepSpeech shows a substantial advantage over the non-native (French-trained) DeepSpeech which is not present for the French datasets. Similarly, in French, the native HuBERT shows an advantage over the non-native (English-trained) HuBERT, while the reverse is true in English. However, these two major differences may be in part explained by global effects: the French-trained HuBERT model is better at predicting the results for all participants (not just French-speaking participants), as is the English-trained DeepSpeech model.

E Using pretrained models on more data

We compare our models with pretrained models available online. For English, we tested a wav2vec and a HuBERT model trained on Librispeech (Panayotov et al., 2015) (960 h) and for French, we tested a wav2vec model trained on the French Voxpopuli dataset (Wang et al., 2021) (4.5k h). The results of these models compared to ours and MFCCs can be seen in Figure 13. Their different ABX scores can also be seen in Table 2. Models trained on English are evaluated on English-

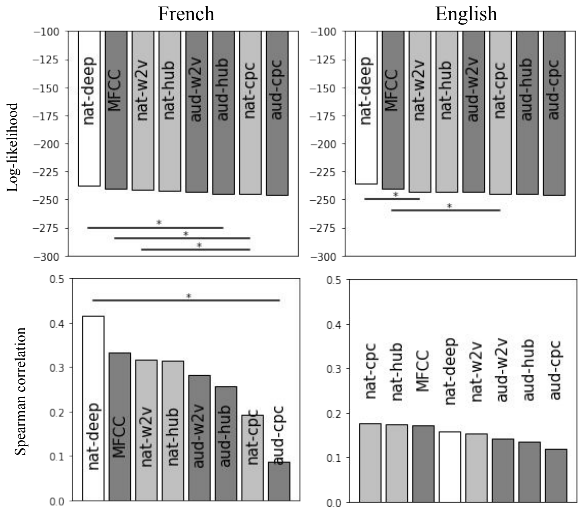

Figure 9: Results on the **pilot-august-2018** subset. Log-likelihood values (top: shorter bars are better) and Spearman correlation (bottom: taller bars are better) for French (*left*) and English participants (*right*). Stars indicate that the pairwise difference is significant. The supervised reference is in white to distinguish it from the self-supervised model trained on speech recordings (in light grey), and the baselines in darker grey (neutral acoustic features and models trained on acoustic scenes).

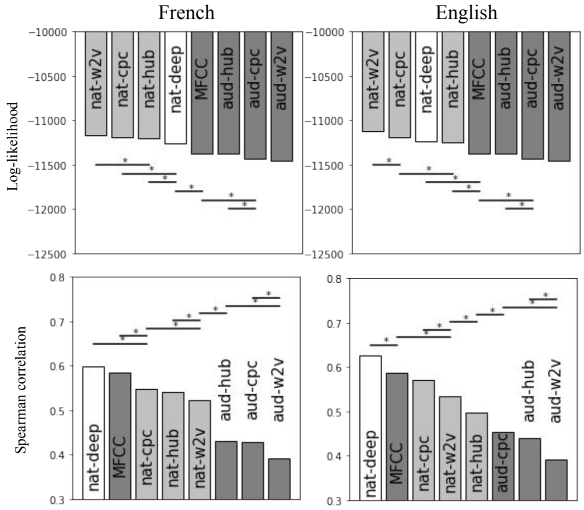

Figure 10: Results on the **Zerospeech** subset. Log-likelihood values (top: shorter bars are better) and Spearman correlation (bottom: taller bars are better) for French (*left*) and English participants (*right*). Stars indicate that the pairwise difference is significant. The supervised reference is in white to distinguish it from the self-supervised model trained on speech recordings (in light grey), and the baselines in darker grey (neutral acoustic features and models trained on acoustic scenes).

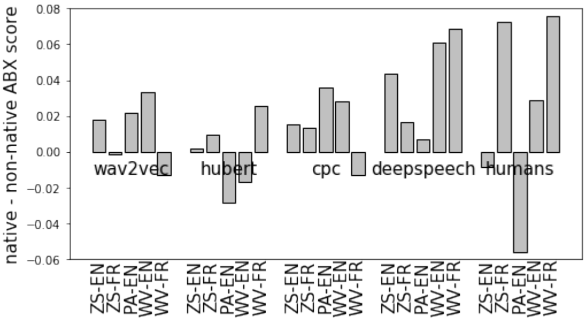

Figure 11: ABX score difference between native setting and non-native setting for the different models tested. The bigger the bar above zero, the bigger difference.

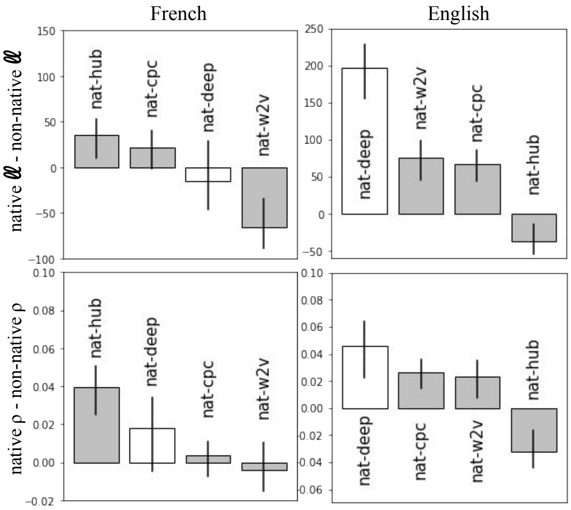

Figure 12: Native minus non-native log-likelihood values (top) and Spearman correlations (bottom) for French (*left*) and English participants (*right*). The higher the bar above zero, the better the native setting is compared to the non-native setting. The supervised reference is in white, the self-supervised models are in light grey. Black lines indicate 95% confidence intervals.

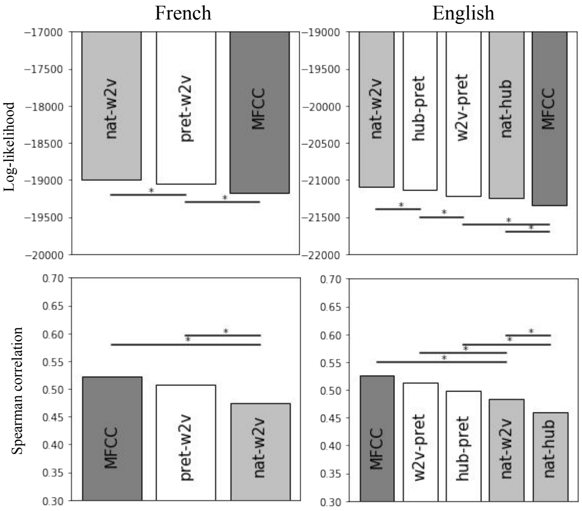

Figure 13: Log-likelihood values (top: shorter bars are better) and Spearman correlation (bottom: taller bars are better) for French (*left*) and English participants (*right*). Stars indicate that the pairwise difference is significant. The pretrained models are in white to distinguish it from our self-supervised models trained on only 600h of speech.

speaking participants (and English contrast for the ABX scores), and same for French.

F Testing DeepSpeech using orthographic transcriptions

We tested two kinds of supervised references: one trained to produce phonemic transcriptions (the one used in the main article) and another trained to produce orthographic transcriptions. In general, training on phonemic transcriptions led the internal representations of the model to be closer to humans' perceptual space, as it can be seen in Figure 14. A comparison of English-speaking participants' discrimination ability and the two supervised models' Δ-values can also be seen in Figure 15. Models trained on phonemic transcriptions are better at

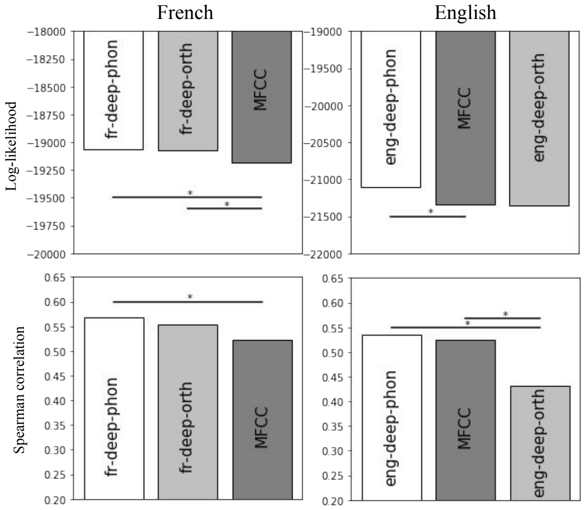

Figure 14: Results of DeepSpeech trained on phonemic transcriptions (phon) or orthographic (orth), compared with MFCCs. Log-likelihood values (top: shorter bars are better) and Spearman correlation (bottom: taller bars are better) for French (*left*) and English participants (*right*). Stars indicate that the pairwise difference is significant.

predicting human behaviour than the ones trained on orthographic transcriptions. These results highlight on the one hand the impact of the labels used during supervised training, which can lead to non human-like speech representational space, and on the other hand the fact that humans probably use informations more similar to phoneme categories than possible orthographic transcriptions during a discrimination task.

The amount of training data may also play a role, as large training sets could lead to “overfitting,” in a loose sense, to fine “superhuman” acoustic details of phone classification. Appendix E shows that training size does *not* have this effect on the self-supervised models studied here. We leave analysis of the supervised case for future work.

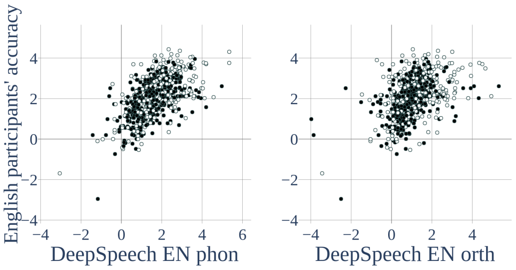

Figure 15: Average of English listeners’ results (higher: better discrimination) against average δ from (**left**) supervised reference trained on phonemic transcriptions (**right**) trained on orthographic transcriptions. Each point is a contrast. Measures are normalized by dividing by standard deviation over the entire data set. Black circles are non-native contrasts, white ones are native (English).

Vision-and-Language Navigation: A Survey of Tasks, Methods, and Future Directions

Abstract

A long-term goal of AI research is to build intelligent agents that can communicate with humans in natural language, perceive the environment, and perform real-world tasks. Vision-and-Language Navigation (VLN) is a fundamental and interdisciplinary research topic towards this goal, and receives increasing attention from natural language processing, computer vision, robotics, and machine learning communities. In this paper, we review contemporary studies in the emerging field of VLN, covering tasks, evaluation metrics, methods, etc. Through structured analysis of current progress and challenges, we highlight the limitations of current VLN and opportunities for future work. This paper serves as a thorough reference for the VLN research community.[1]

1 Introduction

Humans communicate with each other using natural language to issue tasks and request help. An agent that can understand human language and navigate intelligently would significantly benefit human society, both personally and professionally. Such an agent can be spoken to in natural language, and would autonomously execute tasks such household chores indoors, repetitive delivery work outdoors, or work in hazardous conditions following human commands (bridge inspection; fire-fighting). Scientifically, developing such an agent explores how an artificial agent interprets natural language from humans, perceives its visual environment, and utilizes that information to navigate to complete a task successfully.

Vision-and-Language Navigation (VLN) (Anderson et al., 2018b; Chen et al., 2019; Thomason et al., 2019b) is an emerging research field that aims to build such an embodied agent that can communicate with humans in natural language and navigate in real 3D environments. VLN extends visual navigation in both simulated (Zhu et al., 2017; Mirowski, 2019) and real environments (Mirowski et al., 2018) with natural language communication. As illustrated in Figure 1, VLN is a task that involves the oracle (frequently a human), the agent, and the environment. The agent and the oracle communicate in natural language. The agent may ask for guidance and the oracle could respond. The agent navigates and interacts with the environment to complete the task according to the instructions received and the environment observed. Meanwhile, the oracle observes the environment and agent status, and may interact with the environment to help the agent.

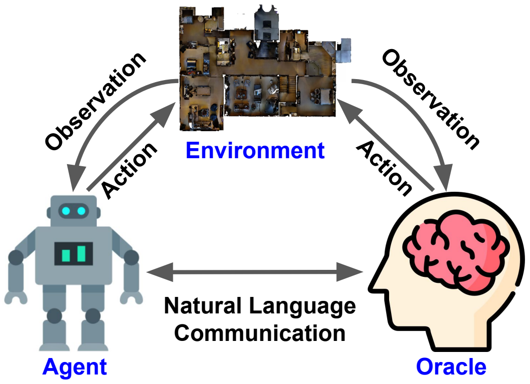

Figure 1: The agent and oracle discuss the VLN task in natural language. Both observe and interact with the navigable environment to accomplish a task.

Since the development and release of works such as Room-to-Room (R2R) (Anderson et al., 2018b), many VLN datasets have been introduced. Regarding the degree of communication, researchers create benchmarks where the agent is required to passively understand one instruction before navigation, to benchmarks where agents converse with the oracle in free-form dialog. Regarding the task objective, the requirements for the agent range from strictly following the route described in the ini-

tial instruction to actively exploring the environment and interacting with objects. In a slight abuse of terminology, we refer to benchmarks that involve object interaction together with substantial sub-problems of navigation and localization, such as ALFRED (Shridhar et al., 2020), as VLN benchmarks.

Many challenges exist in VLN tasks. First, VLN faces a complex environment and requires effective understanding and alignment of information from different modalities. Second, VLN agents require a reasoning strategy for the navigation process. Data scarcity is also an obstacle. Lastly, the generalization of a model trained in seen environments to unseen environments is also essential. We categorize the solutions according to the respective challenges. (1) *Representation learning* methods help understand information from different modalities. (2) *Action strategy learning* aims to make reasonable decisions based on gathered information. (3) *Data-centric learning* methods effectively utilize the data and address data challenges such as data scarcity. (4) *Prior exploration* helps the model familiarize itself with the test environment, improving its ability to generalize.

We make three primary contributions. (1) We systematically categorize current VLN benchmarks from *communication complexity* and *task objective* perspectives, with each category focusing on a different type of VLN task. (2) We hierarchically classify current solutions and the papers within the scope. (3) We discuss potential opportunities and identify future directions.

2 Tasks and Datasets

The ability for an agent to interpret natural language instructions (and in some instances, request feedback during navigation) is what makes VLN unique from visual navigation (Bonin-Font et al., 2008). In Table 2, we mainly categorize current datasets on two axes, *Communication Complexity* and *Task Objective*.

Communication Complexity defines the level at which the agent may converse with the oracle, and we differentiate three levels: In the first level, the agent is only required to understand an *Initial Instruction* before navigation starts. In the second level, the agent sends a signal for help whenever it is unsure, utilizing the *Guidance* from the oracle. In the third level, the agent with *Dialogue* ability asks questions in the form of natural language during the navigation and understands further oracle guidance.

Task Objective defines *how* the agent attains its goal based on the *initial instructions* from the oracle. In the first objective type, *Fine-grained Navigation*, the agent can find the target according to a detailed step-by-step route description. In the second type, *Coarse-grained Navigation*, the agent is required to find a distant target goal with a coarse navigation description, requiring the agent to reason a path in a navigable environment and possibly elicit additional oracle help. Tasks in the previous two types only require the agent to navigate to complete the mission. In the third type, *Navigation and Object Interaction*, besides reasoning a path, the agent also needs to interact with objects in the environment to achieve the goal since the object might be hidden or need to change physical states.[2] As with coarse-grained navigation, some object interaction tasks can require additional supervision via dialogue with the oracle.

2.1 Initial Instruction

In many VLN benchmarks, the agent is given a natural language instruction for the whole navigation process, such as *"Go upstairs and pass the table in the living room. Turn left and go through the door in the middle."*

Fine-grained Navigation An agent needs to strictly follow the natural language instruction to reach the target goal. Anderson et al. (2018b) create the R2R dataset based on the Matterport3D simulator (Chang et al., 2017). An embodied agent in R2R moves through a house in the simulator traversing edges on a navigation graph, jumping to adjacent nodes containing panoramic views. R2R is extended to create other VLN benchmarks. Room-for-Room joins paths in R2R to longer trajectories (Jain et al., 2019). Yan et al. (2020) collect XL-R2R to extend R2R with Chinese instructions. RxR (Ku et al., 2020) contains instructions from English, Hindi, and Telegu. The dataset has more samples and the instructions in it are time-aligned to the virtual poses of the instruction. The English split of RxR is further extended to build Landmark-RxR (He et al., 2021) by incorporating landmark information.

In most current datasets, agents traverse a navigation graph at predefined viewpoints. To facil-

---

[2] Navigation and Object Interaction includes both fine-grained and coarse-grained instructions, which ideally should be split further. But given that there are only few datasets in this category, we keep the current categorization in Table 2.

Comm Complexity	**Task Objective**		
	Fine-grained Navigation	Coarse-grained Navigation	Nav + Object Interaction
Initial Instruction(s)	Room-to-Room (Anderson et al., 2018b), Room-for-Room (Jain et al., 2019), Room-Across-Room (Ku et al., 2020), XL-R2R (Yan et al., 2020), Landmark-RxR (He et al., 2021), VLNCE (Krantz et al., 2020), TOUCHDOWN (Chen et al., 2019), StreetLearn (Mirowski et al., 2019), StreetNav (Hermann et al., 2020), Talk2Nav (Vasudevan et al., 2021), LANI (Misra et al., 2018)	RoomNav (Wu et al., 2018), EmbodiedQA (Das et al., 2018), REVERIE (Qi et al., 2020b), SOON (Zhu et al., 2021a)	IQA (Gordon et al., 2018), CHAI (Misra et al., 2018), ALFRED (Shridhar et al., 2020)
Oracle Guidance	Just Ask (Chi et al., 2020)	VNLA (Nguyen et al., 2019), HANNA (Nguyen and Daumé III, 2019)	None
Dialogue	None	CVDN (Thomason et al., 2019b), RobotSlang (Banerjee et al., 2020), Talk the Walk (de Vries et al., 2018), CEREALBAR (Suhr et al., 2019)	TEACh (Padmakumar et al., 2021), Minecraft Collaborative Building (Narayan-Chen et al., 2019), DialFRED (Gao et al., 2022)

Table 1: Vision-and-Language Navigation benchmarks organized by **Communication Complexity** versus **Task Objective**. Please refer to Appendix for more details about the datasets and the commonly used underlying simulators.

itate transfer learning to real agents, VLN tasks should provide a continuous action space and a freely navigable environment. To this end, Krantz et al. (2020) reconstruct the navigation graph based R2R trajectories in continuous environments and create VLNCE. Irshad et al. (2021) propose Robo-VLN task where the agent operates in a continuous action space over long-horizon trajectories.

Outdoor environments are usually more complex and contain more objects than indoor environments. In TOUCHDOWN (Chen et al., 2019), an agent follows instructions to navigate a streetview rendered simulation of New York City to find a hidden object. Most photo-realistic outdoor VLN datasets including TOUCHDOWN (Chen et al., 2019), StreetLearn (Mirowski et al., 2019; Mehta et al., 2020), StreetNav(Hermann et al., 2020), and Talk2Nav (Vasudevan et al., 2021) are proposed based on Google Street View.

Some work uses natural language to guide drones. LANI (Misra et al., 2018) is a 3D synthetic navigation environment, where an agent navigates between landmarks following natural language instructions. Current datasets on drone navigation usually fall in a synthetic environment such as Unity3D (Blukis et al., 2018, 2019).

Coarse-grained Navigation In real life, detailed information about the route may not be available since it may be unknown to the human instructor (oracle). Usually, instructions are more concise and contain merely information of the target goal.

RoomNav (Wu et al., 2018) requires agent navigate according to instruction "*go to X*", where X is a predefined room or object.

In Embodied QA (Das et al., 2018), the agent navigates through the environment to find answer for a given question. The instructions in REVERIE (Qi et al., 2020b) are annotated by humans, and thus more complicated and diverse. The agent navigates through the rooms and differentiates the object against multiple competing candidates. In SOON (Zhu et al., 2021a), an agent receives a long, complex coarse-to-fine instruction which gradually narrows down the search scope.

Navigation+Object Interaction For some tasks, the target object might be hidden (e.g., the spoon in a drawer), or need to change status (e.g., a sliced apple is requested but only a whole apple is available). In these scenarios, it is necessary to interact with the objects to accomplish the task (e.g., opening the drawer or cutting the apple). Interactive Question Answering (IQA) requires the agent to navigate and sometimes to interact with objects to answer a given question. Based on indoor scenes in AI2-THOR (Kolve et al., 2017), Shridhar et al. (2020) propose the ALFRED dataset, where agents are provided with both coarse-grained and fine-grained instructions complete household tasks in an interactive visual environment. CHAI (Misra et al., 2018) requires the agent to navigate and simply interact with the environments.

2.2 Oracle Guidance

Agents in Guidance VLN tasks may receive further natural language guidance from the oracle during navigation. For example, if the agent is unsure of the next step (e.g., entering the kitchen), it can send a [help] signal, and the oracle would assist by responding *"go left"* (Nguyen et al., 2019).

Fine-grained Navigation The initial fine-grained navigation instruction may still be ambiguous in a complex environment. Guidance from the oracle could clarify possible confusion. Chi et al. (2020) introduce Just Ask—a task where an agent could ask oracle for help during navigation.

Coarse-grained Navigation With only a coarse-grained instruction given at the beginning, the agent tends to be more confused and spends more time exploring. Further guidance resolves this ambiguity. VNLA (Nguyen et al., 2019) and HANNA (Nguyen and Daumé III, 2019) both train an agent to navigate indoors to find objects. The agent could request help from the oracle, which responds by providing a subtask which helps the agent make progress. While oracle in VNLA uses predefined script to respond, the oracle in HANNA uses a neural network to generate natural language responses. CEREALBAR (Suhr et al., 2019) is a collaborative task between a leader and a follower. Both agents move in a virtual game environment to collect valid sets of cards.

Navigation+Object Interaction While VLN is still in its youth, there are no VLN datasets in support of Guidance and Object Interaction.

2.3 Human Dialogue

It is human-friendly to use natural language to request help (Banerjee et al., 2020; Thomason et al., 2019b). For example, when the agent is not sure about what fruit the human wants, it could ask *"What fruit do you want, the banana in the refrigerator or the apple on the table?"*, and the human response would provide clear navigation direction.

Fine-grained Navigation No datasets are in the scope of this category. Currently, route-detailed instruction with possible guidance could help the agent achieve relatively good performance in most simulated environments. We expect datasets to be developed for this category for super long horizon navigation tasks in complex environments especially with rich dynamics where dialog is necessary to clear confusions.

Coarse-grained Navigation CVDN (Thomason et al., 2019b) is a dataset of human-human dialogues. Besides interpreting a natural language instruction and deciding on the following action, the VLN agent also needs to ask questions in natural language for guidance. The oracle, with knowledge of the best next steps, needs to understand and correctly answer said questions.

Dialogue is important in complex outdoor environments. de Vries et al. (2018) introduce the Talk the Walk dataset, where the guide has knowledge from a map and guides the tourist to a destination, but does not know the tourist's location; while the tourist navigates a 2D grid via discrete actions.

Navigation+Object Interaction Minecraft Collaborative Building (Narayan-Chen et al., 2019) studies how an agent places blocks into a building by communicating with the oracle. TEACh (Padmakumar et al., 2021) is a dataset that studies object interaction and navigation with free-form dialog. The follower converses with the commander and interacts with the environment to complete various house tasks such as making coffee. DialFRED (Gao et al., 2022) extends ALFRED (Shridhar et al., 2020) dataset by allowing the agent to actively ask questions.

3 Evaluation

Goal-oriented Metrics mainly consider the agent's proximity to the goal. The most intuitive is *Success Rate (SR)*, which measures how frequently an agent completes the task within a certain distance of the goal. *Goal Progress* (Thomason et al., 2019b) measures the reduction in remaining distance to the target goal. *Path Length (PL)* measures the total length of the navigation path. *Shortest-Path Distance (SPD)* measures the mean distance between the agent's final location and the goal. Since a longer path length is undesirable (increases duration and wear-and-tear on actual robots), *Success weighted by Path Length (SPL)* (Anderson et al., 2018a) balances both Success Rate and Path Length. Similarly, *Success weighted by Edit Distance (SED)* (Chen et al., 2019) compares the expert's actions/trajectory to the agent's actions/trajectory, also balancing SR and PL. *Oracle Navigation Error (ONE)* takes the shortest distance from any node in the path rather than just the last node, and *Oracle Success Rate (OSR)* measures whether any node in the path is within a threshold from the target location.

Path-fidelity Metrics evaluate to what extent an agent follows the desired path. Some tasks require the agent not only to find the goal location but also to follow specific path. Fidelity measures the matches between the action sequence in the expert demonstration and the action sequence in the agent trajectory. *Coverage weighted by LS (CLS)* (Jain et al., 2019) is the product of the *Path Coverage (PC)* and *Length Score (LS)* with respect to the reference path. It measures how closely an agent's trajectory follows the reference path. *Normalized Dynamic Time Warping (nDTW)* (Ilharco et al., 2019) softly penalizes deviations from the reference path to calculate the match between two paths. *Success weighted by normalized Dynamic Time Warping (SDTW)* (Ilharco et al., 2019) further constrains nDTW to only successful episodes to capture both success and fidelity.

4 VLN Methods

As shown in Figure 2, we categorize existing methods into *Representation Learning*, *Action Strategy Learning*, *Data-centric Learning*, and *Prior Exploration*. Representation learning methods help agent understand relations between these modalities since VLN involves multiple modalities, including vision, language, and action. Moreover, VLN is a complex reasoning task where mission results depend on the accumulating steps, and better action strategies help the decision-making process. Additionally, VLN tasks face challenges within their training data. One severe problem is scarcity. Collecting training data for VLN is expensive and time-consuming, and the existing VLN datasets are relatively small with respect to the complexity of VLN tasks. Therefore, data-centric methods help to utilize the existing data and create more training data. Prior exploration helps adapt agents to previously unseen environments, improving their ability to generalize, decreasing the performance gap between seen versus unseen environments.

4.1 Representation Learning

Representation learning helps the agent understand how the words in the instruction relate to the perceived features in the environment.

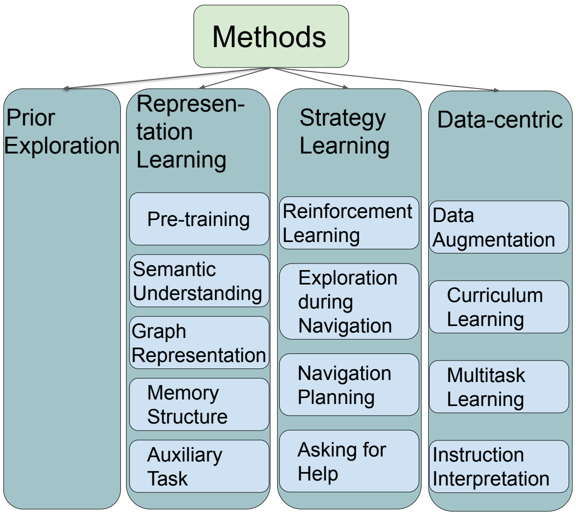

Figure 2: Categories of VLN methods. Methods may not be mutually exclusive to an individual category.

4.1.1 Pretraining

Vision or Language Using a pretrained model to initialize a vision or text encoder provides agents with single-modality knowledge. pretrained vision models may use a ResNet (He et al., 2016) or Vision Transformers (Dosovitskiy et al., 2020). Other navigation tasks (Wijmans et al., 2019b) may also provide visual initialization (Krantz et al., 2020). Large pretrained language models such as BERT (Devlin et al., 2019) and GPT (Radford et al., 2019) can encode language and improve instruction understanding (Li et al., 2019), which can be further pretrained with VLN instructions (Pashevich et al., 2021) before fine-tuning in VLN task.

Vision and Language Vision-and-language pretrained models provide good joint representation for text and vision. A common practice is to initialize the VLN agent with a pretrained model such as ViLBERT (Lu et al., 2019). The agent may be further trained with VLN-specific features such as objects and rooms (Qi et al., 2021).

VLN Downstream tasks benefit from being closely related to the pretraining task. Researchers also explored pretraining on the VLN domain directly. VLN-BERT (Majumdar et al., 2020) pretrains navigation models to measure the compatibility between paths and instructions, which formats VLN as a path selection problem. PREVALENT (Hao et al., 2020) is trained from scratch on image-text-action triplets to learn textual representations in VLN tasks. The output embedding from the [CLS] token in BERT-based pretraining models could be leveraged in a recurrent fashion to represent history state (Hong et al., 2021; Moudgil et al., 2021).

Airbert (Guhur et al., 2021) achieve good performance on few-shot setting after pretraining on a large-scale in-domain dataset.

4.1.2 Semantic Understanding

Semantic understanding of VLN tasks incorporates knowledge about important features in VLN. In addition to the raw features, high-level semantic representations also improve performance in unseen environments.

Intra-Modality Visual or textual modalities can be decomposed into many features, which matter differently in VLN. The overall visual features extracted by a neural model may actually hurt the performance in some cases (Thomason et al., 2019a; Hu et al., 2019; Zhang et al., 2020b). Therefore, it is important to find the feature(s) that best improve performance. High-level features such as visual appearance, route structure, and detected objects outperform the low level visual features extracted by CNN (Hu et al., 2019). Different types of tokens within the instruction also function differently (Zhu et al., 2021b). Extracting these tokens and encoding the object tokens and directions tokens are crucial (Qi et al., 2020a; Zhu et al., 2021b).

Inter-Modality Semantic connections between different modalities: actions, scenes, observed objects, direction clues, and objects mentioned in instructions can be extracted and then softly aligned with attention mechanism (Qi et al., 2020a; Gao et al., 2021). The soft alignment also highlights relevant parts of the instruction with respect to the current step (Landi et al., 2019; Zhang et al., 2020a).

4.1.3 Graph Representation

Building graph to incorporate structured information from instruction and environment observation provides explicit semantic relation to guide the navigation. The graph neural network may encode the relation between text and vision to better interpret the context information (Hong et al., 2020a; Deng et al., 2020). The graph could record the location information during the navigation, which can used to predict the most likely trajectory (Anderson et al., 2019a) or probability distribution over action space (Deng et al., 2020). When connected with prior exploration, an overview graph about the navigable environment (Chen et al., 2021a) can be built to improve navigation interpretation.

4.1.4 Memory-augmented Model

Information accumulates as the agent navigates, which is not efficient to utilize directly. Memory structure helps the agent effectively leverage the navigation history. Some solutions leverage memory modules such as LSTMs or recurrently utilize informative states (Hong et al., 2021), which can be relatively easily implemented, but may struggle to remember features at the beginning of the path as path length increases. Another solution is to build a separate memory model to store the relevant information (Zhu et al., 2020c; Lin et al., 2021; Nguyen and Daumé III, 2019). Notably, by hierarchically encoding a single view, a panorama, and then all panoramas in history, HAMT (Chen et al., 2021b) successfully utilized the full navigation history for decision-making.

4.1.5 Auxiliary Tasks

Auxiliary tasks help the agent better understand the environment and its own status without extra labels. From the machine learning perspective, an auxiliary task is usually achieved in the form of an additional loss function. The auxiliary task could, for example, explain its previous actions, or predict information about future decisions (Zhu et al., 2020a). Auxiliary tasks could also involve the current mission such as current task accomplishment, and vision & instruction alignment (Ma et al., 2019a; Zhu et al., 2020a). Notably, auxiliary tasks are effective when adapting pretrained representations for VLN (Huang et al., 2019).

4.2 Action Strategy Learning

With many possible action choices and complicated environment, action strategy learning provides a variety of methods to help the agent decide on those best actions.

4.2.1 Reinforcement Learning

VLN is a sequential decision-making problem and can naturally be modeled as a Markov decision process. So Reinforcement Learning (RL) methods are proposed to learn better policy for VLN tasks. A critical challenge for RL methods is that VLN agents only receive the success signal at the end of the episode, so it is difficult to know which actions to attribute success to, and which to penalize. To address the ill-posed feedback issue, Wang et al. (2019) propose RCM model to enforces cross-modal grounding both locally and globally, with goal-oriented extrinsic reward and instruction-fidelity intrinsic reward. He et al. (2021) propose to utilize the local alignment between the instruction and critical landmarks as the reward. Evaluation metrics such as CLS (Jain et al., 2019) or nDTW (Ilharco et al., 2019) can also provide informative reward signal (Landi et al., 2020), and natural language may also provide suggestions for reward (Fu et al., 2019).

To model the dynamics in the environment, Wang et al. (2018) leverage model-based reinforcement learning to predict the next state and improve the generalization in unseen environment. Zhang et al. (2020a) find recursively alternating the learning schemes of imitation and reinforcement learning improve the performance.

4.2.2 Exploration during Navigation

Exploring and gathering environmental information while navigating provides a better understanding of the state space. Student-forcing is a frequently used strategy, where the agent keeps navigating based on sampled actions and is supervised by the shortest-path action (Anderson et al., 2018b).

There is a tradeoff between exploration versus exploitation: with more exploration, the agent sees better performance at the cost of a longer path and longer duration, so the model needs to determine when and how deep to explore (Wang et al., 2020a). After having gathered the local information, the agent needs to decide which step to choose, or whether to backtrack (Ke et al., 2019). Notably, Koh et al. (2021) designed Pathdreamer, a visual world model to synthesize visual observation future viewpoints without actually looking ahead.

4.2.3 Navigation Planning

Planing future navigation steps leads to a better action strategy. From the visual side, predicting the waypoints (Krantz et al., 2021), next state and reward (Wang et al., 2018), generate future observation (Koh et al., 2021) or incorporating neighbor views (An et al., 2021) has proven effective. The natural language instruction also contains landmarks and direction clues to plan detailed steps. Anderson et al. (2019b) predict the forthcoming events based on the instruction, which is used to predict actions with a semantic spatial map.

4.2.4 Asking for Help

An intelligent agent asks for help when uncertain about the next action. Action probabilities or a separately trained model (Chi et al., 2020; Zhu et al., 2021c; Nguyen et al., 2021a) can be leveraged to decide whether to ask for help. Using natural language to converse with the oracle covers a wider problem scope than sending a signal. Both rule-based methods (Padmakumar et al., 2021) and neural-based methods (Roman et al., 2020; Nguyen et al., 2021a) have been developed to build navigation agents with dialog ability. Meanwhile, for tasks (Thomason et al., 2019b; Padmakumar et al., 2021) that do not provide an oracle agent to answer question in natural language, researchers also need to build a rule-based (Padmakumar et al., 2021) or neural-based (Roman et al., 2020) oracle. DialFRED (Gao et al., 2022) uses a language model as an oracle to answer questions.

4.3 Data-centric Learning

Compared with previously discussed works that focus on building a better VLN agent structure, data-centric methods most effectively utilize the existing data, or create synthetic data.

4.3.1 Data Augmentation

Trajectory-Instruction Augmentation Augmented path-instruction pairs could be used in VLN directly. Currently the common practice is to train a speaker module to generate instructions given a navigation path (Fried et al., 2018). This generated data have varying quality (Zhao et al., 2021). Therefore an alignment scorer (Huang et al., 2019) or adversarial discriminator (Fu et al., 2020) can select high-quality pairs for augmentation.

Environment Augmentation Generating more environment data not only helps generate more trajectories, but also alleviates the problem of overfitting in seen environments. Randomly masking the same visual feature across different viewpoints (Tan et al., 2019) or simply splitting the house scenes and remixing them (Liu et al., 2021) could create new environments, which could further be used to generate more trajectory-instruction pairs (Fried et al., 2018). Training data may also be augmented by replacing some visual features with counterfactual ones (Parvaneh et al., 2020).

4.3.2 Curriculum Learning

Curriculum learning (Bengio et al., 2009) gradually increases the task's difficulty during the training process. The instruction length could be a metric for task difficulty. BabyWalk (Zhu et al., 2020b) keep increasing training samples' instruction length during the training process. Attributes from the trajectory may also be used to rank task difficulty. Zhang et al. (2021) rearrange the R2R dataset using the number of rooms each path traverses. They found curriculum learning helps smooth the loss landscape and find a better local optima.

4.3.3 Multitask Learning

Different VLN tasks can benefit from each other by cross-task knowledge transfer. Wang et al. (2020c) propose an environment-agnostic multitask navigation model for both VLN and Navigation from Dialog History tasks (Thomason et al., 2019b). Chaplot et al. (2020) propose an attention module to train a multitask navigation agent to follow instructions and answer questions (Wijmans et al., 2019a).

4.3.4 Instruction Interpretation

A trajectory instruction interpreted multiple times in different ways may help the agent better understand its objective. LEO (Xia et al., 2020) leverages and encodes all the instructions with a shared set of parameters to enhance the textual understanding. LWIT (Nguyen et al., 2021b) interprets the instructions to make it clear to interact with what class of objects. Shorter, and more concise instructions provide clearer guidance for the agent compared to longer, semantically entangled instructions, thus Hong et al. (2020b) breaks long instructions into shorter ones, allowing the agent to track progress and focus on each atomic instruction individually.

4.4 Prior Exploration

Good performance in seen environments often cannot generalize to unseen environments (Hu et al., 2019; Parvaneh et al., 2020; Tan et al., 2019). Prior exploration methods allow the agent to observe and adapt to unseen environments,[3] bridging the performance gap between seen and unseen environments.

Wang et al. (2019) introduce a self-supervised imitation learning to learn from the agent's own past, good behaviors. The best navigation path determined to align the instruction the best by a matching critic will be used to update the agent. Tan et al. (2019) leverage the testing environments to sample and augment paths for adaptation. Fu et al. (2020) propose environment-based prior exploration, where the agent can only explore a particular environment where it is deployed. When utilizing graph, prior exploration may construct a map or overview about the unseen environment to provide explicit guidance for navigation (Chen et al., 2021a; Zhou et al., 2021).

5 Related Visual-and-Language Tasks

This paper focuses on Vision-and-Language Navigation tasks with an emphasis on photo-realistic environments. 2D map may also be a uesful virtual environment for navigation tasks (Vogel and Jurafsky, 2010; Chen and Mooney, 2011; Paz-Argaman and Tsarfaty, 2019). Synthetic environments may also be a substitute for realistic environment (MacMahon et al., 2006; Blukis et al., 2020). Tellex et al. (2011) propose to instantiate a probabilistic graphical model for natural language commands in robotic navigation and mobile manipulation process.

In VLN, an agent needs to follow the given instruction and even ask for assistants in human language. An agent in Visual Navigation tasks is usually not required to understand information from textual modality. Visual Navigation is a problem of navigating an agent from the current location to find the goal target. Researchers have achieved success in both simulated environments (Zhu et al., 2017; Mirowski, 2019) and real environments (Mirowski et al., 2018).

6 Conclusion and Future Directions

In this paper, we discuss the importance of VLN agents as a part of society, how their tasks vary as a function of communication level versus task objective, and how different agents may be evaluated. We broadly review VLN methodologies and categorize them. This paper only discusses these issues broadly at an introductory level. In reviewing these papers, we can see the immense progress that has already been made, as well as directions that this research topic can be expanded on.

Current methods usually do not explicitly utilize external knowledge such as objects and general house descriptions in Wikipedia. Incorporating knowledge also improves the interpretability and trust of embodied AI. Moreover, currently several navigation agents learn which direction to move and with what to interact, but there is a last-mile problem of VLN—how to interact with objects. An-

---

[3] Thus prior exploration methods are not directly comparable with other VLN methods.

derson et al. (2018b) asked whether a robot could learn to *"Bring me a spoon"*; new research may ask how a robot can learn to *"Pick up a spoon"*. The environments also lack diversity: most interior terrestrial VLN data consists of American houses, but never warehouses or hospitals: the places where these agents may be of most use.

Below we detail additional future directions:

Collaborative VLN Current VLN benchmarks and methods predominantly focus on tasks where only one agent navigates, yet complicated real-world scenarios may require several robots collaborating. Multi-agent VLN tasks require development in swarm intelligence, information communication, and performance evaluation. MeetUp! (Ilinykh et al., 2019) is a two-player coordination game where players move in a visual environment to find each other. VLN studies the relationship between the human and the environment in Figure 1, yet here humans are oracles simply observing (but not acting on) the environment. Collaboration between humans and robots is crucial for them to work together as teams (e.g., as personal assistants or helping in construction). Future work may target at collaborative VLN between multiple agents or between human and agents.

Simulation to Reality There is a performance loss when transferred to real-life robot navigation (Anderson et al., 2020). Real robots function in continuous space, but most simulators only allow agents to "hop" through a pre-defined navigation graph which is unrealistic for three reasons (Krantz et al., 2020). Navigation graphs assume: (1) perfect localization—in the real world it is a noisy estimate; (2) oracle navigation—real robots cannot "teleport" to a new node; (3) known topology—in reality an agent may not have access to a preset list of navigable nodes. Continuous implementations of realistic environments may contain patches of the images, be blurred, or have parallax errors, making them unrealistic. A simulation that is based on both a 3D model and realistic imagery could improve the match between virtual sensors (in simulation) and real sensors. Lastly, most simulators assume a static environment only changed by the agent. This does not account for other dynamics such as people walking or objects moving, nor does it account for lighting conditions through the day. VLN environments with probabilistic transition functions may also narrow the gap between simulation and reality.

Ethics & Privacy During both training and inference, VLN agents may observe and store sensitive information that can get leaked or misused. Effective navigation with privacy protection is crucially important. Relevant areas such as federated learning (Konečnỳ et al., 2016) or differential privacy (Dwork et al., 2006) could also be studied in VLN domain to preserve the privacy of training and inference environments.

Multicultural VLN VLN lacks diversity in 3D environments: most outdoor VLN datasets use Google Street View recorded in major American cities, but lacks data in developing countries. Agents trained on American data face potential generalization problems in other city or housing layouts. Future work should explore more diverse environments across multiple cultures and regions. Multilingual VLN datasets (Yan et al., 2020; Ku et al., 2020) could be good resources to study multicultural differences from the linguistic perspective.

A Dataset Details

Here in Table 2, we introduce more information about the datasets. Compared with the number of the datasets, the simulators are limited. More specifically, most indoor datasets are based on Matterport3D and most outdoor datasets are based on Google Street View. Also, more datasets are about indoor environments rather than outdoor environments. Outdoor environments are usually more complex and contain more objects compared with indoor environments.

B Simulator

The virtual features of the dataset are deeply connected with the simulator in which datasets are built. Here we summarize simulators frequently used during the VLN dataset creation process.

House3D (Wu et al., 2018) is a realistic virtual 3D environment built based on the SUNCG (Song et al., 2017) dataset. An agent in the environment has access to first-person view RGB images, together with semantic/instance masks and depth information.

Matterport3D (Anderson et al., 2018b) simulator is a large-scale visual reinforcement learning simulation environment for research on embodied AI based on the Matterport3D dataset (Chang et al., 2017). Matterport3D contains various indoor scenes, including houses, apartments, hotels, offices, and churches. An agent can navigate between viewpoints along a pre-defined graph. Most indoors VLN datasets such as R2R and its variants are based on the Matterport3D simulator.

Habitat (Manolis Savva* et al., 2019; Szot et al., 2021) is a 3D simulation platform for training embodied AI in 3D physics-enabled scenarios. Compared with other simulation environments, Habitat 2.0 (Szot et al., 2021) shows strength in system response speed. Habitat has the following datasets built-in: Matterport3D (Chang et al., 2017), Gibson (Xia et al., 2018), and Replica (Straub et al., 2019). AI2-THOR (Kolve et al., 2017) is a near photo-realistic 3D indoor simulation environment, where agents could navigate and interact with objects. Based on the object interaction function, it helps to build a dataset that requires object interaction, such as ALFRED (Shridhar et al., 2020).

Gibson (Xia et al., 2018) is a real-world perception interactive environment with complex semantics. Each viewpoint has a set of RGB panoramas with global camera poses and reconstructed 3D meshes. Matterport3D dataset (Chang et al., 2017) is also integrated into the Gibson simulator.

House3D (Wu et al., 2018) converts SUNCG's static environment into a virtual environment, where the agent can navigate with physical constraints (e.g. it cannot pass through walls or objects).

LANI (Misra et al., 2018) is a 3D simulator built in Unity3D platform. The environment in LANI is a fenced, square, grass field containing randomly placed landmarks. An agent needs to navigate between landmarks following the natural language instruction. Drone navigation tasks (Blukis et al., 2018, 2019) are also built based on LANI.

Currently, most datasets and simulators focus on indoors navigable scenes partly because of the difficulty of building an outdoor photo-realistic 3D simulator out of the increased complexity. Google Street View [4], an online API that is integrated with Google Maps, is composed of billions of realistic street-level panoramas. It has been frequently used to create outdoor VLN tasks since the development of TOUCHDOWN (Chen et al., 2019).

C Room-to-Room Leaderboard

Room-to-Room (R2R) (Anderson et al., 2018b) is the benchmark used most frequently for evaluating different methods. Here we collect all the reported performance metrics in the corresponding papers and the official R2R leaderboard[5]. Since beam search explores more routes, and since prior exploration has additional observations in the test environment, their performance can not be directly compared with other methods.

Learning to Generate Programs for Table Fact Verification via Structure-Aware Semantic Parsing

Suixin Ou, Yongmei Liu[*]
Dept. of Computer Science, Sun Yat-sen University, Guangzhou 510006, China
`ousx@mail2.sysu.edu.cn`, `ymliu@mail.sysu.edu.cn`

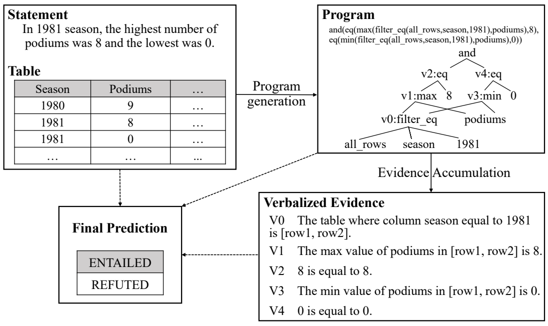
Abstract

Table fact verification aims to check the correctness of textual statements based on given semi-structured data. Most existing methods are devoted to better comprehending logical operations and tables, but they hardly study generating latent programs from statements, with which we can not only retrieve evidences efficiently but also explain reasons behind verifications naturally. However, it is challenging to get correct programs with existing weakly supervised semantic parsers due to the huge search space with lots of spurious programs. In this paper, we address the challenge by leveraging both lexical features and structure features for program generation. Through analyzing the connection between the program tree and the dependency tree, we define a unified concept, operation-oriented tree, to mine structure features, and introduce Structure-Aware Semantic Parsing to integrate structure features into program generation. Moreover, we design a refined objective function with lexical features and violation punishments to further avoid spurious programs. Experimental results show that our proposed method generates programs more accurately than existing semantic parsers, and achieves comparable performance to the SOTA on the large-scale benchmark TABFACT.

1 Introduction

With the rise of misleading information on the Internet, such as fake news, rumors and political deceit, fact-checking has been developed as a means of detecting and filtering false information. *Table fact verification (TFV)* is a specific fact-checking task that requires performing logical operations such as comparison, superlative and aggregation over given tables to verify textual statements.

Programs play an important role in TFV. On one hand, correct programs can provide rationales for model decisions, which make reasoning analysis and failure diagnosis feasible (Zhou et al., 2018). On the other hand, they can be used to fetch the key evidences for verification. Figure 1 gives an example of mainstream methods (Zhong et al., 2020a; Shi et al., 2020b; Yang et al., 2020; Shi et al., 2021) for TFV. It first generates latent programs from statements, then collects evidences from tables by executing the programs over the tables, and finally leverages all information for final predictions. Compared with naive methods(Chen et al., 2020; Zhang et al., 2020a) which simply put statements and linearized tables into language models for verification, the mainstream methods additionally introduce programs to reveal the evidences (e.g., *verbalized evidence V1*) covered by logical operations (e.g., *max([row1, row2]], podiums)*) and to fetch the key information from the table (e.g., *8*). But an incorrect or spurious program may introduce irrelevant or even contradictory evidences. So it is crucial to get correct programs that properly extract evidences from tables, especially when tables are too large to be encoded by neural networks.



In 1981 season, the highest number of podiums was 8 and the lowest was 0.

Season	Podiums	...
1980	9	...
1981	8	...
1981	0	...
...	...	...

```
and(eq(max(filter_eq(all_rows,season,1981),podiums),8),
eq(min(filter_eq(all_rows,season,1981),podiums),0))
```

V0 The table where column season equal to 1981 is [row1, row2].
V1 The max value of podiums in [row1, row2] is 8.
V2 8 is equal to 8.
V3 The min value of podiums in [row1, row2] is 0.
V4 0 is equal to 0.

Figure 1: The pipeline of ProgVGAT (Yang et al., 2020) on TFV. Here the task is, given a table and a statement, to predict whether the table *entails* the statement or *refutes* it. Verbalized evidences are verbal descriptions of the program execution procedure.

Despite being important, program generation remains underexplored for TFV. To the best of our knowledge, only LPA (Chen et al., 2020) works on program generation. It first searches programs

with human-designed features, then ranks them with a neural network, and finally uses the execution result of the top program as the prediction. However, it exhibits an unacceptable performance which means it generates incorrect programs. The remaining approaches just predict the correctness of statements but never concern about generating correct programs. In TFV, there is still a need to find better solutions for program generation.

Intuitively, we can resort to weakly supervised semantic parsing (Liang et al., 2011) for the program generation, but existing semantic parsers may fail in TFV for the amplified spurious program problem caused by the binary label. Due to the lack of program labels, existing methods will sample label consistent programs for model training. In TFV, any sampled program that outputs a Boolean value has a 50% chance of hitting the correct label; hence there are many label consistent programs, while only a small part of label consistent programs are correct, implying that the rest are all spurious.

In this paper, we carefully examine the syntax structures of statements and find that task-related structure features are the key to address the issue mentioned above. We propose a unified operation-oriented tree constructed in three steps. Firstly, we link entities between the table, trigger dictionary and statement. Secondly, we obtain the original tree using a dependency parser with the linked statement as input. Thirdly, the original tree is pruned and merged to a simplified tree that contains only information related to operations. Such a unified tree can provide distant supervision, assisting our model in generating single operations correctly and generating all operations in the correct order. As a result, we have a higher probability of getting correct programs and evading spurious ones. Then we introduce Structure-Aware Semantic Parsing (SASP) by designing a scoring function based on the proposed tree and fusing the sample distributions computed by the scoring function and neural network. At last, we design a refined objective function with lexical features and violation punishments to avoid spurious programs further.

Experimental results on Tabfact and Logic2Text show that SASP improves the performance of the baseline model significantly, and achieves comparable performance to the State-Of-The-Art method. Our contributions are as follows:

- We propose an operation-oriented tree to provide distant supervision for semantic parsing.
- We propose SASP which leverages both lexical features and structure features for the serious spurious problem in weakly supervised semantic parsing for TFV.
- With the proposed method, we can generate more accurate programs which can not only boost existing mainstream methods for TFV, but also provide explanation for verification.

2 Related Work

Fact Verification Fact verification aims at identifying the truthfulness of online textual statements given different sources of evidences, including document sets (Thorne et al., 2018; Nie et al., 2019; Zhong et al., 2020b; Wan et al., 2021), images (Suhr et al., 2019; Li et al., 2020) and structured tables (Chen et al., 2020; Zhong et al., 2020a; Shi et al., 2020b; Zhang et al., 2020a; Yang et al., 2020; Shi et al., 2021). Despite the sources of evidences used to support the verification vary, the methods for different tasks appear to have the same idea. They first locate the key evidences that will aid in their verification, then fuse the collected key evidences with the original statement to make the final prediction. In this paper, we focus on generating better programs that allow existing methods to get key evidences from tables efficiently, hence benefiting existing methods for TFV.

There are also many explainable fact verification works(Kotonya and Toni, 2020a). Attention based methods(Popat et al., 2018; Lu and Li, 2020; Wu et al., 2020) highlight key evidences according to attention weights. Atanasova et al. (2020); Kotonya and Toni (2020b) generate explanations in natural language with text summarization technology. Gad-Elrab et al. (2019); Ahmadi et al. (2020) use horn rules and knowledge graphs to mine explanations. Our work is similar to the third line of works from the perspective of explainability.

Semantic Parsing Due to the expensive cost of annotated programs, weakly supervised semantic parsing (Liang et al., 2011; Berant et al., 2013; Artzi and Zettlemoyer, 2013) has been proposed to learn program generation from sentence-label pairs. Compared with full supervision, weak supervision brings spurious problems: there may be spurious programs that accidentally reach the right answer for the wrong reason, and they will provide wrong supervision for model training. Previous work (Pasupat and Liang, 2016) uses crowd-sourced denotations to prune spurious programs. Liang et al. (2018) use both programs inside and outside the memory buffer to compute the expected return objective in case the neural model is misled by spurious programs inside memory. Dasigi et al. (2019); Misra et al. (2018); Agarwal et al. (2019) rely on lexical features to differentiate between spurious and correct programs. Most recently, Cao et al. (2019); Ye et al. (2019); Shao et al. (2021) exploit the semantic correlations between sentences and programs to rule out spurious programs via jointly learning semantic parser and sentence generator. In this paper, we focus on a more complex problem, learning program generation with (sentence, binary label) pairs, in this field, and take the above approaches a step further by leveraging both lexical features and structure features.

There already exist many works utilizing the structural correlations between a sentence and its programs. Previous works(Reddy et al., 2016; Hu et al., 2018) directly transform the dependency structure of a sentence into a program, which is not satisfactory on complex sentences. In recent years, some works(Wang et al., 2019; Herzig and Berant, 2021; Li et al., 2021) treat structural constraints as latent variables, then parse a sentence into a program under the constraints. However, it is difficult to learn latent variables in a noisy environment. Simultaneously, modeling structural correlations explicitly requres human annotations.(Sun et al., 2020; Shi et al., 2020a). In this paper, we propose a concise and robust method to integrate the structural correlations into semantic parsing.

3 Model

Structure-Aware Semantic Parsing (SASP) centers around the operation-oriented tree to deconstruct some compositionality of statement and generate program correctly. Figure 3 gives an overview of our proposed SASP. In this section, we will first introduce the task formulation, then describe how to construct the operation-oriented tree, and give the way to generate programs following the well-designed tree at last.

3.1 Problem Formulation and Notations

Given a table $T = \{cell_{i,j} | i \leq R, j \leq C\}$ with the table header $H = \{col_j | j \leq C\}$ as evidence, a statement $S = \{w_i | i \leq W\}$ with W words and a true label $y \in Y = \{True, False\}$ where $True$ means T entails S and $False$ means T refutes S, we aim to train a model to do explainable verification. More specifically, we train a model to translate S into an executable program z, then predict a label $\hat{y}_z \in Y$ by accessing the table T with program z such that $\hat{y}_z = y$. Different from most existing methods, which just pay attention to predicting a label $\hat{y} \in Y$ such that $\hat{y} = y$, our model also generates a program as accurate as possible to explain and support the verification.

Incorrect	filter_eq(all_rows, season, 1981); max(v0, podiums); eq(v1, 0); min(v0, podiums); eq(v3, 8); and(v2, v4)
Spurious	filter_eq(all_rows, podiums, 8); max(v0, season); eq(v1, 1981); filter_eq(all_rows, podiums, 0); min(v0, season); eq(v4, v1); and(v2, v5)
Correct	filter_eq(all_rows, season, 1981); max(v0, podiums); eq(v1, 8); min(v0, podiums); eq(v3, 0); and(v2, v4)

Figure 2: Different types of programs for the statement in figure 1. Both spurious and correct programs are label consistent as they can be executed to correct label, while only correct programs are semantic consistent as they reflect the underlying meaning of statements.

Program A program z can be seen as a set of executable operations[†] $\{op_i | i \leq M\}$. Considering the program example in figure 1, there are six operations in total, and each operation $op_i = \{op_i.func, ..., op_i.arg_j, ..., op_i.out\}$ has one operator $op_i.func$ (e.g., *filter_eq* in the figure), multiple operands $op_i.arg_j, 0 < j \leq \nu$ relevant to the table T (e.g., *all_rows*, *season* and *1981*) and one output $v_i = op_i.out$ which may be selected as an operand by subsequent operations. When the whole program is executed by an interpreter, it will be parsed into a tree as shown in figure 1 and executed from bottom to up. According to the execution correctness and the semantic consistency, we divide programs from the executable program set Z into three categories, as shown in figure 2.

3.2 Operation-Oriented Dependency Tree

In this part, we first reveal the connection between the program tree and the dependency tree. Then, we design a unified operation-oriented dependency tree for making full use of the connection.

Syntactic structures, the organization of tokens in a sentence and how the contexts among them are interrelated, can be revealed by a dependency tree whose nodes and edges correspond to words and grammatical relations in the sentence. We observe that: (1) the operations related to descendants tend to be executed before those related to ancestors in the dependency tree; (2) the operator and operands

---

[†] The definition of specific operations are listed in Appendix A.1

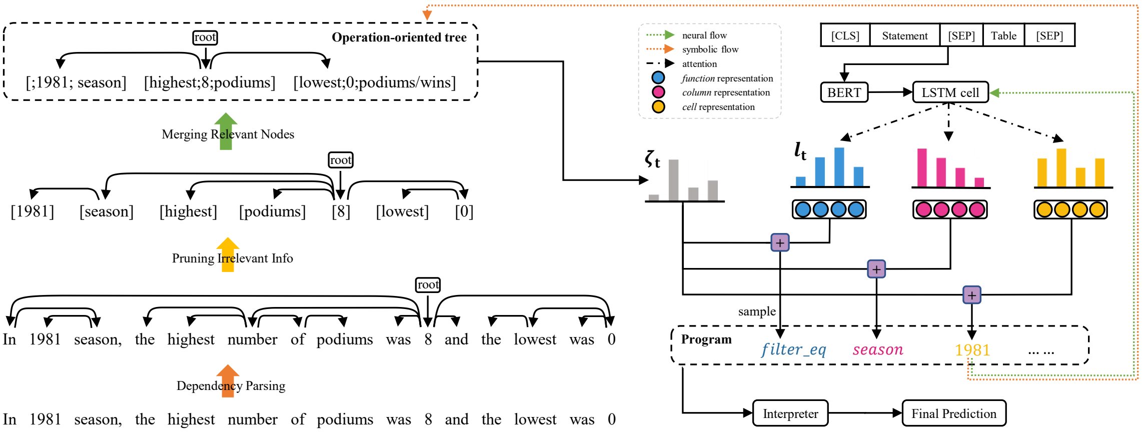

Figure 3: An overview of our proposed approach. The left part illustrates how to construct the operation-oriented tree. The right part depicts how to generate programs with the well-designed tree. The logits computed by LSTM for tokens with *function* type, *column* type and *cell* type are in blue, rose red and yellow respectively. And the scores given by the operation-oriented tree are in grey. They are combined to calculate the final sample distribution.

within one operation tend to have shorter distances in the dependency tree; in the correct program compared with the incorrect or spurious one. Use the dependency tree in figure 3 and the program in figure 1 as an example. The operation *filter_eq* related to the child node is executed before the operation *eq(v1, 8)* corresponding to the father node. What's more, the distance of operands in the incorrect operation *filter_eq(all_rows, podiums, 1981)* is 6, while that in *filter_eq(all_rows, season, 1981)*, a correct operation, is just 1.

The observations above suggest that there exist some structural correlations between a statement and its programs. We will present how to make use of them in the next section. Before that, we propose an operation-oriented dependency tree to strengthen the above rules in two steps. First, we prune the original dependency tree to focus exclusively on the operation-related structure. Then, we merge the information around every operation to make information in a single operation more compact. What's more, it is more convenient to define and calculate the distance in a simplified tree.

The left part of figure 3 illustrates how to construct the proposed tree. First of all, we do rule-based entity linking to find potential operators and operands from the statement. For operators detection, we match strings between the statement and the pre-defined trigger words[‡], and give the matched entities a *function* type. As for operands, we divide them into two types, *cell* and *column*, as they are linked to table cells and the table header respectively (e.g., *1981* has a *cell* type and *season* has a *column* type). Then we pass tokens and linked entities with types into a general dependency parser to get a dependency tree τ. Every linked entity node $n = \{n.children, n.type, n.val\}, n \in \tau$ has a list $type$ with one type and a list val with one entity. For every token node, its $type$ list and val list are both empty. After that, for every entity node with a *cell* type value $cell_{i,j}$, we will add *column* and col_j into its $type$ list and val list respectively. At last,

Algorithm 1 Operation-oriented tree construction

Input: Dependency tree τ with root ρ, where every node has a child list $children$, a type list $type$ and a value list val.
Output: Operation-oriented tree $\hat{\tau}$ with root $\hat{\rho}$.

```
function PRUNE($\rho$)
    $\hat{\rho}.children, \hat{\rho}.type, \hat{\rho}.val \leftarrow \{\}, \rho.type, \rho.val$
    for $c \in \rho.children$ do
        $\hat{c} \leftarrow$ PRUNE($c$)
        if MERGE($\hat{\rho}, \hat{c}$) then
            $\hat{\rho}.type \leftarrow \hat{\rho}.type \cup \hat{c}.type$
            $\hat{\rho}.val \leftarrow \hat{\rho}.val \cup \hat{c}.val$
            $\hat{\rho}.children \leftarrow \hat{\rho}.children \cup \hat{c}.children$
        else
            $\hat{\rho}.children \leftarrow \hat{\rho}.children \cup \{\hat{c}\}$
        end if
    end for
    return $\hat{\rho}$
end function

function MERGE($\hat{\rho}, \hat{c}$)
    for $(i, j) \in \{(i, j) | i < |\hat{\rho}.type|, j < |\hat{c}.type|\}$ do
        if $\hat{\rho}.type[i] = \hat{c}.type[j] \wedge \hat{\rho}.val[i] \neq \hat{c}.val[j]$ then
            Return $False$
        end if
    end for
    Return $True$
end function
```

[‡] All pre-defined trigger words are listed in Appendix A.2

we call PRUNE in algorithm 1 using τ as input and get output $\hat{\tau}$. The nodes left in the tree may contain function info corresponding to the logical operations, cell info and column info from tables.

3.3 Structure-Aware Semantic Parsing

In this section, we will introduce SASP, which unifies both structural features and lexical features with one operation-oriented dependency tree.

As shown in the right part of figure 3, we first employ BERT (Devlin et al., 2019) to encode the statement S and the table T following TABERT (Yin et al., 2020). Then we get representations for the statement and entities with different types, which will be fed into the decoder. During decoding, the logits are computed by an LSTM with attention mechanism(Luong et al., 2015):

$$\begin{aligned} h_t &= LSTM(h_{t-1}, x_{t-1}) \\ a_t &= MLP([h_t; Attention(h_t, S)]) \\ l_t &= MatMul(X_t, a_t) \end{aligned} \tag{1}$$

where h_t is the hidden state, x_{t-1} is the token generated previously, X_t is the candidate token list selected from the vocabulary according to the token type at timestep t (e.g., the type for the second token in the program being predicted is *column*), and l_t are the logits for the tth token over X_t.

However, in TFV, it is difficult to find the correct optimization direction with only attention mechanism, especially at the beginning of the training, because of the serious spurious problem. So we bias the logits with our proposed tree additionally. As a result, our model can give the correct program a higher probability, therefore exploring search space efficiently and evading spurious programs.

Algorithm 2 Scoring function with candidate token list X, operation-oriented tree $\hat{\tau}$ and operation being predicted op as input, where $\lambda < 1$ is a hyper-parameter.

```
function SCORE($X, \hat{\tau}, op$)
    $Score \leftarrow \{\}$
                                        ▷ operator selection
    if $op = \{\}$ then
        for $x \in X$ do
            $d \leftarrow$ Distance_to_leaf($x, \hat{\tau}$)
            $Score \leftarrow Score \cup \{\lambda^d\}$
        end for
        Return $Score$
    end if
                                        ▷ operand selection
    for $x \in X$ do
        $d \leftarrow 0$
        for $o \in op$ do
            $d \leftarrow d +$ Distance_in_tree($x, o, \hat{\tau}$)
        end for
        $Score \leftarrow Score \cup \{\lambda^{d/|op|}\}$
    end for
    Return $Score$
end function
```

More specifically, we design two scoring mechanisms in line with the two rules found in the previous section. As shown in algorithm 2, given $\lambda < 1$, $score = \lambda^{distance}$ means the closer distances, the higher scores. For operator selection, we calculate the average distance from the candidate $x \in X$ to its leaves in the tree $\hat{\tau}$, and set the distance to be $+\infty$ if it is not in the tree. For example, the candidate operator *max* (triggered by *highest*) has a score of λ^1. In this way, we give operators closer to leaves higher scores, which leads to operations related to descendants being generated before those related to ancestors. For operand selection, we compute the average distance from the candidate $x \in X$ to tokens in the operation op. Use the operation in figure 3 as an example, the score of the candidate *1981* is λ^0 when the timestep $t = 3$. In this way, we prioritize the tokens closed to existing information in the operation being generated, so that the distances inside one operation tend to be shorter in the dependency tree. At last, we combine the scores ζ_t given by algorithm 2 and the logits l_t computed by Equation 1 to get the final sample distribution:

$$\begin{aligned} \zeta_t &= Score(X_t, \hat{\tau}, op) \\ P(X_t|S, T, x_{<t}) &= Softmax(l_t + \alpha\zeta_t) \end{aligned} \tag{2}$$

where α is a hyper-parameter, $\hat{\tau}$ is the operation-oriented tree and *op* is the operation being predicted. After we sample $x_t \sim P(X_t|S, T, x_{<t})$, it will be used to update h_t, $\hat{\tau}$ and *op*. We give more details in Appendix A.3.

Previous works(Agarwal et al., 2019; Dasigi et al., 2019) measure the relevance between a sentence and a program by their coverage, and use that lexical coverage to augment the reward function. In a similar spirit, we design the reward based on our proposed tree. Our intuition is that different types of tokens play different roles in the operation-oriented tree, and therefore should be treated under varying degrees. And our reward is defined below.

$$R(z) = \begin{cases} \sum\limits_{\kappa \in Type} \sigma_\kappa r_\kappa, & \hat{y}_z = y \\ 0, & otherwise \end{cases} \tag{3}$$

where $Type = \{“function”, “cell”, “column”\}$, $\{r_\kappa | \kappa \in Type\}$ are relevances, $\{\sigma_\kappa | \kappa \in Type\}$

are hyper-parameters, and $\hat{y}_z$ is the label predicted by accessing the table T with the program z. Since all operation-related tokens of a statement are reserved in the operation-oriented tree, we can calculate the relevance between a statement and a program by

$$r_\kappa = \frac{\sum_{n \in \hat{\tau}} \mathbb{1}\{\exists i, n.type[i] = \kappa \wedge n.val[i] \in z\}}{\sum_{n \in \hat{\tau}} \mathbb{1}\{\exists i, n.type[i] = \kappa\}} \tag{4}$$

where $\{n | n \in \hat{\tau}\}$ are nodes of our proposed tree. For further improvement, we modify the generalized update equation in PolicyShaping (Misra et al., 2018) to get Maximum Likelihood Most Violation Reward. The final objective function is:

$$\begin{aligned} J_\theta = \sum_{(S,T) \in D} \Big(\sum_{z \in Z_{set}} R(z) \pi(z|S,T) \\ - \gamma \max_{z' \in Z_{err}} (\pi(z'|S,T)) \Big) \end{aligned} \tag{5}$$

where D contains all S-T pairs, Z_{set} is the set of sampled executable programs, $Z_{err} \subseteq Z_{set}$ is the set of incorrect programs, π is the sample policy, γ is a hyper-parameter and θ contains all the trainable parameters. We think such an update equation more robust than REINFORCE helps the model learn better with many spurious programs in Z_{set}.

4 Experiments

4.1 Experimental Settings

Dataset and Evaluation Metrics We conduct experiments on the large-scale dataset TABFACT (Chen et al., 2020), which aims to study fact verification given semi-structured data as evidence. TABFACT contains 16,573 tables and 118,275 statements which are divided into training (80%), validation (10%) and testing (10%) sets. The testing set is further partitioned into simple and complex sets. The statements in the complex set are more complicated in semantic compositionality than those in the simple set. Because there is no program ground-truth provided in TABFACT, we just use the label accuracy as metric for comparison, which is also called execution accuracy (Ex.Acc).

We also conduct experiments on WikiTableQuestion (WTQ) (Pasupat and Liang, 2015), a commonly used weakly supervised semantic parsing dataset, for further evaluation. And we use the same setting as previous works.

To test our performance on program generation, we use Logic2Text, a dataset that contains around 10,000 correct statement-table-program tuples, to evaluate parse tree matching accuracy (PT.Match) (Kim et al., 2020) for programs generated by our method and other methods that also provide programs. Because there are only "ENTAILED" statements in Logic2Text, we use the model trained on TABFACT to predict programs without tuning.

Implementation Details We use CRF2o (Zhang et al., 2020b) for dependency parsing. For semantic parsing, we use pytorch neural symbolic machine (Liang et al., 2017, 2018; Yin et al., 2020) as our baseline and improve it with the operation-oriented tree. Further, to bootstrap SASP, we use ζ_t in Equation 2 to sample around 10 label consistent programs per example, and load them into memory buffer before training. For BERT parameters, we set the hidden size to 768, and use Adam optimizer with lr 5e-5, warmup step 30k, dropout 0.2. For LSTM parameters, we set hidden size to 200, and use Adam optimizer with lr 3e-3, train step 150k, dropout 0.2. As for hyper-parameters λ, α, σ_{func}, σ_{cell}, σ_{column} and γ, we set them to 0.7, 2, 0.2, 0.4, 0.4 and 0.2 respectively. All experiments were conducted on a workstation with 128 GB of RAM and 2 RTX 3090 GPUs. Our source code is available at: `https://github.com/ousuixin/SASP`.

Compared Systems We compare our model with the following baselines, including six that focus on label prediction and two that pay extra attention to program generation. Among the former five methods, Table-BERT (Chen et al., 2020) and SAT (Zhang et al., 2020a) focus on table linearization, so they use different ways to change 2-dimensional tables into 1-dimensional sequences composed of tokens, and then feed them into BERT for label prediction. LFC (Zhong et al., 2020a), HeterTFV (Shi et al., 2020b), ProgVGAT (Yang et al., 2020) and LERGV(Shi et al., 2021) pay attention to comprehending tables and programs. They use different ways to encode programs (generated by LPA-ranking) and tables for verification, although the programs they use are not precise at all. The latter two methods will generate programs and use program execution results as final predictions, including LPA-ranking (Chen et al., 2020) and MAPO (Liang et al., 2018) with BERT.

4.2 Experimental Results

Performance on TABFACT Table 1 gives the overall performance of all eight baselines and our proposed SASP, from which we can observe that:

Model	Val	Test	Test(Simple)	Test(Complex)
Table-BERT	66.1	65.1	79.1	58.2
SAT	73.3	73.2	85.4	67.2
Tapas*	78.6	78.5	90.5	72.5
LFC	71.8	71.7	85.4	65.1
HeterTFV	72.5	72.3	85.9	65.7
ProgVGAT	74.9	74.4	**88.3**	67.6
LERGV	**75.6**	**75.5**	87.9	**69.5**
MAPO w/ BERT refined-reward	56.6	57.2	60.2	55.8
LPA-Ranking	65.2	65.0	78.4	58.5
SASP	75.0	74.9	87.6	68.8

Table 1: Overall performance (label accuracy) of different methods on TABFACT dataset. We don't compare our model with Tapas(Eisenschlos et al., 2020) directly. Because they focus on the design of pre-trained model and use extra data besides the TABFACT training data.

(1) As a semantic parsing method, our method achieves performance comparable to the State-Of-The-Art method LERGV while maintaining explainability. This is what previous semantic parsers can not do, and shows our superiority in TFV.

(2) Our proposed method works better than Table-BERT and SAT, demonstrating the power of the content snapshot proposed by Tabert in catching key information from a table.

(3) SASP has a lead of 1.2% on the the complex set compared with ProgVGAT, but falls behind on the simple set. There are two reasons for that. On one hand, mainstream methods like ProgVGAT can fix some errors caused by the symbolic interpreter (e.g., executing *eq("USA", "America")* to *False*). While SASP uses the execution result of the generated program as prediction. Due to the limited expression ability, our interpreter can not cover every statement with a correct program, leading to a lower probability of predicting a correct answer. On the other hand, ProgVGAT can not deal with structural mistakes (e.g., replacing *max* with *min* operation) in programs generated by LPA. As a result, ProgVGAT performs worse in complicated semantic environment where LPA has a higher probability of making a structural mistake.

(4) Our method outperforms MAPO and LPA by significant margins, suggesting that SASP can generate programs more accurately.

Performance on WTQ Table 2 shows the experimental results on WTQ. Our model just has comparable performance with our baseline, MAPO w/ BERT. We give two possible reasons below:

Model	Dev	Test
Pasupat and Liang (2015)	37.0	37.1
Dasigi et al. (2019)	43.1	44.3
Agarwal et al. (2019)	43.2	44.1
Wang et al. (2019)	43.7	44.5
MAPO w/ BERT (Yin et al., 2020)	**49.6**	49.4
SASP	49.3	**49.5**

Table 2: Performance (execution accuracy) of different methods on WikiTableQuestion. The first four are all previous works.

(1) As can be seen in figure 1, the program has more than three operations, which is quite common in TFV, while they use at most three operations to answer a question in previous works (Pasupat and Liang, 2015; Zhong et al., 2017; Liang et al., 2018). Because the compositionality of WTQ is lower than TABFACT, our proposed operation-oriented tree can only provide very limited help.

(2) The spurious program problem is further amplified by the binary label in TABFACT. Any program that outputs a Boolean value has a 50% chance of hitting the correct label; hence there are many label consistent programs. While in WTQ, it is not that easy to hit the correct label. Suppose that the vocabulary list has N tokens, but only one token corresponds to the answer. Every executable program in WTQ will output an answer with the string type, so it only has a $\frac{1}{N}$ probability of hitting the correct label. WTQ has much fewer spurious programs, so lexical features are enough to rule out

Model	PT.Match	Ex.Acc
MAPO w/ BERT	13.4	70.1
LPA	15.6	56.7
SASP	**47.9**	**75.9**

Table 3: Performance (matching accuracy and execution accuracy) of different methods on Logic2Text dataset.

spurious programs in WTQ in many cases.

Performance on Logic2Text Results of different semantic parsing methods are shown in table 3. Our model outperforms other methods with a considerable margin on PT.Match metric. This means SASP can generate more correct programs, which makes it behave well in table fact verification.

In program generation for TFV, the search space is too large to be explored completely. To tackle this problem, MAPO w/ refined reward performs systematic search space exploration guided by lexical features in the advanced reward function. It only obtains PT.Match accuracy of 13.4% on Logic2Text. The high Ex.Acc score shows that it just predicts spurious programs executed to "True". For LPA, it first collects all programs under the search space restricted by a lexical feature based algorithm, then ranks these programs with a neural network (BERT). And LPA also has poor behavior in program generation here.

The big gaps (more than 40% in MAPO and LPA) between PT.Match and Ex.Acc accuracy suggest that with only lexical features, there are still many spurious programs being explored. Use the spurious program in figure 2 as an example, it conforms to lexical features by making full use of sentence tokens, and would be a promising candidate in MAPO and LPA. However, such kind of programs will differ from the correct ones in the order of operators or the position of operands, so they can be distinguished from correct programs by structure features. Our method captures both lexical and structure features, therefore evading such spurious programs and biasing generated programs from label consistent towards semantic consistent. The smaller gap (28% in SASP) between PT.Match and Ex.Acc accuracy confirms our analysis above.

4.3 Ablation Study

Effect of Structural Info We further conduct an ablation study to evaluate the necessity of leveraging structure information through rules (1) and (2). For rule (1), which defines the operator selection mechanism, we just drop types and values related to *function* in our proposed tree to see how it influence. For rule (2), which defines the operand selection mechanism, we drop types and values related to *cell* or *column*. If we drop all types from the tree, the algorithm degenerates into MAPO w/ BERT refined-reward violation. The experimental results are given in Table 4. We can see that *function* is the most important type, then is *column* type, followed by *cell* type. And all of the types make significant contributions to the final performance. The results above show that both mechanisms associated with the rule (1) and the rule (2) are crucial for our model because both operator and operand selections are crucial for program generation.

Model	Val	Test
SASP w/o proposed tree	56.6	57.2
SASP w/o function type	59.3	60.1
SASP w/o column type	60.5	61.5
SASP w/o cell type	70.2	71.1
SASP	**75.0**	**74.9**

Table 4: Results (label accuracy) of ablation study that shows the effectiveness of our proposed tree.

Model	Val	Test
SASP w/ binary-reward	60.1	60.2
SASP w/o violation	73.5	73.1
SASP	**75.0**	**74.9**

Table 5: Results (label accuracy) of ablation study that shows well defined reward function and violation punishiment contribute a lot to our method.

Effect of Objective Function To evaluate the impact of the refined objective function in Equation 5, we conduct another ablation study, and the results are shown in table 5.

We change the reward function in Equation 3 with a binary reward function for comparison. The result shows that refined feedback taking lexical features into account plays an essential role in our model. Without the refined reward, some operations may be omitted because the partial programs are already executed to the right label, resulting in a much worse performance.

We also remove the violation punishment to investigate the necessity of a conservative update policy. The result shows that the robust update policy

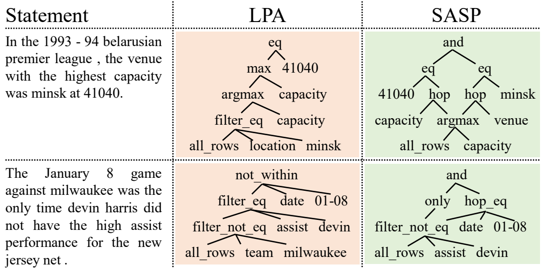

Figure 4: Cases in Logic2Text dataset. We visualize the programs with tree structures.

makes around 1% improvement. The reward function we designed just prioritizes programs that use tokens related to logical operators or tables as much as possible, leading to label inconsistent programs that meet the condition. Giving such programs a punishment complements the refined reward.

4.4 Case Study

In figure 4, we provide two cases to demonstrate the effectiveness of our method for program generation. In both cases, our method generates correct programs that are semantic consistent with the statement, while LPA screws them all up. In the first case, *max* is the descendant compared with *minsk* in the dependency tree, so our method uses *max* before *minsk*, while LPA gets the wrong order. This confirms that our method generates programs in the correct order with the operator selection mechanism. In the second case, *devin* has a more close relation to *not* in the dependency tree, so our method chooses *devin* as an operand of *filter_not_eq*, while LPA selects an incorrect operand *milwaukee* for *filter_not_eq*. This confirms that our method generates single operations correctly with the operand selection mechanism.

4.5 Error Analysis

To check the generalizability and limitations of our proposed method, we randomly sampled 200 examples from the validation set of TABFACT, and manually inspected the top one program of the beam search using SASP. We found that SASP generated correct programs for 99 examples, spurious programs for 57 examples and incorrect programs for 44 examples. The proportion of correct programs (49.5%) and spurious programs (28.5%) is similar to that in table 3 (47.9% and 28%). This shows the generalizability of SASP and the rationality of using Logic2Text for PT.Match evaluation. What's more, we classified the causes of 101 spurious or incorrect programs into four main categories.

Unsupported operations cause 30 error examples. For instance, in *"the new york rangers beat the atlanta flames by 2 points"*, the minus operation in a single table cell *"4 - 2"* is not supported by our interpreter. The second category of errors occur when the functions or entities can not be detected and added to dependency tree nodes correctly. Use *"the maroon played 3 teams located in the united states"* as an example, *"the united states"* can not be linked to *"America"* in the given table; hence it will not be added to the operation tree. 31 error examples are caused by this reason. The first two categories can not be handled by our proposed method, and we leave the development of powerful interpreter and robust entity linker for future work.

The third category is structure error, causing 13 error examples. In other words, the order of operators or the position of operands in the predicted program differs from the correct one. The wrong programs in figure 2 are all this kind of error cases. Underutilized information causes 23 error examples. For the statement in figure 1, *"filter_eq(all_rows, season, 1981); max(v0, podiums), eq(v1, 8)"* causes this kind of error.

5 Conclusion

In this paper, we have proposed a novel approach to do explainable verification by structure-aware semantic parsing. Firstly, we define a unified operation-oriented tree by entity linking, dependency parsing and tree pruning. Then, we demonstrate how to integrate our proposed tree into semantic parsing with the operator-related and the operand-related principles. At last, we introduce the refined objective function which could reduce the influence of spurious programs. Experimental results confirm that our proposed method can bias program generation from label consistent towards semantic consistent and achieve acceptable performance on the benchmark dataset TABFACT.

Future work will collect evidences that are more precise and get better verification performance by replacing LPA with SASP in the first stage of mainstream methods.

A Appendix

A.1 Pre-difined API

As shown in figure 3 and algorithm 1, when we generate an operation, we first select an operand, then check the pre-defined API to get the type information, and finally select operands under the specific type (according to the type information). Here we list detailed descriptions for the pre-defined API in table 6.

Actually, there are seven different types, including *Function*, *Cell-String*, *Cell-Number*, *Bool*, *Sub-Table*, *Column-String* and *Column-Number*. In figure 3 and algorithm 1, we divide them into three types for a clearer illustration:

function	cell	column
Function	Bool, Sub-Table, Cell-String, Cell-Number	Column-String, Column-Number

In practice, we will select operands according to more detailed type information given by our predefined API.

In addition, we will update cell values and representations by adding the execution result of *op* and the LSTM hidden state h to $Cell$ and C, respectively (Line 12). In practice, we will maintain more detailed symbol lists and representation lists. For example, when the last token of the operation *max(v0, podiums)* is generated, the hidden state of LSTM will be added into the *C-Number* list, while the execution result of *max(v0, podiums)*, *v=8*, will be put into the *Cell-Number* list.

A.2 Pre-difined Trigger Words

In the first step of the operation-oriented tree construction, we match strings between the statement and the pre-defined trigger words to find underlying operators. Here we give details about the pre-defined trigger words in table 7, partly following LPA (Chen et al., 2020).

A.3 Implement Details for Decoding Module

Algorithm 3 gives the complete process of our decoding module. We initialize the program as an empty list with no operations, then enlarge it with operations generated progressively until the neural network outputs a *"stop"* token (Line 13-15). As for operation generation, we first sample an operator from the operator list $Func$, then get the type information of its operands through the pre-defined API, with which we can choose representations under the correct type. After that, we will sample operands from $Cell$ if the operand type is *cell*, and sample them from $Header$ otherwise. Once the generation is finished, the whole expression is added to the program (Line 3-11). All these above are similar to what they do in NSM (Liang et al., 2017). But we redesign the SAMPLE function according to equation 2.

Besides, to maintain our proposed tree $\hat{\tau}$, we will update information by dropping out the used operators and *cell* type operands in *op*. What's more, we will update C, the cell representation list, by adding current hidden state into into C (Line 12). At the same time, *op* and $Cell$ are updated by adding the execution result of *op* ($v = op.out$).

Algorithm 3 Program sampling with statement representation V_s, table cell representation list $C = \{V_c | c \in Cell\}$, table column representation list $H = \{V_h | h \in Header\}$, operator representation list $F = \{V_f | f \in Func\}$, special token list $E = \{V_e | e \in \{continue, stop\}\}$, the pre-defined API, neural network $LSTM$ and the operation-oriented tree $\hat{\tau}$ as input.

Abstract

In real-world scenarios, a text classification task often begins with a *cold start*, when labeled data is scarce. In such cases, the common practice of fine-tuning pre-trained models, such as BERT, for a target classification task, is prone to produce poor performance. We suggest a method to boost the performance of such models by adding an intermediate unsupervised classification task, between the pre-training and fine-tuning phases. As such an intermediate task, we perform clustering and train the pre-trained model on predicting the cluster labels. We test this hypothesis on various data sets, and show that this additional classification phase can significantly improve performance, mainly for topical classification tasks, when the number of labeled instances available for fine-tuning is only a couple of dozen to a few hundred.

1 Introduction

The standard paradigm for text classification relies on supervised learning, where it is well known that the size and quality of the labeled data strongly impact the performance (Raffel et al., 2019). Hence, developing a text classifier in practice typically requires making the most of a relatively small set of annotated examples.

The emergence of transformer-based pre-trained language models such as BERT (Devlin et al., 2018) has reshaped the NLP landscape, leading to significant advances in the performance of most NLP tasks, text classification included (e.g., Nogueira and Cho, 2019; Ein-Dor et al., 2020). These models typically rely on pretraining with massive and heterogeneous corpora on a general Masked Language Modeling (*MLM*) task, i.e., predicting a word that is masked in the original text. Later on, the obtained model is fine-tuned to the actual task of interest, termed here the *target task*, using the labeled data available for this task. Thus, pretrained models serve as general sentence encoders which can be adapted to a variety of target tasks (Lacroix et al., 2019; Wang et al., 2020a).

Our work focuses on a challenging yet common scenario, where unlabeled data is available but labeled data is scarce. In many real-world scenarios, obtaining even a couple of hundred of labeled examples per class is challenging. Commonly, a target class has a relatively low prior in the examined data, making it a formidable goal to collect enough positive examples for it (Japkowicz and Stephen, 2002). Moreover, sometimes data cannot be labeled via crowd-annotation platforms due to its confidentiality (be it for data privacy reasons or for protecting intellectual property) or since the labeling task requires special expertise. On top of this, often the number of categories to be considered is relatively large, e.g., 50, thus making even a modest demand of 200 labeled examples per class a task of labeling 10K instances, which is inapplicable in many practical cases (for an extreme example, cf. Partalas et al., 2015).

In such limited real-world settings, fine-tuning a large pretrained model often yields far from optimal performance. To overcome this, one may take a gradual approach composed of various phases. One possibility is to further pretrain the model with the *self-supervised* MLM task over unlabeled data taken from the target task domain (Whang et al., 2019). Alternatively, one can train the pretrained model using a *supervised* intermediate task which is different in nature from the target-task, and for which labeled data is more readily available (Pruksachatkun et al., 2020; Wang et al., 2019a; Phang et al., 2018). Each of these steps is expected to provide a better starting point for the final fine-tuning phase, performed over the scarce labeled data available for the target task, aiming to end up with improved performance.

Following these lines, here we propose a strat-

May 22-27, 2022

egy that exploits *unsupervised* text clustering as the intermediate task towards fine-tuning a pretrained model for text classification. Our work is inspired by the use of clustering to obtain labels in computer vision (Gidaris et al., 2018; Kolesnikov et al., 2019). Specifically, we use an efficient clustering technique, that relies on simple Bag Of Words (BOW) representations, to partition the unlabeled training data into relatively homogeneous clusters of text instances. Next, we treat these clusters as labeled data for an intermediate text classification task, and train the pre-trained model – with or without additional MLM pretraining – with respect to this multi-class problem, prior to the final fine-tuning over the actual target-task labels. Extensive experimental results demonstrate the practical value of this strategy on a variety of benchmark data. We further analyze the results to gain insights as to why and when this approach would be most valuable, and conclude that it is most prominently when the training data available for the target task is relatively small and the classification task is of a topical nature. Finally, we propose future directions.

We release code for reproducing our method.[1]

2 Intermediate Training using Unsupervised Clustering

A pre-trained model is typically developed in consecutive phases. Henceforth, we will refer to BERT as the canonical example of such models. First, the model is *pretrained* over massive general corpora with the MLM task.[2] We denote the obtained model simply as *BERT*. Second, BERT is *finetuned* in a supervised manner with the available labeled examples for the target task at hand. This standard flow is represented via Path-1 in Fig. 1.

An additional phase can be added between these two, referred to next as *intermediate training*, or inter-training in short. In this phase, the model is exposed to the corpus of the target task, or a corpus of the same domain, but still has no access to labeled examples for this task.

A common example of such an intermediate phase is to continue to intertrain BERT using the self-supervised MLM task over the corpus or the domain of interest, sometimes referred to as further or adaptive pre-training (e.g., Gururangan et al., 2020). This flow is represented via Path-2 in Fig. 1, and the resulting model is denoted $BERT_{IT:MLM}$, standing for Intermediate Task: MLM.

A key contribution of this paper is to propose a new type of intermediate task, which is designed to be aligned with a text classification target task, and is straightforward to use in practice. The underlying intuition is that inter-training the model over a related text classification task would be more beneficial compared to MLM inter-training, which focuses on different textual entities, namely predicting the identity of a single token.

Specifically, we suggest *unsupervised* clustering for generating pseudo-labels for inter-training. As the clustering partition presumably captures information about salient features in the corpus, feeding this information into the model could lead to representations that are better geared to perform the target task. These pseudo-labels can be viewed as weak labels, but importantly they are not tailored nor require a specific design per target task. Instead, we suggest generating pseudo-labels in a way independent of the target classification task. The respective flow is represented via Path-3 in Fig. 1. In this flow, we first cluster to partition the training data into n_c clusters. Next, we use the obtained partition as 'labeled' data in a text classification task, where the classes are defined via the n_c clusters, and intertrain BERT to predict the cluster label. In line with MLM, inter-training includes a classifier layer on top of BERT, which is discarded before the fine-tuning stage. The resulting inter-trained model is denoted $BERT_{IT:CLUST}$.

Finally, Path-4 in Fig. 1 represents a sequential composition of Paths 2 and 3. In this flow, we first intertrain BERT with the MLM task. Next, the obtained model is further intertrained to predict the n_c clusters, as in Path-3. The model resulting from this hybrid approach is denoted $BERT_{IT:MLM+CLUST}$.

Importantly, following Path-3 or Path-4 requires no additional labeled data, and involves an *a-priori* clustering of training instances that naturally gives rise to an alternative or an additional inter-training task. As we show in the following sections, despite its simplicity, this strategy provides a significant boost in performance, especially when labeled data for the final fine-tuning is in short supply.

---

[1] `https://github.com/IBM/intermediate-training-using-clustering`

[2] BERT was originally also pretrained over "next sentence prediction"; however, later works (Yang et al., 2019; Liu et al., 2019b) have questioned the contribution of this additional task and focused on MLM.

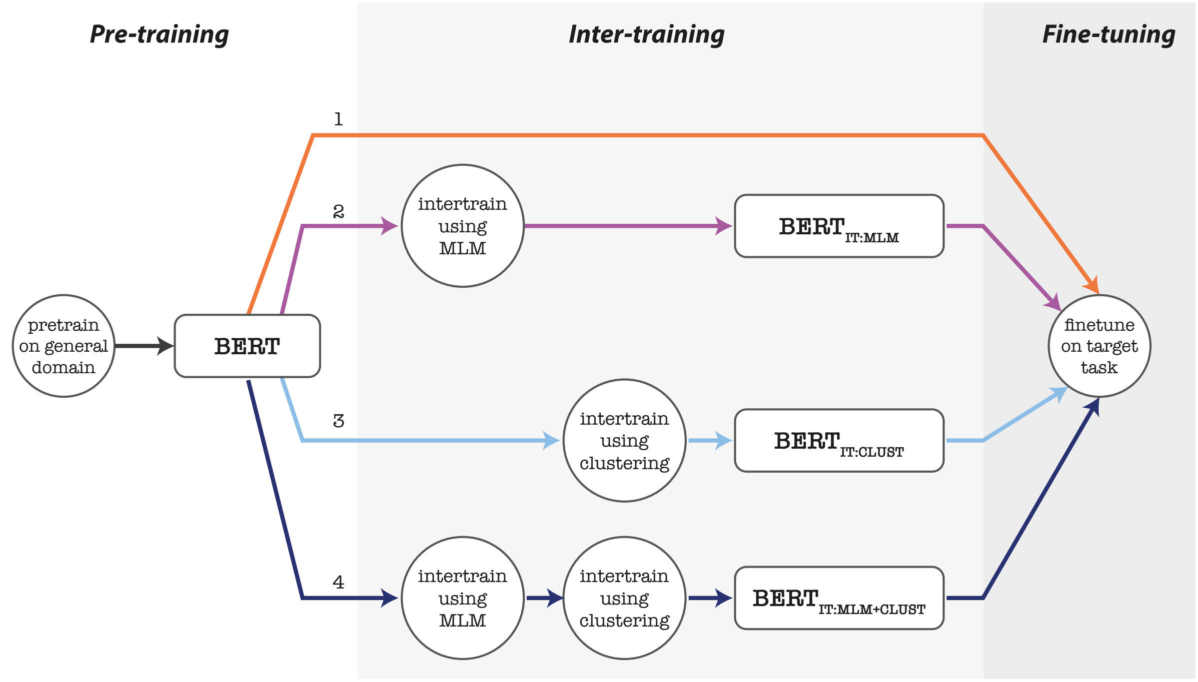

Figure 1: Phases of a pre-trained model (BERT in this figure) - circles are training steps which produce models, represented as rectangles. In the pre-training phase, only general corpora are available. The inter-training phase is exposed to target domain data, but not to its labeled instances. Those are only available at the fine-tuning phase.

3 Experiments

3.1 Tasks and Datasets

We evaluate over 6 topical datasets and 3 non-topical ones (see Table 1), which cover a variety of classification tasks and domains: Yahoo! Answers (Zhang et al., 2015), which separates answers and questions to types; DBpedia (Zhang et al., 2015, CC-BY-SA) which differentiates entity types by their Wikipedia articles; AG's News (Zhang et al., 2015) which categorize news articles; CFPB, which classifies consumer complaints; 20 newsgroups (Lang, 1995), which classifies 20 Usenet discussion groups; ISEAR (Shao et al., 2015, CC BY-NC-SA 3.0), which considers personal reports for emotion; SMS spam (Almeida et al., 2011), which identifies spam messages; Polarity (Pang and Lee, 2005), which includes sentiment analysis on movie reviews, and Subjectivity (Pang and Lee, 2004), which categorizes movie snippets as subjective or objective.

A topical dataset splits sentences by a high-level distinction related to what the sentence is about (e.g., sports vs. economics). Non-topical datasets look for finer stylistic distinctions that may depend on the way the sentence is written or on fine details rather than on the central meaning it discusses. It may also separate almost identical sentences; for example, "no" could distinguish between sentences with negative and positive sentiment.

When no split is provided we apply a $70\%/10\%/20\%$ train-dev-test split, respectively.[3] To reduce the computational cost over the larger datasets (DBpedia, AG's News, Yahoo! Answers and CFPB) we trim the train/test sets of these datasets to $15K/3K$ instances respectively, by randomly sampling from each set.[4] All runs and all methods use only the trimmed versions.

3.2 Experimental Setup

In our main set of experiments, we compare the performance of fine-tuning BERT-based models over a target task, for different settings of intermediate training. We consider four BERT-based settings, as described in Section 2 and in Figure 1. Two baselines – (i) BERT, without intermediate training, and (ii) $\text{BERT}_{\text{IT:MLM}}$ intertrained on MLM; and two settings that rely on clustering – (i) $\text{BERT}_{\text{IT:CLUST}}$, where predicting cluster labels is used for inter-training, and (ii) $\text{BERT}_{\text{IT:MLM+CLUST}}$, which combines the two intermediate tasks.

---

[3] The dev set is not being used by any method.

[4] We verified that relying on the full dataset provides no significant performance improvements to $\text{BERT}_{\text{IT:MLM}}$ and $\text{BERT}_{\text{IT:CLUST}}$. The results are omitted for brevity.

Training samples: For each setting, the final fine-tuning for the target task is performed, per dataset, for training budgets varying between 64 and 1024 labeled examples. For each data size x, the experiment is repeated 5 times; each repetition representing a different sampling of x labeled examples from the train set. The samplings of training examples are shared between all settings. That is, for a given dataset and train size the final training for all settings is done with respect to the same 5 samples of labeled examples.

Inter-training: Intermediate training, when done, was performed over the unlabeled train set for each dataset (ignoring instances' labels). We studied two implementations for the clustering task: K-means (Lloyd, 1982) and sequential Information Bottleneck (sIB) which is known to obtain better results in practice (Slonim et al., 2002) and in theory (Slonim et al., 2013). Based on initial experiments, and previous insights from works in the computer vision domain (Yan et al., 2020) we opted for a relatively large number of clusters, and rather than optimizing the number of clusters per dataset, set it to 50 for all cases.[5] K-means was run over GloVe (Pennington et al., 2014) representations following word stemming. We used a publicly available implementation of sIB[6] with its default configuration (i.e., 10 restarts and a maximum of 15 iterations for every single run). For sIB clustering, we used Bag of Words (BOW) representations on a stemmed text with the default vocabulary size (which is defined as the 10K most frequent words in the dataset). Our results indicate that inter-training with respect to sIB clusters consistently led to better results in the final performance on the target task, compared to inter-training with respect to the clusters obtained with K-means (see Section 5.1 for details). We also considered inter-training only on representative examples of clustering results – filtering a given amount of outlier examples – but obtained no significant gain (data not shown).

Note that the run time of the clustering algorithms is only a few seconds. The run time of the fine-tuning step of the inter-training task takes five and a half minutes for the largest train set (15K instances) on a Tesla V100-PCIE-16GB GPU.

	Train	Test	# classes
Yahoo! answers	15K	3K	10
DBpedia	15K	3K	14
CFPB	15K	3K	15
20 newsgroups	10.2K	7.5K	20
AG's news	15K	3K	4
ISEAR	5.4K	1.5K	7
SMS spam	3.9K	1.1K	2
Subjectivity	7K	2K	2
Polarity	7.5K	2.1K	2

Table 1: Dataset details. Topical datasets are at the top.

BERT hyper-parameters: The starting point of all settings is the BERT$_{\text{BASE}}$ model (110M parameters). BERT inter-training and fine-tuning runs were all performed using the Adam optimizer (Kingma and Ba, 2015) with a standard setting consisting of a learning rate of 3×10^{-5}, batch size 64, and maximal sequence length 128.

In a practical setting with a limited annotations budget one cannot assume that a labeled dev set is available, thus in all settings we did not use the dev set, and fine-tuning was arbitrarily set to be over 10 epochs, always selecting the last epoch. For inter-training over the clustering results we used a single epoch, for two reasons. First, loosely speaking, additional training over the clusters may drift the model too far towards learning the partition into clusters, which is an auxiliary task in our context, and not the real target task. Second, from the perspective of a practitioner, single epoch training is preferred since it is the least demanding in terms of run time. For BERT$_{\text{IT:MLM}}$ we used 30 epochs with a replication rate of 5, and followed the masking strategy from Devlin et al. (2018).[7]

Computational budget: Overall we report the results of 1440 BERT fine-tuning runs (4 experimental settings × 9 datasets × 8 labeling budgets × 5 repetitions). In addition, we performed 288 inter-training epochs over the full datasets (9 datasets × (30 BERT$_{\text{IT:MLM}}$ epochs + 1 BERT$_{\text{IT:CLUST}}$ epoch + 1 BERT$_{\text{IT:MLM+CLUST}}$ epoch)). In total, this would equate to about 60 hours on a single Tesla V100-PCIE-16GB GPU.

4 Results

Table 2 depicts the results over all datasets, focusing on the practical use case of a budget of 64

---

[5] Setting the number of clusters to be equal to the number of classes resulted in inferior accuracy. In addition, one may not know how many classes truly exist in the data, so this parameter is not necessarily known in real-world applications.

[6] `https://github.com/IBM/sib`

[7] In preliminary experiments we found this to be the best configuration for this baseline.

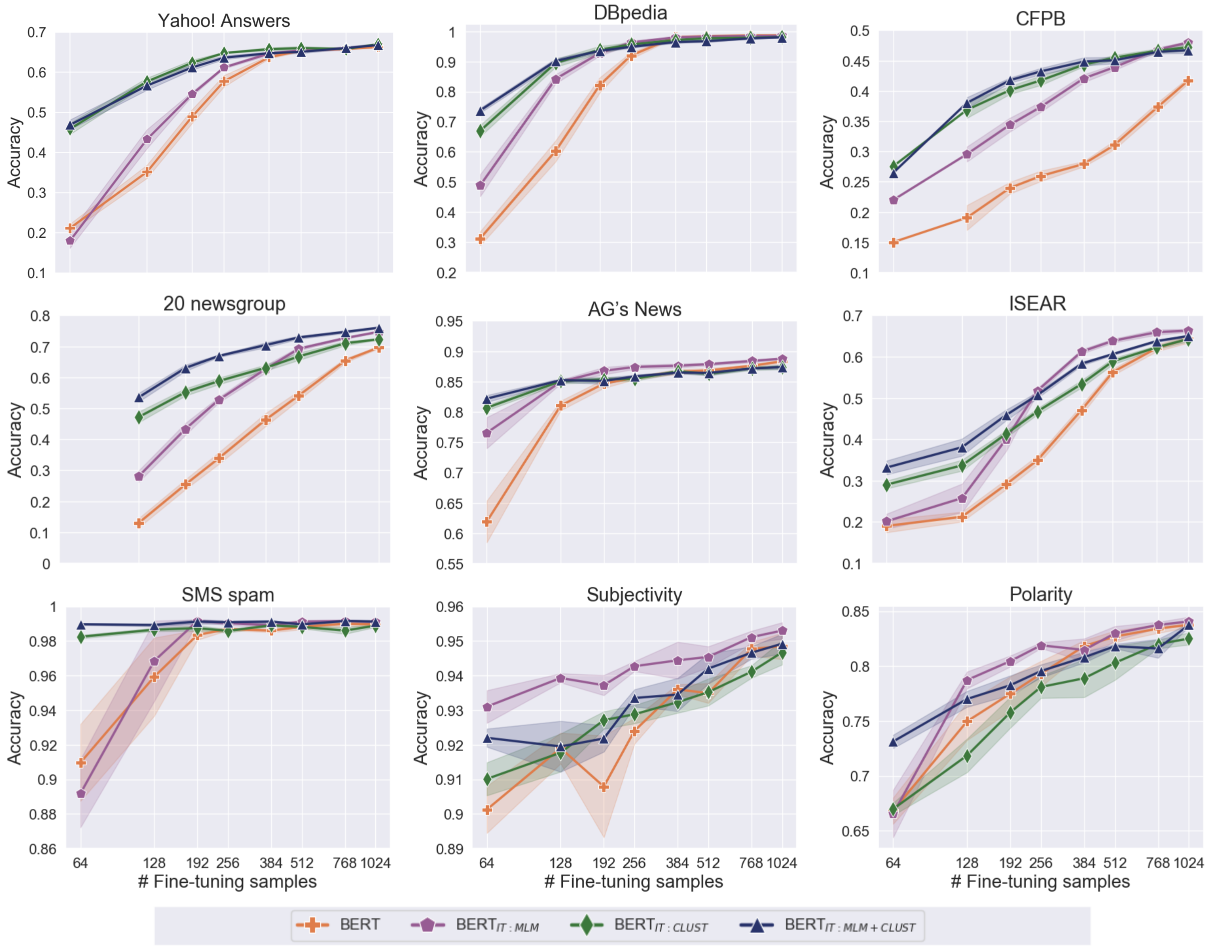

Figure 2: Classification accuracy (±SEM, standard error of the mean) on all datasets vs. the number of labeled samples used for fine-tuning (log scale). Each point is the average of 5 repetitions (for 20 newsgroups and a budget of 64, all 5 repetitions did not cover all classes and hence this data point is not presented).

samples for fine-tuning (128 for 20 newsgroup, see explanation in Fig. 2). As shown in the table, the performance gains of $\text{BERT}_{\text{IT:CLUST}}$ are mainly reflected in the 6 topical datasets. For these datasets, $\text{BERT}_{\text{IT:CLUST}}$ confers a significant benefit in accuracy (110% accuracy gain, 33% error reduction).

Figure 2 depicts the classification accuracy for the different settings for varying labeling budgets, using sIB for clustering-based inter-training. Over the topical datasets, $\text{BERT}_{\text{IT:CLUST}}$ and $\text{BERT}_{\text{IT:MLM+CLUST}}$ clearly outperform BERT and $\text{BERT}_{\text{IT:MLM}}$ in the small labeled data regime, where the gain is most prominent for the smallest labeled data examined – when only 64 labeled examples are available – and gradually diminishes as more labeled samples are added.

We performed paired t-tests to compare $\text{BERT}_{\text{IT:CLUST}}$ with BERT and $\text{BERT}_{\text{IT:MLM}}$, pooling together all datasets and repetitions for a given

Dataset	BERT accuracy	$\text{BERT}_{\text{IT:CLUST}}$ accuracy	Gain	Error reduction
Yahoo! Answers	21.2	45.9	117%	31%
DBpedia	31.2	67.0	115%	52%
CFPB	15.0	27.5	83%	15%
20 newsgroup	13.0	47.2	263%	39%
AG's News	61.9	80.7	30%	49%
ISEAR	19.0	29.0	53%	12%
avg. topical	26.9	49.6	**110%**	**33%**
SMS spam	91.0	98.2	8%	80%
Subjectivity	90.1	91.0	1%	9%
Polarity	66.8	67.0	0%	1%
avg. non-topical	82.6	85.4	**3%**	**30%**

Table 2: $\text{BERT}_{\text{IT:CLUST}}$ outperforms BERT in topical datasets. Comparing 64 samples, the smallest amount for fine-tuning. The accuracy gain and the error reduction (1-accuracy) are relative to BERT's accuracy/error.

Train size	64	128	192	256	384	512	>512
vs. BERT	1×10^{-6}	1×10^{-6}	6×10^{-7}	2×10^{-5}	2×10^{-3}	9×10^{-3}	–
vs. BERT$_{\text{IT:MLM}}$	8×10^{-5}	3×10^{-3}	4×10^{-2}	–	–	–	–

Table 3: Paired t-test p-values (after Bonferroni correction) of classification accuracy for BERT$_{\text{IT:CLUST}}$ compared to BERT and to BERT$_{\text{IT:MLM}}$ (insignificant results, $p \geq 0.05$, are denoted by –).

labeling budget. As can be seen in Tab. 3, the performance gain, over all datasets, of BERT$_{\text{IT:CLUST}}$ over BERT is statistically significant for a budget up to 512.

BERT$_{\text{IT:CLUST}}$ is not as successful in the 3 non-topical datasets (cf. Tab. 2 and Fig. 2). A possible reason for the lack of success of inter-training in these three datasets is that their classification task is different in nature than the tasks in the other six datasets. Identifying spam messages, determining whether a text is subjective or objective, or analyzing the sentiment (polarity) of texts, can be based on stylistic distinctions that may depend on the way the sentence is written rather than on the central topic it discusses. Inter-training over BOW clustering seems to be less beneficial when such considerations are needed. We further analyze this in Section 5.4. Nevertheless, it is safe to apply BERT$_{\text{IT:CLUST}}$ even in these datasets, as results are typically comparable to the baseline algorithms, neither better nor worse.

Both BERT$_{\text{IT:MLM}}$ and BERT$_{\text{IT:CLUST}}$ expose the model to the target corpus. The performance gains of BERT$_{\text{IT:CLUST}}$ over BERT$_{\text{IT:MLM}}$ suggest that inter-training on top of the clustering carries an additional benefit. In addition, these inter-training approaches are complementary - as seen in Fig. 2, BERT$_{\text{IT:MLM+CLUST}}$ outperforms both BERT$_{\text{IT:CLUST}}$ and BERT$_{\text{IT:MLM}}$ (at the cost of some added runtime).

Taken together, our results suggest that in topical datasets, where labeled data is scarce, the pseudo-labels generated via clustering can be leveraged to provide a better starting point for a pre-trained model towards its fine-tuning for the target task.

5 Analysis

5.1 Additional Clustering Techniques

In the literature (Slonim et al., 2002) and on our initial trials, sIB showed better clustering performance, and therefore was chosen over other clustering methods. Next, we analyze whether sIB is also the best fit for inter-training.

We compare (see App. C) sIB over BOW representation to two other clustering configurations; K-means over GloVe representations and Hartigan's K-means (Slonim et al., 2013) over GloVe. For most datasets, inter-training over the results of sIB over BOW representations achieved the best results.

5.2 Comparison to BOW-based methods

Our inter-training method relies on BOW-based clustering. Since knowledge of the input words is potentially quite powerful for some text classification tasks, we examine the performance of several BOW-based methods. We used the same training samples to train multinomial Naive Bayes (NB) and Support Vector Machine (SVM) classifiers, using either Bag of Words (BOW) or GloVe (Pennington et al., 2014) representations. For GloVe, a text is represented as the average GloVe embeddings of its tokens. This yielded four reference settings: NB$_{\text{BOW}}$, NB$_{\text{GloVe}}$, SVM$_{\text{BOW}}$ and SVM$_{\text{GloVe}}$. Overall, all four methods were inferior to BERT$_{\text{IT:CLUST}}$, as shown in App. B. Thus, the success of our method cannot simply be attributed to the information in the BOW representations.

Next, we inspect the contribution of inter-training to BERT's sentence representations.

5.3 Effect on Sentence Embeddings

The embeddings after BERT$_{\text{IT:CLUST}}$ show potential as a better starting point for fine-tuning. Figure 3 depicts t-SNE (van der Maaten and Hinton, 2008) 2D visualizations of the output embeddings over the full train set of several datasets, comparing the [CLS] embeddings before and after inter-training.

Manifestly, for topical datasets, the BERT$_{\text{IT:CLUST}}$ embeddings, obtained after inter-training with respect to sIB clusters, induce a much clearer separation between the target classes, even though no labeled data was used to obtain this model. Moreover, and perhaps not surprisingly, the apparent visual separation resulting from inter-training is aligned with the performance gain obtained later on in the fine-tuning phase

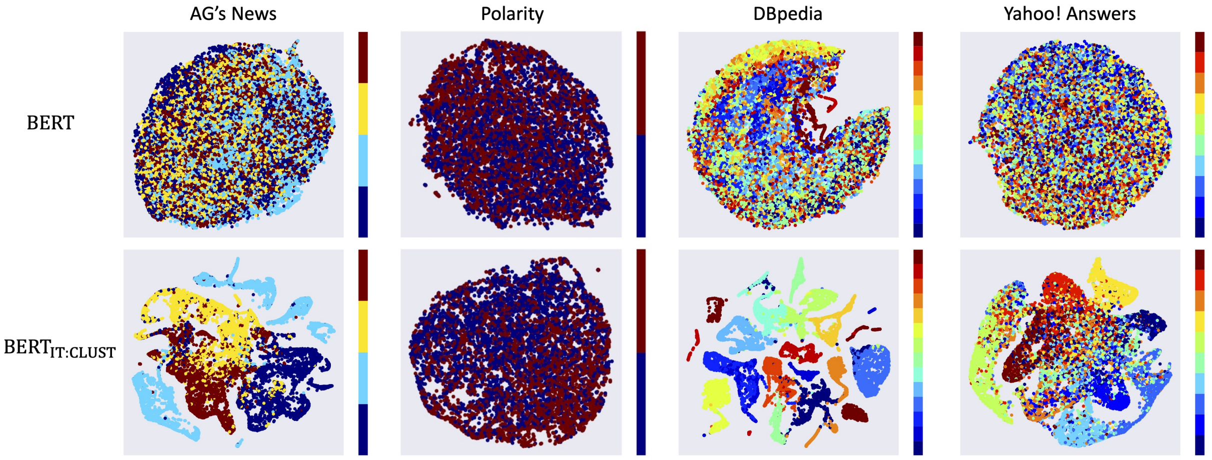

Figure 3: t-SNE visualizations of model embeddings over the train set, using BERT (top) vs. BERT$_{\text{IT:CLUST}}$ (bottom). The colors represent the gold labels for the target task (e.g., four classes in AG's News data set).

over the target task (as seen, for instance, in the visualizations of Polarity versus DBpedia data).

In addition to the qualitative results of the visualization, we pursue a more quantitative path. We assess whether examples of the same class are more closely represented after inter-training. Formally, given a set of instances' embeddings $e_1, \ldots, e_n$ and their corresponding class labels $l_1, \ldots, l_n \in \mathcal{L}$ we compute for each class $l \in \mathcal{L}$ a centroid c_l which is the average embedding of this class. We then compute the average Euclidean *Embeddings' Distance* (*ED*) from the corresponding centroids:[8]

$$ED(l, e) = \mathbb{E}_{i=0}^{n} \|e_i - c_i\|_2$$

As a sanity check, we apply a significance test to the ED statistic, confirming that representations of same-class examples are close to each other. Specifically, we apply a permutation test (Fisher, 1971), with 1000 repetitions, comparing the class labels to random labels. We find that EDs for both BERT and BERT$_{\text{IT:CLUST}}$ are significantly different from random ($p < 0.001$). This implies that both before and after inter-training, same-class representations are close. Next, we compare the representations before and after inter-training. We find that the randomly permuted EDs of BERT$_{\text{IT:CLUST}}$ are about 3 times larger than BERT's, despite similar norm values. This means that the post inter-training representations are more dispersed. Hence, to properly compare, we normalize ED by the average of the permuted EDs:

$$NED(l, e) = \frac{ED(l, e)}{\mathbb{E}_{\tau \in S_n} ED(\tau(l), e)}$$

Where $\tau \in S_n$ is a permutation out of S_n the set of all permutations.

Comparing the *Normalized Embeddings' Distance* (*NED*) before and after inter-training, we find that in all datasets the normalized distance is smaller after inter-training. In other words, BERT$_{\text{IT:CLUST}}$ brings same-class representations closer in comparison to BERT.

5.4 Are Clusters Indicative of Target Labels?

A natural explanation for the contribution of inter-training to BERT's performance is that the pseudo-labels, obtained via the clustering partition, are informative with regards to target task labels. To quantify this intuition, in Figure 4 we depict the Normalized Mutual Information (NMI) between sIB labels and the target task labels, calculated over the entire training set, versus the gain of using BERT$_{\text{IT:CLUST}}$, reflected as the reduction in classification error rate between BERT and BERT$_{\text{IT:CLUST}}$, at the extreme case of 64 fine-tuning samples. Evidently, in datasets where the NMI is around zero, BERT$_{\text{IT:CLUST}}$ does not confer a clear benefit; conversely, where the NMI is relatively high, the performance gains are pronounced as well. Notably, the three datasets with the lowest NMI are those for which inter-training was not beneficial, as discussed in Section 4.

Since the partition obtained via clustering is often informative for the target class labels, we examine whether it can be utilized directly, as opposed

---

[8] Macro average results were similar, we hence report only micro average results. Results with Cosine similarity were also similar, hence omitted.

to as pseudo-labels for BERT inter-training. To that end, we applied a simple heuristic. Given a labeling budget x, we divide it across clusters, relative to their size, while ensuring that at least one instance within each of the 50 clusters is labeled. We use the budget per cluster to reveal the labels of a random sample of examples in that cluster, and identify each cluster with its most dominant label. Next, given a new test example, we assign it with the label associated with its nearest cluster. Results (see App. B) showed that this rudimentary classifier is generally not on par with BERT$_{\text{IT:CLUST}}$, yet it can be surprisingly effective where the NMI is high and the labeling budget is small.

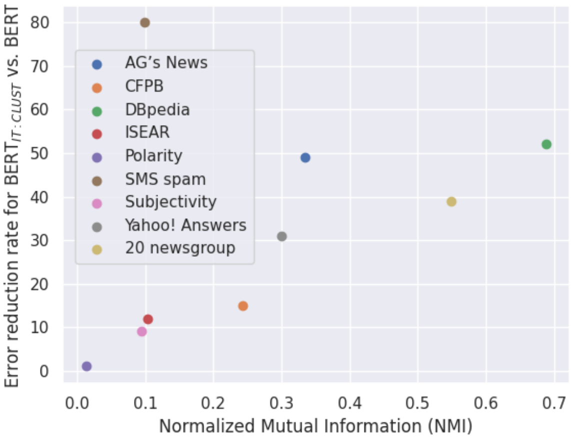

Figure 4: Improvement by BERT$_{\text{IT:CLUST}}$ vs Normalized Mutual Information (NMI) per dataset. x-axis: NMI between the cluster and class labels, over the train set. y-axis: The error reduction (percentage) by BERT$_{\text{IT:CLUST}}$, when fine-tuning over 64 samples.

6 Related Work

In our work, we transfer a pretrained model to a new domain with little data. Transfer learning studies how to transfer models across domains. It suggests methods such as pivoting (Ziser and Reichart, 2018), weak supervision (Shnarch et al., 2018), data augmentation (Anaby-Tavor et al., 2020) and adversarial transfer (Cao et al., 2018).

In Computer Vision, pretrained models are often learnt by image clustering (Caron et al., 2018). In NLP, however, clustering was mainly used for non-transfer scenarios. Ball (2019) relies on pretrained embeddings to cluster labeled and unlabeled data. Then, they fill the missing labels to augment the training data. Clustering itself was improved by combining small amounts of data (Torres and Vaca, 2019; Wang et al., 2016).

Pretrained models improved state-of-the-art in many downstream tasks (Nogueira and Cho, 2019; Ein-Dor et al., 2020) and they are especially needed and useful in low resource and limited labeled data settings (Lacroix et al., 2019; Wang et al., 2020a; Chau et al., 2020). There are many suggestions to improve such models, including larger models (Raffel et al., 2019), changes in the pretraining tasks and architecture (Yang et al., 2019), augmenting pretraining (Geva et al., 2020), or improving the transfer itself (Valipour et al., 2019; Wang et al., 2019b; Sun et al., 2019; Xu et al., 2020). Two findings on pretraining support our hypothesis on the intermediate task, namely that classification surpasses MLM. Some pretraining tasks are better than others (Lan et al., 2020; Raffel et al., 2019) and supervised classification as additional pre-training improves performance (Lv et al., 2020; Wang et al., 2019a; Pruksachatkun et al., 2020). All these works aim to improve the performance upon transfer, making it more suitable for any new domain. In contrast, we focus on improvement given the domain.

With a transferred model, one can further improve performance with domain-specific information. For example, utilizing metadata (Melamud et al., 2019), training on weakly-supervised data (Raisi and Huang, 2018; Meng et al., 2020) or multitasking on related tasks concurrently (Liu et al., 2019a). Given no domain-specific information, it was suggested to further pretrain on unlabeled data from the domain (Whang et al., 2019; Xu et al., 2019; Sung et al., 2019; Rietzler et al., 2020; Lee et al., 2020; Gururangan et al., 2020). This, however, is sometimes unhelpful or even hurts results (Pan, 2019).

Transferring a model and retraining with paucity of labels is often termed few-shot learning. Few shot learning is used for many language-related tasks such as named entity recognition (Wang et al., 2020b), relation classification (Hui et al., 2020), and parsing (Schuster et al., 2019). There have also been suggestions other than fine-tuning the model. Koch (2015) suggests ranking examples' similarity with Siamese networks. Vinyals et al. (2016) rely on memory and attention to find neighboring examples and Snell et al. (2017) search for prototypes to compare to. Ravi and Larochelle (2017) don't define in advance how to compare the examples. Instead, they meta-learn how to train the few shot learner. These works addressed the image classification domain, but they supply general methods which are used, improved and adapted on language domains (Geng et al., 2019; Yu et al., 2018).

In conclusion, separate successful practices foreshadow our findings: Clustering drives pre-training on images; supervised classification aids pre-training; and training on unlabeled domain examples is helpful with MLM.

7 Conclusions

We presented a simple approach for improving pre-trained models for text classification. Specifically, we show that inter-training BERT over pseudo-labels generated via unsupervised clustering creates a better starting point for the final fine-tuning over the target task. Our analyses suggest that BERT can leverage these pseudo-labels, namely that there exists a beneficial interplay between the proposed inter-training and the later fine-tuning stage. Our results show that this approach yields a significant boost in accuracy, mainly over topical data and when labeled data is scarce. Note that the method does require the existence of an unlabeled corpus, in the order of several thousand examples.

We opted here for a practically oriented approach, which we do not claim to be optimal. Rather, the success of this approach suggests various directions for future work. In particular, several theoretical questions arise, such as what else determines the success of the approach in a given dataset; understanding the potential synergistic effect of BOW-based clustering for inter-training; could more suitable partitions be acquired by exploiting additional embedding space and/or more clustering techniques; co-training (Blum and Mitchell, 1998) methods, and more.

On the practical side, while in this work we fixed the inter-training to be over 50 clusters and for a single epoch, future work can improve performance by tuning such hyper-parameters. In addition, one may consider using the labeled data available for fine-tuning as anchors for the intermediate clustering step, which we have not explored here.

Another point to consider is the nature of the inter-training task. Here, we examined a multi-class setup where BERT is trained to predict one out of n_c cluster labels. Alternatively, one may consider a binary inter-training task, where BERT is trained to determine whether two samples are drawn from the same cluster or not.

Finally, the focus of the present work was on improving BERT performance for text classification. In principle, inter-training BERT over clustering results may be valuable for additional downstream target tasks, that are similar in spirit to standard text classification. Examples include Key-Point Analysis (Bar-Haim et al., 2020) and Textual Entailment (Dagan et al., 2013). The potential value of our approach in such cases is left for future work.

8 Ethical considerations

Any use of a language model for classification involves some risk of bias, which stems from the pre-training and training data used to construct the model. Here we aim to improve the language model representations by relying on clustering of data from the target domain. We have no reason to believe this process would introduce bias beyond the potential bias that can occur whenever fine-tuning a model, but this is a potential risk, as we did not verify this directly.

B Additional reference methods

The results of NB_{BoW}, NB_{GloVe}, SVM_{BoW} and $\text{SVM}_{\text{GloVe}}$ are shown in Figure 5.

sIB-based classifier As mentioned in §5.4, we experimented with building a rudimentary classifier that utilizes only the sIB clustering results and the labeling budget. Results for this setting are depicted in Fig. 5 in orange. Comparing these results to the BERT-based approaches reveals that clustering alone is not sufficient.

C Additional clustering techniques

Fig. 6 depicts the comparison of the sIB over BOW representation, denoted $\text{BERT}_{\text{IT:CLUST}}$, to two other configurations for the clustering intermediate task: K-means over GloVe representations and Hartigan's K-means (Slonim et al., 2013) over GloVe. The GloVe representation for each text is an average of GloVe representations for the individual tokens. The comparison reveals that in most cases sIB over BOW outperforms the other clustering configurations.

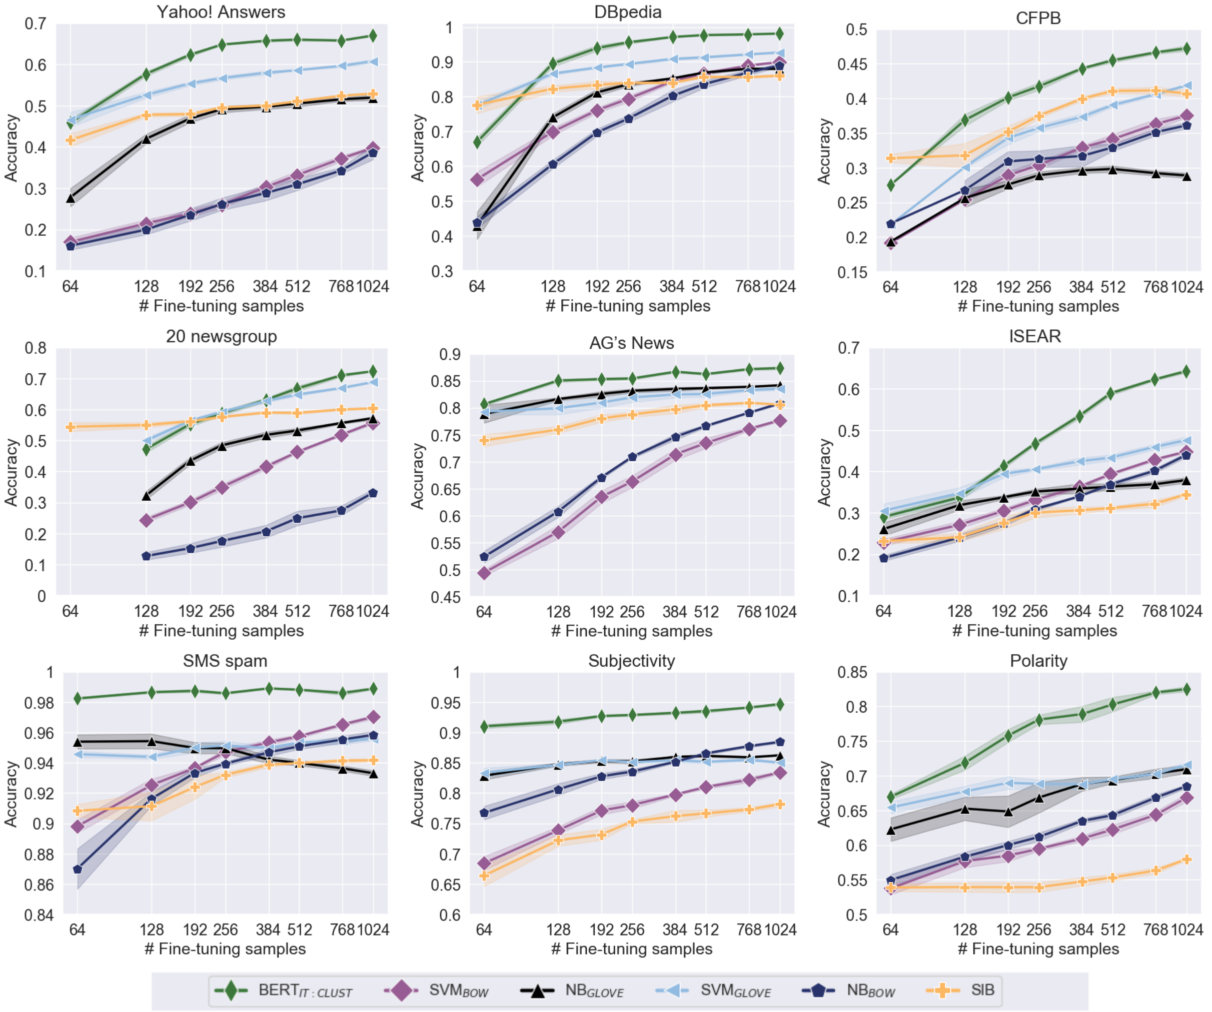

Figure 5: Comparing BOW methods and the BERT$_{\text{IT:CLUST}}$ setting. Each point is the average of five repetitions (± SEM). X axis denotes the budget for training in log scale, and Y accuracy of each model.

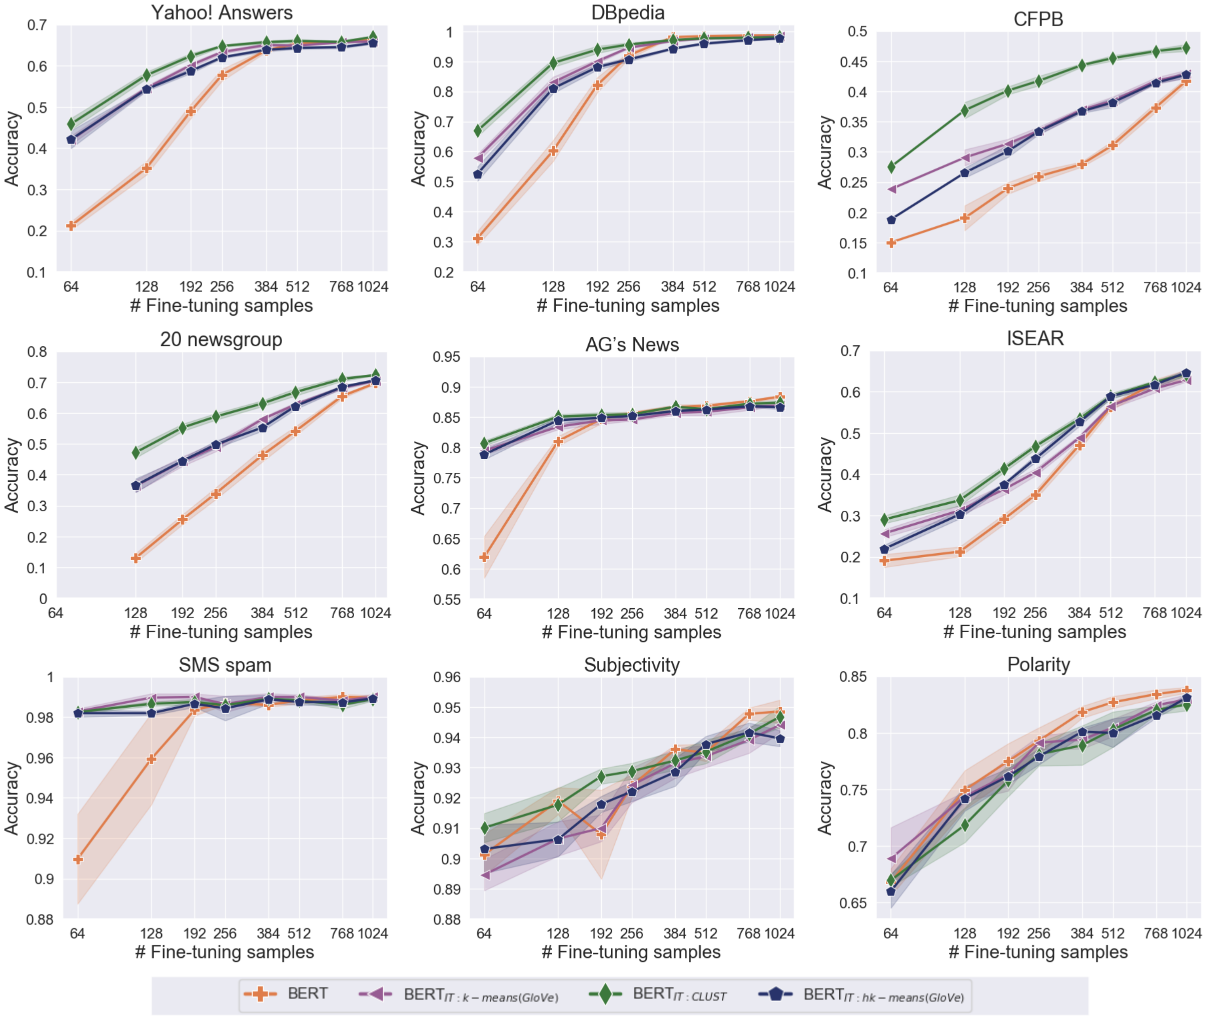

Figure 6: Comparison of clustering configurations for the intermediate task (hk-means stands for Hartigan's K-means). The results with no inter-training (BERT) are also presented for comparison. Each point is the average of five repetitions (± SEM). X axis denotes the number of labeling instances used for fine-tuning (in log scale).

Overcoming a Theoretical Limitation of Self-Attention

Abstract

Although transformers are remarkably effective for many tasks, there are some surprisingly easy-looking regular languages that they struggle with. Hahn shows that for languages where acceptance depends on a single input symbol, a transformer's classification decisions become less and less confident (that is, with cross-entropy approaching 1 bit per string) as input strings get longer and longer. We examine this limitation using two languages: PARITY, the language of bit strings with an odd number of 1s, and FIRST, the language of bit strings starting with a 1. We demonstrate three ways of overcoming the limitation suggested by Hahn's lemma. First, we settle an open question by constructing a transformer that recognizes PARITY with perfect accuracy, and similarly for FIRST. Second, we use layer normalization to bring the cross-entropy of both models arbitrarily close to zero. Third, when transformers need to focus on a single position, as for FIRST, we find that they can fail to generalize to longer strings; we offer a simple remedy to this problem that also improves length generalization in machine translation.

1 Introduction

Although transformers (Vaswani et al., 2017) are remarkably effective for many tasks, there are some surprisingly easy-looking formal languages that they struggle with. Hahn (2020) tries to explain some of these by showing (his Lemma 5) that changing a single input symbol only changes the output of a transformer encoder by $O(1/n)$, where n is the input string length. Thus, for a language where acceptance depends on a single input symbol, a transformer might accept or reject strings with perfect accuracy, but for large n, it must do so with low confidence, giving accepted strings a probability just above ½ and rejected strings a probability just below ½. More precisely, as n increases, the cross-entropy approaches its worst possible value of 1 bit per string.

Here, we examine this limitation using two simple regular languages:

$$\mathsf{PARITY} = \{w \in \Sigma^* \mid w \text{ has an odd number of 1s}\}$$
$$\mathsf{FIRST} = \{w \in \Sigma^* \mid w_1 = 1\}$$

where (here and throughout the paper) $\Sigma = \{0, 1\}$. Hahn's lemma applies to PARITY because the network must attend to all the symbols of the string, and a change in any one of them changes the correct answer. We have chosen FIRST as one of the simplest examples of a language that the lemma applies to. It only requires attention on the first symbol, but the lemma still applies because a change in this symbol changes the correct answer.

Although the lemma might be interpreted as limiting the ability of transformers to recognize these languages, we show three ways that this limitation can be overcome.

First, we show by explicit constructions that transformers do in fact exist that can recognize both languages with perfect accuracy for arbitrary lengths. We have implemented these constructions and verified them experimentally (§3).

As predicted by Hahn's lemma, our constructed transformers have cross-entropy that approaches 1 bit (that is, just barely better than random guessing) as input length increases. But we show that by adding layer normalization, the cross-entropy can be made arbitrarily close to zero, independent of string length (§4).

In practice, we find, like Bhattamishra et al. (2020a), that transformers cannot learn PARITY. Perhaps more surprisingly, when learning FIRST, transformers can have difficulty generalizing from shorter strings to longer strings. Although this is not a logical consequence of Hahn's lemma, it is a consequence of the behavior that Hahn's lemma predicts. Fortunately, this problem can be fixed with a simple modification, multiplying attention logits by $\log n$. This modification also improves length generalization in machine translation (§5).

2 Background

2.1 Notation

If ϕ is a true-or-false statement, we write

$$\mathbb{I}[\phi] = \begin{cases} 1 & \text{if } \phi \text{ is true} \\ 0 & \text{otherwise.} \end{cases}$$

For any $m, n > 0$, we write $\mathbf{0}^{m\times n}$ for the $m \times n$ zero matrix and $\mathbf{I}^{n\times n}$ for the $n \times n$ identity matrix.

2.2 Transformers

Following Hahn (2020), we consider transformer encoders with a sigmoid output layer on a single position. Differently from Hahn (2020), but in line with common practice (Devlin et al., 2019), we prepend a token CLS (for “classification”) and use the encoder output at this token’s position for classifying the string.

We use the original definition of transformers (Vaswani et al., 2017), except for positional encodings.

2.2.1 Input layer

The input to the network is a string $w \in \Sigma^*$. Let $n = |w| + 1$, let $w_0 = \texttt{CLS}$, and let w_i be the i-th symbol of w.

The input layer has a word embedding and positional encodings,

$$\begin{aligned} \text{WE}\colon \Sigma &\to \mathbb{R}^d \\ \text{PE}\colon \mathbb{N} &\to \mathbb{R}^d \end{aligned}$$

which are used to compute input vectors for $i = 0, \ldots n$:

$$\mathbf{a}^{0,i} = \text{WE}(w_i) + \text{PE}(i).$$

The word embeddings are typically learned, while the positional encodings vary somewhat. Originally (Vaswani et al., 2017), they were fixed and defined in terms of sine and cosine waves, but they can also be learned (Gehring et al., 2017), in which case they are defined only up to some maximum position. Here, we allow ourselves to define PE as an arbitrary function on all positions. It would seem that to remain in the spirit of the original paper, PE should be easy to compute, independent of w, and parallelizable over positions.

2.2.2 Encoder layers

The body of the encoder is a stack of L layers, each of which has a self-attention sublayer followed by a position-wise feedforward sublayer. For $\ell = 1, \ldots, L$, layer ℓ is defined as follows, where $h = 1, \ldots, H$, and $i = 0, \ldots, n$:

$$\begin{aligned} \mathbf{q}^{\ell,h,i} &= \mathbf{W}^{\text{Q},\ell,h}\mathbf{a}^{\ell-1,i} \\ \mathbf{K}^{\ell,h} &= \begin{bmatrix} \mathbf{W}^{\text{K},\ell,h}\mathbf{a}^{\ell-1,0} & \cdots & \mathbf{W}^{\text{K},\ell,h}\mathbf{a}^{\ell-1,n} \end{bmatrix}^\top \\ \mathbf{V}^{\ell,h} &= \begin{bmatrix} \mathbf{W}^{\text{V},\ell,h}\mathbf{a}^{\ell-1,0} & \cdots & \mathbf{W}^{\text{V},\ell,h}\mathbf{a}^{\ell-1,n} \end{bmatrix}^\top \\ \mathbf{c}^{\ell,i} &= \text{LN}\left(\sum_{h=1}^{H} \text{Att}(\mathbf{q}^{\ell,h,i}, \mathbf{K}^{\ell,h}, \mathbf{V}^{\ell,h}) + \mathbf{a}_{\ell-1,i} \right) \\ \mathbf{h}^{\ell,i} &= \max\left(0, \mathbf{W}^{\text{F},\ell,1}\mathbf{c}^{\ell,i} + \mathbf{b}^{\text{F},\ell,1}\right) \\ \mathbf{a}^{\ell,i} &= \text{LN}\left(\mathbf{W}^{\text{F},\ell,2}\mathbf{h}^{\ell,i} + \mathbf{b}^{\text{F},\ell,2} + \mathbf{c}^{\ell,i}\right) \end{aligned}$$

where boldface lowercase letters stand for vectors in $\mathbb{R}^d$ and boldface uppercase letters stand for matrices in $\mathbb{R}^{d\times d}$. The learned parameters of the model are the $\mathbf{W}$’s and $\mathbf{b}$’s. The function Att is scaled dot-product attention, defined as

$$\begin{aligned} \text{Att}\colon \mathbb{R}^d \times \mathbb{R}^{(n+1)\times d} \times \mathbb{R}^{(n+1)\times d} &\to \mathbb{R}^d \\ \text{Att}(\mathbf{q}, \mathbf{K}, \mathbf{V}) &= \mathbf{V}^\top \operatorname{softmax} \frac{\mathbf{Kq}}{\sqrt{d}} \end{aligned}$$

where the result of the softmax, sometimes written as α, is a vector of *attention weights*. The function LN is layer normalization, whose definition we defer to §4.

2.2.3 Output layer

Finally, the network linearly projects the encoding of CLS to a scalar and applies a sigmoid function:

$$y = \sigma(\mathbf{W}^{L+1}\mathbf{a}^{L,0} + \mathbf{b}^{L+1})$$

where $\mathbf{W}^{L+1} \in \mathbb{R}^{1\times d}$ and $\mathbf{b}^{L+1} \in \mathbb{R}^{1\times 1}$. The network accepts w iff the output probability is greater than $\frac{1}{2}$.

3 Exact Solutions

The first way to overcome the limitation suggested by Hahn’s lemma is to show by explicit construction that our two languages can in fact be recognized with perfect accuracy by transformers.

3.1 FFNN for PARITY

Rumelhart et al. (1986) showed that for any n, there is a feedforward neural network (FFNN) that computes PARITY for strings of length exactly n. They also showed that a randomly initialized FFNN can learn to do this automatically.

Since our construction is partially based on theirs, it may be helpful to review their construction in detail. Let w be the input string, $|w| = n$, and k be the number of 1s in w. The input is a vector $\mathbf{x}$ such that $\mathbf{x}_i = \mathbb{I}[w_i = 1]$. The first layer computes k and compares it against $1, 2, \ldots, n$:

$$\mathbf{W}^1 = \begin{bmatrix} 1 & 1 & \cdots & 1 \\ 1 & 1 & \cdots & 1 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 1 & \cdots & 1 \end{bmatrix} \qquad \mathbf{b}^1 = \begin{bmatrix} -0.5 \\ -1.5 \\ \vdots \\ -n + 0.5 \end{bmatrix}$$

so that

$$\mathbf{h}^1 = H(\mathbf{W}^1\mathbf{x} + \mathbf{b}^1) = \begin{bmatrix} \mathbb{I}[k \geq 1] \\ \mathbb{I}[k \geq 2] \\ \vdots \\ \mathbb{I}[k \geq n] \end{bmatrix}$$

where H is the step function ($H(x) = \mathbb{I}[x > 0]$), applied elementwise.

The second layer adds up the odd elements and subtracts the even elements:

$$\mathbf{W}^2 = \begin{bmatrix} 1 & -1 & \cdots & (-1)^{n+1} \end{bmatrix} \qquad \mathbf{b}^2 = -0.5$$

$$y = H(\mathbf{W}^2\mathbf{h}^1 + \mathbf{b}^2)$$

which is 1 if k is odd and 0 is k is even.

3.2 Transformer for PARITY

Proposition 1. *There is a transformer encoder with sigmoid output layer that recognizes (in the above sense) the language* PARITY *for strings of arbitrary length.*

Initially, we will construct a transformer encoder without layer normalization (that is, $\mathrm{LN}(\mathbf{x}) = \mathbf{x}$); then we will show how to add layer normalization (§4). Let k be the number of occurrences of 1 in w. All vectors computed by the network have $d = 9$ dimensions; if we show fewer dimensions, assume the remaining dimensions to be zero.

The word and position embeddings are:

$$\mathrm{WE}(\mathbb{0}) = \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} \qquad \mathrm{WE}(1) = \begin{bmatrix} 0 \\ 1 \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

$$\mathrm{WE}(\mathrm{CLS}) = \begin{bmatrix} 0 \\ 0 \\ 1 \\ 0 \\ 0 \end{bmatrix} \qquad \mathrm{PE}(i) = \begin{bmatrix} 0 \\ 0 \\ 0 \\ \frac{i}{n} \\ \cos i\pi \end{bmatrix}.$$

Since we are numbering positions starting from 0, dimension 4 ranges from 0 to $\frac{n-1}{n}$, and dimension 5 is $+1$ for even positions and -1 for odd positions.

We argue that dimension 5, being a cosine wave, is a fairly standard choice, although its period (2) is shorter than the shortest period in standard sinusoidal encodings (2π). Dimension 4 is admittedly not standard; however, we argue that it is a reasonable encoding, and extremely easy to compute.

Thus, the encoding of word w_i is:

$$\mathbf{a}^{0,i} = \begin{bmatrix} \mathbb{I}[w_i = \mathbb{0}] \\ \mathbb{I}[w_i = 1] \\ \mathbb{I}[w_i = \mathrm{CLS}] \\ \frac{i}{n} \\ \cos i\pi \end{bmatrix}.$$

The network has $L = 2$ layers and $H = 2$ heads. The first self-attention layer has one head which finds k, the number of 1s. More precisely, because attention always averages, it must compute the "average" number of 1s, that is, $\frac{k}{n}$, and stores it in dimension 6. It also stores $\frac{1}{n}$ in dimension 7, which we will need later.

$$\mathbf{W}^{\mathrm{Q},1,1} = \mathbf{0}$$

$$\mathbf{W}^{\mathrm{K},1,1} = \mathbf{0}$$

$$\mathbf{W}^{\mathrm{V},1,1} = \begin{bmatrix} & & \mathbf{0}^{5\times 5} & & \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \end{bmatrix}$$

The second head doesn't do anything ($\mathbf{W}^{\mathrm{V},1,2} = \mathbf{0}$; the queries and keys can be anything). After the residual connection, we have:

$$\mathbf{c}^{1,i} = \begin{bmatrix} \mathbb{I}[w_i = \mathbb{0}] \\ \mathbb{I}[w_i = 1] \\ \mathbb{I}[w_i = \mathrm{CLS}] \\ \frac{i}{n} \\ \cos i\pi \\ \frac{k}{n} \\ \frac{1}{n} \end{bmatrix}.$$

In the construction of Rumelhart et al. (1986), the next step is to compute $\mathbb{I}[i \leq k]$ for each i, using step activation functions. There are two differences in our construction. First, we have ReLU activation functions, not step activation functions. Second, because attention must sum to one, if n is odd then the even and odd positions will get different attention weights, so the trick of subtracting even positions from odd positions will not work. Instead, we want to compute $\mathbb{I}[i = k]$ (Fig. 1).

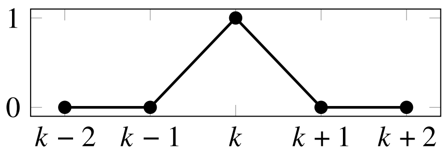

Figure 1: Piecewise linear function equivalent on the integers to $\mathbb{I}[i = k]$.

The first FFNN has two layers. The first is:

$$\mathbf{W}^{\mathrm{F},1,1} = \begin{bmatrix} 0 & 0 & 0 & -1 & 0 & 1 & -1 \\ 0 & 0 & 0 & -1 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 & 0 & 1 & 1 \end{bmatrix}$$

$$\mathbf{b}^{\mathrm{F},1,1} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}.$$

This gives:

$$\mathbf{h}^{1,i} = \frac{1}{n} \begin{bmatrix} \max(0, k - i - 1) \\ \max(0, k - i) \\ \max(0, k - i + 1) \end{bmatrix}.$$

The second layer linearly combines these three values to get $\mathbb{I}[i = k]$ as desired.

$$\mathbf{W}^{\mathrm{F},1,2} = \begin{bmatrix} & \mathbf{0}^{7\times 3} & \\ 1 & -2 & 1 \end{bmatrix} \qquad \mathbf{b}^{\mathrm{F},1,2} = \mathbf{0}.$$

After the residual connection, we have:

$$\mathbf{a}^{1,i} = \begin{bmatrix} \mathbb{I}[w_i = \mathtt{0}] \\ \mathbb{I}[w_i = \mathtt{1}] \\ \mathbb{I}[w_i = \mathtt{CLS}] \\ \frac{i}{n} \\ \cos i\pi \\ \frac{k}{n} \\ \frac{1}{n} \\ \frac{\mathbb{I}[i=k]}{n} \end{bmatrix}.$$

The second self-attention layer tests whether position k is even or odd. It does this using two heads, one which attends more strongly to the odd positions, and one which attends more strongly to the even positions; both average dimension 8:

$$\mathbf{W}^{\mathrm{Q},2,1} = \begin{bmatrix} 0 & 0 & c\sqrt{d} & 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

$$\mathbf{W}^{\mathrm{K},2,1} = \begin{bmatrix} 0 & 0 & 0 & 0 & -1 & 0 & 0 & 0 \end{bmatrix}$$

$$\mathbf{W}^{\mathrm{V},2,1} = \begin{bmatrix} & & & \mathbf{0}^{8\times 8} & & & & \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}$$

$$\mathbf{W}^{\mathrm{Q},2,2} = \begin{bmatrix} 0 & 0 & c\sqrt{d} & 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

$$\mathbf{W}^{\mathrm{K},2,2} = \begin{bmatrix} 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \end{bmatrix}$$

$$\mathbf{W}^{\mathrm{V},2,2} = \begin{bmatrix} & & & \mathbf{0}^{8\times 8} & & & & \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 \end{bmatrix}$$

where $c > 0$ can be any constant. The second FFNN doesn't do anything ($\mathbf{W}^{\mathrm{F},2,1} = \mathbf{b}^{\mathrm{F},2,1} = \mathbf{W}^{\mathrm{F},2,2} = \mathbf{b}^{\mathrm{F},2,2} = \mathbf{0}$). The vector at CLS (position 0) is then

$$\mathbf{a}^{2,0} = \begin{bmatrix} 0 \\ 0 \\ 1 \\ 0 \\ 1 \\ \frac{k}{n} \\ \frac{1}{n} \\ \frac{\mathbb{I}[k=0]}{n} \\ s \end{bmatrix}$$

where s has a somewhat complicated value. If n is even, it turns out to be

$$s = (-1)^{k+1} \frac{2 \tanh c}{n^2}$$

which is positive if k is odd and negative if k is even. As predicted by Hahn, it is in $O(1/n)$. If n is odd, the expression for s is more complicated (see Appendix A), but it is still positive iff k is odd, and it is still in $O(1/n)$.

Finally, the output layer is a sigmoid layer that just looks at dimension 9:

$$\mathbf{W}^3 = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \quad \mathbf{b}^3 = \mathbf{0}$$

$$y = \frac{1}{1 + \exp(-s)}.$$

So the output is greater than $\frac{1}{2}$ iff k is odd.

3.3 Transformer for FIRST

Next, we construct a transformer for FIRST. In line with the common practice of learning per-position word embeddings (Gehring et al., 2017), we use position embeddings that test whether a word is at position 1:

$$\mathbf{a}^{0,i} = \begin{bmatrix} \mathbb{I}[w_i = \mathtt{0}] \\ \mathbb{I}[w_i = \mathtt{1}] \\ \mathbb{I}[w_i = \mathtt{CLS}] \\ \mathbb{I}[i = 1] \end{bmatrix}.$$

The first self-attention layer does nothing ($\mathbf{W}^{\mathrm{V},1,1} = \mathbf{0}$), so after the residual connection, $\mathbf{c}^{1,i} = \mathbf{a}^{0,i}$.

The first FFNN computes a new component (5) that tests whether $i = 1$ and $w_1 = 1$:

$$\mathbf{W}^{\mathrm{F},1,1} = \begin{bmatrix} -1 & 0 & -1 & 1 \end{bmatrix} \qquad \mathbf{b}^{\mathrm{F},1,1} = 0$$

$$\mathbf{W}^{\mathrm{F},1,2} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 1 \end{bmatrix} \qquad \mathbf{b}^{\mathrm{F},1,2} = \mathbf{0}$$

$$\mathbf{a}^{1,i} = \begin{bmatrix} \mathbb{I}[w_i = 0] \\ \mathbb{I}[w_i = 1] \\ \mathbb{I}[w_i = \mathsf{CLS}] \\ \mathbb{I}[i = 1] \\ \mathbb{I}[w_i = 1 \wedge i = 1] \end{bmatrix}.$$

(We have chosen $\mathbf{W}^{\mathrm{F},1,1}$ in a slightly unusual way to avoid using the bias term $\mathbf{b}^{\mathrm{F},1,1}$, in anticipation of §4 when we will add layer normalization.)

The second self-attention layer has a single head, which makes CLS focus on position 1.

$$\begin{aligned} \mathbf{W}^{\mathrm{Q},2,1} &= \begin{bmatrix} 0 & 0 & c\sqrt{d} & 0 & 0 \end{bmatrix} \\ \mathbf{W}^{\mathrm{K},2,1} &= \begin{bmatrix} 0 & 0 & 0 & 1 & 0 \end{bmatrix} \\ \mathbf{W}^{\mathrm{V},2,1} &= \begin{bmatrix} & & \mathbf{0}^{5\times 5} & & \\ 0 & 0 & 0 & -\frac{1}{2} & 1 \end{bmatrix} \end{aligned}$$

where $c > 0$ is a constant. The second FFNN doesn't do anything ($\mathbf{W}^{\mathrm{F},2,1} = \mathbf{b}^{\mathrm{F},2,1} = \mathbf{W}^{\mathrm{F},2,2} = \mathbf{b}^{\mathrm{F},2,2} = \mathbf{0}$). So at CLS (position 0),

$$\mathbf{a}^{2,0} = \begin{bmatrix} 0 \\ 0 \\ 1 \\ 0 \\ 0 \\ s \end{bmatrix}$$

$$s = \frac{\exp c}{\exp c + n - 1} \left(\mathbb{I}[w_1 = 1] - \tfrac{1}{2} \right). \tag{1}$$

The final output layer just selects component 6:

$$\mathbf{W}^3 = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \qquad \mathbf{b}^3 = 0.$$

So the output probability, $y = \sigma(s)$, is greater than $\frac{1}{2}$ iff $w_1 = 1$. However, it will get closer to $\frac{1}{2}$ as n increases.

3.4 Experiments

We implemented both of the above constructions using modified versions of PyTorch's built-in implementation of transformers (Paszke et al., 2019).[1]

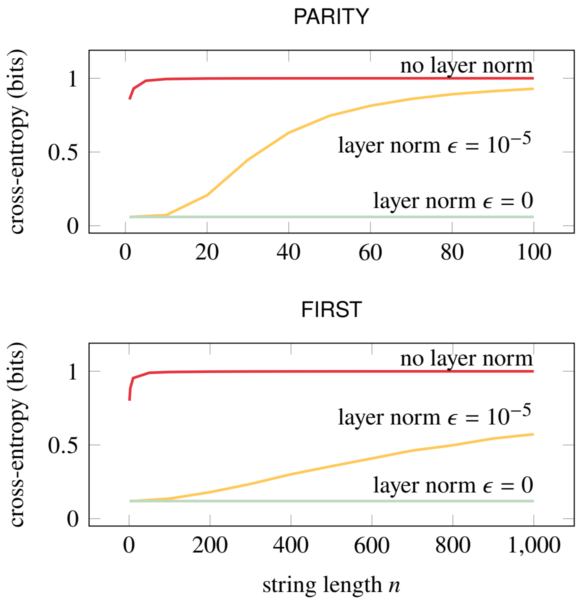

Figure 2: Cross-entropy of exact solutions for PARITY and FIRST computed over 1000 random strings of length n. Without layer norm, the cross-entropy quickly approaches its upper bound of one. With layer norm and $\epsilon > 0$, the cross-entropy is better but still grows with n. With $\epsilon = 0$, cross-entropy is independent of n.

These constructions achieve perfect accuracy for strings with lengths sampled from $[1, 1000]$.

However, in Fig. 2, the red curves ("no layer norm") show that, as strings grow longer, the cross-entropy approaches its worst possible value of 1 bit per string. We discuss this problem next.

4 Layer Normalization

The second way to mitigate or eliminate the limitation of Hahn's lemma is layer normalization (Ba et al., 2016), which is defined, for any vector $\mathbf{x}$, as

$$\mathrm{LN}(\mathbf{x}; \gamma, \beta) = \frac{\mathbf{x} - \mathrm{mean}(\mathbf{x})}{\sqrt{\mathrm{var}(\mathbf{x}) + \epsilon}} \circ \gamma + \beta$$

where the functions mean and var compute the mean and variance, respectively, of the elements of $\mathbf{x}$, and $\circ$ is the elementwise (Hadamard) product. We fix $\beta = 0$ and $\gamma = 1$, so that the result has approximately zero mean and unit variance. The constant ϵ was not present in the original definition (Ba et al., 2016) but is added in all implementations that we are aware of, for numerical stability.

The original transformer definition performs layer normalization immediately after every residual connection.[2] In this section, we modify our

---

[1] The code for this and other experiments in this paper are available at `https://github.com/ndnlp/parity`.

[2] It is also common to place layer normalization before residual connections (Wang et al., 2019; Nguyen and Salazar, 2019), but we follow the original transformer definition here.

two constructions above to use layer normalization. This modification has two steps.

4.1 Removing centering

The first is to nullify the centering effect of layer normalization by making the network compute each value x as well as its negation $-x$. The new word encodings are defined in terms of those in the original construction:

$$\bar{\mathbf{a}}^{0,i} = \begin{bmatrix} \mathbf{a}^{0,i} \\ -\mathbf{a}^{0,i} \end{bmatrix}.$$

Likewise for the self-attention parameters:

$$\begin{aligned}
\bar{\mathbf{W}}^{\mathrm{Q},\ell,h} &= \begin{bmatrix} \mathbf{W}^{\mathrm{Q},\ell,h} & \mathbf{0} \end{bmatrix} \\
\bar{\mathbf{W}}^{\mathrm{K},\ell,h} &= \begin{bmatrix} \mathbf{W}^{\mathrm{K},\ell,h} & \mathbf{0} \end{bmatrix} \\
\bar{\mathbf{W}}^{\mathrm{V},\ell,h} &= \begin{bmatrix} \mathbf{W}^{\mathrm{V},\ell,h} & \mathbf{0} \\ -\mathbf{W}^{\mathrm{V},\ell,h} & \mathbf{0} \end{bmatrix}.
\end{aligned}$$

Likewise for the position-wise FFNN parameters:

$$\begin{aligned}
\bar{\mathbf{W}}^{\mathrm{F},\ell,1} &= \begin{bmatrix} \mathbf{W}^{\mathrm{F},\ell,1} & \mathbf{0} \end{bmatrix} & \bar{\mathbf{b}}^{\mathrm{F},\ell,1} &= \mathbf{b}^{\mathrm{F},\ell,1} \\
\bar{\mathbf{W}}^{\mathrm{F},\ell,2} &= \begin{bmatrix} \mathbf{W}^{\mathrm{F},\ell,2} \\ -\mathbf{W}^{\mathrm{F},\ell,2} \end{bmatrix} & \bar{\mathbf{b}}^{\mathrm{F},\ell,2} &= \begin{bmatrix} \mathbf{b}^{\mathrm{F},\ell,2} \\ -\mathbf{b}^{\mathrm{F},\ell,2} \end{bmatrix}.
\end{aligned}$$

Then each layer of activations is

$$\bar{\mathbf{c}}^{\ell,i} = \mathrm{LN}\left(\begin{bmatrix} \mathbf{c}^{\ell,i} \\ -\mathbf{c}^{\ell,i} \end{bmatrix}\right) \qquad \bar{\mathbf{a}}^{\ell,i} = \mathrm{LN}\left(\begin{bmatrix} \mathbf{a}^{\ell,i} \\ -\mathbf{a}^{\ell,i} \end{bmatrix}\right).$$

The argument to LN always has zero mean, so that layer normalization does not add or subtract anything. It does scale the activations, but in the case of the two transformers constructed above, any activation layer can be scaled by any positive number without changing the final decisions (see Appendix B).

4.2 Reducing cross-entropy

Furthermore, in any transformer, we can use layer normalization to shrink the cross-entropy as small as we like, contrary to Hahn's Lemma 5. In Hahn's formulation, position-wise functions like layer normalization can be subsumed into his f^{act}, but the lemma assumes that f^{act} is Lipschitz-continuous, and layer normalization with $\epsilon = 0$ is not.

Proposition 2. *For any transformer T with layer normalization ($\epsilon = 0$) that recognizes a language $\mathcal{L}$, and for any $\eta > 0$, there is a transformer with layer normalization that recognizes $\mathcal{L}$ with cross-entropy at most η.*

Proof. Let d be the number of dimensions in the original vectors of activations, and let L be the number of layers. Then we add a new layer whose self-attention doesn't do anything ($\mathbf{W}^{\mathrm{V},L+1,h} = \mathbf{0}$) and whose FFNN is defined in terms of the original output layer:

$$\begin{aligned}
\bar{\mathbf{W}}^{\mathrm{F},L+1,1} &= \begin{bmatrix} \mathbf{I}^{d} \\ -\mathbf{I}^{d} \end{bmatrix} \qquad \bar{\mathbf{b}}^{\mathrm{F},L+1,1} = \begin{bmatrix} \mathbf{0}^{d} \\ \mathbf{0}^{d} \end{bmatrix} \\
\bar{\mathbf{W}}^{\mathrm{F},L+1,2} &= \begin{bmatrix} -\mathbf{I}^{d} & \mathbf{I}^{d} \end{bmatrix} + \begin{bmatrix} \mathbf{W}^{L+1} & -\mathbf{W}^{L+1} \\ -\mathbf{W}^{L+1} & \mathbf{W}^{L+1} \\ \mathbf{0}^{(d-2)\times d} & \mathbf{0}^{(d-2)\times d} \end{bmatrix} \\
\bar{\mathbf{b}}^{\mathrm{F},L+1,2} &= \begin{bmatrix} \mathbf{b}^{L+1} \\ -\mathbf{b}^{L+1} \\ \mathbf{0}^{d-2} \end{bmatrix}.
\end{aligned}$$

This causes the residual connection to zero out all dimensions except two, so that if s was the original output logit, the output of this new layer (before layer normalization) is

$$\bar{\mathbf{a}}^{L+1,i} = \mathrm{LN}\left(\begin{bmatrix} s \\ -s \\ \mathbf{0}^{d-2} \end{bmatrix}\right).$$

Now, if $\epsilon = 0$, layer normalization scales this vector to have unit variance exactly, so it becomes

$$\bar{\mathbf{a}}^{L+1,i} = \begin{bmatrix} \pm\sqrt{d/2} \\ \mp\sqrt{d/2} \\ \mathbf{0}^{d-2} \end{bmatrix}.$$

The new output layer simply selects the first dimension, scaling it by c:

$$\bar{\mathbf{W}}^{L+2} = \begin{bmatrix} c & 0 & \mathbf{0}^{d-2} \end{bmatrix} \qquad \bar{\mathbf{b}}^{L+2} = 0.$$

Finally, set $c = -\frac{1}{\sqrt{d/2}} \log(\exp \eta - 1)$. If the input string is in $\mathcal{L}$, then the cross-entropy is $\log \sigma(c\sqrt{d/2}) = \eta$. Similarly, if the input string is not in $\mathcal{L}$, then the cross-entropy is $\log(1 - \sigma(-c\sqrt{d/2})) = \eta$. □

However, in practice, ϵ is always set to a nonzero value, which makes layer normalization Lipschitz-continuous, so Hahn's Lemma 5 still applies.

4.3 Experiments

We tested our exact solutions, modified as described above to use layer normalization. Figure 2 shows that layer normalization with $\epsilon > 0$ improves the cross-entropy, but it still grows with n and approaches 1. With $\epsilon = 0$, the cross-entropy is independent of n and, as argued above (Proposition 2), can be made as low as desired.

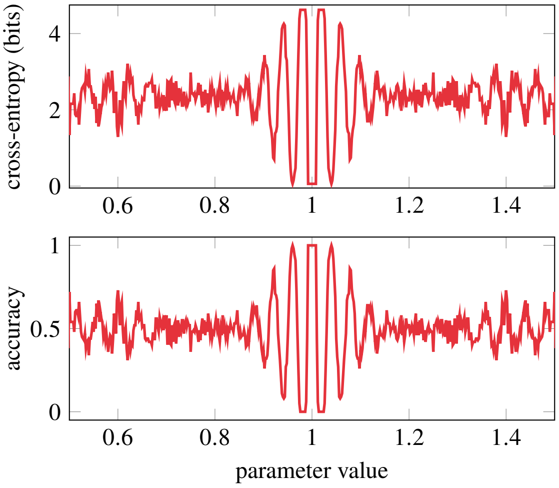

Figure 3: The cross-entropy and accuracy of our solution to PARITY are both extremely sensitive to the parameter $\bar{\mathbf{W}}^{\mathrm{V},1,1}_{6,2}$, which is responsible for computing $\frac{k}{n}$. The correct parameter value is 1.

5 Learnability

In this section, we turn to the question of learnability, which will lead to a third way of overcoming the limitation suggested by Hahn's lemma.

5.1 Experiments: standard transformers

We tried training transformers on both PARITY and FIRST. Each transformer had the same number of layers and heads and the same fixed positional encodings as the corresponding exact solution. We used $d_{\text{model}} = 16$ for word encodings, self-attention, and FFNN outputs, and $d_{\text{FFNN}} = 64$ for FFNN hidden layers. We used layer normalization ($\epsilon = 10^{-5}$) after residual connections. We used PyTorch's default initialization and trained using Adam (Kingma and Ba, 2015) with learning rate 3×10^{-4} (Karpathy, 2016). We did not use dropout, as it did not seem to help.

We found, like Bhattamishra et al. (2020a), that a transformer with the above settings was unable to learn PARITY. We tried many other settings as well, to no avail. To give an idea of why our constructed solution, in particular, is difficult to find, Fig. 3 shows the cross-entropy and accuracy of the model if we start with our solution (with layer normalization, $\epsilon = 0$) and vary the parameter $\bar{\mathbf{W}}^{\mathrm{V},1,1}_{6,2}$, which is responsible for computing $\frac{k}{n}$. At 1, it has a cross-entropy of 0 and accuracy of 1, which are both optimal, but the cross-entropy oscillates so rapidly that even a small perturbation of this parameter would make it difficult to recover the solution by gradient descent.

FIRST is much easier to learn, but the bad news is that the learned transformers do not generalize well to longer sentences. Figure 4 (left column) shows that when a transformer is trained from scratch on shorter strings ($n = 10, 30, 100, 300$) and tested on longer strings ($n = 1000$), the accuracy is not perfect. Indeed, for training $n = 10$, the accuracy is hardly better than random guessing.

5.2 Flawed transformer for FIRST

In our solution above (§3.3), the second self-attention layer attended mostly to the first position, but not totally. It relied on the fact that in the second self-attention layer, the values of the non-first positions ($\mathbf{V}^{2,1}_{i,4}$ and $\mathbf{V}^{2,1}_{i,5}$ for $i \neq 1$) are exactly zero and therefore do not contribute to the output.

In practice, because word embeddings are randomly initialized in all dimensions, and are added to every layer via residual connections, it's unlikely for any activation to be exactly zero. This explains why our exact solution cannot be learned.

But, as a further thought experiment about what the model might be learning instead, consider the following transformer, which uses only a single layer ($L = 1$) and does not zero out the values of the non-first positions. As we will see, it performs worse than the transformer of §3.3 for long strings.

$$\mathbf{W}^{\mathrm{Q},1,1} = \begin{bmatrix} 0 & 0 & c\sqrt{d} & 0 \end{bmatrix}$$
$$\mathbf{W}^{\mathrm{K},1,1} = \begin{bmatrix} 0 & 0 & 0 & 1 \end{bmatrix}$$
$$\mathbf{W}^{\mathrm{V},1,1} = \begin{bmatrix} & \mathbf{0}^{4\times 4} & & \\ -\frac{1}{2} & \frac{1}{2} & -\frac{1}{2} & 0 \end{bmatrix}.$$

The FFNN doesn't do anything ($\mathbf{W}^{\mathrm{F},1,1} = \mathbf{b}^{\mathrm{F},1,1} = \mathbf{W}^{\mathrm{F},1,2} = \mathbf{b}^{\mathrm{F},1,2} = \mathbf{0}$), and the final output layer just selects component 5. So if k is the total number of 1s, the final logit at CLS (position 0) would be

$$\begin{aligned} s = {} & \frac{\exp c - 1}{\exp c + n - 1}\left(\mathbb{I}[w_1 = 1] - \frac{1}{2}\right) \\ & + \frac{1}{\exp c + n - 1}\left(k - \frac{n}{2}\right). \end{aligned}$$

If $c > \log(n-1)$, then this is positive iff $w_1 = 1$. But if $c \leq \log(n-1)$, the new second term can be big enough to make the model output an incorrect answer. This suggests that if we train a transformer on strings with length up to N, then the learned parameters will be large enough to classify strings of length up to N correctly, but may misclassify strings longer than N.

This explanation is corroborated by the bottom-left graph in Fig. 4, which shows the attention weight on the first position of the test string (summed over layers, averaged over strings) as a function of training epoch (starting from random initial parameters). The training strings have varying length (n) and the test strings have fixed length (1000). We might hope that the attention weight would converge to the same value independent of n. But the lower n is, the more the attention weight is diluted, making it easier for the value in position 1 to be outweighed by values in other positions.

5.3 Log-length scaled attention

Fortunately, this problem is easy to fix by scaling the logits of each attention layer by $\log n$, that is, redefining attention as

$$\mathrm{Att}(\mathbf{q}, \mathbf{K}, \mathbf{V}) = \mathbf{V}^\top \operatorname{softmax} \frac{\log n}{\sqrt{d}} \mathbf{K}\mathbf{q}. \qquad (2)$$

Then taking the model in §5.2 with $c = 1$ gives

$$s = \frac{n-1}{2n-1}\left(\mathbb{I}[w_1 = 1] - \frac{1}{2}\right) + \frac{1}{2n-1}\left(k - \frac{n}{2}\right)$$

which is positive iff $w_1 = 1$. Moreover, scaling is another way to make the cross-entropy low:

Proposition 3. *For any $\eta > 0$ there is a transformer with attention defined as in Eq. (2), and with or without layer normalization, that recognizes FIRST with cross-entropy at most η.*

Proof. Without layer normalization, we can take the model in §3.3, set $c = 1$ and log-scale the attention weights, which changes s from Eq. (1) to

$$s = \frac{n}{2n-1}\left(\mathbb{I}[w_1 = 1] - \frac{1}{2}\right)$$

$$\frac{1}{4} < |s| \leq \frac{1}{2}.$$

With layer normalization (and $\epsilon > 0$), we can apply the modification of §4 to nullify the centering effect of layer normalization. Then since the variance of $\mathbf{a}^{2,0}$ is $\frac{1}{6}(1 + s^2)$, the layer-normalized final logit is

$$\bar{s} = s\left(\frac{1}{6}(1 + s^2) + \epsilon\right)^{-\frac{1}{2}}$$

and since $|s| > \frac{1}{4}$,

$$|\bar{s}| > \frac{1}{4}\left(\frac{5}{24} + \epsilon\right)^{-\frac{1}{2}}.$$

In either case, since the final logit has a lower bound not dependent on n, the output layer weights can be scaled as in the proof of Proposition 2 to make the cross-entropy at most η. □

	train all test all	train short test long
train tokens	3M+3M	1M+1M
test tokens	32k+34k	24k+25k
baseline	32.6	11.4
scaled	32.5	12.4

Table 1: When training and testing on data with the same length distribution, scaling attention logits has no significant effect on BLEU, but when training on short sentences (≤ 20 tokens) and testing on long sentences (> 20 tokens), scaling helps significantly ($p < 0.01$).

5.4 Experiments: scaled attention

Figure 4 (right column) shows the training of transformers with scaling of attention logits by $\log n$. For all training lengths n, the model is able to learn with perfect test cross-entropy and accuracy.

We see a similar effect on low-resource English-to-Vietnamese machine translation (Table 1), using Witwicky, an open-source implementation of transformers.[3] We use all default settings; in particular, residual connections come after layer normalization ($\epsilon = 10^{-5}$). We measure translation accuracy using BLEU (Papineni et al., 2002) and use bootstrap resampling with 1000 samples for significance testing.

When train and test length distributions are the same, scaling attention logits has no significant effect. But if we train only on sentences with median length or shorter (≤ 20 tokens) and test only on sentences longer than median length (> 20 tokens), scaling attention logits by $\log n$ improves BLEU by +1, which is statistically significant ($p < 0.01$).

6 Related Work

Using very different assumptions on the form of transformers and inputs, a number of recent theoretical studies of transformers show that they can solve much more difficult problems than the ones studied here. Transformer encoders can be shown to be universal approximators by fixing the string length and using a number of layers exponential in the length (Yun et al., 2020). Transformer encoder–decoders, where the decoder can run for an unbounded number of steps, have been shown to be Turing-complete (Bhattamishra et al., 2020b; Pérez et al., 2021).

---

[3] `https://github.com/tnq177/witwicky`

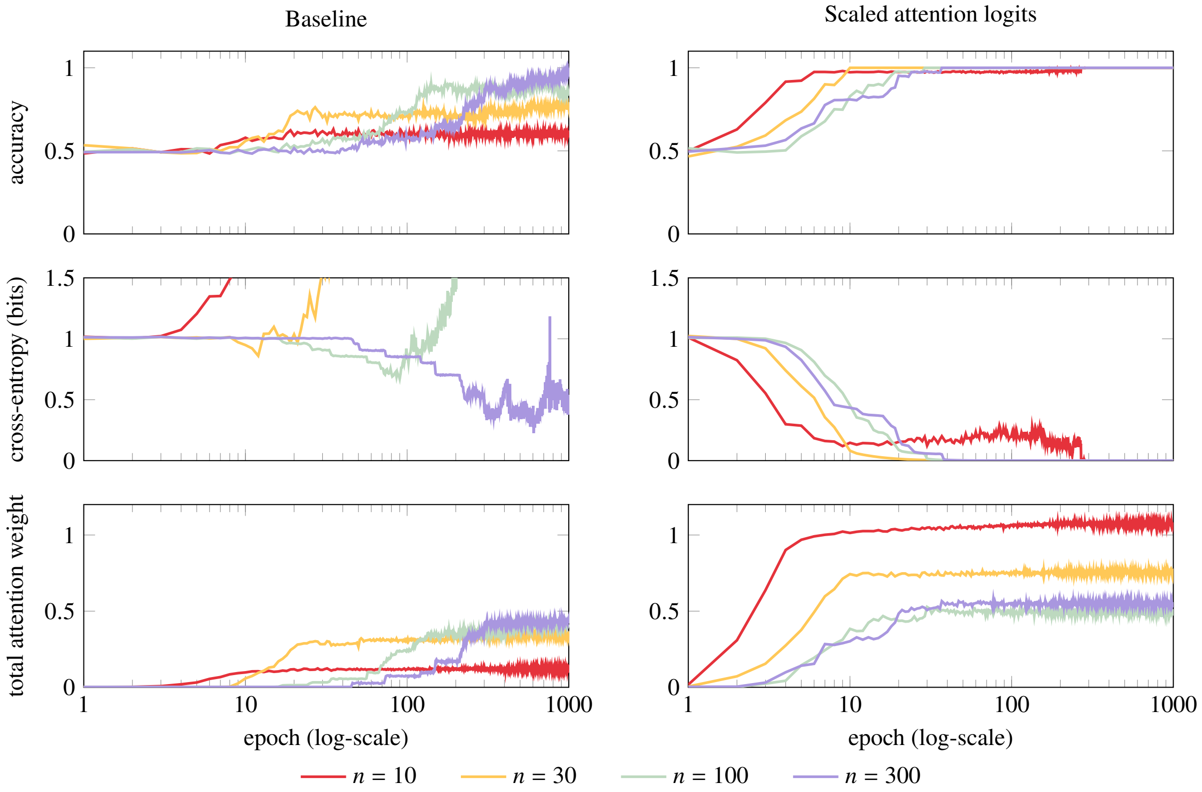

Figure 4: Training a transformer on FIRST. Each epoch has 100 training strings of varying length (see legend) and 100 test strings of length 1000. All curves are averaged over 20 runs. Left: Standard transformer with layer normalization ($\epsilon = 10^{-5}$). Right: Same, with attention logits scaled by $\log n$.

RASP (Weiss et al., 2021) is a simple programming language whose programs can be compiled into transformers. While PARITY can easily be written in RASP, this does not imply in itself the existence of transformers that can recognize PARITY, for two reasons. First, RASP's aggregate operation (which corresponds to attention) always attends uniformly to a subset of positions, unlike softmax attention. Second, RASP's elementwise operations are embedded directly in the output transformer; they are not translated into FFNNs.

Bhattamishra et al. (2020a) carry out theoretical and experimental studies of transformers for various formal languages. The theoretical results are for a different variant of transformers than ours (transformer encoders with self-attention masked so that each position attends only to previous positions), and focus on such transformers' ability to maintain counters that are constrained to be nonnegative. Their experimental results suggest that transformers have difficulty learning some regular languages, including PARITY.

7 Conclusion

We've seen that the questions of (a) whether a neural network can recognize a language, (b) whether it can achieve low cross-entropy on a language, and (c) whether it can learn to recognize a language are three separate questions, because we have given examples of (a) without (b) and (b) without (c).

Namely, our explicit construction for PARITY shows that a neural network can recognize a language with perfect accuracy (a) but poor cross-entropy (b). Adding layer normalization ($\epsilon = 0$) enables it to achieve low cross-entropy (b), but still does not learn well (c). We observe that because the answer to (b) can hinge on small details of the model, (b) is not probably not very useful as a way of measuring expressivity.

However, we did find that the limited influence of a single input symbol, implied by Hahn's lemma, has a serious practical implication for learnability (c). Namely, transformers can fail to generalize from shorter training strings to longer testing strings. Our proposed fix, scaling attention logits by $\log n$, is easy to implement and very effective on a real machine translation task.

A Correctness of PARITY Construction

In §3.2, we constructed a transformer that recognizes PARITY; here we fill in details of calculating $s = \mathbf{a}_9^{2,0}$. If n is even, the first head computes

$$\begin{aligned} \mathbf{q}^{2,1,0} &= c\sqrt{d} \\ \mathbf{K}^{2,1,0}_{i,1} &= -\cos i\pi = (-1)^{i+1} \\ \alpha_i^{2,1,0} &= \frac{\exp(-1)^{i+1}c}{\frac{n}{2}(\exp c + \exp -c)} \\ \mathbf{V}^{2,1,0}_{i,9} &= \frac{\mathbb{I}[i=k]}{n}. \end{aligned}$$

Similarly, the second head computes

$$\begin{aligned} \mathbf{q}^{2,2,0} &= c\sqrt{d} \\ \mathbf{K}^{2,2,0}_{i,1} &= \cos i\pi = (-1)^{i} \\ \alpha_i^{2,2,0} &= \frac{\exp(-1)^{i}c}{\frac{n}{2}(\exp c + \exp -c)} \\ \mathbf{V}^{2,2,0}_{i,9} &= -\frac{\mathbb{I}[i=k]}{n}. \end{aligned}$$

Then

$$\begin{aligned} s = \mathbf{a}_9^{2,0} &= \frac{1}{n}\alpha_k^{2,1,0} - \frac{1}{n}\alpha_k^{2,2,0} \\ &= \frac{\exp(-1)^{k+1}c - \exp(-1)^{k}c}{\frac{n^2}{2}(\exp c + \exp -c)} \\ &= (-1)^{k+1}\frac{\exp c - \exp -c}{\frac{n^2}{2}(\exp c + \exp -c)} \\ &= (-1)^{k+1}\frac{2\tanh c}{n^2} \end{aligned}$$

is negative if k is even and positive if k is odd.

If n is odd, calculating s is more complicated because there are unequal numbers of more- and less-attended positions. The attention weights are

$$\begin{aligned} \alpha_i^{2,1,0} &= \frac{\exp(-1)^{i+1}c}{\underbrace{\frac{n-1}{2}\exp c + \frac{n+1}{2}\exp -c}_{Z_1}} \\ \alpha_i^{2,2,0} &= \frac{\exp(-1)^{i}c}{\underbrace{\frac{n+1}{2}\exp c + \frac{n-1}{2}\exp -c}_{Z_2}} \\ s &= \frac{(\exp(-1)^{k+1}c)Z_2 - (\exp(-1)^{k}c)Z_1}{nZ_1Z_2}. \end{aligned}$$

If k is even,

$$\begin{aligned} s &= \frac{\frac{n-1}{2}\exp -2c - \frac{n-1}{2}\exp 2c}{nZ_1Z_2} \\ &= -\frac{(n-1)\sinh 2c}{nZ_1Z_2} < 0 \end{aligned}$$

whereas if k is odd,

$$\begin{aligned} s &= \frac{\frac{n+1}{2}\exp 2c - \frac{n+1}{2}\exp -2c}{nZ_1Z_2} \\ &= \frac{(n+1)\cosh 2c}{nZ_1Z_2} > 0. \end{aligned}$$

B Scale-Invariance of PARITY and FIRST Constructions

In §4.1, we claimed that the scaling effect of layer normalization has no effect on the decisions of our constructions for PARITY and FIRST. This is related to the property of approximate homogeneity studied by Merrill et al. (2021).

In general, we rely on the fact that the FFNNs we use all have no bias terms ($\mathbf{b}^{\mathrm{F},\ell,1}$ and $\mathbf{b}^{\mathrm{F},\ell,2}$), so the FFNNs are 1-homogenous (scaling the input scales the output by the same amount). For the self-attentions, our $\mathbf{W}^{\mathrm{Q},\ell,h}$ all have a constant factor c built into them, so any scaling of the input can be absorbed into this constant.

For PARITY, suppose that layer normalization scales $\mathbf{c}^\ell$ by C_ℓ and $\mathbf{a}^\ell$ by A_ℓ.

$$\bar{\mathbf{c}}^{1,i} = C_1\begin{bmatrix}\mathbf{c}^{1,i} \\ -\mathbf{c}^{1,i}\end{bmatrix}$$

Because the first FFNN has no bias term,

$$\bar{\mathbf{a}}^{1,i} = A_1C_1\begin{bmatrix}\mathbf{a}^{1,i} \\ -\mathbf{a}^{1,i}\end{bmatrix}$$

In the second self-attention layer, the attention logits and the values are scaled by A_1C_1. We're only interested in what happens to $s = \mathbf{c}_9^{2,0}$. If n is even, s becomes:

$$\bar{s} = (-1)^{k+1}\frac{2C_2A_1C_1\tanh A_1C_1c}{n^2}.$$

Since the second FFNN is the identity function, its layer normalization has no effect ($A_2 = 1$). So the final logit is $\bar{s}$, which is still negative if k is even and positive if k is odd. Similarly if n is odd.

For FIRST, again suppose that layer normalization scales $\mathbf{c}^\ell$ by C_ℓ and $\mathbf{a}^\ell$ by A_ℓ. As before,

$$\bar{\mathbf{a}}^{1,i} = A_1C_1\begin{bmatrix}\mathbf{a}^{1,i} \\ -\mathbf{a}^{1,i}\end{bmatrix}$$

In the second self-attention layer, the attention logits and the values are scaled by A_1C_1. We're only interested in what happens to $s = \mathbf{c}_6^{2,0}$:

$$\bar{s} = \frac{\exp A_1C_1c}{\exp A_1C_1c + n - 1}C_2A_1C_1\left(\mathbb{I}[w_1 = 1] - \tfrac{1}{2}\right)$$

Since the second FFNN is the identity function, $A_2 = 1$. So the final logit is $\bar{s}$, which is still positive if $w_1 = 1$ and negative otherwise.

Prediction Difference Regularization against Perturbation for Neural Machine Translation

Abstract

Regularization methods applying input perturbation have drawn considerable attention and have been frequently explored for NMT tasks in recent years. Despite their simplicity and effectiveness, we argue that these methods are limited by the under-fitting of training data. In this paper, we utilize prediction difference for ground-truth tokens to analyze the fitting of token-level samples and find that under-fitting is almost as common as over-fitting. We introduce prediction difference regularization (PD-R), a simple and effective method that can reduce over-fitting and under-fitting at the same time. For all token-level samples, PD-R minimizes the prediction difference between the original pass and the input-perturbed pass, making the model less sensitive to small input changes, thus more robust to both perturbations and under-fitted training data. Experiments on three widely used WMT translation tasks show that our approach can significantly improve over existing perturbation regularization methods. On WMT16 En-De task, our model achieves 1.80 SacreBLEU improvement over vanilla transformer.

1 Introduction

Neural machine translation models have achieved great success in recent years (Sutskever et al., 2014; Bahdanau et al., 2015; Gehring et al., 2017; Vaswani et al., 2017). Despite their efficiency and superb performance, NMT models are prone to over-fitting that universal regularization techniques such as dropout (Hinton et al., 2012) and label smoothing (Szegedy et al., 2016) have been indispensable. However, over-fitting is still a significant problem for NMT, especially for small and medium tasks, which motivates researchers to constantly explore more specialized and sophisticated regularization techniques.

Particularly, regularization methods applying input perturbation have been frequently explored for NMT models in recent years (Bengio et al., 2015; Wu et al., 2019; Sato et al., 2019; Takase and Kiyono, 2021). In these methods, neural models are trained to maximize the likelihood of perturbed samples that perturbed by a certain type of perturbations, with a primary intention to enhance model's robustness to perturbations, since neural models have been discovered fragile to small input noises (Szegedy et al., 2014; Liang et al., 2018; Belinkov and Bisk, 2018). In the past few years, many types of perturbations have been proposed to machine translation and been shown effective, including word-dropout (Gal and Ghahramani, 2016), word-replacement (Bengio et al., 2015; Wu et al., 2019) and adversarial perturbation (Miyato et al., 2017; Sato et al., 2019), etc.

In this paper, unlike previous works which are devoted to finding stronger perturbations and more appropriate perturbation schedules, we rethink the existing perturb-and-fit mechanism and prove that indiscriminate fitting of perturbed samples ignores and aggravates under-fitting, which dramatically limits the effectiveness of perturbation regularization. We further propose prediction difference regularization (PD-R), a simple and effective method that can alleviate over-fitting and under-fitting at the same time and significantly enhance the effectiveness of perturbation regularization.

Specifically, we use the prediction difference for ground-truth labels before and after input perturbation as an indicator of over-fitting and under-fitting for token-level samples. Quantitative analysis shows that a considerable part of token-level predictions get improved after input perturbation, indicating that the model is less fitted to those original samples compared to the perturbed samples, which has been ignored by previous works. We then divide labels in a batch into relatively under-fitted and over-fitted subsets according to real-time

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 7665 - 7675
May 22-27, 2022

prediction difference and train only one subset to fit the perturbed inputs and the other subset to fit the original inputs. Experiments show that training only the relatively under-fitted subset to further fit the perturbed inputs dramatically degrade the model performance, while the opposite gets better results than the existing indiscriminate way. This indicates that existing methods are hindered by the excessive fitting of perturbed data.

We further propose to use prediction difference as a regularization term, where the prediction difference is the divergence of prediction distribution caused by input perturbation. Since the value of prediction difference reflects the severity of over-fitting or under-fitting, both of which are cases we want to avoid for training models, regularizing prediction difference has been a natural solution to avoid above fitting problems. By combining cross-entropy loss and the prediction difference term, a model can be trained to fit training data with control of over-fitting and under-fitting.

We apply PD-R on simplest word dropout regularization and conduct experiments on three widely used WMT translation tasks covering small-scale, medium-scale, and large-scale data sets. Our method significantly improves over existing perturbation regularization methods. On WMT16 En-De translation task, our method achieves 1.80 SacreBLEU improvement over vanilla transformer model and 1.12 SacreBLEU over traditional word dropout regularization.

2 Background

In this section, we introduce basic principles of neural machine translation, representative types of perturbations as well as their training objectives.

2.1 Neural Machine Translation

For NMT, the probability of a target sentence $Y = y_{1:J}$ conditioned on its parallel source sentence $X = x_{1:I}$ is established based on chain rule:

$$p(Y|X,\boldsymbol{\theta}) = \prod_{j=1}^{J+1} p(y_j|y_{0:j}, X, \boldsymbol{\theta}), \tag{1}$$

where $\boldsymbol{\theta}$ represents the parameters of the model, y_0 and y_{J+1} are special tokens representing the beginning and end of a sentence respectively.

On this basis, NMT models are trained with the cross-entropy loss to minimize the negative log-likelihood of all samples in the training set $\mathcal{D}$:

$$\mathcal{L} = \mathcal{L}(\mathcal{D}, \boldsymbol{\theta}) = -\frac{1}{\mathcal{D}} \sum_{(X,Y)\in\mathcal{D}} \ell(X, Y, \boldsymbol{\theta}), \tag{2}$$

where $\mathcal{D} = \{(X_n, Y_n)\}_{n=1}^{|V|}$, $|V|$ is the size of the data set, $\ell(X, Y, \boldsymbol{\theta}) = \log p(Y|X, \boldsymbol{\theta})$.

2.2 Types of perturbations

Word Dropout and Replacement The simplest way to apply perturbation is to mask or replace one or more tokens of the original input sequence. The resulting sequence $\hat{x}$ is sampled from the original sequence and the perturbation sequence:

$$\hat{x_i} = \begin{cases} x_i, & \text{with probability } 1 \text{ - } \alpha, \\ x_i^p, & \text{with probability } \alpha, \end{cases} \tag{3}$$

where $0 < \alpha < 1$ is the hyper-parameter of bernoulli sampling and x_i^p is the i-th word of the perturbation sequence. Note that the perturbation sequence x^p consists of zero vectors for word dropout (Gal and Ghahramani, 2016), and consists of random words sampled from the vocabulary with uniform or a particular distribution for word replacement (Bengio et al., 2015; Wu et al., 2019).

Adversarial Perturbation Adversarial Training (AdvT) tries to make perturbation that maximize the loss function, which is believed more effective for regularization. As described in Miyato et al. (2017) and Sato et al. (2019), the perturbed input embedding for x_i can be computed as follows:

$$\hat{\mathbf{e}}_i = \mathbf{e}_i + \kappa \hat{\mathbf{r}}_i, \tag{4}$$

where $\mathbf{e}_i$ is original embedding of i-th source word, κ is a scalar hyper-parameter that controls the norm of the perturbation, and $\hat{\mathbf{r}_i}$ is the worst case unit perturbation vector approximated by gradient back-propagation(Goodfellow et al., 2015):

$$\hat{\mathbf{r}}_i = \frac{\mathbf{g}_i}{||\mathbf{g}_i||_2}, \quad \mathbf{g}_i = \nabla_{\mathbf{e}_i} \mathcal{L}(\mathcal{D}, \boldsymbol{\theta}), \tag{5}$$

where $\mathbf{g}_i$ is the gradient of a model's loss function with respect to its input embedding $\mathbf{e}_i$.

In most cases, the inputs of the decoder side can also be perturbed in the same way as the encoder side. For scheduled sampling (Bengio et al., 2015) however, perturbation is limited at the decoder side.

2.3 Training Objectives of Perturbation Regularization

For word dropout and word replacement, the model is trained to fit the perturbed samples $\hat{X}$:

$$\mathcal{L} = \mathcal{L}(\hat{\mathcal{D}}, \boldsymbol{\theta}) = -\frac{1}{\mathcal{D}} \sum_{(\hat{X},Y)\in\hat{\mathcal{D}}} \ell(\hat{X}, Y, \boldsymbol{\theta}), \quad (6)$$

where $\hat{D}$ is the perturbed data set.

For adversarial training, two forward passes and two backward passes are required for computing perturbation vectors and then training with them. The model is trained to fit both the original samples and adversarial samples with loss function:

$$\mathcal{L} = \mathcal{L}(\mathcal{D}, \boldsymbol{\theta}) + \lambda L(\hat{\mathcal{D}}, \boldsymbol{\theta}), \quad (7)$$

where λ is a hyper-parameter. Here samples are perturbed at the embedding layer, rather than token-level perturbation at the input layer.

3 Prediction Difference Fitting Analysis

It is usually believed that a model's prediction for ground-truth target tokens will be hindered when the input is perturbed, which has been the initial motivation for perturbation regularization. However, this conclusion is not necessarily true in experiment for many reasons: Firstly, neural networks are complex and may not behave in an ideally logical way. Secondly, perturbations are randomly produced and may have complex properties. For example, word-replacement may induce synonyms or heteronyms, and high-dimension embedding perturbation is hard to interpret. Thirdly, the model is uncertain during training due to parameter dropout, which further brings uncertainty to the model's reaction to perturbations.

In this section, we analyze the influence of perturbations leveraging token-level prediction difference. Here the prediction difference is defined as the change of model's prediction probabilities for ground-truth target tokens (Gu and Tresp, 2019; Li et al., 2019a):

$$\begin{aligned} \Delta p(y_j) =& p(y_j|y_{0:j-1}, X, \boldsymbol{\theta}) \\ &- p(y_j|\hat{y}_{0:j-1}, \hat{X}, \boldsymbol{\theta}). \end{aligned} \quad (8)$$

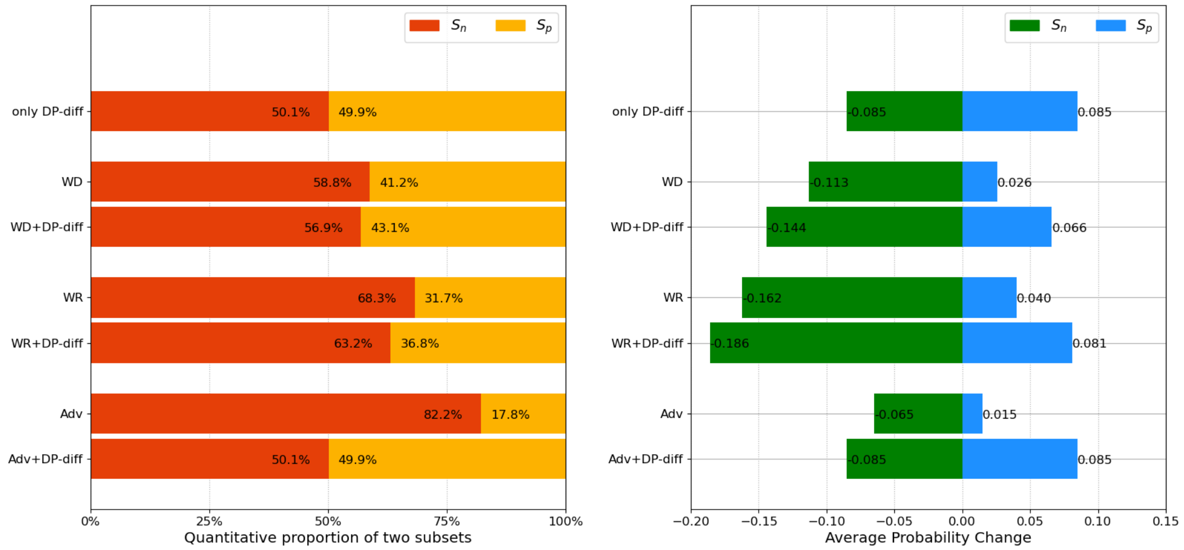
We apply random perturbations to samples in the test set and divide all target labels into two subsets according to their prediction change: positively influenced subset $\boldsymbol{S}_p$ containing labels whose prediction probabilities get bigger after input perturbation and negatively influenced subset $\boldsymbol{S}_n$ containing labels whose prediction probabilities get smaller. We compute the quantitative proportion and the average value of Δp for these two subsets to evaluate the influence of different perturbations.

Since the prediction difference is also under the influence of parameter dropout during training, we also conduct experiments both with and without parameter dropout difference. The original pass and the perturbed pass are carried out by two different sub-models if their parameter dropout mask is different. In experiment, We use a transformer base model trained on WMT16 En-De data set and conduct our experiments on a test set which is a combination of 5 test sets from WMT16 to WMT20. Our analysis covers different kinds of perturbations, including word-dropout, word-replacement, and adversarial perturbation. The word-dropout and word-replacement probabilities are set as 0.05, and all perturbations are applied on both sides of the model.

As illustrated in figure 1, for any certain type of perturbation, the negative impact is principal, especially for adversarial perturbation. However, the positive influence is non-negligible since the proportion of positively influenced tokens could reach 30%-40% for word-dropout and word-replacement. With parameter dropout difference, the positive influence could get further bigger and become more crucial.

We attribute prediction difference to relatively over-fitting and under-fitting of token-level samples. Since perturbations are very small, perturbed samples can be approximately viewed as good samples. For one target label, if its prediction probability gets smaller after a small input perturbation, it indicates the model is relatively over-fitted to the original sample, while the contrary case is the reflection of relatively under-fitting. With parameter dropout, predictions are carried out by sub-models, and these fitting problems also reflect the relative fitting bias of sub-models, which is also what we want to avoid.

As mentioned above, existing perturbation regularization methods are based on the motivation to enhance the model's performance against input perturbation and avoid over-fitting. However, experiments show that a model could be better fitted to the perturbed data rather than the original data, which is regarded by us as a sign of relatively under-fitting. This indicates that training a model



(a)

'$\boldsymbol{S}_n$' represents the negatively influenced set, while '$\boldsymbol{S}_p$' represents the positively influenced set. 'DP-diff', 'WD', 'WR' and 'Adv' represents parameter dropout difference, word-dropout, word-replacement and adversarial perturbation respectively. (a) Quantitative proportion of $\boldsymbol{S}_p$ and $\boldsymbol{S}_n$. (b) Average probability change normalized by subset size for $\boldsymbol{S}_p$ and $\boldsymbol{S}_n$.

	En→Ro	En→De
Transformer	33.4	32.55
only $\boldsymbol{S}_p$	31.59	30.16
only $\boldsymbol{S}_n$	**34.57**	**33.73**
both	34.53	33.20

Table 1: BLEU (Papineni et al., 2002) for selective training of word-dropout perturbation on WMT16 En-Ro and WMT16 En-De translation tasks. Evaluation set for En-De is a combination of 5 test sets form WMT16 to WMT20.

with perturbed data may not be necessary for some circumstances.

We further carry out selective training for word-dropout regularization, where one subset is trained to fit the perturbed inputs and the other subset is trained to fit the original inputs. As presented in table 1, training only $\boldsymbol{S}_n$ gets better results than existing indiscriminate training, while training only $\boldsymbol{S}_p$ gets worse results than vanilla transformer. This implies that the existing method suffers from degeneration caused by aggravated under-fitting.

4 Prediction Difference Regularization (PD-R)

Since both positive and negative prediction difference is a sign of improper fitting of samples, we therefore propose prediction difference regularization (PD-R), to regularize the model directly with the prediction difference:

$$\begin{aligned}\ell_{PD-R}(X,Y,\boldsymbol{\theta}) =&\mathcal{R}[P(*|X,Y_<,\boldsymbol{\theta}^{'}),\\ &P(*|\hat{X},\hat{Y}_<,\boldsymbol{\theta}^{''})],\end{aligned} \tag{9}$$

where $\mathcal{R}[\cdot]$ is the distance of two distributions, (X,Y) is a sample from data set $\mathcal{D}$, "$*$" represents all prediction steps, $P(*|X,Y_<,\boldsymbol{\theta}^{'})$ is the prediction distributions for all steps conditioned on original source input X, target teacher forcing target input $Y_<$ and sub-model with parameters $\boldsymbol{\theta}^{'}$, and $P(*|\hat{X},\hat{Y}_<,\boldsymbol{\theta}^{''})$ is the prediction distributions for all steps conditioned on perturbed source input $\hat{X}$, perturbed target teacher forcing target input $\hat{Y}_<$ and sub-model with parameters $\boldsymbol{\theta}^{''}$. The total regularization loss is averaged over all samples in the data set:

$$\mathcal{L}_{PD-R}(\mathcal{D},\boldsymbol{\theta}) = \frac{1}{\mathcal{D}} \sum_{(X,Y)\in\mathcal{D}} \ell_{PD-R}(X,Y,\boldsymbol{\theta}). \tag{10}$$

The model is trained with a combination of cross-entropy loss and regularization term:

$$\mathcal{L} = \mathcal{L}(\mathcal{D},\boldsymbol{\theta}) + \gamma\mathcal{L}_{PD-R}(\mathcal{D},\boldsymbol{\theta}), \tag{11}$$

where γ is a hyper-parameter controlling the weight of regularization.

Table 2: SacreBLEU for different models on WMT16 En-Ro and WMT17 Zh-En tasks.

In experiment, we apply PD-R on simplest word-dropout perturbation with $\alpha = 0.05$ in Eq.(3) and $\gamma = 1.0$ in Eq.(11) without further hyper-parameter search. $\mathcal{R}[\cdot]$ in Eq.(9) is implemented as L1 distance, which performs slightly better than KL-divergence in our experiments.

5 Experiments

We evaluate PD-R on three public WMT machine translation tasks and compare it with representative related works.

5.1 Data Sets

To fully verify the effectiveness of our method on NMT, we conduct experiments on three machine translation tasks, including small-scale WMT16 English-Romanian(En-Ro), medium-scale WMT16 English-German (En-De), and large-scale WMT17 Chinese-English (Zh-En).

English-Romanian This data set contains about 0.6M processed parallel sentence pairs tokenized by Moses toolkit (Koehn et al., 2007) and segmented with 40K merge operations using BPE (Sennrich et al., 2016). We use news-dev 2016 and news-test 2016 as the validation set and test set respectively.

English-German The WMT16 En-De data set consists of about 4.5M parallel sentences pairs coded with 30K BPE merge-operations. For evaluation, we average the last 5 epochs and report results on all test sets from WMT2016 to WMT2020.

Chinese-English Our data set consists of over 20M parallel sentence pairs. The English and Chinese sentences are tokenized with Moses toolkit and Stanford Segmenter respectively, which are further applied 32K BPE segmentation. We use newsdev2016 for validation and newstest2017 for testing.

5.2 Configuration

To fairly compare each method, we reproduce all compared methods with transformer model (Vaswani et al., 2017) using open-source toolkit *Fairseq* (Ott et al., 2019), with the same model configuration and hardware facilities.

We use transformer `base` configuration for all experiments, with 6 encoder and decoder layers, 512 hidden dimensions, 8 attention heads and 2048 FFN dimensions. We train all models with 4000 warm-up steps, initial learning rate of $7e^{-4}$, label smoothing factor of 0.1, and Adam optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\epsilon = 1e^{-9}$ as Vaswani et al. (2017). We set the dropout rate to 0.2 for small-scale En-Ro task and 0.1 for En-De and Zh-En tasks. All experiments are conducted on 4 GeForce RTX 3090 GPUs with a distributional batch-size of 4096 tokens each GPU and an overall accumulated batch-size of 4096×8 tokens. During inference, we use beam size of 4 and length penalty of 0.6 for all tasks.

For En-Ro and En-De translation tasks, we share the vocabulary for source and target and apply three-way weight tying(TWWT) (Press and Wolf, 2017) for training, the vocabulary sizes of both tasks are limited to 32768 tokens. We train models for 50 epochs for both tasks. For Zh-En translation task, the Chinese and English vocabulary sizes are 44K and 33K respectively, and models are trained for 300K steps.

5.3 Compared Methods

We reproduce four representative perturbation regularization methods and recently proposed R-Drop for comparison.

Table 3: SacreBLEU for different models on WMT16 En-De task.

Word-Drop We implement word-dropout (Gal and Ghahramani, 2016) by randomly replace word embeddings with zero vectors with $\alpha = 0.05$ in Eq.(3).

SSE-SE The SSE-SE is a word-replacement method that randomly replaces input tokens with other tokens in vocabulary. As in Wu et al. (2019), we set $\alpha = 0.01$ in Eq.(3) and sample perturbation sequence with uniform distribution.

Scheduled Sampling Scheduled sampling (Bengio et al., 2015) is a word-replacement method that randomly replace target-side input tokens with model predictions. Each model prediction token is sampled using model's output distribution. The replacement rate α follows a curriculum learning strategy:

$$\alpha_i = \frac{k}{k + exp(i/k)}, \tag{12}$$

where i represents training steps, and k is a hyper-parameter depending on the speed of convergence. Our implementation of scheduled sampling for transformer is parallel as in Mihaylova and Martins (2019) and Duckworth et al. (2019). We set $k = (4590, 29350, 36150)$ for En-Ro, En-De and Zh-En tasks respectively. The hyper-parameter k is set to make sure that α_i is decayed to 0.9 at the end of training.

AdvT For adversarial training, we set $\kappa = 1$ in Eq.(4) and $\lambda = 1$ in Eq.(7) as Sato et al. (2019).

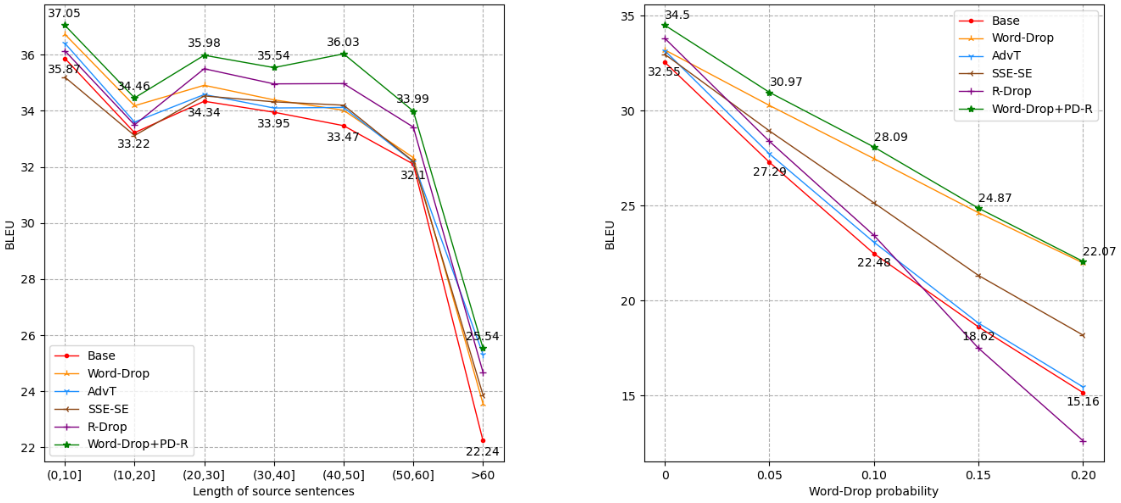
R-Drop R-Drop (Liang et al., 2021) is a very recent work whose implementation is similar to PD-R. However, its motivation is to restrict the freedom of parameters by reducing sub-model divergence, while ours is to avoid token-level sample fitting problems reflected by prediction difference. Since predictions are carried out by sub-models during training, the fitting bias of sub-models is also included in the prediction difference. From this point, R-Drop can be viewed as a sub-component of PD-R.

5.4 Main Results

SacreBLEU (Post, 2018) of compared methods and PD-R on three translation tasks are illustrated in table 2 and table 3. We apply PD-R on encoder-side word-dropout, decoder-side word-dropout, and both-side word-dropout. For all compared methods involving input perturbation, perturbation is applied on both sides of the model except scheduled sampling. Note that selective training of word-dropout regularization (only $\boldsymbol{S}_n$, referred as 'ST') is also presented for comparison with Word-Drop and PD-R.

Experiments show that existing perturbation regularization methods are similarly effective compared to each other, which is consistent with Takase and Kiyono (2021). R-Drop and selective training(ST) of word-dropout regularization are consistently better than existing perturbation regularization. Our PD-R against word-dropout significantly improves over word-dropout and other perturbation regularization methods on all three tasks, and also performs better than R-Drop on small-scale and medium-scale tasks. On WMT16 En-De, PDR achieves 1.80 SacreBLEU improvement over vanilla transformer, 1.12 SacreBLEU improvement over existing word-dropout perturbation regularization, and 0.73 SacreBLEU improvement over R-Drop.

On large scale WMT17 Zh-En task though, the improvement of perturbation regularization gets smaller compared to small and medium tasks, and



(a) (b)

Figure 2: BLEU of models (a) on sentences of different lengths, (b) under different levels of word-dropout perturbation. Experiments are conducted on WMT16 En-De with a combined test set.

R-Drop performs better than PD-R. We attribute it to the fact that large-scale tasks are sufficient in data, regularization in data level has become a burden rather than help while regularizing sub-model bias is still beneficial.

6 Analysis

In this section, we analyze the robustness of our methods and distinguish the contribution of different components via ablation study.

6.1 Performance on long sentences

Longer sentences contain more complex word combinations that are unseen or seldom seen in the training set and suffer more from exposure bias (Ranzato et al., 2016; Zhang et al., 2019). Performance on long sentences reflects the model's robustness to unexpected inputs.

In experiment, we evaluate the performance of different models on WMT16 En-De task. We combine 5 test sets from WMT16 to WMT20 and divide samples into 7 subsets according to sentence length. As shown in figure 2a, PD-R achieves better results in all subsets, and the improvement tends to become larger as the sentence length grows, which implies that PD-R can better handle unexpected inputs of long sentences.

6.2 Robustness against perturbation

To better evaluate model's robustness to perturbations, we conduct perturbation attack for all models, similar as Michel and Neubig (2018) and Moradi and Samwald (2021). In experiment, we apply word-dropout on source sentences and generate target sentences based on perturbed source sentences. Experiment results in figure 2b show that PD-R against word-dropout and existing word-dropout regularization are consistently better than the base model, and the gap becomes larger as the proportion of perturbation grows, which confirms that our approach does improve the model's robustness to perturbation.

Note that our experiments on other types of perturbation attack conclude that a model is robust to a certain type of perturbation only if the model is trained on this kind of perturbation, so comparison of different perturbation regularization methods under one certain type of perturbation attack is not the focus of our discussion in this subsection.

6.3 Ablation Study

Ablation study in table 4 shows that training only the positively influenced subset S_p using PD-R is also effective, even more effective than training only S_n. This indicates that PD-R can properly handle both under-fitting and over-fitting.

As mentioned in section 3, sub-model bias is also a source of improper fitting problems. To dis-

	En→Ro	En→De
Transformer	33.40	32.55
only $\boldsymbol{S}_p$	34.83	34.22
only $\boldsymbol{S}_n$	34.59	34.16
both	35.11	34.50
only DP-diff	**34.70**	**34.10**
WD(enc) w/o DP-diff	33.97	33.97
WD(dec) w/o DP-diff	34.15	33.15
WD(both) w/o DP-diff	**34.40**	**34.02**
WD(enc) w/ DP-diff	34.63	**34.50**
WD(dec) w/ DP-diff	34.92	34.19
WD(both) w/ DP-diff	**35.11**	34.22

Table 4: BLEU for ablation study of PD-R, where 'WD' represents word-dropout, 'w/o DP-diff' represents that the two passes share the same parameter dropout mask, 'w/ DP-diff' represents that two different sub-models are used for the two passes.

tinguish the contribution of parameter dropout and word-dropout, we conduct experiments where the difference of two passes is restricted to only parameter dropout or only word-dropout. We also conduct experiments on the encoder side and decoder side separately. Experiment results show that parameter dropout is an important source of improvement, word-dropout is nearly as important as parameter dropout for PD-R, while using both of them gets the best results. As for the difference between the encoder side and decoder side, the decoder-side word-dropout contributes more on the En-Ro task, while on the En-De task the contribution of the encoder side is much bigger, this is also true when the two passes have no parameter dropout difference. The encoder side gets more important on larger data set, which is consistent with the main results.

7 Related Work

Works involving Input Perturbation Apart from the works mentioned above, some works introduce subword uncertainty at the subword segmentation stage, including sampling multiple subword candidates (Kudo, 2018), applying subword dropout (Park et al., 2020) or producing adversarial subword segmentation (Provilkov et al., 2020). For character-level tasks, there are also works using character-level perturbation including character-level random deletion, insertion, substitution and swap (Belinkov and Bisk, 2018; Karpukhin et al., 2019) and adversarial substitution (Ebrahimi et al., 2018). The mixup technique for NLP tasks can also be seen as a form of perturbation where samples are perturbed (mixed) with other samples for data augmentation or generation diversity (Guo et al., 2020; Li et al., 2021; Fang et al., 2022).

Our work can be regarded as one example of perturbation regularization. However, unlike previous perturbation regularization works which are focused on finding better perturbation, our work improves the training mechanism and can be applied to any type of perturbations.

Influence of Perturbation Perturbation is commonly considered as a negative factor for neural models by previous works (Szegedy et al., 2014; Liang et al., 2018; Belinkov and Bisk, 2018), which is generally correct with the fact that perturbation does degrade the training and inference accuracy of a model. Belinkov and Bisk (2018) demonstrates that the performance of NMT systems degrades monotonously as input modification increases, which is consistent with our observations. Based on the above facts, perturbation regularization is frequently studied to enhance models' robustness to unexpected inputs at the inference stage. From a data selection perspective, Khayrallah and Koehn (2018) and Briakou and Carpuat (2021) demonstrate that noisy or semantically divergent data is harmful to the training of NMT models. In this paper, we find that the interaction between perturbation and model is complicated and positive influence of perturbation is very common, which is further regarded by us as a sign of relatively under-fitting and a variable that needs to be restricted.

Prediction Difference Prediction difference is usually considered as a reflection of the relationship between input and output and is often used to analyze model behavior. Zintgraf et al. (2017) utilizes prediction difference to visualize the importance of a specific input image area to model decision. Li et al. (2019b) uses the prediction difference of a target word when a source word is removed to induce word alignment and find it more accurate than attention weights. Guo et al. (2019) finds that adversarial examples can be accurately and efficiently detected via prediction difference. Liang et al. (2021) proposes R-Drop and take prediction difference as a regularization term to regularize sub-model divergence. In this work, prediction difference is used as an analytical tool to detect improper fitting problems and also a regularization term to regularize the model's fitting bias to token-level samples.

8 Conclusion

In this paper, we propose to use probability difference for ground-truth tokens before and after input perturbation as an indicator to analyze the influence of different types of perturbations and attribute probability difference to improper fitting of token-level samples. We find that under-fitting is almost as common as over-fitting, which is totally ignored and further aggravated by existing perturbation regularization methods. To regularize both under-fitting and over-fitting, we use prediction difference as a regularization term (PD-R) and apply it on word-dropout regularization. Our method achieves significant improvement over existing methods on three WMT translation tasks and is proved more robust to input perturbation.

Make the Best of Cross-lingual Transfer:
Evidence from POS Tagging with over 100 Languages

Abstract

Cross-lingual transfer learning with large multilingual pre-trained models can be an effective approach for low-resource languages with no labeled training data. Existing evaluations of zero-shot cross-lingual generalisability of large pre-trained models use datasets with English training data, and test data in a selection of target languages. We explore a more extensive transfer learning setup with 65 different source languages and 105 target languages for part-of-speech tagging. Through our analysis, we show that pre-training of both source and target language, as well as matching language families, writing systems, word order systems, and lexical-phonetic distance significantly impact cross-lingual performance. The findings described in this paper can be used as indicators of which factors are important for effective zero-shot cross-lingual transfer to zero- and low-resource languages.

1 Introduction

At present, for a large majority of natural language processing tasks, the most successful approach is fine-tuning pre-trained models with task-specific labelled data. Unfortunately, for many languages, and especially low-resource languages, such task-specific labelled data is often not available. A potential solution is cross-lingual fine-tuning of multilingual pre-trained language models (Conneau et al., 2020; Devlin et al., 2018), using available data from some source language to model the phenomenon in a different target language for which labelled data does not exist.

Cross-lingual generalisability of large pre-trained language models is often evaluated by fine-tuning multilingual models on English data and testing them on unseen languages (Conneau et al., 2018; Artetxe et al., 2020; Lewis et al., 2020; Hu et al., 2020). Of course, this approach is influenced by the availability of English training data for given tasks, but also then comes with the implicit assumption that English is a representative source language. This, however, may not be true in practice. Specifically, depending on the task, aspects of similarity between source and target language may be relevant for cross-lingual transfer performance (de Vries et al., 2021). If similarity between source and target language impacts performance, cross-lingual transfer should not be assessed using *only* a single predetermined source language, especially if training sets in multiple languages are available.

Furthermore, target test languages are generally selected based on data availability for the evaluated tasks, but availability may not result in a representative subset of the world's languages. The XTreme benchmark collection (Hu et al., 2020), for example, attempts to alleviate this problem by including a varied selection of languages from different language families. This collection contains token classification, text classification, question answering and retrieval tasks in 40 languages. The language selection does, however, obfuscate the fact that for most non-Indo-European languages no data is available for semantically rich tasks such as question answering. This imbalance regarding tasks in this type of collections may consequently inflate the perceived performance for these languages.

In this work, we aim to shed light on what factors make a language a good source and/or target language for cross-lingual transfer when fine-tuning a large multilingual model. We evaluate this via part-of-speech (POS) tagging data, as this is the only task for which high-quality data is available in a large number of languages, including low-resource languages from different language families. Also, high cross-lingual POS tagging performance may be seen as a precondition for more semantically complex tasks, as a base understanding of syntactic structure in both the source and target language is necessary for any meaningful natural language processing task.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics

May 22-27, 2022

Contributions This paper is a case-study of cross-lingual transfer learning with part-of-speech tagging. We explore the limits and contributing factors to successful cross-lingual transfer and part-of-speech tagging in particular. Among others, we evaluate the effects of (matching) language families, (matching) writing systems, and pre-training on cross-lingual training. Moreover, we provide insights that can help to estimate performance when one tries to transfer to a low-resource language with little or no annotated data. Source code is released on Github,[1] and 65 fine-tuned models are shared via the Hugging Face Hub.[2]

2 Approach

We fine-tune a pre-trained model for the task of part-of-speech tagging using different languages in training and testing. Every combination of source and target language yields an accuracy score, with a large matrix of accuracies as a result. Monolingual, or within-language performance is the accuracy where the source and target language are the same. Overall cross-lingual source or target accuracies can be calculated per column or row in the accuracy matrix, excluding the monolingual accuracy. Such accuracies give an overall indication of (i) how suitable a given language is as source for cross-lingual POS tagging, and (ii) how easy or difficult it is to POS-tag a given target language when monolingual training data is not available.

Predictors Through a mixed-effects regression analysis, with source and target language (family) as random-effect factors, we assess which variables determine a "good" source language. The variables we consider are whether or not the language family is shared between source and target language, the writing systems (and writing system types) of both languages and whether or not these match, the subject-object-verb (SOV) word order of both languages and whether or not these match, and whether or not a (source or target) language was included in pre-training. Additionally, we add the (lexical-phonetic) LDND measure (Wichmann et al., 2010) on the basis of the 40-item word lists from the ASJP database (Wichmann et al., 2010) as a quantitative similarity measure comparing source and target language. Finally, we also consider the size of the training set of the source language as a predictor. We analyse results both from a quantitative and a qualitative viewpoint.

Task data We use the POS tag data from Universal Dependencies 2.8 (Zeman et al., 2021). It contains manually annotated data for 114 languages; among these all have test data and 75 languages have training data. We exclude three mixed-code languages, one sign language, three languages with fewer than 10 test samples and two languages that do not have any word-level annotations. Moreover, we exclude training data for five languages that have fewer than 25 training samples. All other training datasets consist of at least 125 samples. As a result, we have 105 languages which can serve as target languages, of which 65 can also serve as source languages since they have training data.

Model The XLM-RoBERTa base model (Conneau et al., 2020) is used for our experiments.[3] XLM-RoBERTa is pre-trained on web crawled data from 100 languages (with the largest Wikipedia sizes). For our dataset, 53 of our 65 source languages and 58 of our 105 target languages were included in XLM-RoBERTa pre-training.

Data sampling Typical fine-tuning procedures train for a fixed number of epochs on the training data. However, there is a substantial amount of variation in the size of our source language datasets (127 to 163,106 sentences). In such a situation, choosing a fixed number of epochs might result in underfitting for the smaller languages and overfitting for the larger languages. Figure 1 shows that accuracies start decreasing with more than 10K samples, so we choose this threshold for further evaluation. Consequently, the 25 source languages with more than 10K training samples are randomly undersampled, whereas the other 40 languages are oversampled (i.e. multiple epochs). The four languages with more than 50K training samples (German, Czech, Russian and Turkish) achieve highest overall average accuracy with 1250, 20K, 1250 and 10K samples, respectively, showing that undersampling can improve cross-lingual performance. Within-language performance does keep increasing with longer training, which indicates that longer training can cause source language overfitting.

Training procedure All models are trained with the same hyper-parameter settings. Specifically, the

---

[1] `https://github.com/wietsedv/xpos`

[2] `https://hf.co/spaces/wietsedv/xpos`

[3] Preliminary experiments have shown no performance gain with the large model variant, so out of practical and environmental considerations, we limit our experiments to this model.

models are trained for 1,000 batches of 10 samples with a linearly decreasing learning rate starting at 5e−5. We use 10% dropout between transformer layers and 10% self-attention dropout. These hyperparameters were selected based on preliminary experiments with the English, Dutch, Armenian, Marathi and Chinese source languages. Models for different source languages were trained with the same random seed.

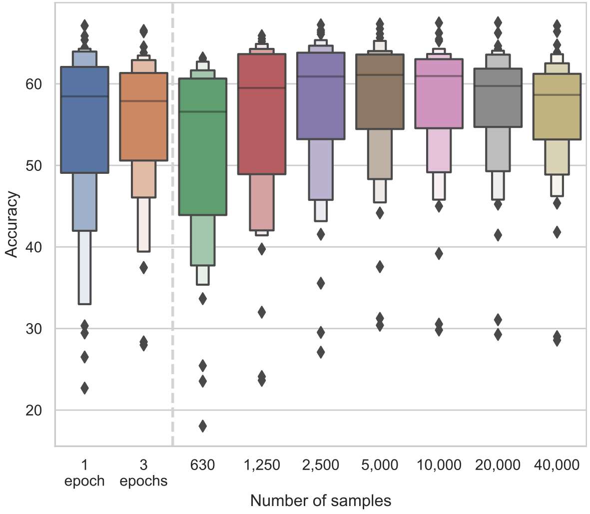

Figure 1: Accuracy distributions for different sampling strategies. Median and mean overall POS-tagging accuracy starts decreasing with more than 10K training samples.

3 Results

Figure 2 illustrates the test accuracies for every combination of source and target language. The heat map shows that the model achieves relatively high performance for cases where the source and target language is the same (outlined in black). While for many languages same-language training is the only way to achieve high performance (for example Maltese), there are also many target languages for which high performance is observed when training on several other languages (for example Russian). Indeed, within-language performance tends to be high with a mean accuracy of 94.1% ($\sigma = 4.5$). However, there is a substantial amount of variation for cross-lingual accuracies with an overall mean of 57.4% ($\sigma = 22.4$). This shows that cross-lingual training does not universally yield good performance.

We evaluate several predictors for inclusion (see Section 2) by adding them to a linear mixed-effects model with random intercepts for source language, target language, and target language family. No other random intercepts were found to improve the model (via model comparison). We ascertained that the predictors of the final model remained significant when the corresponding random slopes were included. These are not further reported, however. Fixed-effect predictors were included if they significantly ($p < 0.05$) improved the model fit as determined via (maximum likelihood) model comparison. Table 1 shows the predictors included in the final model. This mixed-effects regression model yields a conditional R^2 of 91.1% and a marginal R^2 of 47.1%. In other words, the included fixed effects explain 47.1% of variance, whereas an additional 44% is captured by the random effects (i.e. other language-related factors). Regarding the random-effects, the variance explained by the target language was more than three times as high as the variance explained by the source language, reflecting the fact that the POS accuracy is much stronger linked to the target language than to the source language. This is also visible in Figure 2, where the rows are much more variable than the columns.

Predictor	**Coef.**	**Std. Err.**
(Intercept)	42.2	3.3
Target pre-trained	19.2	2.5
LDND distance	−12.7	1.0
Both pre-trained	7.4	7.4
Same family	6.8	6.8
Source pre-trained	5.6	2.0
Same writing system type	3.6	0.4
Same writing system	1.4	0.3
Same SOV word order	1.3	0.2

Table 1: Coefficients and standard errors of predictors in the final mixed-effects regression model with Accuracy as the dependent variable. All predictors were significant at the $p < 0.01$ level. LDND distances were scaled between 0 (minimum) and 1 (maximum). The predictors are sorted in order of decreasing importance.

4 Quantitative discussion

4.1 Pre-training

Table 1 shows that the best predictor for accuracy differences is whether or not the target language is included in pre-training, with an estimated 19.2% higher accuracy for target languages that were included. Similarly, performance is higher when the

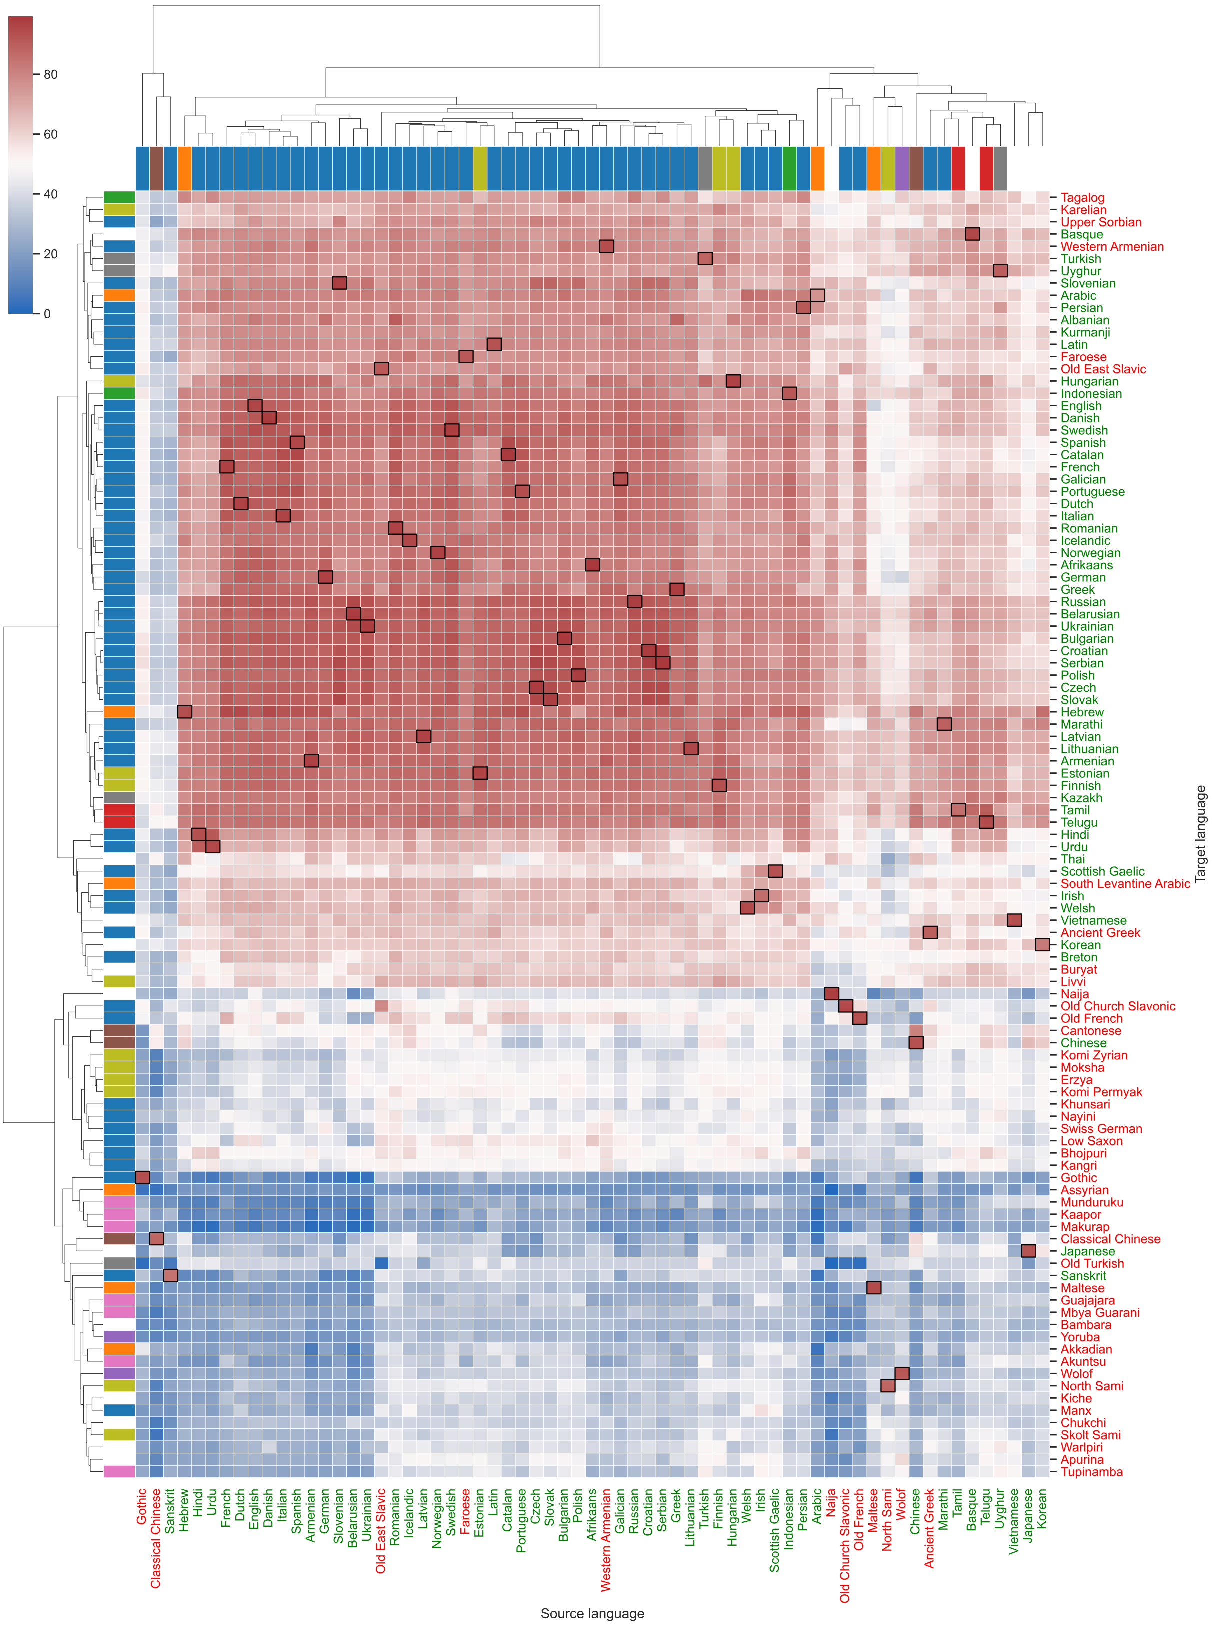

Figure 2: Universal Dependencies part-of-speech tagging accuracies for every combination of source (column) and target (row) languages by fine-tuning XLM-RoBERTa base on the source language. Language names printed in green were included in XLM-RoBERTa pre-training, whereas language names printed in red were not. Group colours in the dendrograms indicate different language families. The white group consists of unrelated singleton languages. Dendrograms are based on hierarchical clusters using unweighted average linkage clustering (UPGMA) with the Euclidean distance metric. Within-language performance is identified by a black outline.

source language is included in pre-training, but with a much smaller effect (5.6%) as the target language. There is an additional increase of 7.4% in accuracy if both the source language and target language are included in pre-training. Consequently, inclusion in pre-training, especially the target language, is highly important for achieving high cross-lingual performance. This is unfortunate for many low-resource languages that are not included in pre-training, as the benefit from cross-lingual transfer will be limited. Specific examples of underperforming languages that were not included in pre-training are discussed in Section 5.1.

4.2 LDND distance

The ASJP-based LDND measure has the strongest effect on predicted accuracy after target language inclusion in pre-training with a coefficient of -12.70 (for the predictor which was scaled between 0 and 1). Figure 3 shows that low LDND distances between source and target language (i.e. when two languages share cognates) are indeed associated with high accuracy, whereas high LDND distances (very dissimilar languages) seem less informative.

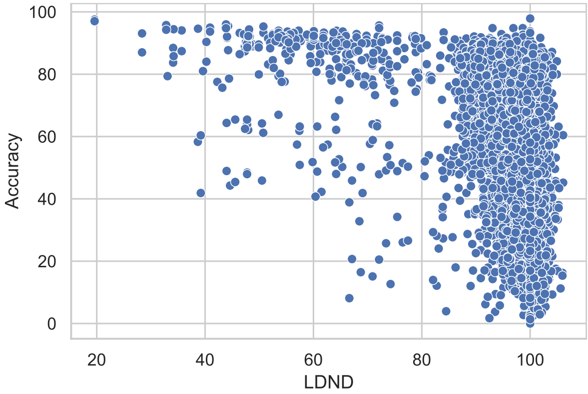

Figure 3: Relation between LDND lexical-phonetic distances and accuracy.

This significant effect might be surprising as the measure is based on (broad) phonetic transcriptions of single words, but measures of linguistic distance at different linguistic levels are correlated (Spruit et al., 2009).

4.3 Language family

Whether source and target languages are part of the same language family has a considerable effect on accuracy (see Table 1).[4] Therefore, when choosing a source language, the best option would be a language from the same family. Figure 4 shows the average accuracies per language family combination. This figure is solely based on target languages that were included in pre-training, since absence from pre-training has a large negative effect on performance as previously discussed (see Section 4.1).

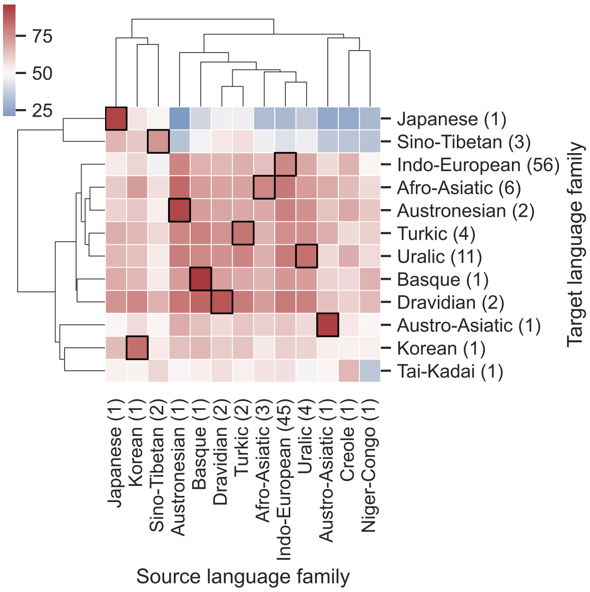

Figure 4: Average accuracies per source and target language family combination based on target languages that were included in pre-training. Numbers between parentheses indicate the number of languages in each family. High performance can be observed within language families (black outlines). Dendrograms are based on hierarchical clusters using unweighted average linkage clustering (UPGMA) with the Euclidean distance metric.

The Japanese and Sino-Tibetan (Chinese, Classical Chinese and Cantonese) target languages only reach reasonable accuracies with Japanese, Sino-Tibetan or Korean source languages. These target languages reach a lower than 50% macro-averaged accuracy across language families. This could be a reflection of the type of writing system in those languages (see Section 4.4 for a dedicated discussion on this), but this is not certain. Tai-Kadai (Thai), Korean, and Austro-Asiatic (Vietnamese) languages also reach relatively low cross-family macro-average accuracies (up to 60%), whereas the remaining target language families generally reach a higher performance.

In Section 3, we found that accuracy is higher if the source and target language are the same, but transfer can work between different families. Fig-

---

[4] Preliminary experiments have shown that splitting the large Indo-European language family into the major branches does not contribute to the explainability of the model.

ure 4 shows that some family combinations might not be suitable for transfer, but since the lower-performing families contain small numbers of languages, it is difficult to reach definitive conclusions.

4.4 Writing systems

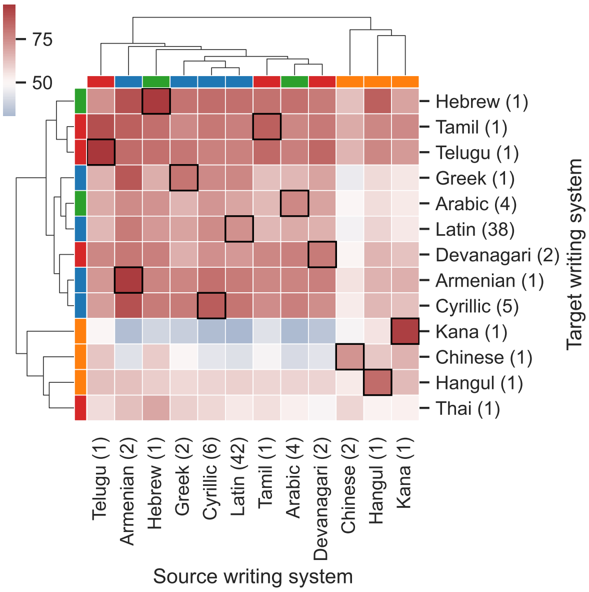

Figure 5: Average accuracies per source and target writing system combination based on target languages that were included in pre-training. Numbers between parentheses indicate the number of languages that use each writing system. Dendrograms are based on hierarchical clusters using unweighted average linkage clustering (UPGMA) with the Euclidean distance metric. Dendrogram colours represent writing system types (blue: alphabetic, orange: logosyllabic, red: abiguda, green: abjad).

Regarding writing systems, we distinguish writing system types (i.e. alphabetic, logosyllabic, abjad, and abiguda[5]) from the more fine-grained writing systems (e.g., Armenian, Greek, Cyrillic, and Latin are all alphabetic). Cross-lingual POS-tagging accuracy is higher if the source and target writing system types are similar. If the two languages share the same writing system, performance is even better (see Table 1).

Languages that share a writing system, such as Latin, can benefit from a shared vocabulary if those languages have some lexical overlap (Pires et al., 2019). However, a shared vocabulary also introduces cross-lingual homography problems, where the same token has different meanings, and thus possibly different grammatical functions, in different languages. Both aspects are not present for languages that use different writing systems, even if the vocabulary is technically shared within a multilingual model.

Figure 5 shows average cross-writing-system accuracies. Some singleton writing systems reach very low accuracies. These are the logosyllabic Chinese characters, Kana (Japanese) and Hangul (Korean) writing systems and Thai, which is an abugida writing system. There are several other writing systems that are used by a single target language and achieve high performance regardless of source writing system, i.e. Hebrew, Tamil and Telugu. This might indicate that the data or the language itself is easier than other target languages.

Cross-script transfer seems to work well for a subset of writing systems. Languages with logosyllabic or the Thai writing system, tend to perform poorly with source languages that use different writing systems. However, these writing systems are not used across language families, so it is difficult to attribute these findings specifically to the writing systems themselves.

5 Qualitative discussion

Having discussed significant predictors in detail, we now take a closer look at “bad" source languages, thereby providing a better understanding of how to choose a “good" source language (Section 5.1). We also identify some optimal source-target language pairs (Section 5.2), and “optimal" source languages for our task (Section 5.3).

5.1 Underperforming source languages

Figure 2 shows that many source languages (columns) achieve high performance for at least a subset of the target languages, and also that some source languages never achieve high cross-lingual accuracies. While overall contributing factors have been discussed in Section 4, here we unpack why some source languages yield low accuracy.

Source languages should achieve highest performance on themselves as target languages. This is not the case for Arabic (higher accuracy on Ukrainian), Korean (higher accuracy on Hebrew) and Spanish (higher accuracy on Catalan). Excluding those languages, the lowest within-language

---

[5] Characters in logosyllabic writing systems represent full words (logograms) or syllables. In abugida writing systems, consonants and vowels are combined as single units. This can make abugida writing systems similar to syllabic writing systems for character-based NLP systems. Abjad writing systems only use characters for consonants, whereas vowels are implied.

accuracy is Sanskrit (84.2%). We identify poorly performing source languages as those where the best cross-lingual accuracy is below that 84.2% threshold. Based on this threshold, we identify 19 source languages that perform sub-optimally on every target language except themselves.

The full set of source languages contains 12 languages that were not included in XLM-RoBERTa pre-training (see red column labels in Figure 2). Out of these 12 languages, nine are in the bottom 25% of source languages ranked by overall accuracy: Ancient Greek, Classical Chinese, Gothic, Maltese, Naija, North Sami, Old Church Slavonic, Old French and Wolof. The remaining three source languages that were not included in pre-training are Faroese, Old East Slavic and Western Armenian. The written forms of these three languages are considered mutually intelligible with at least one language that was included in pre-training.[6] Specifically, mutually intelligible are written Faroese with Icelandic (Barbour and Carmichael, 2000), Old East Slavic with Russian, Belarusian and Ukrainian (Andersen, 2003) and West Armenian with (Eastern) Armenian (Adalian, 2010). No similar mutual intelligibility pairs were found for the nine poorly performing non-pre-trained source languages. This indicates that while inclusion in pre-training is optimal for both the source and target language, inclusion of a mutually intelligible language variant can be sufficient for source languages.

Other source languages that never achieve high transfer performance but that were present in pre-training are Sanskrit, Arabic, Chinese, Japanese, Vietnamese, Uyghur, Irish, Marathi, Hebrew, Tamil. For Uyghur and Irish, no clear cause could be found for their low performance. This is not the case for the other languages, however.

Sanskrit is effectively not present in pre-training, since the Universal Dependencies data mainly contains romanised Sanskrit, whereas the data in the XLM-RoBERTa pre-training uses the Devanagari writing system. Serbian is the only other evaluated source language where the writing system in Universal Dependencies is not used in pre-training. However, the Latin script that is used in Universal Dependencies is used with the Croatian pre-training data, and Croatian is structurally and in written form effectively the same language as Serbian (Kordić, 2010).

For Arabic, the problem seems a poor model fit in general, since the trained model for Arabic also achieves only 75.9% accuracy on Arabic test data. We did not identify a clear external factor for why Arabic performance is so low, since other genetically related languages and other languages that use the Arabic writing system perform better.

Problems with Chinese, Japanese and Vietnamese might originate from issues with logosyllabic writing systems (see Section 4.4). Japanese uses its own unique syllabic writing system, and the Vietnamese language uses a romanised version of (logographic) Chinese characters. Logosyllabic writing systems therefore seem to transfer poorly to other languages. The languages in our set of source languages with logosyllabic writing systems are Japanese, Chinese, Classical Chinese and Cantonese. These four languages are in the bottom 20% lowest performing source languages for average cross-lingual accuracy. While the source writing system type was not identified as a significant predictor in the mixed-effects regression model, this could be because logosyllabic writing systems are not used across multiple language families.

The three remaining poorly performing languages are Marathi, Hebrew and Tamil. Those three languages are the only evaluated source languages with fewer than 200 training sentences. Therefore, the reason for the low performance of these source languages could be the lack of sufficient training data.

Overall, these findings suggest that a good source language should:

- Be included in pre-training data with the same writing system as the task-specific training data. Alternatively, a mutually intelligible related language must be included;
- Achieve good within-language performance. One cannot expect high cross-lingual performance, if a model performs poorly on the source language itself;
- Use the same type of writing system as the target language. Transfer between different alphabetic writing systems (i.e. Latin and Cyrillic) can work well, but lower performance is observed for logosyllabic writing systems (see Section 4.4);
- Have sufficient training data available. Using only 200 training sentences seems too little.

---

[6] If we consider these languages as pre-trained in the mixed effects model of Section 3, the marginal R^2 would increase from 47.1% to 54.6%.

5.2 Optimal language pairs

For every target language, the best source language can be determined by taking the source language with the highest accuracy. Some highly similar languages are each other's best source language. In our set of languages, we found 11 of such pairs:

- Estonian and Finnish
- Icelandic and Faroese
- French and Italian
- Chinese and Japanese
- Irish and Scottish Gaelic
- Croatian and Serbian
- Catalan and Spanish
- Belarusian and Ukrainian
- Hindi and Urdu
- Armenian and Western Armenian
- English and Swedish

All of these pairs, except *English and Swedish*, originate from either the same country, or countries that are geographic neighbours. Moreover, most of these pairs are closest siblings according to the Ethnologue genetic classification scheme (Eberhard et al., 2021), compared to alternative languages in our language set. The exceptions are *English and Swedish* (both are Germanic languages, but for instance Dutch is closer to English, and Norwegian is closer to Swedish), *Chinese and Japanese* (separate families, but Japanese has many Chinese loan words) and *Catalan and Spanish* (Portuguese is genetically closer to Spanish than Catalan).

Some of these pairs are known to have mutual intelligibility (see Section 5.1) and share common ancestor languages. This shows that optimal cross-lingual performance can be achieved by pairing highly similar languages. However, since all of these pairs are languages that were included in pre-training, it is unclear whether this also holds for low-resource languages that were not included.

5.3 The best source language

Romanian and Swedish are the most common best source language for any target language, with 10 and 7 target languages, respectively. Alternatively, optimal cross-lingual performance can be determined by taking the average cross-lingual accuracy per source language. According to this measure the best source languages are still Romanian (67.2%) and Swedish (65.9%). This criterion ranks English as 19th out of 65 source languages, with an average accuracy of 62.4%. All languages that perform better than English are Indo-European except Estonian (Uralic), and English is the fifth-best source language from the Germanic Indo-European branch. Romanian is also, on average, the best source language for both the set of target languages that were included in pre-training (81.5%) as well as the set of non-pre-trained languages (49.8%). This shows that even though cross-lingual tansfer commonly takes English as a source language, English might not be the best source language overall.

However, overall average performance might not be a good measure of source language quality because that introduces a strong Indo-European bias, due to the large amount of Indo-European languages in our target language set. If we determine the best source language per target language family (or Indo-European branch), we find that the best source language is from a different language family for 23 out of 30 families. Again, Romanian is the best general source language since it is the best source language for seven different families. All other best source languages occur twice (Chinese, Uyghur and Wolof) or once (17 languages).

In short, for this particular task, with this particular dataset, Romanian as source language achieves the best cross-lingual performance.

6 Conclusion

We show that simply fine-tuning a large multilingual pre-trained language model on English data does not necessarily make full use of the cross-lingual potential of the model. Especially when one applies cross-lingual training for a low-resource language with little or no evaluation data, the different factors that influence performance should be kept in mind. Unfortunately, one of the most important factors highlighted by our experiments is that the target language, or a highly similar language variant, should be included in pre-training for cross-lingual training to be successful. For current language models, this excludes many languages and a large number of language families. For those languages, the most important step is to collect unlabeled data for pre-training (although the amount of data required may be relatively modest; de Vries et al., 2021).

Languages that are included in pre-training can achieve high cross-lingual performance across language families and writing systems, at least for languages that use alphabetic writing systems. The English language, which is the *de facto* default source language for cross-lingual training, is not necessarily the best source language.

Due to data availability, our experiments focused on POS tagging, but we hypothesise that the factors we identified may be predictive for other tasks too. The significant influence of lexical-phonetic distances and word order differences on accuracies indicate that similar languages are encoded similarly in XLM-RoBERTa, even if there is no lexical overlap due to differing writing systems. Thus, these factors potentially also influence more syntax-dependent tasks, such as parsing, and semantically rich tasks, such as natural-language-inference.

Acknowledgments

We gratefully acknowledge the support of the Dutch Research Council (NWO Aspasia grant for M. Nissim) and the financial support of the Center for Groningen Language and Culture (CGTC).

Ethics statement

We used freely available data and a freely available pre-trained model for our experiments. Our experimental setup required fine-tuning many large language models, but we ran preliminary experiments on a few languages to determine whether we could achieve sufficient performance with a small model size. As this indeed was the case, environmental impact was limited compared to the larger model size. Moreover, to limit the need for future fine-tuning efforts for this task, we release all of the fine-tuned models.

Should a Chatbot be Sarcastic?
Understanding User Preferences Towards Sarcasm Generation

Abstract

Previous sarcasm generation research has focused on *how* to generate text that people perceive as sarcastic to create more human-like interactions. In this paper, we argue that we should first turn our attention to the question of *when* sarcasm should be generated, finding that humans consider sarcastic responses inappropriate to many input utterances. Next, we use a theory-driven framework for generating sarcastic responses, which allows us to control the linguistic devices included during generation. For each device, we investigate how much humans associate it with sarcasm, finding that pragmatic insincerity and emotional markers are devices crucial for making sarcasm recognisable.

1 Introduction

The prevalence of sarcasm on the social web (Khodak et al., 2018; Sykora et al., 2020) has motivated computational investigations across the NLP community. Most focus on textual sarcasm detection, the task of classifying whether or not a given text is sarcastic (Riloff et al., 2013; Wallace et al., 2015; Rajadesingan et al., 2015; Bamman and Smith, 2015; Joshi et al., 2016; Amir et al., 2016; Hazarika et al., 2018; Oprea and Magdy, 2019; Abu Farha et al., 2022).

A recent research direction considers sarcasm generation. Approaches to sarcasm generation introduced so far (Joshi et al., 2015; Mishra et al., 2019; Chakrabarty et al., 2020) are mainly motivated by the potential to create more approachable, human-like conversational agents, considering that sarcasm is a natural part of human discourse. We suggest reconsidering this motivation, as a community, for two reasons.

First, in *human* discourse, sarcasm is not a communicative goal in itself. Rather, it can be used to achieve a wide variety of goals. Some of these goals, such as to diminish the impact of criticism (Dews and Winner, 1995), to create humour (Kreuz et al., 1991; Colston and O'Brien, 2000b,a), to praise (Bruntsch and Ruch, 2017), or to strengthen relationships (Jorgensen, 1996; Pexman and Zvaigzne, 2004), might be desirable in human-machine interactions as well. However, other goals, such as criticising, mocking, or expressing dissociation, often with surface contempt or derogation (Wilson, 2006), might not be desirable in human-machine interactions.

Second, the communicative goals mentioned above were observed in *human* interactions. Even when a machine seeks potentially desirable goals, it is unclear whether sarcastic utterances have the same effect on humans when coming from machines.

Therefore, we suggest it is imperative, not least from an ethical perspective, to consider the following **research questions** (RQs):

- RQ1. When should a chatbot be sarcastic?
  - (a) When do humans consider sarcasm appropriate?
  - (b) When do humans prefer sarcasm, over non-sarcasm?
- RQ2. How should a chatbot formulate sarcasm?
  - (a) What linguistic devices do humans associate with sarcasm?
  - (b) What sarcasm flavour do they prefer?

Here, by *flavour*, we mean a specific conjunction of linguistic devices that humans may associate with sarcasm, such as intensifiers and emotional markers, as introduced in Section 3, and expanded upon in Section 4.

To address our research questions, we suggest the following approach. First, given a set of input utterances, generate several sarcastic responses.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 7686 - 7700
May 22-27, 2022

Each response should be of a specific sarcasm flavour, i.e. should display a specific conjunction of linguistic devices. Next, create a survey that asks human participants: to indicate how appropriate it was to respond sarcastically to the input; to select their preferred response; and to rate the sarcasticness of each response, investigating whether they associate the linguistic devices in the response with sarcasm.

To achieve this, we require a sarcastic response generator that provides control over the linguistic devices used. Most previous generators rely on variants of the traditional theory of sarcasm, which claims that the intended meaning concealed by sarcasm is the opposite of the literal meaning. However, this theory provides a grounding that is neither necessary, nor sufficient, for sarcasm to occur, as discussed in Section 3. To overcome this limitation, we recently introduced Chandler, a novel modular sarcastic response generation framework (Oprea et al., 2021). It is grounded on a formal theory that, from a linguistic-theoretical perspective, specifies devices whose presence is both necessary and sufficient to unambiguously differentiate sarcasm from non-sarcasm. These are allusion to a failed expectation, pragmatic insincerity, and emotional markers. Chandler can generate sarcasm of different flavours, and allows control over flavour its output should reflect. Herein, we also compare Chandler's outputs to those of previous generators, to examine participant preferences toward an even greater range of sarcasm flavours.

Our results indicate that people find sarcastic responses inappropriate for most input utterances. When sarcasm was considered appropriate, the inputs commonly had a positive sentiment, and often had elements of humour. Further, even when considered appropriate, people still did not usually *prefer* sarcastic responses over non-sarcastic ones. Sarcasm was typically preferred when it was also considered funny and not too specific. Finally, we identified pragmatic insincerity and emotional markers (cf. Section 3) as crucial linguistic devices to include in generating recognizable sarcasm.

Contributions We summarise our contributions as follows. First, our approach allows us to understand people's preferences about when sarcasm should be used, and how it should be formulated. Using this information, we provide guidelines for future work in sarcasm generation. Second, observing people's preferences also allows us to quantitatively evaluate the practical advantages of the formal linguistic theory that grounds Chandler.

2 Related Work

The earliest work on sarcasm generation is that of Joshi et al. (2015), who introduce SarcasmBot, a sarcastic response generation system. SarcasmBot uses one of eight possible generators, each containing a set of predefined patterns, one of which is instantiated as the response. The generators do not in fact account for the meaning of the input, rather, they only focus on aspects such as the overall sentiment or presence of swear words. Further, in our experiments, we noticed that most of the time a fallback generator was employed, returning the simple concatenation of a random positive phrase to a random negative one, from a set of predefined phrases that have no specific connection to the input.

Mishra et al. (2019) suggest a sarcastic paraphrase generator. They assume that the input is always of negative polarity, and suggest an unsupervised pipeline of four modules to convert such an input $u^{(-)}$ to a sarcastic version. In the Sentiment Neutralisation module, they filter out negative sentiment words from $u^{(-)}$ to produce $u^{(0)}$. In the Positive Sentiment Induction module, they modify $u^{(0)}$ to convey positive sentiment, producing $u^{(+)}$. Next, in the Negative Situation Retrieval module, they mine a phrase $v^{(-)}$ that expresses a negative situation. $v^{(-)}$ is selected from a set of predefined phrases, based on the similarity to the original input. Finally, the Sarcasm Synthesis module constructs the sarcastic paraphrase from $u^{(+)}$ and $v^{(-)}$.

Chakrabarty et al. (2020) suggest a similar pipeline. Their R^3 system first employs a Reversal of Valence module, which replaces input words of negative valence with their lexical antonyms using WordNet (Miller, 1995) to produce $u^{(+)}$. Next, it builds an utterance v that is incongruous to $u^{(+)}$, and generates sarcasm from $u^{(+)}$ and v.

Previous generators share a limitation that make them unfit for our purposes. Mainly, relying on the traditional theory, they identify sarcasm with linguistic incongruity. Thus, they only provide this single device for investigation, device that is not sufficient for sarcasm to occur, as discussed in Section 3. A further limitation, shared by Mishra et al. (2019) and Chakrabarty et al. (2020), is that their generators only work with input utterances of negative sentiment. However, as discussed earlier, sarcastic communication can have many goals, including to praise, or to strengthen friendships.

3 Linguistic Grounding

In this section, we describe the Implicit Display Theory, a formal linguistic theory that grounds Chandler.

Previous Theories In the *traditional theories*, sarcasm is created by literally saying one thing but figuratively meaning, or conversationally implicating (Grice, 1975), the opposite. However, such incongruity is not necessary for sarcasm. To see this, consider sarcastic understatements such as saying "This was not the best movie ever" to mean the movie was bad. It is also not sufficient. For instance, it also occurs in the construction of certain stylistic devices, such as metaphors, e.g. "Time is money". Further theories have been suggested to address these limitations, including the *echoic mention theory* (Sperber and Wilson, 1981) and its variants (Kreuz and Glucksberg, 1989; Wilson and Sperber, 1992; Sperber and Wilson, 1998), and the *pretense theory* (Clark and Gerrig, 1984) and its variants (Clark, 1996). However they all fail to uniquely identify sarcasm, as argued by Utsumi (2000) and Oprea and Magdy (2020).

Implicit Display Theory (IDT) Introduced by Utsumi (1996), the IDT focuses specifically on making the distinction between sarcasm and non-sarcasm. We invite the interested reader to consult (Utsumi, 2000) for an overview of how it overcomes the limitations of previous theories. We chose it as a grounding for our generation system.

The IDT first defines the concept of an ironic environment. We say a situation in which an utterance occurs is surrounded by an ironic environment if the discourse context includes the following components: (1) The speaker has expectation Q at time t_0; (2) Q fails at time $t_1 > t_0$; and (3) The speaker has a negative attitude towards the failure of Q. Note that the idea of linking sarcasm to an expectation is not new to Utsumi (1996), rather it is supported by previous work (Kreuz and Glucksberg, 1989; Kumon-Nakamura et al., 1995).

Next, according to the IDT, an utterance is sarcastic if and only if it implicitly displays the ironic environment. Implicit display is realised if the following linguistic devices are present in the utterance: (1) allusion to the speaker's failed expectation Q; (2) pragmatic insincerity, realised by intentionally violating one of the pragmatic principles, e.g. Grice's maxims (Grice, 1975); and (3) implication (indirect expression) of the speaker's negative attitude towards the failure of Q. Finally, the theory claims that the degree of sarcasm of an utterance is proportional to how many of these linguistic devices are present in the utterance.

4 Methodology

In this section we look at the methodology employed to address our research questions. Specifically, we first select a set of input utterances. Next, for each input, we generate four sarcastic responses of different flavours using Chandler, and three more responses using other systems. Finally, for each input, in a survey, we ask human participants to rate the responses across several dimensions, to understand their preference towards the appropriateness of sarcasm, and which linguistic devices they associate with sarcasm.

4.1 Selecting Input Texts

As inputs, we select texts from the corpus published by Wilson and Mihalcea (2019). The corpus contains short texts (extracted from tweets) where users describe actions they performed. We compute the sentiment polarity of each text using the classifier from Barbieri et al. (2020), a RoBERTa model (Liu et al., 2019) fine-tuned on the tweet sentiment dataset from Rosenthal et al. (2017). Next, we form five partitions of 50 texts each: *very negative* and *very positive*, containing the top 50 texts based on their negative and positive probabilities, respectively; *negative*, containing random texts for which the probability of being negative was higher that the probabilities of being positive or neutral; and *positive* and *neutral*, partitions that we formed analogously to how we formed the *negative* partition. Our final input dataset contains 250 texts.

4.2 Generating Sarcastic Responses

For completeness, in this section we describe Chandler, the sarcastic response generator that we introduced in Oprea et al. (2021).

The IDT directly suggests an algorithm for sarcasm generation that identifies an ironic environment, then creates an utterance that implicitly displays it. We now discuss how we implement each step.

Ironic Environment As discussed in Section 4.1, each input text U_{in} describes an action. In this scenario, herein, we assume the expectation

Q that is part of the ironic environment negates that action. For instance, say U_{in} expresses the event P = [<user> wins the marathon]. We assume $Q = \neg P$ = [<user> does not win the marathon]. As we shall see, the algorithm we suggest will not, in fact, require us to formulate Q, but it relies on the above assumption.

Allusion to Q Following Utsumi (2000), we define allusion in terms of coherence relations, similar to the relations of rhetorical structure theory (RST) (Mann and Thompson, 1987). That is, if U_α is an utterance that expresses proposition α, we say U_α alludes to the expectation Q if and only if there is a chain of coherence relations from α to Q[1]. So, we need to first select a proposition α to either start or end the coherence chain, then specify the chain between α and Q, and formulate U_α such that it expresses α. We suggest defining such α as objects of if-then relations, where the subject is P, the proposition expressed by input text U_{in}. That is, relations of the form "if P then α" should hold. To infer α given U_{in}, we use COMET (Bosselut et al., 2019), an adaptation framework for constructing commonsense knowledge. Specifically, we use the COMET variant fine-tuned on ATOMIC (Sap et al., 2019), a dataset of typed if-then relations. COMET inputs the subject of the relation, along with the relation type, and outputs the relation object. In our case, the subject is U_{in}, and we set α to the relation object.

In the examples that follow, assume the input text is U_{in} ='<user> won the marathon'. We leverage four relation types: (1) **xNeed**: the object α of a relation of this type specifies an action that the user needed to perform before the event took place, e.g. "if U_{in} then α = [*xNeed* to train hard]"; (2) **xAttr**: the object α specifies how a user that would perform such an action is seen, e.g. "if P then α = [*xAttr* competitive]"; (3) **xReact**: the object α specifies how the user could feel as a result of the event, e.g. "if P then α = [*xReact* happy]"; and (4) **xEffect**: the object specifies a possible effect that the action has on the user, e.g. "if P then α = [*xEffect* gets congratulated]". In Table 1 we show, for each relation type, the coherence chains between the relation object α and the failed expectation Q. Under these conditions, to generate an utterance U_α that alludes to Q, we need to choose any U_α that expresses α.

Algorithm 1: Generate sarcastic response

```
input: utterance $U_{\text{in}}$;
ironic environment
    Let $Q := \neg P$ be the failed expectation;
implicit display
    Choose an if-then relation type $\tau$ from xNeed,
      xAttr, xReact, and xEffect;
    Let $\alpha$ = COMET($U_{\text{in}}, \tau$);
return response $U_{out}$ that expresses emotion($\neg\alpha$);
```

Pragmatic insincerity The second requirement for implicit display is that the utterance generated should include pragmatic insincerity. In this paper, we focus on violating Grice's maxim of quality (Grice, 1975), where we aim for the propositional content of the generated utterance to be incongruous to that of U_{in} (input text). To achieve this, we first choose an if-then relation type, then infer the relation object α from U_{in} using COMET, and construct an utterance that expresses $\neg\alpha$. For instance, if U_{in} ='<user> won the marathon', and we have chosen the *xAttr* relation type, the constructed utterance could express $\neg\alpha$ = [<user> is not competitive].

Negative attitude To fulfill the last requirement of implicit display, the utterance generated should imply a negative attitude towards the failure of the expectation Q. As pointed out by Utsumi (1996), this can be achieved by embedding verbal cues usually associated with such attitudes, including hyperbole and interjections.

Logical form and explainability At this point we formulate Algorithm 1 for generating a sarcastic response U_{out}, given an input utterance U_{in} that expresses proposition P. We refer to *emotion*$(\neg\alpha)$ as the *logical form* of the sarcastic response we generate. Here, *emotion* is a function that augments $\neg\alpha$ to express a negative attitude. Note that the logical form, together with the coherence chain between α and the failed expectation Q, provide a complete explanation for *how* and *why* sarcasm occurs. The explanation is $\epsilon = (\text{emotion}(\neg\alpha), \mathcal{C})$, where is C the coherence chain from α to Q. The coherence chain for each relation type can be selected from Table 1. This makes our sarcasm generation process accountable.

Logical Form to Text To convert the logical form to text, we rely on predefined patterns for each if-then relation type. As a running example,

---

[1] Note that a restriction in Utsumi (2000)'s definition of allusion is that U does not directly express the state of affairs that Q is expected via phrases such as "I've expected ...".

relation type	**example relation**	**coherence chain**
xNeed	if P then $\alpha =$ [xNeed to train hard]	volitional-cause(α, P) and contrast(P, Q)
xAttr	if P then $\alpha =$ [xAttr competitive]	condition$(\alpha, I_P) \wedge$ purpose$(I_P, P) \wedge$ contrast(P, Q)
xReact	if P then $\alpha =$ [xReact happy]	contrast$(Q, P) \wedge$ volitional-result(P, α)
xEffect	if P then $\alpha =$ [xEffect gets congratulated]	contrast$(Q, P) \wedge$ non-volitional-result(P, α)

Table 1: Coherence chains between the object α of an if-then relation and the failed expectation Q, for each relation type, as discussed in Section 4.2. Here, P is the proposition expressed by the input text U_{in}. In the examples, $U_{\text{in}} =$'<user> won the marathon'.

assume the input utterance $U_{\text{in}} =$'<user> won the marathon' and the chosen relation type is *xAttr*. Say $\alpha = \text{COMET}(U_{\text{in}}, \textit{xAttr}) = [\textit{xAttr}\text{ competitive}]$. The logical form is $\textit{emotion}(\neg[\textit{xAttr}\text{ competitive}])$. We first construct an intermediate utterance U_α using the following rule: *<user> <verb> competitive*. Here, *<verb>* is a verb specific to each relation type. In our example, U_α could be '<user> is competitive'. Next, for each input U_{in}, we generate three responses. The first response U_{out}^{-e} only includes pragmatic insincerity, i.e. it expresses $\neg[\textit{xAttr}\text{ competitive}]$. To construct it, we apply a rule-based algorithm to generate the negation of U_α in a manner similar to (Chakrabarty et al., 2020), discussed in Section 2. U_{out}^{-e} could be '<user> is not competitive'. The second response U_{out}^{-i} does not include pragmatic insincerity, but only markers that express an emotional attitude, i.e. it expresses $\textit{emotion}([\textit{xAttr}\text{ competitive}])$. To achieve this, in a pattern-based manner, we augment U_α with hyperbole and interjections, as indicated by Utsumi (2000). U_{out}^{-i} could be '<user> is definitely competitive, yay!'. The third response U_{out} includes both devices, i.e. it expresses $\textit{emotion}(\neg[\textit{xAttr}\text{ competitive}])$. U_{out} could be '<user> is definitely not competitive, yay!'. A full list of patterns is shown in Section A in the appendix.

In the running example we focused on the *xAttr* relation type. Recall there are four relation types that we consider, *xNeed*, *xAttr*, *xReact*, and *xEffect*. As such, for each input text U_{in}, we generate 12 responses: three response types, U_{out}^{-e}, U_{out}^{-i}, and U_{out}, for each relation type. We use the pattern Ch-<relation >$^{(|-i|-e)?}$ to refer to each response of our system, *Chandler*. For instance, Ch-xAttr refers to U_{out} built considering the *xAttr* relation, while Ch-xNeed^{-e} refers to U_{out}^{-e} built considering the *xNeed* relation.

Note that other strategies for converting the logical form of sarcasm to text are possible. For instance, using policy-based generation with external rewards (Mishra et al., 2019) might have lead to higher perceived sarcasticness of our generated responses. However, we leave this to future work. Our goal is to understand user preferences towards when sarcasm should be used, and how sarcasm should be formulated.

4.3 Measuring Users' Preferences

We built three surveys, labelled (a)–(c), that we published on the Prolific Academic[2] crowdsourcing platform, one for each output type, out of U_{out}^{-e}, U_{out}^{-i}, and U_{out}. As such, in the survey corresponding to U_{out}, we presented participants with the input text U_{in}, along with the responses produced by Chandler-xNeed, Chandler-xAttr, Chandler-xReact, and Chandler-xEffect.

In each survey, we also enclosed a response from DialoGPT (Zhang et al., 2020), a recent dialogue system that is not built to be sarcastic; a response produced by SarcasmBot, the sarcastic response generator of Joshi et al. (2015) ; and a response produced by R^3, the state-of-the-art sarcastic paraphrase generator of Chakrabarty et al. (2020)[3].

We make a few observations. First, DialoGPT is used as a reference system, following the reasoning of Joshi et al. (2015): responses designed to be sarcastic should have a higher perceived sarcasticness than responses from DialoGPT, which are not designed to be sarcastic. Second, note that R^3 is designed to produce rephrases. As such, we applied R^3 to the output of DialoGPT to get a sarcastic rephrase of a response to the input. Table 2 shows an example input utterance, along with responses from all systems.

All in all, each survey instance contained a specific input text, and seven responses generated as mentioned above and presented in a random order. In the survey, we asked participants to evaluate each response across four dimensions: (1) Sarcasm: How sarcastic is the response? (2) Humour: How

---

system	response
DialoGPT	I'm not sure if you're being sarcastic or not.
DialoGPT+R^3	I'm sure if you're being sarcastic or not. No one has yet been hurt.
SarcasmBot	That is a very useful piece of information! LMAO
Ch-xNeed	Yay! Good job not knowing how to write.
Ch-xAttr	Yay! You're not a very unintelligent person, that's for sure.
Ch-xReact	You're not feeling very embarrassed right now, that's for sure. Yay!
Ch-xEffect	You're not really going to sigh in frustration right now, that's for sure. Brilliant!
Ch-xNeed^{-i}	You knew how to write, that's for sure. Good job!
Ch-xAttr^{-i}	Brilliant! You're a very unintelligent person, that's for sure.
Ch-xReact^{-i}	You're feeling very embarrassed right now, that's for sure. Brilliant!
Ch-xEffect^{-i}	You're really going to sigh in frustration right now, that's for sure. Brilliant!
Ch-xNeed^{-e}	You didn't know how to write.
Ch-xAttr^{-e}	You're not unintelligent.
Ch-xReact^{-e}	You're not feeling embarrassed right now.
Ch-xEffect^{-e}	You're not going to sigh in frustration right now.

Table 2: Responses generated by all systems to the utterance "I ran out of characters :drooling_face:", as discussed in Section 4.3.

funny is the response? (3) Coherence: How coherent is the response to the input? It is coherent if it sounds like sensible response that a person might give in a real conversation; and (4) Specificity: How specific is the response to the input? It is not specific if it can be used as a response to many other inputs. Each dimension ranged from 0 to 4, in line with previous work (Chakrabarty et al., 2020). Next, we asked participants to select their preferred response out of the seven, i.e. the one they would personally use. Finally, we asked them to judge, on a scale from 0 to 4, how appropriate it was to respond sarcastically to the shown input text.

Each survey instance was presented to three different participants. However, we did not use a voting scheme to aggregate the three survey instances into one. Rather, aggregation was conducted per-system. This is because our metrics (e.g. sarcasticness, preference towards a response, appropriateness) are inherently subjective, depending on the sociocultural background of the participants. See, for instance, the work of Oprea and Magdy (2020). As such, the concept of "correct answer" does not exist in the conventional sense. Indeed, the inter-participant agreement was low, but not surprisingly so, given that participants could have come from different sociocultural backgrounds. However, this does not entail that population statistics are not informative. As related work in this direction, consider that of Amidei et al. (2018), who make the point "an unchecked focus on reduction of disagreement among annotators runs the danger of creating generation goals that reward output that is more distant from, rather than closer to, natural human-like language." (Amidei et al., 2018) Consider also the work of Davani et al. (2021), who discuss the issue of disagreement in subjective tasks. We do, however, encourage more work in this direction.

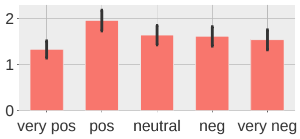

Figure 1: Mean sarcasm appropriateness score for each sentiment category, as discussed in Section 5.1. The error bars represent 95% confidence intervals.

5 Results

We now look at the responses that the participants provided in our survey, addressing our RQs.

5.1 RQ1: Should a Chatbot be Sarcastic?

5.1.1 When is sarcasm appropriate?

Figure 1 shows the mean appropriateness score for each of the five sentiment categories. A one-way ANOVA test between the means yielded a p-value ≈ 0.001. We therefore proceeded with Tukey's range test (Tukey, 1949), to find the means that are significantly different from one another. We noticed that sarcasm was considered significantly more appropriate by survey participants in responses to positive inputs, compared to very positive, and very negative inputs, respectively. This supports our statement from Section 2: the assumption of previous state-of-the-art generators that sarcasm should *only* be generated for negative inputs is problematic. However, even for the positive class, the mean appropriateness is less than 2. This makes it difficult to recommend responding sarcastically based on sentiment only.

To gain more insight, we proceeded with a qualitative inspection of the inputs that yielded the highest and lowest appropriateness scores, respectively. We noticed a few main themes, that we labelled *joke*, *family*, *school*, *leisure* and *death*. We then asked two humans to label all inputs across these dimensions. A third human resolved all disagreements. Finally, we computed the Pearson correlation coefficient of each theme with the sarcasm appropriateness score, across all inputs. We noticed a significant ($p < 0.05$) positive correlation

text	**approp.**
I was a single mom with a sick child	0
I had a wonderful day thanks to my husband	0
I had such a great time with my family at my little prima's quince	1

Table 3: Example inputs with low sarcasm appropriateness (approp.) score.

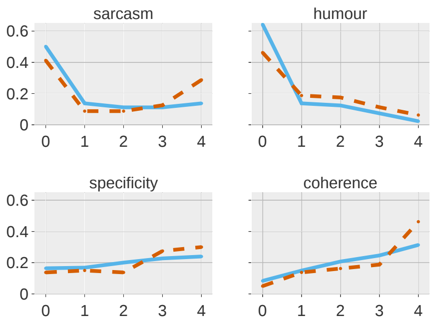

Figure 2: Distribution of the sarcasm, humour, specificity, and coherence scores of the *preferred* response; across all survey instances (continuous blue line) and across instances with a high sarcasm appropriateness (dashed red line), as discussed in Section 5.1.2.

between appropriateness and the category *joke*, and significant negative correlation with belonging to the *family* theme. We show some examples of the theme *family* with low appropriateness scores in Table 3.

Thus, according to our analysis, sarcasm seems to be most appropriate for positive inputs, and for humorous inputs, which may invite more sarcastic responses. In other situations, however, sarcasm might be interpreted as inappropriate and even offensive (Meaney et al., 2021).

5.1.2 When is sarcasm preferred?

We first consider the overall preference towards either sarcasm or non-sarcasm. Recall that participants also specified their preferred response for each input. The distribution of the sarcasm, humour, specificity, and coherence scores of this *preferred* response, across all survey instances, is illustrated in Figure 2 with a blue, continuous, line. The red, dashed, line illustrates the distribution across the 80 survey instances where the sarcasm appropriateness score of the input was higher than the midpoint, i.e. at least 3.

We notice considerably higher preference towards non-sarcastic and non-humorous responses. As indicated by the blue lines, over 50% of the preferred responses were those considered non-sarcastic and non-humorous by participants, the rest of the distribution being highly skewed towards the lower sarcasm and humour regions. Furthermore, note that even when sarcasm was considered highly appropriate, participants still preferred non-sarcastic responses, as indicated by the red, dashed, line in the top-left of Figure 2. Although there is a shift in the distribution towards sarcasm in this case, the skew is still towards the non-sarcastic region. Looking at the bottom row of Figure 2, on the other hand, we notice a negative skew, indicating an overall preference towards higher coherence. This is slightly the case for specificity as well.

To investigate further, we fit a logistic regression model to predict whether a response is preferred based on its sarcasm, humour, specificity, coherence scores, and two-way interactions between these variables. All coefficients are listed in Appendix B. We noticed noticed a significant ($p < 0.05$) positive relationship between coherence and preference, as well as the interaction between sarcasm and humour. The term representing the product of sarcasm and specificity had a significant negative effect on preference. In terms of the specific systems, we notice DialoGPT was preferred about 44% of the time, followed by Ch-xAttr^{-i} (20%), and SarcasmBot (15%), which corresponds exactly to the coherence ranking in Table 4.

Our results indicate that responses with high coherence to the inputs are generally preferred over sarcastic responses. Sarcasm is only preferred when it is also considered humorous. On the other hand, participants seem to have actively avoided sarcastic responses that were very specific.

5.2 RQ2: How Should a Chatbot Formulate Sarcasm

5.2.1 Linguistic Devices

In Table 4 we show mean sarcasm, humour, specificity, and coherence scores provided by participants for each variant of Chandler, across all inputs. In the table, there are four groups (1–4) and three systems within each group (a–c). Rows with index (a) show scores for the complete versions of Chandler, for each if-then relation type. Rows (b) and (c) show partial versions, omitting pragmatic insincerity and emotional markers, respectively.

Allusion We have four strategies for alluding to the failed expectation, depending on the relation type considered. We notice the highest sarcasm score is achieved by Ch-xAttr (row 2a), followed by Ch-xNeed (row 1a), Ch-xReact (row 3a) and Ch-xEffect (row 4a). The same ranking holds for

		System	sarc.	hum.	coh.	spec.
		DialoGPT	0.6	0.3	2.3	2.0
		DialoGPT+R^3	0.8	0.3	0.9	1.3
		SarcasmBot	2.5	0.8	1.4	0.9
1	a.	Ch-xNeed	1.9	0.6	1.3	1.6
	b.	Ch-xNeed^{-i}	1.5*	0.5	1.7*	1.9*
	c.	Ch-xNeed^{-e}	1.0*	0.4*	1.5	1.7
2	a.	Ch-xAttr	2.1	0.6	1.3	1.4
	b.	Ch-xAttr^{-i}	1.6*	0.6	1.8*	1.7*
	c.	Ch-xAttr^{-e}	1.1*	0.4*	1.3	1.2
3	a.	Ch-xReact	1.7	0.4	1.0	1.0
	b.	Ch-xReact^{-i}	1.4*	0.4	1.3*	1.3*
	c.	Ch-xReact^{-e}	0.8*	0.3*	1.0	1.0
4	a.	Ch-xEffect	1.6	0.5	1.1	1.3
	b.	Ch-xEffect^{-i}	1.4	0.5	1.4*	1.6*
	c.	Ch-xEffect^{-e}	1.1*	0.4	1.3	1.4

Table 4: Means of the sarcasm, humour, specificity, and coherence scores provided by participants, for each variant of Chandler (Ch). "*" indicates statistically significant difference from row (a) within the same numbered group (t-tests with Bonferroni correction, $p < 0.001$).

variants of Chandler that do not include pragmatic insincerity or emotional markers. Out of the allusion strategies selected, the responses perceived as most sarcastic are those that mention attributes of the user. Similarly, we notice that variants of Chandler that use the xAttr relation are also perceived and the most coherent, specific to the input, and achieve the highest humour score.

Pragmatic Insincerity Comparing the complete version, Ch-xAttr (row 2a), with Ch-xAttr^{-i} (row 2b), the same model without pragmatic insincerity, we notice a significant drop in average sarcasm score. We observe a similar trend in group 3 for Ch-xReact^{-i}, indicating the importance of pragmatic insincerity. However, this did not hold for the other two relation types. Additionally, both specificity and coherence seem to significantly increase when removing pragmatic insincerity, irrespective of the relation type considered.

Emotional Markers Comparing complete versions of Chandler with those that omit emotional markers, we notice that the omission of such markers leads to significantly lower perceived sarcasm for all relation types. Humour is also significantly impacted by the omission of emotional markers for all relation types considered except for *xEffect* (row 4). Oh the other hand, coherence and specificity are not significantly influenced.

To sum up, the degree of perceived sarcasm is influenced by all linguistic devices considered. Out of the if-then relation types we consider, mentioning attributes of the user seems to lead to the highest perceived sarcasm, humour, specificity and coherence. Being insincere about the state of affairs leads to significantly higher perceived sarcasm, but significantly lower specificity and coherence. Emotional markers increase sarcasm and humour perception, but do not significantly impact specificity or coherence. Finally, recall that a main claim of IDT was that the degree of sarcasticness of an utterance grows with the number of implicit display conditions met. Our results support this claim.

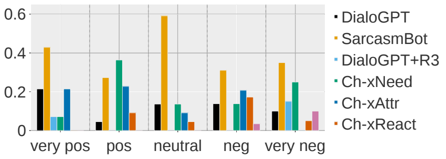

Figure 3: Normalized number of times each system was preferred for instances were the participant preferred a response that they also considered sarcastic.

5.2.2 Preferred Flavour

While we established that participants typically preferred non-sarcatic responses, we next set out to find what sarcasm people preferred in our experiments when they *did* prefer sarcasm. To do this, we consider the set of survey instances that showed the complete versions of Chandler, where the sarcasm score given by the participant to their preferred response was at least 3, leaving us with 107 (around 14%) of the 750 survey instances. We divide these instances into five categories, based on input sentiment. Within each category, for each generation system, we count the number of times that a response produced by that system was preferred. Figure 3 shows the normalised counts across all systems, for each sentiment category.

We observe that, for positive inputs, where sarcasm was considered significantly more appropriate than other sentiment categories, people prefer responses produced by Ch-xNeed. Interestingly, however, we observe that people prefer the fairly nonspecific, pattern-based sarcastic remarks produced by SarcasmBot for most types of input text. However, when analysing its outputs, we noticed it produced a total of only 28 unique responses (listed in Appendix C) to our 250 inputs. While in our experiments each response was only shown at most three times, in a real scenario of a user interacting with a conversational agent, the user might not appreciate repeatedly receiving the same response.

6 Recommendations

We recommend that future work on sarcasm generation should account for the four main findings: (1) People think sarcasm is *inappropriate* as a response to most inputs. However, if it is to be used, it is seen as most appropriate when the input is positive, but not extremely positive. People also found sarcasm to be a suitable response to jokes. (2) Even when deemed appropriate, people usually do not prefer sarcasm. Rather, coherence is the most important factor in explaining their response preferences. When people do prefer sarcasm, they like it mainly when it is also seen funny. Further, they generally dislike sarcasm that is very specific. (3) When generating sarcasm, pragmatic insincerity and emotional markers are important to include as they have a high influence of sarcasm perception. (4) Overall, people commonly prefer the simple general sarcastic responses of SarcasmBot, even compared to more sophisticated generation models, which suggests that presently, a simpler solution to sarcasm generation may actually be advantageous. Nevertheless, more investigation is required to examine if it will be desirable in long conversations, since it has limited diversity in outputs.

7 Conclusion

We have used a linguistically informed framework for sarcasm generation so that we could present human judges with a variety of flavors of sarcastic responses in a range of situations. Our findings suggest that sarcasm should not always be generated, but the decision to generate sarcasm itself should informed by user preferences. People find sarcasm most appropriate as a response to positive utterances and cases in which a joking environment has already been established. Further, judges preferred sarcasm most when they actually found it to be funny, and most often preferred general sarcastic responses. However, people often preferred non-sarcastic responses even more. We recommend that future work in this area carefully considers both the appropriateness and necessity of generating sarcasm at all.

8 Ethical Considerations

In our experiments, we noticed that some of the input tweets contained references to sensitive topics, such as religion and gender, or to tragic life events. Producing sarcasm for such inputs might be inappropriate and offensive to some (as our experiments confirmed). We clearly informed our survey participants about this possibility in the Participant Information Sheet, before accessing our survey. The sheet is enclosed in Appendix D.

A Logical Form to Text Patterns

In this section we show the patterns used by Chandler to convert the logical form of sarcasm to text, as discussed in Section 4.2 of the main paper. We show patterns for each if-then relation type, *xNeed*, *xAttr*, *xReact*, and *xEffect*.

In the patterns below, <inten> is an intensifier, <suff_inten> is an intensifier added at the end of a phrase, <pos> is a positive emotion word, and <interj> an interjection. Inspired by (Utsumi, 2000) and (Joshi et al., 2015), each of these were randomly chosen from the following sets:

- <inten> : [very]
- <suff_inten> : [for sure]
- <pos> : [Good job, Well done]
- <intrj> : [Yay!, Brilliant!]

<obt> below is the object of the corresponding if-then relation object, as provided by COMET when taking in the input tweet.

A.1 Patterns for the Complete Version of Chandler

xNeed patterns:

- You didn't <obt> , that's <suff_inten> . <pos> !

xAttr patterns:

- <interj> You're not <inten> <obt> , that's <suff_inten> .
- <interj> <pos> not being <obt> .
- <interj> You're not a very <obt> person that's <suff_inten> ."

xReact patterns:

- You're not feeling <inten> <obt> right now, that's <suff_inten> . <interj>

xEffect patterns:

- You're not <inten> going to obt_inf right now, that's <suff_inten> . <interj>

A.2 Patterns for Chandler without Pragmatic Insincerity

xNeed patterns:

- You <obt> , that's <suff_inten> . <pos> !

xAttr patterns:

- <interj> You're <inten> <obt> , that's <suff_inten> .
- <interj> <pos> being <obt> .
- <interj> You're a very <obt> person that's <suff_inten> ."

xReact patterns:

- You're feeling <inten> <obt> right now, that's <suff_inten> . <interj>

xEffect patterns:

- You're <inten> going to obt_inf right now, that's <suff_inten> . <interj>

A.3 Patterns for Chandler without Emotional Markers

xNeed patterns:

- You didn't <obt>.

xAttr patterns:

- You're not <obt>.
- You're not a <obt> person.

xReact patterns:

- You're not feeling <obt> right now.

xEffect patterns:

- You're not going to obt_inf right now.

B Logistic Regression Coefficients

In Table 5 we present the full model parameters for the logistic regression experiment from section 5.1.2.

C SarcasmBot Outputs

We noticed SarcasmBot produced a total of only 28 unique responses to our set of 250 inputs, as discussed in Section 5.2.2 of the main paper.

- Unbelievable that you just said 'sucky'! You are really very classy!
- Awesome!
- Brilliant!
- Let's party!
- Oh you poor thing!
- You owe me a drink for that awesome piece of news!
- Wow, you said 'sucks', didn't you? Your mom will be really proud of you!
- Wow, you said 'suck', didn't you? Your mom will be really proud of you!
- I'd feel terrible if I were you!
- You are such a simple person!
- Aww!! That's so adorable!
- That deserves an applause.
- I am so sorry for you!
- Yay! Yawn!
- How exciting! Yawn!
- How exciting! *rolls eyes*
- Wow! *rolls eyes*
- Yay! *rolls eyes*
- Yay! LMAO
- Wow! Yawn!
- How exciting! LMAO
- Wow! LMAO
- That is a very useful piece of information! *rolls eyes*
- That is a very useful piece of information! LMAO
- That is a very useful piece of information! Yawn!
- Unbelievable that you just said 'sobbing'! You are really very classy!
- Unbelievable that you just said 'sucks'! You are really very classy!
- Unbelievable that you just said 'bloody'! You are really very classy!

D Participant Information Sheet

D.1 What will I do?

Imagine someone (we'll call them PersonX), makes a statement. You will be shown a few responses to that statement. The responses were generated by chatbots (computer programs). Some sentences talk about sensitive topics, such as tragic life events. Responses to such sentences could be potentially inappropriate, or even offensive or harmful. Unfortunately, chatbots do not understand whether or not a topic is sensitive for a human. Please be fully aware of this when accepting to take part in our study.

For each response, you will be asked:

1. How sarcastic you find the response? (0 - not sarcastic, 3 - very sarcastic)
2. How funny you find the response? (0 - not funny, 3 - very funny)
3. How specific is the response to PersonX's statement? The response is specific if it mentions details that show a good understanding of PersonX's statement and its implications. Otherwise it's general. (0 - very general, 3 - very specific).
4. How coherent is the response to PersonX's statement? The response is coherent if it makes sense as a response. That is, it's a clear and sensible response that someone might actually give. It does not matter if it's specific or general. (0 - not coherent, 3 - very coherent).

Let's take a quick example. In this example, imagine that PersonX's statement is "I went to the grocery store". Here are some responses about this statement.

About being specific:

- "That's great." - Very general response. You can say this as a response to pretty much anything.
- "Nice to hear you are enjoying this sunny day." - General response. It does provides some details about the day (that it's sunny). However, those details are not uniquely related to PersonX's statement.
- "You must be tired." - More specific response. It shows an understanding that going somewhere (anywhere at all) may cause tiredness.

	coef	std err	z	$P > \|z\|$	[0.025	0.975]
const	-3.1228	0.140	-22.369	0.000	-3.396	-2.849
sarcasm	-0.1328	0.070	-1.897	0.058	-0.270	0.004

specificity	0.1338	0.087	1.542	0.123	-0.036	0.304
coherence	0.8261	0.072	11.508	0.000	0.685	0.967
sarcasm*humour	0.1178	0.031	3.861	0.000	0.058	0.178
sarcasm*specificity	-0.0620	0.031	-1.990	0.047	-0.123	-0.001
sarcasm*coherence	-0.0624	0.032	-1.961	0.050	-0.125	-2.61e-05
humour*specificity	0.0100	0.044	0.225	0.822	-0.077	0.097
humour*coherence	-0.0487	0.047	-1.038	0.299	-0.141	0.043
specificity*coherence	0.0073	0.026	0.281	0.779	-0.044	0.058

Table 5: Detailed results of logistic regression described in section 5.1.2.

- "You probably bought a lot of vegetables." - Specific response. It shows an understanding of what a grocery store is. That is, a place where you can probably buy vegetables.

- "You must have been quite hungry for carrots." - Very specific response. It shows an understanding of what a grocery store is, about what carrots are, and about the link between carrots and the store (mainly, that carrots are sold there).

About being coherent:

- "I'm cold." - Not coherent. It has nothing to do with PersonX's statement

- "I went to the grocery store". It's not a suitable response that someone would normally give.

- "I had such a wonderful dream last night, there were a lot of awesome cars painted blue." - Not coherent. It does not make sense as a response to PersonX's statement.

- "I sometimes dream about eating carrots." - More coherent response. Someone might sometimes say this as a response, although it's not a common response.

- "OK thanks." - Very coherent. One might actually say this as a response. Notice it's not specific to PersonX's statement. You can say it as a response to many other statements. Still, it's coherent to PersonX's statement. Thanks a lot for getting me those carrots, I'll pay you back next week. - Very coherent and very specific to PersonX's statement.

D.2 Participant Information Sheet and Consent Form

- Principal investigator: ⟨our PI's name⟩

- Researcher collecting data: ⟨researcher's name⟩

- Funder (if applicable): ⟨funding bodies⟩

This study is in the process of being certified according to the ⟨details about the ethics committee of our institution ⟩. Please take time to read the following information carefully. You should keep this page for your records.

D.3 Who are the researchers?

We are the ⟨name of our group⟩group, a research group that brings together a range of researchers from ⟨our institution⟩in order to build on our existing strengths in social media research. This research group focuses on mining structures and behaviours in social networks. The principal investigator is ⟨our PI's name⟩.

D.4 What is the purpose of the study?

This study aims to understand what linguistic style people associate with sarcasm.

D.5 Why have I been asked to take part?

We target everyone registered as living in ⟨country⟩on the Prolific Academic platform.

D.6 Do I have to take part?

No—participation in this study is entirely up to you. You can withdraw from the study at any time, without giving a reason. Your rights will not be affected. If you wish to withdraw, contact the PI. We will stop using your data in any publications or presentations submitted after you have withdrawn consent. However, we will keep copies of your original consent, and of your withdrawal request.

D.7 What will happen if I decide to take part?

You will be asked to fill in a survey. The flow of the survey is the following:

- You will be shown a short text (originating from a tweet) and asked whether it is, in your view, appropriate to respond sarcastically to that text.
- If you say "no", you will be shown another text. The process will repeat until you say "yes" or 10 texts have been shown.
- If you say "yes":
  - You will be shown 7 responses to the text that you selected;
  - For each response, you will be asked to specify, on a scale from 1 to 5: (a) How sarcastic it is; (b) How funny it is; (c) How coherent it is to the original text; It is coherent if it sounds like a reasonable response that a person might give. (d) How specific it is to the original text; It is specific if it mentions details about the original text, or its implications, that make this response not appropriate as a response to many other texts.

We estimate it will take around 3 minutes to complete the survey.

D.8 Compensation

You will be paid £0.38 for your participation in this study.

D.9 Are there any risks associated with taking part?

Please note: some of the texts that you will see include content that you might consider sensitive, or might trigger unwanted memories. For instance, they might mention losing a family member, losing friends, break-ups, failure in exams, or health issues.

D.10 Are there any benefits associated with taking part?

Financial compensation of £0.38.

D.11 What will happen to the results of this study?

The results of this study may be summarised in published articles, reports and presentations. Quotes or key findings will be anonymized: We will remove any information that could, in our assessment, allow anyone to identify you. With your consent, information can also be used for future research. Your data may be archived for a minimum of 2 years.

D.12 Data protection and confidentiality

Your data will be processed in accordance with Data Protection Law. Throughout your entire interaction with us, the only information collected about you specifically is your Prolific Academic identification number. This data will only be viewed by the team members of the ⟨our group⟩group, listed here: ⟨our group's website⟩. All other data, including the responses you provide, and the amount of time you took to fill in the survey, will be made public on the internet as part of Open Science, available to be indexed by search engines. The Open Science initiative is described here:
`https://en.wikipedia.org/wiki/Open_science`.

D.13 What are my data protection rights?

⟨our institution⟩is a Data Controller for the information you provide. You have the right to access information held about you. Your right of access can be exercised in accordance Data Protection Law. You also have other rights including rights of correction, erasure and objection. However, we will have no control for the data that will be made public, as specific in the previous section. For more details, including the right to lodge a complaint with the Information Commissioner's Office, please visit ⟨website of the datathe Information Commissioner's office⟩. Questions, comments and requests about your personal data can also be sent to ⟨the data protection officer at our institution⟩. For general information about how we use your data, go to: ⟨website with information on research privacy at our institution⟩.

D.14 Who can I contact?

If you have any further questions about the study, please contact the lead researcher, ⟨lead researcher's name and email address⟩. If you wish to make a complaint about the study, please contact ⟨email address of the ethics committee at our institution⟩. When you contact us, please provide the study title and detail the nature of your complaint.

D.15 Updated information

If the research project changes in any way, an updated Participant Information Sheet will be made available on ⟨website where updates are published⟩.

D.16 Consent

By proceeding with the study, you agree to all of the following statements:

- I have read and understood the above information.
- I understand that my participation is voluntary, and I can withdraw at any time.
- I consent to my anonymised data being used in academic publications and presentations, as well as published publicly on the internet, as part of Open Science.
- I am aware that I will see potentially offensive, harmful, or hurtful content.
- I allow my data to be used in future ethically approved research.

How Do Seq2Seq Models Perform on End-to-End Data-to-Text Generation?

Xunjian Yin and **Xiaojun Wan**
Wangxuan Institute of Computer Technology, Peking University
The MOE Key Laboratory of Computational Linguistics, Peking University
`{xjyin,wanxiaojun}@pku.edu.cn`

Abstract

With the rapid development of deep learning, Seq2Seq paradigm has become prevalent for end-to-end data-to-text generation, and the BLEU scores have been increasing in recent years. However, it is widely recognized that there is still a gap between the quality of the texts generated by models and the texts written by human. In order to better understand the ability of Seq2Seq models, evaluate their performance and analyze the results, we choose to use Multidimensional Quality Metric(MQM) to evaluate several representative Seq2Seq models on end-to-end data-to-text generation. We annotate the outputs of five models on four datasets with eight error types and find that 1) copy mechanism is helpful for the improvement in Omission and Inaccuracy Extrinsic errors but it increases other types of errors such as Addition; 2) pre-training techniques are highly effective, and pre-training strategy and model size are very significant; 3) the structure of the dataset also influences the model's performance greatly; 4) some specific types of errors are generally challenging for seq2seq models.

1 Introduction

Data-to-text generation is a task of automatically producing text from non-linguistic input (Gatt and Krahmer, 2018). The input can be in various forms such as databases of records, spreadsheets, knowledge bases, simulations of physical systems.

Traditional methods for data-to-text generation (Kukich, 1983; Reiter and Dale, 2000; Mei et al., 2015) implement a pipeline of modules including content planning, sentence planning and surface realization. Recent neural generation systems (Lebret et al., 2016; Wiseman et al., 2017a) are trained in an end-to-end fashion using the very successful encoder-decoder architecture (Bahdanau et al., 2014) as their backbone. Ferreira et al. (2019) introduce a systematic and comprehensive comparison between pipeline and end-to-end architectures for this task and conclude that the pipeline models can generate better texts and generalize better to unseen inputs than end-to-end models.

However, with the rapid development of the Seq2Seq models especially pre-trained models, more and more end-to-end architectures based on Seq2Seq paradigm get state-of-the-art results on data-to-text benchmarks nowadays. Although BLEU score (Papineni et al., 2002), which is based on precision, has been improved dramatically on standard data-to-text benchmarks such as WebNLG (Gardent et al., 2017), ToTTo (Parikh et al., 2020) and RotoWire (Wiseman et al., 2017b) over the recent years, it is commonly accepted that, compared with human evaluation, BLEU score can not evaluate the models very well. It is too coarse-grained to reflect the different dimensions of the models' performance and not always consistent with human judgment (Novikova et al., 2017a; Reiter, 2018; Sulem et al., 2018). Moreover, existing human evaluations on data-to-text generation are usually limited in size of samples, numbers of datasets and models, or dimensions of evaluation.

In this study, we aim to conduct a thorough and reliable manual evaluation on Seq2Seq-based end-to-end data-to-text generation based on multiple datasets and evaluation dimensions. We want to know the pros and cons of different Seq2Seq models on this task, and the factors influencing the generation performance. Particularly, following Multidimensional Quality Metric(MQM) (Mariana, 2014), similar to the job on summarization evaluation (Huang et al., 2020), we use 8 metrics on the Accuracy and Fluency aspects to count errors, respectively. Therefore, compared with existing manual evaluation reports, it is more informative and objective.

Using this method, we manually evaluate several representative models, including Transformer (Vaswani et al., 2017), Transformer with Pointer

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 7701 - 7710

Generator (See et al., 2017), T5(small&base) (Raffel et al., 2019), BART(base) (Lewis et al., 2019) [1]. We test these models on four common datasets, including E2E (Novikova et al., 2017b), WebNLG (Gardent et al., 2017), WikiBio (Lebret et al., 2016), ToTTo (Parikh et al., 2020). Thus we can discuss the effectiveness of the pre-training method, some essential techniques and the number of parameters. We can also compare the differences between datasets and how they influence the models' performance. Empirically, we find that:

1. Pre-training: Pre-training is powerful and effective which highly increases the ability of the Seq2Seq paradigm on the data-to-text task.
2. Size: The size of the model makes difference to the results. Particularly, T5-base achieves the best scores on both automatic and human evaluations.
3. Essential Techniques: The copy mechanism can make noticeable improvements for the basic Seq2Seq model, decreasing word-level errors such as Omission and Inaccuracy Extrinsic. But it also introduces more Addition errors slightly.
4. Dataset Structure: The structure of the dataset also influences the model's understanding of the sequence greatly. Content-controlled generation is still a little hard for the Seq2Seq models.
5. Error Type: The most common mistakes of Seq2Seq models on data-to-text task are Omission, Inaccuracy Intrinsic and Inaccuracy Extrinsic, indicating the direction we need to improve the effectiveness of the model. On the other hand, models perform well in fluency.

2 Related Work

Data-to-Text Generation Traditional methods for data-to-text generation (Kukich, 1983; Mei et al., 2015) implement a pipeline of modules including content planning, sentence planning and surface realization. Recent neural generation systems (Lebret et al., 2016; Wiseman et al., 2017a) are trained in an end-to-end fashion using the very successful encoder-decoder architecture (Bahdanau et al., 2014) as their backbone. Many Seq2Seq models have demonstrated their effectiveness on data-to-text tasks. Since we want to make a general comparison on Seq2Seq models, we will focus on this method. Moreover, with the development of pre-training methods, more and more work (Kale, 2020; Wang et al., 2021; Kale and Rastogi, 2020) began to introduce pre-training model for data-to-text generation.

There is some work evaluating and analyzing the data-to-text generation task. Perez-Beltrachini and Gardent (2017) propose a methodology to analyze the data-to-text benchmarks and apply their method to WikiBio, RNNLG (Wen et al., 2016) and IMAGEDESC (Novikova and Rieser, 2016) datasets. Ferreira et al. (2019) introduce a systematic comparison between pipeline and end-to-end architectures for neural data-to-text generation. Thomson and Reiter (2020) propose a methodology for human to evaluate the accuracy of the generated texts.

Sequence-to-Sequence Seq2Seq paradigm is a general and flexible paradigm that is typically implemented by an encoder-decoder framework. Sutskever et al. (2014) discuss sequence to sequence learning with neural networks. Furthermore, there are some representative architectures that have been proposed such as recurrent neural network (Zaremba et al., 2014) and Transformer (Vaswani et al., 2017). Seq2Seq paradigm can be naturally applied to any task, as long as their input and output can be represented as sequences. Therefore, there have been many attempts to apply Seq2Seq to different tasks. More recently, pre-trained models based on Seq2Seq paradigm (Lewis et al., 2019; Raffel et al., 2019) have proved their power on lots of tasks (McCann et al., 2018; Yan et al., 2021). There has been much work analyzing Seq2Seq models which is always task-specific and based on automatic or human evaluation. For example, Huang et al. (2020) analyze the common models' performance on summarization.

To our knowledge, little work has been done to comprehensively evaluate the performance of Seq2Seq models on data-to-text generation. And much work is based on automatic metrics such as ROUGE or BLEU which can be different from human evaluation as some work (Novikova et al., 2017a; Reiter, 2018; Sulem et al., 2018) shows. Therefore it is meaningful to manually evaluate representative Seq2Seq models on the data-to-text task.

---

[1] Due to limited computing resources, we didn't evaluate T5-large and BART-large models.

Dataset	Train Size	Domain	Target Quality	Target Source	Content Selection

Table 1: Summary of data-to-text datasets (Parikh et al., 2020) used in this study

3 Models and Datasets

We conduct experiments using five representative Seq2Seq models on four commonly used data-to-text datasets and evaluate the generated texts accordingly[2]. Note that we do not use models that are designed for specific data sets or data structures (Moryossef et al., 2019; Rebuffel et al., 2020; Puduppully and Lapata, 2021), but adopt models that allow inputs of different formats and structures, which brings convenience to comparison on different data sets. Besides, most specific models for data-to-text generation are actually based on these typical Seq2Seq models (Ferreira et al., 2019; Rebuffel et al., 2020), which also proves the rationality of our selection of these models.

3.1 Models

We choose to explore and compare Transformer, Pointer Generator, BART and T5's performance on data-to-text generation and explore the role of copy mechanism by comparing Transformer and Pointer Generator, the benefits brought by the pre-training technique by comparing Transformer with T5 and BART, the influence of the different pre-training methods by comparing BART and T5, the power of parameter size by comparing T5-base and T5-small.

Transformer Transformer (Vaswani et al., 2017) is widely used in natural language processing and has shown its potential on many tasks. It uses self-attention and multi-head attention which let a model draw from the state at any preceding point along the sequence. The attention layer can access all previous states and weigh them according to a learned measure of relevancy, providing relevant information about far-away tokens. There are also some experiments with Transformer as the baseline model (Zhao et al., 2020) for data-to-text generation. Moreover, many improved models for data-to-text generation are also based on Transformer (Wang et al., 2020; Zhu et al., 2019). Therefore, it is worth and reasonable to explore the performance of Transformer on the data-to-text task.

Pointer Generator Pointer Network is first proposed by Vinyals et al. (2015) and See et al. (2017) introduce Pointer Generator based on it. Pointer Generator can generate words from the vocabulary through the generator or copy content from the source through the pointer, which addresses the problem that Seq2Seq models tend to reproduce factual details inaccurately. Copy mechanism is widely used in data-to-text tasks and has achieved great success (Marcheggiani and Perez-Beltrachini, 2018; Rebuffel et al., 2020; Puduppully et al., 2019). Parikh et al. (2020) and lots of other work also use the Pointer Generator as the baseline model. Therefore, the Pointer Generator is a representative model for data-to-text generation. We implement the Pointer Generator based on Transformer so it can take advantage of the copy mechanism.

BART BART (Lewis et al., 2019) uses a standard Seq2Seq Transformer architecture with a bidirectional encoder like BERT (Devlin et al., 2018) and a left-to-right decoder like GPT (Radford et al., 2018). The pre-training task involves randomly shuffling the order of the original sentences and a novel in-filling scheme, where spans of text are replaced with a single mask token. With the novel pre-training method and a large number of parameters, BART achieves state-of-the-art on many tasks (Lewis et al., 2020; Siriwardhana et al., 2021). Our results show that BART can perform very well on data-to-text generation too.

T5 T5 (Raffel et al., 2019) is an encoder-decoder model pre-trained on a multi-task mixture of unsupervised and supervised tasks and for which each task is converted into a text-to-text format whose basic architecture is Transformer. It achieves state-of-the-art on multiple tasks, which shows the power of the large pre-training model and Seq2Seq paradigm. T5-3b (Kale, 2020) obtains the best result on ToTTo dataset. T5-large with a two-step fine-tuning mechanism (Wang et al., 2021)

---

[2] The codes and annotated data are available at `https://github.com/xunjianyin/Seq2SeqOnData2Text`

achieves state-of-the-art on WebNLG benchmark. We carry out experiments on T5-small which has 60M parameters and T5-base which has 220M parameters to explore the power of model size.

3.2 Datasets

We use the datasets commonly used in data-to-text task in the experiments, including E2E, WebNLG, WikiBio and ToTTo. They have different forms and characteristics, which can give a comprehensive comparison of models. The summary of these data-to-text datasets is shown in Table 1.

E2E The input of E2E dataset (Novikova et al., 2017b) is the information about the restaurant, and the output is its natural language description. It consists of more than 50K combinations and the average length of the output text is 8.1 words.

WikiBio WikiBio (Lebret et al., 2016) is a personal biography dataset containing more than 70K examples. The input is the infobox from Wikipedia, and the output is the first sentence of the biography. The average length of the output text is 26.1 words.

WebNLG The WebNLG challenge (Gardent et al., 2017) consists of mapping sets of RDF triples to text. The latest WebNLG dataset contains more than 40K data-text pairs. The average length of the output text is 22.3 words.

ToTTo ToTTo (Parikh et al., 2020) is an open-domain English table-to-text dataset with over 120,000 training examples that proposes a controlled generation task: given a Wikipedia table and a set of highlighted table cells, produce a one-sentence description.

4 Evaluation Method

We first evaluate models' performance using automatic metric BLEU (Papineni et al., 2002), and the BLEU scores are comparable to the mainstream research. Then, we use human evaluation similar to PolyTope (Huang et al., 2020) to further analyze and evaluate the performance of the models on different datasets.

BLEU is a precision-based metric for evaluating the quality of generated text and it is widely used by work on data-to-text generation.

Multidimensional Quality Metric (MQM) (Mariana, 2014) is a framework for describing and defining custom translation quality metrics. It defines flexible issue types and a method to generate quality scores. Based on MQM, Huang et al. (2020) introduce an error-oriented fine-grained human evaluation method PolyTope. It defines five issue types about accuracy, three issue types about fluency, syntactic labels and three error severity rules. Note that we do not use the syntactic labels in PolyTope, as they are not the focus of our evaluation in this study. The definitions of our evaluation dimensions are very similar to Huang et al. (2020), but for the sake of the integrity of the paper and more specifically to the task of Data2Text, we still explain them below.

After annotating every generated sentence with these error types and severity, we finally calculate an overall score to evaluate the model's performance.

4.1 Issue Type

According to the MQM principle, we define error types in two aspects: accuracy and fluency. Errors related to accuracy mean the generated text is not faithful to the original data or does not reflect the critical information totally from the original data. This type consists of five sub-types:

Addition The generated text contains unnecessary and irrelevant fragments from the source data.

Omission The key point does not exist in the output.

Inaccuracy Intrinsic Terms or concepts appearing in the original data are distorted in the output.

Inaccuracy Extrinsic The generated text shows the content which does not exist in the source data.

Positive-Negative Aspect The generated text is positive, whereas the source data represents a negative statement and vice versa.

Fluency aspect evaluates the linguistic quality of the generated text, which is a primary natural language requirement. It consists of three sub-types:

Duplication Unnecessarily repeat a word or longer part of the text.

Word Form Problems related to the form of words, including consistency, part of speech, tense and so on.

Input	Model's Output
Object: Austin Texas **Property**: is Part Of **Subject**: Texas	Austin is part of Williamson County Texas where the English is spoken . The largest city in Williamson County is **Georgetown**.
Object: Texas **Property**: language **Subject**: English language	
Object: Austin Texas **Property**: is Part Of **Subject**: Williamson County Texas	
Object: Williamson County Texas **Property**: largest City **Subject**: Round Rock Texas	
Object: Williamson County Texas **Property**: county Seat **Subject**: Georgetown Texas	

Table 2: Example output with Inaccuracy Intrinsic and Omission errors. The **Georgetown** is not the largest city but the county Seat so it is the Inaccuracy Intrinsic error. And the generated text do not mention the county Seat so there is an Omission error.

Word Order Problems about the order of words in outputs.

One example output with errors on WebNLG dataset is shown in Table 2.

4.2 Severity

Severity describes how severe a particular error is. There are three levels: Minor, Major and Critical. Each specific error in the sentence will be allocated a severity. It is decided by the annotator and will be considered as a weight to score the quality of the annotated sentence automatically.

Minor Errors that do not affect content availability or understandability. For example, we regard the repetition of function words as an error, but this error will not affect the understanding of the text, so we think this error is Minor.

Major Errors that affect content availability or comprehensibility but do not make content unusable. For example, we think additional attributes will not make the content unsuitable for the purpose although it may cause the reader to make additional efforts to understand the intended meaning.

Critical Errors that make content unsuitable for use thoroughly. Each error type can make the text completely unusable when it is too severe. For example, when the critical elements in the sentence are missing or too many errors are misleading people's understanding, we think this error is the key.

4.3 Calculation

Given original data and generated text, annotators are required to find all errors in the sentence and label them with error types and severity. After the work is done for all samples, the error score of every type and an overall system performance score will be calculated automatically with the below equations:

$$EScore_t = \frac{\sum\limits_{e \in E_t} \alpha_e \times L_e}{word_{count}} \tag{1}$$

$$Score = (1 - \sum_{t \in T} EScore_t) \times 100 \tag{2}$$

where T is the set of error types and E_t is the set of all error segments of type t. α_e is the deduction ratio which is set 1:3:7 for the three severity levels: Minor, Major and Critical. L_e is the word length of the error[3]. $word_{count}$ is the total number of words in samples. We can see the highest system performance score can reach 100 if there is no error in the sentences, and it is the higher the better. Through this method, we can get $Score$, an overall evaluation of each model, and error scores $EScore_t$ that indicate each error type's punishment for the overall score.

4.4 Human Annotation

After training and testing, we hire five annotators with satisfactory levels in reading from eight candidates. They are all highly educated enough to understand structured data and tables, and their English level is also very high to understand the text. Before formal annotation, we conduct detailed training to make them have a clear understanding of various errors and the severity of PolyTope framework. Examples used in training do not appear in the final annotation. In order to ensure objectivity and impartiality, they know nothing about the name, architecture, BLEU score of the model and dataset in the process of annotation.

---

[3] Note that we set the length of an Omission error to 1.

	E2E	WikiBio	WebNLG	ToTTo	Average
Transformer	76.88	81.31	76.32	45.41	69.98
Pointer-GEN	86.97	82.98	78.76	54.57	75.82
T5-small	86.04	86.28	93.92	85.44	87.92
T5-base	**96.36**	**91.38**	**94.10**	88.59	**92.61**
BART-base	91.55	86.37	93.43	**90.71**	90.52
Average	87.56	85.66	87.31	72.94	

Table 3: Human evaluation scores of each model on each dataset (higher means better).

Pointer-GEN	61.57	49.39	27.54	35.28
T5-small	**62.88**	49.45	55.66	45.35
T5-base	59.96	49.12	**59.48**	**48.91**
BART-base	62.66	**53.25**	52.84	48.22

Table 4: BLEU Scores of each model on every dataset (higher means better).

During testing, annotators are asked to locate every error's position, point out the type of the error, choose the severity of the error and explain the reason. We check their answers and score them. Through the overall performance in the test, we select the best five annotators and ensure all of them really understand our evaluation method and have the ability to do the annotation work.

For each dataset, we select 80 data-text pairs and input them into each model respectively. There are four datasets and five models, so we have 1600 texts to annotate. Each text is annotated by two different annotators respectively and if the difference of their error scores is too large, the text will be abandoned and a new text will be selected to join the evaluation. They are not allowed to communicate with each other in the annotation process. They can choose to abandon the texts that confuse them, and these texts will be replaced by candidate texts. Each annotator must label all the five outputs generated by five models of one input sequence at a time to keep equality. In general, we strive to balance the fairness and quality of the evaluation.

5 Result Analysis

We evaluate the five models mentioned above on four datasets using the above metrics. The overall human evaluation score and BLEU score of each model on each dataset are shown in Table 3 and Table 4, respectively. The detailed error scores of different error types are shown in Table 5. We can compare the performance of the models to see the influence of the pre-training technique, the copy technique and the mode size. Comparing the results on different datasets using the same model, we can discover how the structured data input influences the performance of the Seq2Seq models. Moreover, we can also analyze the detailed error scores to find out the weakness and advantages of specific models.

5.1 Copy Mechanism

Through comparing the results of Pointer Generator and Transformer on all datasets, we can see that the copy mechanism has an noticeable effect on the improvement of the results. It improves the generation performance on all the datasets. Particularly, it reduces the Inaccuracy Intrinsic error score by about 3 or 4 points on three datasets (E2E, WebNLG and ToTTo), as shown in Table 5. It is easy to understand because using copy mechanism, the model can generate words from the vocabulary through the generator or copy content from the source through the pointer. Pointer Generator with copy mechanism reduces almost all types of errors compared with vanilla Transformer such as Duplication error. The reason may be that the copy mechanism can interpolate vocabulary level probability with copy probability, reducing reliance on previous outputs.

We can observe that the improvement of Pointer Generator over Transformer is the largest on ToTTo dataset. This may be related to ToTTo's need to pay more attention to the highlighted part of the input sequence, which emphasizes controllability.

Nevertheless, it is interesting that Addition error is increased slightly compared with Transformer. The likely reason may be that the auto-regressive decoder tends to copy longer sequences from the source and it is hard to interrupt the copy action.

dataset	model	Addition	Duplication	Extrinsic	Intrinsic	Omission	Positive-Negative Aspect	Word Form	Word Order
E2E	Transformer	2.52	0	5.46	7.14	5.97	0	0	2

	T5-base	0	0	0.34	3.50	1.49	0.54	0	0
	BART-base	0	0	0.44	4.45	1.66	0	0	0
ToTTo	Transformer	4.38	2.38	11.03	17.02	19.74	0	0	0
	ptr-gen	11.01	1.31	9.11	13.47	7.48	0	3.01	0
	T5-small	0	0	0	5.36	9.19	0	0	0
	T5-base	0	0	1.86	4.38	4.38	0	0	0.76
	BART-base	0	0	1.79	2.41	2.66	0	0	2.41

Table 5: Error score of each error type for each model on 80 data-text pairs of every dataset. The results are scored based on manual evaluation and retained to two decimal places. Lower means better. Errors may be approximated to 0 because there are too few errors.

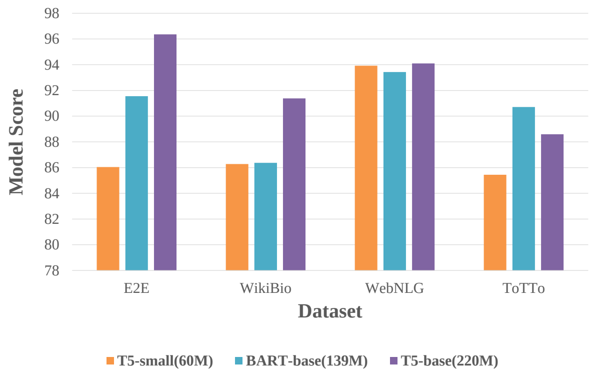

Figure 1: Comparison results of pre-trained models with different numbers of parameters (higher means better).

5.2 Pre-training

In Table 3, we can see almost all the pre-training models outperform the non-pre-training models by a large margin among all the datasets except E2E dataset which may be too simple to evaluate the ability of models. The reason why the pre-training models can achieve better scores may be that they have learned helpful knowledge from lots of raw texts. And the pre-training method also helps the models become more powerful. BART and T5 are both pre-trained on tasks where spans of text are replaced by masked tokens. The models must learn to reconstruct the original document. According to the average scores of all the datasets, we can say that T5-base may be the best Seq2Seq model among our experimented models and BART-base is not far behind. And the models achieve the highest score on different datasets: BART-base is the best on ToTTo and T5-base is the best on the other datasets relatively.

5.3 Model Size

It is evident that the parameter quantity is the critical factor to the pre-trained model's performance. BART-base has 139M parameters, T5-base has 220M parameters and T5-small has 60M parameters only. With the same architecture and same pre-training method, T5-base totally outperforms T5-small. Due to pre-training methods and other factors, T5-base and BART-base achieve the best results on different datasets. But on average, T5-base is the best. The relation between model size and the performance on different datasets is shown in Figure 1. The only exception mentioned above is ToTTo, where BART-base achieves the best results. One of the likely reasons is the pre-training strategy of BART which helps it have better denoising and reconstruction ability. Another reason will be mentioned in section 5.4.

5.4 Dataset

We can compare the difficulty level of the datasets by the average and the highest scores of all models. In Table 3, the ToTTo dataset has the lowest average score of 72.9. And the highest score on it achieved by BART-base is 90.7 which is also the lowest among all the datasets. ToTTo is made as a controlled generation task that given a Wikipedia

	Addition	Duplication	Extrinsic	Intrinsic
Average Scores	1.48	0.63	2.30	5.25
	Omission	Positive-Negative Aspect	Word Form	Word Order
Average Scores	5.97	0.17	0.23	0.56

Table 6: Average error score of each error type across all models and datasets (lower means better).

table and a set of highlighted table cells, the model needs produce a one-sentence description of the highlighted part. It is much more complicated than other datasets describing all the given structured data. Maybe it is a bit confusing for models to find out what actually should be noticed, although the scores of the pre-training models are still very high. And the gap between pre-training models and non-pre-training models is the biggest on ToTTo among all datasets which indicates that the simple non-pre-training models can not handle the complex controlled generation very well. Of course the quantity of the data-text pairs and the length of the input and output sequence also influence the models' performance.

5.5 Error Types

Table 6 shows the average error scores of each error type across all models and datasets. From Table 5 and Table 6, we can find that different types of errors have different effects on the performance of the models. We can find that Omission Error is the most frequent and severe error and its error score is almost up to 6. The likely reason is that the input sequence is too long, so it is hard to encode all its meaning. So the models tend to omit some information from the input. And Inaccuracy Intrinsic Error and Inaccuracy Extrinsic Error also can not be ignored which are 5.25 and 2.31, respectively. From the perspective of the pre-training model, it may be because they learn too much from the raw texts on pre-training stage and the knowledge lets them tend to generate inaccurate texts.

It is excited that all the models perform very well in terms of fluency. The errors of Duplication, Word Form and Word Order are very sporadic. This shows the Seq2Seq models can generate fluent text with the structured input.

6 BLEU or Human Evaluation?

We can see that the overall trend of the BLEU score is consistent with human evaluation, which can basically reflect the overall performance of the model. And many conclusions we made above can also be proved by the BLEU score. For example, the biggest pre-training model T5-base achieves the highest BLEU score too among the selected models, Pointer Generator with copy mechanism still performs better than Transformer and ToTTo is still the most difficult dataset.

Although our primary goal is not to promote a human evaluation metric, our dataset with human annotations gives us a testbed to analyze the correlations and differences between automatic and human metrics. There have been a lot of discussions in the community about the unreliability of BLEU metric. Sulem et al. (2018) recommend not using BLEU on text simplification. They found that BLEU scores can neither reflect grammar nor the meaning of preservation. Novikova et al. (2017a) show that BLEU and some other commonly used indicators are not well consistent with human judgment when evaluating NLG tasks.

We compute the Pearson correlation coefficients between BLEU score and manual evaluation in terms of *Accuracy* and *Fluency*. We categorize the error types into accuracy and fluency aspects according to the definition in Section 4.1, and use Equation 2 to calculate Accuracy score and Fluency score respectively. The Pearson correlation coefficient between BLEU score and *Accuracy* is 0.61 and in *Fluency* aspect is 0.08. There is a huge gap between them and we can see that BLEU can evaluate *Accuracy* to a certain extent and it is poor at *Fluency*. Moreover, the BLEU metric is too coarse-grained to reveal the model's specific problems, which enlighten us on how to improve the model. Our result is consistent with views of other work.

7 Conclusion

We empirically compared five representative Seq2Seq models on the data-to-text task using a fine-grained set of human evaluation metrics based on MQM. We aim to make a systematic and comprehensive evaluation and analysis on end-to-end Seq2Seq models for the data-to-text task. We analyze the effect of milestone techniques such as copy and pre-training, the influence of the dataset and model size and the models' performance in terms of different types of errors. Our evaluation shows that pre-trained models can generate quite good texts. But there is still much room for improvement in this task. Furthermore, the improvement of specific errors such as Omission Error and Inaccuracy Intrinsic Error is also worth exploring in the future.

Abstract

Probing has become an important tool for analyzing representations in Natural Language Processing (NLP). For graphical NLP tasks such as dependency parsing, linear probes are currently limited to extracting undirected or unlabeled parse trees which do not capture the full task. This work introduces DEPPROBE, a linear probe which can extract *labeled* and *directed* dependency parse trees from embeddings while using fewer parameters and compute than prior methods. Leveraging its full task coverage and lightweight parametrization, we investigate its predictive power for selecting the best transfer language for training a full biaffine attention parser. Across 13 languages, our proposed method identifies the best source treebank 94% of the time, outperforming competitive baselines and prior work. Finally, we analyze the informativeness of task-specific subspaces in contextual embeddings as well as which benefits a full parser's non-linear parametrization provides.

1 Introduction

Pre-trained, contextualized embeddings have been found to encapsulate information relevant to various syntactic and semantic tasks out-of-the-box (Tenney et al., 2019; Hewitt and Manning, 2019). Quantifying this latent information has become the task of *probes* — models which take frozen embeddings as input and are parametrized as lightly as possible (e.g. linear transformations). Recent proposals for edge probing (Tenney et al., 2019) and structural probing (Hewitt and Manning, 2019) have enabled analyses beyond classification tasks, including graphical tasks such as dependency parsing. They are able to extract dependency graphs from embeddings, however these are either undirected (Hewitt and Manning, 2019; Hall Maudslay et al., 2020) or unlabeled (Kulmizev et al., 2020), thereby capturing only a subset of the full task.

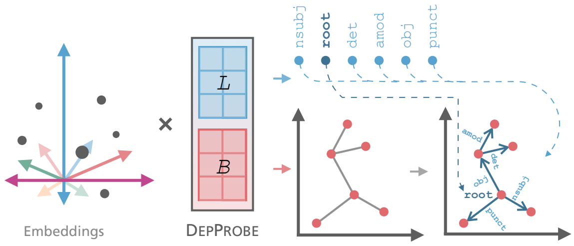

Figure 1: **DEPPROBE** extracts tree structure using transformation B, labels using L and infers directionality using `root`, based on contextualized embeddings.

In this work, we investigate whether this gap can be filled and ask: *Can we construct a lightweight probe which can produce fully directed and labeled dependency trees?* Using these trees, we further aim to study the less examined problem of transferability estimation for graphical tasks, extending recent work targeting classification and regression tasks (Nguyen et al., 2020; You et al., 2021). Specifically: *How well do our probe's predictions correlate with the transfer performance of a full parser across a diverse set of languages?*

To answer these questions, we contribute DEPPROBE (Figure 1), the first linear probe to extract directed and labeled dependency trees while using fewer parameters than prior work and three orders of magnitude fewer trainable parameters than a full parser (Section 3). As this allows us to measure labeled attachment scores (LAS), we investigate the degree to which our probe is predictive of cross-lingual transfer performance of a full parser across 13 typologically diverse languages, finding that our approach chooses the best transfer language 94% of the time, outperforming competitive baselines and prior work (Section 4). Finally, we perform an in-depth analysis of which latent information is most relevant for dependency parsing as well as which edges and relations benefit most from the expressivity of the full parser (Section 5).[1]

2 Related Work

Given the ubiquitous use of contextualized embeddings (Devlin et al., 2019; Conneau et al., 2020; Xue et al., 2021), practitioners have turned to various methods for analyzing their linguistic features (Rogers et al., 2020). Hewitt and Manning (2019) examine these intrinsic properties in greater detail for English dependency parsing using a *structural probe*, finding that *undirected* dependency graphs are recoverable from BERT by learning a linear transformation on its embeddings (Section 3.1).

Extending the structural probe of Hewitt and Manning (2019) to 12 languages, Chi et al. (2020) extract *undirected* dependency graphs from mBERT (Devlin et al., 2019), further showing that head-to-child difference vectors in the learned subspace cluster into relations from the Universal Dependencies taxonomy (de Marneffe et al., 2014).

Building on both the structural and tree depth probes (Hewitt and Manning, 2019), Kulmizev et al. (2020) extract *directed* dependency graphs from mBERT for 13 languages (Section 3.2). Further variations to structural probing include regularization of the linear transformation (Limisiewicz and Mareček, 2021) as well as alternative objective functions (Hall Maudslay et al., 2020).

None of the proposed linear probing approaches so far are able to produce full dependency parse trees (i.e. directed and labeled), however the closer a probe approximates the full task, the better it quantifies relevant information (Hall Maudslay et al., 2020). It would for example be desirable to estimate LAS for parsing a target treebank with a model trained on a different source without having to train a resource-intensive parser (e.g. Dozat and Manning, 2017) on each source candidate. Although performance prediction methods for such scenarios exist, they typically do not cover graph prediction (Nguyen et al., 2020; You et al., 2021).

In order to bridge the gap between full parsers and unlabeled probes, in addition to the gap between full fine-tuning and lightweight performance prediction, this work proposes a linear probe which can extract *labeled* and *directed* dependency parse trees while using less compute than prior methods (Section 3). We use our probe's LAS to evaluate its predictive power for full parser performance and leverage its linear nature to investigate how dependencies are represented in subspaces of contextual embeddings (Section 5).

3 Probing for Dependencies

In order to construct a directed and labeled dependency parse tree for a sentence s consisting of the words $\{w_0, \dots, w_N\}$, we require information on the presence or absence of edges between words, the directionality of these edges $(\overrightarrow{w_i, w_j})$, and the relationships $\{r_0, \dots, r_N\}$ which they represent. Using the contextualized embeddings $\{\boldsymbol{h}_0, \dots, \boldsymbol{h}_N\}$ with $\boldsymbol{h}_i \in \mathbb{R}^e$, prior probing work has focused on the first step of identifying edges (Section 3.1) and later directionality (Section 3.2). In this work, we propose a probe which completes the final relational step (Section 3.3) and simultaneously provides a more efficient method for identifying directionality (Section 3.4).

3.1 Undirected Probing

The structural probe introduced by Hewitt and Manning (2019) recovers the first piece of information (i.e. the undirected graph) remarkably well. Here, the probe is a linear transformation $B \in \mathbb{R}^{e \times b}$ with $b < e$ which maps contextual embeddings into a subspace in which the distance measure

$$d_B(\boldsymbol{h}_i, \boldsymbol{h}_j) = \sqrt{(B\boldsymbol{h}_i - B\boldsymbol{h}_j)^T (B\boldsymbol{h}_i - B\boldsymbol{h}_j)} \tag{1}$$

between $\boldsymbol{h}_i$ and $\boldsymbol{h}_j$ is optimized towards the distance between two words in the dependency graph $d_P(w_i, w_j)$, i.e. the number of edges between the words. For each sentence, the loss is defined as the mean absolute difference across all word pairs:

$$\mathcal{L}_B(s) = \frac{1}{N^2} \sum_{i=0}^{N} \sum_{j=0}^{N} \left| d_P(w_i, w_j) - d_B(\boldsymbol{h}_i, \boldsymbol{h}_j) \right|. \tag{2}$$

In order to extract an undirected dependency graph, one computes the distances for a sentence's word pairs using d_B and extracts the minimum spanning tree (Jarník, 1930; Prim, 1957; MST).

3.2 Directed Probing

Apart from the structural probe B, Hewitt and Manning (2019) also probe for tree depth. Using another matrix $C \in \mathbb{R}^{e \times c}$, a subspace is learned in which the squared L_2 norm of a transformed embedding $\|C\boldsymbol{h}_i\|_2^2$ corresponds to a word's depth in the tree, i.e. the number of edges from the root.

Kulmizev et al. (2020) combine the structural and tree depth probe to extract directed graphs.

This directed probe (DIRPROBE) constructs a score matrix $M \in \mathbb{R}^{N \times N}$ for which each entry corresponds to a word pair's negative structural distance $-d_B(\boldsymbol{h}_i, \boldsymbol{h}_j)$. The shallowest node in the depth subspace C is set as root. Entries in M which correspond to an edge between w_i and w_j for which the word depths follow $\|C\boldsymbol{h}_i\|_2^2 > \|C\boldsymbol{h}_j\|_2^2$ are set to $-\infty$. A word's depth in subspace C therefore corresponds to edge directionality. The directed graph is built from M using Chu-Liu-Edmonds decoding (Chu and Liu, 1965; Edmonds, 1967).

DIRPROBE extracts directed dependency parse trees, however it would require additional complexity to label each edge with a relation (e.g. using an additional probe). In the following, we propose a probe which can extract both directionality and relations while using fewer parameters and no dynamic programming-based graph-decoding algorithm.

3.3 Relational Probing

The incoming edge of each word w_i is governed by a single relation. As such the task of dependency relation classification with l relations can be simplified to a labeling task using a linear transformation $L \in \mathbb{R}^{e \times l}$ for which the probability of a word's relation r_i being of class l_k is given by:

$$p(r_i = l_k | w_i) = \text{softmax}(L\boldsymbol{h}_i)_k \qquad (3)$$

and optimization uses standard cross-entropy loss given the gold label r_i^* for each word w_i:

$$\mathcal{L}_L(s) = -\frac{1}{N}\sum_{i=0}^{N} \ln p(r_i^* | w_i) \ . \qquad (4)$$

Should dependency relations be encoded in contextualized embeddings, each dimension of the subspace L will correspond to the prevalence of information relevant to each relation, quantifiable using relation classification accuracy (RelAcc).

3.4 Constructing Dependency Parse Trees

Combining structural probing (Section 3.1) and dependency relation probing (Section 3.3), we propose a new probe for extracting fully directed and labeled dependency trees (DEPPROBE). It combines undirected graphs and relational information in a computationally efficient manner, adding labels while requiring *less* parameters than prior unlabeled or multi-layer-perceptron-based approaches.

As outlined in Algorithm 1 and illustrated in Figure 1, DEPPROBE uses the distance matrix D_B derived from the structural probe B in conjunction with the relation probabilities of the relational probe L (line 1). The graph is first rooted using the word w_r for which $p(\text{root}|w_r)$ is highest (line 2). Iterating over the remaining words until all w_j are covered in $\mathcal{T}_w$, an edge is drawn to each word w_j from its head w_i based on the minimum distance in D_B. The relation r_j for an edge $(\overrightarrow{w_i, w_j}, r_j)$ is determined by taking the relation label l_k which maximizes $p(r_j = l_k | w_j)$ with $l_k \neq$ root (line 6). The edge is then added to the set of labeled tree edges $\mathcal{T}_e$. With edge directionality being inferred as simply pointing away from the root, this procedure produces a dependency graph that is both directed and labeled without the need for additional complexity, running in $\mathcal{O}(n^2)$ while dynamic programming-based decoding such as DIRPROBE have runtimes of up to $\mathcal{O}(n^3)$ (Stanojević and Cohen, 2021).

Algorithm 1: DEPPROBE Inference

```
1  input Distance matrix $D_B \in \mathbb{R}^{N \times N}$,
     $p(l_k|w_i)$ of relation label $l_k$ given $w_i$
2  $w_r \leftarrow \underset{w_i}{\text{argmax}}\ p(\text{root}|w_i)$
3  $\mathcal{T}_w \leftarrow \{w_r\}, \mathcal{T}_e \leftarrow \{\}$
4  while $|\mathcal{T}_w| < N$ do
5      $w_i, w_j \leftarrow \underset{w_i, w_j}{\text{argmin}}\ D_B(w_i \in \mathcal{T}_w, w_j)$
6      $r_j \leftarrow \underset{l_k}{\text{argmax}}\ p(l_k|w_j)$ with $l_k \neq$ root
7      $\mathcal{T}_w \leftarrow \mathcal{T}_w \cup \{w_j\}$
8      $\mathcal{T}_e \leftarrow \mathcal{T}_e \cup \{(\overrightarrow{w_i, w_j}, r_j)\}$
9  end
10 return $\mathcal{T}_e$
```

Constructing dependency trees from untuned embeddings requires the matrices B and L, totaling $e \cdot b + e \cdot l$ trainable parameters. Optimization can be performed using gradient descent on the sum of losses $\mathcal{L}_B + \mathcal{L}_L$. With $l = 37$ relations in UD, this constitutes a substantially reduced training effort compared to prior probing approaches (with subspace dimensionalities b and c typically set to 128) and multiple magnitudes fewer fine-tuned parameters than for a full biaffine attention parser.

4 Experiments

4.1 Setup

Parsers In our experiments, we use the deep biaffine attention parser (BAP) by Dozat and Manning (2017) as implemented in van der Goot et al. (2021) as an upper bound for MLM-based parsing performance. As it is closest to our work, we further reimplement DIRPROBE (Kulmizev et al., 2020) with $b = 128$ and $c = 128$. Note that this approach produces directed, but unlabeled dependency graphs. Finally, we compare both methods to our directed and labeled probing approach, DEPPROBE with $b = 128$ and $l = 37$.

All methods use mBERT (Devlin et al., 2019) as their encoder ($e = 768$). For BAP, training the model includes fine-tuning the encoder's parameters, while for both probes they remain fixed and only the linear transformations are adjusted. This results in 183M tuned parameters for BAP, 197k for DIRPROBE and 127k for DEPPROBE. Hyperparameters are set to the values reported by the authors,[2] while for DEPPROBE we perform an initial tuning step in Section 4.2.

Target Treebanks As targets, we use the set of 13 treebanks proposed by Kulmizev et al. (2019), using versions from Universal Dependencies v2.8 (Zeman et al., 2021). They are diverse with respect to language family, morphological complexity and script (Appendix A). This set further includes EN-EWT (Silveira et al., 2014) which has been used in prior probing work for hyperparameter tuning, allowing us to tune DEPPROBE on the same data.

Metrics We report labeled attachment scores (LAS) wherever possible (BAP, DEPPROBE) and unlabeled attachment scores (UAS) for all methods. For DEPPROBE's hyperparameters, we evaluate undirected, unlabeled attachment scores (UUAS) as well as relation classification accuracy (RelAcc). One notable difference to prior work is that we include punctuation both during training and evaluation — contrary to prior probing work which excludes all punctuation (Hewitt and Manning, 2019; Kulmizev et al., 2020; Hall Maudslay et al., 2020) — since we are interested in the full parsing task.

Training Each method is trained on each target treebank's training split and is evaluated on the test split. For cross-lingual transfer, models trained on one language are evaluated on the test splits of all other languages without any further tuning. For DEPPROBE tuning (Section 4.2) we use the development split of EN-EWT.

BAP uses the training schedule implemented in van der Goot et al. (2021) while DIRPROBE and DEPPROBE use AdamW (Loshchilov and Hutter, 2019) with a learning rate of 10^{-3} which is reduced by a factor of 10 each time the loss plateaus (see also Hewitt and Manning, 2019).

Both probing methods are implemented using PyTorch (Paszke et al., 2019) and use mBERT as implemented in the Transformers library (Wolf et al., 2020). Each model is trained with three random initializations of which we report the mean.

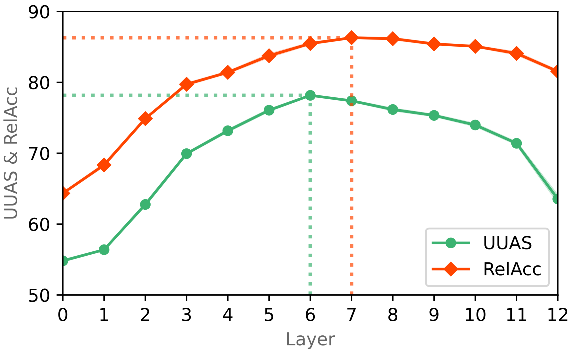

Figure 2: **Layer-wise Performance on EWT (Dev)** for DEPPROBE as measured by UUAS for the structural probe B and RelAcc for the relational probe L.

4.2 DEPPROBE Tuning

As prior work has repeatedly found that MLM layers encode different linguistic information, the layers which are most relevant for a probe's task are typically first identified (Tenney et al., 2019; Hewitt and Manning, 2019). Following this paradigm, we train DEPPROBE on embeddings from each layer of mBERT. Layer 0 is equivalent to the first, non-contextualized embeddings while layer 12 is the output of the last attention heads. The probe is trained on EN-EWT and evaluated on its development split using UUAS for the structural transformation B (akin to Hewitt and Manning, 2019) as well as RelAcc for the relational transformation L.

Figure 2 shows that structure is most prevalent around layer 6 at 78 UUAS, corroborating the 6–8 range identified by prior work (Tenney et al., 2019; Hewitt and Manning, 2019; Chi et al., 2020). Dependency relations are easiest to retrieve at around layer 7 with an accuracy of 86%. The standard deviation across initializations is around 0.1 in both cases. Based on these tuning results, we use layer 6 for structural probing and layer 7 for relational probing in the following experiments.

---

[2] For better comparability, we use the best single layer reported by Kulmizev et al. (2020) instead of the weighted sum over all layers.

(f) DIRPROBE (UAS)

Figure 3: **In-language and Cross-lingual Transfer Performance** for 13 target treebanks (**train** → test) in UAS for BAP (fully tuned parser), DEPPROBE, DIRPROBE and LAS for BAP, DEPPROBE (DIRPROBE is unlabeled).

4.3 Parsing Performance

Figure 3 lists UAS for all methods and LAS for BAP and DEPPROBE both on target-language test data (=L) and zero-shot transfer targets (¬L). Table 3c further shows the mean results for each setting.

Unsurprisingly, the full parametrization of BAP performs best, with in-language scores of 88 LAS and 91 UAS. For zero-shot transfer, these scores drop to 35 LAS and 52 UAS, with some language pairs seeing differences of up to 85 points: e.g. JA → JA (93 LAS) versus AR → JA (8 LAS) in Figure 3a. This again confirms the importance of selecting appropriate source data for any given target.

Both probes, with their limited parametrization, fall short of the full parser's performance, but still reach up to 73 LAS and 79 UAS. DIRPROBE has a mean in-language UAS which is 3 points higher than for DEPPROBE, attributable to the more complex decoder. Due to DIRPROBE's output structures being unlabeled, we cannot compare LAS.

DEPPROBE reaches a competitive 67 UAS despite its much simpler decoding procedure and appears to be more stable for zero-shot transfer as it outperforms DIRPROBE by around 2 UAS while maintaining a lower standard deviation. Most importantly, it produces directed and *labeled* parses such that we can fully compare it to BAP. Considering that DEPPROBE has more than three orders of magnitude fewer tunable parameters, a mean in-language LAS of 60 is considerable and highlights the large degree of latent dependency information in untuned, contextual embeddings. For zero-shot transfer, the performance gap to BAP narrows to 13 LAS and 14 UAS.

4.4 Transfer Prediction

Given that DEPPROBE provides a highly parameter-efficient method for producing directed, labeled parse trees, we next investigate whether its performance patterns are indicative of the full parser's performance and could aid in selecting an appropriate source treebank for a given target without having to train the 183 million parameters of BAP.

Setup Comparing UAS and LAS of BAP with respective scores of DEPPROBE and DIRPROBE, we compute the Pearson correlation coefficient ρ and the weighted Kendall's τ_w (Vigna, 2015). The latter can be interpreted as corresponding to a cor-

MODEL	LAS		UAS	
	ρ	τ_w	ρ	τ_w
L2V	.86	.72	.80	.70
DIRPROBE	—	—	.91	.81
DEPPROBE	**.97**	**.88**	.94	.85

Table 1: **Transfer Correlation with BAP.** Pearson ρ and weighted Kendall's τ_w for BAP's LAS and UAS with respect to DIRPROBE's UAS, DEPPROBE's UAS and LAS as well as lang2vec cosine similarity (L2V).

MODEL	LAS		UAS	
	ρ	τ_w	ρ	τ_w
SSA-STRUCT	.68	.42	.60	.43
SSA-DEPTH	.62	.34	.53	.35
SSA-REL	**.73**	**.55**	.65	.53

Table 2: **SSA Correlation with BAP.** Pearson ρ and weighted Kendall's τ_w for BAP's LAS and UAS with respect to subspace angles between structural (STRUCT), depth (DEPTH) and relation probes (REL).

relation in $[-1, 1]$, and that given a probe ranking one source treebank over another, the probability of this higher rank corresponding to higher performance in the full parser is $\frac{\tau_w+1}{2}$. All reported correlations are significant at $p < 0.001$. Similarly, differences between correlation coefficients are also significant at $p < 0.001$ as measured using a standard Z-test. In addition to the probes, we also compare against a method commonly employed by practitioners by using the cosine similarity of typological features from the URIEL database as represented in lang2vec (Littell et al., 2017; L2V) between our 13 targets (details in Appendix A).

Results Table 1 shows that the L2V baseline correlates with final parser performance, but that actual dependency parses yield significantly higher correlation and predictive power. For UAS, we find that despite having similar attachment scores, DEPPROBE performance correlates higher with BAP than that of DIRPROBE, both with respect to predicting the ability to parse any particular language as well as ranking the best source to transfer from. Using the labeled parse trees of DEPPROBE results in almost perfect correlation with BAP's LAS at $\rho = .97$ as well as a τ_w of .88, highlighting the importance of modeling the full task and including dependency relation information. Using Kendall's τ_w with respect to LAS, we can estimate that selecting the highest performing source treebank from DEPPROBE to train the full parser will be the best choice 94% of the time for any treebank pair.

5 Analysis

5.1 Tree Depth versus Relations

Why does DEPPROBE predict transfer performance more accurately than DIRPROBE despite its simpler architecture? As each probe consists only of two matrices optimized to extract tree structural, depth or relational information, we can directly compare the similarity of all task-relevant parameters across languages against the full BAP's cross-lingual performance.

In order to measure the similarity of probe matrices from different languages, we use mean subspace angles (Knyazev and Argentati, 2002; SSA), similarly to prior probing work (Chi et al., 2020). Intuitively, SSA quantifies the energy required to transform one matrix to another by converting the singular values of the transformation into angles between 0°and 90°. SSAs are computed for the structural probe (SSA-STRUCT) which is equivalent in both methods, DIRPROBE's depth probe (SSA-DEPTH) and DEPPROBE's relational probe (SSA-REL). We use Pearson ρ and the weighted Kendall's τ_w to measure the correlation between cross-lingual probe SSAs and BAP performance. This allows us to investigate which type of information is most important for final parsing performance.

From Table 2, we can observe that SSAs between probes of different languages correlate less with transfer performance than UAS or LAS (Table 1), underlining the importance of extracting full parses. Among the different types of dependency information, we observe that SSAs between the *relational* probes used by DEPPROBE correlate highest with final performance at .73 for LAS and .65 for UAS. Structural probing correlates significantly both with BAP's LAS and UAS at .68 and .60 respectively, but to a lesser degree. Probes for tree depth have the lowest correlation at .62 for LAS and .53 for UAS. Despite tree depth being a distinctive syntactic feature for language pairs such as the agglutinative Turkish and the more function word-based English, depth is either not as relevant for BAP or may be represented less consistently in embeddings across languages, leading to lower correlation between SSAs and final performance.

5.2 Full Parser versus Probe

In the following analysis we investigate performance differences between the full BAP and DEPPROBE across all 13 targets in order to identify finer-grained limitations of the linear approach and also which kinds of dependencies benefit from full parameter tuning and non-linear decoding.

Edge Length Figure 5 shows offsets between gold and predicted head positions. The majority of heads are predicted correctly with a ratio of 92.1% for BAP and 69.7% for DEPPROBE. Both methods are less accurate in predicting long-distance edges with length 150–250, resulting in offsets of ca. 100 (aggregated into $<$ and $>$ in Figure 5). Most likely, this is due to these edges' overall sparsity in the data (only 6.7% of edges cover a distance of more than 10 tokens) as well as their higher overall subjective difficulty. Nonetheless, BAP is able to capture such dependencies more accurately as shown by its lower error rates for long edges compared to those of DEPPROBE.

In addition to very distant head nodes, BAP also seems to recover more of the nuanced edges in the $[-5, 5]$ interval. This range is particularly impactful for downstream performance as the edges in our target treebanks have a median length of 2 (mean length 3.62 with $\sigma = 5.70$). The structural probing loss (Equation 2) and the simple linear parametrization of the probe are able to capture a large number of these edges as evidenced by overall low error rates, but lack the necessary expressivity in order to accurately capture all cases.

Relations Looking at RelAcc for each category in the UD taxonomy (de Marneffe et al., 2014) in Figure 4 allows us to identify where higher parametrization and more complex decoding are required for high parsing performance. While we again observe that performance on all relations is higher for BAP than for DEPPROBE, a large subset of the relations is characterized by comparable or equivalent performance. These include simple punctuation (`punct`), but also the majority of function word relations such as `aux`, `case`, `clf`, `det` and `mark` as well as coordination (e.g. `cc`, `conj`). We attribute the high performance of DEPPROBE on these relations to the fact that the words used to express them typically stem from closed classes and consequently similar embeddings: e.g., determiners "the/a/an" (EN), case markers "di/da" (IT).

Interestingly, some relations expressed through open class words are also captured by the linear probe. These include the modifiers `advmod`, `amod` and `discourse` as well as some nominal relations such as `expl`, `nmod`, `nsubj` and `nummod`. As prior work has identified PoS information in untuned embeddings (Tenney et al., 2019), the modifiers are likely benefiting from the same embedding features. The fact that DEPPROBE nonetheless identifies syntax-specific relations such as `nsubj`, and to a lesser degree `obj` and `obl`, indicates the presence of context-dependent syntactic information in addition to PoS.

The larger the set of possible words for a relation, the more difficult it is to capture with the probe. The functional `cop` (copula) relation provides an informative example: In English (and related languages), it is almost exclusively assigned to the verb "be" resulting in 85% RelAcc, while in non-European languages such as Japanese it can be ascribed to a larger set which often overlaps with other relations (e.g. `aux`) resulting in 65% RelAcc. BAP adapts to each language by tuning all parameters while DEPPROBE, using fixed embeddings, reaches competitive scores on European languages, but performs worse in non-European settings (details in Appendix B).

Besides capturing larger variation in surface forms, BAP also appears to benefit from higher expressivity when labeling clausal relations such as `ccomp`, `csubj`. These relations are often characterized not only by surface form variation, but also by PoS variation of head/child words and overlap with other relation types (e.g. clausal subjects stem from verbs or adjectives), making them difficult to distinguish in untuned embeddings. Simultaneously, they often span longer edges compared to determiners or other function words.

Another relation of particular importance is `root` as it determines the direction of all edges predicted by DEPPROBE. An analysis of the 14% RelAcc difference to BAP reveals that both methods most frequently confuse `root` with relations that fit the word's PoS, e.g. `NOUN` roots with `nsubj` or `nmod`. For the majority PoS `VERB` (70% of all `root`), we further observe that DEPPROBE predicts twice as many `xcomp` and `parataxis` confusions compared to BAP, likely attributable to their `root`-similar function in subclauses. Since their distinction hinges on context, the full parser, which also tunes the contextual encoder, is better equipped to differentiate between them.

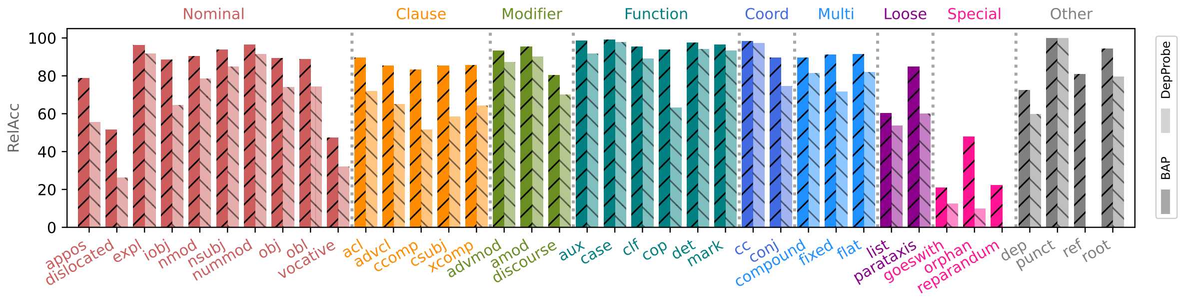

Figure 4: **Relation Accuracy of BAP and DepProbe** compared for all 13 in-language targets, grouped according to the Universal Dependencies taxonomy (de Marneffe et al., 2014).

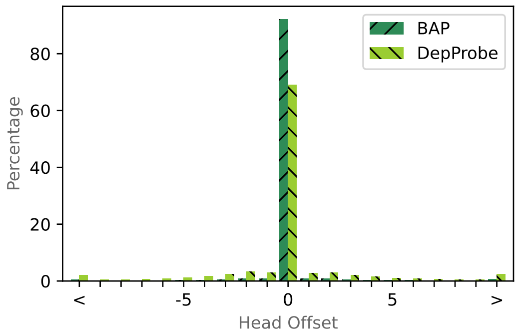

Figure 5: **Ratio of Offsets between Gold and Predicted Heads** for BAP and DepProbe (i.e. 0 is correct) across all 13 targets.

The last category in which BAP outperforms DepProbe includes rare, treebank-specific relations such as `reparandum` (reference from a corrected word to an erroneous one). Again, the larger number of tunable parameters in addition to the non-linear decoding procedure of the full parser enable it to capture more edge cases while DepProbe's linear approach can only approximate a local optimum for any relations which are represented non-linearly.

Efficiency When using a probe for performance prediction, it is important to consider its computational efficiency over the full parser's fine-tuning procedure. In terms of tunable parameters, DepProbe has 36% fewer parameters than DirProbe and three orders of magnitude fewer parameters than BAP. In practice, this translates to training times in the order of minutes instead of hours.

Despite its simple $\mathcal{O}(n^2)$ decoding procedure compared to dynamic programming-based graph-decoding algorithms ($\mathcal{O}(n^3)$), DepProbe is able to extract full dependency trees which correlate highly with downstream performance while maintaining high efficiency (Section 4.4).

6 Conclusion

With DepProbe, we have introduced a novel probing procedure to extract fully labeled and directed dependency trees from untuned, contextualized embeddings. Compared to prior approaches which extract structures lacking labels, edge directionality or both, our method retains a simple linear parametrization which is in fact more lightweight and does not require complex decoders (Section 3).

To the best of our knowledge, this is the first linear probe which can be used to estimate LAS from untuned embeddings. Using this property, we evaluated the predictive power of DepProbe on cross-lingual parsing with respect to the transfer performance of a fully fine-tuned biaffine attention parser. Across the considered 169 language pairs, DepProbe is surprisingly effective: Its LAS correlates significantly ($p < 0.001$) and most highly compared with unlabeled probes or competitive language feature baselines, choosing the best source treebank in 94% of all cases (Section 4).

Leveraging the linearity of the probe to analyze structural and relational subspaces in mBERT embeddings, we find that dependency *relation* information is particularly important for parsing performance and cross-lingual transferability, compared to both tree depth and structure. DepProbe, which models structure and relations, is able to recover many functional and syntactic relations with competitive accuracy to the full BAP (Section 5).

Finally, the substantially higher efficiency of DepProbe with respect to time and compute make it suitable for accurate parsing performance prediction. As contemporary performance prediction methods lack formulations for graphical tasks and handcrafted features such as lang2vec are not available in all transfer settings (e.g. document domains, MLM encoder choice), we see linear approaches such as DepProbe as a valuable alternative.

Table 3: **Target Treebanks** based on Kulmizev et al. (2019) with language family (FAMILY) and total number of sentences (SIZE).

Target Treebanks Table 3 lists the 13 target treebanks based on the set by Kulmizev et al. (2019): AR-PADT (Hajič et al., 2009), EN-EWT (Silveira et al., 2014), EU-BDT (Aranzabe et al., 2015), FI-TDT (Pyysalo et al., 2015), HE-HTB (McDonald et al., 2013), HI-HDTB (Palmer et al., 2009), IT-ISDT (Bosco et al., 2014), JA-GSD (Asahara et al., 2018), KO-GSD (Chun et al., 2018), RU-SynTagRus (Droganova et al., 2018), SV-Talbanken (McDonald et al., 2013), TR-IMST (Sulubacak et al., 2016), ZH-GSD (Shen et al., 2016). In our experiments, we use these treebanks as provided in Universal Dependencies version 2.8 (Zeman et al., 2021). Each method (BAP, DEPPROBE, DIRPROBE) is trained on each target's respective training split and evaluated on each test split both in the in-language and cross-lingual setting without further fine-tuning. For the layer-hyperparameter of DEPPROBE, we use the development split of EN-EWT as in prior probing work (Hewitt and Manning, 2019).

Implementation BAP (Dozat and Manning, 2017) uses the implementation in the MaChAmp toolkit v0.2 (van der Goot et al., 2021) with the default training schedule and hyperparameters. DIRPROBE (Kulmizev et al., 2020) is reimplemented based on the authors' algorithm description and uses their reported hyperparameters. Both it and DEPPROBE (this work) are implemented in PyTorch v1.9.0 (Paszke et al., 2019) and use mBERT (`bert-base-multilingual-cased`) from the Transformers library v4.8.2 (Wolf et al., 2020). Following prior probing work, each token which is split by mBERT into multiple subwords is mean-pooled (Hewitt and Manning, 2019). For lang2vec (Littell et al., 2017), we use its `syntax_knn`, `phonology_knn` and `inventory_knn` features from v1.1.2. For our analyses (Section 5), we use numpy v1.21.0 (Harris et al., 2020), SciPy v1.7.0 (Virtanen et al., 2020) and Matplotlib v3.4.3 (Hunter, 2007).

Training Details Each model is trained on an NVIDIA A100 GPU with 40GBs of VRAM and an AMD Epyc 7662 CPU. Mean training time for BAP is ca. 2 h (± 30 min). DIRPROBE requires around 20 min (± 5 min). DEPPROBE can be trained the fastest in around 15 min (± 5 min) with the embedding forward operation consuming most of the time. The models use batches of size 64 and both probes have an early stopping patience of 3 (max. 30 epochs) on each target's dev data. All models are initialized thrice using the random seeds 41, 42 and 43.

Reproducibility In order to ensure reproducibility for future work, we release the code for our methods and reimplementations in addition to token-level predictions (e.g. for significance testing) at https://personads.me/x/acl-2022-code.

B Additional Results

Subspace Angles (SSA) are used in Section 5.1 in order to identify which types of dependency information are most relevant to final parsing performance. Figure 6 lists all cross-lingual SSAs for the structural (Figure 6a), depth (Figure 6b) and relational probes (Figure 6c). SSA values are converted from radians to degrees $\in [0, 90]$ for improved readability. Correlation in Table 2 is calculated based on negative SSA (Chi et al., 2020).

Relation Accuracy (RelAcc) is used in Section 5.2 to analyze dependency relations which benefit from the full parametrization of BAP compared to the linear DEPPROBE. Figures 7–19 show RelAcc per language in addition to the aggregated scores in Figure 4. As noted in Section 5.2, some relations such as `cop` differ substantially across languages with respect to their realization (e.g. surface form variation). Furthermore, the set of relations represented in each target treebank may differ, especially for specializied categories.

DoCoGen: Domain Counterfactual Generation for Low Resource Domain Adaptation

Abstract

Natural language processing (NLP) algorithms have become very successful, but they still struggle when applied to out-of-distribution examples. In this paper we propose a controllable generation approach in order to deal with this domain adaptation (DA) challenge. Given an input text example, our `DoCoGen` algorithm generates a domain-counterfactual textual example (D-CON) – that is similar to the original in all aspects, including the task label, but its domain is changed to a desired one. Importantly, `DoCoGen` is trained using only unlabeled examples from multiple domains – no NLP task labels or parallel pairs of textual examples and their domain-counterfactuals are required. We show that `DoCoGen` can generate coherent counterfactuals consisting of multiple sentences. We use the D-CONs generated by `DoCoGen` to augment a sentiment classifier and a multi-label intent classifier in 20 and 78 DA setups, respectively, where source-domain labeled data is scarce. Our model outperforms strong baselines and improves the accuracy of a state-of-the-art unsupervised DA algorithm.[1]

1 Introduction

Natural Language Processing (NLP) algorithms are constantly improving and reaching significant milestones (Devlin et al., 2019; Raffel et al., 2020; Brown et al., 2020). However, such algorithms rely on the availability of sufficient labeled data and the assumption that the training and test sets are drawn from the same underlying distribution. Unfortunately, these assumptions do not hold in many cases due to the costly and labor-intensive data labeling process and since text may originate from many different domains. As generalization in low resource regimes and beyond the training distribution are still fundamental NLP challenges, NLP algorithms significantly degrade when applied to such scenarios.

Domain adaptation (DA) is an established field of research in NLP (Roark and Bacchiani, 2003; Daumé III and Marcu, 2006; Reichart and Rappoport, 2007) that attempts to explicitly address generalization beyond the training distribution (§2). DA algorithms are trained on annotated data from source domains to be effectively applied in various target domains. Indeed, DA algorithms have been developed for multiple NLP tasks throughout the last two decades (Blitzer et al., 2006, 2007; Glorot et al., 2011; Rush et al., 2012; Ziser and Reichart, 2017, 2018a,b; Han and Eisenstein, 2019).

A natural alternative to costly human annotation would be to automatically generate labeled examples for model training. Doing so may expose the model to additional training examples and better represent the data distribution within and outside the annotated source domains. Unfortunately, generating labeled textual data is challenging (Feng et al., 2021), especially when the available labeled data is scarce. Indeed, labeled data generation has hardly been applied to DA (§2).

To allow DA through labeled data generation, we present `DoCoGen`, an algorithm that generates domain-counterfactual textual examples (D-CONs). In order to do that, `DoCoGen` intervenes on the domain-specific terms of its input example, replacing them with terms that are relevant for its target domain while keeping all other properties fixed, including the task label. Consider the task of sentiment classification (top example in Table 1). When `DoCoGen` encounters an example from the *Kitchen* domain (its source domain), it first recognizes the terms related to *Kitchen* reviews, i.e., *knife* and *solid*. Then, it intervenes on these terms, replacing them with text that connects the example to the *Electronics* domain (its target domain) while keeping the negative sentiment.

`DoCoGen` is a *controllable generation* algo-

rithm (Li et al., 2016; Russo et al., 2020) that is trained using a novel *unsupervised* sentence reconstruction objective. Importantly, it does not require task-annotated data, or parallel pairs of sentences and their D-CONs. A key component of DoCoGen is the *domain orientation vector*, which guides the model to generate the new text in the desired domain. The parameters of the orientation vectors are learned during the unsupervised training process, allowing the generation model to share information among the various domains it is exposed to.

We focus on two low resource scenarios: Unsupervised domain adaptation (UDA) and any domain adaptation (ADA, Ben-David et al. (2021)), with only a handful of labeled examples available from a single source domain. In both UDA and ADA the model is exposed to limited labeled source domain data and to unlabeled data from several domains. However, in UDA the *unlabeled domains* contain the future target domain to which the model will be applied, while in ADA the model has no access to the target domain during training. To cope with these extreme conditions, we use DoCoGen to enrich the source labeled data with D-CONs from the unlabeled domains. By introducing labeled D-CONs from various domains, we hope to provide the model with a training signal that is less affected by spurious correlations: Correlations between features and the task label which do not hold out-of-domain (OOD) (Veitch et al., 2021).

After a brief evaluation of the intrinsic quality of the D-CONs generated by DoCoGen, we evaluate our complete DA pipeline. We focus on two tasks: Binary sentiment classification of reviews and multi-label intent prediction in information-seeking conversations. In both tasks, we follow the UDA and ADA scenarios, for a total of 12 and 8 sentiment setups, respectively, as well as 30 UDA and 48 ADA intent prediction setups. Our results demonstrate the superiority of DoCoGen over strong DA and textual-data augmentation algorithms. Finally, combining DoCoGen with PERL (Ben-David et al., 2020), a SOTA UDA model, yields new SOTA DA accuracy and stability.

2 Related Work

We first describe research in our DA setups: UDA and ADA. We then continue with the study of counterfactual-based data augmentation, and, finally, we describe research on counterfactual generation methods.

Domain Adaptation (DA) The NLP literature contains several DA setups, the most realistic of which is *unsupervised domain adaptation* (UDA), which assumes the availability of unlabeled data from a source and a target domain, as well as access to labeled data from the source domain (Blitzer et al., 2006). An even more challenging and potentially more realistic setup is the recently proposed *any domain adaptation* setup (ADA, Ben-David et al. (2021)), which assumes no knowledge of the target domains at training time. There are several approaches to DA, including representation learning (Blitzer et al., 2006; Ziser and Reichart, 2017) and data-centric approaches like instance re-weighting and self-training (Huang et al., 2006; Rotman and Reichart, 2019).

Since the rise of deep neural networks (DNNs), most focus in DA research has been directed to deep representation learning approaches (DReL). One line of DReL work employs an input reconstruction objective (Glorot et al., 2011; Chen et al., 2012; Yang and Eisenstein, 2014; Ganin et al., 2016). Another line employs pivot features, which are prominent to the task of interest and common in the source and target domains (Blitzer et al., 2007; Pan et al., 2010; Ziser and Reichart, 2018b; Ben-David et al., 2020; Lekhtman et al., 2021).

We deviate from the DReL approach to DA and propose a data-centric methodology. Contrary to the above works, our approach can be applied to both UDA and ADA. Moreover, unlike previous ADA work, which builds upon multi-source DA, our approach can also perform single-source ADA.

Counterfactually Augmented Data (CAD) Textual data augmentation (TDA) is a technique for increasing the training dataset without explicitly collecting new examples. This is achieved by adding slightly modified copies of already existing examples (local sampling) or newly created data (global sampling). TDA serves as a solution for insufficient data scenarios and as a technique for improving model robustness (Xie et al., 2020; Ng et al., 2020). There are rule-based and model-based approaches to TDA. Rule-based methods commonly involve insertion, deletion, swap and replacement of specific words (Wei and Zou, 2019), or template-based paraphrasing (Rosenberg et al., 2021). Model-based methods typically utilize a pretrained language model (PLM), e.g., for replacing random words (Kobayashi, 2018; Ng et al., 2020), or generating entirely new examples

Original, **Kitchen**: A good knife but Quality Control was poor. The knife is solid and very comfortable in hand, however, when I got it new, the blade is slightly bent. I expect it to be in almost perfect condition, but it's not.
`DoCoGen`, **Kitchen → Electronics**: A good product but Quality Control was poor. The ipod is very easy to use and very comfortable in hand, however, when I got it new, the ipod is slightly flimsy. I expect it to be in almost perfect shape, but it's not.
Original, **DVD**: The direction of this film is excellent. I love all the characters and the way they interact. The storyline is very important also. It's about religious beliefs and neighbors that interact with each other. It's a well-paced and interesting story that's not like anything else I've ever seen.
`DoCoGen`, **DVD → Airline**: The service on this flight is excellent. I love the staff and the way they interact. The safety is very important also. It's nice to have staff and neighbors that can help each other. It's a well-groomed and professional crew that's not like anything else I've ever experienced.
Original, **Electronics**: That relay board is only good for switching AC loads of 100V or more. If you have a lower voltage load, it's not going to work. For low voltage loads use transistors, MOSFETs or a ULN2803 driver board.
`DoCoGen`, **Electronics → Statistics**: That model is only good for data of n or more. If you have a lower n, it's not going to work. For lower n regression use a linear, logistic or a t-test.

Table 1: Domain-counterfactual textual examples (D-CONs) generated by `DoCoGen`. Red terms are replaced with green terms through the process of D-CON generation. For additional examples see §A.

from a prior data-distribution (Bowman et al., 2016; Russo et al., 2020; Wang et al., 2021). Other model-based methods apply backtranslation (Edunov et al., 2018) or paraphrasing (Kumar et al., 2019) for local sampling.

Another approach within local sampling TDA is to change (only) a specific concept that exists in the original example, creating a counterfactual example. Counterfactually-Augmented Data (CAD) is generated by minimally intervening on examples to change their ground-truth label, that is, perturbing only those terms necessary to change the label (Kaushik et al., 2020). CAD is commonly used to improve generalizability (Kaushik et al., 2020; Sen et al., 2021), however empirical results using CAD for OOD generalization have been mixed (Joshi and He, 2021; Khashabi et al., 2020).

In this work, we explore a different type of counterfactuals, namely D-CONs, which are the result of intervening only on the example's domain while holding everything else equal, particularly its task label. For sentiment analysis, we may be, for example, interested in revising a negative movie review, making it a negative airline review. In addition, while CAD is mostly generated via a human-in-the-loop process (Kaushik et al., 2020; Khashabi et al., 2020; Sen et al., 2021), our work focuses on automatic counterfactual generation.

Counterfactual Generation *controllable generation* refers to generation of text while controlling for specific attributes (Prabhumoye et al., 2020). The controlled attributes can range from style (e.g., politeness and sentiment) to content (e.g., keywords and entities) and even topic. Keskar et al. (2019) propose to control the generated text by training an LM on datasets annotated with the controlled attributes, and Meister et al. (2020) modify the model's decoding method. Recently, Russo et al. (2020) introduced a global sampling conditional variational autoencoder (VAE), augmenting text while controlling for attributes such as label and verb tense. However, controlling for the task label is challenging in scarce labeled data scenarios (Chen et al., 2021), since generative models require large amounts of labeled data .

Counterfactual generation lies at the intersection of controllable generation and causal inference (Feder et al., 2021a). Only few works deal with counterfactual generation, mostly by intervening on the task label. Wu et al. (2021) train a model on textual examples and their manually generated counterfactuals. Other works present methods for controlling for the text domain and semantics (Wang et al., 2020; Feng et al., 2019), yet they all experiment with short texts, while our model can generate longer texts, consisting of multiple sentences. A recent work by Yu et al. (2021) focuses on generation of new target-domain examples for aspect-based sentiment analysis (ABSA) (Pontiki et al., 2016). However, this method is designed specifically for ABSA, utilizing predefined knowledge, and is only suitable for UDA setups where source domain labeled data is abundant. Our work presents a novel domain counterfactual generation algorithm, which can be trained in an unsupervised manner, and its generated outputs are demonstrated to be effective in multiple low-resource DA tasks.

3 Domain-Counterfactual Examples

In this section, we formally define the concept of domain-counterfactual textual examples (D-CONs) and discuss the motivation behind them.

Definition x' is a *domain-counterfactual example* (D-CON) of x if it is a coherent human-like text that is a result of intervening on the domain of x and changing it to another domain, while holding everything else equal. Particularly, we would like the task label of x' and x to be identical. Formally, given an example $(x, y) \sim \mathcal{D}$ and a destination domain $\mathcal{D}'$, the goal of D-CON generation is to generate $x' \sim P_{\mathcal{D}'}(X|Y = y)$ such that $x' \simeq_{\mathcal{D}'} x$, where $\simeq_{\mathcal{D}'}$ is the domain counterfactual operator.

In this work, given a labeled source example x we aim to generate coherent human-like D-CONs from the unlabeled domains (see §1). We propose a D-CON generation algorithm, DoCoGen, consisting of two components. The first involves masking domain specific terms of the given example, yielding $\mathtt{M}(x)$. The second is a controllable generation model $\mathtt{G}$ which takes as input $\mathtt{M}(x)$ and a *domain orientation vector* v'. This vector specifies the destination domain $\mathcal{D}'$, controlling the semantics of the generated D-CON. Formally:

$$\mathtt{DoCoGen}(x, \mathcal{D}') = \mathtt{G}(\mathtt{M}(x), v') \simeq_{\mathcal{D}'} x$$

Motivation The NLP community has recently become increasingly concerned with *spurious correlations* (Geirhos et al., 2020; Wang and Culotta, 2020; Gardner et al., 2021). In the case of DA, spurious correlations may be defined as correlations between X and Y which are relevant only to a specific domain or in a certain sample of labeled examples. Such correlations may make a predictor $f : \mathcal{X} \rightarrow \mathcal{Y}$ brittle to domain shifts.

Using counterfactuals w.r.t. a specific variable allows us to both estimate its effect on our predictor (Feder et al., 2021b; Rosenberg et al., 2021) or alleviate its impact on it (Kaushik et al., 2021). We focus on the latter, automatically generating D-CONs by intervening on the domain variable $\mathcal{D}$. Adding these D-CONs to the training set of a predictor should reduce its reliance on domain-specific information and spurious correlations.

From a DA perspective, enriching the training data with D-CONs is motivated by pivot features (§2), which are frequent in multiple domains and are prominent for the task. D-CONs preserve language patterns, such as pivots, which are frequent in multiple domains. Consider the middle example in Table 1, pivot words (such as *excellent* and *important*) are preserved in the D-CON, while non-pivots (*intereseting* and *well-paced*) are replaced due to the domain intervention. Accordingly, a model trained on an example and its D-CON is directed to focus on pivots rather than on non-pivots, consequently generalizing better OOD.

4 DoCoGen: Domain Counterfactual Generation

We propose a corrupt-and-reconstruct approach for generating D-CONs from given source domain examples (Figure 1). We next extend on these two steps, and describe our filtering mechanism used to disqualify low quality D-CONs.

4.1 Domain Corruption

The first step of generating a D-CON is to mask domain specific terms. In order to mask an example $x \sim \mathcal{D}$ with a destination domain $\mathcal{D}'$, we first mask all uni-grams w with $\mathtt{m}(w, \mathcal{D}, \mathcal{D}') > \tau$, where τ is a hyperparameter and $\mathtt{m}$ is a masking score that is defined later in this section. Then, we mask all the remaining bi-grams (that do not contain a masked uni-gram) according to the same masking threshold τ. This process is repeated up to tri-gram expressions. The final output of the corruption step is a masked example $\mathtt{M}(x)$.

In Figure 1, the masking scores of uni-grams and bi-grams appear above the input words. An n-gram is masked if and only if its score is above a $\tau = 0.08$ threshold and the scores of its grams are lower. For example, *system* is not masked although the bi-gram *entertainment system* has a score above the τ threshold, since *entertainment* is masked and the score of *system* is lower than τ.

Masking Score Let w be an n-gram and $\mathcal{D}$ be a domain with $n_{\mathcal{D}}$ unlabeled examples. We denote the number of examples from $\mathcal{D}$ that contain w by $\#_{w|\mathcal{D}}$. By assuming that domains have equal prior probabilities and by using the Bayes' rule, the probability of $\mathcal{D}$ given w can be estimated by $P(D = \mathcal{D}|W = w) \propto \frac{\#_{w|\mathcal{D}} + \alpha}{n_{\mathcal{D}}}$, where α is a smoothing hyperparameter. We define the affinity of w to $\mathcal{D}$ to be:

$$\rho(w, \mathcal{D}) = P(\mathcal{D}|w) \cdot \left(1 - \frac{H(D|w)}{\log N}\right)$$

where N is the number of unlabeled domains and $H(D|w)$ is the entropy of $D|w$, which is upper

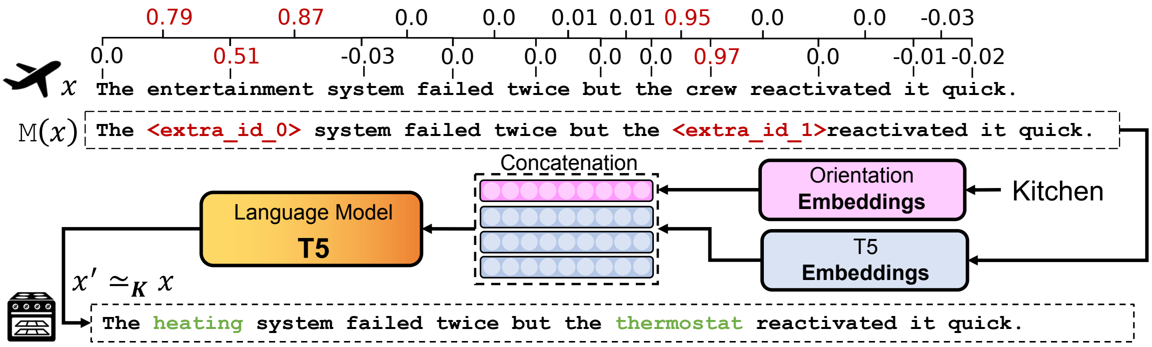

Figure 1: The `DoCoGen` model. Given a review x from the *airline* domain, we aim to generate a D-CON from the *kitchen* domain. We first corrupt the domain of the example by masking domain specific terms. The numbers above the input words are the masking scores of uni-grams and bi-grams. Terms with scores above a threshold ($\tau = 0.08$) are masked. In the reconstruction step we use a T5-based generation model to generate the D-CON $x' \simeq_{\mathbf{K}} x$. The input of the model is a concatenation of the *orientation vector* that represents the target domain with the model's embedding vectors which correspond to the tokens of the masked example $\mathtt{M}(x)$.

bounded by $\log N$. Notice that higher $H(D|w)$ values indicate that w is not related to any specific domain. Finally, we set the masking score of an n-gram w with an origin domain $\mathcal{D}$ and a destination domain $\mathcal{D}'$ as follows:

$$\mathtt{m}(w, \mathcal{D}, \mathcal{D}') = \rho(w, \mathcal{D}) - \rho(w, \mathcal{D}')$$

Note that $\mathtt{m}(w, \mathcal{D}, \mathcal{D}') \in [-1, 1]$. It can be negative due to the right hand side's subtrahend, which aims to prevent masking n-grams that are related to the destination domain and should appear in the counterfactual, like *system* in Figure 1.

4.2 Domain-Oriented Reconstruction

The second step of `DoCoGen` is a reconstruction step that involves a generative model, based on an encoder-decoder T5 architecture (Raffel et al., 2020). Given a masked example $\mathtt{M}(x)$ and a destination domain $\mathcal{D}'$, we concatenate a domain orientation vector v' that represents $\mathcal{D}'$ with the masked input's embedding vectors. Then, the concatenated matrix is passed as an input to the encoder-decoder model for counterfactual generation, yielding x'. We next describe the mechanism behind domain orientation vectors.

Domain Orientation Vectors In addition to the T5 embedding matrix (T5 Embeddings in Figure 1), we equip our model with another learnable embedding matrix, containing $K \cdot N$ orientation vectors, such that each domain is represented by K different vectors (Orientation Embeddings in Figure 1). We initialize the orientation vectors with the T5 embedding vectors of the domain names and the top $K-1$ *representing words* of each domain. The top representing words of domain $\mathcal{D}$ are those which reach the highest score of: $\log\left(\#_{w|\mathcal{D}} + 1\right)\rho(w, \mathcal{D})$. We use K orientation vectors to allow us generate a heterogeneous set of D-CONs for a given destination domain (see examples in §A). We note that although the orientation vectors are initialized with vectors from the T5 embedding matrix, they have a different role and thus are likely to converge to different values during the training process.

Training In the spirit of low resource learning, we would like to train `DoCoGen` in an unsupervised manner, i.e., without access to manually generated D-CONs. Therefore, we use the unlabeled data of our unlabeled domains. For each example x, we provide the model with $\mathtt{M}(x)$, the corrupted version of x, and v, the orientation vector of $\mathcal{D}$, and with x as the gold output. The model hence learns to reconstruct x given $\mathtt{M}(x)$ and v.

Notice that the origin and the destination domains are the same, i.e, $\mathcal{D} = \mathcal{D}'$, and the masking score is $\mathtt{m}(w, \mathcal{D}, \mathcal{D}) = 0$. Hence, for masking purposes, we randomly choose $\tilde{\mathcal{D}} \neq \mathcal{D}$ and plug it as the destination domain in the masking score. We then choose an orientation v for $\mathcal{D}$, by randomly sampling either the domain name or one of its representing words as long as it appears in x.

Finally, since the orientation vector parameters are trained as part of the reconstruction objective, we establish the connection between the orientation vector and the semantics of the completed example. Hence, we expect that at inference time examples will be properly transformed into their D-CONs.

Inference Given $(x, \mathcal{D}, \mathcal{D}')$, we first mask the example to get $\mathtt{M}(x)$ and select one orientation vector v' that represents $\mathcal{D}'$.[2] Together, the tuple $(\mathtt{M}(x), v')$ forms the input, and accordingly the model generates a D-CON $x' \simeq_{\mathcal{D}'} x$. To increase the likelihood that x' originates from $\mathcal{D}'$, we restrict the model to generate only tokens of the original example or tokens that are related to $\mathcal{D}'$ and meet the condition: $\max_{i \in 1,...,N} \mathtt{m}(w, \mathcal{D}', \mathcal{D}_i) > \tau$.

4.3 Filtering Mechanism

In order to properly apply `DoCoGen` within a DA pipeline, we introduce a filtering mechanism that disqualifies low quality D-CONs generated by `DoCoGen`. Particularly, we train a classifier to predict the domain of the original, human-written unlabeled examples, and use it to remove D-CONs if their predicted domain is not the given destination domain. In addition, we disqualify D-CONs with less than four words or when the word overlap with the original example is lower than 25%. We name `DoCoGen` when equipped with this filtering mechanism `F-DoCoGen`.

5 Intrinsic Evaluation

We next assess `DoCoGen` in terms of its generated D-CONs, ensuring they: (i) belong to the correct domain and label (1, 2), and (ii) are fluent (3, 4). To this end, we collected 20 original reviews, equally distributed among four domains (the A, D, E, and K domains, see §6). We then applied `DoCoGen` to generate 60 D-CONs, 3 for each of the original reviews (see §6 for the `DoCoGen` training setup). Finally, we trained the `VAE` model of Russo et al. (2020) on labeled data (all the labeled data of the A, D, E, and K domains) and applied it to generate five reviews from each of the above four domains, with the same number of positive and negative reviews as in the set of original reviews.

We then conducted a crowd-sourcing experiment where five nearly native English speakers rated each example, considering the following evaluation measures: (1) Domain relevance (D.REL) - whether the topic of the generated text is related to its destination domain; (2) Label preservation (L.PRES) - what is the label of the generated example (and we report whether the answer was identical to the desired label); (3) Linguistic Acceptability (ACCPT) - how logical and grammatical the example is (on a 1-5 scale); and (4) Word error rate (WER) - what is the minimum number of word substitutions, deletions, and insertions that have to be performed to make the example logical and grammatical.[3]

	↑D.REL	↑L.PRES	↑ACCPT	↓WER
`VAE`	90.0	46.0	2.11	0.54
`DoCoGen`	93.0	80.0	4.01	0.17
`Original Reviews`	99.0	88.0	4.73	0.10

Table 2: Human intrinsic evaluation. Up arrows (↑) represent metrics where higher scores are better, and down arrows (↓) represent the opposite.

Table 2 reports our results. `DoCoGen` achieves high ACCPT scores and low WER scores, significantly outperforming its `VAE` alternative, which is known to struggle with longer texts (Shen et al., 2019; Iqbal and Qureshi, 2020). Interestingly, `DoCoGen` achieves compatible results to the original reviews, indicating the high quality of its generated texts. Finally, in more than 90% of the cases `DoCoGen` manages to change the example domain to the desired domain, and in 80% it preserves the original example label. In comparison, only 88% of the original examples were annotated as their gold label.

6 Experimental Setup

6.1 Tasks and Domains[4]

In this subsection we describe our tasks and datasets, as well as the two DA setups which are the focus of this work. A full description of the number of samples in each dataset is found in Table 6.

Sentiment Classification We follow a large body of prior DA work, focusing on the task of binary sentiment classification. Specifically, our experiments include six different domains: the four legacy product review domains (Blitzer et al., 2007) - Books (B), DVDs (D), Electronic items (E) and Kitchen appliances (K); the challenging airline review dataset (A) (Nguyen, 2015; Ziser and Reichart, 2018b); and the restaurant (R) domain obtained from the Yelp dataset challenge (Zhang et al., 2015). The focus of this work is on low resource DA, and thus we randomly sample 100 labeled examples to form the training set for the following domains: A, D, E, and K.

As described in §2, we explore two DA setups, UDA and ADA. For UDA, where the model has

---

[2] §B.3 presents the % of masked tokens in our experiments.

[3] We actually asked the annotators to edit the example and then measured the number of edit operations.

[4] URLs of the datasets and the code, implementation and hyperparameter details are described in §B.

access to unlabeled target domain data, we experiment with 12 cross-domain setups, including the following domains: A, D, E, and K. For ADA, where unlabeled data from the target domain is not within reach, we experiment with a total of 8 setups, including B and R as target domains, and A, D, E, and K as source domains. Our reported accuracy scores are averaged across 25 different seeds and randomly sampled training and development sets.

Multi-label intent prediction Our second task is multi-label intent prediction of utterances from information-seeking conversations. We use the multi-domain MANtIS dataset (Penha et al., 2019), consisting of diverse conversations from the question-answering Stack Exchange portal. The authors provide manually annotated user intent utterances, with eight possible intent labels, such as *information request*, *potential answer* and *greetings*. Since we focus on low resource scenarios, we use only the five most common labels, as the frequency of the other three labels is less than 5%, and in some domains they are completely missing.

The MANtIS dataset consists of 14 domains: Apple (AP), DBA (DB), Electronics (EL), Physics (PH), Statistics (ST), askubuntu (UB); DIY (DI), English (EN), Gaming (GA), GIS (GI), Sci-Fi (SC), Security (SE), Travel (TR) and Worldbuilding (WO). We use the first 6 domains as unlabeled domains, randomly sampling train, development and test sets for each. The remaining 8 domains are used as target domains in the ADA setup, resulting in 30 UDA (6 × 5) and 48 ADA (6 × 8) setups.

Following Penha et al. (2019), we use the (Macro) F1-score to measure classifier performances, and, like in the sentiment classification task, our reported results are averaged across 25 different seeds and randomly sampled training sets.

DA by Augmentation The DA pipeline includes a T5-based sentiment classifier trained on labeled data from a single source domain and an augmentation model (e.g., `DoCoGen`) trained on unlabeled data from four unlabeled domains. We first train `DoCoGen` on the unlabeled data, and then use it for generating D-CONs that enrich the classifier's training data. For each labeled training example, `DoCoGen` generates $K = 4$ D-CONs w.r.t. each unlabeled domain, resulting in a total of 16 D-CONs per example. After training the sentiment classifier on the enriched data, we evaluate it on test examples originating from one of the unlabeled domains (UDA) or one of the unseen domains (ADA). We denote each DA model by the algorithm that was used for enriching its training data.

6.2 Models and Baselines

Our main models are `DoCoGen` and `F-DoCoGen`, which is equipped with the filtering mechanism. We compare them to three types of models: (a) baseline models, including both baselines for the entire DA pipeline (1,2,5) and alternative augmentation methods (3,4); (b) ablation models (6,7) that use variants of our D-CON generation algorithm where one component is modified, highlighting the importance of our design choices; and (c) an upper-bound generation model that has access to labeled data from the target domains. Unless otherwise stated, all sentiment classifiers use the same architecture, based on a pre-trained T5 model. We next describe the models in each of these groups.

Baseline DA Models We experiment with five baselines: (1) *No-Domain-Adaptation* (`NoDA`), A model that is only trained on the available training data from the source domain in each DA setup; (2) *Domain-Adversarial-Neural-Network* (`DANN`), A model that integrates the sentiment analysis predictive task with an adversarial domain classifier to learn domain invariant representations (Ganin et al., 2016). This model does not apply augmentation, but instead the unlabeled data is used for training its adversarial component; (3) *Easy-Data-Augmentation (`EDA`)*, an augmentation method that randomly inserts, swaps, and deletes words or replaces synonyms (Wei and Zou, 2019); (4) *Random-masking Random-Reconstructing* (`RM-RR`), another basic augmentation method that randomly masks tokens from the input example and then fills the masks with tokens that are chosen by a masked language modeling head, as suggested by (Ng et al., 2020); and (5) *PERL*, a SOTA model for the UDA setup (Ben-David et al., 2020).

Ablation Models We consider two variants of `DoCoGen`: (6) *No-Orientation-Vectors* (`No-OV`), a generation model that masks tokens by employing a similar masking mechanism as `DoCoGen`, and then employing a masked language modeling head to fill the masked tokens (without domain orientation vectors); and (7) *Random-Masking with Orientation-Vectors* (`RM-OV`), a generation model that randomly masks tokens from the input example and then employs the `DoCoGen`'s reconstruction mechanism to fill the masks.

Table 4: Sentiment classification: accuracy scores for each source and target domain pair in the ADA setup.

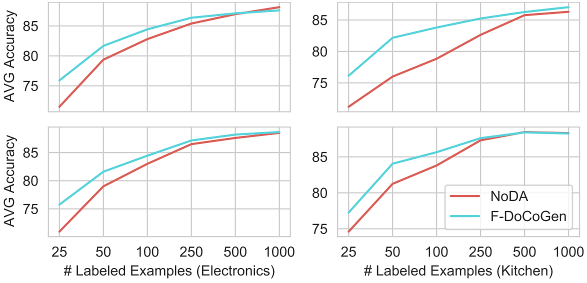

Figure 2: Average accuracy in UDA (top) and ADA (bottom) setups with different number of labeled examples from two source domains: E and K.

Upper-Bound We implement an upper-bound model for D-CON augmentation, *Oracle-Matching* (`Oracle-Gen`). Unlike all other models in this work, `Oracle-Gen` has access to target domain labeled data. Thus, given an example from a source domain, `Oracle-Gen` looks for the most similar example with the same label in the target domain, and adds it to its training data (see §B.1).

7 Results

Tables 3 and 4 present sentiment classification accuracy results for the 12 UDA and 8 ADA setups, respectively. Table 5 presents the average intent prediction F1 scores for each source domain, taken across all target domains, in both UDA and ADA.

D-CON Generation Impact For sentiment classification, our model, `F-DoCoGen`, outperforms all baseline models (`NoDA`, `DANN`, `EDA`, and `RM-RR`) in 10 of 12 UDA setups and in all ADA setups, exhibiting average performance gains of 1.9% and 1.3% over the best performing baseline model in the UDA (`DANN`) and the ADA (`RM-RR`) setups, respectively. Moreover, `DoCoGen` without filtering, is also superior to all baselines, reaching average gains of 1.6% and of 0.6% across all UDA and ADA setups, respectively. For intent prediction, `DoCoGen` (without filtering) is the best performing model, outperforming all baselines across all setups, and reaching average gains of 1.6% and 1.5% across all UDA and ADA setups, respectively. Since many intent examples are not domain-specific, our filtering mechanism tends to easily remove their `DoCoGen` generated D-CONs. We believe that this is the reason for the small degradation in `F-DoCoGen` performance compared to `DoCoGen`. However, `F-DoCoGen` still consistently outperforms all baselines. These results highlight the impact of D-CON generation on model robustness in low-resource setups. Finally, our models are also stable: Their std is lower than all baselines (see §C.1).

Ablation Models The tables further demonstrate that `F-DoCoGen` outperforms its ablation models (§ 6.2), namely `No-OV` and `RM-OV`, in 10 of 12 and 7 of 8 UDA and ADA sentiment classification setups, respectively, and the same holds for `DoCoGen` across all intent prediction setups. Furthermore, in sentiment classification, `F-DoCoGen` achieves an average error reduction of 11.2% and 5.0% in UDA and ADA, respectively, over the strongest ablation model (`RM-OV`), while in intent prediction `DoCoGen` achieves a reduction of 8% and 7.6%, in both setups, respectively. Table 5: Intent prediction: F1 scores for UDA and ADA intent prediction. We report the average F1 score across five or seven target domains (UDA and ADA setups respectively).

nally, our results demonstrate the importance of inappropriate D-CONs disqualification, as in the task of sentiment classification, F-DoCoGen outperforms DoCoGen in 8 of 12 UDA setups and in all ADA setups. On the other hand, when non domain-specific examples are frequent, filtering might lead to small performance degradation, as happens in the intent prediction task. Our results hence stress the importance of each of DoCoGen's algorithmic components, i.e. *domain-corruption* (§ 4.1 F-DoCoGen vs RM-OV) and *oriented-reconstruction* (§ 4.2 F-DoCoGen vs No-OV).

Complementary Effect with SOTA Models We notice that F-DoCoGen replicates the average performance of PERL (Ben-David et al., 2020), the UDA SOTA, in sentiment classification. However, since PERL is based on a different architecture than the rest of the models (BERT vs T5), the models are not directly comparable. PERL is a pivot-based representation learning method for DA, which applies pre-training on unlabeled target data and is hence relevant only for UDA. Since DoCoGen implements a different approach to DA (D-CON generation), we check for the complementary effect of these models: DoCoGen-PERL first augments the labeled data with D-CONs and then continues with the PERL pipeline. As reported in Table 3, DoCoGen-PERL outperforms PERL in 8 of 12 UDA setups, providing an average improvement of 0.7%. Furthermore, the average std of DoCoGen-PERL is 2.1 compared to 3.6 of PERL (§C.1). This stresses the stability of DoCoGen-PERL across these challenging setup (Ziser and Reichart, 2019).

Unfortunately, we cannot perform an equivalent comparison in the ADA setup, since its SOTA models (Ben-David et al., 2021; Wright and Augenstein, 2020) employ labeled data from multiple sources. Likewise, since PERL is not designed for multi-label prediction, we could not apply it to intent prediction. To the best of our knowledge, we are the first to effectively perform single-source ADA.

Training Size Effect We would next like to understand the effect of D-CONs generated by DoCoGen on classifiers trained with manually labeled training sets of various sizes. Figure 2 shows that the effect of D-CON augmentation vanishes when the unaugmented classifier reaches accuracy above 85% and a performance plateau (visualized as an elbow in the curve). These results support our hypotheses that low-resource DA scenarios may result in a model that latch on spurious domain correlations, impeding its performance. Accordingly, generating D-CONs by intervening on the domain essentially reduces the reliance on domain-specific information and spurious correlations.

8 Conclusions

We presented DoCoGen, a corrupt-and-reconstruct approach for generating domain-counterfactuals (D-CONs) and apply it as a data augmentation method in low-resource DA. We hypothesized that D-CONs may mitigate the reliance on domain-specific features and on spurious correlations and help generalize out of domain.

Our augmentation strategy yields robust models that outperform strong baselines across many low-resource DA setups. In future work we would like to further improve the controllable generation quality of DoCoGen, potentially extending it to control for multiple attributes. Moreover, we would like our methodology to address additional NLP tasks and DA setups.

Acknowledgements

We would like to thank the action editor and the reviewers, as well as the members of the IE@Technion NLP group for their valuable feedback and advice. This research was partially funded by an ISF personal grant No. 1625/18.

A Additional Generated Examples

We provide additional D-CONs generated by `DoCoGen` and examples generated by `VAE`.

(1) D-CONs generated by DoCoGen, for different source-target domain pairs:

(1.1) Original, **DVD**:

the best show on t.v. Somehow Denis Leary and Peter Tolan managed to improve on an already amazing show. Rescue me continues to be the best show out there.

DVD → Airline:

the best service on board. Somehow staff and flight crew were very good and Tolan managed to improve on an already amazing flight. iberia for me continues to be the best airline out there.

DVD → Electronics:

the best wireless router out there. Somehow ipaq and ethernet tolan managed to improve on an already amazing router. ethernet to me continues to be the best wireless out there.

DVD → Kitchen:

the best oven on the market. Somehow a little bit of work and chef Tolan managed to improve on an already amazing oven. this for me continues to be the best oven out there.

(1.2) Original, **Airline**:

Took flight on a one way basis as return dates were subject to change. I am a top tier AA flier and the addition to Air Berlin gives some good connection options. Aircraft was a new Airbus with standard seat pitch and seat comfort in economy was uncomfortable. The IFE is good with each seat having independent controls and a reasonable selection of movies etc. Unfortunately the selection is via a touch screen buried in your seat.

Airline → DVD:

Took this movie on a trial basis as release dates are subject to change. I am a top ten fan and the addition to the bonus disc gives some good insight. The storyline with standard actors and dialogue in the main role was well done. The plot is well done with each actor having independent controls and a reasonable script. Unfortunately the movie is not about a man who is buried in your soul.

Airline → Electronics:

Took this item on a trial basis as release dates are subject to change. I am a top ten speaker and the addition to the base gives some great options. I have an ipod with standard earbuds and the built in microphone was very nice. The sound is clear with each speaker having independent controls and a reasonable bass response. Unfortunately the remote is not a good buy buried in your pocket.

Airline → Kitchen:

Took this item on a regular basis as delivery dates are subject to change. I am a top cook and the addition to the nonstick gives some good heat retention. I use it with standard pans and the clean up in the dishwasher was easy. The pan is very nice and each pan having independent controls and a reasonable size. Unfortunately the lid is too small for a stovetop and buried in your cupboard.

(1.3) Original, **Electronics**:

"How I can test it?" perhaps you don't even need one? build a prototype circuit and test the current arrangement, and see what the noise is like. For a supposedly non-moving reference, see what the ADC is reading like. If it stays steady, and noise is less than 1 LSB, then don't do anything.

Electronics → askubuntu:

"How I can test it?" perhaps you don't even need one? remount your hard drive and test the sda arrangement, and see what the sda is like. For a supposedly non-moving reference, see what the sda is reading like. If it stays in memory, and the sda is less than 1 LSB, then don't do anything.

Electronics → DBA:

"How I can test it?" perhaps you don't even need one? build a table and test the column arrangement, and see what the index is like. For a supposedly non-moving reference, see what the index is reading like. If it stays stale, and the load is less than 1 byte, then don't do anything.

Electronics → Physics:

"How I can test it?" perhaps you don't even need one? heat it up and test the particle arrangement, and see what the velocity is like. For a supposedly non-moving reference, see what the waveform is reading like. If it stays steady, and the speed is less than 1 m/s, then don't do anything.

Electronics → Statistics:

"How I can test it?" perhaps you don't even need one? build a regression model and test the sp arrangement, and see what the plot is like. For a supposedly non-moving reference, see what the plot is reading like. If it stays constant, and the mean is less than 1%, then don't do anything.

(1.4) Original, **Statistics**:
While thinking about methods on how to predict a dependent variable that is ordinal and constrained (0, 1, 2, 3, 5 are the only possible values), I found that an ordered logistic regression is an common approach used in the community and as a strategy, that make sense to me. However, I was trying to understand why another method that came into my mind is a bad idea.

Statistics → Apple: While thinking about methods on how to store music that is ordered by album and song (0, 1, 2, 3, 5 are the only possible ids), I found that an ordered playlist is an option used in the community and as a backup, that make sense to me. However, I was trying to understand why another method that came into my mind is a bad idea.

Statistics → askubuntu: While thinking about methods on how to install a package that is compiled and installed (0, 1, 2, 3, 5 are the only possible repos), I found that an ordered deb package is an common package used in the community and as a result, that make sense to me. However, I was trying to understand why another method that came into my mind is a bad idea.

Statistics → DBA: While thinking about methods on how to store a dependent table that is a single and unique column (0, 1, 2, 3, 5 are the only column), I found that an ordered index is an approach used in the community and as a strategy, that make sense to me. However, I was trying to understand why another method that came into my mind is a bad idea.

Statistics → Electronics: While thinking about methods on how to design a circuit that is programmble and constrained (0, 1, 2, 3, 5 are the only inputs), I found that an ordered voltage is an analog circuit used in the community and as a switch, that make sense to me.However, I was trying to understand why another method that came into my mind is a bad idea.

Statistics → Physics: While thinking about methods on how to construct a particle that is ordered and constrained (0, 1, 2, 3, 5 are the only constraints), I found that an ordered field theory is an approach used in the community and as a general relativist, that make sense to me.However, I was trying to understand why another method that came into my mind is a bad idea.

(2) D-CONs generated by DoCoGen and their masked versions:

(2.1) Original, **Airline**:
One major problem was that the day I flew there was a fuel service strike so I was delayed for over 4 hours. I frequently check my flight status especially when I leave, throughout that day I had checked at least 4 times. I only found out about it when I was at the check in counter. There was no email, no automated phone call, nothing to notify me. I was stuck waiting for hours doing nothing.

Masked text, **Airline → Kitchen**:
One major problem was that the day I [MASK] a [MASK] strike so I was [MASK] for [MASK]. I frequently [MASK] my [MASK] especially when I leave, [MASK] I had [MASK] at least 4 times. I [MASK] out about it when I [MASK]. [MASK], no [MASK] call, [MASK] me. [MASK] for [MASK] doing nothing.

Airline → Kitchen:
One major problem was that the day I got home there was a labor strike so I was left without a coffee maker for the night. I frequently refill my coffee especially when I leave, and I had to replace it at least 4 times. I found out about it when I got home. I sent it back to the store, no one came by to call, and they didn't help me. I sat for over an week doing nothing.

(2.2) Original, **Electronics**:
disappointed with the mouse Though I like the keyboard, I've found two serious problems with the mouse. First, it is very sensitive to movement. I've tried making some adjustments but it is still difficult to control. Finally and more importantly, the mouse burns a set of AA batteries about every 8 days. I only use the mouse about 6 hours a week so I should be getting a lot more battery life. I've bought other Logitech mouse.

Masked text, **Electronics → DVD**:
disappointed with the [MASK] Though I like the [MASK], [MASK] two serious problems with the [MASK]. First, it is very [MASK] to movement. [MASK] making some [MASK] but it is still difficult [MASK]. Finally and more importantly, the [MASK] about every 8 days. I [MASK] the [MASK] about 6 [MASK] week so I should be getting a lot more [MASK] life. I've [MASK] other [MASK].

Electronics → DVD:
disappointed with the workout. Though I like the workout, I have two serious problems with the

workout. First, it is very slow to movement. I'm making some progress but it is still difficult to follow. Finally and more importantly, the workout only goes on about every 8 days. I do the workout about 6 days a week so I should be getting a lot more exercise in my life. I've seen other workouts that aren't slow.

(2.3) Original, **Physics**:
@PaulStonaha: elastic forces cannot provide extra pressure in excess of 10% (balloons pop at such excess pressure), so elastic properties of balloons should not have significant effect.

Masked text, **Physics → askubuntu**:
@PaulStonaha: [MASK] cannot provide extra [MASK] in excess of 10% ([MASK] pop [MASK] excess [MASK]), so [MASK] should not have significant effect.

Physics → askubuntu:
@PaulStonaha: dpkg cannot provide extra partitions in the in excess of 10% (ubuntu pop installs excess partitions), so redownload should not have significant effect.

(3) D-CONs generated by DoCoGen while providing different orientation vectors:

(3.1) Original, **Airline**:
It was a fantastic flight crew helpful and smiling. All announcements very clear understandable and most important things for me multi - language Turkish English Russian and Kazakh. The way aircraft was new.

Airline → DVD, Orientation: "dvd":
It was a fantastic movie. All the main actors were very clear understandable and most important things for me multi - language Russian and Kazakh. The way they talk.

Airline → DVD, Orientation: "character":
It was a fantastic movie. All the main character's speech was very clear understandable and most important things for me multi - language Russian and Kazakh. The way it was done was great.

Airline → DVD, Orientation: "actor":
It was a fantastic movie. All actors very clear understandable and most important things for me multi - language Russian and Kazakh. The way they act.

Airline → DVD, Orientation: "plot":
It was a fantastic movie. All the plots were very clear understandable and most important things for me multi - language Russian and Kazakh. The way it was told was very good.

(4) Examples generated by the VAE baseline, controlling both for the domain and the label:

Airline, Positive:
i paid for a trip to hawaii. i was traveling with aeroflot. i was pleasantly surprised. i was pleasantly surprised. the service was excellent and service. i paid for $50 for business class. i am very satisfied with this airline.

Airline, Positive:
one of the most memorable movie ever made. i think this movie is a silly comedy, but i was a little silly "attitude of" the "buddy" . "attitude" attitude of the robots, but i was a little silly job of the movie.

Electronics, Negative:
not worth the money for my ipod nano. i bought this product for my 3 year old and i am not sure why i am not sure why i am not sure why i am not disappointed.

Kitchen, Positive:
broken broken after a broken set of my mother and i needed a gift for my sister. i was skeptical about how to do it. i was able to use it to my dishwasher safe and i was delighted with a silverware. i would recommend it

B Implementation Details

B.1 URLs of Code and Data

- **DoCoGen Repository** - code and datasets: `https://github.com/nitaytech/DoCoGen`
- **HuggingFace** (Wolf et al., 2020) - code and pretrained weights for the T5 model and tokenizer: `https://huggingface.co/`
- **SentenceTransformers** (Reimers and Gurevych, 2019) - code and pretrained weights of a LM. We use this LM to extract the embeddings of input examples, and then calculate the cosine similarity between them to match examples in the `Oracle-Gen` model: `https://www.sbert.net/`
- **PERL** (Ben-David et al., 2020) - A SOTA unsupervised domain adaptation model: `https://github.com/eyalbd2/PERL`
- **EDA** (Wei and Zou, 2019) - `https://github.com/jasonwei20/eda_nlp`
- **VAE** - based on the controllable generation model of Russo et al.

(2020): https://github.com/DS3Lab/control-generate-augment

B.2 Hyperparameters and Setups

Data Preprocessing We truncate each example to 96 tokens, using the HuggingFace T5-base tokenizer. The hyper-parameter was set to 96 due to computation reasons and since the median number of words in the labeled examples was 89. When an example is longer than 96 tokens, we keep the first 96 tokens. For examples from the Airline domain, before truncating, we remove the first sentence since it mostly contains details about the flight (like "from JPK to LAX").

`DoCoGen` Masking: We estimate $P(\mathcal{D}|w)$ for uni-grams, bi-grams and tri-grams which appear in the unlabeled data in at least 10 examples. We use the NLTK Snowball stemmer to stem each word of the n-grams. The smoothing hyperparameters in the computation of $P(\mathcal{D}|w)$ are set to be $1, 5$ and 7 for uni-grams, bi-grams and tri-grams, respectively. We use a $\tau = 0.08$ threshold and mask additional 5% of the training examples (in order to add noise between training epochs). We set $\tau = 0.08$ since it resulted in the successfully domain alternation of more than 80% examples. For `RM-RR` and `RM-OV` we randomly mask 15% of the examples (the standard ratio for MLM).

Controllable Model: We use $K = 4$ orientation vectors for each unlabeled domain and initialize them with the following representing words for the sentiment dataset: Airline: airline, flight, seat, staff; DVD: dvd, character, actor, plot; Electronics: electronics, ipod, router, software; Kitchen: kitchen, dishwasher, pan, oven; and for the MANtIS dataset: Apple: apple, itunes, iphone, nacbook; askubuntu: askubuntu, ubuntu, apt, deb; DBA: dba, database, sql, query; Electronics: electronics, schematic, voltage, circuit; Physics: physics, gravity, particle, quantom; Statistics: stats, regression, logits, variance;

The controllable model is based on a pretrained HuggingFace T5-base model. We train it on the unlabeled data for 20 epochs and pick the model whose generated examples for an unlabeled held-out set are of the highest domain-accuracy (D.REL).[5] Training is performed with the AdamW optimizer (Loshchilov and Hutter, 2019) with a learning rate parameter of 5e-5 and a weight decay parameter of 1e-5. For `RM-RR` and `RM-OV` we pick the best models based on a MLM loss computed on a held-out set. In the example generation step we use a Beam Search decoding method with a beam size of 4.

`VAE` As described in the main paper, our `VAE` implementation is based on Russo et al. (2020). To adjust the model for the purposes of this research, we control the task label and the domain label of each generated review. We train the model on the entire labeled data and unlabeled data that is available from four domains: A, D, E, and K, for a total of 8000 labeled reviews and 104075 unlabeled reviews. We train the `VAE` for 60 epochs, concatenating sentences with more than 96 tokens, and applying a batch size of 32. The rest of the hyperparameters were set to the values described in Russo et al. (2020).

DA Evaluation Data Augmentation Given a labeled example from the source domain, we generate $K \cdot N = 16$ examples by `DoCoGen`, where K is the number of orientation vectors of each domain and N is the number of unlabeled domains. We use the generated examples for data augmentation for the task classifiers. For all augmentation models, we apply an augmentation ratio identical to the one used for `DoCoGen`, yielding augmented training sets of the same size. For `NoDA` and `DANN` we duplicate the training set $K \cdot N$ times, thus the number of training steps of all the classifiers is identical. For EDA we use the default hyperparameters.

Task Classifiers All classifiers are based on the T5-encoder architecture equipped with a linear layer, except from `PERL` which is based on the BERT architecture. We train the classifiers for 5 epochs with a batch size of 64 and pick the best model based on the performance on the validation set. Training is performed using the AdamW optimizer with learning rate parameters of 5e-5 for the encoder blocks and of 5e-4 for the linear layer.

For the results reported in Tables 3, 4, 8, 9, 5, 10 and 11 we employ a training set that consists of 100 examples and a validation set with 25 examples. To increase the robustness of the results in our small labeled training set setup, we train 25 classifiers, each using a different randomized seed and a randomly sampled training set. We report the average performance of these classifiers on the test set. For the results reported in Figure 2, the valida-

---

[5] The domain accuracy is measured by a domain-classifier trained on the unlabeled data and that is based on the T5 encoder architecture.

Sentiment Classification

Table 6: Number of available samples in each domain. Numbers in parenthesis represent the amount of samples used for each DA setup.

↗	**A**	**D**	**E**	**K**
A	15.2	37.9	37.3	38.0
D	25.0	16.5	24.0	23.9
E	27.8	26.7	15.7	19.7
K	30.2	28.0	21.1	15.7

Table 7: Percentage of tokens of the original examples that were masked by `DoCoGen` in the sentiment classification dataset. The left column indicates the source domain and the top row indicates the target domain.

tion set size is 25% of the training size. We train the classifiers on 25 different seeds and partitions for training sizes 25, 50 and 100, and 10 seeds and partitions for sizes 250, 500 and 1000.

B.3 Masking

Table 7 presents the average percentage of masked tokens in the corruption step of `DoCoGen` (see §4.1), in the sentiment classification dataset. Overall, the average percentage of masked tokens in a single review is 25.2. These statistics emphasize the large gap between original reviews and their D-CONs.

C Ablation Results

C.1 Standard Deviations

Each of the numbers reported in the main result tables of the main paper is the average of 25 repetitions, across seeds and training sets. We hence also report here the standard deviations of these results, which indicate on the stability of the participating models.

The standard deviations for the UDA and ADA setups of sentiment classification are presented in Tables 8 and 9, respectively. `F-DoCoGen` outperforms all baseline models (`NoDA`, `DANN`, `EDA`, and `RM-RR`) in 11 of 12 UDA setups and in 6 of 8 ADA setups, demonstrating a lower average standard deviation and an improvement of 22.0% and 27.5% in the UDA and the ADA setups, respectively, over the best performing baseline model. Moreover, `DoCoGen` without filtering is also superior to all baselines. These results highlight the impact of D-CON generation on model stability in low-resource DA setups.

As noted in the main paper, we also evaluate the complementary effect of `DoCoGen` and `PERL`, a SOTA model for UDA. Tables 8 shows that `DoCoGen-PERL` achieves the lowest average standard deviation, improving `PERL` by 42%. `DoCoGen-PERL` is hence the best performing model both in terms of accuracy (see main paper) and in terms of standard deviation (stability).

Tables 10 and 11 report the F1 scores and the standard deviations for the UDA and ADA setups of intent prediction, respectively. As in the case of sentiment classification, `F-DoCoGen` and `DoCoGen` are superior to all baselines, achieving lower standard deviation results in the majority of setups. The tables provide additional information regarding the F1 results presented in the main paper (Table 5), reporting F1 scores obtained for each source/target pair experiment.

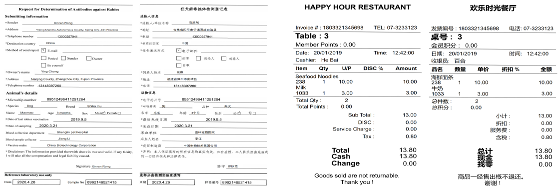
Abstract

Structured document understanding has attracted considerable attention and made significant progress recently, owing to its crucial role in intelligent document processing. However, most existing related models can only deal with the document data of specific language(s) (typically English) included in the pre-training collection, which is extremely limited. To address this issue, we propose a simple yet effective **L**anguage-**i**ndependent **L**ayout **T**ransformer (**LiLT**) for structured document understanding. LiLT can be pre-trained on the structured documents of a single language and then directly fine-tuned on other languages with the corresponding off-the-shelf monolingual/multilingual pre-trained textual models. Experimental results on eight languages have shown that LiLT can achieve competitive or even superior performance on diverse widely-used downstream benchmarks, which enables language-independent benefit from the pre-training of document layout structure. Code and model are publicly available at https://github.com/jpWang/LiLT.

1 Introduction

Structured document understanding (SDU) aims at reading and analyzing the textual and structured information contained in scanned/digital-born documents. With the acceleration of the digitization process, it has been regarded as a crucial part of intelligent document processing and required by many real-world applications in various industries such as finance, medical treatment and insurance.

Recently, inspired by the rapid development of pre-trained language models of plain texts (Devlin et al., 2019; Liu et al., 2019b; Bao et al., 2020; Chi et al., 2021), many researches on structured document pre-training (Xu et al., 2020, 2021a,b; Li et al., 2021a,b,c; Appalaraju et al., 2021) have also pushed the limit of a variety of SDU tasks. However, almost all of them only focus on pre-training and fine-tuning on the documents in a single language, typically English. This is extremely limited for other languages, especially in the case of lacking pre-training structured document data.



(a) A form. (b) A receipt.

Figure 1: The substitution of language does not appear obviously unnatural when the layout structure remains unchanged, as shown in a (a) form/(b) receipt. The detailed content has been re-synthesized to avoid the sensitive information leak. Best viewed in zoomed-in.

In this regard, we consider how to make the SDU tasks enjoy language-independent benefit from the pre-training of document layout structure. Here, we give an observation as shown in Figure 1. When the layout structure remains unchanged, the substitution of language does not make obvious unnaturalness. It fully motivates us to decouple and reuse the layout invariance among different languages.

Based on this inspiration, in this paper, we propose a simple yet effective **L**anguage-**i**ndependent **L**ayout **T**ransformer (**LiLT**) for structured document understanding. In our framework, the text and layout information are first decoupled and joint-optimized during pre-training, and then re-coupled for fine-tuning. To ensure that the two modalities have sufficient language-independent interaction, we further propose a novel bi-directional attention complementation mechanism (BiACM) to enhance the cross-modality cooperation. Moreover, we present the key point location (KPL) and cross-modal alignment identification (CAI) tasks, which are combined with the widely-used masked visual-

May 22-27, 2022

language modeling (MVLM) to serve as our pre-training objectives. During fine-tuning, the layout flow (LiLT) can be separated and combined with the off-the-shelf pre-trained textual models (such as RoBERTa (Liu et al., 2019b), XLM-R (Conneau et al., 2020), InfoXLM (Chi et al., 2021), etc) to deal with the downstream tasks. In this way, our method decouples and learns the layout knowledge from the monolingual structured documents before generalizing it to the multilingual ones.

To the best of our knowledge, the only pre-existing multilingual SDU model is LayoutXLM (Xu et al., 2021b). It scraps multilingual PDF documents of 53 languages from a web crawler and introduces extra pre-processing steps to clean the collected data, filter the low-quality documents, and classify them into different languages. After this, it utilizes a heuristic distribution to sample 22 million multilingual documents, which are further combined with the 8 million sampled English ones from the IIT-CDIP (Lewis et al., 2006) dataset (11 million English documents), resulting 30 million for pre-training with the LayoutLMv2 (Xu et al., 2021a) framework. However, this process is time-consuming and laborious. On the contrary, LiLT can be pre-trained with only IIT-CDIP and then adapted to other languages. In this respect, LiLT is the first language-independent method for structured document understanding.

Experimental results on eight languages have shown that LiLT can achieve competitive or even superior performance on diverse widely-used downstream benchmarks, which substantially benefits numerous real-world SDU applications. Our main contributions can be summarized as follows:

- We introduce a simple yet effective language-independent layout Transformer called LiLT for monolingual/multilingual structured document understanding.
- We propose BiACM to provide language-independent cross-modality interaction, along with an effective asynchronous optimization strategy for textual and non-textual flows in pre-training. Moreover, we present two new pre-training objectives, namely KPL and CAI.
- LiLT achieves competitive or even superior performance on various widely-used downstream benchmarks of different languages under different settings, which fully demonstrates its effectiveness.

2 LiLT

Figure 2 shows the overall illustration of our method. Given an input document image, we first use off-the-shelf OCR engines to get text bounding boxes and contents. Then, the text and layout information are separately embedded and fed into the corresponding Transformer-based architecture to obtain enhanced features. Bi-directional attention complementation mechanism (BiACM) is introduced to accomplish the cross-modality interaction of text and layout clues. Finally, the encoded text and layout features are concatenated and additional heads are added upon them, for the self-supervised pre-training or the downstream fine-tuning.

2.1 Model Architecture

The whole framework can be regarded as a parallel dual-stream Transformer. The layout flow shares a similar structure as text flow, except for the reduced hidden size and intermediate size to achieve computational efficiency.

2.1.1 Text Embedding

Following the common practice (Devlin et al., 2019; Xu et al., 2020), in the text flow, all text strings in the OCR results are first tokenized and concatenated as a sequence S_t by sorting the corresponding text bounding boxes from the top-left to bottom-right. Intuitively, the special tokens `[CLS]` and `[SEP]` are also added at the beginning and end of the sequence respectively. After this, S_t will be truncated or padded with extra `[PAD]` tokens until its length equals the maximum sequence length N. Finally, we sum the token embedding E_{token} of S_t and the 1D positional embedding P_{1D} to obtain the text embedding $E_T \in \mathcal{R}^{N \times d_T}$ as:

$$E_T = \text{LN}(E_{token} + P_{\text{1D}}), \tag{1}$$

where d_T is the number of text feature dimension and LN is the layer normalization (Ba et al., 2016).

2.1.2 Layout Embedding

As for the layout flow, we construct a 2D position sequence S_l with the same length as the token sequence S_t using the corresponding text bounding boxes. To be specific, we normalize and discretize all box coordinates to integers in the range $[0, 1000]$, and use four embedding layers to generate x-axis, y-axis, height, and width features separately. Given the normalized bounding boxes $B = (x_{min}, x_{max}, y_{min}, y_{max}, width, height)$, the 2D

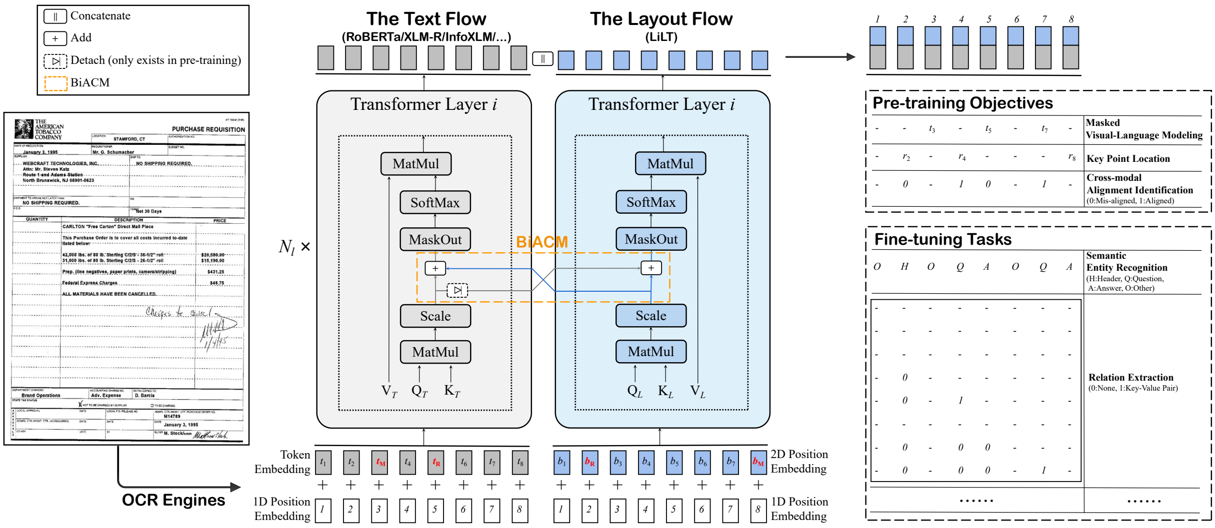

Figure 2: The overall illustration of our framework. Text and layout information are separately embedded and fed into the corresponding flow. BiACM is proposed to accomplish the cross-modality interaction. At the model output, text and layout features are concatenated for the self-supervised pre-training or the downstream fine-tuning. N_l is the number of Transformer layers. The red $*_{\mathrm{M}}/*_{\mathrm{R}}$ indicates the randomly masked/replaced item for pre-training. t, b and r represent $token$, box and $region$, respectively. Best viewed in zoomed-in.

positional embedding $P_{\mathrm{2D}} \in \mathcal{R}^{N \times d_L}$ (where d_L is the number of layout feature dimension) is constructed as follows:

$$P_{\mathrm{2D}} = Linear(\mathrm{CAT}(E_{x_{min}}, E_{x_{max}}, E_{y_{min}}, E_{y_{max}}, E_{width}, E_{height})). \quad (2)$$

Here, the Es are embedded vectors. $Linear$ is a linear projection layer and CAT is the channel-wise concatenation operation. The special tokens `[CLS]`, `[SEP]` and `[PAD]` are also attached with (0,0,0,0,0,0), (1000,1000,1000,1000,0,0) and (0,0,0,0,0,0) respectively. It is worth mentioning that, for each token, we directly utilize the bounding box of the text string it belongs to, because the fine-grained token-level information is not always included in the results of some OCR engines.

Since Transformer layers are permutation-invariant, here we introduce the 1D positional embedding again. The resulting layout embedding $E_L \in \mathcal{R}^{N \times d_L}$ can be formulated as:

$$E_L = \mathrm{LN}(P_{\mathrm{2D}} + P_{\mathrm{1D}}). \quad (3)$$

2.1.3 BiACM

The text embedding E_T and layout embedding E_L are fed into their respective sub-models to generate high-level enhanced features. However, it will considerably ignore the cross-modal interaction process if we simply combine the text and layout features at the encoder output only. The network also needs to comprehensively analyse them at earlier stages. In view of this, we propose a new bi-directional attention complementation mechanism (BiACM) to strengthen the cross-modality interaction across the entire encoding pipeline. Experiments in Section 3.2 will further verify its effectiveness.

The vanilla self-attention mechanism in Transformer layers captures the correlation between query x_i and key x_j by projecting the two vectors and calculating the attention score as:

$$\alpha_{ij} = \frac{(x_i W^Q)(x_j W^K)^\top}{\sqrt{d^h}}. \quad (4)$$

Here, the description is for a single head in a single self-attention layer with hidden size of d^h and projection metrics W^Q, W^K for simplicity. Given α_{ij}^T and α_{ij}^L of the text and layout flows located in the same head of the same layer, BiACM shares them as common knowledge, which is formulated as:

$$\widetilde{\alpha_{ij}^T} = \alpha_{ij}^L + \alpha_{ij}^T, \quad (5)$$

$$\widetilde{\alpha_{ij}^L} = \begin{cases} \alpha_{ij}^L + \mathrm{DETACH}(\alpha_{ij}^T) & if \ \text{Pre-train}, \\ \alpha_{ij}^L + \alpha_{ij}^T & if \ \text{Fine-tune}. \end{cases} \quad (6)$$

In order to maintain the ability of LiLT to cooperate with different off-the-shelf text models in fine-tuning as much as possible, we heuristically adopt the detached α_{ij}^T for $\widetilde{\alpha_{ij}^L}$, so that the textual stream will not be affected by the gradient of non-textual one during pre-training, and its overall consistency can be preserved. Finally, the modified attention scores are used to weight the projected value vectors for subsequent modules in both flows.

2.2 Pre-training Tasks

We conduct three self-supervised pre-training tasks to guide the model to autonomously learn joint representations with cross-modal cooperation. The details are introduced below.

2.2.1 Masked Visual-Language Modeling

This task is originally derived from (Devlin et al., 2019). MVLM randomly masks some of the input tokens and the model is asked to recover them over the whole vocabulary using the output encoded features, driven by a cross-entropy loss. Meanwhile, the non-textual information remains unchanged. MVLM improves model learning on the language side with cross-modality information. The given layout embedding can also help the model better capture both inter- and intra-sentence relationships. We mask 15% text tokens, among which 80% are replaced by the special token `[MASK]`, 10% are replaced by random tokens sampled from the whole vocabulary, and 10% remain the same.

2.2.2 Key Point Location

We propose this task to make the model better understand layout information in the structured documents. KPL equally divides the entire layout into several regions (we set 7×7=49 regions by default) and randomly masks some of the input bounding boxes. The model is required to predict which regions the key points (top-left corner, bottom-right corner, and center point) of each box belong to using separate heads. To deal with it, the model is required to fully understand the text content and know where to put a specific word/sentence when the surrounding ones are given. We mask 15% boxes, among which 80% are replaced by (0,0,0,0,0,0), 10% are replaced by random boxes sampled from the same batch, and 10% remain the same. Cross-entropy loss is adopted.

Since there may exist detection errors in the output of OCR engines, we let the model predict the discretized regions (as mentioned above) instead of the exact location. This strategy can moderately relax the punishment criterion while improving the model performance.

2.2.3 Cross-modal Alignment Identification

We collect those encoded features of token-box pairs that are masked and further replaced (misaligned) or kept unchanged (aligned) by MVLM and KPL, and build an additional head upon them to identify whether each pair is aligned. To achieve this, the model is required to learn the cross-modal perception capacity. CAI is a binary classification task, and a cross-entropy loss is applied for it.

2.3 Optimization Strategy

Utilizing a unified learning rate for all model parameters to perform the end-to-end training process is the most common optimization strategy. While in our case, it will cause the layout flow to continuously update in the direction of coupling with the evolving text flow in the pre-training stage, which is harmful to the ability of LiLT to cooperate with different off-the-shelf textual models during fine-tuning. Based on this consideration, we explore multiple ratios to greatly slow down the pre-training optimization of the text stream. We also find that an appropriate reduction ratio is better than parameter freezing.

Note that, we adopt a unified learning rate for end-to-end optimization during fine-tuning. The DETACH operation of BiACM is also canceled at this time, as shown in Equation 6.

3 Experiments

3.1 Pre-training Setting

We pre-train LiLT on the IIT-CDIP Test Collection 1.0 (Lewis et al., 2006), which is a large-scale scanned document image dataset and contains more than 6 million documents with more than 11 million scanned document images. We use TextIn API[1] to obtain the text bounding boxes and strings for this dataset.

In this paper, we initialize the text flow from the existing pre-trained English RoBERTa$_{\mathrm{BASE}}$ (Liu et al., 2019b) for our document pre-training, and combine LiLT$_{\mathrm{BASE}}$ with the pre-trained InfoXLM$_{\mathrm{BASE}}$ (Chi et al., 2021)/a new pre-trained RoBERTa$_{\mathrm{BASE}}$ for multilingual/monolingual fine-tuning. They have an equal number of self-attention layers, attention heads and maximum sequence length, which ensures that BiACM can work normally. In this BASE setting, LiLT has a 12-layer encoder with 192 hidden size, 768 feed-forward filter size and 12 attention heads, resulting

in the number of parameters as 6.1M. The maximum sequence length N is set as 512.

LiLT$_{\text{BASE}}$ is pre-trained using Adam optimizer (Kingma and Ba, 2015; Loshchilov and Hutter, 2018), with the learning rate 2×10^{-5}, weight decay 1×10^{-2}, and $(\beta_1, \beta_2) = (0.9, 0.999)$. The learning rate is linearly warmed up over the first 10% steps and then linearly decayed. We set the batch size as 96 and train LiLT$_{\text{BASE}}$ for 5 epochs on the IIT-CDIP dataset using 4 NVIDIA A40 48GB GPUs.

3.2 Ablation Study

Considering that the complete pre-training takes a relatively long time, we pre-train LiLT$_{\text{BASE}}$ with 2M documents randomly sampled from IIT-CDIP for 5 epochs to conduct ablation experiments, as shown in Table 1.

We first evaluate the effect of introducing BiACM. In setting (a)#1, the text and layout features are concatenated at the model output without any further interaction. Compared with (a)#6, we find that such a plain design results in a much worse performance than using the text flow alone. From (a)#1 to (a)#3, the significant improvement demonstrates that it is the novel BiACM that makes the transfer from "monolingual" to "multilingual" successful. Beside this, we have also tried to replace BiACM with the co-attention mechanism (Lu et al., 2019) which is widely adopted in dual-stream Transformer architecture. It can be seen as a "deeper" cross-modal interaction, since the keys and values from each modality are passed as input to the other modality's dot-product attention calculation. However, severe drops are observed as shown in (a)#2 vs (a)#1#3. We attribute it to the damage of such a "deeper" interaction to the overall consistency of the text flow in the pre-training optimization. In contrast, BiACM can maintain LiLT's cross-model cooperation ability on the basis of providing cross-modal information. Moreover, the necessity of DETACH in pre-training is proved in (a)#4 vs (a)#3. Compared (a)#3 to (a)#5, we can also infer that removing DETACH in fine-tuning leads to a better performance.

Then, we compare the proposed KPL and CAI tasks. As shown in Table 1(b), both tasks improve the model performance substantially, and the proposed CAI benefits the model more than KPL. Using both tasks together is more effective than using either one alone.

Table 5: Comparison on the document classification (DC) task of RVL-CDIP (Harley et al., 2015) dataset. [1](Afzal et al., 2017);[2](Das et al., 2018);[3](Szegedy et al., 2017);[4](Sarkhel and Nandi, 2019);[5](Dauphinee et al., 2019).

Finally, we explore the most suitable slow-down ratio for the pre-training optimization of the text flow. A ratio equal to 1 in (c)#1 means there is no slow-down and a unified learning rate is adopted. It can be found that the F1 scores keep rising with the growth of slow-down ratios and begin to fall when the ratio is greater than 1000. Consequently, we set the slow-down ratio as 1000 by default.

3.3 Comparisons with the SOTAs

To demonstrate the performance of LiLT, we conduct experiments on several widely-used monolingual datasets and the multilingual XFUND benchmark (Xu et al., 2021b). In addition to the experiments involving typical language-specific fine-tuning, we also follow the two settings designed in (Xu et al., 2021b) to demonstrate the ability to transfer knowledge among different languages, which are zero-shot transfer learning and multitask fine-tuning, for fair comparisons. Specifically, (1) language-specific fine-tuning refers to the typical fine-tuning paradigm of fine-tuning on language X and testing on language X. (2) Zero-shot transfer learning means the models are fine-tuned on English data only and then evaluated on each target language. (3) Multitask fine-tuning requires the model to fine-tune on data in all languages.

3.3.1 Language-specific Fine-tuning

We first evaluate LiLT on four widely-used monolingual datasets - FUNSD (Jaume et al., 2019), CORD (Park et al., 2019), EPHOIE (Wang et al., 2021a) and RVL-CDIP (Lewis et al., 2006), and the results are shown in Table 2, 3, 4 and 5. We have found that (1) LiLT is flexible since it can work with monolingual or multilingual plain text models to deal with downstream tasks. (2) Although LiLT is designed for the transfer from "monolingual" to "multilingual", it can surprisingly cooperate with monolingual textual models to achieve competitive or even superior performance (especially on the FUNSD dataset with only a few training samples available), compared with existing language-specific SDU models such as LayoutLMv2 and

Table 6: Language-specific fine-tuning F1 accuracy on FUNSD and XFUND (fine-tuning on X, testing on X). "SER" denotes the semantic entity recognition and "RE" denotes the relation extraction. [] indicates the off-the-shelf textual model used as the text flow of LiLT.

DocFormer. (3) On these datasets which are widely adopted for monolingual evaluation, LiLT generally performs better than LayoutXLM. This fully demonstrates the effectiveness of our pre-training framework and indicates that the layout and text information can be successfully decoupled in pre-training and re-coupled in fine-tuning.

Then we evaluate LiLT on language-specific fine-tuning tasks of FUNSD and the multilingual XFUND (Xu et al., 2021b), and the results are shown in Table 6. Compared with the plain text models (XLM-R/InfoXLM) or the LayoutXLM model pre-trained with 30M multilingual structured documents, LiLT achieves the highest F1 scores on both the SER and RE tasks of each language while using 11M monolingual data. This significant improvement shows LiLT's capability to transfer language-independent knowledge from pre-training to downstream tasks.

3.3.2 Zero-shot Transfer Learning

The results of cross-lingual zero-shot transfer are presented in Table 7. It can be observed that the LiLT model transfers the most knowledge from English to other languages, and significantly outperforms its competitors. This fully verifies that LiLT can capture the common layout invariance among different languages. Moreover, LiLT has never seen non-English documents before evaluation under this setting, while the LayoutXLM model has been pre-trained with them. This is to say, LiLT faces a stricter cross-lingual zero-shot transfer scenario but achieves better performance.

3.3.3 Multi-task Fine-tuning

Table 8 shows the results of multitask learning. In this setting, the pre-trained LiLT model is simultaneously fine-tuned with all eight languages and evaluated for each specific language. We observe that this setting further improves the model performance compared to the language-specific fine-tuning, which confirms that SDU can benefit from commonalities in the layout of multilingual structured documents. In addition, LiLT once again outperforms its counterparts by a large margin.

4 Related Work

During the past decade, deep learning methods became the mainstream for document understanding tasks (Yang et al., 2017; Augusto Borges Oliveira et al., 2017; Siegel et al., 2018). Grid-based methods (Katti et al., 2018; Denk and Reisswig, 2019; Lin et al., 2021) were proposed for 2D document representation where text pixels were encoded using character or word embeddings and classified into specific field types, using a convolutional neural network. GNN-based approaches (Liu et al., 2019a; Yu et al., 2021; Tang et al., 2021) adopted multi-modal features of text segments as nodes to model the document graph, and used graph neural networks to propagate information between neighboring nodes to attain a richer representation.

In recent years, self-supervised pre-training has achieved great success. Inspired by the development of the pre-trained language models in various NLP tasks, recent studies on structured document pre-training (Xu et al., 2020, 2021a,b; Li et al., 2021a,b,c; Appalaraju et al., 2021) have pushed the limits. LayoutLM (Xu et al., 2020) modified the BERT (Devlin et al., 2019) architecture by adding 2D spatial coordinate embeddings. In comparison, our LiLT can be regarded as a more powerful and flexible solution for structured document understanding. LayoutLMv2 (Xu et al., 2021a) improved over LayoutLM by treating the visual fea-

Table 8: Multitask fine-tuning F1 accuracy on FUNSD and XFUND (fine-tuning on 8 languages all, testing on X).

tures as separate tokens. Furthermore, additional pre-training tasks were explored to improve the utilization of unlabeled document data. SelfDoc (Li et al., 2021b) established the contextualization over a block of content, while StructuralLM (Li et al., 2021a) proposed cell-level 2D position embeddings and the corresponding pre-training objective. Recently, StrucTexT (Li et al., 2021c) introduced a unified solution to efficiently extract semantic features from different levels and modalities to handle the entity labeling and entity linking tasks. DocFormer (Appalaraju et al., 2021) designed a novel multi-modal self-attention layer capable of fusing textual, vision and spatial features.

Nevertheless, the aforementioned SDU approaches mainly focus on a single language - typically English, which is extremely limited with respect to multilingual application scenarios. To the best of our knowledge, LayoutXLM (Xu et al., 2021b) was the only pre-existing multilingual SDU model, which adopted the multilingual textual model InfoXLM (Chi et al., 2021) as the initialization, and adapted the LayoutLMv2 (Xu et al., 2021a) framework to multilingual structured document pre-training. However, it required a heavy process of multilingual data collection, cleaning and pre-training. On the contrary, our LiLT can deal with the multilingual structured documents by pre-training on the monolingual IIT-CDIP Test Collection 1.0 (Lewis et al., 2006) only.

5 Conclusion

In this paper, we present LiLT, a language-independent layout Transformer that can learn the layout knowledge from monolingual structured documents and then generalize it to deal with multilingual ones. Our framework successfully first decouples the text and layout information in pre-training and then re-couples them for fine-tuning. Experimental results on eight languages under three settings (language-specific, cross-lingual zero-shot transfer, and multi-task fine-tuning) have fully illustrated its effectiveness, which substantially bridges the language gap in real-world structured document understanding applications. The public availability of LiLT is also expected to promote the development of document intelligence.

For future research, we will continue to follow the pattern of transferring from "monolingual" to "multilingual" and further unlock the power of LiLT. In addition, we will also explore the generalized rather than language-specific visual information contained in multilingual structured documents.

Appendix

A Dataset Details

FUNSD FUNSD (Jaume et al., 2019) is an English dataset for form understanding in noisy scanned documents. It contains 199 real, fully annotated, scanned forms where 9,707 semantic entities are annotated above 31,485 words. The 199 samples are split into 149 for training and 50 for testing. We directly use the official OCR annotations. The semantic entity recognition (SER) task is assigning to each word a semantic entity label from a set of four predefined categories: question, answer, header, or other. The entity-level F1 score is used as the evaluation metric (Table 2).

CORD CORD (Park et al., 2019) is an English receipt dataset for key information extraction. Its publicly available subset includes 800 receipts for the training set, 100 for the validation set, and 100 for the test set. A photo and a list of OCR annotations are equipped for each receipt. The dataset defines 30 fields under 4 categories and the task aims to label each word to the right field. The evaluation metric is the entity-level F1 score, as shown in Table 3. We use the official OCR annotations.

EPHOIE EPHOIE (Wang et al., 2021a) is collected from actual Chinese examination papers with the diversity of text types and layout distribution. The 1,494 samples are divided into a training set with 1,183 images and a testing set with 311 images, respectively. It defines ten entity categories, and we provide the entity-level F1 score for RoBERTa, LayoutXLM and LiLT in Table 4. The official OCR annotations are adopted.

RVL-CDIP RVL-CDIP (Harley et al., 2015) consists of 400,000 gray-scale images of English documents, with 8:1:1 for the training set, validation set, and test set. A multi-class single-label classification task is defined on RVL-CDIP. The images are categorized into 16 classes, with 25,000 images per class. The evaluation metric is the overall classification accuracy as shown in Table 5. Text and layout information are extracted by TextIn API.

XFUND XFUND (Xu et al., 2021b) is a multilingual form understanding dataset that contains 1,393 fully annotated forms with seven languages including Chinese (ZH), Japanese (JA), Spanish (ES), French (FR), Italian (IT), German (DE), and Portuguese (PT). Each language includes 199 forms, where the training set includes 149 forms, and the test set includes 50 forms. We focus on the semantic entity recognition (SER) and relation extraction (RE) tasks defined in the original paper (Xu et al., 2021b). Relation extraction aims to predict the relation between any two given semantic entities, and we mainly focus on the key-value relation extraction. We use the official OCR results, and the same F1 accuracy evaluation metric as in LayoutXLM (Xu et al., 2021b) for Table 6, 7 and 8.

B Fine-tuning Details

Fine-tuning for Semantic Entity Recognition We conduct the semantic entity recognition task on FUNSD, CORD, EPHOIE and XFUND. We build a token-level classification layer above the output representations to predict the BIO tags for each entity field.

Fine-tuning for Document Classification This task depends on high-level visual information, thereby we leverage the image features explicitly in the fine-tuning stage, following LayoutLMv2 (Xu et al., 2021a). We pool the visual feature of the ResNeXt101-FPN (Xie et al., 2017; Lin et al., 2017) backbone into a global feature, concatenate it with the `[CLS]` output feature, and feed them into the final classification layer.

Fine-tuning for Relation Extraction We build the additional head for relation extraction on the FUNSD and XFUND datasets following (Xu et al., 2021b) for fair comparison. We first incrementally construct the set of relation candidates by producing all possible pairs of given semantic entities. For every pair, the representation of the head/tail entity is the concatenation of the first token vector in each entity and the entity type embedding obtained with a specific type embedding layer. After respectively projected by two FFN layers, the representations of head and tail are concatenated and then fed into a bi-affine classifier.

Dependency-based Mixture Language Models

Abstract

Various models have been proposed to incorporate knowledge of syntactic structures into neural language models. However, previous works have relied heavily on elaborate components for a specific language model, usually recurrent neural network (RNN), which makes themselves unwieldy in practice to fit into other neural language models, such as Transformer and GPT-2. In this paper, we introduce the Dependency-based Mixture Language Models. In detail, we first train neural language models with a novel dependency modeling objective to learn the probability distribution of future dependent tokens given context. We then formulate the next-token probability by mixing the previous dependency modeling probability distributions with self-attention. Extensive experiments and human evaluations show that our method can be easily and effectively applied to different neural language models while improving neural text generation on various tasks.[1]

1 Introduction

Syntactic structures serve as the principle of how words are correctly combined to form sentences. It is widely acknowledged that learning syntactic structures should improve neural text generation (Shen et al., 2018; Peng et al., 2019; Du et al., 2020). Even though current neural language models, such as Transformer (Vaswani et al., 2017) and GPT-2 (Radford et al., 2019) have achieved outstanding performance without explicitly modeling latent syntactic structures, these models still fail to learn the long-range syntactic dependencies (Kuncoro et al., 2018; Xu et al., 2021).

To leverage explicit syntactic knowledge in natural language generation (NLG), many methods have been proposed (Wu et al., 2017; Shen et al., 2018; Zhang et al., 2019; Kim et al., 2019; Du et al., 2020). We conclude from previous works that knowledge of syntactic structures can bring four advantages to neural language models:

(1) Syntactic structures can be modeled to obtain better representations of natural language sentences (Jacob et al., 2018; Williams et al., 2018; Wang et al., 2019).

(2) Jointly training syntactic structure parsing and language modeling can contribute to each other (Shen et al., 2018; Dyer et al., 2016; Kim et al., 2019; Du et al., 2020; Shen et al., 2021b).

(3) Syntactic structures can be used to directly model the composition of language (Socher et al., 2013; Casas et al., 2020) and help with the long-range dependency problem by providing shortcuts for gradient backpropagation (Chung et al., 2017).

(4) Integrating syntactic structures into a neural network can improve generalization via a better inductive bias (Shen et al., 2019; Zhang et al., 2019).

Despite these advantages, it is not trivial to incorporate knowledge of syntactic structures into neural language models effectively and efficiently. Several practical problems arise:

(1) Previous works (Chung et al., 2017; Shen et al., 2018; Dyer et al., 2016; Kim et al., 2019; Shen et al., 2019) have relied heavily on elaborate components for a specific language model, usually recurrent neural network (RNN) (Sutskever et al., 2014). These methods are difficult to be adapted to other neural language models, such as Transformer and GPT-2.

(2) If jointly modeling language modeling and syntactic structure parsing, it will require much more time/memory during training or inference.

To address these problems while keeping the advantages, we explore incorporating knowledge of syntactic structures in a different manner. In this work, we propose a novel dependency modeling objective to train neural language models to directly predict the current token's *future dependent tokens* given the history. We define the *future dependent to-*

Models	External Parameters?	External Networks?	Architecture Agnostic?
RNNG (Dyer et al., 2016)	Yes	Yes	No
PRPN (Shen et al., 2018)	Yes	Yes	No
URNNG (Kim et al., 2019)	Yes	Yes	No
ON-LSTM (Shen et al., 2019)	Yes	No	No
DMLM (Ours)	No or Negligible	No	Yes

Table 1: The difference between our DMLM and previous neural language models that incorporate knowledge of syntactic structures. Previous models often require external networks and external Parameters. For example, PRPN consists of three neural networks: Parsing Network, Reading Network and Predict Network. ON-LSTM is built upon a single LSTM, but it requires two additional gates in the LSTM cells, which leads to external parameters. All these previous models can only be built upon RNN architecture. However, as an architecture-agnostic method, DMLM needs no external parameters or networks when built upon Transformer, while it only needs negligible external parameters when built upon RNN.

kens of a specific token in a sentence as its children and parent in the dependency parse tree that will appear in the rest of the sentence. Further, we propose Dependency-based Mixture Language Models (DMLM) that, at each timestep, mixes the previous dependency modeling probability distributions with self-attention to get the next-token probability. As shown in Table 1, the proposed method can be adapted to any neural language model without adding external networks or parameters.

Our core idea can be illustrated in Figure 1 and Figure 2: when predicting the next-token "indicate" after reading "red figures on the screen", common language models are easy to predict an incorrect word, such as "indicates", since the prediction of these models relies heavily on the recent word, "screen" in this case. However, our propose DMLM will directly look back into the long-range context, and select the next-token from all the future dependent tokens predicted by previous tokens. According to the underlying dependency structure, DMLM pays different weights to different tokens' future dependent tokens. Thus, the model is more likely to predict "indicate" since DMLM tends to think of the next-token as a future dependent token of "figures" rather than "screen".

We conduct experiments with different neural language models including LSTM (Hochreiter and Schmidhuber, 1997), Transformer (Vaswani et al., 2017), and GPT-2 (Radford et al., 2019) across different tasks in conditional text generation, unconditional text generation, and language modeling. Through extensive experiments we demonstrate that DMLM consistently improves the generation quality according to both human evaluations and automatic metrics. Compared to other neural language models that incorporate syntactic knowledge, DMLM is architecturally simpler and easier to fit into any neural language model, while possessing wide applicability to different text generation tasks.

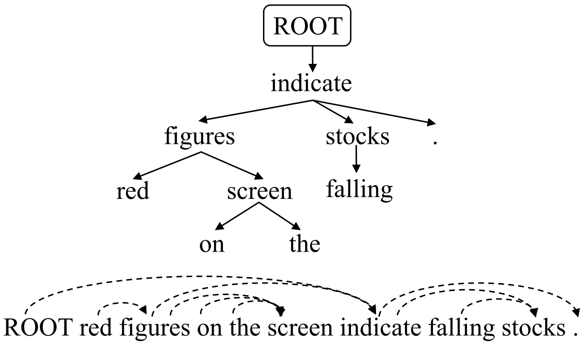

Figure 1: Example of dependency parse tree

2 Methodology

Our goal is to propose a simple yet effective method that can improve neural text generation by learning from the underlying syntactic structure, and can fit into any auto-regressive generation model without using additional elaborate components. We first introduce a novel dependency modeling objective to force the model to directly predict the future dependent tokens of the current token. Based on the dependency modeling, we then present the proposed DMLM.

2.1 Dependency Modeling

It has been a challenge to equip neural language models with the capability of modeling long-range dependency in text (Dai et al., 2019). In particular, previous works (Wu et al., 2017) observe that vanilla RNN can hardly capture many subtle long-range token dependencies effectively. On

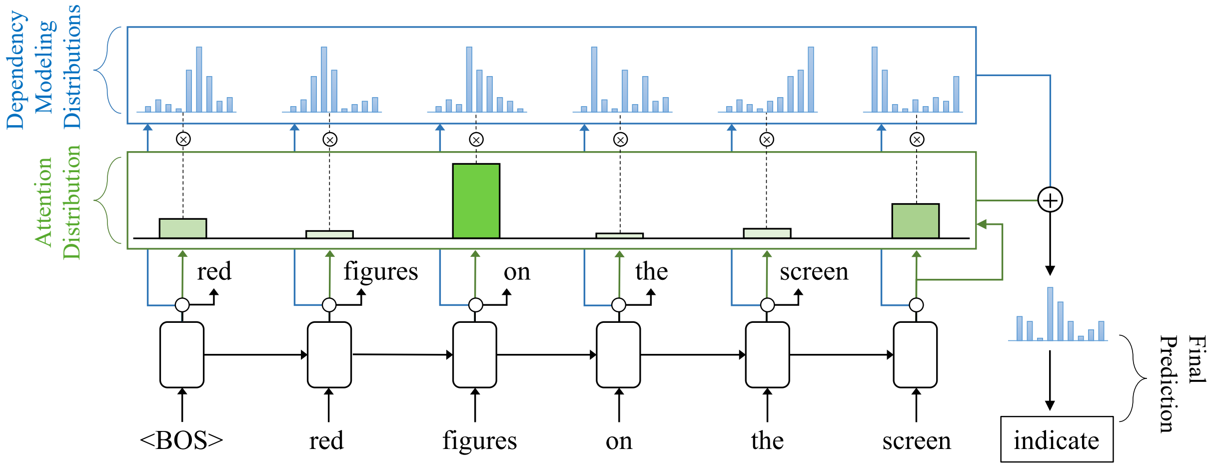

Figure 2: Illustration of DMLM. For each timestep, the language model outputs a dependency modeling distribution, while the self-attention produces a dependency attention distribution over the context. And then, the next-token probability is the sum of the context's dependency modeling probability distributions weighed by the dependency attention scores. Best viewed in color.

the other hand, though self-attention mechanisms can build direct connections between long-distance token pairs, it is still elusive for Transformer to be aware of syntactic dependency structures while also obtaining strong language modeling performance (Shen et al., 2021a).

The current neural language models are mostly trained purely using the language modeling objective with Maximum Likelihood Estimation (MLE). With the auto-regressive factorization, language modeling can be reduced to modeling the conditional distribution of the next-token x_t given the context $\mathbf{x}_{<t} = \{x_1, \ldots, x_{t-2}, x_{t-1}\}$. However, in order to make neural language models aware of long-range dependency and syntactic structures, we propose the dependency modeling objective to train models to learn the probability distribution of the future dependent tokens directly. Following Ahmed et al. (2019), we define the *future dependent tokens* of a specific token in a sentence as its children and parent in the dependency parse tree that will appear in the rest of the sentence. Taking Figure 1 as an example, the future dependent tokens of "figures" are "screen" and "indicate", since "red" does not appear after "figures" in this sentence.

Specifically, given a token sequence $\mathbf{x} = \{x_1, \ldots, x_{T-1}, x_T\}$ where $T \in \mathbb{N}$ denotes the sequence length, we first use dependency parser to generate a dependency tree. Then, we derive the future dependent tokens set Z_t for each token x_{t-1}, where $Z_t = \{x_i \mid i \geq t, x_i \text{ is the child or parent of } x_{t-1}\}$. We train a language model θ to maximize the log-likelihood sum of tokens in Z_t. This equals to minimize:

$$\mathcal{L}_{\mathrm{DM}}(\theta) = -\sum_{t=1}^{T} \sum_{z_t \in Z_t} \log p_\theta^{\mathrm{dep}}(z_t \mid \mathbf{x}_{<t}), \quad (1)$$

which is the dependency modeling objective.

2.2 Dependency-based Mixture Language Models

To give a categorical probability distribution over the next-token, a standard approach for the current neural language models is to encode the context into a fixed-size vector followed by an output embedding layer and a softmax function.

In our case, given the context $\mathbf{x}_{<t}$, we first train the language model to directly learn the probability distribution of x_{t-1}'s future dependent tokens $p_\theta^{\mathrm{dep}}(w \mid \mathbf{x}_{<t})$ by dependency modeling (Section 2.1). We then propose DMLM (depicted in Figure 2) that mixes dependency modeling probability distributions $P^{\mathrm{dep}} = \{p_\theta^{\mathrm{dep}}(w \mid \mathbf{x}_{<1}), \ldots, p_\theta^{\mathrm{dep}}(w \mid \mathbf{x}_{<t-1}), p_\theta^{\mathrm{dep}}(w \mid \mathbf{x}_{<t})\}$. All the probability distributions in P^{dep} are weighed by self-attention, and summed to obtain the final next-token probability distribution.

We can easily implement a self-attention in both Transformer-based and RNN-based language models. For example, in Transformer and GPT-2, the penultimate layer seems to naturally learn alignments (Garg et al., 2019), so we use its average attention weights over all the attentions heads as the dependency attention distribution. In RNN-based models, inspired by Merity et al. (2017) and

Vaswani et al. (2017), at each timestep, we linearly project the current hidden state $h_t \in \mathbb{R}^H$ to a query vector $q_t = W^Q h_t$ and a key vector $k_t = W^K h_t$, where $W^Q \in \mathbb{R}^{H \times H}$, $W^K \in \mathbb{R}^{H \times H}$, $q_t \in \mathbb{R}^H$, and $k_t \in \mathbb{R}^H$. To generate the dependency attention, we compute the match between the query q_t and the context's keys $\{k_1, \ldots, k_{t-1}, k_t\}$ by taking the inner product, followed by a softmax to obtain the dependency attention distribution:

$$\begin{aligned}
\mathbf{e}^{(\mathrm{t})} &= \{e_1^{(t)}, \ldots, e_{t-1}^{(t)}, e_t^{(t)}\}, \\
e_i^{(t)} &= q_t^T k_i, 1 \leq i \leq t, \\
\mathbf{a}^{(\mathbf{t})} &= \operatorname{softmax}(\frac{\mathbf{e}^{(\mathrm{t})}}{\sqrt{H}}), \\
\mathbf{a}^{(\mathbf{t})} &= \{a_1^{(t)}, \ldots, a_{t-1}^{(t)}, a_t^{(t)}\},
\end{aligned} \tag{2}$$

where $\mathbf{e}^{(\mathrm{t})} \in \mathbb{R}^t$, and $\mathbf{a}^{(\mathbf{t})} \in \mathbb{R}^t$. We scale the dot products by $\frac{1}{\sqrt{H}}$ following Vaswani et al. (2017).

The dependency attention distribution reveals which token in the context may have a strong dependency relation with the token to be predicted. Thus, the neural language model should pay more attention to previous tokens with high dependency attention scores, i.e., the next-token is more likely to be the future dependent token of those tokens in the context. Formally, the next-token probability is the sum of the context's dependency modeling probability distributions weighed by the dependency attention scores:

$$p_\theta\left(w \mid \mathbf{x}_{<t}\right) = \sum_{\tau=1}^{t} a_\tau^{(t)} p_\theta^{\text{dep}}\left(w \mid \mathbf{x}_{<\tau}\right). \tag{3}$$

where $p_\theta^{\text{dep}}\left(w \mid \mathbf{x}_{<\tau}\right)$ is the probability distribution of $x_{\tau-1}$'s future dependent tokens, since till now the neural language model is only trained by dependency modeling. Then, we further finetune the neural language model using MLE, but with respect to our modified probability distribution given in Equation 3:

$$\mathcal{L}_{\text{LM}}(\theta) = -\sum_{t=1}^{T} \log p_\theta\left(x_t \mid \mathbf{x}_{<t}\right). \tag{4}$$

For each timestep during inference, DMLM outputs a dependency modeling distribution, and we store it in a list. To predict the next-token, DMLM applies self-attention in Equation 2 to produce a dependency attention distribution over the context, and then the next-token probability can be calculated by Equation 3, where the list preserves all the $p_\theta^{\text{dep}}\left(w \mid \mathbf{x}_{<\tau}\right), 1 \leq \tau \leq t$.

3 Experiments

Despite previous works mainly focusing on language modeling, it has always been a thorny issue whether better language models lead to better performance in downstream tasks. Therefore, we showcase the performance of our proposed DMLM in three different tasks: conditional text generation (Section 3.1), unconditional text generation (Section 3.2), and language modeling (Section 3.3).

To verify the effectiveness and architecturally generalizability of our method, we conduct the generation tasks with three dominant neural language models, including LSTM, Transformer and GPT-2. We prefix the base model name with "**DM-**" to denote the corresponding Dependency-based Mixture language model. Specifically, we adopt AWD-LSTM (Merity et al., 2018) as our base LSTM, and further compare our DM-LSTM with **PRPN** (Shen et al., 2018) and **ON-LSTM** (Shen et al., 2019) which also incorporate knowledge of syntactic structures, and are built on LSTM. In the same task, we use exactly the same hyper-parameters and setups for the pairs of base models and corresponding DM-models. Other details of the experimental setup for each task can be seen in Appendix A.

For all the tasks, we use a state-of-the-art parser, HPSG Parser[2] (Zhou and Zhao, 2019) to get the dependency parse tree for each sentence in the datasets. We discuss the impact of the dependency parser in Appendix B.

3.1 Conditional Text Generation

Setup We take the story ending generation as the conditional text generation task, and evaluate our method on the ROCStories corpus (Mostafazadeh et al., 2016), which consists of 98,161 five-sentences. We follow the preprocessing[3] of Kong et al. (2021) to randomly split ROCStories by 8:1:1 for training/validation/test, respectively, and delexicalize stories by masking all the male/female/unknown names with "[MALE]"/"[FEMALE]"/"[NEUTRAL]". We finally get a word-level vocabulary with $31,216$ unique tokens. The conditional text generation task is to generate a reasonable ending given a four-sentence story context. For all models, we generate stories using nucleus sampling (Holtzman et al.,

Table 4: Results of global metrics for the unconditional text generation task on EMNLP2017 WMT News.

2020) with $p = 0.5$.

We measure the generated story endings by the following automatics metrics: (1) **UNION** (Guan and Huang, 2020): It is a learnable unreferenced metric for evaluating the quality of generated stories; (2) **BERTScore** (Zhang et al., 2020): The metric measures the semantic consistency between the generated and the referenced ones by BERT (Devlin et al., 2019); (3) **BLEU (B-n)** (Papineni et al., 2002): BLEU evaluates n-gram overlap between the generated stories and the references; (4) **Distinct (D-n)** (Li et al., 2016): The proportions of distinct n-grams in the outputs to evaluate the diversity of generated results. Since Distinct score will become extremely low for small n, we calculate it with $n = 2, 3$; (5) **Self-BLEU (SB-n)** (Zhu et al., 2018): The metric is calculated by computing n-grams ($n = 2, 3$) BLEU score of each generated text with all other generated ones as references. Smaller Self-BLEU scores indicate better diversity.

Results The experimental results of baselines and corresponding DM-models are shown in Table 2. Note that we do not conduct significant tests on Distinct since it is a document-level metric. We can see that, all the DM-models significantly outperform baseline models on almost all the metrics. Furthermore, compared with PRPN and ON-LSTM, our DM-LSTM performs significantly better in all the metrics. This indicates that incorporating knowledge of syntactic structures in our proposed way can effectively contribute to both the quality and diversity of the story ending generation. Moreover, no matter what the base model is, our DM-model can substantially improves the conditional text generation. This demonstrates that our method can be effectively adapted to different neural language models, such as the large scale language model, GPT-2, while previous models like ON-LSTM can only be built on LSTM.

Human evaluation To further evaluate the fluency and logic of generated stories, following (Guan et al., 2020), we conduct pair-wise comparisons between DM-models and corresponding

baselines. We randomly sample 100 story endings from each model. For each pair of stories (one by the DM-model and the other by the baseline, along with the beginning), five annotators are hired to give a preference (win, lose, or tie) from the following two aspects: (1) *Grammaticality*: whether a story ending is natural and fluent; (2) *Logicality*: whether a story is coherent to the given beginning and reasonable in terms of causal and temporal dependencies in the context. The detailed questionnaire and other details are shown in Appendix D.

The average win/lose/tie rates of the human evaluation are shown in Table 3. To measure the inter-annotator agreement, we calculate Krippendorff's alpha (Hayes and Krippendorff, 2007) for each pair-wise comparison, and all the results are fair agreement ($0.2 \leq \kappa \leq 0.4$) or moderate agreement ($0.4 \leq \kappa \leq 0.6$). The results show that our DM-models significantly outperform baseline models in both the grammaticality and logicality.

3.2 Unconditional Text Generation

Setup We perform experiments of unconditional text generation on EMNLP2017 WMT News dataset[4]. We use the preprocessed data of a recent work[5] (Caccia et al., 2020) that contains $5,268$ distinct words with maximum sentence length 51. The training/validation/test set consists of $268,586/10,000/10,000$ sentences.

Following Caccia et al. (2020), we evaluate the models with the *global metrics* (Semeniuta et al., 2018): (1) **Language Model score (LM score)**: We use the oracle Language Model to evaluate the negative log-likelihood of generated text as the metric to reflect quality; (2) **Reverse Language Model score (RLM score)** We train a new Language Model on the generated text, and then evaluate the negative log-likelihood of a held-out set of real text. This metric can measure text diversity since the generated text with better diversity would have a broader coverage over the real data space, and the new Language Model can be trained better, thus leading to lower RLM score. Both the LM score and RLM score are usually evaluated on the sentences generated by purely random sampling. Besides, to further measure the generation fluency, we directly use the public GPT-2 checkpoint of pre-trained parameters without finetuning to calculate **GPT-2 Perplexity** of generated samples.

Results Table 4 shows the results of global metrics obtained by various models. All the DM-models again outperform the baselines. The consistently lower LM scores indicate that the generated

Table 7: Various language models' perplexity evaluated on validation and test sets of Penn Treebank dataset. Yang et al. (2018) and Takase et al. (2018) focus on improving the softmax of LSTM LM, which are orthogonal to ours.

sentences of DM-models are of better quality, while the consistently lower RLM scores also demonstrate that DM-models can generate more diverse sentences meanwhile.

In addition, each model is used to generate $1,000$ sentences with various sampling hyper-parameters, and GPT-2 Perplexity is further calculated. As shown in Table 5, our proposed method can make neural language models perform significantly better in terms of generation fluency. In particular, Transformer-based models can gain more significant improvement from DMLM. We conjecture that this is because, in our implementation, we directly uses the penultimate multi-head attention layer of Transformer to obtain the dependency attention distribution of DMLM. Thus, it can easily inherit all the strengths of Transformer-based models.

Human evaluation Following previous work (Yu et al., 2017; Guo et al., 2018), we conduct a Turing test to further evaluate the generated text. In practice, we mix 100 randomly sampled sentences from each model, and another 100 sentences from the real test set. Five annotators are hired to judge whether each of the 900 sentences is created by human or machines. Each sentence gets $+1$ score when it is regarded as a real one, and 0 score otherwise. The detailed questionnaire and other details are shown in Appendix D.

The average score for each model is shown in Table 6, from which we can see all the DM-models surpass the baselines. Both automatic evaluations and human evaluations indicate that DMLM can help neural language models generate more readable, fluent, and natural sentences.

3.3 Language Modeling

Setup We evaluate the proposed method with the word-level language modeling task by measuring **Perplexity (PPL)** on the Penn Treebank (PTB) (Marcus et al., 1993; Mikolov et al., 2012) corpora. The PTB dataset has a vocabulary size of $10,000$ unique words, and the training/validation/test set consists of $42,068/3,370/3,761$ sentences.

For this task, we mainly implement the DMLM on the RNN-based language model, i.e., AWD-LSTM (Merity et al., 2018). For a fair comparison, our DM-LSTM uses exactly the same hyper-parameters and setups as AWD-LSTM. Since Transformer-based models' strong performance relies on training with large datasets, it will perform worse than random when trained on a small dataset (Shen et al., 2021a). We still report Transformer-based models' language modeling results on PTB in Appendix C.

Results We compare our method with its base model, AWD-LSTM, and we report the results along with other state-of-the-art models in Table 7. Compared with the AWD-LSTM, our DM-LSTM reduces the perplexity by 1.4 on the validation set and 1.1 on the test set, indicating that incorporating knowledge of syntactic structures in our proposed manner can substantially improve language modeling. Compared with other models that also leverage syntactic knowledge, our DM-LSTM strongly outperforms RNNG, PRPN, and URNNG. Moreover, though DM-LSTM does not make any changes to the architecture of the AWD-LSTM language model, it still achieves a comparable perplexity with ON-LSTM. Note that, since our method is model-agnostic, it can be harmonically

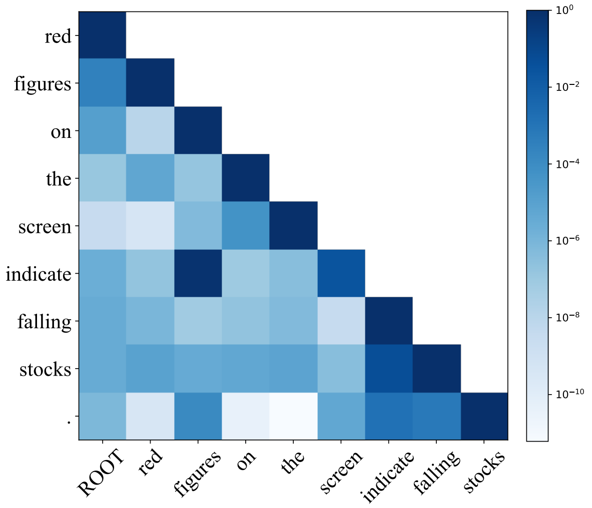

Figure 3: Visualization of dependency attention distributions. We left-shift the sentence by one step in the y-axis to better display the attention between the predicted next-token and the context in each row.

combined with other state-of-the-art models, such as MoS (Yang et al., 2018) and DOC (Takase et al., 2018).

4 Discussion

4.1 Visualization

We show how our proposed method works by visualizing the dependency attention distributions. We use DM-Transformer to generate a sentence: "red figures on the screen indicate falling stocks." For each generation step, we record this step's dependency attention distribution. When we finally generate the whole sentence, we get 9 distributions and plot Figure 3 from them. Each row in Figure 3 shows the dependency attention distribution of the model when generating the corresponding Y-axis token. When predicting the token "indicate", DMLM pays great attention to "figures". This is because these two tokens have a direct dependency connection in the dependency parse tree, and our method successfully captures this relationship. In addition, DMLM also helps the model better organize dependency information when the next-tokens, such as "screen" and "stocks", have dependencies on more than one token in the context.

4.2 Case Study

We perform case studies for a better understanding of the model performance. Table 8 provides examples of conditional text generation produced by our DM-models and other baselines. Obviously, all the DM-models can generate more reasonable and coherent story endings. Additionally, some examples of unconditional text generation are shown in Table 9 and Appendix E. These examples show that our DMLM can help base models generate more reasonable, readable, fluent, and natural sentences.

4.3 Computational Complexity

Compared with vanilla RNN, our DM-RNN indeed increases the computational complexity from $O(T)$ to $O(T^2)$. In practice, we can follow Merity et al. (2017) to set a context window that allows DMLM looks L timesteps into the past at most, where L is the context length. However, our DMLM can efficiently apply to Transformer-based models without additional computational complexity.

5 Related Works

Many previous studies have shown that leveraging the knowledge of syntactic structures can improve NLG (Chelba, 1997; Roark, 2001; Emami and Jelinek, 2005; Buys and Blunsom, 2015). Mirowski and Vlachos (2015) incorporated syntactic dependencies into the RNN formulation, but they limited the scope to the scoring of complete sentences, not to next word prediction. Some other efforts have been done to integrate dependency structure into neural machine translation (NMT) from both the source and target side. Eriguchi et al. (2016) proposed a tree-to-sequence attentional NMT model where source-side parse tree was used. Wu et al. (2017) involved target syntactic trees into NMT model to jointly learn target translation and dependency parsing. Casas et al. (2020) introduced a syntactic inductive bias to NLG in an iterative non-autoregressive way.

For neural language models, recently, Dyer et al. (2016) proposed recurrent neural network grammar (RNNG) to jointly model syntax and surface structure by incrementally generating a syntax tree and sentence. Subsequent work (Kim et al., 2019) extended the model to an unsupervised version. Shen et al. (2018) introduced the Parsing-Reading-Predict Networks (PRPN) to calculate syntactic distances among words and use self-attention to compose previous states. Its subsequent work (Shen et al., 2019) transferred the distance notion to LSTM cell, and introduced Ordered Neurons LSTM (ON-LSTM).

However, all these methods, mainly based on RNN (Sutskever et al., 2014), incorporate knowl-

Story context:	[FEMALE] bought packets of vegetable seeds from the store . she dug up the dirt in her garden . [FEMALE] planted onions , cilantro , and tomatoes . [FEMALE] watered the garden every night .
Golden Text:	by the end of the summer [FEMALE] had enough vegetables to make salsa .
PRPN:	she got to work in the morning and was happy to have a garden .
ON-LSTM:	[FEMALE] planted the plants and made it a huge success .
AWD-LSTM:	[FEMALE] was happy to be helping her plants .
DM-LSTM:	soon , [FEMALE] had enough vegetables to grow in her garden !
Transformer:	she went to the store to buy the seeds .
DM-Transformer:	soon , [FEMALE] had her garden full of vegetables !
GPT-2:	[FEMALE] 's garden grew very quickly and dry .
DM-GPT-2:	[FEMALE] now has fresh fruits and vegetables in her garden .

Table 8: Examples of conditional text generation on ROCStories dataset.

Golden Text:	what this group does is to take down various different websites it believes to be criminal and leading to terrorist acts .
PRPN:	the right point to pay for the purchase of a bike , that ' s all we want to do to build , build together the support that i need to get here .
ON-LSTM:	it ' s great to know that my experience has changed my mind because i ' m not going to work because i ' ve had to talk about that .
AWD-LSTM:	this is a tragic attack and it is understood that the pair will come up with a package of documents which may be possible .
DM-LSTM:	the win over bernie sanders was an emotional moment for clinton , who was running in the general election , though she lost their state of vermont .
Transformer:	' i ' ve just been in that position so i ' ve never seen anything like this before , but it ' s something i have to say and i ' m going to go to and win this series .
DM-Transformer:	in the second quarter of 2015 , the outlook for consumer spending rose 8 . 6 per cent , but for the fourth quarter , the company said it expects to expand by 0 . 7 per cent .
GPT-2:	if i had said a bit of pressure , i would probably be in a different position if i was a coach .
DM-GPT-2:	they ' ve also said that it ' s difficult to know how many emails clinton actually sent to her in recent weeks or whether she would be the nominee .

Table 9: Examples of unconditional text generation on EMNLP2017 WMT News dataset.

edge of syntactic structures by introducing complex architectural changes. Therefore, it can get very unwieldy to adapt them to other neural language models, such as Transformer and GPT-2.

6 Conclusion

In this paper, we introduce Dependency-based Mixture Language Models, which can incorporate knowledge of dependency structures into arbitrary auto-regressive generation models without any changes to the original architectures. Both automatic and human evaluation results in extensive experiments across different tasks and different architectures demonstrate the effectiveness and generalizability of our method.

In the future, we will explore to incorporate the dependency labels into our method, and combine our DMLM with more neural language models. Second, we would like to integrate other linguistic knowledge, such as constituency structures and semantic information, into neural language models in our manner.

A Experimental Setup

All the algorithms are implemented in Pytorch and trained on a machine with 8 NVIDIA GTX 2080Ti GPUs.

A.1 Conditional Text Generation

The dataset statistics of ROCStories dataset is reported in Table 10.

	Train	Validation	Test
#Stories	78,529	9,816	9,816

Table 10: Statistics of ROCStories dataset.

In this task, both the DM-LSTM and base LSTM are built on a AWD-LSTM language model with an embedding size of 400 and hidden layer units 1150. The dropout rates are $0.4, 0.25, 0.4$ for the output of the last layer, outputs between LSTM layers, and input embedding layers, respectively. The weight dropout for the RNN hidden to hidden matrix is 0.5, and the dropout rate to remove words from embedding layer is 0.1. The context length for DM-LSTM is set to 56. For PRPN and ON-LSTM, we keep their original settings.

In this task, all the models are trained on a singe GPU with learning rate 30, weight decay $1.2e-6$. LSTM baselines are trained for 500 epochs with batch size 100. DM-LSTM is first trained by dependency modeling objective for 100 epochs with batch size 80, and then by language modeling in Equation 4 for 400 epochs with batch size 60 due the computational budgets limit.

For both the DM-Transformer and base Transformer, we use a standard 6-layer Transformer language model with 8 attention heads, embedding dimension 512, projection dimension 2048 and dropout rate 0.1. During training, we use Adam optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.98$, weight decay 0.01 and learning rate $5e-4$, and apply the dynamic batching provided by fairseq[6] to train both the models with 4 GPUs. Transformer is trained for 60 epochs, while DM-GPT-2 is first trained by dependency modeling for 30 epochs, and then trained by language modeling in Equation 4 for 30 epochs.

We use the pretrained GPT-2-base model for both the DM-GPT-2 and base GPT-2. In this comparison, we apply the same training settings with Transformer-base models except that learning rate is set to $5e-5$. GPT-2 is trained for 80 epochs, while DM-GPT-2 is first trained by dependency modeling for 40 epochs, and then trained by language modeling in Equation 4 for 40 epochs.

For all the models, we select the best checkpoint according to the loss of validation set for testing.

A.2 Unconditional Text Generation

The dataset statistics of EMNLP2017 WMT News dataset is reported in Table 11.

	Train	Validation	Test
#Stories	268,586	10,000	10,000

Table 11: Statistics of EMNLP2017 WMT News dataset.

The context length for DM-LSTM is set to 36. LSTM baselines are trained for 500 epochs with batch size 300. DM-LSTM is first trained by dependency modeling objective for 100 epochs with batch size 300, and then by language modeling for 400 epochs with batch size 200. Besides, all the other experimental setups are the same with those for the conditional text generation task.

A.3 Language Modeling

The dataset statistics of Penn Treebank dataset is reported in Table 12.

	Train	Validation	Test
#Stories	42,068	3,370	3,761

Table 12: Statistics of Penn Treebank dataset.

The context length for DM-LSTM is set to 16. DM-LSTM is trained for 1000 epochs with batch size 20, following (Merity et al., 2018). Besides, all the other experimental setups are the same with those for the conditional text generation task.

B Impact of the Dependency Parser

In our work, we use an off-the-shelf dependency parser to get the dependency parse trees for dependency modeling. Consequently, the better the quality of dependency parsing, the better the performance of our method. HPSG Parser (Zhou and Zhao, 2019), the dependency parser we use, is one of the state-state-of-the-art parsers. This ensures the high quality of parsing results. Zhou and Zhao (2019) trained HPSG Parser with the training set

---

[6] `https://github.com/pytorch/fairseq`

of PTB, and kept the test set held-out. So, when we do language modeling on PTB, the parser will not inject any future predictions that contribute to testing.

HPSG Parser maintains high-quality on out-of-domain text, as shown in its paper (Zhou and Zhao, 2019). Most importantly, even on the out-of-domain datasets, i.e., ROCStories and EMNLP2017 WMT News, our work can still obtain a significant improvement, as shown in Section 3.1 and Section 3.2.

C Language Modeling on Transformer-based Models

The language modeling results of Transformer-based models evaluated on PTB dataset are shown in following Table 13.

Models	#Params	Dev PPL	Test PPL
Transformer	24M	100.7	106.7
DM-Transformer	24M	**80.6**	**84.6**
GPT-2	163M	62.6	55.2
DM-GPT-2	163M	**58.8**	**51.6**

Table 13: Transformer-based models' perplexity evaluated on validation and test sets of Penn Treebank dataset.

The good performance of Transformer-based models often rely on training with large datasets, but PTB is a very small dataset. Therefore, Transformer-based models perform worse than LSTM-based models, as shown in Table 7 and Table 13. However, our DM-models still substantially reduce the perplexity compared with base models. DM-Transformer improves the base Transformer by over 20 perplexity points on both the validation and test set, and DM-GPT-2 also improves the base GPT-2 by almost 4 perplexity points. These results further confirm the effectiveness our method.

D Human Evaluation

We post the human evaluation questionnaire, as shown in Table 14 and Table 15, and then recruit five workers with sufficient high English skills. We pay each worker 45 US dollars, and let them complete the evaluation within a week.

E Generated Examples

For a more general comparison, we present more generated examples of unconditional text generation in Table 16.

Task Description

Each story contains about five sentences. For each story, we will put the first four sentences into two different systems, and then systems generate the last sentence. The requirement for this manual evaluation is to judge **which story better complies with the English grammar norm, and is more logically related to the first four sentences.**

NOTE that the names in all stories are replaced with "[MALE]" or "[FEMALE]" or "[NEUTRAL]", and all the sentences are preprocessed by lowercasing, separating punctuation, and splitting conjunctions. They are not grammar errors. Please ignore these when evaluating and do not allow them to affect your judgments.

Evaluation Criterion

You need to compare the stories from two metrics: **grammaticality** and **logicality**. And the two metrics are **independent** of each other. One of the judgments should not have any influence on the other one. Specific criteria for evaluating are as follows:

1. Grammaticality

In the process of evaluating grammaticality, it should be considered whether the statement itself complies with the English standard usage. Then annotate which story is better at grammaticality. You may not care about what the generated sentences are saying but **only if there are any grammatical problems in the sentence itself.**

2. Logicality

In the process of evaluating logicality, you need to carefully read the whole story including the first four sentences and the generated sentence, and compare stories in logicality. Then annotate which story is better at logicality in terms of the coherence to the given beginnings and the inter-sentence causal and temporal dependencies. In this process, you may encounter sentences that are not completely grammatical.**Please make a logical evaluation based on the main part of the sentence (such as some keywords, etc.) and what you can intuitively feel.** Under the circumstances, the story can be judged totally illogical only if the grammar is too poor to understand the meaning or the logic is unreasonable.

Notes

- Again, the grammaticality and logicality of the story are **two independent metrics**. Some very logically inappropriate generated stories are good in the grammaticality part, and there are some stories with obvious grammatical errors but they don't affect the respective judgment.
- Sometimes, there may be more than one kind of reasonable story for a beginning. Please do not limit your imagination. **As long as the story is logically reasonable, direct, and able to make sense, it can be judged good in logicality.**
- Some stories may not be accurately judged. In the process of determining the comparison of this type of two stories, according to your own understanding of the examples and the subjective feelings of the stories, choose a better story you think is the most appropriate. **Please ensure that your evaluation criterion for different stories is the same.**

Table 14: Human evaluation questionnaire for conditional text generation.

Task Description

In this review, you will read 900 sentences. For each sentence, you should determine **whether the sentence is written by human**. **Note**: All the sentences are preprocessed by lowercasing, separating punctuation, and splitting conjunctions. They are not grammar errors. Some sentences may have a specific context, or they may be talking about completely fictitious things. Please ignore these when evaluating and do not allow them to affect your judgments.

Evaluation Criterion

The judgment can mainly depend on your own understanding and the subjective feelings. But fluency, readability, engagement (whether you felt interested about the sentence), and anything else that you think is important can also help you make a decision.

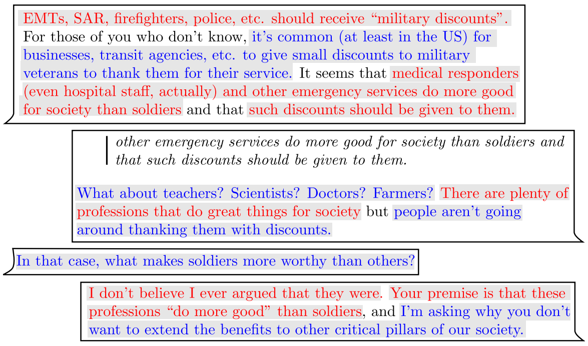
Abstract

Identifying argument components from unstructured texts and predicting the relationships expressed among them are two primary steps of argument mining. The intrinsic complexity of these tasks demands powerful learning models. While pretrained Transformer-based Language Models (LM) have been shown to provide state-of-the-art results over different NLP tasks, the scarcity of manually annotated data and the highly domain-dependent nature of argumentation restrict the capabilities of such models. In this work, we propose a novel transfer learning strategy to overcome these challenges. We utilize argumentation-rich social discussions from the *ChangeMyView* subreddit as a source of unsupervised, argumentative discourse-aware knowledge by finetuning pretrained LMs on a selectively masked language modeling task. Furthermore, we introduce a novel prompt-based strategy for inter-component relation prediction that compliments our proposed fine-tuning method while leveraging on the discourse context. Exhaustive experiments show the generalization capability of our method on these two tasks over within-domain as well as out-of-domain datasets, outperforming several existing and employed strong baselines.[1]

1 Introduction

Computational argument mining from texts is the fine-grained process of understanding opinion dynamics. In the most fundamental sense, argument understanding requires the identification of the opinions posed and justifications provided to support or falsify them. Generally, automated argument mining is a multi-stage pipeline identified with three general steps (Lippi and Torroni, 2015; Stab and Gurevych, 2017) – separating argumentative spans from non-argumentative ones, classifying argument components, and inducing a structure among them (support, attack, etc.). While different argumentation models define different taxonomies for argument components, popular approaches broadly categorize them as 'claims' and 'premises' (Stab and Gurevych, 2017; Egawa et al., 2019; Mayer et al., 2020). As these components are not necessarily aligned to sentence-level segments and can be reflected within clausal levels, the task of argument component identification requires a *token-level boundary detection* of components and *component type classification*.



EMTs, SAR, firefighters, police, etc. should receive "military discounts". For those of you who don't know, it's common (at least in the US) for businesses, transit agencies, etc. to give small discounts to military veterans to thank them for their service. It seems that medical responders (even hospital staff, actually) and other emergency services do more good for society than soldiers and that such discounts should be given to them.

> *other emergency services do more good for society than soldiers and that such discounts should be given to them.*

What about teachers? Scientists? Doctors? Farmers? There are plenty of professions that do great things for society but people aren't going around thanking them with discounts.

In that case, what makes soldiers more worthy than others?

I don't believe I ever argued that they were. Your premise is that these professions "do more good" than soldiers, and I'm asking why you don't want to extend the benefits to other critical pillars of our society.

Figure 1: Token-level claim (red) and premise (blue) annotation of a discussion thread formed by consecutive posts from two users. Second post quotes a span from the first (shown in italics). Highlighted regions signify component boundaries (to demarcate consecutive components of the same kind as in the fourth post).

Context of argumentation in online discussions. Online discussions originating from back-and-forth posts from users reflect a rich interaction of opinion dynamics on large scale. In Figure 1, we show a sample argument component annotation of consecutive posts from two users. The token-level granularity of components ensures that a single sentence may contain multiple components of the same (in 1st post) or different kinds (in 2nd and 4th posts). Moreover, two adjacent spans of texts, even with the same argumentative role, can be defined as two separate components (see the 4th post for example). It is trivial to say that the meaning of any post (as well as its argumentative role) is de-

pendent on the context. To be specific, the third post can be identified as argumentative (a premise in this case) only when its predecessor post and its components are taken as the context. Similarly, a certain span of the first post is quoted in the second one signaling a concrete manifestation of dialogic continuity. One may even observe the user-specific argumentation styles: 1st user (author of the first and third posts) usually keeps claims and premises in separate sentences, while the 2nd user prefers to use multi-component, complex sentences. Existing studies on argumentation formalism recognize such continuity and define inter-post component relations (Ghosh et al., 2014; Hidey et al., 2017). However, the previous approaches for automated extraction, classification and relating argumentative components work on individual posts only and define the inter-post discourse in the later stages of relation prediction.

This is trivially counter-intuitive for two major reasons: (i) if we consider two text spans from separate comments to be linked by some argumentative relation, then there exists a continuity of discourse between these spans and a model is likely to benefit if it decides the boundaries and types of these two components conditioned on that continuous information; (ii) users carry their style of argumentation (simple consecutive sentences vs. long complex ones, usage of particular markers like '*I think that*' etc.), and if the model is informed about these while observing the complete conversation with back-and-forth posts, it is more likely to extract correct components easily.

Scarcity of labeled data. Irrespective of the domain, argument annotation is a resource-intensive process. A few previous studies (Habernal and Gurevych, 2015; Al-Khatib et al., 2016) attempted to exploit a large amount of unlabeled data in a semi-supervised fashion. However, such methods require the components to be defined at sentence-level (and thereby adding redundant spans into the predictions) as they perform some sentence similarity matching to generate pseudo-labels. Pretrained language models like BERT (Devlin et al., 2019) provide a workaround to handle the scarcity of task-specific annotated data. A parameter-intensive model is initially trained in a self-supervised manner on a large bulk of text; this pretraining enables the model to learn general language representation, which is then finetuned on task-specific labeled data. However, the amount of the latter still determines the expressive power of such models (Wang et al., 2020).

Present work. Considering these challenges, we formulate a novel transfer learning method using Transformer-based language models. We use large amount of unlabelled discussion threads from Reddit's *r/ChangeMyView* (CMV) community as the source of argumentative knowledge. Pretrained, Transformer-based language models are finetuned on this dataset using a Masked Language Modelling task. Instead of randomly masking tokens to predict, we select several markers in the text that are shown to signal argumentative discourse in previous works (Chakrabarty et al., 2019; Eckle-Kohler et al., 2015). The language models are then made to predict these markers in the MLM task, thereby learning to relate different components of text according to their role in the argumentation presented. We call this novel finetuning method Selective Masked Language Modeling (**sMLM**). Furthermore, to explore the role of context in argument mining, we use **sMLM** to finetune a post-level language model based on BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) and a thread-level language model based on Longformer (Beltagy et al., 2020). We present efficient incorporation of several Reddit-specific structural cues into the Longformer architecture. These finetuned language models are then used for two fundamental components of argument mining: token-level argument component identification (**ACI**) and inter-component relation type prediction (**RTP**). To further utilize the **sMLM**-based training of the language models, we propose a novel prompt-based approach to predict relations among argument components. We perform exhaustive experiments to explore the efficacy of our proposed methods for argument mining in both *in-domain* and *out-of-domain* benchmark datasets: manually annotated Reddit discussions and scientific papers. Our experiments show clear improvements achieved by our methods (0.59 and 0.69 F1 for ACI and RTP, respectively) over several state-of-the-art baselines.[2]

2 Related Work

A general overview of argument mining can be found in the survey articles by Lytos et al. (2019) and Lawrence and Reed (2019). In the current scope, we look into three major areas of research

---

[2] The source codes and datasets have been submitted separately.

in argument mining.

Argument component detection and classification. Previous studies have sought to address argument boundary detection and component type prediction either as separate, successive tasks in the pipeline (Stab and Gurevych, 2017) or jointly in a single computational pass (Eger et al., 2017). Studies also explored classical machine learning frameworks like SVM-HMM (Habernal and Gurevych, 2017), CRF (Stab and Gurevych, 2017), etc. with rich manual feature engineering. With the development of neural network-based algorithms, BiLSTM-CNN-CRF models emerged as a popular choice (Schulz et al., 2018; Eger et al., 2017; Chernodub et al., 2019). Very recently, large pretrained language models like BERT have also been utilized (Mayer et al., 2020; Chakrabarty et al., 2019).

Discourse markers for learning language representation. Similar to our **sMLM** finetuning strategy, Nie et al. (2019) proposed an unsupervised sentence representation learning strategy where a neural model is trained to predict the appropriate discourse marker connecting two input sentences. Using a set of 15 markers, they showed that such a finetuning can help models in downstream NLI tasks. Chakrabarty et al. (2019) used a distant supervision approach using a single marker *In my honest opinion* to finetune BERT on a large collection of *ChangeMyView* threads and then performed argument component classification. However, they did not deal with the component identification task and performed classification of already identified components at sentence-level. Opitz and Frank (2019) suggested that while identifying the relation between two components, these models often rely more on the context and not the content of the components; discourse markers present within the context provide strong signals for the relation prediction task.

Argument mining over Reddit. A few recent studies explored argumentation over Reddit. Hidey et al. (2017) proposed a two-tier annotation scheme of claim-premise components and their relations, defining five different semantic roles of premises, using *ChangeMyView* discussion data. Egawa et al. (2019) also analyzed semantic roles of argument components over *ChangeMyView* threads; however, their primary focus remained on the dynamics of persuasion, similar to Dutta et al. (2020).

3 Selective MLM finetuning of Pretrained Language Models

Though pretrained language models are developed to overcome the problem of small annotated data on different language processing tasks, they still require task-specific finetuning for better results (Wang et al., 2020). In the specific domain of argument mining, annotated data is scarce, and attempting to finetune a massive language model with very small training data comes with the risk of overfitting. Moreover, different datasets follow different strategies for annotation. We seek to devise a novel transfer learning strategy where a given Transformer-based pretrained language model is directed to focus on argumentative discourse using large-scale, unlabelled data. We choose the *ChangeMyView* (CMV) community as the source of this transfer for two specific reasons: (i) it provides us with a large, readily available resource of interactions strictly focused on debates around versatile topics, and (ii) discussions in CMV contain a mixture of dialogic continuity over successive turns along with elaborate argumentation presented in a single turn. We hypothesize that such a versatile combination of discourse can make the language model more generalizable over dialogic as well as monologic argument mining tasks.

3.1 Discourse structure of CMV

Discussion forums like Reddit facilitate users to begin a discussion with an initial post (*submissions*, in the case of Reddit) and then comments under that post to instantiate a discussion. Users may post a comment in reply to the submission as well as the already posted comments. A typical discussion over Reddit forms a tree-like structure rooted at the submission. Any path from the root to a leaf comment can be perceived as an independent dialogic discourse among two or multiple users; henceforth, we will call such paths as *threads*. Formally, a thread T is an ordered sequence $\{(u_i, P_j)|i, j \in \mathbb{N}, u_i \in U_T\}$, where P_j is a text object (a submission when $j = 1$ and a comment, otherwise), u_i is the author of P_j, and U_T is the set of all unique users engaged in the thread T. For brevity, we indicate P_j as a post in general.

The dialogic nature of discussions naturally assumes this context to be the whole thread T. However, if we consider any two successive posts P_j and P_{j+1} in T, they manifest the interests and styles of two separate participants along with the discourse continuity of the overall thread, which must be distinguished within the definition of the context. To take into account the complete dialogic context of the thread, we represent a thread as a single contiguous sequence of tokens with each post P_j from user u_i being preceded by a special token $[\textbf{USER}\text{-}i]$ with $i \in \{0, \cdots, |U_T| - 1\}$, to encode which post is written by which user.

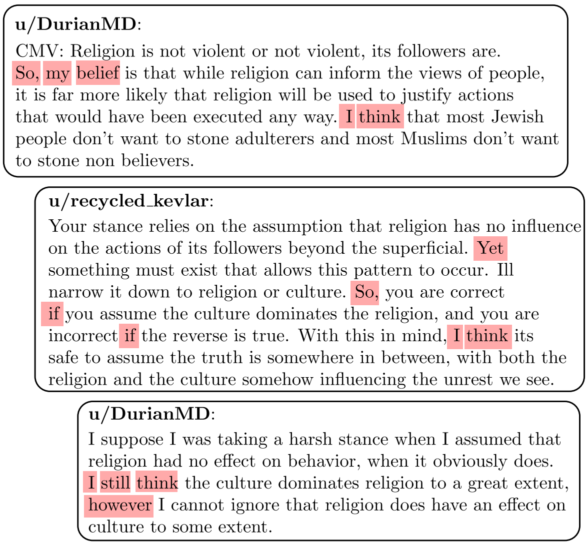
Reddit also offers users a *quoting* facility: users can quote a segment from the previous post (one to which they are replying) within their posts and emphasize that their opinions are specifically focused on that segment. We delimit such quoted segments with special tokens **[STARTQ]** and **[ENDQ]** in the quoting post to demarcate the dialogic discourse. Chakrabarty et al. (2019) also used quoting as signals for following premises. Additionally, we replace URLs with the special token **[URL]** to inform the presence of external references that often act as justifications of subjective opinions.

3.2 Selective MLM finetuning

Masked Language Modeling is a common strategy of training large language models; a certain fraction of the input tokens are masked and the model is trained to predict them, consequently learning a generalized language representation. Instead of randomly selecting tokens to mask, we select specific markers that might signal argumentative discourse. While the model is trained to predict these markers, it learns the roles and relationships of the text spans preceding and following them. Following the work by Eckle-Kohler et al. (2015), we select multiple markers signaling *Opinion*, *Causation*, *Rebuttal*, *Fact presentation*, *Assumption*, *Summary*, and some additional words, which serve multiple purposes depending on the context.

As shown in Figure 2, to predict the marker *I think* in the first post, the model needs to learn that the following text span "*that most Jewish people* $\cdots$" expresses the user's opinion on the topic. Similarly, in the second post, for the input segment "$\langle span_0 \rangle$ *So* $\langle span_1 \rangle$ *if* $\langle span_2 \rangle$", to correctly predict the masked markers as *So* and *if*, a language model needs to learn the fact that the truth value of the statement expressed in $\langle span_1 \rangle$ is conditioned upon $\langle span_2 \rangle$, and this dependence is inferred from $\langle span_0 \rangle$.

Effect of context sizes. CMV threads provide a natural segmentation of the discourse context into comment/post-level vs. thread-level. We seek to explore the effect of the context size at different modules of argument mining (i.e., argument component detection and relation type prediction). For this, we use our proposed selective MLM approach to finetune a pretrained RoBERTa/BERT-base model in the comment/post-level regime, and train Longformer models in the thread-level regime. Longformer uses sparse, global attention (i.e., some tokens attend to all the tokens in the input sequence) to capture the long-range dependencies. We use the special tokens indicating the users (c.f. Section 3.1) as the globally attending tokens for Longformer.



u/DurianMD:
CMV: Religion is not violent or not violent, its followers are. So, my belief is that while religion can inform the views of people, it is far more likely that religion will be used to justify actions that would have been executed any way. I think that most Jewish people don't want to stone adulterers and most Muslims don't want to stone non believers.

u/recycled_kevlar:
Your stance relies on the assumption that religion has no influence on the actions of its followers beyond the superficial. Yet something must exist that allows this pattern to occur. Ill narrow it down to religion or culture. So, you are correct if you assume the culture dominates the religion, and you are incorrect if the reverse is true. With this in mind, I think its safe to assume the truth is somewhere in between, with both the religion and the culture somehow influencing the unrest we see.

u/DurianMD:
I suppose I was taking a harsh stance when I assumed that religion had no effect on behavior, when it obviously does. I still think the culture dominates religion to a great extent, however I cannot ignore that religion does have an effect on culture to some extent.

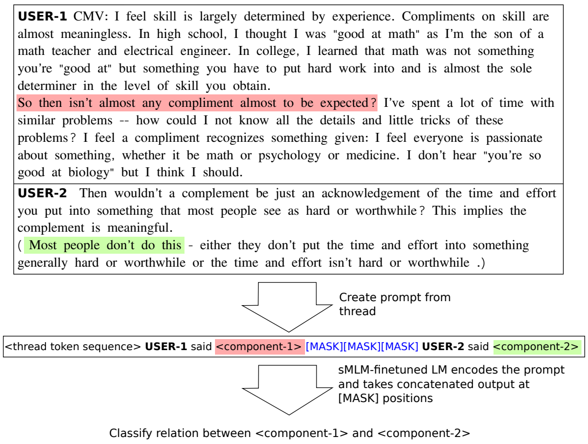
Figure 2: Example of selective masking in a sample CMV thread; **sMLM** finetuning requires a pretrained language model to predict the masked (highlighted in red) tokens (or all the subwords constituting them) based on the context.

3.3 Argument component identification

After finetuning the language model on the selective MLM task, we proceed to our first task of identifying argument components in threads. Since the detection is done in token-level, we use the standard **BIO** tagging scheme: for a component class $\langle type \rangle$, the beginning and the continuation of that component are marked as **B**-$\langle type \rangle$ and **I**-$\langle type \rangle$, respectively, while any non-component token is labeled as **O**. Therefore, if one uses the usual claim-premise model of argumentation, the label set becomes $\{\textbf{B}\text{-claim}, \textbf{I}\text{-claim}, \textbf{B}\text{-premise}, \textbf{I}\text{-premise}, \textbf{O}\}$.

3.4 Inter-component relation prediction

While identifying the relation between two given related argument components, it is important to understand the role of those text segments within the context of the discourse. Furthermore, we seek



USER-1 CMV: I feel skill is largely determined by experience. Compliments on skill are almost meaningless. In high school, I thought I was "good at math" as I'm the son of a math teacher and electrical engineer. In college, I learned that math was not something you're "good at" but something you have to put hard work into and is almost the sole determiner in the level of skill you obtain.
So then isn't almost any compliment almost to be expected ? I've spent a lot of time with similar problems -- how could I not know all the details and little tricks of these problems ? I feel a compliment recognizes something given: I feel everyone is passionate about something, whether it be math or psychology or medicine. I don't hear "you're so good at biology" but I think I should.

USER-2 Then wouldn't a complement be just an acknowledgement of the time and effort you put into something that most people see as hard or worthwhile ? This implies the complement is meaningful.
(Most people don't do this - either they don't put the time and effort into something generally hard or worthwhile or the time and effort isn't hard or worthwhile .)

<thread token sequence> **USER-1** said <component-1> [MASK][MASK][MASK] **USER-2** said <component-2>

Figure 3: Example outline of prompt-based relation prediction where we seek to classify the relation between the claims posed by **USER-1** and **USER-2**, highlighted in red and green, respectively; the thread is converted to the prompt input by appending the prompt template. The language model the converts this prompt token sequence into fixed dimensional vectors from which the vector corresponding to the position of the masking token is used for relation classification.

to utilize the knowledge acquired by a language model in the **sMLM** finetuning step as well. Keeping these two factors in mind, we propose a novel, prompt-based identification of argument components. This approach is inspired by recent popularity of prompt-based fine-tuning methods in the community (Liu et al., 2021). At its core, these methods involve directly prompting the model for the required knowledge, rather than fine-tuning **[CLS]** or mean-pooled embeddings. For example, to directly use a model to summarise a text, we can append "**TL;DR:**" to the text (Radford et al., 2019), and let the model generate tokens following it; we expect the next few tokens to constitute a summary of all the previous text.

Since the underlying Transformer LMs have been trained using some Cloze task (i.e., filling the blanks from the context) previously, it is more natural for it to predict a token given a context. However, there are two challenges: (i) one needs to design a suitable prompt, and (ii) in case of classification tasks like **RTP**, it is challenging to perform **Answer Mapping**, i.e., to map all the possible tokens to some particular relation class. To tackle these challenges, we design our proposed relation prediction method in the following manner (see Figure 3)

For each pair of related components, say, component-1 and component-2, said by user-i and user-j, respectively, where component-2 refers to component-1, we append to the thread, a prompt with the template: "[USER-i] said <component1> [MASK] [MASK] [MASK] [USER-j] said <component2>" (we used three mask tokens since that is the upper bound of the marker size used for **sMLM**). We expect that the words predicted at the masked position such as "because", "in spite of what" etc. would be indicative of the relation of the two components. For the example thread shown in Figure 3, in a zero-shot prediction, **sMLM**-finetuned Longformer predicts "I", "disagree", "I" at the three masked positions. This "disagree" clearly corresponds to the **undercutter** relation between the two components. In fact, the base Longformer without **sMLM** finetuning predicts a space, a full stop and another space at the three masked positions. This additionally proves the efficacy of the **sMLM** finetuning.

Instead of engineering a token-to-relation type mapping, the predicted token embeddings at the masked positions are concatenated and fed into a linear layer to predict probabilities over the set of relation types. This way, we allow the model to learn and map from the token space to the relation type space.

4 Experiment Setup

4.1 Dataset

For the **sMLM** finetuning, we use the subset of *Winning Args (ChangeMyView)* (CMV) dataset (Tan et al., 2016) provided in ConvoKit (Chang et al., 2020). We use 99% of this data for training, and reserve 1% for checking accuracy on the **sMLM** task. The entire data consists of $3,051$ submissions and $293,297$ comments posted in the *ChangeMyView* subreddit by $34,911$ unique users. We extract the threads from these posts following the reply structure and end up with $120,031$ threads in total.

To train and evaluate all the models for **ACI** and **RTP**, we use the manually annotated Reddit discussion threads provided by Hidey et al. (2017) and further extended by Chakrabarty et al. (2019) for training and evaluation. The extended version of this dataset contains 113 CMV discussion threads manually annotated with argument components following the standard claim-premise model.

Additionally, we use the argument annotated **Dr. Inventor Corpus** (Lauscher et al., 2018) which consists of 40 scientific publications from the field of computer graphics. There are three types of argumentative components here: Background Claims

(**BC**), consisting of claims from previous works in the paper, Own Claim (**OC**) consisting of the new claims made by the authors of the paper, and **Data**. The Data class mainly consists of citations, references to figures, etc. This dataset has three relation types, viz., **support**, **contradicts** and **semantically same**. Additional dataset details are provided in Appendix A.

4.2 Baseline methods

For **ACI**, we consider two state-of-the-art token-level argument identification models: ▷ **LSTM-MTL.** Eger et al. (2017) proposed an end-to-end argument mining architecture which uses a BiLSTM-CNN-CRF sequence tagger to jointly learn component detection, classification, and relation parsing tasks. ▷ **LSTM-MData.** Schulz et al. (2018) proposed a BiLSTM-CNN-CRF based model which aims to generalize argument mining using multi-domain training data in an MTL setting. We augment our data with their original set of 6 datasets.

For **RTP**, as no prior work exists to the best of our knowledge, we consider our own baselines. First, we consider ▷ **Context-less RoBERTa**, a pretrained RoBERTa model, which takes the two components with a [SEP] token between them and predicts the relation using [CLS] token's embedding. It is context-less as only two components without the surrounding context are used to predict the label. Second, we consider ▷ **Contextless QR-Bert.** This uses the same fine-tuning methodology as **Contextless RoBERTa** and is initialized from the pre-trained Quote-Response relation prediction model of Chakrabarty et al. (2019).

For **RTP**, we try another traditional strategy, instead of prompting, for our models: ▷ **Mean Pooling**. The mean pooling approach first finds an embedding of each of the two related components by averaging the Transformer embeddings at all token positions within a component. These embeddings are concatenated and passed into a linear layer for predicting the type of relation between the two related components.

To further evaluate the efficacy of our **sMLM** training strategy, we finetune a pretrained Longformer on the Winning Args Corpus, with the usual MLM, i.e., masking 15% of tokens at random, instead of selective masking. We call this the domain-adapted Longformer, **DA-LF**.

Model	**Claim**			**Premise**			**F1**	**Acc**
	P	R	F1	P	R	F1		
sMLM-LF	0.49	0.57	**0.53**	**0.61**	**0.67**	**0.64**	**0.59**	**0.74**

Table 2: Results on Dr. Inventor dataset for argument component identification using **sMLM**-finetuned and base Longformer models.

4.3 Implementation details

We use the pretrained base version of Longformer (12 layers, 768 model size). The size of the local attention window was set to the default 512. The maximum sequence length was fixed at 4096.

Following the suggestions in Reimers and Gurevych (2017), we repeat our experiments on the 5 different data splits. The scores reported in the tables for various models correspond to the average value of the mean of 5 runs, over the last 5 epochs for that particular metric. We provide additional implementation details in Appendix B.

5 Evaluation

We evaluate the models based on precision, recall, and F1 scores for predicting claims and premises. For a more rigorous setting, we use exact match of the whole span between gold and predicted labels, i.e., if the gold label is [**O**, **B**-claim, **I**-claim, **I**-claim, **I**-claim, **O**] then only the predictions [**O**, **B**-claim, **I**-claim, **I**-claim, **I**-claim, **O**], or [**O**, **I**-claim, **I**-claim, **I**-claim, **I**-claim, **O**] can be considered as true positives. We use the popular SeqEval (Nakayama, 2018) framework.

5.1 Argument component identification

Table 1 shows the results for argument component identification on the CMV Modes dataset. We compare models based on their micro-averaged F1 over the two component types (claims, premises), and token level accuracy. Firstly, we observe huge difference in token-level accuracy scores as we move from the existing best performing LSTM based methods with accuracy of 0.54 to BERT,

Model	Support			Agreement			Direct Attack			Undercutter			Partial			Overall

Table 3: Relation type wise Precision (P), Recall (R) and F1 score on the CMV Modes dataset for various models. The highest scores in every column are in **bold**. The suffix "mp" and "prompt" indicate that the model was trained using **Mean Pooling** and **Prompting** strategies, respectively. The **F1** in last column is the Micro/weighted-F1 over all the prediction classes.

Relation types	Base-LF-prompt			sMLM-LF-prompt		
	P	R	F1	P	R	F1
Support	**0.91**	0.90	**0.91**	0.89	**0.92**	**0.91**
Contradict	0.60	**0.60**	**0.60**	**0.65**	0.55	**0.60**
Semantically same	0.74	**0.77**	0.75	**0.77**	0.75	**0.77**

Table 4: Relation Type wise Precision (P), Recall (R) and F1 score on Dr. Inventor Corpus for prompt-based relation prediction using **sMLM** and base Longformer models.

having an accuracy of 0.62. Such a difference is expected since pretrained language models like BERT provide a head-start in case of small datasets like CMV Modes. Though the token-level accuracy increases, the micro-averaged F1 for exact component match does not increase much till we start using RoBERTa. Since pretrained Longformer was trained originally from the RoBERTa checkpoint (Beltagy et al., 2020), we can conclude that RoBERTa provides significant performance gain compared to BERT, owing to its larger training data and protocol. Longformer trained with our proposed **sMLM** finetuning clearly outperforms the rest of the models in terms of overall F1 score for component identification. However, the effects of selective MLM is more prominant in case of thread-level context (i.e, Longformer) compared to comment-level context (i.e, RoBERTa).

We can observe that context plays different roles for different component types: while **sMLM**-finetuned Longformer and RoBERTa perform comparably for claim detection, in case of premises, the access to the complete context helps the Longformer to perform better. We can observe a similar trend in **ACI**-task on Dr. Inventor dataset (see Table 2). While Base Longformer performs comparable to its **sMLM** counterpart to detect Background and Own Claims, **sMLM** provides a 4 point improvement in F1 score for the Data class which plays a similar role of premises towards the claims.

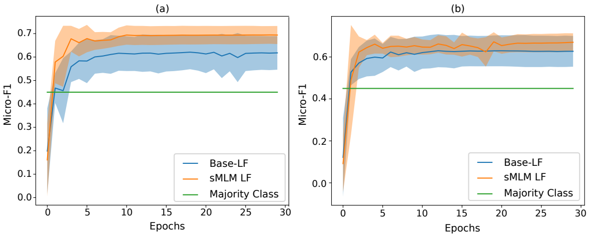

Figure 4: Micro-F1 scores for predicting relation types among argument components by Base and sMLM-finetuned Longformer models over the course of training using (a) 50-50 split and (b) 80-20 split. We use 5 different runs on random splits for each model to report the mean (solid lines) and variance.

Intuitively, textual segments expressing claims contain independent signals of opinion that is less dependent on the context; pretrained language models might be able to decipher their roles without additional information either from the thread-level context (in case of CMV Modes, specifically) or enhanced relation-awareness induced by the **sMLM** finetuning. However, identifying segments that serve the role of premises to a claim intrinsically depends on the claims as well as the discourse expressed in a larger context.

5.2 Relation type prediction

In Table 3, we present the results for relation type identification on the CMV Modes dataset. We again compare models based on their micro-averaged F1 over all relation types. Firstly, we consider the traditional mean pooling approach. Within this approach, we observe a 3 point improvement for the **sMLM** pre-trained Longformer on the 80-20 split, while maintaining same performance on the 50-50 split. Furthermore, the prompt based methods consistently outperform the mean pooling one, irrespective of whether we use base Longformer or **sMLM** pretrained one.

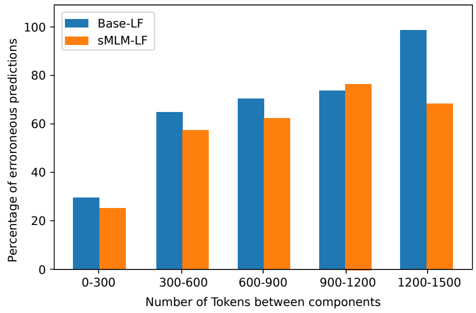

Figure 5: Percentage of erroneous classifications for **RTP** for Base-LF-prompt and LF-sMLM-prompt on component-pairs at different distances.

Within the prompting approach, we also observe increased and consistent improvement in performance due to **sMLM** pretraining on both 80-20 and 50-50 splits. The gap in micro-F1 scores between **sMLM** and base Longformer for 80-20 split increases from 3 points in mean pooling to 5 points in prompting (0 to 7 points improvements for 50-50 split). As we can observe in Figure 4, **sMLM**-finetuned Longformer admits a very narrow margin of variation on random splits, compared to the base Longformer. Furthermore, **sMLM** finetuning consistently outperforms domain-adapted finetuning (**DA-LF**), indicating the unique knowledge transfer achieved by the former.

We hypothesise that this approach works better as this regime models our final **RTP** task, as a task that is *more natural* (in a sense similar to the $(\tau, B)-$natural tasks of Saunshi et al. (2021)) for a Longformer model pre-trained with **sMLM**. Intuitively, the model learns to predict discourse markers at masked positions during **sMLM** pre-training and during fine-tuning on downstream tasks too, the model will naturally try to predict discourse markers at the masked positions. The discourse markers occurring at the masked positions are directly related to the relation between the two components. For instance, when there is a “but” between two components, we know that the two components present opposing views more or less. Here again, we observe that **sMLM** does not hurt the base performance under domain shift (Table 4).

We observe that the RoBERTa model performs worse than Base-LF-prompt, which incorporates the entire context of the thread. Also the effect worsens with reduced training set size, and RoBERTa model performs worse by 7 points in terms of micro-F1 for the 50-50 split. Furthermore, we observe that the mean pooling strategy, even though it uses context, performs worse (by 4 points on 80-20 split) than the context-less RoBERTa. Though, our **sMLM** pretrained model, manages to perform at par with the context-less RoBERTa with the mean pooling strategy. *This means, that the using the right fine-tuning method is essential. Extra context can be utilised fully in longformer, only when pre-training and fine-tuning tasks are nicely aligned.*

Model	**Claim**			**Premise**			**F1**
	P	R	F1	P	R	F1	
base-LF-near	0.39	0.59	0.47	0.63	0.52	0.57	0.52
base-LF-far	0.42	0.57	0.48	0.63	0.55	0.59	0.54
sMLM-LF-near	0.36	0.48	0.40	0.68	0.65	0.66	0.57
sMLM-LF-far	0.46	0.57	0.51	0.63	0.63	0.63	0.58

Table 5: Performance of base Longformer and **sMLM** Longformer for predicting segments having some markers in "**near**" (5 tokens on either side of its) boundaries, and the rest of segments ("**far**").

5.3 Dependence on the presence of markers

Following the analyses presented by Opitz and Frank (2019), we investigate whether the presence/absence of the markers used in the **sMLM** step within the vicinity of the components play any role in the **ACI** or **RTP** performances. Since the relation type among component-pairs that reside distant from each other are less likely to be inferred by the presence of markers in the context, we analyse the percentage of wrong predictions as we vary the distance between two related components, in Figure 5. While error rate does vary proportionally to the distance, we observe that **sMLM-LF** consistently yields lower percentage of wrong predictions as we vary the distance between the related components compared to base Longformer. This clearly indicates the superior capability induced by the **sMLM** finetuning to decipher the relationship among components not linked by direct context (i.e., not within a sentence or a single comment).

For the **ACI** task, however, we observe that the absence of markers in the vicinity of the components actually enables better identification, both in case of **sMLM** finetuned and pretrained Longformer (see Table 5).

6 Conclusion

We presented the results for two important tasks in the argument mining pipeline, viz., **ACI** and **RTP**. The experiments clearly elucidated the importance of alignment between the downstream and pre-trainig tasks, and the effect of various ways of modelling the tasks. The importance of entire thread's context in discussion forums, as well as how to incorporate that into transformer-based models fruitfully has also been made clear.

A Dataset Details

Stats for the CMV Modes dataset are provided in Table 6. These stats are obtained after truncation of threads to 4096 token sequence length. During data analysis, we observed that several threads share the same initial post(*submission*). Hence, we make sure that all threads with the same initial post entirely lie in either the train split, or the test.

For both CMV Modes, and Dr. Inventor Corpus, we only consider contiguous spans of texts as single components, as opposed to the labelling in the dataset. Discontiguous spans are re-labelled as separate components and the model is trained and tested with these new labels, instead.

For CMV Modes dataset, we add an extra "continue" class of relations to denote relation between two dis-contiguous spans of same argumentative component annotated in the data. We group together various relation types annotated in the CMV modes data into the 5 broad classes as follows: **support**("continue" class and "support" class), **agreement**("agreement", "understand" classes), **direct attack**("attack", "rebuttal attack", "rebuttal", "disagreement" classes), **undercutter attack**("undercutter", "undercutter attack" classes), **partial**("partial agreement", "partial attack", "partial disagreement" classes). These groupings are based on the broad annotation guidelines provided for the annotations of CMV Modes data.

For Dr. Inventor Corpus, due to the low number of **semantically same** relations(44) compared to **support**(4535) and **contradicts**(564) in the original dataset, we add the label("**parts-of-same**") which indicates that two dis-contiguous spans belong to the same argumentative component to the **semantically same** category. We also, merge together sections of papers to efficiently utilise 4096 token length of Longformer model. The detailed statistics after truncation to 4096 sequence length are presented in Table 7.

B Implementation Details

We use the pretrained base version of Longformer (12 layers, 768 model size). The size of the local attention window was set to the default 512. The maximum sequence length was fixed at 4096. We added the special tokens that we used, to the pretrained Longformer tokenizer. For **ACI** our models use a CRF layer[3]. **sMLM** training for Longformer based models was done on thread level and for BERT and RoBERTa based models on comment-level. We used mini-batch learning; approximately similar length input threads were batched together keeping the total number of tokens per batch fixed to $8,194$ for Longformer and 1024 for BERT and RoBERTa models, and accumulated gradients over 3 batches.

We trained our models for a total of 10 epochs on sMLM task, while saving checkpoints after each epoch. We used Adam optimizer with a learning rate of 10^{-6}. For all downstream tasks, we train our models for 30 epochs, again, with Adam optimizer with learning rate of $2e-5$ as suggested by Mosbach et al. (2021). We use same batch sizes as **sMLM** training and accumulate gradients over 4 batches. We observe that for prompting **RTP** on CMV-Modes, not making **[USER-i]** tokens global, leads to better performance, hence we report results for same.

We find that **sMLM** training for 4 epochs is most beneficial, for performance on downstream task. Hence, we report results for the same checkpoint. Following the suggestions in Reimers and Gurevych (2017), we repeat our experiments on 5 different data splits and present the distributions in the Appendix. For the results at any epoch, the score plotted corresponds to mean over the 5

Entity-based Neural Local Coherence Modeling

Sungho Jeon and **Michael Strube**
Heidelberg Institute for Theoretical Studies gGmbH
`{sungho.jeon, michael.strube}@h-its.org`

Abstract

In this paper, we propose an entity-based neural local coherence model which is linguistically more sound than previously proposed neural coherence models. Recent neural coherence models encode the input document using large-scale pretrained language models. Hence their basis for computing local coherence are words and even sub-words. An analysis of their output shows that these models frequently compute coherence on the basis of connections between (sub-)words which, from a linguistic perspective, should not play a role. Still, these models achieve state-of-the-art performance in several end applications. In contrast to these models, we compute coherence on the basis of entities by constraining the input to noun phrases and proper names. This provides us with an explicit representation of the most important items in sentences leading to the notion of focus. This brings our model linguistically in line with pre-neural models of computing coherence. It also gives us better insight into the behaviour of the model thus leading to better explainability. Our approach is also in accord with a recent study (O'Connor and Andreas, 2021), which shows that most usable information is captured by nouns and verbs in transformer-based language models. We evaluate our model on three downstream tasks showing that it is not only linguistically more sound than previous models but also that it outperforms them in end applications[1].

1 Introduction

Coherence describes the semantic relation between elements of a text. It recognizes how well a text is organized to convey the information to the reader effectively. Modeling coherence can be beneficial to any system which needs to process a text.

Example Sentence 1
Mr. Specter, seeming exasperated, said in an interview Thursday.
Focus candidates captured by XLNet
“_said”, “_in”, “day”, “_interview”, “_,”, “er”, “_an”, “th”, “s”, “_exasperated”, ..., “spect”
Example Sentence 2
At the same time, unadvertised products may have almost identical ingredients but less name-recognition.
Focus candidates captured by XLNet
“_name”, “ition”, “_products”, “-”, ”_un”, “_may”, “_less”, “_ingredients”, “_have”, ..., “_same”

Table 1: The pretrained language model, XLNet Yang et al. (2019), captures undesirable (sub-)words as focus (Jeon and Strube, 2020). The sub-words are sorted by their attention scores in descending order. In the first example, “Thursday” is split into four: “th”, “ur”, “s”, and “day”. In the second example, some sub-words, such as “ition”, might be beneficial in their vector space but the model might exploit spurious information.

Recent neural coherence models (Mesgar and Strube, 2018; Moon et al., 2019) encode the input document using large-scale pretrained language models (Peters et al., 2018). These neural models compute local coherence, semantic relations between items in adjacent sentences, on the basis of words and even sub-words.

However, it has been unclear on which basis these models compute local coherence. Jeon and Strube (2020) present a neural coherence model, which allows to interpret focus information for the first time. Their investigation reveals that neural models, adopting large-scale pretrained language models, compute coherence on the basis of connections between any (sub-)words or function words (Table 1, 11). In these cases, the model might capture the focus based on spurious information. While such a model might reach or set the state of the art in some end applications, it will do so for

the wrong reasons from a linguistic perspective.

This problem did not appear with pre-neural models, since they compute coherence on the basis of entities. Early work about pronoun and anaphora resolution by Sidner (1981, 1983) assumes that there is one single salient entity in a sentence, its focus, which serves as a preferred antecedent for anaphoric expressions. Centering theory (Joshi and Weinstein, 1981; Grosz et al., 1995) builds on these insights and introduces an algorithm for tracking changes in focus. Centering theory serves as basis for many researchers to develop systems computing local coherence by approximating entities (Barzilay and Lapata 2008; Feng and Hirst 2012; Guinaudeau and Strube 2013, inter alia).

In this paper, we propose a neural coherence model which is linguistically more sound than previously proposed neural coherence models. We compute coherence on the basis of entities by constraining our model to capture focus on noun phrases and proper names. This provides us with an explicit representation of the most important items in sentences, leading to the notion of focus. This brings our model linguistically in line with pre-neural models of coherence.

Our approach is not only linguistically more sound but also is in accord with a recent empirical study by O'Connor and Andreas (2021) who investigate what contextual information contributes to accurate predictions in transformer-based language models. Their experiments show that most usable information is captured by nouns and verbs. Their findings suggest that we can design better neural models by focusing on specific context words. Our work follows their findings by modeling entity-based coherence in an end-to-end framework to improve a neural coherence model.

Our model integrates a local coherence module with a component which takes context into account. Our model first encodes a document using a pre-trained language model and identifies entities using a linguistic parser. The local coherence module captures the most related representations of entities between adjacent sentences, the local focus. Then it tracks the changes of local foci. The second component captures the context of a text by averaging sentence representations.

We evaluate our model on three downstream tasks: automated essay scoring (AES), assessing writing quality (AWQ), and assessing discourse coherence (ADC). AES and AWQ determine text quality for a given text, aiming to replicate human scoring results. Since coherence is an essential factor in assessing text quality, many previous coherence models are evaluated on AES and AWQ. ADC evaluates coherence models on informal texts such as emails and online reviews. In our evaluation, our model achieves state-of-the-art performance.

We also perform a series of analyses to investigate how our model works. Our analyses show that capturing focus on entities gives us better insight into the behaviour of the model, leading to better explainability. Using this information, we examine statistical differences of texts assigned to different qualities. From the perspective of local coherence, we find that texts of higher quality are neither semantically too consistent nor too variant. Finally, we inspect error cases to examine how our model works differently compared to previous models.

2 Related Work

Entity-based modeling has been the prevailing approach to model coherence in pre-neural models. The entity grid is its most well-known implementation (Barzilay and Lapata, 2008). It represents entities in a two-dimensional array to track their transitions between sentences. Many variations have been proposed to improve this model, e.g., projecting the grid into a graph representation (Guinaudeau and Strube, 2013) or converting the grid to a neural model (Tien Nguyen and Joty, 2017).

However, the neural version of the entity grid (Tien Nguyen and Joty, 2017) has two limitations. First, Lai and Tetreault (2018) state that entity grids applied to downstream tasks are often extremely sparse. In their evaluation, it is difficult to find meaningful entity transitions between sentences in the grids. Accordingly, this model performs worse than other neural models. More importantly, this neural model cannot provide any clues of how this model works since Tien Nguyen and Joty (2017) apply a convolutional layer on the entity grid. The feature map of the convolutional layer is not interpretable. They cannot examine which entity is assigned more importance than others by their model. In contrast, we constrain our model to capture focus on entities using noun phrases. Then our model tracks the changes of focus. Hence, it provides us with an interpretable focus (Section 5).

More recently, Moon et al. (2019) propose a neural coherence model to exploit both local and structural aspects. They evaluate their model on an artificial task only, the shuffle test, which determines whether sentences in a document are shuffled or not. However, recent studies (Pishdad et al., 2020) claim that this artificial task is not suitable to evaluate coherence models. Lai and Tetreault (2018) show that the neural coherence models, which achieve the best performance on this task, do not outperform non-neural models on downstream tasks. More recently, Mohiuddin et al. (2021) find a weak correlation between the model performance in artificial tasks and downstream tasks. In our evaluation, we compare Moon et al. (2019) with ours in an artificial task as well as in three downstream tasks. Moon et al. (2019) perform the best in the artificial task, but do not outperform our model in three downstream tasks (Section 4).

3 Our Model

Figure 1 presents the architecture of our model. We first introduce our entity representation and sentence encoding using a pretrained language model. Next, we describe a novel local coherence model. We then combine the two representations of local coherence and the context vector, simply averaged sentence representations. Finally, we apply a feed-forward network to produce a score label.

3.1 Sentence Encoding

We use a pretrained language model (Yang et al., 2019) to encode sentences. XLNet learns bidirectional contexts by maximizing expected likelihood using an autoregressive training objective. Hence it allows to capture the focus in sentences. XLNet outperforms other language models in tasks which require processing long texts.

Recent work investigates that pretrained language models learn linguistic features that are helpful for language understanding (Tenney et al., 2019; Warstadt et al., 2020). Inspired by this, we encode two adjacent sentences at once to capture discourse features, such as coreference relations. In this strategy, items are encoded twice except the items included in the first and the last sentence. We interpolate items encoded twice to consider context with regard to the preceding and succeeding sentence.

We encode an input document using XLNet to obtain word representations. Sentence representations are means of all word representations in a sentence. We then feed sentence representations and the noun phrase representations into the the coherence modules.

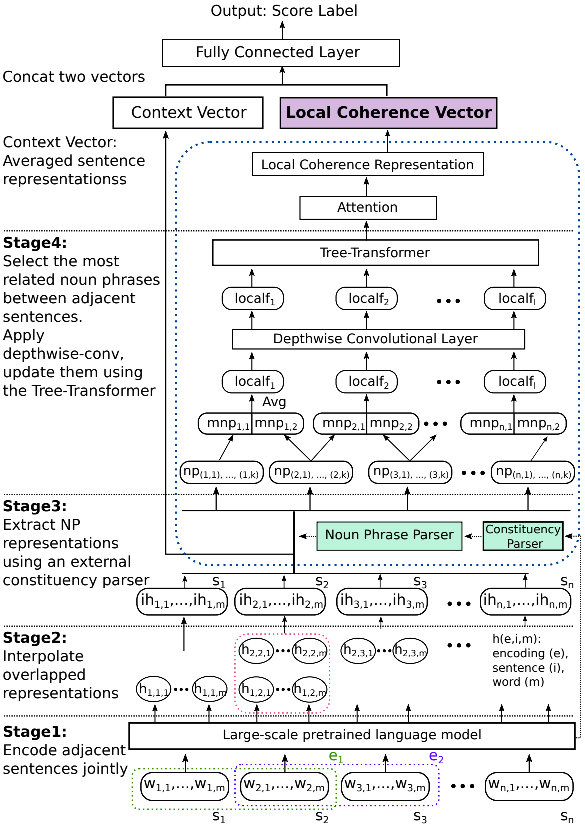

Figure 1: Our model architecture.

In formal definitions, let $E_e = [h_{(e,i,1)}, ..., h_{(e,i,m)}, h_{(e,i+1,1)}, ..., h_{(e,i+1,m)}]$ denote the output of encoding, where e indicates the index of encoding, and m indicates the index of a subword (w) in the sentence (s_i). h indicates the encoded representation of w. This encoding output includes the encoded representations of s_i and s_{i+1} since we encode two adjacent sentences at once. Likewise, $E_{e+1} = [h_{(e+1,i+1,1)}, ..., h_{(e+1,i+2,m)}]$ is the output in the next encoding, and it includes the encoded representations of s_{i+1} and s_{i+2}. Then, the encoded representation of s_{i+1} is a sequence of $ih_{(i+1,m)} = avg(h_{(e,i+1,m)}, h_{(e+1,i+1,m)})$, which is the interpolated representation of s_{i+1} in the two encoding stages (e and $e+1$). We iterate this process to encode all adjacent sentences.

3.2 Entity Identification

Pretrained language models encode sequences as sub-words, but to our knowledge, there is no linguistic parser using sub-words as input. Hence, we use a linguistic parser to identify noun phrases in each sentence separately. Kitaev and Klein (2018) present a neural constituency parser which determines the syntactic structure of a sentence. To identify noun phrases and proper names, we apply this parser to the original sentences, then map parsed constituents to sub-word tokens.

Since pretrained language models do not have the means to represent phrase meaning composition, we average sub-word representations for phrases which consists of multiple sub-words. While this implementation does not capture the complex meaning of phrases, Yu and Ettinger (2020) report that it shows higher correlation with human annotations than using the last word of phrases, assuming that the last word of a phrase is its head.

Let $NP_i = [np_{i,1}, np_{i,2}, ..., np_{i,j}]$ denote a sequence of noun phases (np) in the ith sentence, and j indicates the index of a noun phrase in the sentence. Each representation of a noun phrase is obtained as $np_{i,j} = avg(ih_{i,1}, ..., ih_{i,k})$, where $ih_{i,k}$ indicates the subword tokens contributing to the same entity.

3.3 Local Coherence Module

We compare the semantic representations of noun phrases between adjacent sentences. The two most similar representations of noun phrases are taken as local focus of the respective sentences. These two representations are averaged to capture the common context. We use cosine similarity to measure semantic similarity.

We notice that some sentences do not include noun phrases, approximately 3.5% in the three datasets used in our evaluation. This mostly occurs when some words are omitted as in cases of ellipsis (Hardt and Romero, 2004). In such cases, we maintain the focus of the previous sentence to preserve the context.

A depthwise convolutional layer is applied to the local focus to record its transitions. Unlike a typical convolutional layer, the depthwise convolutional layer captures the patterns of semantic changes between different time-steps for the same spatial information (Chollet, 2017). In our model, this layer captures the semantic changes between local foci considering the context but on the same spatial dimension of each focus. Hence, it does not hurt the explainability of our model. We use the lightweight depthwise convolutional layer (Wu et al., 2019).

Then we update the representations of local foci to track the semantic changes between them. We use the Tree-Transformer which updates its hidden representations by inducing a tree-structure from a document (Wang et al., 2019). It generates constituent priors by calculating neighboring attention which represents the probability of whether adjacent items are in the same constituent. The constituent priors constrain the self-attention of the transformer to follow the induced structure.

Finally, we apply document attention to produce the weighted sum of all the updated local focus representations. The document attention identifies relative weights of updated representations which enables our model to handle any document length.

In formal descriptions, let $mnp_{l,i}$ denote the representations of two noun phrases which have the highest cosine similarity scores between the ith and $i+1$th sentence. Then, we define $LocalF = [localf_1, ..., localf_l]$, where $localf_l$ is an averaged representation of $mnp_{l,i}$ and $mnp_{l,i+1}$. It represents the sequence of local foci between the ith and $i+1$th sentence, and l indicates the index of the local focus in the document. Finally, the local coherence representation is obtained as $lcr = doc\_attn(tree\_trans(dconv(LocalF)))$ where $dconv$ indicates the depthwise convolutional layer, $tree\_trans$ indicates the Tree-Transformer, and doc_attn indicates the document attention.

4 Experiments

4.1 Implementation Details

We implement our model using the PyTorch library and use the Stanford Stanza library[2] for sentence tokenization. We employ XLNet for the pretrained language model. For the baselines which do not employ a pretrained language model (Dong et al., 2017; Mesgar and Strube, 2018), GloVe is employed for word embeddings, trained on Google News (Pennington et al., 2014) (see Appendix A for more details).

To compare baselines within the same framework, we re-implement all of them in PyTorch. We then use our re-implementation to report the performance of models with 10 runs with different random seeds. We verify statistical significance (p-value<0.01) with both a one-sample t-test, which verifies the reproducibility of the performance of each model, and a two-sample t-test, which verifies that the performance of our model is statistically significantly different from other models.

Within the same framework we compare the size of models used in our experiments. Our neural model uses a number of parameters comparable to the state of the art, the transformer-based model

---

(Moon et al. (2019): 118M < Jeon and Strube (2020): 136M < Our model: 137M).

4.2 Baselines: Neural Coherence Models

In all three downstream tasks, we compare our model against recent neural coherence models. First, Mesgar and Strube (2018) propose a neural local coherence model, based on Centering theory. This model connects the most related states of a Recurrent Neural Network, then represents the coherence patterns using semantic distances between the states. Second, Moon et al. (2019) propose a unified neural coherence model to consider local and structural aspects. This model consists of two modules when they employ a pretrained language model (Peters et al., 2018): a module of inter-sentence relations using a bilinear layer and a topic structure module applying a depth-wise convolutional layer to the sentence representations. To ensure fair comparison, XLNet is employed for this model as well, instead of ELMo (Peters et al., 2018). More recently, Jeon and Strube (2020) propose a neural coherence model approximating the structure of a document by connecting linguistic insights and a pretrained language model. This model consists of two sub-modules. First, a discourse segment parser constructs structural relationships for discourse segments by tracking the changes of focus between discourse segments. Second, a structure-aware transformer updates sentence representation using this structural information.

4.3 Artificial Task: Shuffle Test

We first evaluate our model on the artificial setup, the shuffle test, used in earlier works (Table 2). We follow the setup used in Lai and Tetreault (2018). In this setup, our model outperforms a simple neural model relying on the pretrained language model. Moon et al. (2019) evaluate their models only in this setup. It achieves outstanding performance in this setup. However, in the following sections, our results show that this model does not outperform our model in downstream tasks.

	Avg Acc
Moon et al. (2019)-XLNet-1Sent	**90.57**
Our Model	84.35

Table 2: Shuffle Test: Mean (standard deviation) accuracy performance of shuffle test on GCDC, averaged on four domains. 1Sent indicates that each sentence is encoded separately on the pretrained language model.

This result is not surprising. There is a line of recent work which shows that this setup is not capable of evaluating coherence models from diverse perspectives. Laban et al. (2021) show that employing fine-tuned language models simply achieves a near-perfect accuracy on this setup. O'Connor and Andreas (2021) measure usable information by selectively ablating lexical and structural information in transformer-based language models. Their findings show that prediction accuracy depends on information about local word co-occurrences, but not word order or global position. We suspect that exploiting all information of a sentence is sufficient for shuffle tests to capture patterns to distinguish whether sentences in a document are shuffled or not. Based on these findings, we evaluate our model on three downstream tasks used for evaluating coherence models, automated essay scoring, assessing writing quality, and assessing discourse coherence. We advise future work not to evaluate coherence models on the artificial setup solely.

4.4 Automated Essay Scoring (AES)

Dataset. To evaluate the coherence models on AES, we evaluate them on the Test of English as a Foreign Language (TOEFL) dataset (Blanchard et al., 2013). While the Automated Student Assessment Prize (ASAP) dataset[3] is frequently used for AES, TOEFL has a generally higher quality of essays compared to essays in ASAP. The prompts in ASAP are written by students in grade levels 7 to 10 of US middle schools. Many essays in ASAP consist of only a few sentences. In contrast, the prompts in TOEFL are submitted for the standard English test for the entrance to universities by non-native students. The prompts in TOEFL do not vary so much, the student population is more controlled, and essays have a similar length.

Evaluation Setup. We follow the evaluation setup of previous work on AES (Taghipour and Ng, 2016). For TOEFL, we evaluate performance with accuracy for the 3-class classification problem with 5-fold cross-validation. We use the same split for the cross-validation, used by Jeon and Strube (2020). The cross-entropy loss is deployed for training. The ADAM optimizer is used for our model with a learning rate of 0.003. We evaluate performance for 25 epochs on the validation set with a mini-batch size of 32. The model which reaches the

Table 3: AES: TOEFL Accuracy performance comparison on the test sets, 1S indicates that sentences are encoded individually and 2S indicates that two adjacent sentences are encoded at once on the pretrained language model (see Table 12, 13 in the Appendix C for more details).

best accuracy on the validation set is then applied to the test set.

Baselines. We compare against Dong et al. (2017), a neural model proposed for AES. They present a model consisting of a convolutional layer, followed by a recurrent layer, and an attention layer (Bahdanau et al., 2015) between the adjacent tokens.

Results. Table 3 reports the performance on TOEFL. Dong et al. (2017) report better performance than the more recent neural model based on Centering theory (Mesgar and Strube, 2018). A simple model relying on the pretrained language model outperforms this model, which averages all sentence representations (henceforth, Avg-XLNet). Moon et al. (2019) show that their unified model outperforms previous models on the artificial task, the shuffle test. However, it does not outperform the previous models on the AES task. Jeon and Strube (2020) outperform previous models. Finally, our model, which integrates local and structural aspects, achieves state-of-the-art performance. We perform an ablation study to investigate the contribution of individual components. We compare with Jeon and Strube (2020) who encode two adjacent sentences using the pretrained language model (2SentsEnc). Our results verify that this encoding improves performance, but our model benefits from the novel local coherence module even more.

4.5 Assessing Writing Quality (AWQ)

Dataset. Louis and Nenkova (2013) create a dataset of scientific articles from the New York Times (NYT) for assessing writing quality. They assign each article to one of two classes by a semi-supervised approach: typical or good. Though articles included in both classes are of good quality overall, Louis and Nenkova (2013) show that linguistic features contribute to distinguish different classes of writing quality.

	NYT
Liu and Lapata (2018)-reimpl	54.35 (1.00)
Averaged-XLNet-1SentEnc	67.53 (3.48)
Moon et al. (2019)-XLNet-1Sent	74.75 (1.27)
Jeon and Strube (2020)-1Sent	75.12 (1.10)
Jeon and Strube (2020)-2Sents	76.43 (0.88)
Our Model	**77.52 (0.42)**

Table 4: AWQ: Mean (standard deviation) accuracy of assessing writing quality on the test sets in NYT.

Evaluation Setup. For NYT, we follow the setup used in previous work. Louis and Nenkova (2013) and Ferracane et al. (2019) undersample the dataset to mitigate the bias of the uneven label distribution. Following Ferracane et al. (2019), Jeon and Strube (2020) partition the dataset into 80% training, 10% validation, and 10% test set, respectively. We use the ADAM optimizer with a learning rate of 0.001 and a mini-batch size of 32. We evaluate performance for 25 epochs.

Baselines. Liu and Lapata (2018) propose a neural model which induces structural information without a labeled resource. It induces a non-projective dependency structure by structured attention.

Results. Table 4 shows the performance on NYT. Ferracane et al. (2019) reported the best performance of the latent learning model for discourse structure (Liu and Lapata, 2018) on NYT. However, Jeon and Strube (2020) show that the good results are due to embeddings obtained by training on the target dataset. They also report that Avg-XLNet outperforms this model which employs Glove embeddings. Moon et al. (2019) show better performance than this simple model, but it does

not outperform Jeon and Strube (2020). Our model achieves state-of-the-art performance. An ablation study of the joint sentence encoding, Jeon and Strube (2020)-2SentsEnc, verifies that our model gains improvements not only from this encoding but also from our local coherence module.

4.6 Assessing Discourse Coherence (ADC)

Dataset. While previous work evaluates coherence models on formally written texts (Barzilay and Lapata, 2008), GCDC (Lai and Tetreault, 2018) is designed to evaluate coherence models on informal texts, such as emails or online reviews. The dataset contains four domains: Clinton and Enron for emails, Yahoo for questions and answers in an online forum, and Yelp for online reviews of businesses. The quality of the dataset is controlled to have evenly-distributed scores and a low correlation between discourse length and scores[4].

Evaluation Setup. For GCDC, we perform the experiments following previous work (Lai and Tetreault, 2018). We perform 10-fold cross-validation, use accuracy as evaluation measure on the 3-class classification, and use the cross-entropy loss function.

Baselines. Li and Jurafsky (2017) propose a neural model based on cliques, that are sets of adjacent sentences. This model uses the cliques taken from the original article as a positive label and uses cliques with randomly permutated ones as a negative label. Lai and Tetreault (2018) show that a simple neural model which uses paragraph information outperforms previous models on GCDC.

Results. Table 5 summarizes the performance on GCDC. While Avg-XLNet outperforms previous baselines, other advanced neural models show similar performance. Our model performs slightly better than Jeon and Strube (2020) with two sentences encoding. This shows that the gains mainly benefit from this encoding strategy. We suspect that Jeon and Strube (2020) do not benefit from structural information since texts on GCDC are not well-organized. The texts mostly consist of a few sentences, and they express the writers' emotion. Based on this, Lai and Tetreault (2018) state that texts of lower quality have sudden topic changes. We also suspect that human annotators recognize important entities in the texts, such as the name of a person in the US government.

4.7 Ablation Study

Since our model consists of several components, we examine the influence of each component on the performance of the AES task. Specifically, we first examine the influence of our local coherence module. Then we examine the influence of the Tree-Transformer compared to a naive Transformer. Lastly, we examine the influence of the depth-wise convolutional layer deployed ahead of the Tree-Transformer.

Table 7 shows that each component contributes to the performance meaningfully while the depth-wise convolutional layer increases the performance slightly. This suggests that we could design a better component in future work to capture semantic transitions between local foci.

	Avg Acc
Ours - Local Coherence Module	72.27
Ours - Tree-Transformer - Depth-Conv	75.69
Ours - Depth-Conv	76.25
Our Full Model	**76.54**

Table 7: Ablation study on AES. The averaged accuracy performance of all prompts is reported to compare.

---

[4] The Pearson correlation between text length and scores is lower than 0.12 in all domains.

TOEFL: Prompt 1		NYT-1516415	
Focus on any (%)	**Focus on noun phrases** (%)	Focus on any (%)	**Focus on noun phrases** (%)
_broad (3.63)	i (5.45)	_theory (4.03)	it (4.96)
_many (1.79)	you (2.74)	_universe (3.22)	we (4.13)
_special (1.50)	broad knowledge (2.64)	_said (2.42)	the universe (2.48)
i (1.47)	it (2.38)	stan (2.42)	he (2.48)
_specialize (1.46)	we (1.74)	ein (2.42)	physics (1.65)
_know (1.05)	knowledge (1.34)	dr (2.42)	space (1.65)
_specialized (0.99)	he (1.30)	_do (2.42)	string theory (1.65)

Table 6: Comparison of the focus captured on any items using a language model (Jeon and Strube, 2020) and the focus captured on noun phrases using our model. The essays submitted to prompt 1 in TOEFL and NYT article ID 1516415 (see Table 14 in the Appendix D for more details).

5 Analysis

5.1 Capturing Focus Using Entities

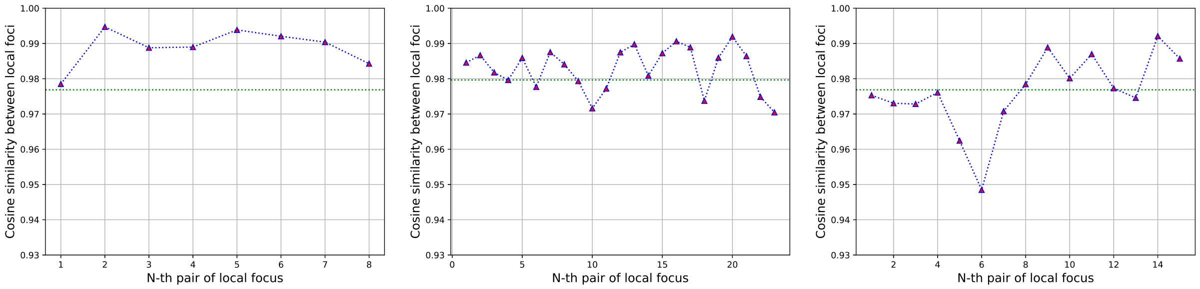
In Centering theory, the focus is described as the most important item in a sentence. Jeon and Strube (2020) capture the focus using attention scores and analyze texts assigned to different qualities using this focus. They state that the focus is difficult to interpret when it is composed of sub-words. To investigate this further, we compare the focus captured on any (sub-)words and the focus constrained to entities. Table 6 indicates that constraining focus to entities leads to better explainability, in particular on NYT. For example, in the NYT-1516415 news article about String theory, a subword of "ein" is not an interpretable focus. It may, however, include useful information in the vector space for a neural model. In contrast, our entity-based model leads to better explainability. Instead of "ein", it provides the more interpretable focus, "Einstein", a theoretical physicist. In TOEFL, "broad knowledge" is a more interpretable focus than a focus consisting of the single subword tokens, "broad". Table 6 also shows that our model mainly uses pronouns, and noun phrases are playing an important role to represent focus. This suggests that further investigation is needed to understand how language models work on pronouns to process a text.

5.2 Local Coherence Patterns

Using interpretable focus information, we investigate differences in focus transitions of texts assigned to different scores. Motivated by the definition of the continue and the shift transition in Centering theory, we define semantic consistency which represents the degree of semantic changes between local foci. Two adjacent sentences are semantically consistent when the semantic similarity (sim_i) between the local foci (lf) is higher than a semantic threshold ($\theta_{sem;score}$). This threshold is determined as the average of semantic similarities between local foci of adjacent sentences in texts assigned the same score. Otherwise, a semantic transition (st) occurs between the local foci: $st_i = 1$ if $sim_i < \theta_{sem;score}$. Finally, the semantic consistency (SC) is defined as follows: $SC = 1 - (count(st_i)/|lf|)$.

Figure 2 illustrates the semantic consistency on TOEFL, and Table 8 shows the statistics of the semantic consistency on texts assigned to different scores. Texts assigned a high score show lower semantic consistency on average. This indicates that texts of higher quality are overall more semantically variant than texts of lower quality. Additionally, we observe that texts assigned a low score show significantly larger proportions of an extreme level of semantic consistency. We define the extreme level as either texts whose semantic consistency is lower than 5%, indicating texts are highly variant, or texts whose semantic consistency is higher than 75%, indicating texts are highly consistent. Hence, these findings indicate that texts of lower quality are semantically too variant or too consistent. Texts of higher quality are neither too variant nor too consistent.

We next inspect the focus of texts assigned to different scores (see Table 15,16, and 17 in the Appendix D for more details). This shows that pronouns more frequently indicate the local focus in texts of lower quality than in texts of higher quality. The essays in TOEFL are argumentative essays, and good essays should use facts and evidence to support their claim (Wingate, 2012). We observe that texts assigned a low score frequently include claims without convincing evidence. This



(a) TOEFL: P1, low score, id: 10226 (b) TOEFL: P1, high score, id: 63719 (c) TOEFL: P1, low score, id: 598381

Figure 2: Semantic consistency on TOEFL. The green horizontal line indicates the average of semantic similarities between local foci. The blue line indicates the semantic similarities between adjacent local foci. A semantic transition occurs when the semantic similarity between the local foci is lower than the green line. Texts of lower quality are mostly semantically too consistent (id:10226) or too variant (id:598381).

causes our model to capture focus based on pronouns more frequently in these texts. In contrast, texts assigned a high score include convincing evidence to support claims, and this lets our model capture different types of foci in these texts.

5.3 Error Analysis

Finally, we conduct an error analysis to investigate how our model works differently compared to previous coherence models on TOEFL. We first compare the predicted scores with Moon et al. (2019) and a simple model which only considers context, averaged-XLNet. These two baselines show biased predictions in the middle score. We suspect that this is caused by the label bias in TOEFL (Blanchard et al., 2013). Biased label distributions cause biased predictions, and they benefit from these biased predictions. In contrast, our model benefits more from predicting high scores correctly as well as other scores, indicating that our coherence model assesses text quality better.

We then compare with the previous state of the art (Jeon and Strube, 2020). This baseline induces discourse structure to model structural coherence. It captures semantic relations between discourse segments, not just between adjacent sentences. We observe two error cases when this baseline struggles to predict correctly. It predicts scores lower than the ground-truth score for texts which lack support and evidence for claims. However, these texts have a well-organized paragraph for one or two claims. We suspect that this leads human annotators to assign a mid or a high score though the text is not well-organized overall. In contrast, it predicts scores higher than ground-truth scores when unrelated claims are listed or claims are listed without evidence. Our model, which captures local coherence between adjacent sentences, deals with these cases better (see Table 18 and 19 in the Appendix D for more details).

	S_{Low}	S_{Mid}	S_{High}
Avg SC (std)	55.87 (24.53)	54.45 (21.38)	54.05 (19.70)
Prop of Ext level	17.63	11.54	8.59

Table 8: Semantic consistency statistics (%) for the texts assigned to different scores (S). An extreme level (Ext) is defined as either semantic consistency to be lower than 5% (semantically too variant) or higher than 75% (semantically too consistent).

6 Conclusions

We propose a neural coherence model based on entities by constraining the input to noun phrases. This makes our model better explainable and sets a new state of the art in end applications. It also allows us to reveal that texts of higher quality are neither semantically too consistent nor too variant.

Our findings suggest a few interesting directions for future work. Our analysis shows that pretrained language models frequently exploit coreference relations to capture semantic relations. We could design an advanced neural model which exploits these relations explicitly. Lastly, our work could be extended to a multilingual setup. Our model is not tied to a specific pretrained language model but connect a language model with linguistic insights. It can employ a multilingual model (Xue et al., 2021), and our datasets can be translated to other languages.

Acknowledgments

The authors would like to thank the anonymous reviewers for their comments. This work has been funded by the Klaus Tschira Foundation, Heidelberg, Germany. The first author has been supported by a Heidelberg Institute for Theoretical Studies Ph.D. scholarship.

A Training and Parameters

For the three datasets, we use a mini-batch size of 32 with random-shuffle. The ADAM optimizer is used to train our models with a learning rate of 0.001 and epsilon of 1e-4. We evaluate performance for 25 epochs. For the baseline models which do not use a pretrained language model, we use Glove pretrained embeddings with 100-dimensional for TOEFL and with 50-dimensional for NYT. We clip gradients by 1.0. To update sentence representations obtained by a pretrained language model, we use the same dimension of the pretrained language model on a tree-transformer. We manually tune hyperparameters.

We encode adjacent two sentences at once using XLNet instead of the whole document at once. Our dataset consists of long documents i.e., journal articles with more than 3,000 tokens. For employing the pretrained model, it is practically infeasible to encode all words in a document at once due to memory limitations. We use 23GB GPU memory a NVidia P40 on ADC and AES and 46GB GPU memory of two NVidia P40s for each run on AWQ. For training our model, it takes approximately 0.8 days on TOEFL, 6.5 days on NYT, and 0.6 days on GCDC.

B Data Description Details

Table 9 describes statistics on two datasets, TOEFL[5] and NYT[6]. We split a text at the sentence level by Stanford Stanza library, and tokenize them by the XLNet tokenizer. Table 10 describes the topic of each prompt in TOEFL. They are all open-ended tasks, that do not have given context but require students to submit their opinion.

C Focus Examples

Table 11 shows the cases that the pretrained language model, XLNet, captures the undesirable (sub-)words as focus. We observe that the subword tokenizer often split named entities into subword tokens unexpectedly, and some words are unexpectedly split into subword tokens as prefixes and suffixes, such as "_un" or "ition". These observations suggest that we need to consider tokens as a span to capture the meaning of words better.

Dataset	#Texts	Avg len (Std)	Max # tokens	Scores
G-Y	1,200	173 (48)	378	1-3
G-C	1,200	200 (65)	385	1-3
G-E	1,200	203 (67)	388	1-3
G-P	1,200	198 (58)	374	1-3
T-P1	1,656	401 (97)	902	1-3
T-P2	1,562	423 (97)	902	1-3
T-P3	1,396	407 (102)	837	1-3
T-P4	1,509	405 (99)	852	1-3
T-P5	1,648	424 (101)	993	1-3
T-P6	960	425 (101)	925	1-3
T-P7	1,686	396 (87)	755	1-3
T-P8	1,683	407 (92)	795	1-3
NYT	8,512	1,841 (1,221)	18,728	1-2

Table 9: Three Datasets statistics on tokenization: i) four domains in GCDC, Yahoo (G-Y), Clinton (G-C), Enron (G-E), Yelp (G-P), ii) each TOEFL prompt (T-P), and iii) NYT.

D Evaluations Details

We report not only the more details of the performance on test sets (Table 12) but also the performance on validation sets on the AES task (Table 13).

E Analysis Details

We compare the focus captured on (sub-)words and the focus constrained to entities on more datasets (Table 14). We observe that our entity modeling leads to better explainability.

Prompt 1	Agree or Disagree: It is better to have broad knowledge of many academic subjects than to specialize in one specific subject.
Prompt 2	Agree or Disagree: Young people enjoy life more than older people do.
Prompt 3	Agree or Disagree: Young people nowadays do not give enough time to helping their communities.
Prompt 4	Agree or Disagree: Most advertisements make products seem much better than they really are.
Prompt 5	Agree or Disagree: In twenty years, there will be fewer cars in use than there are today.
Prompt 6	Agree or Disagree: The best way to travel is in a group led by a tour guide.
Prompt 7	Agree or Disagree: It is more important for students to understand ideas and concepts than it is for them to learn facts.
Prompt 8	Agree or Disagree: Successful people try new things and take risks rather than only doing what they already know how to do well.

Table 10: Topic description: TOEFL.

Example Sentence 3
Einstein’s defection from the quantum revolution was a blow to his more conservative colleagues.
Focus candidates captured by XLNet
“_stein”, “_was”, “_his”, “_more”, “_blow”, “_the”, “””, “ein”, ..., “_from”
Example Sentence 4
On Thursday, responding to evidence that Celebrex and Bextra may pose the same risks, the F.D.A. recommended that physicians limit their use of the drugs.
Focus candidates captured by XLNet
“_on”, “_th”, “_ur”, “_s”, “_day”, “,”, “_responding”, “_to”, “_evidence”, ..., “_drugs”
Example Sentence 5
Dr. Elizabeth Tindall, president of the American College of Rheumatology, said in a statement last week.
Focus candidates captured by XLNet
“_said”, “ology”, “_week”, “_in”, “_of”, “,”, “_college”, “_the”, “_last”, “ll”, “_a”, ..., “dr”
Example Sentence 6
Current American testing focuses only on finding the prion that causes bovine spongiform encephalopa thy in cows and ”variant” Creutzfeldt-Jakob disease in humans.
Focus candidates captured by XLNet
“opathy”, “t”, “_disease”, “-”, “_humans”, “_the”, “vine”, “en”, “_and”, “_cre”, ..., “_pr”
Example Sentence 7
These days the concepts of family values,traditions and culture have lost their meaning and the you$g people often end up neglecting these important concepts.
Focus candidates captured by XLNet
“_concepts”, “ing”, “_lost”, “_of”, “_concepts”, “_the”, “_values”, “_these”, “_end”, “people”, “_have”, ..., “radi”
Example Sentence 8
The community plays an important role in shaping a personhis desires, actions, thoughts, opinions etc.
Focus candidates captured by XLNet
“_etc”, “_role”, “s”, “_desires”, “s”, “_person”, “_the”, “op”, “ions’, ..., “_important”
Example Sentence 9
On the other hand, the time that have been used by them to community service is enough already for the fact that learning is the primary task that they should focus on at their age anyway.
Focus candidates captured by XLNet
“_on”, “_them”, “_at”, “_on”, ”_already”, “_to”, “_used”, “_they”, “_for”, “_that”, “_anyway”, “_by”, ..., “_the”

Table 11: Examples showing the pretrained language model, XLNet Yang et al. (2019), captures undesirable (sub-)words as focus (Jeon and Strube, 2020). The subword tokens are sorted by their attention scores in descending order.

#	Example text of low quality
1	**I**^{1} absolutely agree about the many academic subjects are beneficial for knowledge, because it provide **lots of opportunities**^{1,2}, I mean it's good for our future.
2	In my experience, when **I**^{3} was second grade in middle school, a teacher gave **a homework**^{2} to us which was to find our talant.
3	**I**^{3,4} tried to think what am I good at and what do I like.
4	However, **I**^{4} couldn't, because I couldn't find **my talants**^{5}.
5	after my highschool finally, I found **my talants**^{5}.
6	**My talant**^{6} is to study a law.
7	When **I**^{6} was first grade in the highschool, **I**^{7} had a friend who called Che-Jea-Heong.
8	He was **very special friend**^{7,8}.
9	He always tried to think **strange way**^{8,9}.
10	At first, **I**^{9} didn't want to talk with him, but when **we**^{10} talked about the talant, we became a friend.
11	Actually, **his father**^{10,11} is police.
12	And **his family**^{11} is very poor.
13	So, first **we**^{12} started to talk his father.
14	why **he**^{12,13} is poor.
15	After that **we**^{13,14} began to think law.
16	Then **we**^{14} found **our talant**^{15}.
17	Actually, **this**^{16} I found **this talant**^{15} from the school project.
18	When **I**^{16,17} was 3grade in middle school, I took a class which was Korean language class, in the class, we had a special study which was law.
19	Because, **my teacher**^{17,18} thought law is beneficial for stundent.
20	So **we**^{18} tried to study **the law**^{19} just one semester with a game.
21	However, my friends are really bored about this, but **me**^{20} I really enjoyed **that law class**^{19}.
22	So after that semester, **I**^{20,21} asked the teacher to study more laws, but she couldn't, because lots of people didn't like that.
23	Anyway, **I**^{21,22} really like the law, also I'll study law in the university.
24	From this semester, **I**^{22,23} can think many way to find my talant from the school subjects.
25	**I**^{23,24} can think math, science, music or art.
26	So **we**^{24,25} can have our opportunities.
27	Now days, many students cannot understand the school about the acadmic subjects that why they have to learn **too much subject**^{25,26}.
28	**I**^{26} was too, but now I understand the school. And I really thanks from the school.

Table 16: Local focus on an example text assigned to the low score. The example is rewritten by us following the texts in TOEFL due to the non-public license. Bold style indicates local focus identified in our sentence encoding strategy, which encodes adjacent sentences at once. Superscripts indicate the order of this encoding.

#	Example text of high quality
1	Getting **more knowledge**^{1,2} could expand ones boundary; serve as a parth to discover ones true passion; allow us to talk to other people and be capable of understanding the world around us.
2	Firstly, getting **more knowing**^{2} of many academic subject areas could expand our boundaries because we know different subjects in **different fields**^{3}.
3	Each subject has its own uniquness, therefore **it**^{4} would be beneficial to know a bit about **each areas**^{3}.
4	Secondly, exploring **more knowledge**^{4,5} could serve as a path for people to discover their true passion.
5	Sometimes if we stay 'inside the box', it would be difficult for us to find other ways and have **the oppurtunity**^{5,6} to think whether it was truly their passion or not.
6	When **I**^{6} was in Grade 11, **I**^{7} took courses in different areas, such as Chemistry, Accounting, Physical Education, Business, History etc.
7	**I**^{7} wans't sure of what I wanted to study in university, and I don't want to limit my area of study, therefore **I**^{8} decided to broaden my knowledg by taking many acdemic subjects.
8	However my friend, who seriously wanted to become a doctor, took **all science courses**^{8,9}, because she wanted to explore her passion.
9	As a result, I believe it would be better to have a broad knowledge of **many subjects**^{9,10} before specializing one, unless you have found something that you really want to pursue.
10	Moreover, by studying **more subjects**^{10}, **it**^{11} makes people easy to dive in conversations with new people.
11	Everyone have different backgrounds, therefore if you have knowledge from **different areas**^{12}, **it**^{11} could be easier to socialize with people whom have different fields from we have.
12	A way of knowing **more subjects**^{12,13} can be to read every section of the newspaper such as Businss, World, Entertainment etc.
13	This could help us to know **more knowledge**^{13} and therefore we can be more talkative meeting **new people**^{14}.
14	Since **the world**^{15} changes everyday, everyday **something new** ^{14}will happen.
15	If we don't have the basic background of **a certain subject**^{15,16}, we cannot understand others.
16	Moreover, a lot of subjects are tied on each other, therefore you will need knowledge from **other areas**^{16,17} to understand the material better.
17	For example, business ties with politics, political changes could affect the business environment, henceforth it is mandatory for us to have **a simple background**^{17,18} of politics to understand the changes of business around the world.
18	In conclusion, with all the reasons discussed so far, I believe that it is better to have broad knowledge of **many acadmic subjects**^{18} than specializing in one specific subjects.

Table 17: Local focus on an example text of high quality. The examples is rewritten by us following the texts in TOEFL due to a non-public license. Error Type	Example Essay
C_1	In my opinion is better to have a knowledge specialize in one particular subject since this is better to know a thing as well as you can. This is true in all the experiences of the life: refered to the university, e.g., the italian university, we can take the example of the of the two years of specialization. An other example we can see in a top-tier company, in fact each people that there are in this have a specific work to do and this bring to an excellent final operation. A person that are magnifically prepared on one thing will arrive at a sicure result because that ""is your bred""; we can also observe that the most good professors, scientists, sport players are all specialize on that they work and do not specialize on many works. We can also observe that the colloboration of great brains, each of them specialized on a thing, is important in many ways of the our life.
C_2	I strongly agree with the statement that knowing several subjects and being polyvalent in various fields is much more important that specializing in one area. These days, things are changing so fast that the moment you start a career or a specialization, the minute the facts and figures of the subject have changed. This essence of broad knowledge is what makes people succeed in the world. Unless you are 100% sure that you vocationally desire to specialize in a subject, the risk of not finding a suitable job because of the deviation of job offering is too high. Both with respect to time and money. For example, imagine that you decide to study IT sometime around the Internet boom. After you finish the 5 years of studying, you get out to society with high hopes and great expectations and suddenly you realize that the world does not need for IT people anymore because the market crashed down! Then you would most probably regret not to have chosen a more general Engineering degree such as an Electronical Engineering degree. Take the example of a devoted music students that really loves to play music to the point that they drop classes so they can go and play their music. Perhaps, they will become a succesful singer or solo player, but the chances that they fail are there and when that really comes true, they will not be able to attend university classes because they didn't passed high-school. Good and innovative ideas often are the result of composing other ideas. If on one side, you know how pollution of carbon dioxide is chemically produced and on the other, you are an expert on plant species, perhaps you can find a way to create a system to purify the air in the world. And moreover, if you have skills of marchandising and marketing, you can probably be in the Forbes' next month main page. Think that you can always specialize in the future. Going from the trunck of a tree to the tip of a branch is easy, but getting from one tip to another tip is, literally, as going back in time.

Table 18: Example Essays for Error Cases (C_1, C_2) on TOEFL (the examples are rewritten by us following the texts in TOEFL due to the non-public license). For texts corresponding to the C_1, Jeon and Strube (2020) predicts a low score and our model predicts a mid score ($C_1 : S_{JS} = L, S_O = M$). For texts corresponding to the C_2, Jeon and Strube (2020) predicts a mid score and our model predicts a high score ($C_2 : S_{JS} = M, S_O = H$).

Error Type	Example Essay
C_3	It seems difficult to choose one direction, becuse they are also have colorful life between the young people and the older people, but it does not mean, they are similar to me. I would like to agree with the young people enjoy life more than older people do, if a personal quality can be considerated as criterion to choose things. First of all, nowadays, era of information, many young people enjoy their life via the internet, even everything is possible in the digital industy. For instance, if a grandson of the older people live abroad, and the communication between the grandson and the grandfather is only via the telephone instead the internet online chatting what is cheaper than the international telephone call, but the older people can not use the internet, even they can not use a computer. On the other hand, the young people can adapt an environment quickly, so that they can migrate to another city for the different experience. most of older persons can not accept the different enviroment and what they will eat in the different areas, if the older person migrate to other citys or countries, they will be illness easier. The important things determining the young people enjoy life better is that they are educated in the signifcant era of information, so they are developed with the world development. For all mentioned above is why I agree with the statement that young people enjoy life more than older people do. Now, I do strongly agree with the statement.
C_4	Yes, it is better to have a broad knowledge of many academic subjects than specialisze in one specific area because of various reasons. If people have knowledge about a particular subject,it is good. But if they want to refrain themselves from foraying from other subjects they should make sure that they are very thorough with that subject.Because finally they should find a job on that basis only and more ver all the academic topics are interconnected so, it imperative to have knowledgein various fields. The above option would be good only if they find a job. They should always keep in mind the different possibilities in their carreer. They should ask themselves ""what if i dont get a job in my desired field of study?"" For instance I am a mechanical engineering student. as every one knows there is a difficult of getting jobs for mechanical engineers.if i continue with the same field would be left unemployed.Here I need to have an alternate option.I have my alternate option as computer sciences .I started learning some computer subjects.Now even if i do not get a job in my field of study, i may have a chance of getting it in field of computers.This would not leave me unemployed.I personally feel that being employed is better than being unemployed. This criteria not only works for two fields of same backround, it also works for a technical background and an arts background. For example, an electrical engineer who does not have a job and whose hobby is singing , can survive by giving some stage shows . Which would also be considered as an employment. Additionally, broader knowlege would not leave you speechless when you are in a group. Because when a group is discussing a topic and if you are silent , you may feel embarassing with that. But if you are familiar with the topic you can also give your opinion on the topic. this is possible only if you do not confine yourself to a particular field. Therefore, I conclude that having a broad knowledge is better than to specialize in one subject.

Table 19: Example Essays for Error Cases (C_3, C_4) on TOEFL (the examples are rewritten by us following the texts in TOEFL due to the non-public license). For texts corresponding to the C_3, Jeon and Strube (2020) predicts a mid score and our model predicts a low score ($C_3 : S_{JS} = M, S_O = L$). For texts corresponding to the C_4, Jeon and Strube (2020) predicts a high score and our model predicts a mid score ($C_4 : S_{JS} = H, S_O = M$).

"That Is a Suspicious Reaction!": Interpreting Logits Variation to Detect NLP Adversarial Attacks

Abstract

Adversarial attacks are a major challenge faced by current machine learning research. These purposely crafted inputs fool even the most advanced models, precluding their deployment in safety-critical applications. Extensive research in computer vision has been carried to develop reliable defense strategies. However, the same issue remains less explored in natural language processing. Our work presents a model-agnostic detector of adversarial text examples. The approach identifies patterns in the logits of the target classifier when perturbing the input text. The proposed detector improves the current state-of-the-art performance in recognizing adversarial inputs and exhibits strong generalization capabilities across different NLP models, datasets, and word-level attacks.

1 Introduction

Despite recent advancements in *Natural Language Processing* (NLP), adversarial text attacks continue to be highly effective at fooling models into making incorrect predictions (Ren et al., 2019; Wang et al., 2019; Garg and Ramakrishnan, 2020). In particular, syntactically and grammatically consistent attacks are a major challenge for current research as they do not alter the semantical information and are not detectable via spell checkers (Wang et al., 2019). While some defense techniques addressing this issue can be found in the literature (Mozes et al., 2021; Zhou et al., 2019; Wang et al., 2019), results are still limited in performance and text attacks keep evolving. This naturally raises concerns around the safe and ethical deployment of NLP systems in real-world processes.

Previous research showed that analyzing the model's logits leads to promising results in discriminating manipulated inputs (Wang et al., 2021; Aigrain and Detyniecki, 2019; Hendrycks and Gimpel, 2016). However, logits-based adversarial detectors have been only studied on computer vision applications. Our work transfers this type of methodology to the NLP domain and its contribution can be summarized as follows:

(1) We introduce a logits-based metric called *Word-level Differential Reaction* (WDR) capturing words with a suspiciously high impact on the classifier. The metric is model-agnostic and also independent from the number of output classes.

(2) Based on WDR scores, we train an adversarial detector that is able to distinguish original from adversarial input texts preserving syntactical correctness. The approach substantially outperforms the current state of the art in NLP.

(3) We show our detector to have full transferability capabilities and to generalize across multiple datasets, attacks, and target models without needing to retrain. Our test configurations include transformers and both contextual and genetic attacks.

(4) By applying a post-hoc explainability method, we further validate our initial hypothesis—i.e. the detector identifies patterns in the WDR scores. Furthermore, only a few of such scores carry strong signals for adversarial detection.

2 Background and Related Work

2.1 Adversarial Text Attacks

Given an input sample x and a target model f, an adversarial example $x' = x + \Delta x$ is generated by adding a perturbation Δx to x such that $\arg\max f(x) = y \neq y' = \arg\max f(x')$. Although this is not required by definition, in practice the perturbation Δx is often imperceptible to humans and x' is misclassified with high confidence. In the NLP field, Δx consists in adding, removing, or replacing a set of words or characters in the original text. Unlike image attacks—vastly studied in the literature (Zhang et al., 2020) and operating in high-dimensional continuous input spaces—text perturbations need to be applied on a discrete input space. Therefore, gradient methods used for images such as FGSM (Goodfellow et al., 2014) or BIM (Kurakin et al., 2017) are not useful since they require a continuous space to perturb x. Based on the text perturbation introduced, text attacks can be distinguished into two broad categories.

Visual similarity: These NLP attacks generate adversarial samples x' that look similar to their corresponding original x. These perturbations usually create typos by introducing perturbations at the character level. DeepWordBug (Gao et al., 2018), HotFlip (Ebrahimi et al., 2018) , and VIPER (Eger et al., 2019) are well-known techniques belonging to this category.

Semantic similarity: Attacks within this category create adversarial samples by designing sentences that are semantically coherent to the original input and also preserve syntactical correctness. Typical word-level perturbations are deletion, insertion, and replacement by synonyms (Ren et al., 2019) or paraphrases (Iyyer et al., 2018). Two main types of adversarial search have been proposed. *Greedy algorithms* try each potential replacement until there is a change in the prediction (Li et al., 2020; Ren et al., 2019; Jin et al., 2020). On the other hand, *genetic algorithms* such as Alzantot et al. (2018) and Wang et al. (2019) attempt to find the best replacements inspired by natural selection principles.

2.2 Defense against Adversarial Attacks in NLP

Defenses based on spell and syntax checkers are successful against character-level text attacks (Pruthi et al., 2019; Wang et al., 2019; Alshemali and Kalita, 2019). In contrast, these solutions are not effective against word-level attacks preserving language correctness (Wang et al., 2019). We identify methods against word-level attacks belonging to two broad categories:

Robustness enhancement: The targeted model is equipped with further processing steps to not be fooled by adversarial samples without identifying explicitly which samples are adversarial. For instance, *Adversarial Training* (AT) (Goodfellow et al., 2014) consists in training the target model also on manipulated inputs. The *Synonym Encoding Method* (SEM) (Wang et al., 2019) introduces an encoder step before the target model's input layer and trains it to eliminate potential perturbations. Instead, *Dirichlet Neighborhood Ensemble* (DNE) (Zhou et al., 2020) and *Adversarial Sparse Convex Combination* (ASCC) (Dong et al., 2021) augment the training data by leveraging the convex hull spanned by a word and its synonyms.

Adversarial detection: Attacks are explicitly recognized to alert the model and its developers. Adversarial detectors were first explored on image inputs via identifying patterns in their corresponding Shapley values (Fidel et al., 2020), activation of specific neurons (Tao et al., 2018), and saliency maps (Ye et al., 2020). For text data, popular examples are *Frequency-Guided Word Substitution* (FGWS) (Mozes et al., 2021) and *learning to DIScriminate Perturbation* (DISP) (Zhou et al., 2019). The former exploits frequency properties of replaced words, while the latter uses a discriminator to find suspicious tokens and uses a contextual embedding estimator to restore the original word.

2.3 Logits-Based Adversarial Detectors

Inspecting output logits has already led to promising results in discriminating between original and adversarial images (Hendrycks and Gimpel, 2016; Pang et al., 2018; Kannan et al., 2018; Roth et al., 2019). For instance, Wang et al. (2021) trains a recurrent neural network that captures the difference in the logits distribution of manipulated samples. Aigrain and Detyniecki (2019), instead, achieves good detection performance by feeding a simple three-layer neural network directly with the logit activations.

Our work adopts a similar methodology but focuses instead on the NLP domain and thus text attacks. In this case (1) logits-based metrics to identify adversarial samples should be tailored to

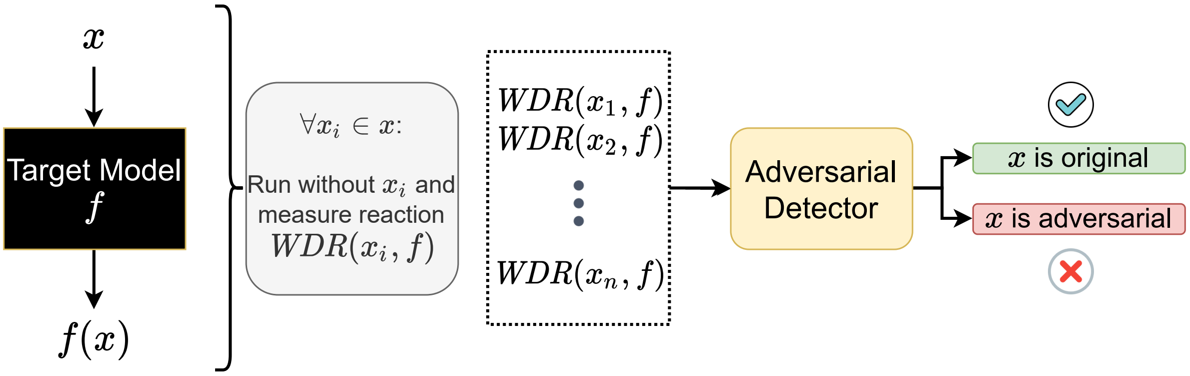

Figure 1: Overview of the proposed method.

the new type of input and (2) detectors should be tested on currently used NLP models such as transformers (Devlin et al., 2019).

3 Methodology

The defense approach proposed in this work belongs to the category of *adversarial detection*. It defends the target model from attacks generated via word-level perturbations belonging to the *semantic similarity* category. The intuition behind the method is that the model's reaction to original- and adversarial samples is going to differ even if the inputs are similar. Hence, it relies on *feature attribution explanations* coupled with a machine learning model to learn such difference and thus identify artificially crafted inputs.

Figure 1 shows the overall pipeline of the approach. Given a text classifier f trained on the task at hand, the pipeline's goal is to detect whether the currently fed input x is adversarial. In 3.1, we explain in greater detail how we measure the model f's reaction to a given input x. This quantity—later indicated with $WDR(x, f)$—is then passed to the adversarial detector, whose training procedure is described in 3.2. Finally, in 3.3, we provide detailed information about the setup of our experiments such as target models, datasets, and attacks.

3.1 Interpreting the Target Model and Measuring its Reaction: Word-Level Differential Reaction

Adversarial attacks based on semantic similarity replace the smallest number of words possible to change the target model's prediction (Alzantot et al., 2018). Thus, we expect the replacements transforming x into x' to play a big role for the output. If not, we would not have $f(x')$ substantially different from $f(x)$. To assess the reaction of the target model f to a given input x, we measure the impact of a word via the *Word-level Differential Reaction* (WDR) metric. Specifically, the effect of replacing a word x_i on the prediction

$$y^* = \arg\max_y p(y|x)$$

is quantified by

$$WDR(x_i, f) = f(x \backslash x_i)_{y^*} - \max_{y \neq y^*} f(x \backslash x_i)_y$$

where $f(x \backslash x_i)_y$ indicates the output logit for class y for the input sample x without the word x_i. Specifically, x_i is replaced by an *unknown word token*. If x is adversarial, we could expect to find perturbed words to have a negative $WDR(x_i, f)$ as without them the input text should recover its original prediction. Table 1 shows an example pair of original and adversarial text together with their corresponding $WDR(x_i, f)$ scores. The original class is recovered after removing a perturbed word in the adversarial sentence. This switch results in a negative WDR. However, even if the most important word is removed from the original sentence (*'worst'*), the predicted class does not change and thus $WDR(x_i, f) > 0$.

Our adversarial detector takes as input $WDR(x, f)$, i.e. the sorted list of WDR scores $WDR(x_i, f)$ for all words x_i in the input sentence. As sentences vary in length, we pad the list with zeros to ensure a consistent input length for the detector.

3.2 Adversarial Detector Training

The adversarial detector is a machine-learning classifier that takes the model's reaction $WDR(x, f)$ as input and outputs whether the input x is adversarial or not. To train the model, we adopt the following multi-step procedure:

Original sentence: Neg. Review (*Class 0*)

This is absolutely the worst trash I have ever seen. It took 15 full minutes before I realized that what I was seeing was a sick joke! [...]

Removed Word x_i	**Logit *Class 0***	**Logit *Class 1***	**WDR $WDR(x_i, f)$**
$\emptyset$	3.44	-3.46	**6.89**
worst	1.68	-1.75	**3.43**
sick	3.34	-3.42	**6.76**
absolutely	3.40	-3.45	**6.86**
realized	3.41	-3.47	**6.89**

Adversarial sentence: Pos. Review (*Class 1*)

This is absolutely the tough trash I have ever seen. It took 15 full minutes before I realized that what I was seeing was a silly joke! [...]

Removed Word x_i	**Logit *Class 0***	**Logit *Class 1***	**WDR $WDR(x_i, f)$**
$\emptyset$	-1.85	2.17	**4.02**
tough	2.14	-1.50	**-3.64**
silly	1.38	-1.37	**-2.75**
absolutely	-0.31	0.48	**0.79**
realized	-1.07	1.36	**2.43**

Table 1: $WDR(x_i, f)$ scores computed for an original sentence and its corresponding adversarial perturbation. Results show how when removing adversarial words such as *tough* or *silly*, the original class is recovered and the WDR becomes negative. $\emptyset$ corresponds to the prediction without any replacements

(S1) Generation of adversarial samples: Given a target classifier f, for each original sample available x, we generate one adversarial example x'. This leads to a balanced dataset containing both normal and perturbed samples. The labels used are *original* and *adversarial* respectively.

(S2) WDR computation: For each element of the mixed dataset, we compute the $WDR(x, f)$ scores as defined in Section 3.1. Once more, this step creates a balanced dataset containing the WDR scores for both normal and adversarial samples.

(S3) Detector training: The output of the second step **(S2)** is split into training and test data. Then, the training data is fed to the detector for training along with the labels defined in step **(S1)**.

Please note that no assumption on f is made. At the same time, the input of the adversarial detector—i.e. the WDR scores—does not depend on the number of output classes of the task at hand. Hence, the adversarial detector is model-agnostic w.r.t. the classification task and the classifier targeted by the attacks.

In our case, we do not pick any particular architecture for the adversarial detector. Instead, we experiment with a variety of models to test their suitability for the task. In the same spirit, we test our setting on different target classifiers, types of attacks, and datasets.

3.3 Experimental Setup

To test our pipeline, four popular classification benchmarks were used: *IMDb* (Maas et al., 2011), *Rotten Tomatoes Movie Reviews* (RTMR) (Pang and Lee, 2005), *Yelp Polarity* (YELP) (Zhang et al., 2015), and *AG News* (Zhang et al., 2015). The first three are binary sentiment analysis tasks in which reviews are classified in either *positive* or *negative* sentiment. The last one, instead, is a classification task where news articles should be identified as one of four possible topics: *World*, *Sports*, *Business*, and *Sci/Tech*.

As main target model for the various tasks we use DistilBERT (Sanh et al., 2020) fine-tuned on IMDb. We choose DistilBert—a transformer language model (Vaswani et al., 2017)—as transformer architectures are widely used in NLP applications, established as state of the art in several tasks, and generally quite resilient to adversarial attacks (Morris et al., 2020). Furthermore, we employ a *Convolutional Neural Network* (CNN) (Zhang et al., 2015), a *Long Short-Term Memory* (LSTM) (Hochreiter and Schmidhuber, 1997), and a full BERT model (Devlin et al., 2019) to test transferability to different target architectures. All models are provided by the TextAttack library (Morris et al., 2020) and are already trained[1] on the datasets used in the experiments.

We generate adversarial text attacks via four well-established word-substitution-based techniques: *Probability Weighted Word Saliency* (PWWS) (Ren et al., 2019), *Improved Genetic Algorithm* (IGA) (Jia et al., 2019), *TextFooler* (Jin et al., 2020), and *BERT-based Adversarial Examples* (BAE) (Garg and Ramakrishnan, 2020). The first is a greedy algorithm that uses word saliency

---

[1] textattack.readthedocs.io/en/latest/3recipes/models.html, released under MIT License

and prediction probability to determine the word replacement order (Ren et al., 2019). IGA, instead, crafts attacks via mutating sentences and promoting the new ones that are more likely to cause a change in the output. TextFooler ranks words by importance and then replaces the ones with the highest ranks. Finally, BAE, leverages a BERT language model to replace tokens based on their context (Garg and Ramakrishnan, 2020). All attacks are generated using the TextAttack library (Morris et al., 2020).

We investigate several combinations of datasets, target models, and attacks to test our detector in a variety of configurations. Because of its robustness and well-balanced behavior, we pick the average F1-score as our main metric for detection. However, as in adversarial detection false negatives can have major consequences, we also report the recall on adversarial sentences. Later on, in 4.3, we also compare performance with other metrics such as precision and original recall and observe how they are influenced by the chosen decision threshold.

4 Experimental Results

In this section, we report the experimental results of our work. In 4.1, we study various detector architectures to choose the best performing one for the remaining experiments. In 4.2, we measure our pipeline's performance in several configurations (target model, dataset, attack) and we compare it to the current state-of-the-art adversarial detectors. While doing so, we also assess transferability via observing the variation in performance when changing the dataset, the target model, and the attack source without retraining our detector. Finally, in 4.3, we look at how different decision boundaries affect performance metrics.

4.1 Choosing a Detector Model

The proposed method does not impose any constraint on which detector architecture should be used. For this reason, no particular model has been specified in this work so far. We study six different detector architectures in one common setting. We do so in order to pick one to be utilized in the rest of the experiments. Specifically, we compare XGBoost (Chen and Guestrin, 2016), AdaBoost (Schapire, 1999), LightGBM (Ke et al., 2017), SVM (Hearst et al., 1998), Random Forest (Breiman, 2001), and a Perceptron NN (Singh and Banerjee, 2019). All models are compared on adversarial attacks generated with PWWS from IMDb samples and targeting a DistilBERT model fine-tuned on IMDb. A balanced set of $3,000$ instances—$1,500$ normal and $1,500$ adversarial—was used for training the detectors while the test set contains a total of 1360 samples following the same proportions.

Model	**F1-Score**	**Adv. Recall**
XGBoost	**92.4**	95.2
AdaBoost	91.8	**96.0**
LightGBM	92.0	93.7
SVM	92.0	94.8
Random Forest	91.5	93.7
Perceptron NN	90.4	88.1

Table 2: Performance comparison of different detector architectures on IMDb adversarial attacks generated with PWWS and targeting a DistilBERT transformer.

As shown in Table 2, all architectures achieve competitive performance and none of them clearly appears superior to the others. We pick XGBoost (Chen and Guestrin, 2016) as it exhibits the best F1-score. The main hyperparameters utilized are 29 gradient boosted trees with a maximum depth of 3 and 0.34 as learning rate. We utilize this detector architecture for all experiments in the following sections.

4.2 Detection Performance

Tables 3a and 3b report the detection performance of our method in a variety of configurations. In each table, the first row represents the setting—i.e. combination of target model, dataset, and attack type—in which the detector was trained. The remaining rows, instead, are w.r.t. settings in which we tested the already trained detector without performing any kind of fine-tuning or retraining.

We utilize a balanced training set of size $3,000$ and $2,400$ samples respectively for the detectors trained on IMDb adversarial attacks (Table 3a) and on AG News attacks (Table 3b). All results are obtained using balanced test sets containing 500 samples. The only exceptions are the configurations (DistilBERT, RTMR, IGA) and (DistilBERT, AG News, IGA) which used test sets of size 480 and 446 respectively due to data availability.

To the best of our knowledge, the FGWS method from Mozes et al. (2021) is the best detector avail-

(b) Performance results for detector trained on (DistilBERT, AG News, PWWS).

Table 3: Adversarial detection performance of our defense against the state of the art *FGWS* under several setups. Results were obtained with a detector trained on two different configurations as indicated in the first row of each table. For all other rows, i.e. test configurations, differences w.r.t the training setup have been highlighted. To increase the results' statistical significance, we average the performance across 30 different data-splits of the training configuration. Additionally, we report the corresponding 95% confidence intervals. Given the deterministic nature of *FGWS*, different data-splits lead to the same performance and hence confidence intervarls are not reported as they are trivial (±0).

able and was already proven to be better than DISP (Zhou et al., 2019) by its authors. Hence, we utlize FGWS as baseline for comparison in all configurations. Analogously to our method, FGWS is trained on the configuration in the first row of each table and then applied to all others. More in detail, we fine-tune its *frequency substitution threshold* parameter δ (Mozes et al., 2021) until achieving a best fit value of $\delta = 0.9$ in both training settings.

From what can be seen in both tables, the proposed method consistently shows very competitive results in terms of F1-score and outperforms the baseline in 22 configurations out of 28 (worse in 5) and is on average better by 8.96 percentage points. At the same time, our methods exhibits a very high adversarial recall, showing a strong capability at identifying attacks and thus producing a small amount of false negatives.

Generalization to different target models: Starting from the training configurations, we vary the *target model* while maintaining the other components fixed (rows 2-4 of each table). Here, the detector achieves state-of-the-art results in all test settings, occasionally dropping below the 90% F1-score on a few simpler models like LSTM and CNN while not exhibiting any decay on more complex models like BERT.

Generalization to different datasets: Analogous to the previous point, we systematically substitute the *dataset* component for evaluation (rows 5-6 of each table). We notice a substantial decay in F1-score when testing with RTMR (74.1 - 75.8%) since samples are short and, therefore, may contain few words which are very relevant for the prediction, just like adversarial replacements. Nevertheless, removing adversarial words still result in a change of prediction to the original class thereby preserving high adversarial recall."

Generalization to different attacks: Results highlight a good reaction to all other text attacks (rows 7-9 of each table) and even experiences a considerable boost in performance against TextFooler. In contrast, the baseline *FGWS* significantly suffers against more complex attacks such as BAE, which generates context-aware perturbation.

Besides testing generalization properties via systematically varying one configuration component at the time, we also test on a few settings presenting changes in multiple ones (rows 10-14 of each table). Also in these settings, the proposed method maintains a very competitive performance, with noticeable drops only on the RTMR dataset.

4.3 Tuning the Decision Boundary

Depending on the application in which the detector is used to monitor the model and detect malicious input manipulations, different performance metrics can be taken into account to determine whether it is safe to deploy the model. For instance, in a very safety-critical application where successful attacks lead to harmful consequences, *adversarial recall* becomes considerably more relevant as a metric than the F1-score.

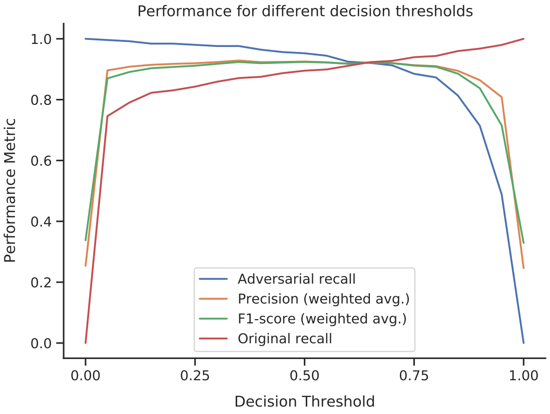

Figure 2: Performance metrics w.r.t. different decision thresholds for our XGBoost classifier on the configuration (IMDb, DistilBERT, PWWS). Input sentences are classified as adversarial when their probability is higher than the decision threshold.

We examine how relevant metrics change in response to different choices for the discrimination threshold. Please note that a lower value corresponds to more caution, i.e. we are more likely to output that a certain input is adversarial.

DT	Precision	F1	Adv. Recall	Orig. Recall
0.5	92.5	92.4	95.2	89.5
0.4	92.3	92.0	96.4	87.5
0.3	92.4	91.8	97.6	85.9
0.15	91.5	90.3	**98.4**	82.3

Table 4: Performance comparison using different *Decision Thresholds* (DT) for our XGBoost classifier on the configuration (IMDb, DistilBERT, PWWS). The used default value is 0.5.

Figure 2 and Table 4 show performance results w.r.t. different threshold choices. We notice that decreasing its value from 0.5 to 0.15 can increase the adversarial recall to over 98% at a small cost in terms of precision and F1-score ($<$ 2 percentage points). Applications where missing attacks—i.e. false negatives—have disastrous consequences could take advantage of this property and consider lowering the decision boundary. This is particularly true if attacks are expected with a low frequency and an increase in false positive incurs only minor costs.

5 Discussion and Qualitative Results

Section 4 discussed quantitative results and emphasized the competitive performance that the proposed approach achieves. Here, instead, we focus on the qualitative aspects of our research findings. For instance, we try to understand *why* our pipeline works while also discussing challenges, limitations, ethical concerns, and future work.

5.1 Understanding the Adversarial Detector

The proposed pipeline consists of a machine learning classifier—e.g. XGBoost—fed with the model's WDR scores. The intuition behind the approach is that words replaced by adversarial attacks play a big role in altering the target model's decision. Despite the competitive detection performance, the detector is itself a learning algorithm and we cannot determine with certainty what patterns it can identify.

To validate our original hypothesis, we apply a popular explainability technique—SHAP (Lundberg and Lee, 2017)—to our detector. This allows us to summarize the effect of each feature at the dataset level. We use the official implementation[2] to estimate the importance of each WDR and use a *beeswarm plot* to visualize the results.

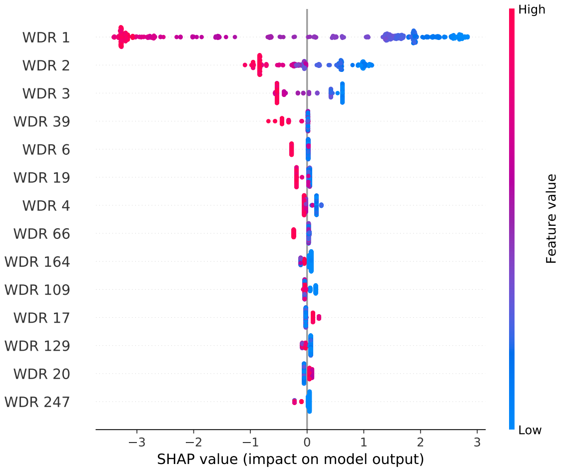

Figure 3: WDR scores with the highest impact (SHAP value) on the detector's prediction. Please recall that the WDR scores are sorted by magnitude. For instance, WDR 1 is the first and largest WDR score.

Figure 3 shows that values in the first positions—i.e. 1, 2, and 3—of the input sequence are those influencing the adversarial detector the most. Since in our pipeline WDR scores are sorted based on their magnitude, this means that the largest WDR of each prediction are the most relevant for the detector. This is consistent with our hypothesis that replaced words substantially change output logits and thus measuring their variation is effective for detecting input manipulations. As expected, negative values for the WDR correspond to a higher likelihood of the input being adversarial.

We also notice that features after the first three do not appear in the naturally expected order. We believe this is the case as for most sentences it is sufficient to replace two-three words to generate an adversarial sample. Hence, in most cases, only a few WDR scores carry important signals for detection.

5.2 Challenges and Limitations

While WDR scores contain rich patterns to identify manipulated samples, they are also relatively expensive to compute. Indeed, we need to run the model once for each feature—i.e. each word—in the input text. While this did not represent a limitation for our use-cases and experiments, we acknowledge that it could result in drawbacks when input texts are particularly long.

Our method is specifically designed against word-level attacks and it does not cover character-level ones. However, the intuition seems to some extent applicable also to sentences with typos and similar artifacts as the words containing them will play a big role for the prediction. This, like in the word-level case, needs to happen in order for the perturbations to result in a successful adversarial text attack and change the target model's prediction

5.3 Ethical Perspective and Future Work

Detecting—or in general defending against—adversarial attacks is a fundamental pillar to deploy machine learning models ethically and safely. However, while defense strategies increase model robustness, they can also inspire and stimulate new and improved attack techniques. An example of this phenomenon is BAE (Garg and Ramakrishnan, 2020), which leverages architectures more resilient to attacks such as BERT to craft highly-effective contextual attacks. Analogously, defense approaches like ours could lead to new attacks that do not rely on a few words to substantially affect output logits.

---

[2] https://github.com/slundberg/shap, released under MIT License

Based on our current findings, we identify a few profitable directions for future research. **(1)** First of all, the usage of logits-based metrics such as the WDR appears to be very promising for detecting adversarial inputs. We believe that a broader exploration and comparison of other metrics previously used in computer vision could lead to further improvements. **(2)** We encourage future researchers to draw inspiration from this work and also test their defenses in settings that involve mismatched attacks, datasets, and target models. At the same time, we set as a priority for our future work to also evaluate the efficacy of adversarial detection methods on adaptive attacks (Tramer et al., 2020; Athalye et al., 2018). **(3)** This work proves the efficacy of WDR in a variety of settings, which include a few different datasets and tasks. However, it would be beneficial for current research to understand how these techniques would apply to high-stakes NLP applications such as hate speech detection (Mosca et al., 2021; Wich et al., 2021).

6 Conclusion

Adversarial text attacks are a major obstacle to the safe deployment of NLP models in high-stakes applications. However, although manipulated and original samples appear indistinguishable, interpreting the model's reaction can uncover helpful signals for adversarial detection.

Our work utilizes logits of original and adversarial samples to train a simple machine learning detector. WDR scores are an intuitive measure of word relevance and are effective for detecting text components having a suspiciously high impact on the output. The detector does not make any assumption on the classifier targeted by the attacks and can be thus considered model-agnostic.

The proposed approach achieves very promising results, considerably outperforming the previous state-of-the-art in word-level adversarial detection. Experimental results also show the detector to possess remarkable generalization capabilities across different target models, datasets, and text attacks without needing to retrain. These include transformer architectures such as BERT and well-established attacks such as PWWS, genetic algorithms, and context-aware perturbations.

We believe our work sets a strong baseline on which future research can build to develop better defense strategies and thus promoting the safe deployment of NLP models in practice. We release our code to the public to facilitate further research and development [3].

Local Languages, Third Spaces, and other High-Resource Scenarios

Steven Bird

Darwin, Australia

Abstract

How can language technology address the diverse situations of the world's languages? In one view, languages exist on a resource continuum and the challenge is to scale existing solutions, bringing under-resourced languages into the high-resource world. In another view, presented here, the world's language ecology includes standardised languages, local languages, and contact languages. These are often subsumed under the label of 'under-resourced languages' even though they have distinct functions and prospects. I explore this position and propose some ecologically-aware language technology agendas.

1 Introduction

This paper is about the world's *local languages*, by which I mean small, primarily-oral languages, often Indigenous or endangered, including the original and emerging languages of Africa, Asia, Australia, the Americas, the Pacific, and the minority languages of Europe. Local languages are often called *under-resourced* because they lack what is required for creating speech and language technologies (Krauwer, 2003). Some have been called *acutely* under-resourced, because they are spoken by few people and are rarely written down (Jimerson and Prud'hommeaux, 2018). From here, it is a small step down to *zero expert resources* and the *zero resource scenario* (Dunbar et al., 2017).

I depict this situation in Figure 1. In the middle we have standardised languages, including 'high-resource' languages (e.g. English, Spanish, Mandarin, and Arabic), and 'under-resourced' languages where there are community aspirations for language technologies, and where commercial, or social, or political resources are being leveraged to create the missing language resources (e.g. Irish, Zulu). I represent these languages with hard boundaries in Figure 1 to remind us that standardisation delimits languages. With standardisation comes writing (Joseph, 1987), along with a standardised orthography, written literature, formal education, widespread literacy, and mass media.

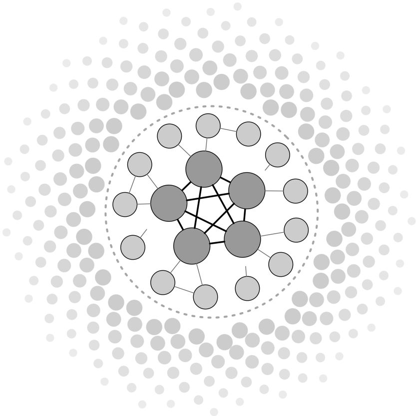

Figure 1: The Central-Peripheral Model: fully-translatable high-resource languages occupy the centre (large dark circles), surrounded by standardised but less translatable under-resourced languages (smaller circles), and outside the resource horizon of the global information society (dotted circle), we have unstandardised languages: under-resourced languages going out to acutely under-resourced languages.

Figure 1 represents what I believe to be the mindset of people who are working in 'low-resource scenarios' and seeking one-size-fits-all solutions. The vision of 'Language Technology for All' (LT4All) is to expand the resource horizon and deliver language technologies like machine translation and speech recognition to all languages. The hope is that, where political will and economic incentive have failed, technological mastery will succeed in delivering digital language equality. Regardless of what one thinks about such prospects, I believe that this agenda is misguided because it does not address the ecology of the world's languages.

In this paper I describe a *multipolar* view of language ecology. I call on researchers working on local languages to make a *local turn*, working from the ground up with speakers to identify new opportunities for language technologies.

2 Poverty-Conscious Language Technology

In the central-peripheral model (Fig. 1), languages outside the high-resource centre are regarded as deficient. In language after language, we problematise complex socio-political situations purely in terms of missing data, and we prioritise solutions that target this shortcoming. I will refer to this as 'poverty-conscious language technology'. Poverty-conscious language technology views the high-resource language situation as normative. It sets up language technologists as the ones who will come to the rescue of deficient languages. This position is a form of Eurocentrism, a colonial worldview centred on Western civilisation. It is marked by several beliefs and values which I illustrate here.

Efficiency. The goal of the DARPA LORELEI program was to "develop methods that apply to languages of any type from any language family, eliminating the need to tailor specific technologies to a narrow set of input languages" (Tzoukermann et al., 2021). The architects of this scheme sought to capture public imagination with the scale of their vision: "Tool kit would work for every language (all 7,000 of them)" (McCaney, 2015).

Language equality. In the present context, this is the belief that languages are equally deserving of technology, that language technology is *for all* languages. It is reflected in the label "Machine Translation For All",[1] and in a manual to "help every language digitize and share equally in the benefits of a connected digital world, ensuring that 'no language is left behind'."[2]

Technologisation. The computer is presented as a neutral tool for manipulating data and implementing and testing theories (Garvin, 1963; Lawler and Aristar Dry, 1998; Bird, 1999; Hanke, 2017; Barnbrook, 2022). We provide computational tools to support language documentation, since "documentation as language salvation has become the operative metaphor used by language experts" (Perley, 2012). We might aim to help society directly, allocating our technical capabilities for maximal social good (Jin et al., 2021), using "language technology [as] the key to achieve full digital language equality in the new multilingual and interconnected world" (Steurs, 2021). Observe that it is *us* who will empower marginalised communities by introducing *our* disruptive language technologies (Joshi et al., 2019), while unwittingly reinforcing the central-peripheral model (cf. Schelenz and Pawelec, 2022).

Scriptism. There is a position that writing is "a more ideal form of linguistic representation than speech" (or 'scriptism', Harris, 1980). It appears in the belief that saving languages involves reducing them to writing (Moore, 2006; Kornai, 2013; Anderson et al., 2019). It appears in the impulse to standardise the writing of indigenous languages so that we can apply language technologies to them (e.g. Mager et al., 2018). It appears when labels such as 'Machine Translation for All' and 'European Language Equality' are used in ways that exclude oral languages.

General-purpose solutions. A field linguist documented the request of a speech researcher for his data: "The scenario was that nothing was known about the language, and the data set consisted solely of audio recordings of sentences plus translations into other languages. Thus, the challenge was to automate all the following tasks: (i) establishing the phoneme inventory, (ii) generating phoneme-level alignments for the audio data, (iii) training an acoustic model, and (iv) identifying words and their pronunciation in the target language. In short, the aim was to make a language accessible for speech technology by only using audio recordings and written translations, bypassing the need for transcriptions, pronunciation dictionaries, and even phoneme set definitions. From the point of view of computer science, this ambitious objective was much more interesting than the creation of a high-quality automatic speech recognition tool" (Michaud et al., 2018, 400f). In the foreground here is the speech technologist and their skill in tackling an artificial problem, for which they need the linguist's data. They show little interest in delivering locally meaningful products. This is a widespread situation, where we apply our *savoir faire* and do more with less (e.g. Bird et al., 2014; Kempton and Moore, 2014; Vetter et al., 2016; Dunbar et al., 2017; Müller et al., 2017).

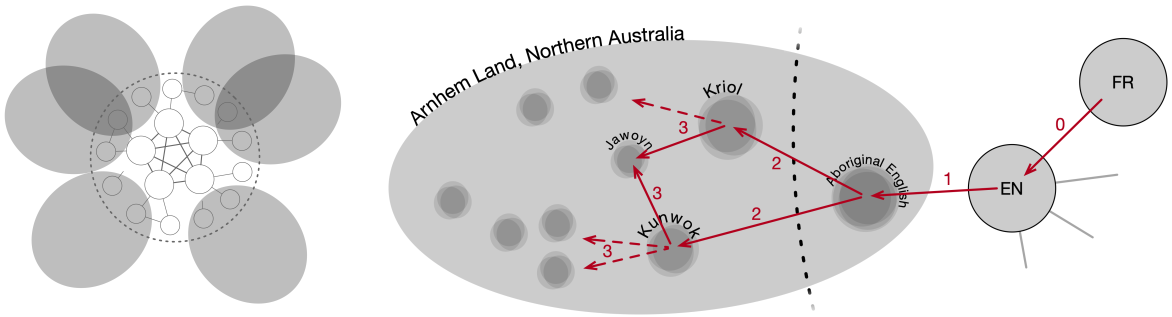
These beliefs and values underlying the central-peripheral model contain unhelpful assumptions about *language ecology* (cf. Haugen, 1972; Calvet, 2006; Lewis and Simons, 2016, 63ff).

One assumption is the 'monolingual mindset'. At least half of the world's population speaks more than one language, employing different languages

---

[1] `https://sigul-2022.ilc.cnr.it/mt4all-shared-task/`

[2] `https://translationcommons.org/impact/language-digitization/`



(a) The centre is ringed by 'culture areas', or 'zones of translatability', each containing local languages, and having a linguistic overlap with the centre due to historical contact and mass media.

(b) A message originating in French is translated into English (step 0), after which local linguistic expertise takes over, in expressing the message in spoken form in the contact language (Aboriginal English, step 1), and interpreting it into local languages (steps 2 and 3); many paths exist thanks to the rich language ecology; local expertise does most of the work (see Sec. 4.2).

Figure 2: A Multipolar Model of Linguistic Diversity: The centre consists of (would-be) standardised languages as in Figure 1, but the periphery contains complex, fine-grained structure

in different domains (Grosjean, 2021). "People who belong to a predominantly monolingual culture are not used to seeing the world in this [multilingual] way, because their mindset has been established through centuries of being part of a dominant culture, in which other people learn your language and you do not learn theirs. It is notable that the nations which are most monolingual in ability and attitude are those with a history of major colonial or religious expansion" (Crystal, 2000, 45).

In reality, many speech communities have a repertoire of languages, each one playing a different role in the local linguistic ecosystem. A common situation is to have 'high' and 'low' prestige varieties (Fishman, 2001), also known as vehicular and vernacular languages, one for participation in commerce and education and one for participation in the local lifeworld.

Another assumption is that written culture is normative. "Fully literate persons can only with great difficulty imagine what a primary oral culture is like... Try to imagine a culture where no-one has ever 'looked up' anything." (Ong, 1982, 31). This assumption does harm: "There is an urgent need to forefront the cultural divide between Aboriginal oral cultures and western literate cultures. The divide is disempowering Aboriginal people because literacy is argued to be a 'passport to success' in the dominant culture... Aboriginal people talk of reviving languages by returning to how the old people passed on the knowledge and the languages, on country and through the spoken word" (Kimberley Language Resource Centre, 2010).

A third assumption concerns the powerlessness of people whose languages are under threat, of speakers "relegated to the role of unwitting casualties victimised by processes greater than themselves" (Perley, 2012). Yet language shift is inevitable, and we can observe the agency of many Indigenous communities who bring epistemic resources – including grammatical distinctions and lexical items – from an ancestral language into a new language (Dickson, 2015; Ponsonnet, 2019).

The model in Figure 1 is an instance of "the central-peripheral model that dominates most technocratic thinking about technology, media, and culture" (Srinivasan, 2017). The main parameter is the quantity of language resources, and whether they are sufficient to bring a language over the line into the highly-connected, global information society.

The language we use gives us away: *for all* projects an agenda on the world; *resource* presumes machine-readability; *expert* means a specific type of western expertise; *language* in 'language resource' implies the ideology of language as data; *scaling* in "scaling up the current language technologies for the rich diversity of human languages" assumes that we have already identified the technological solutions.

3 A Multipolar Model

As an alternative to the central-peripheral model, consider the multipolar model shown in Figure 2(a). The centre contains the standardised languages, i.e., major international languages that are fully translatable. It is ringed by less well-resourced languages, with differing strength of connection the centre. Some of these are regional spoken varieties of standardised languages, which include 'contact languages' (also known as trade languages, vehicular languages, or languages of wider communication). Contact languages connect people to other linguistic regions (cf. Fishman, 1998; Crystal, 2003). These regions are indicated using grey ovals in Figure 2(a).

What are these regions? "In linguistic ecology, one begins not with a particular language but with a particular area, not with selective attention to a few languages but with comprehensive attention to all the languages in the area" (Voegelin and Voegelin, 1964, 2). This is a notion from linguistic anthropology known as a 'culture area' (Newman, 1971). Each culture area contains many local languages, usually languages with primary orality. Translation between these languages is facilitated by a shared geography, culture, and lifeworld, plus a long history of language contact, and so we might also refer to these as 'zones of translatability'.

I avoid the term 'high-resource' when referring to the centre of the multipolar model as this valorises a particular state of a language. It reifies our technological commodities as attributes of a language. The notion of 'standardised' language is pre-existing, suggests standardised orthography, and an institutionally delimited, prestige variety. It reminds us of the existence of complexities and compromises (Ferguson, 1962; Joseph, 1987).

The terms 'under-resourced' and 'low-resource' conflate would-be standardised languages with those having purely local functions.[3] "The term 'low-resource language' is a barrier to understanding. It is applied to languages like Tamil, with 75 million speakers, most of them literate in the language, and a history of written texts that goes back thousands of years. It is ridiculous to use the same term to describe the 'biggest' Indigenous language in Canada, Cree, with 75,000 speakers and few written texts" (Kuhn, 2022, 89). Writing is key to differentiating the two.[4]

I advocate limiting the scope of 'under-resourced' and 'low-resource' labels to just the *would-be standardised* languages. I propose that the community deprecate labels like 'acutely under-resourced' because they are a myopic way to view the linguistic creation of oral cultures. I further propose that we retire the sense of 'zero resource scenario' when referring to local languages (as distinct from child language acquisition). The 'local' descriptor might also supersede others such as 'heritage', 'indigenous', 'endangered', 'threatened', or 'unwritten', which may be seen as valorising, pejorative, or Eurocentric (cf. Grinevald and Pivot, 2013). The 'local' descriptor is apt in reminding us of the local lifeworld and culture area.

In observing three primary linguistic spaces, I do not seek to confine a given language to one of the three spaces. Local languages have diasporas, such as the Nahuatl, Quechua and Hawaiian communities in New York (Kaufman and Perlin, 2018). Regional spoken varieties of a single language may have markedly different functions in different culture areas, e.g. Spanish in Mexico *vs* New Mexico (cf. Lewis and Simons, 2016, 46). Language development efforts may bring local languages into the centre without compromising their local functions.

Even the term 'local language' is problematic insofar as it seems to individuate bounded, homogeneous varieties. If the boundary of a language is unclear, it is not because Western science has not finished its job, but because human languages are not bounded codes in the first place (Dobrin et al., 2009). Diversity within a single language is sometimes problematised as deficit: "*lack* of an orthographic normalization... large dialectal variation, and *missing* standardization" (Mager et al., 2018, 57), yet this diversity within a language is the natural state and only a problem for those who would seek to scale technologies built on the assumptions of a standardised language.

Finally, the 'zero resource scenario' builds in another Eurocentrism which needs to be rooted out. It is the positivist position that we arrive at true knowledge by induction, generalising over cases. When we look at local languages and ask what we can be sure of having for our general purpose models, the answer is raw speech with translations, i.e., the zero resource scenario. This is a lowest-common-denominator approach, and it inevitably brings us back to poverty-conscious language technology. Researchers in the centre need new ways of learning technology lessons concerning local languages (cf. Sec. 5).

---

[3] This is not to say that there are not languages having both aspirations, e.g., contact languages and languages undergoing development.

[4] This is made explicit in the Sustainable Use Model, where 'sustainable literacy' is distinguished from 'sustainable orality' (Lewis and Simons, 2016).

4 Language Technology Agendas

The multipolar model presents an opportunity to consider the agenda of language technology in three primary linguistic spaces. The first space is the global information society, with its standardised and would-be standardised languages (Sec. 4.1). The second space consists of the culture areas, their local languages, and primary orality (Sec. 4.2). The third space is where the first and second spaces intersect. Here we have contact languages, along with local languages undergoing active development (Sec. 4.3). We consider each of these in turn.

4.1 The global information society

From the centre, we want to continue to expand the reach of language technologies to more languages, to serve the purposes of economic integration (Rivera Pastor et al., 2018). This is a version of the original agenda of under-resourced language processing (cf. Fig. 1), restricted to languages with a realistic prospect of standardisation. For example, the goal of the European Language Equality Project is "to enable all [European] languages, regardless of their specific circumstances, to realize their full potential, supporting them in achieving full digital equality in the coming decade" (Gaspari et al., 2021, 2). We can therefore chart the progress of an individual language such as Irish towards digital language equality (Lynn, 2022).

Let us consider language technology in the context of a humanitarian crisis. When it comes to messages like "tsunami warning, move to higher ground", there is global reach through standardised languages alone. We may just need translation between standardised languages (step 0 in Fig. 2(b)). From here on, we can rely on the expertise of speakers of regional varieties who – thanks to historical contact and mass media – readily understand the standardised language (step 1). Some people are highly mobile in this intercultural space, and thanks to their command of both local languages and contact languages, serve as connectors. They can interpret broadcast messages into the local lifeworld (step 2), where there is further expertise to take it to speakers of other varieties (step 3).

Conversely, when a speaker of a local language delivers information in a crisis situation, they will often use a contact language. They will not be hampered by the lack of language technology in their local language, but by the lack of support for their variety of the contact language (e.g. Lewis, 2010; Lewis et al., 2011; Anastasopoulos et al., 2020). This situation can arise even when the person is speaking a major language like English, simply because local spoken varieties of English are still not well supported (cf. Koenecke et al., 2020; Markl and Lai, 2021).

There is an opportunity here: support for contact languages, including creoles and regional spoken varieties of standardised languages, including and their rendering into non-standardised orthography, is a promising pathway for widespread language technology enabled participation in the global information society. Communications beyond these standardised languages and contact languages do not require LT4All, because there is local expertise in bridging lifeworlds and in interpreting between contact languages and local languages.

There is still the risk that broadcast messages may be misunderstood or even cause harm. The need may not be for one-shot translation of a fixed message, but for dialogue and two-way education (Sec. 4.3). Dialogue reduces the chance of messages which – while trivial to translate – are not context aware: e.g. the instruction to Australian Aboriginal people living in overcrowded housing to "stand apart from each other" instead of a more locally aware instruction to "stay in your family groups"; or the instruction to villagers in Flores to "run to higher ground" where they would only be killed by landslides.[5] This points to opportunities in the intercultural space (Sec. 4.3) and to the importance of working with local experts (Sec. 5.2).

4.2 Culture areas

Much computational work already exists for local languages and is being brought together by the ACL SIG for Endangered Languages (SIGEL) and the ISCA SIG in Under-resourced Languages (SIGUL), including workshops on Computational Methods in the Study of Endangered Languages, Spoken Language Technologies for Under-Resourced Languages, Collaboration and Computing for Under-Resourced Languages, and NLP for Indigenous Languages of the Americas. It includes tasks associated with such topics as computer-supported collaborative language documentation, and NLP for polysynthetic languages (e.g. Hanke, 2017; Lane et al., 2022). It includes support for wider participation in NLP (e.g. Nekoto et al., 2020; Mirza-

(a) Indigenous research as the intersection between knowledge practices (following Christie, 2006).

(b) Working together in the intersection of indigenous and academic knowledge practices.

Figure 3: A Third Space at the Intersection of Knowledge Practices

khalov et al., 2021), and language resources with the prospect of connecting local languages in ways that are not mediated by standardised pivot languages (e.g. Madonsela et al., 2016). This work varies in the degree to which it is locally conceived.

In some places there is institutional support for developing a local language, including standardising an orthography, teaching literacy, and translating literature to and from a standardised language (e.g. Zulu, Haitian Creole). Language development may shift a language into the overlap between a culture area and the global information society.

A promising approach for work with speakers of a local language is offered by constructivism (e.g. Charmaz, 2014). A set of methods which have been successful in Arnhem Land is known as *Ground-Up*. It has grown from the observation that Indigenous knowledge is local and performed, and it employs methods that are emergent and situated. Early applications of Ground-Up methods involved content management and health communication (Cass et al., 2002; Verran et al., 2007; Lowell et al., 2021). In the language space, we can work from the ground up to explore the ecology of local speech varieties (cf. Haugen's 'ecological questions', Haugen, 1972, 65). we can explore the language ideology, the practices that support (and draw support from) local languages, and the country itself as a language resource. From this place we can seek new opportunities for language technologies.

Perhaps this will still lead to such agendas as economic participation and multilingual information access. However, where I work in Arnhem Land, people tend to see language as coupled with identity, culture, ancestors, and country. They do not tend to see language as data, or language as lexico-grammatical code. Our conversations about learning centre on human learning not machine learning. When it comes to working with technology, people prefer culturally meaningful work to passive participation in a Western process (cf. Le Ferrand et al., 2022). Many people are passiomate about intergenerational transmission of knowledge, and do not obsess about getting everything transcribed and translated. "Apart from the Inuit, no Indigenous community we've spoken with has shown much interest in machine translation (MT) between their ancestral language and English (or French, in Quebec). Communities are typically more interested in tools to encourage learning and use of their ancestral language" (Kuhn, 2022, 89).

An approach to technology engagements in culture areas is suggested by work on codesign (e.g. Verran and Christie, 2007; Verran et al., 2007; Bidwell et al., 2008; Bidwell and Browning, 2010; Winschiers-Theophilus et al., 2010; Brereton et al., 2013; Winschiers-Theophilus and Bidwell, 2013; Brereton et al., 2014; Soro et al., 2016; Taylor et al., 2018, 2019). We could apply such methods to the study of language technologies in culture areas.

4.3 Third spaces

The third space is a hybrid place, an intersection of worlds. It has been discussed under such headings as the 'contact zone', the 'recognition space', the 'intercultural space', the 'arena', and the 'research interface' (Bhabha, 2012; Pratt, 1991; Somerville and Perkins, 2003; Taylor, 2008; Hunt et al., 2008; Jasper and Duyvendak, 2015; Ryder et al., 2020). One framing is *Indigenous research* (Fig. 3(a)), defined as "that part of an Indigenous knowledge tradition which is recognisable or legible from a Western research perspective... [or conversely] as that part of the Western academic research tradition which is at the same time conceived, shaped, governed and understood within Indigenous knowledge traditions. The area in the middle of the diagram is Indigenous research because it fulfils the criteria for both Indigenous knowledge production and academic research" (Christie, 2006, 80).

Here, my frame of reference is 'working together' (Fig. 3(b)). As a participant in an Aus-

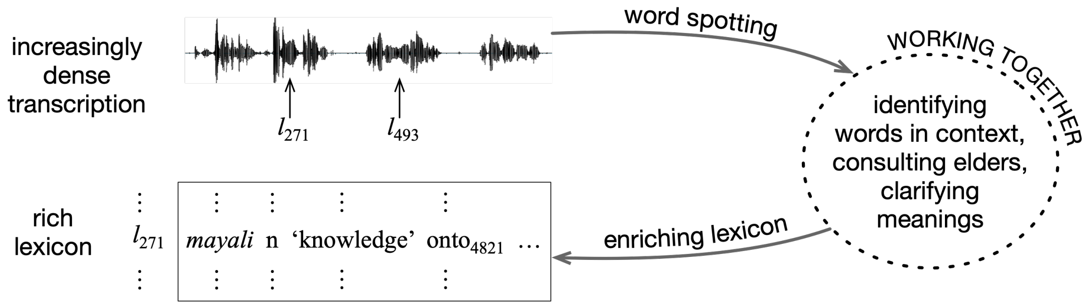

Figure 4: Expert Transcription: High value words are spotted in the audio, discussed by Indigenous and western experts working together, and added to a rich lexicon (Bird, 2020).

tralian Aboriginal community, I need pretexts for sitting with local people, and this comes from the established activities of a ranger program and a school. Here there are opportunities for computer assisted language learning and for spoken document retrieval from an archive of untranscribed media. There may be other opportunities for technology to augment traditional learning processes (Harris, 1984; Trudgen, 2012, 200ff), and for computer supported cooperative work that privileges local languages and knowledge systems (Christie and Verran, 2014; Carew et al., 2015; Hanke, 2017; Bettinson and Bird, 2021b,a).

Part of the dynamic of working together on a language resource is the diverse meanings this may have for participants (cf. Star and Griesemer, 1989; Star, 2010). The externally-driven, telic work of compiling a dictionary may sit alongside local people's atelic, day-to-day participation in exploring the meanings of words with elders and visiting the places where the associated stories can be told. The resulting bound volume or mobile app might be a learning resource to one person and an emblem of prestige to another.

5 Stories of Expertise in a Third Space

The perspective I have articulated in this paper has arisen from living and working in a Kunwinjku-speaking community situated in Arnhem Land, Aboriginal country in the far north of Australia (cf. Fig 2(b)). Here my attempts to pursue my Eurocentric practices in data collection have foundered. Over a period of several years, and with the patient guidance of many local people, I, a western-educated middle-aged white male, have learnt about the local lifeworld, glimpsed local expertise, and borne witness to systemic injustice.

In this section, I describe local responses to western academic practices in transcription and translation, practices where the agendas of language technology and language documentation fortuitously align. From my centralised perspective, the task of rendering speech into text, and the task of translating that text into another language, are disjoint. The technologies of speech recognition and machine translation are similarly distinct. However, I found that matters were different at the local level.

The task of working together on a recording and deciding what was said turns out to be a two-way practice that merges transcription and translation (Sec. 5.1). The task of working together on an emergency broadcast to interpret it into a local language turns out not to be conventional one-shot translation of a fixed message but a two-way practice of "understanding the true stories" (Sec. 5.2). I recount these experiences to reveal the contingent, situated nature of work in a third space, and to suggest that a suitable way to learn lessons from such stories is not induction to lowest common denominator scenarios leading to one-size-fits-all solutions, but abduction to deeper accounts of speech communities and language technologies.

5.1 Expert transcription

Transcription for 'acutely under-resourced' languages has depended on recruiting participants to transcribe speech recordings and to provide phrase-aligned translations into a standardised language, a practice that focusses on surface forms, quantity, and efficiency. Yet transcriptional practices on the ground are far from mechanical, and there is no simple ground-truth transcription (Hermes and Engman, 2017; Himmelmann, 2018; Bird, 2020). On numerous occasions, I have found that there is no local interest in the tedious work of rendering speech recordings into text. When I look at local people's 'transcriptions' I see a practice akin to note-taking or inscription. People write down

In Arnhemland, Yolŋu [Aboriginal] people live in extended family groups with traditional authority structures. When Balanda [Westerners] don't understand or respect our way of governance, they often come up with ways of dealing with problems that undermine the authority of our Elders and their ways of keeping people and places safe.

When trying to spread the word in Yolŋu communities, the Balanda authorities told everyone to wash their hands and *stand apart from each other*. This way of sharing the story had the effect of by-passing the Elders, and of prioritising ways to keep ourselves safe as individuals. It cared for the 'biomedical body' threatened by the virus, but not the 'Yolŋu body' which includes our family and clan groups. They picked one person to take the news to the people in the community, but this did not involve negotiating among ourselves what the right story for Yolŋu should be, and the best way for it to be shared.

There are ways we can work together, beginning with the authority of Elders, to understand the true stories of this virus. We have traditional ways of doing that sort of work and sharing out the right responsibilities to the right people. We know the right ways to keep our relationships strong, including our relations to other clan groups and to our homelands. When we are able to remain connected with each other and our places, this is how we remain healthy.

Figure 5: Caring for Yolŋu and Ways of Life during COVID 19 (exerpt from Wanambi et al., 2021)

enough so that they can reconstruct the story or perform the knowledge. In the process, we discuss the form and meaning of key words and phrases. Here is where local interests intersect with a newcomer's need to expand their vocabulary and improve their ability to recognise words in connected speech.

How can we privilege local interests and expertise, and flip this transcriptional practice from a deficit scenario to a strength scenario? My answer is 'sparse transcription', schematised in Figure 4. We give up the slavish left-to-right phoneme level transcription practice, and instead prioritise our agency in identifying words of interest and discussing their significance.

Thus, on the top left of Figure 4 we have a sparse transcription, where some tokens of lexical items have been found, manually or automatically. We are not concerned about narrow transcription of those items, only with identifying tokens of a lexeme in connected speech. On the right we have the practice of working together where local experts and western learners clarify the meaning of words, and enlarge the lexicon. Through multiple iterations, the transcription of a corpus gets denser. Our ability to automatically spot topic words and to retrieve relevant spoken documents improves.

5.2 Expert translation

Following the onset of the COVID-19 pandemic, the Australian government broadcast "simplistic directives about behaviour change" (Lowell et al., 2021, 172). The assumption seems to be that all knowledge lies in the centre, and when it comes to reaching communities who speak other languages, it is a question of translation.

To us in the language technology community, the government's approach presents a golden opportunity. We could obtain funding, collect a parallel corpus, and build a translation system. We would measure success in terms of the quantity of data collected and the performance of the system on gold translations. Over time, we would bring another language into the centre.

However, in our success we would have missed the point: this is not a translation problem. Consider the response of some local elders to the government's communication strategy (Fig. 5). The elders touch on many issues. What is the utility of an instruction to self-isolate – or what came across in Yolŋu as "stand apart from each other" – in communities with chronic overcrowding?[6] Where is the sense in transmitting messages through a person who is not locally recognised as a knowledge authority, a practice which harms the Yolŋu body?

A likely response in the language technology community would be to collect more data and build a better system. Yet how would we hope to learn, via "the mere exercise of matching words or phrases in one language with those of another" (Duranti, 1997, 154), that Yolŋu have a different metaphysics for an apparently simple term like 'body'? Our approach to translation works best when there is a shared lifeworld, where lexicalised concepts, metaphors and tropes line up across languages, i.e., within a zone of translatability (Fig.2(a)).

The government's practice of COVID communication is more Eurocentrism, and a consequence of "the West's view of itself as the centre of legitimate knowledge, [and of] science as the all-embracing method for gaining an understanding of the world" (Smith, 2012). The Yolŋu elders delivered a sophisticated response to the government's simplistic directives. They identified metaphysical issues, and asked to "work together to understand the true stories". This practice has been called *two-way learning* in Australia (Harris, 1990), cf. *two-eyed seeing* in Canada (Wright et al., 2019).

---

[6] `https://www.creativespirits.info/aboriginalculture/land/overcrowded-houses`

In a more culturally aware approach, "Balanda [Western] educators discussed with the Yolŋu participants how to explain each concept in their own language as it was introduced. This triggered active and collaborative engagement in the learning process and provided opportunities for misunderstandings to be revealed and repaired... This strategy of continual collaborative interpreting of each new concept introduced by the Balanda educators, as well as Yolŋu sharing their knowledge, facilitated a more in-depth understanding than passive listening to an explanation in English" (Lowell et al., 2021, 171). This suggests a new opportunity for language technology, not how to improve translation for 'under-resourced' languages, but how to support people to work together in a third space, and to navigate a metaphysical divide (Fig. 3(b)).

6 Conclusion

The field of language technology has placed the world's languages on a spectrum according to the available machine-readable resources, a self-serving position that I have called poverty conscious language technology. Our category of 'under-resourced' languages conflates the qualitatively different situations of local languages and would-be standardised languages. Our talk of technology for languages of *any type* and of language technology *for all* betrays our Eurocentrism. When we speak of 'acutely under-resourced' languages and 'zero expert resources' we commit an epistemic injustice.

I have described a multipolar model which respects local language ecologies with their orality and multilingualism, and I have articulated implications for the agenda of language technology. I have suggested ways that we can take a local turn and work with local speech communities from the ground up. We still need to be on guard for the colonial impulse in its many guises (cf. Dourish and Mainwaring, 2012). We still need to properly theorise language technology development outside the space of standardised languages.

The result of this program, I hope, will be language technologies that address the distinct opportunities presented in three high-resource scenarios: the global information society with its standardised languages, the culture areas with their local languages, and their intersection in third spaces with their contact languages and local language development activities.

Acknowledgements

I acknowledge the Bininj people of the *Kuwarddewardde* 'Stone Country' and thank them for welcoming me into their community. *Karrimurrngrayekmen kunwok!* I am particularly grateful to Dean Yibarbuk and Lois Nadjamerrek and the Warddeken Rangers for their support. My work in Arnhem Land has been approved by traditional owners, the board of Warddeken Land Management, a research permit from the Northern Land Council, and a human research ethics protocol approved by Charles Darwin University. An earlier version of this material was presented in a keynote address at the 2021 Conference on Empirical Methods in Natural Language Processing, and I am grateful to several participants for their feedback. I thank the following people for discussions that have helped my thinking, and for their feedback on earlier versions of the material presented here: Antonios Anastasopoulos, Laurent Besacier, Mat Bettinson, Michael Christie, Éric Le Ferrand, William Lewis, Teresa Lynn, Helen Verran, Fei Xia, and several anonymous reviewers. This work was supported by a grant from the Australian Research Council.

Abstract

The evolution of language follows the rule of gradual change. Grammar, vocabulary, and lexical semantic shifts take place over time, resulting in a diachronic linguistic gap. As such, a considerable amount of texts are written in languages of different eras, which creates obstacles for natural language processing tasks, such as word segmentation and machine translation. Although the Chinese language has a long history, previous Chinese natural language processing research has primarily focused on tasks within a specific era. Therefore, we propose a cross-era learning framework for Chinese word segmentation (CWS), CROSSWISE, which uses the Switch-memory (SM) module to incorporate era-specific linguistic knowledge. Experiments on four corpora from different eras show that the performance of each corpus significantly improves. Further analyses also demonstrate that the SM can effectively integrate the knowledge of the eras into the neural network.

1 Introduction

As a human-learnable communication system, language does not remain static but instead evolves over time. The rate of change between different aspects of language, such as grammar, vocabulary, and word meaning, vary due to language contact and many other factors, which has led to the diachronic linguistic gap. An example of this can be seen in, "That slepen al the nyght with open ye (That sleep all the night with open eye)," which is a sentence from The Canterbury Tales, written in Middle English by Geoffrey Chaucer at the end of the 14th century. It is difficult for people without an understanding of Middle English to make sense of this sentence. Furthermore, some discourses contain both modern English and Old English due to citation or rhetorical need. For example, Shakespeare's fourteen lines of poetry are often quoted in contemporary novels. This kind of era-hybrid text creates barriers to natural language processing tasks, such as word segmentation and machine translation.

Table 1: Illustration of the different segmentation results for a modern Chinese sentence and an ancient Chinese sentence with different segmentation toolkits.

The Chinese language has the honor of being listed as one of the world's oldest languages and, as such, has seen several changes over its long history. It has undergone various incarnations, which are recognized as Archaic (Ancient) Chinese, Middle Ancient Chinese, Near Ancient Chinese, and Modern Chinese. Notably, most Chinese NLP tasks skew towards Modern Chinese. Previous research has primarily focused on addressing the CWS problem in Modern Chinese and has achieved promising results, such as Chinese Word Segmentation (CWS) (Zheng et al., 2013; Chen et al., 2015; Zhang et al., 2016; Xu and Sun, 2016; Shao et al., 2017; Yang et al., 2017; Zhang et al., 2018; Tian et al., 2020b,a). Although CWS for ancient Chinese has been recognized in recent years, the processing of language-hybrid texts is still an open question. As shown in

Table 1, PKUSeg (Luo et al., 2019a) is a Chinese segmenter that is trained with a modern Chinese corpus; while it can segment modern Chinese sentences correctly, its accuracy drops sharply when applied to ancient Chinese. Conversely, the ancient Chinese segmenter JiaYan[1] performs well on ancient Chinese text but fails to perform well on Modern Chinese texts. Therefore, it is necessary to develop appropriate models to undertake cross-era NLP tasks.

To address this need, we propose CROSSWISE (CROsS-ear Segmentation WIth Switch-mEmory), which is a learning framework that deals with cross-era Chinese word segmentation (CECWS) tasks. The framework integrates era-specific knowledge with the Switch-memory mechanism to improve CWS for era-hybrid texts. More specifically, we utilized the abilities of both CWS and sentence classification tasks to predict segmentation results and era labels. We also incorporated the Switch-memory module to include knowledge of different eras, which consists of key-value memory networks (Miller et al., 2016) and a switcher. In order to store era-specific knowledge by several memory cells, key-value memory networks are used. The sentence discriminator is considered to be a switcher that governs the quantity of information in each memory cell that is integrated into the model. For each memory cell, we map candidate words from the dictionary and word boundary information to keys and values..

The main contributions of this paper are summarized as follows:

- Cross-era learning is introduced for CWS, we share all the parameters with a multi-task architecture. The shared encoder is used to capture information that several datasets from different eras have in common. This single model can produce different words segmentation granularity according to different eras.

- The Switch-memory mechanism is used to integrate era-specific knowledge into the neural network, which can help improve the performance of out of vocabulary (OOV) words. This study proposes two switcher modes (*hard-switcher* and *soft-switcher*) to control the quantity of information that each cell will feed into the model.

- Experimental results from four CWS datasets with different eras confirm that the performance of each corpus improves significantly. Further analyses also demonstrate that this model is flexible for cross-era Chinese word segmentation.

2 Related Work

Chinese word segmentation is generally considered to be a sequence labeling task, namely, to assign a label to each character in a given sentence. In recent years, many deep learning methods have been successfully applied to CWS (Zheng et al., 2013; Chen et al., 2015; Zhang et al., 2016; Xu and Sun, 2016; Shao et al., 2017; Yang et al., 2017; Kurita et al., 2017; Liu et al., 2018; Zhang et al., 2018; Ye et al., 2019a; Higashiyama et al., 2019; Huang et al., 2020b; Tian et al., 2020b,a,c; Liu et al., 2021). Among these studies, some indicate that context features and external knowledge can improve CWS accuracy (Kurita et al., 2017; Yang et al., 2017; Zhang et al., 2018; Liu et al., 2018; Tian et al., 2020b,a,c). Studies from Liu et al. (2018) and Zhang et al. (2018) leveraged the dictionary to improve the task; n-gram is also an effective context feature for CWS (Kurita et al., 2017; Tian et al., 2020b; Shao et al., 2017). The use of syntactic knowledge generated by existing NLP toolkits to improve CWS and part-of-speech (POS) has been established by Tian et al. (2020b). Furthermore, Tian et al. (2020c) incorporated wordwood information for neural segmenters and achieved a state-of-the-art performance at that time.

It is common practice to jointly train CWS and other related tasks based on a multi-task framework. Chen et al. (2017) took each segmentation criterion as a single task and proposed an adversarial multi-task learning framework for multi-criteria CWS by extracting shared knowledge from multiple segmentation datasets. Yang et al. (2017) investigated the effectiveness of several external sources for CWS by a globally optimized beam-search model. They considered each type of external resource to be an auxiliary classification, and then leveraged multi-task learning to pre-train the shared parameters used for the context modeling of Chinese characters. Liu et al. (2018) jointly trained the CWS and word classification task by a unified framework model. Inspired by these successful studies, this study also incorporated ideas from the multi-task framework, and jointly trained the CWS task and

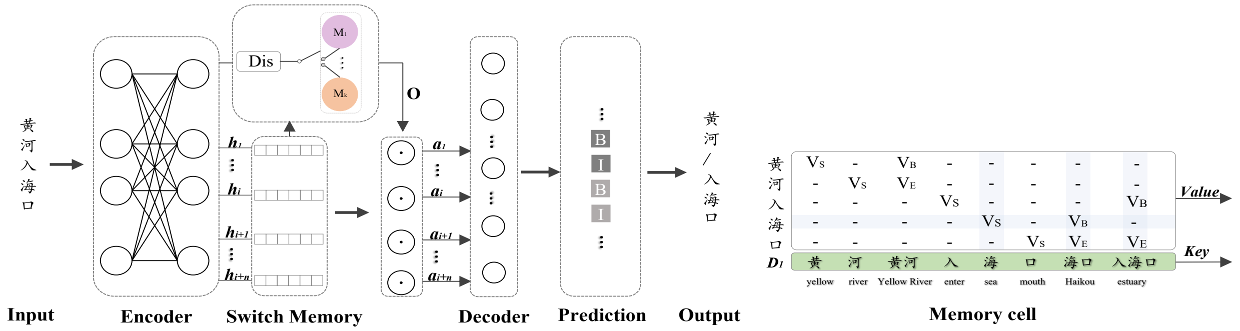

Figure 1: CROSSWISE for cross-era Chinese word segmentation. “Dis” represents the discriminator, specially, the sentence classifier. “M_1” is the first memory cell; its internal structure is shown on the right of the figure. For each character, the first memory cell extracts all candidate words from the input sentence and only retains ones that appeared in the first dictionary (candidate words as keys, words' boundary information as value).

the sentence classification task to enhance the performance of cross-era CWS.

Recently, some studies have noticed the linguistic gap due to the differences between eras. Ceroni et al. (2014) proposed a time-aware recontextualization approach to bridge the temporal context gap. Chang et al. (2021) reframed the translation of ancient Chinese texts as a multi-label prediction task, then predicted both translation and its particular era by dividing ancient Chinese into three periods.

The use of key-value memory networks were introduced to the task of directly reading documents and answering questions by Miller et al. (2016), which helped to bridge the gap between direct methods and the use of human-annotated or automatically constructed Knowledge Bases. Tian et al. (2020c) applied this mechanism to incorporate n-grams into the neural model for CWS.

Encouraged by the above works, this study designed a multi-task model for cross-era CWS by jointly training the sentence classification task and CWS through the use of a unified framework model. Key-value memory networks are used to integrate era-specific knowledge into the neural network, as was done in research by Tian et al. (2020c).

3 The Proposed Framework

3.1 BERT-CRF model for Chinese word Segmentation

Chinese word segmentation is generally viewed as a character-based sequence labeling task. Specifically, given the sentence $X = \{x_1, x_2, ... x_T\}$, each character in the sequence is labeled as one of $\mathcal{L} = \{B, M, E, S\}$, indicating the location of the character as at the beginning, middle, or end of a word, or that the character is a single-character word. CWS aims to determine the ground truth of labels $Y^* = \{y_1^*, y_2^*, \ldots y_T^*\}$:

$$Y^* = arg\ max\ P\left(Y|X\right)_{Y \in \mathcal{L}^T} \tag{1}$$

The universal end-to-end neural CWS architecture usually contains an encoder and a decoder. The framework used in this study is shown in Figure 1; the functions of each part are explained below.

Encoding layer. According to Fu et al. (2020), although BERT-based (Devlin et al., 2019) models for CWS are imperfect, BERT is superior, in many aspects, to models that have not been pre-trained. For example, BERT is more suitable for dealing with long sentences; therefore, this study utilizes BERT released by Google Devlin et al. (2019) as the shared encoder, which is pre-trained with a large amount of unlabeled Chinese data.

$$\{\mathbf{h}_1 ... \mathbf{h}_i ... \mathbf{h}_T\} = Encoder(\{x_1 ... x_i ... x_T\}) \tag{2}$$

where $\mathbf{h}_i$ is the representation for x_i from the encoder.
